Abstract

Coronavirus disease 2019 (COVID-19), caused by the novel severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), is an acute infectious disease that spreads mainly through the respiratory route. Besides interstitial pneumonia, a number of other clinical manifestations were noticed in COVID-19 patients. In particular, liver and spleen dysfunctions have been described both as complications of COVID-19 and as potential predisposing factors for severe COVID-19. Liver damage is rather common in COVID-19 patients, and it is most likely multifactorial, caused by the direct insult of SARS-CoV-2 to the liver by the cytokine storm triggered by the virus, by the use of hepatotoxic drugs, and as a consequence of hypoxia. Although generally mild, liver impairment has been found to be associated with a higher rate of intensive care unit admission. A higher mortality rate was reported among chronic liver disease patients. Instead, spleen impairment in patients with COVID-19 has been poorly described. The main anatomical changes are the architectural derangement of the B cell compartment, white pulp atrophy, and reduction or absence of lymphoid follicles, while, from a functional point of view, the IgM memory B cell pool is markedly depleted. The outcome of COVID-19 in asplenic or hyposplenic patients is yet to be defined. In this review, we will summarise the current knowledge regarding the impact of SARS-CoV-2 on the liver and spleen function, as well as the outcome of patients with a pre-existent liver disease or defective spleen function.

INTRODUCTION

In December 2019, a novel coronavirus-related pneumonia was detected in a Chinese group of patients[1]. The pathogen was later named severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2)[2], and on 30th January 2020 the World Health Organization publicly declared the outbreak of the new virus-related disease, the so-called coronavirus disease 19 (COVID-19)[3].

The most common clinical manifestations of SARS-CoV-2 infection include fever, dry cough, dyspnoea, fatigue, and myalgia[4,5], but the increasing information in published literature reported a wide spectrum of extrapulmonary symptoms and signs, especially arising from the gastrointestinal tract[6]. Hepatic involvement in COVID-19 patients has been largely documented in several observational studies, highlighting a significant prevalence of liver impairment in hospitalized individuals and a correlation with the severity of the disease[7,8]. COVID-19 implications for individuals with a pre-existent chronic liver disease (CLD) have also been evaluated, and a few studies have focused on the management and prognosis of post-transplant patients[9,10].

Little is known about the splenic involvement in COVID-19 patients. The spleen plays a fundamental role in the immune system modulation, regulating the T and B cell responses to the antigenic targets in the blood, and the tropism of the coronaviruses for the spleen has been documented[11]. Although splenic alterations in autoptic specimens have already been shown, and these anatomical changes might contribute to the abnormal immune reaction occurring in COVID-19[12], data on prognosis of COVID-19 individuals with splenic function impairment have been poorly investigated so far.

In this review, we aim at elucidating the pathological role of SARS-CoV-2 in patients with hepatic and splenic involvement, ranging from specific biochemical alterations to any histopathological modifications. Secondly, our purpose is to evaluate the impact of COVID-19 in individuals with a pre-existent diagnosis of hepatic disease or defective spleen function or asplenia.

MATERIALS AND METHODS

From January to March 2021 we searched on MEDLINE (PubMed) by using the medical subject heading terms "liver", "hepatic", "spleen", "splenectomy", "hyposplenic" matched with "coronavirus", "COVID-19", "SARS-CoV-2" for all articles published since database inception. More than 3000 papers were found with this search strategy, most of which were not strictly related to the subject of this review. Hence, we selected human studies exploring relationships between COVID-19 and liver or spleen function, as well as the outcomes of COVID-19 patients with CLD or spleen hypofunction/asplenia. Given the high number of papers and senior authors (SC, MVL, ADS), after a careful review, we selected the most important or representative ones, summarising current evidence. We also searched for additional papers in the reference lists of review articles, and they were included if deemed appropriate.

LIVER IMPAIRMENT IN COVID-19

Pathogenesis

Since the most recent studies reporting clinical manifestation of COVID-19 were carried out, the alteration of liver function tests (LFTs) has been reported[4,13-15]. These abnormalities, which still have an unclear clinical significance, have been repeatedly reported in patients suffering from a more severe disease[4,16-18]. The exact cause of liver damage during SARS-CoV-2 infection is partly unknown and most likely multifactorial (Figure 1)[18]. One of the possible explanations has been found in the direct insult of SARS-CoV-2 to the liver through the binding of the virus to the angiotensin-converting enzyme 2 (ACE2) receptor, which represents the main cell entry receptor for the virus[19-21]. ACE2 receptors, which are key players in regulating arterial blood pressure, are expressed in almost any tissue of the human body, especially in the lungs, kidneys, gut, liver and brain. Their polymorphisms may lead to a cardiovascular disease and a stroke[22]. However, the ACE2 receptor is highly expressed by cholangiocytes rather than hepatocytes; therefore, the hepatic damage would be channelled through the bile duct dysfunction, which might alter the immune responses and liver regeneration[20]. Nonetheless, it should be noted that alkaline phosphatase (ALP) is not constantly raised in these patients[23].

In addition to the aforementioned mechanisms, the cytokine storm resulting from the excessive immune response triggered by the virus could be another factor leading to liver damage[23,24]. An excessive increase in pro-inflammatory cytokines has been found in a high percentage of critically-ill COVID-19 patients, alongside with a reduction in T cells and an increase in the neutrophilic count. The hypothesis that the lymphocytopenia and C-reactive protein (CRP) levels are independently correlated to the presence of liver damage has been proposed, suggesting a role of the cytokine storm in causing liver dysfunction[25]. This hypothesis has also been proved with regard to organs other than the liver, including heart and kidneys[26], supporting the idea that the cytokine storm may cause shock and tissue damage. Another contributing factor is the use of potentially hepatotoxic drugs, including antibiotics (*e.g.*, macrolides), antiviral agents especially used during the first wave of the pandemic, corticosteroids, and paracetamol[23,24]. Lastly, liver damage can be caused by hypoxia, as a result of severe respiratory failure[23,24,27].

Clinical findings

Liver abnormalities are rather common in COVID-19 patients. The proportion of COVID-19 inpatients with an elevated alanine aminotransferase (ALT) has been found to be as high as 36%, and a higher proportion (46%) also had raised aspartate aminotransferase (AST)[18,28]. On the contrary, ALP or gamma-glutamyl transpeptidase (GGT) alterations were reported more rarely[18,29]. Although rather common, in most cases liver injury is mild and it usually manifests in more critically-ill patients[18,30,31]. A mild-to-moderate increase of ALT was reported in 43/87 patients (49.4%), and a higher mortality rate was observed among those with deranged LFT who had developed acute respiratory distress syndrome (ARDS)[29]. Similarly, Richardson *et al*[7], who enrolled more than 5000 patients with liver involvement, showed that acute hepatic injury, although rare, was associated with higher mortality. Liver involvement was reported in 2700 patients (39%), and 1% of the whole cohort developed acute liver injury. Another study enrolling more than 2000 patients confirmed these findings, reporting acute liver injury in a quarter of the included patients and severe liver injury in only 6.4% of the patients. However, this small proportion had a more complex clinical course, including intensive care admission and intubation need in more than 60% of the cases, renal replacement therapy in a third, and mortality as high as 42%[31]. A low incidence of severe liver injury (9%) was also reported by a German study enrolling 44 patients of which 6 had deranged ALT. Also, the German cohort reported AST to be more commonly deranged than ALT[28].

Although generally mild, liver impairment has been found to be associated to a higher rate of intensive care unit admission[30,32], as well as to a longer hospital stay [33]. Ponziani *et al*[30] reported liver involvement in 161 out of 515 patients enrolled (31.3%) and no cases of severe acute liver injury. Moreover, although liver involvement led to a higher need for intensive care, no increase in mortality was recorded among those patients. However, conflicting data have been published on the role of liver impairment in increasing mortality in patients without pre-existing liver disease. Medetalibeyoglu *et al*[32] reported that AST/ALT ratio was a good predictor of mortality (area under the curve [AUC]: 0.713; P = 0.0001) in a cohort of 554 individuals enrolled in Turkey, and that AST and ALT levels were independently

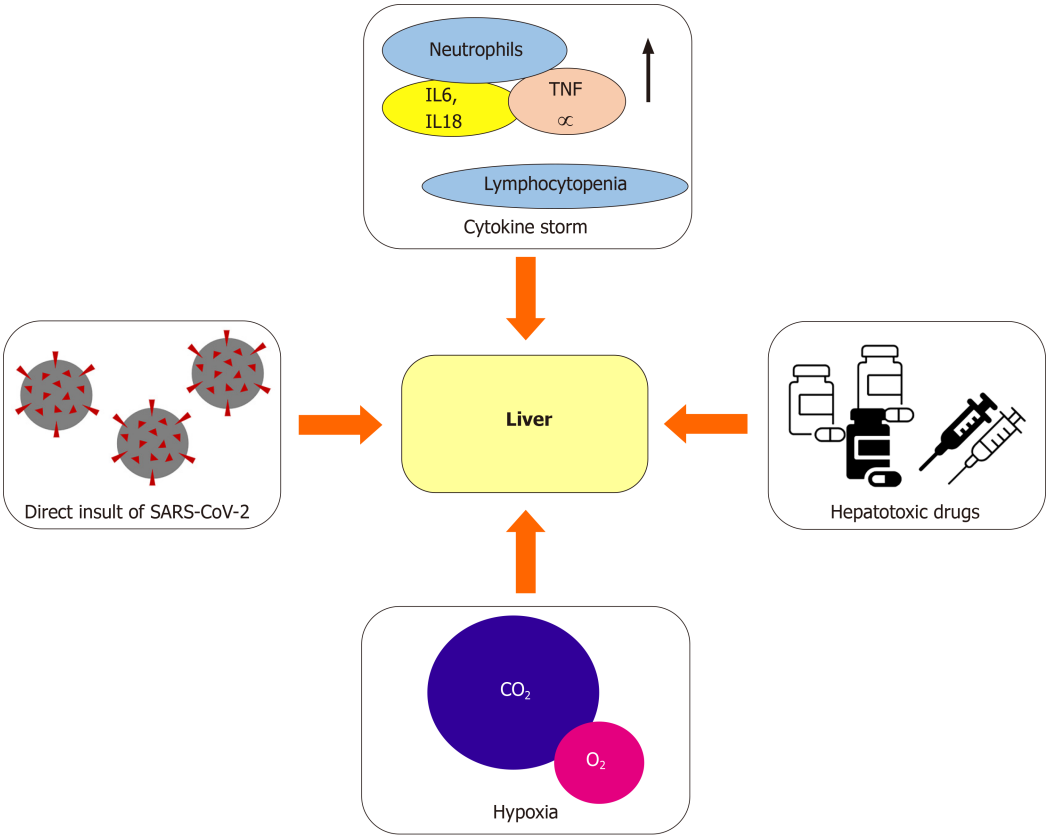

Figure 1 Putative mechanisms of liver damage in coronavirus disease 2019. IL: Interleukin; SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2; TNF: Tumour necrosis factor.

associated with an increased need for intensive care and with mortality (P = 0.001). Table 1 reports the main studies focusing on liver abnormalities in COVID-19 patients.

Histological features

Limited data are available about histological liver findings in COVID-19 patients. Lagana *et al*[34] reported the histological features of 40 patients who died of COVID-19-related complications and who had liver biochemical abnormalities. Two-thirds of the included patients presented macrovesicular steatosis, which was most commonly panlobular, while 2 patients (7%) showed active steatohepatitis. Half of the included patients had mild lobular necroinflammation and, therefore, active hepatitis, which was mild in 80% of the cases and moderate in the remaining 20%. Similarly, portal inflammation was reported in 20 patients, 3 of which had interface hepatitis. Lobular mild and focal cholestasis changes were observed in 15 (38%) cases. Although the ACE2 receptor is mainly expressed by cholangiocytes in the liver, ductopenia was not reported. Vascular alterations (*i.e.* phlebosclerosis, portal arteriolar muscular hyperplasia, focal fibrinoid necrosis, and sinusoidal thrombus) were less common (15%). Interestingly, no significant correlation was found between laboratory and histological findings. Wang *et al*[35] demonstrated, in 2 deceased COVID-19 patients, that SARS-CoV-2 can infect the liver causing direct cytopathy. They also reported massive hepatic apoptosis as well as binuclear hepatocytes. However, due to the small sample size, further studies are needed to confirm these preliminary findings.

COVID-19 IN PATIENTS WITH A PRE-EXISTING CLD

Immune dysregulation is known to affect people with CLD or cirrhosis, leading to the concern that these patients are at higher risk of having a more severe form of COVID-19[36]. A limited number of studies have investigated the role of COVID-19 in patients with a pre-existing CLD and most of them only included a limited number of patients from a restricted geographical area. It is to be noted that all these studies reported a higher mortality rate among CLD patients[37-43]. Marjot *et al*[43] conducted one of the largest studies of CLD cases (745 patients) from 29 different countries. They showed

Table 1 Main studies reporting liver involvement in patients without pre-existing liver disease

Ref.	Country	Patients	Liver involvement criteria	Patients with liver involvement, *n* (%)	Main findings
Fan *et al*[33]	China	148	ALT > 40 U/L or AST > 35 U/L	55 (37.2)	Abnormal liver function is common in COVID-19 inpatients, leading to a longer hospital stay
Goyal *et al*[17]	United States	375	ALT > 40 U/L	120 (32)	Mechanically ventilated patients more likely to have liver involvement.
Lenti *et al*[29]	Italy	100	ALT or GGT > 50 U/L	58/93 (62.4)	Liver involvement correlate to higher mortality and ICU need in those who develop ARDS
Medetalibeyoglu *et al*[32]	Turkey	554	ALT or AST > 40 U/L	153 (27.6)	Higher rate of moderate-to-severe pneumonia and ICU admission need in patients with liver involvement
Phipps *et al*[31]	United States	2273	ALT > 50 U/L	537 (24)	Severe liver involvement was rare (6.4%) and led to worse outcomes (ICU admission, higher mortality)
Ponziani *et al*[30]	Italy	515	AST > 45 U/I orALT > 45 U/I orGGT > 61	161 (31.3)	No cases of severe liver injury in this cohort. Liver involvement was generally mild and, although correlated to a higher need of ICU care, not associated to higher mortality
Richardson *et al*[7]	United States	5700	ALT > 60	2176 (39)	Acute liver injury occurred in 1% of the included patients and was associated with higher mortality
Schattenberg *et al*[28]	Germany	44	ALT >50 U/L	6/38 (15.8)	Severe liver involvement was rare (9%), with AST more commonly deranged than ALT

ALT: Alanine aminotransferase; ARDS: Acute severe respiratory distress syndrome; AST: Aspartate aminotransferase; COVID-19: Coronavirus disease 2019; GGT; Gamma-glutamyl transpeptidase; ICU: Intensive care unit.

that CLD was associated with increased mortality according to the Child-Pugh class. They reported an increase in mortality, ranging from 19% in Child-Pugh-A patients to 51% in Child-Pugh-C patients. Although mortality has consistently reported to be increased in CLD patients, respiratory failure was found to be the main cause of death in these patients. Interestingly, alcohol-related liver disease was found to be independently associated to higher mortality. Liver decompensation was also reported to be common in cirrhotic patients (46%) with half of them having acute-on-chronic liver failure[44].

Among patients with CLD, liver transplant recipients were thought to represent a high risk category due to their frailty, comorbidities, and immunosuppressant therapy. Only few studies evaluated their clinical outcomes, showing conflicting results. Additionally, the majority of these studies are small case series in which patients did not always have the confirmation of SARS-CoV-2 infection[45-49]. Complying with preventive measures (*i.e.* frequent hand washing/sanitisation, use of surgical mask in public places and avoidance of public or crowded places) has been found effective to reduce the infection rate in this population[49]. A large multinational registry-based study[50], including 151 transplanted patients with laboratory-confirmed infection, showed that liver transplantation was not independently associated with higher mortality, hospitalisation rate or intensive care unit admission, whereas age and comorbidities were[47,50]. Tables 2 and 3 report the main studies focusing respectively on the outcome of COVID-19 in patients with CLD and in those with a transplanted liver.

SPLEEN IMPAIRMENT IN COVID-19

Spleen impairment in patients with COVID-19 has been poorly described. It is assumed that it may be driven by several mechanisms, including direct organ attack by the virus, cytokine-mediated immune pathogenesis, microvascular dysfunction, and lymphocyte apoptosis (Figure 2)[51].

Coronavirus detection in biopsies and autopsies has shown a tropism of this virus family for the spleen. The first available evidence is related to studies carried out on patients infected with SARS-CoV[11,52] and in experimental models of the Middle East respiratory syndrome[53]. In 2020, through immunohistochemistry techniques and the real-time reverse-transcript polymerase chain reaction assay, the SARS-CoV-2 nucleocapsid protein and the RNA were detected in the spleen tissue[54-56].

Table 2 Main studies reporting outcomes in patients with pre-existing chronic liver disease

Ref.	Country	Patients	Patients with CLD, *n* (%)	Main findings
Bajaj *et al*[40]	United States	272	37 (13.6)	Higher mortality in cirrhotic COVID-19 positive patients
Hashemi *et al*[41]	United States	363	69 (19)	CLD patients had higher ICU admission and mechanical ventilation rate. CLD was a predictor of mortality
Iavarone *et al*[42]	Italy	50	50 (100)	COVID-19 infection led to liver function deterioration. CLD patients had increased mortality
Marjot *et al*[43]	International	1365	745 (54.6)	CLD correlate to higher mortality rate according to the CPT class. ALD was an independent risk factor for mortality
Qi *et al*[39]	China	21	21 (100)	Respiratory failure was the cause of death in most patients
Singh *et al*[37]	United States	250	60 (46.1)	Pre-existing CLD patients had higher hospitalisation and mortality rates
Sarin *et al*[38]	International	228	228 (100)	Decompensation of pre-existing CLD occurred in one fifth of cirrhotic patients

CLD: Chronic liver disease; COVID-19: Coronavirus disease 2019.

Table 3 Main studies reporting outcomes in liver transplant patients

Ref.	Country	Patients	Patients with LT	Main findings
Bhoori *et al*[45]	Italy	151 (COVID status unknown)	151 (100)	3 deaths recorded in long-term LT recipient on low immunosuppressant dose
Belli *et al*[47]	International	103	103 (100)	Mortality might correlate with age and longer time since LT
Donato *et al*[49]	Italy	640 (8 COVID positive)	640 (100)	Low prevalence of infection in LT patients who adhere to preventive measures
Lee *et al*[48]	United States	38	38 (100)	High mortality in LT patients regardless of time since transplant
Pereira *et al*[46]	United States	90	14 (15)	Solid organ transplant recipient had more severe outcomes
Webb *et al*[50]	International	778	151 (19.4)	LT patients did not have a higher mortality, ICU admission or hospitalisation rate; age and comorbidities correlated with outcomes

COVID: Coronavirus disease; ICU: Intensive care unit; LT: Liver transplant.

This tropism of coronaviruses for the spleen, as for other organs, seems to be mediated by the presence of the ACE2 receptor. In fact, a study published in 2004 already described ACE2 receptors in the red pulp sinus endothelium[57]. More recent studies have confirmed the expression of ACE2 receptor in the splenic tissue, although at lower levels compared to others (*i.e.* small intestine, testis, kidneys, heart, thyroid, and adipose tissue)[58,59]. These studies also highlighted no difference, according to sex and age, in ACE2 receptor expression. Further immunohistochemical studies detected this receptor in tissue-resident CD169+ macrophages[54].

Autopsy studies have revealed interesting anatomical changes in the spleen during SARS-CoV-2 infection[60-63], including a reduction in the splenic cellular composition, with a specific depletion of T and B lymphocyte pools. Some authors assumed that this lymphocytopenia was linked to SARS-CoV-2-induced apoptosis, *via* Fas/Fas-ligand signalling, as well as increased interleukin (IL)-6 secretion by macrophages[54]. Furthermore, other frequent histopathological features were the white pulp atrophy and the reduction or absence of lymphoid follicles, with increased red pulp to white pulp proportion. In addition, spleen autopsies frequently showed a congested and haemorrhagic appearance. Microscopic studies of splenic vessels revealed, in many cases, a splenic infarction due to arterial thrombosis and proliferation of fibrous tissue in the sinuses.

Table 4 Summary of the main studies reporting coronavirus disease 2019 related spleen dysfunction

Ref.	Country	Patients	Patients with spleen involvement, *n* (%)	Main findings
Feng *et al*[54]	China	6	6 (100)	ACE2 expression on tissue-resident CD169+ macrophages in spleen; viral NP antigen found in ACE2+ cells in spleen; direct damage of spleen tissue (lymph follicle depletion, splenic nodule atrophy, lymphocyte reduction, *etc*.)
Remmelink *et al*[55]	Belgium	17	11 (65)	SARS-CoV-2 RNA detected in spleen autopsy samples by RT-PCR assay
Sekulic *et al* [56]	United States	2	2 (100)	SARS-CoV-2 RNA detected at high level in spleen FFPE samples by RT-PCR assay
Han *et al*[58]	China	7356	NA	Expression of ACE2 in spleen tissue (lower than in other tissues), without difference according to sex
Li *et al*[59]	China	31	NA	Expression of ACE2 in spleen tissue (lower than in other tissues), without difference according to sex and age
Xu *et al*[60]	China	10	10 (100)	Decrease in spleen cell composition with decrease in lymphocyte components, white pulp atrophied, lymphoid follicles decreased or absent, increase in red pulp to white pulp ratio
Menter *et al* [61]	Switzerland	21	6 (29)	Acute splenitis and/or septic neutrophilic leucocytosis of the red pulp, suggesting vascular disfunction in patients with COVID-19
Lax *et al*[62]	Austria	11	10 (90)	White pulp atrophy due to lymphocyte depletion, areas of haemorrhage with acute or chronic congestion
Duarte-Neto *et al*[63]	Brazil	5	5 (100)	Lymphoid hypoplasia in 100%, red pulp haemorrhages in 60%, splenitis in 40%, extramedullary haematopoiesis in 50%, endothelial changes in 80%, vasculitis and arterial thrombus in 20%
Lenti *et al*[29]	Italy	63	55 (87.3)	IgM memory B cell depletion that correlates with increased mortality and superimposed infections
Kaneko *et al* [65]	United States	11	11 (100)	Loss of spleen germinal centres due to depletion of Bcl-6+ germinal centre B cells and Bcl-6+ germinal centre T follicular helper cells, resulting in a dysregulated humoral immune response

COVID-19: Coronavirus disease 2019; FFPE: Formalin-fixed paraffin-embedded; NA: Not available; NP: Nucleocapsid protein; RT-PCR: Real-time reverse-transcript polymerase chain reaction; SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2.

The functional impact of these anatomical damages has been poorly investigated. A recent study[12] assessed the splenic immunological function through the detection of circulating IgM+ IgD+ CD27+ B lymphocytes, also known as IgM memory B cells, a unique B cell population in the marginal zone of the spleen which plays a major role in early inflammatory responses, including those caused by viral and bacterial infections [64]. A high prevalence of persistent IgM memory B cell depletion was demonstrated in patients with COVID-19, resulting in a higher mortality rate and an increased risk of developing superimposed bacterial infections. Other molecular studies have suggested that the loss of germinal centres may be due to the depletion of Bcl-6+ germinal centre B cells and Bcl-6+ germinal centre T follicular helper cells, resulting in a dysregulated immune response during the SARS-CoV-2 infection[65]. Although further studies are needed, it can be assumed that splenic involvement could be one of the causes of immune perturbations associated with severe COVID-19[66]. It still has to be ascertained whether the spleen immunological defect is reversible or not. Conversely, the haemocateretic function, assessed by counting pitted red cells (PRCs; red cells with membrane abnormalities [pits] visible under interference phase microscopy[67]) was preserved in patients with acute COVID-19, contrary to what happens in asplenia and spleen hypofunction[12]. The long average life span of circulating erythrocytes (approximately 120 d) might explain the lack of PRC increase in the acute phase of COVID-19.

COVID-19 IN ASPLENIC OR HYPOSPLENIC PATIENTS

It is well known that asplenic or hyposplenic patients are predisposed to a greater risk of developing serious infections or overwhelming post-splenectomy infections, due to the defect in mounting the immune response against encapsulated bacteria[67,68].

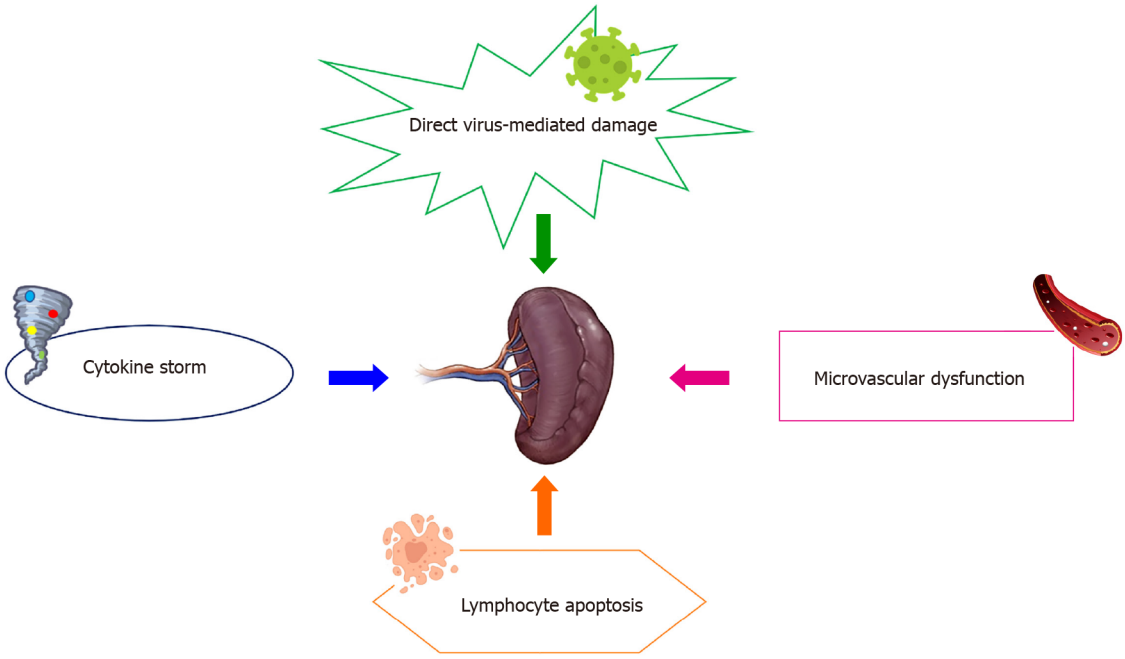

Figure 2 Putative mechanisms of spleen damage in coronavirus disease 2019.

Starting from these premises, it would be interesting to know whether patients with asplenia or spleen dysfunction could be more susceptible to Sars-CoV-2, both in terms of severity and incidence of the disease. Indeed, apart from a document drafted by the British Society of Haematology, stating that asplenic and hyposplenic patients are not exposed to a major risk of COVID-19, data regarding this population are completely missing[69]. Moreover, it is unknown whether patients who might develop spleen hypofunction as a consequence of COVID-19 could be more exposed to infections sustained by encapsulated bacteria and less responsive to vaccine immune-prophylaxis.

According to a single-centre, longitudinal, prospective, study conducted in an academic, tertiary referral hospital from Northern Italy, asplenic/hyposplenic patients did not seem to have an increased risk of developing COVID-19. The study had the purpose of characterising the spleen function, through circulating IgM memory B cell and PRC detection, in patients with COVID-19, in relation to their clinical outcome. Overall, 66 COVID-19 patients (mean age: 74 ± 16.6 years; 29 females) were enrolled; three patients had been splenectomised for trauma, all of them having IgM memory B cell depletion, and one of them died. Most COVID-19 patients had marked IgM memory B cell depletion, and this was associated to a higher mortality rate and a higher risk of developing superimposed infections[12]. Another important study conducted to identify, quantify, and analyse factors associated with COVID-19-related death in one of the largest cohort studies on this topic conducted so far (primary care records of 17278392 adults were linked to 10926 COVID-19-related deaths), considered asplenia as a comorbidity of interest. The results showed that 0.2% of the study population were affected by asplenia, and that the proportion of COVID-19-related death was 0.14%. In addition, asplenic COVID-19 patients had a 1.62 higher risk of death than individuals with a normal spleen function[70].

Indeed, further studies are needed to clarify the impact of SARS-CoV-2 in patients without a spleen or with spleen dysfunction. Table 4 reports the main studies reporting COVID-19 related spleen dysfunction.

CONCLUSION

While the involvement of the respiratory system in SARS-CoV-2 infection is well established, the impact on the liver and spleen has not been explored much. Some studies have shown a direct tropism of the virus for these organs, and this may be one of the mechanisms underlying their damage, in association with the systemic inflammatory response. Regarding the liver, its involvement seems to be quite common, especially in more severe cases of infection, resulting in a worse prognosis for these

patients. The spleen involvement, on the other hand, has been poorly investigated. The splenic immune function appears to be defective in COVID-19 patients, resulting in a higher mortality rate and superimposed infections. Further studies may lead to a better diagnostic and therapeutic approach in SARS-CoV-2-infected patients, especially those with pre-existing liver and spleen diseases, who seem to be at higher risk of a worse outcome.

Abstract

Primary gastric lymphomas (PGLs) are distinct lymphoproliferative neoplasms described as heterogeneous entities clinically and molecularly. Their main histological types are diffuse large B-cell lymphoma (DLBCL) or mucosa-associated lymphoma tissue. PGL has been one of the main fields of clinical research of our group in recent years. Although gastric DLBCLs are frequent, sufficient data to guide optimal care are scarce. Until today, a multidisciplinary approach has been applied, including chemotherapy, surgery, radiotherapy or a combination of these treatments. In this minireview article, we provide an overview of the clinical manifestations, diagnosis and staging of these diseases, along with their molecular pathogenesis and the most important related clinical published series. We then discuss the scientific gaps, perils and pitfalls that exist regarding the aforementioned studies, in parallel with the unmet need for future research and comment on the proper methodology for such retrospective studies. Aiming to fill this gap, we retrospectively evaluated the trends in clinical presentation, management and outcome among 165 patients with DLBCL PGL who were seen in our institutions in 1980-2014. The study cohort was divided into two subgroups, comparing the main 2 therapeutic options [cyclophosphamide doxorubicin vincristine prednisone (CHOP) *vs* rituximab-CHOP (R-CHOP)]. A better outcome with immunochemotherapy (R-CHOP) was observed. In the next 2 mo, we will present the update of our study with the same basic conclusion.

Key Words: Primary gastric lymphoma; Extranodal non-Hodgkin's lymphoma; Diffuse large B-cell lymphoma; Mucosa-associated lymphoid tissue; Immunochemotherapy; Rituximab-cyclophosphamide doxorubicin vincristine prednisone

Specialty type: Gastroenterology and hepatology

Country/Territory of origin: Greece

Core Tip: A few small, heterogeneous, retrospective studies have attempted to determine the optimal treatment for gastric diffuse large B-cell lymphoma, investigating the role of chemotherapy +/- rituximab, surgery and radiation in patient outcomes. Our retrospective research suggests that a better outcome is observed for these patients after the introduction of immunochemotherapy (rituximab-cyclophosphamide doxorubicin vincristine prednisone). Because statistical analysis might differ among various studies, it is crucial to correctly define the terms freedom from progression and lymphoma-specific survival. The latter provides information on whether the patients died from lymphoma or from other causes.

INTRODUCTION

Primary gastric lymphomas (PGLs) are a diverse group of lymphoproliferative disorders that originate from the stomach and comprise many different histologic types. Either of diffuse large B-cell lymphoma (DLBCL) subtype or mucosa-associated lymphoma tissue (MALT) histology, PGL is the second most common gastric malignancy globally, following the adenocarcinoma of the stomach[1,2]. The latter is the most common form of gastric cancer and the fifth most common malignancy in the world[3]. Despite the fact that prevention and treatment of *Helicobacter pylori* infection (*H. pylori* I) has led to a decrease in its overall incidence, gastric cancer remains the 3rd most deadly cancer, with an estimated 783000 deaths in 2018 worldwide[4,5]. Therefore, accurately recognizing and diagnosing gastric cancer from gastric lymphomas is important, as these diseases are treated differently, and any confusion may result in inappropriate treatment management.

The gastrointestinal tract (GIT) is the most common site for the development of extranodal lymphomas. The incidence of these neoplasms has been increasing in recent years[2,6]. The stomach represents 30%-40% of all extranodal lymphomas and 55%-65% of all GI lymphomas. The incidence of PGL varies from 4% to 20% of extranodal non-Hodgkin lymphomas (NHLs) and reaches up to 5% of primary gastric neoplasms[2]. The incidence of PGL is estimated to be 1 per 100000 in Western countries[7]. B-cell lymphomas are more frequent in these countries than in Eastern countries[1].

To date, the term PGL was originally used to describe lymphomas that arise from the stomach. However, within the medical literature, controversy exists regarding the definition, staging and treatment of this entity. Most cases of PGLs are B-cell subtypes of NHLs. The majority of these subtypes have DLBCL histology and are classified as DLBCL of the stomach, not otherwise specified (NOS).

PGLs are histologically heterogeneous neoplasms. This contributes to a different biology, clinical presentation and prognosis and subsequently determines special therapeutic needs for each subtype[8,9]. For example, certain subtypes of PGLs, such as DLBCL, are more aggressive than others and require immediate therapy[8], whereas for patients with MALT histology, unique management is usually applied ranging from watch and wait to antibiotic-based treatment[9].

As stated above, PGLs are histologically, biologically and clinically heterogeneous neoplasms. Although gastric DLBCL is an extranodal high-grade lymphoma, it is considered less aggressive than its nodal counterpart and other extranodal DLBCL locations. Its appropriate treatment has not been satisfactorily determined, and treatment choices vary considerably. Human immunodeficiency virus, Epstein-Barr infection, hepatitis B virus, human T-cell lymphotropic virus 1, immunosuppression, celiac disease, inflammatory bowel disease, and *H. pylori* I have all been implicated in the factors predisposing patients to PGLs, increasing the risk of developing the disease [1,2,10]. PGL usually occurs in patients older than 50 years. There are many older

patients over 80 years of age. Males are more prone to be diagnosed with PGL with a 2-3-fold higher risk than females[2].

This review mainly focuses on DLBCL gastric lymphoma, which is one of the main fields of our clinical research and comments briefly on MALT lymphoma. The molecular etiology and pathophysiology of DLBCL gastric lymphomas and the available clinical data for their optimal management will be discussed. In parallel, a brief review of the MALT subtype that represents almost 50% of PGLs will also be provided. This review aims to meet the therapeutic needs of those who are involved and/or interested in the treatment of GI-DLBCL lymphomas and extensively focuses on the role of rituximab, the first in class anti-CD20 monoclonal antibody (mAb), in the outcome of patients with PGL of the DLBCL subtype.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The stomach is the most common site for the development of extranodal lymphomas in the GI tract, accounting for 60% of cases, followed by the small bowel, ileum, cecum, colon and rectum[7]. Distinguishing PGL from secondary dissemination of the stomach due to primary nodal lymphoma can be difficult. No peripheral and mediastinal lymphadenopathy at the time of diagnosis, no spleen or liver infiltration and normal blood counts are in contrast to the presence of a secondary gastric lymphoma[11].

The diagnosis of PGL can be delayed for many years due to the presence of nonspecific symptoms, mimicking peptic ulcer disease, gastritis, functional gastric or even pancreatic disorder. The main symptoms include nausea, vomiting, anorexia, abdominal distention, fullness or pain, indigestion, dyspepsia and weight loss, whereas weakness, night sweats, fever, jaundice, hematemesis or melena are less common[2,7]. An obvious epigastric mass or perforation is rare as an initial presentation[7,10,12].

An appropriate endoscopic evaluation with generously sized tissue samples is the hallmark of diagnosis. The diagnostic accuracy of endoscopic biopsy is very high, reaching 90%. Endoscopic ultrasonography can improve this diagnostic accuracy. The diagnosis becomes difficult when there is deep infiltration and preservation of the mucosa. Computed tomography (CT), magnetic resonance imaging (MRI) and 18F-fluorodeoxyglucose positron emission tomography (FDG-PET) assist in the diagnosis and staging of PGL[1,7]. Sporadically, PGL might present as multifocal, clonally identical foci surrounded by macroscopically unaffected tissue. Thus, gastric mapping of unaffected mucosa is strongly recommended[13]. Bone marrow infiltration, B symptoms and elevated lactate dehydrogenase (LDH) are more frequently encountered in nodal lymphomas than in gastric lymphomas[13].

Different staging systems have been proposed for PGLs. The Ann Arbor staging system, which is widely used for primary nodal lymphomas, is considered unsatisfactory as PGLs originate from the lining of the stomach instead of the lymph nodes[7,13]. In recent years, a more specific Lugano staging system for PGLs was proposed and applied based on the Lugano score[14,15], which includes the following stages: Stage IE — Lymphoma is confined to the GIT (single lesion or multiple noncontiguous lesions): IE1 = mucosa, submucosa; IE2 = muscularis propria, serosa; Stage II — Lymphoma extends into the abdomen from the primary site within the GI tract: II1 = local nodal involvement; II2 = distant nodal involvement; Stage IIE — Penetration of serosa to involve adjacent organs or tissues; Stage IV — Disseminated extranodal involvement or concomitant supra diaphragmatic nodal involvement. Note: Stage III does not exist because gastric lymphoma is always below the diaphragm.

A complete staging work-up includes the following: Biochemical examinations, chest, abdomen and pelvis CT scan, bone marrow biopsy, thorough endoscopy including biopsies from the stomach, duodenum and gastroesophageal junction, endoscopic ultrasound, evaluation of the Waldeyer ring, investigation for *H. pylori* I, routine histology and immunohistochemistry. Cytogenetic studies and even fluorescence in situ hybridization (FISH) can all be used in biopsies to provide the appropriate information needed for optimal treatment. PET/CT scans have documented diagnostic and prognostic value only for DLBCL lymphomas, in contrast to MALT gastric lymphomas, which can be reported as false-negative because of the small tumor burden of the disease and their indolent behavior[13]. However, there is an unmet need regarding the use of PET scans in the clinical setting to guide treatment. Usually, this examination is performed before and after the end of treatment to guide therapeutic decisions as a standard of care. Because the stomach is

an abdominal organ, it is unclear how PET scans can assist in the aforementioned necessary clinical decisions.

In general, the prognosis of extranodal lymphomas varies according to the affected organ; it is poor in the testis, central nervous system (CNS) and intestine, whereas it is quite good in the stomach, mediastinum and bone. Nevertheless, PGL is an aggressive malignancy characterized by rapid growth. However, the prognosis of DLBCL PGL is relatively good, with a 5-year overall survival (OS) higher than 80%[7].

COMPARISON AMONG CLINICAL STUDIES/TREATMENT

The optimal treatment for DLBCL PGLs is not clear, because prospective clinical studies are missing. In the past, a spectrum of treatment approaches was applied, ranging from gastrectomy or radiotherapy alone to chemotherapy (cyclophosphamide doxorubicin vincristine prednisone, CHOP) or the combination of chemotherapy plus radiotherapy and surgery. Wang *et al*[16] compared surgery over conservative treatment in a retrospective study. Conservative treatment in this study included chemotherapy (CHOP) or radiotherapy alone, chemotherapy plus radiotherapy or *H. pylori* I eradication (HPE). The authors found superiority of surgery alone compared with conservative treatment in the DLBCL type regarding prognosis, but not in the MALT type[16]. Currently, the role of surgical resection has been minimized, even in cases of extreme intestinal obstruction, as immunochemotherapy can induce rapid and complete resolution of large obstructing tumor masses. Gastrectomy is restricted to the management of major complications, including perforation or hemorrhage of DLBCL PGLs.

In contrast, other studies demonstrated that DLBCL PGL is a potentially curable disease with rituximab-CHOP (R-CHOP)-like treatment, leading to long-term survival [17]. Investigators found that surgical treatment did not offer survival benefits when compared with chemotherapy for 5-year progression-free survival (PFS) and OS estimates and that no significant differences were noted in these endpoints for patients treated with R-CHOP or conventional chemotherapy[18].

Sohn *et al*[19] directly compared CHOP *vs* R-CHOP as a front-line approach in 93 patients with DLBCL PGL. With a median follow-up of 48 mo, no differences were noted among the 2 groups regarding OS, EFS and CR. High serum levels of β2-microglobulin were associated with worse OS and EFS in patients who received R-CHOP[19]. In a retrospective analysis of 95 Japanese patients, the clinical outcomes of gastric DLBCL were extremely favorable for localized-stage patients in the rituximab era. Conversely, these treatments were poor for advanced-stage patients[20]. Interestingly, an effective approach in treating deeply infiltrated DLBCL PGL patients by switching fractioned R-CHOP (rituximab d0, 50% dose of CHOP d1 and d5) to standard R-CHOP cycles guided by endoscopic ultrasonography has been proposed [21].

The following factors were identified as having a negative impact on survival: age above 65, Eastern Cooperative Oncology Group 2-3, B symptoms, bulky disease, IPI 3-4, more than 3 treatment lines, and absence of response to first-line treatment[17].

Conversely, other factors were considered negative for prognosis in the subsequent study: elevated LDH levels, chemotherapy or radiotherapy alone or the combination of chemotherapy plus radiotherapy[16]. The non-germinal center B-cell-like lymphoma (GCB) subtype has also been associated with shorter OS[18]. *H. pylori* I negativity, advanced Lugano stage and elevated LDH levels have been reported as adverse prognostic factors in gastric DLBCL[22].

Low serum albumin at diagnosis was the only risk factor for developing gastric complications, such as bleeding and stenosis, in patients with gastric DLBCL who received R-CHOP[23]. Furthermore, a low CD4:CD8 ratio at diagnosis is an independent poor prognostic factor for subsequent OS and EFS24 (24 mo after diagnosis) in patients with gastric DLBCL[24]. Finally, the microRNA miR-150 is reportedly a negative independent prognostic biomarker for primary GI DLBCL[25].

Some patients with DLBCL PGL also have a MALT component. The 5-year PFS and OS estimates were similar when de novo DLBCL patients were compared with DLBCL/MALT patients, suggesting that patients with a MALT component, along with DLBCL, might have the same biological type of lymphoma as de novo DLBCL patients [18]. In such DLBCL/MALT cases, an important deregulation of Bcl-2 and an upregulation of p53 protein of uncertain clinical significance have been observed[26]. A synopsis of the studies comparing R-CHOP *vs* CHOP for DLBCL PGLs is shown in Table 1. Indeed, there is a lack of a head-to-head comparison between CHOP and R-

Table 1 Studies comparing rituximab-cyclophosphamide doxorubicin vincristine prednisone *vs* cyclophosphamide doxorubicin vincristine prednisone for diffuse large B-cell lymphoma primary gastric lymphomas

Ref.		Number of Pts	R-CHOP OS	CHOP OS	R-CHOP PFS	CHOP PFS	Comments
Sohn *et al* [19], 2012	Double-arm Retrospective Study (R-CHOP *vs* CHOP as 1st line treatment)	93 (55 R-CHOP, 38 CHOP)	3-yr 84.7% ($P > 0.05$)	3-yr 94.7% ($P > 0.05$)	3-yr 81.7% (EFS) ($P > 0.05$)	3-yr 86% (EFS) ($P > 0.05$)	CR: (CHOP: 93.9%), (R-CHOP: 92.5%)

CHOP in PGLs.

Regarding the role of radiotherapy, more data are available for patients with gastric MALT lymphoma or early-stage gastric lymphoma. When there is an unsatisfactory response to HPE, recurrence after HPE or in MALT cases negative for *H. pylori* I, gastric radiotherapy of the entire stomach plus irradiation of the pathological and perigastric lymph nodes (30-440 Gy, 15-20 fractions) has been proposed. However, it is less clear whether radiotherapy should be applied in cases of DLBCL PGLs. However, involved-field radiotherapy has a role, especially for patients with DLBCL PGL of advanced stage who achieve partial remission (PR) after immunochemotherapy (R-CHOP)[27]. R-CHOP plus additional local treatment for gastric lesions (*e.g.*, consolidative radiotherapy or surgical resection) has also been recommended[28]. Alternatively, several studies have found that in the era of immunochemotherapy (R-CHOP), radiotherapy does not improve OS[29-31]. The side effects of radiotherapy should always be taken into account in clinical decision making[27].

Despite the presence of several clinical series involving primary gastric DLBCL lymphomas mainly addressing the issue of selecting the optimal treatment, there are sporadic single cases in the literature[22,32-34]. Some very rare, more aggressive cases of DLBCL lymphoma originating from the stomach and infiltrating the adrenals bilaterally have been reported[32,34]. The first patient presented with nausea, vomiting, abdominal pain and hypotension, was treated with glucocorticoids and died after developing respiratory failure, severe hypotension refractory to vasopressors and severe metabolic acidosis[34]. The second case was a DLBCL, PGL of the non-germinal center (non-GC) type. This patient received 8 cycles of rituximab therapy, 6 cycles of CHOP and 3 cycles of prophylactic intrathecal chemotherapy. The patient maintained a CR for approximately 14 mo after the completion of the aforementioned treatment. The latter is in favor of the hypothesis that DLBCL lymphomas of the stomach have a better prognosis than other DLBCL nodal and extranodal lymphomas. In contrast to the very dismal prognosis of primary adrenal lymphomas (PALs)[35], this patient survived, likely because the primary neoplasm was gastric DLBCL, which has better biological and clinical behavior for unknown molecular reasons (even though it is considered an aggressive neoplasm, being DLBCL).

Regarding the role of HPE, Nakamura *et al*[36] studied 420 patients with gastric MALT lymphoma and found a significant responsiveness to HPE therapy (77%), with treatment failure (relapse or progressive disease) occurring in only 9% of the patients. However, this primary refractory disease was not associated with a dismal outcome, as the subsequent therapy still yielded a 90% OS rate after 10 years[36].

Nevertheless, even though HPE has already been established as an optimal strategy for the management of gastric MALT lymphoma, there are conflicting results, either in favor of or against HPE for patients with DLBCL PGLs. Thus, HPE has been reported to be a suitable strategy for patients with DLBCL PGLs[37,38]. The concept of a less

aggressive biological behavior for *H. pylori* I-dependent gastric DLBCL has been proposed with the suggestion to apply HPE in such cases[39]. However, it is not clear how accurately these lymphomas can be distinguished. Alternatively, high-grade gastric lymphomas can rapidly progress if they do not respond to HPE. The loss of *H. pylori* I dependency and the possible high-grade lymphomatic evolution/transformation are separate and distinct events in the natural history of PGL[38,40]. The description of defined molecular markers linked to *H. pylori* I dependency of PGLs is beyond the scope of this article.

Moreover, a substantial portion of early-stage *H. pylori* I-positive gastric de novo DLBCLs remain *H. pylori* I-dependent and respond to antibiotic treatment (HPE). Prospective studies to validate these findings are needed[41]. Our personal opinion is that HPE should not be applied as monotherapy, even in the early stage of *H. pylori* I-positive DLBCL PGLs.

MOLECULAR PATHOGENESIS

Extranodal lymphomas are distinct types of lymphomas that show a predilection for anatomical sites harboring extranodal lymphoid tissue, such as the CNS, testis, mediastinum, bone and GIT, in contrast to the typical pattern of the nodal counterpart in the lymph nodes for nodal lymphomas[42]. Extranodal lymphomas can even appear in immune-privileged (sanctuary) sites (CNS, testis) or arise in sites of chronic inflammation, effusions or other closed spaces within the body. The complex mechanisms of local immune evasion leading to extranodal lymphoproliferations have not been fully elucidated[43]. The capacity of mature lymphocytes to recirculate between blood and lymphoid tissue and to migrate to extranodal anatomical sites is crucial for the pathogenesis of the disease. During this process, lymphocytes interact with endothelial venules, mediated by receptor molecules (integrins and lymphocytes)[44].

The role of specific B-cell receptor (BCR) antigens has been proposed in the process of lymphomagenesis. Oncogenic translocations during BCR development and generation (VDJ rearrangement), the activation of mature B-cells and the germinal center reaction, the mechanisms of loss of immunological self-tolerance, and the role of infectious agents and autoantigens are all hallmarks and basic elements of lymphomagenesis, a complex multifactorial process, in both aggressive and indolent lymphomas[45]. Gastric DLBCL is a high-grade lymphoma compared to low-grade MALT lymphomas. Whether DLBCL transforms from low-grade MALT lymphoma or whether it arises de novo in the stomach is unknown. DLBCL gastric lymphoma has been associated with a lower CR and shorter survival than MALT lymphoma[2,46]. Nevertheless, transformed DLBCLs from MALTs are CD10- and Bcl-2-negative, while de novo DLBCLs are CD10- and Bcl-2-positive[31,46].

The oncogene Bcl-6 is located on chromosome 3q27 and is frequently present in the majority of extranodal high-grade lymphomas. Conversely, Bcl-2 oncogene expression was significantly lower in gastric lymphomas than in other primary extranodal high-grade B-cell lymphomas (HGBCLs). p53 protein expression did not differ significantly between these 2 groups[2].

Primary gastric DLBCL

DLBCL is described by diffuse proliferation of large, atypical cells, with vesicular nuclei, prominent nucleoli, and basophilic cytoplasm. These cells typically express CD19, CD20, CD22 and CD79a (pan-B-cell markers). Bcl-6 is expressed in 60% of cases. FISH can identify poor prognostic subtypes of DLBCL, such as double-hit (DH) or triple-hit (TH) lymphomas (high-grade, B-cells), characterized by translocations of MYC and Bcl-2 and/or Bcl-6[47,48]. DH or TH lymphomas are defined by their genetic aberrations, irrespective of their morphology. Genetic variability has been documented for DLBCL PGL[47]. Gene expression profiling distinguishes DLBCL into GCB and non-GCB or activated B-cell-like (ABC) subtypes based on the cell of origin profile. ABC lymphomas show a worse prognosis than GCB lymphomas[49]. In routine diagnostic practice, this screening is conducted by immunohistochemistry based on the assessment of three markers (CD10, bcl-6 and MUM1)[50] (Figure 1).

More analytically, ABC DLBCLs are characterized by nuclear factor kappa beta (NF-κB) activation, showing a higher frequency of Bcl-2 amplifications, Bcl-6 rearrangements and recurrent mutations of MYD88, PRDM1 and CD79B, whereas GCB-like DLBCLs are enriched for activating EZH2 and Bcl-2 mutations, defined by perturbations/molecular defects in the JAK/STAT and PI3K/AKT signaling pathways [48]. EZH2 overexpression has been associated with inferior outcomes in patients with

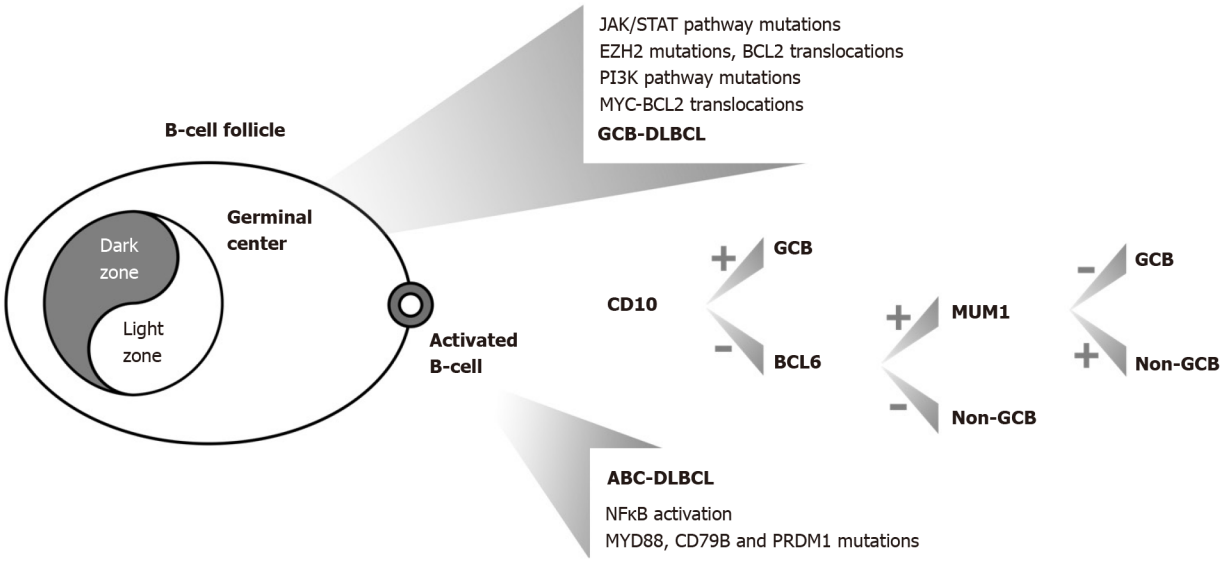

Figure 1 Primary gastric diffuse large B-cell lymphoma lymphomas and related molecular lesions. GCB: Germinal center B-cell lymphoma; ABC: Activated B-cell-like lymphoma; the combination of MYC plus BCL2 translocations corresponds to 'double hit lymphomas'; DLBCL: Diffuse large B-cell lymphoma; NF-κβ: Nuclear factor κappa beta.

DLBCL PGL[51] (Figure 1).

Interestingly, 2 HGBCLs were included in the recent revised WHO classification of lymphoid neoplasms. These entities are clinically and biologically distinct from DLBCL NOS and Burkitt lymphoma (BL). The HGBCL, NOS entity includes cases previously termed 'unclassifiable, with features intermediate between DLBCL and BL', or showing blastoid morphology but lacking DH/TH translocations[49].

High levels of Bcl-6 expression were found in GCB gastric lymphomas, whereas in the non-GCB cases, a high Bcl-6 expression level correlated importantly with mutations producing Bcl-6 deregulation, even if in the latter cases no correlation was found between survival rates[2].

Clinical studies addressing the role of programmed cell death 1 (PD-1) and its ligand (PD-L1) have shown promising results. PD-1 blockade in patients with PD-L1 expression on tumor cells has been linked with clinical responses. Investigators from Japan evaluated the role of PD-L1 expression on neoplastic and non neoplastic immune cells in the microenvironment (miPD-L1) in a retrospective study of patients with GI DLBCL lymphoma. They found that elevated miPD-L1 expression had a favorable impact on the outcome of these DLBCL patients, regardless of the anatomical site of the disease[52].

Gastric MALT lymphoma

MALT lymphoma is a low-grade B-cell NHL, and the majority of cases (approximately 90%) are directly related to *H. pylori* I. However, 10% of gastric MALT lymphomas are *H. pylori* I negative[53]. Chronic *H. pylori* I of the gastric mucosa and the accompanying inflammation have been strongly linked to MALT lymphomagenesis. Moreover, abnormalities in the expression of various miRNAs contribute to the neoplastic gastric phenotype[54,55].

H. pylori I expresses proteins related to the corresponding genes, contributing to the related lymphomagenesis from the bacterium. These are cytotoxin-associated gene A (CagA), vacuolization cytotoxin A (VacA) and heat shock proteins (Hsps). The Cag pathogenicity island (a common gene sequence considered responsible for the pathophysiology of the infection) contains over 40 genes, which mainly code for a complex type IV secretion system. This pathogenicity island is usually absent from *H. pylori* I strains isolated from asymptomatic human carriers. The CagA protein is frequently co-expressed with the vacuolating cytotoxin VacA[56].

Hamoudi *et al*[57] established the connection between abnormal NF-κB signaling due to the chromosomal translocations, t(11;18)(q21;q21)/*API2-MALT1*, t(1;14)(p22;q32)/BCL10-IGH, t(14;18) (q32;q21)/IGH-MALT1 and t(3;14) (p13;q32)/FOXP1-IGH,in gastric MALT lymphomas[57,58] (Figure 2).

MALT1 and BCL10 proteins are involved in surface immune receptor-mediated activation of the NF-κB transcription factor; chromosomal translocations involving

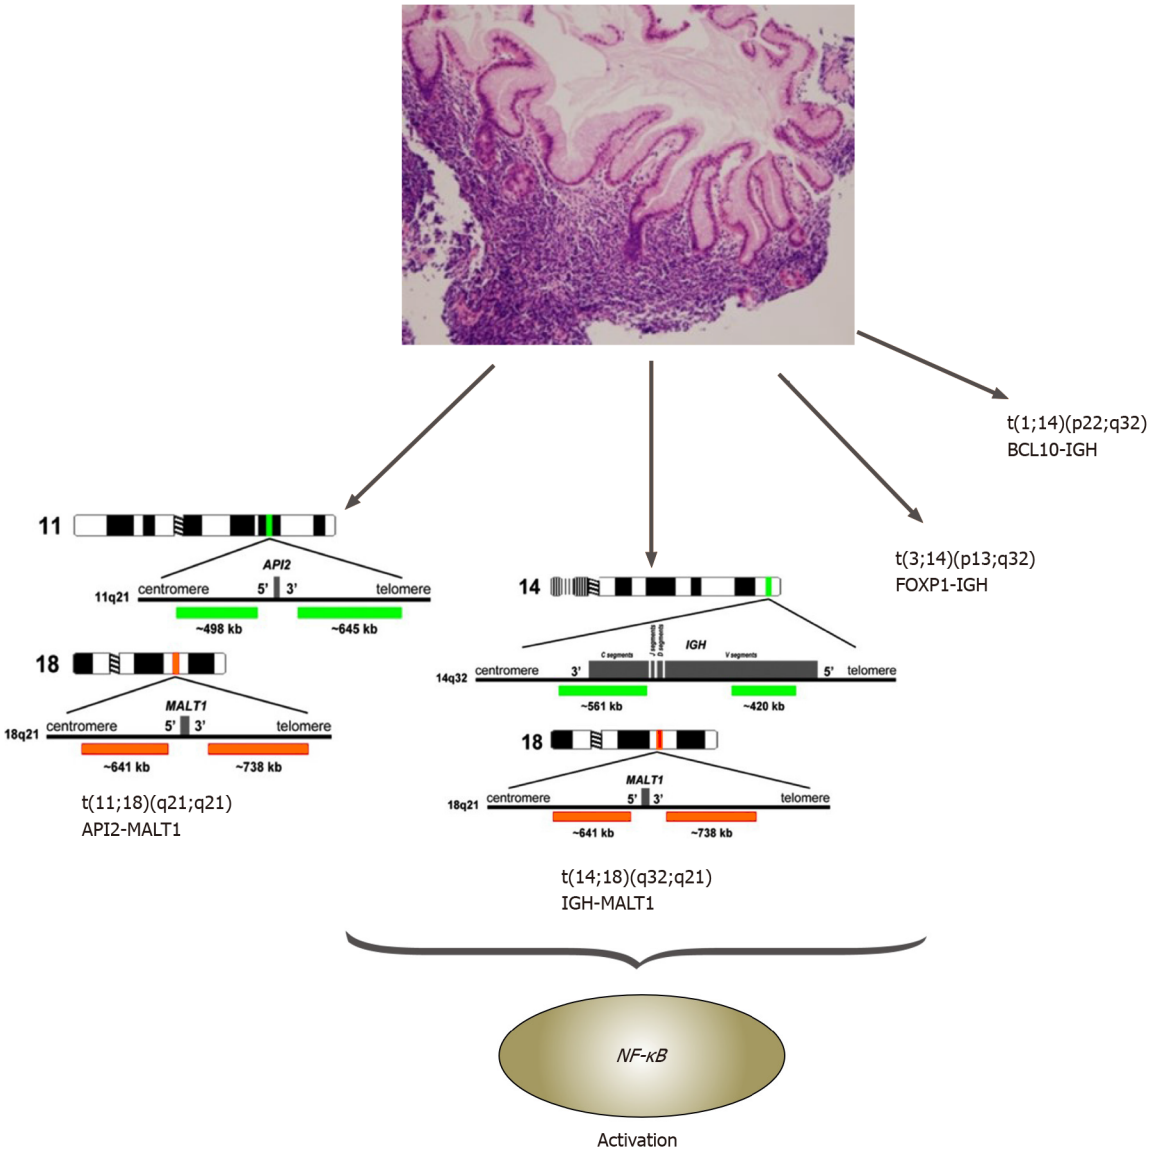

Figure 2 Gastric mucosa-associated lymphoid tissue lymphomas and related chromosomal translocations. BCL: B-cell lymphoma; FOXP: Forkhead box protein; IGH: Immunoglobulin heavy (chain); MALT: Mucosa-associated lymphoid tissue; NF-κB: Nuclear factor κappa beta.

these genes are believed to exert their oncogenic activities through constitutive activation of the NF-κB pathway, leading to the expression of numerous genes important for cell survival and proliferation[40,55,57,58] (Figure 2).

In gastric MALT lymphoma, t(11;18)/*API2-MALT1* is the most frequent translocation, detected in 20% of cases. This translocation fuses the N-terminal region of *API2* to the C-terminal region of *MALT1* and generates a functional chimeric fusion, which can activate the NF-κB pathway. Clinically, t(11;18) is more frequently associated with the absence of *H. pylori* I, and the majority of translocation-positive cases do not respond to HPE therapy. Interestingly, t(11;18)-positive cases rarely transform to DLBCL[55,58].

Gastric MALT lymphoma is indirectly influenced by *H. pylori* I through T-cell stimulation, and recent studies have shown that *H. pylori*-triggering chemokines and their receptors, *H. pylori*-associated epigenetic changes, *H. pylori*-regulated miRNA expression and tumor infiltration by $CD4^+$ $CD25^+$ regulatory T cells contribute to lymphomagenesis of gastric MALT lymphoma (Figure 3). Recent studies have also demonstrated that the translocation of CagA into B lymphocytes inhibits apoptosis through p53 accumulation, BAD phosphorylation and the upregulation of Bcl-2 and Bcl-XL expression (Figure 3). In gastric MALT lymphoma, CagA may stimulate lymphomagenesis directly through the regulation of signal transduction, and intracellular CagA is associated with *H. pylori* I dependence. These findings represent a substantial paradigm shift compared with the classical theory of *H. pylori*-reactive T cells contributing indirectly to the development of MALT lymphoma[40].

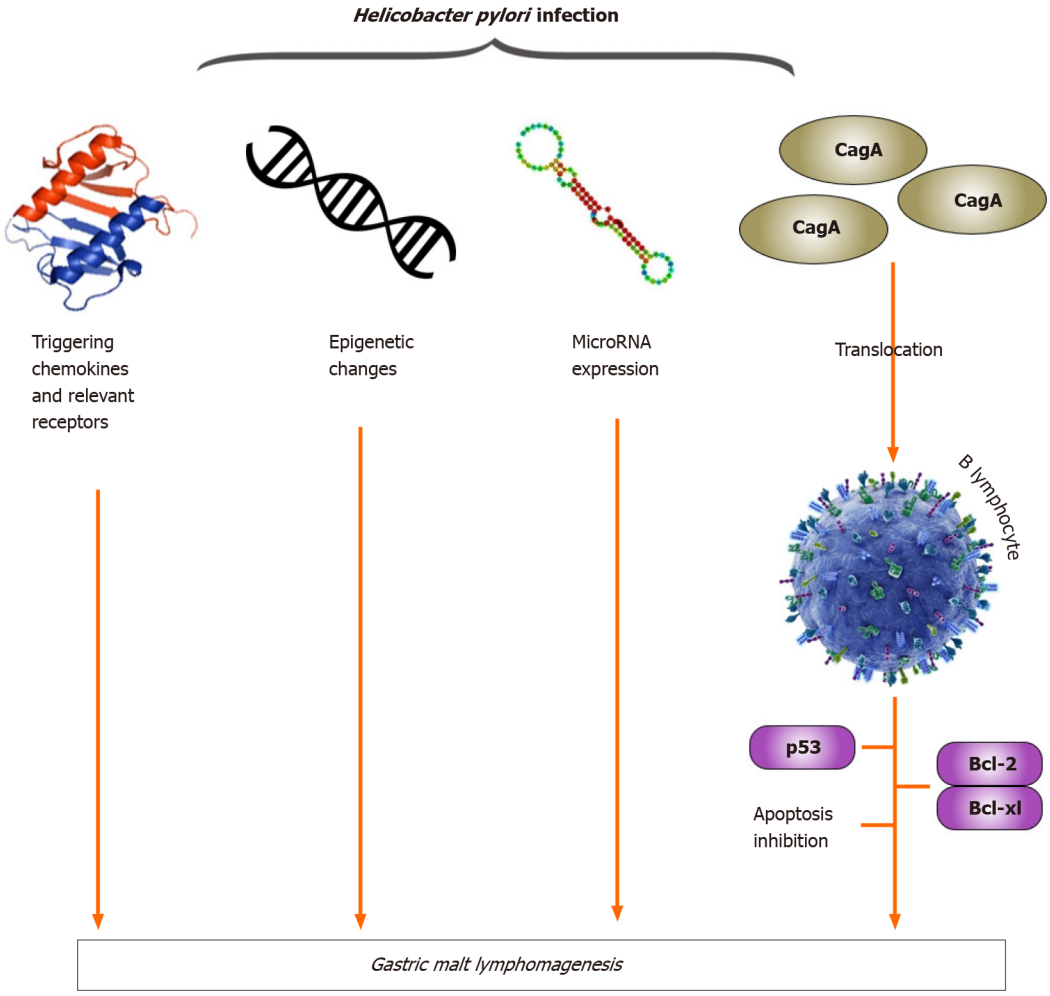

Figure 3 *Helicobacter pylori* infection, molecular mechanisms and gastric mucosa-associated lymphoid tissue lymphomagenesis. BCL: B-cell lymphoma; Bcl-XL: B-cell leukemia XL; CagA: Cytotoxin-associated gene A.

Other cytogenetic aberrations, often associated with one of the four main chromosomal translocations described above, include trisomies 3, 12 and/or 18, which can also present as a sole abnormality in one-fifth of the total cases. Somatic missense mutations in PIM1 and cMYC have been reported in 46% of MALT gastric lymphomas and in 30% of transformed MALT lymphomas. The majority of these genetic lesions are not MALT lymphoma specific. Aberrant somatic hypermutation can still be encountered in indolent lymphomas, such as MALT, but not at the extent noted in DLBCL lymphomas[40,55,58]. Interestingly, the loss of the chemokine receptor CXCR4 and the upregulation of CXCR7 have been associated with the progression of gastric MALT lymphoma to DLBCL lymphoma[59]. Furthermore, lower expression of the microRNA miR-34a has also been linked to the transition from MALT to DLBCL lymphoma[54]. Finally, among the proposed pathogenetic etiologies for *H. pylori*-negative MALT lymphoma cases, genetic alterations in NF-κB signaling are the main hypothesis[53].

SCIENTIFIC GAPS

While gastric DLBCLs are frequent, sufficient data to guide optimal care are still limited. In the past, gastrectomy was the treatment of choice for these patients. Nevertheless, due to the observed high morbidity rates linked with this procedure, novel therapeutic approaches have emerged, such as radiation and combination chemotherapy. Hence, until today, a multidisciplinary approach has been applied, including chemotherapy, surgery, radiotherapy or a combination of these modalities.

Today, immunochemotherapy with R-CHOP is the most acceptable option for treating gastric DLBCL, as for nodal DLBCL. R-CHOP was established as a standard approach for DLBCL patients; in the study of patients aged 60-80 years, the rate of

complete response (CR) was significantly higher in the group that received R-CHOP *vs* CHOP[60]. Since then, a few small, heterogeneous, retrospective studies have attempted to determine the optimal management of gastric DLBCL, investigating the role of immunochemotherapy, surgery and radiation in patient outcomes[16-21,23,61-63].

Significant advances in diagnosis, treatment and response assessment options over the last years have been made in the field of high-grade lymphomas. Molecular characterization of DLBCL has also described 3 major lymphoma subgroups that correlate with distinct biological and clinical behavior (ABCs, GCBs, double hit lymphomas), supporting the rationale for distinct therapeutic options[48]. However, these advances were extracted from nodal DLBCL, while the intrinsic pathogenesis of primary gastric DLBCL is unclear, and similar studies on this particular type of lymphoma are lacking.

The heterogeneity of the various clinical retrospective studies investigating the outcomes of patients with DLBCL PGLs is impressive. For example, these studies differ in the number of patients, in the time intervals when each therapeutic approach was applied, or in the type of therapeutic approaches compared. Other studies calculate surgery alone and other surgeries with chemotherapy and/or radiotherapy, without separating treatment subgroups of patients. Some researchers place all DLBCL patients together into the statistical analysis, regardless of the anatomical site (stomach, intestine). Hence, comparisons are difficult and not head-to-head. Thus, evidence-based conclusions cannot be drawn, and these results should be regarded with caution.

Finally, the use of various staging systems combined with the variability in the applied procedures for staging make the application of meaningful comparisons among the published series difficult.

CURRENT AND FUTURE RESEARCH — FRONTIER PERSPECTIVE

We retrospectively evaluated the clinical profile and the patterns of outcome among patients who were treated after the diagnosis of aggressive, B-cell, primary endocrine lymphoma (another type of extranodal lymphoma). The patients were diagnosed with either primary testicular lymphoma, primary thyroid lymphoma (PTHL), or PAL. Better outcomes were observed in patients with PTHL for whom the median OS had not been reached until the end date of the study, whereas the PAL group had the worst prognosis[35].

To better understand the nature and outcome of extranodal DLBCL PGL, we described patients' and disease characteristics and assessed trends in treatment options, management and outcome among 159 newly diagnosed patients with primary gastric DLBCL who were seen in our institutions in the years 1971-2017.

Previously, we retrospectively evaluated the trends in clinical presentation, management and outcome among 165 consecutive patients with biopsy-proven primary gastric DLBCL who were seen in 1980-2014. The study cohort was divided into two subgroups based on the era of treatment (CHOP *vs* R-CHOP, before and after the initiation of rituximab). A better outcome after immunochemotherapy (R-CHOP) was observed comparatively[64].

Our novel manuscript and update of the same cohort of patients will be sent for peer review within the next 2 mo (under preparation). We have been preparing and analyzing it for years, focusing on the proper methodology and aiming to correct the perils and pitfalls seen in other relevant studies in the past. We will still have the same conclusion that a better outcome has been noted for the R-CHOP patient cohort, as in the past[64]. However, there are individual variations of the results regarding the OS and freedom from progression (FFP) time intervals, which will be analyzed accordingly, now that a longer follow-up of the patients has been achieved.

The term FFP is based on the strict scientific definition for this type of lymphoma and is preferable to define the aforementioned important endpoint for retrospective clinical studies. PFS has disadvantages in nonrandomized studies because in such studies, there is a lack of specific or concrete criteria for the comparison between time intervals (fixed check points), necessary for the re-evaluation of the disease and the definition of relapse in a similar way (for example, with CT or MRI). However, the term PFS is more widely used in the literature in an equivalent meaning for these lymphomas without being absolutely accurate or to the point in a strict scientific sense. We especially focused on defining FFP accurately, as this is crucial for this novel study. FFP for our novel update will be measured from the initiation of the first treatment until relapse or until death or until the last day of the study for the non

relapsed patients or until the day of the last follow-up for the censored patients (lost to follow-up).

Per-protocol analysis will be used in our clinical research compared to intention-to-treat analysis. The latter is considered a better marker of treatment efficacy for prospective, randomized studies and not for retrospective studies.

Finally, lymphoma-specific survival, another important endpoint, will be measured from diagnosis until the time of death from lymphoma. The number of patients who died from causes other than lymphoma was not calculated at this endpoint. As the long-year follow-up continued, we noted a proportion of our patients dying from lymphoma but also other patients dying from causes other than lymphoma. This analysis is important because it attributes the specific hazard ratio to DLBCL gastric lymphoma (death risk) and separates causes of death other than lymphoma for patients who have survived longer. Importantly, when a patient died from another cause in addition to lymphoma, there was no relapse because the patient was in follow-up. Thus, the possible drug might have protected the patient from relapse, and these patients contributed to the studied time-to-event analysis.

CONCLUSION

In conclusion, retrospective studies, despite their limitations, if conducted with the correct methodology, can provide useful clinical information for treating patients. Our research in recent years has shown that immunochemotherapy (R-CHOP) is the optimal treatment for patients with DLBCL PGLs, as it is associated with a better outcome.

Abstract

BACKGROUND

Crohn's disease (CD) is an incurable intestinal disorder with unclear etiology and pathogenesis. Currently, there is a lack of specific biomarkers and drug targets for CD in clinical practice. It is essential to identify the precise pathophysiological mechanism of CD and investigate new therapeutic targets.

AIM

To explore a new biomarker and therapeutic target for CD and verify its role in the CD pathological mechanism.

METHODS

Proteomics was performed to quantify the protein profile in the plasma of 20 CD patients and 20 matched healthy controls. Hub genes among the selected differentially expressed proteins (DEPs) were detected *via* the MCODE plugin in Cytoscape software. The expression level of one hub gene with an immunoregulatory role that interested us was verified in the inflamed intestinal tissues of 20 CD patients by immunohistochemical analysis. After that, the effects of the selected hub gene on the intestinal inflammation of CD were identified in a CD cell model by examining the levels of proinflammatory cytokines by enzyme-linked immunosorbent assays and the expression of the NF-κB signalling pathway by quantitative real-time PCR analysis and Western blot assays.

RESULTS

Thirty-five DEPs were selected from 393 credible proteins identified by proteomic analysis. Among the DEPs, fibrinogen-like protein 1 (*FGL1*), which attracted our attention due to its function in the regulation of the immune response, had 1.722-fold higher expression in the plasma of CD patients and was identified as a hub gene by MCODE. Furthermore, the expression of *FGL1* in the intestinal mucosal and epithelial tissues of CD patients was also upregulated ($P < 0.05$). *In vitro*, the mRNA levels of *FGL1* and *NF-κB*; the protein expression levels of FGL1, IKKα, IKKβ, p-IKKα/β, p-IκBα, and p-p65; and the concentrations of the proinflammatory cytokines IL-1β, IL-6, IL-17, and TNF-α were increased ($P < 0.05$) after stimulation with lipopolysaccharide, which were reversed by knockdown of FGL1 with siRNA transfection ($P < 0.05$). Conversely, FGL1 overexpression enhanced the abovementioned results ($P < 0.05$).

CONCLUSION

FGL1 can induce intestinal inflammation by activating the canonical NF-κB signalling pathway, and it may be considered a potential biomarker and therapeutic target for CD.

Key Words: Crohn's disease; Fibrinogen-like protein 1; Proteomics; NF-κB pathway

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: In this study, fibrinogen-like protein 1 (FGL1) was identified to be significantly upregulated in the plasma and intestinal mucosa of Crohn's disease (CD) patients. *In vitro*, silencing FGL1 downregulated the levels of the proinflammatory cytokines IL-1β, IL-6, IL-17, and TNF-α. Furthermore, FGL1 knockdown suppressed the mRNA expression of *NF-κB* and the protein levels of IKKα, IKKβ, p-IKKα/β, p-IκBα, and p-p65. These results could be reversed by the overexpression of FGL1. Taken together, these data suggest that FGL1 may induce intestinal inflammation by activating the canonical NF-κB signalling pathway and has the potential to be a therapeutic target for CD.

INTRODUCTION

Crohn's disease (CD) is a chronic, idiopathic intestinal inflammatory disease affecting any segment of the gastrointestinal tract. Although CD is believed to be a result of an imbalanced interaction among genetic susceptibility, environmental factors, the intestinal microflora, and the immune system, the precise pathogenesis is still not entirely clear[1]. Consequently, CD remains incurable even though great advancement has been achieved in medical therapy. Symptoms evolving in a relapsing and remitting manner indicate that CD has a progressive disease course that may induce complications, such as abscess, fistula, and stricture development. Eventually, up to 70% of CD patients require at least one intestinal surgery over their lifetime[2]. Targeted therapy is anticipated to change the natural course of CD, and even to cure it.

Currently, anti-tumor necrosis factor (TNF) agents (infliximab, adalimumab, and certolizumab pegol) are the most potent drugs for inducing and maintaining remission of CD. Unfortunately, anti-TNF treatment failure is common. Primary non-response occurs in 21.9% of infliximab-treated CD patients and 26.8% of adalimumab-treated patients[3]. More than 60% of patients treated with infliximab or adalimumab do not achieve deep remission[3]. These data indicate that increased TNF-α levels may be the result of an immunoinflammatory response instead of the cause. Vedolizumab blocking the α4β7 integrin can induce endoscopic remission in approximately one-

third of CD patients at week 52[4]. The decreased long-term efficacy of biologic medications makes it urgent to investigate new therapeutic targets for CD.

Omics techniques, including genomics, metabolomics, and proteomics, have been applied to explore potential biomarkers and targets for CD in recent years. It is widely known that cellular function and biological behaviour are primarily regulated by proteins. The protein domain is likely the most ubiquitously affected in disease development, treatment response, and physical recovery. Hence, it is promising to reveal the crucial changes in CD pathogenesis and discover novel drug targets by proteomics directly profiling protein expression. Proteomic techniques are classified into three major stages: Discovery, verification, and validation. Currently, the application of proteomics in CD remains in the initial discovery phase[5].

In the present study, we applied proteomics to identify differentially expressed proteins (DEPs) in the plasma of CD patients in an attempt to discover a potential biomarker and therapeutic target for CD. Our data showed that fibrinogen-like protein 1 (FGL1) was significantly upregulated in the plasma of CD patients. FGL1, also known as hepassocin or hepatocyte-derived fibrinogen-related protein 1 (HFREP1), is a hepatocyte-secreted protein that belongs to the fibrinogen family[6]. However, FGL1 lacks a platelet-binding site, a cross-linking region, and a thrombin-sensitive site, which are crucial for fibrin clot formation. Several studies have demonstrated that FGL1 can regulate immune systems to induce inflammatory response and tumor immune evasion[7,8]. To date, whether FGL1 is correlated with the development of CD remains unclear. Therefore, we further verified the expression of FGL1 in intestinal tissues of CD patients and validated its crucial role in the pathogenesis of CD *in vitro*.

MATERIALS AND METHODS

Clinical samples

Plasma samples were collected from 20 treatment-naive patients with CD and 20 age- and sex-matched healthy individuals between July 2017 and August 2018. The protein profiles in the plasma were analysed by tandem mass tag (TMT)-based quantitative proteomics. Paraffin-embedded mucosal biopsy specimens from an additional 20 treatment-naive patients with active CD and 20 matched healthy individuals undergoing colonoscopy screening were obtained for immunohistochemical examination. The protocols of this study were approved by the ethics committee of the Affiliated Hospital of Nanjing University of Chinese Medicine (2018NL-171-02). All patients provided informed consent.

TMT-based quantitative proteomics

Plasma samples were homogenized in sodium dodecyl sulfate (SDS) lysis buffer. Centrifugation was performed to collect the supernatant. Total protein concentrations were quantified using a bicinchoninic acid (BCA) assay (Thermo Scientific, United States). Protein extracts were reduced with reducing buffer (10 mmol/L dithiothreitol, 8 mol/L urea, and 100 mmol/L tetraethylammonium bromide (TEAB), pH 8.0) at 60 °C for 1 h. All samples were alkylated with iodoacetamide for 40 min at room temperature in the dark. After centrifugation, the protein pellets were digested with TEAB (100 mmol/L) and sequencing-grade trypsin (1 μg/μL) at 37 °C for 12 h.

For TMT labelling, 100 μL of protein sample was incubated with a mixed solution of 41 μL of TMT labelling reagent (Thermo Fisher Scientific, United States) and 41 μL of anhydrous acetonitrile for 1 h at room temperature. The reaction was terminated with 8 μL of 5% hydroxylamine. The samples from the CD patients were labelled with TMT-130 and TMT-131, while those from the healthy controls were labelled with TMT-126 and TMT-127.

The TMT-labelled peptides were eluted by using an Agilent Zorbax Extend-C18 column (2.1 mm × 150 mm, 5 μm) and fractionated with a high-performance liquid chromatography (HPLC) system at a flow rate of 300 μL/min. The elution gradient was set to 98%, 95%, 75%, 60%, and 10%. The collected peptides were loaded on a reverse-phase trap column (C18, 100 μm × 20 mm, Thermo Fisher Scientific, United States) and enriched on an analysis column (C18, 75 μm × 150 mm, Thermo Fisher Scientific, United States) following redissolution in nano-HPLC buffer (HPLC water containing 0.1% formic acid). The flow rate was 300 nL/min, and the linear elution gradient was set as 5%, 30%, 50%, and 100%.

For mass spectrometry (MS) survey scans, the ion spray voltage, interface heating temperature, MS resolution, and ion population were set to 1,800 V, 250 °C, 70000, and 1×10^6, respectively. The precursor ion was acquired at 300-1600 m/z. A maximum of

10 precursors were selected for higher-energy collisional dissociation with analysis in an LTQ Orbitrap Velos Pro (Thermo Fisher Scientific, United States), and the normal chemical energy was 32%. For MS/MS detection, the tandem MS resolution, ion population, ion maximum injection time, and dynamic exclusion time were set to 17500, 2×10^5, 80 ms, and 30 s, respectively.

Quantitative proteomic analysis

The raw proteomic data were analysed using Proteome Discoverer software (version 2.2, Thermo Fisher Scientific, United States) and searched against the UniProtKB database (Hunam, 2015-09, 88473 sequences). Andromeda was used as the search engine with the following parameters: (1) *Homo sapiens* taxonomy; (2) Q Exactive plus as instrument type; (3) Trypsin as the proteolytic enzyme, with two missed cleavages allowed; (4) TMT 6 plex and cysteine carbamidomethylations as fixed modifications; (5) Oxidation of methionine as a variable modification; (6) 20 ppm as the MS tolerance; and (7) Seven amino acids as minimum cut-off for peptide length. A false discovery rate (FDR) of less than 1% was set to refine the results.

For quantitative analysis, the TMT reporter ion intensity of each protein was analysed using Proteome Discoverer software. Proteins with empty values were discarded. Student's *t* test was performed to examine the difference in each protein between the two groups with Perseus software. Proteins with a fold change > 1.5 or < 0.67 and a *P* value < 0.05 were considered to be DEPs.

Bioinformatics analysis

Genes of DEPs were visualized in Cytoscape software (version 3.7.2), in which the MCODE plugin was used to select significant modules for identification of hub genes. Subsequently, the hub genes were input into the Search Tool for the Retrieval of Interacting Genes/Proteins (STRING) database (https://string-db.org/) to construct a protein-protein interaction (PPI) network. The Database for Annotation, Visualization and Integrated Discovery (DAVID) database (https://david.ncifcrf.gov/) was applied for gene ontology (GO) enrichment analysis. Reactome pathway analysis (https://www.reactome.org/) was performed for pathway enrichment analysis.

Immunohistochemical staining

Immunohistochemical staining was implemented to detect the expression of FGL1 in inflamed intestinal tissues of CD patients and normal intestinal biopsies. Mucosal biopsy specimens were fixed in 10% neutral formalin for 24 h. Afterwards, they were embedded in paraffin and cut into 5 μm sections. The sections were deparaffinized and rehydrated and then incubated in citrate buffer (pH 6.0) for antigen retrieval. After endogenous peroxidase activity was quenched with 3% hydrogen peroxide, the samples were incubated in 1% bovine serum albumin (BSA) to block non-specific immunoglobulin binding. Subsequently, the slides were incubated with an anti-FGL1 antibody (1:200 dilution, 16000-1-AP, Proteintech, United States) at 4 °C overnight. Following washing with phosphate buffered saline (PBS), the slides were incubated with a secondary IgG antibody (1:1000 dilution, ab6721, Abcam, United Kingdom) at room temperature for 1 h, counterstained with haematoxylin, and stained with a diaminobenzidine kit (DAB, Beyotime, China). All the sections were visualized under a light microscope (Nikon 80i, Japan). ImageJ software (version 1.52) was used to calculate the integrated optical density (IOD) values.

Cell culture and treatment

The human colonic adenoma cell line HT-29 (ATCC, United States) was cultured with Dulbecco's modified Eagle's medium, supplemented with 10% fetal bovine serum, 100 μg/mL penicillin, and 100 U/mL streptomycin at 37 °C with 5% CO_2. The HT-29 cells were stimulated with 100 ng/mL lipopolysaccharide (LPS, Sigma, United States) to establish a cell model of intestinal inflammation. To uncover the impact of FGL1 on intestinal inflammation, the HT-29 cells were transfected with *FGL1* siRNA and plasmid DNA (Nanjing KeyGen Biotech Co., Ltd., China) before stimulation with LPS. The transfection efficiency was determined by examining the mRNA expression of *FGL1*.

Quantitative real-time PCR analysis

Total RNA in HT-29 cells was extracted using a TRIzol reagent kit (Takara, Japan) according to the manufacturer's instructions. A PrimeScript RT reagent kit (Takara, Japan) was used for reverse transcription of the extracted RNA into cDNA. Quantitative real-time PCR (qRT-PCR) was conducted to detect the mRNA expression

of *FGL1* and *NF-κB* by using a SYBR green kit (Takara, Japan). The housekeeping gene β-actin was used for normalization to an endogenous reference. The relative gene expression was evaluated by using the $2^{-\Delta\Delta Ct}$ method. The sequences of the PCR primers are as follows: *FGL1*-forward: 5′-ATGGCAAAGGTGTTCAGTTTCA-3′, reverse: 5′-ACAATCTGCATACTGCCTCTTG-3′; *NF-κB*-forward: 5′-GAAGCACGAATGACAGAGGC-3′, reverse: 5′-GCTTGGCGGATTAGCTCTTTT-3′; and β-actin-forward: 5′-CATGTACGTTGCTATCCAGGC-3′, reverse: 5′-CTCCTTAATGTCACGCACGAT-3′.

Enzymelinked immunosorbent assay

The levels of the proinflammatory cytokines IL-1β, IL-6, IL-17, and TNF-α (Sigma, United States) in the culture medium collected after 48 h were examined by enzyme linked immunosorbent assay (ELISA) according to the manufacturer's protocol.

Western blot assay

Cells lysed with radioimmunoprecipitation assay (RIPA) lysis buffer were centrifuged at 12000 *g* for 20 min at 4 °C. Protein concentrations in the collected supernatant were quantified with a BCA assay kit. After equal amounts of protein (20 μg/well) were loaded and separated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), they were transferred onto polyvinylidene difluoride (PVDF) membranes and incubated in 5% BSA for 1 h at room temperature. The membranes were washed with Tris-borate saline containing 0.1% Tween-20 (TBST) and were incubated with primary antibodies against FGL1 (1:1000 dilution, 16000-1-AP, Proteintech, United States), IKKα (1:1000 dilution, ab32041, Abcam, United Kingdom), IKKβ (1:1000 dilution, ab32135, Abcam), p-IKKα/β (1:1000 dilution, ab194528, Abcam), IκBα (1:1000 dilution, ab32518, Abcam), p-IκBα (1:1000 dilution, ab133462, Abcam), NF-κB (p65, 1:1000 dilution, ab32536, Abcam), p-p65 (1:1000 dilution, ab76302, Abcam) and β-actin (1:1000 dilution, 20536-1-AP, Proteintech) at 4 °C overnight. The membranes were washed with TBST again and incubated with a horseradish peroxidase (HRP)-conjugated secondary antibody for 1 h at room temperature. The blots were imaged using enhanced chemiluminescence (ECL). ImageJ software was used to calculate the protein signal grey values.

Statistical analysis

All data were statistically analysed with SPSS 22.0 (SPSS Inc., United States). Continuous variables with a normal distribution are summarized using the mean ± SD, which in a skewness distribution are expressed as the median with range. The Mann-Whitney *U* test, Student's *t* tests, and chi-square test were performed to compare numerical variables and categorical variables as appropriate. One-way analysis of variance was used for multi-group comparisons. A two-sided *P* value < 0.05 was considered statistically significant.

RESULTS

Patients' characteristics

Twenty treatment-naive CD patients and 20 healthy controls were recruited for plasma proteomic analysis. The diagnostic criteria for CD referred to the clinical guidelines of the American College of Gastroenterology (ACG)[9]. Thirteen males and seven females with a median age of 20.5 (14-43) years were included in the CD group, and eleven males and nine females with a median age of 24.5 (18-46) years were included in the normal control group. Baseline demographic characteristics were comparable between the two groups ($P > 0.05$).

Colonoscopic biopsy specimens from an additional 20 treatment-naive patients with active CD and 20 healthy controls were used for immunohistochemical staining. There was no significant difference in sex distribution, age, or biopsy site between the two groups ($P > 0.05$). The baseline clinical characteristics of patients for plasma proteomic detection and immunohistochemical analysis are presented in Tables 1 and 2, respectively.

FGL1 is significantly upregulated in plasma proteomic analysis

Plasma samples in each group were randomly divided into four subclusters. A total of 393 credible proteins were identified by proteomic analysis, among which 35 had differential expression between the two groups (Figure 1A). Among the DEPs, FGL1

attracted our attention because of its function in the regulation of the immune response. The expression level of FGL1 in the plasma of CD patients was 1.722-fold greater than that in healthy people (Figure 1B). Three MCODE modules were established to screen hub genes *via* Cytoscape software. As *FGL1* was contained in the 3rd module, the genes in this module were used for further bioinformatics analysis. Figure 1C shows the PPI network of the genes. GO enrichment analysis showed that the genes were involved in the biological processes of platelet degranulation, acute phase response, platelet activation, and negative regulation of endopeptidase activity, and the molecular functions of heparin binding and serine-type endopeptidase inhibitor activity. Reactome pathway analysis demonstrated that the genes were related to the common pathway of fibrin clot formation and the pathways of platelet degranulation, peptide ligand-binding receptors, haemostasis, G alpha (i) signalling events, and innate immune system.

FGL1 expression is increased in intestinal tissues of CD patients

Immunohistochemical analysis was performed to verify the expression of FGL1 in the intestinal tissues of CD patients. The results demonstrated that the FGL1 levels in the intestinal mucosal and epithelial tissues were higher than those in the normal intestinal tissues ($P < 0.01$, Figure 2).

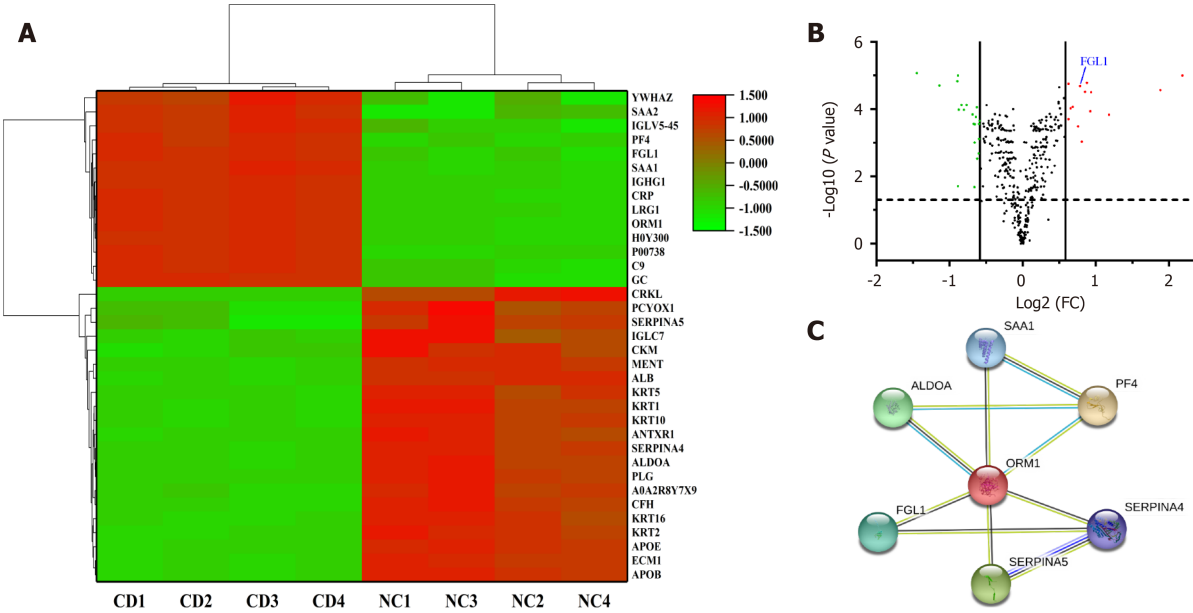

Figure 1 Fibrinogen-like protein 1 expression in the plasma of Crohn's disease patients. A: Heat map showing 35 differentially expressed proteins between Crohn's disease (CD) patients and healthy individuals, among which fibrinogen-like protein 1 (FGL1) expression was upregulated in the CD group; B: The FGL1 expression level in the plasma of CD patients was 1.722-fold greater than that in healthy people; C: Protein-protein interaction network of an MCODE module containing *FGL1* as a hub gene. CD: Crohn's disease; NC: Normal control; FGL1: Fibrinogen-like protein 1.

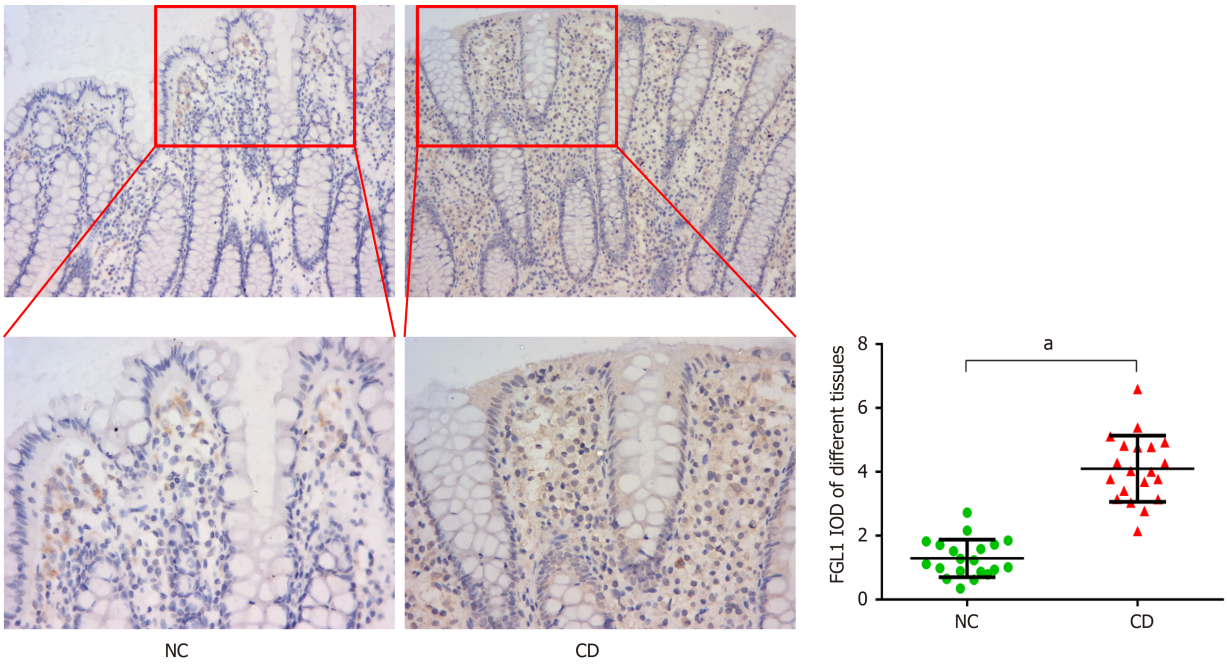

Figure 2 Fibrinogen-like protein 1 expression, as determined by immunohistochemical analysis (× 200, × 400), was increased in the intestinal mucosal and epithelial tissues of Crohn's disease patients. [a]*P* < 0.01 *vs* normal control group. NC: Normal control group; CD: Crohn's disease group; FGL1: Fibrinogen-like protein 1.

FGL1 mediates the expression of proinflammatory cytokines in intestinal epithelial cells

To investigate the regulation of intestinal inflammation by FGL1, proinflammatory cytokines were detected by ELISA after *FGL1* siRNA and plasmids were transfected into HT-29 cells. After LPS stimulation, the IL-1β, IL-6, IL-17, and TNF-α levels were significantly upregulated. FGL1 knockdown reversed the expression of IL-1β, IL-6, IL-17, and TNF-α, while overexpression of FGL1 elevated the levels of the four proinflammatory cytokines ($P < 0.05$, Figure 3).

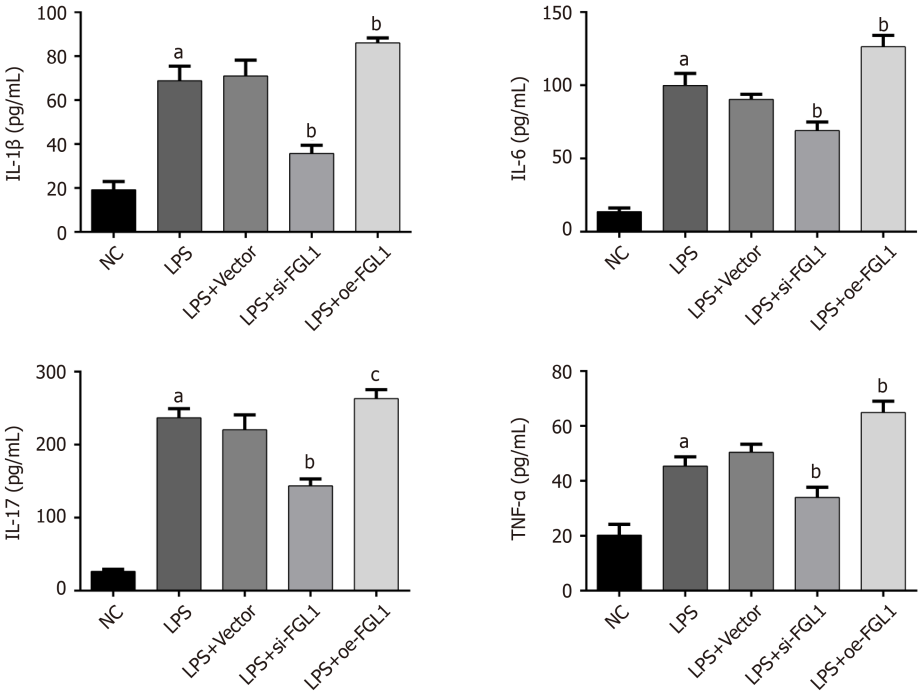

Figure 3 Expression of proinflammatory cytokines in different groups, as determined by enzyme linked immunosorbent assay. $^{a}P < 0.01$ *vs* normal control group; $^{b}P < 0.01$, $^{c}P < 0.05$ *vs* lipopolysaccharide. NC: Normal control group; LPS: Crohn's disease (CD) model induced by lipopolysaccharide (LPS); LPS+Vector: Transfected with an empty vector based on the CD model; LPS+si-FGL1: Transfected with FGL1 siRNA based on the CD model; LPS+oe-FGL1: Transfected with the FGL1 plasmid based on the CD model; FGL1: Fibrinogen-like protein 1.

FGL1 activates the NF-κB signalling pathway

Given that NF-κB plays a fundamental role in the intestinal inflammation of CD, the modulation of the NF-κB signalling pathway by FGL1 was investigated. The mRNA expression levels of *FGL1* and *NF-κB* were increased by LPS stimulation. After intervention with *FGL1* siRNA, the mRNA expression levels of *FGL1* and *NF-κB* were both downregulated, while the mRNA levels were enhanced following FGL1 overexpression with plasmid transfection ($P < 0.01$, Figure 4A and B).

The exact mechanism by which FGL1 regulates the NF-κB signalling pathway was revealed by Western blot assay. The protein levels of FGL1, IKKα, IKKβ, p-IKKα/β, p-IκBα, and p-p65 were upregulated in HT-29 cells stimulated with LPS ($P < 0.05$). *FGL1* gene knockdown inhibited the protein expression of FGL1 and downregulated the protein expression of IKKα, IKKβ, p-IKKα/β, p-IκBα, and p-p65 ($P < 0.05$). Conversely, the overexpression of the *FGL1* gene enhanced the protein expression of FGL1, IKKα, IKKβ, p-IKKα/β, p-IκBα, and p-p65 ($P < 0.05$, Figure 4C).

DISCUSSION

In the present study, we took advantage of proteomics for a large-scale screen of DEPs between the plasma of CD patients and healthy people. The expression of *FGL1*, a hub gene among the DEPs, was increased in the plasma of CD patients, which was verified in intestinal mucosal and epithelial tissues. Furthermore, FGL1 was validated to exacerbate the inflammatory response in intestinal epithelial cells by activating the NF-κB signalling pathway.

At present, knowledge about the etiology and pathogenesis of CD is limited, which makes it incurable. Hence, it is essential to detect potential drug targets for CD. As proteins are directly involved in nearly all pathophysiological processes, proteomics has become a hotspot tool for the discovery of novel biomarkers or therapeutic targets for CD, differential diagnosis between CD and ulcerative colitis, and disease stratification by examining and quantifying thousands of proteins encoded by the genome in a holistic manner[10-13]. To our knowledge, the present study revealed for the first time by proteomics that FGL1 may be a key contributor to CD onset and progression.

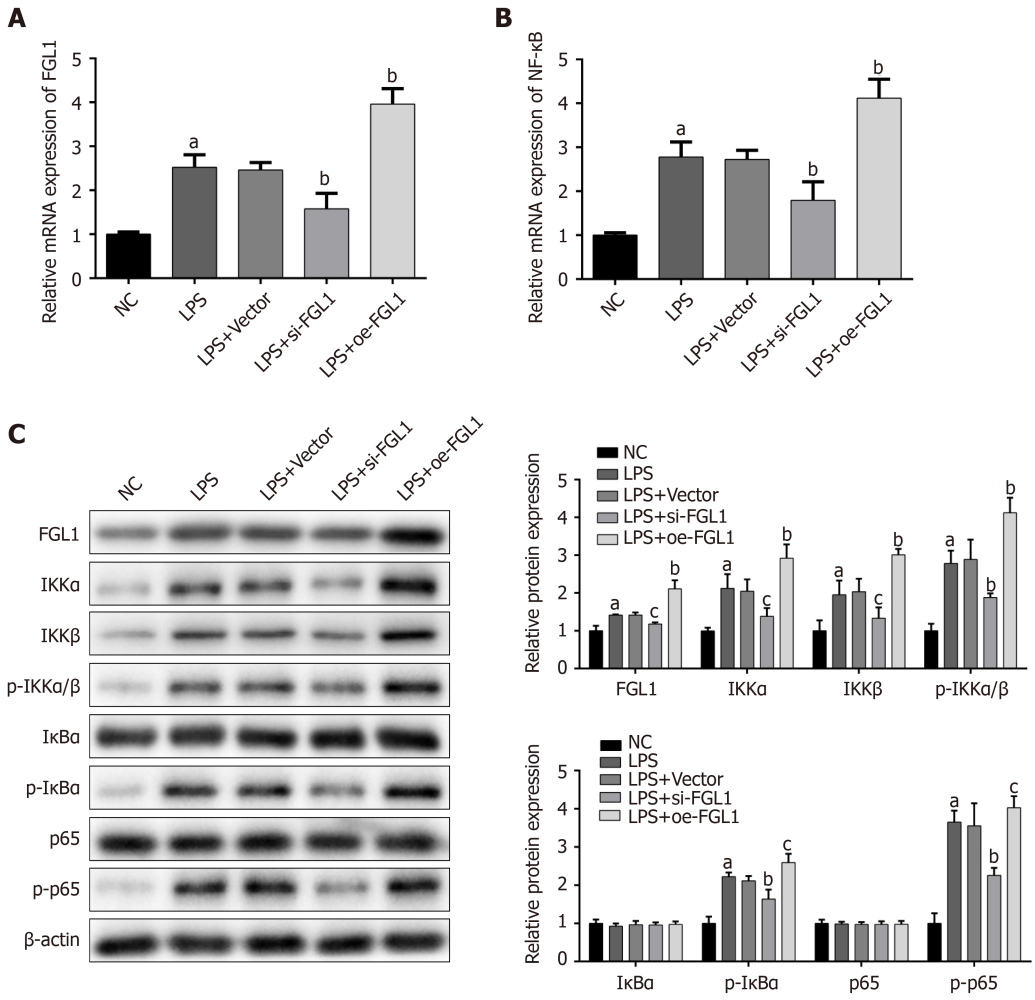

Figure 4 Impact of fibrinogen-like protein 1 on the NF-κB signalling pathway. A and B: Effect of knockdown or overexpression of fibrinogen-like protein 1 (FGL1) on the mRNA expression of *FGL1* and *NF-κB*, as determined by quantitative real-time PCR assay; C: Effect of FGL1 on the protein expression of related proteins in the canonical NF-κB signalling pathway, as determined by Western blot assay. $^{a}P < 0.01$ *vs* NC; $^{b}P < 0.01$, $^{c}P < 0.05$ *vs* LPS. NC: Normal control group; LPS: Crohn's disease (CD) model induced by LPS; LPS+Vector: Transfected with an empty vector based on the CD model; LPS+si-FGL1: Transfected with FGL1 siRNA based on the CD model; LPS+oe-FGL1: Transfected with the FGL1 plasmid based on the CD model; LPS: Lipopolysaccharide; FGL1: Fibrinogen-like protein 1.

Accumulating evidence has demonstrated that FGL1 plays a prominent role in the pathogenesis of various diseases, including hepatocellular carcinoma, gastric cancer, lung cancer, diabetes mellitus, and obesity[14-19]. Additionally, FGL1 is also considered a potential biomarker and drug target in certain inflammatory conditions. FGL1 may promote liver injury-induced inflammation *via* the IL-6/STAT3 signalling pathway[20]. Proteomics revealed that FGL1 is a specific biomarker for predicting the progression of rheumatoid arthritis[7]. This finding displays a fundamental role of FGL1 in regulating immune-mediated inflammation.

Pierre and colleagues have demonstrated that CD relapse is correlated with the innate immune response of the liver[21]. Given that FGL1 is a liver-derived protein and is involved in the innate immune system pathway, we hypothesize that FGL1 may influence the pathophysiology of CD based on the evidence of increased expression of FGL1 in the plasma and intestinal tissues of CD patients. Although FGL1 has been demonstrated to be a potent target for cancer immunotherapy, its precise role in CD therapy is unknown[8]. To unravel the mystery, a cell experiment was designed in the current study that focused on the FGL1-mediated regulation of signalling by NF-κB, an important proinflammatory transcription factor for inflammatory disorders.

Activation of NF-κB plays a central role in the induction and exacerbation of the intestinal inflammatory response of CD patients[22]. The NF-κB family consists of p65 (RELA), RELB, c-REL, p50/p105 (NF-κB1), and p52/p100 (NF-κB2). Activated p65 can translocate into the nucleus to upregulate the transcriptional expression of proinflammatory cytokines. In the present study, the mRNA and protein levels of FGL1 and NF-κB and the concentrations of IL-1β, IL-6, IL-17, and TNF-α were markedly upregulated

in HT-29 cells stimulated with LPS, and these effects were reversed by depleting FGL1 with specific siRNA. Correspondingly, the expression of NF-κB and the four proinflammatory cytokines was enhanced following overexpression of FGL1. These results indicate that FGL1 may promote the intestinal inflammatory response by activating NF-κB signalling. The canonical pathway of NF-κB activation involves the IKK complex, consisting of NEMO, IKKα, and IKKβ, and the IκB protein family, including IκBα, IκBβ, and IκBe. After stimulation, IKKα and IKKβ activation promotes phosphorylation of IκBα. Degradation of phosphorylated IκBα releases the p65-p50 dimer for nuclear translocation[23]. In this study, the protein expression levels of IKKα , IKKβ, p-IKKα/β, p-IκBα, and p-p65 were decreased after knockdown of FGL1 compared to those in the cell model, and the inverse effect was verified by overexpression of FGL1. Therefore, FGL1 may induce intestinal inflammation by activating the canonical NF-κB pathway.

CONCLUSION

In summary, we found for the first time that the expression of FGL1 is considerably upregulated in the plasma and intestinal mucosal and epithelial tissues of CD patients. FGL1 might induce intestinal inflammation by activating the canonical NF-κB signalling pathway to stimulate the secretion of proinflammatory cytokines, such as IL-1β, IL-6, IL-17, and TNF-α. Hence, FGL1 may be considered a potential biomarker and therapeutic target for CD. However, given the exploratory design of our study, the precise role of FGL1 in the pathogenesis of CD needs to be deeply investigated and further validated.

ACKNOWLEDGEMENT

The authors are deeply grateful to Fan Yang from the Faculty of Art and Science, St. George Campus, University of Toronto, for helping us analyze the data in the statistics of this study.

ARTICLE HIGHLIGHTS

Research background

Currently, the etiology and pathogenesis of Crohn's disease (CD) are not completely known, which makes it incurable. It is urgent to reveal the pathophysiological mechanism of CD and investigate new therapeutic targets.

Research motivation

To explore a potential therapeutic target for CD and verify its role in the CD pathological mechanism.

Research objectives

In this study, we attempted to find a potential therapeutic target for CD and verify its role in the CD pathological mechanism *in vitro*.

Research methods

Proteomics was implemented to quantify the protein profile in the plasma of CD patients. Among the differentially expressed proteins, a hub gene that could regulate the immune response was selected for further study. The expression of the selected hub gene in the inflamed intestinal mucosa was verified by immunohistochemical staining. *In vitro*, the effects of the hub gene on the expression of proinflammatory cytokines and the NF-κB signalling pathway were evaluated by ELISA, qRT-PCR, and Western blot analysis.

Research results

Fibrinogen-like protein 1 (*FGL1*), as a hub gene of the differentially expressed proteins, was confirmed to be markedly upregulated in the plasma and intestinal mucosa of CD patients. Silencing FGL1 downregulated the levels of the proinflammatory cytokines IL-1β, IL-6, IL-17, and TNF-α. Furthermore, FGL1 knockdown repressed the mRNA

expression of *NF-κB* and the protein levels of IKKα, IKKβ, p-IKKα/β, p-IκBα, and p-p65. Overexpression of FGL1 enhanced these results.

Research conclusions

FGL1 may promote intestinal inflammation modulated by the canonical NF-κB signalling pathway and has the potential to be a therapeutic target for CD.

Research perspectives

Our findings indicate a critical role of FGL1 in the onset and progression of CD, which may serve as a potential prognostic biomarker and therapeutic target for CD.

Abstract

BACKGROUND

Endoscopic resection of duodenal subepithelial lesions (SELs) is a difficult procedure with a high risk of perforation. At present, dealing with perforation after endoscopic resection of duodenal SELs is still considered a great challenge.

AIM

To evaluate the effectiveness and safety of an over-the-scope clip (OTSC) in the treatment of perforation post-endoscopic resection of duodenal SELs.

METHODS

From May 2015 to November 2019, 18 patients with perforation following endoscopic resection of duodenal SELs were treated with OTSCs. Data comprising the rate of complete resection, closure of intraprocedural perforation, delayed bleeding, delayed perforation, and postoperative infection were extracted.

Rehabilitation of Digestive System Tumor of Zhejiang Province, No. 21SZDSYS01 and No. 21SZDSYS09.

Institutional review board statement: The study was reviewed and approved by the Ethics Committee of Taizhou Hospital of Zhejiang Province affiliated to Wenzhou Medical University Institutional Review Board (approval No. K20210412).

Informed consent statement: All study participants, or their legal guardian, provided informed written consent prior to study enrollment.

Conflict-of-interest statement: The authors declare that they have no conflict interests.

Data sharing statement: No additional data are available.

Open-Access: This article is an open-access article that was selected by an in-house editor and fully peer-reviewed by external reviewers. Peer-review started: May 10, 2021
First decision: June 27, 2021

RESULTS

The rate of complete removal of duodenal SELs and successful closure of the perforation was 100%. The median perforation size was 1 cm in diameter. Seventeen patients had minor intraoperative bleeding, while the remaining 1 patient had considerable amount of bleeding during the procedure. Seven patients had postoperative abdominal infections, of which 1 patient developed an abscess in the right iliac fossa and another patient developed septic shock. All 18 patients recovered and were discharged. No delayed bleeding or perforation was reported. The mean time taken to resume normal diet after the procedure was 6.5 d. The mean postoperative hospital stay was 9.5 d. No residual or recurrent lesions were detected during the follow-up period (15-66 mo).

CONCLUSION

Closing a perforation after endoscopic resection of duodenal SELs with OTSCs seems to be an effective and reasonably safe therapeutic method.

Core Tip: This study presents the use of over-the-scope clip in closing duodenal perforation of 18 patients. We believe that our study makes a significant contribution to the literature because dealing with perforation after endoscopic resection of duodenal subepithelial lesions is challenging. This study aimed to evaluate the effectiveness and safety of over-the-scope clip in closing perforation after endoscopic resection of duodenal subepithelial lesions. The rate of successful closure was 100%. No delayed perforation occurred in any of the patients. Seven patients had postoperative infection, of which 1 patient developed septic shock and underwent surgery. All 18 patients recovered.

INTRODUCTION

Duodenal subepithelial lesions (SELs) include Brunner's adenomas, lipomas, heterotopic pancreas, leiomyomas, neuroendocrine tumors, and gastrointestinal stromal tumors (GISTs). Most of these are benign, while some lesions, such as neuroendocrine tumors and GISTs, are potentially malignant[1-3]. Resection of these lesions may contribute to improvement in diagnosis and treatment outcomes.

Surgery, including pancreatoduodenectomy and limited resection, is the most basic treatment for duodenal lesions. However, due to the complexity of the operation, risk of trauma, high incidence of postoperative complications, poor quality of life of patients after surgery, and other difficulties, these surgeries are not easily consented by patients, which also puts the medical staff in a difficult position. With the recent development of minimally invasive endoscopic treatment technologies, such as endoscopic submucosal dissection (ESD), endoscopic muscularis excavation, and endoscopic full-thickness resection, endoscopic treatment has become increasingly popular, which brings hope for the use of minimally invasive treatment of duodenal SELs in the future.

However, endoscopic resection of duodenal SELs is still regarded as a challenging procedure due to a high risk of perforation. The incidence of perforations in duodenal ESD has been reported to range from 6.7%-36.6% during the procedure and 0%-14.3% during the postoperative period[1,4-7]. Management of perforations after endoscopic removal of duodenal SELs is particularly challenging. However, this may be achieved

by using over-the-scope clips (OTSCs). An OTSC was developed as an endoscopic full-thickness gastrointestinal closure device and has become one of the treatment options for gastrointestinal perforation because it is less invasive compared to conventional surgical closure. At present, there are few reports on endoscopic resection of duodenal SELs and endoscopic methods for the management of perforations[1,2,8,9]. To explore further this area, this study aimed to assess the effectiveness and safety of OTSCs in the treatment of perforation after endoscopic resection of duodenal SELs.

MATERIALS AND METHODS

Patients

This was a retrospective study and was approved by the ethics committee of Taizhou Hospital of Zhejiang Province (Linhai, China). The study included 18 consecutive patients who were treated with OTSCs to close perforations that resulted after endoscopic resection of duodenal SELs, from May 2015 to November 2019. Patients were recruited if they met all of the following criteria: (1) Patients with duodenal SELs diagnosed by computed tomography and endoscopic ultrasound (EUS) with a high-frequency miniprobe (UM-2R, 12 MHz; UM-3R, 20 MHz, Olympus Optical, Tokyo, Japan); (2) Patients who underwent endoscopic resection of duodenal SELs and had intraoperative or postoperative perforations; (3) The duodenal perforation was closed using an OTSC; and (4) Patients who were able to tolerate general anesthesia and had no blood coagulation disorders prior to the procedure.

Before the endoscopic procedure, informed consent was obtained from all 18 patients. Patients were also informed that an OTSC might be used, and surgical intervention might be required in case of unsuccessful resection of the lesion or the occurrence of severe complications that cannot be successfully managed by endoscopic methods and conservative treatment.

The main outcome measurements were as follows: (1) The rate of complete closure of intraprocedural perforation; (2) Delayed perforation rate; and (3) Postoperative infection rate. All endoscopic resection procedures were performed by an experienced endoscopist in a sterile operating room while the patients were under general anesthesia with tracheal intubation.

Endoscopic procedures

The main equipment and accessories used were as follows: A single-accessory channel endoscope (Q260J; Olympus) with a transparent cap (ND-201-11802; Olympus) attached to its tip, an argon plasma coagulation unit (APC 300; ERBE, Tübingen, Germany), a high-frequency electronic cutting device (ICC 200; ERBE), a hook knife (KD-620LR; Olympus), an insulated-tip knife (KD-611L, IT2; Olympus), hot biopsy forceps (FD-410LR; Olympus), foreign body forceps (FG-B-24, Kangjin, Changzhou, China), a snare (SD-230U-20; Olympus), a carbon dioxide insufflator (Olympus), twin graspers (Ovesco Endoscopy AG, Tuebingen, Germany), an OTSC (12/6 t-type, Ovesco Endoscopy AG,), a titanium clip (HX-600-135; Olympus and M00522600), and endoloop (Leo Medical Co., Ltd, Changzhou, China).

Endoscopic resection was performed as follows (Figure 1): (1) Several marking dots were initially made around the lesion using a needle-knife to define the border; (2) A submucosal elevation was made by injection of solution (100 mL saline plus 1 mL epinephrine and 2 mL indigo carmine); (3) Subsequently, the mucosa was incised with a hook knife outside the border to reveal the lesion; (4) A circumferential excavation was made as deep as the submucosa or muscularis propria layer around the lesion using an insulated tip knife; (5) After the lesion was completely resected, it was removed using a snare or foreign body forceps; and (6) Duodenal tissues adjacent to the perforation were clamped with twin graspers and then drawn into the transparent cap of the OTSC device until they were fully inhaled into the transparent cap following which the OTSC closure system was released to close the wound. If defect closure was not complete, several clip and/or endoloops were used to close the remaining portions. The mucosa defect was closed with several clips in a 'side to center' manner, and an endoloop was placed to trap all the clips. Finally, the endoloop was slowly tightened, and all the clips were tied together with the endoloop[8].

Postoperative management and follow-up

After the operation, all patients were treated with postoperative fasting, gastrointestinal decompression, proton-pump inhibitors, and antibiotics for infection prevention. Oral intake was gradually resumed depending on the speed of recovery.

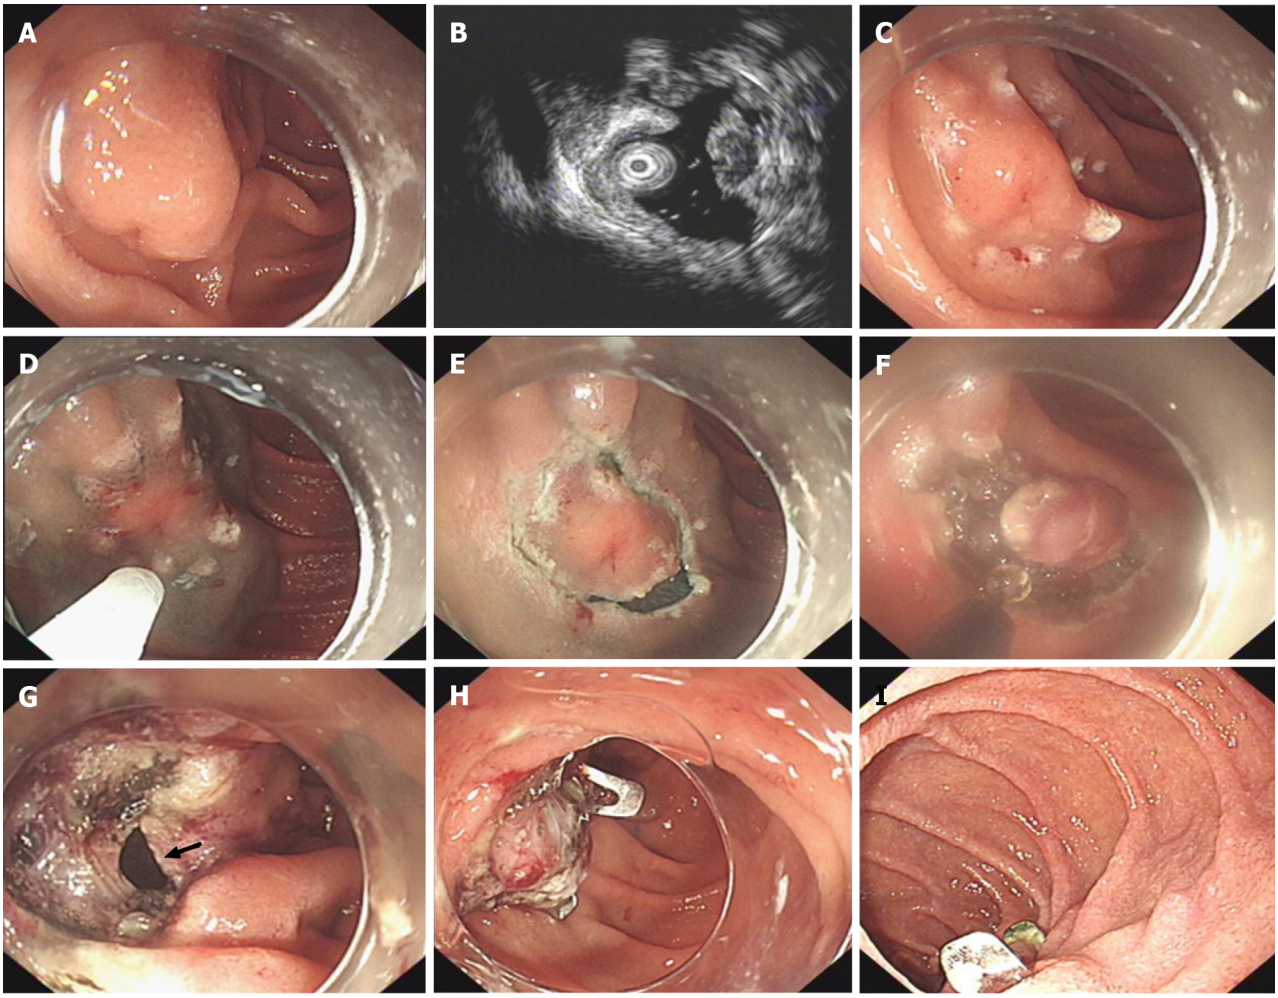

Figure 1 Endoscopic resection of a subepithelial lesion located in the descending duodenum with perforation closure using an over-the-scope clip. A: Endoscopic view of a subepithelial lesion located in the descending duodenum; B: Endoscopic ultrasound evaluation of the same lesion; C: Several marking dots are made around the lesion; D: Injection solution used to elevate the submucosa; E: The mucosa is incised outside the marking dots; F: A circumferential excavation is made as deep as the submucosa around the lesion; G: A duodenal perforation is observed (black arrow) after removal of the lesion; H: The perforation is closed with an over-the-scope clip; I: Healed wound 9 mo after the procedure.

Every patient underwent follow-up endoscopies to monitor wound healing at 3 mo and 6 mo after endoscopic resection. EUS was performed to check for residual lesions after 3 mo. Patients with potentially malignant lesions, such as neuroendocrine tumors and GISTs, were monitored by endoscopy and/or EUS to detect recurrent lesions, and abdominal US and/or computed tomography to detect distant metastasis every 12 mo.

Statistical analysis

Data were analyzed using SPSS software (version 20.0; SPSS Inc., Armonk, NY, United States). Descriptive statistics were used for this study. The median was used for variables with a skewed distribution, while the mean was used in the case of a normal distribution of variables. Enumeration data are expressed as case numbers and percentages (%).

RESULTS

Clinical characteristics and therapeutic outcome

Patient information is summarized in Table 1 and therapeutic outcomes, are described in Table 2. The rate of successful *en bloc* resection was 100%. The vertical and horizontal margins of all specimens were tumor-free. Thus, the complete resection rate was 100%.

Table 1 Clinical characteristics of the 18 patients with duodenal subepithelial lesions, *n* (%)

Patients	
Median age, yr (range)	53.5 (29-74)
Gender	
Male	8 (44.4)
Female	10 (55.6)
Symptom	
Upper abdominal pain	3 (16.7)
Abdominal distention	4 (22.2)
Melena	5 (27.8)
Asymptomatic	6 (33.3)
Lesions	
Median size, cm (range)	2.0 (1.3-5.0)
Location of lesion	
Duodenal bulb	11 (61.1)
Descending junction of duodenal bulb	4 (22.2)
Descending duodenum	3 (16.7)
Origination of lesion	
Submucosal layer	9 (50.0)
Muscularis propria layer	9 (50.0)

All 18 patients had intraoperative perforations. The median perforation size was 1 cm in diameter (range, 0.5-3.0 cm). The wound was closed with an OTSC in 6 cases, an OTSC + a titanium clip in 1 case, and an OTSC + a titanium clip + an endoloop in 5 cases. The rate of successful intraprocedural perforation closure was 100%.

Seventeen patients had minor intraoperative bleeding. The remaining 1 patient, who had a tumor originating from the lamina propria, growing mainly out of the lumen, with rich blood supply, had considerable amount of bleeding during the procedure. All patients were treated with hot biopsy forceps to achieve hemostasis during the procedure.

None of the patients developed delayed bleeding or perforation. Seven patients had postoperative abdominal infections and were administered intensive antibiotic therapy. Among the 7 patients, 1 patient developed an abscess in the right iliac fossa that improved after puncture and drainage, while another patient developed septic shock and received peritoneal lavage and underwent distal subtotal gastrectomy with duodenal bulb resection. All 18 patients recovered and were discharged. The mean time taken to resume normal diet after the procedure was 6.5 d. The mean postoperative hospital stay was 9.5 d.

Follow-up

The median follow-up period after the procedure was 27 mo (range, 15-66 mo). No residual or recurrent lesions, duodenal stenosis, or adhesions were detected during the follow-up period in any of the patients.

DISCUSSION

Currently, endoscopic resection of duodenal SELs is a challenging procedure with a high risk of perforation. Published studies about endoscopic resection of duodenal SELs and endoscopic methods for management of perforations are limited[1,2,8,9]. In this study, we used OTSCs to close perforations in 18 patients. The rate of complete removal of duodenal SELs and successful perforation closure was 100%. No delayed bleeding or perforation occurred in any of the patients. This suggests that the use of OTSCs can effectively close perforations following endoscopic resection of duodenal

GIST: Gastrointestinal stromal tumor.

SELs when performed by an experienced endoscopist.

The clinical manifestations of duodenal SELs are nonspecific and related to the location, size, growth pattern, presence of mucosal ulcers, and invasion or compression of adjacent organs. Most duodenal lesions have no symptoms and are usually found incidentally during endoscopic examinations. Clinical symptoms such as gastrointestinal bleeding, abdominal pain, and abdominal distention may occur when the lesion is very large or when an ulcer develops on the surface of the lesion.

Though most duodenal SELs, such as lipomas, Brunner's adenomas, heterotopic pancreas, and cysts, are benign, some including neuroendocrine tumors and GISTs are potentially malignant[1-3]. Endoscopy and EUS are of great value in the diagnosis of duodenal SELs; however, they may be difficult to diagnose on some occasions. Patients with duodenal SELs can be monitored by endoscopy, especially for asymptomatic tumors that lack high-risk features as identified by EUS[10]. However, surveillance using only endoscopy may increase the risk of delayed diagnosis of a malignancy[11]. Furthermore, the difficulty of the operation and risk of combined evisceration will increase if the lesion is large. In such cases, removal of the lesion is inevitable.

Traditional surgical approaches for duodenal lesions, including pancreatoduodenectomy and limited resection, are traumatic and may result in serious complications, such as bleeding, perforation, and infection. Considering these potential risks associated with surgical therapy, endoscopic treatment is used as an alternative choice, which may be safer, more effective, and is minimally invasive. However, endoscopic resection of duodenal SELs is still considered to be a challenging procedure because the duodenal lumen is narrow and the initial part (ball to lower part) is an anti-c loop, which renders the endoscope unstable. Moreover, the abundant blood vessels and Brunner glands in the submucosa of the duodenum make it difficult to lift the mucosa after injection. In addition, compared to other parts of the gastrointestinal tract, the muscularis propria layer of the duodenum is soft and thin, and the posterior wall lacks the serosal layer; therefore, perforation can occur easily during or after the endoscopic resection of duodenal lesions, especially duodenal SELs[8]. The incidence of intraprocedural perforations in duodenal ESD has been reported to range from 6.7%-36.6%, and is 0%-14.3% in delayed perforations[1,4-7]. Moreover, emergency operations have been performed in 3.3%-25.0% of patients due to intraprocedural uncontrollable perforation or delayed perforation[1,4-7]. Our previous study reported that the perforation rate of endoscopic resection of duodenal SELs in our hospital was 7.4%[8].

Perioperative perforation associated with endoscopic therapy was previously considered a serious complication that usually requires surgery. With the development of endoscopic suture instruments and techniques, patients with iatrogenic gastrointestinal perforation can be successfully managed using endoscopic methods and conservative treatment without surgical intervention[12,13]. Thus, most perforations related to endoscopic treatment are no longer life-threatening complications. However, endoscopic closure of perforations after endoscopic resection of duodenal SELs remains a great challenge.

In the past, titanium clips were used for endoscopic closure of gastrointestinal perforations, especially for small acute perforations (< 5 mm). However, a titanium clip has a narrow wingspan and lacks the ability to approximate adequately the margins of the defect. Consequently, the rate of leakage after repairing a large perforation of more than 1 cm is high as the seal is confined to the surface rather than the full-thickness of the mucosa[14-16]. An OTSC has a greater holding strength[16,17]; it can clamp the entire wall of the lumen and grasp more tissue. The design can manage full-thickness perforations with diameters of up to 3 cm[14]. Moreover, the gap between the teeth of an OTSC allows blood to pass through to avoid tissue necrosis. The advantage of an OTSC lies in its ease of use, ability to close defects between 1 and 3 cm with a single clip, and safety, which allows endoscopists to deal effectively with acute perforations immediately after identification[18]. Thus, OTSCs are easy to operate and can effectively shorten operation times. Moreover, The European Society of Gastrointestinal Endoscopy recommends OTSCs for endoscopic closure of iatrogenic perforations[18]. According to a systematic review, the success rate of using OTSCs to manage perforations was 85.3%, while 9.4% of patients still required surgical intervention after an OTSC placement to achieve complete closure [19]. Voermans *et al*[14] reported 12 cases of duodenal perforation that were treated with OTSCs, nine of which were effectively closed, with an overall success rate of 75%. In our study, the rate of successful closure of intraprocedural perforations was 100%. However, we have also used a titanium clip in 1 case and a titanium clip along with an endoloop in 5 cases. It seems that if the perforation is larger than 1.5 cm, using an OTSC alone may fail to achieve complete closure. We speculate that the combination of OTSC, titanium clip, and endoloops may be more effective. Given that the duodenal lumen is narrow, caution should be exercised to avoid grasping too much tissue to avoid further narrowing of the lumen while deploying the OTSC in the duodenum. In our study, no duodenal stenosis was detected in any patient during the follow-up period.

The duodenum is exposed to pancreatic juices and bile, causing delayed perforations more likely to occur after endoscopic resection of duodenal lesions. Complete closure of the wound facilitates prevention of delayed perforation[6,7,17]. Due to its the strong tightening force and the gap between its teeth, an OTSC can manage to close full-thickness duodenal perforations and avoid tissue necrosis, which effectively reduces the occurrence of delayed perforations. A carbon dioxide pump is also recommended to use with endoscopic treatment, especially when a perforation occurs. The use of gastrointestinal decompression after endoscopic closure of perforation is helpful for the absorption of gas and liquid in the intestinal cavity. It also reduces tension in the wound, and promotes wound healing, which can reduce the incidence of delayed perforations. In this study, we placed a jejunal nutrition tube next to the wound and a gastrointestinal decompression tube to extract gas and digestive juice. Thereafter, none of the patients developed delayed perforations.

The duodenum is an interperitoneal organ, most of which is located in the retroperitoneum. After perforation or full-thickness resection, digestive fluid from the duodenum (mainly bile and pancreatic juice) flows into the peritoneal cavity or retroperitoneal cavity, which may cause serious abdominal or retroperitoneal infection. In our study, 7 patients (38.9%) had postoperative abdominal infection, including 1 who developed an abscess in the right iliac fossa and another who developed septic shock. Severe infection in the 2 cases were considered to be caused by long operation times and large amounts of digestive juice entering the abdominal cavity. Timely conversion of the endoscopic procedure to surgery or combining with laparoscopy when the resection is found to be difficult may help avoid such complications.

Due to their strong holding strength, OTSCs are more difficult to detach spontaneously from the mucosa than normal titanium clips. The OTSC is made of nitinol, which has favorable biocompatibility. Thus, this device is considered a permanent implanted material. However, OTSCs should be removed in the following circumstances: (1) Poor healing; (2) OTSC misplacement; (3) Repeat biopsy/therapy or further treatment; (4) Adverse events after OTSC implantation, such as ulcers and

stenosis of the digestive tract; (5) Removal after recovery; and (6) Patient's wishes[20]. In our study, there were no such indications for removal. During the follow-up period, OTSCs detached spontaneously in most cases.

This study has a few limitations. First, this was a single-center retrospective study and the sample size was relatively small; therefore, selection bias may have been present. Second, since this was a retrospective study, it lacked randomized and control samples. Third, our institution is a tertiary endoscopic center in Zhejiang Province where the procedures were performed by an experienced operator; thus, the results of this study may not be applicable to all other endoscopic centers.

CONCLUSION

Closing of perforations after endoscopic resection of duodenal SELs with OTSCs is an effective and reasonably safe therapeutic method. However, this procedure should be performed by an experienced endoscopic team. If the endoscopic procedure fails or the postoperative complications are difficult to manage, the patient should be planned to undergo surgery immediately.

ARTICLE HIGHLIGHTS

Research background

Currently, endoscopic resection of duodenal subepithelial lesions (SELs) is a challenging procedure with a high risk of perforation.

Research motivation

It is importance to deal with perforation after endoscopic resection of duodenal SELs. However, so far, there were few reports on endoscopic methods for management of perforations.

Research objectives

We aim to evaluate the effectiveness and safety of over-the-scope clip (OTSC) in the closing the perforation after endoscopic resection of duodenal SELs.

Research methods

This was a retrospective study. We collected data of 18 consecutive patients who were treated with OTSCs to close the perforation after endoscopic resection of duodenal SELs and analyzed the rate of complete resection, closure of intraprocedural perforation, delayed bleeding, delayed perforation, and postoperative infection.

Research results

All the perforations after endoscopic resection of duodenal SELs were successfully closed. No delayed bleeding or perforation occurred in any of the patients.

Research conclusions

OTSC can effectively and safely close the perforations after endoscopic resection of duodenal SELs by an experienced endoscopist.

Research perspectives

We need to expand the sample size to confirm further the effectiveness and safety of OTSC in closing the perforation after endoscopic resection of duodenal SELs. In addition, the long-term outcome of OTSC should be observed by extending the follow-up time.

Abstract

BACKGROUND

Perivascular epithelioid cell tumor (PEComa) is an uncommon tumor of mesenchymal origin. Cases of PEComa in the liver are extremely rare.

AIM

To analyze the clinicopathological features and treatment of hepatic PEComa and to evaluate the prognosis after different treatments.

METHODS

Clinical and pathological data of 26 patients with hepatic PEComa were collected. All cases were analyzed by immunohistochemistry and clinical follow-up.

RESULTS

This study included 17 females and 9 males, with a median age of 50 years.

No. BYLK201812.

Institutional review board statement: This study was approved by the Ethics and Research Committees of the First Affiliated Hospital of Bengbu Medical College (Anhui Province, China).

Informed consent statement: Informed written consent was obtained from all the patients.

Conflict-of-interest statement: The authors declare no conflicts of interest for this manuscript.

Data sharing statement: No additional data are available.

Open-Access: This article is an open-access article that was selected by an in-house editor and fully peer-reviewed by external reviewers. Lesions were located in the left hepatic lobe in 13 cases, in the right lobe in 11, and in the caudate lobe in 2. The median tumor diameter was 6.5 cm. Light microscopy revealed that the tumor cells were mainly composed of epithelioid cells. The cytoplasm contained heterogeneous eosinophilic granules. There were thick-walled blood vessels, around which tumor cells were radially arranged. Immunohistochemical analysis of pigment-derived and myogenic markers in PEComas revealed that 25 cases were HMB45 (+), 23 were Melan-A (+), and 22 SMA (+). TFE3 and Desmin were negative in all cases. All the fluorescence *in situ* hybridization samples were negative for *TFE3* gene break-apart probe. Tumor tissues were collected by extended hepatic lobe resection or simple hepatic tumor resection as the main treatments. Median follow-up was 62.5 mo. None of the patients had metastasis or recurrence, and there were no deaths due to the disease.

CONCLUSION

Hepatic PEComa highly expresses melanin and smooth muscle markers, and generally exhibits an inert biological behavior. The prognosis after extended hepatic lobe resection and simple hepatic tumor resection is semblable.

Key Words: Hepatic tumor; Perivascular epithelioid cells; PEComa; Immunohistochemistry; Treatment; Prognosis

Core Tip: Hepatic perivascular epithelioid cell tumor (PEComa) exhibits an inert biological behavior, and its diagnosis, treatment, and follow-up are challenging. Our study revealed that there was no difference in the prognosis between simple resection of liver tumor and extended resection of liver lobe. Optimal surgical resection currently is the best treatment option, and radiotherapy, chemotherapy, and immunotherapy may become more effective in future. The number of cases in the current retrospective study was limited by the rarity of hepatic PEComa. Therefore, further multicenter, larger-cohort studies are warranted to investigate the clinicopathological features and biological behavior of hepatic PEComa.

INTRODUCTION

Perivascular epithelioid cells were first described in 1992 by Bonetti *et al*[1]. In 2013, the World Health Organization[2] defined perivascular epithelioid cell tumor (PEComa) as "a mesenchymal tumor, which shows a local association with the vessel wall and usually expresses melanocyte markers and smooth muscle markers." Bonetti *et al*[1] were the first to propose the concept of a PEComa family, which includes angiomyolipoma, clear cell sugar tumor of the lung, lymphangioleiomyomatosis, and a group of histologically and immunophenotypically similar tumors that include primary extrapulmonary sugar tumor, clear cell myomelanocytic tumor, and abdominopelvic sarcoma of perivascular epithelioid cells. PEComas are mainly composed of eosinophilic and clear epithelioid cells, which are usually arranged in nests of different sizes associated with blood vessels[3,4]. The diagnosis of PEComa relies on its pathological features, including epithelioid cellular shapes with ample clear to eosinophilic cytoplasm, and in some cases, arrangement around thick-walled blood vessels and immunohistochemical phenotypes, including melanocyte and smooth muscle markers[1,4,5]. Cases of PEComa in the liver are extremely rare[6], and surgical resection currently is the most effective therapeutic strategy to cure patients or prolong

the survival period. In this study, the clinical and pathological features, immunohistochemical phenotypes, and information on treatment modalities of 26 cases of hepatic PEComa were collected, and the effects of different surgical methods on prognosis were evaluated to provide information for the guidance of clinical treatment.

MATERIALS AND METHODS

Patient selection

The study included 17 women and 9 men who were diagnosed with hepatic PEComa for the first time. Tumor tissue samples were collected at the time of diagnosis between January 2010 and December 2018 at the First Affiliated Hospital of Bengbu Medical College (Anhui Province, China). None of the patients received preoperative radio- or chemo-therapy. Sixteen patients underwent extended hepatic lobe resection, eight underwent simple hepatic tumor resection, and two received the oral mTOR inhibitor sirolimus. None of the 26 patients had metastasis or recurrence, and there were no deaths due to the disease. Only two patients with extended liver lobectomy had a poor prognosis (one had postoperative pain in the liver area, and the other was diagnosed with liver cancer 2 years after surgery). Informed consent was obtained from all patients. The study protocol was approved by the ethics committees of the hospitals partaking in this study.

Imageological examination

Imaging data of all patients were collected and reviewed by two experienced physicians who analyzed the imaging characteristics of the patients.

Histological observation and immunohistochemical analysis

Two experienced pathologists reviewed hematoxylin and eosin-stained sections of each tissue sample, marked the representative regions of tissue blocks, and assessed the following histological features: Tumor boundary (infiltration), tumor cell structure (trabecular and nested), tumor cell type (epithelial and fusiform), cytological features (cytoplasm and nucleus), nuclear features (atypical and pleomorphic), presence of pleomorphic tumor cells, and tumor necrosis.

Immunohistochemical staining was conducted on 4-μm-thick serial PEComa tissue sections using the standard ElivisionTM Plus/HRP detection system (Fuzhou Maixin Biotechnology, Fuzhou, China) and DAB substrate, generating a brown color. The antibodies, clones, dilutions, and pretreatment conditions used, as well as the positively stained sites, are listed in Table 1. Serial sections were incubated in parallel with rabbit IgG instead of the primary antibody as a negative control. Immunoreactivity was graded according to the percentage of positive tumor cells (0, negative; 1+, 1%-5%; 2+, 6%-25%; 3+, 26%-50%; 4+, 51%-100%), and tumor cell immunoreactivity was also semi-qualitatively graded: Weak, heterogeneous, or strong[7,8]. For calculation of IHC totals, a score of 1+ with weak, heterogeneous, or strong staining was considered positive for all antibodies except TFE3. A minimum of 3+ was required for TFE3 immunopositivity[8].

Fluorescence in situ hybridization

FISH was performed on paraffin-embedded tissue sections with a thickness of 4 μm and labeled with a *TFE3* gene break-apart probe (Guangzhou Anbiping Medical, Guangzhou, Guangdong Province, China). For probe preparation, *TFE3* gene was labeled with green fluorescence on the centromere side and red fluorescence on the telomere side. FISH interpretation criteria are as follows: The positive pattern for *TFE3* translocation should be 1 red, 1 green, and 1 fusion (yellow) signal in females, and 1 red, 1 green, and 1 negative signal in males; the pattern for intact *TFE3* alleles should be 2 fusion (yellow) signals in females and 1 fusion (yellow) signal in males. When the distance between the red and green signals exceeds 1 fusion signal size, it is interpreted as a red-green signal separation. A case was scored as positive if at least 10% of 100 scored nuclei showed a split signal pattern.

RESULTS

Clinical features

The clinical and pathological data for all 26 cases are summarized in Table 2. We enrolled 26 patients, including 17 females and 9 males. The median patient age was 50 years (range, 26–77 years). Of the 26 patients, 23 had liver-occupying lesions, 2 had hepatic hemangioma, and 1 had hepatic hamartoma. Six patients had a history of liver disease (cysts, hamartoma, or hemangioma). The most common site of tumors was the left hepatic lobe. Sixteen patients underwent extended hepatic lobe resection, eight underwent simple hepatic tumor resection, and two were treated only with the mTOR inhibitor sirolimus (both patients were treated for 8 mo). The clinical symptoms of hepatic PEComa were non-specific. Most patients were admitted to one of our hospitals because of space-occupying lesions in the liver during medical examination, nausea, vomiting, loss of appetite, or weight loss. During physical examination, the abdomen was soft, with no tenderness or rebound tenderness, occasional contact with the ribs at the liver margin, and no pain in the liver area. Some patients experienced compression pain under the ribs and xiphoid, or in the right abdomen when the tumor involved the caudate lobe, or in the right kidney.

Imaging findings

B-ultrasound usually revealed strong echoes in the liver, the boundary was clear, and the internal echo was uneven, suggesting that the liver had substantial space-occupying lesions (data not shown). Plain computed tomography (CT) scans commonly revealed an irregular soft tissue density (Figure 1A). Enhanced scanning in the arterial phase revealed obvious enhancement of the mass edge and of central heterogeneity (Figure 1B). Portal vein scanning revealed a low mass density (Figure 1C). Magnetic resonance imaging (MRI) revealed a solid cystic space in the liver, and tumors had clear boundaries and uneven internal signal (data not shown).

Macroscopic features

The median tumor diameter was 6.5 cm (range, 0.5-13.0 cm). PEComa tumors were located in the liver parenchyma and were round or oval. The surface was smooth and occasionally highlighted the surface of the liver. The boundary was clear and appeared to be enveloped. Tumors did not invade the surrounding tissue. The cut surface was solid and grayish yellow, had a slightly hard texture, and showed loose necrotic tissue in the center. The liver tissue surrounding the tumor was normal, and the lymph nodes in the hilar region were not swollen. Focal hemorrhage and necrosis were seen in two cases.

Microscopic features

Microscopically, the tumor cells were clearly distinct from normal liver cells, and were largely composed of proliferating epithelioid cells and spindle cells, nested in trabeculae or lamellae. In most cases, the tumor cell nest was surrounded by capillaries. Tumor cells were arranged radially around the thick-walled blood vessels (Figure 2A). Tumor cells were polygonal and cytoplasm was translucent, with hetero-

obvious, chromatin was sparse, part of the cells were heteromorphic, and mitotic figures were not common. Collagen fibers were observed in the interstitium and were generally feathery, and a few fibers were accompanied by hemorrhage and necrosis (Figure 2B).

Immunohistochemistry findings are summarized in Table 3. Of the 26 cases, 25 were HMB45 (+), usually with multifocal or diffuse distribution and occasionally, with scattered distribution (Figure 2C), 23 were Melan-A (+) (Figure 2D), 22 were SMA (+) (Figure 2E), 20 were VIM (+), and 12 were S-100 (+). Only three cases showed focal staining (1%-5%) for TFE3. All tumors were desmin (–) (Figure 2F). The positive rate for Ki-67 was < 10%. All cases expressed at least one smooth muscle or melanocyte marker. FISH showed that no abnormal *TFE3* separation signal was found in 26 cases of hepatic PEComa (Figure 3).

Treatment and follow-up

Sixteen patients underwent extended hepatic lobe resection, eight underwent simple hepatic tumor resection, and two were treated with the mTOR inhibitor sirolimus. During a follow-up period of 25 mo to 99 mo, none of the 26 patients had metastasis or recurrence, and there were no deaths due to the disease. Only two patients with extended liver lobectomy had a poor prognosis (one had postoperative pain in the liver area, and the other was diagnosed with liver cancer 2 years after surgery). There was no difference in patient prognosis between the two surgical treatment methods, and long-term follow-up indicated that the patients went into remission.

DISCUSSION

Hepatic PEComa is a rare mesenchymal tumor derived from pericytes. Ultrasound, CT, and MRI are commonly used for preoperative diagnosis of PEComa. On contrast-enhanced CT, PEComa is characterized by vascular proliferation and arteriovenous connections[5,9,10]. MRI scans have revealed significant enhancement in PEComa in the arterial phase, but not in the portal venous and delayed phases[10]. Contrast-enhanced ultrasonography is another commonly used diagnostic method, in which the contrast agent characteristically reaches the tumor rapidly and drains the arterial blood rapidly to the vein[11]. However, due to the different proportions of smooth muscle cells, adipose tissue, blood vessels, and rare tumors, the accuracy of preoperative diagnosis is currently low. In our study, only one patient was diagnosed with hepatic PEComa before undergoing surgery.

Martignoni *et al*[12] defined PEComa as a tumor that is composed mainly of epithelioid cells and is closely associated with dilated blood vessels and contains eosinophils, but not fat cells or disordered blood vessels. The final diagnosis of PEComa currently depends on pathological features and immunohistochemical analysis. Hepatic PEComa is mainly composed of proliferating epithelioid cells and spindle cells. The tumor cells are polygonal, have translucent cytoplasm, and contain eosinophilic particles, and thick-walled blood vessels are visible in the tumors. Epithelioid cells are arranged radially around thick-walled blood vessels. Feather-like collagen fibers are visible. Nearly all PEComas have specific immunological characteristics, with melanocyte markers (*e.g.*, HMB-45 and/or melan-A) and smooth muscle markers (*e.g.*, SMA) being strongly expressed[11,13], whereas desmin, hepatocyte-

Weakly positive (1%-5%), only scattered cells.

specific antigen, and TFE3 are generally negative. In this study, 25 cases were HMB-45 (+), 17 were SMA (+), and only 3 showed focal staining (1%-5%) for TFE3.

TFE3 is a member of the MiTF family of transcription factors. A recent study[14] showed that *TFE3* gene rearrangements occur in approximately 14% of PEComas. Similar to other *TFE3* translocation-associated tumors, TFE3 (+) PEComa usually exhibits an acinar structure and epithelioid cell morphology, shows aggressive biological behavior, and has a poor prognosis. *PSF-TFE3* gene fusion has been detected in gastrointestinal tract PEComa, but fusion partners in other cases remain unknown [15]. In this study, TFE3 expression was weak and detected in only three patients with small tumors and typical morphological PEComa images, and was associated with a low malignancy and good prognosis. Moreover, no break-apart of the *TFE3* gene was detected by FISH method. Whether there is a *TFE3* fusion gene still needs to be confirmed by subsequent studies. This suggests that liver PEComa may be less malignant than PEComas in other organs.

PEComas are mainly benign tumors[16] that usually do not recur after surgical resection; however, some are malignant, and their biological behavior has not been fully elucidated. In 2005, Folpe *et al*[17] reviewed 26 cases of PEComa of soft tissue and gynecological origin, and suggested to classify PEComa into benign, uncertain malignant potential, and malignant. Further, the authors proposed seven evaluation criteria for PEComa malignancies: (1) Tumor size > 5 cm; (2) Infiltration and growth into surrounding normal tissue; (3) High nuclear grade; (4) Excessive cells; (5) Mitotic figures in > 1/50 high-power fields; (6) Coagulative necrosis of tumor; and (7) Vascular invasion. PEComas with two or more of these features are considered to be malignant, and tumors with only nuclear polymorphism, multinucleated giant cells, or tumors > 5 cm in size are considered to have malignant potential[18].

Because of the rare disease types and the scarcity of cases, treatment plans for hepatic PEComa can only be developed based on statistical analysis of a small number of cases. Surgical resection currently is the main means of treating hepatic PEComa. In clinical practice, surgical methods are usually selected based on the tumor size and on whether the tumor is benign or malignant. Larger and malignant tumors are removed by extended hepatic lobe resection, whereas simple hepatic tumor resection is used for smaller or benign tumors. In this study, the 26 cases showed clinical and biological manifestations of inertness, and no morphological criteria for malignant PEComa. Sixteen patients underwent extended hepatic lobe resection, eight underwent simple hepatic tumor resection, and two received sirolimus. The survival rate of the patients treated with the three different modalities was good, and there was no significant difference among the treatments. Hepatic pain complications were reported only in a few cases with extended lobe resection. It has been reported that when the tumor diameter is less 5 cm, resection can be suspended or regular follow-up suffices[18].

Current data do not support that chemo- or radio-therapy improves the survival time in patients with PEComa[12]; however, sirolimus is expected to improve outcomes either when used alone or in combination with other treatments[4,10,19,20]. A 31-year-old woman with hepatic PEComa showed a significant reduction in tumor

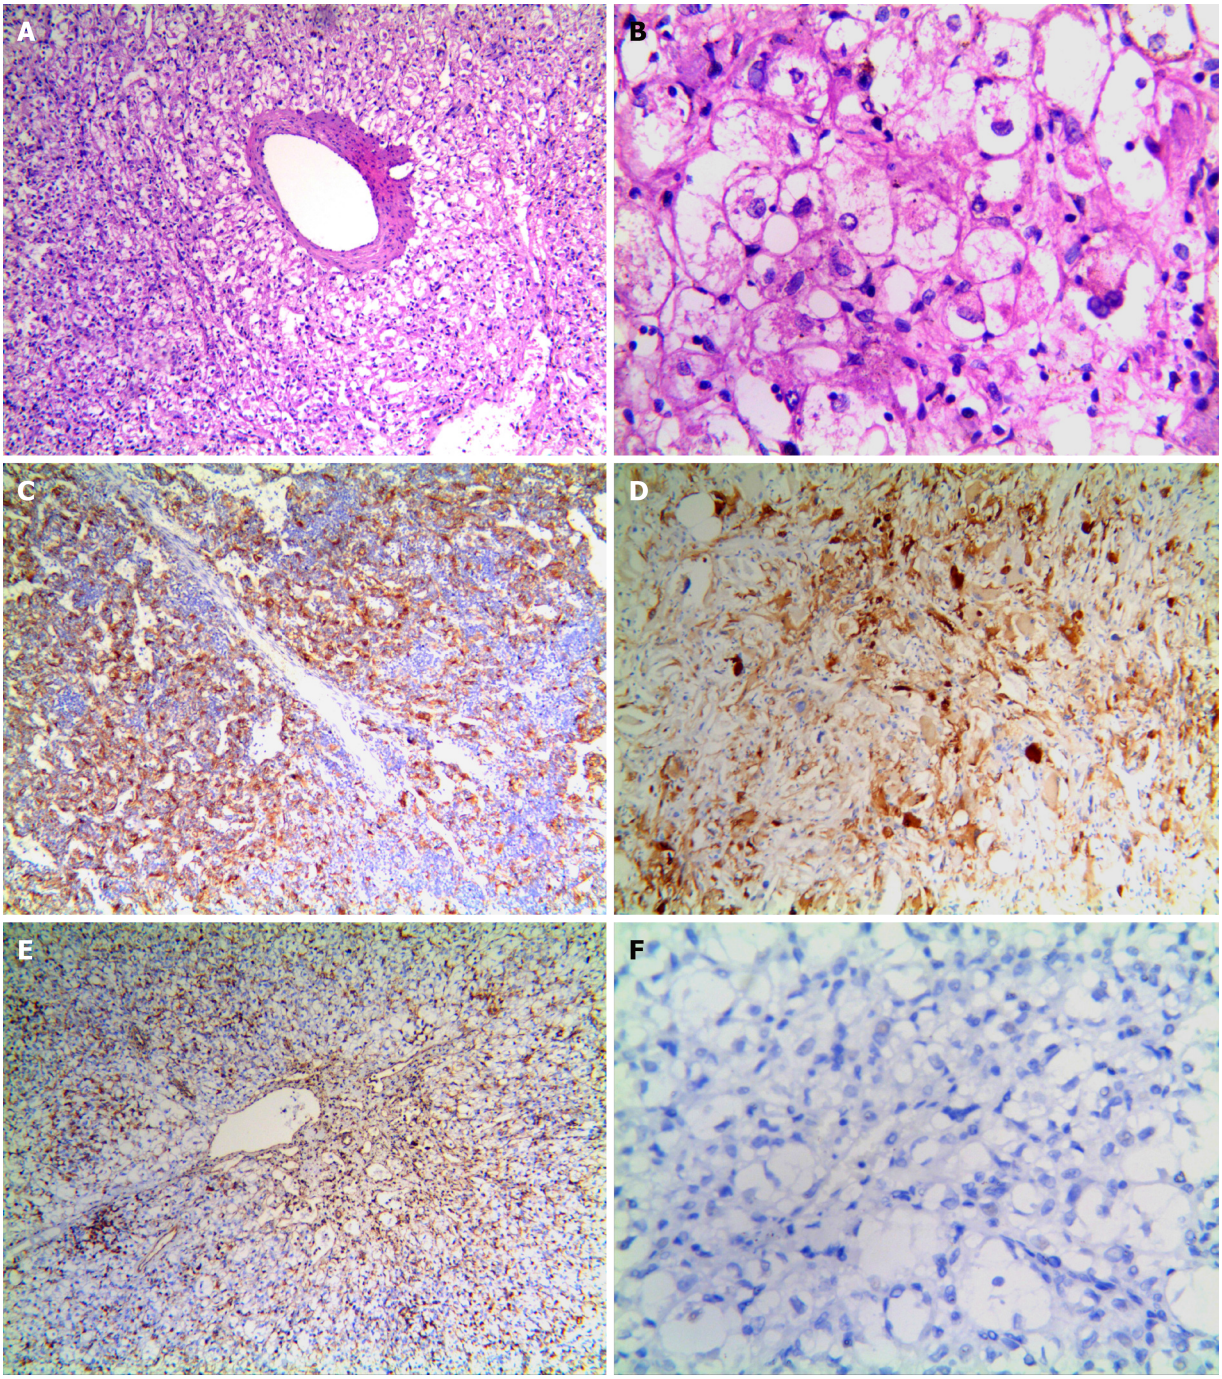

Figure 2 Morphologic appearance of hepatic PEComa. A: Tumor cells consists of proliferating epithelioid cells nested in trabeculae or lamellae and radially arranged around thick-walled vessels (HE, magnification: 100 ×); B: Tumor cells are polygonal, have translucent cytoplasm, and contain uneven eosinophilic granules. Nuclei are round or oval, with a clear nucleolus and sparse chromatin. Interstitial collagen fibers are feathery (HE, magnification, 400 ×); C: Immunoreactivity for HMB45 was detected in the cytoplasm of tumor cells in contrast to normal liver cells, which were negative for this marker (magnification, 100 ×); D: Increased expression of Melan-A was observed in both the cytoplasm and nuclei of carcinoma cells, whereas normal cells displayed lower expression of this marker (magnification, 100 ×); E: Vimentin was detected in the cytoplasm of tumor cells (magnification, 100 ×), whereas normal tissues were negative for this marker (magnification, 100 ×); F: Desmin immunoreactivity was not detected in tumor cells and normal tissues (magnification, 400 ×). Elivision™ Plus/HRP was used.

volume after 8 mo of treatment with sirolimus[19]. After subsequent surgical resection, there were no complications and the prognosis was favorable. This suggests that hepatic PEComa has a better prognosis when surgery is combined with chemotherapy [13,14]. In addition, Wagner *et al*[21] treated three patients with PEComa with sirolimus and found that the tumors responded to the drug, suggesting that sirolimus can be used alone or in combination to treat PEComa. Italiano *et al*[22] reported similar efficacy in a number of cases. However, large-scale clinical trials are needed. Numerous previous studies and this study showed that hepatic PEComa displays an inert biological behavior. However, due to the heterogeneous nature of PEComa, the

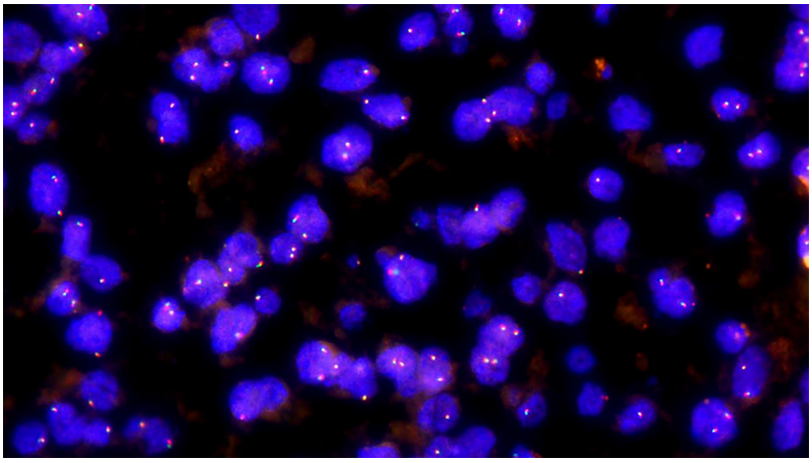

Figure 3 FISH detection of *TFE3* gene break-apart in hepatic PEComa. Most of the tumor cells show fused (yellow) signals, and the distance between the red and green signals is less than 1 fusion signal. For each sample, 100 cells were counted. Only less than 10% of tumor cells showed break-apart signals (magnification, 1000 ×).

existing diagnostic criteria cannot accurately determine the nature of this tumor, which has led to overtreatment in some cases. In addition, because the nature of hepatic PEComa is not entirely clear, there is no standard treatment, and it is difficult to develop an optimal treatment plan. Therefore, clinical observation and follow-up of more cases, and the establishment of a clinical online registration system for hepatic PEComa are needed to provide clinical data for future exploration of the differentiation and distribution of the disease and the development of more accurate diagnostic criteria.

CONCLUSION

Hepatic PEComa is a rare mesenchymal tumor that exhibits an inert biological behavior, and its diagnosis, treatment, and follow-up are challenging. Our study of 26 cases of hepatic PEComa revealed that there was no difference in the prognosis between simple resection of liver tumor and extended resection of liver lobe. Optimal surgical resection currently is the best treatment option, and radiotherapy, chemotherapy, and immunotherapy may become more effective in future[4,9]. The number of cases in the current retrospective study was limited by the rarity of hepatic PEComa. Therefore, further multicenter, larger-cohort studies are warranted to investigate the clinicopathological features and biological behavior of hepatic PEComa.

ARTICLE HIGHLIGHTS

Research background

Perivascular epithelioid cell tumor (PEComa) is an uncommon tumor of mesenchymal origin. Cases of PEComa in the liver are extremely rare.

Research motivation

Cases of PEComa in the liver are extremely rare, and surgical resection currently is the most effective therapeutic strategy to cure patients or prolong the survival period. In this study, the clinical and pathological features, immunohistochemical phenotypes, and information on treatment modalities of 26 cases of hepatic PEComa were collected, and the effects of different surgical methods on prognosis were evaluated to provide information for the guidance of clinical treatment.

Research objectives

We aimed to analyze the clinicopathological features and treatment of hepatic PEComa and to evaluate the prognosis after different treatments.

Research methods

Clinical and pathological data of 26 patients with hepatic PEComa were collected. All cases were analyzed by immunohistochemistry and clinical follow-up.

Research results

This study included 17 females and 9 males, with a median age of 50 years. Lesions were located in the left hepatic lobe in 13 cases, in the right lobe in 11, and in the caudate lobe in 2. The median tumor diameter was 6.5 cm. Light microscopy revealed that the tumor cells were mainly composed of epithelioid cells. The cytoplasm contained heterogeneous eosinophilic granules. There were thick-walled blood vessels, around which tumor cells were radially arranged. Immunohistochemical analysis of pigment-derived and myogenic markers in PEComa tumors revealed that 25 cases were HMB45 (+), 23 were Melan-A (+), and 22 SMA (+). TFE3 and Desmin were negative in all cases. All the FISH samples were negative for *TFE3* gene break-apart probe. Tumor tissues were collected by extended hepatic lobe resection or simple hepatic tumor resection as the main treatments. Median follow-up was 62.5 mo. None of the patients had metastasis or recurrence, and there were no deaths due to the disease.

Research conclusions

Hepatic PEComa is a rare mesenchymal tumor that exhibits an inert biological behavior, and its diagnosis, treatment, and follow-up are challenging. Our study of 26 cases of hepatic PEComa revealed that there was no difference in the prognosis between simple resection of liver tumor and extended resection of liver lobe. Optimal surgical resection currently is the best treatment option, and radiotherapy, chemotherapy, and immunotherapy may become more effective in future.

Research perspectives

The number of cases in the current retrospective study was limited by the rarity of hepatic PEComa. Therefore, further multicenter, larger-cohort studies are warranted to investigate the clinicopathological features and biological behavior of hepatic PEComa.

Abstract

BACKGROUND

The nature of input data is an essential factor when training neural networks. Research concerning magnetic resonance imaging (MRI)-based diagnosis of liver tumors using deep learning has been rapidly advancing. Still, evidence to support the utilization of multi-dimensional and multi-parametric image data is lacking. Due to higher information content, three-dimensional input should presumably result in higher classification precision. Also, the differentiation between focal liver lesions (FLLs) can only be plausible with simultaneous analysis of multi-sequence MRI images.

AIM

To compare diagnostic efficiency of two-dimensional (2D) and three-dimensional (3D)-densely connected convolutional neural networks (DenseNet) for FLLs on multi-sequence MRI.

METHODS

We retrospectively collected T2-weighted, gadoxetate disodium-enhanced arterial phase, portal venous phase, and hepatobiliary phase MRI scans from patients with focal nodular hyperplasia (FNH), hepatocellular carcinomas (HCC) or liver metastases (MET). Our search identified 71 FNH, 69 HCC and 76 MET. After volume registration, the same three most representative axial slices from all

sequences were combined into four-channel images to train the 2D-DenseNet264 network. Identical bounding boxes were selected on all scans and stacked into 4D volumes to train the 3D-DenseNet264 model. The test set consisted of 10-10-10 tumors. The performance of the models was compared using area under the receiver operating characteristic curve (AUROC), specificity, sensitivity, positive predictive values (PPV), negative predictive values (NPV), and f1 scores.

RESULTS

The average AUC value of the 2D model (0.98) was slightly higher than that of the 3D model (0.94). Mean PPV, sensitivity, NPV, specificity and f1 scores (0.94, 0.93, 0.97, 0.97, and 0.93) of the 2D model were also superior to metrics of the 3D model (0.84, 0.83, 0.92, 0.92, and 0.83). The classification metrics of FNH were 0.91, 1.00, 1.00, 0.95, and 0.95 using the 2D and 0.90, 0.90, 0.95, 0.95, and 0.90 using the 3D models. The 2D and 3D networks' performance in the diagnosis of HCC were 1.00, 0.80, 0.91, 1.00, and 0.89 and 0.88, 0.70, 0.86, 0.95, and 0.78, respectively; while the evaluation of MET lesions resulted in 0.91, 1.00, 1.00, 0.95, and 0.95 and 0.75, 0.90, 0.94, 0.85, and 0.82 using the 2D and 3D networks, respectively.

CONCLUSION

Both 2D and 3D-DenseNets can differentiate FNH, HCC and MET with good accuracy when trained on hepatocyte-specific contrast-enhanced multi-sequence MRI volumes.

Core Tip: Our study aimed to assess the performance of two-dimensional (2D) and three-dimensional (3D) densely connected convolutional neural networks (DenseNets) in the classification of focal liver lesions (FLLs) based on multi-parametric magnetic resonance imaging (MRI) with hepatocyte-specific contrast. We used multi-channel data input to train our networks and found that both 2D and 3D-DenseNets can differentiate between focal nodular hyperplasias, hepatocellular carcinomas or liver metastases with excellent accuracy. We conclude that DensNets can reliably classify FLLs based on multi-parametric and hepatocyte-specific post-contrast MRI. Meanwhile, multi-channel input is advantageous when the number of clinical cases available for model training is limited.

INTRODUCTION

Artificial intelligence (AI)-based analysis is one of the fastest evolving fields in medical imaging, thanks to the rapid development of medical physics, electronic engineering, and computer science. The need for computer-aided diagnostics has been further amplified by the continuously increasing demand for imaging studies and the arrival of new modalities that put extra pressure on radiologists while also increasing the probability of diagnostic errors[1]. Meanwhile, deep learning (DL)-based algorithms have started to gain attention among medical researchers, since they provide excellent reproducibility and the ability to quantify aspects of imaging data unobservable to the human eye, resulting in automatically generated statistical reports and predictions, such as the potential of malignancy or metastatic spread and automated volume

the World Medical Association guidelines and Declaration of Helsinki, revised in 2000 in Edinburgh, No. SE-RKEB 136/2019.

Informed consent statement: As this is a retrospective study, in compliance with the Hungarian legal code, the need for written patient consent was waived by the ethics committee. Patients were not required to give informed consent to the study because the analysis used only anonymized clinical data that were obtained after each patient agreed to treatment and gave written informed consent to the MRI scan in compliance with our institutional protocol.

Conflict-of-interest statement: The authors have no financial relationships to disclose.

Data sharing statement: Additional anonymized data are available upon request from the corresponding author.

assessment, among other uses. Nowadays, AI has become compatible with the full spectrum of imaging modalities and has evolved the capacity to diagnose lesions in various organ systems with greater accuracy than a human reader[2]. The processed data often include two-dimensional (2D) slices or three-dimensional (3D) image volumes; moreover, in the case of magnetic resonance imaging (MRI) studies, the different sequences are condensed into a multi-channel input. Due to their efficiency, convolutional neural networks (CNNs) have replaced other machine learning (ML) approaches in most image classification and segmentation tasks[3,4]. Recently, densely connected CNNs (DenseNets) have become more popular than plain CNN architectures. DenseNets use shortcut connections between the convolutional layers to facilitate gradient flow and optimize the number of trainable parameters. In return, these networks yield improved accuracy and efficiency in medical image classification tasks[5].

Focal liver lesions (FLLs) are common incidental findings during imaging studies, and the work-up often requires further diagnostic procedures, such as dynamic contrast-enhanced ultrasound, computed tomography and liver biopsy. Meanwhile, the excellent soft-tissue contrast, volumetric image acquisition and avoidance of ionizing radiation make multi-phase dynamic post-contrast MRI the primary tool for detection and characterization of liver lesions. The use of hepatocyte-specific contrast agents (HSAs), such as gadoxetic acid and gadobenate dimeglumine, further improves the sensitivity and specificity of the diagnosis of FLLs, as the enhancement characteristics of these lesions in the hepatobiliary phase (HBP) correlates with hepatocyte uptake[6,7]. Additionally, HSA-enhanced MRI is capable of detecting lesions smaller than 10 mm, making it an optimal modality for the early detection of liver metastases (METs)[8].

In the present study, we compared the performance of 2D and 3D-DenseNets in the classification of three types of FLLs, including focal nodular hyperplasia (FNH), hepatocellular carcinoma (HCC) and MET. To guarantee the highest possible prediction rate, we used HSA-enhanced multi-phase dynamic post-contrast MRI scans for the classification task. According to our knowledge, this is the first study to evaluate 2D and 3D-DenseNets for the diagnosis of FLLs and using multi-channel images combining four different MRI sequences. The reporting of this study follows the STROBE Statement checklist of items[9].

MATERIALS AND METHODS

Patient and MRI study selection

In our single-center study, we retrospectively collected multi-phasic MRI studies of patients with FNHs, HCCs or METs, that were acquired using Primovist (gadoxetate disodium), an HSA, from the picture archiving and communication system of the Medical Imaging Centre of our university. As this is a retrospective study, the need for written patient consent was waived by the Institutional Research Ethics Committee. The collected images were acquired between November 2017 and October 2020 using a Philips Ingenia 1.5 T scanner (Cambridge, MA, United States). T2-weighted (T2w) spectral-attenuated inversion recovery (commonly referred to as SPAIR), arterial phase (HAP), portal venous phase (PVP), and HBP scans were collected from each eligible patient for further analysis. Included lesions were either histologically confirmed or exhibited typical characteristics of the given lesion type with MRI. Patients younger than 18 years of age at the time of imaging were excluded from the study. Table 1 contains details of patient demographics, properties of each lesion class, and metastatic lesion origin.

Data preparation and dataset creation

MRI scans were exported as DICOM files, that were then anonymized to remove the patients' social security numbers, birth date, sex, age, body weight, and date of the imaging study. Anonymized PVP and HBP files were resampled and spatially aligned to the corresponding T2w volume using BSpline as a non-rigid registration method *via* an open-source visualization and medical image computing software, called 3D Slicer (www.slicer.org). 3D Slicer was also used for annotation cropping and file conversion [10,11]. Lesions were annotated by cubic regions of interest (referred to as ROIs). The lesions were then cropped from the aligned HAP, PVP, HBP, and T2w volumes using the same ROI. The cropped volumes were saved as NIfTI files, which were then combined into one four-dimensional (4D) file for each lesion (Figure 1). Cropped lesions were randomly sorted into datasets. After 10-10 lesions were added to the test

and validation dataset from each class, the remaining tumors were added to the training dataset. NIfTI files were sliced up into axial PNG images. The resulting T2w, HAP, PVP, and HBP PNG files were concatenated (Figure 2) using a custom-written computer program in Python. The training and validation datasets contained three axial slices of each lesion (*i.e.* three most representative axial slices of the NIfTI files), while the test set consisted of only one slice from each lesion.

Data processing, training, and testing

Parameters of concatenated files were modified *via* transform functions. Image pixel intensity was scaled between -1.0 minimum and 1.0 maximum values. Data augmentation transforms were applied to the training samples, including random rotation (70° range along two axes) and zoom (0.7–1.4 scaling) to enrich training data. PNGs were resized to 64 × 64 resolution. Transformed images were converted to tensors (2D images were converted into 3D tensors, with the additional dimension equaling the number of network input channels), which were then fed to DenseNet264 that used 2D convolutional layers[5].

In the case of the 3D-DenseNet264 network, NIfTI voxels were resampled to isovolumetric shape, voxel intensities were rescaled between -1.0 minimum and 1.0 maximum value and NIfTI files were resized to 64 × 64 × 64 spatial resolution. The four NIfTI files were concatenated (T2w, HAP, PVP, HBP) to be used as multi-channel input for the 3D CNN. We used random 90° rotation (along two spatial axes), random 60° rotation (along x and y axes), random zoom (between 0.8 and 1.35), and random flipping on the training samples. MR volumes were converted to 4D tensors (number of channels, x-, y- and z-dimensions) that were used as network input. We used DenseNet264 models through the Pytorch-based open-source Medical Open Network For Artificial Intelligence (*i.e.* MONAI) framework[12]. We used categorical cross-entropy loss to measure the prediction error of the network during training and an Adam optimizer to update model parameters[13]. Networks were trained for 70 epochs. Using a Tesla T4 graphical processing unit, the 2D network was trained for 18 min, while the 3D CNN was trained for 41 min. Validation set area under the receiver operating characteristic curve (AUROC) values were calculated after each epoch, and the model with the highest average AUC value was saved as the final model.

The trained models were used to make predictions on an independent test dataset consisting of 10 lesions from each class. The tumor type with the highest probability, according to the last softmax layer of the convolutional networks, was chosen as the predicted lesion type *via* an argmax function, encoding the predicted diagnosis as 1, while the predicted incorrect classes as 0. Specificity, sensitivity, f1 score, positive predictive value (PPV), negative predictive value (NPV) were calculated for each class based on these outputs.

Classification performance was also measured using AUC values of each class, calculated from the softmax layer probability outputs. DeLong's test was used to determine the statistical significance between the test performance of the 2D and 3D classifiers[14].

RESULTS

The 2D model achieved the highest average validation set AUC after the 46th epoch, while the best average AUC value of the 3D network was reached after the 62nd epoch. These models were saved and then used to make test set predictions (Figure 3).

The finalized 2D and 3D networks were evaluated on the same independent test set, consisting of 10 lesions from each tumor type. On the independent test set, the finalized 2D model achieved 0.9900 [95% confidence interval (CI): 0.9664–1.0000], 0.9600 (95%CI: 0.8786–1.0000) and 0.9950 (95%CI: 0.9811–1.0000) AUC values for FNH, HCC and MET respectively, with an average AUC of 0.9783 (95%CI: 0.9492–1.0000). The finalized 3D model achieved 0.9700 (95%CI: 0.9077–1.0000), 0.9050 (95%CI: 0.7889–1.0000) and 0.9550 (95%CI: 0.8890–1.0000) AUC values for FNH, HCC and MET diagnosis, and an average AUC value of 0.9433 (95%CI: 0.8942–0.9924) on the test dataset (Figure 4). No statistically significant difference was found between the diagnostic performance of the 2D and 3D classifiers based on the ROC curve comparison for the three classes (Z = 0.7007, P = 0.4835 for FNH; Z = 0.7812, P = 0.4347 for HCC; Z = 1.3069, P = 0.1913 for MET). The 2D input data achieved excellent results in the distinction between all three lesion classes, similar to the 3D network (Table 2). Both networks achieved excellent PPV, sensitivity, f1 score, NPV, and specificity values for all three classes. The highest diagnostic accuracy was achieved by both networks for FNH and MET, while both networks demonstrated lower AUC values for HCC (Table 2). PPV, sensitivity, f1 score, specificity and an NPV of 0.9091, 1.0000, 0.9524, 0.9500, 1.000 values were achieved by the 2D model for FNH diagnosis. The 3D network performed FNH classification with similar PPV (0.9000), sensitivity (0.9000), f1 score (0.9000), specificity (0.9500) and NPV (0.9500) values as the 2D network. During HCC classification both the 2D and 3D models reached acceptable metrics with PPVs of 1.000 and 0.8750, sensitivities of 0.8000 and 0.7000, f1 scores of 0.8889 and 0.7778, specificities of 1.000 and 0.9500, lastly NPVs of 0.9091 and 0.8636. For the differentiation of METs from FNHs and HCCs the use of the 2D DenseNet resulted in a PPV of 0.9091, sensitivity of 1.000, f1 score of 0.9524, specificity of 0.9500 and NPV of 1.000, while the 3D DenseNet achieved values of 0.7500, 0.9000, 0.8182, 0.8500 and 0.9444 for PPV, sensitivity, f1 score, specificity and NPV respectively. On average, both the 2D and 3D trained models could distinguish FNHs, HCCs and METs reliably with PPVs of 0.9394 and 0.8417, sensitivities of 0.9333 and 0.8333, f1 scores of 0.9312 and 0.8320, specificities of 0.9667 and 0.9167, NPVs of 0.9697 and 0.9194.

In addition, these results are supported by the extraction of attention maps from the trained models using test set images. We implemented an open-source software (M3d-CAM) to visualize the most important regions for diagnosis-making[15]. The extracted attention maps may correlate with the certainty with which a model classifies FLLs. By marking the areas within images, based on which the model makes a decision, attention maps form optimal bases of training dataset tailoring for certain radiological or other medical computer vision tasks by focusing on image regions that are difficult to analyze for the trained neural network (Figure 5).

DISCUSSION

FLLs are common findings during liver imaging, and the differentiation of benign and malignant types of FLLs is a significant diagnostic challenge, as imaging signs may overlap between different pathologies which can substantially alter the therapeutic decision. Therefore, precise and reproducible differential diagnosis of FLLs is critical for optimal patient management.

Today, the most accurate imaging modality to diagnose FLLs is multi-phase dynamic contrast-enhanced MRI. Extracellular contrast agents (ECAs) are commonly used to perform multi-phase dynamic post-contrast MRI studies to differentiate between lesions based on their distinct contrast enhancement patterns, such as HAP hyper-enhancement or washout in the PVP[16]. In comparison to ECAs, HSAs are taken up by hepatocytes and (in part) excreted through the biliary tract; thus, they can better differentiate between those lesions that consist of functionally active and impaired hepatocytes or those that are extrahepatic in origin[7]. This behavior of HSAs is utilized for making a distinction between FNH and hepatocellular adenoma, or to detect small foci of HCC and MET within the surrounding liver parenchyma[17,18].

In the current study, we evaluated different AI models on liver MRI images for the prediction of 216 FLLs compiled from three different types of lesions, namely FNHs, HCCs and METs. To ensure that the models could achieve the highest possible

Table 2 Evaluation metrics of the two-dimensional and three-dimensional densely connected convolutional neural networks

Input data	PPV	Sensitivity	F1 score	Specificity	NPV
FNH 2D	0.9091	1.0000	0.9524	0.9500	1.0000
3D	0.9000	0.9000	0.9000	0.9500	0.9500
HCC 2D	1.0000	0.8000	0.8889	1.0000	0.9091
3D	0.8750	0.7000	0.7778	0.9500	0.8636
MET 2D	0.9091	1.0000	0.9524	0.9500	1.0000
3D	0.7500	0.9000	0.8182	0.8500	0.9444
Mean 2D	0.9394	0.9333	0.9312	0.9667	0.9697
3D	0.8417	0.8333	0.8320	0.9167	0.9194

2D: Two-dimensional; 3D: Three-dimensional; FNH: Focal nodular hyperplasia; HCC: Hepatocellular carcinoma; MET: Metastasis; NPV: Negative predictive value; PPV: Positive predictive value.

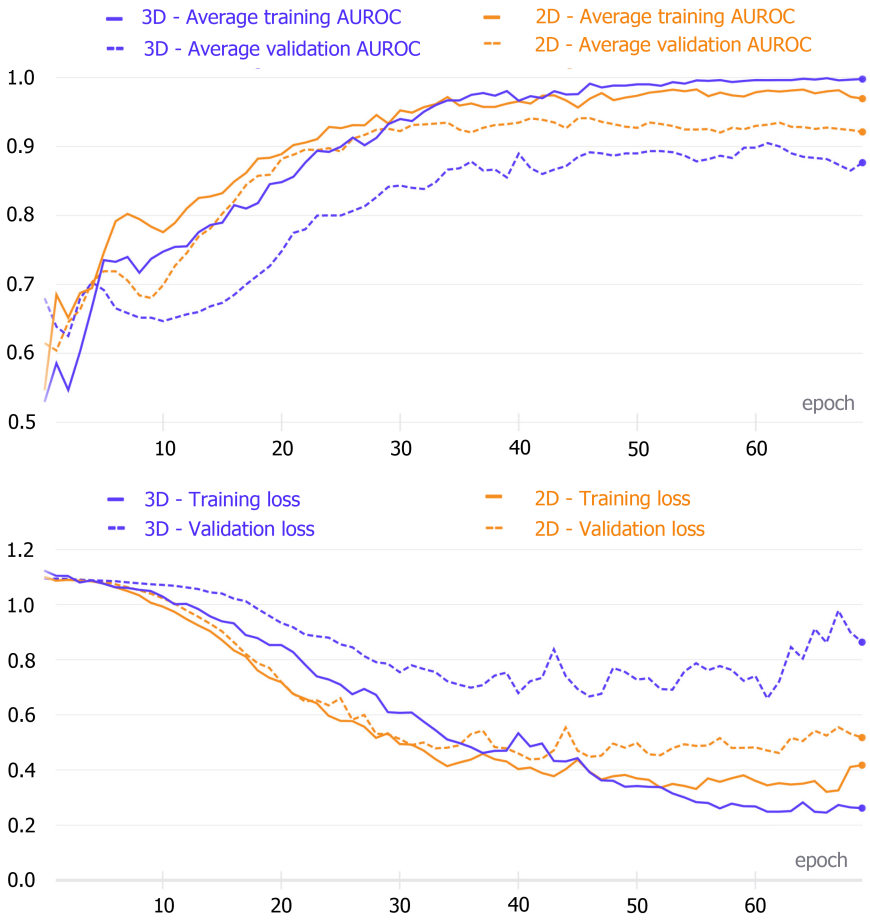

Figure 3 Comparison of the training evaluation metric curves and loss curves. The upper figure shows the area under the receiver operating characteristic curve (AUROC) values after each training epoch of the two-dimensional (2D) and three-dimensional (3D) densely connected convolutional neural networks (DenseNets). The best average AUC was obtained after the 46th (2D network) and 62nd (3D network) epochs. The lower figure indicates the loss values for each training epoch of the two networks. 2D: Two-dimensional; 3D: Three-dimensional; AUROC: Area under the receiver operating characteristic curve.

prediction rate, we narrowed down our data collection to only those four MRI sequences that provided the highest tissue contrast compared to the neighboring parenchyma or depicted distinctive imaging features of the lesion types. For the same reason, we used only HSA-enhanced scans for the analysis. We collected post-contrast images from HAP, PVP and HBP, and a T2w SPAIR image in the case of each lesion. A similar image analysis strategy was used by Hamm *et al*[19], who predicted 494 FLLs from six categories, including simple cyst, cavernous hemangioma, FNH, HCC,

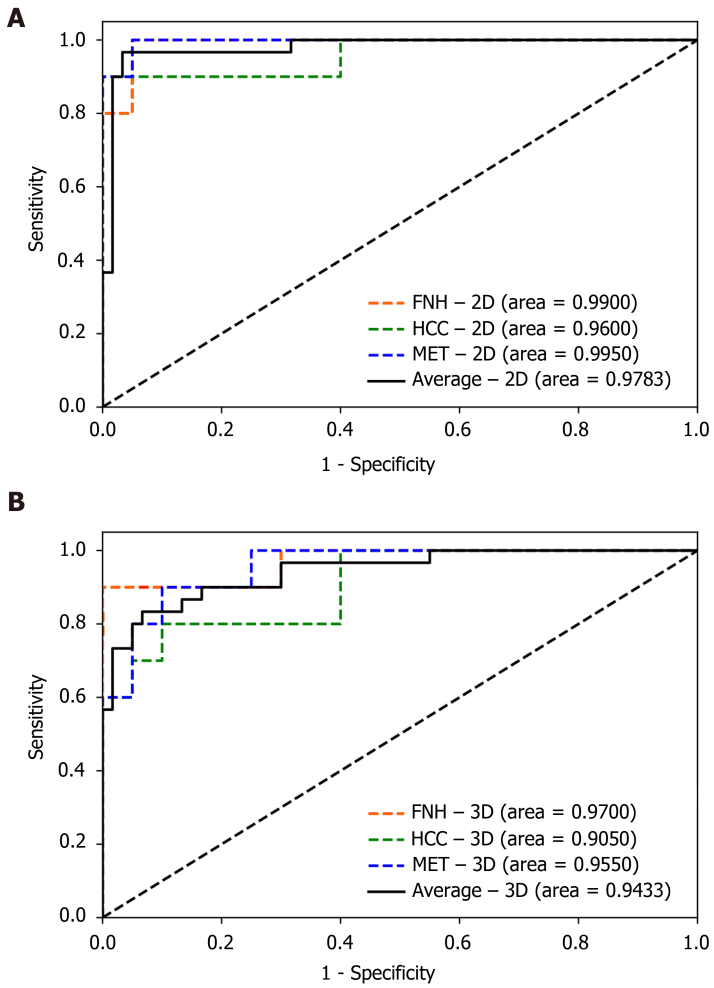

Figure 4 Receiver operating characteristic curves of the two-dimensional and three-dimensional densely connected convolutional neural network 264 models' performance on the test set. A: Two-dimensional; B: Three-dimensional. 2D: Two-dimensional; 3D: Three-dimensional; FNH: Focal nodular hyperplasia; HCC: Hepatocellular carcinoma; MET: Metastasis.

intrahepatic cholangiocarcinoma, and colorectal cancer METs using a 3D CNN model. The authors used HAP, PVP and delayed venous phase MRI images for the classification of the FLLs. They reported that the CNN model demonstrated 0.92 accuracy, 0.92 sensitivity and 0.98 specificity. The disadvantage of this study compared to ours was that it did not include HBP images, with only ECA images used for the MRI scans.

There are a handful of studies that included conventional ML methods and achieved reasonably good results. Wu *et al*[20], for example, extracted radiomics features from non-enhanced multi-parametric MRI images of FLLs and used them in ML models to differentiate between hepatic haemangioma and HCC. The final classifier achieved an AUC of 0.89, a sensitivity of 0.822 and a specificity of 0.714. Jansen *et al*[21], in their 2019 paper, used traditional ML methods for the same problem achieving an average accuracy of 0.77 for five major FLL types.

Our models' performance in the test set was comparable to or even surpassed those from previous publications, as the AUC, sensitivity and specificity were excellent for both the 2D (0.9783, 0.9333 and 0.9667 respectively) and 3D (0.9433, 0.8333 and 0.9167 respectively) architectures, which demonstrates the robustness of our data collection and analysis.

The quality and quantity of input data are pivotal when training neural networks. MRI liver tumor analysis using DL methods has steeply increased, but there is evidence lacking to support the use of 2D or 3D data. The additional dimension in 3D network inputs makes them computationally more demanding and the different data augmentation methods and hyperparameters must be well chosen to avoid artifacts. The 2D neural networks have the advantage of pretraining, which may improve classification accuracy[16,22,23]. Our study supports the results of Wang *et al*[24] and Hamm *et al*[19], emphasizing the need for multi-channel input volumes in order to achieve better accuracy. In contrast to these approaches, we have also utilized HBP

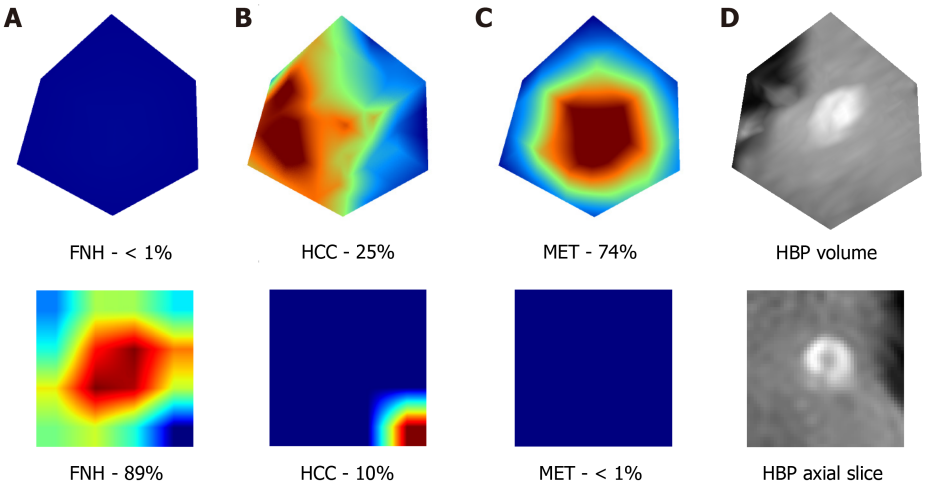

Figure 5 Visualization of the attention maps extracted from the two-dimensional and three-dimensional densely connected convolutional neural networks compared to the hepatobiliary phase input images. Two-dimensional (lower row) and three-dimensional (upper row) attention maps (column A-C) and hepatobiliary phase (column D) images were extracted from the 3rd dense block of the trained network. A-C: Two-dimensional (lower row) and three-dimensional (upper row) attention maps; D: Hepatobiliary phase images. Column A contains the attention maps for focal nodular hyperplasia (FNH), column B for hepatocellular carcinoma, and column C for metastasis diagnosis. The correct diagnosis is FNH in this case. Probabilities for different lesion classes are annotated below each attention map. The red areas are more important for the classification than other image regions. FNH: Focal nodular hyperplasia; HCC: Hepatocellular carcinoma; MET: Metastasis; HBP: Hepatobiliary phase.

images, thereby increasing the number of input channels to four in order to improve accuracy and additionally trained 2D CNNs, proving them to be just as effective classifiers as 3D models.

The selected architecture of the DL model can substantially alter classification accuracy. It is a novelty of our analysis that compared to previous examinations we utilized a DenseNet architecture. DenseNets contain multiple dense blocks, where each layer is connected with the residuals from previous layers. DenseNets require fewer trainable parameters at the same depth than conventional CNNs, as newly learned features are shared through all layers[5]. Our results are among the first to indicate that this highly efficient network design can enhance the performance of AI models for the classification of multi-parametric MRI images of FLLs.

Our study's limitations are the low number of patients involved, the retrospective nature of the study, and that it was conducted within a single institute. Further improvement may be achieved by additional data collection (including additional lesion classes) and the use of more MRI volumes and different data augmentation methods as well as the use of pre-trained networks.

CONCLUSION

Based on our study, we can say that routinely acquired radiological image materials can be used for analysis with AI methods, such as CNNs. According to our results, densely connected CNNs trained on multi-sequence MRI scans can be promising new alternatives to single-phase approaches; furthermore, the use of multi-dimensional input volumes can help the AI-based diagnosis of FLLs. According to our results, 3D and 2D DenseNets can reach similar performance in the differentiation of FLLs based on a small dataset of MRI images. The use of gadoxetate disodium-enhanced MRI scans can also enhance the diagnostic performance of MRI-based hepatic lesion classification.

ARTICLE HIGHLIGHTS

Research background

Interest in medical applications of artificial intelligence (AI) has steeply risen in the last few years. As one of the most obvious beneficiaries of the advances in computer vision, radiology research has also put AI in a prominent position. Convolutional

neural networks are the state-of-the-art methods used in computer vision. Focal liver lesions (FLLs) are common findings during imaging, which can best be evaluated *via* hepatocyte-specific contrast-enhanced magnetic resonance imaging (MRI).

Research motivation

Though convolutional neural networks are widely used for medical image research purposes, the effect of input, such as data dimensionality and the effect of multiple input channels, has not yet been widely examined in this area. MRI volumes presumably hold more complex information about each lesion; as such, three-dimensional inputs may be more difficult to process and properly use for classification tasks in comparison to two-dimensional axial slices. The combination of multiple MRI sequences in addition to the use of hepatocyte-specific contrast agents (HSAs) may also affect diagnostic accuracy.

Research objectives

Our research aimed to compare two- and three-dimensional DenseNets264 networks for the multi-phasic hepatocyte-specific contrast-enhanced MRI-based classification of FLLs.

Research methods

T2-weighted, arterial phase, portal venous phase, and hepatobiliary phase volumes of focal nodular hyperplasias, hepatocellular carcinomas and liver metastases were used to train the two models. Diagnostic performance was evaluated on an independent test set, based on area under the curve, positive and negative predictive values (NPVs), sensitivity, specificity and f1 score.

Research results

The study found that *via* the use of either two- or three-dimensional convolutional neural networks and the combination of multiple MRI sequences, the average area under the curve, sensitivity, specificity, NPV, positive predictive value and f1 scores of comparable level can be achieved.

Research conclusions

According to our findings, two- and three-dimensional networks can both be used for highly accurate differentiation of multiple classes of FLLs by combining multiple MRI phases and using HSAs.

Research perspectives

This study's findings can help to clarify the potential applicability of two- and three-dimensional multi-channel MRI images for the convolutional neural network-based classification of FLLs using HSAs.

ACKNOWLEDGEMENTS

The authors would like to express their gratitude to Dr. Endre Szabó, mathematician from the Alfréd Rényi Institute of Mathematics of The Hungarian Academy of Sciences, for expert review of the manuscript and discussion of the AI analysis and statistical methods. The authors also thank Tamás Wentzel and Lilla Petovsky, technicians of the MRI unit of the Medical Imaging Center, Semmelweis University, for their enthusiasm for the current research and professionalism during patient examinations.

Editorial Board Member of *World Journal of Gastroenterology*, Mark D Gorrell, BSc, PhD, Professor of Liver Science, Head, Liver Enzymes in Metabolism and Inflammation Program, Centenary Institute, Faculty of Medicine and Health, The University of Sydney, New South Wales 2006, Australia. m.gorrell@centenary.org.au

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, and Scopus. The 2021 edition of Journal Citation Report® cites the 2020 impact factor (IF) for *WJG* as 5.742; Journal Citation Indicator: 0.79; IF without journal self cites: 5.590; 5-year IF: 5.044; Ranking: 28 among 92 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2020 is 6.9 and Scopus CiteScore rank 2020: Gastroenterology is 19/136.

Abstract

Laparoscopic cholecystectomy (LC) is one of the most frequently performed gastrointestinal surgeries worldwide. Bile duct injury (BDI) represents the most serious complication of LC, with an incidence of 0.3%-0.7%, resulting in significant perioperative morbidity and mortality, impaired quality of life, and high rates of subsequent medico-legal litigation. In most cases, the primary cause of BDI is the misinterpretation of biliary anatomy, leading to unexpected biliary lesions. Near-infrared fluorescent cholangiography is widely spreading in clinical practice to delineate biliary anatomy during LC in elective and emergency settings. The primary aim of this article was to perform an up-to-date overview of the evolution of this method 12 years after the first clinical application in 2009 and to highlight all advantages and current limitations according to the available scientific evidence.

laparoscopic and robotic surgery. The visualization of biliary anatomy using fluorescence during surgery is becoming one of the most promising frontier approaches in minimally invasive surgery. This novel method is a powerful tool to detect biliary variants that could guide surgeons during dissection to prevent major bile duct lesions, and it has enormous potential to be considered the gold standard during all cholecystectomies. The up-to-date overview of this method confirms the efficacy of indocyanine green fluorescence cholangiography in detecting biliary anatomy, its importance as a teaching tool for young surgeons, and the effects on the reduction of conversion rate and bile duct injury, even if further considerable research remains necessary to optimize its use.

INTRODUCTION

Laparoscopic cholecystectomy (LC) is one of the most frequently performed gastrointestinal surgeries worldwide. Bile duct injury (BDI) represents the most serious complication of LC, with an incidence of 0.3% to 0.7%, resulting in significant perioperative morbidity and mortality, impaired quality of life, and high rates of subsequent medico-legal litigation[1,2]. In most cases, the primary cause of BDI is the misinterpretation of biliary anatomy, leading surgeons to unexpected biliary lesions (71%-97% of all cases)[3,4]. Various methods have been proposed and used to prevent iatrogenic biliary tract lesions[4]. Among them, near-infrared fluorescent cholangiography (NIRF-C) is widely spreading in clinical practice to delineate biliary anatomy during LC in elective and emergency settings. It is becoming one of the most popular and promising clinical applications in minimally invasive surgery[5,6]. In 2006, Stiles BM *et al*[7] first proposed fluorescent cholangiography in a mouse model by exploiting the unique auto fluorescent properties of bile for the intraoperative identification of the biliary anatomy in mice. The first application in humans was performed and described by *Ishizawa et al*[8] a few years later (2009). This classical method involves the intravenous injection of indocyanine green (ICG) dye before surgery. ICG binds to plasma proteins, with albumin as the principal carrier (95%), and is eliminated exclusively by the liver. The excitation of ICG by means of near-infrared light causes fluorescence, thereby delineating the anatomy of the biliary elements in real time. This innovative method was introduced as a means to prevent bile duct injuries during LC due to a better visualization of biliary anatomy during dissection. In 2015, we performed a systematic review of available studies by analyzing the efficacy of the novel technique in detecting bile duct structures during surgery. Detection rates of the biliary anatomy in 590 pooled patients were as follows: Cystic duct (CD) 96.2% (94.7%-97.7%), common hepatic duct (CHD) 78.1% (74.8%-81.4%), CD-CHD junction 72.0% (69.0%-75.0%), and common bile duct (CBD) 86.0% (83.3%-88.8%)[9]. Overall, these preliminary studies indicated that ICG fluorescence cholangiography is highly sensitive for the detection of extrahepatic biliary anatomy and may facilitate the prevention of bile duct injuries. Over the years, several single-center experiences from different countries[10-12] have been published regarding the usefulness of ICG fluorescence cholangiography in detecting biliary anatomy and analyzing patient outcomes after LC. The level of scientific evidence on ICG fluorescence cholangiography remains low. However, recent studies have significantly propelled the literature forward.

The primary aim of this article was to perform an up-to-date overview of the evolution of this method 12 years after its first clinical application and to highlight all the advantages and current limitations according to the available scientific literature.

TECHNIQUES

ICG administration can be performed in two different ways. The classical method described by Ishizawa T *et al*[8] in 2009 consists of the intravenous injection of ICG 30 min before surgery. Biliary visualization should be obtained prior to any dissection, during the dissection of the hepatocystic triangle, and after complete dissection according to the critical view of safety (CVS) method[13,14].This approach enables surgeons to check the biliary anatomy intraoperatively at any time. Recently, Dip F *et al*[15] summarized 10 important steps for the correct performance of fluorescent cholangiography during LC. The first two steps involve ICG intravenous administration and complete exposure of the hepatoduodenal ligament prior to any dissection. The primary objective of step 3 is the localization of the main biliary structures after the partial dissection of the hepatocystic triangle. Steps 4-7 are characterized by the identification of the CD, gallbladder-CD junction, CD-CHD junction, and CBD; step 8 is the identification of the cystic artery, in some cases by repeating ICG injection for fluorescent angiography to detect any anatomical arterial variations; step 9 is called "time-out", and it consists of the re-evaluation of the CVS before clipping and cutting any structures (as shown in Figures 1-2). After completing gallbladder removal, near-infrared (NIR) light should be turned on to identify any potential biliary leaks from the liver bed (step 10). At the current stage, there are two unresolved issues regarding NIRF-C, *i.e.*, the dose and the time required to obtain an optimal bile duct-to-liver fluorescence ratio >1. An elevated background liver signal may hinder the correct visualization of biliary anatomy. The dose and the time of administration of ICG are quite variable, as reported in the literature[16]. A recent study with data from the European Fluorescence Image-Guided Surgery (FIGS) registry[17] has shown a wide disparity in ICG dose and timing in NIRF-C across different European countries. Boogerd L *et al*[18] demonstrated that the highest bile duct-to-liver ratio was achieved 3 to 7 h after administration of 5 mg of ICG and 5 to 25 h after administration of 10 mg of ICG. Another study by Zarrinpar A *et al*[19] confirmed that a single dose of 0.25 mg/kg administered at least 45 min prior to visualization of the hepatocystic triangle facilitates intra-operative anatomical identification. Recently, Chen Q *et al*[20] demonstrated that the optimal effect of fluorescent cholangiography can be achieved by injecting 10 mg of ICG 10 to 12 h prior to surgery. Matsumura M *et al*[21] recommended the administration of 0.25 mg/kg ICG on the evening before surgery, as it may increase bile duct detectability in fluorescence cholangiography during LC. Based on our experience, we think that the administration of ICG 45 to 60 min before surgery is—from a logistical point of view - more practical since most patients are usually hospitalized on the same day as the surgical procedure. Indeed, the debate remains open, and a consensus conference may help the surgical community.

The direct injection of ICG into the gallbladder is a technique that allows overcoming the strong background signal in the liver. Liu YY *et al*[22] were the first to describe intracholecystic ICG administration during LC in a porcine model, proving the feasibility and usefulness of this technique to achieve adequate CVS. Few clinical studies of NIR cholecystocholangiography with direct ICG injection into the gallbladder were conducted, namely, two case reports, one case-control study, and a few prospective cohort studies, for a total of 80 patients, of whom 49 underwent surgery for symptomatic cholelithiasis and 31 for acute cholecystitis[22-26], as summarized in Table 1.

Liu YY *et al*[22] and Škrabec C *et al*[23] conducted the two widest studies, namely, a prospective cohort study of 46 patients and a case-control study including 20 patients, respectively. The authors described two different routes for intracholecystic ICG injection, *i.e.*, percutaneous transhepatic gallbladder drainage (trans-PTGBD) and intra-operative direct gallbladder puncture. A 1 mL amount of an ICG bile solution was used (ICG concentration = 0.025 mg/mL) made from a combination of 9 mL of bile mixed with 1 mL of a preparation of ICG and sterile water at a concentration of 0.25 mg/mL. NIR cholecystocholangiography with direct gallbladder injection was more successful in acute cholecystitis patients who underwent early or interval LC after the preliminary positioning of a PTGBD. Among all cases reported in the literature, only one patient required conversion to open cholecystectomy due to acute necrotic cholecystitis, which precluded safe laparoscopic dissection.

Intracholecystic ICG injection provides relevant advantages compared to intravenous NIR cholecystocholangiography, such as the real-time visualization of the biliary anatomy, including the gallbladder neck and Hartmann's pouch, which are safe landmarks to start the dissection. Additionally, the timing of ICG injection is irrelevant, and small dosages can be used.

Table 1 Cholecysto-cholangiography with direct intra-gallbladder indocyanine green injection

Ref.	Type of publication	No. of patients	No. of patients with gallbladder lithiasis	No. of patients with acute cholecystitis	Technique	Complication	Conversion to open surgery
Jao *et al* [26], 2020	Case series	2	0	2	2 trans-PTGBD cases	Lymphatic spillage	0
Nitta *et al* [24], 2020	Case report	1	0	1	1 case through DGBP	-	0
Škrabecet al [23], 2020	Case-controlled study	20	19	1	20 cases through DGBP	ICG bile leakage in 1 case; No progression of dye into the CD in 3 cases	1
Liu *et al* [22], 2017	Cohort study	46	21	25	18 trans-PTGBD cases; 28 cases through DGBP	ICG leakage in 5 cases	0
Graves *et al* [25], 2017	Cohort study	11	9	2	11 cases through DGBP	No progression of dye into the CD in 1 case	0

PTGBD: Percutaneous transhepatic gallbladder drainage; DGBP: Direct gallbladder puncture; ICG: Indocyanine green; CD: Cystic duct.

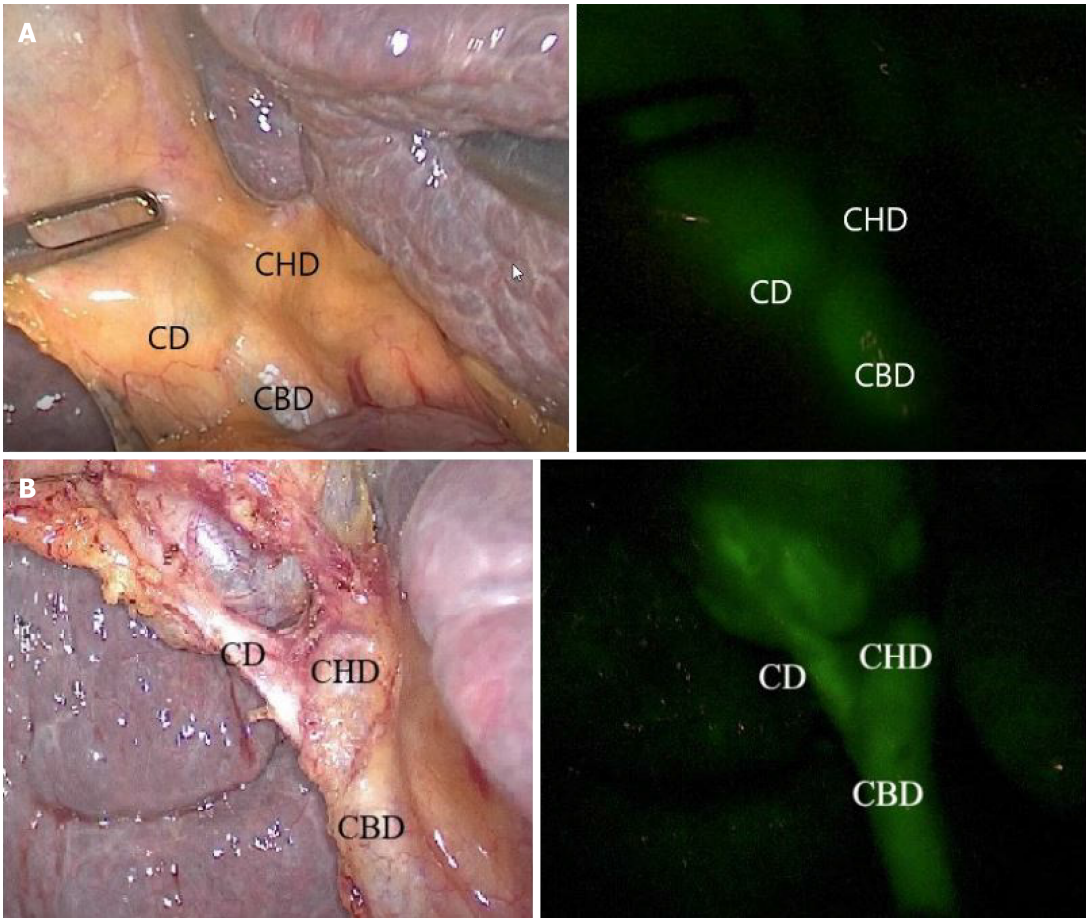

Figure 1 Intra-operative real-time identification of biliary structures in a cirrhotic patient, with visible light to the left and NIRF-C to the right. A: Pre-dissection visualization of biliary anatomy; B: After complete dissection. One can observe the posterior implantation of the cystic duct on the common hepatic duct. CD: Cystic duct; CHD: Common hepatic duct; CBD: Common bile duct.

The downside of direct ICG injection lies in the possibility of ICG bile leakage or lymph spillage during gallbladder dissection for acute cholecystitis, as ICG may enter through the necrotic gallbladder mucosa into the submucosal lymphatic drainage. In regard to the widest experiences reported in the literature[22,23], ICG bile leakage occurred in six patients in whom ICG was directly injected through a fine-needle puncture. Another limitation lies in the absence of progression of the dye into the CD

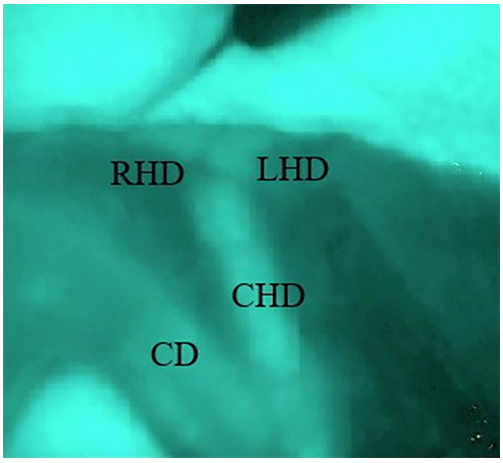

Figure 2 Classical extrahepatic biliary anatomy with identification of the right and left hepatic ducts using near-infrared fluorescent cholangiography. CD: Cystic duct; CHD: Common hepatic duct; RHD: Right hepatic duct; LHD: Left hepatic duct.

in cases of stone obstruction.

Based on the available data, we suggest that larger studies are necessary to validate the technique of intracholecystic ICG injection for NIR fluorescent cholangiography.

ICG FLUORESCENT CHOLANGIOGRAPHY IN PATIENTS WITH ACUTE CHOLECYSTITIS

Early LC is the gold standard treatment for patients with mild (grade I) and moderate (grade II) acute cholecystitis who have no response to initial (within 24 h) conservative treatment if performed within 72 h from the onset of symptoms according to 2018 Tokyo guidelines[27].

Fluorescent cholangiography may be very challenging in an emergency setting, when inflammation and adhesions at the hepatoduodenal ligament may impair the identification of biliary elements during dissection. Reaching the CVS may be particularly difficult in such situations[28].

In a recent meta-analysis, Dip F *et al*[29] suggested that using NIRF-C during elective cholecystectomy led to decreased BDI and conversion to open surgery compared to white light alone. However, there are limited data about its feasibility in an emergency setting. The identification of biliary structures may be challenging, especially in cases where there is an abundance of adhesions and severe inflammation of the gallbladder wall and surrounding tissues[9].

The literature contains four articles that provide data of patients who underwent LC for acute cholecystitis with NIR devices, *i.e.*, two cohort studies[30,31], one international European registry[17], and one randomized controlled trial (RCT)[32] are reported in Table 2.

In a large retrospective study involving 184 consecutive patients, Daskalaki E *et al*[31] reported the results of 24 patients who underwent robotic cholecystectomies (RCs) with ICG fluorescence for acute and gangrenous cholecystitis. The authors evaluated the detection rate of four biliary structures, *i.e.*, CD, CHD, CBD, and CD-CHD junction. In this subset of challenging surgical cases, the CD, CHD, CBD, and CD-CHD junction were successfully visualized in 91.6%, 79.1%, 79.1%, and 75% of cases, respectively.

Agnus V *et al*[17] reported data from the Euro-FIGS database, which enrolled 314 cases from 12 European surgical centers, including patients affected by symptomatic cholelithiasis (n = 248) and patients with acute cholecystitis (n = 58). A 5-point Likert scale was used to evaluate the quality of biliary anatomy visualization before and after the dissection of the hepatocystic triangle during LC with NIR devices. When the two groups (cholelithiasis *vs* acute cholecystitis) were compared, lower visualization quality scores were obtained in the CD group (2.76 ± 1.9 *vs* 3.54 ± 1.6, P = 0.001) and CD-CHD junction (2.43 ± 2 *vs* 3 ± 1.9, P = 0.04) before the preliminary dissection. The impact of variable inflammation on the visualization score of the biliary tree was also confirmed by means of multivariate linear regression analysis.

Table 2 Fluorescent cholangiography in patients with acute cholecystitis

Yoshiya *et al*[33], 2019	Retrospective cohort study	LC after-PTGBD	130

FIGS: Fluorescence image-guided surgery; RCT: Randomized controlled trial; LC: Laparoscopic cholecystectomy; RC: Robotic cholecystectomy; PTGBD: Percutaneous transhepatic gallbladder drainage.

Similar data have been reported in a single-blinded randomized controlled trial[32] comparing the efficacy of NIR fluorescent cholangiography *vs* white light alone. The primary objective was the structure detection rate, defined as the total number of patients in whom a particular biliary structure was detected, both before and after dissection, in each study arm, divided by the total number of patients in each arm. The authors found that the degree of gallbladder inflammation was the most important variable, affecting the detection of CD and CBD before and after dissection, respectively, and of the CD-gallbladder junction only after dissection.

The usefulness of NIRF-C was also confirmed by Yoshiya S *et al*[33] during LC after PTGBD in patients with severe acute cholecystitis. The ICG fluorescence cholangiography group showed a significantly shorter operative time, a lower conversion rate, and a lower proportion of subtotal cholecystectomies[33].

NIR fluorescence cholangiography in emergency cholecystectomies is a safe and useful tool to prevent BDI during LC. However, the available data require further elaboration in randomized controlled studies in larger numbers of patients with acute cholecystitis undergoing LC with the aid of intra-operative fluorescent cholangiography.

DETECTION OF BILIARY VARIANTS USING ICG FLUORESCENCE

Various reports have underlined the importance of fluorescence image-guided cholecystectomy in detecting biliary variants. Fluorescent cholangiography allows the intraoperative identification of subvesical Luschka's ducts[34,35], aberrant bile ducts [36-38], anatomical CD variations[39], and gallbladder aberrations[40,41].

In specific studies, the diagnostic accuracy of NIRF-C in the evaluation of CD anatomy has been compared to that of magnetic resonance cholangiopancreatography (MRCP), which is the gold standard radiology diagnostic tool for the preoperative study of the biliary tree[42,43]. Pesce A *et al*[44] evaluated the ability of the two imaging methods to identify three selected features, namely, the insertion of CD, CD-CHD junction, and CD course. The level of insertion, course, and wall implantation of the CD were achieved by means of NIRF-C with diagnostic accuracy values of 65.2%, 78.3%, and 91.3%, respectively, in comparison with MRCP data.

In 2017, Diana M *et al*[45] prospectively evaluated the combination of three imaging modalities during robotic cholecystectomy, *i.e.*, virtual reality 3D modeling of MRCP, NIRF-C, and intraoperative cholangiogram (IOC). Surprisingly, expert hepatobiliary radiologists missed 5 out of 8 anatomical variants on preoperative MRCP, while surgeons were able to identify all variants through a virtual surgical exploration complemented with intraoperative fluorescent cholangiography.

In another observational study in 65 patients by Hiwatashi K *et al*[46], the authors found a statistically significant correlation between the delineation of CD using ICG cholangiography and preoperative MRCP.

Based on the current scientific literature (RCTs shown in Table 3), we strongly believe that NIRF-C is a useful tool to detect biliary variants that could guide surgeons during dissection to prevent any major bile duct lesions.

FLUORESCENT CHOLANGIOGRAPHY *VS* STANDARD INTRAOPERATIVE CHOLANGIOGRAPHY

NIRF-C has been recognized as providing some advantages over conventional radiographic IOC, such as feasibility and safety, real-time visualization of biliary anatomy with safer dissection of the hepatocystic triangle, the lack of a learning curve, reduced X-ray exposure, and reduced costs and operative times[5,47-49]. In a Danish randomized controlled single-blind clinical trial[50], the authors compared NIRF-C *vs* IOC. They demonstrated that fluorescent cholangiography has the same capacity to identify the CVS, and is significantly faster and easier to perform than X-ray cholangiography[50]. In a recent meta-analysis by Lim SH *et al*[51], the authors concluded that there was no difference in the visualization of the CD, CBD, and CD-CBD junction using ICG fluorescence cholangiography compared to IOC. However, the ICG group reported increased rates of CHD visualization.

Dip F *et al*[52] analyzed medical costs and stated that the median cost of ICG fluorescence cholangiography was cheaper than that of IOC (13.97 ± 4.3 *vs* 778.43 ± 0.4 USD per patient, $P = 0.0001$).

Quaresima S *et al*[53] proposed that NIRF-C is a safe and effective procedure for the early recognition of anatomical biliary landmarks, with an important reduction in operative times compared to LC with intraoperative cholangiography.

In an article by Prevot F *et al*[54], the authors analyzed the ability to identify the CD, the CD-hepatic duct junction, and the CBD using fluorescence in comparison with standard IOC. The results of this study suggested that ICG fluorescence cholangiography is more effective than IOC in identifying the biliary tract after dissection.

In conclusion, we believe that there is considerable scientific evidence supporting the usefulness of NIRF-C with important advantages over conventional intraoperative cholangiography. NIRF-C represents a powerful real-time diagnostic tool for the detection of extrahepatic biliary anatomy during LC. Advantages and current limitations are summarized in Table 4.

FLUORESCENT CHOLANGIOGRAPHY IN OBESE PATIENTS

As reported in previous studies[9,31,55-57], the presence of dense adipose tissue surrounding the hepatocystic triangle may negatively affect the visualization of extrahepatic biliary tract using fluorescence. Obesity may represent a limitation of NIRF-C because NIR light has a penetration capability of only 5 to 10 mm[7-9]. In 2016, Dip F *et al*[58] conducted a prospective study to evaluate the accuracy of NIRF-C in obese *vs* non-obese patients. The results showed no difference in hepatic duct, CBD, or accessory duct detection rates between the two groups ($P = 0.09$, 0.16, and 0.66,

Table 4 Advantages and current limitations of fluorescent cholangiography in comparison to intraoperative cholangiogram and laparoscopic ultrasonography

Advantages	Limitations
Real-time visualization of biliary anatomy in elective and emergent settings	Limited in patients with specific conditions, such as overweight and obesity; it needs a preliminary dissection and exposure of the hepatocystic triangle
Safer dissection of the hepatocystic triangle	Limited scientific evidence in the setting of acute cholecystitis
Detection of biliary variants and biliary leaks	High variability about indocyanine green dose and dosing time
Implementing method in combination with adequate dissection and identification technique to achieve critical view of safety	Detection of bile duct stones
Feasibility and safety	Need for consensus conference and international guidelines
Reduced medical costs	
Time/faster	
Lack of X-ray exposure	
Simplicity and lack of learning curve	
Teaching tool for young surgeons	
Possibility to associate fluorescent angiography	
Strong potential to become a gold standard during all cholecystectomies	

respectively) before and after dissection of the hepatocystic triangle.

On the other hand, a German study[59] suggested that a BMI > 25 kg/m² and male sex significantly reduced the identification rate of CD before dissection of the hepatocystic triangle.

In a randomized controlled multicenter trial[32] comparing ICG *vs* white light alone, an increased BMI was associated with a reduced detection of most biliary structures in both groups, especially before dissection.

In general, our opinion is to use fluorescence to perform a complete dissection of the hepatocystic triangle in overweight and obese patients to obtain a good quality visualization of the biliary anatomy. In difficult cases where the surgeon is not able to clearly check the biliary anatomy, the surgeon should respect a sufficient thickness between the dissecting site and the main bile duct by working close to the gallbladder infundibulum to avoid unexpected biliary lesions. NIR imaging cannot be considered a substitute for good dissection and structure identification.

FLUORESCENT INCISIONLESS CHOLANGIOGRAPHY AS A TEACHING TOOL FOR YOUNG SURGEONS

It is well established that the risk of BDI correlates with the quality of the procedure performed, rather than the number of cases seen by the surgeon[1,2]. A clear identification of the biliary anatomy is crucial to perform a safe cholecystectomy and achieving CVS is now being taught as a key step of the operation to young surgeons[4,13]. In a recent randomized controlled trial[60], the time to achieve CVS from the gallbladder fundus retraction was measured by analyzing different levels of difficulty. The mean time, expressed in minutes, to achieve CVS was 22.3 ± 12.9 in the ICG-LC group (n = 30) and 22.8 ± 14.3 in the conventional LC group (P = 0.867). The authors concluded that fluorescent cholangiography may be a useful tool in difficult LC and in surgical training. A randomized controlled multicenter Dutch trial (FALCON trial) regarding the time to visualize CVS with NIRF-C compared to white light alone is still ongoing[61]. However, biliary structures are not always easily visualized laparoscopically. Fluorescence incisionless cholangiography may be a promising tool for training new surgeons in safe laparoscopic cholecystectomies by helping with biliary anatomy identification. To date, few studies have been conducted regarding the potential role of this technique in surgical training programs[62-64].

In 2016, Roy M *et al*[62] tested the ability of surgical students and residents to identify major biliary structures at NIR light. Participants were shown pictures taken at the same stage of hepatocystic triangle dissection in 10 cases of LC, first with NIR

light and then with Xenon white light. Both students and residents had a higher success rate of biliary tree identification with NIR fluorescence cholangiography. The authors also underlined the importance of NIRF-C to achieve appropriate intraoperative communication to guide residents, as it allows us to point out glowing structures in real time.

Similarly, in 2020, Rungsakulkij N *et al*[63] conducted a study to investigate the beneficial impact of fluorescence cholangiography on the ability of surgical residents to identify biliary structures. Participants were asked to identify the CD and artery, CBD and CHD in five LC videos, first without fluorescence, and then with NIRF-C. The results showed a higher misidentification rate among surgical residents in the without-FC modality than in the with-FC modality, proving the benefit of the technique among trainees.

In a study by Pesce A *et al*[47] on the usefulness of fluorescent cholangiography for biliary anatomy identification, surgical residents completed a survey on the perceived benefits of the technique. Responses were measured with a Likert scale. All participants agreed that NIRF-C facilitates the dissection of the hepatocystic triangle, hence being a useful adjuvant to training programs; 92% of respondents found the method easy to perform; 88% declared that it was effective in visualizing the biliary tree, and 84% found that the image quality was good. Consequently, residents consider the novel method a useful tool to visualize biliary anatomy and perform a safe dissection of the hepatocystic triangle, decreasing the risk of BDI.

From these experiences, it is safe to conclude that there is a large consensus regarding the beneficial role of NIRF-C in the training process of young surgeons. However, larger studies proving the benefits on the skills of surgical residents are required for the technique to be routinely performed in a teaching setting.

FLUORESCENT CHOLANGIOGRAPHY AND DETECTION OF BILIARY STONES

To date, there is no evidence that FC can effectively identify CBD stones by replacing IOC[64,65]. Intraoperative laparoscopic ultrasound (IOUS) could well represent a valid alternative to IOC in the detection of CBD stones[66,67]. Current limitations are related to the difficult learning curve and the lack of randomized controlled trials[66]. According to Daskalaki M *et al*[27], ICG fluorescence cholangiography can help to detect CD dilation and gallbladder stones (as shown in Figure 3), but it cannot rule out the presence of CBD stones. In a recent correspondence by Labil PL and Aroori S published in *Br J Surg*[65], the authors suggested performing an RCT comparing IOUS with X-ray and/or fluorescence cholangiography in LCto detect a difference in the rate of bile duct stone identification, as well as viewing the critical junction.

NIRF-C AND ROBOTIC CHOLECYSTECTOMY

Since the introduction of the robotic surgical platform in the 2000s, approximately 10% of all cholecystectomies are performed robotically[68] today. ICG technology was soon incorporated into the robotic platform, and the first case series involved patients who underwent single-incision or multiport robotic cholecystectomy (RC) with NIRF-C, as summarized in Table 5.

In a large retrospective cohort study including 184 patients, Daskalaki D *et al*[31] proved the feasibility of this technique. The four main biliary structures (CD, CHD, CD-CHD junction, CBD) were recognized using fluorescence imaging in 83% of cases. At least one structure was visualized in 99% of cases. Similar data have been reported by other authors[55,69-71].

Spinoglio G *et al*[70] showed that after dissection of the hepatocystic triangle, the visualization rates for each structure (CD, CHD, CD-CHD junction, CBD) increased to 97%. In addition, the rate of patients with two or three ducts visualized with NIR fluorescent cholangiography increased from 91% to 97% and from 86% to 95% before and after dissection, respectively.

In recent years, some authors compared data of patients who underwent robotic cholecystectomy with the use of ICG *vs* conventional LC[72,73]. In a retrospective cohort study, Sharma S *et al*[72] analyzed 287 consecutive cases, including 96 RCs and 191 LCs. The authors found a lower open conversion rate in the robotic cohort (2.1% *vs* 8.9% in LC), although this difference was not statistically significant.

Table 5 Studies reporting robotic cholecystectomy and near-infrared fluorescent cholangiography

Ref.	Type of publication	No. of patients	Technique	Incidence of conversion rate to open surgery (%)
Sharma *et al*[72], 2017	Retrospective cohort study	96	RC	2.1
Gangemi *et al*[73], 2017	Retrospective cohort study	676	RC	0.15
Maker *et al*[71], 2017	Cohort study	35	RC	NR
Daskalaki *et al*[31], 2014	Retrospective cohort study	184	RC	0.00
Spinoglio *et al*[70], 2013	Cohort study	45	SIRC	0.00
Buchs *et al*[55], 2013	Cohort study	23	SIRC	0.00
Buchs *et al*[69], 2012	Prospective cohort study	12	SIRC	0.00

RC: Robotic cholecystectomy; SIRC: Single-incision robotic cholecystectomy; NR: Not reported.

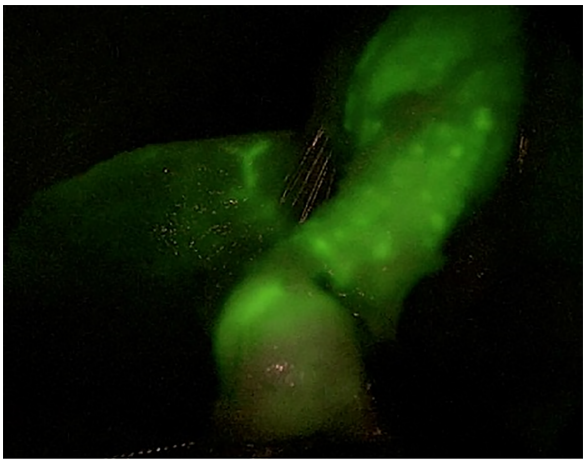

Figure 3 Identification of cystic duct stones by means of fluorescence.

Gangemi A *et al*[73] conducted a case-control study comparing the outcomes of ICG-aided RC *vs* LC at the University of Illinois (Chicago, United States). The authors reported a statistically significant difference between RC performed with the help of ICG and traditional LC in terms of the overall open conversion rate (0.15% *vs* 4.5%), open conversion rate in the acute setting (0.76% *vs* 9.57%), mean blood loss during surgery (14.37 mL *vs* 21.08 mL), and minor biliary injury rate (0.15% *vs* 1.04%). Additionally, a biliary tree anomaly was found in 2.07% of patients who underwent ICG-aided RC compared to 0.69% of patients who underwent LC with conventional intraoperative cholangiography.

Recently, Dip *et al*[29] conducted a meta-analysis evaluating whether NIFC with ICG could reduce conversion to open surgery and bile duct injuries during laparoscopic and robotic cholecystectomy. Patients who underwent ICG-aided RC showed a marked reduction in the rate of conversion to open surgery compared to RC without NIFC (weighted rate: 12/10.000 *vs* 322/10.000). Similar data were reported in the ICG-aided LC group (weighted rate: 23/10.000 *vs* 255/10.000). For BDI, a reduction was reported in the ICG-aided LC group compared to LC without NIFC (weighted rate: 23/10.000 *vs* 255/10.000), while no difference was noted regarding RC with and without NIFC. In conclusion, we believe that the use of NIRF-C may reduce the conversion rate in both minimally invasive procedures, laparoscopic and robotic cholecystectomy, while the reduction rate only exists in LC for BDI. However, further studies are required.

CONSENSUS CONFERENCES AND GUIDELINES

During the 4th International Congress of Fluorescence-Guided Surgery in Boca Raton, Florida in 2017, Dip F *et al*[74] conducted a pilot survey of 51 attending surgeons who

routinely performed laparoscopic cholecystectomies to identify their surgical practice and perceptions of intraoperative fluorescent cholangiography. Ten experts in ICG fluorescence-guided LC from North and South America, Europe, and Asia designed the survey for conference attendees. Seventy-eight percent of respondents underlined the importance for surgeons of having a noninvasive, simple, and reproducible diagnostic tool to identify the extrahepatic biliary anatomy in real time. In general, they recommended the routine use of NIRF-C during LC as a complimentary imaging technique, and 93.3% of them felt that the procedure would be useful in surgical training programs.

In a recent state-of-the-art consensus conference on the prevention of BDI during cholecystectomy published in *Annals of Surgery*[75], a pool of experts from five surgical societies (Society of Gastrointestinal and Endoscopic Surgeons, Americas Hepato-Pancreato-Biliary Association, International Hepato-Pancreato-Biliary Association, Society for Surgery of the Alimentary Tract, and European Association for Endoscopic Surgery) analyzed the scientific evidence among surgical practices to prevent bile duct injuries. At question 5B, *i.e.*, "Should intraoperative NIR biliary imaging with white light versus white light biliary imaging alone be used to limit the risk or severity of BDI during LC?", they answered the following question: We suggest that the use of NIR imaging may be considered an adjunct to white light alone to identify the biliary anatomy during cholecystectomy (conditional recommendation, very low certainty of evidence).

However, in a Delphi survey of 19 international experts in fluorescence-guided surgery attending a 1 d consensus meeting in Frankfurt, Germany in September 2019, fluorescence imaging was almost unanimously perceived to be both effective and safe across a broad range of clinical settings[76]. No specific recommendations were given for fluorescent cholangiography. Moreover, the safety of ICG dye has been underlined: the risk of adverse reactions to ICG injection, such as anaphylactic shock, is very small (approximately 0.003% at doses exceeding 0.5 mg/kg) according to the literature data [9,77].

CONCLUSION

The results of the current up-to-date overview confirmed the efficacy of ICG-fluorescence cholangiography in detecting biliary anatomy, its importance as a teaching tool for young surgeons, and the effects on the reduction of conversion rate and BDI, even if further considerable research remains necessary to optimize its use. This frontier method has enormous potential to become the gold standard during all cholecystectomies in elective and emergency settings due to its safety and limited costs. However, clear clinical guidelines are necessary for the surgical community.

Abstract

Pancreatic cancer (PC) is an aggressive human cancer. Appropriate methods for the diagnosis and treatment of PC have not been found at the genetic level, thus making epigenetics a promising research path in studies of PC. Histone methylation is one of the most complicated types of epigenetic modifications and has proved crucial in the development of PC. Histone methylation is a reversible process regulated by readers, writers, and erasers. Some writers and erasers can be recognized as potential biomarkers and candidate therapeutic targets in PC because of their unusual expression in PC cells compared with normal pancreatic cells. Based on the impact that writers have on the development of PC, some inhibitors of writers have been developed. However, few inhibitors of erasers have been developed and put to clinical use. Meanwhile, there is not enough research on the reader domains. Therefore, the study of erasers and readers is still a promising area. This review focuses on the regulatory mechanism of histone methylation, and the diagnosis and chemotherapy of PC based on it. The future of epigenetic modification in PC research is also discussed.

Key Words: Pancreatic cancer; Epigenetics; Histone modification; Methylation; Demethylation; Clinical application

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Pancreatic cancer is a highly lethal malignancy of the digestive tract that is difficult to diagnose and treat. Histone methylation/demethylation equilibrium is altered in carcinogenesis, resulting in changes in chromatin structure and gene expression. Not only are histone methylation writers related to histone methylation

Specialty type: Gastroenterology and hepatology

Country/Territory of origin: China

INTRODUCTION

Pancreatic cancer (PC) is a malignant tumor. The lack of adequate diagnostics for PC limits the efficacy of the few currently available treatment options. Current diagnostic methods include clinical biomarkers, imaging, biopsy, *etc.* To date, carcinoembryonic antigen 19 (CA-19) is the only PC clinical biomarker approved by the U.S. Food and Drug Administration[1], but the use of CA-19 is limited by its inadequate sensitivity and specificity[2,3]. Percutaneous biopsy can result in micrometastases in younger patients who receive surgery, so it is only appropriate for inoperable patients[4]. Current diagnostic methods are either inaccurate or limited. Conventional treatment methods for PC mainly include surgery, adjuvant chemotherapy, drug therapy, and radiation therapy[5]. Surgery remains the most important treatment, followed by adjuvant chemotherapy[5]. At present, only 15% to 20% patients can be surgically treated after diagnosis, and only 20% of the patients survive 5 years after receiving surgery[6,7]. Regarding chemotherapy, gemcitabine and other drugs have proved effective for advanced and metastatic PC, but the development of drug resistance has limited the effectiveness[8]. The survival rate of PC patients has not changed much in the past 40 years[8]. The robust molecular biomarkers need to be developed for diagnosis and targeted therapies.

Cancer development is a complex process involving both genetic and epigenetic changes. Genome instability, regulated by both genetic mutations and epigenetic modifications, contributes to tumor progression[9]. The concept of epigenetics itself is evolving with the increase of our knowledge of the molecular mechanism and regulation of gene expression. It is currently widely acknowledged that epigenetics is the study of alternations in gene expression patterns without changes in DNA sequences[10]. Epigenetic modifications include DNA methylation, histone modification and non-coding RNAs. Epigenetic modifications present a new direction for cancer prevention, clinical diagnosis, and drug development.

Histone modification is one of the most important and complicated epigenetic regulatory mechanisms and is crucial in PC. Histone modification affects chromatin structure, transcription, and DNA repair process[11]. Histone modification takes part in the regulation of chromatin architecture and specific loci regulation by recruiting cell-specific transcription factors and interacting with initiation and elongation factors [12]. Histone modification also regulates the transcription process by influencing RNA processing[12]. In terms of regulating chromatin structure, histone modification affects the higher-order chromatin structure by changing the interactions of histones with DNA, and/or by recruiting chromatin remodeling complexes indirectly[13-15].

Histone modifications include histone acetylation, methylation, phosphorylation, and ubiquitination. Histone methylation plays crucial roles in the development of PC. Therefore, this review focuses on histone methylation and its clinical applications.

HISTONE METHYLATION

Post-translational methylation in histone tails is a reversible dynamic chromatin modification. Methyl is dynamically added by methyltransferases-writers, removed by demethylase-erasers, and interpreted by effector proteins-readers[16]. Readers recognize specific sites and promote the recruitment of transcription factors or chromatin-associated protein complexes and bind to histones to enable the localization of enzymes to specific targets[17].

Histone methylation takes place on the residues of arginine, lysine, and histidine. According to the amino acid residues modified, there are arginine residue methyltransferases and lysine residue methyltransferases[18]. Histone arginine methylation is a universal post-translational modification, and aberrant histone arginine methylation is strongly associated with carcinogenesis and metastasis[19]. Arginine residues may be differentially methylated by different types of protein arginine N-methyltransferases (PRMTs)[19].

The maintenance of the balance between histone methylation and demethylation is fundamental to normal cellular development and function[20,21]. The break of the balance between histone methylation and demethylation results in oncogenesis and progression[21,22]. Corresponding to writers, erasers can be divided into arginine residue demethylases and lysine residue demethylases. However, current research on histone arginine residue demethylases is limited, so we only discuss lysine residue demethylases. Based on their mechanism of action, lysine demethylases (KDMs) are classified into two families: Flavin adenine dinucleotide (FAD)-dependent and Fe(II) and 2-oxoglutarate (2OG)-dependent[23-25].

The appropriate localization of histone methyltransferase and histone demethylase is dependent on the readers that can recognize histone modifications[26]. The reader can either be an independent polypeptide or a part of methyltransferase/demethylase [27-31]. Some reader domains such as chromodomain[32,33], Tudor domain[34], tryptophan-aspartic acid 40 (WD40) domain[35,36] and plant homeodomain (PHD) finger[37,38] are well known. These reader domains all have their own specific structure[32-38].

HISTONE METHYLATION WRITERS IN PC

Among histone methylation, arginine and lysine methylation are the most widely studied in PC[39]. Histone methylation is performed mainly by two types of writers: PRMTs and lysine methyltransferases (KMTs) (Table 1), with S-adenosyl-L-methionine (SAM) as the methyl donor[40].

PRMTs

PRMTs catalyze the transfer of a methyl group from SAM to a guanidino-nitrogen atom[41]. Three types of methylated arginine residues are found in mammalian cells: Asymmetric dimethyl-arginine (ADMA), symmetric dimethyl-arginine (SDMA) and monomethyl-arginine (MMA)[41]. Depending on their catalytic activity, PRMTs can be classified in three types[42]. Type I PRMTs are responsible for producing ADMA, whose methyl groups are linked to the same guanidino nitrogen atom. Type II PRMTs add the methyl groups on each of the guanidino nitrogen atom of arginine symmetrically, producing SDMA[42]. PRMT7 is the sole member of type III, exclusively catalyzing the formation of MMA[43]. PRMT1 and PRMT5 function in PC[44,45]. PRMT1 belongs to type I and PRMT5 belongs to type II[42].

PRMT1: PRMT1 is the founding member of the PRMT family, and PRMT1 can methylate histone H4 at arginine 3. This modification is associated with transcriptional activation[44]. Upregulation of PRMT1 is found in various cancer types[46-49]. PRMT1 is highly expressed in pancreatic ductal adenocarcinoma (PDAC) cells, and elevated PRMT1 levels predict a poor clinical outcome[44]. PRMT1 promotes PC cell growth *in vitro* and *in vivo*[44]. PRMT1 increases the β-catenin protein level in PC cells[44]. Overactivation of β-catenin signaling promotes the growth, migration, and metastasis of PC cells[50-52]. PRMT1 downregulation inhibits PC cell proliferation and invasion [53]. GLI family zinc finger 1 (Gli1) is a substrate of PRMT1 in PDAC. Methylation of Gli1 at R597 by PRMT1 promotes its transcriptional activity by enhancing the binding of Gli1 to the promoters of its target gene[54]. Interruption of Gli1 methylation attenuates oncogenic functions of Gli1 and sensitizes PDAC cells to gemcitabine treatment[54].

PRMT5: PRMT5 is a type II writer, responsible for symmetric demethylation[19,55]. PRMT5 regulates the expression of a wide spectrum of target genes by modifying the chromatin structure or transcriptional machinery[56]. Specifically, PRMT5 can catalyze the methylation of arginine 8 on histone H3 and arginine 3 on histone H4 (H4R3)[57]. High expression of PRMT5 has been observed in various cancers. PRMT5 expression improves cancer cell survival, proliferation, migration and metabolism while inhibiting cancer cell apoptosis[55]. PRMT5 expression is significantly upregulated in PC tissues[56]. PRMT5 promotes tumorigenesis and PC cell proliferation[45]. PRMT5

Table 1 Histone methyltransferases play a major role in pancreatic cancer

Family	Subfamily	Alias	Site	Function in pancreatic cancer
PRMTs	PRMT1	HRMT1L2, HMT2, ANM1	H4R3me2a	Increase the β-catenin protein level; Methylate Gli1 at R597[44,54]
	PRMT5	HRMT1L5, SKB1, HSL7	H3R2me2s	Silence the expression of the tumor suppressor FBW7; Promote EMT *via* activating EGFR/ AKT/β-catenin signaling[45,56,188,189]
KMTs	SMYD3	ZNFN3A1, ZMYND1	H4K5me3	Affect the PC progression by regulating MMP-2; Potentiate Ras signaling through methylation of MAP3K2[62,64]
	EZH2	KMT6, WVS, ENX-1	H3K27me3	Suppress miR-139-5p expression by upregulating H3K27me3; Repress the E-cadherin by tri-methylation of H3K27[78,190]

All current research on reprogramming histone methyltransferases that play a role in pancreatic cancer. EMT: Epithelial-mesenchymal transition; FBW7: F-Box and WD repeat domain containing 7; KMTs: Histone lysine methyltransferases; PC: Pancreatic cancer; PRMTs: Protein arginine N-methyltransferases.

promotes cell migration, invasion, and the epithelial-mesenchymal transition (EMT) *via* activating EGFR/AKT/β-catenin signaling in PC cells[45]. PRMT5 knockdown reduces glucose intake and lactate levels in PC cells[56]. PRMT5 can inhibit the expression of F-Box and WD repeat domain containing 7 (FBW7)[58,59]. PRMT5 inhibits FBW7 *via* suppression of *FBW7* gene promoter activity and elevation of cMyc stability, leading to tumorigenicity and aerobic glycolysis in PC cells[56]. PRMT5 induces the phosphorylation of epidermal growth factor receptor (EGFR) at Y1068 and Y1172[45]. Then PRMT5 activates phosphorylation of AKT and its downstream GSK3β [45].

KMTs

KMTs transfer one, two, or three methyl-groups to histone lysine residues[60]. KMTs are categorized into two protein families based on catalytic domain sequence similarity and structural organization[61]. Two major writers, SMYD3 (KMT3E) and EZH2 (KMT6), are related to PC[62,63]. SMYD3 is a member of SET and MYND-domain family[64]. EZH2 belongs to the polycomb family[61].

SMYD3: SMYD3 belongs to the SET and MYND-domain family. SMYD3 can promote the proliferation, migration, and invasion of many types of cancer[64]. SMYD3 is a protooncogene in liver, colon and breast tissue based on its high level of endogenous expression and cancer-related promoter polymorphism[65-70]. SMYD3 is upregulated in PC. SMYD3 is positively associated with caspase-3 and MMP-2 expression in PC tissues[62]. Active Src phosphorylates p300 in the nucleus, and then the complex binds to HMGA2 and SMYD3 genes. Therefore, HMGA2 and SMYD3 are regulated to promote PC cell migration and invasion[71].

EZH2: EZH2 is the enzymatic subunit of polycomb repressive complex 2 (PRC2), a complex that methylates lysine 27 of histone H3(H3K27) to promote transcriptional silencing[72]. High expression of EZH2 protein has been associated with several cancers[73-75]. EZH2 is overexpressed in PC[76]. FBW7 interacts with EZH2 and downregulates EZH2 *via* ubiquitination and degradation in PC cells[76]. Downregulation of FBW7 induces high EZH2 protein expression and promotes tumor progression in PC[76]. Long non-coding RNA (lncRNA) *BLACAT1* facilitates proliferation, migration, and aerobic glycolysis of PC cells by repressing *CDKN1C via* EZH2-induced histone H3 lysine 27 trimethylation (H3K27me3)[77]. EZH2 regulates the expression of miR-139-5p *via* H3K27me3, and the EZH2/miR-139-5p axis participates in the progression of PC, whereby downregulation of EZH2 and upregulation of miR-139-5p repress the EMT and lymph node metastasis of PC[78]. EZH2 can bind to the promoters of P15 and KLF2 to induce H3K27me3[79]. LncRNA *SNHG15* knockdown inhibits PC cell proliferation and tumorigenesis while inducing cell apoptosis, and the *SNHG15*-mediated oncogenic effect is partly by repressing P15 and KLF2 expression *via* EZH2-induced H3K27me3[79].

HISTONE METHYLATION ERASERS IN PC

The demethylation of arginine and lysine in histone tails is the two main forms of histone demethylation. Due to the large gaps in research on arginine demethylation, the main situation of KDMs in PC will be mainly described. KDMs can catalyze monomethyl, dimethyl or trimethyl labeling of histone lysine residues[12]. There is some evidence that occurrence, development, and therapy of PC are all related to KDMs[80,81] (Table 2).

KDM1

Flavin-dependent KDMs are a subfamily of amine oxidases that catalyze the selective posttranslational oxidative demethylation of methyl lysine side chains within substrates[82]. Two subtypes of KDMs, KDM1A and KDM1B, are related to PC[83,84]. They are expressed at high levels in PC tissues. To date, the expression patterns and physiological functions of KDM1A/LSD1 in PC have not been fully elucidated. KDM1A and hypoxia inducible factor-1α (HIF1α) are the interaction partners of the homeobox protein PROX1[85,86]. KDM1A acts synergistically with HIF1α in maintaining glycolysis[87]. Compared with KDM1A, KDM1B/LSD2 lacks a "tower domain" and has a zinc finger domain in the N-terminal region, which makes KDM1B endowed with different biochemical properties[24,25,88]. KDM1B is related to many important biological functions, including transcriptional regulation, genome imprinting, somatic cell reprogramming, DNA methylation, and signal transduction [89-92]. The downregulation of KDM1B can inhibit PC cell proliferation and promote PC cell apoptosis *in vitro*[93,94].

JmjC domain-containing protein family

JmjC domain-containing (JMJD) protein family is a type of Fe (II) and α-ketoglutarate-dependent dioxygenases. The JMJD protein family now consists of 33 members. There are 18 members with the ability to demethylate H3K4, H3K9, H3K27, H3K36, and H4K20[23,95-108].

KDM2B: KDM2B acts on H3K36 demethylation. KDM2B enhances the bypass of primary cell senescence by directly binding to tumor suppressor gene *CDKN2A* sites and demethylating histones, thereby guiding the recruitment of PRC2; thus, it plays an important role in cell cycle progression and senescence[109,110]. KDM2B regulates cell proliferation, migration, and angiogenesis[111-113]. KDM2B plays a crucial role in poorly differentiated PDAC, and there is an interaction between EZH2 and KDM2B [114].

KDM3A: KDM3A/JMJD1A, one member of the JMJD1 family, participates in transcriptional regulation by demethylating monomethyl or dimethyl H3K9[115,116]. Since cells are heterogeneous in early PDAC tissues, new progress has been made in the study of PDAC morphology, which is specifically manifested by the upregulation of *DCLK1* expression[117]. KDM3A plays a key role in the upregulation of *DCLK1* expression, and KDM3A expression inhibitors can inhibit the malignant properties of PDAC[118].

KDM4: The KDM4 subfamily consists of 12 demethylases including KDM4A, B, C, and D, which can catalyze the removal of inhibitory trimethyl marker of H3K9 and H3K36 related to transcription[98,119]. KDM4A, B, and D play a role in PC mainly. The interaction between regulatory factor X-associated protein RFXAP and KDM4A can disrupt DNA damage repair[120]. RFAXP is a key transcription factor for MHC II molecules[121,122]. It can bind to the promoter of *KDM4A* and induce its expression [120]. In PC, Fisetin can interact with RFXAP/KDM4A to inhibit PC tumor growth *in vivo* and cell proliferation *in vitro*[120]. In PC, KDM4B shows the ability to downregulate E-cadherin[123]. The high nuclear expression of KDM4D in the samples of pancreatic resection margins significantly and independently predicts an earlier recurrence in PC patients[124].

KDM5: KDM5 subfamily consists of four members, KDM5A, KDM5B, KDM5C, and KDM5D[125]. The role of KDM5 family in PC is not completely clear. KDM5A is associated with the development of PC[126]. KDM5A inhibits the expression of mitochondrial pyruvate carrier-1 (MPC-1) and controls the metabolites of pyruvate in mitochondria in PDAC[126]. Upregulation of MPC-1 seems to inhibit the development of cancer. Therefore, it can be inferred that KDM5A promotes the development of PDAC.

Table 2 Histone demethylase that plays a major role in pancreatic cancer

Family	Subfamily		Alias	Site	Function in pancreatic cancer
KDM1	KDM1A		LSD1	H3K4me1	Promote the occurrence of cancer[83]
	KDM1B		LSD2, AOF1	H3K4me2	Related to tumor tissue apoptosis[84]
Jumonji C	KDM2B		Ndy1, FBXL10, JHDM1B	H3K4me3, H3K36me2	Promote senescence of primary cells[109,110]
	KDM3A		JMJD1A, JHDM2A	H3K9me2 (preferential), H3K9me1	Regulate biological and pathological processes, including embryonic development, stem cell self-renewal and differentiation, genome integrity and tumorigenesis[191,192]
	KDM4 family	KDM4A	JMJD2A	H3K36me3, H3K9me3	Destruction of homologous recombination[120,138]
		KDM4B	JMJD2B	H3K9me3	Promote epithelial-mesenchymal transition[123]
		KDM4D	JMJD2D	H3K9me2/me3	Stimulates *in vitro* proliferation and cell survival, and plays a vital role in DNA double-strand break repair[193,194]
	KDM5A		JARID1A, RBBP2	H3K4me2	Promote the inhibition of active transcription and repair of DNA double-strand breaks[139,195]
	KDM6 family	KDM6A	UTX	H3K27me2/me3	The effect of KDM6A on PC tissue is currently unclear[196]
		KDM6B	JMJD3	H3K27me2/me3	Enhance the aggressiveness of cancer cells[176]
	PHD finger and zinc finger protein family	KDM7A	JHDM1D	H3K9me2, H3K27me2	May be related to the upregulation of E-cadherin gene expression[93]

All current research on reprogramming histone demethylases that play a role in pancreatic cancer. The table is sorted by family. PC: Pancreatic cancer; PHD: Plant homeodomain.

KDM6: KDM6 subfamily is mainly composed of KDM6A/UTX, its paralogs UTY and KDM6B[127]. They can demethylate the dimethyl and trimethyl groups of H3K27. They play important roles in the occurrence and development of many cancers. KDM6A/UTX has been the most frequently mutated epigenetic regulator in cancers including PC[128-133]. In addition, KDM6A also antagonizes PRC2-mediated H3K27 trimethylation catalyzed by EZH2, thereby regulating development[99,104,134]. KDM6A has not been found to function in PC tissues. Downregulation of KDM6B is widespread in many cancer cells[135,136]. Almost all pancreatic epithelial tissues have been detected *KRAS* gene mutations before they become cancerous[137]. KDM6B, which is located downstream of the *KRAS* gene, is upregulated in the pre-tumor phase of pancreatic intraepithelial tumors[138]. It is worth noting that the expression of KDM6B decreases with cancer development.

KDM7 (PHF and ZF protein subfamily): At present, the effect of KDM7 subfamily on PC has been seldom developed. According to relevant data, KDM7A may be related to the occurrence and development of PC[139].

READER DOMAIN IN WRITERS AND ERASERS

PHD fingers are central "readers" of histone post-translational modifications. They recognize specific histone modifications and bind to histone to ensure the different enzymes to locate in special targets[140,141]. They are structurally conserved, represented by the canonical C4HC2C/H sequence coordinating two zinc ions. They present in many chromatin-modifying proteins, such as demethylases or methyltransferases, or act as scaffolding proteins that can connect multi-subunit enzymatic complexes with a particular genomic region[30,140,141]. In this part, we will discuss how PHD fingers regulate histone methylation/demethylation and their binding substrates (Table 3).

Regulation of writers by PHD finger

KMT2A-E all have PHD fingers, but the number of PHD fingers in these proteins is different. KMT2A and KMT2B have four PHD fingers, while KMT2C has eight PHD fingers and KMT2D has seven PHD fingers, but KMT2E only has one PHD finger.

Table 3 Different enzymes and plant homeodomain finger domain

Type of enzyme	Name of enzyme	PHD domain	Histone substrates	Function
Histone demethylation enzyme	KDM1B/LSD2	PHD	H3K4me2	Unknown[25]
	KDM2A	PHD	H3K36me2/me1	Unknown[150]
	KDM4A-C	Two PHD	Unknown	Unknown[155,197]
	KDM5A	PHD1	Unmethylated H3K4 histone tail	PHD1 finger by H3 N-terminal tail peptides stabilizes binding of the substrate to the catalytic finger and improves the catalytic efficiency of demethylation[198,199]
		PHD2	Unmodified H3K4	Unknown[158]
		PHD3	H3K4me3	PHD3 finger can recruit substrate and it relates to demethylation propagation along nucleosomes *via* a positive-feedback regulatory mechanism[151,199]
	KDM5B	PHD1	H3K4me0	PHD1 finger recognizes the N-terminus of histone H3, provides an anchoring mechanism for KDM5B and PHD1-H3K4me0 is interaction is important for inhibition of migration[17]
		PHD2	Couldn't bind to histone	Unknown[17]
		PHD3	H3K4me3/H3K4me0	PHD3 finger detects H3K4me3, anchors at chromatin and spreads the transcriptionally inactive state
	KDM5C	PHD1	H3K4	PHD1 finger stabilizes the substrate peptide and helps to position the H3K4 in the JmjC finger exactly[162]
	PHF8(KDM7subfamily)	PHD1	Suppressive marks on H3K9me2/me3 and H3K27me2/me3 and H4k20me2/me3	PHD1 finger plays a significant role in PHF8 substrate recognition and helps to improve substrate affinity and specificity[164]
Histone methylation enzyme	KMT2A, KMT2B	PHD1	Unknown	PHD1 finger is necessary for a context-dependent regulation of holocomplex formation and implicated in tumor suppression[143]
		PHD2	Unknown	PHD2 finger shows the E3 ubiquitin ligase activity and involve in homo-dimerization[144,200]. Mutation in PHD2 will enhance transactivation ability and help to recruit target gene promoters
		PHD3	H3K4me3/me2	Unclear, one possibility is binding of H3K4me3 by PHD3 is necessary for the transcription-promoting effects of KMT2A/2B, another is to set a broad, methylated chromatin finger[145]
		PHD4	Unknown	PHD4 finger mediates intramolecular interactions between the N-terminal and C-terminal fragments of KMT2A with PHD1, and improves its stability[143]
	KMT2C	Eight PHD fingers	Unknown	These fingers help KMT2C to recruit to its target genes correctly[30,146]
	KMT2D	Seven PHD fingers	Unmodified histone H4 and asymmetrical H4R3me2	These fingers are essential for methyltransferase activity of KMT2D and KMT2D-mediated differentiation[201]
	KMT2E	PHD	H3K4me3	PHD finger binds to H3K4me3 specially and facilitates the recruitment of KMT2E to active transcription chromatin regions[148,149,202]

All current research on the regulation of writers and erasers by plant homeodomain domain. "Unknown" means that the corresponding literature was not mentioned. This table is sorted by types and subfamilies of enzymes. JmjC: Jumonji C; KMT: Histone lysine methyltransferase; PHD: Plant homeodomain.

There are 24 PHD fingers in KMT2A-E[142].

Regulation of KMT2A and KMT2B by PHD finger: KMT2A and KMT2B have similar domain architecture and both contain three consecutive PHD fingers, PHD1-3. These consecutive PHD fingers are followed by a bromodomain and the fourth PHD4 finger [142]. The precise function of PHD1 finger in KMT2A and KMT2B is unclear, but it can regulate the intramolecular interactions between N-terminal and C-terminal segments [143]. PHD1 fingers are necessary for holocomplex formation and are implicated in

tumor suppression[143]. PHD2 finger has an E3 ubiquitin ligase in the presence of the E2-conjugating enzyme CDC34[144]. Mutation of the PHD2 finger will cause increased transactivation ability of KMT2A and its recruitment to target genes[142], because of increased protein stability[144]. PHD3 finger binds to H3K4me3/me2, but the affinity between PHD3 finger and H3K4me2 is eight times lower than the affinity between PHD3 finger and H3K4me3[145]. Although PHD3 finger can recognize H3K4me3, the special function of KMT2A in transcriptional maintenance is unclear[145]. One possibility is that binding of H3K4me3 by PHD3 finger is necessary for the transcription-promoting effects of KMT2A, and another possibility is that newly deposited H3K4me3 mark helps KMT2A slide along the gene to set a broad, methylated chromatin domain[145]. The stability of KMT2A is dependent on its intramolecular interaction which is mediated *via* its PHD1 finger with PHD4 finger and the phenylalanine/tyrosine-rich domain of KMT2A[143]. Therefore, PHD4 finger in KMT2A can improve the stability of KMT2A in case of hydrolysis.

Regulation of KMT2C by PHD finger: KMT2C contains eight PHD fingers while KMT2D contains seven PHD fingers[142]. Although the function of PHD fingers in KMT2C is unclear, the functional extended PHD finger is important for KMT2C to be recruited to its target genes[146]. PHD4, PHD5, and PHD6 in KMT2D are tandem and these tandem PHDs can bind to unmethylated or asymmetrically demethylated H4 arginine3[147]. This connection is important for nucleosomal methylation activity and mediates stem cell differentiation by KMT2D[147]. But this binding ability is repressed by symmetrical demethylation on arginine-3 of histone H4 (H4R3me2s), because H4R3me2s can hinder the histone binding ability and catalytic activity in PHD4-6[142,147].

Regulation of KMT2E by PHD finger: The binding of KMT2E and histone is based on its single PHD finger which can bind to H3K4me3, and this special spatial structure of KMT2E makes it possible to recognize H3K4me3[148]. Although KMT2E can also bind to H3K4me2 and H3K4me1, the stability of binding of H3K4me2 and KMT2E is five times weaker than H3K4me3, while the stability of binding of H3K4me1 and KMT2E is sixteen times weaker than H3K4me3[148]. This can facilitate the recruitment of KMT2E to active transcription chromatin regions[148,149].

Regulation of erasers by PHD finger

PHD fingers can be found in KDMs[150,151]. These PHD fingers bind to the tail of H3 to enable the localization of enzymes to specific targets[152], and promote the recruitment of transcription factors or chromatin-associated protein complexes[17].

Regulation of KDM4 subfamily by PHD finger: PHD fingers can be found in KDM4 subfamily. KDM4A, KDM4B, and KDM4C have a catalytic histone demethylase domain, double PHD and Tudor domains, whereas KDM4D contains only a catalytic domain and lacks PHD and Tudor domains[153,154]. Although KDM4A-C have PHD fingers, the function of PHD fingers is unclear[155].

Regulation of KDM5 subfamily by PHD finger: KDM5 subfamily, including KDM5A-D, catalyze demethylation of the transcriptionally activating trimethylated and demethylated lysine-4 mark on H3[100,103,156,157]. KDM5A contains three PHD fingers (PHD1, PHD2, PHD3). Qualitative pull-down assays with isolated PHD1 domain of KDM5A show that it binds to unmodified H3K4 peptide[158]. The PHD1 finger preferentially recognizes unmethylated H3K4 histone tail, which is a KDM5A-mediated trimethylation products of H3K4 (H3K4me3) demethylation[151]. The function of PHD2 finger is unknown. PHD3 finger has been studied in the context of its fusion with nucleoporin NUP98 and it specifically binds to the H3K4me3, with a decrease in affinity for lower methylation states[17,158]. Since these preferred binding substrates are the products of KDM5A-mediated demethylation, a model in which demethylation can propagate along nucleosomes *via* a positive-feedback regulatory mechanism, has been put forward[151].

The KDM5B PHD1 finger can recognize the N-terminus of H3, which is unmodified or methylated at Lys9[17]. The KDM5B PHD2 finger cannot bind to histone. The KDM5B PHD3 finger prefers to bind to H3K4me3[17]. The PHD1 finger specifically binds to H3K4me0, and the PHD3 finger is selective for H3K4me3. A combination of two 'readers' capable of recognizing distinctive epigenetic marks is likely to impact KDM5B activity. Binding of PHD1 to H3K4me0 may provide an anchoring mechanism for KDM5B to sense H3K4me3 through PHD3 and slide along the H3K4me3-enriched promoters, demethylating nearby methylated H3K4 and further spreading the

transcriptionally inactive state of chromatin[17]. In addition, abrogation of H3 tail recognition by point mutation in the PHD1 domain of KDM5B decreases H3K4 demethylation in cells, resulting in the repression of tumor suppressor genes[159]. Therefore, the importance of interaction between PHD1 and H3 tail is proved.

Similarly, the PHD1 finger domain in KDM5C is close to the JmjC domain, and the linker of JmjC domain is 13 amino acids long and is expected to recognize and bind to H3K9me3[157,160]. Although the PHD1 domain is not necessary for the demethylase activity, it helps to recognize the substrate peptide[157,161]. The interaction between PHD1 domain and JmjC domain stabilizes the substrate peptide and the PHD1 domain can help precisely position H3K4 in the JmjC domain[162].

Regulation of KDM7 by PHD finger: PHF8 belongs to KDM7 subfamily and transcriptionally removes suppressive demethylation and monomethylation of lysine 9 and 27 on H3 and lysine 20 on H4[163]. PHF8 has a PHD finger which is closed to the catalytic domain. PHD finger in PHF8 plays a significant role in PHF8 substrate recognition, because it helps to improve substrate affinity and specificity[164]. PHF8 can be recruited to the promoters through the combination of its PHD finger and H3K4me2/3 during the cell cycle transition from G1 to S[107]. Although the functions of PHD fingers can be found in gastric cancer[165], breast cancer[166], colorectal cancer[167], lung cancer[168], *etc*., the functions of PHD finger are still unclear in PC.

CLINICAL APPLICATION

Epigenetic genes play vital roles in maintaining structural stability and physiological functions of normal chromosomes and are deficient in some patients with PC, thereby serving as potential targets for correcting these deficiencies and precisely killing these aberrant PC cells[169]. The discovery of histone methyltransferases, demethylases and their active sites has provided new insights in the diagnosis and treatment of PC. The active sites and mechanism of the inhibitors in PC treatment are shown in Table 4.

Histone modifications define the previously unrecognized subsets of PC patients with different epigenetic states and therefore represent the prognostic and predictive biomarkers that can be used to guide clinical decisions, such as the use of fluorouracil chemotherapy[170]. H3K4me2, H3K9me2, or H3K18AC expressed at low levels are positively correlated with the poor prognosis of PC[170]. EZH2 expression is higher in PC cells than in normal cells; thus, EZH2 can be used as a potential biomarker for early diagnosis of PDAC[171]. High expression of KDM4D in benign cells near the edge of surgically resected PC tissues is predictive of early recurrence[124]. The discovery of epigenetic biomarkers can provide a great reference for early diagnosis, drug selection and surgery prognosis of PC.

SMYD3 is a candidate therapeutic target against PC, lung cancer and potentially other RAS-driven tumors[172]. In mice, complete loss of SMYD3 function with no apparent phenotype suggests that SMYD3 inhibitors, as chemotherapeutic agents, cause minimal collateral toxicity. The clinically used combination of Raf protein kinase or dual specificity threonine/tyrosine kinase inhibitors and SMYD3 inhibitors can reduce drug toxicity and suppress the development of drug resistance[172].

SMYD3 inhibitor piperidine-4-formamide-acetanilide compound, BCI-121, is a small molecule inhibitor that significantly inhibits proliferation in PC cell lines with high expression of SMYD3. BCI-121 and histone competitively bind to SMYD3; BCI-121 binds inside the lysine channel, which connects cofactor binding sites and histone peptide binding sites[173].

The PRMT5 inhibitor EZP015556 targets *MTAP* (a gene commonly lost in PC) negative tumors, which indicates that it is an effective treatment for a subpopulation of *MTAP* positive tumors. According to the individualized medication approach, the therapeutic response in different patient-derived organoids (PDOs), developed directly from patient tumor tissue is different. The PDO model is used to validate the effectiveness of PMRT5 inhibition as a potential treatment for PDAC[174]. EZH2 expression in PC cells is significantly higher than that in normal pancreatic duct cells and fibroblasts. 3-Deazaneplanocin A (DZNeP) regulates the expression of EZH2 and H3K27me3, synergically enhancing the anti-proliferative activity of gemcitabine and significantly increasing the apoptosis rate of cells[175]. DZNeP is an S-adenosine homocysteine hydrolase inhibitor. DZNeP also enhances the mRNA and protein expression of nucleoside transporter HENT1/HCNT1[175]. The combination of DZNeP and DZNeP/gemcitabine significantly reduces the growth volume of PDAC spheres in selective medium[175].

Table 4 Inhibitors for the treatment of pancreatic cancer

Drug type	Drug name	Active site	Mechanism	Effect	Targeting tumors
Relating to histone methyltransferase	SMYD3 inhibitor piperidine-4-formamide-acetylaniline compound (BCI-121)	It competes with histones to bind SMYD3, binding sites are formed within the SET and post-SET fingers and contained in a deep and narrow substrate binding cavity	BCI-121 is a competitive inhibitor significantly inhibits; SMYD3-substrate interaction and chromatin recruitment	It inhibits cancer cell growth and accumulates during the cell cycle S	High expression of SMYD3 protein in cancer cell lines (pancreatic cancer, lung, prostate and ovarian cancer)[173]
	PRMT5 inhibitor EZP015556	MTAP	-	It works for MTAP He and MTAP PDO	A negative tumor MTAP (a commonly lost gene in pancreatic cancer) [174]
	EZH2 inhibitor 3-Dazocycline A (DZNeP)	It regulates EZH2 and H3K27me3 protein expression	DZNeP inhibit the activity of S-adenosine-L-homocysteine (AdoHcy) hydrolase, which reversely hydrolyzes AdoHcy to adenosine and homocysteine, thereby inhibiting histone methylation	It synergistically enhanced antiproliferative activity of gemcitabine and significantly increased apoptosis rate	Pancreatic ductal carcinoma[175]
Relating to histone demethylase	BET inhibitor JQ1 related to KDM6A	Reducing activity and p63 levels of MYC pathways	GLI1 is the main target gene of the Hh pathway JQ1 reduces the mRNA and protein levels of primary human CAFs. TGF-β is an interstitial activator that JQ1 its induced response	Altered KMT2C (MLL3)-KDM6A (UTX)- PRC2 regulating axis	Pancreatic ductal carcinoma[169,176, 177]

All current research on inhibitors for the treatment of pancreatic cancer developed based on histone methylation modification. "-" means that the content does not exist here. This table is sorted according to the correlation with histone methyltransferases and demethylases. CAF: Cancer-associated fibroblast; KMT: Histone lysine methyltransferases; PDO: Patient-derived organoid; PRC2: Polycomb repressive complex 2; TGF-β: Transforming growth factor β.

Bromodomain and extra-terminal (BET) inhibitors and EZH2 inhibitors are designed to rescue the dysregulated KMT2C/MLL3-KDM6A/UTX-PRC2 regulatory axis and have achieved preliminary success in preclinical models. The regulatory axis regulates the expression of various downstream tumor suppressor genes[169]. Therefore, rebalancing this axis represents a new approach to PDAC therapy.

Defects in KDM6A make sex-specific squamous PC sensitive to bromouracil and BET inhibitors[169]. BET inhibitor JQ1 reverses squamous cell differentiation and inhibits tumor growth *in vivo* by decreasing MYC pathway activity and p63 levels [176]. JQ1 affects cancer-associated fibroblast (CAF) activation by acting on the Hedgehog and TGF-β pathways. JQ1 inhibitor converts α-SMA-positive CAFs to α-SMA-negative CAFs, but does not eliminate CAFs[177].

Small molecules containing 8-hydroxyquinoline structure are competitive inhibitors of KDM4 (also known as JMJD2) family, binding active iron to inhibit the activity of KDM4 and regulate demethylation of H3K9 sites[178]. KDM4C inhibitor SD70 can inhibit the growth of prostate cancer cells[179].

Many types of inhibitors of KDM1A have been reported, but the inhibitors of this enzyme are mainly targeted at acute myeloid leukemia or small cell lung cancer, *etc.* And there are few studies on PC. For example, SP2509 is a noncompetitive inhibitor, and is used in current clinical trials for the treatment of acute myeloid leukemia or small cell lung cancer[180]. Ory-1001 effectively inactivates LSD1 and is highly selective for FAD-dependent ammonia oxidase[181]. The application of histone demethylase inhibitors in the treatment of PC is still limited, so it is necessary to strengthen the exploration of the treatment of PC based on the existing research.

FUTURE DIRECTIONS

Histone writers and erasers do not work independently. In fact, the interactions between writers and erasers include the positive correlativity between EZH2 and KDM2B, and the synergistic effects of EZH2 and KDM6A[182,183]. In bladder cancer, the H3K27 demethylase KDM6A gene often has mutations[131,184]. This makes cancer tissues that have lost KDM6A more vulnerable to EZH2 attack[185]. This accelerates the onset of tumors. The expression of EZH2 and KDM2B in ovarian cancer is

positively correlated[183]. Therefore, knocking down the KDM2B gene is beneficial to inhibit the migration of ovarian cancer cells *in vitro*.

Many problems remain in the research of histone modifications. Research on histone methyltransferases is relatively adequate, but there are few articles about the mechanism of SMYD2, so SMYD2 is not mentioned in our review. Current research on histone arginine residue demethylases has not yet fully achieved results. Therefore, only histone lysine residue demethylases are discussed. However, the effect of KDM7 subfamily demethylases on PC has seldom been proved, so only some guesses about the effect of KDM7A are mentioned. Besides, the study of the interactions between writers and erasers in PC is still in a blank state. The role of the reader domain in PC remains unclear. This review only lists the roles of the PHD domain in the localization of histone modifications and the recruitment of related protein complexes. Reader domain is still a potential research direction in PC.

The study of histone methylation and demethylation has enlightening effects on the diagnosis, treatment, and prognosis of PC. Histone modifications can be used to predict in the prognosis of PC patients[171]. Histone methyltransferase and demethylase inhibitors are used clinically to treat PC. The corresponding inhibitors act on the signal regulatory pathway and change the signal expression of downstream target cells, thus regulating the growth and development of cancer cells. At present, the research of histone demethylase inhibitors is inadequate. Therefore, histone demethylase inhibitors need to be further explored.

The effect of histone modifications on PC is interdependent. The interactions between histone modifications and other epigenetic forms can influence the occurrence and progression of cancers such as cervical cancer and breast cancer. The effect of these interactions enlightens the research on PC. DNA methylation and the expression of miRNAs can be regulated by histone methyltransferases and demethylases, thereby causing alternations of developing process of cancer. Histone methyltransferase EZH2 epigenetically silences tumor-suppressor miRNAs, such as miR-139-5p, miR-125b, miR-101, let-7c and miR-200b, thereby promoting cancer cell metastasis[186]. Histone demethylase KDM5B targets H3K4 demethylation of miR-let-7e and promotes tumor cell proliferation through epigenetically inhibiting the tumor suppressor miR[187]. The combination of EZH2 and promoter region induces the expression of specific target protein H3K27me3, thereby reducing the expression of downstream gene, DNA (cytosine-5)-methyltransferase 3A (DNMT3A)[10]. EZH2-H3K27me3-DNMT3A is the key factor of regulating cervical total stimulus molecule Tim-3/galectin-9, which results in immune escape in the process of malignant transformation[10]. It is reasonable to speculate that the interaction between histone methylation and other epigenetic modifications may also play a role in PC. This opinion draws some inspiration and reference to future research of PC.

CONCLUSION

This review focuses on the mechanism of histone methylation in PC. Histone methylation is mainly regulated by writer, reader and eraser. Writer refers to histone methyltransferase, eraser refers to histone demethylase and reader refers to the modification domain of histone methyltransferase and demethylase. Reader can be an independent polypeptide or a component of methyltransferase and demethylase. On the one hand, histone methyltransferase can promote the proliferation and invasion of PC cells. On the other hand, histone methyltransferase can inhibit the proliferation of cancer cells. Histone demethylase promotes the occurrence of PC and is related to apoptosis. Reader domain plays a role in guiding related methyltransferases and demethylases to identify corresponding sites during the methylation and demethylation process.

Abstract

Elimination of viral hepatitis in sub-Saharan Africa by 2030 is an ambitious feat. However, as stated by the World Health Organization, there are unprecedented opportunities to act and make significant contributions to the elimination target. With 60 million people chronically infected with hepatitis B virus (HBV) of whom 38800 are at risk of developing highly fatal hepatocellular carcinoma (HCC) every year, sub-Saharan Africa faces one of the greatest battles towards elimination of viral hepatitis. There is a need to examine progress in controlling the disproportionate burden of HBV-associated HCC in sub-Saharan Africa within the context of this elimination target. By scaling-up coverage of hepatitis B birth dose and early childhood vaccination, we can significantly reduce new cases of HCC by as much as 50% within the next three to five decades. Given the substantial reservoir of chronic HBV carriers however, projections show that HCC incidence and mortality rates in sub-Saharan Africa will double by 2040. This warrants urgent public health attention. The trends in the burden of HCC over the next two decades, will be determined to a large extent by progress in achieving early diagnosis and appropriate linkage to care for high-risk chronic HBV infected persons.

hepatocellular carcinoma (HCC) in sub-Saharan Africa. In 2020, HBV-associated HCC accounted for approximately 36700 deaths. By 2040, it is projected that approximately 72200 people will die each year from this disease without an intensive public health response. The high mortality-to-incidence ratio associated with HCC in sub-Saharan Africa suggests significant inequities in access to appropriate health care. This review examines the evidence on the extent of the disease burden in sub-Saharan Africa and advocates for prioritizing HCC control as part of ongoing viral hepatitis elimination strategies within this region.

INTRODUCTION

Despite the availability of a safe and effective prophylactic vaccine since 1982, chronic hepatitis B which is a serious liver disease caused by hepatitis B virus (HBV), remains a major global public health threat. Estimates from the World Health Organization's (WHO) current Global Hepatitis Report suggest that in 2015, 3.5% (257 million persons) of the world's population were living with chronic hepatitis B, with the Western Pacific and sub-Saharan African regions bearing the brunt (68%) of the disease burden (WHO, 2017). In addition to this, 887000 deaths due to HBV-associated hepatic sequelae such as acute hepatitis, liver cirrhosis and liver cancer or hepatocellular carcinoma (HCC), were recorded worldwide[1].

With an estimated 830180 associated deaths recorded in 2020, liver cancer remains a leading cause of cancer-related death worldwide, third only to lung (1.8 million deaths) and colorectal (935153 deaths) cancers[2]. Globally, incidence rates of liver cancer have remained high, with 905677 newly diagnosed cases in 2020 [compared to 748000 (5.9% of all cancers) new cases in 2008, for example[3]], representing 4.7% of all cancer cases recorded in that year alone[2]. The most common type of malignant transformation in the liver is HCC (75%-85%), followed by intrahepatic cholangiocarcinoma (10%-15%), with other rare types accounting for the remainder of all primary liver cancers. The geographic distribution of the incidence of HCC tends to mirror that of its major risk factors, chronic hepatitis B and hepatitis C virus (HCV) infection, which account for approximately 56% and 20% of all HCC cases, respectively[2,4-6]. This implies that the highest incidence rates [age-standardized incidence rate (ASIR) > 20 cases per 100000 persons per year] of HCC are recorded in hepatitis B endemic countries including those in sub-Saharan Africa, while non-endemic regions like Europe and North America report relatively lower incidence rates (ASIR < 10 cases per 100000 persons per year)[2,7-9]. A further cause for concern in most resource limited countries within regions like sub-Saharan Africa where HCC screening and diagnostic services, and medical interventions are often inadequate, is the poor survival and extremely high mortality rates associated with HCC. Approximately 93% of patients die within a year of the onset of symptoms[7,9-11]. Evidently, elimination of viral hepatitis caused by HBV and HCV presents the best opportunity to reduce the incidence of HCC, especially in regions like sub-Saharan Africa, where the disease burden and need for intervention are oftentimes the greatest.

Recognizing the devastating impact of viral hepatitis on global health, the WHO in May 2016 adopted a Global Health Sector Strategy on Viral Hepatitis aimed at achieving a 90% reduction in new cases and a 65% reduction in mortality due to HBV and HCV infection, towards an ambitious target of eliminating viral hepatitis by 2030 [12]. To eliminate chronic hepatitis B, the health service targets to be attained by 2030 include; 90% coverage of routine childhood hepatitis B vaccination, a reduction in mother-to-child transmission (MTCT) of HBV such as through > 90% coverage of hepatitis B birth dose vaccination, 100% of all blood donations screened for HBV, 90% of all HBV infections diagnosed, and 80% of eligible persons with chronic hepatitis B linked to appropriate treatment and care[12]. While largely in the planning phase of executing this global strategy, a recent WHO report suggests that overall, member

states are making progress in developing national viral hepatitis management guidelines and strategic plans towards attaining the elimination targets, although availability of dedicated funding to support implementation appears to be an important challenge in some countries[13].

To contribute to the knowledgebase on the scope of the burden of chronic hepatitis B in sub-Saharan Africa, the status and public health response to HBV-associated HCC in sub-Saharan Africa are reviewed. Opportunities and challenges towards achieving the 2030 viral hepatitis elimination target – at least where chronic hepatitis B and HCC are concerned – are also identified, with the intent of arguing for continued financial and technical investments to support ongoing health sector strategies and interventions within sub-Saharan Africa.

GLOBAL BURDEN OF CHRONIC HEPATITIS B

The seroprevalence of chronic hepatitis B which is based on the detection of the hepatitis B surface antigen (HBsAg) within the general population, is highly variable worldwide. This variability is demonstrated by substantial regional and inter-country disparities in the burden of the disease. Available estimates[14] suggest that HBsAg prevalence rates in the Americas, for example, range from < 2% in countries like the United States of America, Mexico, and Guatemala, to 13.55% (95%CI: 9.00-19.89) in Haiti. In the South East Asian region, HBsAg prevalence rates range from 0.82% (95%CI: 0.80–0.84) in Nepal to as high as 6.42% (95%CI: 6.37–6.47) in Thailand. Overall, countries within the Eastern Mediterranean and European regions mostly have lower-intermediate endemicity levels (HBsAg prevalence ranging from 2% to 4.99%) while the Western Pacific can be classified as a high-intermediate endemic region with most countries recording HBsAg prevalence rates > 5%. Within the African region, the lowest HBsAg prevalence rates are reported in countries like Seychelles [0.48% (95%CI: 0.12-1.90)], Eritrea [2.49% (95%CI: 2.32-2.67)], and Algeria [2.89% (95%CI: 2.50-3.33)], while Mauritania [16.16% (95%CI: 14.92-17.49)], Liberia [17.55% (95%CI: 15.70-19.55)], Swaziland [19% (95%CI: 17.65-20.43)], and South Sudan [22.38% (95%CI: 20.10-24.83)] have recorded some of the highest prevalence estimates[14].

EPIDEMIOLOGICAL SHIFT IN THE BURDEN OF CHRONIC HEPATITIS B IN SUB-SAHARAN AFRICA

Historically, sub-Saharan Africa has been classified as hyper-endemic for chronic hepatitis B based on the detection of HBsAg among ≥ 8% of the general population. Table 1 shows the variable prevalence of HBsAg among populations in some sub-Saharan African countries prior to introduction of universal hepatitis B vaccination and how this has changed over time post-vaccine introduction[15-47]. At the peak of the hepatitis B epidemic in sub-Saharan Africa, the disease burden was characterized by a preponderance of horizontal transmission of HBV among young children (between 1-4 years of age), 30%-50% of whom would go on to develop chronic hepatitis B, and later progress to potentially fatal sequelae (mainly liver cirrhosis and HCC) within 30-50 years after infection[15,29,48]. This contrasts with HBV infection acquired during adulthood which carries a considerably lower risk (< 5%) of progression to chronic disease as observed in non-endemic regions of the world.

Currently, the prevalence of HBsAg in sub-Saharan Africa is reported to be 6.1%, equating to 60 million people living with chronic hepatitis B, of which approximately 4.8 million are children < 5 years of age[1]. The decline in the prevalence of HBsAg within the population can be largely attributed to the success of universal childhood hepatitis B vaccination programmes implemented in sub-Saharan Africa since the early 1990s[49]. In most sub-Saharan African countries, the first dose of the hepatitis B vaccine is administered at 6 weeks of age, with the remainder of the regimen completed within the 1st year of life in an effort to interrupt transmission and prevent incident HBV infection in early childhood. Coverage of the third dose of the hepatitis B vaccine in the region is currently estimated at 73%[50]. Countries like The Gambia and South Africa with longstanding hepatitis B vaccination programmes have achieved marked declines in incident infections over time, especially among children < 5 years of age (Table 1).

Despite this success, we are still decades away from realizing the full benefits of universal childhood hepatitis B vaccination programmes in sub-Saharan Africa, given

Table 1 Prevalence of hepatitis B surface antigen among pre- *vs* post-hepatitis B vaccine introduction populations in some sub-Saharan African countries

[1]The year the hepatitis B vaccine was introduced into national Expanded Programme on Immunization. HBsAg: Hepatitis B surface antigen.

the protracted natural history of chronic hepatitis B, and the long interval between early childhood infection and development of chronic sequelae[51,52]. As such, high prevalence rates of HBsAg persist among a reservoir of adult populations, including women of childbearing age, most of whom were born before the introduction of the hepatitis B vaccine or were not fully vaccinated in infancy (Table 1). This continues to feed the epidemic in sub-Saharan Africa, contributing to the 87890 HBV-associated deaths (approximately 10% of the global total) recorded each year[1]. What further compounds the situation in sub-Saharan Africa is the disproportionate burden of human immunodeficiency virus (HIV) co-infection (69% of all HBV-HIV co-infected persons reside in sub-Saharan Africa) which is associated with a more severe prognosis than that observed in HBV mono-infected individuals[53-55]. Emerging evidence also suggests that perinatal transmission or MTCT of HBV, which was previously presumed to be insignificant in the epidemiology of chronic hepatitis B in sub-Saharan Africa, actually contributes to 367250 incident HBV infections (twice the number of paediatric HIV infections) among neonates annually[56]. In fact, the risk of HBV MTCT increases by up to 2.5-fold among the substantial population of HBV-HIV co-infected pregnant women in sub-Saharan Africa, compared to their HBV mono-infected counterparts[57-60]. This is concerning, given that perinatally acquired HBV infections carry a 90% risk of progression to chronic hepatitis B. This implies that hepatitis B vaccination from 6 weeks of age may be inadequate in preventing incident HBV infections among neonates, especially where the burden of maternal HBV-HIV co-infection is high and prevention of HBV MTCT (PMTCT) strategies are sub-optimal, as is the case in most sub-Saharan African countries. This is a stark contrast to HIV MTCT in sub-Saharan Africa which is on course for elimination due to rapid expansion of antenatal screening and access to timely HIV antiretroviral therapy[61]. The marked decline in HIV MTCT has led to a growing population of HIV-exposed uninfected children in sub-Saharan Africa. Of the 14.8 million HIV-exposed uninfected children in the world, 90% live in sub-Saharan Africa[62]. Although inconclusive, there is some evidence to suggest that HIV-exposed uninfected children may have a modified immune response to hepatitis B vaccination and may also be at increased risk for HBV infection, presenting an additional complexity to elimination strategies in sub-Saharan Africa[58,63-66].

EPIDEMIOLOGICAL TRENDS IN HBV-ASSOCIATED HCC IN SUB-SAHARAN AFRICA

Of the 60 million people currently living with chronic hepatitis B in sub-Saharan Africa, 38800 are at risk of developing HCC every year, characterized by an aggressive clinical course[2,67,68]. In addition, approximately 93% (36700) of persons with HCC will die within a year of their diagnosis without appropriate and timely medical intervention[2,11,67]. Most of these HCC cases (and deaths) will occur among a predominantly male population (sex ratio of 2:1) with age at diagnosis ranging between 38-67 years (compared to 50-70 years in resource rich countries), who are in their prime reproductive and working years, draining productive capacity, and placing a further burden on already strained economic, societal, and health, systems in sub-Saharan Africa[9,11,69-71]. While cases of paediatric HCC are diagnosed more frequently in some sub-Saharan African countries than those in Europe and North America for example, they remain uncommon when compared to the HCC incidence among adult populations[72-75]. Within the next two decades, HCC incidence and mortality rates in sub-Saharan Africa are predicted to double (Figure 1[67,76,77]) unless addressed through reforms in regional and national health policy and practice, including intensifying prevention, diagnostic and treatment strategies, in a whole system approach.

A comparison of the 2020 estimates of age-standardized liver cancer (mainly HCC) incidence and mortality (ASMR) rates in sub-Saharan Africa *vs* other regions of the world is shown in Figure 2[2,67,78]. With ASIRs of 8.1 and 4.2, and ASMRs of 7.8 and 4.0 per 100000 persons per year among men and women, respectively, HCC is a common cause of cancer-related morbidity and mortality in sub-Saharan Africa. There are substantial regional variations in HCC incidence and mortality rates across sub-Saharan Africa. Among males for example, the highest HCC ASIRs (> 12.9 per 100000 persons per year) and ASMRs (> 12.6 per 100000 persons per year) are recorded in West African countries, while East African countries generally appear to experience a lower burden (ASIRs < 5.1 and ASMRs < 4.9 per 100000 persons per year) of the disease (Figures 3 and 4)[2,67,78]. It should be noted however, that the true burden of HCC in sub-Saharan Africa is grossly underestimated by as much as 40%, given that cases are often underreported due to challenges in effectively diagnosing the disease, while the quality and coverage of data in population-based cancer registries are suboptimal[9,11,79].

The overall HCC mortality-to-incidence ratio (MIR = 0.95) in sub-Saharan Africa is comparable to that in the Western Pacific and South-East Asian regions (MIR = 0.95) but higher than that in Northern America (MIR = 0.82)[80]. This high MIR reflects disparities in outcomes of HCC in sub-Saharan Africa compared to resource-rich regions, owing to limited availability and accessibility of diagnostic and treatment services[81,82]. These disparities go beyond the clinical context and are rooted in socio-economic inequities. A recent South African study[82] investigating trends in liver cancer-associated mortality found key socio-economic and sex disparities. The average MIR for black South African men and women was 4.0 and 3.3 respectively, compared to 2.2 and 1.8 among their white counterparts. This underscores the inequities in HCC prognosis experienced by socio-economically disadvantaged populations[82]. Evidently, addressing the disproportionate burden of HCC in sub-Saharan Africa will require careful consideration of socio-economic and demographic inequities prevalent within its population.

PREDOMINANCE OF HBV-ASSOCIATED HEPATOCARCINOGENESIS IN SUB-SAHARAN AFRICA

The association of chronic hepatitis B with the development of most cases of HCC [attributable fraction, AF = 50% (95%CI: 39-60)] occurring among sub-Saharan African populations is well established in the literature[5,6,83,84]. The remainder of HCC cases are typically associated with HCV infection [AF = 21% (95%CI: 13-32)] and exposure to the dietary carcinogen, aflatoxin B1, although metabolic syndrome is emerging as an important risk factor in sub-Saharan Africa[6,85-88]. In comparison, the major risk factors for HCC development in low incidence regions of the world (North America, and Western, Central, and Eastern Europe) include host and environmental factors such as genetic predisposition to primary liver cancer, chronic alcohol intake, obesity, hemochromatosis, and exposure to nitrosamines, followed by HCV infection[71,89-

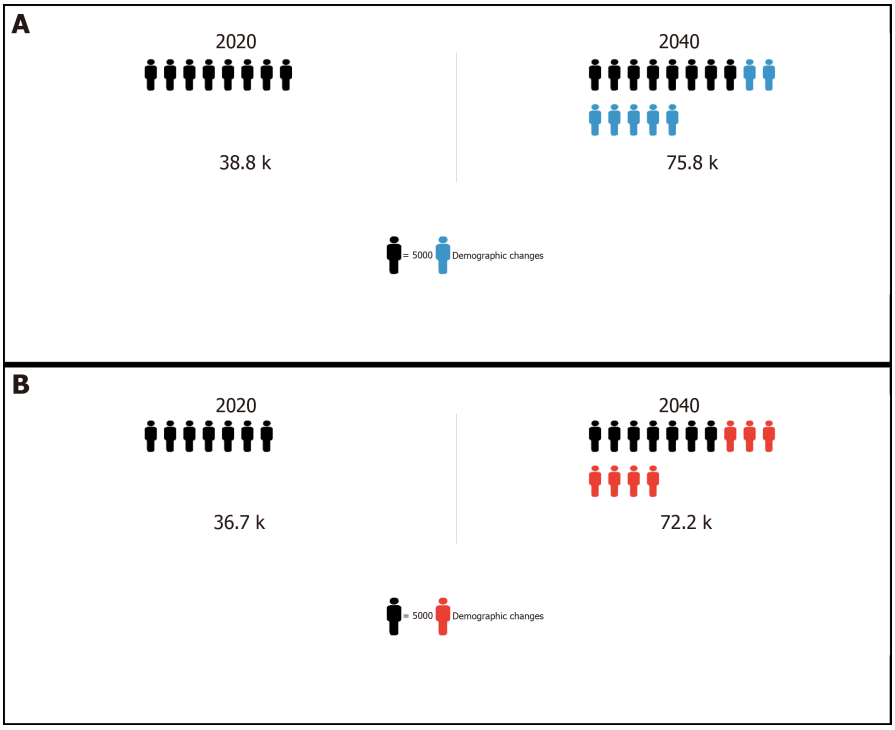

Figure 1 Projected increase in estimated number of cases and deaths due to cancers of the liver and intrahepatic bile ducts within sub-Saharan Africa from 2020 to 2040[67,76,77]. GLOBOCAN 2020 (https://gco.iarc.fr/). A: Estimated number of cases from 2020 to 2040, both sexes, age (0-85+); B: Estimated number of deaths from 2020 to 2040, both sexes, age (0-85+).

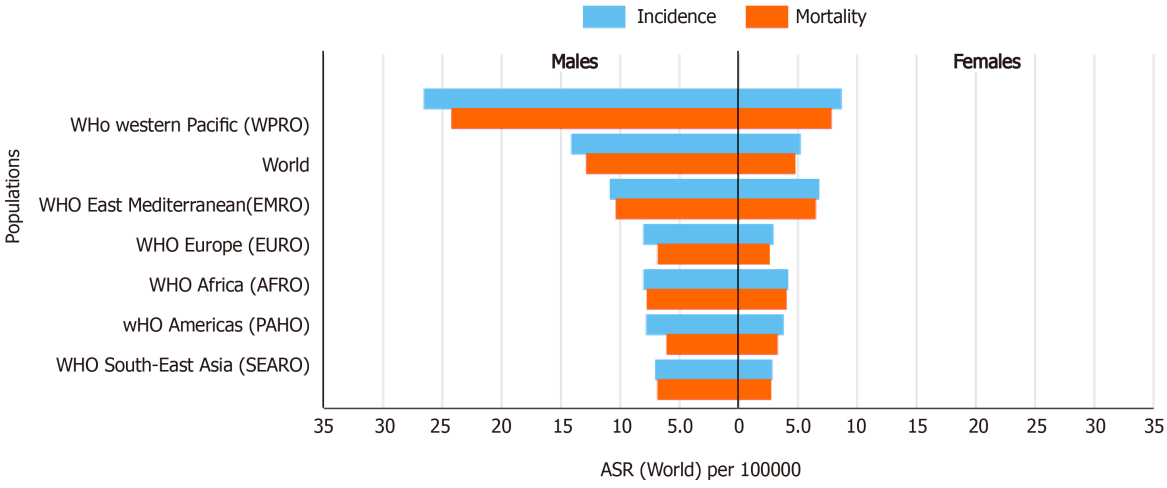

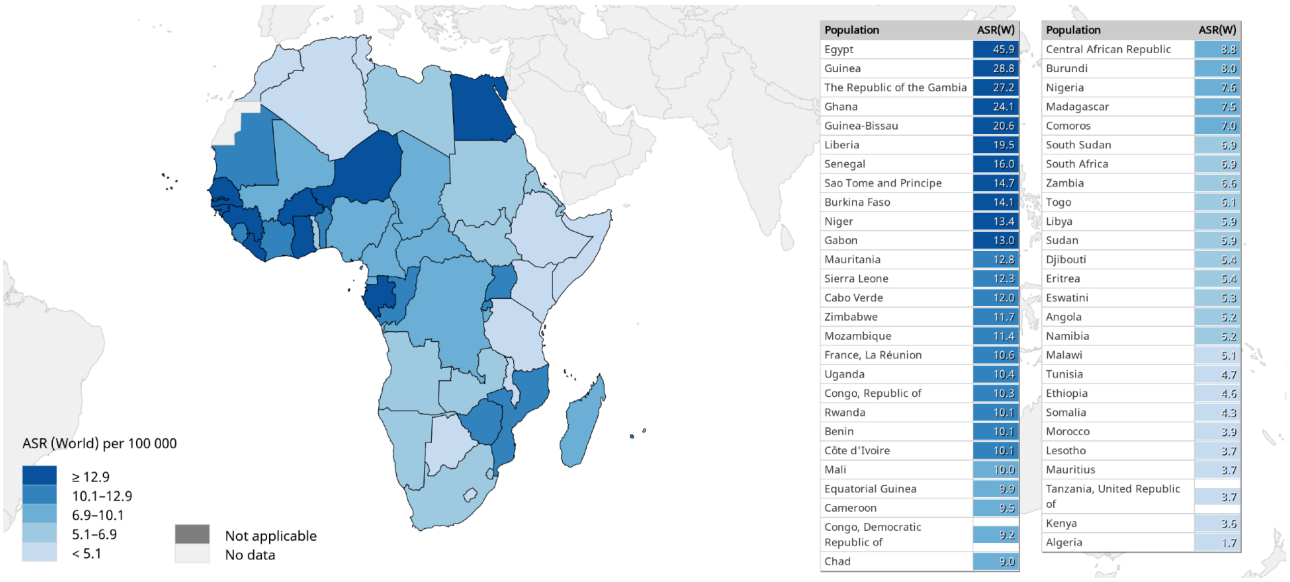

Figure 2 Estimated age-standardized liver cancer incidence and mortality rates per 100000 persons per year shown worldwide in 2020[2,67,78]. GLOBOCAN 2020 (https://gco.iarc.fr/). WHO: World Health Organization; ASR: Liver cancer age standardized incidence rate.

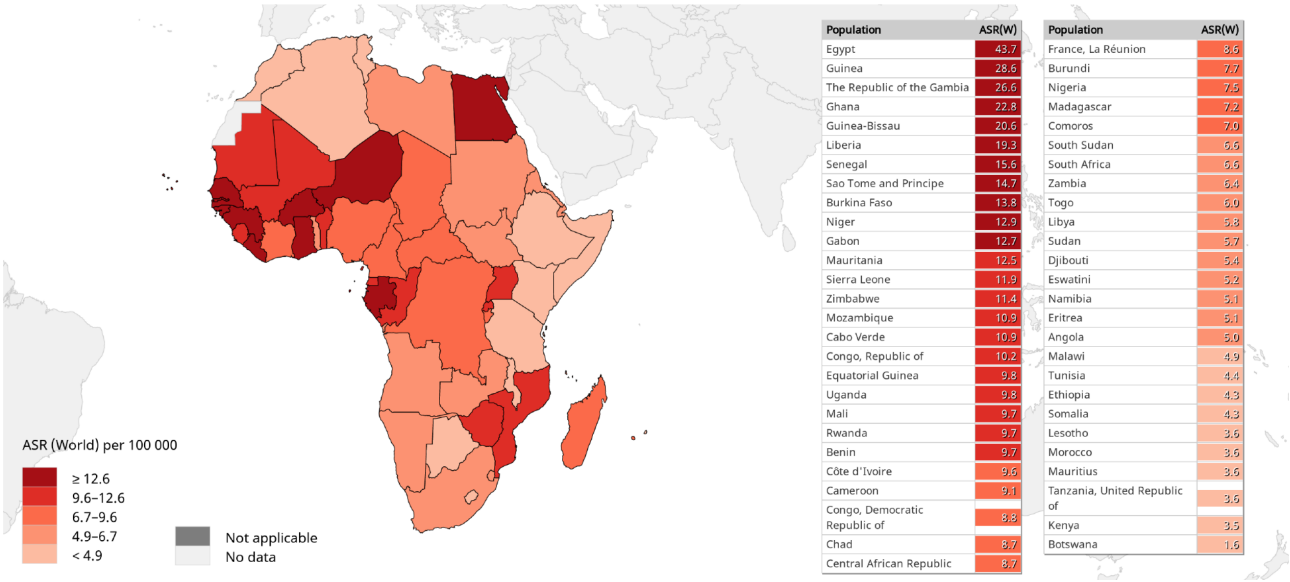
91]. It is worth noting however, that the potential for interaction among these different risk factors, leading to synergistic or additive effects in the development of HCC in both endemic and non-endemic regions of the world cannot be undervalued.



The mechanism underlying HBV-associated hepatocarcinogenesis is multifactorial, involving various direct and indirect viral mechanisms required to stimulate the host oncogenic pathway and achieve hepatocyte transformation[92,93]. These mechanisms, which may act synergistically, include integration of the viral DNA into host genome, persistent and enhanced HBV replication, as well as infection with specific HBV genotypes and HBV genetic variants. Important HBV-specific risk factors involved in the development of HCC have been identified in previous studies conducted in sub-Saharan Africa. In a recent case control study, Atsama Amougou *et al*[94] demonstrated the role of circulating quasi-genotypes and viral genetic variations in HBV-

associated hepatocarcinogenesis among Cameroonian HCC patients. A previous study [95] conducted in South Africa found an increasing risk of HCC with increasing HBV viremia, showing an increasing trend in odds ratio (OR) from ≥ 2000 IU/mL (OR = 8.55, 95%CI: 3.00 ± 24.54) to ≥ 200000 IU/mL (OR 16.93, 95%CI: 8.65 ± 33.13). While this finding is consistent with that from another study conducted in The Gambia, there is evidence to suggest that low-level viremia may also be a significant risk factor for HCC[96]. The South African study further demonstrated a 4-fold increase in the risk of developing HCC among participants with occult HBV infection (HBsAg negative but HBV DNA positive infections) compared to controls[95]. Interestingly, a previous longitudinal study conducted in The Gambia which followed chronic carriers of HBV

over a median duration of 28.4 years (interquartile rage = 17.7-32.7) found that maternal HBsAg positivity – as a proxy of MTCT of HBV – was statistically significantly ($P < 0.001$) associated with a higher incidence of HCC [crude incidence rates of 89.2 (95%CI: 22.3–356.8) *vs* 0 (unadjusted) per 100 000 persons per year, among those born to HBsAg positive *vs* HBsAg negative mothers][70]. Based on these findings, the authors recommend further investigation into the feasibility of scaling-up implementation of hepatitis B birth dose vaccination and other PMTCT strategies within sub-Saharan Africa in order to interrupt incident HBV infections among neonates[70]. Of the 111 countries which report having introduced a hepatitis B birth dose as part of national routine immunization programmes, only 11 (Algeria, Botswana, Cabo Verde, Côte d'Ivoire, The Gambia, Mauritania, Namibia, Nigeria, Sao Tome and Principe, Senegal, and Zambia) are in Africa[50]. While the global coverage of the birth dose is reported to be suboptimal (43%), that in the sub-Saharan African region is even more dismal at an estimated 6%[50]. When considered together with the reported low coverage of maternal screening for HBV infection and linkage to antiviral prophylaxis, current PMTCT strategies are inadequate to significantly reduce perinatal transmission and avert neonatal HBV infections within the region[97,98].

CHALLENGES AFFECTING MANAGEMENT OF HBV-ASSOCIATED HCC IN SUB-SAHARAN AFRICA

Management of chronic hepatitis B involves suppressing HBV viremia and minimizing the risk of progression to liver cirrhosis, chronic liver failure and HCC, using oral nucleotide/nucleoside analogues like tenofovir disoproxil fumarate (TDF) and entecavir. Treatment with nucleotide/nucleoside analogues is indicated in chronic carriers with elevated HBV viremia, elevated liver enzymes, and evidence of liver fibrosis and cirrhosis. Appropriate linkage to care requires the identification of chronically infected individuals who are eligible for treatment through HBV screening programmes[99]. It is estimated that < 1% of chronic HBV infected individuals in sub-Saharan Africa are currently being diagnosed[100]. In addition, there are major gaps in determining treatment eligibility. Significant limitations have been identified when applying internationally recommended treatment eligibility criteria in the sub-Saharan African context. Only 10%–15% of persons with liver cirrhosis are detected for linkage to appropriate treatment[99-102].

Low uptake of HBV screening and treatment services in sub-Saharan Africa has been attributed to the lack of publicly funded, national HBV screening and treatment programmes. This leaves the responsibility for seeking an HBV test to the patient, which is highly detrimental when considered in the context of limited public awareness of the virus, and the asymptomatic nature of the infection until onset of late-stage sequelae[103]. As currently available nucleotide/nucleoside analogues cannot eradicate intrahepatic HBV DNA, treatment is typically lifelong, and this amounts to a significant cost[100,102]. A recent WHO report indicates that by 2019, < 8 of the 47 member states within the WHO African region (WHO AFRO) had established subsidized HBV treatment programmes[16]. This suggests that a substantial proportion of chronic HBV carriers continue to incur undue financial burden as a consequence of paying out-of-pocket for the treatment they need, while others may be unable to afford it altogether. In Ghana, the annual cost of TDF is estimated at $670 which, when considered against an average annual income of $1778, is a major constraint to accessing lifesaving treatment[104]. It should not come as a surprise then that most patients in sub-Saharan Africa present to health care facilities with established liver cirrhosis or symptomatic advanced-stage HCC, at which point the prognosis is grim and therapeutic options are limited to palliative care.

TOWARDS ELIMINATION OF CHRONIC HEPATITIS B AND CONTROL OF HCC IN SUB-SAHARAN AFRICA

Future trends in the burden of HCC in sub-Saharan Africa will be determined by our progress in preventing new HBV infections, screening and treating existing chronic hepatitis B cases, as well as detecting and appropriately managing HCC. As part of a scorecard to monitor progress towards elimination of viral hepatitis within WHO AFRO in 2019, six core indicators were listed; (1) development of national hepatitis policies in the form of a national strategic plan for viral hepatitis; (2) implementation

of hepatitis B birth dose vaccination; (3) achieving > 90% national coverage of the third dose of the hepatitis B vaccine; (4) being on track for the HBV and HCV 2020 testing target; (5) implementation of a national hepatitis treatment programme; and (6) commemoration of World Hepatitis Day in 2018. Overall, most sub-Saharan African countries were found lagging in almost all indicators[16].

Within the next decade, there is a need to scale-up primary prevention of incident HBV infections in sub-Saharan Africa. Despite adopting resolutions to improve hepatitis B birth dose and routine childhood vaccination in WHO AFRO by 2020, implementation and coverage of the birth dose remains unacceptably low, while coverage of routine childhood vaccination remains well below the global average of 84%[49,105,106]. Recognizing the significant threat of HBV MTCT to public health in sub-Saharan Africa, there have been renewed calls to expand access to the hepatitis B birth dose and leverage HIV PMTCT infrastructure in screening pregnant women and providing timely prophylaxis[56,98,107]. The future research agenda in sub-Saharan Africa should include investigating the need for tailored hepatitis B vaccination strategies for unique populations like HIV-exposed uninfected children.

As national governments grapple with the feasibility of implementing subsidized hepatitis surveillance and treatment programmes, the success of the HIV test and treat model in sub-Saharan Africa has been recognized as an opportunity to expand screening and antiviral treatment for chronic hepatitis B in the interim. To ensure a comprehensive package of care, there is a need to prioritize integration of cost-effective point-of-care screening tests with good diagnostic accuracy, guided by appropriate treatment eligibility criteria[49,108].

Within the past decade, there have been significant advances in the development of new diagnostic and therapeutic approaches for HCC, with prospects for further innovation in the field[109,110]. These advances present unique opportunities to improve surveillance and management of HCC. Biannual surveillance among high-risk chronic carriers of HBV using both liver ultrasonography and serum α-fetoprotein concentrations, is commonly used for early detection of progression to HCC. Curative treatment approaches for early-stage HCC include surgical resection, tumour ablation, or liver transplantation. For advanced-stage HCC, combination treatment using atezolizumab and bevacizumab over sorafenib alone, have shown promising long-term outcomes in phase III clinical trials[110]. Other immunotherapeutic agents for the treatment of late-stage HCC have also been recently explored[109]. While all these advancements present much needed opportunities to improve the quality of life of patients with HCC, the cost and feasibility of implementation within the sub-Saharan African public health context are always important considerations.

CONCLUSION

Ultimately, sub-Saharan Africa faces one of the toughest battles against chronic hepatitis B and HCC. Despite this, there are opportunities to achieve significant reductions in incident HBV infections and alter future trends in the burden of HCC. This calls for strong political will, regional coordination, and effective partnerships with donor agencies and non-governmental organizations in order to mobilize financial investments and technical support. Finally, the role of advocacy and awareness campaigns like World Hepatitis Day in enabling public ownership and demand for accessible, equitable, and quality health services cannot be undervalued.

Abstract

The global social, economic and political crises related to coronavirus disease 2019 (COVID-19) presumably had more indirect than direct negative impacts on health systems. Drastic lifestyle changes, social isolation and distancing, and individual and global financial crises resulted in robust populations forfeiting healthy habits and seeking comfort in alcoholic beverages, drugs and unhealthy diets. The inevitable consequences are increases in the incidence of nonalcoholic fatty liver disease, viral hepatitis, acute alcoholic hepatitis, liver cirrhosis decompensation

and ultimately liver-related mortality. The inaccessibility of regular clinical and sonographic monitoring systems has caused difficulties in the treatment of patients with chronic liver disease (CLD) and has prevented prompt hepatocellular carcinoma detection and treatment. A dramatic reduction in the number of liver donors and the transformation of numerous transplantation centers into COVID-19 units drastically decreased the rate of orthotopic liver transplantation. The indirect, unavoidable effects of the COVID-19 pandemic in the following years have yet to be determined. Substantial efforts in the management of patients with liver disease in order to overcome the inevitable COVID-19-related morbidity and mortality that will follow have yet to be initiated. Several questions regarding the impact of the COVID-19 pandemic on liver disease remain. The most important question for general CLD patients is: How will the modification of clinical practice during this pandemic affect the outcomes of CLD patients? This article reviews the influence of COVID-19 on patients with liver disease during the pandemic, with particular emphasis on the disease course associated with pandemic resolution.

INTRODUCTION

The coronavirus disease 2019 (COVID-19) pandemic has spread rapidly worldwide and poses a serious threat to healthcare systems globally. It is common to encounter patients with both COVID-19 and abnormal liver function. Because COVID-19 is a newly discovered disease, additional data are needed to improve our understanding of its impact on the liver and of the appropriate management of such patients[1-15]. Information on how COVID-19 infection affects the liver and the relevance of pre-existing liver disease in acquiring the infection or developing severe disease is increasing, although we still do not know the exact mechanism. Additionally, considerations with regard to liver transplant patients, those with hepatocellular carcinoma (HCC) and those under immunosuppressive therapy are being analyzed as information is being generated. Various treatments for COVID-19 are currently under study but some of these may be potentially hepatotoxic[4-6,15].

The first and most evident consequence of the COVID-19 pandemic is its impact on the routine care of patients with chronic liver disease (CLD). The COVID-19 pandemic shifted our perception of ambulatory patient care from face-to-face examinations to virtual patient management[15-18]. Expert recommendations guiding clinicians in the treatment of patients with CLD and of transplanted patients during the pandemic are available in the form of guidelines published by the European Association for the Study of the Liver (EASL) and the American Association for the Study of Liver

Diseases (AASLD)[16-18].

Although patients with CLD are not at higher risk of acquiring the infection, whether COVID-19 and the underlying liver disease will follow an unfavorable course remains to be answered[19]. Nonetheless, questions regarding the treatment of patients with CLD following resolution of the COVID-19 pandemic remain unknown. One must consider that a considerable number of patients with CLD did not attend regular appointments, prevented by fear of acquiring the infection. Preventive, surgical and transplant programs have become secondary focuses. In light of the present circumstances, it is evident that the burdens of the pandemic-related consequences have yet to be elucidated, not only regarding global economics but also global health[19].

This article reviews the effects of COVID-19 in patients with liver disease during the pandemic, with particular emphasis on the disease course associated with pandemic resolution (Figure 1). We performed a PubMed search using the keywords "chronic liver disease" and "COVID-19". When using this algorithm there were 396 results. In this review, 74 articles with particular emphasis on COVID-19 and liver disease were analyzed.

PRE-EXISTING CLD AND COVID-19

The reported prevalence of patients with CLD in cohorts of patients with COVID-19 does not exceed 1%, suggesting that the risk of infection acquisition is similar to that in the general population[18,20]. However, the risk of a severe course of disease might be increased due to the etiology of the underlying liver disease along with the degree of liver fibrosis[18].

Liver test abnormalities

According to reports from regular and intensive care units, elevated liver enzymes, lactate dehydrogenase, creatinine kinase and myoglobin, as well as prolonged prothrombin time, are found in more than one-third of patients during COVID-19 progression[21]. A retrospective Chinese study revealed a dynamic pattern of liver molecules regardless of the severity of infection: Aspartate aminotransferase (AST) increased, followed by an increase in alanine aminotransferase (ALT) concurrent with mild oscillations in bilirubin levels. AST levels were significantly associated with mortality risk in this group of patients[22]. Another comprehensive Chinese review also reported elevated AST and ALT levels in 6%-22% and 21%-28% of patients, respectively[23]. Compared to other Chinese regions in which 16% of patients had AST elevation, studies from Wuhan reported a higher percentage, ranging from 24% to 37%. Studies have revealed a high prevalence of liver test abnormalities in men and elderly individuals[23,24]. A large American study including 5700 patients reported that 58.4% of patients had elevated AST levels (> 40 U/L) and 39% had elevated ALT levels (> 60 U/L)[25]. Two percent of patients developed acute hepatic injury and the majority of this subgroup (95%) did not survive[25]. A severe cholestatic pattern has not been reported as correlating with COVID-19 but studies have reported hyperbilirubinemia in 11%-18% of cases[21].

Several pathological mechanisms are considered to be involved in liver injury, including direct viral infection of liver cells, drug hepatotoxicity, cytokine storm and pneumonia-associated hypoxia[15,26,27]. According to several studies, the expression of ACE2 receptors on liver cells facilitates SARS CoV-2 entrance; expression is increased in bile duct cells, whose destruction appears to be primarily responsible for COVID-19-related liver injury[15,26]. Studies clarifying the exact mechanisms of liver injury are warranted[15,27-30].

It must be considered that elevated aminotransferases might be of cardiac or muscular origin and that abnormalities in liver tests are frequently transient. On the other hand, studies have reported an increased risk of severe disease in patients who present with liver injury on admission[15,28]. The severity of liver dysfunction seems to be closely associated with the severity of COVID-19[15]. As predicted by multiple studies, the usual culprits of pathological biochemical liver abnormalities are underlying CLD, sepsis-related cholestasis and drug hepatotoxicity[6]. We must not ignore the fact that the frequency and severity of liver injury in asymptomatic individuals and patients under out-of-hospital treatment remains unknown[6]. Therefore, further investigations are needed to strengthen conclusions.

Finally, the most crucial question for clinicians treating COVID-19 patients is in whom and how often to perform liver function tests. The optimal interval has not yet

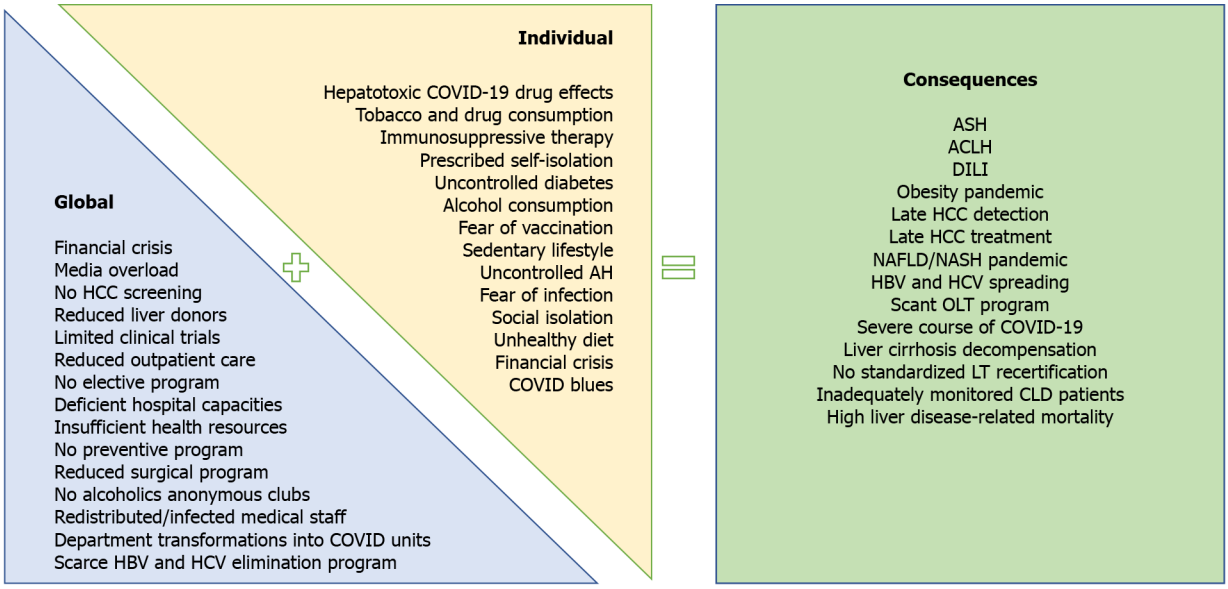

Figure 1 Global and individual effects of the coronavirus disease 2019 pandemic on liver-related morbidity and mortality. been defined, but physicians should certainly be attentive when treating severely ill patients and individuals taking novel antiviral drugs such as remdesivir or tocilizumab[6].

Nonalcoholic fatty liver disease and COVID-19

Nonalcoholic fatty liver disease (NAFLD), also known as metabolic dysfunction-associated fatty liver disease, is a common manifestation of metabolic syndrome and is remarkably prevalent in Western industrialized countries[21]. It is usually comorbid with obesity, which represents a significant risk factor for severe COVID-19 pneumonia[3,18,31]. The assumed mechanism relies on the immunological properties of adipose tissue, which also plays a role as a viral reservoir[3,18,25]. Additional risk factors accompanying NAFLD, such as arterial hypertension, obesity and diabetes, are also commonly observed in patients with a severe COVID-19 course[3,18,25].

As predicted in several studies, patients with NAFLD seem to have a longer period of viral replication and dispersion[32] and experience progression to the severe form of disease, with worsening dyspnea, hypoxia and typical radiological findings [32], even in younger patients without other comorbidities[33,34]. Among patients with NAFLD, the underlying liver fibrosis seems to correlate with severe COVID-19 presentation, regardless of other metabolic comorbidities[11,21,35]. Targher *et al*[35] also found an interrelation between advanced liver fibrosis (defined as increased Fibrosis 4 and NAFLD fibrosis scores) and severe COVID-19 presentation in a subgroup of 94 (30.3%) patients with NAFLD. However, Lopez-Mendez *et al*[36] did not confirm these findings. According to their study, although the prevalence of NAFLD and significant liver fibrosis was high in COVID-19 patients, it was not associated with worse clinical outcomes.

The exact mechanism of NAFLD-associated liver fibrosis leading to an undesired COVID-19 course has not yet been defined but presumably is potentiated by the hepatic release of multiple proinflammatory cytokines, exacerbating the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2)-induced cytokine storm[35]. On the other hand, virus-related cytokines might increase the risk of liver inflammation. This interplay of cytokine-related events forms a vicious cycle, making the NAFLD population at very high risk of COVID-19 complications[11,21].

Additional large-scale analyses are needed to determine whether NAFLD is an independent risk factor for severe COVID-19 or whether confounding factors are responsible for the previously published results. Studies based on other available noninvasive methods, including transient elastography and acoustic radiation force impulse-based techniques, are also warranted.

It is also important to note the increased predisposition for drug-induced liver injury in patients with liver steatosis[6]. Antiretrovirals such as lopinavir/ritonavir, antibiotics, antifungal agents and other drugs required to treat acute respiratory distress syndrome and systemic inflammation may induce drug-induced liver injury [37]. The possible mechanism of increased susceptibility in this group of patients is associated with oxidative stress, diminished activity of xenobiotic-metabolizing enzymes, mitochondrial malfunction and changes in lipid homeostasis[37-39]. Caution must be taken with steatogenic drugs such as amiodarone, sodium valproate, tamoxifen, methotrexate and frequently used glucocorticoids because they may induce steatohepatitis in predisposed individuals[40].

Finally, the effect of the COVID-19 pandemic on the social aspects of an individual's daily routine is the last but not least important undesirable sequela. A sedentary lifestyle, social isolation and increased consumption of processed foods are all metabolic antagonists that are especially unfavorable in patients with NAFLD[18]. The COVID-19 "blues" associated with lockdowns, loss of income and deterioration of socioeconomic status might lead to unhealthy lifestyles and consequently the promotion of obesity and associated metabolic diseases[41]. Therefore, COVID-19 will presumably be an indirect cause of expansion of the NAFLD epidemic[42]. In light of the global psychosociological COVID-19 burden, the Mayo Clinic advocates increased caution against NAFLD-promoting behaviors[42,43].

Increases in body mass index uncontrollable arterial hypertension and underregulated diabetes will certainly contribute to the worsening of NAFLD. It is therefore mandatory to treat associated metabolic comorbidities in these patients[18]. In addition, the deleterious effects of delayed detection of HCC in hepatic steatosis patients are the consequences of missed routine ultrasound examinations.

In conclusion, the EASL suggests considering early admission for all patients with NAFLD and COVID-19[18]. Encouraged by the AASLD guidelines, we recommend regular monitoring of liver function in all hospitalized COVID-19 patients[17,21]. Governments and policy makers should implement certain interventions in response to the increase in NAFLD that will insidiously follow after the COVID-19 pandemic [41]. Finally, when contemplating the introduction of lockdown in the future, the potential consequences on metabolic health should be considered[41].

Autoimmune liver disease and COVID-19

Evidence of the influence of immunosuppressive regimens on the acquisition of COVID-19 is still scarce. However, observational studies have suggested an association between glucocorticoid therapy and a severe COVID-19 course[18,44]. When treating autoimmune hepatitis (AIH) flares, the EASL suggests the administration of budesonide rather than systemic corticosteroid therapy in patients without liver cirrhosis[18]. In the clinical setting of a chronic immunosuppressive regimen it is recommended to continue treatment, except in cases of severe COVID-19, superinfections or lymphopenia that frequently follow SARS-CoV-2 infection[16]. According to the largest study of patients with AIH and COVID-19 infection there were no significant differences in the incidence of major adverse COVID-19 outcomes between patients with AIH and those with other CLD[10]. However, in this study, independent risk factors for adverse events (*i.e.*, death) in these patients were age and baseline liver disease severity. In this study, the use of immunosuppression was not associated with death in AIH patients[10]. Additional studies are needed to determine whether AIH per se or adjacent immunosuppressive treatment affect COVID-19 outcomes[18].

Alcoholic liver disease and COVID-19

Patients with alcohol use disorder (AUD) and alcohol-associated liver disease (ALD) are exemplars of the wide range of potentially negative impacts of COVID-19[45]. Primarily, social isolation and the unavailability of professional help may lead to psychological decompensation and an increased risk of relapse[45]. Depressed immune systems and other underlying comorbidities, including renal failure, obesity, chronic viral hepatitis, sarcopenia, alcoholic cardiomyopathy, tobacco use disorder and many others, make these patients easy targets for viral infection. Finally, according to published data, these patients are more prone to developing interstitial pneumonia and acute respiratory distress syndrome secondary to SARS-CoV-2 infection than their counterparts[18]. Case series of ALD individuals reported a rapid disease course, including bilobar pneumonia and acute respiratory distress syndrome requiring mechanical ventilation, with unfavorable outcomes including cardiopulmonary insufficiency and multiorgan failure[46,47]. Patients admitted for acute alcoholic steatohepatitis (ASH) are usually assessed using Maddrey's discriminant function (DF) score, with DF > 32 predicting a higher mortality rate[46]. The usual

treatment of ASH in patients with DF > 32 using the classical prednisone regimen is an additional risk factor for a severe course of COVID-19 and is therefore not recommended for patients who are self-isolating or considered at high risk of acquiring SARS-CoV-2 infection[45]. Liver impairment is frequently observed in patients with COVID-19[46]. It is also well known that ASH increases the risk of hepatorenal syndrome development, especially after contrast agent application. Cytokine damage, inadequate organ perfusion, nephrotoxic drug effects and nosocomial infections all potentiate the acute kidney injury, usually resulting in the need for continuous renal replacement therapy[47].

In order to obviate the described critical disease course with severe consequences and high mortality rate, we should focus on two main aspects in the care of ALD patients. The primary focus is the prevention, of infection by following strict epidemiologic recommendations, as well as the prevention of AUD relapse by implementing vigorous social and psychiatric care by telephone. The unavailability of support groups such as Alcoholics Anonymous should be bridged using individual or smaller group treatment[47]. The secondary focus is the prevention of a deleterious disease course using vigilant intrahospital clinical care and timely recognition of hepatobiliary, renal and respiratory complications[18].

Viral hepatitis and COVID-19

Whether chronic viral hepatitis specifically affects the COVID-19 course remains unknown. In a retrospective Italian multicenter study that included 50 patients with liver cirrhosis and SARS-CoV-2 infection, 28% had hepatitis C virus (HCV)-related cirrhosis and 10% had hepatitis B virus (HBV)-related cirrhosis. The patients were either HCV-RNA negative after anti-HCV treatment or on long-term anti-HBV treatment. The severity of liver disease was an independent predictor of mortality[29]. The same conclusion was derived from an international registry that included 152 patients with CLD and COVID-19, among which 22.5% of the CLD was due to chronic HBV or HCV infection[30].

In the last year, the COVID-19 outbreak has redirected attention from other morbidities, including viral hepatitis: as a consequence of this pandemic, most viral hepatitis elimination programs have diminished or stopped altogether[14,19,48,49]. The World Health Organization's goal of eliminating HBV and HCV and thus significantly reducing the associated mortality until 2030 has therefore been put on hold. Elimination programs are already scarce, as well as involvement by liver disease societies, epidemiologists, infection specialists and general practitioners, despite the WHO Global Hepatitis Report 2017 stating that the viral hepatitis global mortality is 1.5 million per year[19,48,49]. Preventing mother-to-child transmission and promoting blood safety are presumably the only intact weapons in the battle against HBV and HCV[19,48]. Although we will realize the full impact of reducing or delaying programs targeting hepatitis elimination in the near future, there are some mathematical models that can predict the possible impact on the global burden of viral hepatitis and hepatitis-associated morbidity and mortality that will result as a consequence of program delay[49]. A recent study used certain mathematical models to analyze the impact of delayed programs on viral hepatitis elimination[49]. The authors reported that a 1-year delay in viral hepatitis diagnosis and treatment will result in an additional 44800 HCC cases as well as 72300 deaths from HCV globally in the next 10 years[49].

If we cannot make progress in achieving the aforementioned elimination goals due to the COVID-19 crisis, then education campaigns, extensive screening, diagnostic tests, vaccination programs and treatment should at least be maintained at the former level[19,48,49].

Liver cirrhosis and COVID-19

Patients with liver cirrhosis, particularly decompensated cirrhosis, are by far the most vulnerable liver disease patients. Immune dysfunction makes them prone to any kind of infection, including SARS-CoV-2, with potentially deleterious effects on the disease course. Data suggest that the course of COVID-19 is directly connected to the degree of liver disease defined by the Child-Pugh (CP) and Model for End Stage Liver Disease scores[18].

An international registry including 103 patients with liver cirrhosis reported a 40% mortality rate, strongly correlated with the grade of liver failure: 23.9% mortality in patients with CP class A, 43.3% mortality in patients with CP class B and 63.0% mortality in patients with CP class C cirrhosis[50]. Similarly, an Italian study involving 50 patients with liver cirrhosis suffering from COVID-19 found a 30-d mortality rate of 34%, among which 71% of patients died due to COVID-related respiratory failure[51].

The largest published study to date was based on two international registries and included 745 patients with CLD (among which 52% had liver cirrhosis) and acute COVID-19 infection. When compared to the data of non-CLD patients with SARS-CoV-2 infection in a UK hospital network, a statistically significant difference in mortality ($P < 0.001$) was reported: 32% in patients with liver cirrhosis compared to 8% in those without[52]. The main cause of death was respiratory failure, with acute decompensation of liver cirrhosis occurring in 46% of patients. The authors concluded that the CP score and ALD were independent risk factors for death due to COVID-19 [52].

A prospective American multicenter study by Singh and Khan[53] compared patients with both liver cirrhosis and COVID-19 to patients with only COVID-19 and found a significant difference in the outcome (30% *vs* 13%, $P = 0.03$). However, the fact that there was no significant difference in the outcomes of patients with liver cirrhosis regarding COVID-19 infection is intriguing. It seems important to emphasize that the proportion of SARS-CoV-2-positive cirrhosis patients in this study was approximately three times lower than that in the other two subgroups.

In summary, in patients suffering from COVID-19, mortality is significantly greater in those with liver cirrhosis than in those without and is directly related to the stage of liver failure[18]. However, it remains unclear whether COVID-19-related mortality is higher than that related to other causes of decompensation that are often also infective in origin[18].

Liver cirrhosis causes 2 million deaths globally per year. Prevention of liver decompensation and prompt diagnosis and treatment of cirrhosis-related complications are of the utmost importance[54,55]. Management with endoscopic variceal screening, primary and secondary prophylaxis, implementation of telecommunication and electronic communication in drug titration, especially regarding beta-blockers and diuretic therapies, is warranted. HCC screening and diagnostic persuasion, including radiologic methods and liver biopsy, as well as therapeutic treatments ranging from radiofrequency ablation to liver transplantation (LT), should be preserved despite scarce resources, physician burnout and lack of hospital capacity[54,55].

Tapper and Asrani[55] proposed a three-wave theory to explain the effects of the COVID-19 pandemic on liver cirrhosis from the current period to future years. The first wave describes the period of physical distancing and is defined by high-acuity care and delayed elective procedures[55]. For example, patients with esophageal varices are admitted only for bleeding episodes, and elective endoscopic band ligation (EBL) is not performed due to fear of viral spread and limited healthcare resources. The direct consequence of the first phase is the second wave, appearing after the resolution of physical distancing and characterized by a high frequency of cirrhosis decompensation[55]. Continuing with the given example, a substantial number of patients with indefinitely delayed or skipped EBL procedures will begin to experience variceal bleeding episodes, leading to cirrhosis decompensation or even acute-on-chronic liver failure. Accessible, inexpensive, processed foods rich in salt, as well as alcoholic beverages, both highly consumed during pandemics, will result in the exacerbation of volume overload and also potentiate sarcopenia, which is a well-known risk factor for cirrhosis-associated morbidity and mortality[55]. The third wave will presumably comprise long-term complications. Delayed diagnosis of hepatobiliary malignancies, progression of HCC reaching the Milan criteria and the consequent elimination of patients from transplant lists, insidious deterioration of renal function, no standardized recertification of patients awaiting LT and many more complications are to be encountered. As Tapper and Asrani[55] stated, the curable will be transformed into the incurable.

HCC and COVID-19

Although there are no specific data on the outcomes of patients with HCC and COVID-19 infection, it is assumed that HCC patients will have poor outcomes, similar to those in other oncology patients[15]. However, we know that most HCC patients have pre-existing CLD and in comparison to other patients with cancers we can assume that such patients are more susceptible to the effects of COVID-19: that is, hepatic injury caused by COVID-19 can complicate existing CLD in most patients with HCC. The COVID-19 pandemic has greatly limited the medical care of HCC patients, with effects ranging from early diagnosis to treatment. As ultrasound screening examinations have mostly been delayed indefinitely, without precise upcoming appointment dates and resulting in prolonged periods without control, the risk of discovering HCC at a later stage increased in approximately 25% of patients with the biologically aggressive type of disease[55,56].

Elective hospital admissions were also delayed in the peak of the COVID-19 pandemic due to low hospital capacity and the fear of viral spread. Outpatient ambulatory care was unavailable for a certain time. Subsequently, a substantial number of patients were afraid to visit medical facilities. Therefore, diagnostic procedures such as contrast-enhanced ultrasound, multislice computed tomography, magnetic resonance imaging and liver biopsies have been delayed. Additionally, treatment options have been insufficiently maintained. Surgical resection and LT are the most affected due to a shortage of anesthetists and other medical personnel[6]. Procedures such as transarterial (chemo)embolization (TACE/TAE) and radiofrequency ablation are therefore the most important tools in treating patients with HCC. Data on the impact of COVID-19 on HCC patient care are underrepresented[56,57]. A colleague from an Italian center managed HCC patients with the goal of minimizing the impact of COVID-19 and reported their experience from February 24 to March 20, 2020, regarding the treatment of HCC patients in comparison to the same period during 2019[57]. The authors found that 11% of patients had delayed treatment of HCC for 2 mo or longer. The delayed treatment modalities comprised transarterial procedures in eight HCC patients, thermal ablation in three HCC patients and systemic therapy in two patients. Thermal ablation in the three patients was performed as an alternative procedure to surgical treatment. The results of this study represent the best efforts of clinicians to manage HCC during the COVID-19 pandemic[57].

In the case of early-stage HCC, the capacity of most hospitals for surgical treatment (resection) is limited due to the limited number of anesthesiologists as well as shortages in intensive care unit beds. Clinicians can select some patients who have been prioritized for resection and have a relatively low disease burden. Treatment modalities such as radiofrequency and microwave ablation, upfront transarterial treatment and systemic therapy may be considered as alternative methods according to the guidelines for each treatment modality[56,58]. Additionally, during the pandemic, the number of LTs were reduced or reached zero for some time due to reduced anesthetic capacity as well as a shortage of donors[56,58]. In the case of intermediate-stage HCC, a more selective approach can be used with respect to TACE in hospitals that are greatly affected by the COVID-19 pandemic. Additionally, if a specific center cannot perform TACE, systemic therapy or adequate surveillance, then imaging could be an alternative approach[56,58]. Finally, in the case of advanced-stage HCC, HCC patients who receive oral multitargeted tyrosine kinase inhibitors could be followed by clinicians for prolonged intervals or monitored by telephone or another telemedicine interface, depending on the patient's tolerance and clinical status during the COVID-19 pandemic[56,58]. The impact on the long-term outcomes of HCC due to these modifications in treatment options, as well as the delays in treatment, will soon be realized[57].

The decision to treat HCC during the pandemic should consider the availability of medical staff, risk of infection and the risk-benefit ratio for an individual patient. The management of HCC in patients is complex because it relies heavily on multidisciplinary approaches involving gastroenterologists, radiologists, hepatobiliary surgeons and oncologists, who are significantly burdened during this pandemic[15,56]. Extra coordination among different specialties is necessary to maintain clinical services for patients with HCC. It is recommended that the care and treatment of HCC patients is maintained according to the guidelines by using alternative methods of communication whenever possible in order to minimize the COVID-19 exposure risk to medical staff[15]. Widely available SARS-CoV-2 polymerase chain reaction testing is recommended before elective hospital admission, although there can never be a definite guarantee for medical personnel because a patient may be in the incubation phase of infection or the patient may contract the infection in the hospital. If the patient is acutely infected, it is reasonable to defer HCC treatment for a few weeks until after recovery from COVID-19[6].

LT AND COVID-19

LT programs have been weakened globally, even in regions where the COVID-19 prevalence has been low[59-61]. During this period of readjustment no specific guidelines were offered; however, multiple organizations released recommendations for medical personnel involved in solid organ transplantation[59-66].

Primarily, obtaining an organ from a SARS-CoV-2-infected patient is contraindicated. Moreover, screening of deceased donors, as well as recipients, is highly recommended[59-66]. In the case of unidentified infection, the donor could spread the

virus to multiple recipients, which would presumably have an unfavorable or even lethal course under severe immunosuppression[6,62].

As the risk of contracting the virus is high, even under hospital conditions, it would be appropriate to limit the number of face-to-face contacts for patients at risk of severe COVID-19. They should be advised against travel and should strictly practice physical distancing[6]. Due to cirrhosis-associated immune dysfunction, the aforementioned recommendations apply to all patients awaiting transplantation.

A further challenge is related to the staff involved in LT, who cannot be easily replaced. Quarantined, infected or redistributed personnel can prevent program realization for a certain period of time, which can have deleterious effects on potential LT recipients[59]. Therefore, splitting the team involved in LT and postoperative care into smaller subteams, as well as screening and segregating staff working with immediate post-LT patients, is recommended[59]. Compared to some other solid organ transplantations, LT is performed to preserve life. In contrast, although renal transplantation reduces dialysis morbidity and future medical costs, it is not directly lifesaving and can therefore be postponed[62]. Lifesaving transplantations, such as liver, heart and lung, have far more urgent indications and postponement may have deleterious consequences. Accordingly, it is of utmost importance that LT centers worldwide aim to restore their transplantation services.

Finally, according to preliminary data, age and comorbidity are key to determining the outcome from SARS-CoV-2 infection in LT patients[6,9].

Whether to receive vaccination is currently an unavoidable global question potentiated by substantial social media involvement. Three vaccines were approved by February 2021. Two of these, the BNT162b2 (Pfizer-BioNTech) and mRNA-1273 (Moderna) vaccines, are based on mRNAs that encode variants of the SARS-CoV-2-spiked glycoprotein[63]. Both must be administered twice, 21-28 d apart. The third approved vaccine is AZD1222, also known as the Oxford-AstraZeneca vaccine. This is an adenovirus vector that contains the full-length, codon-optimized gene that encodes the SARS-CoV-2 spike protein and should also be administered in two doses, with the second dose administered 4-12 wk after the first dose[63]. The EASL position paper recommends vaccination against SARS-CoV-2 in patients with CLD, hepatobiliary cancer and LT[63].

Post-transplant patients and COVID-19

Patients taking immunosuppressive drugs after transplantation are at increased risk of infection or viral reactivation. The exact influence of the SARS-CoV-2 virus in post-LT patients is unclear[15].

Regarding the disease course in post-transplant patients, it seems that immunosuppression might have favorable effects by disabling cytokine release syndrome, characterized by increased serum levels of interleukin (IL)-6, IL-8 and tumor necrosis factor [15,64]. A Spanish study analyzed 111 LT patients diagnosed with COVID-19[65]. During a median follow-up of approximately 3 wk, 86.5% of patients were admitted to hospital, among which 19.8% required respiratory support[65]. Surprisingly, their mortality rate (18%) was lower than in the complementary general population. Mycophenolate mofetil (MMF) administered at a dose of > 1000 mg/d was an independent predictor of severe COVID-19[65]. In contrast, treatment with calcineurin inhibitors and the mammalian target of rapamycin (mTOR) inhibitor everolimus were not associated with a severe COVID-19 course. Complete withdrawal of immunosuppression showed no benefit[65]. Therefore, MMF withdrawal or transient conversion to calcineurin inhibitors or everolimus could be beneficial for hospitalized patients until the COVID-19 resolves[65].

Vaccination in post-LT patients is recommended at approximately 3-6 mo after transplantation when immunosuppression can be reduced. This is because the immune system is too suppressed to mount the proper vaccination response in the early post-transplant period. Accordingly, vaccination of household members and of healthcare professionals caring for immunocompromised patients is advocated[63].

LIVER DISEASE AND COVID-19 IN CHILDREN

A recent review by Di Giorgio *et al*[67] nicely summarizes the current data from 105 studies on the association among pre-existing CLD and COVID-19 infection in children. According to the data, the most common liver manifestation was an elevation of transaminases[67]. The authors found that children with CLD, including those on immunosuppressive therapy (autoimmune liver disease and LT), actually do not have

a higher risk for a severe disease course of COVID-19. Additionally, they have little or no liver dysfunction[67]. As mentioned earlier, we still do not know the exact pathogenetic mechanism of liver damage in either adults or children, therefore we still do not fully understand the clinical outcomes of patients with CLD infected with COVID-19. Furthermore, there are no clear data on infectivity rates in children with CLD or regarding the presence of asymptomatic carriage of the virus in children[67]. Finally, there are no data regarding the long-term outcome of COVID-19 infection in this group of immunocompromised children[67]. Thus, further data are needed.

CURRENT STUDIES AND FUTURE DIRECTIONS

The COVID-19 pandemic has caused serious damage to the global health system and prevented the anticipation, recruitment or completion of numerous clinical trials. However, according to ClinicaTrials.gov, there are currently more than 1500 studies related to 'liver disease' in the recruitment phase[68]. In line with active clinical research and databases including patients with NAFLD and CLD, it is evident that this remains a trending topic, despite the COVID-19 pandemonium. The utilization of noninvasive methods in the assessment of liver and spleen stiffness and indirect prediction of portal hypertension remains the desired goal in the field of CLD. At the same time, clinicians worldwide are determined to find a proper therapy for NAFLD. The effects of glucagon-like peptide agonist (GLP-1) semaglutide, peroxisome proliferator-activated receptor (PPAR) agonist lanifibranor, thiazolidinediones, sodium-glucose cotransporter 2 inhibitors, prebiotics and probiotics are currently being tested in clinical trials[69-73]. Furthermore, the impact of fecal microbiota transplantation on obese patients with NAFLD is being researched on participants in India[74]. A selective thyroid hormone receptor-β agonist, resmetirom (MGL-3196), is in its third trial phase and the mitochondrial-derived peptide (MOTS-c) analog CB4211 is in its 1a/1b phase of evaluation among the NAFLD population[75,76]. Considering the global proportion of obese patients suffering from NAFLD, whose number under the COVID-19-created environment will undoubtedly grow, extension of the mentioned research and anticipation of future studies is encouraged.

CONCLUSION

The global social, economic and political crises related to the COVID-19 pandemic presumably had more indirect than direct negative impacts on health systems. Drastic lifestyle changes, social isolation and distancing, and individual and global financial crises resulted in a robust population forfeiting healthy habits and seeking comfort in alcoholic beverages, drugs and unhealthy diets[19,41]. The inevitable consequences are the rising incidence of NAFLD, viral hepatitis, acute alcoholic hepatitis, liver cirrhosis decompensation and ultimately liver-related mortality[19].

The inaccessibility of regular clinical and sonographic examinations has resulted in difficulties in the treatment of patients with CLD or prompt HCC detection and treatment. A dramatic reduction in the number of liver donors and the transformation of numerous transplantation centers into COVID-19 units have greatly reduced the rate of orthotopic LT.

The indirect unavoidable effects of the COVID-19 pandemic in the following years have yet to be determined[19]. Although the health system has been tremendously challenged, resulting in overwhelming damage that is continuously being revealed, focus should remain on the current and upcoming periods involving patients with uncontrolled chronic diseases[16,19]. Swift resumption of care practices, especially for patients with HCC or individuals requiring LT, must be initiated while simultaneously maintaining social distancing and balancing inadequate hospital resources[16,19].

Substantial efforts should be initiated for the management of patients with liver disease in order to prevent and control the inevitable COVID-19-related morbidity and mortality that will follow.

Several questions regarding the impact of the COVID-19 pandemic on liver disease remain. One of the most important questions is: What will be the effect of long-term anticoagulants on liver disease? The main question for general CLD patients is: How will the modification of clinical practice during this pandemic affect outcomes in CLD patients.

Abstract

Hepatitis B virus (HBV) infection is one of the main causes of morbidity and mortality worldwide. Most children acquire the infection perinatally or during early childhood and develop a chronic hepatitis characterized by a high viral replication and a low-inflammation phase of infection, with normal or only slightly raised aminotransferases. Although a conservative approach in children is usually recommended, different therapies exist and different therapeutic approaches are possible. The main goals of antiviral treatment for children with chronic HBV infection are to suppress viral replication and to warn the disease progression to cirrhosis and hepatocellular carcinoma, although these complications are rare in children. Both United States Food and Drug Administration (US-FDA) and European Medicines Agency (EMA) have approved interferon alfa-2b for children aged 1 year and older, pegylated interferon alfa-2a and lamivudine for children aged 3 years and older, entecavir for use in children aged 2 years and older, and adefovir for use in those 12 years of age and older. Tenofovir disoproxil fumarate is approved by EMA for children aged 2 years and older and by US-FDA for treatment in children aged 12 years and older. Finally, EMA has approved the use of tenofovir alafenamide for treatment of children aged 12 years and older or for children weighing more than 35 kg independent of age. This narrative review will provide the framework for summarizing indications to antiviral therapy in the management of chronic HBV infection in children and adolescents.

Core Tip: Hepatitis B virus (HBV) is a major cause of acute and chronic liver disease. During childhood, asymptomatic chronic hepatitis B is the most common outcome of the infection, and a conservative approach is usually recommended. In selected patients there is a strict indication for treatment. Different drugs have been approved by United States Food and Drug Administration and European Medicines Agency for treatment of children and adolescents with chronic HBV infection. The main goal of the treatment is to reduce the risk of progression to cirrhosis and hepatocellular carcinoma through the suppression of HBV replication.

INTRODUCTION

Hepatitis B virus (HBV) infection is one of the major causes of acute and chronic liver disease and associated morbidity and mortality worldwide. In 2015, 257 million people were estimated as being chronically infected by the World Health Organization (WHO), with a global prevalence of 3%-5%, and 887,000 people died due to chronic HBV infection (CHB)[1].

Hepatitis B is a vaccine-preventable disease but, despite the availability of effective vaccine and vaccination programs, it remains a global health problem[2]. It has been estimated that annually there are almost 2 million new infections in children younger than 5 years of age. Most of the infected children acquire the infection around the time of birth through vertical transmission or during early childhood through horizontal transmission[3-5].

NATURAL HISTORY OF HBV INFECTION IN CHILDREN

The natural history and the long-term outcome of HBV infection acquired in childhood vary depending upon the age at infection. CHB is the most common outcome (90%) of the infection acquired vertically in neonates and infants. The risk of CHB is reduced to 30% when infection occurs during the first 5 years of life and < 5% for older immunocompetent children and adults[5].

HBV infection is usually asymptomatic during childhood, but sometimes acute infection could present with severe symptoms and fulminant hepatitis both in adult and children[6]. The development of complications of CHB, such as cirrhosis, hepatocellular carcinoma, and extrahepatic manifestations, is manly observed in adulthood but can also present in infancy and early childhood[7-10].

In 2017 the European Association for the Study of the Liver (EASL) proposed a new nomenclature for CHB that is no more based on the concept of immune-tolerant, immune-active, immune-control, and immune-escape, which have been previously used to describe the different phases of infection[7]. The new nomenclature emphasizes the distinction between infection and active hepatitis (defined basing on the presence of normal or raised alanine aminotransferase levels, respectively) and is based on Hepatitis B e Antigen (HBeAg) status, HBV viremia, and liver histology (Table 1)[11].

Another biomarker to monitoring HBV infection is the covalently closed circular DNA (ccc-DNA), a new biomarker related to viral replication and persistence of infection. A "complete cure" of HBV infection requires also the clearance of ccc-DNA, as well as HBsAg loss and undetectable serum HBV DNA (otherwise it is defined "functional cure")[12].

TREATMENT FOR CHRONIC HBV INFECTION

The common and main goals of antiviral treatment for adults, adolescents, and

Table 1 Patients' categories and phases in natural history of chronic hepatitis B virus infection defined by European Association for the Study of the Liver guidelines 2017[11]

	HBeAg positive	HBeAg negative	HBsAg negative
HBV infection (normal ALT)	High HBsAg	Low HBsAg	HBcAb-positive with/without positive HBsAb
	HBV DNA > 10^7 IU/mL	HBV DNA < 2000 IU/mL	HBV DNA usually undetectable
	None/minimal liver disease	No liver disease	No liver disease
	Old terminology: Immune-tolerant	Old terminology: Inactive carrier/immune control	Old terminology: Occult HBV infection
Hepatitis B (abnormal ALT)	High or intermediate HBsAg	Intermediate HBsAg	
	HBV DNA 10^4-10^7 IU/mL	HBV DNA > 2000 IU/mL	
	Moderate to severe liver disease	Moderate to severe liver disease	
	Old terminology: immune-active	Old terminology: immune escape	

HBV: Hepatitis B virus; ALT: Alanine aminotransferase levels; HBeAg: Hepatitis B e antigen; HBsAg: Hepatitis B s antigen; DNA: Deoxyribonucleic acid; HBcAb: Hepatitis B c antibodies.

children with chronic HBV infection are the effective and sustained suppression of HBV replication and consequently to decrease the risk of disease progression to cirrhosis and hepatocellular carcinoma[13-15]. Guidelines for treatment of children and adolescents have been issued by the European Society for Pediatric Gastroenterology Hepatology and Nutrition (ESPGHAN), EASL, American Association for the Study of Liver Diseases (AASLD), and Asian Pacific Association for the Study of the Liver (APASL)[11,16-18].

The aim of this narrative review is to summarize the available evidence on the use of drugs for treatment of CHB in children and adolescents, to summarize the main recommendations for treatment, and to highlight research gaps.

Interferon alfa-2b

Interferon alfa-2b has both antiviral and immunomodulatory actions. Binding to the specific transmembrane receptor, it activates intracellular signaling and gene transcription, resulting in the reduction of viral DNA level and viral injury. Furthermore, it directly stimulates the cell-mediated immune response against HBV-infected hepatocytes, thus reducing the number of cells containing ccc-DNA[19].

Interferon alfa-2b for subcutaneous injection is approved by European Medicines Agency (EMA) and United States Food and Drug Administration (US-FDA) for treatment of children and adolescents (1-17 years of age) with CHB. Treatment duration is 16 to 24 wk. The recommended dose is 6 million IU/m^2 three times a week (Table 2).

A large open-label, multinational randomized controlled trial evaluated the safety and efficacy of interferon alfa-2b[20]. Interferon alfa-2b was started at a dose of 3 million IU/m^2 of body surface area three times a week for 1 week. The dose was increased to 6 million IU/m^2 of body surface area at the second week, and this was continued for a minimum of 16 wk and a maximum of 24 wk based on results of virological testing for evidence of response (treatment was stopped at 16 or 20 wk if HBeAg was undetectable on two serum determinations taken 1 month apart). One hundred and forty-nine children were enrolled, 144 were evaluable of whom 70 received the treatment and 77 were untreated controls. Patients in the treatment arm had a better response (loss of HBV DNA and HBeAg at 24 wk of follow-up) compared to the untreated controls (26% *vs* 11%, P = 0.02). Loss of HBsAg occurred in 7 treated children (10%) but in only 1 untreated child (1.2%) (P = 0.03). Patients with lower baseline HBV DNA (< 50 pg/mL) were more likely to respond to interferon alfa-2b therapy than patients with a baseline HBV DNA greater than 200 pg/mL (41% *vs* 7%, respectively). All children in the treatment group reported at least one adverse event, the most common being influenza-like symptoms (100%), irritability, sleep disturbance and depression (40%), nausea or vomiting (40%), diarrhea or gastrointestinal distress (46%), alopecia (17%), and neutropenia (19%). The dose of interferon alfa-2b was reduced in 17 children (23%), most commonly because of neutropenia, thrombocytopenia, and fever. Three children discontinued treatment because of an adverse event. Subsequent studies confirmed the same efficacy and safety results[21-23].

Table 2 Antiviral drugs approved for children and adolescents with chronic hepatitis B virus infection[14]

	Ages approved for drug administration	Drug dosage	Drug formulations
Interferon alfa-2b	≥ 1 yr	6 million UI/m^2 three times a week	Subcutaneous injection
Peginterferon alfa-2a	≥ 3 yr	180 μg/1.73 m^2 once a week	Subcutaneous injection
Lamivudine	≥ 3 yr	3 mg/kg daily (maximum 100 mg)	Oral solution (5 mg/mL) or tablets (100 mg)
Entecavir	≥ 2 yr	10-30 kg: 0.015 mg/kg daily (maximum 0.5 mg)	Oral solution (0.05 mg/mL) or tablets (0.5 mg and 1 mg)
		> 30 kg: 0.5 mg daily	
Adefovir	≥ 12 yr	10 mg daily	Tablets (10 mg)
Tenofovir disoproxil fumarate	≥ 2 yr[1]	8 mg/kg daily (maximum 300 mg)	Oral powder (40 mg per 1 g) or tablets (150 mg, 200 mg, 250 mg and 300 mg)
	≥ 12 yr[1]	300 mg daily	
Tenofovir alafenamide	≥ 12 yr[2]	25 mg daily	Tablet (25 mg)

[1]Approved for ≥ 2 yr by the European Medicines Agency and ≥ 12 yr by the United States Food and Drug Administration.
[2]Approved independent of age for weight > 35 kg.

Peginterferon alfa

Peginterferon alfa comprises an inert, branched, 40 kD polyethylene glycol molecule attached to interferon alfa. Through the direct stimulation of immune system, it is effective in the achievement of serological response and reduction of ccc-DNA level [19].

Peginterferon alfa-2a

Peginterferon alfa-2a for subcutaneous injection is approved by EMA and US-FDA for treatment of children and adolescents (3-17 years of age) with CHB. Treatment duration is 16 to 24 wk. The recommended dose is 180 μg/1.73 m^2 once a week (Table 2).

The efficacy and safety of peginterferon alfa-2a treatment in children with CHB was assessed in the PEG-B-ACTIVE study, a phase III randomized, controlled, open-label, multicenter study[24]. Peginterferon alfa-2a was prescribed at a dose of 180 μg/1.73 m^2 once a week and was continued for a minimum of 48 wk. One hundred and sixty-one HBeAg-positive children with raised aminotransferase levels without advanced fibrosis or cirrhosis were enrolled. One hundred and fifty-one were evaluable, of whom 101 received the treatment and 50 were untreated controls. Twenty-four weeks after the end of treatment, patients who received peginterferon alfa-2a had a better response compared to untreated controls with higher HBeAg seroconversion rates (25.7% *vs* 6%, $P = 0.0043$), higher rates of hepatitis B surface antigen (HBsAg) clearance (8.9% *vs* 0%, $P = 0.03$), HBV DNA < 2000 IU/mL (28.7% *vs* 2%, $P < 0.001$) or undetectable (16.8% *vs* 2.0%, $P = 0.0069$), and alanine aminotransferase (ALT) normalization (51.5% *vs* 12%, $P < 0.001$). Loss of HBsAg occurred in 9 treated children (8.9%) and in none of those who were untreated. The most common adverse events included fever (49%), headache (30%), abdominal pain (19%), and neuropsychiatric disorder (12%). Laboratory abnormalities reported during treatment were ALT flares (53%) and neutropenia (10%) and were managed without dose modification. Short-term effects on growth appeared minimal. The study highlighted the efficacy and positive benefit/risk profile of peginterferon alfa-2a for the treatment in children and adolescents with CHB, consistent with the extensive data available in adults.

Peginterferon alfa-2b

Peginterferon alfa-2b is not approved by the US-FDA or EMA for treatment of children or adolescents with CHB but is approved for treatment of chronic hepatitis C for children 3 years of age or older (Table 2)[25-30].

Lamivudine

Lamivudine is a synthetic nucleoside analogue (analogue of cytidine) that inhibits viral replication in human cells by interfering with the DNA polymerase enzyme of HBV, and it acts as a chain terminator of DNA synthesis. If the nucleoside analogue is

incorporated in the DNA chain, it prevents the formation of the 5' to 3' phosphodiester linkage essential for DNA chain elongation, consequently terminating viral DNA growth[31].

Lamivudine is approved by EMA and US-FDA for treatment of children and adolescents (3-17 years of age) with CHB. The recommended dose is 3 mg/kg daily, oral (maximum 100 mg; Table 2).

The efficacy and safety of lamivudine treatment in children with CHB was originally assessed in one randomized, double-blind, placebo-controlled study[32]. Children and adolescents aged between 2 and 17 years received either oral lamivudine (n = 191) or placebo (n = 97) once daily for 52 wk. This study demonstrated that treatment with lamivudine was safe, efficacious, and superior to placebo, consistent with the results observed in adults with CHB. Virologic response defined by the loss of serum HBeAg and by the reduction of serum HBV DNA to undetectable levels occurred by week 52 in 23% of the children in the treatment group, as compared with 13% of children in the placebo group (P = 0.04). The rate of virologic response increased with higher baseline ALT values and scores on the histologic activity index. Loss of HBsAg occurred in 3 treated children (2%) and in none of those who were untreated. The treatment was highly safe and the nature, incidence, and severity of adverse clinical events and abnormal laboratory values in patients receiving lamivudine were similar to those receiving placebo. The emergence of YMDD-variant HBV was detected in 19% of patients who received lamivudine for 52 wk. YMDD-variant HBV may reverse the response in some patients and has been considered a limitation of lamivudine therapy.

The efficacy of lamivudine was explored in other studies. According to a recent systematic review with meta-analysis, lamivudine, when compared to placebo, was associated with significantly higher likelihood of ALT normalization, HBeAg clearance or loss, and HBV DNA suppression but not HBeAg seroconversion or HBsAg clearance after 48 wk of treatment[33-35].

Although lamivudine is a safe drug, it has low barrier to resistance.

Entecavir

Entecavir is a nucleoside analogue (analogue of deoxyguanosine). In the intracellular environment, it is rapidly phosphorylated to the active intracellular 50-triphosphate form; this active metabolite competes with the natural substrate (*i.e.*, deoxyguanosine triphosphate) of HBV polymerase and inhibits HBV replication[36].

Entecavir is approved by US-FDA and EMA for treatment of children and adolescents aged 2 years and older with CHB. The recommended treatment dose is 0.015 mg/kg daily (maximum 0.5 mg; weight > 30 kg: 0.5 mg daily; Table 2).

The efficacy and safety of entecavir were studied in a randomized, double-blind, multicenter study including children and adolescents (2 to < 18 years) with CHB[37]. Blinded treatment was administered for a minimum of 48 wk. One hundred and seventeen patients received entecavir treatment, and 56 received placebo. Patients who achieved HBeAg seroconversion continued blinded treatment while those who did not (n = 50) were switched to open-label entecavir up to week 96 of treatment. Response rates for the combined endpoint of HBeAg seroconversion and HBV DNA < 50 IU/mL at treatment week 48 occurred in 24.2% in the entecavir group, as compared with 3.3% in the placebo group (P = 0.0008). After 48 wk of treatment, patients who received entecavir had a better response compared to untreated controls with higher rates of virological suppression (49.2% *vs* 3.3%, P < 0.0001), ALT normalization (67.5% *vs* 23.3%, P < 0.0001), and HBeAg seroconversion (24.2% *vs* 10, P = 0.02). At week 96, loss of HBsAg occurred in 7 treated children (5.8%) and in none of those who were untreated. The rate of virologic response increased with low baseline HBV DNA (< 8 Log_{10} IU/mL) and high baseline ALT (> 2 × upper limit of normal). The cumulative probability of emergent entecavir resistance through years 1 and 2 of entecavir was 0.6% and 2.6%, respectively. The treatment was well tolerated with no observed differences in adverse events or changes in growth compared with placebo. A subsequent study confirmed the same efficacy and safety results[38].

Adefovir

Adefovir is an acyclic nucleotide analogue (analogue of deoxyadenosine-5´-monophosphate). It is converted by adenylate kinase to adefovir diphosphate, an active derivate that selectively inhibits the HBV polymerase. Adefovir diphosphate competes with deoxyadenosine-5´-triphosphate during HBV DNA synthesis, and, when incorporated into the HBV DNA chain, it discontinues further elongation of DNA chain, stopping HBV replication[39].

Adefovir is approved by US-FDA and EMA for treatment adolescents aged 12 years and older with CHB. The recommended treatment dose is 10 mg daily (Table 2).

The efficacy and safety of adefovir were studied in a randomized, double-blind, multicenter study including children and adolescents (2 to < 18 years) with CHB[40]. Treatment was administered for 48 wk. One hundred and eighteen patients have received adefovir treatment and 58 received placebo. Response rates for the combined endpoint of HBV DNA < 1000 copies/mL and normal ALT at treatment week 48 occurred in 19.1% in the adefovir group, as compared with 1.7% in the placebo group ($P < 0.001$). This result was primarily due to response in the 12 to 17 years age group as in the younger children, although there were apparent differences in response to those treated with adefovir compared to those who received placebo, they did not reach statistical significance. After 48 wk of treatment, patients who received tenofovir had a better response compared to untreated controls with higher rates of ALT normalization (56% *vs* 21%, $P < 0.0001$) and HBeAg seroconversion (15.9% *vs* 5.3%). More patients treated with adefovir met the combined endpoint of HBeAg seroconversion and HBV DNA < 1000 copies/mL plus normal ALT (10.6% *vs* 0/57, $P = 0.009$). Only 1 patient in the adefovir group achieved HBsAg seroconversion. The rate of virologic response increased with low baseline HBV DNA (< 8.8 Log_{10} IU/mL) and high baseline ALT (> 2.3 X upper limit of normal). No subject developed the rtA181V or rtN236T mutation associated with adefovir resistance by treatment week 48. The treatment was well tolerated with no observed differences in adverse events compared with placebo.

A subsequent study confirmed the same efficacy and safety results[41].

Tenofovir disoproxil fumarate

Tenofovir disoproxil fumarate (DF) is an inhibitor of DNA polymerase. *In vivo* it is converted by diester hydrolysis to tenofovir, an acyclic nucleotide analogue (analogue of deoxyadenosine-5´-monophosphate), and after two phosphorylation steps to its active metabolite, tenofovir diphosphate. In this form, tenofovir binds to active site of enzyme, avoiding the attaching of the natural substrate deoxyadenosine-5´-triphosphate, and inhibits the HBV DNA polymerase activity[42].

Tenofovir DF is approved by EMA for children aged 2 years and older and by US-FDA for treatment of children aged 12 years and older with CHB. The recommended treatment dose is 8 mg/kg daily (maximum 300 mg) for younger children and 300 mg daily for those older than 12 years (Table 2).

The efficacy and safety profile of tenofovir DF were studied in a randomized, double-blind, multicenter study including adolescents (12 to < 18 years) with CHB [43]. Blinded treatment was administered for 72 wk. One hundred six patients were enrolled, and 101 completed 72 wk of treatment. Fifty-two patients have received tenofovir DF treatment and 54 received placebo. Virologic response (HBV DNA < 400 copies/mL) at treatment week 72 was observed in 89% of patients who received tenofovir DF and none of those who received placebo ($P < 0.001$). The treatment was well tolerated with no observed differences in adverse events compared with placebo. No resistance to tenofovir DF developed through week 72.

Tenofovir alafenamide

Tenofovir alafenamide is a pro-drug of tenofovir diphosphate, thus it presents the same action mechanism of tenofovir DF causing causes viral DNA chain termination and preventing viral DNA transcription[42].

Tenofovir alafenamide is approved by EMA for treatment of children aged 12 years and older and, independent of age, for children weighing more than 35 kg. The recommended treatment dose is 25 mg daily. Tenofovir alafenamide was approved on the basis of studies in children with human immunodeficiency virus infection[44,45].

Telbivudine

Telbivudine is not approved by the FDA or EMA for pediatric use.

Pros and cons of anti-HBV treatment

Overall interferon based treatments are associated with higher HBeAg and HBsAg seroconversion rates and could be used for treatment of finite duration. Concerns are present with regard to tolerance and safety, and recently the availability of the drug on the market has been questioned. Furthermore, interferon and peginterferon treatments have the disadvantage of subcutaneous administration that is relevant for treatment of children.

Nucleot(s)ide analogues have been classified as having low (lamivudine, adefovir, telbivudine) and high (tenofovir, entecavir) genetic barrier to resistance and are generally used for oral treatment of indefinite duration, with an overall good safety profile[14,15].

New prospective antiviral treatment strategies

Recently, there is a growing interest in some new therapeutic strategies, targeting viral life cycle or improving antiviral immune response, that could eliminate all replicative intermediates, including ccc-DNA. The drugs targeting different steps of HBV life cycle include entry inhibitors; polymerase inhibitors; core protein (nucleocapsid) inhibitors; HBsAg release inhibitors; RNA silencers. On the other hand, the new therapies to improve anti-HBV immunity response include therapeutic vaccines, generating "new" T cells; toll-like receptor 7 and toll-like receptor 8 agonists, stimulating antiviral effector cells; retinoic acid-inducible gene I agonist; anti-HBV antibodies; checkpoint inhibitors; programmed cell death protein 1 (PD1) and PD1 ligand inhibitors, rescuing the T-cell exhaustion that can be observed in chronic HBV infection. Results of preclinical and early clinical studies are promising; thus, soon, these treatment options could be available and could potentially transform the future indications for hepatitis B treatment[46-49].

INDICATION FOR TREATMENT

The decision to start treatment in a child with CHB is based on the combined assessment of stage of liver disease, HBV DNA and ALT concentrations, and HBeAg status. Presence of other features, such as a family history of hepatocellular carcinoma, human immunodeficiency virus coinfection or other concomitant liver disease, is an additional factor to support treatment initiation. Regardless of age, all guidelines recommend treatment for children with cirrhosis, histological evidence of necroinflammation and fibrosis (active hepatitis), and fulminant or severe acute hepatitis B infection and for those undergoing immunosuppression or chemotherapy with evidence of past or ongoing HBV infection[11,13,16-18].

There are some differences between recommendations provided by the available guidelines for the treatment of CHB in children not satisfying the above treatment criteria that are highlighted in Table 3[14].

Interferon, entecavir, and tenofovir DF are recommended for treatment of chronic HBV infection in children by ESPGHAN, AASLD, and APASL. Entecavir is recommended for children aged 2–12 years in WHO guidelines while interferon is not included because its use in resource limited settings is often not feasible as a result of its high cost, requirement for injection, and high rate of adverse effects that require careful monitoring. The advantages of interferon and peginterferon as compared with nucleoside and nucleotide analogues are the absence of viral resistance and the predictable finite duration of treatment. However, the use of interferon and peginterferon requires subcutaneous injections and is associated with a high risk of adverse events. Tenofovir (tenofovir DF or tenofovir alafenamide) or entecavir have high genetic barrier and are recommended as preferred initial therapies for adults by EASL, AASLD, and WHO.

CONCLUSION

Treatment guidelines provided by the different major scientific international societies (ESPGHAN, AASLD, APASL, EASL) clearly agree on treating all patients with advanced liver disease (cirrhosis) and histological features of active hepatitis and patients with fulminant or severe acute hepatitis B infection, preventing uncontrolled HBV replication and serious complications such as cirrhosis and hepatocellular carcinoma in young adult life. The guidelines also recommended antiviral therapy for children and adolescents with HBV infection (immune-tolerant patients) undergoing immunosuppressive therapy, such as those patients who will be receiving chemotherapy or stem cell or solid organ transplantation.

All others HBV infected children who not satisfy the above treatment criteria are not typically candidates for treatment. For these patients a tight clinical, biochemical and no invasive imaging (abdominal ultrasound) follow-up will be important to monitoring the natural course of HBV infection, to identify patients undergoing

Table 3 Differences among recommendations and indications for treatment of chronic hepatitis B virus infection in adults, adolescents, and children from five professional societies or international organizations

Organization	
ESPGHAN[16]	HBeAg-positive adolescents and children with persistent alanine aminotransferase elevation for at least 6 mo
	HBeAg-negative adolescents and children with persistent alanine aminotransferase elevation for at least 6 mo for at least 12 mo
	HBV DNA > 2000 IU/mL and either
	Moderate necroinflammation or fibrosis
	Mild inflammation or fibrosis with a family history of hepatocellular carcinoma
AASLD[17]	HBeAg-positive adolescents and children with both elevated alanine aminotransferase and measurable HBV DNA concentrations
	Therapy should be deferred when HBV DNA is < 10000 IU/mL, until spontaneous HBeAg seroconversion is excluded
APASL[18]	Non-cirrhotic HBeAg-positive adolescents and children when HBV DNA level is higher than 20000 IU/mL and alanine aminotransferase is more than twice the upper limit of normal for more than 12 mo
	Non-cirrhotic HBeAg-positive adolescents and children either HBV DNA > 20000 IU/mL and ALT more than two times ULN for more than 12 mo, or a family history of hepatocellular carcinoma or cirrhosis and moderate-to-severe inflammation or pronounced fibrosis
	Non-cirrhotic, HBeAg-positive chronic HBV infection, HBV DNA < 20000 IU/mL and moderate to severe inflammation or pronounced fibrosis
	Non-cirrhotic, HBeAg-negative chronic HBV infection, HBV DNA > 2000 IU/mL, and ALT more than two times ULNNon-cirrhotic, HBeAg-negative chronic HBV infection and moderate to severe inflammation or pronounced fibrosis, regardless of HBV DNA concentration
EASL[11]	A conservative approach is warranted

ESPGHAN: European Society for Paediatric Gastroenterology Hepatology and Nutrition; HBeAg: Hepatitis B e antigen; HBV: Hepatitis B virus; DNA: Deoxyribonucleic acid; AASLD: American Association for the Study of Liver Diseases; APASL: Asian Pacific Association for the Study of the Liver; ALT: Alanine aminotransferase levels; ULN: Upper limit of normal; EASL: European Association for the Study of the Liver.

spontaneous HBeAg seroconversion, and above all to recognize rapidly those children with chronic HBV infection who may benefit from treatment (*e.g.*, patients with persistently abnormal ALT levels).

The establishment of pediatric treatment registries and of new international associations would be the most important strategy to inform best practices for the management, care, and treatment of children with HBV infection and to promote collaborative research.

Abstract

BACKGROUND

Colorectal cancer (CRC) is the third most common cancer and the second most common cause of cancer-related death worldwide. The 5-year survival rate of patients with early-stage CRC could reach 90%, but it is very low in patients with advanced-stage CRC. Recent studies have shown that circular RNAs play important roles in regulating the migration and invasion of CRC cells.

AIM

To elucidate the role of circRNA_0084927 (circ_0084927) in the migration and invasion of CRC cells and its underlying mechanism.

METHODS

Clinical tissue samples and cells were collected, and the expression of circ_0084927 was detected by quantitative polymerase chain reaction (qPCR). The diagnostic performance of circ_0084927 was assessed by receiver operating characteristic curve analysis. The role of circ_0084927 in CRC cell proliferation, migration, and invasion was determined using cell counting kit-8 assay, wound healing assay, and transwell assay, respectively. The regulatory relationship among circ_0084927, miRNA-20b-3p (miR-20b-3p), and glutathione S-transferase mu 5 (GSTM5) was identified using databases, luciferase reporter assay, qPCR,

and Western blot analysis. AKT-mTOR signaling was also verified after circ_0084927 knockdown or miR-20b-3p mimic treatment.

RESULTS

The expression of circ_0084927 was significantly increased in CRC tissues and cells, and it was higher in advanced-stage CRC compared with early-stage CRC. The area under the curve (AUC) of circ_0084927 was 0.806 [95% confidence interval (CI): 0.683-0.896]. In addition, the AUC was 0.874 (95%CI: 0.738-0.956) in patients with advanced-stage CRC and 0.713 (95%CI: 0.555-0.840) in those with early-stage CRC. Knockdown of circ_0084927 inhibited the migration and invasion of HCT116 cells. Moreover, circ_0084927 was found to act as a sponge of miR-20b-3p. MiR-20b-3p activation reduced the circ_0084927 level, whereas miR-20b-3p inhibition increased the circ_0084927 level. But the effect was not found after circ_0084927 mutation. In addition, miR-20b-3p expression in CRC patients was also reduced and negatively correlated with circ_0084927 expression. The function of circ_0084927 in HCT116 cells with circ_0084927 knockdown was rescued by miR-20b-3p. Moreover, GSTM5 expression was significantly decreased after overexpressing miR-20b-3p or inhibiting circ_0084927, but its expression was rescued when circ_0084927 and miR-20b-3p were both inhibited. Finally, AKT-mTOR signaling was markedly regulated by circ_0084927 and miR-20b-3p.

CONCLUSION

The expression of circ_0084927 is significantly increased in CRC and higher in advanced-stage CRC than in early-stage CRC. Moreover, circ_0084927 potentially regulates CRC cell migration and invasion *via* the miR-20b-3p/GSTM5/AKT/mTOR pathway.

INTRODUCTION

Colorectal cancer (CRC) is the third most common cancer and the second most common cause of cancer-related death worldwide, and the numbers of new cases and deaths in 2018 were 1.8 million and 881000, respectively[1]. With the development of diagnostic and therapeutic technologies, the 5-year survival rate for CRC patients has reached 65%[2] and can reach 90% in early-stage CRC patients. However, the 5-year survival rate of patients with advanced-stage CRC is very low due to tumor metastasis and other complications. Although colonoscopy is the gold standard of CRC screening, approximately 60% of CRC patients are diagnosed at an advanced stage

P-Editor: Liu JH

given the rate of missed lesions and incomplete colonoscopy coverage[3-5]. Therefore, it is urgent to elucidate the pathogenesis and molecular mechanism of CRC with metastasis.

Circular RNAs (circRNAs), as important regulatory noncoding RNAs, have become a new research hotspot following microRNAs (miRNAs) and long noncoding RNAs. Researchers have demonstrated that circRNAs play important roles in tumors, including CRC[6-9], and their functions are completed in a variety of ways, such as acting as sponges of miRNAs[6,7], acting as transcriptional regulators[10,11], and translating proteins by combining with RNA binding proteins[12-15]. However, to date, the functions of circRNAs in CRC remain largely unknown, especially in CRC with metastasis. Further study to elucidate the function of circRNAs in CRC with metastasis is needed.

In this study, we first verified the differential expression of circRNA_0084927 (circ_0084927) according to previous circRNA sequencing data[16] and further found that circ_0084927 was associated with the pathological stage of CRC. Then, we demonstrated that knockdown of circ_0084927 markedly inhibited HCT116 cell migration and invasion. Regarding the regulatory mechanism of circ_0084927, it acts as a sponge of miRNA-20b-3p (miR-20b-3p), regulating glutathione S-transferase mu 5 (GSTM5) and the AKT-mTOR pathway. Therefore, our findings elucidated the role of circ_0084927 and provided a new treatment strategy for CRC with metastasis.

MATERIALS AND METHODS

Clinical tissue specimens

Thirty pairs of CRC tissues and adjacent normal tissues (normal) were obtained during surgery at the Longhua Hospital Affiliated to Shanghai University of Traditional Chinese Medicine (Shanghai, China). The diagnosis of CRC was confirmed based on pathological evidence. Tissues were snap-frozen in liquid nitrogen and stored at -80 °C before detection. The study was approved by the Ethics Committee of Longhua Hospital (No. 2019LCSY020), and informed consent was obtained from all participants.

Cell culture and transfection

Normal colon cells (FHC) and CRC cells (HCT116, HT29, SW480, and SW620) (Shanghai Cell Bank, shanghai, China) were cultured in Dulbecco's modified Eagle's medium supplemented with 10% fetal bovine serum and penicillin/streptomycin (100 U/mL) (Gibco, Carlsbad, United States) in an incubator with 5% CO_2 at 37 °C. In addition, human embryonic kidney 293T (HEK-293T) cells obtained from American Type Culture Collection (ATCC) (Manassas, United States) were cultured in Roswell Park Memorial Institute 1640 medium with 10% fetal bovine serum and penicillin/streptomycin (100 U/mL). Short hairpin circ_0084927 plasmid (sh-circ_0084927; GeneChem, China) and miR-20b-3p mimic/inhibitor or negative control (NC, Genomeditech, China; 200 nM) were transfected using FuGene HD transfection reagent (Promega, United States) according to previous studies[17,18].

Cell counting kit-8 assay

After transfection, HCT116 cells were seeded into 96-well plates at a concentration of 1 × 10^4 cells and cultured for 0 h, 24 h, 48 h, and 72 h. Then, 10 μL of cell counting kit-8 reagent was added to each well. After incubation at 37 °C for 1 h, the absorbance value was detected at 450 nm.

Wound healing assay

After transfection, HCT116 cells were seeded in a 6-well dish with a culture insert (Ibidi, Germany) at a concentration of 3 × 10^4 cells. After 24 h, the culture insert was removed, and the cells were washed twice with polybutylene succinate. Two milliliters of serum-free medium were added to each dish for 48 h. Images were captured, and the wound area was measured using Image J software (National Institutes of Health, United States).

Cell migration invasion assay

Six-well plates with 8-μm chambers (Corning, United States) were used to assess cellular migration (without Matrigel) or invasion (with Matrigel). Briefly, transfected HCT116 cells were seeded in 6-well plates at a concentration of 1 × 10^5 cells. Two

hundred microliters of serum-free medium was added to the upper chamber, and six hundred microliters of medium with 30% fetal bovine serum was added to the lower chamber for 48 h. Then, the cells were fixed with 4% paraformaldehyde for 30 min and stained with 0.1% crystal violet solution for 15 min. Four fields were randomly selected to calculate the number of migrating or invading cells and to evaluate the ability of cell migration or invasion.

Quantitative polymerase chain reaction

Total RNA was extracted using TRIzol reagent (Ambion, United States). For circRNA and mRNA analysis, cDNA was synthesized using an EVM-MLV reverse transcription kit (Aikeri Biotech, Hunan, China). For miRNA analysis, cDNA was synthesized using a miRNA cDNA synthesis kit (Sangon Biotech, Shanghai, China). The amplification reaction was performed using the SYBR-Green quantitative polymerase chain reaction (qPCR) kit (Thermo Fisher Scientific, MA, United States) or the miRNA fluorescence quantitative PCR kit (Sangon Biotech). Gene expression was normalized using β-actin or U6. The primers are listed in Table 1.

Western blot analysis

Cells were collected and lysed. Protein concentration was determined using a protein assay kit (Beyotime, China). The protein was separated and transferred to a polyvinylidene fluoride membrane followed by incubation with 5% milk at room temperature for 1 h. The membrane was incubated at 4 °C overnight with the following antibodies: GSTM5 (GTX108776, Genetex, United States), PI3 kinase p85 (PI3K, 4292S, CST, United States), phospho-PI3K (BS-3332R, Bioss, China), Akt (4685S, CST), phospho-Akt (4060S, CST), mTOR (2983S, CST), phospho-mTOR (5536S, CST), and β-actin (4970s, CST). Then, the secondary antibody was added and incubated at room temperature for 2 h, and protein expression was observed using a chemiluminescence gel imaging system (Tanon 5200, China).

Double luciferase reporter assay

HEK-293T cells were seeded in 24-well plates and transfected using FuGene HD transfection reagent (Promega, United States) according to previous studies[17,18]. Briefly, HEK-293T cells were transfected using circ_0084927 wild type (circ_0084927-WT; Genomeditech, China) or circ_0084927 mutant (circ_0084927-Mut; Genomeditech) plasmid with or without miR-20b-3p mimic/inhibitor. After transfection for 22 h, luciferase activity was detected using the dual-luciferase reporter system (Promega).

Statistical analysis

Statistical analyses were conducted using SPSS 24.0 software. Data were assessed using Student's *t*-test or one-way ANOVA. Pearson correlation was used to analyze the correlation between circRNA and miRNA. Receiver operating characteristic (ROC) curve analysis was performed to evaluate the diagnostic value using MedCalc software. $P < 0.05$ was considered statistically significant. Dr. Ming Yang from the Good Clinical Practice Office, Longhua Hospital, Shanghai University of Traditional Chinese Medicine reviewed the statistical methods of this study before submission.

RESULTS

Circ_0084927 is markedly increased in CRC and associated with the pathological stage of CRC

Our previous study has proved that circRNAs play important roles in the transition of adenoma into CRC[16], but the function of circRNAs in advanced-stage CRC remains largely undetermined. According to previous circRNA sequencing data[16], five differentially expressed circRNAs were chosen and verified. The results showed that circ_0084927 expression was significantly increased in the CRC group compared with the normal group and was higher in advanced-stage CRC compared with early-stage CRC (Figure 1A and B). The other four circRNAs were not significantly different (Supplementary Figure 1). In addition, circ_0084927 expression in CRC cells (HCT116, HT29, and SW620) was also increased (Figure 1C). ROC curve analysis was used to evaluate the diagnostic performance of circ_0084927 in CRC. The area under the curve (AUC) of circ_0084927 was 0.806 (95%CI: 0.683 to 0.896) ($P < 0.001$). In addition, the AUC was 0.874 (95%CI: 0.738-0.956) in patients with advanced-stage CRC and 0.713 (95%CI: 0.555-0.840) in those with early-stage CRC, indicating that circ_0084927 had

higher diagnostic performance in advanced-stage CRC ($P = 0.0153$) (Figure 1D and E).

Knockdown of circ_0084927 inhibits HCT116 cell migration and invasion

To explore the function of circ_0084927 in CRC, circ_0084927 expression was inhibited in HCT116 cells using shRNA plasma (Figure 2A), and circ_0084927 knockdown markedly inhibited HCT116 cell proliferation at 48 h and 72 h (Figure 2B). In addition, circ_0084927 knockdown also significantly inhibited HCT116 cell migration and invasion (Figure 2C-G). These results demonstrated that circ_0084927 is an oncogene

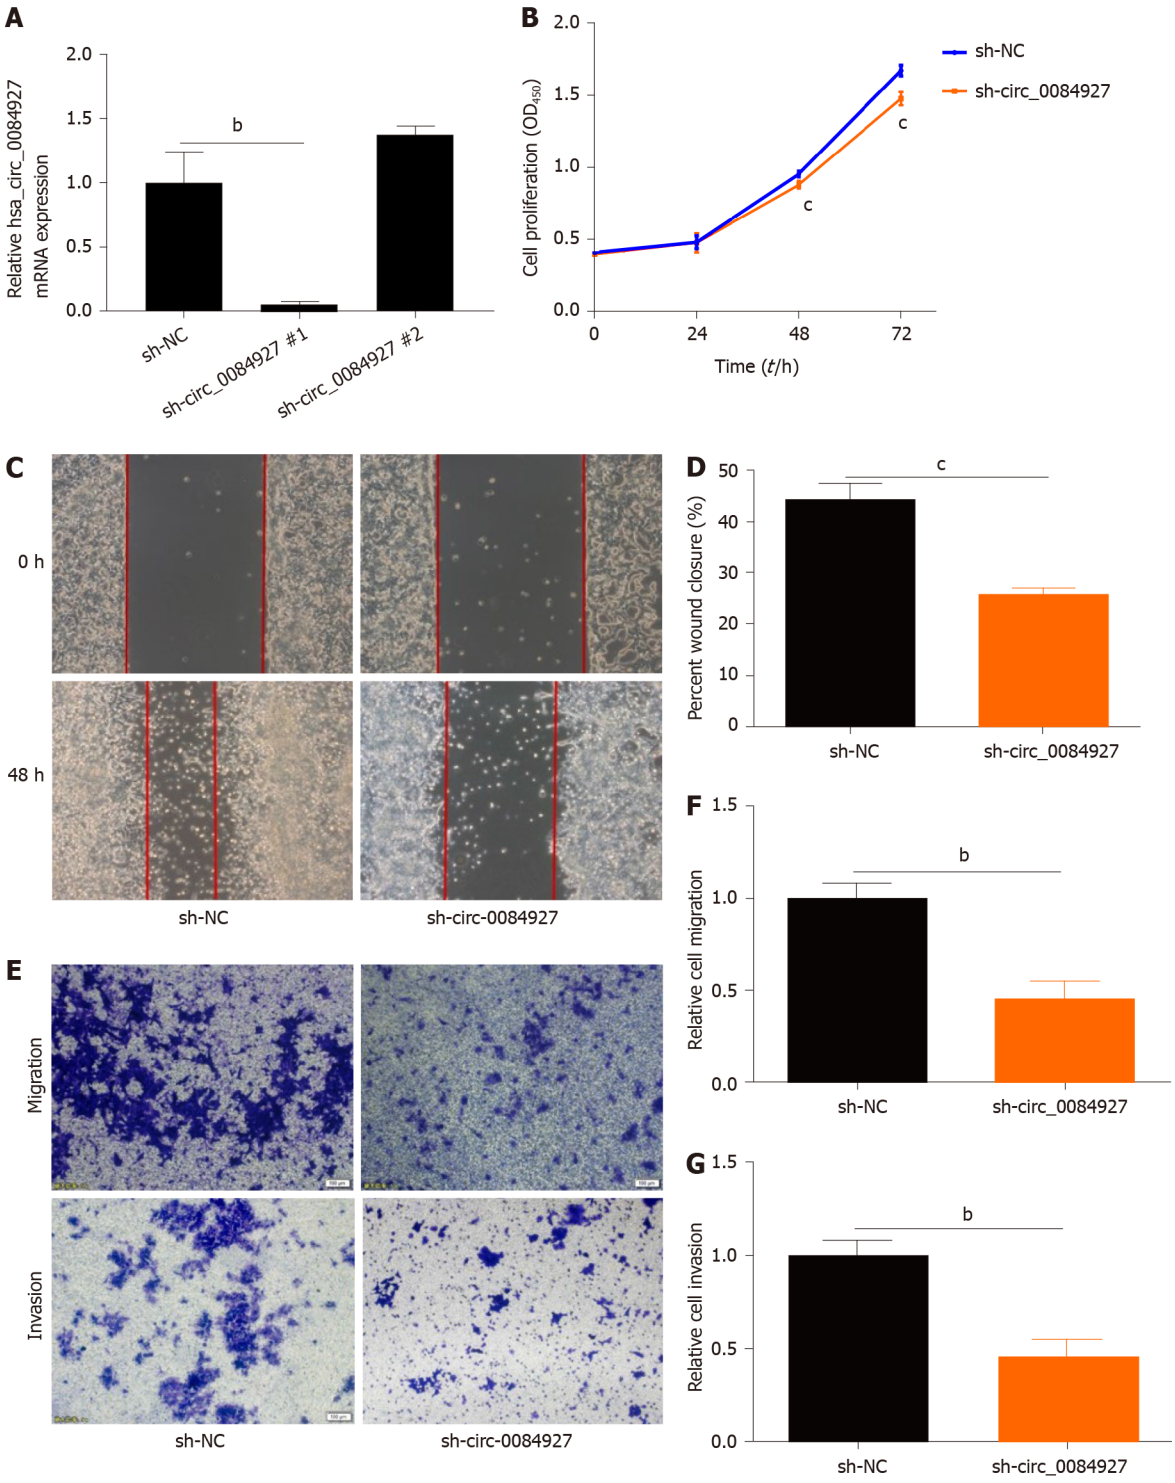

Figure 2 Knockdown of circRNA_0084927 inhibits the migration and invasion of HCT116 cells. that promotes CRC function.

Circ_0084927 acts as a sponge of miR-20b-3p in CRC

The biological function of circRNAs mainly involves acting as a sponge of miRNAs [19]. In this study, circ_0084927 may act as a sponge of miR-20b-3p as demonstrated by bioinformatics analysis (Figure 3A). The miR-20b-3p mimic markedly reduced the luciferase activity of circ_0084927, whereas the miR-20b-3p inhibitor markedly increased the luciferase activity of circ_0084927, but had no effect on circ_0084927-Mut (Figure 3B and C). qPCR results also indicated that knockdown of circ_0084927

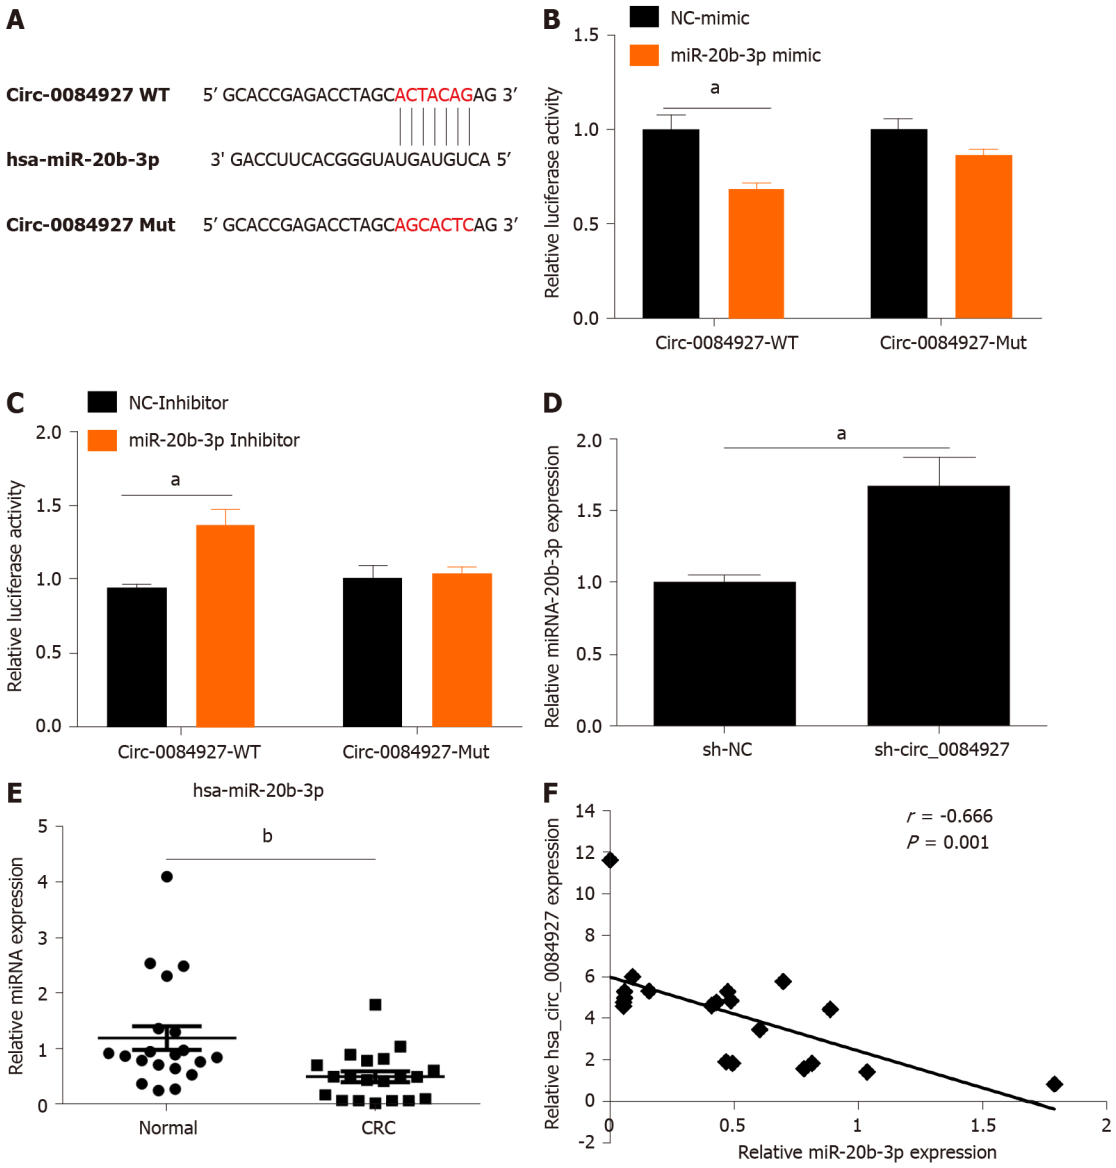

Figure 3 CircRNA_0084927 acts as a sponge of miRNA-20b-3p in colorectal cancer. A: CircRNA_0084927 (Circ_0084927) potentially acts as a sponge of miRNA-20b-3p (miR-20b-3p) in database; B: miR-20b-3p mimic could markedly reduce the luciferase activity of circ_0084927; C: miR-20b-3p inhibitor could markedly increase the luciferase activity of circ_0084927; D: circ_0084927 knockdown markedly increased the level of miR-20b-3p; E: Expression of miR-20b-3p in colorectal cancer (CRC); F: Correlation of circ_0084927 and miR-20b-3p. Data are presented as the mean ± SEM. $^{a}P < 0.05$; $^{b}P < 0.01$. Circ_0084927: CircRNA_0084927; MiR-20b-3p: MiRNA-20b-3p; NC: Negative control; CRC: Colorectal cancer; Normal: Adjacent normal tissues; Circ_0084927-WT: CircRNA_0084927 wild type; Circ_0084927-Mut: CircRNA_0084927 mutant; Sh-circ_0084927: Short hairpin circ_0084927 plasmid; Sh-NC: Short hairpin negative control plasmid.

promoted the expression of miR-20b-3p (Figure 3D). We also tested the expression of miR-20b-3p in CRC tissue samples, and its expression was significantly reduced (Figure 3E). Spearman correlation coefficient analysis revealed that circ_0084927 was negatively correlated with miR-20b-3p (Figure 3F). All of the data suggested that circ_0084927 acts as a sponge of miR-20b-3p.

The function of circ_0084927 in HCT116 cells with circ_0084927 knockdown is rescued by miR-20b-3p

To assess whether the function of circ_0084927 in HCT116 cells is mediated by miR-20b-3p, HCT116 cells with circ_0084927 knockdown was transfected with or without miR-20b-3p inhibitor (Figure 4A). The CCK-8 assay showed that circ_0084927 knockdown inhibited the proliferation of HCT116 cells, while the effect was rescued by the miR-20b-3p inhibitor (Figure 4B). Wound healing and transwell assays showed that circ_0084927 knockdown inhibited the migration and invasion of HCT116 cells, whereas miR-20b-3p inhibition rescued this effect (Figure 4C-G).

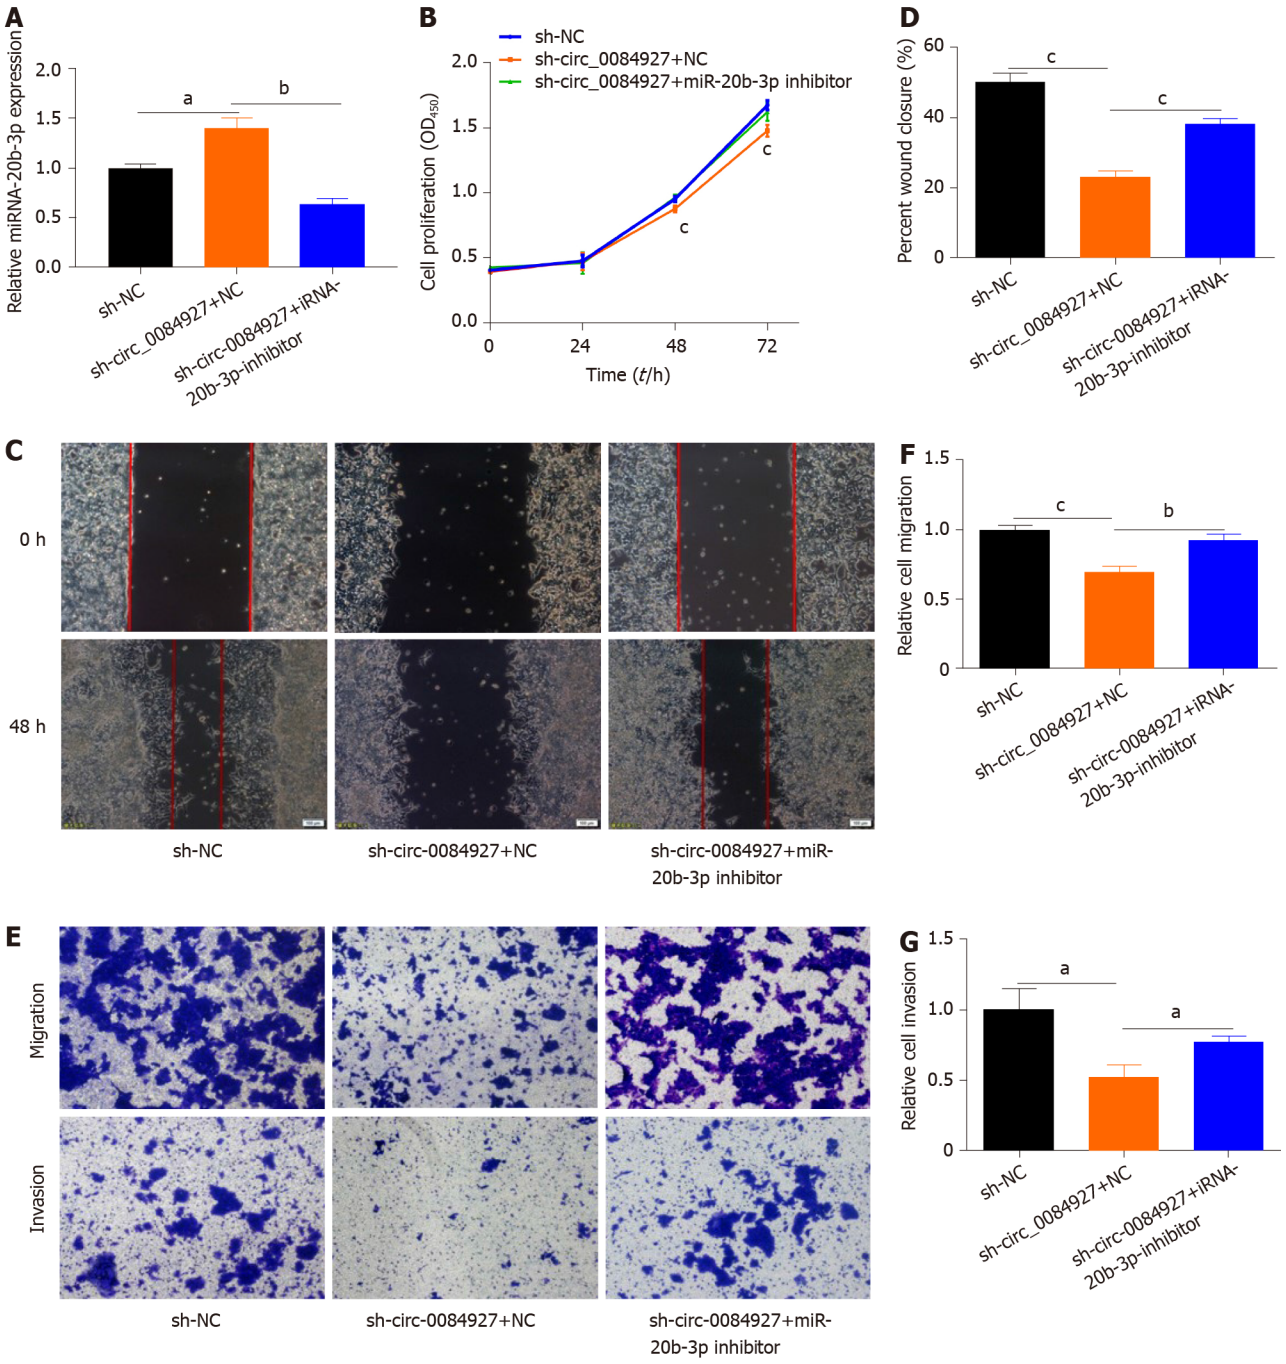

Figure 4 The function of circRNA_0084927 in HCT116 cells with circRNA_0084927 knockdown is rescued by miRNA-20b-3p. A: Expression of miRNA-20b-3p (miR-20b-3p); B: Viability of HCT116 cells detected after transfecting circRNA_0084927 (circ_0084927) or miR-20b-3p inhibitor; C-G: Migration and invasion of HCT116 cells tested by wound healing assay (C and D) and transwell assay (E-G) after transfecting sh-circ_0084927 plasmid or miR-20b-3p inhibitor. Data are presented as the mean ± SEM. $^{a}P < 0.05$; $^{b}P < 0.01$; $^{c}P < 0.001$. Sh-circ_0084927: Short hairpin circ_0084927 plasmid; Sh-NC: Short hairpin negative control plasmid; miR-20b-3p: miRNA-20b-3p.

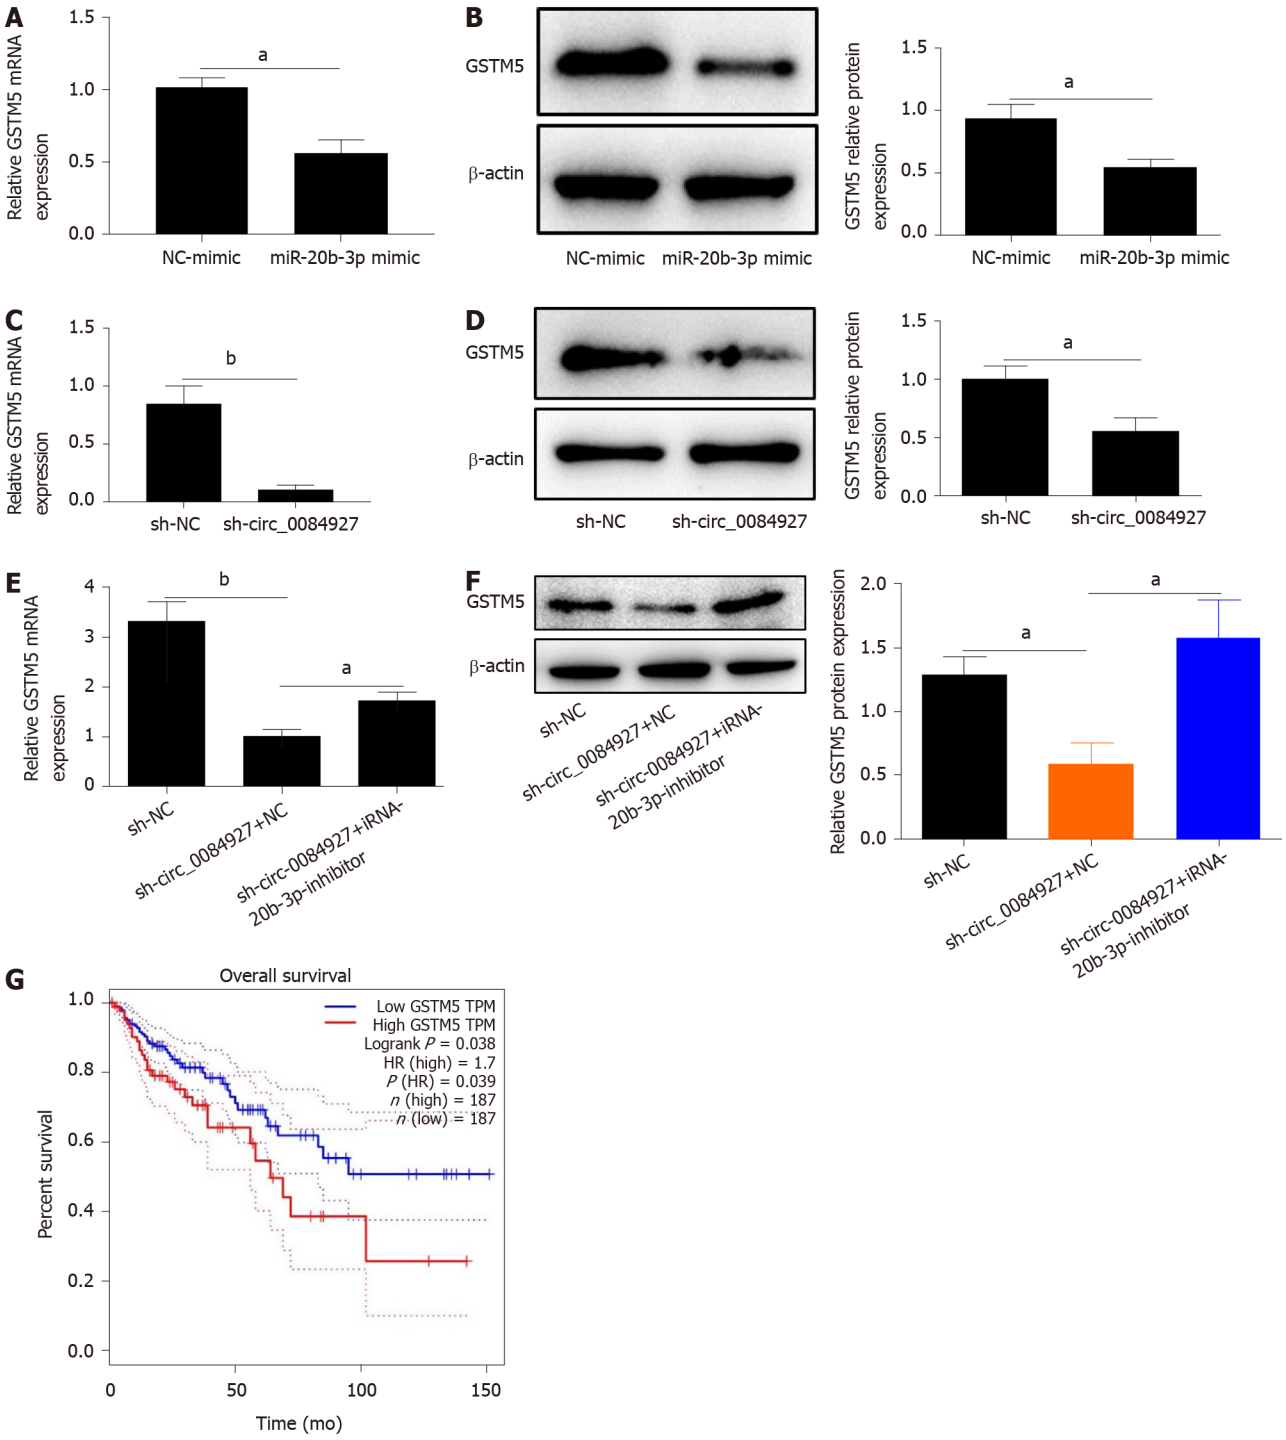
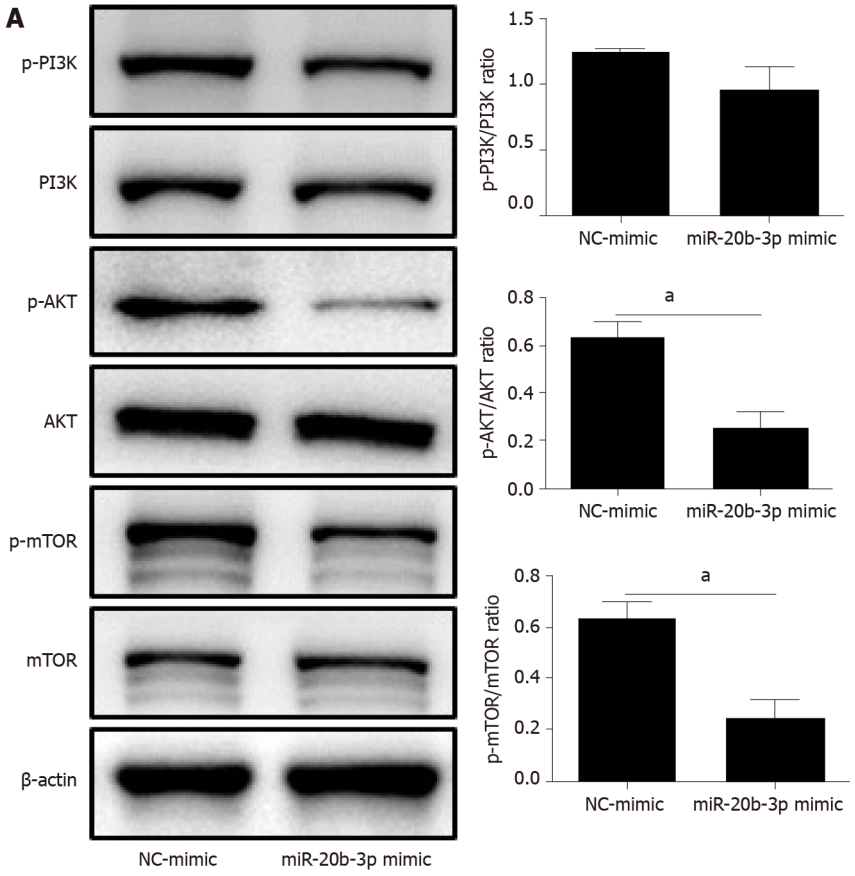
GSTM5 is a target of miR-20b-3p

According to bioinformatics analysis, we found that GSTM5 is a target of miR-20b-3p. We then assessed GSTM5 expression after overexpressing miR-20b-3p. The results showed that *GSTM5* mRNA expression was significantly reduced after overexpressing miR-20b-3p (Figure 5A). GSTM5 protein level was consistent with its mRNA level (Figure 5B). Moreover, GSTM5 mRNA and protein expression was also markedly reduced after silencing circ_0084927 (Figure 5C and D). After transfecting the miR-20b-3p inhibitor into HCT116 cells with circ_0084927 knockdown, GSTM5 mRNA and protein expression was rescued (Figure 5E and F). The survival curve results using The Cancer Genome Atlas (TCGA) data also showed that patients with high GSTM5 levels had a poor survival, indicating that GSTM5 was negatively correlated with CRC





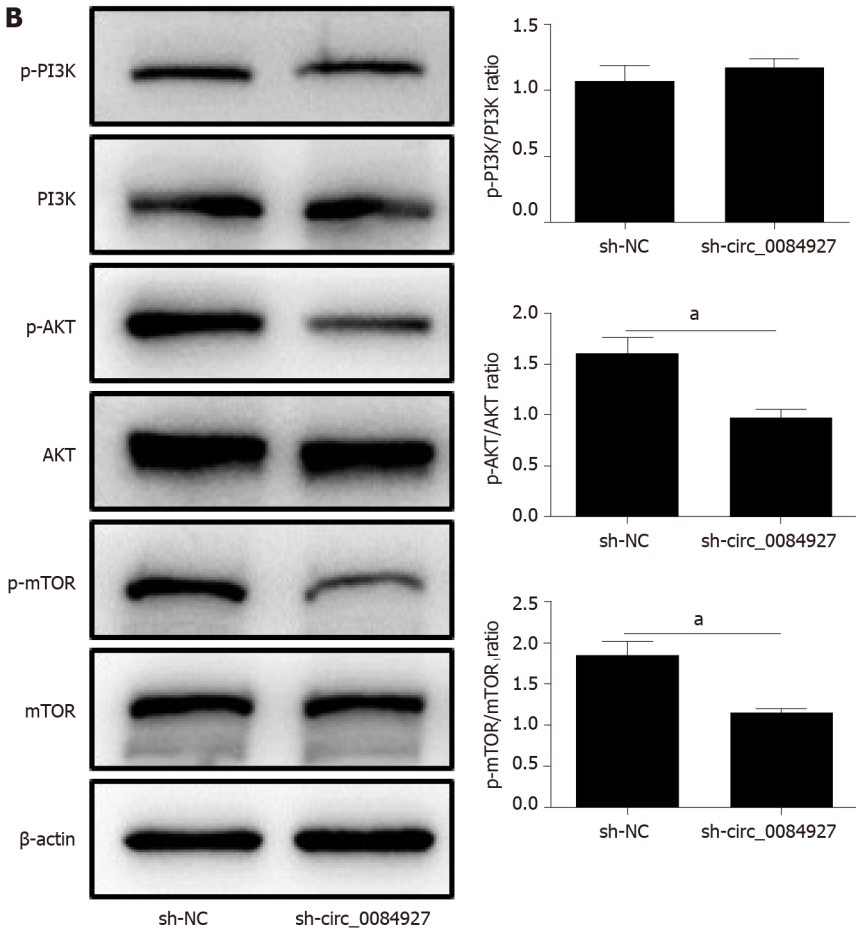


Figure 5 Glutathione S-transferase mu 5 is a target of miRNA-20b-3p. A and B: Expression of glutathione S-transferase mu 5 (GSTM5) after transfecting miRNA-20b-3p (miR-20b-3p) mimic; C and D: Expression of GSTM5 after transfecting circRNA_0084927 (circ_0084927); E and F: Expression of GSTM5 after transfecting sh-circ_0084927 plasmid and miR-20b-3p inhibitor; G: Overall survival by GSTM5 expression. Data are presented as the mean ± SEM. $^{a}P < 0.05$, $^{b}P < 0.01$. NC mimic: Negative control mimic; GSTM5: Glutathione S-transferase mu 5; miR-20b-3p: miRNA-20b-3p; Sh-circ_0084927: Short hairpin circ_0084927 plasmid; Sh-NC: Short hairpin negative control plasmid.

patient survival (Figure 5G).

The AKT-mTOR pathway is inactivated by circ_0084927 knockdown and rescued by miR-20b-3p

Further experiments found that circ_0084927 knockdown or miR-20b-3p overexpression both reduced the phosphorylation levels of AKT and mTOR (Figure 6A and B). In addition, AKT and mTOR phosphorylation levels were rescued after inhibiting miR-20b-3p in HCT116 cells with circ_0084927 knockdown (Figure 6C). These results showed that circ_0084927 regulated CRC migration and invasion *via* the miR-20b-

DISCUSSION

As a malignant tumor, the incidence of CRC has recently increased. Although the 5-year survival rate of CRC patients is 65%[2], it is very low in patients with advanced-stage CRC. Therefore, it is urgent to develop techniques for the early diagnosis of CRC, which would improve patient survival. Moreover, new treatment strategies for advanced-stage CRC are also very important. Studies have indicated that circRNAs are very stable and not easily degraded due to loop properties[20] and have demonstrated the specificity of their expression in particular tissues and tumor developmental stages[20-23]. Therefore, circRNAs, such as serum exosomal hsa-circ-0004771 and circ-PNN[24,25], could act as biomarkers for the diagnosis of CRC. In addition, circRNAs could promote the progression of CRC and act as therapeutic targets[6,8,26,27]. Circ_0084927 originates from epithelial splicing regulatory protein 1 (ESRP1), which is upregulated in CRC (Supplementary Figure 2) and associated with the pathogenesis of CRC[28]. Studies have demonstrated that circ_0084927 facilitates cervical cancer advancement[29-31], but its function in CRC is unclear. In this study, we found that circ_0084927 expression was significantly increased in CRC tissues and cells, and was higher in advanced-stage CRC than in early-stage CRC. Further studies indicated that knockdown of circ_0084927 inhibited the migration and invasion of CRC cells, showing that circ_0084927 played an important role in CRC progression.

CircRNAs perform biological functions by acting as sponges of miRNAs[6,7]. In cervical cancer, miRNAs related to circ_0084927 mainly include miR-142-3p, miR-634, and miR-1179[29-31]. Our study found that circ_0084927 acts as a sponge of miR-20b-3p in CRC. In addition, miR-20b-3p activation reduced circ_0084927 level, whereas miR-20b-3p inhibition increased circ_0084927 level. The expression of circ_0084927 was not altered after the binding site with miR-20b-3p was mutated. In addition, miR-20b-3p expression in CRC patients was also reduced and was negatively correlated with circ_0084927. Studies have shown that miR-20b-3p is related to temozolomide

resistance in glioblastoma[32] and diabetic retinopathy progression[33], but the function of miR-20b-3p in CRC has not been reported. In this study, we demonstrated that miR-20b-3p rescued the effect of circ_0084927 on CRC cells, indicating the role of miR-20b-3p in CRC.

Further studies found that GSTM5 is a target of miR-20b-3p. GSTM5 expression was significantly reduced after overexpressing miR-20b-3p or silencing circ_0084927. However, GSTM5 expression was rescued after silencing circ_0084927 and inhibiting miR-20b-3p. Studies have demonstrated that glutathione S-transferases are pro-carcinogenic in CRC[34]. AS a glutathione S-transferase, GSTM5 is also involved in various tumors, including breast cancer[35,36], prostate cancer[36], ovarian carcinoma [37], and CRC[38,39]. Although previous studies have demonstrated that glutathione metabolism is involved in the progression of tumors[40-42] and GSTM5 could be a prognostic and predictive marker in CRC[38,39], the regulatory mechanism is unknown. In this study, we demonstrated that circ_0084927 regulated the migration and invasion of CRC by the miR-20b-3p/GSTM5 axis and finally regulated the AKT-mTOR pathway, which plays an important role in CRC[43-45]. Therefore, our results revealed that circ_0084927 regulated the progression of CRC *via* the miR-20b-3p/GSTM5/AKT-mTOR pathway.

CONCLUSION

In summary, we have demonstrated that circ_0084927 expression is significantly increased in CRC and is higher in advanced-stage CRC than in early-stage CRC. Mechanistically, circ_0084927 regulates the migration and invasion of CRC cells *via* the miR-20b-3p/GSTM5/AKT-mTOR pathway. This is the first study to demonstrate the role of circ_0084927 in CRC, and these findings provide a new perspective for targeted therapy of CRC with metastasis.

ARTICLE HIGHLIGHTS

Research background

Colorectal cancer (CRC) is the third most common cancer and the second most common cause of cancer-related death worldwide. Recent studies have shown that circular RNAs play important roles in regulating the progression of CRC. However, the biological role and underlying mechanism of circRNA_0084927 (circ_0084927) in CRC remain unclear.

Research motivation

Due to tumor metastasis and other complications, the 5-year survival rate of patients with advanced-stage CRC is very low. We hope to provide a new treatment strategy for CRC with metastasis.

Research objectives

The present study aimed to investigate the role and mechanism of circ_0084927 in regulating the progression of CRC.

Research methods

Clinical tissue samples and cells were collected, and the expression of circ_0084927 was detected by quantitative polymerase chain reaction (qPCR) The diagnostic performance of circ_0084927 was assessed by receiver operating characteristic curve analysis. The role of circ_0084927 in proliferation, migration, and invasion was determined using cell counting kit-8 assay, wound healing assay, and transwell assay, respectively. The regulatory relationship among circ_0084927, miRNA-20b-3p (miR-20b-3p), and glutathione S-transferase mu 5 (GSTM5) was identified using databases, luciferase reporter assays, qPCR, and Western blot analysis. AKT-mTOR signaling was also verified after circ_0084927 knockdown or miR-20b-3p mimic treatment.

Research results

The expression of circ_0084927 was significantly increased in CRC tissues and cells, and was increased in advanced-stage CRC compared with in early-stage CRC. The area under the curve (AUC) of circ_0084927 was 0.806 (95%CI: 0.683 to 0.896). In

addition, the AUC was 0.874 (95%CI: 0.738-0.956) in patients with advanced-stage CRC and 0.713 (95%CI: 0.555-0.840) in those with early-stage CRC. Knockdown of circ_0084927 inhibited the migration and invasion of HCT116 cells. Moreover, circ_0084927 was found to act as a sponge of miR-20b-3p. MiR-20b-3p activation reduced the circ_0084927 level, whereas miR-20b-3p inhibition increased the circ_0084927 level. But the effect was not found after circ_0084927 mutation. In addition, miR-20b-3p expression in CRC patients was also reduced and negatively correlated with circ_0084927 expression. The function of circ_0084927 in HCT116 cells with circ_0084927 knockdown was rescued by miR-20b-3p. Moreover, GSTM5 expression was significantly decreased after overexpressing miR-20b-3p or inhibiting circ_0084927, but its expression was rescued when circ_0084927 and miR-20b-3p were both inhibited. Finally, AKT-mTOR signaling was markedly regulated by circ_0084927 and miR-20b-3p.

Research conclusions

The expression of circ_0084927 is significantly increased in CRC and higher in advanced-stage CRC than in early-stage CRC. Moreover, circ_0084927 potentially regulates CRC migration and invasion *via* the miR-20b-3p/GSTM5/AKT/mTOR pathway.

Research perspectives

Circ_0084927 could promote CRC progression and provide a new treatment strategy for CRC with metastasis.

Abstract

BACKGROUND

Gastric cancer is a prevalent malignant cancer with a high incidence and significantly affects the health of modern people globally. Cisplatin (DDP) is one of the most common and effective chemotherapies for patients with gastric cancer, but DDP resistance remains a severe clinical challenge.

AIM

To explore the function of M2 polarized macrophages-derived exosomal microRNA (miR)-588 in the modulation of DDP resistance of gastric cancer cells.

METHODS

M2 polarized macrophages were isolated and identified by specific markers using flow cytometry analysis. The exosomes from M2 macrophages were identified by transmission electron microscopy and related markers. The uptake of the PKH67-

authors have read the ARRIVE guidelines, and the manuscript was prepared and revised according to the ARRIVE guidelines.

labelled M2 macrophages-derived exosomes was detected in SGC7901 cells. The function and mechanism of exosomal miR-588 from M2 macrophages in the modulation of DDP resistance of gastric cancer cells was analyzed by CCK-8 assay, apoptosis analysis, colony formation assay, Western blot analysis, qPCR analysis, and luciferase reporter assay in SGC7901 and SGC7901/DDP cells, and by tumorigenicity analysis in nude mice.

RESULTS

M2 polarized macrophages were isolated from mouse bone marrow stimulated with interleukin (IL)-13 and IL-4. Co-cultivation of gastric cancer cells with M2 polarized macrophages promoted DDP resistance. M2 polarized macrophages-derived exosomes could transfer in gastric cancer cells to enhance DDP resistance. Exosomal miR-588 from M2 macrophages contributed to DDP resistance of gastric cancer cells. miR-588 promoted DDP-resistant gastric cancer cell growth *in vivo*. miR-588 was able to target cylindromatosis (CYLD) in gastric cancer cells. The depletion of CYLD reversed miR-588 inhibition-regulated cell proliferation and apoptosis of gastric cancer cells exposed to DDP.

CONCLUSION

In conclusion, we uncovered that exosomal miR-588 from M2 macrophages contributes to DDP resistance of gastric cancer cells by partly targeting CYLD. miR-588 may be applied as a potential therapeutic target for the treatment of gastric cancer.

Key Words: Gastric cancer; Cisplatin resistance; M2 polarized macrophages; Exosome; miR-588; Cylindromatosis

INTRODUCTION

Gastric cancer belongs to the most common malignant tumors and is the third cause of cancer-related death throughout the world[1]. Patients diagnosed with gastric cancer are usually at an advanced or late stage, which makes chemotherapy a prevalent strategy over the past decades[2]. Among the clinical chemotherapy agents, cisplatin (DDP) is capable of disrupting DNA repairment, which further causes DNA damage and apoptosis of cancer cells[3]. However, the developed therapeutic resistance makes the chemotherapy far less satisfactory in clinical application, which makes it urgent to decipher the mechanisms underlying this chemoresistance[4].

Tumor-associated macrophage (TAMs) are macrophages that participate in the tumor microenvironment function, and play a critical role in tumor development, including growth, metastasis, angiogenesis, and therapeutic resistance[5]. Recent studies have proposed that TAMs were capable of communicating with neighboring or distant cells *via* secreting exosomes[6,7]. Exosomes are membrane-derived transporting vesicles secreted by almost all types of cells, usually defined with a diameter ranging from 40 nm to 100 nm[8]. It is widely recognized that exosomes act as a communicator between cells through transporting various cargos such as mRNA, lipid, proteins, as well as microRNAs (miRNAs), and hence are related to various

functions of targeted cells[9,10]. miRNAs are endogenous short noncoding RNAs that play pivotal roles in the regulation of cancer development by directly targeting mRNA [11]. Besides, miRNAs are recently proposed to be involved in drug resistance of cancer cells[12-14]. Among which, miR-588 is upregulated in human prostate cancer with prognostic significance and notably facilitates the proliferation of prostate cancer cells[15]. Importantly, it has been reported that miR-588 serves as a promising prognostic marker for gastric cancer[16]. However, the role of miR-588 in DDP resistance of gastric cancer cells is still unknown. Accordingly, we were interested in the correlation of TAM-derived exosomes with miR-588 and its role in the modulation of DDP resistance of gastric cancer cells.

Cylindromatosis (CYLD) is a representative deubiquitinating enzyme that could counteract the E3 ubiquitin ligases-mediated protein ubiquitination[17]. It plays an important role in multiple cellular processes during tumorigenesis, such as cell apoptosis, cell cycle, cell migration, and DNA damage[17]. Mechanistically, CYLD is profoundly related to multiple critical signaling transduction pathways, especially the NF-κB signaling pathway, and acts as a tumor suppressor[18]. It has been extensively demonstrated that CYLD could negatively regulate the activation of NF-kB through deubiquitinating its upstream K63, which further inhibits the activation of NF-kB-related pro-survival signaling and promotes caspase-8-induced cell apoptosis[19]. It is noteworthy that recent studies also proposed that loss of CYLD could trigger DDP resistance in several cancers, including gastric cancer and oral squamous cell carcinoma[20,21].

In this study, we adopted a M2-polarized macrophage model to mimic TAM function, and testified that TAM-derived exosomes conferred DDP resistance in gastric cancer. We showed that the exosomes secreted by TAM contained miR-588, which directly interacts with the 3′ untranslated region of *CYLD* to suppress its expression and its tumor-suppressing function. This process subsequently hindered cell apoptosis and promoted the proliferation as well as DDP resistance of gastric cancer cells. Our study illustrated the connection between TAM and DDP resistance of gastric cancer cells, providing a potential target for gastric cancer therapy.

MATERIALS AND METHODS

Cell culture and treatment

Gastric cancer cell line SGC7901, purchased from ATCC, was maintained in DMEM containing 10% fetal bovine serum (FBS) and 1% penicillin and streptomycin (Sigma, United States) at 37 °C with 5% CO2. DDP-resistant SGC7901/DDP cells were developed from the parental SGC7901 cells that were subjected to persistent gradient exposure to DDP for about 12 mo, through increasing DDP concentration from 0.05 μg/mL until the cells acquired resistance to 1 μg/mL[22]. Mouse bone marrow cells (MBMCs) were purchased from Chinese Academy of Sciences Cell Bank of Type Culture Collection, and cultured in a normal DMEM:F12 medium containing 10% FBS and macrophage colony-stimulating factor (Sigma). To achieve polarization to M2, MBMCs were stimulated with interleukin (IL)-4 and IL-13 (30 ng/mL, Sigma) for 2 d. A transwell chamber assay was adopted to perform co-culture experiments, in which polarized macrophages were placed in the upper tanswell chamber and gastric cancer cells were cultured in the bottom well.

Flow cytometry

The M2 polarization was determined by staining for critical biomarkers and detection by flow cytometry. Briefly, cells were collected and incubated with fluorescence probe-conjugated antibodies against CD86, CD68, CD11b, CD80, CD206, CD163, and F4/80 at 4 °C for 30 min. Next, the cells were washed with PBS and analyzed by flow cytometry (BD Biosciences, United States). The antibodies used in this experiment were purchased from Abcam (United States).

For cell apoptosis, cells were processed with an apoptosis detection kit (Solarbio, China). Briefly, cells were collected and suspended in binding buffer, followed by staining with PI and Annexin V at room temperature for 20 min in dark. Next, the stained cells were collected and resuspended in binding buffer for analysis by flow cytometry.

Exosome isolation and analysis

Macrophages were cultured in medium containing 10% exosome-free FBS for 48 h. The medium was collected for extraction of exosomes with an exoEasy Maxi Kit (QIAGEN,

Germany) following the manufacturer's instruction.

To determine exosome internalization, the exosomes were labeled with PKH67 (Sigma) according to the manufacturer's protocol. Subsequently, the labeled exosomes were used to incubate with cells in each experiment, and observed using a confocal microscope (Carl Zeiss, Germany).

Transmission electron microscopy

The images of exosomes were captured by transmission electron microscopy (TEM). In brief, the samples were dropped on cleaned cooper grids coated with carbon, and washed with Milli-Q water to remove extra samples, followed by 1-min staining with uranyl acetate and air dry. Then, the samples were observed and pictured with a transmission electron microscope (Carl Zeiss).

Cell transfection

SGC7901 cells were placed in 6-well plate at a density of 3×10^5 cells per well. After incubation for 12 h, miR-588 mimic (RiboBio, China), miR-588 inhibitor (RiboBio, China), or negative control (RiboBio, China) was mixed with lipofectamine 200 (Invitrogen, United States) in Opti-MEM medium (Sigma, United States) for 20 min and added into cell culture medium. Eight hours after transfection, the medium was replaced with fresh DMEM containing 10% FBS to incubate for another 24 h. Then, the cells were used for further experiments.

Cell viability and colony formation assay

Cell viability was determined with a CCK-8 kit (Beyotime, China). MFC cells and SGC7901 cells were seeded in 96-well plates at a density of 3×10^3 cells/well and processed accordingly. Twenty-four hours after incubation, the CCK-8 reagent was added into each well. The absorbance values were detected at 450 nm at 24 h, 48 h, and 72 h, respectively.

For colony formation experiment, SGC7901 cells transfected with miR-588 inhibitor or negative control were placed in a 6-well plate (1000 cells per well), and incubated in complete medium for 2 wk to form visible colonies. Subsequently, the colonies were washed, stained with crystal violet, and captured with a microscope (Carl Zeiss).

RNA extraction and quantitative real-time PCR

Total RNA was extracted with TRIzol reagent (Takara, Japan) and reversely transcribed to cDNA with an EasyScript Reverse Transcriptase kit (TransGen, China). The quantification of cDNA was performed by using a TransStart Green qPCR SuperMix kit (TransGen), and PCR was performed on a Real-Time PCR System (BD bioscience). For detection of miR-588, the extracted RNA was processed with a poly(A) tailing kit (Invitrogen) before reverse transcription. For normalization of mRNA and miRNA, *GAPDH* and *U6* were used as the internal controls, respectively. The quantification of cDNA was analyzed by the $2^{-\Delta\Delta Ct}$ method. The sequences of primers are as follows: *GAPDH* sense, 5′- ACAACTTTGGTATCGTGGAAGG-3′ and antisense, 5′-GCCATCACGCCACAGTTTC-3′; *U6* sense, 5′-AGTAAGCCCTTGCTGTCAGTG-3′ and antisense, 5′-CCTGGGTCTGATAATGCTGGG-3′; *Arg1* sense, 5′-GTGGAAACT-TGCATGGACAAC-3′ and antisense, 5′-AATCCTGGCACATCGGGAATC-3′; *IL-10* sense, 5′-GTACCACAGCAATGGCTACC-3 and antisense, 5′-TGTTGGTGACG-GTCCAGTTG-3′; *TGF-β* sense, 5′-CTAATGGTGGAAACCCACAACG-3′ and antisense, 5′-TATCGCCAGGAATTGTTGCTG-3′; miR-588, 5′-CCGCTATTGCACAT-TACTAAGTTGCA-3

Western blot analysis

SGC7901 cells were placed in a 6-well plate at a density of 3×10^5 cells per well and transfected with miR-588 inhibitor. Total protein was extracted by using ice-cold RIPA buffer, separated by SDS-PAGE, and transferred to a nitrocellulose membrane. The membrane was then blocked by 5% non-fat milk at room temperature for 1 h, and incubated with specific primary antibodies against CD63 (1:1000, Abcam), CD9 (1:1000, Abcam), CD81 (1:1000, Abcam), HSP70 (1:500, Abcam), GAPDH (1:1000, Proteintech), Bax (1:1000, CST), pro-caspase-3 (1:2000, CST), cleaved caspase-3 (1:1000, CST), pro-caspase-9 (1:1000, CST), cleaved caspase-9 (1:1000, CST), CYLD (1:1000, Proteintech), and β-actin (1:2000, Proteintech) at 4 °C overnight. Next day, the blots were washed and incubated with secondary antibodies at room temperature for 2 h. The blots were visualized by using an ECL reagent and a gel imaging system (BD Bioscience).

Xenograft tumor model

C57 nude mice aged 5 wk were purchased from Shanghai Laboratory Animal Center of China. SGC7901 cells were transfected with miR-588 inhibitor or negative control, and suspended in saline at a density of 1 × 10^7 cells/mL. A total of 200 μL of SGC7901 cell suspension was subcutaneously injected to the left back of mice. A week after tumor cell inoculation, the mice were intraperitoneally injected with 15 mg/kg DDP. The mice were euthanized at day 30, and the tumors were isolated, weighted, and processed for subsequent analysis. Tumor size was measured every 5 d and calculated using the following formula: Width^2 × length/2.

Statistical analysis

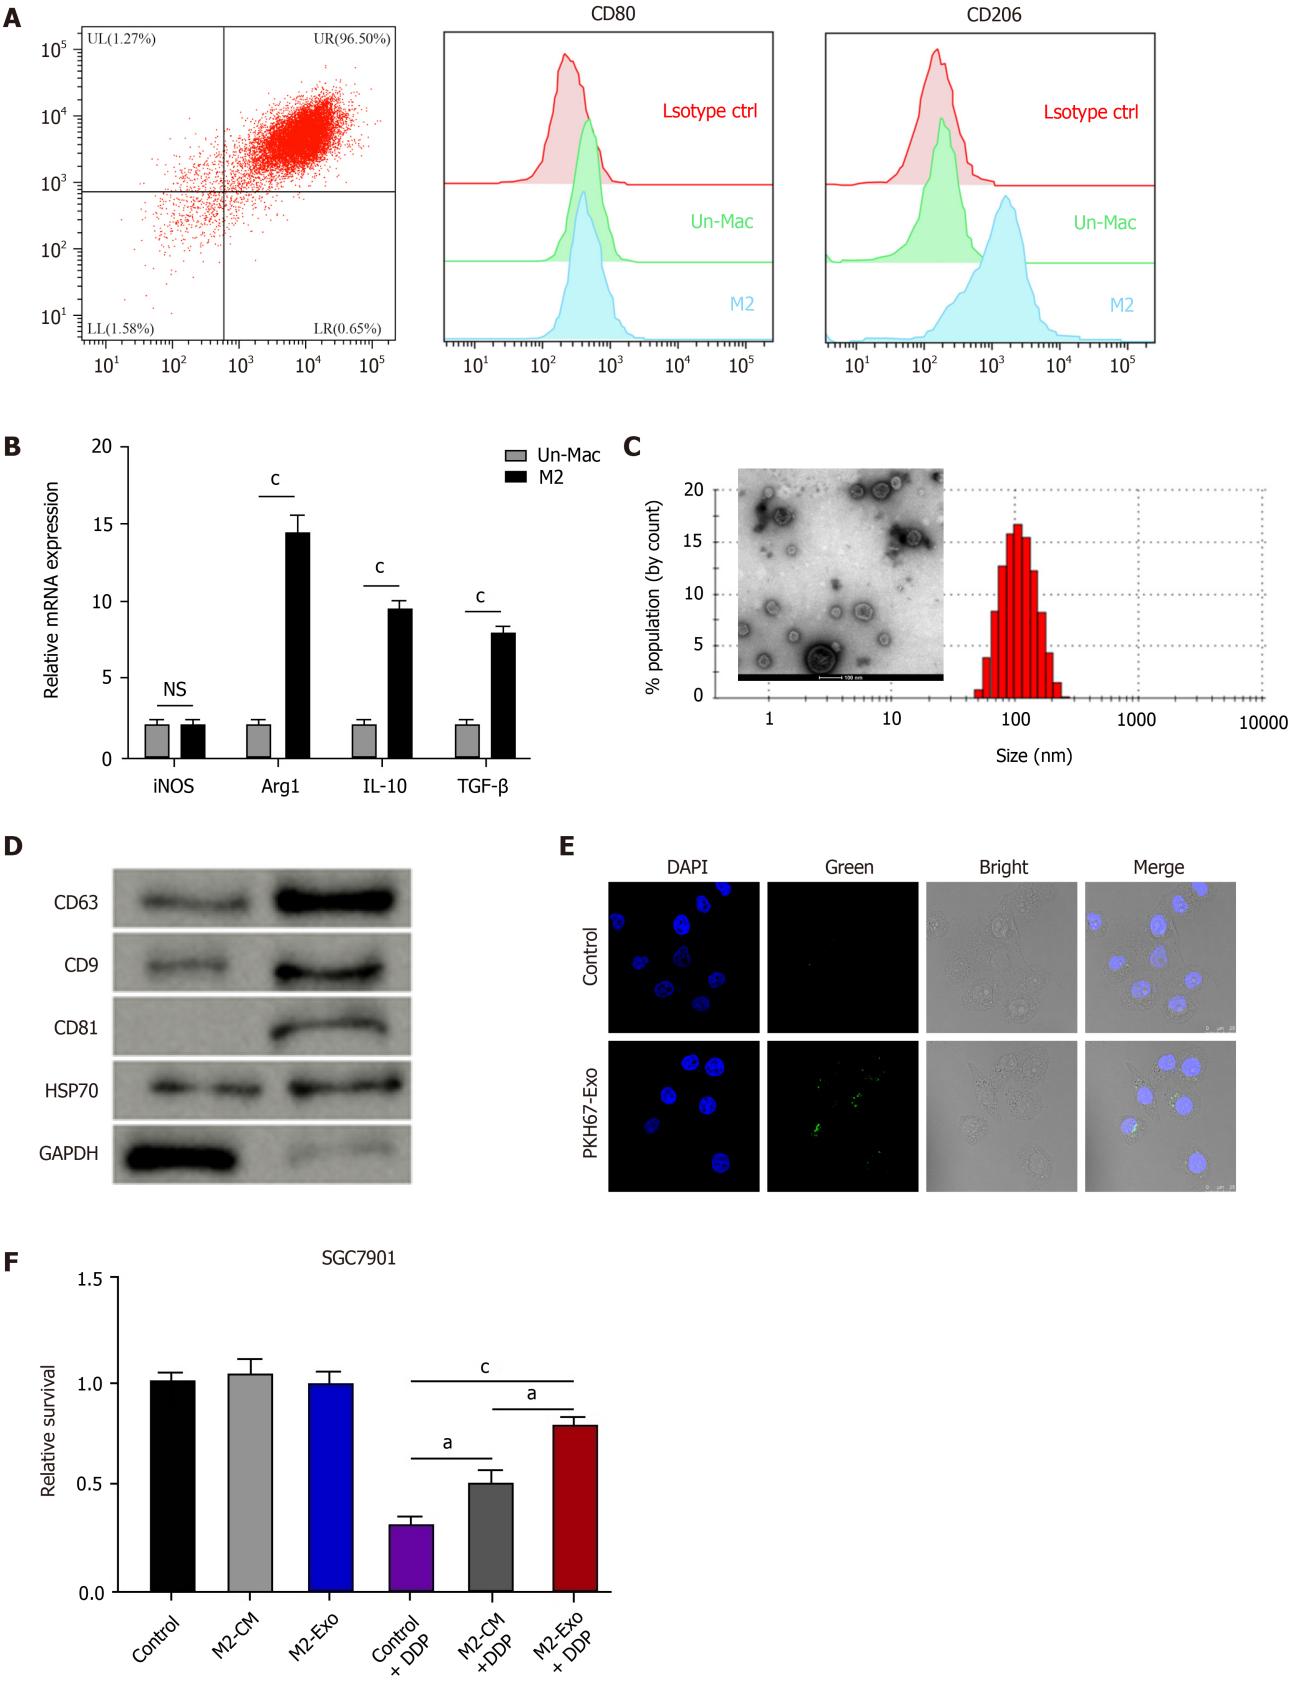
All experiments in this study were performed at least three times independently. All data are presented as the mean ± SD and analyzed with GraphPad Prism 6.0 software. The statistical difference between two groups or multiples groups was analyzed by Student's *t*-test or one-way ANOVA, and was considered significant at $P < 0.05$.

RESULTS

M2 polarized macrophages-derived exosomes can transfer in gastric cancer cells to enhance DDP resistance

To evaluate the effect of M2 polarized macrophages on DDP resistance of gastric cancer cells, M2 polarized macrophages were isolated from murine bone marrow induced with IL-13 and IL-4 and were identified by the M2 specific marker CD206 (Figure 1A). Meanwhile, we found that the expression of M1 polarized marker iNOS was not chanced but the M2 markers, such as Arg1, IL-10, and TGF-β, were enhanced in M2 polarized macrophages compared with inactivated macrophages (Figure 1B). Then, the exosomes were isolated from M2 polarized macrophages and analyzed by TEM and identified by the expression of CD63, CD9, CD81, and HSP70 (Figure 1C and D). Moreover, the delivery of PKH67-labelled exosomes from M2 polarized macrophages was found in SGC7901 cells (Figure 1E). Significantly, M2 macrophages-derived conditioned medium and exosomes enhanced the cell survival of SGC7901 cells exposed to DDP (Figure 1F). The exosomes from M2 polarized macrophages repressed DDP-treated SGC7901 cell apoptosis (Figure 1G).

Co-culture of gastric cancer cells with M2 polarized macrophages promotes DDP resistance



Next, we found that DDP treatment reduced the proliferation of SGC7901 cells in a time-dependent manner (Figure 2A). The co-culture of inactivated macrophages inhibited apoptosis of DDP-treated SGC7901 cells, while the co-culture of M2 polarized macrophages further reduced the cell apoptosis (Figure 2B and C).

Exosomal miR-588 from M2 macrophages contributes to DDP resistance of gastric cancer cells

We then observed that the expression of miR-588 was elevated in the exosomes from M2 macrophages compared with inactivated macrophages (Figure 3A). The miR-588 expression was enhanced in macrophages relative to SGC7901 cells, especially in the M2 polarized macrophages (Figure 3B). Meanwhile, the expression of miR-588 was increased in the DDP-resistant SGC7901 cells co-cultured with M2 macrophages or exosomes from M2 macrophages (Figure 3C). Moreover, we found that the inhibition of miR-588 by inhibitor repressed colony formation of DDP-resistant SGC7901 cells (Figure 3D). The repression of miR-588 induced DDP-resistant SGC7901 cell apoptosis (Figure 3E). The expression of Bax, cleaved caspase-3, and cleaved caspase-9 was enhanced by miR-588 inhibitor in DDP-resistant SGC7901 cells (Figure 3F). Moreover, the IC_{50} of DDP in the inhibition of SGC7901 cell viability was inhibited by miR-588 inhibitor (Figure 4A). Treatment with DDP induced apoptosis of SGC7901 cells, in which miR-588 inhibitor reinforced this effect (Figure 4B and C).

miR-588 can target CYLD in gastric cancer cells

We then identified the binding site for miR-588 in *CYLD* in the bioinformatic analysis (Figure 5A). The luciferase activity and mRNA expression of *CYLD* were significantly repressed by miR-588 mimic in the DDP-resistant SGC7901 cells (Figure 5B and C). Similarly, the protein levels of CYLD were inhibited by miR-588 mimic in DDP-

Figure 4 miR-588 contributes to cisplatin resistance of gastric cancer cells. A: Detection of cell viability by CCK-8 assay in SGC7901 cells treated with miR-588 inhibitor and exposed to cisplatin (DDP) at the indicated doses; B and C: Detection of cell apoptosis by flow cytometry in DDP-resistant SGC7901 cells co-treated with DDP and miR-588 inhibitor. Data shown are the mean ± SD, $^{b}P < 0.01$. DDP: Cisplatin.

by siRNA reversed the effect of miR-588 inhibition (Figure 6A). Moreover, treatment with DDP induced apoptosis of SGC7901 cells; miR-588 inhibitor further enhanced the cell apoptosis, while CYLD knockdown reversed the effect of miR-588 inhibitor (Figure 6B). Moreover, tumorigenicity analysis in nude mice demonstrated that miR-588 inhibitor suppressed the tumor growth *in vivo* (Figure 7A-D). Meanwhile, we validated that the overexpression of CYLD or treatment with miR-588 inhibitor repressed the tumor growth in nude mice, while the depletion of CYLD rescued miR-588 inhibitor-reduced tumor growth in the model (Figure 7E and F).

DISCUSSION

Gastric cancer is a common malignant cancer with a high death rate and limited therapeutic strategies. DDP is widely applied in the treatment of gastric cancer patients with significant effectiveness, but DDP resistance remains a critical clinical issue. In this study, we identified that M2 polarized macrophages-derived exosomal miR-588 contributes to DDP resistance of gastric cancer cells.

Previous investigations have shown that M2 polarized macrophages-derived exosomes are involved in the modulation of cancer development. It has been reported that tumor-related macrophages-derived exosomes contribute to gastric cancer cell invasion *via* apolipoprotein E[23]. Macrophage-derived exosomal miR-21 regulates DDP resistance of gastric cancer cells[24]. M2 macrophages-derived exosomes promote metastasis of hepatocarcinoma by delivering αMβ2 integrin[25]. These studies have shown the critical function of macrophages-derived exosomal miRNAs in the modulation of cancer development. Meanwhile, miR-588 is a widely reported cancer regulator in previous studies. It has been found that miR-588 is enhanced in prostate

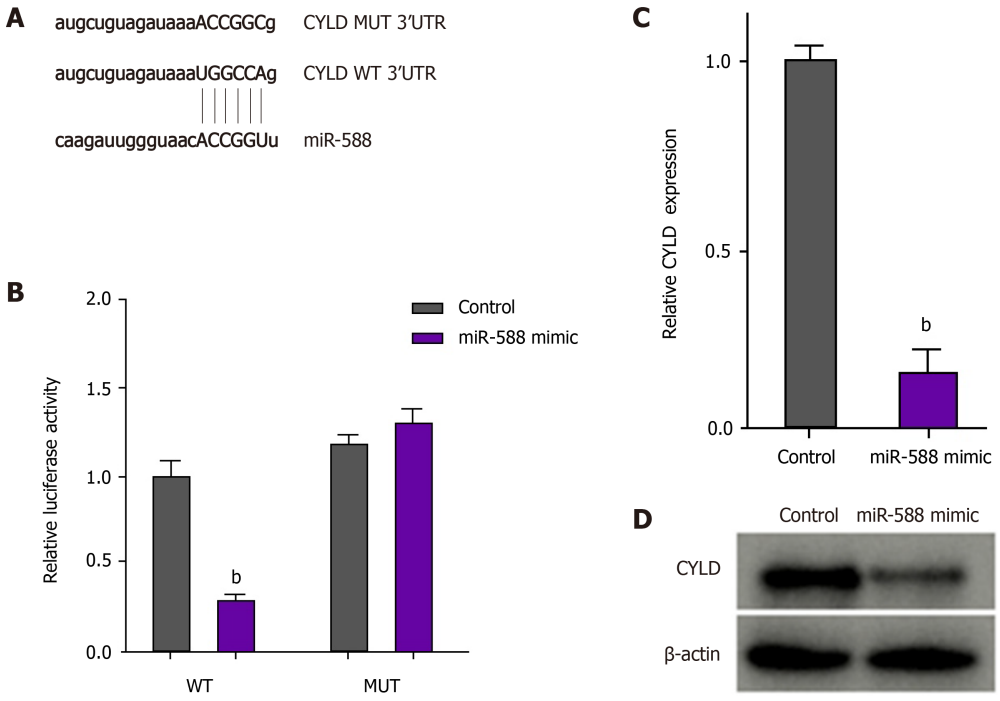

Figure 5 miR-588 can target cylindromatosis in gastric cancer cells. A: The binding site of miR-588 and cylindromatosis (CYLD) was predicted in TargetScan database; B-D: After cisplatin (DDP)-resistant SGC7901 cells were treated with miR-588 mimic, the luciferase activity of CYLD was measured by luciferase reporter assays (B); the expression of CYLD was determined by qPCR (C); and the expression of CYLD was measured by Western blot analysis (D). Data shown are the mean ± SD. $^{b}P < 0.01$. CYLD: Cylindromatosis.

cancer and is correlated with a poor prognosis[15]. miR-588 modulates epithelial-mesenchymal transition, migration, and invasion of gastric cancer cells by targeting EIF5A2 signaling[26]. The PICSAR/miR-588/EIF6 axis contributes to the regulation of hepatocellular carcinoma progression by targeting AKT/mTOR signaling[27]. Moreover, it has been reported that miR-588 serves as a prognosis biomarker for gastric cancer[16]. In previous reports, miR-588 has not been prominently implicated in gastric cancer through interaction between tumor and the surrounding microenvironment. We were interested in the function of M2 macrophages-derived exosomes in cancer development and noticed the potential function of miR-588 in gastric cancer. Therefore, we explored the correlation of M2 macrophage-derived exosomes with miR-588 and their function in gastric cancer. Our data showed that co-cultivation of gastric cancer cells with M2 polarized macrophages promoted DDP resistance. M2 polarized macrophages-derived exosomes could transfer in gastric cancer cells to enhance DDP resistance. Exosomal miR-588 from M2 macrophages contributed to DDP resistance of gastric cancer cells. miR-588 promoted DDP-resistant gastric cancer cell growth *in vivo*. These data not only provide new evidence of the critical function of M2 polarized macrophages-derived exosomes in regulating cancer progression, but also indicate the innovative role of miR-588 in gastric cancer. The correlation of M2 polarized macrophages-derived exosomal miR-588 and miR-588 in the cancer cells in regulating cancer development is an interesting scientific issue, which is needed to explore in the future. Besides, the function of other pivotal miRNAs that have been described as crucial regulators in exosomes-mediated cellular communication should be explored by more investigations. Meanwhile, the mechanisms of miR-588 transfer from macrophage to gastric cancer cells remain unclear. According to previous studies, the communications between macrophages and gastric cancer cells can be mediated by exosomes, which can engulf local tissues immediately or swarm into body fluid to affect distant target organs through endocytosis[7,24,28]. The mechanisms of miR-588 transfer from macrophage to gastric cancer cells should be confirmed by more complicated investigations in future.

Moreover, it has been reported that inhibition of CYLD enhances IFN-γ-regulated PD-L1 expression in thymic epithelial cancer[29]. LINC01260 serves as a tumor inhibitor by regulating the miR-562/CYLD axis in lung cancer[30]. CYLD enhances nasopharyngeal carcinoma cells apoptosis by modulating NDRG1[31]. MiR-454 contributes to oxaliplatin resistance and cell proliferation by targeting CYLD in gastric cancer[32]. These reports have identified the tumor suppressive function of CYLD in

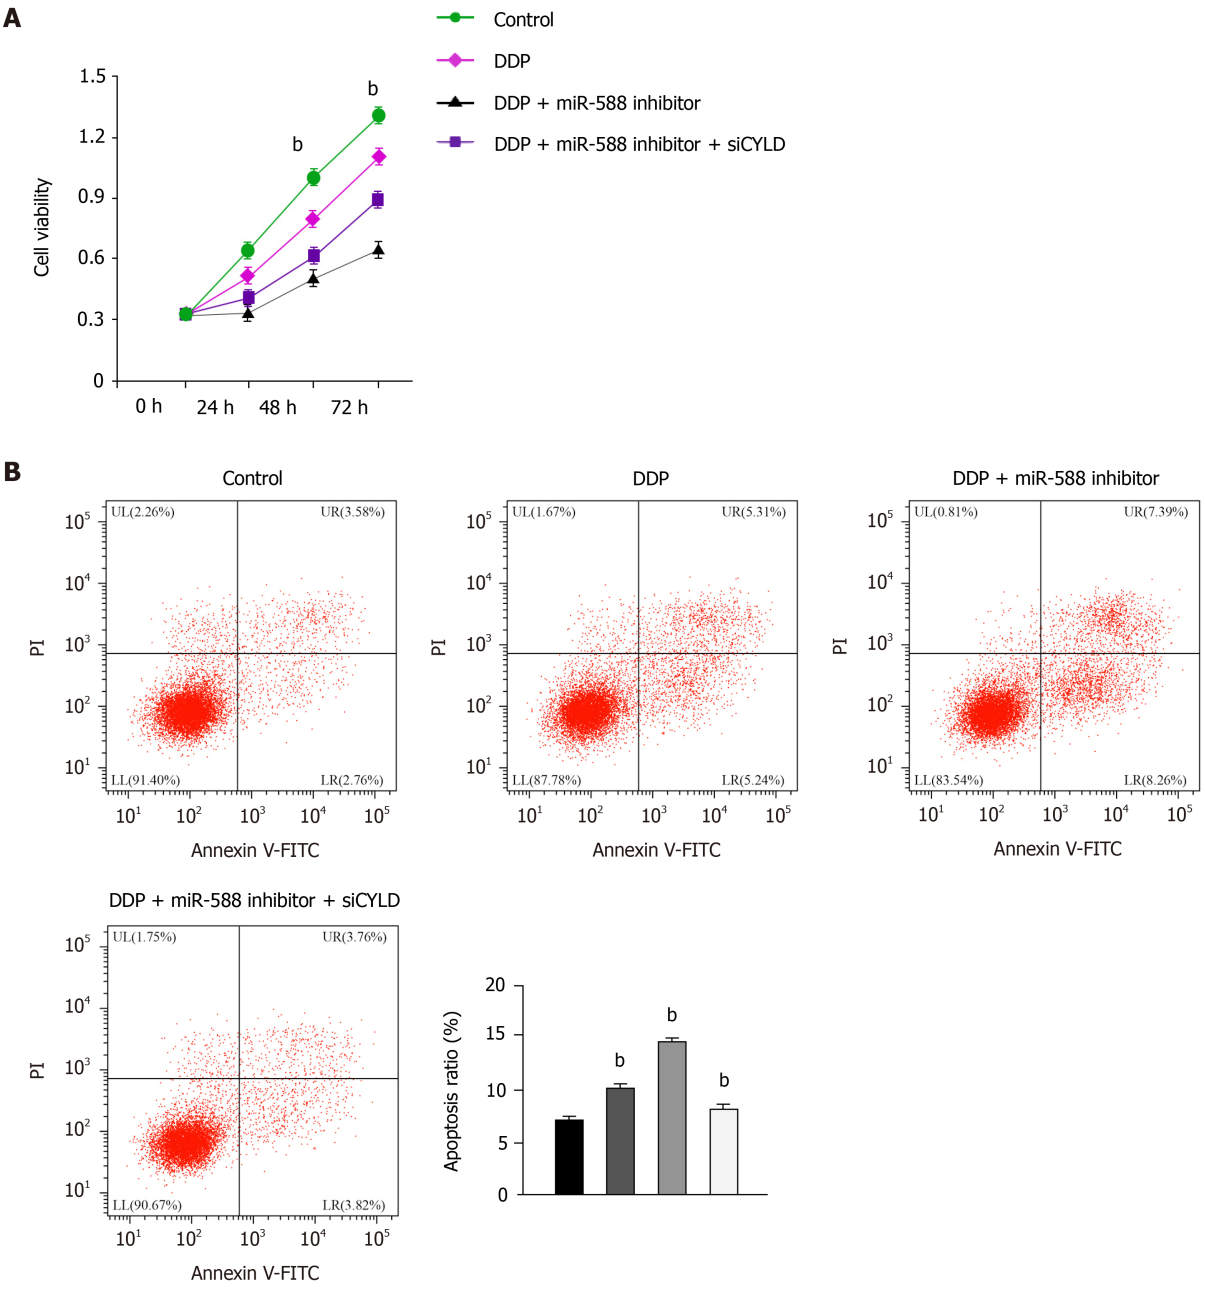

Figure 6 miR-588/cylindromatosis axis regulates cisplatin resistance of gastric cancer cells. A: Cell viability detected by CCK-8 assay; B: Cell apoptosis analyzed by flow cytometry. The SGC7901 cells were treated with cisplatin (DDP), or co-treated with DDP and miR-588 inhibitor with or without cylindromatosis siRNA. Data shown are the mean ± SD. $^{b}P < 0.01$. DDP: Cisplatin; CYLD: Cylindromatosis.

cancer progression. Our mechanical investigation showed that miR-588 targeted CYLD in gastric cancer cells and miR-588/CYLD axis contributed to the progression of gastric cancer. It presents a crucial mechanism underlying miR-588-mediated cancer development. CYLD may not be the only downstream factor underlying miR-588-mediatde tumorigenesis. Other regulators in miR-588-modulated cancer pathogenesis and their crosstalk may be investigated further in future. Targeting exosomal miR-588 from M2 macrophages may be a promising therapeutic strategy for gastric cancer and the clinical translation should be explored in future investigations.

CONCLUSION

In conclusion, we uncovered that exosomal miR-588 from M2 macrophages contributes to DDP resistance of gastric cancer cells by partly targeting CYLD. miR-588 may be applied as a potential therapeutic target for the treatment of gastric cancer.

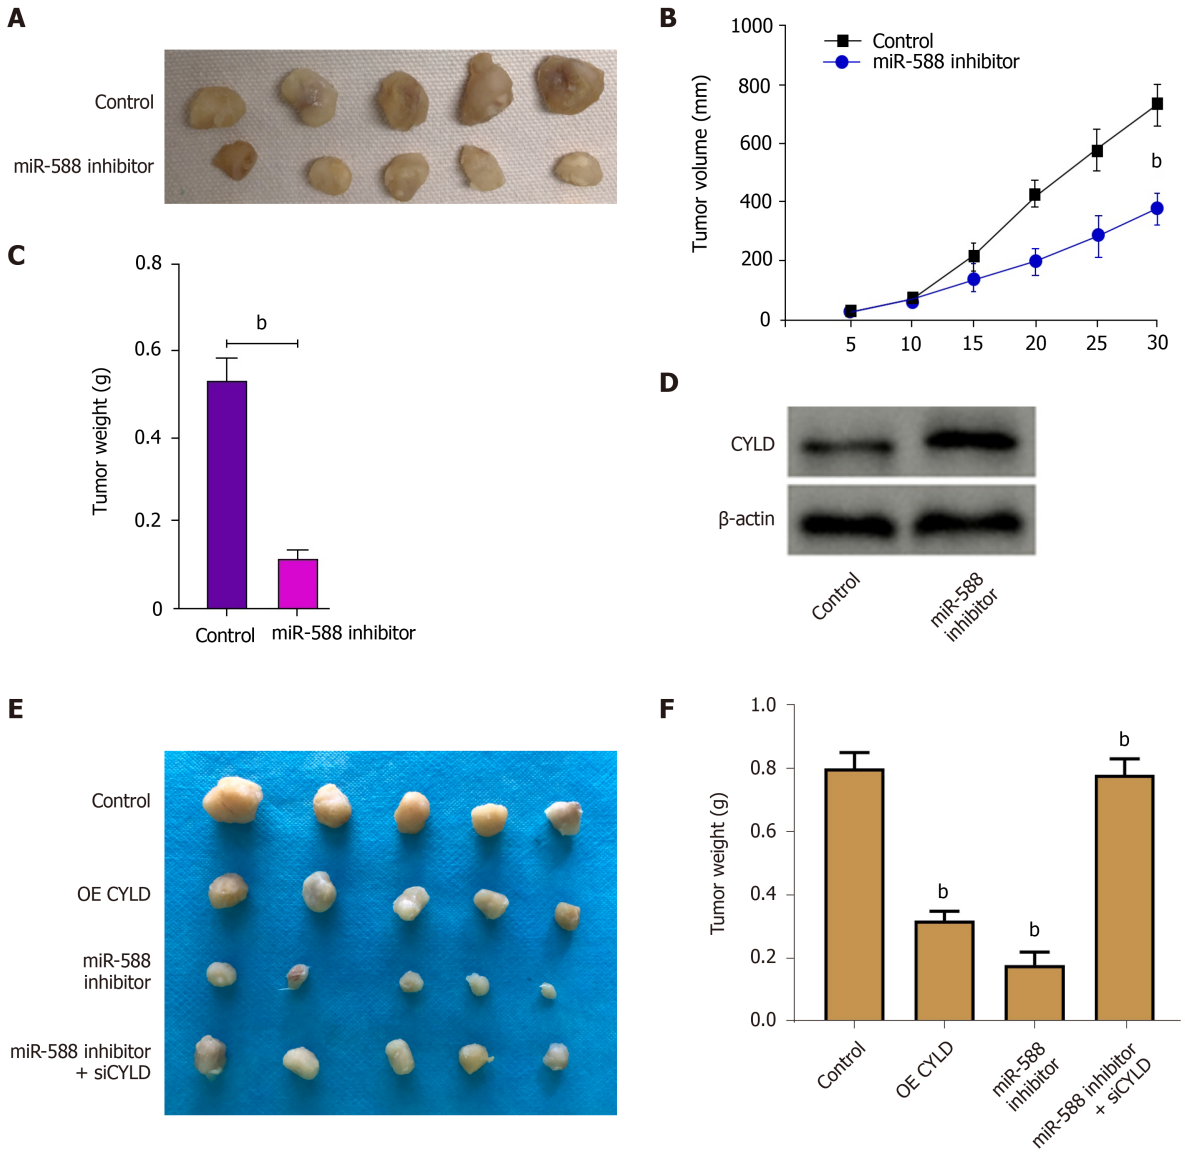

Figure 7 miR-588/cylindromatosis axis modulates cisplatin-resistant gastric cancer cell growth *in vivo*. A-D: The nude mice were injected with SGC7901 cells treated with miR-588 inhibitor, the tumor tissues (A), tumor volume (B), and tumor weight (C) were measured, and the expression of cylindromatosis (CYLD) was detected by Western blot analysis in the tumor tissues (D); E and F: The nude mice were injected with SGC7901 cells treated with CYLD overexpressing plasmid or miR-588 inhibitor, or co-treated with miR-588 inhibitor and CYLD siRNA, and the tumor tissues (E) and tumor weight (F) were measured. Data shown are the mean ± SD (n = 5). $^{b}P < 0.01$. CYLD: Cylindromatosis.

ARTICLE HIGHLIGHTS

Research background

Gastric cancer is a prevalent malignant cancer with a high incidence and significantly affects the health of modern people globally. Cisplatin (DDP) is one of the most common and effective chemotherapies for patients with gastric cancer, but DDP resistance remains a severe clinical challenge.

Research motivation

To identify the function of M2 polarized macrophages-derived exosomal miR-588 in gastric cancer cells.

Research objectives

To explore the effect of M2 polarized macrophages-derived exosomal miR-588 on DDP resistance of gastric cancer cells.

Research methods

M2 polarized macrophages were isolated and identified by specific markers using flow cytometry analysis. The exosomes from M2 macrophages were identified by TEM and related markers. The uptake of the PKH67-labelled M2 macrophages-derived exosomes was detected in SGC7901 cells. The function and mechanism of exosomal miR-588 from M2 macrophages in the modulation of DDP resistance of gastric cancer cell was analyzed by CCK-8 assay, apoptosis analysis, colony formation assay, Western blot analysis, qPCR analysis, and luciferase reporter assay in SGC7901 and SGC7901/DDP cells, and by tumorigenicity analysis in nude mice.

Research results

Polarized macrophages were isolated from mouse bone marrow stimulated with interleukin (IL)-13 and IL-4. Co-culture of gastric cancer cells with M2 polarized macrophages promoted DDP resistance. M2 polarized macrophage-derived exosomes could transfer in gastric cancer cells to enhance DDP resistance. Exosomal miR-588 from M2 macrophages contributed to DDP resistance of gastric cancer cells. miR-588 promoted DDP-resistant gastric cancer cell growth *in vivo*. miR-588 was able to target cylindromatosis (CYLD) in gastric cancer cells. The depletion of CYLD reversed miR-588 inhibition-regulated cell proliferation and apoptosis of gastric cancer cells exposed to DDP.

Research conclusions

In conclusion, we uncovered that exosomal miR-588 from M2 macrophages contributes to DDP resistance of gastric cancer cells by partly targeting CYLD.

Research perspectives

miR-588 may be applied as a potential therapeutic target for the treatment of gastric cancer.

Abstract

BACKGROUND

Pancreatic cancer (PC) is one of the deadliest malignancies with an alarming mortality rate. Despite significant advancement in diagnostics and therapeutics, early diagnosis remains elusive causing poor prognosis, marred by mutations and epigenetic modifications in key genes which contribute to disease progression.

AIM

To evaluate the various biological tumor markers collectively for early diagnosis which could act as prognostic biomarkers and helps in future therapeutics of PC in Kashmir valley.

METHODS

A total of 50 confirmed PC cases were included in the study to evaluate the levels of carbohydrate antigen 19-9 (CA 19-9), tissue polypeptide specific antigen (TPS), carcinoembryonic antigen (CEA), vascular endothelial growth factor-A (VEGF-A), and epidermal growth factor receptor (EGFR). Mutational analysis was performed to evaluate the mutations in Kirsten rat sarcoma (*KRAS*), Breast cancer type 2 (*BRCA-2*), and deleted in pancreatic cancer-4 (*DPC-4*) genes. However, epigenetic modifications (methylation of CpG islands) were performed in the promoter

regions of cyclin-dependent kinase inhibitor 2A (*p16; CDKN2A*), MutL homolog 1 (*hMLH1*), and Ras association domain-containing protein 1(*RASSF1A*) genes.

RESULTS

We found significantly elevated levels of biological markers CA 19-9 ($P \leq 0.05$), TPS ($P \leq 0.05$), CEA ($P \leq 0.001$), and VEGF ($P \leq 0.001$). Molecular genetic analysis revealed that *KRAS* gene mutation is predominant in codon 12 (16 subjects, $P \leq 0.05$), and 13 (12 subjects, $P \leq 0.05$). However, we did not find a mutation in *DPC-4* (1203G > T) and *BRCA-2* (617delT) genes. Furthermore, epigenetic modification revealed that CpG methylation in 21 ($P \leq 0.05$) and 4 subjects in the promoter regions of the *p16* and *hMLH1* gene, respectively.

CONCLUSION

In conclusion, CA 19-9, TPS, CEA, and VEGF levels were significantly elevated and collectively have potential as diagnostic and prognostic markers in PC. Global data of mutation in the *KRAS* gene commonly in codon 12 and rare in codon 13 could augment the predisposition towards PC. Additionally, methylation of the *p16* gene could also modulate transcription of genes thereby increasing the predisposition and susceptibility towards PC.

Core Tip: This study demonstrates that the collective evaluation of genetic mutations, epigenetic modifications in key genes and elevated levels of serum carbohydrate antigen 19-9, tissue polypeptide specific antigen, carcinoembryonic antigen, and vascular endothelial growth factor-A could be used as predictive biomarkers for diagnostics and prognostics in pancreatic cancer patients of the ethnic Kashmiri population. This could be useful to track the disease status of pancreatic cancer patients who are on a different regimen of chemotherapeutic interventions. To validate these results in the ethnic Kashmiri population, future studies need comprehensive, cohort, and replicative studies with large sample size.

INTRODUCTION

Pancreatic cancer (PC) is one of the deadliest malignancies among several solid malignancies. It is the 15th leading cancer in the world with an overall estimated incidence of 277000 new cases which is being diagnosed every year[1]. In the United States, PC is the fourth leading cause of death with a 5-year survival rate of less than 5%[2]. PC is mostly found in elderly people and has been reported to be associated with several risk factors[3]. The predominant risk factors include age, cigarette smoking, a high-fat diet, decreased serum levels of folate, diabetes mellitus, obesity, and chronic pancreatitis[4,5]. The familial history of pancreatitis increases the probability of developing PC by around 40%[6]. PC has the lowest prognosis among several solid-type tumors, mainly because almost 80% of PC patients are diagnosed when the disease is in the advanced or metastatic stage[7]. Owing to the lack of specific biological biomarkers used in clinical practice for the detection of PC and its nonspecific symptomology at the initial stage of the malignancy, the early diagnosis is extremely critical to detect and analyze disease progression[8]. Therefore, it is vital to identify specific biomarkers that play a key role in early diagnosis thereby improving the management and therapeutic outcome in PC.

P-Editor: Xing YX

Tumor biomarker(s) are the substances that can be examined in body fluids (blood, urine, and other fluids), synthesized and excreted by malignant cells within the tumor tissue besides exceeding the normal level potentiating its use for cancer diagnosis and/or prognosis[9]. Thus, ideally, the tumor markers should have high sensitivity and specificity, however, none of the tumor biomarkers have attained such precision [10]. Recent reports suggest that commonly used biomarkers for various malignancies include carbohydrate antigen 19-9 (CA 19-9), tissue polypeptide specific antigen (TPS), carcinoembryonic antigen (CEA), vascular endothelial growth factor-A (VEGF-A), and epidermal growth factor receptor (EGFR)[11]. The CA 19-9 and CEA are high molecular weight glycoproteins attached to the surface of tumor cells predominantly used in the diagnosis and prognosis of gut-associated cancers. However, marred by low sensitivity and specificity, they far from qualify for the diagnosis of other cancers [12]. The group of intermediate filament proteins to which TPS belongs is mainly used to measure cytokeratin 18 and 19 and expected to reflect the tumor progression. A few studies have examined TPS expression in PC; however, the findings are contentious. Although, individually TPS expression in PC may not provide significant information about the disease progression; in concert with other tumor biological markers it is worthwhile to evaluate its role for early diagnosis, prognosis, and to predict metastatic growth of PC[13]. A predominant dimeric, heparin-associated glycoprotein, VEGF-A has powerful pro-angiogenic and mitogenic activity. Elevated expression of VEGF-A enhances vascular permeability of endothelial cells and is reported to be involved in PC-associated angiogenesis[14], thus potentiates as a predictive biomarker. EGFR is a transmembrane protein that regulates cell growth and development. Mutation or elevated expression of EGFR is a key event in the pathogenesis of various malignancies such as glioblastoma, lung and oral carcinomas. There are reports of EGFR-mediated signaling associated with EGFR mutation in PC patients[15]. Consequently, these reports suggest that evaluation of serum EGFR levels in PC can be a promising putative biomarker for early diagnosis and prognosis to monitor the disease status post-therapeutic interventions. Although, individually the tumor biomarkers could aid in diagnostic and prognostic evaluation to a certain level, however, collectively, they can be more beneficial to track tumor progression and could be more useful to monitor disease status. Therefore, the current study aims to evaluate the collective role of various tumor biomarkers in PC patients for their potential role in early diagnosis and application in prognosis to examine post-treatment disease status in the ethnic Kashmiri population.

Genetic mutations play a pivotal role in tumor progression and genetic markers are critically important for the detection of malignant changes in PC[16]. Approximately, 97% of PC patients have alterations in genes that either follow the germline inheritance mode of transmission or occur sporadically[17]. These mutations could be either oncogenic (gain of function) or diminish tumor suppressor activity (loss of function). Gain-of-function in Kirsten rat sarcoma (*KRAS)* a proto-oncogene that encodes guanosine triphosphatase (GTPase), is one of the prominent mediators in signal transduction pathways that are implicated in neoplastic transformation and inflammation[18]. Approximately 95% of all cancers including PC are reported to harbor a *KRAS* gene mutation which is a key event in early tumorigenesis. The major *KRAS* activating gene mutations reportedly occur at codon 12 and less commonly at codon 13 and codon 61. Therefore, evaluation of genetic mutational analysis at the hotspot regions of the *KRAS* gene could help in early diagnosis and prognosis in PC. Breast cancer type 2 *(BRCA-2)*, a tumor suppressor gene is associated with the maintenance of the genome by enhancing homologous recombination of a double-stranded break. Around 80% of *BRCA-2* mutations are either frameshift or nonsense mutations that result in the formation of premature stop codons to encode non-functional BRCA-2 protein[19]. Almost 7.3% of PC patients have a hereditary mutation in the *BRCA-2* gene which increases the risk of developing PC by approximately 20-fold[20] implicating a critical role of *BRCA-2* in the early diagnosis of PC. Another vital gene, 'deleted in pancreatic cancer-4' *(DPC-4)* also known as SMAD family member 4, mothers against decapentaplegic homolog 4 (*SMAD-4)* is a tumor suppressor gene involved in the regulation of gene transcription. DPC-4 protein a downstream target of transforming growth factor-beta (TGF-β) pathway plays a critical role in the activation of TGF-β signaling thereby promotes neoplastic growth. It is reported that 30% of PC cases develop due to homozygous mutations in the *DPC-4* gene[21,22]. Thus, mutational analysis of the *DPC-4* gene could be a promising factor for the early diagnosis and prognosis of PC.

Besides genetic mutations, recent evidence suggests the epigenetic modifications such as DNA methylation plays a critical role in the pathogenesis of PC. In the recent past, reports suggest that methylation at the promoter regions of key tumor

suppressor genes induces gene silencing and contributes to the development and progression of tumorigenesis[23]. Various tumor suppressor genes were inactivated by epigenetic modifications. Cyclin-dependent kinase inhibitor 2A (*p16; CDKN2A*), a tumor suppressor gene that encodes a member of cyclin-dependent kinase inhibitor which arrests the G_1-S phase of the cell cycle to prevent tumor cell progression. Loss of the *p16* gene is reported in 70% of cancers and around 10%-15% of the loss was due to promoter methylation[24]. Thus, screening of epigenetic modifications at the promoter region of the *p16* gene could help in the early diagnosis of PC. MutL homolog 1 (*hMLH1)* a tumor suppressor gene that belongs to the mismatched repair gene family and prevents DNA damage by radiations and other associated mechanisms. *hMLH1* is also reported to be inactivated epigenetically by promoter methylation which leads to DNA damage. The accumulation of mismatched and damaged DNA promotes tumor cell progression[25]. Ras association domain-containing protein 1*(RASSF1A)* is another tumor suppressor gene inactivated by promoter methylation. It is a component of RAS/PI3K/AKT and RAS/MAPK pathways. Recent reports suggest that epigenetic modifications in the *RASSF1A* promoter region promote tumor progression in various cancers including kidney, breast, lung, prostate, and thyroid[26]. Recent evidence suggests that 64% of pancreatic adenocarcinoma patients have *RASSF1A* hypermethylation at the promoter region, indicating that analysis of hypermethylation of *RASSF1A* at promoter region could be a promising approach for early diagnosis of PC. To summarize, these studies suggest that genetic mutations, epigenetic modulations, and elevated levels of serum biological markers play a critical role in the early diagnosis, therapeutics, and prognosis of various cancer. Therefore, keeping in consideration the documented role of tumor biomarkers, genetic mutations, and DNA methylation of tumor suppressor/protooncogenes in various malignancies including PC. The current study aimed to evaluate the serum levels of various biological tumor markers, genetic mutations, and epigenetic modifications of some key regulatory genes in PC. This would prove immensely helpful in the early diagnosis of PC, which helps in the identification of high-risk PC and may enable their development as biomarkers for future diagnostics, therapeutic interventions, and prognostics in the ethnic Kashmiri population.

MATERIALS AND METHODS

In this study, a total of 50 patients with pancreatic carcinoma and 50 healthy controls were included.

Inclusion criteria

Only the patients with histologically confirmed pancreatic carcinoma were included in this study. Written consent was taken at the very beginning from all the patients and healthy controls that were included in the study.

Exclusion criteria

The patients with a history of other malignancies and those who were not willing to comply with pre-requisite protocol were excluded from the study.

Physical examination and lifestyle habits

The study was designed and approved by the institutional review board of the Sher-i-Kashmir Institute of Medical Sciences (SKIMS), and informed consent was obtained from all participants. A comprehensive physical/clinical examination was performed in the Department of Medical Oncology, SKIMS, and the patients were evaluated for Jaundice (by examining features like yellowing of eyes and skin), pruritis (by examining features like redness, bumps, spots or blisters, dry/cracked skin and leathery/scaly skin), muscle wasting (by evaluating features like weakness or numbness in the limbs, loss of muscle coordination, tingling or weakness of the extremities, impaired balance while walking, fatigue and a general illness, facial weakness, progressive weakness, gradual memory loss and liver enlargement (were examined by features like abdominal pain, nausea/vomiting, fatigue, whitening of eyes and yellowing of the skin).

Besides the physical examination, lifestyle activities of the PC patients were also recorded which included smoking status, salt tea consumption, spicy and non-spicy food intake, dried vegetable consumption, mutton, and beef consumption, fish consumption, oil intake, urine habits, bowel habits, and daily physical activity were also recorded.

Laboratory findings

The basic clinical laboratory findings were performed by using automated analyzers. The laboratory findings are liver function test (like aspartate transaminase-AST, alanine transaminase-ALT, bilirubin, and alkaline phosphatase-ALP), diabetic status (hyperglycemia) by measuring glucose levels, and anemia by measuring red blood cell (RBC) count.

Diagnostic imaging

For any other malignancy PC patients were initially screened by using multiphase multidetector computed tomography (CT) scan, magnetic resonance imaging (MRI), ultrasonography (USG), endoscopic ultrasound (EUS), and chest X-ray (CXR).

Sample collection

A total of 5 mL blood sample was collected in clot activator and Ethylenediaminetetraacetic acid (EDTA) vial from PC patients. The serum was separated from the clot activator vials using centrifugation and was stored at -80 °C for further analysis. EDTA vials contain blood was stored at -20 °C for DNA extraction. A tissue chunk (12-50 µm thick tumor tissue section) was obtained from the PC patient by endoscopy using USG-guided probes for mutational analysis and epigenetic modifications.

Tumor biomarkers

Tumor markers including CA19-9, TPS, CEA, VEGF-A, and EGFR were estimated in the serum obtained from blood collected from the PC patients. Measurement of CA 19-9, CEA, VEGF-A, and EGFR levels in serum were performed by using a modular E-170 analyzer. However, TPS levels in the serum were measured by using an Immulite instrument.

Genetic mutation analysis

Genomic DNA was extracted by the phenol-chloroform method from mononuclear cells. Hypaque density gradient centrifugation was performed to extract leucocytes from blood and tissue samples obtained from PC patients. The quantity and quality control analysis of genomic DNA was performed by carrying out UV spectrophotometer (Eppendorf Biospectrometer®, Hamburg Germany) analysis and Gel electrophoresis, respectively. However, polymerase chain reaction (PCR) was carried out with a different set of primers for *KRAS*, *DPC-4*, and *BRACA-2* genes under different PCR conditions. The PCR products obtained were subjected to Restriction Fragment Length Polymorphism (RFLP) using restriction enzymes BstN1 and BglI for mutational analysis of *KRAS* codon 12 and 13, respectively. GGA→TGA in exon 8, codon 358 of *DPC-4* gene was analyzed by using MnlI restriction enzyme. 6174delT of *BRCA-2* was analyzed by using allele-specific PCR technique and polyacrylamide gel electrophoresis (PAGE) was carried out to study any change in the *BRCA-2* gene.

Epigenetic analysis

The epigenetic analysis was performed by examining the methylation status of the promoter and exon regions of genes including *p16*, *RASSF1A*, and *hMLH1*. The methylation status of *p16*, *RASSF1A*, and *hMLH1* genes was determined by methylation-specific (MSP) PCR. Briefly, DNA extracted from tissue samples was first subjected to bisulfite conversion using EZ direct methylation kit. The bisulfite-converted DNA was then subjected to PCR using methylated and unmethylated primers specific for the respective genes. The results were analyzed on 2% agarose gel.

Statistical analysis

Numerical data collected from experiments for statistical analysis were performed by using non-parametrical statistical analysis tools which are the Kruskal-Wallis test and Mann-Whitney *U* test.

RESULTS

The current study included 50 PC patients with a mean age of 47.82 years at the time of diagnosis for the evaluation of various tumor biological markers for the PC diagnosis. Radio-diagnostics such as USG and CT, confirmed that all 50 patients had PC. Further, histopathological analysis supported the radio-diagnostic results and revealed that out of 50 confirmed PC patients, 47 PC patients had characterized to

have adenocarcinoma whereas the remaining 3 PC patients have neuroendocrine carcinoma in the pancreas as shown in Figure 1. The other demographic parameters and daily activities of all confirmed 50 PC patients are presented in Table 1.

Owing to have relative ease in blood collection and non-invasive, it is preferred to evaluate the biological tumor markers in serum. Therefore, we also intended to evaluate the biological tumor markers which included CA 19-9, TPS, CEA, VEGF-A, and EGFR levels in the blood collected from PC patients. Our results demonstrated that the levels of serum biological tumor markers CA 19-9, CEA, VEGF-A, TPS, EGFR of PC patients were significantly raised in 33 (66%), 32 (64%), 48 (96%), 48 (96%) and 0 out of 50 PC patients, respectively (Table 2) and Figure 2.

Although the PC progression is a heterogeneous and complex process that includes cell proliferation of intraepithelial and dysplasia to form a mass of cells, followed by an invasion of cells to neighboring tissues. Subsequently, one of the important driving factors of PC progression is genetic mutations of protooncogenes (gain-of-function) and tumor suppressor genes (loss-of-function). Among genetic mutations, *KRAS* mutation is the key point mutation followed by deletion mutation in tumor suppressor genes *BRCA-2, DPC-4,* and *p16* in PC. To evaluate whether the PC patients in our study harbor these mutations, we sought to perform mutational analysis of *KRAS* hotspot codons (codon 12 and codon 13), *DPC-4* (1203G>T), and *BRCA-2* mutation (6174delT) in our PC subjects. Our mutational analysis results revealed that out of 50 PC patients, 16 and 12 PC patients had *KRAS* mutation at codons 12 and 13, respectively. However, we could not find mutation(s) at codons 12 and 13 of the *KRAS* gene in the remaining 34 and 38 PC patients, respectively Figure 3. The representative agarose gel picture of the amplification product of codons 12 and 13 of the *KRAS* gene and their RFLP pattern is shown in Figures 4 and 5. Subsequently, the mutational analysis of tumor suppressor gene *DPC-4* (1203G>T) and *BRCA-2* (6174delT) were also evaluated in all PC subjects. Interestingly, we did not find any mutations in *DPC-4* and *BRCA-2* mutation at (1203G>T) (6174delT) sites, respectively Figure 3. The representative agarose gel picture of *DPC-4* (1203G>T) amplification and RFLP pattern is shown in Figure 6, respectively, and that of amplification and RFLP pattern of *BRCA-2* (6174delT) is shown in Figure 7. The results obtained from the genetic mutation analysis are summarized in Table 3.

Epigenetic alterations have been documented to play a crucial role in PC progression. The *p16, RASSF1A,* and *hMLH1* are key tumor suppressor genes regulating mismatch repair to minimize DNA damage and are frequently inactivated by epigenetic modification in various malignancies. Therefore, we intended to investigate the epigenetic modification (methylation of CpG islands) of *p16, RASSF1A,* and *hMLH1* genes by determining the methylation in their respective promoter regions in all PC subjects. Our epigenetic modification results demonstrated that 21 out of 50 PC subjects were found methylated in the CpG islands of the promoter region of the *p16* gene while the remaining 29 were unmethylated. However, the CpG islands in the promoter region of *RASSF1A* were found to be unmethylated in all 50 PC patients. Additionally, we observed that 4 out of 50 PC patients showed methylation patterns in the promoter region of the *hMLH1* gene, whereas the remaining 46 PC patients had the *hMLH1* gene unmethylated in their promoter regions. The representative agarose gel pic of MS-PCR for *hMLH1* and *RASSF1A* is shown in Figure 8. The methylation and unmethylation status as observed in the present study for *p16, hMLH1,* and *RASSF1A* are summarized in Table 4 and Figure 9.

DISCUSSION

Despite new therapeutic approaches to improve the outcome of PC patients by the introduction of molecular target approaches and combinatorial therapy, there is an unmet need to find the prospective biomarkers for early diagnosis of PC[27]. Therefore, the aim of the current study was to collective evaluation of tumor biological markers, mutational status, and epigenetic modulations in PC patients of the ethnic Kashmiri population for early diagnosis. Our findings revealed the elevated levels of serum biomarkers CA 19-9, TPS, CEA, and VEGF-A, in the blood samples of PC patients, however, EGFR levels were found to be in the normal range. The mutational analysis demonstrated that the *KRAS* gene mutation which is the major driver in PC progression was found in codons 12 (16 subjects) and 13 (12 subjects). Furthermore, DNA of CpG islands of 21 subjects was found significantly methylated in the promoter regions of the *p16* gene. Collectively, these results suggest that in combination with mutational analysis and epigenetic modulations (CpG methylation), the biological

tumor markers evaluated in PC subjects could be valuable for early diagnostics and could strongly predict the PC prognostics. Additionally, these types of studies could further strengthen the validation of biological tumor markers and have a promising perspective for the predisposition and susceptibility towards PC.

A biological tumor marker is an entity in the body that gives information about a diagnosis, prognosis, and therapeutic modalities for a particular disease. The preferred entity to be eligible as a biomarker should be available in body fluids and non-invasive [28]. One of the important tumor biomarkers used in various malignancies is a high molecular weight glycoprotein CA 19-9. Biochemically, a carbohydrate antigen, CA19-9 is mainly expressed by the cells of the pancreaticobiliary system. Previous studies suggest that CA 19-9 levels were elevated in gut-associated malignancies such as gastric, bile duct, colorectal, and ovarian cancers. Owing to its relatively higher sensitivity and specificity among other biomarkers in PC patients, CA 19-9 is an important and valuable biomarker in the diagnostics of PC[29]. Although reports suggest a significant progress in overall survival and reduction in CA19-9 levels in PC, however, a recent study by Hess *et al*[30] did not support these findings. O'Brien *et al* [31] reported that CA 19-9 levels were raised in PC patients and may act as a better biomarker for the early diagnosis of PC. Besides, the levels of CA 19-9 were found directly associated with tumor size, tumor burden, and stage of tumorigenesis in PC, the pre-and post-operative levels of CA 19-9 in PC patients could be used as a prognosticator. Consistent with these findings, our results revealed that out of 50 PC

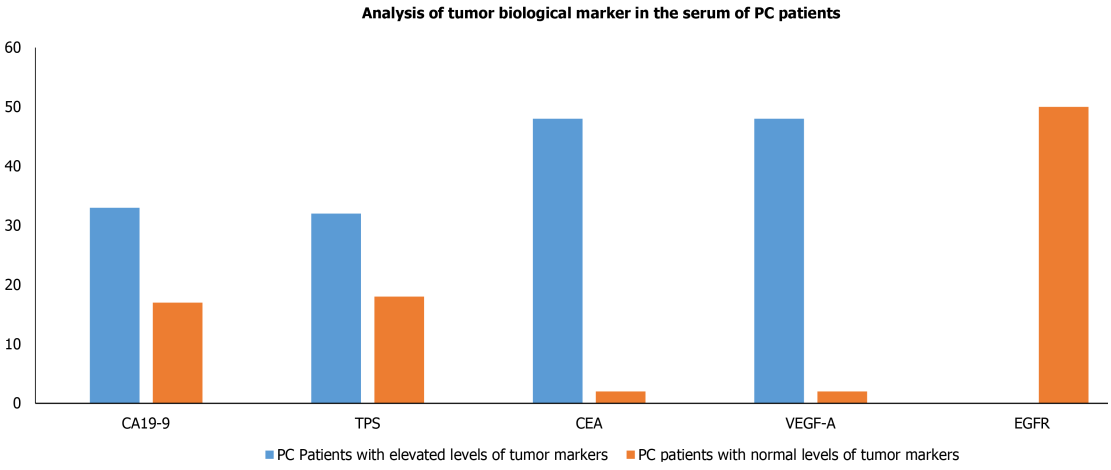

Figure 2 Analysis of tumor biological marker (carbohydrate antigen 19-9, tissue polypeptide specific antigen, carcinoembryonic antigen, vascular endothelial growth factor-A, and epidermal growth factor receptor) in the serum of pancreatic cancer patients. PC: Pancreatic cancer; CA19-9: Carbohydrate antigen 19-9; TPS: Tissue polypeptide specific antigen; CEA: Carcinoembryonic antigen; VEGF-A: Vascular endothelial growth factor-A; EGFR: Epidermal growth factor receptor.

patients 33 had significantly elevated levels of CA 19-9 in their blood samples, which indicates that more studies with a large cohort size are needed in the future to validate CA 19-9 as a better early diagnostic biomarker in PC.

Another valuable biomarker used in the diagnosis of various malignancies is TPS. It is essentially an antigen that binds to the epitope of soluble cytokeratin 18 fragments. The striking feature of TPS is to differentiate between PC and chronic pancreatitis and it is a better marker than CA 19-9 for differentiating PC and pancreatitis[32]. Previous studies suggested that serum TPS levels have a better correlation with gastric, colorectal, and pancreatic cancer than CA 19-9, CA 195, or CEA biomarkers[33,34]. Consistent with the previous studies, our results revealed that 48 out of 50 confirmed PC patients had significantly elevated levels of TPS, which suggests that elevated levels of serum TPS are better correlated with PC than CA 19-9 and could act as a better diagnostic and prognostic biomarker in PC. CEA, a glycoprotein, first identified in 1965, is present normally in the fetal pancreas, gastrointestinal tract, and liver. In the adolescent stage, it is found in lesser quantity in endodermal tissue and colon. CEA was used as a diagnostic marker of PC decades before and is now replaced by markers that have greater sensitivity for the detection of PC[35]. Elevated serum levels of CEA

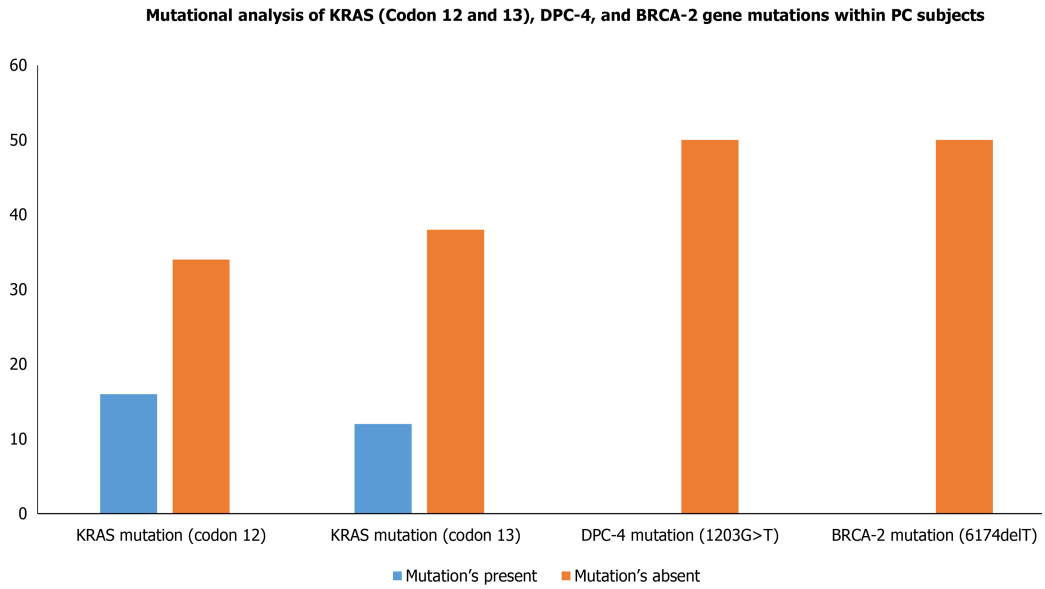

Figure 3 Mutational analysis of *KRAS* (Codon 12 and 13), *DPC-4*, and *BRCA-2* gene mutations within pancreatic cancer cases. KRAS: Kirsten rat sarcoma; DPC-4: Deleted in pancreatic cancer-4; BRCA-2: Breast cancer type 2.

have been documented in more than 60% of cases of PC. Consistent with previous findings, our results demonstrated that 64% of patients (32 out of 50 confirmed PC) had elevated levels of serum CEA. However, if used with other biomarkers for early diagnostics, CEA could be adding up great value to early diagnostics of PC[36]. High expression of VEGF-A is associated with tumor size and progression. Overexpression of VEGF-A has been reported in head and neck, non-small cell lung, ovarian, endometrial, osteosarcoma, bladder, B cell lymphoma, ocular adnexal lymphoma, papillary renal cell carcinoma, and pancreatic cancers. VEGF-A is reported to have an

80 gene loci whose alterations are reported in hepatocarcinoma, lung, pancreatic, and endometrial cancers[36]. A study conducted by Seo *et al*[37] demonstrated that 93% of ductal pancreatic adenocarcinomas showed high expression of VEGF-A protein. In the recent past, around 77% of VEGF-A expression was observed in PC tissues whereas only 15% of VEGF-A expression was found in the normal range[38]. Consistent with these findings, our results showed that out of 50 confirmed PC subjects, 48 cases had elevated levels of VEGF-A expression, which indicates that VEGF-A plays a critical role and had a strong causal association with PC progression, thus could act as a valuable tumor biomarker in combination with other biomarkers for early diagnosis of PC.

Besides, the currently available biomarkers for PC diagnostics, it is worthy to introduce genetic markers to develop more sophisticated tools for early detection of PC. PC is a disease that harbors somatic as well as hereditary mutations. Approximately, 5%-10% of the familial PC is caused by a mutation in a myriad of genes and surges the predisposition to PC by several-fold[24]. Previous studies reported that several genes showed a strong causal association with PC progression, among these most important are *KRAS, DPC-4,* and *BRCA-2* which in turn are associated with

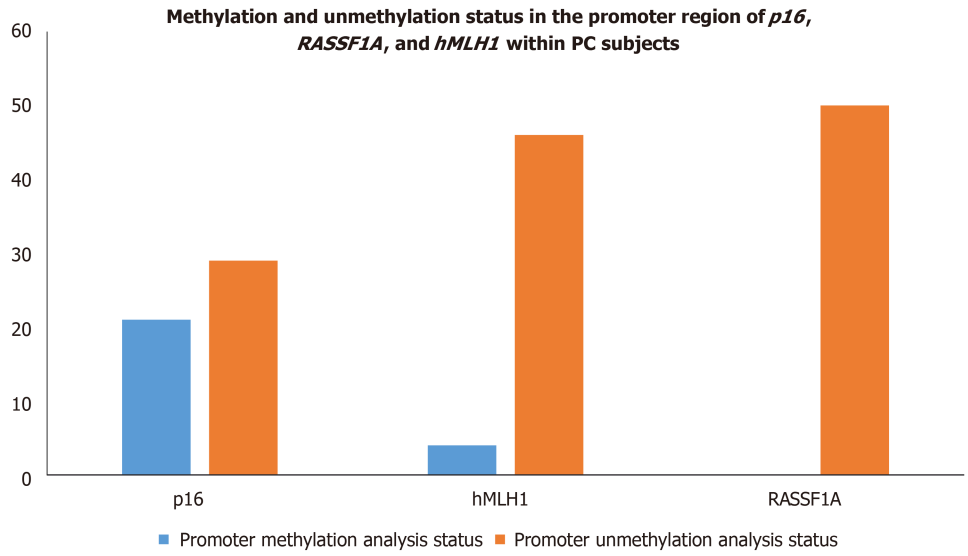

Figure 9 Methylation and unmethylation status in the promoter region of *p16*, *RASSF1A*, and *hMLH1* within pancreatic cancer subjects.
PC: Pancreatic cancer.

different other genes using different interactions like physical interaction, genetic interaction, shared protein interaction, *etc.* as depicted in Figure 10[39]. The most common mutation reported in PC is *KRAS* mutation and is the earliest recognizable event in its pathogenesis. Studies have reported that mutations in the *KRAS* gene are mainly limited to codon 12 and rarely on codon 13[40,41]. The pathological mutation in *KRAS* encodes constitutive Ras protein which belongs to GTP binding protein family. The constitute Ras protein facilitates the oncogenic signaling pathway which leads to inflammation, deregulated cellular growth, cell motility, and remodeling of the cytoskeletal elements. *KRAS* gene mutations are known to be driver mutations that occur sporadically. It accounts for 30% of early neoplasms of the pancreas and nearly 100% in pancreatic adenocarcinomas. Besides PC, a mutation in the *KRAS* gene is adequate to promote lung cancer, colon cancer, breast cancer, and other cancers as well [42,43]. Recent clinical data suggest that *KRAS* mutations act as significant prognostic biomarker to predict therapeutic intervention for PC management. Kim *et al*[44] demonstrated that out of 136 PC patients, 70 PC patients harbored point mutation in codon 12 of the *KRAS* gene, and these patients have shown dismal response to gemcitabine-based chemotherapy compared to those who had wild type allele for *KRAS* gene[44]. Another study revealed that out of 173 PC patients, 121 were found to harbor point mutations in codon 12 of the *KRAS* gene, and among them are nonresponders to erlotinib. However, patients with wild-type alleles displayed a promising overall survival rate[45]. Consistent with these studies, our mutational analysis results revealed that 16 PC patients had *KRAS* point mutation at codon 12, interestingly we observe point mutation in the *KRAS* gene at codon 13. These findings suggest that further studies are needed to validate the high frequency of point mutation in codon 13 of the *KRAS gene. BRCA-1 and BRCA-2* germline mutations substantially increase the lifetime risk of breast cancer tumorigenesis. Recent reports suggest that the mutations in these genes also have a strong causal association with other cancers including PC[46]. The primary role of the *BRCA-2* gene is the maintenance of the genome by enhancing homologous recombination of a double-stranded break. Approximately, 80% of *BRCA-2* mutations are either frameshift or non-sense mutations which result in the formation of premature stop codons to encode non-functional BRCA-2 protein. *BRCA-2* mutations have been found in 7.3% of familial PC patients which indicates an increased risk of cancers by about 20-fold[47]. *DPC-4* (*SMAD-4)* is a tumor suppressor gene intricated in the regulatory mechanisms of gene transcription. Approximately, 30% of PC cases have been reported to harbor homozygous mutations in the *DPC-4* gene[21]. The mutated *DPC-4* gene-encoded hyperactivated Smad-4 protein leads to the activation of TGF-β pathways thereby promote cell proliferation and tumor growth. Mutations in the *DPC-4* gene have been reported in approximately 50% of PCs and serves as a leading cause of protein inactivation[48]. Inconsistent with previous studies, our mutational analysis of *BRCA-2* and *DPC-4* genes revealed a zero frequency of *DPC-4* 1203 G>T and *BRCA-2* 6174 deletion in PC patients. Collectively, these findings suggest that a larger sample size is

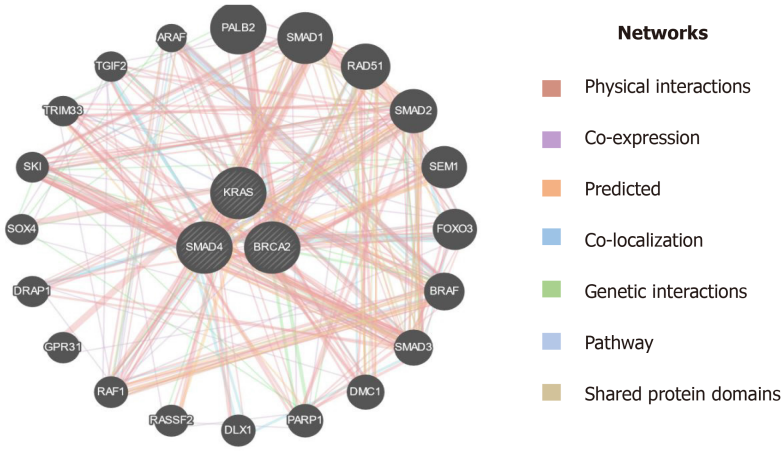

Figure 10 Interaction of *KRAS*, *SMAD4* (*DPC4*), and *BRCA2* with other genes based on various parameters. KRAS: Kirsten rat sarcoma; DPC-4: Deleted in pancreatic cancer-4; BRCA-2: Breast cancer type 2.

needed to validate our results in the ethnic Kashmiri population.

Epigenetic modulations play a critical role in tumorigenesis. Change in DNA methylation of tumor suppressor genes has indispensable importance in therapeutics and could serve as biomarkers for diagnostics and prognostics in various cancers[49]. *p16* is a tumor suppressor gene that encodes cyclin-dependent kinase inhibitors to arrest the cellular growth of malignant cells. Besides point mutations and homozygous deletions in the *p16* gene, recent evidence suggests that methylation of CpG islands in the promoter regions of *p16* stimulates transcriptional silencing of the *p16* gene and contributes to PC progression. In the recent past, hypermethylation in the promoter region of *p16* is significantly raised in chronic pancreatitis compared to normal; suggesting that hypermethylation in the promoter region of the *p16* gene might deregulate cell cycle kinetics and could promote PC progression. Further, reports demonstrated that *p16* hypermethylation in chronic pancreatitis might increase the risk of PC development many-fold[48]. Moore *et al*[50] demonstrated the role of *p16* promoter hypermethylation and associated molecular pathways involved in exocrine and endocrine development of PC. Further, studies suggest that the reduction in overall survival rate associated with *p16* alterations signifies the fact that *p16* could act as an important diagnostic and prognostic biomarker in resected ductal PC patients [51]. *RASSF1A* is another tumor suppressor and an important component of RAS/PI3K/AKT and RAS/RAF/MEK/ERK pathways that have been epigenetically inactivated in various sporadic human malignancies. A higher frequency of promoter methylation status of *RASSF1A* has been implicated in several cancers. The highest frequency of *RASSF1A* promoter hypermethylation was reported in prostate cancer (99%), followed by lung cancer (95%) and breast cancer (88%)[52]. Recent reports suggest that a low frequency of *hMLH1* hypermethylation was detected in PC. The loss of the *hMLH1* gene which encodes for Mut L protein homology 1 is common in various cancers. Further, whole-genome sequencing revealed that somatic *hMLH1* mutations are rare in cancers with an observed frequency of < 1%[53]. In the present study, we carried out epigenetic modifications (CpG methylation) of promoter regions of *p16*, *RASSF1A*, and *hMLH1* genes. Our results demonstrate that significant hypermethylation (CpG islands) was reported in the promoter regions of the *p16* gene in PC patients. However, we observed an extremely low frequency of methylation in the promoter region of the *hMLH1* gene in PC patients. Interestingly, the CpG methylation in the promoter region of the *RASSF1A* gene was completely absent in PC patients. Additionally, *in-silico* analysis suggest that plethora of genes are associated through various interactions with the key genes (*hMLH1*, *RASSF1A*, and *CDKN2A*) as in Figure 11, which could play a key role in the progression of PC[39]. Together, these results suggest that a cohort and comprehensive study with larger sample size is needed to document our findings in the ethnic Kashmiri population.

CONCLUSION

In conclusion, the present study strongly suggests that the elevated levels of serum CA

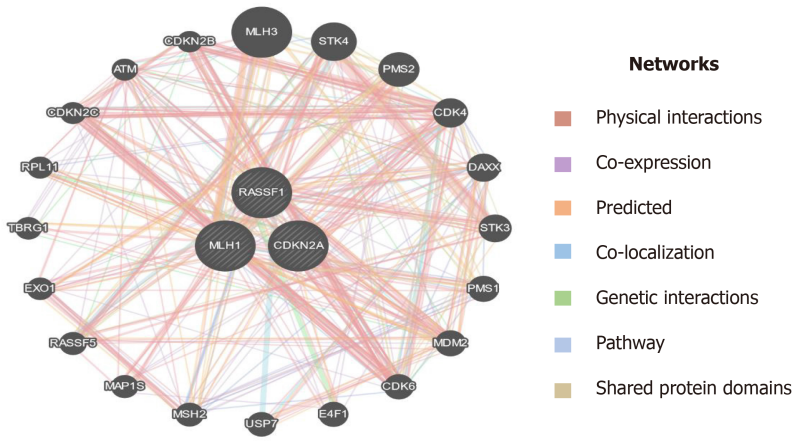

Figure 11 Interaction of *MLH1*, *RASSF1*, and *CDKN2A* (*p16*) with other important genes which have a role in the progression of pancreatic cancer.

19-9, TPS, CEA, and VEGF-A can be used as predictive biomarkers in PC patients of the ethnic Kashmiri population and may act as prognostic biomarkers to benefit the patients who are on a different regimen of chemotherapeutic interventions. Further, mutational analysis data suggest that besides harboring point mutation in codon 12 of *KRAS* gene, the PC patients of the current study significantly harbored codon 13-point mutation as well, which is very rarely reported in the previous studies. This may act as a genetic risk predictor in the development of PC. Additionally, considerable hypermethylation (CpG islands) in the promoter region of the *p16* gene in the current study may lead to silencing of the *p16* gene and could also increase the predisposition towards PC. However, we could not find the association of *DPC*-4G>T and *BRCA*-2 6174 deletion mutations and hypermethylation of CpG islands in the promoter region of *RASSF1A* and *hMLH1* gene towards the risk of PC. To validate these results in the Kashmiri population the future studies need to be comprehensive and with larger sample sizes.

ARTICLE HIGHLIGHTS

Research background

Pancreatic cancer (PC) is one of the deadliest malignancies with an alarming mortality rate. Despite significant advancement in diagnostics and therapeutics, early diagnosis remains elusive causing poor prognosis, marred by mutations and epigenetic modifications in key genes which contribute to disease progression.

Research motivation

To explore the various biological tumor markers collectively and mutational analysis of key regulatory genes for early diagnosis and prognosis of PC.

Research objectives

To evaluate various biological tumor markers collectively in PC and their association with genetic mutation and epigenetic modification of key regulatory genes that could act as early diagnostic and prognostic biomarkers and will help in future therapeutics of PC in Kashmir valley.

Research methods

The current study includes 50 confirmed PC cases to evaluate the levels of carbohydrate antigen 19-9 (CA 19-9), tissue polypeptide specific antigen (TPS), carcinoembryonic antigen (CEA), vascular endothelial growth factor-A (VEGF-A), and epidermal growth factor receptor (EGFR) by enzyme-linked immunosorbent assay (ELISA) method. Mutational analysis of key genes Kirsten rat sarcoma (*KRAS*), Breast cancer type 2 (*BRCA*-2), and deleted in pancreatic cancer-4 (*DPC*-4) genes was performed to evaluate the mutations at hotspot regions. Furthermore, epigenetic modifications were performed in the promoter regions of cyclin-dependent kinase

inhibitor 2A (*p16; CDKN2A*), MutL homolog 1 (*hMLH1*), and Ras association domain-containing protein 1 (*RASSF1A*) genes.

Research results

Besides significant elevation in levels of tumor markers CA 19-9 ($P \leq 0.05$), TPS ($P \leq 0.05$), CEA ($P \leq 0.001$), and VEGF ($P \leq 0.001$), our mutational analysis observed that *KRAS* gene mutation is predominant in codon 12 (16 subjects, $P \leq 0.05$), and 13 (12 subjects, $P \leq 0.05$). Additionally, epigenetic modification analysis suggests that CpG methylation was observed in 21 ($P \leq 0.05$) and 4 subjects in the promoter regions of the *p16* and *hMLH1* gene, respectively.

Research conclusions

The study revealed the significant elevation of serum biological markers in PC patients and the causal association of hotspot mutations and epigenetic modification of key with PC pathogenesis thus indicates the potential of biological markers, mutational status, and epigenetic modifications of key genes collectively for predisposition, susceptibility as well as diagnostics and prognostics of PC.

Research perspectives

The study strongly suggests that the elevated levels of serum CA 19-9, TPS, CEA, and VEGF-A can be used as predictive biomarkers in PC subjects. Additionally, mutational analysis epigenetic modifications in the promoter region of key genes may act as prognostic biomarkers to benefit the patients who are on a different regimen of chemotherapeutic interventions. Further to validate these results, future studies need comprehensive, cohort, and explicative studies with large sample sizes.

Abstract

BACKGROUND

Esophageal cancer (ESCA) is the sixth most common malignancy in the world, and its incidence is rapidly increasing. Recently, several microRNAs (miRNAs) and messenger RNA (mRNA) targets were evaluated as potential biomarkers and regulators of epigenetic mechanisms involved in early diagnosis. In addition, computed tomography (CT) radiomic studies on ESCA improved the early stage identification and the prediction of response to treatment. Radiogenomics provides clinically useful prognostic predictions by linking molecular characteristics such as gene mutations and gene expression patterns of malignant tumors with medical images and could provide more opportunities in the management of patients with ESCA.

AIM

To explore the combination of CT radiomic features and molecular targets associated with clinical outcomes for characterization of ESCA patients.

METHODS

Of 15 patients with diagnosed ESCA were included in this study and their CT imaging and transcriptomic data were extracted from The Cancer Imaging Archive and gene expression data from The Cancer Genome Atlas, respectively. Cancer stage, history of significant alcohol consumption and body mass index (BMI) were considered as clinical outcomes. Radiomic analysis was performed on CT images acquired after injection of contrast medium. In total, 1302 radiomics features were extracted from three-dimensional regions of interest by using PyRadiomics. Feature selection was performed using a correlation filter based on Spearman's correlation (ρ) and Wilcoxon-rank sum test respect to clinical outcomes. Radiogenomic analysis involved ρ analysis between radiomic features associated with clinical outcomes and transcriptomic signatures consisting of eight N6-methyladenosine RNA methylation regulators and five up-regulated

miRNA. The significance level was set at $P < 0.05$.

RESULTS

Of 25, five and 29 radiomic features survived after feature selection, considering stage, alcohol history and BMI as clinical outcomes, respectively. Radiogenomic analysis with stage as clinical outcome revealed that six of the eight mRNA regulators and two of the five up-regulated miRNA were significantly correlated with ten and three of the 25 selected radiomic features, respectively ($-0.61 < \rho < -0.60$ and $0.53 < \rho < 0.69$, $P < 0.05$). Assuming alcohol history as clinical outcome, no correlation was found between the five selected radiomic features and mRNA regulators, while a significant correlation was found between one radiomic feature and three up-regulated miRNAs ($\rho = -0.56$, $\rho = -0.64$ and $\rho = 0.61$, $P < 0.05$). Radiogenomic analysis with BMI as clinical outcome revealed that four mRNA regulators and one up-regulated miRNA were significantly correlated with 10 and two radiomic features, respectively ($-0.67 < \rho < -0.54$ and $0.53 < \rho < 0.71$, $P < 0.05$).

CONCLUSION

Our study revealed interesting relationships between the expression of eight N6-methyladenosine RNA regulators, as well as five up-regulated miRNAs, and CT radiomic features associated with clinical outcomes of ESCA patients.

Key Words: Esophageal cancer; Radiogenomics; Computed tomography; Radiomics; MicroRNAs; N6-methyladenosine

Core Tip: This is a retrospective study aiming at investigating the relationship between the expression levels of transcriptomic features (eight N6-methyladenosine RNA methylation regulators and five up-regulated microRNAs) and radiomic features extracted from computed tomography images that were significantly associated to clinical outcomes (stage, alcohol history, body mass index) in patients with esophageal cancer . Radiogenomic analysis revealed significant correlations between the expression of the N6-methyladenosine RNA regulators, as well as five up-regulated microRNAs, and several computed tomography radiomic features associated with three investigated clinical outcomes of esophageal cancer patients.

INTRODUCTION

Esophageal cancer (ESCA) is one of the most common malignancies and ranks sixth as a cause of lethal cancer worldwide[1]. Despite the different types of treatment, ESCA remains a devastating pathology with an overall 5-year survival rate of 15%–25%. The main issue related to ESCA is that, given the late symptoms manifestation, most patients are diagnosed with advanced-stage ESCA characterized by unresectability or metastatic disease, for which the best treatment choices are palliative interventions such as concurrent chemoradiotherapy and combination chemotherapy[2,3]. The majority of ESCAs fall into two main histologic subtypes: Esophageal adenocarcinoma and esophageal squamous cell carcinoma (ESCC)[4]. Imaging plays a key role in each step of the management of ESCA. Computed tomography (CT) plays an important role in the diagnosis, staging and treatment guidance of ESCA. This imaging technique allows to evaluate the loco-regional extension of ESCA by showing the extent of involvement of the esophageal wall by tumor, as well as the tumor invasion of the peri-esophageal fat[5]. Moreover, it is also useful to detect the presence of distant

because the analysis used anonymous clinical data that were obtained after each patient agreed to treatment by written consent.

metastases[6,7]. However, CT has several limitations associated with the ability to evaluate the intra-tumor heterogeneity of the ESCA, as well as in visually distinguishing the post-treatment residual tumor[8,9].

Therefore, since it is well-recognized that information arising from images may be substantially enhanced by quantitative imaging analysis, the radiomics role has rapidly increased in the last decade for cancer applications, including those related to ESCA[10-12]. Radiomics is evolving as medical technology and is currently one of the most interesting research fields. Through radiomics, quantitative data can be extrapolated from diagnostic images, and these extracted parameters (radiomic features) have the potential to identify tumor characteristics[10,11,13]. The innovative field of radiomics could provide opportunities in the management of ESCA patients for improvements in every step of ESCA management[12,14]. Recent studies on CT radiomics in ESCA analyzed CT radiomics features for several steps of ESCA management, such as preoperative stage identification[15] and prediction of response to treatment[3,16].

On the other hand, the emerging clinical relevance of genomics in cancer medicine by applying the next generation sequencing technologies has provided unprecedented opportunities to understand the biological basis of different cancer types, identify genomic biomarkers in carcinogenesis, identify potential bio-molecular targets for drug response and resistance and to guide clinical decision-making regarding the personalized medicine and the clinical practice[17,18].

Gene expression profiling can improve knowledge about the molecular alterations during carcinogenesis. Biomarkers of these molecular alterations, in turn, may be useful in diagnosing cancers, particularly early, curable cancers. Recently, results from gene expression data analyses have made it possible to investigate the complex pathological mechanisms involved in ESCA, with the aim to discover novel molecular markers for tumor diagnosis and to customize therapy based on an individual tumor genetic composition[19-21]. Several microRNA (miRNA), such as miR-93, miR-21, miR-4746 and miR-196a, were evaluated as potential biomarkers for the early diagnosis of cancer, highlighting their diagnostic values[22]. Recently, several studies also suggested that N6-methyladenosine (m6A) methylation can play a crucial role in cancer progression by regulating biological functions that affect noncoding RNA expression[23,24] In particular, a recent study[25] highlighted the role of m6A methylation regulators aberrantly expressed in ESCA to predict clinical outcomes.

Combining radiomic features with molecular and genomic characteristics can provide insights to characterize tumor phenotype[26]. In this direction, radiogenomics, as a new field that provides clinically useful prognostic predictions by linking molecular characteristics such as gene mutations and gene expression patterns of malignant tumors with medical images, could provide more opportunities in the management of patients with ESCA for improvements in staging, predicting treatment response and survival[7,21]. Based on promising results obtained from preliminary CT-based radiomics studies on ESCA[16,27] and considering the capability of miRNAs as potential biomarkers able to characterize differential expression of different cancer tissues, as well as the critical role of m6A as epigenetic regulator in cancer biology, we aimed to combine these findings in a radiogenomic study, using appropriate variables as clinical endpoints. Specifically, we used the preoperative ESCA stage as a clinical outcome, since the survival of ESCA patients with early stage (stage I−II) could be up to 85%[28]. Additionally, surgical resection, chemoradiation or other optimal therapeutic approaches depend on accurate preoperative staging. Therefore, accurate preoperative staging is important for predicting prognosis and choosing a suitable therapeutic strategy for patients with ESCA[15]. We also used the history of significant alcohol consumption as a clinical outcome, since this is considered as one of the major risk factors for ESCA[29]. Lastly, we evaluated body mass index (BMI) as a clinical outcome, due to its association with increased risk of ESCA[30,31].

Using publicly available integrated ESCA cohort from The Cancer Genome Atlas (TCGA) and The Cancer Imaging Archive (TCIA)[32,33], we aimed at investigating possible relationships between CT-radiomic features associated with the three above-mentioned clinical outcomes and correlated with esophageal up-regulated miRNAs, which were *in silic*o-validated from Zeng *et al*[22], in order to evaluate potential biomarkers for the early diagnosis of ESCA. Furthermore, we evaluated if the same CT-radiomics features could be associated with epigenetic signatures, considering m6A RNA methylation regulators-based prognostic signature for ESCA from Xu *et al* [25] in order to support important information for developing diagnostic and therapeutic strategies.

MATERIALS AND METHODS

Patient population and definition of clinical outcomes

The study was conducted in accordance with the Declaration of Helsinki, and the study protocol was approved by the Ethics Committee of the Istituto Nazionale Tumori "Fondazione G. Pascale (protocol number 1/20). Sixteen patients with diagnosed ESCA were extrapolated by combining the public databases TCIA-TCGA and included in this study[32,33]. All subjects performed CT investigation with iodized contrast medium injection. Of 16 patients, one was excluded due to the presence of artifacts on acquired images. Due to their availability for all 15 patients, the transcriptome profiling and the following clinical variables were extracted and considered as outcomes for this study: Cancer stage, history of significant alcohol consumption and BMI value. We did not perform analyses on smoking measurements (tobacco history, age at starting smoking, pack-year smoked) due to the incompleteness of these data. To perform radiogenomic analyses, we divided patients into two groups according to stages I−II or III−IV, making stage outcome binary. Refer to Table 1 for clinical characteristics and outcomes of included patients.

Image acquisition and processing

CT examinations were acquired on GE Medical Systems (9 patients) and Siemens (6 patients) CT scanner, with slice thickness ranging from 1.25 mm to 2.5 mm and pixel size varying from 0.67 to 0.9. three-dimensional (3D) regions of interest (ROIs) encompassing the tumor were manually delineated slice-by-slice by using ITK-SNAP (version 3.6.0, http://www.itksnap.org) on the post-administration of contrast agents CT images. The tumor localization was divided into three regions: 7 patients presented lesions at the middle level, 2 subjects in the middle/distal area and 6 patients in the distal esophagus.

Gray-levels normalization was not performed, since CT gray values reflect absolute world values (Hounsfield units) and should be comparable between scanners. To correct variability from parameters related to voxel size and so unify voxel size across the cohort, radiomics data were extracted from images resampled to isotropic voxels of $1 \times 1 \times 1$ mm^3 using B Spline interpolator.

Radiomic analysis

Radiomic features extraction: A total of 1302 radiomics features were extracted from segmented ROIs by using the open source Python package PyRadiomics (https://pyradiomics.readthedocs.io/en/Latest/). The extracted radiomics features were categorized into five groups: (1) Shape features (n = 14); (2) First-order features including 18 intensity statistics; (3) 74 multi-dimensional texture features including 23 gray level co-occurrence matrix (GLCM), 16 gray level size zone matrix (GLSZM), 16 gray level run length matrix (GLRLM), 14 gray level dependence matrix (GLDM) and 5 neighboring gray tone difference matrix (NGTDM) features; 1196 transformed first-order and textural features including; (4) 736 wavelet features in frequency channels LHL, LLH, HHH, HLH, HLL,HHL, LHH and LLL, where L and H are low- and high-pass filters, respectively; and (5) 460 LoG filtered features with sigma ranging from 1.0 and 5.0, with step size = 1. Features of groups (2) and (3) were grouped together and, from now on, this group will be referred to as "original features". The extracted radiomics features grouped by similarity in four categories are listed in the Supplementary Table 1. The computing algorithms can be found at www.radiomics.io and the image biomarker standardization initiative presented a document to standardize the nomenclature and definition of radiomic features[34].

Radiomic features selection: Features selection was performed separately for shape features, original features, wavelet features and LoG filtered features in two steps, followed by a third step involving the whole set of features passed through the step I and II. In the first step, a correlation filter based on the absolute values of pairwise Spearman's correlation (ρ) coefficient was used to reduce feature redundancy. Threshold for ρ was set to 0.8. Briefly, if two features had $\rho > 0.8$, the function looks at the mean absolute correlation of each variable and the variable with the largest mean absolute correlation is removed. The second step varied according to the type of outcome variables. For binary outcomes, a further feature restriction through a univariate analysis was performed by using non-parametric Wilcoxon rank-sum test to investigate the statistical significance with respect to the outcome. Statistical significance was set to $P < 0.05$. The significantly different features were then selected and further reduced in the third step. For continuous outcomes, the second step

consisted of computing ρ between each feature selected through the step I and the reference outcome. Then, all features with a significant $\rho > 0.5$ and P value < 0.05 were considered. In order to check for redundancies among features belonging to the different four groups, the third step consisted in applying the correlation filter described in step I to the whole feature set passed through step II. All steps were implemented using Matlab R2020a (The MathWorks Inc., Natick, MA, United States).

Predictive models building and analysis for stage assessment: In order to evaluate the predictive power of CT radiomic features taken by them for ESCA staging, a fourth step of feature selection was performed for features that were associated with stage. The latter step consisted in ranking the remaining features based on the mutual information (MI) between the distribution of the values of a certain feature and the membership to a particular class. Features were evaluated independently, and the final feature selection occurred by aggregating the five top ranked ones[35-37]. For the binary stage I-II/stage III-IV classification task, the reduced feature set was used to build logistic regression models of order from 1 to 5 that would best predict ESCA stage by using an imbalanced-adjusted bootstrap resampling (IABR) approach on 1000 bootstrap samples[38]. Specifically, the training set was made up 1000 bootstrap samples randomly drawn with replacement from the available dataset. The testing set consisted of the instances that did not belong to the bootstrap sample. Then, application of the imbalance-adjustment step made the probability of picking a positive and a negative instance in the bootstrap sample the same[39-41].

For each model order, the combination of features maximizing the 0.632+ area under the receiver operating characteristic curve (AUC) within 1000 bootstrap training and testing samples was identified. Finally, IABR on 1000 samples was performed again for all models to assess prediction performances[38,42].

Additional analyses were performed starting from the first two, three and four features surviving after the MI-based feature selection step (which was used to build logistic regression models of order from 1 to 2, 1 to 3 and 1 to 4, respectively) that would best predict ESCA stage. Moreover, given that the overall stage is determined after the cancer is assigned categories describing the tumor (T), node (N) and metastasis (M) categories, we tested the capability of these features for predicting T and N status. Analyses assuming M status as clinical outcome were not performed due to the extremely unbalanced sample. Patients were divided into two groups according to T1-T2 or T3−T4 tumor status, making T stage outcome binary. Similarly, we evaluated if CT radiomic features could assess N status by dividing patients into two groups according to the absence (N0) or presence (N1-N2-N3) lymph node status[43].

Transcriptomic data collection

RNA-Seq and miRNA-Seq data of esophageal carcinoma of tumor tissues were downloaded from the GDC Data Portal (https://gdc-portal.nci.nih.gov/) considering for TCGA-ESCA project only patients with associated imaging data from TCIA database (see Supplementary Tables 2 and 3 for Clinical and Transcriptomic data, respectively). The mRNAs expression levels were considered as read count based on gene length and the total number of mapped reads (FPKM values). Moreover, miRNA expression quantification was downloaded and normalized counts in reads-per-million-miRNA-mapped were considered.

Radiogenomic analysis

An integrative study design was defined (see Figure 1 for the flowchart reporting the organization of data and analyses in the study) and reported as radiogenomic workflow in Figure 2 in order to evaluate potential association between significant radiomic features according to selected clinical variables (stage, history of significant alcohol consumption and BMI) with biomarkers and RNA regulators characterizing esophageal cancer. For this purpose, a Spearman's correlation analysis was investigated between radiomic features selected after the three features selection steps described above and transcriptomic signatures suggested by Zeng *et al*[22] and Xu *et al*[25]. Specifically, we calculated ρ between the whole selected feature set and the eight

m6A RNA methylation regulators (KIAA1429, HNRNPC, RBM15, METTL3, WTAP, YTHDF1, YTHDC1, YTHDF2), as well as ρ between the whole selected feature set and the five up-regulated miRNAs (miRNA-93, miRNA-21, miRNA-4746, miRNA-196a-1, miRNA-196a-2). The significance level was set to 0.05. All analyses were performed

using Matlab R2020a. The statistical methods of this study were reviewed by our bioinformatics and biostatistics group of our research support center.

RESULTS

Radiomic analysis

Radiomic feature selection: None of the 14 shape features passed the step II of features selection, both considering binary outcomes (namely stage and alcohol history) and BMI. So, radiogenomic analysis was not performed for this feature group. Concerning original, wavelet and Log sigma feature groups, the step I of feature selection reduced the feature sets from 92, 736 and 460 to 23, 127 and 65, respectively. Concerning stage analysis, Wilcoxon rank-sum test used in step II of feature selection revealed significant results for 26 radiomic features, of which 25 belonging to the wavelet feature set and the remaining one was the original first order maximum value. However, the latter feature did not pass the second correlation filter of step III (refer to Table 2). Considering the presence of alcoholic history as clinical outcome, Wilcoxon rank-sum test revealed significant results for five features, of which one belonging to original feature set (Kurtosis) and the remaining ones to wavelet feature set. These five features passed step III, since Kurtosis showed a correlation lower than 0.8 with all four wavelet features (refer to Table 2). Lastly, considering BMI as the clinical outcome, 26 wavelet and three LoG sigma features were selected due to a significant $\rho > 0.5$ ($P < 0.05$) with BMI. In total, 29 radiomic features (see Table 3) survived after the second correlation filter and were associated with the three examined clinical outcomes.

Predictive models building and analysis for stage assessment: The top five features selected after the MI-based feature selection step were wavelet LLH GLDM high gray level emphasis, LLH NGTDM complexity, HHH GLCM joint entropy, HLH entropy and HLL GLCM cluster prominence. Prediction performances of multivariable logistic regression models for the stage I-II/stage III-IV classification task were very high for both five model orders. However, by inspecting prediction performances values in Table 4, we determined that the simplest multivariable model with the best prediction performances were reached by the second order model (AUC = 87%, sensitivity = 64%, specificity = 83% and accuracy = 79%), which was based on wavelet LLH NGTDM complexity and HHH GLCM joint entropy. These results were also confirmed by additional analyses (Supplementary Tables 4-6). The top five features were also found to be able to predict T and N staging, with best AUCs (0.79 and 0.80, respectively) reached by second order models (see Supplementary Tables 7 and 8 for analyses involving five features). Results of additional analyses for T and N prediction by using two, three and four features are reported in Supplementary Tables 9-11 (T staging) and Supplementary Tables 12-14 (N staging).

Radiogenomic analysis

Stage: Overall, radiogenomic analysis revealed that six of the eight mRNA regulators were significantly correlated with 10 of the 25 selected radiomic features, which were all belonging to the wavelet group. In particular, HRNPC and WTAP were positively correlated with wavelet HHL NGTDM strength ($\rho = 0.61$, $\rho = 0.61$, $P < 0.05$, respectively); METTL3 was positively correlated with wavelet LHL GLDM high gray level emphasis, HLL GLRLM gray level variance, HLL GLDM dependence entropy and LLL GLDM small dependence high gray level emphasis ($\rho = 0.54$, $\rho = 0.53$, $\rho = 0.56$, $\rho = 0.6$, $P < 0.05$, respectively) and negatively correlated with wavelet HLL GLCM inverse variance ($\rho = -0.6$, $P < 0.05$); YTHDF1 reported a positive and significant correlation with the wavelet feature HLL GLCM maximum probability ($\rho = 0.6$, $P < 0.05$) and a negative correlation with HLL 90th percentile ($\rho = -0.61$, $P < 0.05$); YTHDF2 was positively correlated with the wavelet feature HHH GLCM contrast and HHH GLSZM zone percentage ($\rho = 0.57$, $\rho = 0.56$, $P < 0.05$, respectively); the latter feature was also positively correlated with YTHDC1 ($\rho = 0.6$, $P < 0.05$). Moreover, correlation analysis with the five up-regulated miRNA revealed a significant positive correlation between miRNA-93 and two radiomic features, namely wavelet LHL GLDM high gray level emphasis ($\rho = 0.69$, $P < 0.05$) and HHH GLCM joint entropy ($\rho = 0.58$, $P < 0.05$). Notably, HHH GLCM joint entropy contributed to building the best predictive models for stage assessment, as well as T and N assessment. Finally, a positive correlation between miRNA-4746 and HHL GLCM cluster shade was found ($\rho = 0.53$, $P < 0.05$). The radiogenomic results for stage are shown through a heatmap in the Figure 3.

Table 2 Selected radiomic features after the three feature selection steps for binary outcomes

Selected radiomic features, stage	Stage I-II, mean ± SD	Stage III-IV, mean ± SD	*P* value

The first column includes the two binary clinical outcomes investigated in this study (stage, alcohol history). GLCM: Gray level co-occurrence matrix; GLDM: Gray level dependence matrix; GLRLM: Gray level run length matrix; GLSZM: Gray level size zone matrix; H: High-pass filter; L: Low-pass filter; NGTDM: Neighboring gray tone difference matrix; SD: Standard deviation.

Alcohol history: From the integrated analysis, none of the five selected radiomic features was significantly correlated with any of eight RNA regulators (data not shown). Conversely, correlation analysis with the five up-regulated miRNA revealed a significant correlation between the wavelet feature LHH first order Mean and three up-regulated miRNA, namely miRNA-21 ($\rho = -0.56$, $P < 0.05$), miRNA-4746 ($\rho = 0.64$, $P < 0.05$) and miRNA-93 ($\rho = 0.61$, $P < 0.05$), as reported in the heatmap in Figure 4.

BMI: Overall, radiogenomic analysis revealed that four of the eight mRNA regulators were significantly correlated with 10 of the 29 selected radiomic features, of which five belonging to wavelet group and three belonging to LoG sigma group as reported in Figure 5. In particular, METTL3 was positively correlated with HLH median, LHL GLDM high gray level emphasis, HLL GLRLM gray level variance and LLL GLDM small dependence high gray level emphasis ($\rho = 0.71$, $\rho = 0.54$, $\rho = 0.53$, $\rho = 0.6$, $P < 0.05$, respectively) and negatively correlated with HLL GLCM inverse variance and LoG sigma 10th percentile calculated with sigma = 5.0 ($\rho = -0.6$, $\rho = -0.66$, $P < 0.05$, respectively); YTHDF1 was positively correlated with wavelet feature HLL GLCM maximum probability ($\rho = 0.6$, $P < 0.05$), whereas YTHDC1 was positively correlated with the wavelet HHH GLCM difference average ($\rho = 0.67$, $P < 0.05$) and inversely

Table 4 Results of multivariate analysis for the stage I-II/stage III-IV classification task

correlated with and LoG sigma root mean squared calculated with sigma = 1.0 (ρ = -0.67, P < 0.05); similarly, YTHDF2 was positively correlated with the wavelet HHH GLCM contrast (ρ = 0.57, P < 0.05) and inversely with the LoG sigma 10th percentile calculated with sigma = 5.0 (ρ = -0.56, P < 0.05). Moreover, correlation analysis with the five up-regulated miRNA revealed a significant correlation only between miRNA-93 and two radiomic features as reported in Figure 5 and in particular with the wavelet feature LHL GLRLM high gray level run emphasis (ρ = 0.69, P < 0.05) and the LoG sigma 10th percentile calculated with sigma = 5.0 (ρ = -0.54, P < 0.05).

DISCUSSION

Several studies reported that some miRNAs, such as miR-21, miR-183, miR-574-5p and miR-601, can regulate the pathways in esophageal carcinogenesis by their altered

expression associated with the increasing of risks factors, including dietary, smoking and drinking habits[44]. Moreover, a recent study, through an integrated approach, evaluated how dysregulated miRNAs by regulating RNA targets changed the relative miRNA-mRNA expression to survival and clinical characteristics[45]. In addition, miRNAs, more generally noncoding RNAs, have the ability to regulate m6A modifications, thereby affecting gene expression in cancer progression. Previous studies highlighted a strong relation between RNA methylation and breast cancer. In particular, Zhang *et al*[46] reported significant difference in expression levels and prognostic value of five m6RNA regulators (YTHDF3, ZC3H13, LRPPRC, METTL16, RBM15B) in breast cancer. Furthermore, in a recent study, Zhao *et al*[47] showed that m6A regulator genomic aberration is associated with prognosis of ESCA patients.

It is recognized that the use of CT radiomics is rapidly increasing in the field of ESCA management, playing an important role in preoperative nodal staging, diagnosis and prognosis and for predicting treatment response to chemoradiotherapy [3,48-52]. Wu *et al*[15] showed that CT radiomic features were able to discriminate between stage I-II and III-IV ESCA. In a study by Yang *et al*[45], predictive models based on CT radiomic features were able to predict complete pathologic response after neoadjuvant chemoradiotherapy of ESCA patients. CT texture features were also found to be independent predictors of survival[48], while CT wavelet features were associated with the 3-year overall survival after chemoradiotherapy in a study involving 165 patients performed by Larue *et al*[51].

In our pilot study, we examined the relationship between the expression levels of eight m6A RNA methylation regulators (KIAA1429, HNRNPC, RBM15, METTL3, WTAP, YTHDF1, YTHDC1, YTHDF2), as well as five up-regulated miRNAs (miRNA-93, miRNA-21, miRNA-4746, miRNA-196a-1 and miRNA-196a-2) and radiomic features extracted from CT images that were significantly associated to clinical outcomes (stage, alcohol history, BMI) in patients with ESCA belonging to the public integrated datasets TCGA/TCIA. We decided to evaluate by combining radiomic and transcriptomic data the above-mentioned m6A RNA methylation regulators and up-regulated miRNA since previous studies on gene expression in ESCA found interesting results on specific mRNAs associated with tumor stage through epigenetic regulation and miRNAs signature as a prognostic biomarker[22,25].

Interestingly, both considering binary clinical outcomes (namely stage and alcohol history) and BMI, CT radiomic features that survived after radiomic feature selection were mostly belonging to the wavelet group, while only histogram Kurtosis and three LoG sigma features (one textural and two histogram features) survived after feature selection for alcohol history and BMI analysis, respectively. Wavelet features were also able to differentiate between stage I-II and III-IV ESCA, with an AUC superior to 80%. Similar performances were achieved when using the same features for predicting T and N, and this could be because T and N assignments contribute to determine the overall ESCA stage[43]. These results are in line with those found by Liu *et al*[53], even if they did not include textural features from wavelet CT images.

These results were in line with previous radiomics studies, in which CT imaging features describing tumor heterogeneity also were shown to have prognostic value in esophageal cancer[51,54]. Wavelet radiomic features from pretreatment CT were found to be useful to predict overall survival of ESCA patients after chemoradiotherapy in a study by Larue *et al*[51]. Moreover, in the work by Qiu *et al*[54], wavelet features resulted predominant in the radiomic-based predictive model developed to estimate recurrence-free survival in ESCA patients achieving a pathologic complete response.

Radiogenomic analysis performed for stage assessment revealed significant correlations between 10 wavelet textural features and six of the eight m6A RNA methylation regulators (HRNPC, WTAP, METTL3, YTHDF1, YTHDF2, YTHDC1). Moreover, correlation analysis with the five up-regulated miRNA revealed a significant positive correlation between miRNA-93 and two radiomic wavelet features, namely LHL GLDM high gray level emphasis and HHH GLCM joint entropy. It is worth to note that the wavelet feature HHH GLCM joint entropy was positively correlated with miRNA-93 and contributed to building the best predictive models for the overall stage assessment and for the assessment of the T and N categories. From the literature, miR-93 is reported to be associated in various tumors and it is recently found to regulate mechanisms of drug resistance in triple negative breast cancer[55]. Moreover, Ansari *et al*[56] evaluated miR-93 as potential deregulated biomarker for early detection of ESCA. Based on these considerations, combining genomic features with radiomic ones might be of further added value for ESCA staging, thereby influencing the personalized medicine workflow in the field of ESCA. Concerning radiogenomic analysis performed using alcohol history as clinical outcome, there were no significant associations between selected CT features and the eight m6A RNA methylation regulators, while the correlation analysis with the five up-regulated miRNA revealed a significant correlation between the wavelet feature LHH first order mean and three up-regulated miRNA, namely miRNA-21, miRNA-4746 and miRNA-93. Finally, the radiogenomic analysis on BMI revealed a significant correlation between wavelet and LoG sigma features and METTL3, YTHDF1, YTHDC1 and YTHDF2. Wavelet and LoG sigma features were also associated with miRNA-93 in radiogenomic analysis involving the five up-regulated miRNAs.

In addition, a recent study has experimentally verified that overexpression of METTL3 in tumor tissues of ESCA patients compared with normal condition from adjacent tissues is associated with metabolic status, highlighting a significant correlation with tumor size and histological differentiation; this result suggests that MTLL3 may become a possible pathological index for diagnosis and a potential therapeutic target[57].

However, to our knowledge, this is the first ESCA radiogenomic study investigating the association with clinical staging and potential risk factors. Although previous radiogenomic studies were performed on ESCA[21,49,58], the strength of our study was that this is the first radiogenomic study investigating the association with stage, alcohol history, and BMI. Moreover, is not to be neglected that it is a radiogenomic study on an unexplored cancer type such as ESCA.

However, several limitations are worth noting. First, due to the extremely small sample size and the retrospective nature of the study, our results remain to be validated with a larger and prospective patient sample in the future. Second, the small sample size may have affected also prediction model performances. Therefore, a larger and more balanced study group is needed to conduct better a radiomic analysis and build more robust prediction models. In particular, although the IABR strategy we used for model building is a common reliable approach in case of small and imbalanced datasets, a larger sample size would allow using part of the dataset for the training and part for testing and validating the performance of the classifier with external datasets. In addition, it should be considered that the availability of the eight m6A RNA methylation regulators and the five up-regulated miRNAs only for a small population has prevented us from investigating other clinical outcomes, which were missing for the investigated patients. It would have been interesting to perform similar analyses considering smoking variables as clinical outcomes. In fact, in addition to alcohol, tobacco is an established risk factor for ESCA and has been proven to act synergically with alcohol to increase the risk of ESCA[59,60]. However, we could not perform analyses involving outcomes associated with smoking due to the incompleteness of these data for the included patients' cohort.

CONCLUSION

In conclusion, our preliminary study revealed interesting relationships between the expression levels of eight m6A RNA methylation regulators, as well as the five up-regulated miRNAs, and CT radiomic features that were significantly associated with clinical outcomes. Our results strengthen the role of miRNA overexpression and the possible characterization of biomarkers from liquid biopsy for ESCA assessment and staging, introducing new insights for omics integration toward a personalized medicine approach. Further prospective and retrospective studies involving larger groups of patients are essential to validate obtained results and perform in-depth analyses.

ARTICLE HIGHLIGHTS

Research background

Esophageal cancer (ESCA) is the sixth most common malignancy in the world, and its incidence is rapidly increasing. Radiogenomics provides clinically useful prognostic predictions by linking molecular characteristics such as gene mutations and gene expression patterns of malignant tumors with medical images and could provide more opportunities in the management of patients with ESCA.

Research motivation

Recently, several microRNAs (miRNAs) and messenger (RNA) targets were evaluated as potential biomarkers and regulators of epigenetic mechanisms involved in ESCA. In addition, the use of computed tomography (CT) radiomics is rapidly increasing in the field of ESCA and plays an important role in different ESCA management steps. Moreover, there are no previous radiogenomic studies on ESCA investigating the association with clinical staging and potential risk factors. This has motivated us to investigate on the relationship between the expression levels of eight N6-methyl-adenosine (m6A) RNA methylation regulators, as well as the five up-regulated miRNAs, and radiomic features extracted from CT images that were significantly associated to clinical outcomes.

Research objectives

To explore the combination of CT radiomic features and molecular targets associated with clinical outcomes for characterization of ESCA patients.

Research methods

Fifteen patients with diagnosed ESCA were included in this study, and their CT imaging and transcriptomic data were extracted from The Cancer Imaging Archive and gene expression data from The Cancer Genome Atlas, respectively. Cancer stage, history of significant alcohol consumption and body mass index (BMI) were

considered as clinical outcomes. Radiomic analysis was performed on CT images acquired after injection of contrast medium. In total, 1302 radiomics features were extracted from three-dimensional regions of interest by using PyRadiomics. Radiogenomic analysis involved Spearman's correlation (ρ) analysis between radiomic features associated with clinical outcomes and transcriptomic signatures consisting in eight m6A RNA methylation regulators and five up-regulated miRNA.

Research results

Radiogenomic analysis with stage as clinical outcome revealed that six of the eight mRNA regulators and two of the five up-regulated miRNA were significantly correlated with 10 and three of the 25 selected radiomic features, respectively. Assuming alcohol history as clinical outcome, no correlation was found between the five selected radiomic features and mRNA regulators, while a significant correlation was found between one radiomic feature and three up-regulated miRNA. Radiogenomic analysis with BMI as clinical outcome revealed that four mRNA regulators and one up-regulated miRNA were significantly correlated with 10 and two radiomic features, respectively.

Research conclusions

Our study revealed interesting relationships between the expression of eight m6a RNA regulators, as well as five up-regulated miRNAs, and CT radiomic features associated with clinical outcomes of ESCA patients.

Research perspectives

This preliminary study revealed interesting associations between m6a RNA regulators, as well as miRNAs, and CT radiomic features associated with clinical outcomes of ESCA patients. Further investigations on different ESCA omics data are required. Moreover, multimodal data combined with artificial intelligence techniques characteristics are desirable.

known about the impact of MGISTs on the survival of patients with gastrointestinal stromal tumors (GIST). The diagnosis, treatment and follow-up strategies of MGISTs is not specifically described in guidelines.

AIM

To compare the clinicopathological characteristics and prognosis of MGISTs and solitary GISTs (SGISTs)

METHODS

Patients diagnosed with primary GISTs from March 2010 to January 2020 were included. Due to the inhomogeneous distribution of several baseline characteristics and uneven MGIST and SGIST group sizes, propensity score matching was performed according to comorbidities, body mass index, tumor location, mitotic index, sex, age and American Society of Anesthesiologists score. Differences in clinicopathological characteristics and prognosis between patients with MGISTs and patients with SGISTs were compared.

RESULTS

Among the entire cohort of 983 patients, the incidence of MGISTs was 4.17%. Before matching, patients with MGISTs and those with SGISTs had disparities in body mass index, surgical approach, tumor size and mitotic index. After 1:4 ratio matching, the clinical baseline data were comparable. The 5-year progression-free survival rate was 52.17% in the MGIST group and 75.00% in the SGIST group (P = 0.031). On multivariate analysis, tumor location, tumor size, mitotic index, imatinib treatment and MGISTs (hazard ratio = 2.431, 95% confidence interval = 1.097-5.386, P = 0.029) were identified as independent prognostic factors of progression-free survival. However, overall survival was similar between the SGIST and MGIST groups.

CONCLUSION

Patients with MGISTs had poorer progression-free survival than patients with SGISTs. Risk criteria and diagnostic and treatment strategies should be developed to achieve personalized precision therapy and maximize the survival benefit.

Key Words: Gastrointestinal stromal tumors; Synchronous; Multiple tumors; Solitary tumor; Propensity score matching; Prognosis

Core Tip: Whether the clinicopathological characteristics and long-term survival of patients with multiple gastrointestinal stromal tumors are different from those of patients with solitary gastrointestinal stromal tumors is unclear. This is the first study to compare and describe these features. For accuracy and clarity, propensity score matching was used to balance the differences to explore the prognostic factors for patients with multiple gastrointestinal stromal tumors. To date, this study has the most detailed data and the largest number of patients, which may bring new insight to the diagnosis and treatment of multiple gastrointestinal stromal tumors.

increasing attention[1-3]. GISTs are commonly located in the stomach and small intestine and rarely found in the esophagus, colon and rectum[4].

Multiple GISTs (MGISTs) refer to GISTs with two or more synchronous tumors in the gastrointestinal tract[5]. With the rapid advancement of precise diagnostic techniques and detailed pathological examinations, the detection and reporting of MGISTs have increased gradually. MGISTs accounted for nearly 2% of all GISTs in a multicenter study in China from 2001 to 2014[6]. However, due to the low incidence, there is currently no large-scale demographic survey showing the incidence of MGISTs.

Whether the clinical and pathological features of MGISTs are different from those of solitary GISTs (SGISTs) also remains unclear. Additionally, little is known about the impact of MGISTs on the survival of patients with GISTs. The diagnosis, treatment and follow-up strategies for MGISTs are not specifically described in the guidelines from the National Comprehensive Cancer Network, European Society for Medical Oncology and other academic institutions. Thus, we analyzed the clinicopathological characteristics and long-term survival of a large cohort of patients with MGISTs. It is urgent to gain insight into these questions to achieve personalized precision therapy in the future.

MATERIALS AND METHODS

Study design and approval

This retrospective cohort study was performed based on a prospectively collected database of GISTs at our hospital. All relevant procedures were approved by the Institutional Review Board. This study was designed in compliance with the Declaration of Helsinki and approved by the Ethics Committee of our hospital. The Reporting and Guidelines in propensity score analysis were also followed[7].

Patients

A total of 1163 consecutive patients diagnosed with GISTs and undergoing resection at our hospital between March 2010 and January 2020 were initially pooled; of whom, 1054 were classified as having primary GISTs (Figure 1). All oncological resections with curative intent were performed by senior surgeons specialized in achieving the rigorous standard at our institution. The inclusion criteria were: (1) Age > 18 years; (2) Pathological diagnosis of GIST; (3) No evidence of recurrent GIST or distant metastasis before treatment; and (4) Physiological status based on an Eastern Cooperative Oncology Group score < 3 points. The exclusion criteria were: (1) Any previous or concurrent malignancies; (2) First operation performed in other institutions; (3) Missing or illegible baseline information; and (4) Missing follow-up data. Finally, 983 patients with regular follow-up were included and analyzed. The follow-up was performed every 3 mo for the first 3 years, then every 6 mo up to 5 years, and then every year or until death in the following years. The latest follow-up date was December 2020.

Data collection

The following clinicopathological characteristics were routinely collected from the GIST database: Age, sex, tobacco and alcohol use, body mass index (BMI), comorbidities, chief complaint, tumor location, tumor size, mitotic index (per 50 high power fields), American Society of Anesthesiologists score, modified National Institutes of Health risk category, surgical approach, intraoperative blood transfusion, operation time, postoperative complications, hospitalization time, postoperative imatinib, immunohistochemistry results and hematological indices. BMI was classified into the following categories: < 18.5, 18.5-24.9 and ≥ 25 kg/m2, based on the World Health Organization classification. The comorbidities analyzed comprised hypertension, diabetes mellitus, anemia, pulmonary disease (asthma, pneumonia, chronic obstructive pulmonary disease, *etc*.), heart disease (arrhythmia, coronary atherosclerotic heart disease, *etc*.), liver disease (hepatitis, cirrhosis, *etc*.), renal disease (nephritis, chronic kidney disease, *etc*.) and central nervous system disease (cerebrovascular disease, neurodegenerative disease, *etc*.).

The primary outcome was progression-free survival (PFS), which was defined as the interval between the date of resection and the date of confirmed disease progression or death. The secondary outcome was overall survival (OS), which was calculated from the date of surgery until the date of death. Patients were censored at the date of the last follow-up without the above event.

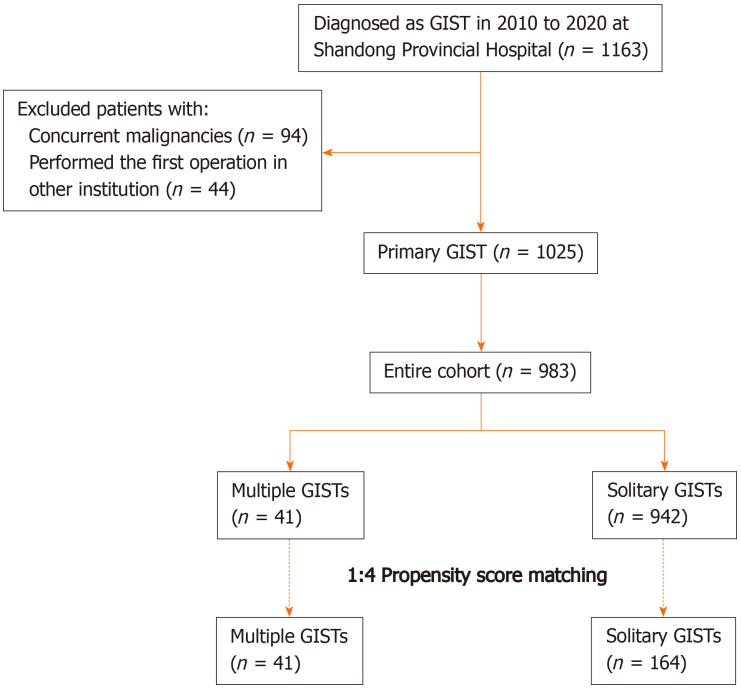

Figure 1 Flow chart of the of this study. GIST: Gastrointestinal stromal tumors; MGIST: Multiple gastrointestinal stromal tumors.

Definition of MGISTs

There is currently no authoritative and recognized definition of MGISTs. With reference to the criteria for multiple other cancers[8-11], especially multiple gastric cancers[12], we defined MGISTs as follows: (1) Each lesion must be pathologically proven; (2) All lesions must be separated microscopically; and (3) The possibility that one of the lesions represents a local extension of a metastatic tumor must be ruled out beyond reasonable doubt. It is because of the above criteria that all patients with any GIST outside the digestive tract (such as the omentum) were excluded. We defined MGISTs as two or more GISTs in the digestive tract. When MGISTs were different in size and mitotic index, the tumor was recorded according to the most advanced tumor. Similarly, in clinical practice, a modified National Institutes of Health risk category was also defined and assessed according to the most advanced tumor.

Statistical analysis

Categorical variables were analyzed using Pearson's χ^2 test or Fisher's exact test, according to the expected values. The Mann–Whitney *U* test was utilized to compare continuous variables, which are presented as medians and interquartile ranges and as the mean ± SD. The Kaplan–Meier method and log-rank test were performed to conduct survival analyses and evaluate differences in survival time, respectively. Univariate and multivariate analyses were performed using the Cox proportional hazards model. Univariate analysis was primarily performed, and variables with $P < 0.2$ were subsequently input into the multivariate analysis to determine the independent prognostic factors. Hazard ratios with their 95% confidence intervals were also derived. Statistical significance was defined as $P < 0.05$. SPSS version 26.0 (IBM, Armonk, NY, United States) and R version 3.5.3 (The R Foundation for Statistical Computing, Vienna, Austria) were used for statistical analysis.

Propensity score matching

Due to the inhomogeneous distribution of several baseline characteristics and uneven group sizes between patients with MGISTs and SGISTs, propensity score matching was performed. First, a propensity score was calculated using a logistic regression model in which the MGIST group was regressed as a dependent variable on relevant baseline parameters. The propensity score matching ratio was set to a 1:4 ratio to minimize the differences due to comorbidities, BMI, tumor location, mitotic index, sex, age and American Society of Anesthesiologist score with the nearest neighbor method. The assessment of propensity score matching is shown in Supplementary Figure 1.

RESULTS

Patient characteristics

The flow chart for the study is shown in Figure 1. Of the 983 consecutive patients who were pooled into the entire cohort between March 2010 and January 2020 at our institution, 41 (4.17%) with MGISTs were identified.

The preoperative clinical characteristics are described in Table 1. Before matching, most of the baseline characteristics were similar between the two groups, with significant differences only in BMI (P = 0.010). Regarding surgical and postoperative pathological characteristics and treatment of the SGISTs and MGISTs (Table 2), there were significant differences in surgical approach (P = 0.028), tumor size (P = 0.007), mitotic index (P = 0.009) and modified National Institutes of Health risk category (P = 0.044).

After propensity score matching at a 1:4 ratio, all baseline characteristics of the 41 patients in the MGIST group were compared with those of the 164 patients in the SGIST group (Tables 1 and 2). Supplementary pathological characteristics and blood indicators are shown in Supplementary Table 1. We also listed the clinical characteristics of patients with multiple tumors in detail (Supplementary Table 2) and showed several pathological images from these patients (Supplementary Figure 2).

Impact of MGISTs on PFS and OS

The median follow-up time of the entire matched cohort was 1468 d (IQR, 938-2225 d), and the 1-, 3- and 5-year PFS rates were 96.06%, 83.66% and 70.09%, respectively. For the patients with MGISTs, the 1-, 3- and 5-year PFS rates were 90.00%, 74.19% and 52.17%, respectively and compared with the 1-, 3- and 5-year PFS rates of 97.55%, 86.78% and 75.00% for the patients with SGISTs (P = 0.031) (Figure 2). We continued to explore the impact of MGISTs on OS. The 1-, 3- and 5-year OS rates were 98.16%, 92.50% and 83.75% for patients with SGISTs compared with 100%, 86.67% and 60.00% for patients with MGISTs, respectively, with no significant differences (P = 0.085) (Figure 3).

Univariate and multivariate analyses

Univariate analysis identified the following prognostic factors for PFS: age (P = 0.069), tumor location (P < 0.001), tumor size (P = 0.001), mitotic index (P < 0.001), blood transfusion (P = 0.018), intraoperative tumor rupture (P = 0.011), imatinib treatment (P = 0.133) and MGISTs (P = 0.035). On multivariate analysis, tumor location (P = 0.002), tumor size (P = 0.035), mitotic index (P = 0.001), imatinib treatment (P < 0.001) and MGISTs (P = 0.029) were eventually identified as independent prognostic factors for PFS (Table 3).

Univariate analysis revealed that tumor location (P < 0.001), tumor size (P = 0.021), mitotic index (P < 0.001), blood transfusion (P = 0.008), intraoperative tumor rupture (P = 0.113), imatinib treatment (P = 0.030) and MGISTs (P = 0.092) were correlated with OS. Subsequent multivariate analysis showed that tumor location (P = 0.003), mitotic index (P= 0.015) and imatinib treatment (P < 0.001) could be identified as independent risk factors for OS (Table 4). OS of patients with MGISTs (P = 0.106) was similar to that of patients with a single GIST.

DISCUSSION

MGISTs are often found in clinical treatment but ignored or misinterpreted as recurrence or metastasis. With the current lack of convincing results from large-scale studies based on demographics or clinicopathological characteristics, this is the first study to analyze the clinicopathological differences between patients with MGISTs and those with SGISTs. For accuracy and clarity, propensity score matching was used to balance the differences to explore the prognostic factors for patients with MGISTs.

A total of 983 patients were included in the cohort, including 41 with MGISTs. MGISTs accounted for approximately 4.17% of all GISTs in our study. With a median age of 60 years, patients with MGISTs had a similar age at initial diagnosis as patients with SGISTs. The incidence of GISTs is almost equal in men and women[13]; however, in our study, a male predisposition (M/F=27/14) was observed.

The BMI of patients with MGISTs was significantly lower than that of patients with SGISTs, which was pointed out for the first time, but the reason for this finding is not clear. Smoking and alcohol consumption did not affect the occurrence of MGISTs. There were no significant differences in American Society of Anesthesiologists classi-

difficulty in clinical diagnosis. MGISTs are often reported to be associated with type 1 neurofibromatosis[14], the Carney triad[15] and Carney–Stratakis syndrome[16]. In the records of our medical center, there was only one patient with neurofibromatosis, who

has been reported in our previous study[17]. However, this patient was not included in this cohort because of concurrent colon cancer. Familial and pediatric GISTs are also associated with multicentric risk[18]. However, these types of MGISTs were not found

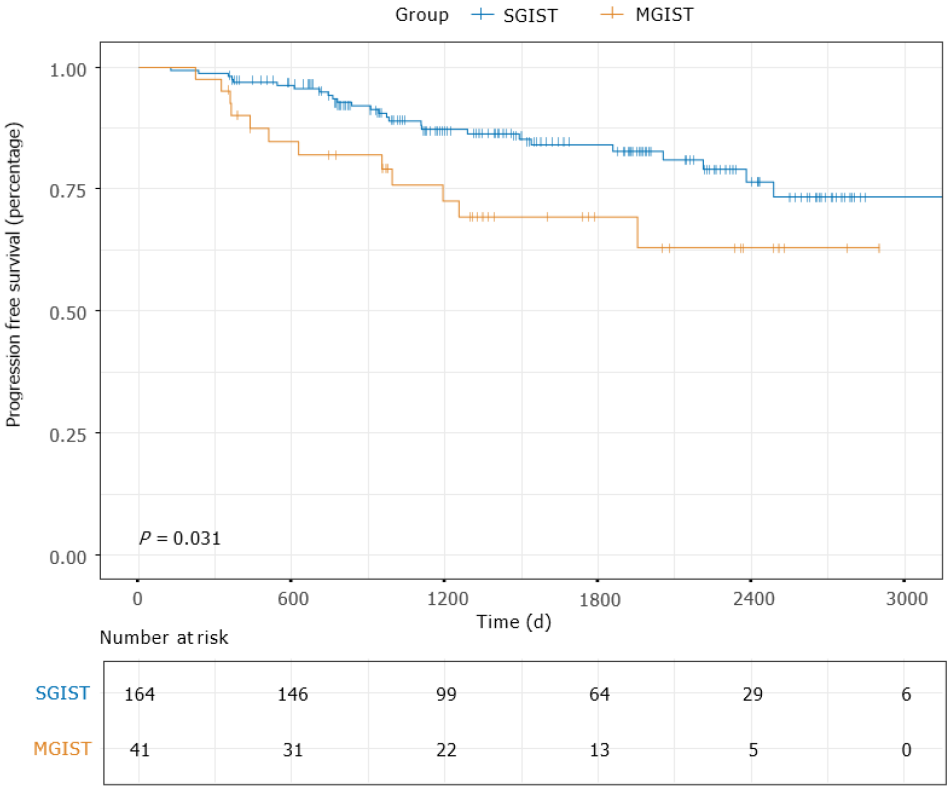

Figure 2 Kaplan–Meier survival analysis of progression-free survival. MGIST: Multiple gastrointestinal stromal tumors; SGIST: Solitary gastrointestinal stromal tumors.

in our study. This may be due to bias in the publication of case reports on these particular patients or the fact that the examination strategy has not been perfected so that such patients are missed by our colleagues. In addition, all cases of GISTs predominantly affected a single organ, and we should still pay attention to patients with multiorgan involvement to prevent misdiagnosis.

Imaging examination is an important basis for diagnosis[19]. Computed tomography or enhanced computed tomography is currently recommended but does not play an adequate role in the diagnosis of MGISTs. Of the 41 MGIST patients in our hospital, 38 underwent computed tomography examination, but only four were diagnosed accordingly. None of the MGISTs < 1 cm were detected, but this may be due to the large size of the major tumor or insufficient imaging evidence to diagnose the small tumor. For endoscopic examination, 8 of the 26 patients were suspected to have MGISTs before surgery, but endoscopy only revealed the tumor growing into the intestinal cavity, and none of the 15 cases of small intestinal MGISTs was detected. No case of MGISTs was diagnosed by B-ultrasonography or upper digestive tract radiography. Magnetic resonance imaging might be useful for diagnosis but is seldom used in ordinary examinations. Micro-GISTs, with low or no mitotic activity and little clinical significance, are common in the stomach (20%-35%)[20,21] and can transform to clinical GISTs by unknown mechanisms. Therefore, the development or modification of an examination method for preoperative screening of MGISTs can develop a more appropriate treatment plan for patients and obtain a greater survival benefit.

Heterogeneous morphology could be observed and the common growth patterns of MGISTs manifest a satellite phenomenon, that is, one or more main tumors surrounded by several small tumors. Of course, homogeneous morphology was still present in some tumors of MGISTs. Almost all gastric MGISTs consisted of two tumors and grew inside. On the contrary, small intestinal GISTs, especially in the jejunum, almost always had more than two tumors, and most of them grew outside. Unfortunately, the phenomenon has rarely been described in other studies, and it is difficult to determine whether it is a general finding. It is possible that MGISTs have different growth patterns and prognoses from SGISTs, and further research is needed.

The cellular types of the tumors were similar. Before propensity score matching, there was a significant difference in tumor necrosis. In addition, the proportion of calcification and cystic degeneration of MGISTs was higher than that of SGISTs, but

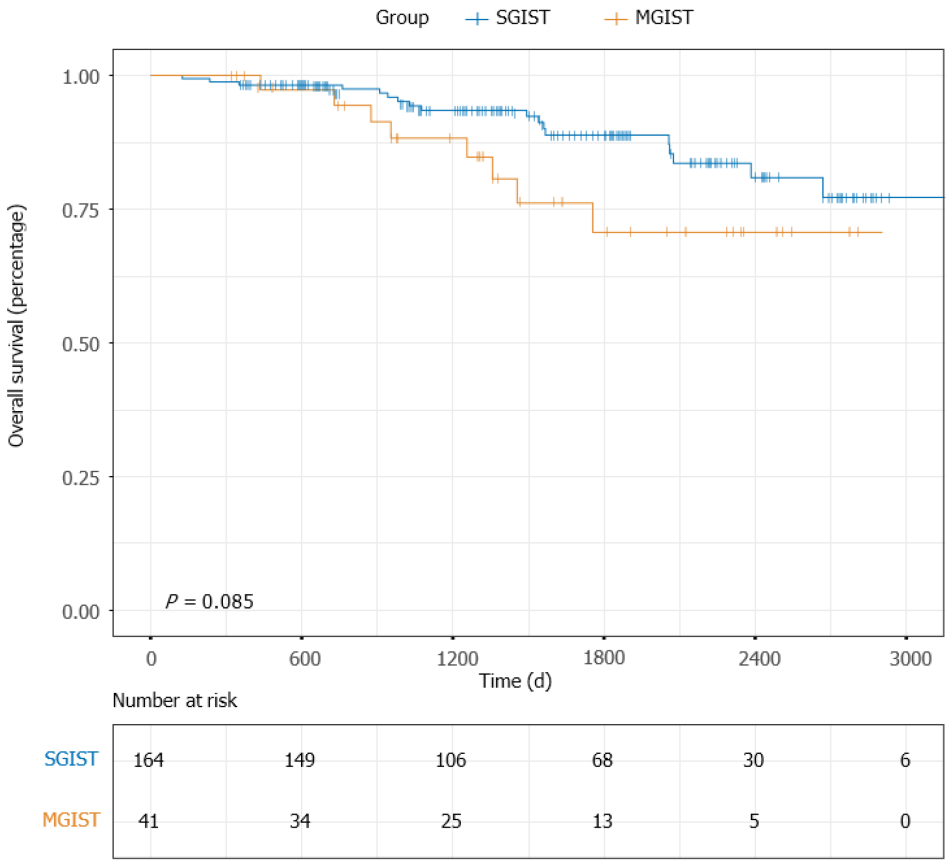

Figure 3 Kaplan–Meier survival analysis of overall survival. MGIST: Multiple gastrointestinal stromal tumors; SGIST: Solitary gastrointestinal stromal tumors.

the difference was not significant. In the propensity score matched cohort, all the above characteristics of MGISTs were compared with those of SGISTs.

For blood parameters, except for prealbumin, no significant differences were found. Immunohistochemical staining for Ki-67 antigen is often used, although this score is relatively subjective[22]. With regard to immunohistochemical markers, KIT (CD117) and ANO1 (DOG1) are two of the most sensitive and specific for GISTs[23]. S-100 and CD34 can also be used as auxiliary diagnostic indicators[24]. Unfortunately, there was no significant difference in these indicators between the patients with MGISTs and those with SGISTs.

The tumor mitotic rate is the most significant independent prognostic factor for GIST recurrence after surgery for both the stomach[25] and small intestine[26]. In our cohort, patients with MGISTs had larger tumors and a higher mitotic index, which also contributed to more advanced tumor stages.

The main treatment strategy for GISTs > 2 cm is surgical resection, and this is also the case for MGISTs. R0 resection, minimally invasive surgery and regular imaging surveillance are required to ensure perioperative and postoperative safety of patients. MGISTs may involve many segments of the gastrointestinal tract, so extensive resection is more common than with SGISTs. Therefore, consultation with experienced specialists is required to assess surgical extension and perioperative adjuvant therapy. In the practice of our medical center, the rate of open surgery for MGISTs is significantly higher than that for SGISTs. Imatinib was used for KIT/PDGFRA mutated GISTs[27] and is usually recommended for high-risk patients after surgery.

Of the 41 patients evaluated, 11 received intraoperative blood transfusions, which is higher than the rate for other operations and should compel surgeons to conduct a thorough preoperative evaluation and develop appropriate protocols. However, there was only a slight increase in operation time, intraoperative tumor rupture, postoperative hospital stays and postoperative complications in patients with MGISTs, and the difference was not significant.

After propensity score matching, all the above parameters were well balanced. We then tried to evaluate the clinical, perioperative and therapeutic factors associated with OS through Cox univariate and multivariate hazard ratio models.

There have been few studies related to the prognosis of patients with MGISTs[28]. Our study demonstrated that PFS of patients with MGISTs was significantly poorer than that of patients with SGISTs and that MGISTs were an independent risk factor for poor PFS. However, OS was similar between patients with SGISTs and those with MGISTs. This may be related to the characteristics of patients with MGISTs, suggesting that clinicians should closely monitor the condition of these patients, and it may be necessary to improve the risk classification of MGIST patients.

Given the lack of clinical trials, SGIST therapy has conflicting results in MGIST patients with regard to factors such as surgical excision and perioperative adjuvant therapy. This study suggests that more attention should be paid to such patients to explore more suitable treatment strategies. Gene detection and molecular biological experiments are also needed to explain specific manifestations[29,30].

There were some shortcomings in our research. First, as a single-center design with a small sample size, the statistical power of our findings might have been weakened. Moreover, due to the high cost, few of these patients had undergone gene detection. Last, there may have been a possibility of missed diagnoses, which could have led to an underestimation of the incidence of MGISTs.

To date, this study has the most detailed data and the largest number of patients, which may bring new insight to the diagnosis and treatment of MGISTs.

CONCLUSION

Patients with MGISTs may have demographic characteristics and immunohistochemical markers that are similar to those of patients with SGISTs, but MGIST patients also have unique tumor features. In this study, we found that MGISTs were an independent factor for PFS after propensity score matching analysis; however, OS was similar. The perioperative and long-term prognosis of patients remains of concern and requires multicenter, large sample, long-term follow-up, prospective studies. Most importantly, risk criteria, diagnostic strategies and treatment procedures suitable for this disease of lower morbidity should be developed to achieve personalized precision therapy and maximize the survival benefit of these patients.

ARTICLE HIGHLIGHTS

Research background

Synchronous primary multiple gastrointestinal stromal tumors (MGISTs) are specific and rare. The diagnosis, treatment and follow-up strategies of MGISTs are not specifically described in guidelines.

Research motivation

Due to the low incidence, there is currently no large-scale demographic survey showing the incidence of MGISTs. Additionally, little is known about the impact of MGISTs on the survival of patients with gastrointestinal stromal tumors (GISTs).

Research objectives

This study aimed to compare the clinicopathological characteristics and prognoses of patients with MGISTs and patients with solitary GISTs (SGISTs).

Research methods

Due to the inhomogeneous distribution of several baseline characteristics and uneven MGIST and SGIST group sizes, propensity score matching was performed according to comorbidities, body mass index, tumor location, mitotic index, sex, age and American Society of Anesthesiologists score.

Research results

Among the entire cohort, the incidence of MGISTs was 4.17%. Patients with MGISTs and those with SGISTs had disparities in body mass index, surgical approach, tumor size and mitotic index. Tumor location, tumor size, mitotic index, imatinib treatment and MGISTs were identified as independent prognostic factors of progression-free survival. However, overall survival was similar between the SGIST and MGIST groups.

Research conclusions

Patients with MGISTs may have demographic characteristics and immunohistochemical markers that are similar to those of patients with SGISTs, but MGIST patients also have unique tumor features. Without specific diagnostic indicators and symptoms, patients with MGISTs were identified as having a poorer progression-free survival than patients with SGISTs.

Research perspectives

Risk criteria, diagnostic strategies and treatment procedures suitable for these tumors of lower morbidity should be developed to achieve personalized precision therapy and maximize the survival benefit of these patients.

ACKNOWLEDGEMENTS

We extend our thanks to all patients involved in the study. We would also like to thank the Medical Records Department of Shandong Provincial Hospital for providing data support and the efforts of medical workers over the past decades.

Abstract

BACKGROUND

Patients with inflammatory bowel disease (IBD) are associated with increased cardiovascular risk and have increased overall cardiovascular burden. On the other hand, urotensin II (UII) is one of the most potent vascular constrictors with immunomodulatory effect that is connected with a number of different cardiometabolic disorders as well. Furthermore, patients with ulcerative colitis have shown increased expression of urotensin II receptor in comparison to healthy controls. Since the features of IBD includes chronic inflammation and endothelial dysfunction as well, it is plausible to assume that there is connection between increased cardiac risk in IBD and UII.

AIM

To determine serum UII levels in patients with IBD and to compare them to control subjects, as well as investigate possible associations with relevant clinical and biochemical parameters.

METHODS

This cross sectional study consecutively enrolled 50 adult IBD patients (26 with

Crohn's disease and 24 with ulcerative colitis) and 50 age and gender matched controls. Clinical assessment was performed by the same experienced gastroenterologist according to the latest guidelines. Ulcerative Colitis Endoscopic Index of Severity and Simple Endoscopic Score for Crohn's Disease were used for endoscopic evaluation. Serum levels of UII were determined using the enzyme immunoassay kit for human UII, according to the manufacturer's instructions.

RESULTS

IBD patients have significantly higher concentrations of UII when compared to control subjects (7.57 ± 1.41 *vs* 1.98 ± 0.69 ng/mL, $P < 0.001$), while there were no significant differences between Crohn's disease and ulcerative colitis patients (7.49 ± 1.42 *vs* 7.65 ± 1.41 ng/mL, $P = 0.689$). There was a significant positive correlation between serum UII levels and high sensitivity C reactive peptide levels ($r = 0.491$, $P < 0.001$) and a significant negative correlation between serum UII levels and total proteins ($r = -0.306$, $P = 0.032$). Additionally, there was a significant positive correlation between serum UII levels with both systolic ($r = 0.387$, $P = 0.005$) and diastolic ($r = 0.352$, $P = 0.012$) blood pressure. Moreover, serum UII levels had a significant positive correlation with Ulcerative Colitis Endoscopic Index of Severity ($r = 0.425$, $P = 0.048$) and Simple Endoscopic Score for Crohn's Disease ($r = 0.466$, $P = 0.028$) scores. Multiple linear regression analysis showed that serum UII levels retained significant association with high sensitivity C reactive peptide (β ± standard error, 0.262 ± 0.076, $P < 0.001$) and systolic blood pressure (0.040 ± 0.017, $P = 0.030$).

CONCLUSION

It is possible that UII is involved in the complex pathophysiology of cardiovascular complications in IBD patients, and its purpose should be investigated in further studies.

Key Words: Inflammatory bowel disease; Crohn's disease; Ulcerative colitis; Urotensin II; Cardiovascular risk; Endoscopic activity

Core Tip: Urotensin II (UII) is a potent vasoconstrictor with an immunomodulatory effect that is connected to various cardiovascular disorders. On the other hand, patients with inflammatory bowel disease (IBD) have increased cardiovascular burden as well as increased expression of UII receptors. It is plausible that UII is involved in the complex pathophysiology of IBD complications. In the current study, we investigated UII levels in the IBD population and compared it to matched control subjects, as well as connection of UII with relevant clinical and biochemical parameters. The results of this study showed that serum UII levels are higher in IBD patients in comparison with the control group.

INTRODUCTION

Inflammatory bowel disease (IBD) is a relapsing chronic inflammation of the gastrointestinal tract with an unpredictable course[1]. It can be divided into two disorders: Crohn's disease (CD) and ulcerative colitis (UC). Although the two disorders have a similar clinical manifestation, they differ in the location and the depth of the inflammation. The etiology of the disease is considered to be multifactorial as a complex interrelation between extrinsic factors, genetic predisposition, immunological

imbalance and microbiota disturbances. Furthermore, IBD can exhibit a wide range of extraintestinal manifestations that affect the kidneys, eyes, joints, liver, skin, heart and blood circulation[2-6].

Urotensin II (UII) is a pleotropic peptide originally found 40 years ago in the neurosecretory system of the teleost fish, while in the meantime its activity was also found in humans. UII is considered to be the most potent vasoconstrictor discovered so far, with the effect 10-fold stronger than that of endothelin-1[7]. Furthermore, its expression was found distributed in most organs and tissues, including both the central nervous and cardiovascular systems, as well as the lungs, kidneys, spleen, hypophysis, adrenal glands, stomach, pancreas, ovaries and liver[8,9]. UII activity is regulated through the urotensin receptor (UTR), which after activation induces calcium mobilization in cellular plasma, smooth muscle cells proliferation and collagen synthesis[10]. Due to the wide range of functions, UII has an extensive effect on most of the organ systems in the body, and consequently it is also associated with numerous diseases and disorders[11-13]. Moreover, recent studies are pointing to possible UII immunomodulatory effects, as it was shown that UII is involved in the regulation of the inflammation process[14,15].

In the last few decades, the extraintestinal manifestations and complications of IBD are a major issue that is increasingly investigated for an improvement of both diagnostic and treatment criteria. It is well-established that patients with IBD are associated with a high cardiovascular risk, and it was shown that they have a higher prevalence cardiovascular diseases[16-18]. However, a Danish cohort study showed that patients with IBD have a lower prevalence of the traditional cardiovascular risk factors in comparison to the general population, while on the other hand they had a higher cardiovascular burden[19]. This ambiguity is well-established, yet it is unclear what are the factors that contribute to high cardiovascular risk in patients with IBD. Since UII is one of the most potent vasoconstrictors known, and it is well-known that it is associated with cardiovascular diseases, it is reasonable to presume that there is a possible connection between cardiovascular risk in IBD patients and UII[20,21]. Moreover, seeing that recent studies are pointing to UII immunomodulatory effect and since the hallmark of IBD is the chronic inflammation, this further suggests the need to investigate clinically the possible association between them[14,15]. Additionally, a recent study conducted on patients with UC showed that they have an increased expression of UTR compared to healthy controls[22]. Moreover, that expression was found to be increased in both disease lesions and healthy tissue biopsies.

Hence, the aim of this study was to evaluate serum UII levels in patients with IBD and to compare them with healthy, gender and age matched controls. Moreover, we further investigated the possible association between UII levels and the relevant clinical and biochemical parameters.

MATERIALS AND METHODS

Study design and ethical considerations

This cross-sectional study was conducted at the University Hospital of Split and the University of Split School of Medicine during the period from January 2018 to March 2019.

Before the start of the study, every participant was informed about the aim, course and procedures involved, and they all signed an informed written consent. The study was conducted in accordance with all ethical principles of the Seventh Revision of the Helsinki Declaration, and it was approved by the Ethics Committee of University Hospital of Split (date of approval: November 23, 2017).

Subjects

This study included 50 adult patients with pre-diagnosed IBD (24 patients with UC and 26 patients with CD) and 50 healthy, age and gender matched controls. The diagnosis of UC and CD was established on clinical, radiological, endoscopic and histological traits in accordance with the European Consensus on Crohn's Disease and Ulcerative Colitis[23]. Inclusion criteria were: Disease duration of at least 1 year, stable disease activity in the past 3 mo and age between 18 and 65 years. Exclusion criteria were: Diabetes, obesity, arterial hypertension, use of statins, cardiovascular disorders, therapy with corticosteroids during 3 mo prior to study onset, substance abuse and consumption of alcohol more than 40 g/d.

Additionally, we checked medical records of the control subjects regarding gastrointestinal conditions, and additionally we performed screening for abdominal pain presence, symptoms related to defecation and change in frequency and form of stool according to the Rome IV criteria for irritable bowel syndrome[24], as well as any other symptoms that could suggest gluten and lactose intolerance. If any of these conditions were present, we excluded the subject from the control group. Furthermore, all potential control group subjects underwent detailed physical examination along with laboratory analysis of the complete blood count and biochemical parameters. We excluded all participants who showed any sign of inflammation in any of these steps.

Disease severity assessment

Disease activity evaluation was performed using clinical and endoscopic indices. The assessment was conducted by the same experienced gastroenterologist according to the latest guidelines, and the colonoscopy needed for the evaluation of the disease activity was performed within 2 wk of blood sampling. We used endoscopic indices for the evaluation of the disease activity since they have an advantage before clinical indices according to the European Consensus on Crohn's Disease and Ulcerative Colitis guidelines[25]. Moreover, all IBD patients had their high sensitivity C reactive peptide (hsCRP) and fecal calprotectin evaluated to assess further the activity of the disease.

Ulcerative Colitis Endoscopic Index of Severity (UCEIS) is a quantitative grading system used for the evaluation of UC activity. Depending on the score, there are four possible grades for disease activity: (0-1)–remission; (2-4)–mild; (5-6)–moderate and (7-8)–severe activity[26].

Simple Endoscopic Score for CD (SES-CD) is a quantitative grading system used for the evaluation of CD activity. According to the majority of studies, the threshold values for interpretation of the results are: (0-2)–remission; (3-6)–mild activity; (7-15)–moderate activity and (≥ 16)–severe disease[27].

Blood sampling and laboratory analysis

All blood samples were taken from the cubital vein after 12-h fasting. After extraction, all samples were processed in the same day except for the UII samples, which were centrifuged and stored at -80 °C for further analysis. All the procedures were conducted according to the international standards, in the same laboratory and by the same experienced medical biochemist who was blinded to the subjects group in the study. Serum levels of UII were determined using the enzyme immunoassay kit for human UII (Phoenix Pharmaceuticals, Burlingame, CA, United States), according to the manufacturer's instructions. Concentration of the analyzed quality control sample that arrived from the manufacturer was within predefined acceptable deviation. The linear range of the assay was 0.06-8.2 ng/mL, and sensitivity was 0.06 ng/mL. Coefficient of variation within the probe was less than 10% and between probes was less than 15%. Other biochemical parameters were analyzed according to standard laboratory procedures.

Stool samples were received by a trained laboratory technician in sterile containers within 3 d of sampling. Fecal extraction and analyses were performed by an experienced medical biochemist.

Anthropometric and clinical assessment

All participants were subjected to detailed anamnesis, physical examination and measurements of anthropometric characteristics - body weight, body height and body mass index (BMI). For measurement of body weight and height, a calibrated medical scale with built-in heights (Seca, Birmingham, United Kingdom) was used. BMI was calculated according to the formula = [body weight (kg)]/[height per square (m^2)].

Statistical analysis

Collected data were analyzed with statistical software MedCalc (version 17.4.1; MedCalc Software, Ostend, Belgium,). Quantitative data were expressed as mean ± SD or median and interquartile range, while qualitative data were expressed as whole number and percentage. Kolmogorov-Smirnov test was used to estimate the normality of data distribution. Comparison of serum UII levels and other parameters between patients with IBD and control subjects was done by Student *t*-test for independent samples or Mann-Whitney *U* test. For comparison of qualitative variables, Chi-squared test was used. Pearson's correlation or Spearman's correlation was used to estimate the correlation between biochemical, anthropometric and clinical parameters with serum UII levels. Furthermore, multiple linear regression analysis was used to determine

significant independent predictors of serum UII levels, with reporting corresponding *P* values with unstandardized β-coefficients, standard error and t-values. The level of statistical significance was set at $P < 0.05$.

RESULTS

Baseline characteristics of the study population

There were no statistically significant differences regarding age, gender and anthropometric features between the IBD patients and healthy controls (Table 1). Laboratory analyses showed that the IBD group compared to the control group had significantly lower erythrocytes (4.7 ± 0.5 *vs* 5.0 ± 0.4 × 10^{12}/L, $P = 0.020$), hemoglobin (140.4 ± 17.3 *vs* 148.1 ± 13.7 g/L, $P = 0.015$) and albumins (39.5 ± 5.1 *vs* 43.7 ± 2.4 g/L, $P < 0.001$), while they had significantly higher hsCRP levels (3.4 ± 2.6 *vs* 1.2 ± 1.1 mg/L, $P < 0.001$) (Table 2).

Serum urotensin II levels

Serum UII levels were significantly higher in the IBD group compared to the control group (7.26 ± 1.67 *vs* 1.98 ± 0.68 ng/mL, $P < 0.001$) (Figure 1A). Furthermore, there were no statistically significant differences in serum UII levels between the patients with UC and patients with CD (7.15 ± 1.63 *vs* 7.36 ± 1.73 ng/mL, $P = 0.672$) (Figure 1B).

Correlations between urotensin II and other biochemical, anthropometric and clinical parameters

There was a significant positive correlation between serum UII levels and hsCRP levels ($r = 0.491$, $P < 0.001$) and a significant negative correlation between serum UII levels and total proteins ($r = -0.306$, $P = 0.032$). There were no significant correlations with other biochemical parameters (Table 3).

There was a significant positive correlation between serum UII levels with both systolic ($r = 0.387$, $P = 0.005$) and diastolic ($r = 0.352$, $P = 0.012$) blood pressure. Moreover, serum UII levels had a significant positive correlation with UCEIS ($r = 0.425$, $P = 0.048$) and SES-CD ($r = 0.466$, $P = 0.028$) scores (Table 3).

Multiple linear regression

Multiple linear regression analysis showed that serum UII levels retained significant association with hsCRP (β ± standard error, 0.262 ± 0.076, $P < 0.001$) and systolic blood pressure (0.040 ± 0.017, $P = 0.030$) after model adjustment for age, gender, BMI and diastolic blood pressure, with serum UII levels as a dependent variable (Table 4).

DISCUSSION

The results of this study showed that serum UII levels are higher in patients with IBD compared to the healthy controls, while there was no significant difference between patients with UC and patients with CD. To the best of our knowledge, this is the first clinical study to investigate serum UII levels in both UC and CD.

Association between UII and IBD was only explored in a recent experimental pilot study that investigated expression of the UII receptor UTR in patients with UC[22]. They measured UTR expression from biopsies of the UC lesions and healthy colon tissue, and their outcomes determined that UTR expression was significantly higher in both the UC lesions and healthy tissue of the UC patients compared to the control group biopsies. Furthermore, a Chinese animal study conducted on mice with dextran sulfate sodium induced colitis explored the mechanisms of UTR in colonic inflammation[28]. They administrated the mice with urantide, a special antagonist of UTR that consequently alleviated rectal bleeding, tissue injury and production of interleukin (IL)-17 and tumor necrosis factor alpha (TNF-α). Furthermore, they showed that the inhibition of UTR reduced the activation of the nuclear factor-κB both *in vitro* and *in vivo*. Similarly, a study conducted on mice with induced acute liver failure assessed UTR expression and mechanisms involved[15]. They found that mice treated with urantide and consequent UTR downregulation expressed prevention of pro-inflammatory cytokines increase. TNF-α, IL-1β and interferon-γ were significantly lower compared to the mice with induced acute liver failure that were not treated with urantide. Additionally, a recent study explored UTR effects in acute liver failure by using Kupffer cells as a model system[29]. They found that UTR mediates production

and release of proinflammatory cytokines TNF-α, IL-1β and interferon-γ by using the inflammatory pathway nuclear factor-κB. All of these aforementioned studies point to the possibility that UII, besides the already well-established vasoconstriction, is also involved in the development and enhancement of the inflammatory response.

Table 3 Correlation analysis between serum urotensin II levels and different biochemical, anthropometric and clinical parameters in the inflammatory bowel disease group (*n* = 50)

According to these results, it could be hypothesized that in IBD, among other mechanisms, higher UII levels and consequently greater UTR activity can be associated with elevated TNF-α concentrations, which cause the development of the aberrant inflammatory response[30]. It is well established that IBD is linked with elevated TNF-α levels in the mucosa of the gastrointestinal tract and consequently an abnormal inflammatory response that is associated with the dysregulation of mucosal immune cells and tissue injury[31]. Moreover, TNF-α contributes to inflammation through disruption of the epithelial barrier, stimulation of villous epithelial cells apoptosis and secretion of chemokines from intestinal epithelium[32]. This possibility is further supported by our results that UII is in a significant positive association with

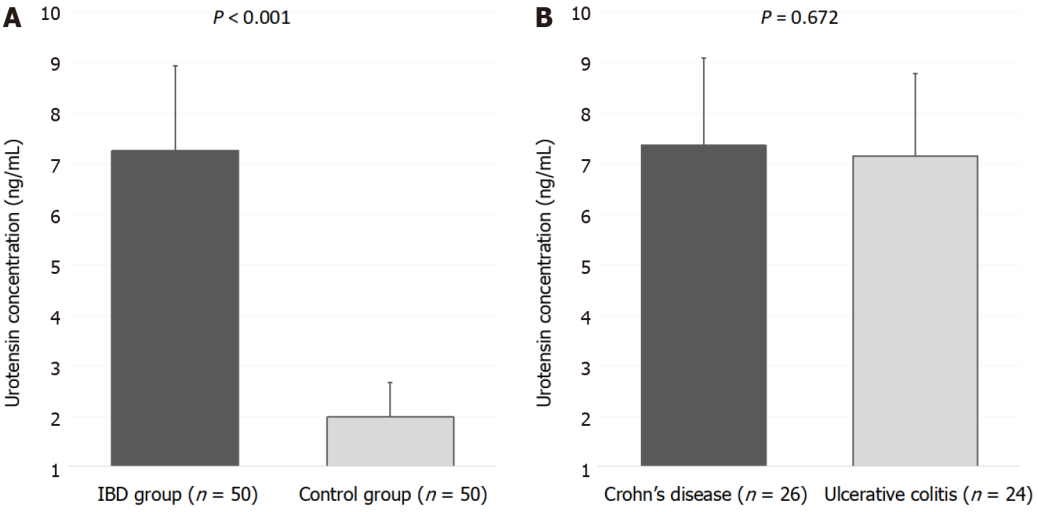

Figure 1 Serum urotensin II levels. A: Comparison between the inflammatory bowel disease group and the control group. B: Comparison between patients with Crohn's disease and patients with ulcerative colitis.

hsCRP, which was additionally supported with multiple linear regression, and clinical indices of IBD activity as well. These results implicate that disease activity could be closely related to UII levels.

Moreover, it is important to highlight that the previous studies have shown that high TNF-α levels play a major role in the disruption of macro and microvascular circulation[33]. It induces the production of reactive oxygen species, which results in endothelial dysfunction, while several studies presented that the administration of anti-TNF-α therapy to patients with IBD results in a significant improvement of endothelial dysfunction[32,34]. It is possible that functional and structural changes of the vascular endothelium due to chronic inflammation consequently results in higher cardiovascular risk in IBD patients[35]. Furthermore, with more severe disease activity and consequent greater inflammation, the resulting endothelial dysfunction that accompanies these changes is more advanced. It was presented by two recent studies that heart dysfunction, as well as fibrosis and cell hypertrophy, were significantly decreased in experimental heart models treated with UTR antagonists[36,37]. Moreover, a recent study showed that elevated UII levels are associated with the severity of cardiovascular risk factors[38].

In the last 2 decades, it has become clear that chronic systemic inflammation plays a major part in the initiation and progression of atherosclerosis[39,40]. Circulating UII was reported to promote increase of reactive oxygen species levels, which are important molecules in the initiation of atherosclerosis[41]. In a Chinese animal study, urantide administration reduced the proportion of the macrophage lesion area as well as improved the plaque characteristics in hyperlipidemic rabbits by increasing the collagen content[42]. Even though UTR antagonist downregulated proinflammatory cytokines, it did not significantly change the lipid profile. In summary, although the UTR antagonist did not change the progression of atherosclerosis, it significantly affected composition of atherosclerotic plaque. These results imply that UII is associated with the process of atherosclerosis, but the downregulation of its receptor UTR only affects the properties of the atherosclerotic plaque, while it does not stop its actual progression.

Our results also determined a significant positive correlation between serum UII levels with systolic and diastolic blood pressure. This is in alignment with several other clinical and experimental studies that have found an association between UII and arterial pressure, probably present due to its established vasoconstrictive effect[43,44]. Moreover, studies have shown that IBD patients have a lower incidence of some of the traditional risk factors for cardiovascular diseases, including hypertension[19]. In a current scenario, it is still questionable why IBD patients have lower incidence of hypertension, although UII levels are elevated in comparison with healthy subjects. It is hard to hypothesize from our results what are the possible reasons for this ambiguity, and further studies are needed to elaborate this issue. However, it is possible that UII vasoconstriction effect is diminished by other factors that are present in IBD patients.

This study had several limitations. It was a single center study with a cross-sectional design. Moreover, our sample size was relatively low, and we were not able to eliminate completely all possible confounding effects.

CONCLUSION

In conclusion, this study showed that patients with IBD have a higher serum level of UII compared to the control group. This implied association with IBD was further supported with the positive correlation between UII and hsCRP, UCEIS and SES-CD. All of these results suggest that UII could be involved in the pathophysiology of IBD, especially in the inflammation severity and disease activity. However, future studies need to clarify these connections.

ARTICLE HIGHLIGHTS

Research background

Patients with inflammatory bowel disease (IBD) are associated with increased cardiovascular risk and have increased overall cardiovascular burden. On the other hand, urotensin II (UII) is one of the most potent vascular constrictors with immunomodulatory effect that is connected with a number of different cardiometabolic disorders as well. Since the features of IBD includes chronic inflammation and endothelial dysfunction, it is plausible to assume that there is connection between increased cardiac risk in IBD and UII.

Research motivation

While a recent study showed that patients with ulcerative colitis (UC) have increased expression of urotensin II receptor in comparison to healthy controls, a larger clinical study regarding UII serum levels in patients with IBD is still missing.

Research objectives

The aim of this study was to compare serum levels of UII between patients with IBD and healthy controls. The additional goal was to investigate the association of serum UII levels with the anthropometric, clinical and biochemical parameters.

Research methods

This study included 50 adult patients with pre-diagnosed IBD (24 patients with UC and 26 patients with Crohn's disease (CD) and 50 healthy, age and gender matched controls. Serum levels of UII were determined using the enzyme immunoassay kit for human UII, according to the manufacturer's instructions. Other parameters were analyzed according to the standard laboratory procedures.

Research results

Analysis has shown that IBD patients have significantly higher concentrations of UII when compared to control subjects (7.57 ± 1.41 *vs* 1.98 ± 0.69 ng/mL, $P < 0.001$), while there were no significant differences between CD and UC patients (7.49 ± 1.42 *vs* 7.65 ± 1.41 ng/mL, $P = 0.689$). There was a significant positive correlation between serum UII levels and high sensitivity C reactive peptide levels ($r = 0.491$, $P < 0.001$), UC Endoscopic Index of Severity ($r = 0.425$, $P = 0.048$) and Simple Endoscopic Score for CD ($r = 0.466$, $P = 0.028$) scores.

Research conclusions

Our clinical results suggest that UII could be involved in the pathophysiology of IBD, especially in the inflammation severity and disease activity.

Research perspectives

Future larger scale multicenter studies need to clarify the connection between UII and IBD.

Abstract

BACKGROUND

Meckel's diverticulum is a common asymptomatic congenital gastrointestinal anomaly. However, its presentation as an inverted Meckel's diverticulum is a rare complication, of which few cases have been reported in the literature.

CASE SUMMARY

Here, we report the case of a 33-year-old man with iron deficiency anemia without manifestation of gastrointestinal bleeding. An upper gastrointestinal endoscopy and total colonoscopy were performed, but no abnormalities were found within the observed area. Finally, a capsule endoscopy was performed and offered us a clue to subsequently confirm the diagnosis of inverted Meckel's diverticulum *via* computed tomography scan. Laparoscopic intestinal resection surgery was performed. The final pathology report described a Meckel's diverticulum.

CONCLUSION

Since inverted Meckel's diverticulum is an uncommon disease and its clinical presentation is not specific, it may go undetected by capsule endoscopy.

Core Tip: Inverted Meckel's diverticulum is an uncommon disease with a wide spectrum of accompanying nonspecific symptoms. We present, here, a case of iron deficiency anemia with negative endoscopic study, in which capsule endoscopy played a key role in confirming the diagnosis. Since inverted Meckel's diverticulum is an uncommon disease with few cases described in the literature, this report aims to contribute more information concerning the clinical characteristics as well as radiological and capsule endoscopy findings of inverted Meckel's diverticulum that can help clinicians make the correct diagnosis.

INTRODUCTION

Meckel's diverticulum is a common congenital gastrointestinal anomaly which is a remanent of the omphalomesenteric duct[1]. It is often within 100 cm of the ileocecal valve and located in the antimesenteric surface of the ileum[2]. According to autopsy studies, this condition is found in 0.3%-2% of the general population[3,4].

Patients with Meckel's diverticulum are usually asymptomatic. However, up to 6.4% develop complications that require surgery[5]. The most common complications are gastrointestinal bleeding in association with ectopic gastric and/or pancreatic mucosa, intestinal obstruction, intussusceptions, diverticulitis or volvulus. The inversion of Meckel's diverticulum is a rare complication with a pathophysiology not clearly understood, that can be a clinical challenge given its diagnostic difficulty. Moreover, the clinical presentation is nonspecific, the most frequent mode of presentation being intussusception, abdominal pain, anemia or gastrointestinal bleeding[6].

Although Meckel's diverticulum is the most common congenital anomaly of the small bowel, inversion or invagination of the diverticulum is a rare occurrence. To date, there are only around 100 cases in the literature that demonstrate the presence of inverted Meckel's diverticulum.

Herein, we present the case of iron deficiency anemia without manifestation of gastrointestinal bleeding, in which capsule endoscopy played a key role in the final diagnosis of inverted Meckel's diverticulum.

CASE PRESENTATION

Chief complaints

A 33-year-old male with no significant medical history presented to the emergency room with progressive weakness, easy fatigability and headache. He had no evidence of lower or upper gastrointestinal bleeding and he reported no abdominal pain, nausea, vomiting, anorexia, fever or weight loss.

History of present illness

The patient's symptoms started 3 wk prior and had worsened over the last 4 d.

History of past illness
There was no significant medical history.

Personal and family history
There was no significant medical history.

Physical examination
In the emergency room, the patient was clinically stable, with a normal temperature (36.7 °C). The patient exhibited an oxygen saturation level of 97% while he was breathing ambient air. His blood pressure was 102/61 mmHg and his heart rate was 91 beats per minute. The patient was awake, alert, and fully oriented. Physical examination revealed signs of pallor and an absence of lymphadenopathy, hepatosplenomegaly, bone tenderness or jaundice. Examination of the rectum revealed a few external hemorrhoids, but there was no blood or melena in the rectal vault; there were no skin tags, fissures or palpable masses.

Laboratory examinations
The initial laboratory findings showed low hemoglobin levels (7 g/dL), a white blood cell count of 11250 per mm^3, a platelet count of 221000 per mm^3 and a C-reactive protein of 1.31 mg/dL. Two pints of packed red blood cells were therefore transfused and the patient was admitted to the gastroenterology department. Electrocardiography (ECG) showed sinus rhythm at 93 beats per minute and the results of the patient's chest radiography were normal.

The patient's next blood test, showed a mean corpuscular volume of 72.5 fl, a mean corpuscular hemoglobin of 25.6 pg, and a reticulocyte count of 1%. The patient's iron level was 38 μg/dL, his ferritin level was 17 ng/mL, and his transferrin saturation was 9%. The hemolysis study was negative. Hence, the patient's anemia was classified as iron deficiency anemia.

Imaging examinations
During this period, an upper gastrointestinal endoscopy and a colonoscopy were performed to study the patient's anemia. The colonoscopy revealed internal hemorrhoids without any other relevant findings while the upper gastrointestinal endoscopy showed no abnormalities. The patient remained stable and was discharged and the study was completed on an outpatient basis with oral iron treatment.

During his visit to the outpatient clinic 3 wk later, the patient remained anemic, with a hemoglobin level of 8.8 g/dL. The anemia study was completed with a capsule endoscopy, which revealed a lifted erosion and mild bulge in the ileum of approximately 8-9 mm in size (Figure 1). These findings of appearance of a subepithelial bulge in the ileum suggested an inverted Meckel diverticulum. Normal intestinal mucosa was seen on the surface of the tumor with a longer small intestine transit time suggestive of Meckel's diverticulum. A technetium-99m pertechnetate radioisotope scintigraphy (Meckel's scan) was performed and was negative. The patient subsequently underwent an ultrasound examination, which revealed no pathological findings. Finally, an abdominal computed tomography (CT) was performed and showed a central area of fat attenuation surrounded by a thick collar of soft tissue attenuation (Figure 2) suggestive of inverted Meckel's diverticulum.

FINAL DIAGNOSIS
The patient was diagnosed with an inverted Meckel's diverticulum and underwent a laparoscopic surgery. A large intraluminal polyp-like mass in the mid-ileum was observed. The remainder of the small bowel was normal to the level of the ligament of Treitz. A segmentary resection of the small bowel with adequate margin was performed and side-to-side anastomosis was carried out using a stapling device.

On gross examination, the specimen consisted of a segmental resection of the small bowel of 8 cm × 4 cm × 2.6 cm with a sausage-shaped polypoid lesion.

Histological examination (Figure 3) showed a polypoid lesion, with a central fatty and collagenous core lined with an intestinal type mucosa. A central area of ulceration was seen, with no presence of gastric or pancreatic heterotopia. The final pathology report described a Meckel's diverticulum.

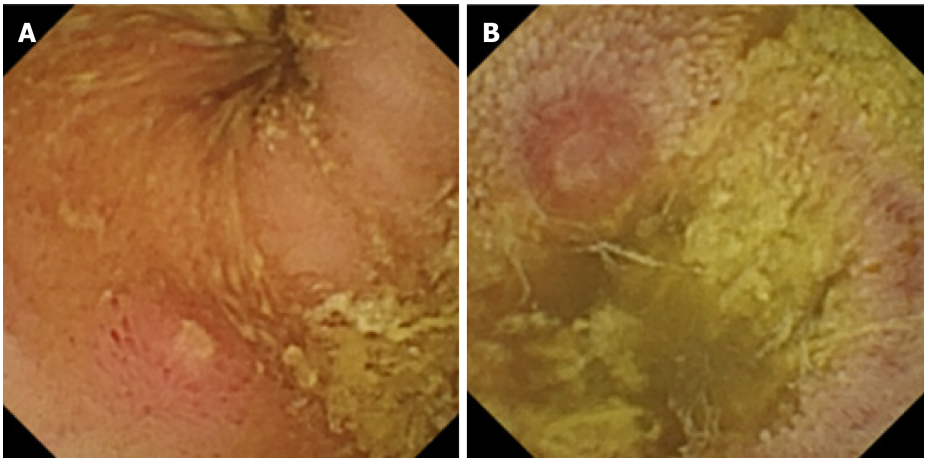

Figure 1 Capsule endoscopy with protruding lesion. A: Capsule endoscopy with protruding lesion, with a depressed erosion at the tip suggestive of Meckel's diverticulum; B: Capsule endoscopy with protruding lesion suggestive of Meckel's diverticulum.

Figure 2 Abdominal computed tomography scan revealed a central area of fat attenuation surrounded by a thick collar of soft tissue attenuation suggestive of Meckel's diverticulum.

TREATMENT

The patient was diagnosed with an inverted Meckel's diverticulum and underwent a laparoscopic surgery. A large intraluminal polyp-like mass in the mid-ileum was observed. The remainder of the small bowel was normal to the level of the ligament of Treitz. A segmentary resection of the small bowel with adequate margin was performed and side-to-side anastomosis was carried out using a stapling device.

OUTCOME AND FOLLOW-UP

The patient had an uneventful postoperative course and was discharged 4 d after surgery.

DISCUSSION

Meckel's diverticulum is the most common congenital anomaly in the gastrointestinal tract[1] and is often incidentally discovered during evaluations performed for other reasons, as it is usually an asymptomatic condition. However, complications can occur in up to 6.4% of patients[7]. These are more frequent in the pediatric population and mainly involve bowel obstruction with or without intussusception, gastrointestinal hemorrhage, diverticulitis and inflammation, and Littre hernia (hernia involving the

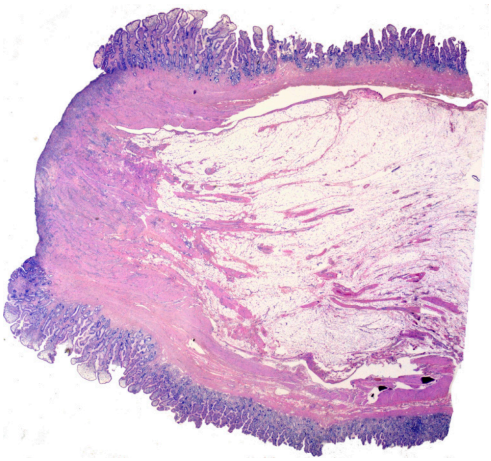

Figure 3 Low power histologic examination of a polypoid lesion lined by an intestinal type mucosa with a central ulcerated area. No gastric or pancreatic heterotopic tissue can be found.

bowel segment bearing Meckel's)[4,7].

Inverted Meckel's diverticulum is an unusual condition that is not yet clearly understood and there are no more than 100 cases reported in literature.

It has been proposed that the mechanism that could produce the inversion is an abnormal peristaltic movement around an ulceration or ectopic tissue. Nevertheless, no ectopic tissue was found in 41% of patients with inverted Meckel's diverticulum[6]. In this regard, tc-99m pertechnetate scintigraphy can help detect ectopic gastric mucosa and has been used for years as a diagnostic method for Meckel's diverticulum, especially in children, with a sensitivity of 92.1% and a specificity of 95.4%[8]. In adults, the sensitivity of this method is significantly less (54%)[9]. No cases of diagnosis of inverted Meckel's diverticulum by scintigraphy have been described, while there is only 1 case with gastric and pancreatic mucosa in the histopathological sample where the scintigraphy was negative[10]. Our patient's scintigraphy was negative. Therefore, this suggests that a negative scan does not preclude the presence of ectopic mucosa and the diagnosis of possible inverted Meckel's diverticulum.

This inversion of the Meckel's diverticulum can lead to a complete intussusception of the bowel or compromise blood flow to that bowel, ulceration and then gastrointestinal bleeding. The bleeding can also be explained by repetitive mechanical trauma to the mucosa from the reversible intussusception.

As in our patient, anemia or gastrointestinal bleeding are the most frequent clinical manifestations, found in up to 80% of patients[6]. This usually leads to an upper and lower gastrointestinal endoscopy, where the cause of the bleeding cannot be found.

Other clinical manifestations which can occur are abdominal pain (68%) and intussusception (39%). The median age of presentation is 27.7 years, younger than that reported for Meckel's diverticulum, which has been 33, with a male to female ratio of approximately 2.33:1[6].

Regarding the diagnostic tools, abdominal ultrasonography can contribute to the diagnosis, but often shows nonspecific findings such as thickened intestinal wall, fluid fille target or distended loops of bowel[11,12]. In our case, abdominal ultrasonography revealed no pathological findings.

One of the most useful tools is a CT scan. It usually shows a thickened small intestinal wall, with an elongated, intraluminal, fat-attenuating lesion[13], as in our case. In the case of intussusceptions, a CT scan is especially useful as it can reveal the characteristic "target sign". Inverted Meckel's diverticulum is sometimes confused with a lipoma on CT scans because it also consists of macroscopic fatty tissue. However, in most cases, abdominal CT scans provide useful information for the diagnosis and treatment of inverted Meckel's diverticulum[6].

Capsule endoscopy has recently been considered a useful diagnostic tool for diagnosing Meckel's diverticulum[9,14,15]. However, the role of capsule endoscopy in the identification of Meckel's diverticulum is not yet clear, with only a few case reports and case series available. Furthermore, in the case of inverted Meckel's diverticulum, the information is very limited, represented by only 2 case reports[16,17]. The capsule findings compatible with inverted Meckel's diverticulum were described as an elevated lesion with normal mucosa[16] or as pedunculated polyp[17].

In our case, the capsule endoscopy images were similar (a subepithelial protruding lesion in the ileum with the presence of blood, hematin, ulcer or erosion) and offered us a clue to subsequently confirm the diagnosis of inverted Meckel's diverticulum. In addition, the clinical suspicion due to the clinical characteristics (such as the fact that the patient was a young man with anemia) and a negative endoscopic study was of great importance for the diagnosis of inverted Meckel's diverticulum.

Regarding the risk of possible intestinal obstruction of the endoscopic capsule due to Meckel's diverticulum, no events have been described.

Surgery is the treatment of choice for symptomatic Meckel's diverticulum. The general consensus is that it should be treated with resection. In the case of asymptomatic Meckel's diverticulum, there is some debate. Resection is generally recommended for patients younger than 40-years-old, with diverticulum longer than 2 cm, diverticula with narrow necks, fibrous bands, and/or ectopic gastric tissue, and/or when the diverticulum appears thickened and inflamed[4,6,18].

It is important to note that in cases of anemia without abdominal pain, like that of our patient, it may take a long time for the patient to be diagnosed with inverted Meckel's diverticulum, given that it is an unusual condition with a nonspecific clinical presentation. Capsule endoscopy is usually performed in those patients with anemia with a normal upper and lower gastrointestinal endoscopy. However, if clinicians are unaware of the characteristics of this lesion, it may go undetected since it is an uncommon disease. Therefore, this report aims to contribute more information concerning the clinical characteristics, radiological findings and especially, the capsule endoscopy findings of inverted Meckel's diverticulum that can help clinicians suspect that this disease is present and enable them to establish a definitive diagnosis.

CONCLUSION

To date, inverted Meckel's diverticulum is a pathology that is still not completely well known, with few cases described in the literature. Its clinical presentation is not specific, its most frequent symptoms being anemia or lower gastrointestinal bleeding. Patients are often given an upper and lower gastrointestinal endoscopy which reveals no abnormalities and a subsequent capsule endoscopy. Therefore, increased awareness of the disease and a greater understanding of the features of this lesion in capsule endoscopy findings could ultimately help clinicians make the correct diagnosis.

ABOUT COVER

Editorial Board Member of *World Journal of Gastroenterology*, Yoichi Matsuo, MD, PhD, Professor, Department of Gastroenterological Surgery, Nagoya City University Graduate School of Medical Sciences, Kawasumi 1, Mizuho-cho, Mizuho-ku, Nagoya 4678601, Japan. nukemat0328@gmail.com

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, and Scopus. The 2021 edition of Journal Citation Report® cites the 2020 impact factor (IF) for *WJG* as 5.742; Journal Citation Indicator: 0.79; IF without journal self cites: 5.590; 5-year IF: 5.044; Ranking: 28 among 92 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2020 is 6.9 and Scopus CiteScore rank 2020: Gastroenterology is 19/136.

Abstract

Liver-gut communication is vital in fatty liver diseases, and gut microbes are the key regulators in maintaining liver homeostasis. Chronic alcohol abuse and persistent overnutrition create dysbiosis in gut ecology, which can contribute to fatty liver disease. In this review, we discuss the gut microbial compositional changes that occur in alcoholic and nonalcoholic fatty liver diseases and how this gut microbial dysbiosis and its metabolic products are involved in fatty liver disease pathophysiology. We also summarize the new approaches related to gut microbes that might help in the diagnosis and treatment of fatty liver disease.

Key Words: Fatty liver disease; Alcoholic fatty liver disease; Non-alcoholic fatty liver disease; Gut microbiome; Dysbiosis

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: In this review, we compare the gut microbial composition in two different fatty liver diseases: Alcoholic fatty liver and nonalcoholic fatty liver. This review enables readers to recognize the gut microbiota compositional differences that occur in these two histopathologically analogous conditions and to explore these gut microbial compositional variations in their research. Additionally, this review will also be helpful in the design of new experiments aiming to develop new diagnostic and/or therapeutic methodologies.

INTRODUCTION

Significant increases in mortality and morbidity due to chronic fatty liver disease have raised great global health concerns. Alcoholic fatty liver disease (AFLD) and nonalcoholic fatty liver disease (NAFLD) are the most common chronic fatty liver illnesses in the Western world, with prevalences of 6% and 25%, respectively[1], and are the leading causes of liver transplantation[2,3]. Both AFLD and NAFLD start with fat accumulation in the liver, known as benign or simple steatosis, which leads to inflammation identified as steatohepatitis. Advanced disease includes fibrosis and cirrhosis, which can lead to a more severe state, including hepatocellular carcinoma and liver failure, and ultimately can cause death. Only 20% of patients with AFLD and NAFLD develop progressive liver disease[4,5]. In addition to fat accumulation, increased inflammation, and alcohol consumption, other causes, such as an altered gut microbial composition, gut microbial metabolites, or gut barrier function, are associated with the exacerbation of chronic liver disease[6,7].

The recent increase in the understanding of the microbiota and its metabolites has changed the perspectives of various chronic diseases[8]. The human gut microbiota represents a complex ecosystem with various species of microbes that are approximately 1-2 kg in weight in total[9,10]. The gut microbiota maintains homeostasis by interacting with the host and has important functions, including metabolism, digestion, vitamin production, mucosal immune reaction, and the translocation of microbial-associated molecular patterns[11-14]. Importantly, the gut microbiota is known to have a significant role in liver disease progression, but the associated mechanisms are still not fully established.

The liver is the first organ exposed to gut microbial metabolites through portal vein blood. Therefore, the gut microbial community has a vital role in liver homeostasis, and dysbiosis in gut microbial ecology can produce microbial metabolites and components that can have a direct impact on the liver[15-19]. Similarly, the liver also influences gut microbial ecology, particularly in the intestine, through primary bile acids[20-22]. In this way, the liver and gut share a close bidirectional relationship. Interestingly, fecal microbiota transplantation (FMT) studies showed a proof of concept in alcohol-associated and metabolic disease generation and establishment[19,23,24].

Although AFLD and NAFLD have similar histopathological characteristics, they have different etiologies[25]. Thus, gut microbial composition in AFLD and NAFLD could have some commonalities as well as dissimilarities at various classification levels[16,26]. These gut microbial compositional similarities in AFLD and NAFLD could help not only establish common pathophysiological pathways but also increase the chance of finding common treatments. Conversely, gut microbial compositional variations in AFLD and NAFLD could be helpful for the development of specific disease-based signatural gut microbiota profiles. Additionally, these disease-specific gut microbiota profiles could be valuable for the design of gut-microbiota-based therapies such as probiotics[27], synbiotics[28], postbiotics[29] and/or FMT[30] to ameliorate liver disease. These microbial therapeutics also could provide access for developing personalized patient-based treatments to restore liver functions in AFLD and/or NAFLD. AFLD and/or NAFLD-specific gut microbiota profiles could also be useful in the future as diagnostic biomarker tools for the early diagnosis of these diseases.

Considering the importance of the disease-specific gut microbial signature in AFLD and/or NAFLD, herein, we review the gut microbial compositions related to AFLD and/or NAFLD development, especially focusing on the relationship of these compositions with the progression of both diseases, particularly in humans. We also explicitly focus on the microbial signature pertaining to AFLD and/or NAFLD and common microbes in both fatty liver conditions. This review also helps in the understanding of the deep association between the gut microbiota and fatty liver diseases, which can also be considered microbiota-associated fatty liver diseases.

GUT MICROBIAL COMMUNITY EUBIOSIS

The gut microbiota is an endogenous ecosystem that coevolves with the host as a symbiotic organ and regulates the normal physiological functions of the gut, such as food digestion and nutrient absorption, and provides essential micronutrients to the host[31]. The gut microbial ecosystem maintains a balance between the microbial species living inside the gut known as "eubiosis" that is crucial for good health.

Microbial colonization in the gastrointestinal tract starts immediately after birth and is dominated by the *Bifidobacterium* genus, and a decline in this dominance is observed in the first year of life[32]. The infant gut microbiota is changeable, as this microbial colonization is affected by multiple external factors, such as the mode of delivery, medications, nourishment[33,34], age, genetic background, and cultural/geographic influence[32,35,36]. Similarly, breastfed infants have a less diverse gut microbiota than formula-fed infants, which is the best possible explanation for the difference in gut microbial composition between United States infants and non-United States infants, as United States infants have 28 operational taxonomic units dominated by the *Prevotella* genus[32]. As children start consuming solid foods, the gut microbiota becomes more diverse and starts stabilizing[32,35,37,38]. Fecal samples collected from different geographical regions showed that the gut microbiota composition took shape toward an adult-like configuration until 3 years of age[32], after which the gut composition became more persistent[39].

Primarily, the *Firmicutes* and *Bacteroidetes* phyla dominated the adult human gut microbial composition, and *Actinobacteria*, *Proteobacteria* and *Verrucomicrobia* were found in lesser abundance. Fecal metagenomic analysis from 4 different countries identified well-classified robust gut microbial communities, named enterotypes, represented through multiple numbers of 3 genera: *Prevotella*, *Ruminococcus* and *Bacteroides*[40], and this classification of enterotype was independent of nationality, age, body mass index (BMI), and sex. However, this enterotype-based classification remains a topic of debate because external factors such as diet are considered primary regulators of gut microbiota composition and functions[41,42] and fail to be identified in healthy and elderly individuals[43]. In addition to diet, aging is also a considerable factor that changes the gut microbiota composition. Bacteria belonging to the *Bacteroidaceae*, *Lachnospiraceae* and *Ruminococcaceae* families are negatively correlated with aging independent of geographical region, lifestyle, and dietary habits[44-46]. Moreover, healthy aging showed increased microbial richness and higher numbers of *Bifidobacterium*, *Oscillospira*, *Akkermansia*, and *Christensenellaceae*[45]. Emerging metagenomic empirical evidence suggests that a healthier gut always has a more diverse microbiota population and that a healthy gut is essential to maintain human health[47,48].

GUT MICROBIAL COMMUNITY DYSBIOSIS

A change or alteration in gut microbial composition, which can be related to diseased conditions, is termed "dysbiosis"[49]. Gut microbiota composition varies from birth to death[50] and is influenced by various environmental factors[51-54]. Gut microbial dysbiosis also has a close connection with AFLD and NAFLD.

Gut microbiota alteration in AFLD

Persistent high intake of ethanol is the root cause of AFLD[55], as it disrupts the multilayered intestinal defense system involving physical, immunological, and humoral components[56]. Normally, the liver enzyme alcohol dehydrogenase and the ethanol-oxidizing system convert ethanol to acetaldehyde, which is toxic to hepatic cells. Acetaldehyde is immediately metabolized to acetate, released into the bloodstream, and used as a biological fuel by cells for energy production. In a persistently elevated ethanol consumption state, the accumulation of toxic acetaldehyde is increased in the liver, which leads to the production of highly reactive molecules that generate an oxidative stress milieu and contribute to liver injuries[16]. An increase in the flow of ethanol in the liver alters SIRT1 signaling and initiates fat accumulation in hepatocytes[57]. Ethanol reduces SIRT1 expression in the liver, which leads to the fat accumulation in liver cells by disrupting multiple SIRT1-dependent transcription factors and cofactors, such as peroxisome proliferator-activated receptor α, PPARγ coactivator-1α, AMP-activated kinase, lipin-1, β-catenin, forkhead transcription factor O1, sterol regulatory element-binding protein 1, nuclear factor activated T cells c4, and nuclear transcription factor-κB[57-59]. Ethanol facilitates the inhibition of SIRT1, which leads to various signaling network disruptions that increase the accumulation of fat in hepatocytes by decreasing β-oxidation and lipolysis, boosting lipogenesis and inflammation, and collectively leading to AFLD. Recently, human and animal models suggested that even a small intake of alcohol can harm intestinal barrier integrity and raise microbial byproduct levels in the circulation[60,61]. Moreover, there is adequate experimental evidence proving that the interrelationship between alterations in the intestinal microbiota and alcohol abuse and acute and

chronic alcohol exposure is primarily responsible for gut microbiota dysbiosis and can lead to AFLD through various pathways, as shown in Figure 1[62]. Animal model-based studies explain that alcohol-induced microbial dysbiosis in the intestine changes homeostasis in the gut-liver axis and that this altered intestinal microbiota plays a crucial role as a mediator in the production of the many negative effects of alcohol.

Animal studies have shown that 3 weeks of alcohol exposure causes a 'leaky gut', which increases the number of *Bacteroidetes* and *Verrucomicrobia* and decreases the growth of bacteria with anti-inflammatory activity, such as *Firmicutes* (genera such as *Lactobacillus, Lactococcus, Leuconostoc* and *Pediococcus*), in the cecum[63]. Another rodent alcohol-based model showed that changes in intestinal permeability associated with intestinal microbial alterations are related to the decreased expression of hypoxia-induced factor 1α. These studies showed a relative increase in *Actinobacteria* and *Proteobacteria* and a decline in the *Firmicutes* phylum. Moreover, these changes were restored by treatment with probiotic *Lactobacillus rhamnosus* (*L. rhamnosus*) GG therapy[64-67].

Interestingly, gnotobiotic animals have become an imperative alcoholic model to explore the relationship between the gut and the liver. A comparative study of gnotobiotic and wild-type rats showed less proinflammatory cytokine release and inflammation in gnotobiotic rats than in wild-type rats when treated with alcohol for one week. Moreover, fecal transplantation from alcohol-fed wild-type rats in gnotobiotic animals increased hepatic and intestinal inflammation, indicating the involvement of the intestinal microbiota in AFLD[68]. Chronic alcohol intake also changes the intestinal mucus composition, and mucin knockout animals have less bacterial overgrowth, minimal translocation of the bacteria and reduced intestinal inflammation when administered alcohol[69]. In other studies, the bacterial species *Akkermansia muciniphila* (*A. muciniphila*) from the *Verrucomicrobia* phylum showed potential anti-inflammatory properties in AFLD[70], and the depletion of *A. muciniphila* species was noticed in alcoholic animal models[71,72]. *A. muciniphila* improves intestinal markers such as gut barrier function and mucus thickness and diminishes the liver damage produced by alcohol[73]. Cumulatively, animal studies strongly indicate that alcohol intake considerably changes the intestinal microbial composition (as shown in Table 1), which can be responsible for producing early-onset AFLD by inducing proinflammatory changes, translocating the bacteria and bacterial material by reducing mucus thickness and increasing intestinal permeability.

Likewise, human studies also support the close association between alcohol intake and intestinal microbial dysbiosis in the onset of AFLD, similar to animal models. Prolonged alcohol intake markedly decreases the *Bacteroidetes* population and increases *Proteobacteria*, which leads to compromised intestinal permeability and an increase in the level of bacterial materials such lipopolysaccharides (LPS) and endotoxins in the hepatic circulation and ultimately causes liver injuries[74]. The families *Ruminococcaceae* and *Lachnospiraceae* and their ratio are considered to be protective, whereas *Enterobacteriaceae* to *Bacteroidaceae* and their ratio are believed to be potential pathobionts in the intestine, especially in those with a liver disease with an alcoholic etiology. Therefore, the overgrowth of potentially pathogenic species in the gut in chronic alcohol abuse conditions is related to the initiation of liver injuries[74-76]. The effect of these microbial alterations in the gut is not yet completely understood. However, the administration of *L. rhamnosus* GG improves the *Lachnospiraceae* population and limits the growth of *Enterobacteriaceae,* which leads to a decline in proinflammatory cytokines[77]. A reduction in *A. muciniphila* was observed in patients with alcoholic steatohepatitis compared with healthy controls, and this decline in *A. muciniphila* seems to be related to the severity of liver injuries[73]. Additionally, *A. muciniphila* was considered a health-boosting bacterial species along with *Bifidobacterium* spp., *Roseburia hominis*, and *Feacalibacterium prausnitzii*[78]. However, human and animal empirical data hinted that alcohol-induced gut microbial dysbiosis, especially ethanol consumption, but that some alcoholic beverages, such as red wine, could exert a positive impact on gut microbial ecology. A human crossover study demonstrated that red wine consumption increased the number of *Bacteroides, Enterococcus*, and *Bifidobacterium*[79].

Alterations in the gut microbiota due to persistent alcoholic intake are not restricted to bacterial species; the fungal composition also changes. Remarkably, alcoholic liver disease (ALD) patients have a high risk of bacterial infection, and patients with advanced cirrhosis are more prone to fungal infections. Moreover, fungal infections increased the mortality rate in cirrhosis and alcoholic hepatitis patients[80-82]. In an alcoholic murine model, increased fungal growth, particularly *Candida* spp., was observed and was related to an increase in liver damage[83]. The study results showed that liver inflammation was induced by β-glucan, which is a fungal cell wall component. β-Glucan binds with Kupffer cell C-type lectin-like receptor and

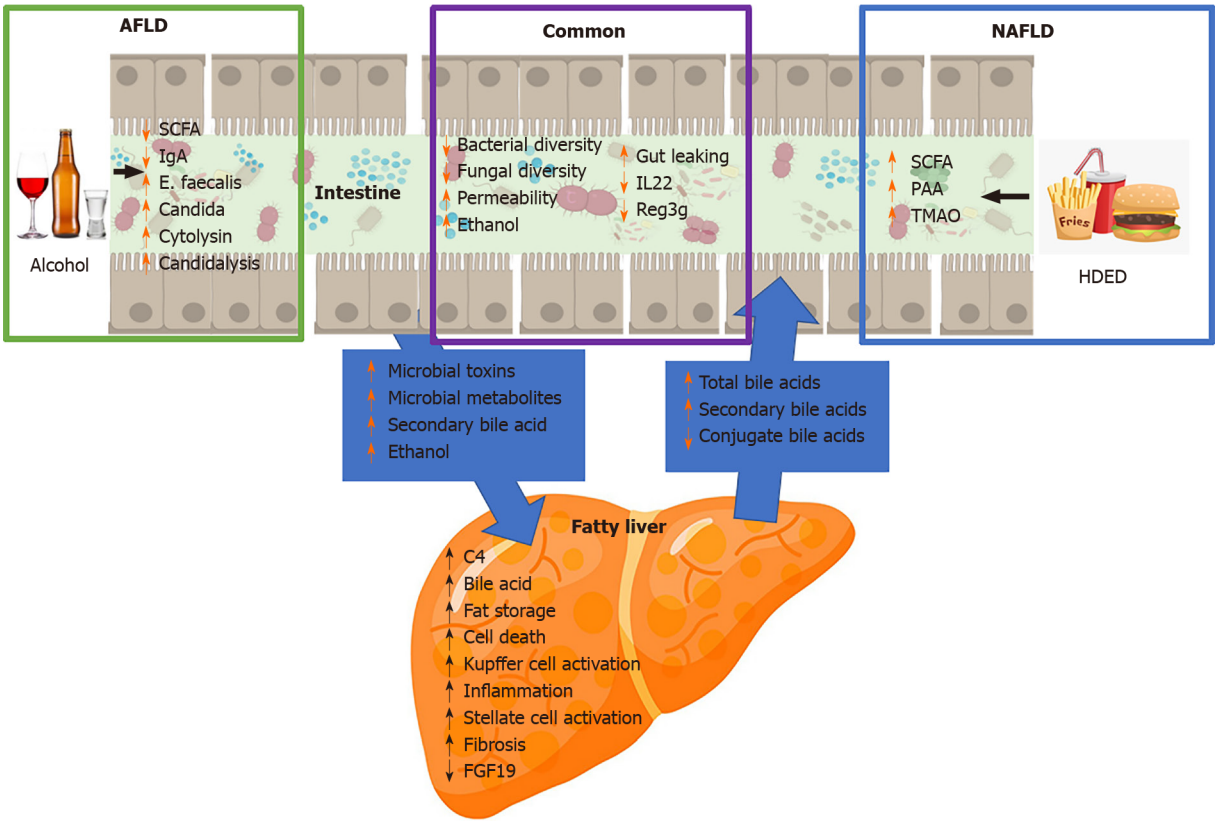

Figure 1 Gut microbiota role in alcoholic fatty liver disease and non-alcoholic fatty liver disease pathogenesis. Intestinal microbes have the potential relationship with fatty liver disease progression. Regular intake of alcohol and overnutrition altered the gut microbial composition which influence the various pathways and induce the liver injuries and produce the alcoholic fatty liver disease (AFLD) and non-alcoholic fatty liver disease (NAFLD). There are some common pathways found in both AFLD and NAFLD diseases (in the purple box) and others are specifically related to a particular disease. AFLD: Alcoholic fatty liver disease; NAFLD: Non-alcoholic fatty liver disease; HDED: High dense energy diet; SCFA: Short chain fatty acids; IgA: Immunoglobulin A; IL22: Interleukin 22; Reg3g: Regenerating islet-derived protein 3 gamma; C4: Precursor 7α-hydroxy-4-cholesten-3-one; FGF19: Fibroblast growth factor 19; PAA: Phenylacetic acid; TMAO: Trimethylamine N-oxide.

upregulates IL-1β. Similarly, ALD patients also showed an increased immune response to intestinal fungi compared to healthy controls. These findings suggest that the composition of nonbacterial gut microbes, such fungi, can also affect AFLD generation, progression, and final outcomes in patients with AFLD.

Gut microbiota alterations in NAFLD

The gut microbiota exacerbates and/or alleviates NAFLD conditions through several pathways (Figure 1). Animal and human studies have presented a causal involvement of the gut microbiota in NAFLD establishment[84-86] and its severity[87-89]; however, a robust correlation between the gut microbiota and NAFLD advancement has not yet been established. Differences in gut microbial composition at various hierarchical

levels have been recorded in NAFLD patients compared with healthy controls[90,91]. In NAFLD, alterations in the gut microbial community have been shown to start at the phylum level, where increased Proteobacteria have been reported in many studies[90,92,93]. Likewise, altered composition has also been observed at the family level, where an overgrowth of *Enterobacteriaceae*[84,92] and suppression of *Rikenellaceae*[84,94] and *Ruminococcaceae*[91,92,95] have been reported. Moreover, genera such as *Escherichia*[84,90], *Dorea*[94,95], and *Peptoniphilus*[84,94] were overpopulated, and *Anaerosporobacter* [91], *Coprococcus*[84,90,91], *Eubacterium*[84,90], *Faecalibacterium*[84] and *Prevotella*[90,96] were less populated.

In a comparative study, Wang *et al*[91] showed a higher proportion of gram-negative bacteria, including *Bacteroidetes*, and decreased *Firmicutes* in NAFLD patients when the gut microbiota was compared with lean healthy subjects. The decline in *Firmicutes* is associated with short-chain fatty acid (SCFA)-producing bacteria such as *Lactobacillaceae*, *Lachnospiraceae*, and *Ruminococcaceae*. An overgrowth of gram-negative bacterial species was seen in children with NAFLD, with an increased ratio of Gammaproteobacteria and Epsilonproteobacteria compared to their obese and lean counterparts[97]. In contrast, bacteria from the *Firmicutes* phylum (such as *Lactobacillus*, *Roseburia, Dorea*, and *Robinsoniella*) were found to be increased in the population of NAFLD patients in another study[95]. However, contradictory results were reported in other studies that showed increases in *Dorea* and *Ruminococcus* in NAFLD patients[94,98]. Variability in gut microbial composition was observed with different levels of NAFLD severity. Bacteria belonging to *Firmicutes* were more dominant in moderate NAFLD, while the prevalence of *Proteobacteria* was noted to be associated with the severity of disease, as in fibrosis[93]. The bacterial species that were dominant in mild NAFLD compared to severe NAFLD conditions were *Eubacterium rectale* and *Ruminococcus obeum*[93]. These human study results reflect the conflicting gut microbiota composition in NAFLD, which needs to be evaluated further by implementing a greater number of NAFLD patient-based gut microbial compositional studies.

The gut microbial composition was also assessed in severe NAFLD conditions such as fibrosis and/or in nonalcoholic steatohepatitis (NASH) to examine the functional role of gut microbial dysbiosis in fibrosis progression. The results of these comparative studies exhibited a decline in gram-negative bacterial abundance. Comparative analysis of the gut microbiota between individuals with severe NAFLD and healthy or less severe NAFLD conditions showed a decrease in the *Fusobacteria* phylum population and an increase in *Enterobacteriaceae* family bacteria such as the genera *Shigella*, *Ruminococcin* and *Bacteroides*[92,96]. Similarly, gram-positive bacteria from the *Firmicutes* phylum, the family *Prevotellaceae* and the genus *Prevotella* also showed increases in severe NAFLD conditions[93]. Recently, a study presented a significant alteration based on fibrosis severity in nonobese patients but not in obese patients, where *Ruminococcaceae* and *Veillonellaceae* were the leading microbes related to fibrosis severity in nonobese subjects[99]. Interestingly, oral microbes, including *Streptococcus* [76,100,101], *Veillonella*[91,100], and *Prevotella*[100,102], are discriminatory microbes for advanced NAFLD conditions (especially cirrhosis). Additionally, some microbe representations were constant in NAFLD patients compared with healthy individuals, but some showed conflicting tendencies[103]. Conclusively, microbial composition in NAFLD patients presented a drastic shift in taxonomic group composition by showing an increased ratio of pathogenic microbes and a decline in microbes that are considered metabolically beneficial microbes. Subsequently, this compositional shift in microbial composition might be responsible for NAFLD pathogenesis and exacerbate the severity of the disease from simple steatosis to NASH and from NASH to cirrhosis. Summarized information on gut microbial dysbiosis in NAFLD is listed in Table 2, which provides details regarding the increased and decreased populations of bacteria in NAFLD.

The gut microbiota composition in NAFLD presented a considerable contradiction, where some microbial taxa showed variability in their occurrence, as shown in Table 2. The underlying reasoning behind these contradictory compositional variabilities might be related to study design, clinical study end points, result interpretation, *etc*. Moreover, these underlying reasons could be fundamental restraints in the process of establishing a robust relationship between the gut and NAFLD. Thus, to determine the pathophysiological association between the gut and liver, these fundamental limitations should be resolved.

GUT ROLE IN FATTY LIVER

Trillions of microorganisms reside in the gut, including bacteria, archaea, fungi, and viruses, but liver-disease-related research primarily targets the bacterial community, which includes more than 10 bacterial phyla[104,105]. The gut microbiota includes more than 3 million genes collectively, in comparison to the 23000 genes of the human genome; however, human cells and gut bacterial cells are roughly equal in number [106]. This gut microbial genetic material certainly has a defining role in human pathophysiology through multiple mechanisms, especially in liver disease, due to its close relationship with the gut[6,107,108].

Gut microbial dysbiosis

Generally, the gut microbiota starts to be shaped at birth and becomes stable in early childhood. This balanced and stable gut microbiota acquires a unique quotient for each microbial species in a healthy state[38]. As discussed above, gut microbial dysbiosis, defined by diminished microbial diversity and distorted gut microbial composition, is observed in both AFLD and NAFLD patients compared to healthy controls[18,103]. Alcohol abuse and overnutrition deplete several bacterial species and shift the microbial composition toward gram-negative bacteria. Microbial species depleted in liver diseases are considered beneficial microbes, and overgrown microbial species are associated with liver pathophysiology and known as pathobionts[109]. Alcohol consumption is linked with diminished fungal diversity generated by an increased number of *Candida* species[83,110,111]. Moreover, gut viruses are the most abundant gut microbes; nonetheless, they have not yet been characterized in liver disease.

This gut compositional proclivity toward gram-negative bacterial species influences multiple pathways directly or indirectly that contribute to AFLD and NAFLD establishment[16,91,92]. The distorted gut microbiota alters various metabolic processes, such as bile acids, short-chain fatty acids, and energy harvesting, which leads to the initiation of fatty liver disease[112]. The distorted gut microbiota also damages gut barrier function, through which microbes and their metabolites can translocate and activate the inflammasome in the liver and cause fatty liver[112]. The detailed role of the gut microbiota in fatty liver pathogenesis is presented in Figure 1.

Leaky gut syndrome

In the intestine, there are multiple layers of barriers, including physical, biochemical, and immunological barriers, that restrict the translocation of microbes and their products. Chronic alcohol abuse causes gut barrier dysfunction by altering the gut microbial composition[113]. Thus, pathogen-associated molecular patterns, such as LPS, are able to translocate from the lumen of the intestine to the liver *via* the portal vein and are recognized by inflammasomes such as Toll-like receptors in the liver to stimulate hepatic inflammation, which leads to hepatocyte injuries and liver fibrosis [112]. Likewise, similar pathophysiological pathways are involved in NAFLD progression, but gut disruption and inflammation are stimulated by dietary factors other than alcohol[112]. Other types of inflammasomes, including NOD-like receptor protein 3 (NLRP3), also respond to LPS and cause liver inflammation. The activation of NLRP3 triggers the caspase 1 pathway and produces interleukin-1β and several other inflammatory cytokines, which cause apoptosis and fibrosis. Higher levels of inflammasomes such NLRP3 and others were found in severe fatty liver conditions induced by both alcohol and overnutrition[114,115]. The translocation of the microbial metabolites from the intestine to the liver because of the dysfunction of intestinal barriers and increased intestinal permeability could be the contributing factor for AFLD and NAFLD, but more studies are required to establish robust associations.

Bile acid dysregulation

Bile acid synthesis and secretion are essential functions performed by liver cells. Importantly, bile acids not only are crucial for dietary fat emulsification but also act as ligands for nuclear and G-protein coupled receptors and regulate various metabolic functions, including glucose and fat metabolism[116]. Therefore, smooth regulation of bile acids is important for maintaining a healthy metabolic profile, but gut microbial

dysbiosis is associated with bile acid dysregulation and is associated with fatty liver pathogenesis through metabolites[117].

Normally, conjugated bile acids are released from hepatocytes, carried by the biliary duct, and secreted into the intestine. After lipid emulsification, the remaining bile acids (primary, hydrophilic, and conjugated) are reabsorbed in the terminal ileum. Bile acid secretion from hepatocytes is primarily regulated by the farnesoid X receptor (FXR) negative feedback mechanism[118]. The release of primary bile acids in the intestine activates intestinal FXR, which precedes the transcription of fibroblast growth factor 19 (FGF19). The ileal hormone FGF19 is carried to the liver *via* the portal vein, where FGF19 suppresses CYP7A1 expression and controls bile acid secretion[119]. The disruption of bile acid homeostasis is the leading cause of fatty liver[119-121].

The change in the gut microbial composition induced by alcohol abuse and a high intake of energy-dense food cause the dysregulation of the bile acid system and instigate fatty liver diseases (AFLD and NAFLD)[122,123]. In AFLD and NAFLD, pathobionts increased in number and were responsible for the conversion of secondary bile acids from primary bile acids and reduced FXR signaling. This downregulation of FXR expression increased insulin resistance and altered glucose and lipid metabolism, which are the key regulatory pathways in AFLD and NAFLD generation. Moreover, AFLD and NAFLD patients showed higher levels of secondary bile acids than primary bile acids in feces and blood. Similarly, the dysregulation of FXR signaling and FGF19 is increased with the severity of the disease in both AFLD and NAFLD[124-127]. These outcomes suggest that FXR and bile acid compositional dysregulation are the metabolic features of AFLD and NAFLD and that the dysregulation of both metabolic factors (FXR and bile acids) increases with the severity of AFLD and NAFLD.

Although gut bacteria control bile acid metabolism, the involvement of intestinal bacteria or other gut microbes (including archaea, fungi, and viruses) in bile acid dysregulation in fatty liver patients is not completely understood, and more experimental evidence is required to fill the fundamental gaps.

Short-chain fatty acid dysregulation

Nondigestible carbohydrates in food are fermented by gut bacteria, and SCFAs are produced. Butyrate, acetate, and propionate are the most abundant SCFAs found in the intestine. SCFAs have many beneficial effects, including being used as an energy source by colonocytes and enterocytes, maintaining gut barrier function, suppressing hepatic cell proliferation, reducing inflammation, and lowering food intake by increasing satiety[128]. Considering the beneficial function of SCFAs in regulating metabolic pathways, their level in the body is crucial to maintain good health.

Chronic alcohol abuse is related to reduced SCFA levels in the stool[129]. The SCFA concentration and SCFA-producing bacterial concentration are decreased in the feces of alcoholic hepatitis patients[109]. The low circulatory butyrate level is also associated with serum endotoxin, inflammation, and more advanced liver diseases[130]. In contrast, a higher level of SCFAs and an increased number of SCFA-producing bacteria were found in NASH patients; however, the study population was small[131]. Additionally, increasing levels of SCFAs are related to immune regulation and NAFLD progression[131]. Higher fecal concentrations of propionate and butyrate were observed in mild to severe NAFLD patients, whereas higher fecal concentrations of acetate and formate were found in advanced fibrosis patients[132,133]. There is an insufficient amount of empirical proof to establish a concrete relationship between SCFAs and fatty liver diseases, and more studies are required to determine the association between SCFAs and fatty liver diseases.

Endogenous ethanol production

Microbial fermentation of dietary sugar increases the endogenous alcohol level in pediatric NASH patients[84]. Recently, a *Klebsiella pneumonia* strain was identified in a NASH patient fecal sample and was responsible for producing endogenous ethanol and increasing the blood ethanol level without alcohol consumption[134]. FMT from NASH patients to animals results in liver damage, and the elimination of alcohol-producing *Klebsiella pneumoniae* strains reduces liver damage. Additionally, NASH patient weight reduction was also related to a reduced ability to produce ethanol in the gut microbiome[134]. Another study focusing on comparing the gut microbial profile in pediatric NAFLD patients showed higher circulatory ethanol levels in diseased patients, which was related to the higher number of *Prevotella* and Gammaproteobacteria[97]. The results from another study showed that a higher circulatory level of ethanol in NAFLD patients could be the end result of ethanol dehydrogenase activity in insulin-dependent impairment conditions[135]. Thus, gut

microbial dysbiosis, which can lead to an increasing level of endogenous ethanol in the body, could be an underlying cause of NAFLD and could be responsible for producing the same histopathological characteristics as AFLD. However, some inconsistencies in the results were observed, and establishing an association between this endogenous ethanol phenomenon and NAFLD generation needs more experimental proof[16,136,137].

Gut microbial virulence factors

Virulence factors are microbial proteins and peptides that help pathobionts colonize and are associated with disease generation. A recent study recognized that cytolysin, a protein secreted (exotoxin) by *E. faecalis*, damages hepatocytes and is highly associated with increased mortality in alcoholic hepatitis patients[18,138]. Unfortunately, few studies have shown any further toxins or other proteins related to gut microbiota that can be associated with liver disease.

FUTURE PERSPECTIVES

Fatty liver disease (both AFLD and NAFLD) is intricately linked with the gut microbiota and its dysbiosis. Recent advancements in gut microbiome-based metagenomics studies related to liver disease have shown that an increase in and/or depletion of the specific microbial content could contribute greatly to liver injuries and is possibly the key regulator in fatty liver disease establishment and progression[112]. Growing evidence regarding the role of the gut microbiota in fatty liver disease generation and progression turns this noncommunicable disease into a communicable disease[139]. Therefore, targeting the gut microbiota through various techniques may be an approach for the management of liver disease in the future.

Prognostic and/or diagnostic biomarkers

As discussed above, the microbial composition in fatty liver diseases is different from that in healthy individuals. Gut microbes themselves or their microbial metabolites might be useful as prognostic and/or diagnostic tools for the early detection of fatty liver conditions. Generally, constant alcohol intake of more than 60 g per day leads to alcoholic hepatic steatosis, which also presents with higher levels of liver enzymes, such aspartate aminotransferase (AST) and alanine aminotransferase (ALT), and in NAFLD, daily alcohol intake is approximately 30 g per day. Typically, two to three times higher serum AST levels have been observed compared to serum ALT due to alcoholic liver injuries. Patients with AFLD also have higher serum gamma-glutamyl-transpeptidase levels[140]. Similarly, NAFLD also has noninvasive biomarker detection protocols, such as the NAFLD fibrosis score (including age, BMI, the AST-to-ALT ratio, impaired fasting glucose and diabetes, albumin and platelets), FIB-4 index (including age, ALT, AST, and platelets), and FibroTest (including total bilirubin, α2-macroglobulin, γ-glutamyl transferase, haptoglobin, and apolipoprotein A1 corrected for sex and age)[141]. These are the common diagnostic parameters used for AFLD and NAFLD diagnosis. However, there is a lack of conclusive biomarkers that can help in the early diagnosis of hepatic steatosis, and the repertoire of gut microbes and their metabolite profiles might help to fill this gap. Interestingly, a set of gut bacteria combined with age and BMI was used to identify liver disease, and a much more accurate diagnosis was able to be made with its use in patients with advanced fibrosis [93]. The gut microbes used as a marker in this study were first identified from NAFLD and advanced fibrosis patients *via* metagenomics analysis and then further used for diagnostic purposes[93]. In a separate study, the combination of metagenomic signature microbes with age and serum albumin levels precisely identified cirrhosis in patients with geographically different origins. Additionally, adding serum aspartate aminotransferase levels to these diagnostic tools increased diagnostic efficacy even in the early stage of fibrosis[142]. In other studies, gut-microbe-derived metabolites showed great potential as diagnostic markers for fatty liver diseases and other liver conditions[18,90,143].

Although gut microbes and their metabolites have the potential to be noninvasive prognostic and/or diagnostic tools for fatty liver and other liver diseases, larger population-based studies are still required to eliminate constraints related to geographical factors, ethnicity, and dietary factors. Further studies are also warranted to compare the diagnostic ability of gut microbes and their metabolites with contemporary in-use investigative practices such as biopsy and image-based approaches.

CONCLUSION

Gut microbiota is crucial in fatty liver diseases (in both AFLD and NAFLD), thus relevance of fatty liver disease specific gut microbial signatures should be further explored in longitudinal human studies. Where, a team of clinician and researchers can prospectively correlate the deterioration of liver with the alteration in the gut microbiota community. Merging fatty liver disease specific gut microbiota with microbial derived metabolites can be helpful in the future to diagnose and treat the AFLD and NAFLD patients.

Abstract

Surveillance for hepatocellular carcinoma (HCC) in high-risk patients with semiannual ultrasound examinations is advocated by all international guidelines. However, as long as the identification of the population to be screened and the surveillance programs are not well implemented, the real-life impact of HCC surveillance in reducing mortality for HCC cannot be known. We propose a new approach that promotes the identification of cirrhotic patients by primary care physicians (PCPs) and referral of patients to the hepatologist for surveillance. Surveillance should be incorporated, when feasible, in a hub and spoke model of comprehensive hepatology care. Training PCPs to identify cirrhotic patients and performing surveillance in a subspecialist setting are equally important to improve the effectiveness of real-life surveillance and to decrease HCC mortality over time.

INTRODUCTION

Primary liver cancer is the third leading cause of cancer related mortality worldwide [1]. It includes hepatocellular carcinoma (HCC), comprising of 75%-85% cases, intrahepatic cholangiocarcinoma (10%-15%), and other rare types[1]. The HCC death toll is the highest in East Asia and Africa, with an annual mortality rate greater than 20/100000 people[2]. Mortality is lower in Western Europe and in the United States (12-12.7/100000) but it has increased rapidly in the last decade[3]. On the other hand, Eastern Europe, Scandinavia, and India have the lowest mortality rate (less than 4/100.000). The great majority of HCC cases in the Western world are diagnosed in cirrhotic patients, while in Asia and Central Africa the most significant risk factor for HCC is chronic hepatitis B virus infection with or without cirrhosis. Therefore, patients with those risk factors (cirrhosis and/or chronic hepatitis B infection) should undergo surveillance, with the goal of identifying the tumor at an early stage when curative treatments are feasible. A randomized study of chronic hepatitis B patients in China [4], several longitudinal cohort studies in patients affected by cirrhosis of any etiology [5-7], and a meta-analysis[8] have demonstrated the benefit of ultrasound surveillance (US) in improving survival. In addition, several studies have shown that US is cost effective for the surveillance of patients affected by chronic hepatitis B and of cirrhotic patients. Indeed, HCC incidence in those populations is 0.2% and 1.5% per year respectively, which is considered acceptable to define cost effectiveness[9-11]. On the other hand, the effectiveness of US is still uncertain in young Non-Asian inactive carriers of hepatitis B surface antigen (HBsAg), in patients with chronic hepatitis C infection with advanced fibrosis, and by those with nonalcoholic fatty liver disease (NAFLD) without cirrhosis. For those reasons, the three most important international guidelines advocate periodic abdominal ultrasound scans with or without alpha-fetoprotein (AFP) in all cirrhotics and chronic hepatitis B patients, irrespective of antiviral treatment[2,12,13] as a cost effective and noninvasive surveillance modality. According to the guidelines, US should be performed on a semiannual basis, with the exclusion of decompensated cirrhotics not listed for liver transplantation, in which surveillance is considered futile.

Despite the recommendations, real-life implementation of surveillance programs is far from optimal. It has recently been shown that, in addition to an increase in the proportion of HCC diagnosed at an early stage, 64% of the cases detected in the United States between 2006 and 2012 were diagnosed at an intermediate or an advanced stage [14]. That is probably the result of the low implementation of surveillance programs, with less than 20% of cirrhotics undergoing regular surveillance[15]. Surveillance is hindered by several issues, insufficient identification of patients at risk, failure to order surveillance, failure to perform surveillance with effective tools, poor patient adherence to the surveillance program, failure to establish a care-unit network to provide effective treatment. This review aims to analyze these steps one-by-one in order to identify the obstacles hampering the implementation of surveillance in real life.

FAILURE TO IDENTIFY THE PATIENTS AT RISK

One of the most important factors responsible for the low uptake of surveillance is the failure of primary care physicians (PCPs) to identify patients at risk to be enrolled in surveillance programs. In two web-based surveys, PCPs reported lack of knowledge of current guidelines. They could not correctly identify the at-risk categories and ordered random surveillance of chronic liver disease patients[16,17]. It is noteworthy that cirrhosis is widely under diagnosed and that increased identification and surveillance

of cirrhotic patients would be very cost effective in detecting HCC at an early stage. As an example, assuming an ultrasound sensitivity of 65% for early-stage HCC[18], an increase in the detection rate of cirrhotic patients from 50% to 75% would result in a significant increase of early-stage HCC diagnosed by abdominal ultrasound. Thanks to the identification of high-risk patients, ultrasound screening would thus allow the identification of a number of early-stage HCC comparable to magnetic resonance imaging (MRI) use, which has a higher sensitivity (90%) but is more expensive and has a higher false-positive rate. Another negative consequence of the failure to identify cirrhotic patients is that the cause of liver damage is not treated, and consequently HCC would often be diagnosed in a critical patient not eligible for radical treatment anymore.

Fortunately, the performance of PCPs can be improved by training interventions[19] and by participation in specialist networks, as shown by the French experience in hepatitis C[20]. To address the problem, in 2006 we started an education program targeting 120 PCPs, aimed at the identification of cirrhotic patients and their surveillance for HCC[21]. The program was started in the southern part of the Province of Bergamo in two hospitals, Policlinico S. Marco, Zingonia, and Azienda Ospedaliera di Treviglio, that have hepatology clinics providing medium-complexity specialist care. More complex cases are referred to a tertiary care hospital in Bergamo, which has a liver transplant center. Two hepatologists had established a network of collaboration with PCPs for the management and referral of patients with liver disease, but also provided care for patients from the nearby provinces, where no specific network had been implemented. The training program consisted of a 1-year intensive course in 2006, followed by annual refreshers from 2007 to December 2013. PCPs were instructed to perform screening of all patients at risk of liver cirrhosis, *i.e.* hepatitis C virus (HCV) infection, HBsAg positivity, alcohol abuse (> 60 g/d in women and > 80 g/d in men), body mass index > 30 kg/m^2, and to refer them to the liver specialist for diagnostic confirmation and US planning[20]. Abdominal ultrasound was performed, and the data were analyzed, by hepatologists or by radiologists who worked at the same hospital and had strong expertise in liver cancer detection.

The results showed that 6 years after training PCPs, there was a significant increase in the number of HCC patients detected by US at an early stage and suitable for radical treatment (Figure 1). As a consequence, 3- and 5-year survival of HCC patients improved significantly from 35% to 48% and 20% to 40%, respectively ($P < 0.05$) after training. In contrast, both the proportion of HCCs detected by US, and patient survival did not change in areas where PCPs were not trained. The study has some limitations. Firstly, PCPs did not record the number of cirrhotic patients who were identified, but only the number of HCC patients who were diagnosed. Secondly, the cirrhosis criteria used by PCPs to refer the patient to the hepatologist were mainly ultrasound based using two of the following ultrasound criteria, liver surface nodularity, nonhomogeneous liver texture, left lobe or caudate lobe hypertrophy, distorted hepatic veins, spleen longitudinal diameter > 12 cm or one ultrasound criterion plus a platelet count < 130.000/mL. Currently, those criteria are obsolete, as the availability of new proprietary (*e.g.*, Fibrotest, Enhanced Liver Fibrosis, and Fibrometer) and nonproprietary biochemical scores (fibrosis-4, aspartate transaminase to platelet ratio index), and NAFLD fibrosis scores) have improved diagnostic accuracy. Nonetheless, the study showed that it is essential to establish a collaboration network among hepatologists and PCPs, and that strengthening PCP skills in identifying and referring suspected cirrhotic patients may result in an increased number of HCCs diagnosed at an early stage and improved patient survival. In the following years, the network of collaboration was extended to the whole province of Bergamo, and specific training aimed at the diagnosis of cirrhosis was incorporated into a comprehensive hepatology education program that involved 900 PCPs. The program consists of specific courses organized every 3 years by the local health authority and annual symposia organized by the tertiary care hospital of Bergamo. The percentage of HCCs diagnosed at an early stage in the following years was still high, indicating that the positive effect of training persisted in time. Indeed, 166 (77%) of 202 HCCs diagnosed in cirrhotic patients at Policlinico S. Marco Hospital from January 2014 through December 2020, were found at an early stage and could be effectively treated. It is worth noting that only 14 HCCs were diagnosed in noncirrhotic patients, seven with chronic hepatitis B and currently under surveillance, six were detected at an early stage, five had chronic hepatitis C infection, and two had noncirrhotic nonalcoholic steatohepatitis (NASH). Therefore, our real-life data confirm the adequacy of the official guidelines recommending US only in patients affected by cirrhosis or chronic hepatitis B.

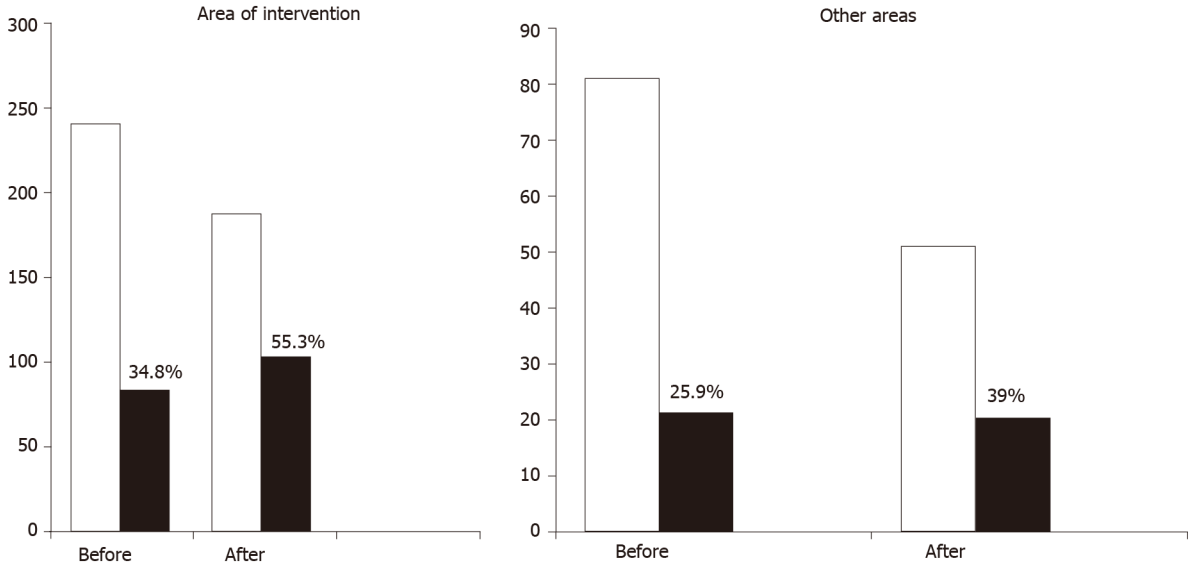

Figure 1 Hepatocellular carcinoma diagnosis before and after implementation of the training program in the area where primary care physicians were trained and in other areas where primary care physicians were not trained. White bars indicate the total number of hepatocellular carcinomas. Black bars indicate hepatocellular carcinomas diagnosed by surveillance. In the intervention area the diagnoses under surveillance increased from 85 of 244 (34.8%) to 105 of 190 (55%) after training (Δ = + 20.5%, $P < 0.001$). The diagnoses increased from 21 of 81 (25.9%) to 20 of 51 (39%) in other areas (Δ = + 13.1%, $P = 0.11$, not significant).

FAILURE TO ORDER SURVEILLANCE

The identification of cirrhotic patients for surveillance does not imply that surveillance will be effectively performed. In fact, surveillance is sometimes carried out by the PCP and ultrasound scans are performed by radiologists without specific expertise in liver disease. In that case, the patient is referred to the hepatologist or gastroenterologist only if a focal lesion is detected, a scenario called "population-based surveillance". In Italy and other countries, thanks to the widespread diffusion of ultrasound equipment and the motivation of an active medical sonography society, US is directly performed by hepatologists with sonographic skills and able to perform the examinations by themselves (*i.e.* specialist or subspecialist surveillance). Population-based surveillance is mainly implemented in the United States, while specialist surveillance is more widespread in Europe and Asia. A systematic review and meta-analysis comparing the two US modalities reported a much higher effectiveness of surveillance in the specialist setting (73.7%) rather than in population-based cohorts (8.8 %), with the lowest effectiveness in patients with alcoholic and NASH cirrhosis[22]. There are many reasons for the difference. PCPs and radiologists without specific expertise in liver disease may have limited knowledge of the international guidelines[17,23]. Concerns of other serious comorbidities, logistic problems such as poor accessibility of ultrasound facilities, and difficulties in the scheduling process. Consequently, the need to access low-cost, affordable ultrasound facilities may result in delays or absence of PCP surveillance[24]. Several interventions can be introduced to improve US programs, namely the use of automatic reminders for PCPs or the implementation of protocols that can be carried out by nurses or pharmacists[22]. Beste *et al*[25] reported that a primary care-oriented clinical reminder integrated into clinical records improved PCP surveillance from 18.2% to 27.6%[25], whereas no improvement was observed in the control sites (from 16.1% to 17.5%). Similarly, in a large study of 1800 cirrhotic patients, Singal *et al*[26] observed that mailed outreach invitations increased surveillance from 24% to a staggering 44.5% with no benefit seen by the addition of patient navigation [26]. Overall, it can be concluded that surveillance performed in subspecialist settings, if feasible, would be preferable to population surveillance. In the latter case, decreased use of US could be expected, and even after the interventions mentioned above (*i.e.* internal modalities such as medical reminders, nurse-based protocols, and patient navigation and outreach modalities such as mailed invitations), it was only slightly improved. Therefore, it is essential to ensure that PCPs are aware of the importance of appropriate specialist surveillance and to reinforce the need of specific education programs addressed to them.

FAILURE TO USE THE APPROPRIATE SURVEILLANCE TOOL

Liver ultrasound

Liver sonography is recommended by all existent guidelines as the standard HCC surveillance test to be used. A meta-analysis of 15 studies of cirrhotic patients showed that abdominal ultrasound had good sensitivity (84%) and excellent specificity (91%) for the detection of HCC at any stage[27]. However, the pooled sensitivity for the detection of early-stage HCC was as low as 47%, with only marginal improvement (53%) after exclusion of the studies performed before the introduction of high-density crystal probes and harmonic imaging. It is noteworthy that the sensitivity of ultrasound is characterized by a wide range of variation (from 21% to 81%), reflecting the operator dependency of US scans. In fact, in a single study performed at a university-based tertiary care center, the sensitivity of abdominal ultrasound was 82% [28]. Similarly, in a large Italian cohort study, where examinations were performed in both outside facilities and hospital wards, the sensitivity rose to 66%[18]. It is important to consider that ultrasound examinations in the United States were performed by technicians who recorded the images, which were subsequently reviewed and interpreted by radiologists. That can affect the accuracy of the examinations reported in those studies, as real-time interpretation of ultrasound findings is of paramount importance in ensuring the adequacy of the examination, especially in patients who are difficult to examine. In conclusion, it seems that pooled study results underestimate the sensitivity of ultrasound for the detection of early-stage HCC. It is more likely that the sensitivity of ultrasound carried out with high quality scanners and by well-trained doctors in a real-time manner, would be as high as 70%. Admittedly, even in optimal conditions, US fails to detect early-stage HCC in approximately one-third of the patients[18]. Two studies have addressed the causes of surveillance failure. Overall, both studies found that male sex, obesity, and advanced liver disease were associated with failure to detect HCC at an early stage[18,29]. Fatty liver, often associated with obesity and more frequently observed in males, may hinder good visualization of the liver, while advanced liver disease may produce a coarse echo pattern that masks early-stage tumors. It is important to distinguish poor visibility of the tumor by abdominal ultrasound, which represents a true limitation of this technology, from biologically aggressive tumors, which may show an infiltrative or rapidly growing pattern that may be difficult to detect regardless of the diagnostic tool.

Computed tomography and magnetic resonance imaging

The use of CT or MRI can obviate the above-mentioned technical limitations of ultrasound, but they rarely can identify an aggressive tumor at an early stage. In one study, 20% of the ultrasound examinations were considered technically inadequate for excluding HCC[29]. In another study, 32% of HCCs were detected beyond the early stage by semiannual US, 12% of them showing biologically aggressive features, *i.e.*, AFP > 1000 ng/mL, vascular thrombosis, distant metastasis, or infiltrative pattern[18]. Therefore, technical limitations of US to detect early-stage HCC can be deemed to be around 20%, hence it is important that ultrasound reports include a statement about the quality of the examination and the potential recommendation to perform second-level imaging (CT or MRI). MRI has a sensitivity of 83.7% for the detection of early-stage HCC[30] and should be preferred to CT, which has lower sensitivity (62.5%), similar to that of ultrasound[31]. However, it is noticeable that biologically aggressive tumors are poorly detected by MRI (16% failure to detect HCC) as well as by US (12% failure). Those tumors thus represent a hardcore of HCCs eluding both kinds of imaging surveillance. The good news is that only a small percentage of HCCs have those characteristics. However, it should be recognized that the pattern of HCC growth is heterogeneous[32] and many indolent tumors can develop an aggressive pattern with time, as shown by an increase of the percentage of biologically aggressive tumors detected by annual compared with semiannual surveillance, (*i.e.* 28% *vs* 12%) [18]. The possibility that indolent HCCs might transform into more aggressive tumors with time has raised some concerns of the common real-life practice of performing annual instead of semiannual MRI to reduce surveillance cost

Contrast-enhanced ultrasound

Contrast-enhanced US with intravascular agents (*e.g.*, Levovist, Sonovue) has a limited role in surveillance as it is impossible to scan the whole liver in the arterial phase when small tumors are detected[33]. On the other hand, perfluorocarbon (Sonazoid) seems to a promising agent[34], as it is taken up and retained by Kupffer cells for 60 min after

bolus injection, allowing a scan of the entire liver in the late phase when HCC appears as a black hole. Sonazoid-enhanced US might therefore be useful to detect HCC developing in livers with a coarse echotexture, but it cannot be of any advantage in obese patients or severe fatty livers, where CT or MRI remain the only option to accurately exclude HCC.

AFP

The sensitivity of AFP to detect early-stage HCC is too low to be used alone as a surveillance tool[35]. Only the Asian-Pacific Guidelines recommend the use of AFP in surveillance programs, with a cutoff of 200 ng/mL[2]. This cutoff is highly specific but reduces AFP sensitivity to a level as low as 22%[12]. However, new and effective pharmacological treatment of hepatitis B and C may remove false-positive AFP results caused by necro-inflammatory activity and enable the use of lower cutoff levels, providing better AFP sensitivity without compromising its specificity. Another method to improve AFP diagnostic accuracy is to monitor its changes over time[36]. An algorithm including AFP variations has been created and was tested in the Hepatitis C Antiviral Long-Term Treatment Against Cirrhosis Trial cohort, with good results in identifying patients at increased risk of HCC[37]. A recent meta-analysis showed that the addition of AFP levels to abdominal ultrasound improved the overall sensitivity for the detection of early-stage HCC from 45% to 63%[27], but as pointed out before, the low sensitivity of US in the meta-analysis raises doubts on the quality of the ultrasound examinaions. It therefore remains an open question whether AFP can improve the performance of properly executed sonography. It is important to stress that the addition of AFP screening to abdominal sonography could adversely affect the already low level of surveillance application by PCPs because of the logistic and financial burden introduced by duplicating the surveillance tool. In our real-life practice we assess AFP levels alongside abdominal US only in patients with cured hepatitis C or well-controlled chronic hepatitis B and optimal adherence to follow-up visits. A change in AFP values over time prompts performing second-level imaging, particularly in cases with a coarse echo pattern on sonography. On the other hand, stable AFP levels permit advising the continuation of standard US, avoiding additional cost.

New biochemical markers

In recent years, new markers have been proposed for the diagnosis of early HCC. Each of them by itself does not seem to confer any benefit in diagnostic accuracy compared with US with or without AFP[35]. However, a combination of AFP-L3, AFP, and des-gamma-carboxy prothrombin was tested in a large study and proved to have a sensitivity greater than 60% for early HCC, which is similar to the sensitivity of currently approved surveillance tools[38]. The algorithm is interesting, and if confirmed could be used as an alternative to ultrasound in the setting of population surveillance, especially where ultrasound scanners are not available or not accessible.

THE PROBLEM OF ADHERENCE

Patient adherence is key to the effectiveness of the surveillance program. Racial and ethnic minorities have poor awareness of surveillance programs, probably because of their low socioeconomic status. Patients also report difficulties scheduling surveillance ultrasound, concerns of the cost, need of off-work days, and difficulties reaching the facilities where the exam is performed[39]. The difficulties have a greater impact on subspecialty-based than on population-based surveillance, and should be addressed by appropriate interventions. In our hospital, the great majority of examinations are performed by hepatologists (PD and SL) and each appointment is directly booked by the specialist, thus making the scheduling process much easier. Visits and US examinations are reimbursed by the National Health Care System, with no additional cost for the patient. They are both performed at the same time to minimize off-work time, and if the patient is under antiviral treatment, the drug can be collected from the hospital pharmacy on the same day. Table 1 shows adherence to surveillance in 362 cirrhotic patients followed from January 2013 through December 2020 in our outpatient clinic. Adherence was defined as the performance of regular annual or semiannual ultrasound examinations in the last 24 months. Overall adherence to surveillance was rather good and only slightly lower than that observed in studies from other subspecialty clinics, (*i.e.* 65% *vs* 73%)[22]. It should be highlighted that in 2020 Northern Italy was heavily hit by the coronavirus disease 2019 pandemic and that the liver clinic was

Table 1 Adherence to surveillance by 362 cirrhotic patients followed from January 2013 through December 2020 at the hepatology unit of Policlinico S. Marco

Etiology of cirrhosis	Adherent	Semiannual	Annual	Nonadherent
Alcoholic (103)	55 (52%)	31 (56%)	24 (44%)	48 (46%)
HBV (53)	39 (73%)	35 (90%)	4 (10%)	14 (27%)
HCV (164)	119 (72%)	101 (85%)	18 (15%)	45 (28%)
NAFLD (42)	24 (57%)	17 (71%)	7 (29%)	18 (43%)
Total: 362	237 (65%)	184 (77%)	53 (23%)	125 (35%)

Adherence was defined as the performance of regular annual or semiannual ultrasound examinations in the previous 24 mo. HBV: Hepatitis B virus; HCV: Hepatitis C virus; NAFLD: Nonalcoholic fatty liver disease.

closed down for 2 months until April 2020. The restrictions and the fear of being infected and contracting the disease might have induced patients to avoid medical appointments, as observed for other screening programs during the pandemic. Despite that, nearly two-thirds of the patients continued surveillance, which in 77% of the cases was semiannual and in line with the official recommendations. It should be emphasized that the definition of adherence is not unequivocal, as some investigators used restrictive definitions while others, as we did, use operational definitions. Patients who underwent at least 1 or 2 surveillance exams in the last 12 months were considered adherent to the surveillance program. Moreover, as adherence decreases over time, studies with longer follow-up show lower adherence rates and cannot be compared with studies that have a shorter follow-up. To solve this conundrum it has been proposed to define adherence to the surveillance program as the proportion of time up-to-date with screening[22], although in retrospective studies complete patient data are often lacking, and this parameter may be difficult to achieve. In accord with other studies, we found a lower adherence to surveillance programs in alcoholic and metabolic cirrhotic patients (NAFLD). In those patients, the time interval between screening exams was more frequently annual than semiannual. On the other hand, patients affected by cirrhosis secondary to hepatitis B and C, had a higher adherence to the surveillance programs (72% and 73% respectively) and exams were almost exclusively performed with semiannual periodicity. The reasons for the low adherence in the former categories are multifactorial. Lack of family support and low socio-economic status are important and can hinder the access to the health care system as well as social stigma associated with alcohol abuse and obesity. It is well known that marginalized and stigmatized patients are more dependent on a good relationship with the healthcare provider than on getting the right information from scientific sources or mail reminders. They may also overestimate the prescription of drugs compared with regular screening tests, and perceive the periodicity of ultrasound examinations as a mere waste of time. It is therefore important to establish an empathic nonjudgmental relationship with those patients. The ultrasound examination should be integrated with the hepatologist consultation, a longer time for the visit should be scheduled, medical issues should be discussed, and drugs prescribed if necessary. It is important to make the patient understand that surveillance is essential to take care of their liver disease. For that purpose, it would be helpful to establish a close collaboration with Alcoholics Anonymous or other self-help groups, that could help the patients to be actively involved and aware of the importance of surveillance.

CONCLUSION

In conclusion, despite generalized consensus of all scientific guidelines on the utility of surveillance for HCC in high-risk patients, the implementation of surveillance at the community level is far from ideal. Low access to surveillance programs is associated with a lower number of HCC diagnosed at an early stage and decreased survival. Therefore, it is important to study the obstacles hampering the adherence to surveillance of the high-risk population in order to implement appropriate interventions.

Adherence to surveillance programs is higher in hospital/subspecialty-based surveillance compared with population-based surveillance, in which tests are ordered by PCPs and performed by general radiologists. Subspecialty-based surveillance should therefore be the first choice when feasible. However, the geographic location of the facilities and the distance from the hospital may result in population surve-illance as the only available choice. In both cases, lack of identification of the at-risk categories by PCPs, (*i.e.* cirrhotic patients and chronic hepatitis B patients), is the most important issue hindering implementation of adequate surveillance. Education programs targeted to PCPs to improve their skills in identifying the patients at risk can facilitate prompt referral to the hepatologist/gastroenterologist for US. PCPs should be encouraged to use biochemical scores to raise the suspicion of cirrhosis, and if feasible, portable elastography scanners. Once the diagnosis of cirrhosis has been established by transient elastography, acoustic radiation force impulse elastography, or other modalities, the patient should be followed up in a specialty setting. Regarding the surveillance tools, real-life experience confirms that semiannual ultrasound examination with the addition of sequential AFP monitoring in selected cases is the most appropriate method, with a sensitivity of about 70%. Ultrasound examinations should be of high quality and hence preferably performed by radiologists with good expertise in liver imaging, or when feasible, by the hepatologist himself. When ultrasound examinations are unsatisfactory (about 20% of cases), it should be explicitly noted in the sonographic report and the patient preferably surveilled with an annual MRI, which brings the total detection rate of early-stage HCC up to 85%. Fifteen percent of HCCs are aggressive tumors that cannot be diagnosed at an early stage with the currently available tools. Adherence to scheduled examinations is still a problem, particularly in some categories of patients, *i.e.* alcoholic and NAFLD cirrhotic patients. In order to improve patient adherence, a less complex approach that reducing the number of visits to the hospital and reducing bureaucratic procedures should be used. Once a diagnosis of HCC is made. It should be promptly treated in the appropriate setting, with evaluation of the necessity to refer the patient to a tertiary care hospital for more advanced treatments or to be evaluated for liver transplantation. Figure 2 shows the hub and spoke model of care of cirrhotic patients implemented in our province. According to the model, cirrhotic patients are identified by PCPs using appropriate screening tests. The patients are then referred to the liver clinics of general hospitals (Spokes) for diagnosis confirmation and implementation of surveillance programs. Therapeutic interventions are performed locally when feasible or the patient is referred to the tertiary referral hospital (Hub) for further treatment.

KEY TAKE AWAY MESSAGES

Surveillance for HCC in cirrhotic patients and chronic hepatitis B patients allows detection of the tumor at an early stage and improves survival.

International guidelines recommend semiannual ultrasound with or without AFP monitoring in these patients, but surveillance implementation at the community level is low.

Education programs targeting PCP and aiming at improving the identification and referral of patients at risk of HCC should be implemented.

Subspecialty-based surveillance performed by the hepatologist or gastroenterologist in the setting of the liver clinic of a general hospital is the preferred model, when feasible.

Ultrasound and MRI should be used sequentially in case of inadequate sonography.

Surveillance should be incorporated into the specific care and follow-up provided by the liver clinic to enhance adherence.

The liver clinic of the general hospital should be integrated into a hub and spoke model of care alongside PCPs and tertiary referral hospitals to ensure proper access to care.

ACKNOWLEDGMENTS

We thank Dr. Francesca De Martini for scientific and language revision of the English text.

Abstract

Artificial intelligence (AI) is an umbrella term used to describe a cluster of interrelated fields. Machine learning (ML) refers to a model that learns from past data to predict future data. Medicine and particularly gastroenterology and hepatology, are data-rich fields with extensive data repositories, and therefore fruitful ground for AI/ML-based software applications. In this study, we comprehensively review the current applications of AI/ML-based models in these fields and the opportunities that arise from their application. Specifically, we refer to the applications of AI/ML-based models in prevention, diagnosis, management, and prognosis of gastrointestinal bleeding, inflammatory bowel diseases, gastrointestinal premalignant and malignant lesions, other nonmalignant gastrointestinal lesions and diseases, hepatitis B and C infection, chronic liver diseases, hepatocellular carcinoma, cholangiocarcinoma, and primary sclerosing cholangitis. At the same time, we identify the major challenges that restrain the widespread use of these models in healthcare in an effort to explore ways to overcome them. Notably, we elaborate on the concerns regarding intrinsic biases, data protection, cybersecurity, intellectual property, liability, ethical challenges, and transparency. Even at a slower pace than anticipated, AI is infiltrating the healthcare industry. AI in healthcare will become a reality, and every physician will have to engage with it by necessity.

INTRODUCTION

Artificial intelligence (AI) is an umbrella term to describe any application where computer systems are used to perform tasks normally associated with human intelligence[1,2]. AI is a cluster of interrelated fields, including machine learning (ML) and probabilistic reasoning, planning and decision making, fuzzy systems, computer vision, natural language processing, knowledge representation, and neural networks (NN)[1]. Despite their differences, these fields are all driven by advancements in computing power and Big Data.

ML could be described as a model that learns from past data in order to predict future data[3]. The application of ML in healthcare was catalyzed by several healthcare trends, such as electronic healthcare records and patient summaries, genomic analyses and biomedical research, routine imaging, and telemedicine, that have transformed the healthcare industry into a data-rich science with data as an omnipresent concept[4-6]. Specifically, while in 2013, the healthcare industry produced 153 exabytes (10^{18} gigabytes) of data, it has been projected to reach 2314 exabytes in 2020[7]. Therefore, the healthcare industry generates an enormous amount of data that conform with the features that define Big Data: Volume, high-velocity, high-variety, and veracity, which cannot be analyzed or managed by traditional software[5,8,9]. AI promises to process and analyze these extensive repositories of data and turn them into meaningful insights.

Several studies have described AI as the potential solution to long-standing healthcare challenges such as increasing diagnostic accuracy, enhancing telemedicine, providing substantial cost reduction, promoting evidence-based medicine, facilitating targeted literature search, and delivering individualized care[10-14]. More importantly, AI could substantially alleviate the burden of diseases by reducing the associated mortality and morbidity through optimizing patient outcomes[15,16].

In gastroenterology and hepatology, physicians handle large amounts of clinical data and an extensive repository of imaging data generated from endoscopy, ultrasound, and computed tomography (CT). Therefore gastroenterology and hepatology are data-rich fields, and thus fruitful ground for AI applications with extensive research conducted in these fields, particularly regarding the prevention, diagnosis, management, and prognosis of diseases[17,18]. We aim to comprehensively review the applications of AI in gastroenterology and hepatology and identify the current challenges of utilizing AI in healthcare in an effort to explore ways to overcome them.

SEARCH STRATEGY

We conducted a comprehensive literature review of the Medline, Cochrane, and Scopus databases using the following algorithm: [(artificial intelligence OR machine learning OR deep learning OR neural networks OR support vector machine OR computer-assisted OR computer-aided) AND (gastroenterology OR hepatology OR

esophageal OR small bowel OR large bowel OR gastric cancer OR capsule endoscopy OR polyps OR colonoscopy OR colorectal cancer OR gastrointestinal bleeding OR inflammatory bowel disease OR Crohn's disease OR celiac disease OR ulcers OR hepatocellular carcinoma OR cholangiocarcinoma OR liver fibrosis OR fatty liver OR chronic liver disease OR cirrhosis)]. Articles were reviewed for eligibility by the two authors independently (CC, GT), and disagreements were solved by a discussion between the two authors. Finally, the reference lists of eligible articles were reviewed to identify further related literature, including articles, books, and other forms of publication. We excluded studies written in a language other than English and publications of abstracts. The review of the literature was completed on January 27, 2021.

AI CLASSIFIERS

Before discussing AI's current applications and challenges in gastroenterology and hepatology, we briefly describe the AI classifiers in ML models that we identified as the most commonly used among the eligible articles. Specifically, we describe the basic features of the support vector machine (SVM), the artificial NN (ANN), and the convolutional NN (CNN). ML is divided into supervised and unsupervised based on whether the training data is labeled or not[19]. In other words, through supervised ML, a new data set is classified for an outcome based on previous data sets that trained the ML model, while in unsupervised ML, there is no outcome but rather an attempt to detect unknown patterns and correlations within the data[20].

SVMs are supervised learning models with associated learning algorithms trained to assign classes to new cases. SVMs require a training set of data where each case is pre-labeled regarding the outcome classification. The data points of the features of each case are treated as points in a high-dimensional space[21]. Based on these mapped points, separating hyperplanes are drawn, aiming to distinguish these points upon their labeled class[22]. The hyperplane with the maximum distance from the mapped data points, known as the maximum functional margin, is selected since it provides the SMV's full potential to classify new examples correctly[21,22]. SVMs typically perform linear classification analysis. For non-linear analysis, kernel function could introduce additional dimensions to the raw data; and thus turning a non-linear problem into a linear problem in a higher-dimensional space[23].

An ANN is an ML model inspired by the human brain's neuronal connections that consist of an input layer, an output layer, and a hidden layer between them[18]. ANNs are applied both in supervised and unsupervised ML[24]. When multiple hidden layers are inserted between the input and output layers, and the network's architecture becomes more complex with multiple interconnections, the concept of deep NN (DNN) emerges[24,25]. During DNN training, the model adjusts the weighted correlations between the nodes of the input layer and the nodes of the multiple hidden layers[18,20]. Within DNN, CNNs are biologically variants inspired by multi-layer perceptrons[26]. CNNs have been extensively applied for medical image analysis[17,18]. During the CNN model development, the images are preprocessed using multiple filters, and multiple feature maps are created in a process called convolution[26].

APPLICATIONS OF AI IN GASTROENTEROLOGY

AI/ML-based models have been extensively applied in the prevention, diagnostics, management, and prognosis of gastrointestinal (GI) diseases, including GI bleeding (GIB), inflammatory bowel diseases (IBDs), malignant and premalignant lesions, and other nonmalignant lesions/diseases such as gastroesophageal reflux, *Helicobacter pylori* (*H. pylori*) infection, ulcers, celiac disease, and intestinal hookworms.

Prevention

Table 1 summarizes the findings of the identified studies applying AI/ML models in the prevention of gastroenterological diseases. AI/ML-based software could be used in screening programs to identify high-risk patients not currently identified by standard screening guidelines. In a recent study, researchers developed seven different AI/ML models to identify patients at high risk of developing gastric cancer following the eradication of *H. pylori* infection[27]. The extreme gradient boosting (GB) model demonstrated the highest performance[27]. A CNN was developed in a different study to classify patients at low, moderate, and high risk of developing gastric cancer using

endoscopic images[28]. A similar study used multiple classification and regression trees (CART) to develop a model that predicts future gastric cancer development[29]. Another notable example is the ColonFlag test, an ML algorithm that uses age, sex, and complete blood count data to identify patients at high risk of developing colorectal cancer[30,31]. In a recent study, among 254 individuals who underwent colonoscopy, 19 cancers (7.5%) and 22 (8.7%) advanced adenomas were identified in a population of patients who would otherwise have avoided screening[31]. These studies demonstrate how AI/ML-based models could be used in a real clinical setting to establish targeted screening programs.

Diagnostics

Table 2 summarizes the findings of the identified studies applying AI/ML models to diagnose gastroenterological diseases. AI/ML-based software is applied in Computed Aided Detection or Diagnosis (CAD) systems used in radiology to augment medical images' interpretation accuracy. A CAD typically includes the stages of preprocessing, extraction of features, and feature selection and classification[32]. CAD systems could also aid endoscopists in navigating through the different anatomical locations of the GI tract. Specifically, a model based on a CNN employed esophagogastroduodenoscopy images to recognize the anatomical locations with outstanding performance[33].

Regarding the diagnosis of gastroesophageal reflux, an ANN model was developed as a non-invasive diagnostic tool by employing only clinical data[34]. For patients with Barrett's esophagus, a deep learning-based (DL) CAD system was developed to differentiate patients with malignant from patients with nondysplastic Barret's esophagus [35]. The CAD system also identified the optimal site to perform a biopsy with an accuracy between 92% and 97%[35]. An SVM model was developed in another study employing white-light endoscopic imaging to identify early neoplastic lesions[36]. In a recent study, images from volumetric laser endomicroscopy were used to develop a CAD system to detect neoplastic lesions for patients with Barret's esophagus[37]. A similar study using volumetric laser endomicroscopy developed an ML model for detecting neoplastic lesions[38]. Notably, the model outperformed the experts in volumetric laser endomicroscopy[38]. Finally, to diagnose esophageal squamous cell carcinoma, a CNN model was developed by employing endocytoscopic images as an alternative to biopsy[39].

For diagnosing patients with *H. pylori* infection, a CNN was developed in a study employing gastroscopic images[40]. A different CNN for *H. pylori* diagnosis was developed in a prospective pilot study analyzing images taken from the stomach's lesser curvature using either white light imaging, blue light imaging, or linked color imaging[41]. Notably, employing blue light and linked color imaging yielded significantly higher performance than white light imaging[41]. In a similar study, a

CNN model employed images from upper GI endoscopy to detect *H. pylori* infection

[42]. Finally, Shichijo *et al*[43] developed two different CNN models to diagnose *H. pylori* infection. The first, a 22-layered deep CNN, performed comparably with endoscopists, while the second, which classified images based on their location in the stomach, performed comparably with endoscopists in terms of sensitivity and specificity but demonstrated a significantly higher accuracy[43]. The time needed to analyze all the images was 3 min and 18 s and 3 min and 14 s for the two CNNs, while for endoscopists, the average time needed was 230.1 min[43]. A recent meta-analysis evaluating the performance of CNNs to diagnose infection with *H. pylori* concluded that it is currently equivalent to physicians[44].

Regarding the diagnosis of gastric cancer, an SVM-based CAD model was developed to identify early gastric cancer features in narrow-band imaging (NBI) gastroscopy[45]. In a different retrospective study, a CNN was developed to detect gastric cancer from endoscopic images. Even though the model managed to correctly classify 71 of the 77 gastric cancer lesions (92.2% sensitivity), it also falsely identified 161 non-cancerous lesions as gastric cancer, yielding a low positive predictive value of 30.6%[46]. Approximately half of these lesions were gastritis with an irregular mucosal surface or changes in color tone[46]. Finally, in a recent study, a non-invasive GB/decision tree (DT) model employing only nonendoscopic parameters was developed to diagnose gastric cancer[47].

Regarding the diagnosis of celiac disease, five different AI/ML-based models were developed in a study using clinical data as a base for non-invasively diagnosing celiac disease[48]. Interestingly, the models were tested using 13 different algorithms and different input variables variations, resulting in 270 different tested models[48]. Among them, a model based on the Bayesian classifier demonstrated the highest performance[48]. A different study developed an SVM that employed images from the endomysial autoantibody test for IgA-class antibodies to classify patients with celiac disease[49]. Finally, in a different study, the authors aimed to develop several AI/ML-based models, which employ clinical data, to predict celiac disease in a group of patients who remained undiagnosed[50]. The models were unsuccessful, with only two models slightly outperforming random chance in predicting celiac disease[50].

In the diagnosis of IBDs, a recent study developed five different AI/ML-based models using data from the gut microbiome to classify patients with IBD[51]. The Random Forest (RF) model demonstrated the highest performance with AUROCs of 0.80 when bacterial taxa were used and 0.82 when operational taxonomic features were used[51]. Finally, the models were tested in distinguishing between Chron's disease (CD) and ulcerative colitis (UC), with the RF model demonstrating an AUROC > 0.9[51]. A multicentered, genome-wide association study used data from single-nucleotide polymorphisms to develop several AI/ML-based models to classify patients with CD and UC[52]. For pediatric IBDs, an SVM-based model employed data from histologic and endoscopic images to classify pediatric patients with CD, UC, or unclassified IBD[53]. Other studies have employed images from wireless capsule endoscopy to build SVM models that identify patients with CD with reported accuracies between 80.2% and 100%[54-57].

Focusing on capsule endoscopy, in a recent study, magnetically controlled capsule endoscopy imaging was employed to develop a CNN that provides an automatic detection and classification system for gastric lesions[58]. These lesions included erosions, polyps, ulcers, submucosal tumors, normal mucosa, and xanthomas[58]. A different study used images generated by a wireless capsule to develop a CNN able to classify the small bowel motility among six distinct intestinal motility events[59]. In a recent study, an AI-assisted capsule endoscopy reading model was developed to assist lesion identification[60]. Notably, the model significantly shortened the reading time of images by trainees[60].

To distinguish between hemorrhagic and ulcerative lesions, a CNN was developed using images from small bowel capsule endoscopy[61]. In a similar, recent study, a DNN model used capsule endoscopy images to classify different small bowel lesions (erosions, ulcers, tumors, and vascular lesions)[62]. SVM-based models were developed in two other studies employing images from capsule endoscopy to identify peptic ulcers[63,64]. In three different studies, CNNs have been developed, employing images from capsule endoscopy to diagnose intestinal hookworms, GI angiectasia, and celiac disease[65-67]. Finally, a CNN was developed in a recent study to detect colorectal neoplasias in images from colon capsule endoscopy[68].

Regarding the identification of colorectal polyps in coloscopy, a CNN model was designed to analyze colonoscopy images and videos and identify colorectal polyps [69]. Interestingly, the model's sensitivity to identify flat isochromatic, less than 0.5 cm polyps, which are typically associated with a higher missing rate, was estimated at 91.65% per image[69]. A different study, employing short videos from colonoscopies,

developed a CNN model that identifies colorectal polyps[70]. In another study, a CNN was developed employing videos and images from coloscopy to detect colorectal polyps in real-time[71]. Interestingly, when experts reviewed the colonoscopy videos, they managed to identify additional non-removed polyps with the assistance of the CNN model[71]. In a recent study, an automated polyp detection model based on CNN was developed to identify and then classify colorectal polyps into adenomas, hyperplastic, sessile serrated adenomas, and cancer[72]. The model managed to process the images at a speed of 20 m per frame[72].

Specifically for colorectal polyps classification, in a prospective study, an SVM-based model was developed using NBI and methylene blue staining images to classify diminutive rectosigmoid adenomas in real-time[73]. A prospective pilot study developed an SVM model that employed NBI images to detect and classify colorectal polyps based on vascularization features as neoplastic and non-neoplastic[74]. In a comparative study, an SVM model demonstrated comparable performance at classifying the neoplastic nature of diminutive polyps (< 10 mm) to that of experts in NBI colonoscopy but surpassed the performance of non-experts[75]. Two other studies developed SVM models that employed NBI images to classify colorectal lesions (neoplastic or non-neoplastic)[76,77]. Finally, an SVM model was developed in a retrospective study to diagnose invasive colorectal cancer based on NBI endocytoscopy images[78].

Except for SVMs, several studies employed CNNs for colorectal polyps classification. One comparative study developed a CNN employing NBI colonoscopy images to classify neoplastic polyps[79]. Notably, the model's performance was found comparable to that of experts but superior to the performance of non-experts[79]. In another study focusing on NBI colonoscopy, a CNN model was developed to classify adenomatous from non-adenomatous polyps[80]. A different study developed a CNN model to classify adenomas from hyperplastic polyps during NBI colonoscopy[81].

The performances reported by the majority of the AI/ML-based models surpass both the NPV threshold recommended by the American Society of Gastrointestinal Endoscopy (90%) for adenoma detection and the estimated pooled NPV reported in a meta-analysis conducted by the society (91%)[82,83]. Finally, we should mention that currently, the majority of the CAD systems that we reported have the shortcoming of manual segmentations of lesions. The endoscopists should identify the areas of interest before the model could analyze and attempt to classify. This weakness has been acknowledged by the European Society of Gastrointestinal Endoscopy[84]. Other obstacles to developing CAD systems constitute the lack of large datasets and the lack of variability in images. A recent study aimed to resolve this by developing a CNN that "adds" polyps to the images to increase the repository of images for training and advance the development of automated polyp detection models[85].

Management

Table 3 summarizes the findings of the identified studies applying AI/ML models for the management of gastroenterological diseases. In a recent study, data from baseline impedance, nocturnal baseline impedance, and acid exposure time were used as a base for a DT model to predict the treatment response with proton pump inhibitors for patients with gastroesophageal reflux disease[86]. The aim was to establish a decision-making framework for treatment allocation[86].

AI/ML-based models have been used in the management of malignant GI lesions. Regarding gastric cancer, a CNN has been developed to predict whether the early gastric cancer has invaded the mucosa and submucosa layers of the stomach and act as a decision tool for endoscopic resection[87]. Interestingly, the CNN model outperformed endoscopists[87]. In the same concept, a DNN was developed to classify gastric cancer based on invasion depth as a basis for treatment allocation[88]. Specifically, the model demonstrated accuracy for predicting T1, T1a, T1b T2, T3, T4, and an overall accuracy of 77.2%, 68.9%, 63.6%, 49.1%, 51.0%, 55.3%, and 64.7%, respectively[88]. In colorectal cancer, the identification of microsatellite instability significantly impacts the treatment allocation process. A DL model was developed to identify microsatellite instability directly from hematoxylin and eosin-stained whole slide image[89]. Notably, the model outperformed a group of pathologists[89]. Finally, an SVM model that predicted the lymph node metastasis status of patients with colorectal cancer was designed as a tool to identify patients who would benefit from additional treatment following the endoscopic resection of T1 tumors[90]. Notably, the model outperformed the staging systems endorsed by current guidelines[90].

Regarding the management of GIB, in a recent study, an ML model was developed using data from patients admitted to the intensive care unit (ICU) following a GIB to predict the need for transfusion[91]. The authors suggested that it could potentially be

used as a decision-making tool to triage patients to the ICU or the ward[91]. A different study developed several AI/ML models for patients with acute GIB to predict four different outputs: The source of bleeding, the need for urgent blood transfusion, the need for urgent endoscopy, and the disposition[92]. The study aimed to establish a decision-making framework for the efficient management of GIB. The RF model outperformed all seven other models for all four outputs[92].

Focusing on the upper GIB, an ANN model was developed as a non-invasive triage tool for patients with upper GIB[93]. In the external cohort, the ANN performed similarly to the complete Rockall Score (includes endoscopic variables) in predicting stigmata of recent hemorrhage[93]. A different study developed a CART model regarding acute variceal hemorrhage to predict rebleeding and mortality and achieved the discrimination of three distinct prognostic groups of low, intermediate, and high risk[94]. Its performance was significantly superior to Child-Pugh and Model for End-Stage Disease (MELD) but comparable to a conventional logistic regression (LR) model [94].

Focusing on the lower GIB, two different ANN models were developed in a study aiming to predict severe acute lower GIB and the need for surgical intervention[95]. The first ANN significantly outperformed the Strate prediction rule for predicting severe bleeding (AUROCs: 0.98 *vs* 0.66)[95]. A different study employed nonendoscopic variables to develop a model based on a GB classifier to predict severe lower GIB, recurrent bleeding, and the need for clinical intervention[96]. On external validation, the model was found equally accurate to a conventional LR model for recurrent bleeding and the need for clinical intervention but superior in predicting severe lower GIB[96].

Prognosis

Table 4 summarizes the findings of the identified studies applying AI/ML models regarding the prognosis of gastroenterological diseases. Several SVM-based nomograms were developed in a study to predict distant metastasis for operated patients with oesophageal squamous cell carcinoma[97]. A different study employed clinicopathological data to develop an ANN model to predict the survival of patients with esophageal cancer operated with curative intends[98]. The model surpassed the Tumor–Node–Metastasis (TNM) model[98]. Regarding gastric cancer, a recent study developed five different AI/ML-based models to predict recurrence in operated patients[99]. Among the models, the RF demonstrated the best performance[99].

An ANN model was developed for patients with IBD, which used meteorological data to predict seasonal variations of onset and relapse in patients with CD and UC [100]. In the validation cohort, the model predicted the onset frequency and the frequency of relapse of the IBD with a mean absolute percentage error of 37.58% and 17.1%, respectively[100]. A study focusing on CD developed an ANN model to predict mucosal remission for patients treated with azathioprine 16 wk following treatment [101]. In a study focusing on UC, an ANN was developed employing clinical data to predict the patients with UC treated with cytoapheresis, who will eventually require operation[102].

Regarding the prognosis of GIB, a CART model was developed to predict in-hospital mortality of cirrhotic patients presenting with upper GIB[103]. In a multicentered study, an ANN model was developed employing pre-endoscopic variables to predict 30-d mortality in patients with non-variceal upper GIB[104]. Similarly, a prospective, multicentered study employed pre-endoscopic variables to develop an ANN model that predicts 30-d mortality in patients with non-variceal upper GIB[105]. The ANN significantly outperformed the Rockall scoring system (AUROCs: 0.95 *vs* 0.67)[105].

Regarding colorectal cancer, a recent study developed several ML models to predict the RAS and BRAF mutation status for patients with advanced colorectal cancer[106]. Notably, the ANN demonstrated the best performance[106]. In a different study employing clinicopathologic variables and data generated from immunochemistry, a least absolute shrinkage and selection operator regression model was developed to predict the lymph node metastasis status in a cohort of operated patients for T1 colorectal cancer[107].

Opportunities of AI application in gastroenterology

Therefore, the opportunities that arise from applying AI/ML-based software in gastroenterology include:

AI/ML models could be developed and integrated into the clinical setting to employ routinely collected data directly from the patient's electronic health records and flag patients at high risk of developing certain GI diseases in real-time. Current efforts include the prevention of gastric[27-29] and colorectal cancer[30,31]. Such ML models could become the basis for tailoring targeted screening programs.

Endoscopy is the gold standard for the diagnosis of a plethora of GI diseases. AI/ML models employing non-invasive parameters that provide reliably accurate diagnosis could substitute endoscopy or significantly minimize its use, thus ameliorating the impact of endoscopy-related complications, significantly decreasing

Table 4 Artificial intelligence applications in gastroenterology: Prognosis

Ref.	Parameters employed	AI classifier	Sizes of the training/validation sets	Outcomes	Performance
Yang *et al*[97]	Laboratory results, immunomarkers, clinicopathological parameters	SVM	319/164 patients	Distant metastasis of oesophageal squamous cell carcinoma following surgery	69.5-80.1[1,6], 44.7-67.2[3,6], 81.6-97.7[4,6]
Sato *et al*[98]	Laboratory results, clinicopathological parameters, tumor characteristics	ANN	395 patients (training:validation:test = 53:27:20)	1-year and 5-year survival of patients with esophageal cancer following surgery	0.883-0.884[2,7], 78.1-80.7[3,7], 84.7-86.5[4,7]
Zhou *et al*[99]	Laboratory results, clinicopathological parameters, tumor characteristics	Several	2012 patients (training:validation = 8:2)	Recurrence of gastric cancer following surgery	0.790-0.962[2,5], 0.771-0.795[2,6]

[7]External validation/testing. ANN: Artificial neural network; CART: Classification and regression tree; CD: Chron's disease; CRC: Colorectal cancer; CT: Computed tomography; GIB: Gastrointestinal bleeding; IBD: Inflammatory bowel disease; LASSO: Least absolute shrinkage and selection operator; SVM: Support vector machine; UC: Ulcerative colitis.

the cost for diagnosis, and providing an alternative to an unpleasant intervention for the patient. Current efforts include the diagnosis of gastroesophageal reflux disease [34], gastric cancer[47], celiac disease[48,50], and IBDs[51].

Expect from replacing endoscopy; AI/ML models could also improve its efficacy. CAD systems could facilitate navigating the GI tract and serve as the second "observer" for the endoscopist, an "observer" non-susceptible to distraction, which identifies lesions missed by the endoscopist. Particularly for capsule endoscopy, a CAD system that automatically detects and classifies lesions could significantly decrease the time required to evaluate the images by endoscopists while increasing diagnostic accuracy. Current efforts include the diagnosis of IBDs[53-57], gastric lesions[58], small bowel mobility disorders[59], small bowel lesions such as hemorrhagic and ulcerative lesions[60-64], intestinal hookworms[65], GI angiectasia[66], celiac disease[67], and colorectal cancer[68].

Physicians could use CADs to augment the accuracy of classifying polyps based on their neoplastic nature. As a result, the morbidity and mortality associated with failing to remove a neoplastic polyp could be lessened. At the same time, the complications related to removing a non-neoplastic polyp could be avoided. Therefore, CADs could significantly increase the cost-effectiveness of polyp management. Current efforts include the development of SVMs[73-76] and CNNs[79-81] for the classification of the neoplastic nature of colorectal polyps during NBI colonoscopy.

AI/ML models that accurately predict the response to different treatments could be used as a basis for individualized treatment allocation. Current efforts include the response of treatment with proton pump inhibitors for patients with gastroesophageal reflux disease[86], the mucosal remission for CD patients treated with azathioprine [101], and the need for operation for UC patients treated with cytoapheresis[102].

Particularly for GIB management, AI/ML models could be used to identify the source of bleeding[92] and as frameworks for decision-making, including the need to transfuse patients[92], perform emergent endoscopy[92,93] or emergent surgery[95, 96], and finally, triage patients with severe GIB to the ICU[95,96].

Finally, AI/ML models could be used as predictive tools that stratify the risk of complications and predict overall survival and recurrence following treatment. Such models could be used to tailor individualized follow-up schedules and for patient and family counseling. Current efforts include the prediction of overall survival for patients with esophageal cancer[98], the risk of recurrence of operated patients with gastric cancer[99], and 30-d mortality of patients with non-variceal GIB[104,105].

APPLICATIONS OF AI IN HEPATOLOGY

Prevention

Table 5 summarizes the findings of the identified studies applying AI/ML models for the prevention of disease in the field of hepatology. In a recent study, a prospective cohort of apparently healthy volunteers was enrolled in a study, which developed a DT-based model to classify patients based on their risk of developing non-alcoholic fatty liver disease (NAFLD) and liver fibrosis[108]. A similar study used routinely collected laboratory and clinical parameters to develop several AI/ML-based models to identify patients with NAFLD in the general population[109]. In a different study, several AI/ML models were developed as potential tools for targeted screening for NAFLD[110]. The Bayesian network model demonstrated the highest accuracy, followed by an SVM model[110]. Notably, an LR model outperformed all the models. These studies are examples of how AI/ML-based models could be used in primary care as tools for detecting chronic liver diseases. In a different study, multiple AI/ML models were developed as a basis for a non-invasive tool for assessing the level of fibrosis progression in NAFLD patients[111]. Notably, the RF model demonstrated the highest performance[111]. A different study managed to develop an ML model for patients at high risk of developing NAFLD to classify patients with non-alcoholic fatty liver (NAFL) and non-alcoholic steatohepatitis (NASH)[112]. Several AI/ML models were developed in a different study to classify healthy individuals from patients with NAFL and NASH[113]. Among them, a GB tree model demonstrated the highest performance, followed by an RF model[113]. In another study, four different AI/ML-based models were developed utilizing data from biochemical and enzyme-linked immunosorbent assays to classify patients with NAFLD and alcoholic liver disease with or without cirrhosis[114].

AI/ML models that utilize data directly from the electronic health records from patients infected with hepatitis B (HBV) and hepatitis C (HCV) could be used as the basis for targeted screening tools for liver carcinomas. A GB model was developed in a study using only serum markers aiming to predict fibrosis and classify the stage of fibrosis in two cohorts of patients with HBV and HCV[115]. An ANN model was developed in another study that employed only routine clinical data to predict significant fibrosis for patients with HBV[116]. In a similar study, an ANN model was developed by employing only routine laboratory data from HBV patients to identify patients with cirrhotic liver[117]. A different study developed an ANN model employing only non-invasive data to predict advanced liver fibrosis in HCV patients [118]. A similar study developed several AI/ML-based models to develop a non-invasive tool for identifying HCV patients with advanced fibrosis[119]. Among the developed models, a model based on alternating DTs demonstrated the highest performance[119]. These studies demonstrate how AI/ML models using routine clinical data could be used to identify patients who will benefit from a sustained

virological response (SVR) to delay chronic liver disease progression.

Regarding the development of HCC, a recent study investigated if a DNN could outperform conventional LR models in predicting HCC development in patients with HCV[120]. A different study using variables including demographic, laboratory results, and clinical findings, developed RF, DNN, and LR models to reliably predict

the stage of liver cirrhosis in patients infected with HCV[121]. Accurately predicting patients with HCV prone to develop HCC could help identify patients who would be benefited from a targeted screening and are in a greater need of antiviral treatment to achieve an SVR.

Diagnostics

Table 6 summarizes the findings of the identified studies applying AI/ML models for diagnosis in the field of hepatology. Regarding chronic liver disease, a study used CT imaging data of patients with a confirmed liver fibrosis diagnosis to develop a CNN model for the staging of liver fibrosis[122]. Notably, the model outperformed the radiologists' interpretation[122]. A different study employed ultrasound imaging of patients with fatty liver disease to develop an SVM model and an extreme learning machine model (a type of ANN) for diagnosis and risk stratification[123]. A different study that employed ultrasound shear wave elastography features developed an SVM model to identify patients with chronic liver disease[124]. Another study used images from real-time tissue elastography to develop four different AI/ML-based models to classify liver fibrosis[125]. Notably, the RF model outperformed the rest, followed by the KNN and the SVM models[125].

In a study, CT imaging was employed to develop an ANN model that differentiates between HCC, intrahepatic peripheral cholangiocarcinoma (CCA), hemangioma, and metastasis[126]. Interestingly, when radiologists evaluated the images, their performance significantly increased when they considered the ANN's output, from an AUROC of 0.888 to one of 0.934[126]. Focusing on HCC diagnosis, a recent retrospective study developed a CNN that employed MRI images of patients with HCC. The model was trained with a combination of images that met the Liver Imaging Reporting and Data System (typical) and with images that did not (atypical)[127]. In a multicenter, retrospective study, a CNN was developed that employed MRI scans to identify HCC lesions[128]. Notably, the model surpassed the performance of less experienced radiologists in the diagnosis of small HCC lesions[128]. The model was able to analyze 100 images in just 3.4 s[128]. Finally, a different study aimed to develop a non-invasive ANN model that predicts the presence of microscopic vascular invasion and the tumor grade of HCC[129].

Regarding diagnosis of CCA and pancreatic adenocarcinoma, a study developed an ANN model using data generated by metabolomic and proteomic analyses of bile from patients undergoing endoscopic retrograde cholangiopancreatography aiming to classify patients with and without cancer[130]. A different study used data from the plasma levels of bile acids to develop six different AI/ML-based models to classify patients as having CCA or a benign biliary disease[131]. Among the six developed models, a model based on the Naive Bayes classifier demonstrated the highest performance[131]. Finally, in another study, an ANN model was designed to analyze images from magnetic resonance cholangiopancreatography to diagnose CCA with a reported accuracy of 92.8%[132].

Management

Table 7 summarizes the findings of the identified studies applying AI/ML models to manage hepatic diseases. With the guidance of AI/ML-based software trained by data generated from gene mutation biomarkers, serum markers, imaging, and the clinical setting, high-quality, evidence-based, and individualized treatments could be employed regarding chemotherapy, radiotherapy, and immunotherapy. In HBV management, a recent study developed several AI/ML-based models that use soluble immune markers to predict early virological relapse after discontinuation of nucleoside analogs treatment[133]. The model could be used to exclude patients at high risk of virological relapse from treatment cessation. In HCV management, a study utilized data from full-length HCV genome sequencing of variants of HCV to develop multiple AI/ML-based models that classify HCV anti-viral resistance variants[134]. Notably, the SVM model demonstrated the highest performance[134].

In HCC management, a recent study used data from DNA methylation profiling to develop an RF-based model that predicts 6-mo progression-free survival. Such models could be used to personalize patient surveillance[135]. In an international, multi-institutional study, a CART model was developed that aimed to create a framework beyond the Barcelona-Clinic-Liver-Cancer (BCLC) staging system, which is currently endorsed by guidelines for treatment allocation[136,137]. The model defined six distinct prognostic groups of patients based on predictive factors of overall survival that could be used as a framework for treatment allocation[137]. Notably, the radiologic tumor burden score, which is not integrated into the BCLC staging system, was found as the best predictor of long-term outcome for BCLC stage B patients[137].

These findings could help us reevaluate HCC management into a multidisciplinary, individualized approach that goes beyond the BCLC criteria[138].

In the management of patients with CCA, in an international study, a CART model was developed with solely preoperative variables to identify patients who would be more likely to benefit from surgery[139]. The model managed to isolate four distinct prognostic groups of patients with similar patient outcomes[139]. The authors concluded that this model could be used to inform presurgical decisions-for example, the use of neoadjuvant therapy for patients with poor prognoses[139]. In a different study, the researchers developed a DNN model to establish an AI framework through which specific prognostic groups could be used to identify which patients were more likely to benefit from different treatment modalities such as neoadjuvant chemotherapy or transarterial chemoembolization[140]. The framework was found to be

significantly more accurate than the current guidelines of the American Joint Committee of Cancer[140]. Finally, a study developed an ANN to predict which patients with inoperable hilar CCA will develop early occlusion following a bilateral plastic stent placement[141].

Prognosis

Table 8 summarizes the findings of the identified studies applying AI/ML models regarding prognosis in the field of hepatology. An ANN model was developed in a study to identify patients with HBV cirrhosis at a high risk of developing esophageal varices[142]. In a different study, two different RF models were created using clinical data, the first to identify esophageal varices and the second to classify patients with esophageal varices that require treatment[143].

Regarding HCC, several studies have focused on developing AI/ML-based models that would reliably predict patient outcomes (survival and recurrence). A retrospective study compared the performance among an ANN, an LR model, and a DT to predict the 1-, 3-, and 5-year disease-free survival in patients with HCC following resection [144]. A similar study used a nationwide database to compare an ANN and an LR model in predicting the 5-year survival of patients with HCC following hepatic resection and concluded that the ANN model surpassed the performance of the LR model[145]. In a different study by the same department, an ANN model and an LR model were compared, but instead, the outcome was in-hospital mortality, and the ANN was found superior to the LR model[146]. Interestingly, the study reported that the surgeon volume was the best single predictor of in-hospital mortality[146]. Regarding predictors, a different study comparing ANN and LR models reported that the ANN model identified a greater number of significant predictors than the LR model, except for outperforming it in survival predictions[147]. In a prospective study that aimed to compare an ANN model's performance to the performance of traditional staging systems in predicting survival for patients with early HCC, the ANN model outperformed the Hepato-Pancreato-Biliary Association's, the TNM 6th, and the BCLC staging systems with higher reported AUROCs in all training, internal validation, and external validation cohorts[148]. In a recent study, a GB survival classifier-based

ALBI: Albumin-bilirubin; ANN: Artificial neural network; APO: Artificial plant optimization; CNN: Convolutional neural network; CTP: Child–Turcotte–Pugh; DT: Decision tree; GB: Gradient boosting; HBV: Hepatitis B; HCC: Hepatocellular carcinoma; PSSP: Patient-specific survival prediction; RF: Random forest; RFA: Radiofrequency ablation; SVM: Support vector machine; WSI: Whole-slide image.

model was developed to stratify the risk of an HCC-related death into three distinct categories[149]. Finally, in another recent study, an ANN identified albumin-bilirubin grade as the most important prognostic factor for the survival of patients with HCC treated with the combination of transarterial chemoembolization and sorafenib as initial treatment[150]. A systematic review aimed to compare the performance of AI/ML-based software and that of traditional linear prediction models in predicting survival for patients with HCC concluded that AI/ML models provided enhanced accuracy[151].

Except for survival, other studies have developed AI/ML models to predict the recurrence of HCC following therapeutical treatment. An interesting study employed several AI/ML methods, including Artificial Plant Optimization, SVM, and RF to predict HCC recurrence following radiofrequency ablation[152]. A recent study developed a CNN employing histopathologic images to predict recurrence in operated HCC patients[153]. A different study developed an SVM model to predict the recurrence in a group of patients who underwent radiofrequency ablation[154].

Regarding primary sclerosing cholangitis, a team of researchers derived and validated a risk estimate tool based on GB algorithms to predict the outcomes of the disease[155]. In a different study, an ML model was developed to predict survival curves for patients with primary sclerosing cholangitis following liver transplantation [156]. The P value of the χ^2 test of the distributional calibration was 1, indicating excellent calibration of the model[156].

Focusing on liver transplantation, a team developed an ANN model combined with genotyping for microsatellite mutations/deletion to predict HCC recurrence in a cohort of patients receiving a liver transplant[157]. Several other studies have focused on the survival of individual liver grafts following transplantation[158-160]. In a multi-centered study, the authors developed an ANN model to predict the 3-mo graft survival and loss[160]. Interestingly, their model outperformed all extensively validated scores, including the MELD, the donor risk index (DRI), the survival outcome following liver transplantation, and the balance of risk, with their performance significantly lower (AUROCs range: 0.42-0.67)[160]. In a different study, an RF model was developed to predict the 30-d failure graft. Notably, this model too outperformed MELD and DRI[158]. These findings could help reevaluate our thinking regarding the current models of recipient-donor matching.

Opportunities of AI application in hepatology

Therefore, the opportunities that arise from applying AI/ML-based software in hepatology include:

Regarding primary care, ML models could be integrated into the clinical setting and flag individuals in the general population at high risk of developing chronic liver disease in real-time by employing routinely collected data from the electronic health records. Current efforts include models that identify patients at high risk to develop NAFLD, NASH, fibrosis, and cirrhosis[108-114]. These models could be used to design targeted screening programs.

Particularly for patients with chronic HBV and HCV infection, AI/ML models could be used to stratify each individual's risk to progress through the several stages of cirrhosis and develop HCC. Multiple studies have been conducted in this regard for both HBV-related[115-117] and HCV-related[115,118-121] cirrhosis. Such models could be used to identify patients in greater need of SVR and tailor individualized follow-up schedules.

In diagnosis, AI/ML models provide the opportunity for increased diagnostic accuracy of various hepatic diseases and in multiple diagnostic modalities (such as

US/CT/MRI imaging and histologic images). Current efforts include CAD models for the diagnosis of chronic liver disease, HCC[127-129], and CCA[130-132].

AI/ML models that accurately and reliably predict the response to specific treatments could be used to tailor evidence-based frameworks for individualized treatment allocation. Current efforts include the development of frameworks for the management of HCC[136,137] and CCA[139,140].

Regarding prognosis, AI/ML models could be used to reliably predict complications, in-hospital mortality, overall survival, and recurrence following treatment. Current efforts include the prediction of in-hospital and HCC-related death[146,149], of overall survival of HCC patients following surgery[144,145,147,148], and HCC recurrence following surgery or RFA[152-154]. Such models could be used to tailor individualized follow-up schedules and for patient and family counseling.

Particularly for liver transplantation, AI/ML models could be used to predict graft failure or cancer recurrence for patients transplanted for cancer. Such models could be used to reevaluate and optimize our current practices regarding recipient-donor matching for graft allocation[157-160].

CURRENT CHALLENGES OF AI APPLICATIONS

Intrinsic bias and accuracy

The level of accuracy of AI systems is mostly dependent on the quality of the training dataset. Existing biases and prejudices in the training data set will inadvertently be built into the algorithms limiting the AI/ML-based software's accuracy[161]. Discrepancies in the data collection process, imperfections of standardization, and incorrectly labeled cases become part of the algorithms' training and are thus integrated into the end product. Two of the most common biases found in these models are: (1) Spectrum bias; and (2) Overfitting. Spectrum bias occurs when the patients (whose generated data were used during the training and internal validation of these models) do not constitute a representative sample of the target population[162]. On the other hand, overfitting refers to the tendency of models to be customized for the training data [162]. The performance of the model is thus exaggerated for the training dataset but is significantly inferior in new datasets[162]. CNNs, which are extensively used in gastroenterology and hepatology, are particularly vulnerable to overfitting[26]. Another substantial bias source is that physicians often misrecord data in the electronic health records, sometimes even the chief complaint[163]. These biases significantly impact the performance of AI/ML-based models and undermine their applications. A measure to alleviate the impact of biases is the standardization of data collection methods while establishing evaluation systems that scrutinize underlying biases and check data accuracy[15,164]. Another crucial step to tackle these biases is the external validation of models, in a clinical setting, from data generated from patients prospectively enrolled in the study[165]. Initial implementation of AI/ML-based models in the clinical setting should occur on a small scale, similar to phase I and phase II of the clinical trials[166]. Existing tools, such as the PROBAST tool, could be used during the development of AI/ML-based models to comprehensively assess the risk of bias[164,167]. The American Medical Association has recently acknowledged the need to identify and address bias in data when testing or deploying AI/ML-based software to avoid introducing or exacerbating health care disparities [168]. Therefore, the real challenge is to develop an AI/ML-based software that taps into the true potential hidden by the data without picking up the biases.

Several other limitations affect the performance of these models. An example is the limited resolution of capsule endoscopy images compared to other types of endoscopy [18]. A different limitation is the in silico nature of most of the currently developed models, which significantly impacts the expectations of similar performances in a real clinical setting. Another limitation of these algorithms is that they utilize a series of variables that in the real clinical setting are derived in a series of careful decisions made by physicians and are not readily available as a complete set of data. Therefore, these variables' presence or absence could become a significant shortcoming of these models in a real clinical setting, making them impractical to use. Finally, there is a lack of consistency in the metrics used to assess performance (sensitivity, specificity, AUROC, accuracy, *etc.*), limiting the ability to draw meaningful comparisons between the models[17].

Data protection and cybersecurity

Similarly, with all patient data, those utilized in AI/ML-based software should

conform with the seven principles described in Article 5 of the General Data Protection Regulation. Specifically, the personal data are required to: (1) Be processed fairly, lawfully, and transparently; (2) Be relevant, adequate, and limited to the intended purpose; (3) Be collected for explicit, specific, and lawful purposes; (4) Be accurate and up to date; (5) Permit identification for only as long as necessary; (6) Ensure appropriate security; and (7) Demonstrate compliance and accountability[169]. A particular challenge for AI is the resistance to the concept of utterly electronic tracking of healthcare records due to the belief that it exposes the vast amount of stored sensitive health record data to massive disclosures[170]. These concerns are not entirely unjustifiable if one considers examples such as the transfer of data from 1.6 million patient records from the Royal Free Nathional Health Service Foundation Trust to Google DeepMind, which was later ruled illegal[171]. Nevertheless, any effort or policy towards paper-based data due to data protection concerns could substantially undermine the application of AI modes in healthcare.

The healthcare industry is a particularly attractive target for cyberattacks as it contains sensitive personal data and financial information. Several physical and technical safeguards have been implemented under the Health Insurance Portability and Accountability Act to protect against the breach of sensitive patient data[172]. However, from the application of AI technology in the healthcare industry, new vulnerabilities and dangers emerge except traditional cybersecurity concerns. If ML models can learn from data, they could also be fooled by data. Data could be introduced malevolently in the algorithms to manipulate the developed AI/ML models into making wrong decisions with currently unknown ramifications to patient outcomes[173]. In a recent study, the authors demonstrated how attackers could use DL to add or remove lung cancer tumors in CT scans[174]. This study demonstrated how both a group of radiologists and a state-of-the-art deep AI model were particularly susceptible to the attack[174]. How could we, therefore, be confident that the AI/ML model has not been compromised? Evidently, healthcare facilities will have to develop additional information technology infrastructure to shield the healthcare system from these new threats.

Intellectual property

The Food and Drug Administration (FDA) recently acknowledged that it receives a high volume of submissions regarding AI/ML-based software marketing, with the list of already approved algorithms increasing rapidly[175,176]. A challenging point will be determining the law framework and regulatory standards that AI/ML-based software should follow. The key is classifying AI/ML software as "medical device", "service", or as "product", and achieving this requires a careful evaluation of the intentive use of AI/ML-based software. AI/ML-based software that aims to assist physicians in diagnosing, interpreting, and treatment decisions could be classified as medical devices and fall under the respective regulations[12]. In 2019, the FDA announced its aim to review AI/ML-based software regulation and has recently published the AI/ML– Based Software as a Medical Device Action Plan[175,177]. The action plan published by the FDA focuses on five pillars aimed to facilitate innovation and advance AI/ML-based software that are classified as medical devices. These include: (1) A tailored regulatory framework; (2) Good ML practice that could be achieved by consensus standards efforts; (3) A patient-centered approach incorporating transparency to users that takes into account usability, trust, equity, and accountability; (4) Regulatory science methods related to algorithm bias and robustness, and finally; and (5) Real-world performance[175]. When it comes to law and regulation, the real challenge is finding the golden snitch between too much regulation that strangles innovation and creation and too little regulation, which could have unexpected and devastating consequences for healthcare, and by extension, the well-being of patients.

Another interesting point regarding intellectual property and safety is the substantial divergence of the AI/ML-based software from the original product years after its approval and distribution[178]. What are the rights of developers on the product following its purchase? Since the original product constantly changes by learning from the clinical setting's data, the deviated model years after the purchase and the original software could be seen as two entirely different products. The first is protected under copyright law. However, the latter has now produced intellectual property on its own since it encompasses data generated by the healthcare facility [173]. Who could therefore claim legal rights over the final product? Also, who ensures the credibility and safety of the model as it deviates from the original product? Clearly, there is a need for lifecycle regulation of AI/ML-based software that ensures postapproval guardrails such as built-in audits[165]. Alternatively, time-limited authoriz-

ations could be employed to allow the FDA to perform periodic audits to review the accumulated modifications to the initial product[165].

Liability

Except for intellectual property, another legal challenge that arises from applying AI/ML-based software in the clinical setting is liability. A quite intriguing concept is that AI's findings and decisions could become legally binding in the future. As AI/ML-based models evolve and become more sophisticated, it is fair to assume that they will eventually surpass physicians, at least in specific tasks. How could then, the physicians justify ignoring the decision presented by AI? Especially when their decisions are made solemnly based on data and lack any sense of subjectivity. And who is liable when the followed decision made by the model causes injury? Currently, there is no legal precedent that assigns liability in a case where the injury was inflicted on a patient due to an erroneous output generated by AI/ML-based software[179].

To avoid malpractice liability, a physician is required to provide medical care at the same level as a competent physician of the same specialty while considering the available resources[180]. However, when an AI/ML-based software recommendation is involved, the concept of liability becomes more complicated. In an insightful recent legal analysis, the authors provide eight scenarios based on the combinations of whether the AI recommendation follows standard care and/or is accurate, the physician follows or rejects that recommendation, and whether a medical injury occurs [179]. The authors conclude that since current law shields physicians from liability when the standard care is followed, it also incentivizes physicians to minimize AI's actual usefulness, transforming AI into a confirmatory tool rather than a tool to augment the level of care[179]. Until a comprehensive legal framework regarding liability is developed, healthcare facilities would justifiably hesitate to adopt AI technologies due to the fear and unawareness of how they will expose the facility and its staff to liability[181].

Ethical challenges and transparency

AI could become the third participant in the physician-patient relationship and potentially undermine the trust between them. First, the idea that data are shared with third parties for AI model development could lead patients to withhold information from physicians and become less transparent[182]. Second, AI/ML-based models cannot act like compassionate human beings, which is an integral part of a physician's clinical life. Therefore, AI-driven decision-making neither encompasses an understanding of the patient's needs nor respects the patient's wishes nor demonstrates empathy, nor realizes when a patient feels discomfort or requires some rest or a hand to hold on to. Therefore, retaining the trust in the physician-patient relationship could be proven challenging in the AI era.

Another challenge is patient consent in AI applications. Clearly, it is practically impossible to acquire informed consent from each and every patient whose data are used during the development and validation of AI/ML-based software. In any case, we cannot predict how the algorithms would use specific data points during the training of the model and whether data of a specific patient have any significant impact on the model as a whole[183]. However, when AI/ML-based models are used in the clinical setting, especially for patient recording (in computer vision), patients should be adequately informed, and explicit consent should be acquired[184].

Achieving equilibrium between ensuring a high level of care and avoiding privacy encroachment could be challenging. For example, with computer vision advancement, monitoring could be used to detect any deviations from the optimal bedside practices such as patient mobilization and hand hygiene practices, which leaves patients vulnerable to identification[185,186]. Practices such as data minimization (collecting the least data needed) could address these challenges[185].

Changing the physicians' and patients' stance towards AI technologies could be proven a herculean task. Currently, around 2/3 of the population feels uncomfortable using their data to improve care quality and are unfavorable to AI/ML-based software performing tasks typically performed by physicians[183]. There are justifiable concerns that certain biases included in the training data due to racism, sexism, and socioeconomic inequality would be integrated into the AI/ML-based software. A notorious example is the COMPAS algorithm, which was found to falsely flag black people as likely to re-offend[187]. This was aggravated when developers made the argument that the algorithm was protected under intellectual property law and thus is not open to scrutiny[187]. These examples could erroneously undermine the trust towards AI altogether. A trustworthy AI/ML-based software should be built around the principles of transparency, credibility, auditability, reliability, and recoverability

[188].

The last but not least challenge in applying AI/ML-based software in healthcare is the lack of transparency, which is currently a major concern. The lack of transparency is demonstrated by the non-interpretability associated with these algorithms, described as a "black-box", where the inner logic is hidden[18]. This violates a fundamental tenet of medical ethics that physicians should comprehend at least the basic features of the devices they use and could undermine the trustworthiness of these technologies[189]. Thus, those who develop AI/ML-based models and physicians should collaborate to reach at least a degree of explainability on how AI/ML-based algorithms reach decisions. Attention maps and saliency region are examples of methods that could lessen the lack of interpretability of these models[190]. A slightly different and intriguing point of view is that withholding the widespread application of AI/ML-based software, due to their opacity, when their application could significantly benefit patients is, in fact, unethical[183]. With most of the population being prejudiced against AI, developing trust for these technologies would require several steps, including addressing bias, increasing transparency, communicating with the patients their role in provided care, protecting data privacy, and developing a robust regulatory framework.

CONCLUSION

Even though multiple efforts for AI's integration into healthcare have been made, they all originate from high-income countries[191]. Understandably, since all AI/ML-based software is data-driven, the opportunities to participate in the AI ecosystem for low- and middle-income countries, where the healthcare system does not generate extensive electronic, standardized data, are significantly limited. Not being included in the development of these models would introduce a significant spectrum bias, which could undermine these models' application in low- and middle-income countries. Thus, despite being described as the key to healthcare equity, AI could become another brick in the wall of inequality. A challenge for the future would be to include low- and middle-income countries in AI model development initiatives.

Even though these AI/ML-based software's central idea is that they could surpass physicians in performing certain tasks, the existing literature comparing AI/ML-based models and physicians' performance is limited[192]. A recent meta-analysis, which included multidisciplinary comparative studies, identified only 25 studies meeting their inclusion criteria from all medical specialties[193]. The authors concluded that currently, DL models' diagnostic performance in detecting diseases from medical imaging is equivalent to that of healthcare professionals[193]. Clearly, there is a contrast between the abundance of studies developing and validating ML algorithms and the lack of studies comparing these models' performance to physicians' performance at the investigated task. Thus, there is a crystalline need for further comparative studies in the clinical setting.

Another challenge for the future would be to combine AI with other emerging fields, such as 3D printing and bioprinting, augmented reality, novel biomarkers such as microRNAs, and robotics[194-198]. Envision a world where all these technologies and their applications are unified and integrated into everyday clinical practice. AI could be the means through which this new sophisticated, complex clinical setting is handled. The future AI clinician rejects oversimplifying an inherently complex field but instead embraces the complexity.

AI can outperform physicians in the ability to precisely quantify correlations even in domains where physicians possess in-depth knowledge[173]. However, AI models are simply tools like any other and should be treated as such. Tools with their accuracy, sensitivity, and specificity in performing certain tasks, tools that carry biases, and whose findings should be evaluated in conjunction with other clinical and paraclinical findings. Reliance on AI should not exclude non-quantifiable information from decision-making[183]. Clinical reasoning and critical thinking should not be subsumed by AI at the altar of technological advancement. AI's integration into healthcare should not replace the physicians' intelligence but rather augment it. Thus, we should aim for AI-assisted and not AI-driven clinical practice[14]. Finally, AI systems should be applied in healthcare along with equally advanced evaluation systems, which properly assess their ramifications within the clinical practice environment, investigate their unintended consequences, and, most notably, evaluate their impact on patient outcomes[163]. An example of an evaluative initiative is the Digital Health Innovation Action Plan launched by the FDA that aims to assess medical software under

development based on five excellence criteria: product quality, patient safety, clinical responsibility, cybersecurity responsibility, and proactive culture[199].

Despite being on the front line for several decades, AI still comes short of delivering the presumable solutions to long-standing healthcare problems. AI winters, where AI funding is significantly reduced, demonstrate the frustration that AI is not evolving at a pace investors would feel comfortable sustaining the funding[1]. AI may seem like a field that constantly overpromises but usually underdelivers, given its current impact on healthcare. In this review, we have highlighted the current challenges that we believe restrain the extensive application of AI in healthcare in an attempt to explore ways to overcome them.

Nevertheless, even at a slower pace, AI will eventually "infiltrate" not only the hospital setting but rather the healthcare industry as a whole, from central healthcare facilities to private practice and telemedicine, from medical schools and teaching hospitals to pharmaceutical companies, and even healthcare policy-makers in government. AI will become a reality; everyone will have to conform with, to avoid becoming obsolete. Therefore, sooner or later, physicians will have to engage with the field of AI by necessity. The role of physicians in this upcoming "revolution", however, remains to be seen. Will we be shaping this "revolution", or will we be mere observers?

Limitations

Finally, our review has few limitations. First, our study is a narrative review, and despite our best effort to follow a carefully designed search strategy to provide a comprehensive review of the current literature, our study is prone to selection bias due to its nature. Second, each study described in our study carries its own risk of bias and faces several limitations described in each study. We did not use any bias risk assessment tool to systematically evaluate if a study was worth inclusion rather than the followed search strategy and our judgment. Again this makes our review prone to selection bias. In addition, the majority of our included studies were performed in silico, and the performances reported could deviate substantially when the models are applied in a real clinical setting. Finally, with few exceptions, the majority of results report a superior or at least equivalent performance of AI/ML-based algorithms compared to the performance of conventional statistic models, widely used staging systems, extensively investigated and validated scores, and physician knowledge and reasoning, which have dominated decision-making in healthcare for decades. Thus, at least in the concept of publication bias, our findings should be interpreted with caution.

Abstract

A number of studies have revealed the association between *Helicobacter pylori* (*H. pylori*) infection and the gut microbiota. More than half of the investigations on the impact of *H. pylori* on the gut microbiota have been the sub-analyses of the influence of eradication therapy. It was observed that *H. pylori* eradication altered gut microbiota within a short period after eradication, and majority of the alterations took a long period of time to reverse back to the original. Changes in the gut microbiota within a short period after eradication may be attributed to antibiotics and proton pump inhibitors. Modification of gastric acidity in the stomach caused by a long-term *H. pylori* infection alters the gut microbiota. Analysis of the gut microbiota should be conducted in a large population, adjusting for considerable biases associated with the composition of the gut microbiota, such as age, sex, body mass index, diet and the virulence of *H. pylori*.

Key Words: *Helicobacter pylori*; Gut microbiota; Atrophic gastritis; Eradication; Proton pump inhibitor

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: *Helicobacter pylori* (*H. pylori*) eradication alters gut microbiota within a short period after eradication; this is attributed to antibiotics and proton pump inhibitors. However, most of these alterations reverse back to baseline levels over a long period of time. Modification of acidity in the stomach with mucosal atrophy caused by *H. pylori* infection alters the gut microbiota. As the human gut microbiome is diverse among individuals, a large population size is needed to study. Adjustment of biases associated with the composition of the gut microbiota is also crucial for accurate evaluation of the association between *H. pylori* infection and the gut microbiota.

INTRODUCTION

In recent years, a number of studies related to gut microbiota have been published, shedding light on the association between gut microbiota and human health. The human microbiota consists of as many as 10-100 trillion symbiotic microbial cells harbored in the intestinal tract of every person[1]. The gut microbiota plays a pivotal role of in the metabolic, physiological, and immunological systems of the human body [2], and its structure is closely associated with an individual's health and past illnesses [3].

Accordingly, research on the association between *Helicobacter pylori* (*H. pylori*) infection and the microbiota has also increased[4]. Most of the studies, including our previous studies that revealed the influence of *H. pylori* infection on the gut microbiota, have focused on the gastric microbiota, while only a few studies have investigated the gut microbiota harbored in the intestinal tract of patients with *H. pylori* infection[5,6]. Subsequently, some published studies have revealed new findings and have improved our understanding of this phenomenon. Therefore, the current review aims to summarize the recent evidence on the influence of *H. pylori* infection on the gut microbiota, while focusing on the gut microbiota in the intestinal tract, and to discuss the mechanisms underlying the *H. pylori* mediated alterations in the gut microbiota.

H. PYLORI AND GUT MICROBIOTA

More than half of the investigations on the impact of *H. pylori* on the gut microbiota have been the sub-analyses of the influence of eradication therapy on the gut microbiota[7-11] (Table 1). Two earlier studies were based on in situ hybridization and bacterial culturing using fecal samples. A study showed that the gut microbiota of *H. pylori*-positive patients was characterized by an increase in the growth of acid-tolerant *Lactobacillus acidophilus*[7]. Another study found that the total amount of *Anaerobes* and *Clostridia* present in *H. pylori*-positive patients was significantly lower as compared to that of *H. pylori*-negative subjects[8]. Subsequent studies were based on the analysis of the fecal 16S rRNA. The analysis of the fecal 16S rRNA from 70 *H. pylori*-positive subjects and 35 *H. pylori*-negative subjects showed a decrease in the abundance of *Clostridia* as well as total anaerobes in the fecal samples of *H. pylori*-positive individuals[9]. In a study on young adults, the microbial diversity of the gut microbiota was higher in patients infected with *H. pylori* than in healthy controls. Moreover, at the phylum level, the relative abundance of *Proteobacteria* significantly increased in patients infected with *H. pylori*[10]. In contrast, only the study by Martín-Núñez *et al*[11] revealed that in comparison with uninfected individuals, the alpha diversity of gut microbiota was significantly lower in patients infected with *H. pylori*. In these studies, the composition of the gut microbiota between subjects infected and uninfected was not the primary endpoint. Moreover, the number of subjects taken into consideration was relatively small. As the diversity of the human gut microbiome varies among individuals, a large population size is needed.

A few studies have been conducted to investigate the influence of *H. pylori* infection on the gut microbiota[5,6,12,13]. Our large population study performed using 16S rRNA amplification from fecal samples revealed that *Lactobacillus* in the human gut microbiota may be influenced by *H. pylori* infection[5]. In a small-sample study, Dash *et al*[12] showed that the gut microbiota of *H. pylori*-infected individuals were enriched with members of *Succinivibrio*, *Coriobacteriaceae*, *Enterococcaceae*, and *Rikenellaceae* families. Furthermore, several studies have suggested that the composition of the human gut microbiota changes with age, body mass index (BMI), and sex[14-16]. Therefore, we excluded the influence of these factors using the propensity score matching, which has not been considered in previous studies. We compared 214 *H. pylori*-positive subjects and 214 matched *H. pylori*-negative subjects from a large population study and found a higher gut microbial diversity and a different gut microbiota composition in subjects with *H. pylori*[6]. Furthermore, at the genus level,

Table 1 Studies for the influence of *Helicobacter pylori* infection on gut microbiota

Ref.	Study groups *H. pylori* (+) *vs* (-)	Aim	Main findings for *H. pylori* positive subject

Helicobacter pylori: *H. pylori*.

the abundance of *Actinomyces*, *Gemella*, *Streptococcus*, and *Haemophilus* was significantly higher in the gut microbiota of *H. pylori*-infected subjects. Another recent study conducted by Frost *et al*[13] assessed the microbiota composition of 212 *H. pylori*-positive subjects and 212 matched negative controls. Similar to our study, all control samples were matched with respect to age, sex, BMI, alcohol consumption, smoking, proton pump inhibitor (PPI) usage, history of peptic ulcer disease, and dietary habits. This study demonstrated that *H. pylori* infection was associated with alterations in fecal microbiota and an overall increase in fecal microbial diversity. A later study on the long-term effects of *H. pylori* eradication demonstrated that the structure of the gut microbiota is more closely associated with subject-specific parameters, such as age or BMI, than with the eradication therapy itself[17]. Therefore, adjusting for biases associated with the composition of the gut microbiota is crucial for accurate evaluation of its composition. Diet is a key modifiable factor affecting the composition of the gut microbiota[18]. However, only one study has addressed this parameter[13].

THE INFLUENCE OF *H. PYLORI* ERADICATION ON GUT MICROBIOTA

A number of published studies have investigated the changes in the gut microbiota after *H. pylori* eradication. A recent systematic review of 24 articles examining the effect of *H. pylori* eradication on the gut microbiota revealed that most studies identified a significant decrease in the alpha diversity of the gut microbiota within a short period after eradication but no further alterations were observed for over 6 mo after *H. pylori* eradication[19]. Additionally, the abundance of *Proteobacteria* increased during a short-term follow-up whereas that of *Lactobacillus* decreased; *Enterobacteriaceae* and *Enterococcus* increased during the short-term and interim follow-up. Moreover, a more recent study evaluating the long-term effects of *H. pylori* eradication found out that the composition of the gut microbiota was restored to baseline status over the 2 years after eradication, and the relative abundances of the microbial species at the genus level before and after eradication did not differ significantly[17]. However, modest differences in the taxonomic composition were observed before and after eradication. The findings of this study where diversity of the microbiota tends to decrease in the short period after eradication and returns to baseline thereafter, it was consistent with the findings of most studies[9,10,20-26]. However, the taxonomic composition before and after eradication varied among the studies[21,22]. Some studies demonstrated that the relative abundance of all genera was restored to baseline

levels. Other studies revealed notable changes at the genus level[10,24-26]. Thus, it may be assumed that after the microbial diversity returns to baseline, the levels of each strain might demonstrate minor variations following the eradication of *H. pylori*.

THE MECHANISMS UNDERLYING *H. PYLORI* INFECTION INDUCED GUT MICROBIOTA

Although the mechanisms underlying *H. pylori* infection associated alterations in gut microbiota are still unknown, some studies have suggested possible contributing factors; these included host immune responses, virulence factors, physical contact and modification of gastric acidity[4,27]. A previous study performed using a transgenic *Drosophila* model revealed that the virulence factor, cytotoxin-associated gene A (CagA), of *H. pylori* may contribute to gut microbiota dysbiosis[28]. CagA, which is translocated into host epithelial cells after bacterial attachment, impairs cell polarity and affects host signaling pathways, thereby promoting inflammation[29]. Vacuolating cytotoxin A (VacA) is also an important virulence factor of *H. pylori*. VacA is a secreted toxin that lead to damages of gastric epithelial cells, and promotes cell death[30]. CagA and VacA counter-regulate each other to manipulate host cell responses[31]. CagA and VacA can alter the gastric microbiota and immune phenotypes previously attributed to *H. pylori* infection in the stomach[28]. Therefore, CagA and VacA have been associated with important requirements for long-term sequelae in humans. As such, ongoing crosstalk between *H. pylori* and gastric commensal microbiota may affect the host immune response. The altered host immune response may also modulate the gut microbiota[9,32]. A previous review suggested the possibility of a direct interaction of *H. pylori,* which migrates from the stomach towards the intestinal tract, with the local gut microbiota[4]. However, this hypothesis is yet to be proven. In fact, in our previous study, the presence of *H. pylori* in the intestinal tract was found to be rare even in subjects with *H. pylori* infection[6]. Therefore, the influence of *H. pylori* in the intestine on gut microbiota seems to be limited.

Modification of gastric acidity as a result of *H. pylori* infection is one of the variable effects on altered gut microbiota. PPIs, which decrease gastric acidity, affect the gut microbiota[33,34]. Reduced gastric acid promotes the passage of acid-sensitive bacteria and changes the intestinal environment[35]. Similar to the interference with the action of PPIs, *H. pylori* can regulate gastric luminal acidity. *H. pylori* infection is generally acquired during childhood and persists for life unless eradicated by treatment. In the initial stages of *H. pylori* infection, acute gastritis temporarily leads to impaired gastric acid secretion[36]. In later stages, a significant decrease in gastric acid secretion is observed in individuals who develop severe atrophic gastritis[36,37]. Previous studies investigating the gut microbiota following PPI administration detected an increase in the *Lactobacillus* population in the gut microbiota[33,34]. We evaluated *Lactobacillus* according to the degree of gastric atrophy in subjects with and without *H. pylori* infection[5]. The relative abundance of *Lactobacillus* in the human gut microbiota significantly increased after the development of severe atrophic gastritis. In another study, after adjusting for biases, we demonstrated that among *H. pylori*-infected subjects, a significant increase in the abundance of the genus *Streptococcus* was observed in subjects with severe atrophic gastritis[6]. These results support the hypothesis that severe atrophic gastritis reduces gastric acid secretion and affects the composition of the gut microbiota, similar to the results of PPI administration. Most previous studies examining the association between *H. pylori* infection and gut microbiota have not considered the influence of gastric mucosal atrophy. However, atrophic gastritis may be an important mechanism associated with the changes in the gut microbiota induced by *H. pylori* infection.

In previous studies, although *H. pylori* eradication was observed to alter gut microbiota within a short period, most of the changes induced tended to return to baseline levels over a long periods after eradication therapy[9,10,20-26]. The changes in the gut microbiota within a short period after eradication may be attributed to antibiotics and PPIs that were administered for *H. pylori* eradication. This finding was represented by a study that demonstrated a decrease in gut microbial diversity within a short period after eradication therapy in both patients with and without successful eradication[38]. The changes in the diversity within a short period after eradication may be attributed to the eradication therapy itself. Hence, the influence of eradication therapy on the gut microbiota would diminish over a long period of time. After eradication, the influence of host immune responses towards *H. pylori,* virulence factors, and physical contact with *H. pylori* could decrease or disappear. In contrast, the

modification of gastric acidity depends on the degree of mucosal atrophy. Hence, after *H. pylori* eradication, gastric acid secretion gradually improves in patients without gastric mucosal atrophy[39]. However, this improvement is not observed in patients with severe atrophic gastritis[40]. Further studies demonstrating minor changes in the gut microbiota over a long period need to be conducted using a large number of subjects with severe atrophic gastritis. Especially after *H. pylori* eradication, mechanisms other than gastric acid modification would not have a significant impact on the gut microbiota.

CONCLUSION

Although all the studies demonstrated a compositional change in the gut microbiota of *H. pylori*-infected patients, the results of these studies were not consistent with each other. This incompatibility may be attributed to several factors. Although remarkable variations are observed in the gut microbiota among individuals, the sample size considered in these studies was relatively small, and subjects were included regardless of biases associated with the composition of the gut microbiota, such as, age, gender, BMI and diet. Therefore, an analysis of gut microbiota in a large population should be conducted while adjusting to considerable biases. Particularly, it is necessary to evaluate of the degree of atrophic gastritis, which is associated with gastric acid production, when investigating the influence of *H. pylori* infection on the gut microbiota. Additionally, the virulence of *H. pylori* differs depending on the status of CagA. The prevalence of CagA-positive *H. pylori* infection varies, and the prevalence of the most virulent strain, eliciting the East Asian-type CagA phenotype, is dependent on geographical area[41]. Therefore, the investigation of the influence of *H. pylori* infection on the gut microbiota may yield different results depending on the area in which the study is conducted. Future studies should consider these points and predict the mechanisms underlying *H. pylori* infection induced changes in the gut microbiota.

Abstract

Inflammatory bowel disease (IBD) is a chronic condition that significantly affects the quality of life of its patients. Biologic drugs have been the mainstay treatment in the management of IBD patients but despite their significant contribution, there remains a proportion of patients that do not respond or lose response to treatment. Therapeutic drug monitoring (TDM) involves measuring levels of serum drug concentrations and anti-drug antibodies. TDM of biologic drugs initially emerged to understand treatment failure in other immune mediated inflammatory diseases. This was then introduced in IBD to rationalize primary non-response or secondary loss of response, given that low serum drug concentrations or the formation of anti-drug antibodies are variably associated with treatment failure. The aim of this narrative review is to provide an overview regarding the current use of TDM in clinical practice and to present the evidence available regarding its use in both proactive and reactive clinical settings in preventing and managing treatment failure. This review also presents the existing evidence regarding the association of various clinical outcomes with specific thresholds of drug concentrations, in everyday practice. A narrative review of published articles and conference abstracts regarding the use of TDM in IBD management, through an electronic search using PubMed and ScienceDirect. TDM has proven to be superior and more cost effective in guiding management of

patients with treatment failure compared to empiric dose escalation or change in treatment. Despite a trend towards an association between clinical outcomes and drug concentrations, proactive TDM based strategies have not been shown to achieve clear benefit in long-term outcomes. In the clinical setting, TDM has proven to be useful in managing IBD patients, and its use in the reactive setting, as an additional tool to help manage patients with treatment failure, is being promoted as newer guidelines and consensus groups implement TDM as part of the management plan.

Key Words: Therapeutic drug monitoring; Inflammatory bowel disease; Biologic therapies; Loss of response; Reactive; Proactive

Core Tip: In this review, we discuss the existing studies that looked at both proactive and reactive therapeutic drug monitoring (TDM) and concluded that in current practice, reactive TDM has been shown to be useful. When used as an adjunct to clinical assessment and biomarkers in patients with treatment failure, TDM has proven to be a valuable tool for subsequent management.

INTRODUCTION

The management of patients with inflammatory bowel disease (IBD) has changed dramatically over the past decade, more so since the use of biologic agents[1]. Biologics such as anti-tumor necrosis factor (anti-TNF) agents have revolutionized the treatment of patients with IBD during this time in addition to newer classes of biologic agents, such as selective adhesion molecule and interleukin 12 and 23 inhibitors that are also being used. Furthermore, with advances in the treatment of IBD, goals of therapy have also changed as specialists worldwide have adopted the 'treat to target' approach in the management of IBD[2]. Despite these advances, treatment failure still occurs in a significant proportion of IBD patients[3], prompting a need in dose intensification or discontinuation of therapy with a change to another class of drug[4,5]. In the past, treatment failure in IBD, defined as either a primary non-response (PNR) or secondary loss of response (sLOR) to a drug, has been difficult to explain and predict. But as a result of a better understanding of the pharmacodynamics (PD) and pharmacokinetics (PK) of biologic drugs, the idea of therapeutic drug monitoring (TDM) emerged as an important tool. It plays a role in not only identifying the mechanism of loss of response but also in guiding clinicians in their treatment approach[6,7].

TDM is defined as the measurement of serum drug and/or anti-drug antibody (ADA) concentrations. ADAs refer to antibodies that are formed in response to the immune system's recognition of biologic drugs. In several studies, ADAs have been found to be associated with treatment failure because of an up-regulated clearance of the drug[8,9]. Another mechanism of treatment failure relates to a non-immune mediated clearance, resulting in sub-therapeutic levels of the drug.

Over the years, TDM was initially used in the reactive setting for patients, when there was a suspected loss of response to a biologic drug, mainly the anti-TNF agents. Based on the serum drug levels and/or presence of ADAs, the management was changed with the aim of optimizing their current treatment, thus avoiding unnecessary dose intensification or targeted switching between anti-TNF agents or out of class. However, preliminary results from recently published data have shown that TDM used in the proactive setting, by preemptively targeting specific thresholds of serum drug levels, may in fact result in more favorable clinical outcomes[10-17]. Despite growing evidence supporting the use TDM in IBD, there still exist limitations

of its use, such as when to use it and how best to apply it. This is evident in the fact that routine use of TDM in the management of IBD patients is not recommended in guidelines, but rather made as suggestions by organizations when faced with a patient with suspected treatment failure[18-22].

This review article summarizes the latest evidence with regards to the use of TDM in both the reactive and proactive settings in addition to its limitations and how it is currently being used in clinical practice.

BACKGROUND OF TDM

The idea of TDM involves measuring the serum concentration of a drug, to maintain an adequate dose that would ensure drug efficacy and to avoid drug toxicity[23]. Use of TDM in clinical practice has existed for many years, even before the development of biologics. In the past, TDM was used for a variety of medications, such as antibiotics and immunosuppressants. More recently, it has been applied to biologics mainly to monitor drug efficacy and to guide management in suspected treatment failure for IBD patients on biologics. In IBD, TDM involves the measurement serum drug levels, in addition to the measurement of ADAs, both of which are related to drug efficacy[8,9]. Although many studies have proved its utility, many issues exist such as timing of TDM, identification of target thresholds for serum drug levels and ADAs, and the practical application of the results. Data looking into this shows that there is considerable variability in target thresholds because of multiple factors that come to play, such as the different methods and assays used in TDM measurements, or the desired clinical outcome.

Lastly, given that the first class of biologics were anti-TNF agents, the use of TDM was first applied for patients who were treated with either infliximab or adalimumab, thus most studies looking into TDM revolved around anti-TNFs. With time, as newer classes of biologics emerged for their use in IBD, more studies were done regarding the application of TDM with vedolizumab or ustekinumab.

OVERVIEW OF TECHNICAL ASPECTS OF TDM

In TDM, the measurement of serum drug levels involves measuring the trough level (TL), meaning the lowest concentration of the drug just before the next dose. With the TL, the goal is to maintain a level sufficient enough for the drug to reach its maximal efficacy[24], and this is where the issue of target thresholds comes to play[25]. Before discussing the clinical relevance of these targets, it is important to know the technical aspects of TL and ADA measurements.

Assays used for TDM

Current tests for TL and ADA concentrations include various commercially available assays such as enzyme-linked immunoassay (ELISA), radioimmunoassay, high pressure liquid chromatography based homogeneous mobility assay, with ELISA being the most commonly used[26,27]. Drug assays use the drug as a calibrator while ADA assays use a monoclonal ADA as a calibrator, with titers often expressed as milligrams *per* liter. Several studies comparing various drug assays showed good correlation, however since assay methodologies and sensitivities differ, it is best to use the same assay when applying TDM[28]. Additionally, it is important to note that in the case of ELISA assays, the presence of the drug in the serum interferes with the detection of ADAs, thus not adequately quantifying ADA concentrations[29,30]. Various modified ELISA methods have been constructed to circumvent this problem, *e.g.*, by improved puffer technologies, labeled 'drug resistant' assays for ADA detection.

Additionally, other factors that may influence results include human factors such as appropriate collection, handling, and storage. Newer studies looking into improving TDM have suggested the idea of point of care (POC) testing in the near future, where TDM measurements are made available on spot, without the need for a laboratory-based testing method[30].

MECHANISMS OF TREATMENT FAILURE IN IBD

To better comprehend the application of TDM in IBD, it is essential to understand the idea of drug PD and PK, as they are significant in understanding the mechanism of treatment failure[24]. Various factors affect a patient's response to treatment, including low or sub-therapeutic drug levels related to increased clearance, whether it is immune or non-immune mediated in addition to the underlying pathway targeted by the drug.

PNR vs sLOR

Biologic agents, namely anti-TNF drugs, have significantly advanced the management of IBD patients. However, despite this, up to 30% of IBD patients fail to show an initial response after the induction period, also known as PNR, and up to 50% showing sLOR during the maintenance phase, especially during the first year 3-5]. Those with sLOR are patients who had initially responded after the induction phase, but then started to develop symptoms of disease activity, suggestive of treatment failure. Pharmacokinetic mechanisms underlining PNR and sLOR are thought to be due to inadequate serum drug concentrations as evidence has shown that those with low serum drug concentrations during induction or maintenance are less likely to achieve clinical response[31,32].

One study that signified this is the personalized anti-TNF therapy in Crohn's disease (CD) study (PANTS), which was a prospective observational study carried out in the United Kingdom that included 955 patients with active luminal CD[33]. Results of the study revealed that anti-TNF failure is highly dependent on low drug concentration and that this was associated with immunogenicity and the development of ADAs, especially during induction[33]. This finding mimics other studies that also revealed that higher drug concentrations early on is associated with a reduced risk of PNR and in preventing sLOR[34,35].

Clinical relevance of ADAs

One important aspect of treatment failure in IBD revolves around the idea of immunogenicity, which is an important downside of biologics. Immunogenicity deals with the fact that the immune system recognizes protein aspects of the drug as foreign and forms antibodies in response. These antibodies then form complexes with the drug, resulting in increased drug clearance and lower concentrations of the drug, rendering it ineffective[30]. However, it is important to note that not all antibodies work in the same way. In fact, two types of antibodies exist, neutralizing (NAb) *vs* non-neutralizing antibodies (non-NAb). Although they both bind to the drug, each render it ineffective in a different way[36]. NAb inhibits the pharmacological function of the drug, thus preventing target binding, whereas non-NAb promotes increased clearance of the drug[37]. This is relevant to the understanding of TDM since there is evidence pointing to a correlation between ADA formation and low serum drug levels[38-40].

One study that evaluated the clinical significance of ADAs was by Baert *et al*[32] that looked at a cohort of 125 CD patients receiving episodic infusions of infliximab. Results of this study revealed an association between the development of antibodies against infliximab response to treatment, as low trough infliximab level and high ADA level was found in 83% (10/12) with complete loss of response to infliximab. This finding reflects results of other studies that have also shown that ADA association was independently associated with LOR. There was also a large proportion of patients (61%) that had detectable ADAs and that there was an inverse relationship between ADA titers and duration of response ($P < 0.0001$)[32]. Moreover, they also noted that the median duration of clinical response was longer in patients with low ADA concentrations compared to those with higher ADA concentrations (71 d *vs* 35 d; $P < 0.001$). Similar conclusions were drawn in a study by Reinhold *et al*[41], where 16/104 (14%) patients had positive ADA titers and 15 of them had sub-therapeutic TLs, reflecting the increased drug clearance effect of ADAs[41].

As explained, ADAs play a significant role in treatment failure of IBD patients on biologics as antibodies neutralize the effect of the biologic agent, but the evidence linking ADA to LOR is not straightforward. This was demonstrated in a prospective study by Gonczi *et al*[42] that followed 112 IBD patients who were on therapy with adalimumab. Results of this study revealed that ADA positivity was significantly associated with LOR ($P = 0.007$), but the association between low TL and ADA positivity was not statistically significant ($P = 0.054$). They concluded that despite the development of ADA, low TL was not associated with LOR and that mainly ADA development should be considered a predictor for treatment failure[42]. This reiterates

the significance of NAb in that they inhibit the pharmacological function of the drug resulting in clinical non-response. As opposed to non-NAb, which affect drug efficacy by increased drug clearance thus resulting in low drug levels. For this reason, interpretation of ADA and TL when dealing with LOR should be made with caution.

Another clinically relevant aspect involves patients who develop infusion reactions. These are often found in those with persistently low drug concentrations and a significant concentration of ADAs[32,43], and this was demonstrated in the same study by Reinhold *et al*[41]. In this retrospective study that followed 104 IBD patients treated with infliximab or adalimumab, the authors delineated a positive correlation between the presence of ADAs and the development of infusions reactions as 44% (7/13) of patients with infusion reactions had positive ADA titers[41].

In conclusion, it has become clear that different ADAs exist and that not all types of antibodies affect drug clearance. Available data suggests that the presence of ADAs has a potential negative impact on clinical outcomes. Additionally, the relationship between ADA and treatment failure is not clear cut and that the impact of ADAs, may be more relevant to certain biologics than others[44-46].

ASSOCIATION OF SERUM DRUG CONCENTRATIONS WITH CLINICAL OUTCOMES

Numerous studies have demonstrated an association between drug levels and favorable outcomes[33,47-50]. Additionally, recent data has shown that higher serum drug concentrations during induction especially, is strongly associated with positive outcomes[34]. However, it is important to note that serum drug concentrations of different biologics vary as a result of many factors, such as patient demographics (age and body size), degree of underlying inflammation, and severity of disease[51]. As a result, there exists a large variation in target thresholds of TLs for each biologic drug. Current thresholds for serum drug concentrations are determined from observational studies and post HOC analyses, by looking at a variety of drug concentrations that have been found to be associated with specific outcomes; these can be seen in Table 1 [48,52-56].

In a retrospective multi-center study carried out by Juncadella *et al*[47], 98 IBD patients on therapy with adalimumab, underwent TDM and were followed to determine factors associated with outcomes such as biochemical, endoscopic, and histological remission. Results revealed that higher drug concentration during maintenance associated with good clinical outcomes and drug concentration > 12 μg/mL were associated with endoscopic (P = 0.003) and histological remission (P = 0.012) in CD[47]. Similar results were found in another retrospective study by Ungar *et al*[57], where serum drug levels of both infliximab and adalimumab were significantly higher in patients with mucosal healing compared to those with active disease on endoscopy (P = 0.002 for infliximab and P = 0.01 for adalimumab)[57].

Moreover, results of the PANTS study, showed that the only factor independently associated with PNR was a low infliximab (IFX) concentration at week 14 and that drug concentrations values associated with remission at weeks 14 and 54 were > 7 μg/mL for infliximab and > 12 μg/mL for adalimumab[33].

In terms of disease severity, for CD patients with peri-anal fistula, current evidence supports the idea of targeting higher serum drug concentrations in those patients compared to those without fistulizing disease[56,58,59]. A study by Davidov *et al*[56], showed a positive association between infliximab TLs during induction and closure of perianal fistula in CD patients, further suggesting that those patients may benefit from a drug level guided treatment.

Interestingly, despite evidence that shows a positive association of higher serum drug levels with clinical outcomes, preliminary results from the SERENE CD and SERENE ulcerative colitis (UC) trials did not show an added benefit. In both trials, patients with CD and UC, were randomized to either induction by standard dosing (SIR) of adalimumab or by an intensified dosing regimen (HIR). Results of both trials revealed that there was no added benefit from those who underwent an intensified regimen even though that subset of patients had higher serum drug concentrations[60,61]. Additionally, in terms of primary endpoints, the rates of clinical and endoscopic remission were similar among both groups.

Table 1 Association between various thresholds for serum drug concentrations and clinical outcomes

Drug	Serum drug level	Clinical outcome
Infliximab (IFX)		
IFX	< 2 μg/mL for CD/UC at week 14	Increased incidence of IFX antibodies[52]
IFX	> 2.1 μg/mL at week 14 in UC	Associated with mucosal healing[53]
IFX	≥ 3 μg/mL during maintenance	Clinical remission[48]
IFX	> 3 μg/mL at week 14 or 22 in CD	Sustained response[54]
IFX	3-7 μg/mL during maintenance	Remission[16]
IFX	≥ 7 μg/mL during maintenance	Mucosal healing[48]
IFX	< 7 μg/mL at week 14 in luminal CD	Absence of primary response[53]
IFX	> 9.2 μg/mL at induction week 2 in CD	Fistula response at weeks 14 and 30[56]
IFX	≥ 10 μg/mL at induction week 6	Clinical response[48]
IFX	> 15 μg/mL at week 6 in UC	Associated with mucosal healing[53]
IFX	≥ 20 μg/mL at induction week 2	Clinical response[48]
IFX	≥ 22 μg/mL at week 6 in UC	Clinical response at week 8[55]
IFX	≥ 25 μg/mL at induction week 2	Mucosal healing[48]
Adalimumab (Ada.)		
Ada.	≥ 3 μg/mL during maintenance	Clinical response[48]
Ada.	≥ 5 μg/mL post induction (week 14)	Clinical response[48]
Ada.	≥ 7 μg/mL post induction (week 14)	Mucosal healing[48]
Ada.	≥ 8 μg/mL during maintenance	Mucosal healing[48]
Ada.	< 12 μg/mL at week 14 in luminal CD	Absence of primary response[53]
Ustekinumab (UST)		
UST	≥ 1 μg/mL during maintenance	Clinical response[48]
UST	≥ 3.5 μg/mL post induction (week 8)	Clinical response[48]
UST	≥ 4.5 μg/mL during maintenance	Mucosal healing[48]
Vedolizumab (VDZ)		
VDZ	≥ 12 μg/mL during maintenance	Clinical response[48]
VDZ	≥ 14 μg/mL during maintenance	Mucosal healing[48]
VDZ	≥ 15 μg/mL post induction (week 14)	Clinical response[48]
VDZ	≥ 17 μg/mL post induction (week 14)	Mucosal healing[48]
VDZ	≥ 24 μg/mL at induction (week 6)	Clinical response[48]
VDZ	≥ 28 μg/mL at induction (week 2)	Clinical response[48]

Many studies that looked at exposure response relationship studies of anti-tumor necrosis factor drugs have demonstrated that specific drug concentration thresholds are associated with certain clinical outcomes, such as clinical response, improvement in biochemical markers, endoscopic remission, and mucosal healing.

MANAGEMENT OF TREATMENT FAILURE IN IBD USING A TDM BASED STRATEGY-REACTIVE TDM

Prior to TDM, the standard of care for suspected treatment failure, after exclusion of secondary causes such as infections and non-compliance, was either by empiric dose escalation, change to an alternative anti-TNF, or change to a different class of biologic.

The empiric approach of managing loss of response is considered frequently suboptimal and may lead to additional costs. The TDM-based strategy, by applying measurements of anti-TNF drug levels and anti-drug antibodies at the time of treatment failure offers an alternative. With time, more studies looking into benefits of

TDM emerged. These studies highlighted that TDM may be a useful adjunct to optimize the treatment of IBD patients, more cost effective than the standard of practice of empiric changes in management and can be useful in identifying patients who may be supra-therapeutic and instead, may benefit from dose reduction[6,62-64].

A multi-center study carried out by Guidi *et al*[65], was one of the first prospective studies carried out in a clinical practice setting that compared the management of sLOR by a TDM based algorithm to empiric dose escalations for IBD patients on infliximab. Results of their study demonstrated that the group of patients who underwent TDM based management of LOR resulted in lower rates of dose escalations with similar rates of clinical response, in addition to the fact that the TDM approach was more cost-effective[65]. Another study that reflected similar results was a randomized controlled study (RCT) carried out by Steenholdt *et al*[66], which recruited 69 Danish patients with CD on treatment with infliximab, who had developed sLOR. Patients were randomized to either routine infliximab dose or TDM based interventions. Rates of clinical response, measured by CD activity index were the same in both groups, 53% *vs* 58% ($P = 0.81$) respectively, however the costs *per* patients was 34% lower in TDM based group ($P < 0.001$)[66].

An important study that supported the use of reactive monitoring was by Afif *et al*[67], which looked at measurements of serum drug and ADA levels of 155 IBD patients who were on treatment with infliximab. Results of this study highlighted the importance of TDM in the management of partial or loss of response, as it provided insight into who might benefit from a change in drug or dose escalation. In this study, it can be seen that in ADA positive patients, the decision to change to another anti-TNF resulted in a complete or partial response in 92% of patients compared to 17% for those who underwent dose escalation. Additionally, with regards to drug levels, those who underwent dose escalation because of sub-therapeutic drug levels had a higher rate of complete or partial response compared to those who changed to an alternate drug[67]. Similarly, Yanai *et al*[6] demonstrated the utility of TDM in managing loss of response, as results from their study showed that patients with high ADA levels had longer duration to response when there was a drug change compared to dose escalation ($P = 0.03$) and that dose escalation was found to be more effective for those with low or undetectable ADA levels[6].

Additionally, in a study carried out by Kelly *et al*[63], which followed primary responders on infliximab who initially presented with clinical disease activity, authors revealed that those who underwent TDM based escalation had significantly higher clinical response ($P < 0.01$) and lower rates of hospitalization (22% TDM *vs* 35% non-TDM, $P = 0.025$) compared to the non-TDM based group[63].

A study by Ungar and colleagues that looked at infliximab levels during induction, brought to light an important finding that may help better manage patients with acute severe UC. Results of their study indicated that at day 14, those with acute severe UC had lower serum drug levels compared to patients with moderately severe UC. This is significant as it suggests that patients with acute severe UC may benefit from an intensified regimen as drug efficacy may have been affected by the high degree of inflammation[68].

In terms of cost-effectiveness, Steenholdt *et al*[66] was able to demonstrate that an individualized approach using reactive TDM was in fact more effective[66]. Results of this multi-center RCT showed that the costs for the intention to treat patients were substantially lower in the TDM based group compared to various infliximab dosing regimens (€ 6038 *vs* € 9178, $P < 0.001$). Similar results were also replicated in a study by Velayos *et al*[62], again demonstrating that dose adjustments made based on a TDM based algorithmic approach is more cost effective than empiric dose escalation[62].

The key recommendations at sLOR regarding the clinical scenarios of different combinations of TL and ADA level results at TDM are consistent based on the above studies. The suggested therapeutic algorithm for the optimal management of anti-TNF treatment failure based on TDM results is summarized in Figure 1[69].

As mentioned earlier, TDM can be approached in one of two ways, either in the reactive or proactive setting. Although much debate exists around the many issues surrounding the use of TDM, in current practice, it is mainly used in the reactive setting. Prior to TDM, standard of practice for the management of treatment failure in IBD is through empiric dose escalation. But with growing evidence highlighting the utility of reactive TDM in guiding subsequent management and that it may in fact be more cost effective, more specialists are using it in their practice[62,66].

As a result of numerous exposure-response relationships linking target TLs to therapeutic outcomes, the idea of proactive approach emerged in the hopes of targeting a specific threshold to avoid PNR or sLOR.

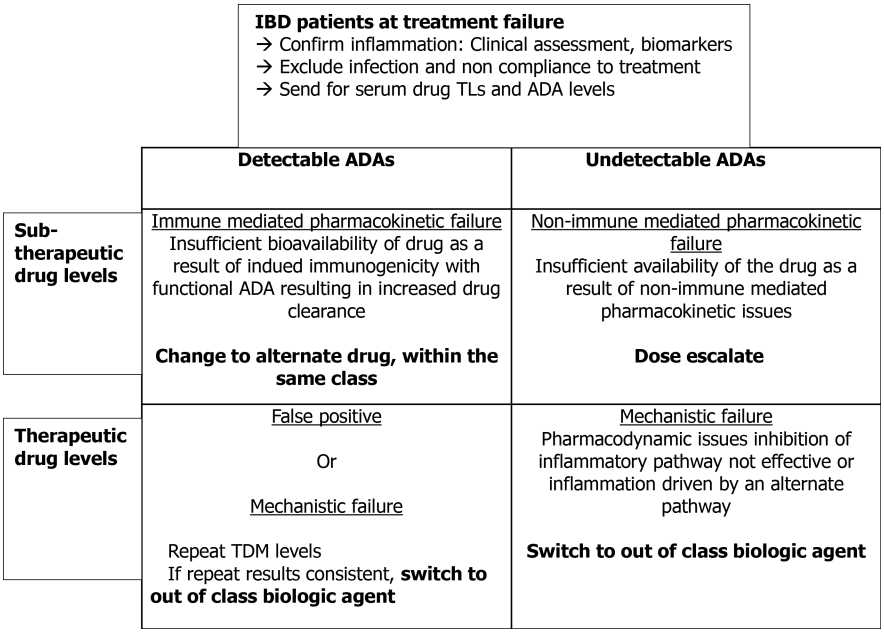

Figure 1 Therapeutic drug monitoring based approach to treatment failure. IBD: Inflammatory bowel disease; ADA: Anti-drug antibody.

PROACTIVE TDM

The idea of using a proactive approach stemmed from preliminary data revealing that targeting a specific drug concentration at various intervals is associated with better clinical outcomes, compared to empiric dose escalation and TDM done in the reactive setting[13,16,47-50]. A pivotal trial that demonstrated the potential benefits of proactive TDM is the landmark TAXIT trial (Trough Level Adapted Infliximab Treatment). This was a single center RCT of 263 IBD patients on infliximab, whose progress was followed to compare clinical benefit and cost effectiveness of concentration *vs* clinical based approach. As a result of the design study, the primary end point, of clinical and biochemical remission after 1 year, was not met. However, important findings included lower rates of undetectable drug levels and disease relapse in the proactive group[16].

More recently, Fernandes *et al*[15] carried out a prospective study of 205 IBD patients with results strongly supporting the proactive approach. Patients were randomized to two groups, those who were treated with IFX without TDM (data collected retrospectively) and those who underwent proactive TDM. In terms of outcomes, they looked at mucosal healing, need for hospitalization, and surgery. Results demonstrated that there were higher rates of treatment escalation in the TDM group ($P < 0.001$) with less need for surgery in addition to higher rates of mucosal healing ($P < 0.0001$), concluding that the proactive approach significantly decreased odds of reaching any unfavorable outcomes[15].

In a multi-center, retrospective cohort study of 102 IBD patients on infliximab, Papamichael and colleagues compared outcomes associated between those who underwent reactive *vs* proactive drug monitoring. The study demonstrated that those who underwent proactive testing after initial reactive testing was associated with greater drug persistence in addition to fewer IBD related hospitalizations (HR 0.18, CI 0.05-0.99; $P = 0.007$)[10].

Another multi-center study carried out by Papamichael *et al*[11], involving IBD patients on adalimumab also showed promising results with regards to the proactive approach as results also demonstrated that those who underwent proactive TDM had a reduced risk of treatment failure compared to the standard of care[11].

A recent study that strongly supports the proactive approach is the PAILOT study (Pediatric CD Adalimumab-Level based Optimization Treatment) by Assa *et al*[14]. This was a RCT of 78 children with CD who were on treatment with adalimumab and their primary end point was sustained steroid free remission. Authors of the study reached their primary endpoint with 82% in the proactive *vs* 48% in the reactive ($P = 0.002$) in addition to lower biochemical markers in the proactive group ($P = 0.003$)[14]. This study is considered a step forward supporting proactive TDM as this was the first proactive RCT whose primary endpoint was reached.

The TAILORIX trial (Tailored Treatment with Infliximab for Active CD) by D'Haens *et al*[12], was another important proactive trial carried out with the aim of promoting the treat to trough approach. This trial followed 122 biologic naïve patients with active CD who received induction with infliximab and were randomized to three different groups of maintenance infliximab. The three various groups comprised of various dose intensifications based on clinical assessment, biomarkers and/or serum infliximab levels with the primary outcome being sustained corticosteroid free clinical remission at one year. In the end, this trial failed to show the benefit of the proactive approach as results demonstrated that increasing infliximab dose based on combination of symptoms, biomarkers, and drug concentrations does not lead to increased rates of steroid free remission (P = 0.50) compared to dose escalation based on symptoms alone[12]. Interestingly, it is worth noting that less than 50% of patients in each group failed to reach the primary endpoint of corticosteroid free remission in addition to the fact that dose optimization was only carried out at week 14.

Interestingly, new evidence looking at proactive TDM was revealed through several studies including both the SERENE-CD and SERENE-UC trials. In the post induction phase of both trials, authors followed patients into the maintenance phase following induction with high dose *vs* standard dose adalimumab in the treatment of patients with moderate to severe CD and UC[60,70]. In the maintenance phase of SERENE-CD study, clinical responders from the induction phase were recruited and the authors explored outcomes after 44 wk on adalimumab using a clinical based assessment with the use of biomarkers or through proactive TDM with specified target thresholds. Preliminary results presented at United European Gastroenterology conference (UEG) showed that in terms of efficacy endpoints, the rates were the same in both arms and that the addition of TDM as a criteria showed no added benefit as the rates of clinical response, steroid free clinical remission, and endoscopic remission were similar[70]. A study by Bossuyt *et al*[71], presented at UEG 2020, showed similar results in terms of clinical endpoints, by comparing outcomes of two groups, ultra-proactive TDM *vs* reactive TDM. In this study, at the end of one year, there was no difference noted between both groups in terms of composite endpoints of: IBD related hospitalizations, IBD related surgeries, and change of treatment[71].

On the other hand, the SERENE-UC trial looked at outcomes of patients who were randomized to either a high dose or standard dose adalimumab maintenance regimen. Colombel *et al*[60], concluded that there was a higher number of patients who achieved clinical remission at week 52 in the high dose group, compared to the standard dose group. However, despite the clear numerical difference, it was not statistically significant. Here, the hypothesis was that with an intensified regimen, there would be higher drug bioavailability, which could result in positive outcomes. This theory was based on a previous trial that an intensive regimen in patients with severe UC resulted in lower rates of patients requiring colectomy[72]. Although drug levels were higher in the intensified regimen in both trials, the rates of clinical endpoints were the same.

Although more studies are demonstrating results in favor of proactive TDM, the range of studies remain limited in that the majority are retrospective in nature. Additionally, even with the current use of TDM, used by IBD specialists in the reactive setting, multiple factors are considered in the subsequent management of treatment failure, and not simply by a treat to trough concentration approach.

TDM IN CLINICAL PRACTICE

Despite the issues surrounding the application of TDM involving how and when it should be used, it has proven to be a valuable tool. The current use of TDM as one of many tools of clinical assessment has helped in advancing the care of these patients. As such, the use of TDM has been recommended in certain guidelines and by consensus groups as an adjunct to manage patients with suspected treatment failure. Furthermore, because of the lack of evidence from proactive trials to support the idea of improved clinical outcomes associated with this approach, many support the use of TDM in the reactive setting. For further information, refer to Table 2 for a list of the main TDM based trials including both reactive and proactive[6,10-12,14-16,66,67,70,71,73-77].

As evident, the debate over when to apply TDM is still ongoing because of limited prospective large trial studies. For this reason, TDM has not been fully incorporated into guidelines but rather hinted at as suggestions to help guide treatment in those with suspected treatment failure. One example is the guideline by the American

Table 2 A list of the main trials looking at both reactive and proactive therapeutic drug monitoring

Ref.	Study design; *n*	Population studied	Type of intervention	Primary outcome	Results
Vande Casteele *et al*[16], 2015 (Proactive)	Prospective single center study RCT, *n* = 263	Adults with mod to severe UC responders to infliximab (IFX)	IFX. Target 3-7 μg/mL during maintenance phase. Clinical *vs* concentration-based dose escalation	Clinical and biochemical remission	Fewer flares in concentration-based group. No difference in remission rates at 1 yr
Papamichael *et al*[73], 2017 (Proactive)	Retrospective multi-center RCT, *n* = 264	Adults with CD + UC	IFX 5-10 μg/mL	Treatment failureNeed for IBD related hospitalization or surgery. Adverse events	Proactive was associated with better clinical outcomes, including greater drug durability, less need for IBD-related surgery or hospitalization
Perinbasekar *et al*[74], 2017 (Proactive)	Retrospective single center study, *n* = 127	Adult IBD patients initiating treatment with either IFX or adalimumab (Ada)	IFX target ≥ 3 μg/mL; Ada target ≥ 5 μg/mL	Clinical response at 1 yr. Endoscopic response. Persistence with anti-TNF at 1 yr	Persistence with therapy and clinical and endoscopic response were superior for proactive compared to control patients treated with infliximab
Bernardo *et al* [75], 2017 (Proactive)	Retrospective single center study, *n* = 117	Adult IBD patients on treatment with infliximab	Clinical based *vs* proactive TDM. (1) Target IFX CD 3-7 μg/mL; (2) Target IFX UC 5-10 μg/mL; (3) Target Ada CD 5-7 μg/mL; and (4) Target Ada UC 7-9 μg/mL	At 48 wk (1) Clinical remission; (2) Rates of hospitalizations; (3) Rates of surgery; and (4) Therapeutic failure	No difference noted in relation to outcomes. Higher rates of drug escalation in proactive group. Longer period of remission in proactive group
D'Haens *et al* [12], 2018 (Proactive)	Prospective multi-center RCT, *n* = 122	Adults with mod to severe luminal CD biologic naïve on infliximab maintenance	Dose escalation using combined approach of clinical + TDM *vs* symptom-based approach. IFX target > 3 μg/mL during maintenance phase	Sustained steroid-free clinical remission at weeks 22-54 and mucosal healing at week 54	No difference in terms of rates of steroid-free remission
Papamichael *et al*[10], 2018 (Proactive *vs* reactive)	Retrospective multicenter study, *n* = 102	Adult IBD patients on infliximab	Reactive TDM followed by subsequent proactive TDM *vs* reactive testing IFX target 5-10 μg/mL	Treatment failure. IBD related hospitalization and surgery	Proactive monitoring after reactive testing associated with greater drug persistence and fever IBD related hospitalizations
Papamichael *et al*[11], 2019 (Proactive)	Retrospective multicenter study, *n* = 382	IBD patients on maintenance therapy with adalimumab	Proactive *vs* reactive TDM. Ada > 10 μg/mL	Treatment failure	Proactive associated with lower risk of treatment failure
Assa *et al*[14], 2019 (Proactive)	Prospective multi-center RCT, *n* = 78	Ages 6-17 yr with CD with response to adalimumab	Ada target trough levels ≥ 5 μg/mL	Sustained steroid-free clinical remission (weeks 8-72)	Higher rates of steroid free clinical remission in proactive group
Strik *et al*[76], 2019 (Proactive)	Retrospective multi-center RCT, *n* = 80	UC + CD in clinical remission on infliximab maintenance therapy	Dashboard driven dose escalation with TDM *vs* non TDM. IFX level > 3 μg/mL	Clinical remission	Dashboard-guided dosing resulted in a significant higher proportion of patients who maintained clinical remission during 1 yr of treatment
Danese *et al* [70], 2020 (Proactive)	Prospective multi-center RCT, *n* = 184	Clinical responders from induction phase of SERENE-CD	Clinical based group *vs* proactive TDM (TL 5-10 μg/mL) adalimumab every week or every other week	Clinical remission and endoscopic response and remission at 1 yr	No difference in terms of clinical end points
Fernandes *et al* [15], 2020 (Proactive)	Prospective study, *n* = 205	IBD patients completing infliximab induction therapy	Prospective arm (TDM-based dose escalation) *vs* retrospective arm (non-TDM). IFX levels 3-7 μg/mL CD; IFX levels 5-10 μg/mL UC	Need for surgery, hospital admission, treatment endrates of mucosal healing at 2 yr of treatment	Proactive TDM associated with fewer surgeries and higher rates of mucosal healing
Bossuyt *et al* [71], 2020 (Proactive *vs* reactive)	Prospective multi-center RCT	All IBD patients on infliximab therapy > week 14	Using point of care testing at the time of infusion > proactive *vs* reactive TDM	Clinical remissionDiscontinuation of infliximab. Composite end points of IBD related hospitalizations and surgeries, change of treatment	No difference in terms of rate of clinical remission or treatment discontinuationUltra-proactive not superior to reactive
Afif *et al*[67], 2010 (Reactive)	Retrospective study, *n* =155	IBD patients who had infliximab	Measurements of human anti-chimeric antibodies	Loss of response. Change in treatment	Measurement of both antibody and drug levels lead to

			(HACAs) and infliximab concentrations		improved response
Steenholdt *et al* [66], 2014 (Reactive)	Prospective RCT, *n* = 69	CD patients failing on infliximab therapy	Infliximab intensification *vs* algorithm defined using TDM	Clinical and economic outcomes at week 20	Lower healthcare costs in algorithm-based group. Similar rates of clinical response and remission
Kelly *et al*[63], 2017 (Reactive)	Retrospective study, *n* = 312	Primary responders on infliximab who underwent dose escalation	TDM *vs* clinical based dose escalation of infliximab	Endoscopic remissionClinical response	Higher rates of endoscopic remission with TDM
Pouillon *et al* [77], 2018 (Reactive)	Retrospective single center study, *n* = 226	IBD patients who completed maintenance phase of TAXIT	Clinical based *vs* trough concentration-based dosing of infliximab, infliximab level 3-7 μg/mL	IBD related hospitalization and surgery. Steroid use. Mucosal healing	Similar rates of mucosal healing in both groups. Higher rates of treatment discontinuation in clinic-based group

TDM: Therapeutic drug monitoring; TNF: Tumor necrosis factor; IBD: Inflammatory bowel disease; RCT: Randomized controlled study; IFX: Infliximab; Ada: Adalimumab.

Gastroenterological Association, in which the use of TDM is suggested for patients with active IBD on anti-TNFs but not recommended for those with quiescent IBD[18]. Table 3 lists the various recommendations and statements made by various gastroenterology guidelines and consensus groups[18-22].

PRACTICAL ASPECTS-HOW BEST TO APPLY TDM

Although much evidence exists supporting the use of TDM in the proactive setting, it has become clear that current evidence has not supported its use as routine practice in the management of IBD patients. Instead of dividing TDM into two separate entities, TDM should be considered as a useful tool in the management of IBD patients. As clinicians, we treat patients as a whole, in the sense that we treat their conditions by looking at various aspects including their clinical assessment in addition to biomarkers. Therefore, TDM should be considered as another adjunct that will help guide management as opposed to looking at it as the sole means of ensuring clinical response and remission.

Given the fact that various thresholds for serum drug levels and ADAs exist, it can be difficult to choose which one to target, especially since another variable that complicates this is the type of assay used for these measurements. However, despite the wide range, in current practice, certain thresholds have been followed to ensure clinical response in IBD patients who are on biologic agents. An example of these thresholds to target during maintenance therapy can be seen clearly in Table 4[16,41,78,79] The values listed in the table have been determined by a panel of IBD specialists that have carefully looked at existing literature relating to TDM[79]. Interestingly, the cut-off values listed by this group differs from the suggestions put forth in the AGA 2017 guideline[18]. It is important to note that these cut-off values are not absolute and should always be made in context with the clinical picture and that higher values might be needed for more rigorous clinical outcomes[48]. In the end, optimal TLs are difficult to define because of the multiple factors discussed above and because of the limited data from observational studies and post HOC analyses, thus it is important to be aware that the idea of 'one size' fits all may not be appropriate.

LIMITATIONS OF TDM

In research, RCTs are considered the gold standard in providing evidence for causal relationships and to support changes to clinical practice, and this seems to be lacking with regards to TDM. Thus, the majority of data available regarding TDM has been based mainly on prospective and retrospective observational studies or post HOC analyses. In addition to the timing of TDM and how often it should be carried out, other issues around TDM have to do with how to best interpret the results given the difficulty in obtaining results in a timely manner and being able to implement changes immediately[79]. Also, the bulk of evidence supporting TDM revolves mainly around

Table 3 Recommendations and statements made by various gastroenterology guidelines and consensus groups

Guideline/Consensus group	Recommendation
AGA[18,19]	Active IBD with anti-TNF → suggest use of reactive TDM
	Quiescent IBD with anti-TNF → not recommended
Inflammatory bowel disease Sydney/Australian Inflammatory bowel disease consensus working group (2017)[20]	Use of TDM preferred in (1) Upon suspected treatment failure; (2) Following successful induction; and (3) When completed drug holiday
	For those in clinical remission, consider TDM periodically only if it will change management
British guidelines (2019)[21]	Good practice recommendation → ALL IBD patients should be reviewed 2-4 wk post loading dose to assess response and check drug levels and anti-drug antibodies
	Use of serum drug trough & anti-drug antibody concentrations to be incorporated when deciding in change of therapy (dose escalation *vs* switch to other anti-TNF drug or out of class change)
ECCO (2020)[22]	CD in remission on anti-TNF → insufficient evidence to recommend FOR or AGAINST TDM
	CD patients who have lost response → insufficient evidence

AGA: American Gastroenterology Association; ECCO: European Colitis & Crohn's Organization; TDM: Therapeutic drug monitoring; TNF: Tumor necrosis factor; IBD: Inflammatory bowel disease.

Table 4 Therapeutic drug monitoring thresholds used in current practice (Using enzyme-linked immunoassay)

Drug	Cut-off for serum drug concentration	Cut-off for detectable ADA
Infliximab	> 3 μg/mL	Present if > 10 μg/mL
Adalimumab	> 5 μg/mL	Present if > 10 μg/mL
Certolizumab	> 15 μg/mL	-
Ustekinumab	Insufficient evidence to make a suggestion	-
Vedolizumab	Insufficient evidence to make a suggestion	-

ADA: Anti-drug antibody.

anti-TNF and less so with the other biologics such as vedolizumab and ustekinumab [80-82]. These newer biologics are now being used more in IBD thus it is imperative that well designed studies are done looking into outcomes associated with TDM based approach using these drugs.

Nonetheless, results from recent trials are promising and provide hope that more guidance may come soon. One example of such trials, is the PRECISION trial by Strik *et al*[76], which was the first prospective trial that demonstrated clinical benefit of a more personalized approach involving a dashboard system that incorporates patient features and TDM[76]. The ultra-proactive trial put forth by Bossuyt *et al*[71] is another example, making it one of the first studies to involve the use of POC testing, suggesting that this technology may be feasible to facilitate future research and the application of TDM. Lastly, the NOR-DRUM study also brings hope as this will be the first large sized RCT looking at the safety and effectiveness of TDM in patients receiving anti-TNF for a range of immune-mediated diseases, including IBD[83].

CONCLUSION

In the end, despite its issues, TDM has evolved the management of IBD patients and is being used more in clinical practice in the hopes of preventing loss of response and to ensure maximal use of biologic drugs. Even though more studies are showing results that support proactive TDM usage, many of them have methodological issues, making their data less reliable to be able to implement changes in clinical practice. Hence making it difficult to prove that proactive TDM is associated with better therapeutic outcomes. At present, TDM has been shown to be a useful tool in managing patients

suspected of loss of response and although it has not been fully implemented in guidelines, its usefulness in current practice brings hope that this might soon change.

Abstract

BACKGROUND

Shigella flexneri (*S. flexneri*) is a major pathogen causing acute intestinal infection, but the systematic oxidative damage incurred during the course of infection has not been investigated.

AIM

To investigate the incurred systemic RNA oxidative damage and the diagnostic value of RNA oxidative metabolites during *S. flexneri*-induced intestinal infection.

METHODS

In this study, a Sprague-Dawley rat model of acute intestinal infection was established by oral gavage with *S. flexneri* strains. The changes in white blood cells (WBCs) and cytokine levels in blood and the inflammatory response in the colon were investigated. We also detected the RNA and DNA oxidation in urine and tissues.

RESULTS

Institutional animal care and use committee statement: This study was approved by the Ethical Committee of the Institute of Medical Biotechnology, Chinese Academy of Medical Sciences (approval number: IMB-201803140206).

Conflict-of-interest statement: The authors declare no conflicts of interest in association with the present study.

Data sharing statement: No additional data are available.

ARRIVE guidelines statement: The authors have read the ARRIVE guidelines, and the manuscript was prepared and revised according to the ARRIVE guidelines.

Open-Access: This article is an open-access article that was selected by an in-house editor and fully peer-reviewed by external reviewers. S. flexneri infection induced an increase in WBCs, C-reactive protein, interleukin (IL)-6, IL-10, IL-1β, IL-4, IL-17a, IL-10, and tumor necrosis factor α (TNF-α) in blood. Of note, a significant increase in urinary 8-oxo-7,8-dihydroguanosine (8-oxo-Gsn), an important marker of total RNA oxidation, was detected after intestinal infection (P = 0.03). The urinary 8-oxo-Gsn level returned to the baseline level after recovery from infection. In addition, the results of a correlation analysis showed that urinary 8-oxo-Gsn was positively correlated with the WBC count and the cytokines IL-6, TNF-α, IL-10, IL-1β, and IL-17α. Further detection of the oxidation in different tissues showed that *S. flexneri* infection induced RNA oxidative damage in the colon, ileum, liver, spleen, and brain.

CONCLUSION

Acute infection induced by *S. flexneri* causes increased RNA oxidative damage in various tissues (liver, spleen, and brain) and an increase of 8-oxo-Gsn, a urinary metabolite. Urinary 8-oxo-Gsn may be useful as a biomarker for evaluating the severity and prognosis of infection.

Key Words: 8-oxo-7,8-dihydroguanosine; *Shigella flexneri*; Infection; Oxidative damage

Core Tip: *Shigella flexneri* (*S. flexneri*) is a major pathogen causing acute intestinal infection, but the systematic oxidative damage incurred during the course of infection has not been investigated. By establishing a Sprague-Dawley rat model with *S. flexneri* infection in the intestine, we found that 8-oxo-7,8-dihydroguanosine (8-oxo-Gsn) levels were markedly increased in the colon, ileum, liver, spleen, and brain after infection, showing that *S. flexneri* can exacerbate systemic RNA oxidation. The changing trend in levels of urinary 8-oxo-Gsn (as the RNA oxidative metabolites) was consistent with the changes in the white blood cell count, C-reactive protein level, and cytokine levels during infection. Urinary 8-oxo-Gsn may be useful as a biomarker for evaluating the severity and prognosis of infection.

INTRODUCTION

Shigella infection is a major public health concern around the world, causing acute diarrhea, known as shigellosis or bacillary dysentery. There are almost 165 million cases of diarrhea caused by *Shigella* each year, of which 163 million occur in developing countries[1]. People of all ages can be infected by *Shigella*, but children under five years old are most susceptible[2].

Shigella flexneri (*S. flexneri*) is the most frequently isolated *Shigella* species worldwide [2]. The pathogenesis of *S. flexneri* involves invasion of the mucosa by bacteria, which replicate within and spread between the mucosal epithelial cells, resulting in a subsequent severe inflammatory response and epithelial destruction in the colon tissue. However, the oxidative damage in the colon during *S. flexneri*-induced infection has not been investigated. In the present study, the oxidative stress changes in the intestine during *S. flexneri*-induced acute intestinal infection were investigated.

Shigella infection can cause inflammatory responses in the intestine, which is also a potential source of inflammation-related cytokines[3]. Researchers have established cell models/animal models and observed the infected patients to investigate the inflammation-related cytokine production. In cell models, *S. flexneri* was able to cause an increase in interleukin (IL)-1, IL-10, and tumor necrosis factor α (TNF-α) in macrophage-like cells[4]. Outer membrane protein A of *S. flexneri* can trigger B cells to

secret the cytokines IL-6 and IL-10[5]. The production of the cytokines IL-4, IL-6, and IL-8 is increased in HeLa cells with *S. flexneri* infection[6]. Researchers also found that the TNFα and IL-1β production is reduced in mouse macrophages with an *S. flexneri msbB* gene mutation[7]. In mouse models, *S. flexneri* infection can cause an increase in the IL-1β production[8]. In *S. flexneri*-infected patients, the TNF-α, IL-1, IL-4, IL-6, and interferon-γ levels increased significantly after infection[3].

In the present study, we established an *S. flexneri*-infected rat model to explore the changes in the levels of the above-mentioned cytokines (IL-1, IL-6, IL-10, and TNF-α) as well as IL-17α, which plays important roles in host immunity against intracellular pathogens.

Urinary 8-oxo-7,8-dihydroguanosine (8-oxo-Gsn) and 8-oxo-7,8-dihydro-2-deoxyguanosine (8-oxo-dGsn) are oxidative stress by-products of RNA and DNA, respectively, which are widely used as markers of oxidative stress[9,10]. Previous studies have reported their utility as biomarkers for predicting aging-related diseases[11] and neurodegenerative diseases[12]. Our lab found that 8-oxo-Gsn may have potential utility as a marker for evaluating the severity of *Salmonella*-related infection[13]. The present study investigated the diagnostic value of 8-oxo-Gsn and 8-oxo-dGsn in intestinal infection induced by *S. flexneri*. In addition, we investigated the correlation between cytokine levels and oxidative production of 8-oxo-Gsn.

Accumulating evidence suggests that intestinal infection caused by Gram-negative bacteria may also influence other organs. For example, the Gram-negative bacterium *Escherichia coli* can form extracellular amyloid, which may play a role in causing sporadic Alzheimer's disease[14]. *S. dysenteriae*, a causative agent of bloody diarrhea, may cause diarrhea-associated hemolytic uremic syndrome and neurological disorders [15]. Acute intestinal infection induced by *Salmonella* can cause oxidative damage to the intestine, liver, and spleen[13]. However, the effects of *Shigella*-induced intestinal infection on other tissues have not been reported.

We hope that the rat infection model established in the present study will help improve our understanding of how vertebrates regulate their response to *S. flexneri* infection. We further intended to explore whether or not *S. flexneri* infection in the intestine can cause oxidative damage to other organs, such as the liver, spleen, and brain.

MATERIALS AND METHODS

Bacterial strains

The *S. flexneri* strain used in this study (CICC 21534) was purchased from the China Center of Industrial Culture Collection (CICC; Beijing, China). The source of the CICC 21534 strain was Guizhou Health and Epidemic Prevention Station, China. The serotype of CICC 21534 was F1a.

S. flexneri strain CICC 21534 was stored at -80 °C. The isolate was subcultured on blood agar plates twice and then suspended in Trypticase Soy Broth (bioMérieux SA, 69280 Marcy I'Etoile, France). The bacterial concentration was measured spectrophotometrically and confirmed by serial dilution on blood agar.

Animal experimental design

Twenty-four 4-wk-old healthy male Sprague-Dawley (SD) rats were purchased from Vital River (Beijing, China). All appropriate measures were taken to minimize the pain or discomfort of the rats. The rats were housed in a temperature-controlled room (24 ± 2 °C). Drinking water and food were provided *ad libitum*. There were three rats in each cage. The rats were not pretreated with any antibiotics and were all healthy before treatment, with normal white blood cell (WBC) counts and a normal flora in the feces.

The rats were divided randomly into either an infection group or a control group. In the infection group (n = 12), rats were infected by gavage with 1 dose of 1×10^9 colony-forming units (CFU) of the *S. flexneri* strain. In the control group (n = 12), rat gavage was performed with phosphate-buffered saline (PBS). On days 1, 5, 9, and 18, three rats per group were euthanized by intraperitoneal injection of pentobarbital sodium (200 mg/kg), and tissues were obtained.

For the establishment of the infection model, before infection, the rats were starved overnight. To neutralize the gastric acid, 400 μL of 3% $NaHCO_3$ was administered orally 15 min before infection. The rats in the infection group were then orally administered with 1×10^9 CFU of *S. flexneri* in a volume of 1 mL. The establishment of infection was verified by the continuous detection of *S. flexneri* in feces, an increased WBC count, and obvious lymphocyte infiltration in the colon. In the control group,

rats were also starved overnight and administered with 3% $NaHCO_3$ orally 15 min before PBS administration.

We took care of and sacrificed the animals strictly according to animal welfare laws and regulations. This study was approved by the Ethical Committee of the Institute of Medical Biotechnology, Chinese Academy of Medical Sciences (approval number: IMB-201803140206).

Body temperature and body weight of rats

The body temperature (rectal temperature) and body weight of the rats were measured every morning.

Microbiological detection

For the qualitative detection, conventional bacterial culture methods were used to detect *S. flexneri* in feces. Samples were collected and inoculated onto blood agar, China blue agar plates (Jinzhang Science and Technology Development Co. Ltd, Tianjin 300190, China), and Salmonella-Shigella (bioMérieux SA, 69280 Marcy I'Etoile, France) agar plates within 2 h of collection. *S. flexneri* was identified using morphologic observation on the selective medium, combined with triple-iron slants and Vitek 2 (bioMérieux, Inc., NC, United States) detection.

For the quantitative detection of *S. flexneri*, the feces and tissues were weighed after collection and then diluted in 1 mL of PBS and homogenized with a tissue homogenizer (PRO Scientific Inc., CT, United States). After centrifugation, the supernatant was diluted and inoculated onto Salmonella-Shigella (bioMérieux SA, Marcy I'Etoile, France) agar plates. The plates were incubated at 37 °C overnight. The number of *Shigella* colonies was counted on each plate. *Shigella* was quantitatively detected in the infection and control groups at fixed time points on days 1, 3, 5, 7, 9, 13, 15, and 18.

White blood cell count

WBCs in blood samples were counted manually. A 20-μL blood sample was added to 380 μL of 2% ethanoic acid solution. Then, WBCs were counted in a hemacytometer using a conventional light microscope.

C-reactive protein and cytokine detection

Blood samples were collected by the tail vein sampling method. Serum C-reactive protein (CRP) levels were detected with a Rat CRP ELISA kit (Immunology Consultants Laboratory, Inc., OR, United States). The CRP test kit is a highly sensitive two-site ELISA for measuring CRP in rat biological samples. The assay for quantification of CRP in samples requires that each test sample be diluted before use. For the serum samples of the rats in our study, 1/12000 dilution was appropriate for detection. The dilution ratio was determined based on the data provided by the kit and the data of the preliminary experiment.

The cytokines TNF-α, IL-6, IL-10, IL-1β, IL-4, and IL-17α were measured using a commercially available MILLIPLEX MAP Kit (Rat Cytokine/Chemokine Magnetic Bead Panel, 96-Well Plate Assay, Cat. #RECYTMAG-65K, RECYMAG65K27PMX, RECYMAG-65PMX27BK; Millipore Corporation, MA, United States) according to the manufacturer's protocol. In this study, 1/2 dilution of serum was appropriate for detection. A Luminex 200 System (Luminex Corporation, TX, United States) was used for quantification.

Detection of urinary 8-oxo-dGsn and 8-oxo-Gsn levels

The manual bladder expression method was used to collect the urine samples of rats. Urine samples were stored at -80 °C. Urinary 8-oxo-dGsn and 8-oxo-Gsn were detected by the liquid chromatography with tandem mass spectrometry method as reported [13]. In brief, all urine samples were analyzed using an Agilent 1290 Infinity UHPLC instrument equipped with an Agilent 6490 triple-quadrupole mass spectrometer with a Jet Stream ESI source and iFunnel (Agilent, United States; parameters are shown in Supplementary Tables 1-3). The concentrations of 8-oxo-dGsn and 8-oxo-Gsn were then normalized by urinary creatinine to correct for the impact of water intake/excretion on urine. The results are presented as the ratio of the concentrations of nucleosides (8-oxo-dGsn and 8-oxo-Gsn) and creatinine.

Hematoxylin and eosin staining of tissues

Histopathological tests were performed using standard laboratory procedures. Tissue samples were fixed in 10% neutral-buffered formalin and embedded in paraffin. The paraffin-embedded tissue was then sliced into 4-μm-thick sections with a microtome

and placed onto glass slides for further experiments. The tissue sections were deparaffinized with xylene, hydrated through an alcohol series, and then stained with hematoxylin and eosin (H&E). After dehydration and clearing, the mounting tissue sections were observed under a light microscope. H&E Stain kit was purchased from ZSGB-BIO (Beijing, China).

Immunohistochemical detection of 8-oxo-Gsn and 8-oxo-dGsn

Immunohistochemical staining was performed to detect the expression of 8-oxo-Gsn in the ileum, colon, liver, spleen, and brain. In brief, paraffin-embedded tissue sections were deparaffinized in xylene and rehydrated through a series of graded alcohols. Antigen retrieval was performed in citric acid buffer at 95 °C for 40 min. DNase I (TaKaRa Biotechnology Co., Ltd., Dalian, China) was added to slides to remove genomic DNA from samples. The slides were washed with 1 × PBS, and 3% hydrogen peroxide was added to eliminate endogenous peroxidases. Slides were then blocked with goat serum working solution. Primary monoclonal 15A3 antibody (ab62623; Abcam, Cambridge, United Kingdom) was added, and slides were incubated at 37 °C for 2 h (antibody dilutions: Colon, 1:700; ileum, 1:2000; liver, 1:700; spleen, 1:700; brain, 1:2000). The sections were incubated with HRP-conjugated secondary antibody (PV-6002; ZSGB-BIO) for 20 min. Coloration was performed with DAB (ZSGB-BIO), and the sections were observed under a microscope[16].

To detect the expression of 8-oxo-dGsn in tissue, tissue sections were treated with RNase A (TaKaRa Biotechnology Co., Ltd.) to remove RNA from samples. The primary monoclonal antibody was N45.1 (ab48508; Abcam). The dilutions of primary antibody were 1:2000 for the colon, 1:3000 for the ileum, 1:3000 for the liver, 1:500 for the spleen, and 1:2000 for the brain.

Statistical analysis

The SPSS 16.0 software program was used for the statistical analyses. Quantitative data are expressed as the mean ± SD and were analyzed by a *t*-test or one-way analysis of variance (ANOVA) after the normality test. Pearson's correlation coefficient (*r*) was used when comparing the linear relationship between the variables with a normal distribution. An area under the receiver operating characteristic (ROC) curve was created to assess the predictive value of urinary 8-oxo-Gsn and cytokines for the presence of infection. The results were considered significant only when $P < 0.05$.

RESULTS

Orally administered S. flexneri can provoke pathogen colonization and intestinal inflammation in rats

The body temperature showed no significant changes during the infection progression. Furthermore, the body weight increase of the rats was not significantly different between the infection and control groups.

After the intragastric administration of *S. flexneri*, serial fecal cultures were performed at fixed time points (days 1, 3, 5, 7, 9, 13, 15, and 18) in the two groups. In the control group, *S. flexneri* was undetectable during the experiment. In the infection group, *S. flexneri* was detectable in the feces of all infected rats after infection (day 1) and remained until day 7, whereas it was undetectable on day 9 (Figure 1A). In the intestine, liver, and spleen, *S. flexneri* was detectable on days 1 and/or 5. *S. flexneri* was undetectable in the brain at all time points.

Shigella can invade the colonic epithelial cells and provoke an intense inflammatory response. Compared with the control group (Figure 1B), obvious leukocyte infiltration was observed in the colonic mucosa on day 1 ($P < 0.001$ *vs* control; Figure 1C and G) and day 5 ($P < 0.001$ *vs* control; Figure 1D and G) after infection with *S. flexneri*, as detected by H&E staining. Intestinal inflammation was decreased on day 9 (Figure 1E), which was accompanied by pathogen elimination. By day 18, the colonic mucosa had returned to normal (Figure 1F).

A: Interleukin (IL)-6; B: Tumor necrosis factor-α; C: IL-1β; D: IL-17α; E: IL-10. 0: Before infection. 1-18: The number of days after the establishment of the *Shigella flexneri* infection model. n = 12 per group on day 0 and day 1; n = 9 per group on day 5; n = 6 per group on day 9; n = 3 per group on day 18. Data are presented as the mean ± SEM. $^{a}P < 0.05$; $^{b}P < 0.01$; and $^{c}P < 0.001$ (two-tailed unpaired Student's t-test). PBS: Phosphate-buffered saline; IL: Interleukin; TNF: Tumor necrosis factor.

Changes in WBC count and CRP levels during the course of infection

The WBC count is often used to assess bacterial infections. The changes in the WBC count after the establishment of intestinal infection are shown in Figure 1H. The WBC count increased after oral exposure to *S. flexneri* and peaked on day 5 ($P < 0.0001$, $WBC_{day5} = 27.42 \pm 3.77 \times 10^9$ cells/L). The WBC count then decreased and returned to baseline after day 13. In the control group, there were no significant changes in the WBC count during the experiment.

Furthermore, it was shown that the level of CRP, an acute-phase response protein commonly used as a marker of inflammation, was significantly increased after exposure to *S. flexneri* on day 1 (CRP = $4.87 \pm 1.59 \times 10^3$ mg/L, $P = 0.005$), and the level remained high when it was detected on day 5 (CRP = $4.85 \pm 1.41 \times 10^3$ mg/L, $P = 0.002$). The CRP level then decreased and returned to baseline on day 18 (Figure 1I).

Induction of inflammatory cytokine production

The expression of IL-6, an important mediator of the acute-phase response, was significantly increased in the infection group on day 1 (207.26 ± 19.93 pg/mL, $P = 0.02$) and remained high when detected on day 5 (207.99 ± 21.49 pg/mL, $P = 0.01$; Figure 2A). After pathogen clearance on day 9, the levels of IL-6 decreased and returned to baseline.

The expression of TNF-α, a cell-signaling protein involved in systemic inflammation and one of the cytokines that make up the acute phase reaction, was also significantly increased after infection (day 1: 96.07 ± 8.29 pg/mL, $P < 0.001$) and peaked on day 5 (119.11 ± 9.69 pg/mL, $P < 0.001$). The TNF-α level then decreased and returned to the baseline at the end of the experiment (Figure 2B).

Consistent with this trend, increased levels of proinflammatory IL-1β (Figure 2C) and IL-17α (Figure 2D) were observed after infection and peaked on day 5. IL-10, a cytokine with multiple, pleiotropic effects in immunoregulation and inflammation, was also significantly produced after bacterial infection (Figure 2E).

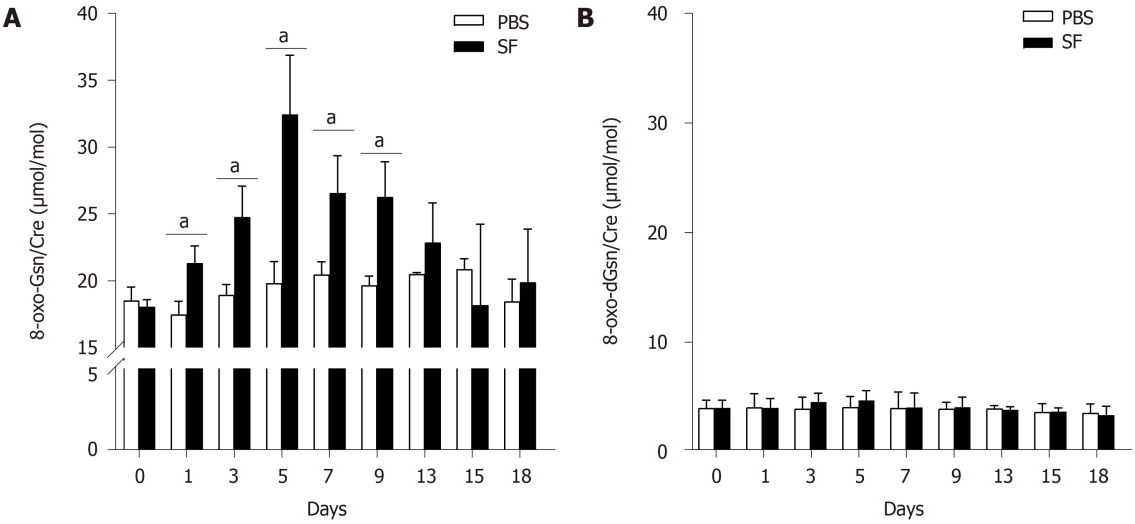

Figure 3 Liquid chromatography-tandem mass spectrometry measurement of 8-oxo-7,8-dihydroguanosine and 8-oxo-7,8-dihydro-2-deoxyguanosine in the urine of Sprague-Dawley rats. A: Urinary 8-oxo-7,8-dihydroguanosine; B: Urinary 8-oxo-7,8-dihydro-2-deoxyguanosine. *n* = 12 per group on day 0 and day 1; *n* = 9 per group on day 3 and day 5; *n* = 6 per group on day 9; *n* = 3 per group on day 13, day 15, and day 18. 0: Before infection. 1-18: The number of days after the establishment of the *Shigella flexneri* infection model. [a]*P* < 0.05. 8-oxo-Gsn: 8-oxo-7,8-dihydroguanosine; 8-oxo-dGsn: 8-oxo-7,8-dihydro-2-deoxyguanosine.

High levels of oxidized guanosine in urine after Shigella infection

8-oxo-Gsn levels were increased after oral exposure to *S. flexneri*. Compared with the control group, significantly increased levels of 8-oxo-Gsn were observed from day 1 to day 9 ($P < 0.05$), with the level peaking on day 5 ($P = 0.017$). After day 5, the level of 8-oxo-Gsn began to decrease and returned to baseline on day 15 (Figure 3A). The trends in the changes in the urinary 8-oxo-Gsn level were consistent with the changes in colonic tissue inflammation, the WBC count, and the CRP level, suggesting that urinary 8-oxo-Gsn may serve as a biomarker for assessing the severity of the infection.

In the control group, no significant changes in the 8-oxo-Gsn level were observed at any time point. For 8-oxo-dGsn, no significant changes were observed at any time point (Figure 3B).

Shigella infection leads to RNA oxidative damage in tissues

Immunohistochemical staining showed that the 8-oxo-Gsn staining intensity in the infected colon tissue was significantly altered compared with normal colon tissue ($P < 0.05$; Figure 4A). In infected colon tissues, antibodies directed against the RNA damage marker 8-oxo-Gsn produced more intense staining than uninfected colon tissues, thereby indicating a general increase in oxidative stress and RNA damage. Although 8-oxo-Gsn was more highly expressed on day 1 than on day 5, the difference between the two time points was not statistically significant. In the ileum (Figure 4B), liver (Figure 4C), spleen (Figure 4D), and brain tissues (Figure 4E), the expression of 8-oxo-Gsn was significantly higher on days 1 and day 5 than that in uninfected tissues.

The levels of the DNA damage marker 8-oxo-dGsn were significantly increased in the colon and brain tissues after infection (Figure 5A and E). In the infection group, there was no significant change in the 8-oxo-dGsn expression in the ileum, liver, or spleen (Figure 5B-D).

Correlation of 8-oxo-Gsn with WBC, CRP, and inflammatory cytokines

The 8-oxo-Gsn concentration in the urine of the infection group was positively correlated with the WBC count ($r = 0.652$, $P < 0.001$) and levels of IL-6 ($r = 0.461$, $P = 0.005$), TNF-α ($r = 0.541$, $P = 0.001$), IL-10 ($r = 0.359$, $P = 0.032$), IL-1β ($r = 0.402$, $P = 0.017$), and IL-17α ($r = 0.431$, $P = 0.009$). No significant correlation was found between 8-oxo-Gsn and CRP ($r = 0.289$, $P = 0.203$).

HE staining and fecal discharge are the gold standards for diagnosing the presence of infection. The predictive value of 8-oxo-Gsn in identifying the presence of intestinal infection was assessed using a ROC curve. The area under the ROC curve of urinary 8-oxo-Gsn was 0.750 (95%CI, 0.615–0.885, $P = 0.001$) (Figure 6A).

The predictive value of the WBC count and CRP for identifying intestinal infection was also assessed using a ROC curve. The area under the ROC of the WBC count was

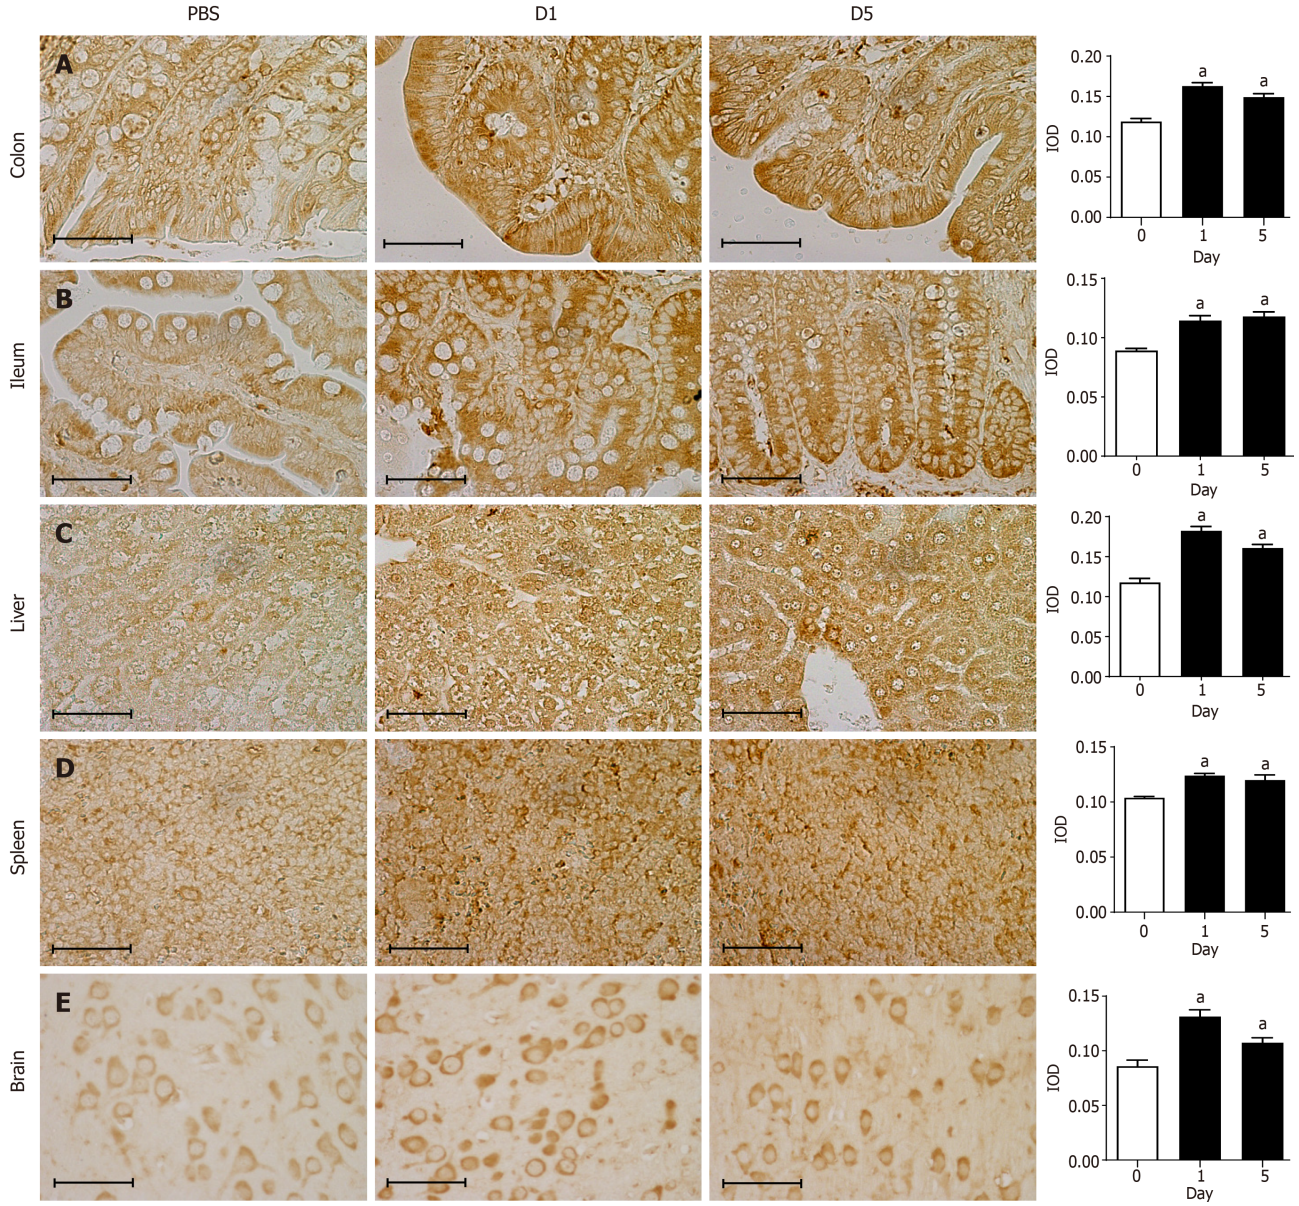

Figure 4 Immunohistochemical staining for 8-oxo-7,8-dihydroguanosine in tissues. Histogram: The quantitative analysis of immunohistochemical staining of 8-oxo-Gsn in tissues of the infection and control groups. Scale bar, 50 μm. $^{a}P < 0.05$. The immunohistochemical images were analyzed using the Image Pro-Plus (IPP) software. The integrated optical density (IOD) is a representative parameter for assessing the immunostaining quantification in the IPP analyses, and it indicates the total amount of staining material in that area. IOD: Integrated optical density.

0.792 (95%CI, 0.674–0.911, $P < 0.001$) (Figure 6B), and that for CRP was 0.733 (95%CI, 0.544–0.923, $P = 0.014$) (Figure 6C).

For inflammatory cytokines, the area under the ROC of IL-6 (Figure 6D), TNF-α (Figure 6E), IL-1β (Figure 6F), IL-17α (Figure 6G), and IL-10 (Figure 6H) was 0.838 (95%CI, 0.698–0.978, $P = 0.003$), 0.980 (95%CI, 0.948–1.012, $P < 0.001$), 0.948 (95%CI, 0.882–1.014, $P < 0.001$), 0.964 (95%CI, 0.917–1.012, $P < 0.001$), and 0.864 (95%CI, 0.752–0.977, $P < 0.001$), respectively.

DISCUSSION

The present findings suggested that urinary 8-oxo-Gsn can be used to identify the presence of infection and to assess the severity of infection. In this study, *Shigella* infection in the gastrointestinal tract induced significant increases in the 8-oxo-Gsn

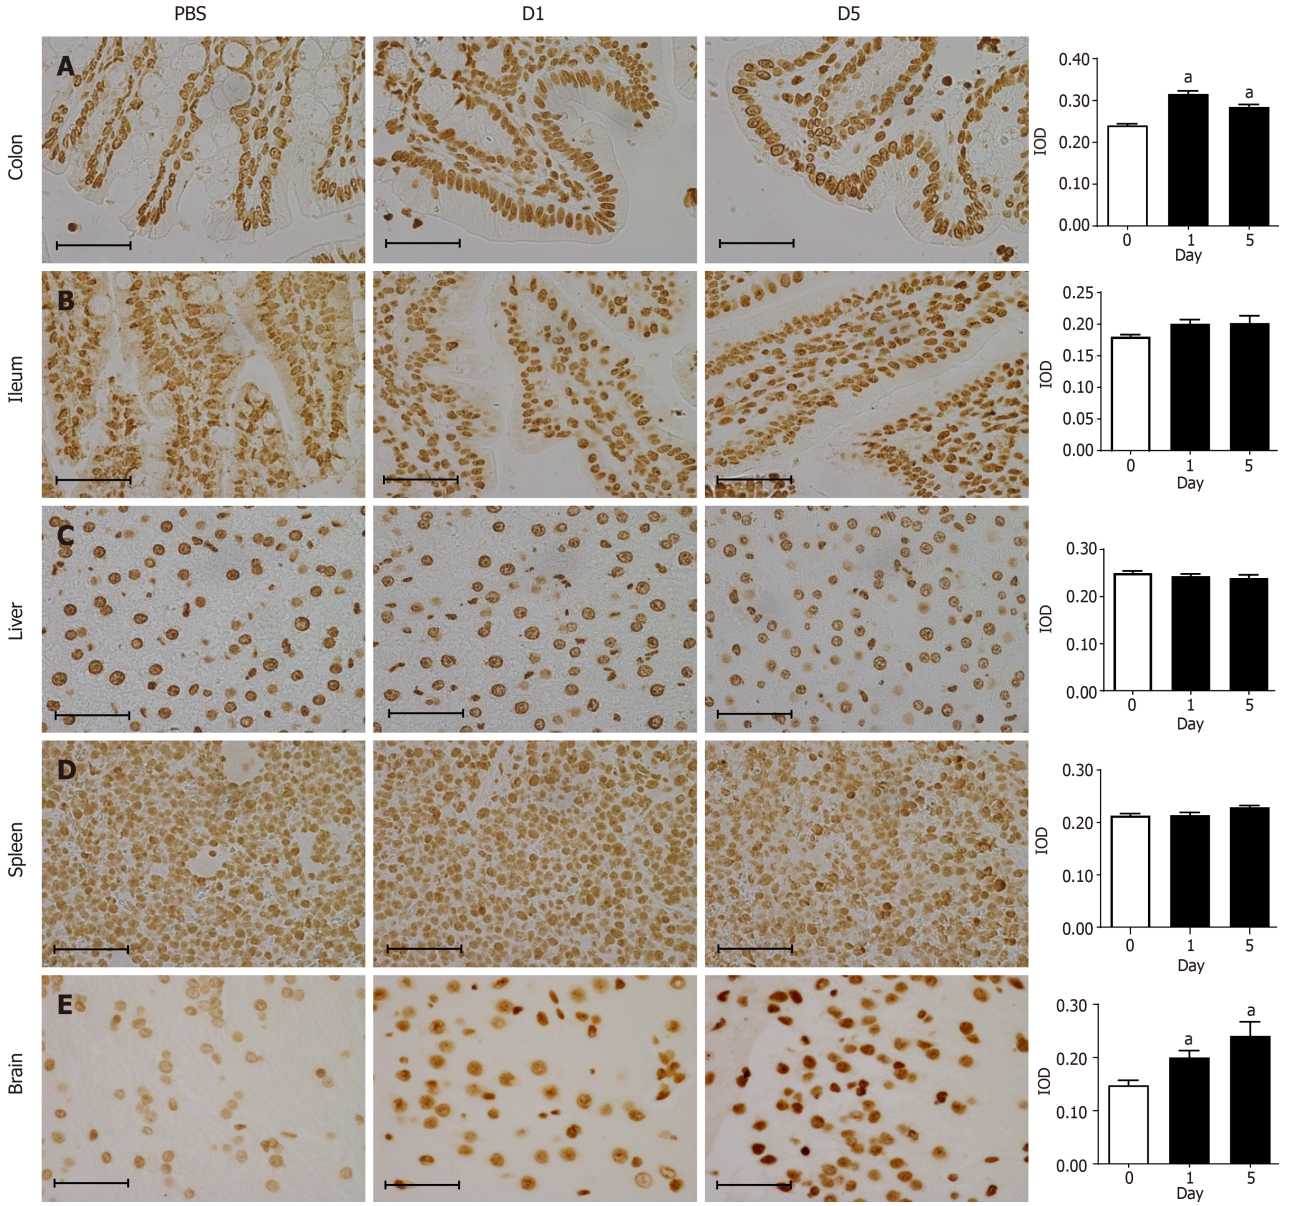

Figure 5 Immunohistochemical staining for 8-oxo-7,8-dihydro-2-deoxyguanosine in tissues. concentration, the WBC count, and the CRP level. The WBC count is widely used to evaluate the severity of bacterial infections. CRP, an acute-phase protein of hepatic origin, is a non-specific marker of inflammation and one of the most sensitive acute-phase reactants.

The levels of 8-oxo-Gsn, a marker of oxidative stress, as well as the WBC count and the CRP level, which are markers of inflammation, were all increased significantly on day 1 and peaked on day 5. Following the clearance of the pathogen, the values for these biomarkers returned to the baseline level.

The correlation analysis showed that 8-oxo-Gsn was positively correlated with the WBC count. Although no significant correlation was found between 8-oxo-Gsn and CRP, the trend of the urinary 8-oxo-Gsn concentration was consistent with the changes of the WBC count and CRP level. The sharp increase in the CRP level on day 1 (20 times higher than that on day 0) may be the reason for the absence of a significant correlation. The predictive value of the 8-oxo-Gsn concentration, WBC count, and CRP level for differentiating between infection and non-infection was assessed using the

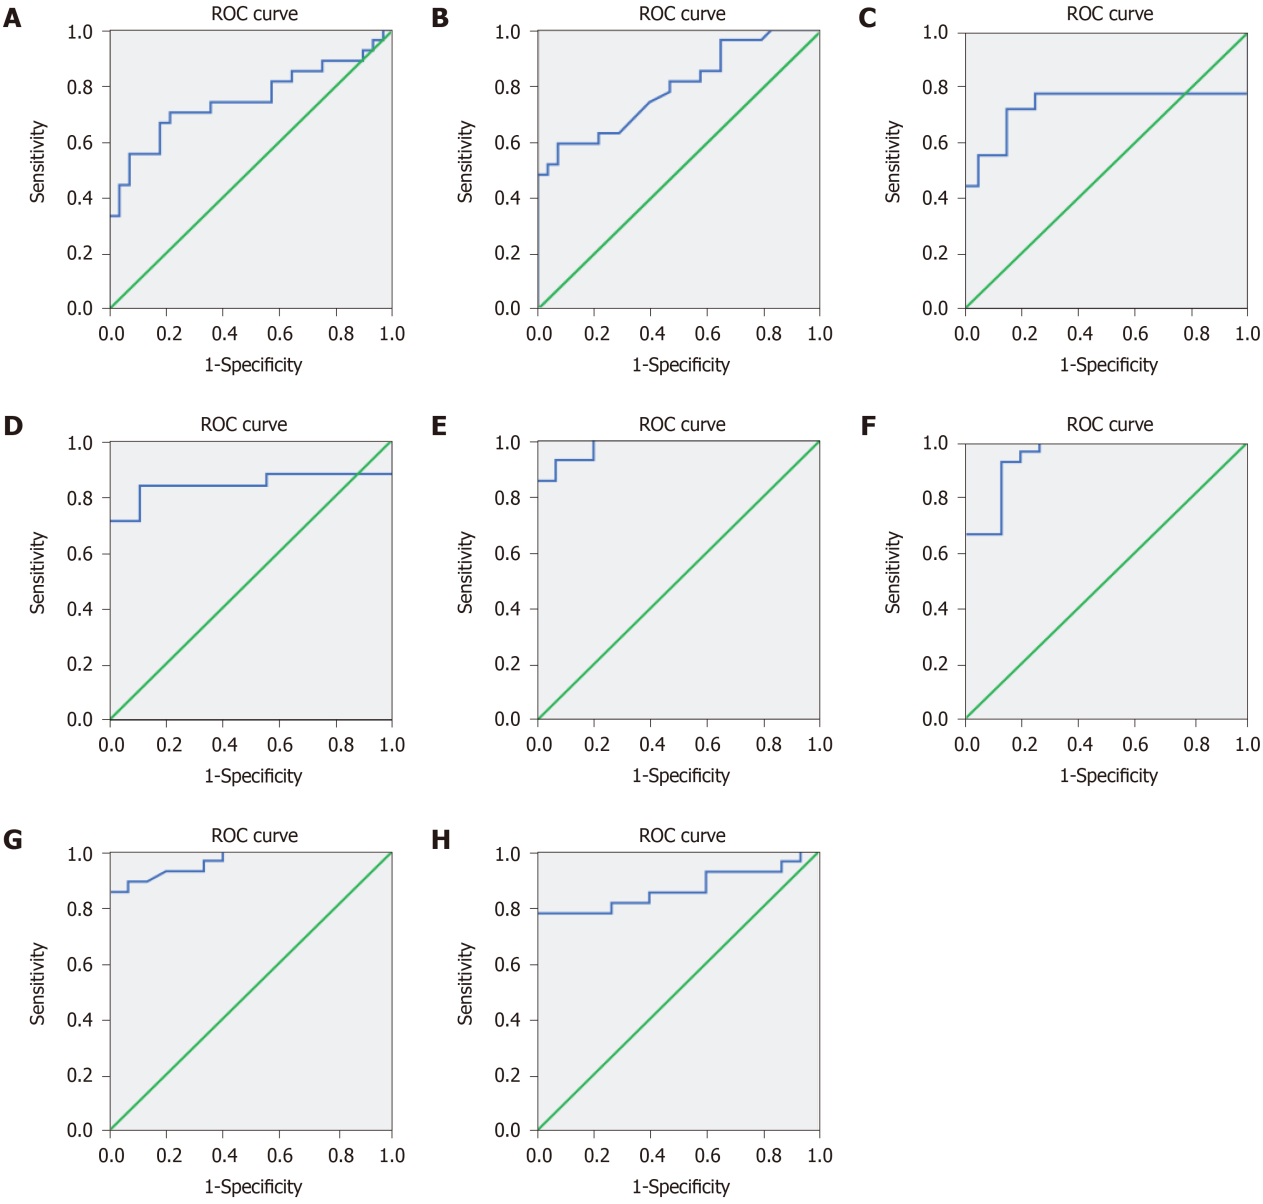

Figure 6 Receiver operator characteristic curves of 8-oxo-7,8-dihydroguanosine, white blood cell count, C-reactive protein, interleukin-6, tumor necrosis factor α, interleukin-1β, interleukin-17α, and interleukin-10 for assessing the infection status. A: Receiver operator characteristic (ROC) curve of urinary 8-oxo-7,8-dihydroguanosine; B: ROC curve of white blood cell count; C: ROC curve of C-reactive protein; D: ROC curve of interleukin (IL)-6; E: ROC curve of tumor necrosis factor α; F: ROC curve of IL-1β; G: ROC curve of IL-17α; H: ROC curve of IL-10. ROC: Receiver operator characteristic.

ROC curve. The results showed that 8-oxo-Gsn achieved a fair accuracy in classifying subjects as infected or uninfected. When the area under the ROC curve for the 8-oxo-Gsn concentration was compared to those of the WBC count and CRP level, all values ranged from 0.70 to 0.80, indicating that these diagnostic markers have a similar discrimination ability for the infection status[17]. Furthermore, urinary 8-oxo-Gsn is a noninvasive biomarker and can be measured more frequently than blood biomarkers, such as the WBC and CRP.

The immunohistochemistry results showed that in addition to intestinal tract tissue, 8-oxo-Gsn (RNA oxidative product) levels were increased in the liver, spleen, and brain tissues. Previous studies have shown that *Shigella* has a predilection to infect and colonize the large bowel[2,18]. The increased oxidative stress in other tissues might be induced by endo- or exotoxin produced by *Shigella* strains, according to previous studies[14,15,19]. Our study suggested that diarrhea caused by *Shigella* bacteria could induce a transient elevation in systemic oxidative stress.

The levels of the DNA oxidative product 8-oxo-dGsn showed no significant changes in urine, ileum, liver, or spleen tissues. The increase was only detected in the colon and brain. The results suggested that DNA oxidative damage occurred less frequently than

RNA oxidative damage in the course of acute infection. This might be because DNA molecules have a double-stranded structure, which is protected by histones and the cell nucleus[11]. All of these protections reduce the DNA oxidative damage during acute infection. Previous studies have shown that, in the course of chronic infection, DNA oxidative damage occurred more frequently, which helps promote inflammation-mediated carcinogenesis[20,21].

The present study showed that the levels of the cytokines IL-6, TNF-α, IL-1β, IL-17α and IL-10 were significantly increased after infection. Previous studies also showed that *S. flexneri* induced the release of both inflammatory (IL6, IL-8, and IL1β) and anti-inflammatory cytokines (IL-10)[22-24]. However, changes in the levels of IL-17α in *S. flexneri*-related infection have not been investigated. IL-17 has emerged as a central player in the mammalian immune system[25]. To promote inflammation, IL-17 acts in concert with IL-1β and TNF-α[26], with IL-1β being required to mediate inflammation in *S. flexneri* infection[8]. The present results suggested that *S. flexneri* infection activates inflammatory cytokines. Our findings also showed that the cytokine levels were positively correlated with the concentration of 8-oxo-Gsn, a marker of RNA oxidation, which proved again that 8-oxo-Gsn was useful as a diagnostic biomarker in infection.

CONCLUSION

In summary, during the early stage of *Shigella* infection, tissue inflammation occurs at the site of pathogen colonization, accompanied by an increase in reactive oxygen species (ROS) and the release of inflammatory cytokines. With the clearance of *Shigella*, the levels of oxidative stress markers and inflammatory cytokines decline, and the tissue inflammation recovers. The results suggested that although an increase in ROS can induce RNA oxidative damage in the colon and various tissues, this is temporary and differs from DNA oxidative damage, which occurs more frequently under conditions of chronic infection[20]. Thus, the combination of oxidative stress and inflammatory cytokines promotes infection recovery. A previous study showed that the RNA oxidative nucleic acid 8-oxoGTP increased protein variation[27]. The influence of various mutated proteins in infection, especially in the course of chronic infection, should be investigated in future studies.

ARTICLE HIGHLIGHTS

Research background

Shigella infection is a major public health concern around the world. *Shigella flexneri* (*S. flexneri*) is a major pathogen causing acute intestinal infection and is more frequently fatal than other *Shigella* species. The white blood cell (WBC) count and levels of C-reactive protein (CRP) and cytokines have always been used to evaluate the severity of *Shigella*-induced infection. Because RNA oxidation plays a substantial role in the progression of multiple diseases, the RNA oxidative product 8-oxo-7,8-dihydroguanosine (8-oxo-Gsn) may be useful as a biomarker for predicting infectious disease progression and severity.

Research motivation

There is no information regarding the diagnostic value of urinary 8-oxo-Gsn and 8-oxo-7,8-dihydro-2-deoxyguanosine (8-oxo-dGsn) in intestinal infection induced by *S. flexneri*. In addition, the correlation of blood inflammatory-related cytokines with RNA oxidative metabolites is unclear. Furthermore, the systematic tissue oxidative damage during *Shigella*-induced intestinal infection has not been investigated.

Research objectives

To determine the systemic RNA oxidative damage incurred in *S. flexneri*-induced intestinal infection and to evaluate the diagnostic value of the RNA oxidative metabolites 8-oxo-Gsn in urine.

Research methods

Sprague-Dawley rats were used to establish an acute intestinal infection model by oral gavage of *S. flexneri* strains. The CRP level was measured by ELISA, and cytokines

were detected using the MILLIPLEX MAP Kit according to the manufacturer's protocol. Hematoxylin and eosin staining was performed to detect tissue inflammation. Liquid chromatography with tandem mass spectrometry was used to determine the 8-oxo-dGsn and 8-oxo-Gsn levels in urine. Immunohistochemical staining was performed to detect the expression of 8-oxo-Gsn and 8-oxo-dGsn in the ileum, colon, liver, spleen, and brain.

Research results

Intestinal infection induced by *S. flexneri* caused an increase in inflammation-related markers in the blood [WBCs, CRP, tumor necrosis factor α (TNF-α), interleukin (IL)-6, IL-10, IL-1β, IL-4, and IL-17a] and RNA oxidative damage-related markers in the urine (8-oxo-Gsn). The urinary 8-oxo-Gsn level increased after infection and returned to the baseline level after recovery from infection. A correlation analysis showed that urinary 8-oxo-Gsn was positively correlated with the WBC count and the cytokines IL-6, TNF-α, IL-10, IL-1β, and IL-17α. The evaluation of oxidation in different tissues showed that intestinal infection caused by *S. flexneri* induced an increase in RNA oxidative damage in various tissues, including the intestine, liver, spleen, and brain.

Research conclusions

This study demonstrated that acute intestinal infection induced by *S. flexneri* not only causes RNA oxidative damage in the intestine but also other tissues as well (liver, spleen, and brain). Furthermore, the urinary metabolite of RNA oxidation 8-oxo-Gsn was shown to be useful as a diagnostic index to evaluate the infection status.

Research perspectives

Urinary 8-oxo-Gsn can be used as a noninvasive diagnostic biomarker to evaluate the severity and prognosis of infection in clinical practice.

Abstract

BACKGROUND

Genome-wide association studies from Asia indicate that HLA-DP and HLA-DQ loci are important in persistent hepatitis B virus (HBV) infections. One of the key elements for HBV-related carcinogenesis is persistent viral replication and inflammation.

AIM

To examine genetic and nongenetic factors with persistent HBV infection and viral load in families with hepatocellular carcinoma (HCC).

METHODS

The HCC families included 301 hepatitis B surface antigen (HBsAg) carriers and 424 noncarriers born before the nationwide vaccination program was initiated in 1984. Five HBV-related single nucleotide polymorphisms (SNPs) — rs477515, rs9272105, rs9276370, rs7756516, and rs9277535 — were genotyped. Factors associated with persistent HBV infection and viral load were analyzed by a generalized estimating equation.

RESULTS

In the first-stage persistent HBV study, all SNPs except rs9272105 were associated with persistent infection. A significantly higher area under the reciprocal operating characteristic curve for nongenetic factors *vs* genetic factors ($P < 0.001$)

suggests that the former play a major role in persistent HBV infection. In the second-stage viral load study, we added 8 HBsAg carriers born after 1984. The 309 HBsAg carriers were divided into low (n = 162) and high viral load (n = 147) groups with an HBV DNA cutoff of 10^5 cps/mL. Sex, relationship to the index case, rs477515, rs9272105, and rs7756516 were associated with viral load. Based on the receiver operating characteristic curve analysis, genetic and nongenetic factors affected viral load equally in the HCC family cohort (P = 0.3117).

CONCLUSION

In these east Asian adults, the mechanism of persistent HBV infection-related SNPs was a prolonged viral replication phase.

Core Tip: Hepatitis B virus (HBV)-related single nucleotide polymorphisms (SNPs) have been identified in East Asians. We evaluated five SNPs and nongenetic factors associated with HBV infection in a hepatocellular carcinoma family cohort. The factors were correlated with hepatitis B surface antigen (HBsAg) in the first-stage and with HBV viral load in the second-stage. The SNPs, sex, generation, and index case HBsAg contributed to persistent HBV infection. Neonatal tolerance and SNPs in the HLA loci were both independently associated with persistent HBV infection. A prolonged HBV replication phase in parents could be the main mechanism of persistent HBV infection in children in East Asia.

INTRODUCTION

Chronic hepatitis B is a global disease, with the highest prevalence in Africa and Asia [1,2]. Hepatitis B virus (HBV) is highly infectious[3,4], and those who are infected early in life are likely to develop a persistent infection[5-7]. Intra-familial spread of infection is common, resulting in the clustering of chronic hepatitis B surface antigen (HBsAg) carriers and hepatocellular carcinoma (HCC) in families[8-10]. Recent genome-wide association studies (GWASs) in Japan, Korea, Saudi Arabia, China, and Taiwan have consistently shown that single nucleotide polymorphisms (SNPs) at the HLA-DP and HLA-DQ loci play important roles in persistent HBV infection[11-19]. However, risk alleles of HBV-related SNPs are not present in the majority of Africans[20,21], so the high prevalence of HBsAg carriers in Africa cannot be completely explained by the SNPs.

It is well known that clearance of the hepatitis B e antigen (HBeAg) occurs earlier in African than in Asian HBsAg carriers[22-25]. In east Asia, the annual HBeAg seroconversion rate is < 2% in children younger than 3 years of age and around 5% in children older than 3 years of age[22,23]. On the contrary, an HBeAg annual clearance rate of 14%-16% has been found in Euro-Mediterranean and African children[24,25]. HBeAg clearance is associated with a decreased viral load and results in a decrease of perinatal infections and the development of chronic persistent HBV infection[7,23]. We propose that persistent HBV infection-related SNPs may be one of the reasons for the prolonged HBV replication phase in east Asians. To evaluate this hypothesis, we analyzed the HBV-related SNP and demographic data obtained from HCC families. HCC families are known to have higher perinatal transmission and a longer HBV replication phase than the general population[9,10]. We expect that the genetic and nongenetic factors characteristic of HCC families may help us to understand the

and data comparisons were carried out in compliance with relevant laws and guidelines, and in accord with the ethical standards of the Declaration of Helsinki.

nature of persistent HBV infection.

MATERIALS AND METHODS

Ethics statement

Our study was approved by the institutional review board of Chang Gung Memorial Hospital, Taiwan (IRB 104-2596). Written informed consent was obtained from all participants. All experiments and data comparisons were carried out in compliance with relevant laws and guidelines, and complied with the ethical standards of the Declaration of Helsinki.

Study participants

Patients with HCC who were diagnosed at Chang Gung Memorial Hospital, Lin-Kou Medical Center were included as index cases. From 2003 to 2007, relatives of the patients were prospectively invited to complete a liver disease survey. The details of the survey can be seen in our previous report[10]. Briefly, after confirmation of their relation to the index HCC patient, the relatives received a structured questionnaire and underwent assessments of their liver biochemistry, alpha-fetoprotein, viral markers, and HBV genotyping. Peripheral blood samples were collected for host genome analysis.

Study size

We calculated sample sizes and statistical power to detect genetic effects in the study. The calculation considered the impact the minor allele frequency (MAF, from 0.1 to 0.4), odds ratio (OR, from 1.05 to 3), statistical power (from 0.5 to 0.9) and measurement error (type I error = 0.05) have on sample size. Power calculations were performed with QUANTO power calculator, version 1.2.4 (https://preventivemedicine.usc.edu/download-quanto/).

SNP selection and genotyping

Four genetic variants (rs477515, rs9276370, rs7756516, rs9277535) associated with persistent HBV infection that were previously identified[17] were included in the analysis. One additional HCC-related SNP (rs9272105) previously identified in China was also included[26]. Genomic DNA was extracted from peripheral blood cells using MagNA Pure LC DNA isolation kits with automated DNA isolation instruments (MagNA Pure LC II; Roche Diagnostics, Mannheim, Germany). Triple-SNP (rs477515, rs9272105, rs9277535) genotyping was performed with *Taq*Man Genotyping assays (Applied Biosystems, Foster City, CA, United States). Two SNPs (rs7756516, rs9276370) were genotyped with a Sequenom MassARRAY System (Sequenom, San Diego, CA, United States). The *Taq*Man assays were carried out by Vita Genomics (New Taipei City, Taiwan), and the Sequenom MassARRAY assays were performed by the Academia Sinica National Genotyping Center (Taipei, Taiwan). The overall genotype call rate was > 95%.

Statistical analysis

The statistical analyses were performed with SAS version 8.2 for UNIX (SAS Institute, Cary, NC, United States), PLINK (http://zzz.bwh.harvard.edu/plink/) (http://zzz.bwh.harvard.edu/plink/summary.shtml), R 2.15.1 (http://www.r-project.org/), and the Family-Based Association Test software (http://www.biostat.harvard.edu/~fbat/fbat.htm)[27]. A two-tailed P value < 0.05 was considered statistically significant. All associations were controlled for confounding factors. SNP data was quality controlled using the following criteria: (1) Call rate > 0.95; (2) MAF > 0.01; and (3) Deviation from Hardy-Weinberg equilibrium P > 0.001.

Individual locus analysis: We assessed the association of SNPs with persistent HBV infection or viral load in an additive genetic model using univariate and multivariate logistic regression of the data from unrelated male participants. In the family analysis, relatives included individuals living in the same household. First- and second-stage analyses were conducted with a generalized estimating equation (GEE) that included data correlated with a binary response (*e.g.*, to HBsAg status and HBV DNA level) using an exchangeable working correlation structure[28,29]. Univariate and multivariate analysis of the first- and second-stage results were assessed using the GEE method combined with the PROC GENMOD procedure in SAS 9.3 (SAS Institute). ORs were reported with 95% confidence intervals (CIs).

Weighted genetic risk score calculation: The weighted genetic risk score (WGRS) was calculated for the SNPs that were significantly associated with persistent infection or viral load. We assumed that each SNP was independently associated with risk according to an additive genetic model. The WGRS was calculated by multiplying the number of risk alleles at each polymorphic locus (0, 1, or 2) by each person for the corresponding relative logarithm of the OR (w_i) from the multivariate individual locus analysis and rescaling it with the factor $m/\sum_i w_i$, as follows: $WGRS = (m/\sum_i w_i) \cdot \sum w_i n_i$, where m is the number of statistically significant SNPs and n_i is the number of risk alleles for SNPi[30]. We divided the continuous WGRS into quartiles (Q1-4) and compared the risks among them.

Evaluation of genetic and nongenetic factors: We analyzed factors associated with persistent HBV infection or viral load using the logistic regression model unrelated participants and the GEE method for family data. Three prediction models were used: (1) The genetic model included only SNPs and WGRS; (2) The nongenetic model included only demographic data; and (3) The mixed model included both genetic and nongenetic variables. The contribution of the WGRS was evaluated using the area under the receiver operating characteristic curve (AUC), net reclassification improvement (NRI) method[31], and integrated discrimination improvement (IDI)[32] with the prediction model with and without the WGRS. To assess the demographic impact of including the WGRS in the model, an AUC of 0.5 indicated no discrimination and an AUC of 1 indicated perfect discrimination. The NRI indicated the proportion of subjects reclassified correctly (NRI > 0) or incorrectly (NRI < 0) into the various risk categories. An IDI > 0 indicated a statistically significant prediction of improvement as a result of adding variables to the model.

RESULTS

The HCC family cohort included 835 participants (Figure 1), of whom 301 HBsAg-positive and 424 of HBsAg-negative family members were selected for the first-stage HBV infection-persistence analysis. We excluded those born after the nationwide vaccination program was initiated in 1984. In the second-stage viral load study, we added 8 HBsAg carriers born after 1984 (Figure 1). A cohort of 309 HBsAg carriers was divided into high (n = 147) and low (n = 162) viral load groups using an HBV DNA cutoff of 10^5 cps/mL.

First stage: Factors associated with persistent HBV infection

Risk factors associated with being an HBsAg carrier were identified in the first-stage analysis. Demographic factors, which included age, sex, index case sex, relation to the index case, index HBsAg, and maternal HBsAg, are shown in Table 1. Age (OR = 1.018, P = 0.0013), sex (OR = 1.641, P = 0.0001), relation to the index case (OR = 3.203, P < 0.0001; index generation compared with children and grandchildren), index HBsAg (OR = 4.913, P < 0.0001), maternal HBsAg (OR = 3.31, P < 0.0001), and serum glutamic pyruvic transaminase (SGPT) (OR = 1.017, P < 0.0001) were significantly associated with persistent HBV infection. The associations remained significant after controlling for sex and age.

The SNPs rs477515 (OR = 1.377, P = 0.0274), rs9276370 (OR = 1.790, P = 0.0012), rs7756516 (OR = 1.654, P = 0.0048), and rs9277535 (OR = 1.519, P = 0.0004) were significantly associated with chronic HBV infection (Table 1). The ORs remained statistically significant after controlling for sex and age. HCC families carrying more risk alleles had an increased OR (Table 2, upper panel). Compared with participants with a WGRS in Q1, those with scores in Q2 and Q3–4 had higher risks of HBsAg positivity (Q2 OR = 1.878, P = 0.0014; Q3-4 OR = 2.538, P < 0.0001).

Results of the multivariate GEE analysis of the risk factors associated with persistent HBV infection are shown in Table 3. In the nongenetic model, sex, index generation, and index and maternal index HBsAg were associated with persistent HBV infection. In the genetic model, rs9277535 and WGRS were associated with persistent HBV infection. In the mixed model, all the risk factors were significant (male sex P = 0.0205; index generation P = 0.0001; index HBsAg P < 0.0001; maternal HBsAg P = 0.0072; rs9277535 P = 0.0029; WGRS P = 0.0012; Table 3).

The AUC for persistent HBV infection (Table 3) was 0.786 (P < 0.0001) in the nongenetic model and 0.620 (P < 0.0001) in the genetic model. Although the SNPs were identified by GWAS in unrelated subjects, the AUC data suggest that nongenetic factors were more important than genetic factors for the development of persistent

	Q2 (WGRS = 4.583-5.291)	2.204 (1.253-3.878)	0.0061
	Q3,4 (WGRS > 5.291)[2]	3.156 (1.780-5.595)	< 0.0001
	Cochran-Armitage trend test		< 0.0001

[1]The number of hepatitis B surface antigen negative individuals in Q4 was < 5, so Q3 and Q4 were combined.
[2]The number of individuals with hepatitis B virus DNA < 10^5 cps/mL in Q4 was < 1, so Q3 and Q4 were combined. The cumulative effect was calculated from: Four single nucleotide polymorphisms (SNPs) (rs9272105, rs9276370, rs7756516, and s9277535) in unrelated male hepatitis B surface antigen (HBsAg) carriers; four SNPs (rs477515, rs9276370, rs7756516, and rs9277535) in the first-stage hepatocellular carcinoma (HCC) family cohort analysis; and three SNPs (rs477515, rs9272105, and rs7756516) in HBsAg-positive carriers in the second-stage HCC family cohort analysis. CI: Confidence interval; OR: Odds ratio; Q: Quartile; WGRS: Weighted genetic risk score; HBV: Hepatitis B virus.

HBV infection (P < 0.0001; Figure 2). The combination of genetic and nongenetic factors resulted in an AUC of 0.795 (P < 0.0001; Figure 2 and Table 3). The IDI was 0.017 (95%CI: 0.009-0.026, P < 0.0001) and the NRI was 0.330 (95%CI: 0.192-0.467, P < 0.0001). The IDI and NRI values indicated statistically significant predicted improvement in the mixed, relative to the nongenetic model (Table 3).

Second stage: Factors associated with HBV viral load in HBsAg-positive HCC families

Factors associated with the HBV viral load were evaluated in HBsAg-positive families (Table 4). In that group, male sex (OR = 1.922, P = 0.0078), relation to the index case (OR = 2.033, P = 0.0029), index HBsAg (OR = 2.508, P = 0.0036), and SGPT (OR = 1.010, P = 0.0105) were significantly associated with the HBV viral load. The associations remained statistically significant after controlling for sex. HBV genotypes were also evaluated in HCC families, and of the participants with known HBV genotypes, the prevalence of genotype C was higher in those with high viral loads (41/143, 28.7%) than in those with low viral loads (15/90, 16.7%, P = 0.0431). The difference was marginally significant in multivariate analysis (P = 0.0515; Table 4).

Of the five SNPs included in the analysis, rs477515 (OR = 3.107, P = 0.0002), rs9272105 (OR = 1.747, P = 0.0009), and rs7756516 (OR = 1.951, P = 0.0272) were significantly associated with HBV viral load. The associations remained significant after controlling for sex (Table 4). Participants carrying more risk alleles had higher ORs for HBV viral load (Table 2, lower panel) and compared with patients having a WGRS in Q1, those in Q2 (OR = 2.204, P = 0.0061) and Q3-4 (OR = 3.156, P < 0.0001) had higher odds of having an HBV viral load.

The results of multivariate GEE analysis of factors associated with the HBV viral load in the genetic, nongenetic, and mixed models are shown in Table 5. In the nongenetic model, the risk of HBV viral load was higher in males (OR = 1.955, P = 0.0162) and in those with index HBsAg positivity (OR = 2.219, P = 0.0187). In the genetic model, the risk allele rs477515 (OR = 2.246, P = 0.0159) and the WGRS (OR = 1.644, P < 0.0001) were significantly different between the groups with high and low viral loads. In the mixed model, sex, rs477515, and WGRS were significantly different in the groups with high and low viral loads (Table 5).

The AUC of the HBV viral load was 0.674 (P < 0.0001) for the nongenetic model, 0.632 (P < 0.0001) for the genetic model, and 0.704 (P < 0.0001) for the mixed model (Figure 3 and Table 5). The results suggest that both genetic and nongenetic factors

had an effect on HBV viral load. Both the IDI (0.042, 95%CI: 0.019-0.065, $P = 0.0003$) and the NRI (0.440, 95%CI: 0.236–0.644, $P < 0.0001$) indicated that the mixed model represented a significant improvement (Table 5).

DISCUSSION

In this HCC family cohort, we found that both genetic and nongenetic factors were significantly associated with persistent HBV infection. In addition, HBV-related SNPs in the HLA-DP and HLA-DQ regions were associated with HBV viral load. GWASs conducted in diverse Asian populations have revealed that the HLA-DP and -DP loci play roles in persistent HBV infection[10-19]. We evaluated persistent HBV infection in the first-stage HCC family study. Expression of four of the five HBV-related SNPs differed significantly between the HBsAg carriers and the noncarriers. When only the risk alleles of the four SNPs were included in the univariate analysis, the OR for

[1]Each single nucleotide polymorphism was added in the mixed model.
[2]The weighted genetic risk score was added in the mixed model. AUC: Area under the receiver operating characteristic curve; GEE: Generalized estimating equation; IDI: Integrated discrimination improvement; NRI: Net reclassification improvement; CI: Confidence interval; HBsAg: Hepatitis B surface antigen; OR: Odds ratio.

persistence was significant if the WGRS was > 7 (Table 2, upper panel). In the genetic model, multivariate GEE analysis found that expression of one SNP (rs9277535) and the WGRS were significantly different between HBsAg carriers and noncarriers, and the differences remained significant in the presence of nongenetic factors (Table 3). Regression analysis showed that HBV-related SNPs were associated with persistent HBV infection in these HCC families. This is the first study to confirm that SNPs identified by GWAS were associated with persistent HBV infection in a family cohort.

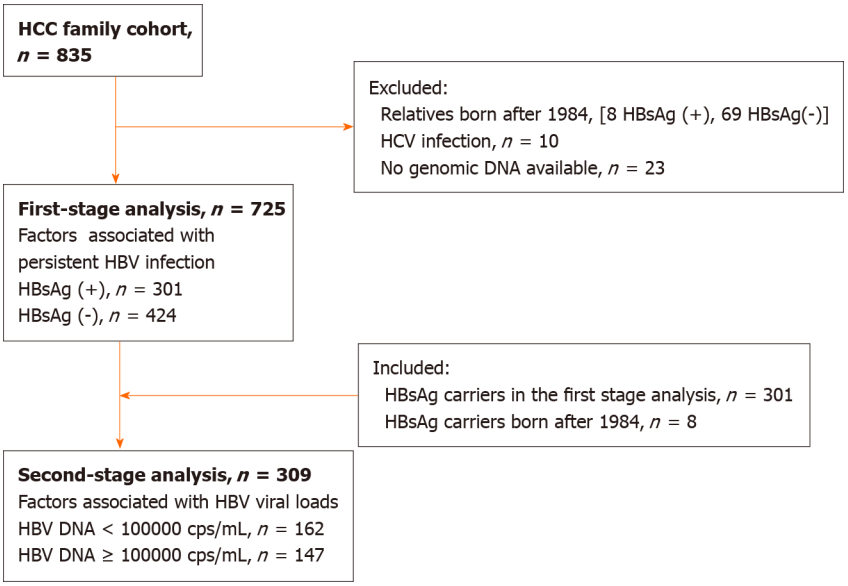

Figure 1 Study flow chart. Hepatitis B virus persistent infection and viral load were analyzed in a hepatocellular carcinoma family cohort. HCC: Hepatocellular carcinoma; HBV: Hepatitis B virus; HCV: Hepatitis C virus; HBsAg: Hepatitis B surface antigen.

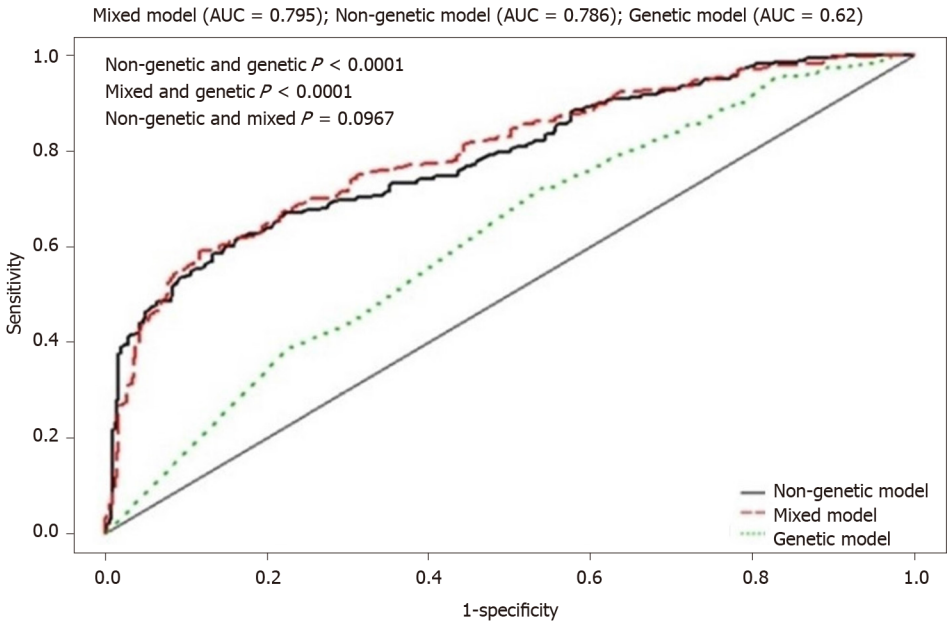

Figure 2 First-stage persistent hepatitis B virus infection. Genetic, nongenetic, and combined risk factors for persistent hepatitis B virus (HBV) infection were evaluated by area under the receiver operating characteristic curves derived from generalized estimating equation regression models. Significantly higher areas under the curve for nongenetic compared with genetic factors ($P < 0.001$) suggest that nongenetic factors played a major role in persistent HBV infection. AUC: Area under the receiver operating characteristic curve.

Nongenetic factors also affected persistent HBV infection. Age, sex, generation, index HBsAg status, and maternal HBsAg status all differed significantly between HBsAg carriers and noncarriers (Table 1). The AUC was 0.786 in the nongenetic model, 0.620 in the genetic model, and 0.795 in the mixed model (Table 3). The ROC analysis thus implied that nongenetic factors contributed more to persistent HBV infection than genetic factors did (genetic *vs* nongenetic factors $P < 0.0001$ and mixed *vs* nongenetic factors $P < 0.0001$; Figure 2). The results are consistent with exposure to HBV early in life and an important influence on the persistence of HBV infection[5-7]. Our overall findings indicate that the HCC family members may have been exposed to HBV early in life because of the high HBsAg prevalence in the index cases and/or their mothers. Accounting for both genetic and nongenetic cofactors, the prevalence of HBsAg was 41.5% (301/725) in this HCC family cohort.

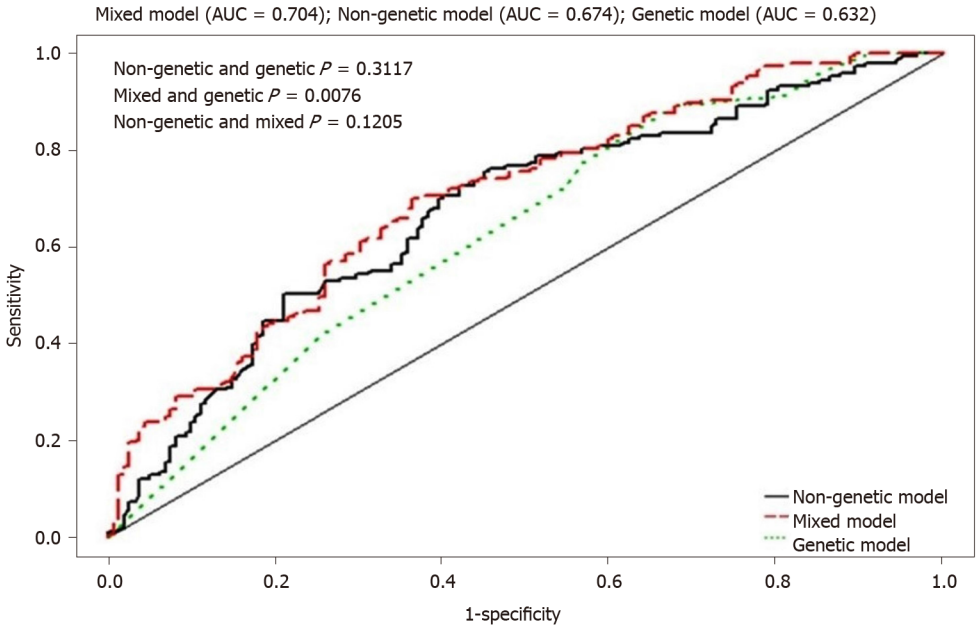

Figure 3 Second-stage hepatitis B virus viral load. The genetic, nongenetic, and combined risk factors for hepatitis B virus (HBV) viral load were evaluated by area under the receiver operating characteristic curves derived from generalized estimating equation regression models. The difference between the receiver operating characteristic curves of genetic and nongenetic factors was not significant (P = 0.3117). The finding suggests that both factors contributed to the HBV viral load. AUC: Area under the receiver operating characteristic curve.

In the presence of SNPs identified in a GWAS, nongenetic factors remain important in persistent HBV infection. The persistence of infection induced by the SNPs might depend on a delay in clearance of the HBeAg. It is known that in HBsAg carriers, HBeAg clearance occurs earlier in African than in Asian populations[22-25]. That means East Asians of reproductive age are likely to have higher HBV viral loads and a higher rate of perinatal HBV infection of their babies[7,10,22,23]. Perinatal infection usually persists as a chronic infection[7,23]. As African women usually clear HBeAg before reproductive age[24,25], the viral load during pregnancy is likely to be lower than that in East Asians, which would decrease the chance of perinatal HBV infection [24]. We suspect that a prolonged HBV replication phase in parents could be the mechanism of persistent HBV infection associated with SNPs.

Univariate analysis of the factors associated with HBV viral load in the HCC family cohort revealed that three of the five SNPs (rs477515, rs9272105, rs7756516) differed significantly between the high and low viral load groups (Table 4). The cumulative effect of the WGRS was also greater in the high viral load group (Table 3, lower panel). Multivariate GEE analysis found that the rs477515 SNP (OR = 2.242, P = 0.0238) and WGRS (OR = 1.567, P < 0.0001) were independently associated with a high viral load in the mixed model (Table 5). Our data thus support the prevailing view that the SNPs associated with persistent HBV infection promote persistent HBV replication. The mean ages of our study groups ranged from 41.25-45.03 years (Tables 1 and 4). Persistent high viral loads in these age groups were likely to have resulted in perinatal transmission of chronic HBV infection during the reproductive age.

Our previous study demonstrated that nongenetic factors influenced the HBV viral load in HCC families[10]. In this study, we observed that sex, generation, and index HBsAg cases were associated with a high viral load in the nongenetic model (Table 4). We also compared the relative contributions of genetic and nongenetic factors associated with viral load in the HCC family cohort. The AUCs of the viral load were 0.674 in the nongenetic model and 0.632 in the genetic model. The AUC in the mixed model was up to 0.704 (Table 5). Therefore, both genetic and nongenetic factors were associated with HBV viral load in the HCC family cohort. It should be noted that we included only SNPs in the HLA region. The association of other loci, such as polymorphisms of interferon gamma, complement factor B, CD40, and INST10, which have also been reported to be associated with HBV viral load, was not investigated[33-35].

One of the five SNPs we evaluated, rs9277535, was reported by Tao *et al*[36] to be associated with more aggressive liver disease, but it was reported by Li *et al*[37] not to be associated with disease progression. Our previous GWAS revealed that rs9276370 was associated with HBV therapeutic response[17]. Univariate analysis found that the

two SNPs were not significantly associated with viral load in this HCC family cohort. Two previous studies found that rs477515 was associated with HBV vaccine response [38,39], and that SNP was found to be associated with viral load in this cohort. Li *et al* [26] reported that rs9272105 was associated with HCC in a GWAS, and univariate analysis found that it was associated with viral load in this HCC family cohort. All these previous reports suggest that a single SNP provides a small contribution to HBV viral loads. Persistent HBV replication seems to be determined by multiple genetic and nongenetic risk factors.

This study provides information that may help to establish more accurate models of disease through the incorporation of genetic and nongenetic factors, but it was limited by the relatively small number of HCC families. Another limitation was that HBV genotype studies were not available in patients with low viral loads. HBV genotype C has been associated with a lower HBeAg clearance rate than genotype B[40]. We found a high adjusted OR (2.066, P = 0.0515) for the association of genotype C with a high viral load relative to a low viral load in this HCC family cohort (Table 4).

CONCLUSION

We conclude that SNPs associated with persistent HBV infection prolong the replication phase in the parent generation and increase the burden of persistent infection in the offspring generation.

ARTICLE HIGHLIGHTS

Research background

Genome-wide association studies (GWASs) in Asian populations indicate that the HLA-DP and HLA-DQ loci are involved in the persistence of hepatitis B virus (HBV) infections. Persistent viral replication and inflammation are key influencers in HBV-related carcinogenesis.

Research motivation

HBV-related single nucleotide polymorphisms (SNPs) have been identified in east Asian populations but are uncommon in African populations. Different mechanisms may drive persistent infection in those regions.

Research objectives

We examined genetic and nongenetic factors associated with persistent HBV infection and viral load in families with hepatocellular carcinoma (HCC).

Research methods

HCC families were enrolled. Five HBV-related SNPs (rs477515, rs9272105, rs9276370, rs7756516, and rs9277535) were genotyped. Factors associated with persistent HBV infection and viral load were identified with the use of generalized estimating equations.

Research results

In the first-stage persistent HBV study, all SNPs except rs9272105 were associated with persistent infection. A significantly higher contribution of nongenetic than genetic factors (P < 0.001) to persistent HBV infection was found. In the second-stage viral load study, sex, relationship with index case, rs477515, rs9272105, and rs7756516 were associated with viral load. Receiver operating characteristic curve, and genetic and nongenetic factors had equal effects on viral load in the HCC family cohort (P = 0.3117).

Research conclusions

GWAS identified SNPs that have roles in persistent HBV infection and HBV viral loads in an HCC family cohort. Nongenetic factors were more important than genetic factors in persistent HBV infection but had equal contributions to HBV viral load. HBV-related SNPs resulting in high viral loads in parents may drive persistent infection in East Asian populations. The mechanism of persistent HBV infection-related SNPs involves a prolonged viral replication phase in East Asian adults.

Research perspectives

Termination of the HBV replication phase before pregnancy will be a therapeutic goal in East Asian countries.

Abstract

BACKGROUND

Little is known about the engagement in hepatitis C virus (HCV) care and completion of HCV treatment in people living with human immunodeficiency virus (HIV) (PLWH) who have HCV coinfection in the Asia-Pacific region. Examining the HCV care cascade can identify barriers to the completion of HCV treatment and facilitate achievement of HCV micro-elimination in PLWH.

AIM

To investigate the care cascade of incident HCV infections among PLWH in

Institutional review board statement: This retrospective study was approved by the Research Ethics Committee of National Taiwan University Hospital (registration number: 201605103RINC and 201605128RINC).

Informed consent statement: Written informed consents were obtained from all included participants prior to study inclusion.

Conflict-of-interest statement: The authors have no competing interest to disclose.

Data sharing statement: The datasets generated and/or analyzed during the current study are available from the corresponding author upon reasonable request.

METHODS

PLWH with incident HCV infections, defined as HCV seroconversion, were retrospectively identified by sequential anti-HCV testing of all archived blood samples at National Taiwan University Hospital between 2011 and 2018. All PLWH with incident HCV infections were followed until December 31, 2019. The care cascade of HCV examined included all incident HCV-infected patients, the percentages of anti-HCV antibodies detected by HIV-treating physicians in clinical care, plasma HCV RNA load tested, HCV RNA positivity diagnosed, referral to treatment assessment made, anti-HCV treatment initiated, and sustained virologic response achieved. Those who had HCV seroconversion during the interferon (IFN) era (2011–2016) and the direct-acting antiviral (DAA) era (2017–2018) were analyzed separately. The duration of HCV viremia—from the date of seroconversion to viral clearance by treatments or until the end of observation—and the incidence of sexually transmitted infections (STIs) during the HCV viremic period were estimated.

RESULTS

During the study period, 287 of 3495 (8.2%) PLWH (92.3% being men who have sex with men) who were HCV-seronegative at baseline developed HCV seroconversion by retrospective testing of all archived blood samples. Of the 287 incident HCV infections, 277 (96.5%) had anti-HCV antibodies detected by HIV-treating physicians, 270 (94.1%) had plasma HCV RNA determined and 251 (87.5%) tested positive for HCV RNA. Of those with HCV viremia, 226 (78.7%) were referred to treatment assessment, 215 (74.9%) initiated anti-HCV treatment, and 202 (70.4%) achieved viral clearance. Compared with that in the IFN era, the median interval from HCV seroconversion by retrospective testing to detection of HCV seropositivity by HIV-treating physicians was significantly shorter in the DAA era {179 d [interquartile range (IQR) 87-434] *vs* 92 d (IQR 57-173); $P < 0.001$}. The incidence rate of STIs in the DAA *vs* the IFN era was 50.5 per 100 person-years of follow-up (PYFU) and 38.5 per 100 PYFU, respectively, with an incidence rate ratio of 1.31 (95% confidence interval 0.96-1.77), while the duration of HCV viremia was 380 d (IQR 274-554) and 735 d (IQR 391-1447) ($P < 0.001$), respectively.

CONCLUSION

While anti-HCV therapies are effective in achieving viral clearance, our study suggests more efforts are needed to expedite the linkage of PLWH diagnosed with incident HCV infections to HCV treatment.

Key Words: Recent hepatitis C virus infection; Cascade of care; Direct-acting antivirals; People living with human immunodeficiency virus; Sustained virologic response; Sexually transmitted infections

Core Tip: We examined the hepatitis C virus (HCV) care cascade among people living with human immunodeficiency virus who acquired incident HCV infections at a university hospital in Taiwan between 2011 and 2018. We observed high rates of linkage to HCV care and retention in care in both interferon (IFN, 2011 to 2016) and direct-acting antiviral (DAA, 2017 to 2018) eras. The rate of referral to treatment assessment had increased from the IFN era to the DAA era. Moreover, the duration of HCV viremia was markedly shortened because of early diagnosis and linkage to effective treatment in the DAA era compared to that in the IFN era.

INTRODUCTION

Viral hepatitis is a major public health threat and approximately 2.3 million people living with human immunodeficiency virus (HIV) (PLWH) are coinfected with hepatitis C virus (HCV) globally[1-3]. Injection drug users (IDUs) have been the major contributors to HCV transmission[4]. In Asia-Pacific region, the prevalence of HCV coinfection among PLWH ranges from 3.8% to 42.6%, and may be as high as 80.8% to 98.5% among IDUs[5,6]. Since 2000, incident HCV infections among PLWH who are MSM have continued to increase in the United States, European countries, and Australia[7-9]. Similar increasing trends were observed among PLWH who are MSM in Asia-Pacific region[10,11]. The causes of the increases of HCV transmission among MSM are multifactorial and are related to concurrent sexually transmitted infections (STIs), unprotected anal intercourse, traumatic sexual contacts, and use of recreational drugs by inhalation or injection[12].

The evolution of HCV treatment from interferon (IFN)-based therapy to IFN-free direct-acting antivirals (DAAs) has significantly improved tolerability and effectiveness in achieving viral clearance[13]. The rates of viral clearance with DAAs are similarly high for HCV-monoinfected patients and HCV/HIV-coinfected patients in clinical trials and real-world experience[14-18]. With the introduction of effective DAAs, ending the HCV epidemic is considered an achievable goal by scaling up diagnosis and treatment of HCV infection[1]. Among the interventional strategies proposed to achieve hepatitis elimination, the continuum assessed by the "cascade of care" on the population level is suggested to evaluate the status of hepatitis treatment services and the level of engagement in care[19,20]. The proportion of patients in each step of the cascade—infected, tested, status confirmed, engagement in care, treatment initiated, cured, and followed up for chronic care—reflects the coverage of diagnosis, access to treatment, and quality of care.

In Taiwan, pegylated IFN plus ribavirin (PEG-IFN/RBV) has become the standard anti-HCV treatment regimen since 2004 and has been fully reimbursed by the National Health Insurance (NHI) since 2009[21,22]. DAAs were not available until 2017, when the regimens were restricted to individuals with chronic HCV infection with evidence of significant hepatic fibrosis. Generic versions of patented DAAs could be purchased for individual use from Bangladesh[23]. Before 2019, referral to a hepatologist for hepatitis C evaluation and treatment was required according to NHI regulations. The reimbursement restrictions on the use of DAAs were lifted in January of 2019 by allowing HCV viremic patients to initiate DAAs regardless of liver fibrosis status. Subsequently, PLWH with HCV viremia could be evaluated and DAAs initiated by HIV-treating physicians at infectious disease clinics.

In this study, we aimed to examine the HCV care cascade among PLWH who received a diagnosis of incident HCV infection at a university hospital in Taiwan.

MATERIALS AND METHODS

Study design and data collection

We retrospectively reviewed the medical records of all PLWH aged 18 years or older seeking medical care for HIV at the National Taiwan University Hospital (NTUH), the largest designated hospital for HIV inpatient and outpatient care in Taiwan, from January 2011 to December 2018; and those included were followed until death, loss to follow-up, transfer of care, or the end of the study on December 31, 2019, whichever occurred first. The study period (2011-2018) spanned two different eras of anti-HCV treatment, from the IFN/RBV era (2011-2016) to the DAA era (2017-2018) before restricted access to HCV treatments were completely lifted in early 2019. In this study, the IFN-based regimen was PEG-IFN plus weight-based RBV with response-guided treatment duration. From 2016 to 2018, generic versions of patent IFN-free DAAs (sofosbuvir/velpatasvir) were used for treatment of recently acquired HCV infection.

Anti-HCV antibodies were detected using a fourth-generation enzyme immunoassay (Dia.Pro Diagnostic Bioprobes Srl. Italy)[11] and the HCV serostatus of the first available blood samples during the study period were regarded as the baseline serostatus. For those with a negative anti-HCV status at baseline, anti-HCV testing of

all their archived blood samples were performed retrospectively on an annual basis to detect HCV seroconversion. Patients who developed HCV seroconversion within the past 12 mo were identified as having recently acquired HCV infection and were included in this study.

The date of HCV seroconversion was arbitrarily assigned as the mid-point between the dates of the first positive and the last negative anti-HCV test. Using a standardized case record form, we collected data on patient demographics, HIV transmission risk groups, and laboratory test results, including CD4 lymphocyte count and plasma HIV RNA load (PVL), hepatitis B surface antigen (HBsAg), rapid plasma reagin (RPR) titer, plasma HCV RNA load and genotype when HCV viremia was detected.

The study was approved by the Research Ethics Committee of the hospital (registration number: 201605103RINC and 201605128RINC) and informed consent was obtained from all the participants.

Definitions

The HCV care cascade comprised the following steps of care: (1) "HCV infected" included all seroconverters in the past 12 mo identified by testing of archived blood samples; (2) "antibody detected" defined as a confirmed anti-HCV-positive test identified by HIV-treating physicians and documented in the medical records; (3) "HCV RNA tested" as the performance of a plasma HCV RNA test either after a positive anti-HCV test or when HCV viremia is detected during an acute infection with a negative anti-HCV test; (4) "HCV RNA positivity" as detectable plasma HCV RNA at the time of testing; (5) "Referred to treatment assessment" as successful referral of HCV-infected individuals to a hepatology clinic for evaluation of liver fibrosis or HCV treatment; or completion of pretreatment blood testing in infectious disease clinics as required by NHI regulation in 2019, including evaluation of liver fibrosis, renal function, HCV genotype, and plasma HCV RNA load[16]; (6) "Treatment initiated" as patients who had been prescribed HCV treatment medications; and (7) "Sustained virologic response (SVR) achieved" as the state of persistently undetectable HCV RNA until 24 wk after completion of IFN-based regimens and 12 wk after completion of DAA treatments.

The durations between two consecutive steps of the care cascade were recorded. Those who had HCV seroconversion during the IFN era (2011–2016) and the DAA era (2017–2018) were analyzed separately for comparison of the proportion of patients attaining each step and the interval between two consecutive steps of the cascade. The total duration of HCV viremia was defined as the interval between the estimated date of HCV seroconversion to the end of HCV treatment in those with undetectable HCV RNA; those who did not achieve SVR were followed until the completion of re-treatment with undetectable HCV RNA, the end of observation, or loss to follow-up, whichever occurred first.

The number of STIs, including syphilis (defined as a four-fold increase of RPR titers, consistent clinical symptoms, or administration of syphilis treatment), and gonorrhea (defined as culture-confirmed *Neisseria gonorrhoeae* infection or consistent clinical symptoms and administration of gonorrhea treatment), during the defined intervals of HCV viremia was calculated. We used occurrences of STIs as surrogate markers for unprotected sex contacts of the included PLWH during the HCV viremic period without effective treatment to indicate the risk for onward transmission of HCV.

Statistical analysis

The cascade of care after diagnosis of recently acquired HCV infection was examined by each step using descriptive analysis. Comparisons of categorical variables were performed by chi-square analysis and those of continuous variables by a Mann-Whitney *U* Test. The incidence rate of STIs during HCV viremia was calculated as the number of STIs per 100 PYFU. All analyses were two-tailed, and a $P < 0.05$ was considered statistically significant. All statistical analyses were performed using Stata/SE, version 14.0. The statistical methods of this study were reviewed by the staff of National Taiwan University Hospital–Statistical Consulting Unit (NTUH-SCU).

RESULTS

Between January 2011 and December 2018, 3,495 PLWH had a negative anti-HCV antibody test at baseline (Figure 1) and HCV seroconversion was detected in 294 (8.4%) PLWH. After excluding 7 PLWH who were lost to follow-up when seroconversion occurred, a total of 287 PLWH were included in the analysis of the HCV care

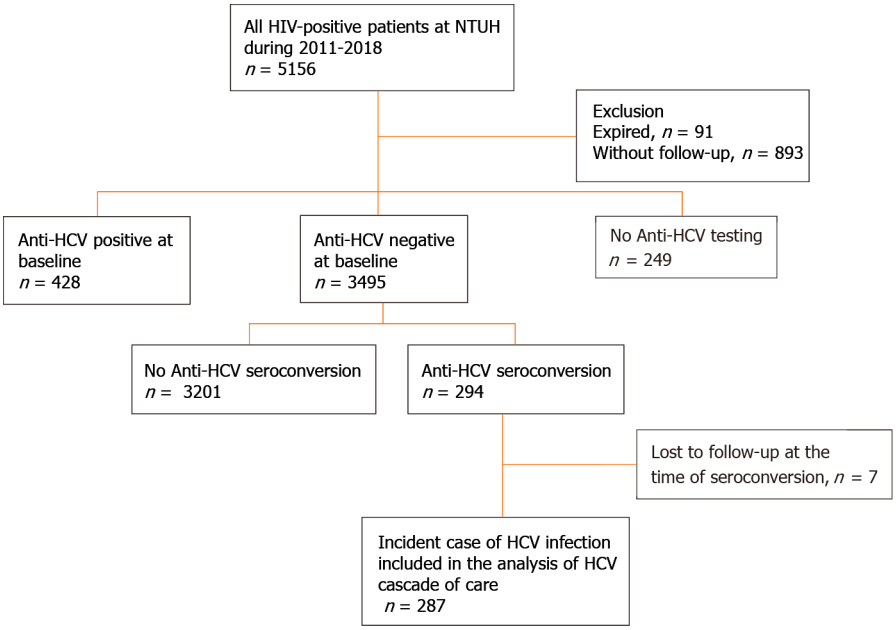

Figure 1 Patient flow. Between 2011 and 2018, 3495 people living with human immunodeficiency virus (HIV) (PLWH) had negative anti-hepatitis C virus (HCV) antibody tests at baseline and HCV seroconversion was detected in 294 (8.4%) PLWH. After excluding 7 PLWH who were lost to follow-up when HCV seroconversion occurred, a total of 287 PLWH were included in the analysis of the care cascade of incident HCV infections. HIV: Human immunodeficiency virus; NTUH: National Taiwan University Hospital; HCV: Hepatitis C virus.

cascade.

The clinical characteristics of the included 287 PLWH with recently acquired HCV infection are shown in Table 1. All of them were male, with a mean age of 34.5 years [standard deviation (SD) 7.6]. The mean PVL was 1.72 $\log_{10}$ copies/mL (SD 1.09) and mean CD4 count was 597.7 cells/mm^3 (SD 251.1) at the time of HCV seroconversion. The HBsAg seropositivity rate was 14.9% and active or previous syphilis was present in 89.2%. The risk groups of HIV acquisition included 265 (92.3%) MSM, 5 (1.8%) heterosexuals, 4 (1.4%) IDUs, and 13 (4.5%) unknown. The mean plasma HCV RNA load was 5.72 $\log_{10}$ copies/mL (SD 1.50). Twenty-two (7.7%), 84 (29.3%), 119 (41.5%), 6 (2.1%), and 34 (11.8%) PLWH had infection with HCV genotypes 1a, 1b, 2a, 3, and 6, respectively, and 3 (1%) had mixed infections of genotypes 1b and 2.

Of the 287 PLWH, 277 (96.5%) were found to have HCV seroconversions by HIV-treating physicians, including 8 diagnosed at the stage of acute infection with positive HCV RNA and negative anti-HCV antibody. Plasma HCV RNA load was determined in 270 (94.1%) PLWH after seroconversion, with 19 (12.5%) clearing viremia spontaneously and 251 (87.5%) remaining viremic (Table 2). Overall, 226 (78.7%) PLWH were referred to hepatology clinics for treatment assessment, and anti-HCV treatments were initiated in 215 (74.9%) PLWH, of whom 202 (70.4%) achieved SVR (Table 2).

Compared with PLWH who had HCV seroconversion in the IFN era (2011–2016), those who seroconverted in the DAA era (2017–2018) had higher achievement rates of all sequential steps of the care cascade (Figure 2), though not reaching statistical significance. The rate of antibody diagnosis within one year of HCV seroconversion was significantly higher in the DAA era than that in the IFN era (88.2% *vs* 69.5%; $P < 0.001$) (Figure 2). In the IFN era, the major gap of engagement in care was from HCV RNA positivity to referral for assessment and treatment, which resulted in a loss of 11.8% of those found to be HCV viremic.

The median interval from seroconversion to detection of HCV seropositivity by HIV-treating physicians was 130 d [interquartile range (IQR), 80-295], which was significantly shorter in the DAA era than in the IFN era [92 d (IQR, 57-173) *vs* 179 d (IQR 87-434); $P < 0.001$] (Table 2, Figure 3). From detection of HCV seropositivity to HCV RNA testing, the interval was 21 d (IQR 6-39) and 12 d (IQR 6-68) in the IFN and DAA eras, respectively ($P = 0.19$). The intervals from HCV RNA testing to treatment assessment and from assessment to treatment initiation were longer in the DAA era compared with those in the IFN era, 81 d (IQR 14-169) *vs* 26 d (IQR 7-208), and 42 d (IQR 18-84) *vs* 35 d (IQR 27-90), which were not statistically significantly different ($P = 0.25$ and $P = 0.55$, respectively). The duration of viremia was 735 d (IQR 391-1447) in the IFN era, which was significantly longer than that in the DAA era (380 d; IQR 274-

554; $P < 0.001$).

Among the HCV seroconverters in the IFN era, a total of 165 episodes of STIs were observed in the entire HCV viremic duration of 428.2 PYFU, resulting in an incidence rate of 38.5 per 100 PYFU. In the DAA era, the HCV seroconverters acquired a total of 55 episodes of STIs during 108.8 PYFU of viremia, leading to an incidence rate of 50.5 per 100 PYFU. The incidence rate ratio (IRR) of STIs in the DAA era *vs* the IFN era was 1.31 (95%CI 0.96-1.77).

Figure 4 demonstrates the breakdown of HCV treatment uptake by year. The annual number of PLWH with HCV viremia who received IFN-based therapy was unchanged from 2012 to 2016. With the introduction of DAAs in 2016, the number of PLWH receiving DAA treatment increased year by year, especially in 2019, when restrictions on DAA reimbursement were lifted and all HCV viremic patients could be treated with DAAs.

Table 2 Care cascade of incident hepatitis C infections among people living with human immunodeficiency virus in the interferon and direct-acting antiviral eras

	Total 2011-2018, *n* = 287	Seroconversion in		*P* value
		2011-2016 IFN era, *n* = 176	2017-2018DAA era, *n* = 111	
Antibody detected, *n* (%)[1]	277 (96.5)	167 (94.9)	110 (99.1)	0.09
HCV RNA tested, *n* (%)[1]	270 (97.5)	162 (97.0)	108 (98.2)	0.08
HCV RNA positivity, *n* (%)[1]	251 (93.0)	152 (93.8)	99 (91.7)	0.48
Referred to treatment assessment, *n* (%)[1]	226 (90.0)	134 (88.2)	92 (92.9)	0.17
Treatment initiated, *n* (%)[1]	215 (95.1)	131 (97.8)	84 (91.3)	0.81
SVR achieved, *n* (%)[1]	202 (94)	120 (91.6)	82 (97.6)	0.19
Interval between each step, median days (IQR)				
Seroconversion to antibody detected	130 (80-295)	179 (87-434)	92 (57-173)	< 0.001
Antibody detected to HCV RNA tested	19 (6-81)	21 (6-93)	12 (6-68)	0.19
HCV RNA tested to treatment assessment	43 (11-181)	26 (7-208)	81 (14-169)	0.25
Treatment assessment to treatment initiation	36 (21-90)	35 (27-90)	42 (18-84)	0.55
Duration of viremia[2]	502 (325-945)	735 (391-1447)	380 (274-554)	< 0.001
Events of STIs during HCV viremia	220	165	55	< 0.001
Incidence rate of STIs during HCV viremia, (per 100-PYFU)	41.0	38.5	50.5	0.09

[1]Percentage that moved from the previous step to current step of care cascade.

[2]From the time of seroconversion to end of treatment. DAA: Direct-acting antiviral; IFN: Interferon; IQR; Interquartile range; PYFU: Person-years of follow-up; STIs: Sexually transmitted infections; SVR: Sustained virologic response.

DISCUSSION

In this study, we observed high rates of linkage to HCV care and retention in the care system among PLWH at our institution, in both the IFN and DAA eras. The retention rates between each step of the care cascade after detection of incident HCV infection primarily exceeded 90% (Figure 2). A major barrier noted in the IFN era was referral to treatment assessment (88.2%) after detection of HCV viremia, while this gap seemed diminished in the DAA era. In addition, the duration of HCV viremia, from seroconversion to completion of HCV treatment, was markedly shortened in the DAA era compared to that in the IFN era (380 d *vs* 735 d; $P < 0.001$). The improvement was mainly due to early diagnosis of recently acquired HCV infection by HIV-treating physicians because the diagnostic rate within one year after seroconversion increased from 69.5% (116/167) to 88.2% (97/110), and the median time from seroconversion to antibody diagnosis was shortened from 179 d to 92 d ($P < 0.001$).

The occurrence of STIs during HCV viremia represented risky sexual behavior, potentially resulting in onward transmission of HCV to their contacts. The incidence rate of STIs observed in the DAA era was higher than that in the IFN era, though not reaching statistical significance (50.5 *vs* 38.5 per 100 PYFU; IRR 1.31, 95%CI 0.96-1.77). In contrast, the total number of STI episodes was far fewer in the DAA era *vs* the IFN era (55 episodes among 111 patients *vs* 165 episodes among 176 patients, respectively), likely due to a shorter duration of HCV viremia. The curtailing of HCV viremia with the initiation of effective DAAs may indicate reduced opportunities to transmit HCV during the viremic period.

There are limited data to describe the care cascade after incident HCV infections were diagnosed both in the general population and in HCV-coinfected PLWH in the Asia-Pacific region. In our study, we tested archived blood samples to include all patients who had recent HCV infections in the previous year and estimated the time of seroconversion. In doing so, we could assess the rate of antibody diagnosis of HCV infection by treating physicians, the interval of delay in clinical diagnosis, and the duration of HCV viremia before effective anti-HCV treatments were initiated. Prior population-level studies of the care cascade either estimated the seroprevalence of

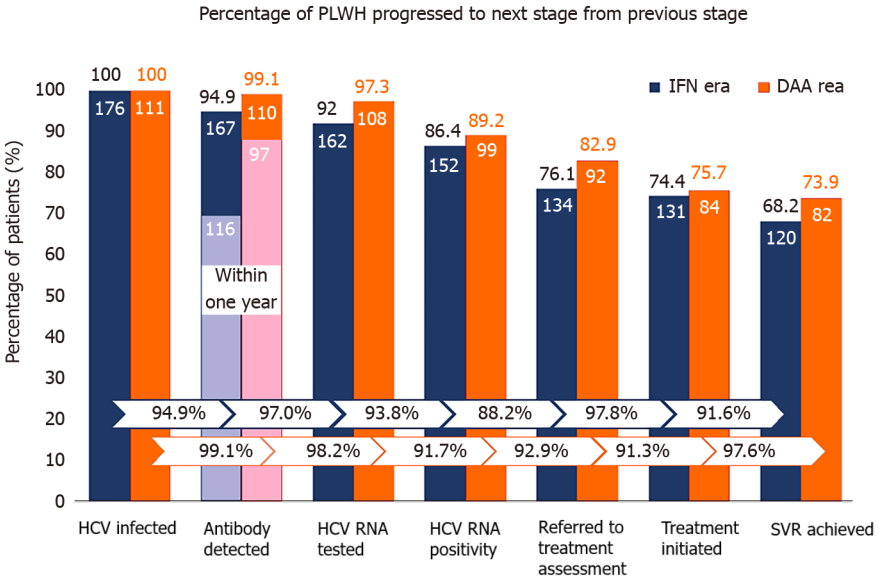

Figure 2 Care cascade of incident hepatitis C virus infections in the interferon and direct-acting antiviral eras. In the interferon era (blue columns), 176 people living with human immunodeficiency virus (HIV) (PLWH) had incident hepatitis C virus (HCV) infections by retrospective testing of all archive blood samples; 167 (94.9%) were found to have HCV seroconversion by HIV-treating physicians; and the diagnostic rate within one year after seroconversion was 69.4% (116 out of 167). Plasma HCV RNA was tested in 162 (97.0%) PLWH after seroconversion, of which 152 (93.8%) were viremic. A total of 134 (88.2%) viremic PLWH were referred to hepatology clinics; anti-HCV treatments were initiated in 131 (97.8%), and 120 (91.6% of all treated PLWH) achieved sustained virologic response (SVR). In the direct-acting antiviral era (orange columns), 111 PLWH had incident HCV infections; 110 (99.1%) were found to have HCV seroconversion by HIV-treating physicians; and the diagnostic rate within one year after seroconversion was 88.2% (97 out of 110). Plasma HCV RNA was detected in 108 (98.2%) PLWH after seroconversion and 99 (91.7%) were viremic. A total of 92 (92.9%) viremic PLWH received treatment assessment, anti-HCV treatments were initiated in 84 (91.3%), and 82 (97.6% of all treated patients) achieved SVR. IFN: Interferon; DAA: Direct-acting antiviral; HCV: Hepatitis C virus; PLWH: People living with human immunodeficiency virus.

HCV[24,25] or described the cascade since the diagnosis of anti-HCV positivity[26]. In single-center studies focusing on HCV-coinfected PLWH, the actual numbers of HCV infections were not shown in the care cascade[27,28].

Previous population-based care cascade assessments for HCV infection in the IFN era revealed low rates of retention in care and treatment initiation, probably related to concerns about inconvenience, lower effectiveness, intolerability, and higher rates of adverse effects with IFN/RBV treatment. The antibody diagnostic rate was 50% to 75%; HCV RNA testing was performed in 30 to 50% of patients; less than 20% of patients received HCV treatment; and the final SVR rate was lower than 10%[24,25]. At our institution during the IFN era, the antibody diagnosis, HCV RNA testing, treatment initiation, and SVR rates were 94.9%, 92.0%, 74.4%, and 68.2%, respectively, much higher than those of previous population-level studies. We believe that regularly scheduled follow-up visits for fully-reimbursed HIV antiretroviral treatments in the majority of PLWH might have provided an opportunity to facilitate HCV testing and increase engagement of HCV care[29,30]. However, mandatory referrals to a hepatologist for HCV pretreatment assessment and management may have raised the barrier to anti-HCV treatment initiation and achievement of viral clearance, as such a requirement negatively impacts convenience and costs, thereby potentially increasing the risk of dropout from HCV care. This barrier has diminished since 2019 when NHI approved HIV-treating physicians to participate in HCV assessment and treatment for PLWH at infectious disease clinics. The rate of treatment assessment after HCV RNA positivity increased from 88.2% (134/152) in the IFN era to 92.9% (92/99) in the DAA era.

The introduction of DAAs has been shown to improve engagement of HCV care and treatment uptake. The British Columbia Hepatitis Tester Cohort demonstrated improvement of the care cascade in the DAA era. Of the patients who tested anti-HCV-positive, 83% had HCV RNA testing done; and, of those who were HCV viremic and were genotyped, 61% received DAA therapy, with 90% achieving SVR[31]. In a report from seven HCV elimination studies among PLWH in the early DAA era, the average treatment uptake increased to 48% and treatment completion rates reached 96%[32]. Our current study showed a significantly higher rate of linkage to care, with > 90% of PLWH consistently advancing from each cascade step to the next in the DAA era, which resulted in a total of 84.8% (84/99) viremic patients initiating anti-HCV

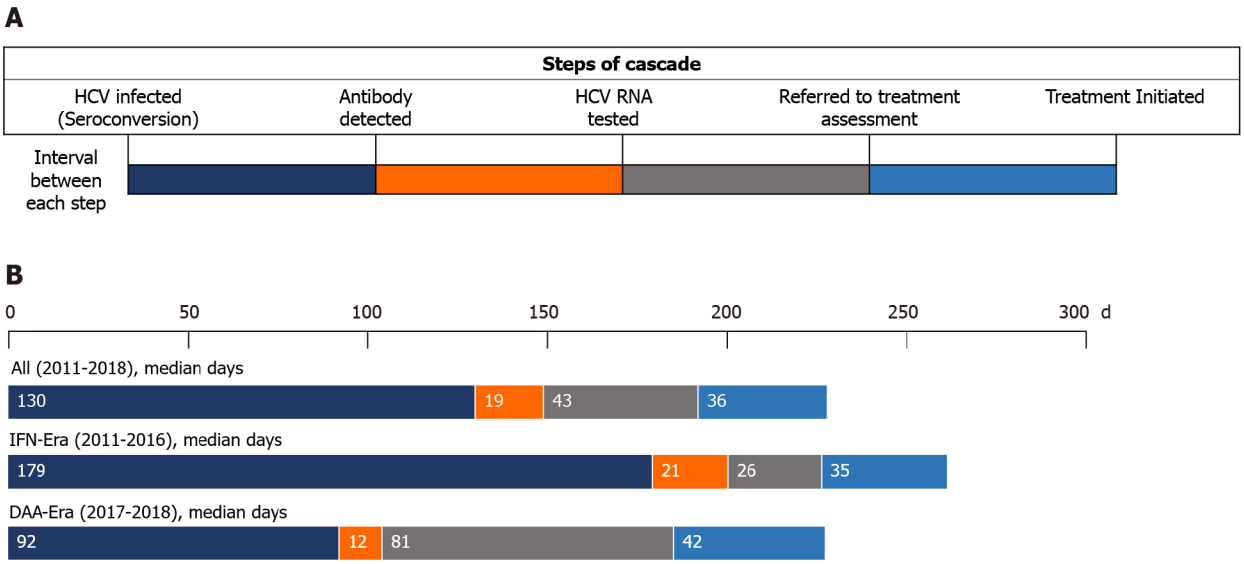

Figure 3 Intervals between steps of the care cascade of incident hepatitis C virus infections. A: Demonstration of the intervals between each step of the care cascade; B: In all included people living with human immunodeficiency virus (HIV) (PLWH), the median interval from seroconversion to detection of hepatitis C virus (HCV) seropositivity by HIV-treating physicians was 130 days, which was significantly shorter in the direct-acting antiviral (DAA) era (median 92 d) than that in the interferon (IFN) era (median 179 d) ($P < 0.001$). In the IFN era, the median interval from detection of HCV seropositivity to HCV RNA testing was 21 d, that from RNA testing to referral to treatment assessment was 26 d, and that from assessment to treatment initiation was 35 d. In the DAA era, the median interval from detection of HCV seropositivity to HCV RNA testing was 12 d, that from RNA testing to referral to treatment assessment was 81 d, and that from assessment to treatment initiation was 42 d. The differences in the intervals after antibody diagnosis were not statistically significant between PLWH included in the IFN era and those in the DAA era. HCV: Hepatitis C virus; IFN: Interferon; DAA: Direct-acting antiviral.

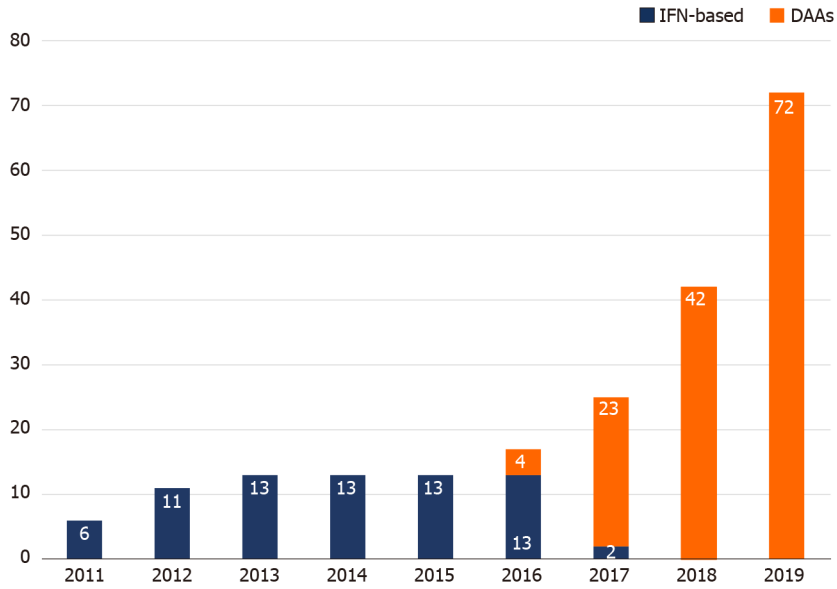

Figure 4 Hepatitis C virus treatment uptake by year from 2011 to 2019. The annual numbers of people living with human immunodeficiency virus (PLWH) who received interferon-based therapy were unchanged from 2012 to 2016. With the introduction of direct-acting antivirals (DAAs) since 2016, the number of PLWH receiving DAAs increased annually, especially in 2019, when the restrictions on the DAA reimbursement were lifted and all hepatitis C virus viremic patients could be treated with DAAs. DAA: Direct-acting antiviral; IFN: Interferon.

treatments, and 97.6% (82/84) achieving SVR. In the Swiss HIV Cohort Study, the treatment incidence increased from 4.5 per 100 PYFU before the availability of DAAs, to 22.4 per 100 PYFU after the introduction of second-generation DAAs[33]. These findings were in line with observations from our study. While the annual number of IFN-based therapy remained unchanged from 2012 to 2016, the number of DAA treatment initiated progressively increased from 2016 to 2018, which further rocketed in 2019, when the restriction on DAA reimbursement was lifted (Figure 4). During the period between 2016 and 2018, when access to DAA through NHI reimbursement

remained limited, generic DAAs could be purchased overseas by PLWH themselves; however, accessibility was limited by the cost incurred. During this period, we found that the median intervals from HCV RNA testing to referral to treatment assessment, and those from referral to treatment initiation were longer than those in the IFN era, though not reaching statistical significance (Table 2 and Figure 3).

There are several limitations in this study. First, the cascade of HCV care from this single-center study might not be generalizable to other institutions in Taiwan, given that discrepancies in the patients' demographic and clinical characteristics and socio-economic status may exist. At our institution, PLWH with recent HCV infection were mainly MSM, accounting for more than 90% of the included patients, while the percentages of heterosexual and IDUs were both lower than 2%. Prior studies suggested from an assessment of the HCV care cascade in IDUs that active drug users had poorer treatment adherence, resulting in lower rates of viral clearance[34-36]. Second, our study did not investigate factors that may be associated with failure of engagement in the HCV care cascade. Third, HCV reinfection, which can occur in this high-risk group[37-39], were not included in the analyses of the HCV care cascade.

CONCLUSION

In conclusion, we describe the HCV care cascade at a referral hospital in Taiwan from the IFN era to the DAA era. The rates of engagement in each step of the HCV care cascade were high in both eras and the barriers to referral and reimbursement diminished over time. However, given both the longer intervals of HCV viremia observed in the DAA era and a higher incidence of STIs potentially contributing to onward transmission of HCV, more efforts are needed to expedite the linkage of PLWH diagnosed with incident HCV infections to HCV treatment.

ARTICLE HIGHLIGHTS

Research background

Recently acquired hepatitis C virus (HCV) infections are increasingly reported in people living with human immunodeficiency virus (HIV) (PLWH) who are men who have sex with men. With availability of highly effective direct-acting antivirals (DAAs) for the treatment of HCV, microelimination HCV is considered an achievable goal in this at-risk population.

Research motivation

To achieve microelimination of HCV in PLWH, each step of the continuum of HCV care, from diagnosis, linkage to and engagement in care, initiation of anti-HCV treatment, treatment completion, to prevention against reinfection, is crucial. Examining the HCV care cascade can identify barriers to the completion of HCV treatment and facilitate achievement of HCV micro-elimination in PLWH.

Research objectives

The study aimed to evaluate the care cascade of PLWH with recently acquired HCV infections at a university hospital designated for HIV care in Taiwan.

Research methods

The authors retrospectively reviewed the medical records of all PLWH testing negative for anti-HCV at baseline who developed anti-HCV seroconversion between 2011 to 2018 and were observed till the end of 2019. The number of people in each step of HCV care cascade was assessed and the duration between two sequential steps was estimated.

Research results

A total of 287 PLWH recently acquired HCV infections during the study period. High rates of linkage to HCV care and retention in the care were observed in our cohort. Compared with the interferon (IFN, 2011-2016) era, the barrier of referral to anti-HCV treatment assessment was diminished and the total duration of HCV viremia marked decreased in the direct-acting antiviral (DAA, 2017-2018) era.

Research conclusions

The achievement rates of engagement in each step of the HCV care cascade were high in both IFN and DAA eras and the barriers to referral and treatment initiation diminished over time.

Research perspectives

The impact of scale-up of HCV testing and DAA treatment after lifting the restriction on DAA reimbursement on the trends of incident HCV infections in PLWH warrants more long-term observation.

ACKNOWLEDGEMENTS

The authors would like to express their gratitude to the staff of National Taiwan University Hospital-Statistical Consulting Unit (NTUH-SCU) for statistical consultation and analyses.

Abstract

BACKGROUND

Helicobacter pylori (*H. pylori*) is a spiral-shaped bacterium responsible for the development of chronic gastritis, gastric ulcer, gastric cancer (GC), and MALT-lymphoma of the stomach. *H. pylori* can be present in the gastric mucosa (GM) in both spiral and coccoid forms. However, it is not known whether the severity of GM contamination by various vegetative forms of *H. pylori* is associated with clinical and morphological characteristics and long-term results of GC treatment.

AIM

To establish the features of *H. pylori* infection in patients with GC and their correlations with clinical and morphological characteristics of diseases and long-term results of treatment.

METHODS

Of 109 patients with GC were included in a prospective cohort study. *H. pylori* in the GM and tumor was determined by rapid urease test and by immunohistochemically using the antibody to *H. pylori*. The results obtained were compared with the clinical and morphological characteristics and prognosis of GC. Statistical analysis was performed using the Statistica 10.0 software.

RESULTS

H. pylori was detected in the adjacent to the tumor GM in 84.5% of cases, of which a high degree of contamination was noted in 50.4% of the samples. Coccoid forms of *H. pylori* were detected in 93.4% of infected patients, and only coccoid-in 68.9%.

It was found that a high degree of GM contamination by the coccoid forms of *H. pylori* was observed significantly more often in diffuse type of GC (P = 0.024), in poorly differentiated GC (P = 0.011), in stage T3-4 (P = 0.04) and in N1 (P = 0.011). In cases of moderate and marked concentrations of *H. pylori* in GM, a decrease in 10-year relapse free and overall survival from 55.6% to 26.3% was observed (P = 0.02 and P = 0.07, respectively). The relationship between the severity of the GM contamination by the spiral-shaped forms of *H. pylori* and the clinical and morphological characteristics and prognosis of GC was not revealed.

CONCLUSION

The data obtained indicates that *H. pylori* may be associated not only with induction but also with the progression of GC.

Key Words: Gastric cancer; *Helicobacter pylori*; Coccoid and spiral forms of bacteria; Rapid urease test; Relapse free survival; Overall survival

Core Tip: The role of *Helicobacter pylori* (*H. pylori*) in the progression of gastric cancer (GC) is not well understood. Our results indicate that in GC, a high degree of gastric mucosa contamination by coccoid forms of *H. pylori* is associated with advanced stages of the disease and deterioration of long-term results of treatment.

INTRODUCTION

Gastric cancer (GC) continues to be one of the most common malignant diseases in the world[1,2]. Despite a decreasing trend in the incidence of GC in most countries of the world, the treatment results of this pathology cannot be considered satisfactory. In the structure of mortality from malignant neoplasms, this pathology firmly occupies 2nd place in most developed countries of the world, and the 5-year survival rate of radically operated patients does not exceed 15%-30%[3,4].

It is important to note that it is impossible to improve the long-term results of malignant neoplasms treatment without knowledge of the mechanisms associated with their progression[3]. Clinical studies in recent years indicate that inflammatory infiltration of the tumor stroma and surrounding tissues can have an important prognostic value and affect the long-term results of malignant neoplasm treatment[5-9]. A number of studies have shown that inflammatory infiltration of the tumor stroma is associated with the body's adequate immune response to the tumor, and may be a favorable prognosis factor in various malignant neoplasms[10,11], including GC[12,13]. At the same time, the data obtained by other researchers indicates that pronounced inflammatory infiltration of the tumor stroma, especially T-reg lymphocytes and macrophages, may be a factor contributing to the progression of malignant neoplasms[14,15]. There was a decrease in the overall survival (OS) and relapse-free survival (RFS) of GC patients with a high content of Foxp3 + T-reg in the tumor stroma and regional metastases[16-18] and macrophages[16,19]. It is believed that inflammatory infiltration of the tumor stroma can contribute to tumor progression by activating the mechanisms of angiogenesis, expression of E- and L-selectins, formation of the products of lipid peroxidation and free radicals, destruction of connective tissue matrix and basement membranes of epithelia by proteolytic enzymes, and activation of epithelial-mesenchymal transformation[20-23].

When studying the role of inflammation in the progression of GC, it is impossible to ignore the problem of *Helicobacter pylori* (*H. pylori*) infection. *H. pylori* is a gram-negative, spiral-shaped bacterium, the habitat of which is the gastric mucosa (GM) and

duodenum. *H. pylori* differs from other bacteria in a set of properties that make it possible to colonize the GM and persist for a long time under conditions that are unfavorable for other microorganisms[24,25]. These include: (1) The ability to produce a special enzyme-urease; (2) Synthesis of lytic enzymes that cause the depolymerization and dissolution of gastric mucus, consisting mainly of mucin; (3) The mobility of the bacterium, which is ensured by the presence of 5-6 flagella; (4) The high adhesiveness of bacteria to GM epithelial cells of the GM and elements of connective tissue due to the interaction of bacterial ligands with the corresponding cells receptors; (5) Production of various exotoxins (VacA, CagA, and others); (6) Instability of the *H. pylori* genome; (7) The presence of vegetative and coccoid forms of bacteria; and (8) possibility of intracellular persistence and translocation outside the GM [26-29].

It should be noted that despite the huge number of studies devoted to *H. pylori*, it is still not clear whether *H. pylori* is involved only in the initiation of the tumor process in the stomach, or whether it can affect the mechanisms of tumor progression. The relationship between the severity of *H. pylori* infection and the clinical and morphological characteristics of GC and long-term results of this pathology treatment remains poorly studied, and in this connection, the question of the expediency of anti-Helicobacter therapy in patients with invasive GC remains open.

Objective

To assess the features of *H. pylori* infection in patients with Stage I-IIIB GC and their correlation with the clinical and morphological characteristics of the disease, the presence of antibiotic therapy (AT) before surgery, and long-term treatment results.

MATERIALS AND METHODS

The patients

One hundred and nine patients with GC who had undergone radical surgery (R0) between May 2007 and March 2010 at the Orenburg Regional Clinical Oncology Center, were included in this prospective cohort pilot study. Study inclusion criteria were: Histologically proven invasive GC; no evidence of distant metastases; radical surgery (R0); no prior gastric surgery; no previous chemotherapy or radiotherapy. The study did not include patients with decompensation of cardiovascular and renal diseases, exacerbation of chronic inflammatory processes, severe allergic processes, or who received glucocorticoids, antihistamines, and non-steroidal anti-inflammatory drugs. The study was performed in accordance with the Helsinki Declaration and internationally recognized guidelines, and the privacy of patients was protected by decoding the data according to the privacy regulations of the Orenburg Regional Clinical Oncologic Center (Russia, Orenburg). All patients provided written informed consent. The protocol was approved by the Institutional Review Board of the Orenburg State Medical University (Russia, Orenburg).

Clinical and pathological data including age, tumor localization, stage, type of surgery, histology, the presence of AT before surgery, postoperative therapy, and long-term results of treatment were retrieved from the routine reports for analyses. The distribution of patients according to the clinical and pathological characteristics of GC is presented in Table 1.

When interviewing patients, it was found that 45 patients received AT before admission to the clinic due to a preliminary wrong diagnosis of gastric ulcer or chronic gastritis. The following combinations of antibacterial drugs were most commonly ordered: Amoxicillin + clarithromycin (34 patients), amoxicillin + clarithromycin + metronidazole (6 patients), amoxicillin + metronidazole (3 patients), other drugs (2 patients). Information about the antibacterial drugs, the timing and duration of their intake was entered into the primary patient documentation and then taken into account in the analysis. We considered only those patients who underwent AT in the period from 1 to 1.5 mo before the operation, lasting at least seven days, and using two or more antibacterial drugs.

The long-term results of treatment were assessed for the period from May 12, 2007 to April 12, 2021. The median follow-up period was 86.2 mo. As of April 12, 2021, 26 (24.5%) patients were alive, 54 (50.9%) had died from the progression of GC, 20 (18.9%) had died from causes other than GC, and six (5.6%) left the region at different follow-up periods. Malignant tumors of other localizations were diagnosed in 8 patients at different times after the operation: Non-Hodgkin's lymphomas-in three, prostate cancer-in one, lung cancer-in two, laryngeal cancer-in one, and breast cancer-in one patient. With the exception of one patient with non-Hodgkin's lymphoma, the other

patients died from the progression of these diseases. The causes of death were not associated with malignant tumors for the other patients. During the period 2020-2021, seven patients contracted coronavirus disease-19, one of whom died from the disease, but the rest are alive.

Detection H. pylori infection

H. pylori in the GM and tumor was determined by rapid urease test (RUT) and by immunohistochemically (IHC) using the antibody to *H. pylori*.

RUT

After removal of the stomach (within 30 min) a greater curvature of the organ was opened and biopsy samples were taken from the tumor and the adjacent macroscopically non-tumorous GM at a distance of 3-5 cm from the tumor margin. The samples were placed on test strips (HELPIL–test, "AMA", Russia) for three minutes. The presence and the severity of the infection were evaluated by the color change of the indicator from yellow to blue.

According to the intensity and the time of the appearance of a blue color, we distinguished three degrees of infection: 3+: Marked (+++)-bright staining in the first minute of the study; 2+: Moderate (++)–for an average intensity of staining for 2 min and 1+ mild (+)-weak staining for three minutes. If the color of the indicator did not change, or became dirty gray, and if after repeated research the same result was received, the test was evaluated as negative. The same samples were later used for histological analysis and IGH.

Immunohistochemistry

The presence and features of *H. pylori* infection were studied in samples of the GM adjacent to the tumor, in the tumor tissue, in the omentum, and regional lymph nodes of 46 patients, by immunohistochemistry.

The sections for IGH were dewaxed and rehydrated by sequential immersion in xylene and graded ethanol and water. For antigen retrieval, the sections boiling for 10 min in citrate buffer (pH 6) and endogenous peroxidase activity was blocked with 30 mL/L hydrogen peroxide solution. Slides were incubated at room temperature with the anti-*H. pylori* (RB-9070, Thermo Fisher Scientific, the immunogen is purified *H. pylori*) rabbit polyclonal antibodies in diluted at 1:1000 for 30 min.

The visualization system included DAB (UltraVision LP Detection System HRP Polymer & DAB Plus Chromogen) and hematoxylin counterstaining. For negative control sections, the primary antibody was replaced with phosphate-buffered saline and processed in the same manner.

The concentration of *H. pylori* in the GM detected by IGH was graded as 1+ for mild, 2+ for moderate, and 3+ for marked according to the Sydney system[30]. The presence of point inclusions giving a positive reaction with antibodies to *H. pylori* in the cytoplasm of epithelial cells of deep gastric glands and of the lymphoid cells of the lamina propria of GM as well as in omentum and lymph node, were taken into account.

All sections were carefully and completely scanned by two of the authors (MS and OT) without knowledge of the clinical and pathological data.

The data obtained was compared with clinical features of GC: Stage, localization, histology, the presence of AT before surgery, and 10-year OS and RFS.

Statistics

Statistical analysis was performed using the Statistica 10.0 software. The correlations between different data were evaluated using the nonparametric Spearman's rank correlation or gamma correlation. Chi-square tests were carried out to analyze the difference of distribution among the categorized data. Mann–Whitney U nonparametric test was used to compare the value of the quantitative data. The survival was analyzed using the Kaplan-Meier method. The log-rank test was used to compare survival curves between subgroups of patients. A value of $P < 0.05$ was considered statistically significant.

RESULTS

The features of H. pylori infection in GC

Of 93 patients (84.5%) demonstrated positive RUT. According to RUT the concentration of *H. pylori* in GM was mild (1+) in 38 (34.8%) patients, moderate (2+)-in 37 (33.9%) and marked (3+)–in 8 (16.5%). RUT was negative in 16 patients (14.7%).

It was found that urease activity 2+ and 3+ were significantly more frequent in GM than in tumors (in 55.5% and 13.3% of cases, respectively, $P = 0.01$). In more than half the cases (53.3%), the urease activity in the tumor was lower than in the adjacent GM.

Forty-six samples of GM were stained by IHC. The coccoid forms of *H. pylori* were found to prevail in GM adjacent to the tumor (Figure 1A). Coccoid forms of *H. pylori* only were identified in 31 (63.1%) patients, and coccoid and spiral in 12 (30.4%) patients (Figure 1B). No signs of infection were found in 3 (6.5%) patients. The concentration of coccoid and spiral forms of *H. pylori* in GM according to IGH was 1+ in 24 (52.2%) and 1 (19.6%) patients, 2+-in 11 (23.9%) and 4 (8.7%), and 3+-in 8 (17.4%) and 1 (2.2%) patients. A positive correlation between the concentration of coccoid and spiral forms of *H. pylori* (gamma = 0.642, $P < 0.0001$) was noted.

The localization of *H. pylori* in GM was observed not only in the surface mucous gel layer of the stomach (Figure 1C) but also within the cytoplasm of the gastric superficial-foveolar epithelium (Figure 1D). The point inclusions giving a positive reaction with antibodies to *H. pylori* were also revealed in the cytoplasm of the epithelial cells of deep gastric glands (in 41.3% samples) and of the immune cells (Figure 1E) of the lamina propria of GM (in 43.5% samples), as well as of the intraepithelial lymphocytes (Figure 1F). The close relationship between the presence of point inclusions in immune cells and epithelial cells (gamma = 0.642, $P < 0.0001$) was noted. The individual cocci or their small clusters, and sometimes the short rod bacterium, were also often detected in the lamina propria of the GM. We also found bacteria in the omentum and lymph nodes. In the omentum the bacteria were presented predominantly by cocci between 0.5 and 1 μm in diameter (Figure 2A). Cocci were arranged most commonly by the small compact groups up to 10-15 cells in the immediate vicinity of the LN capsule. The bacteria were located mainly between the adipocytes. However, it was not clear whether bacteria were outside of the cells or in a narrow rim of cytoplasm of the fat cells.

In the tissue of lymph nodes we usually observed the small accumulations of cocci between 10 and 15 cells (Figure 2B). Bacteria were located between lymphocytes of the paracortical area, but not so compact, as in the omentum. Quite often the concentration of bacteria was observed around the nuclei of cells that can testify to their intracellular localization.

Correlations of clinical and pathological characteristics of GC with the severity of H. pylori infection according to RUT data

The gamma correlation coefficient test (gamma) showed that the severity of *H. pylori* in GM according to RUT positively correlated with the T status (gamma = 0.537, $P < 0.00001$), N status (gamma = 0.371, $P = 0.0007$) and stage (gamma = 0.520, $P < 0.00001$), and negatively correlated with the presence of AT in anamnesis (gamma = -0.418, $P = 0.003$). The marked (+++) and moderate (++) degrees of *H. pylori* infection were more often observed in Grade 2 and Grade 3, in T3-4 status, in N1 status, in the T3-4N1-2 stage, and in the absence of AT in anamnesis (Table 2). Correlations of *H. pylori* concentration in GM according to RUT with 10-year OS and RFS of GC patients were not determined.

It is important to note that the presence in AT 1-1.5 mo before surgery was associated with a significant improvement in RFS and OS (Figure 3), however, this applied only to patients with local GC (T1-3N0). In advanced GC (T3-4N1 and T3-4N2) there were no significant differences in patient survival (Figure 4).

Correlations of clinical and pathological characteristics of GC with the concentration of spiral and coccoid forms of H. pylori in the GM

It is important to note that correlations between the clinical and pathological characteristics of GC and the concentration of *H. pylori* spiral forms in GM were not found. However, the concentration of *H. pylori* coccoid forms correlated with age ($\rho = -0.502$, $P = 0.0006$), histology (gamma = 0.550, $P = 0.0004$), T status (gamma = 0.709, $P = 0.0001$), N status (gamma = 0.509, $P = 0.002$) stage (gamma = 0.636, $P = 0.0002$), and 10-year RFS (gamma = -0.521, $P = 0.008$) and OS (gamma = -0.500, $P = 0.044$). In cases with a moderate and marked concentration (2+ or 3+) of *H. pylori* coccoid forms in GM compared to cases with a low concentration (1+ or without infection) the patients were younger (57.9 ± 2.5 years *vs* 66.2 ± 1.4 years, respectively, $P = 0.004$) and the diffuse type of GC, poorly differentiated tumors (G3), T3-4 stage and N1 stage of GC were more often observed (Table 3). In cases of moderate and marked concentrations of *H. pylori* in GM, a decrease in 10-year progression-free survival (PFS) and OS survival from 55.6% to 26.3% was observed ($P = 0.02$ and $P = 0.07$, respectively). PFS and OS curves, depending on the concentration of coccoid forms of *H. pylori* in GM, are presented in Figure 5.

RUT: Rapid urease test; GC: Gastric cancer.

There were no correlations between the presence of point inclusions in the cytoplasm of epithelial cells of deep gastric glands, in the stroma immune cells, and in the intraepithelial lymphocytes with the clinical and pathological characteristics of GC.

DISCUSSION

A large amount of clinical and experimental data testifies to the important role of *H. pylori* in the occurrence of GC[31-34], but, there is less research into the features of *H. pylori* infection in patients with GC and its role in tumor progression, and the results are quite contradictory. These contradictions relate to many aspects, such as: (1) The frequency of infection in patients with GC. This data varies widely and ranges from 36% to 100%[35-40]; (2) The relation of infection with GC prognosis. Some researchers have noted an improvement in the long-term results of GC treatment in infected patients[41,42], while others, on the contrary, found that the presence of H. pylori infection was associated with a decrease in patient survival[43,44]; and (3) The connection between the infection and a histologic type of GC. In some studies, it was noted that patients with an intestinal type of GC are more often infected with *H. pylori* than patients with the diffuse type of GC[45,46]. Other researchers did not find a

difference in *H. pylori* infection in patients with different histological types of tumors [47].

It is believed that the differences noted are associated with the fact that to reveal the infection the authors used the methods that were significantly different in their sensitivity, and primarily, to coccoid forms of bacteria. Most of the studies were carried out without considering coccoid forms of *H. pylori* and the concentration of bacteria in GM. The use of the biochemical method for the detection of urease activity and immunohistochemistry for visualization of bacteria in our study allowed us not only to assess the presence of infection in patients with GC, but also to mark some of its features associated with the localization of bacteria in the stomach, with a ratio of cocci and spiral forms, and the degree of bacterial contamination of GM.

Our data for the Orenburg region recorded a high rate of *H. pylori* infection in patients with GC (84.5%). The coccoid forms of *H. pylori*, preserving a high degree of urease activity, dominated in GM in patients with GC. They were found in 93.4% of infected patients, with only coccoid forms of *H. pylori*-in 68.9%.

It is known that the coccoid forms of *H. pylo*ri can arise in response to unfavorable environmental factors, such as AT [47,48]. These forms are resistant to AT[49,50] and are able to form biofilms[51] and avoid the immune system[50]. They express a higher rate of cagE mRNA than their spiral counterparts[52], and by increasing the synthesis

of tumor necrosis factor-alpha (TNF-α)-inducing protein (Hps), which is introduced into the cytosol and cell nuclei, they can activate nuclear factor-kappaB (NF-κB) and the expression of TNF-α and other cytokines involved in carcinogenesis[53,54]. The effect on the proliferation of gastric epithelial cells in the *H. pylori* coccoid forms is also stronger than in the helical forms[55], and they can induce the expression of VEGF-A and transforming growth factor-β[56]. The ability to transform into coccoid forms was also found to be characteristic of the most virulent strains of *H. pylori*[50,54].

It should be noted that the higher infection by coccoid forms of *H. pylori* in patients with GC, compared to patients with gastritis or gastric ulcer, had been mentioned by

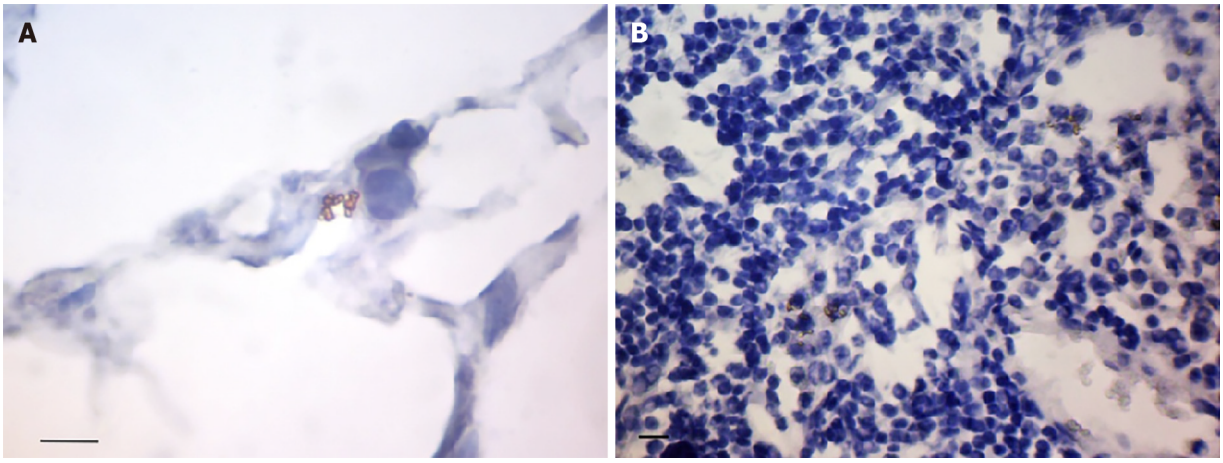

Figure 2 The features of *Helicobacter pylori* localization in omentum and lymph node in patients with gastric cancer. Figure 3 10-year overall surviving and relapse-free surviving of patients with gastric cancer depending on the presence of antibiotic therapy 1-1.5 mo before surgery (*P* = 0.02). A: 10-year overall surviving; B: Relapse-free surviving.

other researchers[57]. A number of studies have shown that coccoid forms of *H. pylori* retained urease activity[58] and the expression of such antigens as CagA, UreA, porin, components of the Cag type IV secretion system (TFSS), antigen-binding adhesin of the blood group BabA and others[59,60].

The use of immunohistochemistry in this study made it possible to detect the bacteria not only in the gastric mucus and on the surface of epithelial cells, but also within the cytoplasm of epithelial and immune cells of GM. Such intracellular expression was characterized by point inclusions giving a specific reaction with antibodies to *H. pylori*.

The intracellular persistence of *H. pylori* has been demonstrated by many investigators. They found *H. pylori* in the cytoplasm of epithelial cells, intercellular spaces, in the lamina propria of GM, and in the lumen of small vessels[61-63]. We assume that the point inclusions in the cytoplasm of epithelial and immune cells giving a positive reaction with antibodies to *H. pylori* is similar to those particle-rich cytoplasmic structure (PaCS) described earlier in the human superficial-foveolar epithelium and its metaplastic or dysplastic foci[64]. The authors found that the PaCS are a colocalization of VacA, CagA, urease, and outer membrane proteins with NOD1 receptor, ubiquitin-activating enzyme E1, polyubiquitinated proteins, proteasome components, and potentially oncogenic proteins like SHP2 and ERKs[64]. They believe that PaCS is a novel, proteasome-enriched structure arising in ribosome-rich cytoplasm at sites of *H. pylori* product accumulation.

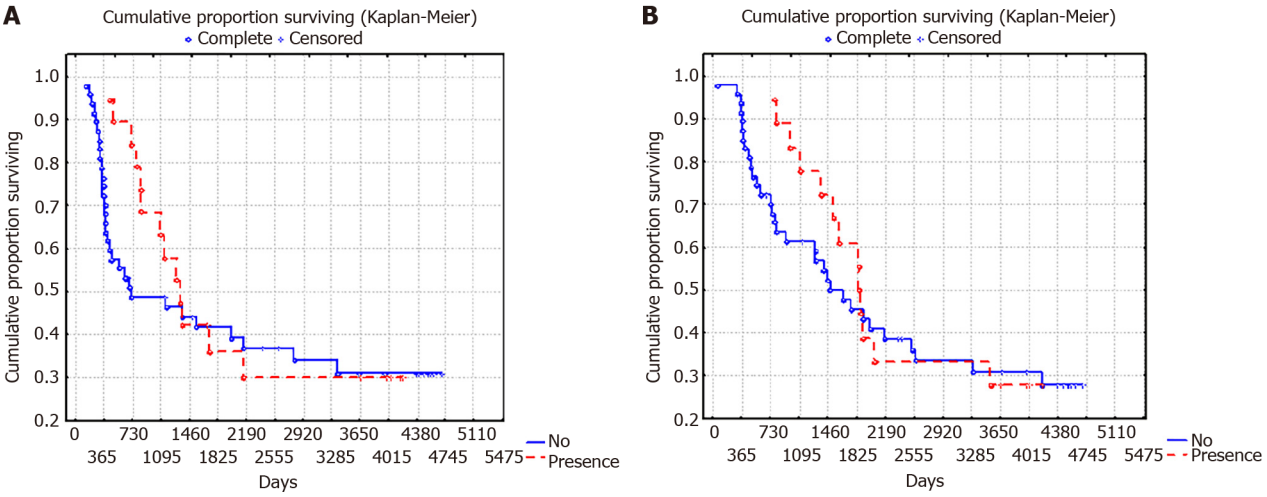

Figure 4 10-year overall surviving and relapse-free surviving of patients with T3-4N1-2M0 stages of gastric cancer depending on the presence of antibiotic therapy 1-1.5 mo before surgery (*P* = 0.78). A: 10-year overall surviving; B: Relapse-free surviving.

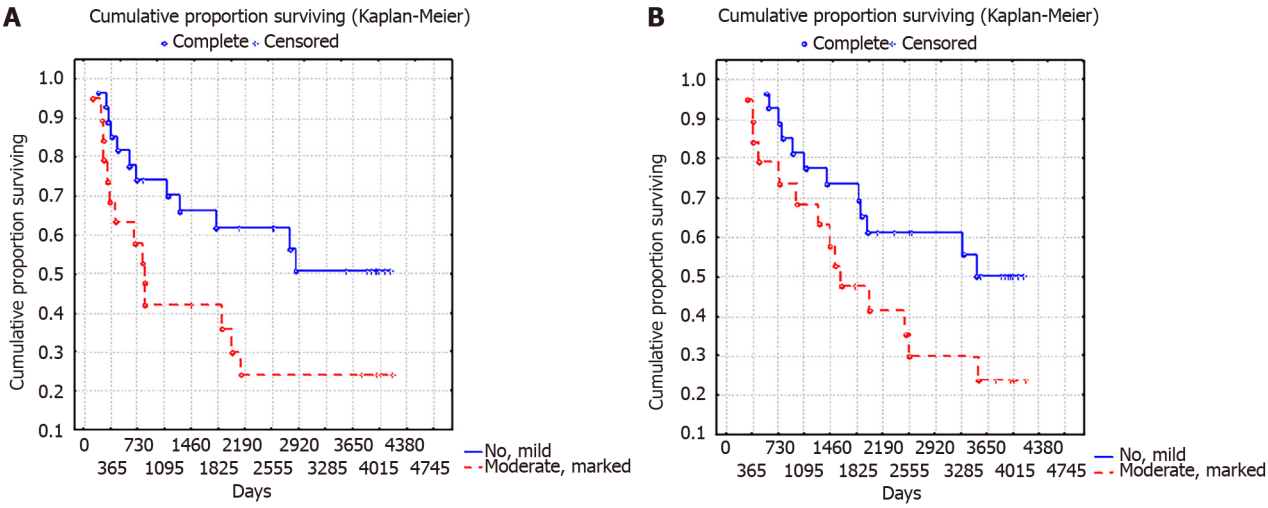

Figure 5 10-year overall surviving and relapse-free surviving of patients with gastric cancer depending on the concentration of *Helicobacter pylori* coccoid forms in the gastric mucosa (*P* = 0.02). A: 10-year overall surviving; B: Relapse-free surviving.

We believe that the immune cells with point inclusions in the lamina propria of GM are likely to be macrophages. The data obtained by several researchers suggests this conclusion[65,66]. It is noted that even the absorbed bacteria retains their viability in macrophages, which may be associated with the violation of the phagosome maturation[66-68]. The use of confocal microscopy enabled the localization of the bacteria within the cells to be associated with the endosomal and lysosomal markers, and found that *H. pylori* could use the vesicles of autophagosomes (autophagic vesicles) for its own replication[63,69].

The study found that the concentration of *H. pylori* coccoid forms in GM was the most significant clinical factor. This factor was associated with the tumor histology, T status, N status, stage, 10-year PFS, and OS. The moderate and marked concentrations of coccoid forms of *H. pylori* were more often found in the diffuse type of GC (P = 0.024) and T3-4 (P = 0.04) stage. Interestingly, the high concentration of *H. pylori* is more frequent in Stage N1 than in N2 (at 90.0% and 53.1%, respectively, P = 0.024).

The moderate and marked concentrations of coccoid forms of *H. pylori* represented a prognostic factor associated with the decrease of 10-year RFS and OS from 55.6% to 26.3% (P = 0.02 and P = 0.07, respectively).

It should be noted that the results of this study do not allow us to unambiguously judge the effect of *H. pylori* on GC progression. A decrease in OS and DFS in patients with moderate and marked concentrations of *H. pylori* coccoid forms in the GM may be due to the fact that these patients had more advanced stages and more aggressive

forms of GC. Meanwhile, there are more and more studies showing that *H. pylori* infection can promote GC progression by activating the NF-κB signaling pathway and induction of interleukin-8 secretion[70], the activation of epithelial-mesenchymal transformation[71-74] and angiogenesis[75,76], as well as increasing the invasive properties of tumor cells[77]. It can be assumed that the administration of AT before surgery contributes to the reduction of the inflammatory process activity and normalization of the adhesive properties of tumour cells, which in turn decreases metastasis risk and improves the long-term results of the treatment of GC. The data literature on the improvement of the long-term results of malignant tumours treatment when using antibacterial drugs testify in favour of this hypothesis[78-80].

CONCLUSION

The data obtained indicates that *H. pylori* may be associated not only with induction but also with the progression of GC. It can be assumed that the prevalence of coccoid forms of bacteria and their intracellular persistence can affect the mechanisms of tumor progression. Further appropriate studies regarding the role of *H. pylori* in the progression of GC are obviously advisable.

ARTICLE HIGHLIGHTS

Research background

Gastric cancer (GC) continues to be one of the most common malignant diseases in the world. It is known that *Helicobacter pylori* (*H. pylori*) infection, initiating the development of a chronic inflammatory process in the gastric mucosa (GM), is the leading risk factor for GC. At the same time, clinical studies indicate that inflammatory infiltration of the tumor stroma and surrounding tissues can have an important prognostic value and affect the long-term results of malignant neoplasm treatment.

Research motivation

It is still not clear whether *H. pylori* is involved only in the initiation of the tumor process in the stomach, or whether it can affect the mechanisms of tumor progression.

Research objectives

The aim of this study was to establish the features of *H. pylori* infection in patients with GC and their correlations with clinical and morphological characteristics of diseases and long-term results of treatment.

Research methods

In this prospective observational study, we included all patients with GC who had undergone radical surgery (R0) between May 2007 and March 2010 at the Orenburg Regional Clinical Oncology Center. Features of the *H. pylori* infection and its severity was determined by rapid urease test and by immunohistochemically using the antibody to *H. pylori*. The data obtained we compared with clinical features of GC: Stage, localization, histology, the presence of antibiotic therapy (AT) before surgery, and 10-year overall and disease-free survival.

Research results

We found *H. pylori* infection in the adjacent to the tumor GM in 84.5% of cases. We have established that the coccoid forms of *H. pylori* predominate in the GM of patients with GC. A high rate of infection by coccoid forms of *H. pylori* has been associated with more aggressive type of GC, advanced stage, and decline of a 10-year overall and disease-free survival. The presence of AT 1-1.5 mo before the operation was associated with an improvement in the 10-year survival rate of patients with local (T1-3N0M0), but not advanced (T3-4N1-2M0) stages of GC.

Research conclusions

These results indicate that *H. pylori* may be associated not only with induction but also with the progression of GC.

Research perspectives

The results obtained do not allow one to draw unambiguous conclusions about the role of *H. pylori* in the progression of GC. Further appropriate prospective studies regarding the role of *H. pylori* in the progression of GC are obviously advisable.

Abstract

BACKGROUND

Gluten is a complex mixture of proteins with immunogenic peptide sequences triggering the autoimmune activity in patients with celiac disease (CeD). Gluten immunogenic peptides (GIP) are resistant to gastrointestinal digestion and are then excreted *via* the stool and urine. Most common detection methods applied in the follow-up visits for CeD patients such as serology tests, dietetic interviews, questionnaires, and duodenal biopsy have been proved to be inefficient, invasive, or inaccurate for evaluating gluten-free diet (GFD) compliance. Determination of excreted GIP in stool and urine has been developed as a non-invasive, direct, and specific test for GFD monitoring.

AIM

To summarize published literature about the clinical utility of GIP determination in comparison to the tools employed for GFD monitoring.

METHODS

PubMed and Web of Science searches were performed using the keywords "gluten immunogenic peptides" or "gluten immunogenic peptide" and a

fully peer-reviewed by external reviewers. combination of the previous terms with "feces", "stools", "urine", "celiac disease", "gluten-free diet", and "adherence" to identify relevant clinical studies published in English and Spanish between 2012 to January 2021. Reference lists from the articles were reviewed to identify additional pertinent articles. Published articles and abstracts reporting the clinical use of GIP determination in stool and/or urine for the follow-up of patients with CeD in comparison with other tools in use were included. Case reports, commentaries, reviews, conference papers, letters, and publications that did not focus on the aims of this review were excluded.

RESULTS

Total of 15 publications were found that involved the use of GIP determination in stool and/or urine to monitor the adherence to the GFD in comparison to other tools. Studies included both children and adults diagnosed with CeD and healthy volunteers. Overall, these preliminary studies indicated that this novel technique was highly sensitive for the detection of GFD transgressions and therefore could facilitate the follow-up of patients with CeD. Tools identified in this work included the CeD-specific serology, dietetic questionnaires, symptomatology, and the duodenal biopsy. Review of the literature revealed that the rates of GFD adherence may vary between 30%-93% using either stool or urine GIP determination, 49%-96% by the serology, 59%-94% using the dietetic questionnaires, 56%-95% by the reported symptoms and 44%-76% with the duodenal biopsy. In addition, the association between the different methods and histological abnormalities (Marsh II-III) was found to be 33%-100% for GIP determination (stool and urine), 25%-39% for CeD-specific serology, 3%-50% for dietetic questionnaires, and 22%-28% for the symptomatology.

CONCLUSION

Excreted GIP detection is the precise approach for determining voluntary or involuntary gluten consumption in CeD patients preventing future complications arising from gluten exposure.

Core Tip: A strict gluten-free diet (GFD) is the only available treatment for celiac disease. However, treatment adherence is difficult due to the ubiquitous nature of gluten, hurting patients' quality of life. Despite several tests to evaluate GFD compliance, it has been proven to be invasive or inefficient. The determination of gluten immunogenic peptides (GIP) in stool and urine has been developed as a non-invasive, direct, and specific test for GFD monitoring. We herein summarized the current available literature meeting the clinical utility of GIP determination compared to the available tools in use.

INTRODUCTION

Gluten is a heterologous polymorphic mixture of proteins called prolamins. Wheat prolamins are termed gliadins and glutenins. Prolamins provide food products with special functional properties such as elasticity as well as extensibility and are characterized by high proline and glutamine content, allowing for the more efficiently

packing of proteins but also complicating the enzyme-mediated hydrolysis of their tight structures[1]. Consequently, many of these proteins are insufficiently degraded by gastric and pancreatic enzymes in the gastrointestinal tract. Therefore, after the ingestion of gluten-containing foods, some gluten peptides can enter the intestinal epithelium and trigger an immune response in genetically predisposed individuals suffering from celiac disease (CeD)[2-4].

Evidence suggests that gluten can cross the intestinal barrier *via* the transcellular pathway perpetuating intestinal inflammation in the context of gluten intolerance[5, 6]. The α-gliadin 33-mer peptide has been described as one of the most immunodominant gluten peptides, harboring several T cell epitopes[2]. Another three gluten peptides have been shown to trigger high immunogenicity observed in most CeD patients[7]. Thus, most of the immune response against gluten may be accounted for by a limited group of gluten epitopes[7]. The anti- α-gliadin 33-mer antibodies A1 and G12 could specifically and sensitively detect excreted gluten immunogenic peptides (GIP) in stool and urine[8,9], confirming the resistance of GIP to human gastrointestinal digestion as well as their absorption into the bloodstream.

CeD is a systemic disease, involving well-known key immune factors, including the human leukocyte antigen (HLA-DQ2 and HLA-DQ8), the anti-tissue transglutaminase (anti-tTG) antibodies, and gluten[10]. As a systemic disease, there are intestinal and extraintestinal symptoms that can be presented individually or in combination. In addition, patients may also be completely asymptomatic[11]. Intestinal presentation of CeD is common in both the pediatric and adult patient population and is characterized by diarrhea, loss of appetite, abdominal distention, bloating, pain, constipation, or weight loss[12,13]. The most common extraintestinal symptoms are iron deficiency anemia, osteopenia or osteoporosis, hypertransaminasemia, neurological afflictions, or changes in reproductive function[10]. Nevertheless, a relevant proportion of patients present atypical symptoms or remain asymptomatic despite damage to the intestinal mucosa and elevated CeD-specific serum antibodies, which may delay diagnosis or even be undiagnosed[14].

Following CeD diagnosis, patients must follow a strict, life-long gluten-free diet (GFD), the only treatment currently available, which not only reduces disease symptoms but also allows for the healing of the intestinal epithelia and prevents long-term complications[15-17]. However, following a strict GFD is challenging and requires substantial daily effort, hurting the quality of life in addition to psychological problems and fear of involuntary gluten intake, even in patients considering themselves to be strictly adherent[15,18-20]. Gluten-free food availability, inadequate food labeling regulations, cost, and safety are the main barriers related to GFD[18,21, 22]. Therefore, the frequency of voluntary and involuntary transgressions is high. It was reported that at least 50% of adult patients are not fully adherent to the GFD in a daily or weekly period of observation[8,9,23,24]. In addition, 36%-55% of patients who expressed their complete adherence to a GFD did not achieve histological remission, potentially from inadvertent lapses in their daily gluten intake[24-27]. Inadvertent gluten ingestion was suggested to be more frequent than intentional intake, not only when eating out, but also at home[28-30]. A systematic review recently reported adherence rates ranging from 23% to 98% in the pediatric population, determined by using all available methods for evaluating adherence[31].

Although continuous patient monitoring is expected to improve GFD adherence, there is no consensus on how frequent and which tools to use in the patient follow-up [32-35]. All available guidelines recommended clinical and dietary evaluation as well as serology tests at least once a year or every two years to confirm the GFD adherence in addition to detecting possible complications[14]. However, monitoring approaches have not been comprehensively assessed with a clear lack of a gold standard for comparisons[36-38]. Thus, various questions often arise among caregivers and patients regarding the best approach for detecting gluten exposure. GFD follow-up through the detection of excreted GIP has the benefits of being non-invasive, objective, and specific, highlighting its potential as a complementary technique for monitoring CeD treatment[8,9].

Despite the increasing number of studies on the use of GIP excretion determination for the assessment of GFD compliance, there are limited reference guidelines on the detection of GIP in stool and urine for monitoring the treatment in patients diagnosed with CeD. The purpose of this systematic review is to compile insights from studies that tackled the practical issues related to the clinical utility of the available methods for GIP determination compared to current GFD adherence monitoring methods.

MATERIALS AND METHODS

Literature search strategy

PubMed and Web of Science searches were performed using the search terms "gluten immunogenic peptides" or "gluten immunogenic peptide" and a combination of the previous terms with "feces", "stools", "urine", "celiac disease", "gluten-free diet", and "adherence" using the Boolean AND operator, which allows the establishments of logical relations among concepts. References of included full-text articles were scrutinized for additional studies.

Inclusion and exclusion criteria

The eligibility criteria were based on the PICOS (Participants, Intervention, Comparison, Outcomes, Study design) acronym. Articles eligible to be included in this review were required to meet the following criteria: (1) The study reported both children and adult patients diagnosed with CeD, since it would be more useful for readers as the evidence available about the use of this tool is limited; (2) The intervention was the use of GIP determination in stool and/or urine as a tool for monitoring the rate of adherence to the GFD in comparison with the current tools in use, like the serology, dietetic questionnaires, symptomatology, and duodenal biopsy; (3) It was a prospective cohort/cross-sectional/case-control study; (4) The article was written in English or Spanish language; and (5) The article was published between 2012 and January 2021.

We excluded publications that did not focus on the aim of this review. If a full-text paper could not be obtained, but the abstract presented sufficient data, the publication was included. Case reports, commentaries, reviews, conference papers, and letters were excluded.

Retrieved manuscripts were reviewed by the authors, and the data were extracted and described.

RESULTS

Through the literature review, our searches yielded 67 results after the removal of duplicates. In total, 52 entries were excluded for different reasons: 23 did not respond to the aim of this publication, 28 were reviews, case reports, or conference papers, and one had not abstract or full-text available. After screening, 15 publications were eligible for further study. Of these, 14 had a full text in English and one had an English abstract. Two publications reported complementary data about the same study (Figure 1).

The 15 publications included both children and adults diagnosed with CeD. Healthy adult and pediatric volunteers were also included in many of the studies. The articles were published between 2016 and 2021. The characteristics of included studies are summarized in Table 1[8,9,22-24,29,30,39-46].

DISCUSSION

Methods for the determination of excreted GIP

Analytical methods require a standard analyte for quantitative determination. The main issue is the selection of a standard gluten peptide in the huge heterogeneity of the gluten proteins and the countless number of gluten hydrolyzed fragments. The a-gliadin 33-mer peptide (LQLQPFPQPQLPYPQPQLPYPQPQLPYPQPQPF) is resistant to hydrolysis *via* gastric, pancreatic, and intestinal brush-border membrane proteases, which allows for its detection in human excretions. This peptide is considered one of the most immunodominant gluten peptides for CeD patients, as it contains three overlapping T cell epitopes, repetitions of p57-68[2,47,48]. Monoclonal antibodies A1 and G12 were generated against the α-2-gliadin 33-mer peptide specifically and sensitively detecting significant amounts of excreted GIP in stool and urine[8,9]. The reactive epitope profile may thus play an important role in the detection of excreted GIP. Even though there are a variety of antibodies on the market that allow for gluten detection in food, such as R5, 401.21, α20, 14G11, and 13F6, only G12 and/or A1 are useful for gluten peptide sensitive detection in stool and urine[8,9,49-52].

Urine samples are highly heterogeneous matrices with low protein content, making complicating the development of immunoassays for biomarkers detection. Urine

Table 1 Studies that have used gluten immunogenic peptides determination in stool and/or urine for gluten-free diet monitoring

Ref.	Design	Study population	Intervention	Main results
Comino *et al* [8]	Prospective, multicenter, observational study	184 adult and pediatric CeD patients	Fecal GIP ELISA, serology, questionnaires, and symptoms to evaluate adherence to the GFD	GIP-positive results were found in 12%-28% of children < 12 years-old, 30% in > 13 years-old females and 60% in > 13 years-old males. Low correlation of anti-tTG and anti-DGP markers and poor adherence to the GFD
Moreno *et al* [9]	Randomized controlled study	58 adult and pediatric CeD patients and 76 healthy controls	Urine GIP LFIA test, serology, and duodenal biopsy to evaluate adherence to the GFD	About 50% CeD patients were GIP-positive. High correlation of GIP quantifiable concentration in urine with persistent villus atrophy in treated CeD patients (n = 25). No correlation between serology and mucosal damage
Gerasimidis *et al*[39]	Cross-sectional study cohort for a subgroup	63 pediatric CeD patients	Fecal ELISA GIP test, serology, and questionnaires to evaluate gluten intake during diagnosis and adherence to the GFD after diagnosis	GIP-positive results in 95% of de novo patients with CeD during diagnosis. GIP-positive results were found in 17% and 27% of patients after 6 and 12 months of the beginning of the GFD, respectively. GIP-positive results were found in 16%, 16%, and 14% of patients considered compliant according to the Biagi score, tTG, and clinical assessment, respectively
Comino *et al* [40]	Prospective, multicenter, observational study	64 pediatric CeD patients	Fecal GIP ELISA, serology, questionnaires, and symptoms to evaluate adherence to the GFD after diagnosis	Most children (97%) were GIP-positive at diagnosis. A decrease of GIP detection was observed on a GFD, but the rate of GIP-positive results increased from 13% at 6 months to 25% at 24 months. Anti-tTG antibody levels showed low sensitivity to identify patients with GIP-positive results. Dietitian assessment was only moderately correlated with GIP detection
Costa *et al*[41]	Cross-sectional study and prospective cohort	44 adult CeD patients	Fecal GIP ELISA, stool and urine LFIA GIP tests, serology, questionnaires, and symptoms to evaluate adherence to the GFD	25% of patients had at least one GIP-positive test, 32% in asymptomatic patients and 15.8% in symptomatic patients. Dietary assessment estimated gluten intake in only 50% of GIP-positive samples. Anti-tTG and anti-DGP positive results in 3/12 and 6/12 of GIP-positive cases, respectively
Silvester *et al* [29,30]	Prospective longitudinal study	18 adult CeD patients	Monitoring GFD adherence by collection of daily food, stool, and urine samples for the analysis of GIP content, and relationship with duodenal biopsy, serology, questionnaires, and symptoms	GIP were detected in 66,7% patients. No significant correlation was found between gluten ingestion and non-invasive measures of GFD adherence. Most patients with normal anti-tTG had ≥ 1 GIP-positive sample (64%), 2/3 of these had persistent villous atrophy (Marsh 3a) and 2/3 of those with all GIP-negative samples had normal villous architecture (Marsh 0-1) but 4/6 with Marsh 0 had detectable gluten in ≥ 1 sample
Ruiz-Carnicer *et al* [23]	Prospective observational study	22 newly diagnosed CeD patients, 77 CeD patients following a GFD and 13 healthy volunteers	Urine LFIA GIP test to evaluate adherence to the GFD and comparison with serology, clinical manifestations, dietary questionnaire, and histological results	Mucosal damage (Marsh II-III) was found in 24% of CeD patients, 94%of these had ≥ 1 GIP urine sample. 60-80% of these were asymptomatic, had negative serologic results and were compliant with treatment regarding the dietary questionnaire. GIP-negative results were found in 97% of the patients without mucosal damage
Fernandez-Miaja *et al*[22]	Cross-sectional study	80 pediatric CeD patients	Relationship of fecal LFIA GIP for GFD monitoring GFD with CDAT, serology and sociodemographic and clinical data	Acceptable agreement was found between GIP detection and CDAT questionnaire (92.5% and 86.3% adherence rate, respectively). Most patients (83.3%) with GIP-positive results had negative anti-tTG antibodies
Porcelli *et al* [42]	Cross-sectional study	25 CeD patients	Assessment of compliance with the GFD using Fecal GIP ELISA testing, the Biagi questionnaire, evaluation of symptoms and serology	GIP-positive results were found in 4 patients, 2 of these complied with the GFD according to the Biagi questionnaire. All GIP-negative patients were asymptomatic. Levels of anti-tTG antibodies were significantly higher in GIP-positive patients than in GIP-negative patients
Roca *et al*[43]	Prospective, cross-sectional study	43 pediatric CeD patients at follow-up (Group 1) and 18 at diagnosis (Group 2)	Fecal GIP ELISA and LFIA analysis to monitor in real life the adherence to GFD Comparison to food record questionnaire and serology	Group 1: GIP-positive results were found in of 34.9% patients by ELISA (46,7% also by LFIA). 48.8% of patients had positive anti-tTG antibodies (4 reported symptoms) and 10 of these had GIP-positive results by ELISA (70% also by LFIA) (2 reported symptoms). All the transgressions detected by food record were also detected with GIP
Porcelli *et al* [44]	Cross-sectional study	55 CeD patients: 27 adults and 28 children	Assessment of compliance with the GFD using Fecal GIP ELISA, the Biagi questionnaire, evaluation of symptoms and serology	GIP-positive results were found in 8 patients, 71.4% of these were asymptomatic and 37.5% had raised anti-tTG antibodies. A significant association was found between the Biagi score and GIP-positive results but according to the Biagi score, 57.1% of GIP-positive patients followed the diet strictly and 5.4% of GIP-negative subjects did not comply with the diet

Laserna-Mendieta *et al* [45]	Prospective observational study	97 adolescent and adult CeD patients	Evaluation of the sensitivity and specificity of fecal GIP LFIA test to detect duodenal lesions in CeD patients on a GFD and comparison to serology and questionnaires	Compared to the duodenal histology, GIP LFIA test showed similar sensitivity (33%) and specificity (81%) to anti-tTG antibodies. No relationship was found between GIP and questionnaires but an association between GIP and patients' self-reported gluten consumption was seen
Stefanolo *et al* [24]	Prospective observational study	53 adult CeD patients	Fecal GIP ELISA and urine LFIA GIP test, anti-tTG, anti-DGP, and questionnaires to evaluate adherence to the GFD in symptomatic and asymptomatic patients	At least one GIP-positive result in 88.7% of patients for the 4 wk period. Patients who had symptoms had elevated GIP levels for more weeks than patients who did not have these symptoms ($P < 0.05$). Correlation was found between GIP and anti-DGP antibodies but not with levels of anti-tTG antibodies
Fernández-Bañares *et al* [46]	Multicenter prospective observational study	76 adult CeD patients	Fecal GIP ELISA, anti-tTG, questionnaires and symptomatology to evaluate villous atrophy persistence after 2 years on a GFD	Persistent villous atrophy was present in 53% of patients at follow-up, 72% of these were asymptomatic and 75% had negative anti-tTG antibodies. Most patients were adherent to the GFD according to the dietary evaluation. In contrast, GIP-positive results were found in ≥ 1 fecal sample of 77% of patients with villous atrophy and in 60% of patients with mucosal recovery

GIP: Gluten immunogenic peptides; LFIA: Lateral flow immunoassay; GFD: Gluten-free diet; CeD: Celiac disease; anti-tTG: Anti-tissue transglutaminase; anti-DGP: Anti-deamidated gluten peptide; CDAT: Celiac disease adherence test.

contains organic molecules such as urea, creatinine, and uric acid, inorganic ions such as K^+, Na^+, Cl^-, and Ca^{2+}, cells, as well as peptides of more than 1500 proteins[53]. The concentration of these compounds and the pH usually exhibit considerable variability not only among individuals but also between different urine samples taken from the same individual[54]. The complex composition of these samples and its variability, in addition to the high frequency of matrix interferences, complicate the reproducibility and robustness of urine immunoassays. Chatziharalambous *et al*[53] evaluated 11 commercial ELISA assays for the detection of urine biomarkers, reporting that only three of them met the requirements of FDA validation guidelines[55].

The currently available tests for GIP detection in stool and/or urine (Table 2) are immunoassays adapted from those used for gluten detection in foods to maximize sensitivity. Lateral flow immunoassay (LFIA) tests can detect GIP from concentrations of 0.15 μg GIP/g in stool and 2.2 ng GIP/mL in urine after less than 30 minutes, showing both tests a high sensitivity (98.5% and 97%, respectively) and specificity of 100%[9,56]. While these tests provide qualitative data, semiquantitative results could also be obtained in urine samples using the LFIA coupled with a lateral flow reader [9]. A quantitative G12-based sandwich ELISA test for stools was developed to increase the sensitivity and quantitative determinations. The analytical sensitivity of the assay was 0.16 μg GIP/g stool (limit of quantification), and it was validated in a multicenter clinical study, showing a diagnostic sensitivity and specificity of 98.5% and 100%, respectively[8].

Estimation of the time and amount of ingested gluten

Although a significant correlation between gluten intake and excreted GIP concentration was reported, high variability is usually observed among subjects[9,29,30,43]. Interindividual diversity (weight, sex, age, gut microbiota, *etc.*), the type of gluten-

Table 2 Available immunomethods to detect gluten immunogenic peptides in stool and urine

Technique	Antibodies	Sample	Analytical sensitivity	Diagnostic sensitivity	Diagnostic specificity	Ref.
ELISA	G12/G12	Stool	0.16 μg/g	0.98	1	[8]
LFIA	G12/A1	Stool	0.15 μg/g	0.97	1	[56]
LFIA	G12/A1	Urine	2.2 ng/mL (LOD), 6.25 ng/mL (LOQ)	0.91	0.99	[9]

containing food (beer, pasta, bread, cookies, *etc.*), the amount of daily liquid intake, and the accompanying diet may have a considerable impact on the resulting GIP concentration as well as the excretion time in urine and stool samples, especially when the gluten exposure is not regular[9,29,30,43].

It appears difficult to predict the specific time and amount of gluten intake with high accuracy based on excreted GIP concentration and even considering the time of sample collection. However, some constraints regarding the expected time for GIP detection and the limits of detection could have been determined in different studies (Table 3).

It was observed that after consuming normal gluten containing diet, a negative result in both urine and stool samples was rarely observed in the following 6-12 h and 3-5 days, respectively, after the last gluten-containing meal[9,43]. Moreover, in individuals with multiple regular transgressions, the interval between gluten ingestion and urine sample collection for maximal sensitivity of detection was generally consistent between 4 and 24 h[29,30].

Despite the variability of GIP concentrations found among individuals in most studies, a significantly low GIP content was typically observed in patients with CeD compared to healthy individuals with no diet restrictions[8,9].

Clinical utility of GIP determination in urine or stools

Fecal immunoassays were first suggested as a novel method for the detection of gluten intake during diagnosis and GFD monitoring[57]. Two different methods could be used to estimate the amount of ingested gluten depending on the situation: LFIA test for either clinical laboratories or point-of-care settings due to its simplicity, while ELISA would be more suitable when a quantitative analysis and/or high throughput are convenient[58,59]. In a prospective, nonrandomized, partially-blinded, multicenter study GFD compliance of CeD children and adults was examined by measuring fecal GIP (determined by ELISA), a dietary questionnaire, celiac serology, and clinical response, as markers of diet adherence[8]. Their results revealed detectable amounts of GIP in the stools of about 30% of the analyzed patients on a GFD for at least one year in comparison to the 18% found when assessing by dietary questionnaire or by determination of anti-tTG antibodies in the serum alone. Indeed, less GIP-positive results were found in those declared non-compliant by the food questionnaire, while 70% of patients who did not declare any gluten intake had positive levels of GIP in stools[8].

Then, Moreno *et al*[9] demonstrated that urine samples could be used to monitor GFD compliance *via* an LFIA test. These tests revealed a high level of GFD infringement in patients on long-term treatment (48% and 45% in adults and children, respectively)[9]. Thus, several studies have compared GIP detection results in stool and urine for GFD monitoring, with information obtained *via* CeD-specific serology, dietary questionnaires, symptomatology, and duodenal biopsies, revealing the limitations of all these methods used to evaluate GFD transgressions and the concordance between them (Table 4).

A branch of the first study with newly diagnosed pediatric CeD patients (n = 64) showed that the percentage of diet adherence decreased on follow-up at 6, 12, and 24 mo, as the rate of GIP-positive stools increased from 13% to 25%[40]. Meanwhile, anti-deamidated gliadin peptide (anti-DGP) antibodies normalized by 24 mo, and anti-tTG antibodies were elevated in 20% of the patients. Some children, particularly the older ones, were reported to have a propensity for GFD non-compliance, and 46% of non-adherent participants had at least two GIP-positive stools during follow-up[40]. Similar data were reported by other groups[22,44]. Patients with higher levels of gluten exposure exhibited prolonged ascension of anti-tTG antibodies (P < 0.05) than those with GIP-negative results.

Table 3 Parametrical features of the gluten immunogenic peptides excretion using lateral flow immunoassay and enzyme-like immunosorbent assay methods

Specifications for the determination of GIP excretion after gluten intake	Sample	Time ranges (h)	Gluten source (amount)	Method
Shortest time to detect GIP	Urine	3-9	GCD (> 2 g)	LFIA [9,29,30]
	Stool→	< 24	GCD (> 2 g)	LFIA; ELISA[43]
Longest time to detect GIP	Urine	36	GCD (> 2 g)	LFIA[9,29,30]
	Stool	> 72	GCD (> 2 g)	LFIA; ELISA[29,30,43]
Minimal gluten intake to detect excreted GIP	Urine		> 40-500 mg/d; 25-50 mg	LFIA; SPE + LFIA[9,41]
	Stool		> 40 mg/d	ELISA, LFIA[41,43]

GIP: Gluten immunogenic peptides; GCD: Gluten containing diet including different food types; LFIA: Lateral flow immunoassay; ELISA: Enzyme-like immunosorbent assay; SPE: Solid phase extraction.

[1]Questionnaires used were Celiac Disease Adherence Test (CDAT), Biagi Score and standard food records evaluated by dietitians.
GFD: Gluten-free diet; GIP: Gluten immunogenic peptides; anti-tTG: Anti-tissue transglutaminase; anti-DGP: Anti-deamidated gluten peptide; -: Not available.

In agreement with these data, Gerasimidis *et al*[39] found that most patients following a GFD had GIP-negative results, while 18% exhibited recent gluten exposure, which was not detected by using anti-tTG antibodies and the Biagi score. These findings confirmed the limitations of dietary evaluation and serology in adult patients with CeD on a GFD. A quarter of patients considered adherent by those methods had detectable GIP, using both LFIA and ELISA tests, in at least one of two independent tests during the 2 wk of the study. A 65,9% of concordance was observed between dietary reports and GIP results. Only four patients had high serum antibody values and two of them confirmed dietary non-compliance, in agreement with GIP results[41].

Recent research demonstrated that both ELISA and LFIA methods confirmed suspected and unsuspected dietary exposure in stool samples of CeD children and adolescent patients on a long-term GFD. However, no significant association was found between longer GFD duration, and the amount of GIP recovered in stool[43].

GIP-positive results were obtained from 35% of patients by ELISA (47% of these were also confirmed by LFIA). However, based on the dietary questionnaire, 90.7% of patients were compliant with the treatment. All the patients revealed as non-adherent by the questionnaire had GIP-positive stools. Furthermore, anti-tTG antibodies were detected in five patients, three of whom were also GIP-positive. However, the authors suggested that these elevated levels may be related to the short length of treatment (< 12 mo) and a lack of GFD adherence, as a patient with negative serology and GIP-negative stools was identified.

Differences in diet compliance rates based on a GIP LIFA test in stools and a validated adherence questionnaire (CDAT) (92.5% *vs* 86.3%, respectively) were observed among 80 CeD children and adolescent patients[22]. Nevertheless, the methods exhibited acceptable concordance (Kappa: 0.31, $P = 0.004$). Of those patients with good adherence using CDAT ($n = 66$), three had GIP-positive results. Porcelli *et al* [44] also found a significant association between strict diet adherence estimated by the Biagi score and fecal GIP detection. According to the Biagi score, 94.6% of GIP-negative patients exhibited good adherence. However, the questionnaire failed in the identification of 57.1% of GIP-positive patients, while GIP detection did not recognize 5.4% of gluten exposures declared *via* the questionnaire. In this study, 62.5% of GIP-positive patients exhibited negative anti-tTG antibodies levels.

The results from the DOGGIE BAG study[29,30] also confirmed that diet transgressions in patients with CeD were frequent despite efforts made to strictly follow the GFD. In this prospective longitudinal study, the food consumed by patients, in addition to their urine and stool samples, were analyzed for gluten intake and GIP excretion, respectively, throughout 10 days before a biopsy at 24 mo after the diagnosis. Gluten was found in the food of 9/18 participants at concentrations as high as 200 ppm, and GIP-positive results were obtained in 12/18 participants reporting good adherence to the GFD (8 of these had positive urine samples, and five had positive stool samples). No correlation was observed between gluten exposure and commonly used non-invasive measures of GFD adherence. Most of the participants (73%) who suspected a gluten exposure had at least one positive food, stool, or urine sample. Among the remaining participants who did not suspect any gluten intake, four of them resulted positive for GIP[29,30]. Other authors also found a significant association between patient self-reported gluten consumption and GIP detection. GIP was detected in 52.9% of patients who suspected gluten intake in the last month in comparison to 16.3% for those who were not aware of any gluten exposure[45].

On the other hand, several studies examined the association between the available tools for GFD monitoring and the duodenal biopsy, currently considered the gold standard (Table 5). Moreno *et al*[9] assessed the correlation between duodenal biopsies and GIP concentration in urine samples. Analysis of duodenal biopsies revealed that all the adult patients with small intestine damage (Marsh II/III) had GIP-positive urine samples ($n = 7$). In addition, there was a significant correlation between the absence of GIP in urine and the absence of villus atrophy in the gut intestinal epithelium. In agreement with other publications[60-62], this study confirmed the poor correlation of serological tests with mucosal healing as well as the limitations of dietary history questionnaires in the assessment of GFD adherence.

In addition, a comprehensive study with a cohort of 77 participants under treatment with a GFD for ≥ 24 mo revealed that 58% had detectable GIP in their urine in at least one sample of three collected during the week[23]. Among the patients with GIP-negative results, 97% of them did not present histological abnormalities (Marsh 0–I), while among patients with GIP-positive results, 17 of 44 (39%) had histological damage in the intestinal epithelial (Marsh II-III), with only 16% presenting positive serological results. Significant differences were found in GIP concentrations between participants with Marsh II–III and Marsh 0–I. The highest sensitivity was observed when at least one of three urine samples tested GIP-positive (94.4%). However, this combination exhibited low specificity (53.4%). In contrast, the optimal specificity was obtained when a single urine sample was collected on the visit day (84.2%). Then, it was expected that one GIP-positive urine sample on the day of the visit would reveal a regular habit of GFD non-compliance not-restrained by the medical supervision. The authors did not observe concordance between gluten exposure measured by GIP and serology, or through a CDAT questionnaire and symptomatology, all of which exhibited low sensitivity for mucosal damage (38.9%, 22.2%, and 42.9%, respectively).

About the association of duodenal biopsy and GIP in fecal samples, Fernández-Bañares *et al*[46] found that most of CeD patients (77%) with persistent villous atrophy obtained a GIP-positive result in at least 1 stool sample after 2 years under GFD. In contrast, dietary evaluation failed to detect most of these gluten exposures, considering these cases as excellent or good adherent to the diet. In addition, 72.5% of

GFD: Gluten-free diet; GIP: Gluten immunogenic peptides; -: Not available.

those patients were asymptomatic, and 75% of them obtained negative anti-tTG antibodies. Despite GIP-positive results were also found in 60% of patients with mucosal recovery, no significant differences were found in the amount of GIP between patients with persistent villous atrophy and recovered patients[46].

Other authors reported a weaker association between evident gluten exposure, as measured by GIP detection in urine and stool, and persistent villous atrophy[29,30,45]. In the DOGGIE BAG study referred to above, at least one GIP-positive sample was found in 7 of 11 patients with normal serology, and 2/3 of them had persistent villous atrophy (Marsh IIIa) after 24 mo of follow-up. Further, 2/3 of patients with GIP-negative results for all samples were Marsh 0-I, showing significant mucosal recovery [29,30]. A possible explanation for the discordance described before is that occasional or low gluten exposure may be sufficient for GIP detection but not enough to induce mucosal damage in some patients with CeD[23,29,30,45]. A delay of intestinal mucosal recovery[29,30,45] and improved compliance of participants during the study was also considered[29,30]. Besides, Laserna-Mendieta *et al*[45] reported a low sensitivity but acceptable specificity of GIP for the detection of mucosal damage, however for the calculation they included in the same group Marsh 1 patients (n = 21), who do not present mucosal damage but lymphocytic infiltration, and Marsh 2 and 3 patients (n = 6). Moreover, in this study, weak GIP-positive results were discarded for analysis and duodenal biopsies were performed in two hospitals with different pathologists, entailing a risk of interobserver variability[63,64]. Hence, with these results, the introduction of GIP detection as a non-invasive and sensitive assessment approach for GFD adherence may reduce the need for endoscopy and could identify potential intestinal mucosal damage not detectable *via* serological tests or dietary questionnaires. In addition, intestinal mucosal recovery could be predicted based on recurring negative GIP tests.

Regarding the relationship between symptoms and GIP excretion, only a small percentage of CeD patients reported symptoms in the studies with the highest number of celiac volunteers, although a score system for symptomatology was not used[8]. Roca *et al*[43] detected GIP in samples from 22.7% of asymptomatic pediatric patients negative for anti-tTG antibodies. In contrast, Costa *et al*[41] reported that most adult patients with gluten transgressions determined *via* GIP detection were asymptomatic, although the difference was not statistically significant due to the low number of cases enrolled. Similar data were published by Porcelli *et al*[44] wherein the rate of asymptomatic patients with GIP-positive results was 71.4%.

A recent publication[24] studied the relationship of stool and urine GIP results with gastrointestinal symptoms in CeD adult patients for 4 wk to represent a real-life scenario. 62% of the patients were found to have at least one GIP-positive stool test,

and 69.9% had positive urine samples. The results suggested that symptoms in CeD patients under a GFD are the consequence of gluten exposure. A significantly higher rate of GIP-positive stool samples was observed in symptomatic compared to asymptomatic patients (77.8% *vs* 54.3%, respectively). However, a group of asymptomatic patients also had the highest number of GIP-positive urine samples per patient. This observation highlights the importance of distinguishing asymptomatic patients due to no gluten consumption from those patients consuming gluten because they were asymptomatic.

Considering that avoiding symptoms is the main motivation for adhering to a GFD, GIP content could be a useful indicator for the identification of asymptomatic patients with considerable immunogenic gluten exposure preventing gut mucosal recovery. Furthermore, GIP detection may help in symptomatic patients with CeD to determine whether non-responsive celiac disease or refractory celiac disease occurs due to recurrent gluten exposure or due to additional factors inducing persistent symptoms, such as the consumption of FODMAPs or intestinal dysbiosis[40,41,65,66].

CONCLUSION

Excreted GIP detection in either stool or urine is a precise approach for determining voluntary or involuntary gluten consumption. However, isolated GIP measurements might not identify intermittent compliance, unless punctual transgressions took place close to the moment of sample collection. It appears that the use of multiple samples (at least two) contributes to higher sensitivity and specificity of GIP detection[23,24]. In a considerable number of studies, biopsies and recurrent excretion of GIP indicated that serological tests, symptoms, and dietary questionnaires were not sufficient indicators of GFD adherence[9,23,29-31]. However, anti-tTG antibodies and clinical dietary assessment have been recently suggested as complementary tools in the evaluation of GFD adherence[44,45]. In this context, Porcelli *et al*[44] proposed the use of the Biagi score in combination with fecal GIP tests using a binary logistic regression model. In contrast, other groups did not find anti-tTG levels to be a relevant marker of adherence even though anti-DGP antibodies levels have been shown to significantly correlate with the quantity and frequency of GIP excretion in stools[24,41].

Regarding which method is more appropriate, Roca *et al*[43,67] proposed GIP testing of fecal samples as a non-invasive method that allows patient empowerment for self-managing the disease. ELISA is to be used for the laboratory quantification of GIP, while LFIA strips should be used for patient self-control following suspected involuntary infringements. Even though GIP evaluation may represent an extra cost for CeD patients monitoring, its inclusion in the pursuing of strict GFD adherence would reduce health expenditure by preventing future complications arising from gluten exposure in overlooked asymptomatic patients and would improve the self-esteem or "peace of mind" of patients adhering to the GFD, decreasing the need for additional assessment and endoscopy in non-responsive celiac disease or refractory celiac disease, especially in children.

Some authors have already proposed algorithms for the application of the determination of GIP in stools[39] and urine[23] for the follow-up of patients with CeD. It is expected that the application of those protocols with some variations will be progressively introduced in the guidelines to assess the adherence of patients to the GFD. Future studies may also determine the utility of GIP excretion analysis for other applications, such as the confirmation that sufficient gluten has been ingested before diagnosis or to discover unknown aspects of gluten protein metabolism.

ARTICLE HIGHLIGHTS

Research background

A lifelong strict gluten-free diet (GFD) is the only available treatment for celiac disease (CeD), which reduces symptoms and allows the healing of the intestinal mucosa, preventing long-term complications. However, total exclusion of gluten is difficult to achieve in practice and voluntary and involuntary transgressions are highly frequent.

Research motivation

Gluten immunogenic peptides (GIP) detection in stool and urine is becoming increasingly apparent as a noninvasive and reliable marker for close and efficient GFD

monitoring in patients with CeD.

Research objectives

The authors aimed to summarize published data regarding the performance of GIP determination in stool and urine in comparison to other available tools in assessing GFD adherence in patients with CeD.

Research methods

The authors conducted a systematic review searching in PubMed and Web of Science clinical studies that reported the performance of GIP determination in stool and/or urine with other biomarkers for the evaluation of treatment adherence in adult and pediatric patients with CeD.

Research results

The authors screened 67 articles and 15 articles were included for full-text analysis. In the selected publications GIP determination in stool and/or urine were compared with at least one of the following markers: levels of CeD-specific serology, results from CeD-specific non-specific questionnaires, symptomatology, and duodenal biopsy. Fecal determination by ELISA was the most investigated GIP marker, followed by urine rapid test and stool rapid test. Variability was seen in the concordance between the different tools among the studies reviewed due to the differences found in the study design, the target population, and the methods used. One of the main outcome measures reviewed was the diagnostic accuracy of these tools in assessing mucosal healing. An association of mucosal status and GIP detection was observed in some publications, where serology, questionnaires, and symptomatology showed lower sensitivity. Furthermore, GIP detection may help in symptomatic patients to determine whether non-responsive CeD or refractory CeD occurs due to recurrent gluten exposure or due to additional factors.

Research conclusions

The introduction of GIP detection in stool and/or urine as a non-invasive marker for GFD monitoring in patients with CeD may reduce health expenditure by preventing future complications arising from gluten exposure not detectable by other tools in use. Stool and urine rapid tests may be an option for disease self-managing by the patient, while fecal ELISA test could be used for GIP quantification in the laboratory.

Research perspectives

The introduction of algorithms for GIP determination within the follow-up of patients with CeD in guidelines will allow its routine use in clinical practice. In addition, future studies may also determine their utility for other applications such as the confirmation of gluten consumption during the diagnosis process or the investigation of gluten metabolism.

ACKNOWLEDGEMENTS

This paper will be part of Laura Coto's doctorate that is being carried out within the context of "Human Nutrition Program" at the University of Granada.

Abstract

BACKGROUND

Pancreatic paragangliomas (PPGL) are rare benign neuroendocrine neoplasms but malignancy can occur. PPGL are often misdiagnosed as pancreatic neuroendocrine tumor or pancreatic adenocarcinoma.

CASE SUMMARY

We reviewed 47 case reports of PPGL published in PubMed to date. Fifteen patients (15/47) with PPGL underwent endoscopic ultrasound-guided fine needle aspiration (EUS-FNA). Only six (6/15) were correctly diagnosed as PPGL. All patients with PPGL underwent surgical resection except three (one patient surgery was aborted because of hypertensive crisis, two patients had metastasis or involvement of major vessels). Our patient remained on close surveillance as she was asymptomatic.

CONCLUSION

Accurate preoperative diagnosis of PPGL can be safely achieved by EUS-FNA with immunohistochemistry. Multidisciplinary team approach should be considered to bring the optimal results in the management of PPGL.

Key Words: Pancreatic paraganglioma; Endoscopic ultrasound-guided fine needle aspiration; Meta-iodobenzylguanidine scan; Metanephrines; GATA-3; Immunohistochemistry; Case report

Core Tip: The morphologic overlap between pancreatic paraganglioma and neuroendocrine tumor is significant. An accurate diagnosis by endoscopic ultrasound-guided fine needle aspiration requires firstly that the possibility of paraganglioma is considered and secondly that a cell block is available for immunohistochemical stains. A patient-centered approach supported by a multidisciplinary team of radiologists, advanced endoscopists, endocrinologists, pathologists, oncologists, and surgeons is paramount in the management of pancreatic paraganglioma.

INTRODUCTION

Paragangliomas are rare neuroendocrine neoplasms arising from the sympathetic and parasympathetic paraganglia. This tumor is called pheochromocytoma in the adrenal medulla and elsewhere is known as extra-adrenal paraganglioma or simply as paraganglioma. The malignant potential of these tumors is difficult to predict. Most behave in a benign manner, but metastasis, which best defines malignant paraganglioma, may occur in 15%-20%[1]. When found in or around the pancreas this tumor is often misdiagnosed as pancreatic neuroendocrine tumor (PNET) or even pancreatic adenocarcinoma. In this study, we report a case of pancreatic paraganglioma diagnosed by endoscopic ultrasound-guided fine needle aspiration (EUS-FNA) and review of the literature on pancreatic paraganglioma.

CASE PRESENTATION

Chief complaints

A 73-year-old female presented with a chief complaint for evaluation of an incidental finding of peripancreatic lymph node.

History of present illness

She underwent computed tomography (CT) of the abdomen and pelvis as part of her routine surveillance for extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue (MALT-lymphoma) of the lung and was found to have peripancreatic lymph node. She denied any abdominal pain, change in bowel habit, weight loss, nausea, or vomiting.

History of past illness

Her medical history was significant for MALT-lymphoma, invasive lobular breast carcinoma, hypertension, atrial fibrillation, mitral valve prolapse, mitral valve stenosis, and actinic keratosis. Her surgical history included a mastectomy with sentinel lymph node dissection, laparoscopic cholecystectomy, tonsillectomy, left knee replacement, and bilateral carpal tunnel repair.

Personal and family history

Her family history was significant for colon cancer in maternal grandmother at the age of 65 years, prostate cancer in brother at the age of 63 years, and melanoma in mother. She had no history of alcohol or tobacco abuse. She has 2 children and attained menopause at the age of 52 years. Her medications included aspirin, furosemide, carvedilol, rosuvastatin, amiodarone, digoxin, anastrozole, and Eliquis.

Physical examination

Her physical examination was unremarkable, and her abdomen was soft nontender, nondistended with no palpable mass.

Laboratory examinations

Laboratory exam including fractionated metanephrines, chromogranin, and gastrin were negative.

Imaging examinations

CT of the abdomen and pelvis showed 2 cm × 1.1 cm lymph node adjacent to the pancreatic head (Figure 1A).

Endoscopy

EUS showed a 19 mm × 11.5 mm hypoechoic lesion near the pancreatic head (Figure 1B). Two FNA passes using a 25-gauge needle were performed *via* trans-duodenal approach (Figure 1C).

Pathology

Direct FNA smears showed tumor with neuroendocrine features. Initial immunoperoxidase stains performed on cell block sections were positive for synaptophysin and chromogranin, which seemed to confirm the morphologic impression of PNET. The pathologist was subsequently informed about the peripancreatic location and lack of a definite pancreatic lesion.

FINAL DIAGNOSIS

After additional testing showed the tumor to be positive for GATA-3 and negative for keratin with low expression of Ki-67 (less than 1%), the FNA diagnosis was revised to paraganglioma.

TREATMENT

Our patient was referred to endocrine surgery team after the FNA diagnosis of paraganglioma. After a thorough discussion with the patient on the benefits and risks of surgical resection, the patient elected to remain on close surveillance since she was asymptomatic with a 2-cm, nonfunctioning paraganglioma.

OUTCOME AND FOLLOW-UP

After a 1-year follow up, patient was found to have stable asymptomatic peripancreatic paraganglioma with no increase in size.

DISCUSSION

Paragangliomas are non-epithelial neuroendocrine neoplasms arising in close association with components of the parasympathetic and sympathetic nervous systems [2]. Most parasympathetic paragangliomas are nonfunctional and located along the glossopharyngeal and vagal nerves in the neck and base of the skull[3]. Sympathetic paraganglia secrete catecholamines (functional) and they are commonly located in the paravertebral ganglia of thorax, abdomen, and pelvis[3]. The incidence of extra-adrenal paraganglioma is unclear as these are often described with pheochromocytoma. In the United States, approximately 500-1600 cases are diagnosed every year and the combined annual incidence of pheochromocytoma/paraganglioma is approximately 0.8 per 100000 person-years[4,5]. Pancreatic paragangliomas are more common in women than men (2:1) and the mean age of incidence is 52 years (19-85 years)[6].

Patients with functional paragangliomas can experience hypertension, headache, sweating, and palpitations due to the excessive secretion of catecholamines[7]. Nonsecretory paragangliomas may present with abdominal mass with or without abdominal pain, but most are found incidentally on imaging studies[8,9]. CT has a sensitivity of approximately 90% in the identification of extra-adrenal paragangliomas, which frequently appear as highly vascular structures with areas of intralesional hemorrhage and necrosis[8,10]. The CT findings of pancreatic paragangliomas differ from those of pancreatic ductal adenocarcinoma by their location at the pancreatic

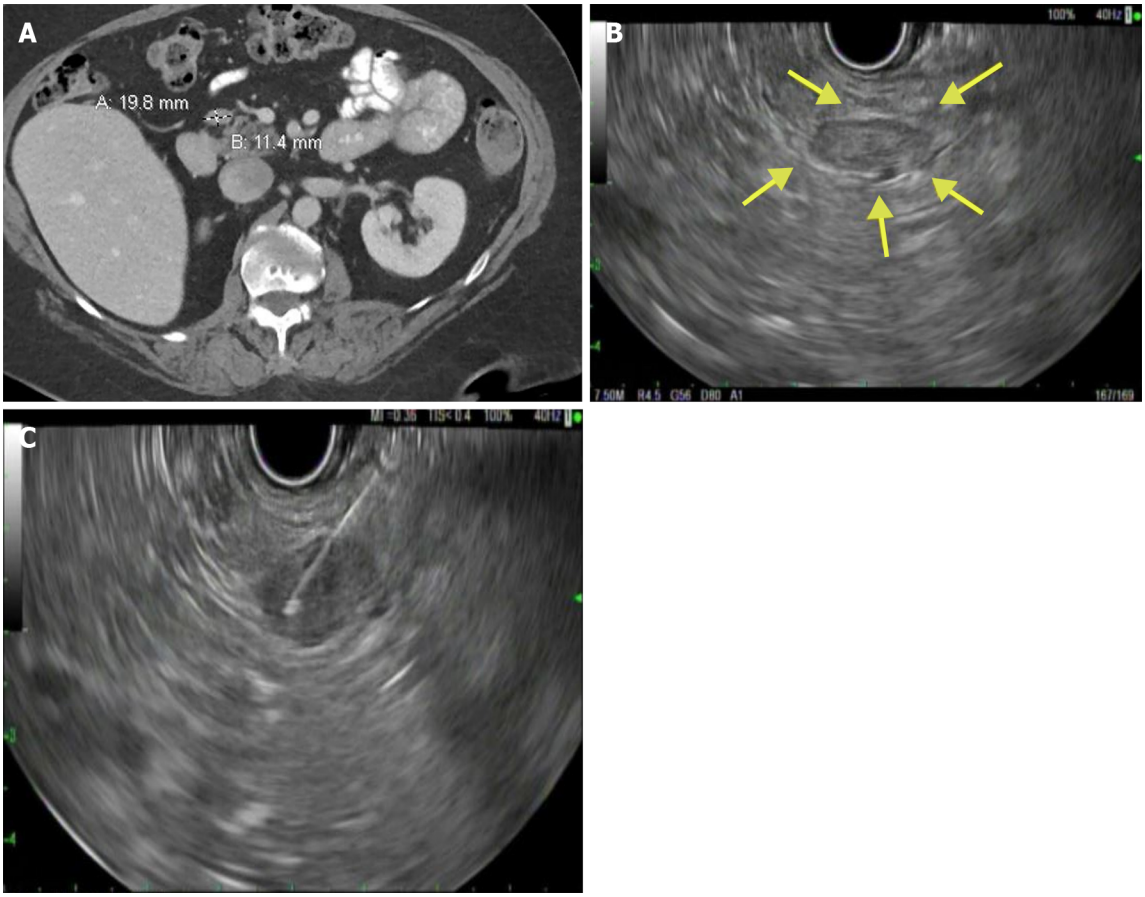

Figure 1 Computed tomography and endoscopy examinations. A: Computed tomography of abdomen pelvis showing a peripancreatic lymph node adjacent to the pancreatic head; B: Endoscopic ultrasonography showing a hypoechoic lesion near the pancreatic head; C: Endoscopic ultrasound-guided fine needle aspiration of the peripancreatic lesion.

head and absence of biliary dilation, although mild pancreatic duct dilatation is sometimes seen[11]. Paragangliomas are also differentiated from nonfunctioning islet cell tumor of the pancreas by observation of early contrast filling of the prominent draining veins of the tumor and the portal vein[12]. Magnetic resonance imaging (MRI) provides tissue characterization superior to CT without radiation[13]. Working synergistically, meta-iodobenzylguanidine (MIBG, I^{123} or I^{131}) scan is useful in differentiating functional from nonfunctional paragangliomas as well as in the detection of tumors in unusual locations, multiple primary tumors, and metastasis[13]. MIBG scan has a sensitivity of 85% and specificity of 95%-100% in the detection of extra-adrenal paragangliomas. Plasma or urinary metanephrines can be used to further establish the diagnosis of functional paragangliomas[13,14].

While most paragangliomas are solitary and sporadic, they can be multicentric and hereditary. Genetic testing should be considered in all patients diagnosed with paraganglioma as nearly 40% (pheochromocytoma and paraganglioma) carry germline mutations. Genetic testing allows for the identification of simultaneous cancers in hereditary syndromes and assists with screening family members at high risk[15]. The most common genetic mutations associated with paragangliomas are *RET* gene in multiple endocrine neoplasia type 2A and 2B, *VHL* in von Hippel-Lindau disease, *NF1* in neurofibromatosis type 1, and succinate dehydrogenase (*SDH*) B, D, C genes[15].

One of the most valuable tools that can assist in establishing the diagnosis of paraganglioma is EUS, which both enables localization of the mass and acquisition of tissue samples for cytology *via* FNA. When not considered in the differential diagnosis, pancreatic paragangliomas can be easily misdiagnosed on EUS-FNA cytology as pancreatic neuroendocrine tumor (NET)[16,17]. Some authors suggest that EUS-FNA should not be done in functional paragangliomas as it can trigger the secretion of catecholamines[18]. In our case, the diagnosis was not established before EUS-FNA and there were no complications during and after the procedure.

On cytology, the cells of paragangliomas are relatively uniform in size, epithelioid in appearance with round to oval nuclei, and arranged in loosely cohesive clusters

PPGL: Pancreatic paraganglioma; PNET: Pancreatic Neuroendocrine tumor; EUS-FNA: Endoscopic ultrasound-guided fine needle aspiration.

[19]. Morphological patterns like acinar/glandular architecture and rosette-like arrangements can be observed in paragangliomas[20]. In histologic sections, the tumor is typically composed of nests of cells separated by a highly vascularized network[21].

Although the morphologic overlap between paraganglioma and NET is significant, the distinction can be confidently made with immunoperoxidase stains, which require a cell block preparation. Both pancreatic paragangliomas and NETs readily express neuroendocrine markers like synaptophysin and chromogranin[19]. While most NETs are immunoreactive to pancytokeratins (AE1/AE3 and CAM 5.2) but not vimentin, paragangliomas show the opposite profile[19]. GATA-3 and PAX-8 can also be used to distinguish paragangliomas from NETs. Paragangliomas from any anatomic site are immunoreactive to GATA-3 in approximately 55% of the cases, but NETs are always nonreactive[22]. Of note, GATA-3 can be positive in cells of breast, urothelial, and pancreatic origin[23]. PAX-8 has a sensitivity of 88% and specificity of 74% for primary pancreatic NETs, but paragangliomas have weak or negative immunoreactivity to PAX -8[24-26]. In our case, FNA smears with Papanicolaou stain showed abundant, tangled cellular processes and relatively uniform nuclei with finely granular chromatin and indistinct nucleoli (Figure 2). FNA cell block with hematoxylin and eosin stain (Figure 3A), diffuse cytoplasmic staining with chromogranin (Figure 3B),

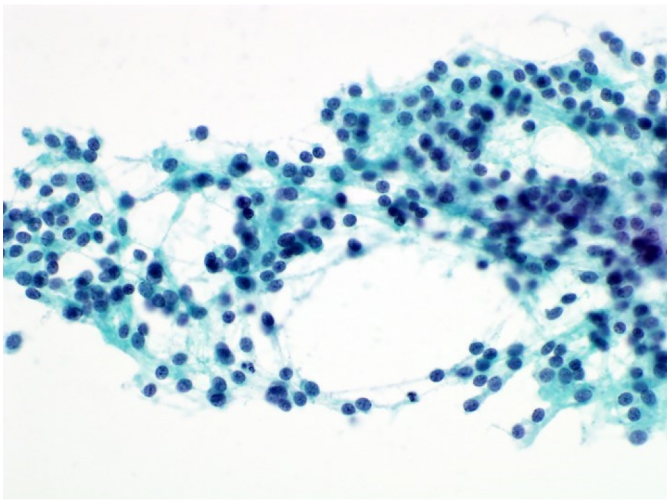

Figure 2 Fine needle aspiration direct smear. Papanicolaou stain, × 400.

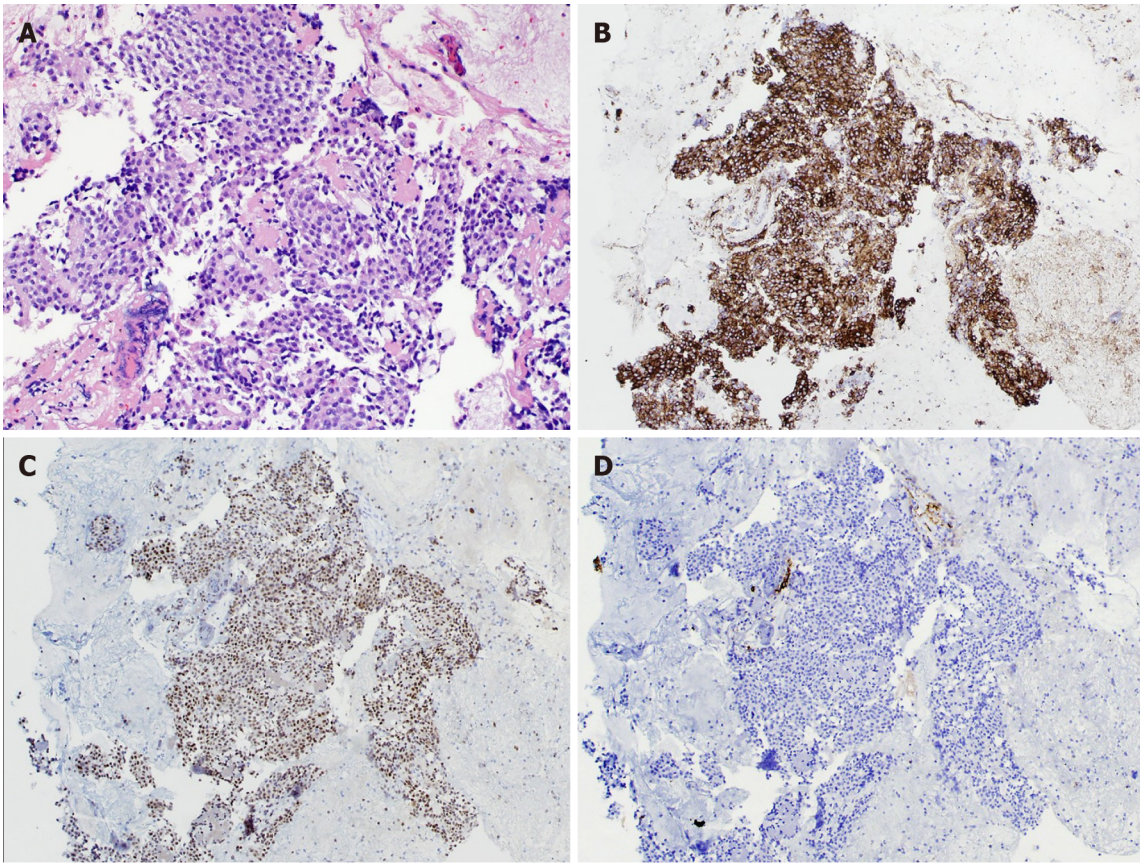

Figure 3 Fine needle aspiration cell block. A: Hematoxylin and eosin stain, × 200; B: Diffuse cytoplasmic staining, chromogranin (× 100); C: Diffuse nuclear staining, GATA-3, (× 100); D: No staining, keratin cocktail (× 100).

diffuse nuclear staining with GATA-3 (Figure 3C), and no staining with keratin cocktail (Figure 3D).

Since there are no definitive criteria for the diagnosis of malignancy in paraganglioma apart from metastasis, the treatment of choice for paraganglioma is surgical resection. For functional paragangliomas, preoperative administration of α-adrenergic receptor blocker can help prevent a hypertensive crisis during the surgery[27]. The most common sites of metastasis include the regional lymph nodes, bone, lung, and liver, and the dissemination usually occurs through blood or lymph nodes[28]. When surgery is not feasible, radiation therapy can be considered[29]. For malignant paragangliomas, treatment with I^{131} MIBG or combination chemotherapy (cyclophos-

phamide, vincristine, and dacarbazine) is effective[30]. Octreotide is also useful in inoperable paragangliomas[31].

Our review of the literature in the English language found 47 case reports of pancreatic paragangliomas published in PubMed to date (Table 1). Fifteen patients with pancreatic paragangliomas underwent EUS-FNA; six were correctly diagnosed as paraganglioma; six were misdiagnosed as NET; one had no diagnosis; one was diagnosed as spindle cell neoplasm; and one was diagnosed as pseudocyst. All patients with a pancreatic paraganglioma underwent surgery except three: one patient who developed a hypertensive crisis during the surgery (thus surgery was aborted) [32]; and two patients with metastasis or involvement of the major vessels[10,16].

Our case illustrates that accurate preoperative diagnosis of paraganglioma can be safely made by EUS-FNA. When paragangliomas are small and asymptomatic, it would be reasonable to follow them with periodic imaging studies.

CONCLUSION

Pancreatic paragangliomas are rare and EUS-FNA is a valuable tool in establishing the diagnosis. When assessing a lesion in the pancreas, paraganglioma should be included in the differential diagnoses along with PNET and pancreatic ductal adenocarcinoma. As EUS-FNA can trigger a hypertensive crisis in functional pancreatic paragangliomas, pre-procedure use of alpha-adrenergic blocker should be considered. To bring the optimal result in the management of paraganglioma, it is imperative to have a multidisciplinary team approach involving radiologists, advanced endoscopists, endocrinologists, pathologists, oncologists, and surgeons.

Abstract

BACKGROUND

Abdominal cocoon or "encapsulating peritoneal sclerosis" (EPS) is an uncommon and rare cause of intestinal obstruction. Only a few cases have been reported in paediatric patients. Typically, EPS is described as the primary form in young adolescent girls from tropical and subtropical countries because of viral peritonitis due to retrograde menstruation or a history of peritoneal dialysis. Most patients are asymptomatic or present with abdominal pain, which is likely to occur secondary to subacute bowel obstruction. Findings at imaging, such as ultrasound, computed tomography, and magnetic resonance imaging, are often nonspecific. When diagnosed, EPS is characterized by total or partial encasement of the bowel within a thick fibrocollagenous membrane that envelopes the small intestine in the form of a cocoon because of chronic intraabdominal fibroinflammatory processes. The membrane forms a fibrous tissue sheet that covers, fixes, and finely constricts the gut, compromising its motility.

CASE SUMMARY

We present a case of EPS in a 12-year-old boy 8 wk after primary surgery for resection of symptomatic jejunal angiodysplasia. There was no history of peritoneal dialysis or drug intake.

CONCLUSION

In this report, we sought to highlight the diagnostic, surgical, and histopathological characteristics and review the current literature on EPS in paediatric patients.

Core Tip: Abdominal cocoon syndrome is rare in children. Cases with no history of previous peritoneal dialysis are practically nonexistent. Our report of a 12-year-old boy reveals that abdominal surgery can be a trigger for the development of encapsulating peritoneal sclerosis (EPS). Indications for surgery for EPS are usually due to mechanical ileus, and the final diagnosis is made intraoperatively. Surgical therapy for EPS is the first choice, and total intestinal enterolysis of EPS seems to be the best approach. The long-term prognosis for children is good.

INTRODUCTION

Encapsulating bowel disease is a very rare but serious condition. The differentiation between congenital peritoneal encapsulation (CPE) and encapsulating peritoneal sclerosis (EPS) is obvious. CPE, reported for the first time in 1868 by Cleland[1], is the result of an embryological intestinal malformation that occurs when the yolk sac returns to the abdominal cavity, creating an accessory membrane covering the bowel. This is to be distinguished from EPS, which is far more common than CPE and was first described in 1907 by Owtschinnikow[2] with the term "peritonitis chronica fibrosa incapsulata". In 1987, Foo *et al*[3] used the term "abdominal cocoon" for primary or idiopathic EPS in cases where no established cause could be identified.

EPS has been recognized to occur in various geographically and ethnically diverse locations. In addition to various terms, such as "peritoneal sclerosis, peritoneal fibrosis, sclerosing peritonitis, sclerotic thickening of the peritoneal membrane, sclerosing obstructive peritonitis or encapsulating peritonitis", EPS is the most common name[4]. Because inflammatory features are not always apparent, the use of the word peritonitis, as in the general terminology, is not preferred. ESP has been proposed as the appropriate term by the International Society for Peritoneal Dialysis when peritoneal dialysis is the reason for the ubiquitous inflammatory processes that cause cocoon formations. Today, most authors use the term abdominal cocoon not only for the primary or idiopathic form but also for the secondary form of EPS[5-8] (Figure 1). The primary type is classically described in young adolescent girls from tropical and subtropical countries, which is mostly idiopathic in nature. A few of the etiopathogenesis proposed for the primary form are viral peritonitis, retrograde menstruation with superimposed viral infection, and gynecological infection-inducing cell-mediated immunological tissue damage. However, these theories may not explain the etiopathogenesis in all patients, as this condition is also seen in men, premenstrual women, and children. The secondary form can occur secondary to multiple predisposing factors in addition to peritoneal dialysis, *e.g.*, peritoneum inflammation with fibroblastic proliferation, systemic lupus erythematosus, liver cirrhosis, endometriotic cyst, abdominal trauma/surgery, abdominal tuberculosis, or malignancy[9,10].

EPS is characterized by total or partial encasement of the bowel within a thick fibrocollagenous membrane that envelopes the small intestine in the form of a cocoon as a result of chronic intraabdominal fibroinflammatory processes[11]. The result is the formation of fibrous tissue sheets that cover, fix, and ultimately constrict the gut, compromising its motility. Most patients are asymptomatic or present with (recurrent) abdominal pain, which is likely to occur secondary to partial/complete bowel obstruction. Usually, patients have had prior episodes with similar symptoms that have resolved spontaneously. With the development of complete sclerosis due to the formation of a cocoon, there are overt signs of mechanical ileus.

Clinically, the abdomen is often soft at palpation. A soft nontender mass may be palpable in the central part of the abdomen, which represents clumped-up bowel loops. Imaging findings seen on ultrasound (US), computed tomography (CT), and magnetic resonance imaging (MRI) are often nonspecific[7]. Other imaging modalities, such as barium studies or positron emission tomography studies, have been discussed and have not revealed any appreciable advantage in the diagnosis of EPS. Therefore,

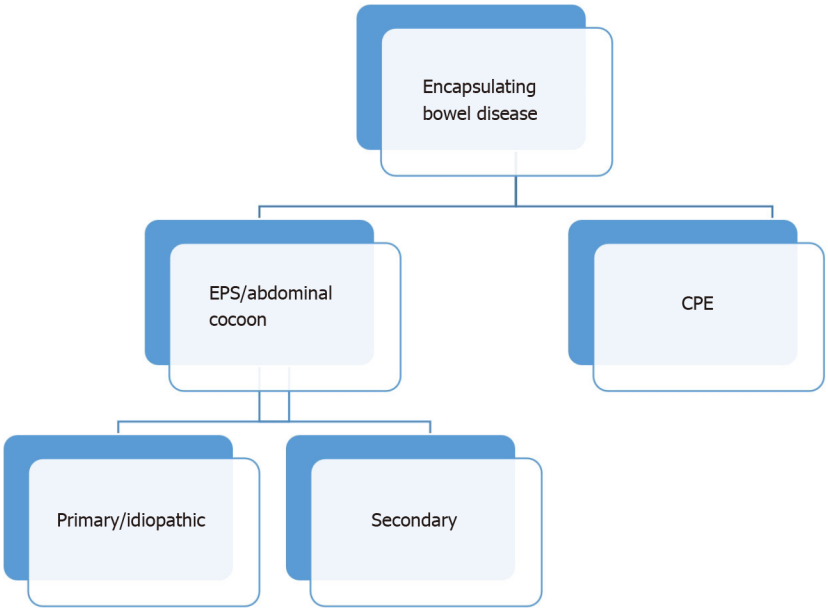

Figure 1 Flow chart and classification for encapsulating bowel diseases. EPS: Encapsulating peritoneal sclerosis; CPE: Congenital peritoneal encapsulation.

this condition is often only diagnosed intraoperatively, followed by histological analysis[12].

EPS has a clearly different histology than CPE. The thin membrane on the visceral peritoneum contributes to the formation of the intestinal encapsulation of EPS. Histologically, the membrane is comprised mainly of organized fibrin, probably derived from plasma exudation from the peritoneal microvasculature. Peritoneal fibroblasts appear swollen and exhibit an increased level of cellularity, accompanied by the expression of various activation and proliferation markers. Persistent inflammatory changes are also predictive of the onset of EPS[4].

The development of EPS has been divided, taking into account clinical and pathological findings in four stages, as proposed by Nakamoto[13]. The pre-EPS stage is characterized by the presence of ultrafiltration failure and/or altered solute transport status; this is followed by inflammatory, encapsulating, and obstructive phases, the last of which is characterized by intestinal obstruction and the formation of an "abdominal cocoon". A staging system has been proposed in the peritoneal catheter (PD)-associated EPS literature based on a combination of clinical, laboratory, and radiographic findings. Nakamoto[13] categorized patients with EPS into Stage 1 (pre-EPS), Stage 2 (inflammatory), Stage 3 (encapsulating), and Stage 4 (chronic) based on abdominal symptoms, inflammation, encapsulation, and intestinal findings (Figure 2). Different conservative therapeutic approaches have been proposed depending on the stage of the disease, which include nutritional support, immunosuppression with corticosteroids as the best studied, colchicine, azathioprine, mycophenolate mofetil, cyclosporine, and mammalian target of rapamycin. Furthermore, antifibrotics such as tamoxifen can increase the efficiency of immunosuppressive drugs.

The division into four disease stages enables stage-appropriate therapy for EPS. Table 1 shows the stage-dependent therapy of EPS according to Nakamoto[13]. For a long time, surgical treatment of EPS was not considered appropriate due to the high perioperative mortality rate of up to 70%. On the other hand, several studies showed that, independent of the therapy procedure, the overall mortality in EPS patients was 67%. In a recent study, the mortality in surgically treated patients was only 42%. This reduction in mortality can only be achieved by timely and adequate surgical therapy. However, to date, there is neither a uniform surgical therapy concept nor standardized perioperative management.

To our knowledge, there has been no prior definitive, systematic review of EPS in children without a history of PD. Due to the assumption that younger patients are at greater risk for EPS, it is important to highlight the age groups of the patients.

In the following, we present a case of a 12-year-old boy with EPS 8 wk after primary laparotomy. We report his medical history, clinical presentation at admission, laboratory values, preoperative diagnostic and intraoperative findings, histological results, and days until discharge (short-term outcomes). The main objective of the

Table 1 Summary of therapy options of encapsulating peritoneal sclerosis according to the staging system

Stage	Therapy options
Stage 1/pre-EPS	Discontinuation of pertioneal dialysis
	("Sedation" of the peritoneum)
	Peritoneal lavage
	Glucocorticoids
Stage 2	Glucocorticoids
Stage 3	Glucocorticoids
	Total parenteral nutrition
Stage 4	Operation

EPS: Encapsulating peritoneal sclerosis.

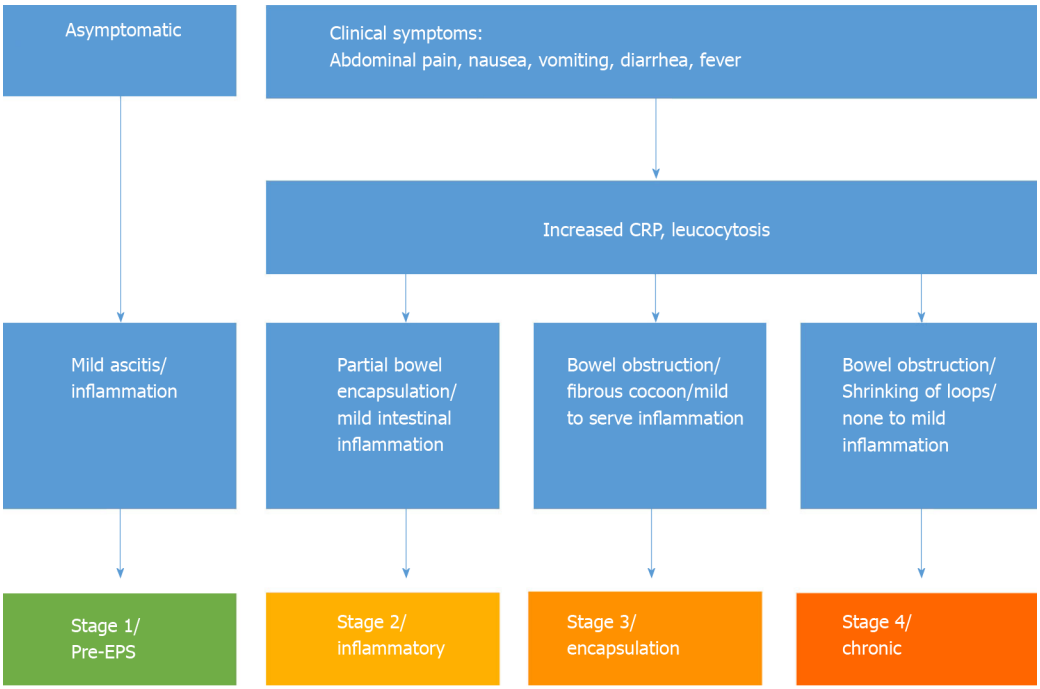

Figure 2 Stages of encapsulating peritoneal sclerosis with associated clinical, serologic, and intestinal findings. EPS: Encapsulating peritoneal sclerosis; CRP: C-reactive protein.

present study was to perform a systematic review of the literature to identify studies on EPS/abdominal cocoons in children. For review, we scanned PubMed, Medline, and Google Scholar search engines for articles containing the terms "EPS", "abdominal cocoon", "abdominal cocoon syndrome", "encapsulating bowel disease", and "SEP", children and paediatric" published from January 1990 to January 2020. Terms were entered alone or in combinations.

We included all articles reporting case series or case reports in the English and German languages. All series and case reports reporting patients younger than 18 years were included (quantitative screening). Further eligibility criteria were a report of the clinical presentation, sex and age, operation as the treatment, and histopathological findings (qualitative screening). Data for all clinical, diagnostic, therapeutic, and etiologic findings were collected from the different databases. We included primary (idiopathic) and secondary forms [abdominal surgery, abdominal trauma, abdominal tuberculosis, peritoneal shunts, liver transplantation, recurrent peritonitis, beta-blocker treatment (practolol or propranolol), chemotherapy, gastrointestinal malignancy, systemic lupus erythaematosus, or parasitic infection] of EPS with the exception of EPS due to PD. We excluded PD-associated EPS because, as mentioned above, in these cases, ESP is the appropriate term with inflammatory processes in the

cocoon, such as formation of the bowel. We then created a PRISMA flow chart showing the results of the literature search (Figure 3).

CASE PRESENTATION

Chief complaints

A 12-year-old boy with Xq24 deletion syndrome presented with symptoms of intermittent intestinal obstruction 8 wk after primary surgery.

History of present illness

The child was symptomatic with a distended abdomen, refusal of feeds, and episodes of abdominal pain. Furthermore, he presented with large gastric residuals that became bilious in the next week.

History of past illness

Eight weeks previously, he presented with suspected intestinal bleeding without further symptoms. US, abdominal MRI, endoscopy, and laparoscopy did not reveal the cause of the chronic bleeding. Specialized angiographic MRI was suspicious for a small intraluminal vascular tumour in the ileum. Limited laparotomy and meticulous palpation of the small bowel enabled the identification of the tumour in the lower ileum. Limited small bowel resection and primary anastomosis were performed. Further clinical investigation of the whole small and large bowel did not reveal any further pathological findings. Histopathological examination showed a venous malformation (2.5 cm × 2.0 cm) at the transition of the jejunum to the ileum. The following clinical course was uneventful. The boy was discharged on the 5th postoperative day.

Personal and family history

Except for Xq24 deletion syndrome, there was no other personal or family history of acute or chronic disease.

Physical examination

On physical examination, the patient showed a distended abdomen and abdominal pain. The examination of the heart, lungs, and further organ status showed no abnormalities. Due to his Xq24 deletion syndrome, he showed psychomotor delay, intellectual disability, and a characteristic craniofacial dysmorphism.

Laboratory examinations

Laboratory findings showed slightly elevated C-reactive protein (0.3 mg/dL) and normal findings across the rest of the blood panel.

Imaging examinations

The abdominal US showed pendulum peristalsis and free fluid in the abdominal cavity, and a plain abdominal X-ray showed some air fluid levels (Figure 4A). A gastrointestinal contrast study was performed, which revealed distended small bowel loops (maximum diameter of 50 mm) and narrow segments of the large intestine. There was appropriate intestinal transit, with the presence of contrast in the jejunal and ileal loops after 1 h of administration. The contrast agent arrived at the terminal ileum and caecum at 2 h of intestinal transit. Due to the inconclusive results, we performed MRI, which revealed a distended duodenum and small bowel loops with multiple intraluminal air fluid levels and thickened walls but with no signs of obstruction (Figure 4B).

FINAL DIAGNOSIS

Due to the clinical symptoms of obstructive bowel disease and inconclusive radiological signs, the patient underwent relaparotomy. Intraoperatively, we found a completely encapsulated small bowel (Figure 5). The massive, fibroconnective membrane encapsulated the bowel from the ligament of Treitz to the ileocecal junction. The thick, firm, and white membrane was not attached to the parietal peritoneum. Microscopic findings showed partially mesothelium-covered, predom-

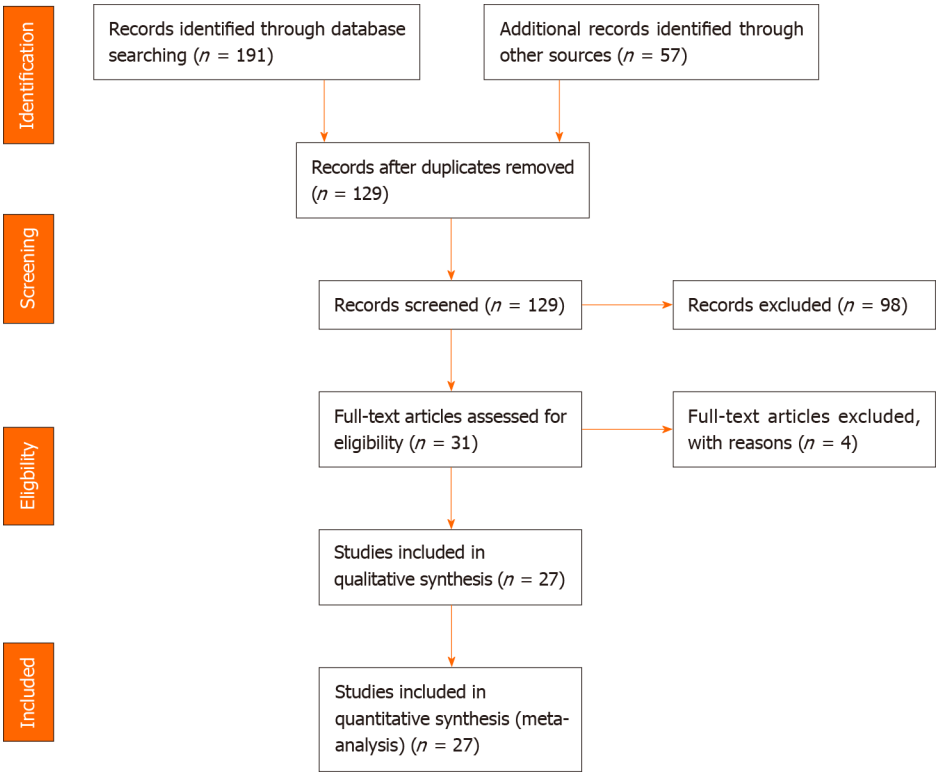

Figure 3 PRSIMA Flow chart showing the results of the literature search.

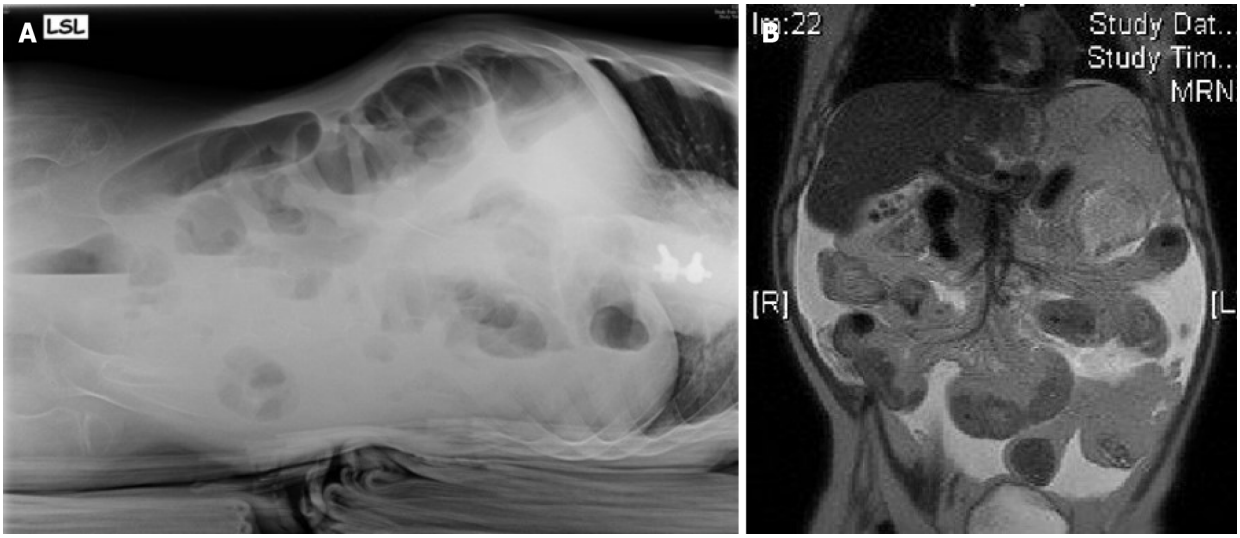

Figure 4 Diagnostic imaging. A: X-ray with lateral abdominal view showing some air fluid levels; B: Magnetic resonance imaging in coronal plane with distended duodenum and small bowel loops with multiple intraluminal air fluid levels and thickened walls.

inantly edematous loosened fibre-rich connective tissue with prominent, predominantly small vessels with a prominent endothelial lining with hyperchromatic oval nuclei, mostly positive for CD31 and CD34. No evidence of malignancy was found (Figure 6).

TREATMENT

We performed extensive adhesiolysis by peeling the fibrous pseudocapsulae from the small bowel. This resulted in freeing of the small bowel but also in multiple serosal injuries with diffuse bleeding. No bowel perforation occurred.

Figure 5 The small bowel is shortened, considerably thickened, and covered with a fibrous membrane, which separates and constricts the entire small intestine from approximately 10 cm distal to Treitz's ligament to approximately 5 cm proximal to the ileocecal junction.

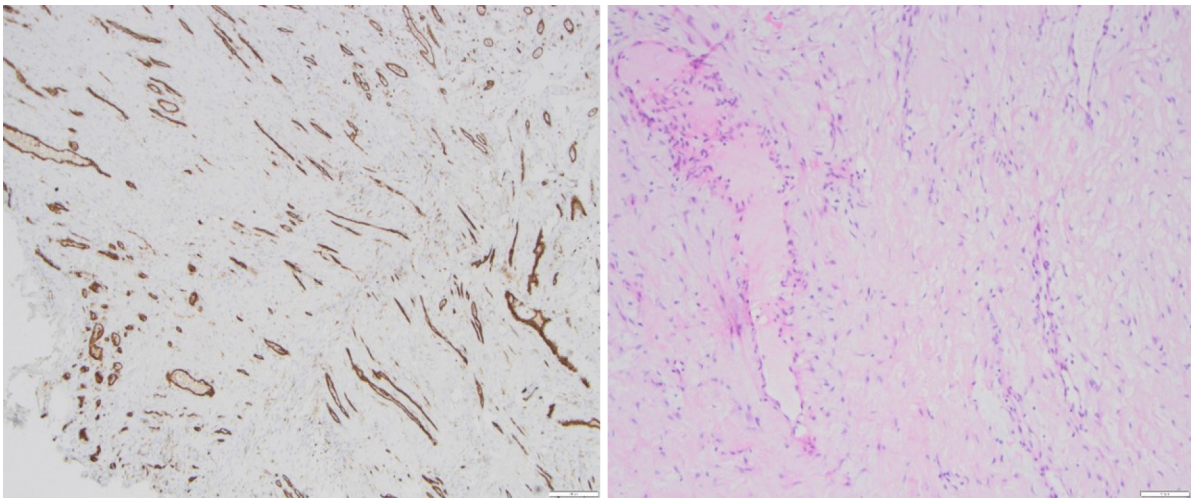

Figure 6 Microscopic findings showed partially mesothelium-covered, predominantly edematous loosened fiber-rich connective tissue with prominent, predominantly small vessels with prominent endothelial lining with hyperchromatic oval nuclei.

OUTCOME AND FOLLOW-UP

The following clinical course was prolonged due to peritonitis, massive ascites, and paralytic ileus. Eventually, 2 wk after surgery, the first feeds could be established, and the child was discharged on the 23rd postoperative day. The follow-up is now 12 mo and uneventful. A summary of the most relevant aspects of the case is listed in Table 2.

DISCUSSION

Literature review

Articles identified after reviewing and applying the inclusion criteria are listed in Table 3. No comparable case could be found in children presenting with EPS after surgery. Sahoo *et al*[14] reported EPS as an idiopathic form in a case series of 4 patients (3 boys, 1 girl) between 6 and 8 years of age, and Mehta *et al*[15] and Bassiouny *et al*[16] reported EPS in a 7-year-old boy without underlying disease. Ahmad *et al*[17] mentioned a case report of EPS in a newborn as a consequence of meconium peritonitis. In total, 27 articles could be found reporting 33 patients (Table 3). Among these patients, 24 were girls and 9 were boys. Their ages ranged from 2 d to 17 years.

Table 2 Summery of our patient data

Age	Clinical symptoms	Labatory findings	Intraoperive findings	Histology
11 yr	Abdominal pain; Distended abdomen; Vomiting (bilious)	CRP: 0.3 mg/dL	Complete; encapsulation of the small bowel	Fibrous connective tissue with prominent vas-cularization, predomi-nantly from the venous type

CRP: C-reactive protein.

Especially in older patients (≥ 10 years of age), EPS was detected more often in girls (f:m = 22:2). Various radiological modalities for diagnosis (singly or in addition) were reported, such as abdominal X-rays (n = 21), US (n = 18), contrast studies (n = 8), and CT scans (n = 11). In three cases, no diagnostic tool was mentioned. Thirty-two patients underwent surgery (laparotomy), while 1 patient underwent conservative treatment with antitubercular medications. When laparotomy was performed, adhesiolysis and excision was the treatment of the choice (n = 32). Two patients underwent appendectomy simultaneously, and two patients underwent temporary enterostomy due to pronounced bowel inflammation. In 3 patients, limited bowel resection, including the ileocecal region, was performed since it was too difficult to incise and release the envelope without injuring the intestines. In all reported cases with surgical treatment, the operation and postoperative period were uneventful.

Discussion

The clinical picture of EPS is largely unknown in the medical world[18]. The embryonal condition is characterized by an accessory peritoneal sac derived from the peritoneum of the yolk sac as it is withdrawn into the abdominal cavity during the 12th week of gestation[3]. Only a few risk factors are known[9]. This disease can occur as a late consequence of long-term peritoneal dialysis[19-23]. However, even this is not necessarily always the case, since cases are known in which EPS is already visible shortly after initiation of PD therapy[11]. In these cases, the mortality depends on the duration of PD, ranging between 30% and 60%. In other cases where EPS is not associated with PD, various reports have reported beta blockers as the cause of EPS [10]. In animal models, practolol inhibits the release of surfactant from type II pneumocytes, resulting in damage to the abdominal serosa[24]. Tumours with peritoneal dissemination and infectious peritonitis are other frequently mentioned risk factors for EPS, supported by epidemiological data. Pathogens significantly increase the risk, highlighting *Staphylococcus aureus*, fungi, *Pseudomonas* spp., and *Haemophilus influenza*[3,4,10]. Fowler *et al*[25] suggested echovirus infection as an etiologic factor, and Foo *et al*[3] thought tuberculosis could be involved.

Several theories have been formulated about the pathogenesis of idiopathic EPS [26], for example, retrograde menstruation due to virus infection or pelvic peritonitis with tissue damage incurred by cell-mediated immunity[3,5,11]. Retrograde menstruation explains the relatively high number of adolescent girls with idiopathic abdominal cocoons (Table 3). Moreover, several tumour entities and/or abdominal operations may lead to adhesions and peritoneal fibrosis[27-29]. Therefore, overall, the most common theory is developing a membrane in the form of sclerosis secondary to peritonitis[17,18]. Prospectively controlled randomized studies are lacking, and most studies on EPS present small patient collections over a long period of time[10-13].

The presented case is very unusual because of the child's young age, the atypical geographical region, and a very rare cause (secondary to abdominal surgery). Most of the other publications with paediatric patient collections are secondary forms after tuberculosis infection or after prolonged PD. The short time interval to the primary laparotomy in our patient is a special feature that has not been described in the literature thus far. EPS after kidney transplantation (as an abdominal surgical intervention) has been reported in case reports; however, these patients also had a history of PD or chronic kidney diseases[30]. In many cases of idiopathic EPS, no correlation can be detected with any potential risk factor[4,31-33]. Nevertheless, two considerations are important: First, in these forms, peritoneal disorders are often associated with general connective tissue damage, particularly of the serous membranes, such as abdominal trauma; this indicates a major role of immunopathogenesis in EPS. The second factor can be a genetic predisposition, which is suggested due to the high frequency of EPS in women from subtropical regions and familial forms such as multifocal family fibrosclerosis.

In reports including patients with long-term PD, pathogenesis is often described with the "two-hit"-hypothesis[3,4] when disruption of normal peritoneal/mesothelial physiology is a result of extensive PD over a period of years and predisposes the individual to a second hit that triggers the process. This second hit may take the form of an episode of peritonitis, discontinuing PD, or an acute intra-abdominal event. In our case, this hypothesis is unlikely because he was a non-PD patient, and there was a very short period between the two events. Therefore, the reason for the development of EPS in our patient must be found in the previous operation with resection of lymphangioma as an abdominal trauma and trigger for sclerosis. Another reason for developing EPS could be cystic lymphangioma of the small bowel itself as a benign vascular tumour with peritoneal dissemination. Garosi[19] and Célicout *et al*[34] described different tumour entities in connection with EPS in patients without PD, including histiocytic lymphoma, gastric, ovarian, pancreatic and renal cell carcinoma, and oedematous polyposis of the colon. Cystic lymphangioma as a trigger for EPS could not be found in the literature thus far. Because the lymphangioma was resected in total during the first operation, we believe that primary abdominal surgery was the trigger for EPS in our patient.

Diagnostic modalities

Because the early clinical features are often nonspecific[35,36], it is difficult to make a definite preoperative diagnosis of EPS. There are no specific serological markers for EPS. Ultrasonography may show dilated small bowel loops, ascites with or without parietal loculations, and a membrane covering the small bowel loops with occasional formation of a mass of bowel loops and adhesions[37]. Abdominal X-rays have a low sensitivity, showing mostly dilated small bowel loops with multiple air fluid levels. Peritoneal and bowel wall calcification has also been reported. Abdominal CT has a higher sensitivity (70%-90%) to detect the etiology of high-grade small bowel obstruction but should be used cautiously due to radiation risks in young patients. In our search of the literature, MRI has not been reported in paediatric patients with abdominal cocoons. Nevertheless, MRI has been recently reported as another useful modality in diagnosing EPS and may be a preferred technique in children.

Surgical procedures

In the international literature, two surgical therapy approaches for EPS have been described but were only reported in studies within adult patient collections. In 1998, C élicout *et al*[34] published a study in which 3 of 32 patients had dialysis-associated EPS. In the remaining patients, the EPS was the result of a malignancy (14 of 32) or due to b-blocker intake (5 of 32). The indication for the operation was, in all cases, the ultima ratio after long-lasting ileus disease. Japanese reports are based on studies that only included PD patients[38]. The intraoperative approach in Japan includes removal of the interenteric adhesions and the detachment of the encapsulating small intestinal membranes. The occlusive membranes on the intestine are dissected through longitudinal incisions. However, peritoneal sclerosis makes it difficult to identify the "right" layer, so special attention must be paid to serosa lesions. These are insidious because they can lead to occult perforations postoperatively with an increase in small bowel motility and the resulting increased pressure. In case of doubt, any altered segments of the small intestine are therefore resected. In Japan, in suitable cases, solitary stenoses are dilated with a Miller-Abott probe from the intraluminal side. Thus, even tandem stenoses can be corrected without resection. The balloon is deflated after completion of the dilatation and left *in situ* for splinting of the intestine. Usually, the probe is removed after 1 wk. In the opinion of the Japanese authors, the Noble plicature can prevent reobstruction by kinking as well as the reoccurrence of adhesions or entrapment of the small intestine in the Douglas cavity or in the excavation rectovesicalis, respectively.

The use of probes for intestinal splinting and the methods of plication have been discussed very controversially in Germany and have only historical significance. In our opinion, these methods, which carry their own risk, are not reliable enough to prevent the recurrence of ileus disease. In an international comparison, Japan has the most experience with EPS.

In addition to total intestinal enterolysis, which was performed in all cases with surgical treatment, deserosation, and decapsulation, peritonectomies, fibrin membranectomy, and omentectomies were performed in accordance with the findings. Additionally, an opening of the bursa omentalis for the decompression of fluid or for complete unleashing of the stomach may be essential.

There are hardly any reports from the Anglo-American region regarding surgical therapy for EPS. Studies from Australia[39] and Canada[8] mostly refer to conservative therapy for the disease. The surgical procedure is only mentioned as laparotomy and adhesiolysis. Therefore, our strategy was like the international approach with the avocation of extensive enterolysis and detachment of the encapsulating small intestinal membranes.

Postoperative complications

In work published in 1998 by Célicout *et al*[34], the authors showed a mortality rate of 19% and an anastomosis failure rate of 12%. The total complication rate of 38% was the lowest at that time in the literature but was still considered too high[21]. Ten years later, Kawaguchi *et al*[5] published a retrospective study that included 130 surgically treated EPS patients. The reported mortality was 6.9%. However, the recurrence rate was very high (25.4%). Of the 130 patients, 33 had to be reoperated on for recurrence or postoperative ileus, and some patients underwent reoperations up to six times. In our reported case, as well as in the reports with paediatric patients, there were no complications after the operation, and no recurrence was described.

Histological examination

A few histological features, such as fibrin deposits, fibroblast swelling, angiogenesis, and mononuclear inflammatory infiltrate, differentiate peritoneal fibrosis from actual EPS. Since this means that even fewer predictive histological features are available, the German Peritoneal Biopsy Register was established at the initiative of the German Society of Nephrology. Here, we present prospective histomorphology characteristics of peritoneal biopsies with the aim of analysing the pathogenesis of the disease and producing reproducible algorithms for histological diagnosis confirmation. Therefore, the histological evaluation of EPS can now be increasingly based on standardized criteria. The Institute of Pathology at the Robert Bosch Hospital has become the reference centre for the histomorphology evaluation of peritoneal biopsies of the "European EPS Working Group". Our histological results showed fibrous connective tissue with prominent vascularization, predominantly from the venous type, matching an early form of EPS.

CONCLUSION

The diagnosis of EPS is mainly made intraoperatively, and surgery is often indicated due to symptomatic ileus. A history of abdominal trauma, surgery, or abdominal tumour can be a trigger for developing EPS. Surgery, including adhesiolysis and excision, is the first choice of treatment. Total intestinal enterolysis of EPS is the best surgical approach. The long-term prognosis for children is good.

Abstract

Coronavirus disease 2019 (COVID-19) is caused by the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). Although, respiratory symptoms are typical the digestive system is also a susceptible target with gastrointestinal symptoms present even in the absence of respiratory symptoms. The gastrointestinal symptoms of COVID-19 include diarrhea, abdominal pain, anorexia, and nausea among other symptoms. Some questions that remain to be answered include: Do patients with gastrointestinal symptoms have a higher mortality? SARS-CoV-2 variants are already a global reality: Do these variants present with a greater prevalence of gastrointestinal symptoms? Do patients with these symptoms warrant more intensive care unit care?

Key Words: COVID-19; SARS-CoV-2; Gastrointestinal symptoms; Intensive care unit; Variant

Core Tip: With the emergence of new variants of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) and its clinical manifestations, the following questions have arisen: are gastrointestinal symptoms and complications the same as the other variants or are they different? And are these related to severity of the disease? In this letter to the editor, we discuss the relationship between the new SARS-CoV-2 variants with gastrointestinal manifestations and the severity of disease with the new variants.

TO THE EDITOR

We read with interest the article by Cao *et al*[1] titled "Coronavirus disease 2019 (COVID-19) and its effects on the digestive system."

In 2020, our team conducted a cohort study[2] evaluating 400 patients diagnosed with COVID-19 that, even though it is the largest study in Latin America, unfortunately, was not included in the author's review. In our study, 33.25% of patients reported one or more gastrointestinal symptoms, with diarrhea being the most common, representing approximately 17% of the total. This data corroborates the author's review. It was also found that when these patients had gastrointestinal symptoms, they had a greater tendency to have other concomitant symptoms, especially myalgia and fatigue ($P < 0.05$).

It was also observed that patients with chronic kidney disease ($P < 0.05$), using chronic immunosuppressants, or chronic use of angiotensin receptor blockers or angiotensin-converting enzyme inhibitors had a higher prevalence of gastrointestinal symptoms. Admission to the intensive care unit (ICU), need for mechanical ventilation, length of stay in the ICU, length of hospital stay, need for vasopressor support, laboratory results, and hospital mortality did not differ based on the presence of gastrointestinal symptoms ($P > 0.05$). Regression analyzes showed that immunosuppression [odds ratio (OR): 2.60 (95% confidence interval (CI): 1.20-5.63)], male sex [OR: 1.94 (95%CI: 1.12-3.36)], and older age [OR: 1.04 (95%CI: 1.02-1.06)] were associated with increased mortality.

As described above, our study[2] demonstrated, before the emergence of the new variants of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2)[3,4], that gastrointestinal symptoms were not associated with a greater need for ICU admission or the severity of the disease in patients in Latin America.

This is a very controversial topic; some studies suggest a less severe clinical evolution in patients with gastrointestinal symptoms[5,6], whereas in the study by Redd *et al*[7], there was no statistical difference.

The study by Leal *et al*[8], evaluating 234 European patients with digestive symptoms, also had a more favorable and non-severe prognosis.

In a review carried out by Wang *et al*[9], it was observed that pancreatic damage or mesenteric ischemia/thrombosis could increase mortality.

In the pediatric population, in the study by de Paula *et al*[10], logistic regression analysis identified that laboratory-confirmed COVID-19 pediatric patients with gastrointestinal symptoms had an increased risk of cardiac abnormalities confirmed by echocardiogram (OR: 6316; 95%CI: 1.717-79043; $P = 0.012$).

We emphasize that in all these studies there was no distinction regarding the variety of SARS-CoV-2 studied.

It is currently known that the high expression of angiotensin-converting enzyme 2 in the lung and the intestinal tract makes the small bowel and colon highly susceptible to SARS-CoV-2 infection, which offers a potential explanation for diarrhea observed in many COVID-19 patients. Since tryptophan absorption requires angiotensin-converting enzyme 2, its deficiency can alter the intestinal microbiota and cause intestinal inflammation[11].

Given the above, we believe a more realistic discussion to be made, and we ask the authors the following: (1) Do patients with gastrointestinal symptoms have more severe disease outcomes or not? (2) Do SARS-CoV-2 variants have a greater gastrointestinal involvement? (3) Do SARS-CoV-2 variants have a relationship between gastrointestinal symptoms and/or disease severity? and (4) Do these patients have a greater need for admission to ICUs?

Finally, we would like to congratulate and thank the authors on the level of shared evidence.

ACKNOWLEDGMENTS

We would like to thank Dr. Sergio A. Sánchez-Luna for reviewing the English translation of this article.

ABOUT COVER

Editorial Board Member of *World Journal of Gastroenterology*, Veerapol Kukongviriyapan, PhD, Professor, Department of Pharmacology, Faculty of Medicine, Khon Kaen University, 123 Moo 16, Mittraphap Road, Muang District, Khon Kaen 40002, Thailand. veerapol@kku.ac.th

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, and Scopus. The 2021 edition of Journal Citation Report® cites the 2020 impact factor (IF) for *WJG* as 5.742; Journal Citation Indicator: 0.79; IF without journal self cites: 5.590; 5-year IF: 5.044; Ranking: 28 among 92 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2020 is 6.9 and Scopus CiteScore rank 2020: Gastroenterology is 19/136.

Abstract

Thiopurines are immunomodulators used in the treatment of acute lymphoblastic leukemia and inflammatory bowel diseases. Adverse reactions to these agents are one of the main causes of treatment discontinuation or interruption. Myelosuppression is the most frequent adverse effect; however, approximately 5%-20% of patients develop gastrointestinal toxicity. The identification of biomarkers able to prevent and/or monitor these adverse reactions would be useful for clinicians for the proactive management of long-term thiopurine therapy. In this editorial, we discuss evidence supporting the use of *PACSIN2*, *RAC1*, and *ITPA* genes, in addition to *TPMT* and *NUDT15*, as possible biomarkers for thiopurine-related gastrointestinal toxicity.

Key Words: Thiopurines; Gastrointestinal adverse effects; Biomarkers; *PACSIN2*; *RAC1*; *ITPA*

INTRODUCTION

Mechanisms of action and adverse effects of thiopurine

Thiopurines, such as mercaptopurine (MP) and its prodrug azathioprine (AZA), are immunomodulatory drugs used in the treatment of pediatric acute lymphoblastic leukemia (ALL) and nonmalignant conditions, such as inflammatory bowel diseases (IBDs)[1,2]. These immunomodulators undergo a complex biotransformation that leads to the production of different thionucleotides (TGNs), such as thioguanosine mono-, di-, and triphosphate (tGMP, tGDP, and tGTP) and deoxythioguanosine mono-, di-, and triphosphate (tdGMP, tdGDP, and tdGTP) (Figure 1). These purine antimetabolites exert their cytotoxic activity through different mechanisms, such as inhibition of *de novo* purine synthesis, interference with the incorporation of guanosine nucleotides into DNA and RNA, and induction of apoptosis due to inhibition of the Ras-related C3 botulinum toxin substrate 1 (Rac-1) protein, a Rho-GTPase[3]. Under physiological conditions, Rac-1-GTP activates the MEKK/IκB/NF-κB and STAT3 survival pathways in activated lymphocytes, resulting in an increase in the antiapoptotic protein Bcl-xL, whereas during thiopurine treatment, the binding of tGTP to Rac-1 impairs these pathways, enhancing apoptosis[3]. Thiopurines are also processed through catabolic pathways, in which xanthine oxidase and thiopurine methyltransferase (TPMT) are the main enzymes involved, producing inactive metabolites such as thiouric acid and methylmercaptopurine, respectively. TPMT also catalyzes the S-methylation of intermediates resulting from MP conversion to TGN, leading to the production of secondary methylated nucleotides (MMPNs) (Figure 1). The role of MMPN metabolites is not fully characterized; however, they could contribute to the inhibition of *de novo* purine synthesis. Factors affecting the TGN/MMPN ratio could influence thiopurine efficacy and toxicity. For example, the amount of TGN in white blood cells is responsible for the immunosuppressive effects; when TPMT activity is compromised, TGN levels increase, leading to dangerous myelosuppression[3].

Thiopurines have a narrow therapeutic index, with an increased risk of severe toxicity and treatment discontinuation[4]. Direct cytotoxic damage can occur in proliferating cells of different tissues and organs. In particular, thiopurines have been associated with the dose-dependent hematological toxicity observed in approximately 80% of ALL cases; in IBD patients, the incidence of bone marrow toxicity is lower (approximately 10%)[5,6]. Neutropenia and leukopenia are the most frequent outcomes of myelosuppression, related to an increased risk of infection, and the main reasons for therapy discontinuation or interruption that can lead to disease aggravation in both ALL and IBD[7-9]. Thiopurine-induced gastrointestinal (GI) toxicity occurs in approximately 5%-20% of ALL and IBD patients; the main symptoms are nausea, vomiting, stomatitis, abdominal pain or cramping, gastritis, gastric ulcer, GI bleeding, and diarrhea[10,11]. Moreover, these immunosuppressors are associated with the risk of neurological complications, hepatotoxicity, pancreatitis, arthralgia, and skin rush[10,12-16].

In the clinic, white blood cell counting is commonly performed to monitor the immunosuppressive effects of these drugs; however, recently, pharmacogenetic biomarkers for predicting thiopurine-induced hematological adverse events have been identified. From a pharmacogenetic point of view, *TPMT* is one of the best characterized genes[17]. Both TPMT protein expression and enzymatic activity are affected by the presence of variants in the *TPMT* gene. More than 44 *TPMT* variant alleles have been described; *TPMT**2 (rs1800462, 238G>C, pAla80Pro), *TPMT* **3B* (rs1800460, 460G>A, p. Ala154Thr), *TPMT***3C* (rs1142345, 719A>G, p. Tyr240Cys), and *TPMT***3A* (rs1800460 and rs1142345 haplotypes) are the most frequent variants in Europeans and can explain up to 95% of TPMT deficiencies[18-20]. As reported above, decreased TPMT activity leads to higher TGN levels and lower MMPN in white blood cells; these

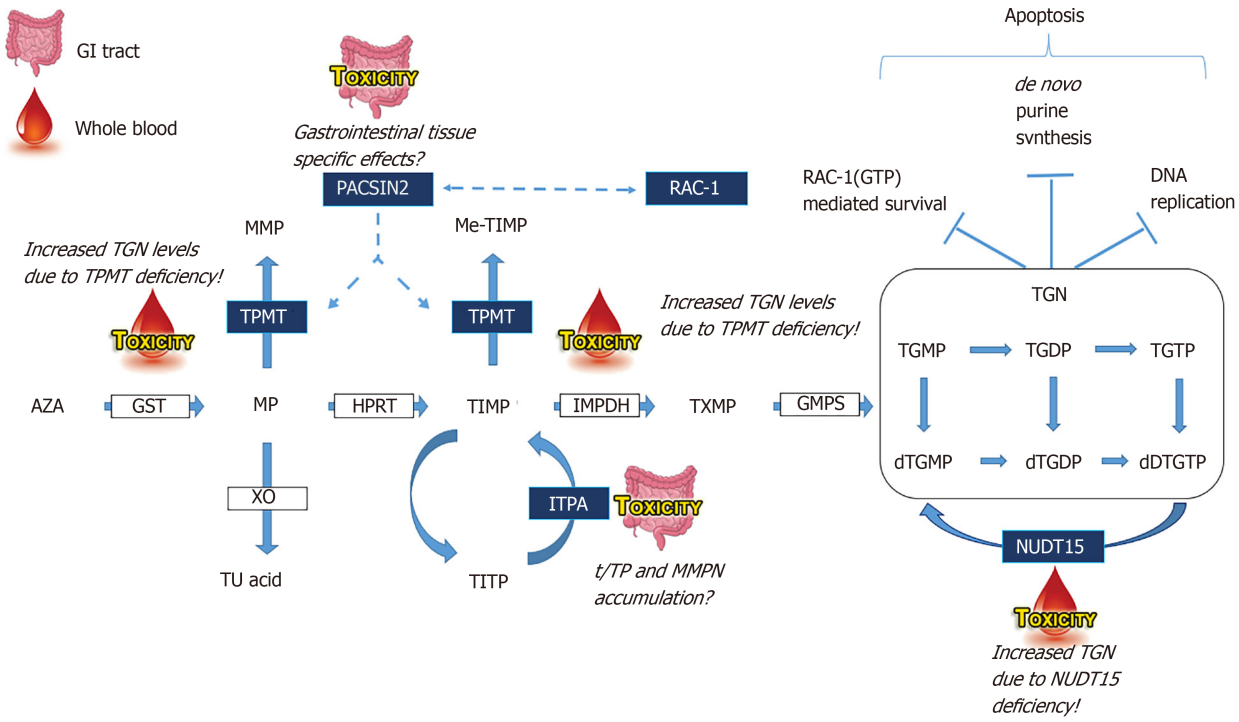

Figure 1 Thiopurine metabolic pathway and possible biomarkers for drug-related toxicity. Dashed arrows indicate the impact of PACSIN2 on TPMT activity and the interaction between PACSIN2 and Rac-1. AZA: Azathioprine; ITPA: Inosine triphosphate pyrophosphatase; IMPDH: Inosine-5'-monophosphate dehydrogenase; GMPS: GMP synthase; GST: Glutathione-S-transferase; Me-TIMP: Methyl-thioinosine monophosphate; Me-TITP: Methyl-thioinosinetriphosphate; MP: Mercaptopurine; MMP: Methyl-mercaptopurine; NUDT15: Nudix hydrolase 15; PACSIN2: Protein kinase C and casein kinase substrate in neurons protein 2; TGDP: Thioguanine diphosphate; TGMP: Thioguanine monophosphate; TGTP: Thioguanine triphosphate; TIMP: Thioinosine monophosphate; TITP: Thioinosine triphosphate; TNG: 6-Thioguanine nucleotide; TPMT: Thiopurine S-methyltransferase; TXMP: Thioxanthine monophosphate; 6-TU acid: Thiouric acid; XO: Xanthine oxidase.

variants are indeed associated with a higher risk of myelosuppression[21]. Variable number tandem repeats (VNTRs) in the *TPMT* promoter are associated with reduced *TPMT* expression levels and a higher risk of MP hematological toxicity[22]. Furthermore, genetic variants in nudix hydrolase 15 (*NUDT15*) have been identified as additional pharmacogenetic markers for the prediction of thiopurine-induced toxicities, especially in Asian individuals. NUDT15 removes a pyrophosphate group by canonical GTP and drug-derived tGTP active metabolites. The most studied *NUDT15* variants are rs116855232 (c.415C> T, p. Arg139Cys), rs147390019 (G>A, p. Arg139His), rs186364861 (G>A, p. Val18Ile), and rs746071566 (36_37insGGAGTC insertion, p.Val18_Val19insGlyVal). Variant alleles encode NUDT15 with compromised activity, leading to a higher tGTP/tGMP ratio and incorporation of TGN into DNA[23,24]. Indeed, these variants have been associated with MP and AZA intolerance[23,25]. On these bases, different guidelines for thiopurine dose adjustment based on *TPMT* and *NUDT15* genotypes have been released to reduce the occurrence of drug-related side effects[26].

In addition to pharmacogenetic markers, TGN levels could be monitored in erythrocytes to avoid severe myelosuppression during therapy. In particular, TGN levels higher than 450 pmol/8 × 10^8 red blood cells (RBCs) and higher than 1000 pmol/8 × 10^8 RBCs have been shown to be associated with myelotoxicity in IBD and ALL patients, respectively, while levels of MMPN above 5700 pmol/8 × 10^8 RBCs have been shown to be related to a higher hepatotoxicity risk in IBD patients[27,28].

BIOMARKERS FOR THIOPURINE-INDUCED GASTROINTESTINAL ADVERSE EVENTS

Although genome-wide association studies (GWAS) have indicated that TPMT activity is predominantly a monogenic trait[29], a percentage of wild-type *TPMT* carriers present reduced TPMT activity, suggesting the existence of other regulatory mechanisms able to modulate its function[30,31]. In 2012, Stocco *et al*[32] demonstrated

that the expression levels and the single nucleotide polymorphism (SNP) rs2413739 of the protein kinase C and casein kinase substrate in neurons 2 (*PACSIN2*) gene were associated with TPMT activity in HapMap cell lines and in a cohort of ALL pediatric patients enrolled at St. Jude Research Children Hospital (SJRCH, Memphis, United States), suggesting a possible role of *PACSIN2* as a TPMT modulator[32]. The authors found that the intronic variant rs2413739 (C>T) was associated with an increased risk of severe GI toxicity during consolidation therapy in two independent cohorts of ALL pediatric patients treated according to the SJRCH Total 13B protocol and to the Associazione Italiana Ematologia Oncologia Pediatrica/Berlin-Frankfurt-Münster (AIEOP-BFM) 2000 protocol[32]. Patients received 75 mg/m^2 MP daily and 2 g/m^2 high-dose methotrexate (HD-MTX) i.v. twice a week for 2 wk at SJRCH, whereas those undergoing the AIEOP-BFM 2000 protocol were treated daily with 25 mg/m^2 MP and received four HD-MTX (2-5 g/m^2) infusions once every 2 wk. To further validate these results, Franca *et al*[33] investigated the possible role of *PACSIN2* rs2413739 in an additional cohort of ALL pediatric patients treated according to the AIEOP-BFM 2009 protocol, with the same consolidation phase as AIEOP-BFM ALL 2000, and in a cohort of IBD pediatric patients undergoing AZA therapy. In the ALL cohort, the *PACSIN2* T allele was associated with decreased TPMT activity during maintenance therapy, particularly in patients heterozygous for *TPMT* rs1142345 and rs1800460. Moreover, the *PACSIN2* TT genotype was associated with a higher risk of GI toxicity during the consolidation phase. The latter association was borderline, likely because of the limited number of clinical data available (n = 81); however, it was in line with the findings of Stocco *et al*[32]. Far more complex to understand is thiopurine-induced GI toxicities in IBD patients, where the occurrence of adverse effects can overlap with clinical manifestations of the disease. Interestingly, Franca *et al*[33] showed that IBD patients carrying the *PACSIN2* T allele and undergoing AZA treatment presented a more active disease, measured as pediatric ulcerative colitis activity/pediatric Crohn's disease activity (PUCAI/PCDAI) indices > 10, according to standard clinical practice. No association between the rs2413739 variant and either TPMT activity or TGN/MMPN levels was found, suggesting a thiopurine-independent effect on the clinical phenotype [33]. Enzymatic activity was significantly higher in the ALL patients than in the IBD patients[33]. The different impact of *PACSIN2* SNP rs2413739 on TPMT activity could be partially explained by patient age: The ALL cohort comprised children under 10 years, while the IBD patients were mainly teenagers. The authors hypothesized that the *PACSIN2* genetic impact on TPMT activity could be more evident in younger patients, who seemed to have increased TPMT activity[34,35]. Moreover, concomitant treatment with MTX in the ALL cohort could contribute to discrepancies in the results; MTX could impact S-adenosyl methionine levels, a TPMT cofactor responsible for the stability of the protein[36]. Since Franca *et al*[33] did not detect significant changes in TGN levels in *PACSIN2* T allele carriers, they hypothesized a thiopurine-independent effect of PACSIN2 on GI toxicity and a tissue-specific role of *PACSIN2* in the intestine. Notably, the Genotype-Tissue Expression Portal (GTEx) shows that *PACSIN2* and *TPMT* expression levels are increased in blood and in the esophageal mucosa of healthy *PACSIN2* rs2413739 T allele carriers but not in the small intestine and colon of these subjects, supporting the idea that the enhanced GI toxicity observed in TT patients is not related to differential expression of *TPMT* in the GI tract[37]. Other evidence regarding PACSIN2 suggests its role as a regulator of intestinal mucosal homeostasis and inflammation. Intriguingly, an underinvestigated mechanism of IBD pathogenesis is VE-cadherin-directed vascular barrier disruption[38], and PACSIN2 has been recognized as a regulator of cell–cell adhesion in the endothelium through the inhibition of asymmetric VE-cadherin internalization from adherens junctions[39]. Stocco *et al*[32] performed an agnostic gene expression analysis in the human B leukemia cell line NALM6 and identified autophagy as one of the pathways significantly affected by *PACSIN2* knockdown, thus suggesting a possible role of this gene in autophagy, another mechanism involved in IBD pathogenesis[32,40,41]. Moreover, the human protein ATLAS report shows that lower levels of PACSIN2 are related to a reduced survival probability in colorectal adenocarcinoma patients, leaving open the question of whether PACSIN2 is a marker of therapeutic response or a contributing factor to intestinal cancer progression[42]. Dedicated studies to clarify the issue of PACSIN2 and GI pathology are needed; however, all this evidence supports the hypothesis that PACSIN2 could be a susceptibility factor for intestinal tissue damage.

Thiopurine-derived tGTPs are able to compete with GTP on Rac-1, a Rho-GTPase involved in cellular proliferation. It can be hypothesized that factors reducing Rac-1 expression or activity could influence cell susceptibility to cytotoxic stimuli, thus contributing to thiopurine efficacy and toxicity. Interestingly, Rac-1 was able to bind

PACSIN2 through a physical interaction[3]; this protein–protein interaction seemed to be responsible for reciprocal regulation: Rac-1 activity controlled PACSIN2 cellular distribution, whereas PACSIN2 could negatively modulate Rac-1 activity[43]. *In vitro* data showed decreased activity of Rac-1 in the presence of the rs34932801 (G>C) SNP in the *RAC1* promoter, and interestingly, this polymorphism was associated with MP hematologic toxicity in a cohort of European IBD patients[44]. Another study reported that Rac-1 expression levels decreased during thiopurine maintenance therapy in IBD patients and that MP responders presented lower Rac-1 expression and activity levels, whereas in nonresponders, these parameters were increased. On these bases, Rac-1 was proposed as a potential biomarker of thiopurine effectiveness in IBD[45]. Intriguingly, conditional disruption of Rac-1 in phagocytes of mice resulted in protection from colitis[46]. In contrast, Rac-1 and STAT3 signaling have been considered contributing factors to IBD development[47], and it was found that both the expression and activity levels of Rac-1 were directly related to colon inflammation grade[46]. Sustained Rac-1-GTP activity in lamina propria T lymphocytes could be more difficult to counteract by thiopurines and lead to resistance of T lymphocytes to apoptosis and thus to their unrestrained accumulation, which subsequently results in the amplification of the inflammatory response in the GI tract. In this sense, in IBD patients, Rac-1 could represent a biomarker of thiopurine-induced GI toxicity and of disease severity and progression, without a clear discrimination between the two clinical phenotypes.

Another potential biomarker for thiopurine GI toxicity is the inosine triphosphate pyrophosphatase (*ITPA*) gene. ITPA is one of the enzymes involved in the thiopurine metabolic pathway. By hydrolyzing inosine triphosphate (ITP) and xanthosine triphosphate nucleotides (XTP) into their monophosphate derivatives (IMP and XMP, respectively), ITPA prevents the accumulation of these noncanonical metabolites in cells and their incorporation into DNA or RNA, where they can interact with DNA/RNA polymerase activity[48]. The thioinosine analog (tIMP), an intermediate of MP conversion to TGN, is converted to tITP, which is also an ITPA substrate (Figure 1). A study performed on a large childhood ALL cohort (n = 511), treated according to the AIEOP-BFM-2000 protocol, showed that the missense variant rs1127354 (C>A, p. Pro32Thr) in *ITPA* was associated with a higher risk of severe GI toxicity during induction/consolidation therapy[10]. This missense variant partially reduces ITPA enzymatic activity in heterozygotes and completely reduces ITPA enzymatic activity in variant homozygotes[49,50], stimulating the accumulation of unusual tITP with the potential to cause adverse metabolic effects[51]. Other studies in pediatric ALL patients showed contradictory results on the *ITPA* rs1127354 association with myelotoxicity[52-54]. Stocco *et al*[53] found significantly higher concentrations of MMPN in patients with the nonfunctional *ITPA* allele. The association between the *ITPA* polymorphism and MP metabolism or neutropenia in ALL patients treated with an MP dose adjusted on the basis of the *TPMT* genotype underlined the important role of this gene in thiopurine toxicity.

CLINICAL IMPLEMENTATIONS

The *PACSIN2* rs2413739 SNP could be considered a potential biomarker for thiopurine-related GI toxicity, being associated with this clinical phenotype in three independent ALL cohorts and with increased active disease in a cohort of IBD patients. Further investigations are needed to understand the molecular basis of this genetic effect and the functional role of the PACSIN2 protein in the healthy and damaged GI epithelium before its possible translation into the clinic. Additionally, the contribution of *RAC1* and *ITPA* SNPs, as potential biomarkers for thiopurine-related GI toxicity, requires further validation in patients undergoing therapy with these drugs. Currently, there are no clinical trials focusing on the role of these genes/proteins in GI toxicity in ALL and IBD patients.

If these candidates would be confirmed as markers for GI toxicity, several applications could be speculated in clinical practice. For example, in patients treated with thiopurines, clinicians could be warned of the patients' genetic predisposition to GI damage (*e.g.*, patients carrying the *PACSIN2* rs2413739 or *ITPA* rs1127354 homozygous variant genotypes). Pharmacogenetic information could be used as an alert for physicians, identifying patients who need intensive monitoring for adverse effects or those who should undergo supportive care earlier, even when less severe episodes of toxicity occur.

CONCLUSION

While highly effective, thiopurines are responsible for serious toxicities in ALL and IBD. This scenario points out the importance of identifying predictive biomarkers for detecting and monitoring the tissue-specific side effects of thiopurine. Data reported in this editorial underline the complexity of thiopurine pharmacokinetic mechanisms, which could be influenced by multiple genes and nongenetic factors able to exert their function on the whole body or through a tissue-specific mechanism of action.

Abstract

Fully covered self-expandable metal stents (FCSEMS) represent the latest advancement of metal biliary stents used to endoscopically treat a variety of obstructive biliary pathology. A large stent diameter and synthetic covering over the tubular mesh prolong stent patency and reduce risk for tissue hyperplasia and tumor ingrowth. Additionally, FCSEMS can be easily removed. All these features address issues faced by plastic and uncovered metal stents. The purpose of this paper is to comprehensively review the application of FCSEMS in benign and malignant biliary strictures, biliary leak, and post-sphincterotomy bleeding.

Key Words: Fully covered self-expandable metal stents; Plastic stents; Endoscopy; Chronic pancreatitis; Biliary stricture; Biliary leak; Stent migration

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Fully covered self-expandable metal stents (FCSEMS) are composed of a metal alloy tubular mesh with a synthetic covering to minimize tumor ingrowth. They have a broad range of biliary endoscopic applications, including the treatment of strictures, biliary leak, and post-sphincterotomy bleeding. Novel anchoring designs have been effective at addressing the common problem of stent migration with FCSEMS.

INTRODUCTION

Recent advances in endoscopic stenting have enabled the treatment of a wide range of obstructive biliary pathologies previously requiring surgical and percutaneous intervention[1]. Early randomized control studies found that endoscopic stenting compared to surgical or percutaneous intervention was associated with decreased 30 d morbidity and mortality, decreased complications rates, lower overall cost, and higher quality of life[2-4]. Plastic stents were the earliest stent type used, and metal stents were introduced later in the 1980s[5]. The purpose of this report is to review the current applications of fully covered self-expandable metal stents (FCSEMS) for biliary strictures, biliary leak, and post-sphincterotomy bleeding.

PLASTIC STENTS

Plastic stents are commonly used because of their efficacy, easy insertion and removal, and low cost[1,6,7] (Figure 1A). Plastic biliary stents come in various shapes and can be made of Teflon, polyethylene or polyurethane materials. Standard diameters of plastic biliary stents are 7.0 Fr, 8.5 Fr, 10.0 Fr and 11.5 Fr, and standard lengths range from 5 cm to 18 cm. Appropriate stent length is determined using a graduated guide wire and guiding catheter. Initial placement is guided using a radio-opaque guidewire. Plastic stents are equipped with side holes that allow for drainage even when the ends are impacted against the biliary or digestive tract wall, or clogged with debris. Additionally, plastic stents may have anchoring flaps to prevent stent migration. Multiple plastic stents (MPS) can be inserted during each endoscopic retrograde cholangiopancreatography (ERCP) session.

A major disadvantage of plastic stents is the tendency for occlusion due to the formation of a bacterial biofilm, leading to recurrent jaundice and pruritis[8,9]. Acute cholangitis may develop in up to 20%-40% of cases requiring the need for stent exchange[10]. Stent occlusion rates and complications of acute cholangitis are lower with large stent diameters of 10 Fr and 11.5 Fr compared to 7 Fr or 8.5 Fr stents, likely due to a higher biliary flow rate[11]. However, a retrospective study of 33 patients comparing the efficacy and complications of 10 Fr biliary stents to 11.5 Fr stents for use in malignant and benign biliary tract disease found no significant differences in success rates or complications[12]. Median patency for 10 Fr plastic stents is an estimated 4-5 mo[13]. Moreover, a special therapeutic duodenoscope with a wide working channel of 4.2 mm diameter is needed to use 11.5 Fr plastic stents.

SELF-EXPANDABLE METAL STENTS

Self-expandable metal stents (SEMS) were designed with a larger luminal diameter than plastic stents to prolong stent patency and address occlusion complications faced by plastic stents[14-16]. The core structure of a SEMS comprises a 4-12 cm long tubular mesh made up of metal alloys, including stainless steel, Nitinol, Elgiloy and Platinol [17] (Figure 1B). Metal alloys allow adequate radial expansible force without compromising on flexibility inside the duct. Each metal stent is more expensive than a plastic stent. However, SEMS have a lower risk of recurrent biliary obstruction compared to plastic stents. Overall, SEMS is more cost-effective than plastic stents over time, especially when life expectancy exceeds 4 mo[18-22]. Comparisons between plastic stents and different types of SEMS are summarized in Table 1.

SEMS are constrained by an 8-8.5 Fr surrounding sheath while it is inserted through a channel in the duodenoscope. Deployment occurs when the sheath is retracted, expanding the stent to a maximal diameter of 10 mm.

Mechanisms of SEMS occlusion differ from plastic stents *via* the following: (1) Tissue in-growth through the stent mesh; (2) Tumor overgrowth around the proximal or distal end of the stent; (3) Mucosal hyperplasia into the stent because of a chronic inflammatory reaction to the stent mesh; and, less commonly; and (4) Biliary sludge [23-26]. In contrast to plastic stents, occluded SEMS with tumor or tissue in-growth or over-growth are often difficult to reposition or remove once deployed[27]. Treatment of a SEMS occlusion involves insertion of new plastic stents or deployment of another SEMS within the initial stent. Mechanical cleaning with an extraction balloon may also be helpful[28]. Additional complications of SEMS include duodenal wall erosion by the stent, which may lead to duodenal perforation and acute bleeding[29].

Table 1 Strengths and disadvantages of plastic stents and self-expandable metal stents

	Strengths	Disadvantages
Plastic stents	Easy placement, removal, and exchange; Cost-effective for use < 4 mo; Variety of shapes and sizes	Tendency for stent occlusion after several months
Uncovered self-expandable metal stents (USEMS)	Long stent patency due to large luminal diameter; Stent malposition is rare	Cost-effective for use > 4 mo; High risk for tissue ingrowth or tumor overgrowth; Risk for duodenal wall erosion; Biliary leakage possible; Difficult to reposition or remove
Partially covered self-expandable metal stents (PCSEMS)	Long stent patency due to large luminal diameter; Biliary leakage is rare	Cost-effective for use > 4 mo; Intermediate risk for tissue ingrowth or tumor overgrowth; Risk for duodenal wall erosion; Difficult to reposition or remove; Side branch obstruction possible
Fully covered self-expandable metal stents (FCSEMS)	Long stent patency due to large luminal diameter, covering inhibits tissue/tumor in-growth through mesh; No biliary leakage	Cost-effective for use > 4 mo; Risk for duodenal wall erosion; Difficult to reposition or remove; High risk of stent migration; Side branch obstruction possible

Stent designs continue to evolve to overcome these factors. Silicone, polyurethane, and expanded polytetrafluoroethylene coverings may be applied over a part (partly-covered) or entire (fully-covered) length of SEMS to prevent tumor in-growth through the mesh[27,30] (Figures 1C, 1D, and 1E). Additionally, the covering allows for easier SEMS removal compared to bare-metal stents[31].

BENIGN BILIARY STRICTURES

Benign biliary strictures (BBS) form after an initial insult to the biliary duct that leads to inflammation, collagen deposition, fibrosis, and bile duct narrowing[32]. Common causes include post-operative injury, chronic pancreatitis (CP), and chronic inflammatory cholangiopathies (Table 2)[33]. BBS may present with pain, jaundice, pruritis, and/or elevated liver function tests[34]. A combination of magnetic resonance cholangiopancreatography (MRCP) and/or endoscopic (ERCP) retrograde cholangiopancreatography may be used during the evaluation process to elucidate biliary ductal anatomy[35]. Tissue sampling *via* endoluminal biopsy or biliary brushings will confirm non-malignant tissue and determine the primary etiology. ERCP is the therapeutic modality of choice for BBS because of its efficacy, safety, and noninvasive nature[36-38].

Post-operative BBS

The most common causes of post-operative BBS occur after cholecystectomy and biliary duct surgery[39,40]. An effective means of therapeutic decompression using plastic stents can be achieved with the placement of MPS side-by-side across the stricture[41]. Plastic stents used for up to 1 year with interval replacement in 3-4 mo intervals have demonstrated excellent safety, high clinical success rates, and low rates of stricture recurrence[42]. Plastic stent occlusion within 4-5 mo requiring endoscopic stent exchange is a major limitation because of overall cost and requirement for patient compliance[13,43].

In contrast, FCSEMS can expand to a large stent diameter equivalent to three 10 Fr stents, and its chemical covering limits tissue hyperplasia and in-growth. A single FCSEMS can remain in place for a prolonged period without the need for repeated stent exchange prior to removal[44,45].

In a retrospective study of 69 patients comparing the efficacy and safety of FCSEMS and plastic stents for postsurgical BBS, findings revealed a similar technical success rate (100% in both groups) and stricture recurrence (16% in the PS group and 22% in the FCSEMS group)[46]. However, the median duration of stenting in the FCSEMS group (5.2 mo) was significantly lower than that of the PS group (10.7 mo), requiring multiple stent exchanges. In fact, the FCSEMS group had a shorter total operation and fluoroscopy time because only one metal stent needed to be deployed compared to 2-5 plastic stents in the PS group. The study highlighted the use of FCSEMS as a practical and effective alternative means to the endoscopic treatment of post-surgical BBS with plastic stents.

A prospective, nonrandomized study of 18 patients also evaluated the 6-12 mo temporary use of FCSEMS for symptomatic post-cholecystectomy BBS, including a 5 year follow-up time period[47]. Successful FCSEMS placement deployment and

Table 2 Etiology of benign biliary strictures

Extrinsic	Intrinsic
Chronic pancreatitis	Post-operative (*i.e.*, post-liver transplantation and post-cholecystectomy)
Pancreatic fluid collection	Primary sclerosing cholangitis
Cholecystitis	IgG Cholangiopathy

IgG: Immunoglobin G.

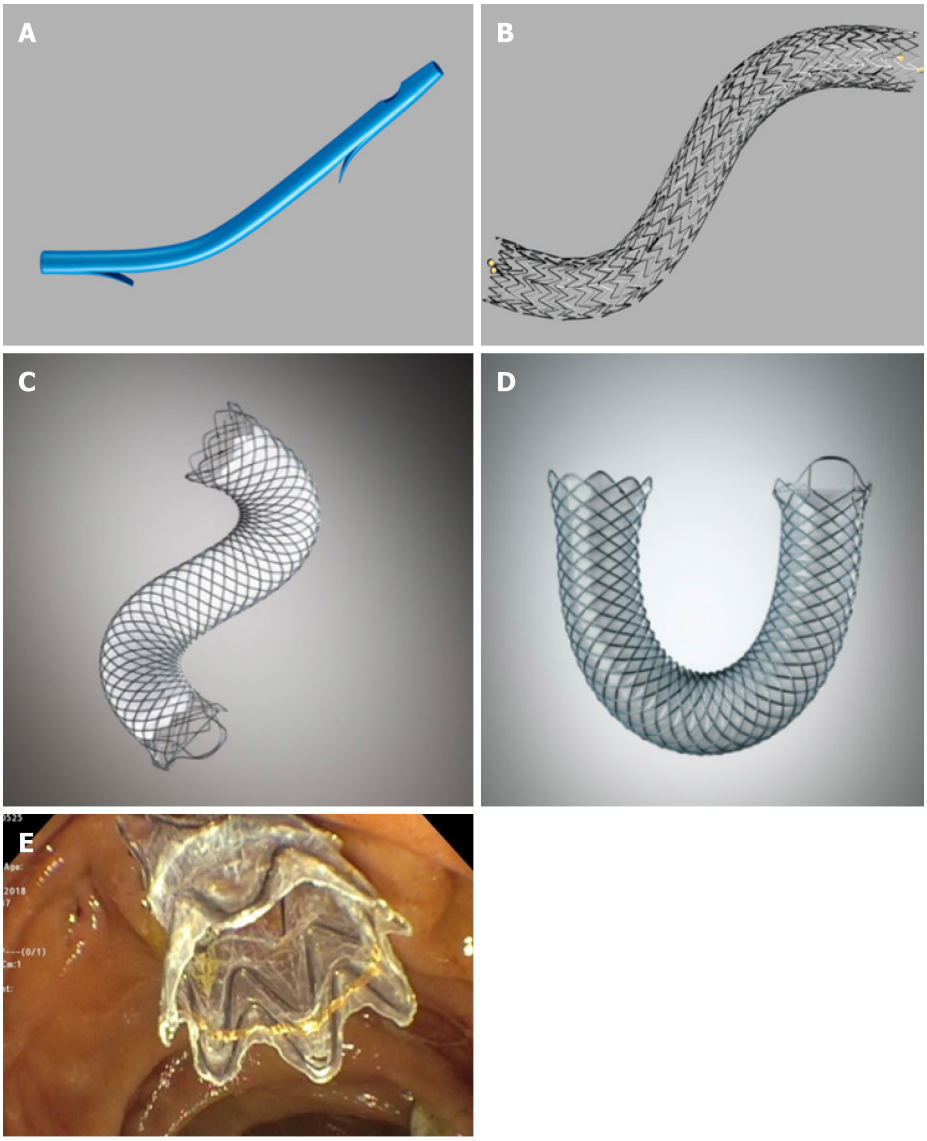

Figure 1 Various types of plastic and metal stents for endoscopic treatment. A: Plastic biliary stent (10 Fr with flaps); B: Uncovered metal biliary stent; C: Partially covered metal biliary stent; D: Fully covered self-expandable metal biliary stent; E: Fully covered self-expandable metal biliary stent with anti-migration fins (Images B-D courtesy of Boston Scientific Corporation, Boston, United States).

removal was achieved in 83% of patients with a median indwell time of 11 mo. As well, 72% of patients achieved stricture resolution at the end of the FCSEMS indwell period. Kaplan Meier analysis predicted 61% probability of remaining stent-free among patients who received FCSEMS. Complications included spontaneous stent migration (17%) and stent-related adverse events, including cholangitis (33%) and pancreatitis (6%). Despite a large sample size and absence of a control group, the study showcased that temporary 1-year placement of FCSEMS can maintain long-term stricture resolution. Table 3 highlights differences in study outcomes between plastic stents and FCSEMS for use in post-operative BBS.

Table 3 Comparison of study outcomes of plastic stents and fully covered self-expandable metal stents for treatment of post-operative benign biliary strictures

[1]Clinical success defined as removal of stent for resolution of benign biliary stricture. FCSEMS: Fully covered self-expandable metal stents.

Anastomotic biliary strictures from orthostatic liver transplantation

Anastomotic biliary strictures (AS) are responsible for nearly 80% of biliary strictures after orthostatic liver transplantation (OLT)[48,49]. They typically occur within 1-2 mo of surgery, and are characterized as single BBS short in length. Existing strategies to treat AS associated BBS include balloon dilatation and endoscopic stenting[50]. While the use of MPS is the gold standard similar to the treatment post-cholecystectomy BBS, premature stent occlusion is a major limitation[51-53].

In the only meta-analysis to date comparing FCSEMS to plastic stents in the use of post-OLT AS, there was no significant difference in stricture resolution, complications, and recurrence[54]. However, FCSEMS use was associated with reduced treatment time (mean difference of -3.58 mo). Complications of pancreatitis and post-procedural pain were more common in FCSEMS. While prior studies have identified FCSEMS with stent migration rates as high as 33%, this adverse event could not be compared in the metanalysis because it was inconsistently reported across the 7 included studies [55,56].

Novel FCSEMS designs with antimigration properties have been developed to address shortcomings with stent migration. A retrospective multicenter Australian study evaluated the use of a novel FCSEMS in 36 patients for treatment of AS after OLT. Some of the patients within the cohort had failed the MPS approach[57]. The Niti-S FCSEMS biliary stent (Taewoong Medical Co Ltd., South Korea) used had an antimigration waist, short stent length, and a removable string for easy removal. Average duration of indwell treatment time was 3.8 mo. Stricture resolution was achieved in 100% of patients and all stents were removed without any difficulty. Only 2.8% of patients experienced stent migration. Nearly 75% of patients remained free of AS recurrence. Excellent clinical and technical success in this study with low rates of stent migration was a major breakthrough in the use of FCSEMS with anti-migration features for AS.

A more recent British retrospective study also evaluated the same type of antimigration FCSEMS (Taewoong Medical Co Ltd., South Korea) in a cohort of 62 patients[58]. Approximately 96% of patients had immediate stricture resolution after 12 wk indwell time. Furthermore, 72% of patients continued to maintain long-term resolution of the AS with a mean follow up period of 548 d. No stent migration occurred in any of the patients. Complication rates were low at 15%, and were primarily stent and procedure-related, such as pancreatitis, cholangitis and wire-guided perforation.

Overall, study findings using FCSEMS with new antimigration designs have shown promise in their application for post-OLT AS treatment. Larger cohort and randomized controlled studies should compare these novel FCSEMS to plastic stents. Alternative antimigration designs should be considered to maximize safe indwell time of stents.

CP

CP-associated BBS are a consequence of recurrent inflammation and subsequent fibrosis. Stricture formation occurs in up to 30% to 40% of cases[59]. Endoscopic intervention is focused on draining the main pancreatic duct to provide pancreatic decompression[60]. Historically, the strictures were treated *via* balloon dilation and endoscopic plastic stent placement, requiring up to 3 or more ERCP sessions[61].

Current recommendations from the Asia-Pacific guidelines recommend the use of FCSEMS or MPS for the endoscopic treatment of CP-associated BBS[62]. To date, the WallFlex Biliary RX Fully Covered Stent (Boston Scientific, United States) is the only FCSEMS approved by the United States Food and Drug Administration for treatment of BBS due to CP for indwell time up to 12 mo[63].

Existing retrospective and case series studies have supported the use of FCSEMS for the treatment of refractory pancreatic duct strictures: clinical and technical success rates have been as high as 90%-100% with a shorter indwell time compared to plastic stents[64-66]. The largest and longest prospective study to date investigated long-term outcomes after 10-12 mo indwell of a single FCSEMS for CP-associated BBS[67]. The cohort consisted of 118 patients, most of whom had failed previous treated with plastic stents. Patients were regularly followed for 5 years after FCSEMS removal. Approximately 80% of patients had stricture resolution at the time of stent removal. Nearly 62% of patients remained stent-free following 75 mo of FCSEMS placement. The success rate was relatively high compared to traditional outcomes with a single plastic stent, which faces issues of short occlusion time[68,69]. In fact, 78% of patients who had a resolved BBS post-indwell continued to remain stent free for 5 years. Of note, 23% of patients experienced serious adverse events that were mostly stent-related, including cholangitis, pancreatitis, and cholecystitis. This study was important in further demonstrating the single-use application of FCSEMS for CP BBS with long term stricture-free durability. This is notable in CP BBS, which notoriously has a poor response to endoscopic intervention with high risks of recurrence.

MALIGNANT BILIARY STRICTURES

Malignant biliary strictures (MBS) are most commonly caused by pancreatic cancer, but can also be caused by cholangiocarcinoma and metastatic disease[70,71]. Clinical presentation is consistent with biliary duct obstruction, including jaundice and cholestatic pattern of transaminase elevation. While MBS shares the same diagnostic evaluation as BBS with MRCP and/or ERCP modalities, tissue sampling will be the differentiating factor with findings of malignancy. Prognosis is poor 5-year survival rates for pancreatic cancer and cholangiocarcinoma are 8% and 10% respectively[72,73].

Non-hilar MBS

Among the 30% of MBS cases which are surgically resectable, endoscopic intervention may be considered to provide preoperative biliary decompression (PBD) (Figures 2A and 2B). PBD decompression is an area of great controversy because of the risks for serious complications, including pancreatitis and cholangitis. A landmark randomized control trial of 202 patients with a pancreatic head cancer compared the outcomes of preoperative biliary drainage for 5 wk to 6 wk preceding surgery to surgery alone. The biliary drainage group had significantly higher (74%) rates of complications than the surgery alone group (39%). Mortality or hospital length of stay did not differ between both groups[74]. Metanalyses investigating the benefits of preoperative biliary drainage has found similar results–length of hospital stay and mortality rate are comparable in preoperative biliary drainage and surgery alone groups[75,76]. Currently, preoperative biliary drainage is indicated for patients with MBS with concurrent severe symptomology (*i.e.*, severe pruritis, cholangitis), elevated bilirubin > 250 μmol/L, or patients undergoing neoadjuvant chemotherapy[77,78].

Nearly 70% of MBS are surgically unresectable at the initial presentation[79]. Endoscopic palliative stent placement for symptom relief is one approach to management. SEMS placement is preferred over plastic stents, especially when life expectancy is greater than 4-6 mo – SEMS have lower rates of stent dysfunction, reintervention, and cholangitis, and higher survival and stent patency rates[80-82].

Outcomes of FCSEMS compared to uncovered self-expandable metal stents (USEMS) in patients with unresectable MBS have also been extensively studied. A randomized controlled trial (RCT) of 749 patients with MBS investigated the outcomes of FCSMES *vs* USEMS placement. No significant difference was found between both groups for patency or survival rates[83]. Tumor ingrowth was higher in the USEMS group compared to the FCSEMS group. However, patients in the FCSEMS were more prone to stent migration and acute pancreatitis. Another recent RCT compared the use of FCSEMS to USEMS in 158 patients with nonresectable MBS. Surprisingly, median stent patency was lower for the FCSEMS (240 d) than the USEMS (541 d) group[84]. Consistent with the other study, FCSEMS had a significantly higher rate of migration,

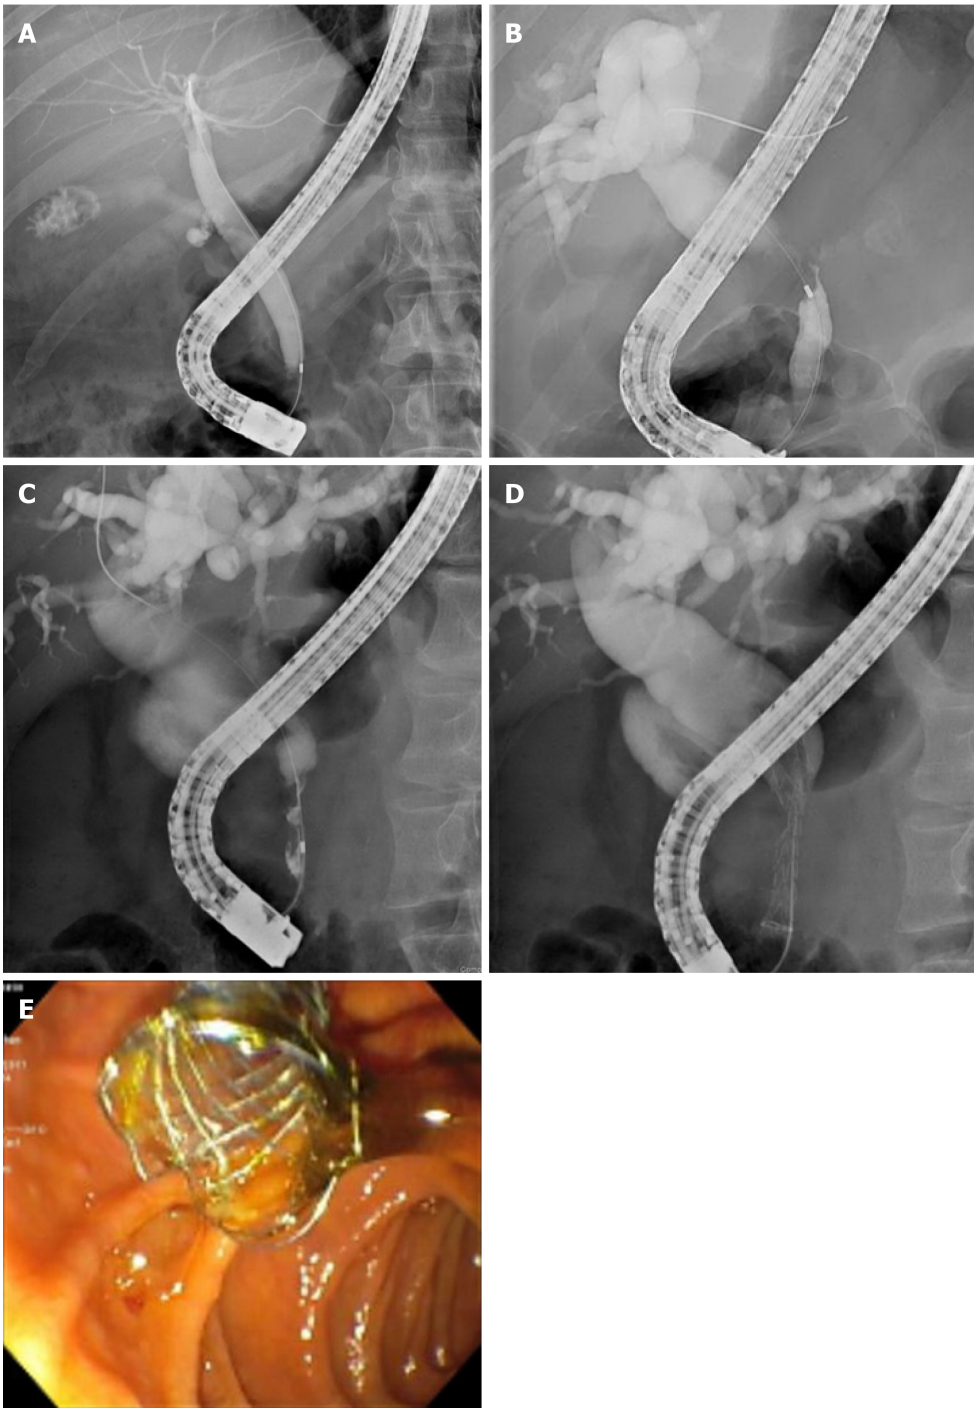

Figure 2 Endoscopic retrograde cholangiopancreatography showing cholangiocarcinoma in mid and distal common bile duct compared to normal anatomy. A: Normal anatomy demomonstrating patent cystic, common bile, and intrahepatic ducts; B: Mid common bile duct biliary stricture with dilated common bile duct and intrahepatic ducts; C: Distal common bile duct biliary stricture with dilated common bile duct and intrahepaptic ducts; D: Fully covered self-expandable metal stent (FCSEMS) placement in the common bile duct; E: Endoscopic view of FCSEMS placed in the distal common bile duct.

with no difference in overall survival between both groups[84]. To explain the stent patency finding in the FCSEMS group, the study proposed that occlusion may not be due to tumor ingrowth per se. The specific NitiS FCSEMS stent chosen for the study may promote an inflammatory reaction causing tissue hyperplasia. Thus, this finding may not be generalizable to all FCSEMS.

Metanalyses have also investigated this topic with mixed results, including studies with partly covered SEMS. A metanalysis involving 5 RCTs with 781 patients showed that CSEMS had superior patency rates compared with UCSEMS for MBS[85]. However, another metanalysis involving 9 RCTs with 1061 patients found no difference in stent patency between both groups[86].

Overall, there is no consensus regarding the superiority of FCSEMS or USEMS for palliative decompression of MBS. FCSEMS may be preferred for ease of removal or in circumstances where tumor ingrowth risk is high, such as in pancreatic cancer or cholangiocarcinoma. However, the problem of stent migration should be factored into the management decision. UCSEMS should be considered when there is short survival time or where likelihood of tumor in growth is low.

Hilar MBS

Malignant Hilar Strictures (MHS) are most commonly unresectable at presentation[87] (Figure 2C). MHS are classified by the Bismuth-Corlette classification, which accounts for the extent of involvement of the hilum and/or left or right main hepatic ducts[88]. The goal of management is to provide palliative decompression to improve quality of life, reduce jaundice, and decrease risk of cholangitis[89]. As with other MBS, metal stents are preferred over plastic ones because of superior patient survival, drainage rate, and stent patency[90]. Stent placement in the hilar region is technically difficult, and can be managed by unilateral or bilateral stenting (Figures 2D and 2E). Bilateral stenting can be approached *via* stent in stent or side by side approach[91].

A RCT involving 159 patients with malignant hilar biliary obstruction showed that patients with unilateral stenting (88.6%) had significantly higher rate of technical success than bilateral stenting (76.9%)[92]. Additionally, the bilateral stent group (16.6%) had significantly higher rates of early cholangitis. Study findings suggested that unilateral drainage was superior to bilateral stenting with lower risk of adverse complications. However, a more recent multicenter RCT found no significant difference in the technical success rate between bilateral (95.5%) and unilateral groups (100%). The median stent patency was higher in the bilateral group (252 d) than the unilateral (139 d), with fewer reinterventions needed for the bilateral group[93]. A metanalysis with 1292 patients found higher success rate in the unilateral group (97%) than the bilateral group (89%)[94]. Other retrospective studies have found comparable rates of technical success between both groups[95-98]. Overall, there is no clear consensus whether the unilateral or bilateral approach is superior. Unilateral approach may be preferred given the technical difficulty of bilateral placement.

Y-shaped bilateral SEMS devices have also been designed, which offers an effective and safe approach for unresectable MHS[98,99]. However, they are yet to be practiced routinely across endoscopic centers.

BILIARY LEAK

Biliary leak occurs due to traumatic injury or iatrogenic injury to the biliary duct from cholecystectomy, ERCP, liver resection, or orthostatic liver transplantation[100-103]. Biliary leak tends to present within 1 wk postoperatively, and are commonly located at the end of the cystic duct stump or duct of Luschka[104]. Minor bile duct leaks are characterized by low drain output and self-resolve without intervention[105]. In contrast, complex bile leaks are characterized by the persistent biliary discharge from an open T-tube or drain[106,107]. Standard of care involves plastic stent placement with or without sphincterotomy to reduce transpapillary pressure gradient[108]. As a result, bile drainage will preferentially drain into the duodenum and bypass the site of bile leak. Complex bile leaks commonly occur in anastomotic bile leaks following orthostatic liver transplantation or cholecystectomy, and may be refractory to plastic stent intervention[103,109]. FCSEMS have been investigated for use in these situations because of the larger expansile diameter and membrane coating, which theoretically provides an effective seal at the site of the leak (Figures 3A and 3B).

In a retrospective study investigating patients with complex post-OLT bile leaks treated with CSEMS placement, successful deployment and long-term leakage control was achieved using FCSEMS with fins (77.8% of patients) and FCSEMS with flared ends (70%)[110]. A concerning finding was that large number of patients who received FCSEMS with fins (35%) experienced post-stent removal biliary strictures. This likely occurred due to stent-induced biliary duct compression and ischemia, which highlights one of the major risks of FCSEMS use for biliary leak.

Another US-based study evaluated the use of Viabil FCSEMS (Gore, United States) placement for 5 patients with bile leaks[111]. All patients had successfully sealed bile leaks confirmed with cholangiogram. Most patients did not have any complications. However, 1 patient developed a hepatic abscess and sepsis. Another patient had stent occlusion after being lost to followup for 8.5 mo, but post-ERCP removal of the occluded stent revealed a sealed bile leak on cholangiogram.

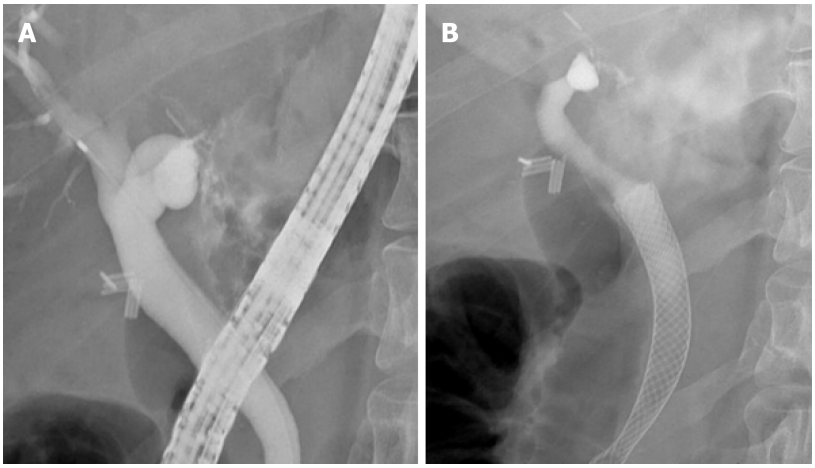

Figure 3 Endoscopic treatment of biliary leak after donor liver transplantation. A: Extravasation of contrast at site of biliary leak; B: Resolution of biliary leak after placement of a fully covered self-expandable metal stent.

A pilot study consisted of 16 patients who underwent CSEMS placement for a biliary leak. These patients either failed to respond to conventional ERCP or had severe comorbidities that prevented multiple procedures[112]. Nearly all (15/16 patients) of the patients had complete resolution of the leak confirmed with cholangiogram. Only 1 proximal and distal migration complication was documented.

In summary, existing studies have demonstrated proof of successful bile leak closure using FCSEMS (Table 4). However, complications, including stent migration and post-removal strictures, make the widespread use of FCSEMS for complex biliary leaks debatable. Future studies should investigate this topic using larger cohort sizes.

POST-SPHINCTEROTOMY BLEEDING

Biliary endoscopic sphincterotomy (ES) refers to the resection of the biliary sphincter and intraduodenal segment of the common bile duct. It is an essential procedure for ERCP in the treatment for a variety of biliary and papillary disease, including choledocholithiasis, bile leak, and biliary strictures[113]. Post-endoscopic bleeding is a major complication of biliary sphincterotomy[114]. Most post-ES bleeds are small and resolve spontaneously[115]. Other cases present with significant bleeding requiring blood transfusion support and urgent endoscopic intervention. While existing methods include injection, balloon tamponade, and mechanical (*e.g.*, embolization) approaches, endoscopic hemostasis can also be achieved by tamponade effect *via* FCSEMS deployment[113].

The largest retrospective study to date evaluated 67 patients with post-ES bleeding, and compared the use of FCSEMS treatment *vs* non-FCSEMS treatment (*e.g.*, balloon tamponade, sclerotherapy, epinephrine injection, thermal cautery or clip placement) [116]. At 72 h post intervention, the study found that the FCSEMS group (0.66 g/dL) had a significantly lower bleeding rate than the non-FCSEMS group (1.98 g/dL) even though the proportion of patients determined to be at high risk for post-ES bleeding was higher in the FCSEMS treatment group (40%) *vs* non-FCSEMS treatment group (9%). All patients in the FCSEMS group achieved hemostasis, and no adverse events were documented. The study findings supported the use of FCSEMS in patients with severe or immediate bleeding not responsive to initial endoscopic treatment.

Smaller-sized retrospective and case studies have demonstrated similar success with complete hemostasis using FCSEMS for difficult-control post-ES bleeding[117,118]. No studies to date have investigated the use of FCSEMS as primary post-ES treatment therapy. Larger perspective and randomized controlled studies should be conducted to evaluate the optimal timing for FCSEMS removal after achieving hemostasis.

COMPLICATIONS

Stent migration is the most frequent complication of FCSEMS, which occurs in 20%-40% of cases[119,120]. Proximal stent migration refers to FCSEMS migration into the

Table 4 Comparison of study outcomes usng fully covered self-expanding metal stents for treatment of biliary leak

biliary duct, while distal stent migration refers to migration to the duodenum or bowel. Endoscopic intervention is needed to remove and replace the displaced stent. A prospective study comparing the temporary use of FCSEMS with unflared ends to flared ends in patients with CP-related BBS revealed the migration rate was 100% for unflared FCSEMS compared to 40% of flared FCSEMS[121]. FCSEMS designed with anchoring flaps or flared ends are preferred as they reduce the risk of migration. A multicenter, prospective study of compared the antimigration effects and efficacy of FCSEMS with an anchoring flap to a flared end at the proximal end. After a median followup time of 6 mo, none of the patients in the anchoring flap had stent migration compared to 33% of patients in the flared end, suggesting that the anchoring flap design was superior to the flared end design. Both types of FCSEMS were able to be removed in all of the patients[122]. Overall, new stent designs including anchoring flaps, flared ends, and additional anchoring plastic stents have been validated in studies to reduce migration risk[123-125].

Cholecystitis is another complication associated with FCSEMS use most commonly in MBS. The pathophysiological mechanism is thought to be obstruction of biliary flow if the cystic duct orifice is obstructed by the synthetic covering of the FCSEMS[126, 127].

Stent occlusion may occur from tumor ingrowth, tissue overgrowth, or sludge, predisposing to the development of cholangitis[23-26]. However, time to and rate of occlusion is considerably less compared to plastic stents[128]. Factors such as FCSEMS location and treatment indication dictate different levels of risk[129].

CONCLUSION

FCSEMS represents the latest development of SEMS used by endoscopists treat a variety of benign and malignant biliary pathology, including biliary leak, post-sphincterotomy bleeding, and strictures. A chemical covering reduces the risk of tissue hyperplasia and tumor ingrowth, prolonging stent patency. The studies examined in our review have shown that FCSEMS can be clinically effective for a variety of endoscopic applications. However, FCSEMS commonly face problems of stent migration, which can be addressed with modifications including flared ends and anchoring flaps. Future areas of research will continue to expand the interventional applications using FCSEMS, and design new modifications to reduce complications.

Abstract

Indocyanine green (ICG) fluorescence imaging is widely used in abdominal surgery. The implementation of minimally invasive rectal surgery using new methods like robotics or a transanal approach required improvement of optical systems. In that setting, ICG fluorescence optimizes intraoperative vision of anatomical structures by improving blood and lymphatic flow. The purpose of this review was to summarize all potential applications of this upcoming technology in rectal cancer surgery. Each type of use has been separately addressed and the evidence was investigated. During rectal resection, ICG fluorescence angiography is mainly used to evaluate the perfusion of the colonic stump in order to reduce the risk of anastomotic leaks. In addition, ICG fluorescence imaging allows easy visualization of organs such as the ureter or urethra to protect them from injury. This intraoperative technology is a valuable tool for conducting lymph node dissection along the iliac lymphatic chain or to better identifying the rectal dissection planes when a transanal approach is performed. This is an overview of the applications of ICG fluorescence imaging in current surgical practice and a synthesis of the results obtained from the literature. Although further studies are need to investigate the real clinical benefits, these findings may enhance use of ICG fluorescence in current clinical practice and stimulate future research on new applications.

Core Tip: There is growing interest in real-time fluorescence-guided surgery. The intraoperative use of indocyanine green (ICG) during rectal cancer surgery has found many applications over time. Given the wide availability in current practice, it is important for clinicians to be aware of all potential uses of ICG fluorescence technology in order to facilitate the procedures, limit injuries, and improve outcomes. Herein, we provide a concise overview of the literature regarding the use of ICG fluorescence imaging in this setting.

INTRODUCTION

Colorectal carcinoma is the third most common cancer for both men and women and the second leading cause of cancer-related deaths[1]. Primary rectal localization occurs in 35% of cases[2]. Although multidisciplinary management of rectal cancer is the standard of care, surgery remains the cornerstone of curative treatment. Total mesorectal excision (TME), described for the first time by Heald *et al*[3,4], should now be performed routinely in cases of middle and lower rectal tumors after neoadjuvant therapy for locally advanced cancer (T3-4 and/or N+)[5]. Respect for the principles of surgical oncology, including complete TME, and negative distal and circumferential resection margins is mandatory to achieve improved survival. Also, much effort has been made to achieve faster and enhanced recovery[6,7] and better quality of life after rectal cancer surgery[8] over time. Advances in oncology research[9] have resulted in increasing roles for the latest technologies in surgery. Enhanced video/camera systems [10], robotic technology[11], powered staplers[12], and specialized operating platforms for natural orifice transluminal endoscopic surgery[13] are just a few examples of surgical innovations in colorectal surgery introduced in the last decades. In this setting, laser fluorescence using indocyanine green (ICG) dye is a promising and widespread real-time technology because of its easy accessibility, accuracy and cost-effectiveness.

The concept of ICG intraoperative angiography is based on the ability of ICG to absorb near-infrared light (NIR) at 800 nm and to emit fluorescence at a wavelength of 830 nm. Albumin is the most important intravascular binding-protein for ICG so that tissue microperfusion is revealed by the presence of fluorescence. In brief, a bolus of ICG is injected into the patient intravenously, NIR light is then absorbed by ICG in the tissue, and the resulting fluorescence is a reflection of perfusion. After the introduction of ICG angiography in clinical practice in 1989 to evaluate choroidal circulation[14], fluorescence imaging technology has been used in hepatobiliary[15,16], gastric cancer [17], gynecologic cancer[18], breast cancer[19] and transplantation surgery[20]. Furthermore, many colorectal surgeons routinely use ICG imaging to assess bowel viability during colorectal anastomosis. However, several applications of ICG angiography have been described in colorectal surgery with increasing interest for rectal cancer resection. In fact, the implementation of minimally invasive rectal surgery using new approaches (*e.g.*, robotic, and transanal) required the improvement of optical systems. In that regard, ICG fluorescence has optimized the intraoperative vision of anatomical structures by the enhancement of blood and lymph flow. The aim of this review is to identify and synthesize data from original research evaluating any possible application of ICG fluorescence imaging in rectal cancer surgery. In the last 5 years, the use of ICG fluorescence in rectal cancer surgery has attracted great interest.

The items regarding different intraoperative applications are summarized below.

ASSESSMENT OF VASCULAR PERFUSION AT THE ANASTOMOTIC SITE

Anastomotic leakage (AL) is the most feared complication after TME because it is associated with increased mortality, reoperation, and definitive stoma formation[21,22]. Additionally, the relationship between AL and local recurrence has been found to lead to significant differences in long-term outcomes[23]. It has a significant impact on postoperative functional outcome[24] and increases the economic burden of public health systems[25]. That easily explains the importance of developing prevention strategies in order to reduce the amount of related complications affecting survival and quality of life. The AL rate after anterior rectal resection ranges from 3% to 23%[26,27]. AL is defined by the International Study Group of Rectal cancer as a defect at the level of the anastomotic site that allows communication between the intraluminal and extraluminal compartments identified through clinical evaluation with digital rectal exploration, endoscopic examination, computed tomography radiological evidence of contrast leakage through the suture gap or the presence of perianastomotic hydro-aerial collection. It is also classified as grade A if it does not affect the postoperative course, grade B when conservative management antibiotic therapy or percutaneous/transanal drainage is required, and grace C when surgical revision is required[26,28].

Various risk factors are associated with AL, but insufficient blood perfusion is generally considered as one of the main causes[29,30]. ICG is a water soluble, tricarbocyanine dye that provides real-time visualization of vascular structures by emitting fluorescence when stimulated by polarized light[31]. The evaluation of perfusion of the supposed proximal section line starts within 60 s of an intravenous bolus injection of ICG. An NIR camera detects the fluorescence of the microcirculation of the colonic wall receiving adequate vascularization. Therefore, ICG fluorescence reflects the colonic stump perfusion allowing the choice of the most appropriate site for the final section and then for the anastomosis (Figure 1). A second check can be also performed after the anastomosis construction both by injecting a second bolus of ICG to verify fluorescence of the stumps and by transanal endoscopic suture line visualization. Some limitations of the technique are related to its being, once again, a subjective evaluation by the surgeon of the intensity of the emitted infrared light. Furthermore, it is not a completely standardized technique as there are variables related to the dose of injected ICG (0.013-0.89 mg/kg), the proximity of the laparoscope to the colic wall, the number and type of checks performed, and differences in the equipment available on the market[32-34].

Kudszus was the first to show the usefulness of ICG fluorescence angiography (FA) in colorectal surgery[35]. The study reported that ICG FA led to a change in the location of the planned proximal resection line in 13.9% of patients. ICG FA significantly reduced AL by 4% compared with the control group. Furthermore, Jafari *et al*[36] assessed the utility of ICG FA in left colectomy and anterior resection in the PILLAR II study. The incidence of AL in their study was 1.4%, with a change in the surgical strategy in 8% of patients. Boni *et al*[37] reported that ICG FA could be safely and effectively performed in rectal surgery. The use of IGC-FA changed the surgical plan in 4.7% of their patients and AL did not occur in the ICG group, compared with an incidence of 5.2% in the control group. However, the differences were not statistically significant. The studies agree on the safety and feasibility of the technique and demonstrate its usefulness in the assessment of tissue perfusion.

Several comparative retrospective and prospective studies investigated the relationship between the use of ICG and the 30-d AL rate as the primary outcome[31,33,38-40]. They showed a statistically significant correlation between ICG FA and reduction in the risk of AL associated with the modification of the proximal section line. In a propensity score-matched analysis[41], AL rates of Clavien-Dindo grade ≥ II and ≥ III were 10.4% (22/211) and 9.5% (20/211) in the non-ICG FA group and 4.7% (10/211) and 2.8% (6/211) in the ICG FA group, respectively. Similarly, Foo *et al*[42] demonstrated that the use of ICG FA was significantly associated with a lower AL rate in TME (4.7% *vs* 11.6%; P = 0.043) but not non-TME resections. However, not all studies agree on the results. Two propensity score-matched studies failed to demonstrate a statistically significant difference in the rate of AL between the two compared groups, although both reported a change in the proximal section after ICG injection of 27.1% and 18.18%, respectively[43,44]. Most of the studies had limitations such as a small sample size or their retrospective nature. Only two randomized

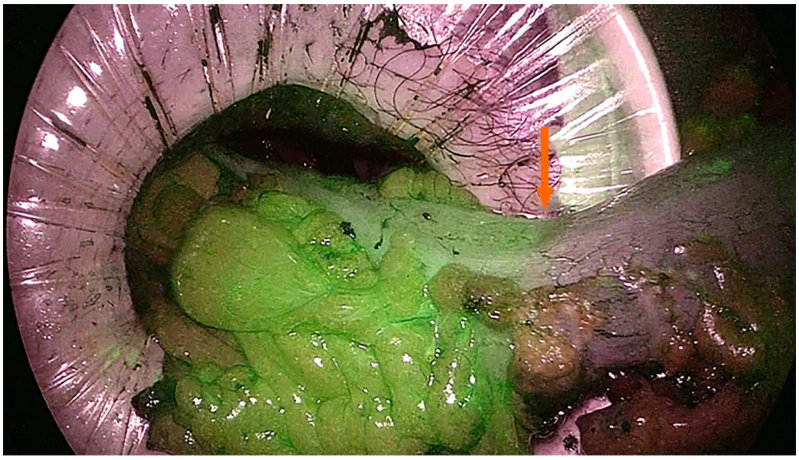

Figure 1 Evaluation of intestinal perfusion after intravenous injection of indocyanine green during total mesorectal excision allows identification of the section line before anastomosis construction (orange arrow).

controlled trials (RCTs) were published. In the first one[45], differences in AL or reoperation rates between ICG and the control group (5% *vs* 9% and 6.7% *vs* 6.5%) were not significant. Although the authors confirmed the efficacy of ICG in bowel viability assessment during left colectomy or anterior resection, a real advantage related to AL was not demonstrated. The FLAG trial[46] involved 377 patients who underwent anterior rectal resection, 187 in the ICG FA group and 190 in the control group. The results showed that changes in the transection line were performed in almost 20% of patients. A decrease in AL was achieved using ICG FA, but the difference was statistically significant only in cases with low rectal anastomosis (14.4% with ICG FA *vs* 25.7% without ICG FA; $P = 0.04$). Two recent meta-analyses assessed the role of ICG FA imaging on the incidence of AL after rectal cancer surgery[34,47]. In a pooled analysis of 2088 patients, the AL rate in the ICG group was significantly lower than that in the control group, and the intraoperative use of ICG was associated with a decreased overall complication rate and reduced reoperation rate. However, both analyses suffer from the same limitations as the studies taken into consideration and the lack of RCTs in the analysis.

Finally, evaluation of bowel perfusion by ICG FA was reported exclusively after transanal total mesorectal excision (TaTME) by Mizrahi *et al*[48]. In their retrospective cohort of 54 patients who received a very low anastomosis, a check was performed before proximal transection and at the completion of anastomosis. In 18.5% of the cases the surgeon changed the proximal resection margin because of impaired fluorescence. All those anastomoses were shown to be successful at the second control. Two patients (3.7%) suffered from AL, and in neither of them was the splenic flexure mobilized. Furthermore, ICG FA improved clinical outcomes also after robotic sphincter-saving rectal resections[49]. In conclusion, the use of fluorescent angiography with ICG injection has proven to be a safe and feasible method to evaluate bowel perfusion whatever the surgical approach for rectal resection. At the time of the construction of the anastomosis, ICG FA can influence decision making by reconsidering the resection line. Several studies have found a significant decrease in the rate of AL after ICG FA imaging, and that has had a large impact on recovery. Future high quality trials should confirm the impact on AL rates and standardize the technique.

URETHRA VISUALIZATION DURING TRANSANAL TME

TaTME is a relatively new procedure[50] for the curative resection of rectal tumors. It was developed to overcome the difficult dissection at the lower third of the rectum, especially in obese male patients and/or bulky tumors. Some retrospective series have reported that enhanced visualization of the dissection plane allowed better nerve preservation, improved resection margins, and improved functional outcomes compared with laparoscopic TME[51,52]. However, the bottom-up transanal approach is not without complications. Incidence of iatrogenic urethral injuries has been reported, ranging from 1% to 6.7% during TaTME procedures[53]. An international inquiry reported 34 urethral injuries from 32 surgical teams worldwide between 2010

and 2017, resulting in a significant postoperative morbidity rate of 26%[50]. However, there is still concern that urologic injuries during TaTME may be underreported and that their incidence might be related to surgeon experience. Therefore, enhancement of urethral visualization should be considered useful and advantageous in the early learning experience. Several bioimaging modalities exist that can improve urethral identification, including ICG NIR fluorescence[54]. Different systems have been successfully used to detect the urethra by ICG fluorescence imaging such as the IRIS ureteral kit (Stryker, Kalamazoo, MI, United States)[55] or the PINPOINT laparoscopic system (Stryker, United States)[56] with intraurethral ICG injection or infiltration adjacent to the catheter in the urethra, respectively. Experimental studies demonstrated that direct ICG instillation into the urethra or through a urine catheter for NIR fluorescence imaging seem to be easily applicable and clinically reproducible during TaTME[55-57]. Although an open-label clinical feasibility study (NCT03204201) with intraoperative direct instillation of ICG into the urethra for low rectal cancers was terminated because of technique failures, implementation of the technique has been described by some authors. Barnes *et al*[58] evaluated the efficacy of two novel methods in cadaveric models. In the first, ICG mixed with silicone was infiltrated into 10-Fr one-way Foley catheter and allowed to set for 1 wk. In the second, new preclinical IRDye 800BK (LI-COR Biosciences®, Lincoln, Nebraska, United States) was infiltrated directly into the urethra *via* the urethral meatus prior to dissection. Both methods were effective in identifying the fluorescence located only within the urethra. IRDye 800BK provided a greater depth of penetration than the ICG-silicone mix, suggesting it could be a more satisfactory alternative to ICG. In addition, Barberio *et al*[59] demonstrated the superior brightness of near-infrared coating of equipment (NICE) coated catheter compared with ICG-based solutions in cadaveric experiments by exhibiting a higher fluorescence intensity than urinary catheters filled with ICG. In conclusion, no final specific recommendations can be drawn from the clinical use of ICG fluorescence imaging to identify and prevent urethral injuries during TaTME procedures because of the very limited data available. However, future studies will have to take into account that fluorescence technology plays a major role in this setting.

URETER IDENTIFICATION

The incidence of iatrogenic urethral injuries (IUI) ranges from 0.24% to 1.95% in colorectal surgery, and rectal cancer is considered a risk factor for IUI because of the close proximity of the ureters to the dissection plane[60], similar to the risk with deep pelvic endometriosis[61,62]. Despite its low incidence, IUI significantly affects postoperative morbidity, mortality, length of stay and hospital charges[60]. Visualization of the ureters is thus advocated during pelvic surgery by the visible peristalsis that occurs when the ureter is gently pressed (Kelly's sign). However, adhesions, obesity, and an incorrect plane of dissection contribute to the lack of or incorrect recognition of the ureter, which can jeopardize its integrity. For that reason, a selective use of prophylactic urethral stents in high risk procedures is commonly accepted, but there is no sufficient evidence to support a decrease in IUI or intraoperative identification[63,64]. In that setting, interest in fluorescence imaging has been increasing over time. While contrasting results were found for intravenous administration of methylene blue dye to urethral detection in colorectal surgery[65,66], ICG FA proved to be a viable alternative to real-time ureter identification and IUI prevention. Before surgery, a 6-Fr catheter is placed into the urethral orifice by cystoscopy. As ICG binds to the proteins of the ureteric epithelium[67], a retrograde injection of 5 mg ICG diluted in 2 mL of distilled water is made, and infrared emission is captured by the filtered lens system and electronically converted into green color visualizing ureter location. The technique has proven to be safe and helpful to identify the ureter in several small case-series who underwent minimally invasive pelvic surgery[68-72]. As a catheter insertion of only 1 cm is required, there is a lower risk of IUI during catheterization than during conventional endoscopic stenting procedures, thus avoiding additional cystoscopies to remove the catheter. Furthermore, ICG urethral instillation is less expensive than other fluorescence-based systems such as illuminated catheters [68].

White *et al*[73] recently evaluated the safety and efficacy of intraurethral ICG FA along with any potential benefit related to the technique during colorectal robotic surgery. In their experience involving 16 patients, there were short procedure times, low morbidity, and reliable urethral identification and avoidance. The United States

Food and Drug Administration approval of ICG is limited to intravenous use[74]. Therefore, disclosure of intraurethral off-label use would be needed. In contrast, new intravenous fluorescent dyes with renal clearance, such as fluorescein sodium[75] and IRDye® 800-BK[76] have been used in experimental models to test the penetration of fluorescence in the ureters, with promising results for surgical practice. Additionally, the formulation of ICG in a liposome-based delivery system allows its excretion in urine in animal models and seems a promising fluorophore solution[77,78]. In conclusion, evidence supporting the use of intraurethral ICG instillation in order to improve intraoperative ureter detection is based on few noncomparative feasibility studies involving mixed pelvic surgeries. Despite the efficacy demonstrated in ordinary or complex situations, no study exclusively focused on rectal cancer resections exists to date. It remains to be proven whether this innovation significantly affects surgical procedures and provides clinical benefits by reducing IUI.

LYMPH NODE MAPPING

Lateral pelvic lymph node dissection (LLND) allows the removal of the nodal compartment along the common iliac, internal iliac, and obturator arteries. The lymphatic stations are considered a major cause of locoregional recurrence in rectal cancer and are treated with preoperative chemoradiotherapy and curative resection [79]. While it is widely accepted to perform LLND in selected patients with rectal cancer and lateral lymph nodes that are clinically positive[5], the Japanese Society for Cancer of the Colon and Rectum guidelines[80] recommend LLND even when lateral lymph node metastasis is not detected by preoperative or intraoperative diagnosis. Indeed, LLND is associated with a lower rate of local recurrence compared with TME alone despite no significant differences in either overall survival or local recurrence-free survival[81].

As ICG fluorescence imaging has proven to be a useful tool for identifying lymphatic drainage in colorectal surgery[82,83], ICG-enhanced NIR fluorescence-guided imaging has been used to improve the accuracy and the completeness of LLND. In such cases, ICG fluorescence imaging is carried out the injection of ICG dye into the submucosal layer on the distal side of the tumor through the anus immediately before surgery. In a comparative retrospective series of 42 mid and low rectal cancer patients, the ICG group experienced a significantly lower intraoperative blood loss and a larger number of harvested lateral pelvic lymph nodes[84]. The use of ICG may improve the safety of LLND that is affected by the technical difficulties of the procedure, complicated pelvic wall anatomy, and the effects of preoperative radiation on the tissues. In that setting, real-time identification of lateral pelvic nodes could help to distinguish lymphatic tissue from vascular and nervous structures, thus avoiding postoperative genitourinary dysfunction and providing better surgical staging. However, evidence is still limited[85-87] and additional studies are needed to address the real clinical advantages and standardization of this technique.

A sentinel node (SN) is defined as the first node in the regional peritumoral area that drains the tumor. SN biopsy, in addition to conventional resection, may add clinically significant prognostic information in colorectal surgery[88-90]. NIR laparoscopy with ICG mapping allowed easy intraoperative identification of mesocolic lymphatic drainage and SN during colorectal oncologic resections[91]. Similarly Noura *et al*[92] described the detection of SN by ICG with an NIR system in 25 patients who had no preoperative diagnosis of metastatic lateral pelvic lymph nodes. The success rate of detecting the lateral SN was 92%, and 100% concordance was observed between SN and dissected lateral lymph nodes status. That preliminary study highlighted the feasibility and reliability of lateral SN biopsy as a potential discriminator to perform LLND, but the sensitivity may be compromised by preoperative neoadjuvant chemoradiotherapy[93,94].

TUMOR LOCALIZATION

Several reports have described the intraoperative identification of colonic tumors by NIR with ICG fluorescence imaging, with satisfactory results[95-98]. Accurate identification of the location of colorectal tumors is crucial in minimally invasive surgery because of the lack of tactile perception, especially for cancer at an early stage because of its small size or location on a movable part of the colon. As for rectal cancer, precise tumor site localization allows achieving a clear and safe distal resection margin, which

may affect not only oncological outcomes but also bowel function and quality of life. In that setting, endoscopic tattooing of rectal tumors, both with a high-definition fluorescence imaging system (Karl Storz GmbH & Co. KG, Tuttlingen, Germany)[93] and the PINPOINT® endoscopic fluorescence imaging system (PINPOINT system; Novadaq Technologies Inc., Mississauga, ON, Canada)[99], is feasible and has clinical advantages. In a comparative retrospective series, 342 patients scheduled for laparoscopic colorectal resection were enrolled after propensity score matching[100]. The tumor was tattooed in 114 patients. In a subgroup analysis of 160 patients who underwent anterior resection, the tattooed group had a significantly shorter operative time (unlike right and left colectomy), less blood loss, and a shorter hospital stay than the non-tattooed group. In addition, Goo *et al*[101] compared 200 tattooed colorectal cancer patients (44 rectal cancers) with 879 non-tattooed patients (300 rectal cancers) to evaluate the effect of preoperative colonoscopic tattooing with ICG on adequate lymph node harvest in colorectal cancer. They found that preoperative tattooing in T1 colorectal cancer significantly improved adequate lymph node harvest, with a higher number of retrieved lymph nodes in rectal cancer than in colon cancer.

Fluorescence technology to localize rectal tumors has been developed not only in the field of imaging systems[99], but also by ICG formulation. Fenestrated peritumoral capillaries and impaired lymphatic drainage delay the washout of large molecules from tumors, which has been described as the enhanced permeability and retention effect[102]. The formulation of ICG as a liposome-based delivery system improved tumor-specific localization in experimental models, with the advantages of intravenous injection and better results than free ICG[103,104]. Finally, there are limited data on the role of ICG in the detection of peritoneal carcinomatosis of colorectal origin. Cytoreductive surgery followed by hyperthermic intraperitoneal chemotherapy is the only potentially curative option in patients with limited peritoneal metastases[105]. Intraoperative injection of ICG seems a useful tool to identify peritoneal metastases and detect additional subclinical malignant peritoneal nodules, resulting in modification of the planned surgery in 29% of patients[106]. However, further investigations are required to draw firm conclusions.

OTHER USES

Peritumoral injection of ICG may help the surgeon to perform an adequate dissection along the embryological surgical planes and visualize the relationship with surrounding structures during TaTME[107], conventional laparoscopic TME[108], and abdominoperineal resection (APR)[109]. Omentoplasty is a well-known method to fill the pelvic cavity after APR or in case of complications after rectal cancer surgery. A pilot study of the intraoperative value of NIR fluorescence imaging with ICG to assess omental perfusion after the creation of a pedicled omentoplasty found that a change in decision making occurred in 80% of the cases[110], and a positive impact on the nonhealing rates of patients undergoing salvage surgery for chronic pelvic sepsis was also observed[111].

CONCLUSION

The adoption of ICG fluorescence imaging in rectal cancer surgery and its multiple applications has increased over time. The major field of application is the evaluation of bowel perfusion at the time of anastomosis construction along with a better intraoperative identification of anatomical structures such as the ureter, urethra, lymph nodes, and tumor location. These objectives are relevant because they aim to improve patient safety by avoiding or reducing the risk of complications. However, further investigations are needed to assess the impact of intraoperative ICG fluorescence imaging on clinical, oncological and cost-effective outcomes.

Abstract

Specificity protein (Sp) transcription factors (TFs) Sp1, Sp3 and Sp4, and the orphan nuclear receptor 4A1 (NR4A1) are highly expressed in pancreatic tumors and Sp1 is a negative prognostic factor for pancreatic cancer patient survival. Results of knockdown and overexpression of Sp1, Sp3 and Sp4 in pancreatic and other cancer lines show that these TFs are individually pro-oncogenic factors and loss of one Sp TF is not compensated by other members. NR4A1 is also a pro-oncogenic factor and both NR4A1 and Sp TFs exhibit similar functions in pancreatic cancer cells and regulate cell growth, survival, migration and invasion. There is also evidence that Sp TFs and NR4A1 regulate some of the same genes including survivin, epidermal growth factor receptor, PAX3-FOXO1, α5- and α6-integrins, β1-, β3- and β4-integrins; this is due to NR4A1 acting as a cofactor and mediating NR4A1/Sp1/4-regulated gene expression through GC-rich gene promoter sites. Several studies show that drugs targeting Sp downregulation or NR4A1 antagonists are highly effective inhibitors of Sp/NR4A1-regulated pathways and genes in pancreatic and other cancer cells, and the triterpenoid celastrol is a novel dual-acting agent that targets both Sp TFs and NR4A1.

Core Tip: Specificity protein (Sp), transcription factors (TFs), Sp1, Sp3 and Sp4, and nuclear receptor 4A1 (NR4A1, Nur77) are highly expressed in pancreatic cancer cells and tumors. Results of gene silencing studies show that Sp TFs and NR4A1 are pro-oncogenic and regulate pathways/genes associated with cell proliferation, survival and migration/invasion. Bis-indole derived ligands (CDIMs) that bind NR4A1 act as NR4A1 antagonists and we discuss an important mechanism of gene regulation by NR4A1/Sp complexes which can be inhibited by NR4A1 antagonists.

INTRODUCTION

Pancreatic cancer is a devastating disease and it is estimated that in 2020, the number of diagnosed cases in the United States will be 57600 and 47050 will die because of this disease[1]. Despite advances in treating pancreatic cancer with surgical intervention and various therapeutic regimens, the five-year survival rate from pancreatic cancer is < 10%[1] and this is due, in part to the late detection of the tumors due to lack of symptoms and lack of early biomarkers of this cancer. There are many risk factors for pancreatic cancer and this includes pancreatitis, obesity and metabolic syndrome; due to the obesity crisis in many countries, it is estimated that by 2030, pancreatic cancer will be the second leading cause of cancer deaths[2]. Development of pancreatic cancer is associated with the temporal increases in expression of various oncogenes and inactivation of tumor suppressor genes resulting in enhanced cancer cell proliferation, survival, migration, invasion and metastasis[3-6]. Gemcitabine has largely replaced 5-fluorouracil as the major cytotoxic drug for treatment of pancreatic cancer and many other mechanism-based drugs targeting critical genes associated with various pro-oncogenic pathways in pancreatic cancer are being developed or are in clinical trials[7, 8]. The success of these agents in combination therapies targeting one or more pro-oncogenic pathways has been limited but promising. For example, one study using the vascular endothelial growth factor inhibitor bevacizumab in combination with leucovorin, nab-paclitaxel, oxiplatin and 5-fluorouracil and this resulted in a one-year survival of 82% for the treated patients[9]. In this review, we will focus on three transcription factors (TFs), namely specificity proteins (Sps) Sp1, Sp3 and Sp4, and nuclear receptor 4A1 (NR4A1, TR3, Nur77) and their overlapping pro-oncogenic roles in pancreatic cancers. We will also highlight an interesting convergence of these TFs and outline approaches for simultaneous targeting NR4A1 and Sp TFs by mechanism-based agents resulting in inhibition of cancer cell growth, survival, migration and invasion.

Sp and NR4A1: Background

Sp TFs are members of the Sp-Kruppel-like factor family (Sp/KLF) of TFs which includes 9 Sp TFs and 17 KLF proteins[10-14]. Sp1-Sp4 genes have a similar domain structure, however, it is evident that among other Sp/KLF family of TFs, their domain structures are highly diverse with the most common features being the zinc finger DNA binding domain and its subsequent interactions with GC/GT-rich gene promoter sequences[10-14]. Sp1 was the first TF identified and characterized[15] and Sp1 knockout mouse embryos exhibited retarded development and other abnormalities, and embryolethality is observed (day 11)[11]. Comparable studies on other Sp family members indicate that these TFs play important roles in early development and differentiation by their regulation of key genes involved in these functions. A detailed analysis of the age-dependent expression of individual Sp TFs is not available, however, there is evidence that for Sp1, there is an age-dependent decrease in expression in both rodent and human tissues[16-19]. Presumably the functions of Sp1 in aging animals are replaced by other TFs. The concern and subsequent focus on Sp1 and other Sp TFs (Sp3 and Sp4) in cancer emerged from studies showing that Sp1, Sp3 and Sp4 were overexpressed in cancer cells and tumors

[20]. These TFs were also identified as negative prognostic factors for cancer patient survival from several cancers and functional studies demonstrated the pro-oncogenic activity for Sp TFs[20]. The overexpression and prognostic value of Sp TFs have primarily focused on Sp1 and one of the first studies showed that Sp1 was overexpressed in patients with pancreatic tumors and was a negative prognostic factor for patient survival[21]. Most studies on cancer patients have reported that Sp1 or Sp3 is overexpressed and/or is a negative prognostic factor for glioma, astrocytoma, colon, gastric, liver, prostate and head and neck cancers; in lung and breast cancers; in addition, there are some conflicting results[22-40]. An important linkage between Sp1 and cancer was observed in studies showing that carcinogen- or oncogene- induced transformation of human fibroblasts into fibrosarcomas was accompanied by an 8-18-fold increase in expression of Sp1. Moreover, the ability of fibrosarcoma cells to form tumors in athymic nude mice was abrogated after Sp1 knockdown[41]. Subsequent studies show that Sp TFs are pro-oncogenic and regulate pathways and genes associated with cell growth, survival, migration and invasion (Figure 1).

NR4A1 and two related receptors NR4A2 (Nurr1) and NR4A3 (Nor1) are orphan nuclear receptors with structures and endogenous functions that differ significantly from Sp TFs[42,43]. NR4A1 and NR4A3 knockout mice are viable whereas NR4A2$^{-/-}$ mice exhibit early mortality due to dopaminergic and other neuronal deficits[44-48]. Endogenous ligands for NR4A have not been identified, however, NR4A bind structurally diverse synthetic compounds and these receptors interact with nerve growth factor β response elements (NBREs: AAAGGTCA) and Nur response elements [NuRE: AAAT(GA)C/T/CA] as monomers and dimers respectively[49-51]. In addition, NR4A1 and NR4A2 form a heterodimer with retinoid X receptor and bind a DR5 motif[52,53]. NR4As are immediate early genes induced by diverse stressors and they play important roles in maintaining cellular homeostasis and in pathophysiology [42,43,54]. NR4A1 and Sp TFs are remarkably distinct in their structures and functions in maintaining cellular homeostasis, however, in pancreatic cancer and other tumor types, their functions are similar. Like Sp1, NR4A1 is overexpressed in solid tumors from patients with pancreatic, breast, liver, glioblastoma, ovarian, colon, melanoma, endometrial, cervical, rhabdomyosarcoma and gastric cancer[55-64]. Moreover, high expression of NR4A1 in tumors is a negative prognostic factor for lung, breast, colon and ovarian cancer patients[58-60,63]. The negative prognostic significance of NR4A1 overexpression is paralleled by studies showing that like Sp TFs, NR4A1 is pro-oncogenic and regulates pathways comparable to that described for Sp TFs (Figure 1). Thus, there is an interesting parallel in the expression, functions and prognostic values of Sp TFs (primarily Sp1) and NR4A1 in multiple tumor types. This review will focus on the individual roles and interactions of Sp TFs and NR4A1 in pancreatic cancer and this will include genes commonly regulated by NR4A1/Sp complex in which NR4A1/Sp1 and NR4A1/Sp4 interact at GC-rich gene promoter sites that bind Sp.

Sp TFs and pancreatic cancer

Shi *et al*[65] first reported the overexpression of Sp1 in pancreatic cancer cell lines and in pancreatic tumors compared to non-tumor tissue and subsequent studies showed that Sp1, Sp3 and Sp4 were co-expressed in most pancreatic cancer cells[66]. The three structurally related TFs target similar GC-rich sequences in gene promoters and there is evidence for some genes, that Sp3 acts as a transcriptional repressor. A systematic study of the functions of Sp1, Sp3 and Sp4 was investigated in Panc1, MiaPaCa2 and L3.6pL pancreatic cancer cells and also in cell lines derived from lung, colon, kidney and breast tumors[66]. Figure 1 illustrates the functional effects of Sp1 knockdown which resulted in decreased pancreatic cancer cell growth, induced Annexin V staining (apoptosis) and decreased migration and this was accompanied by PARP cleavage, another marker of apoptosis. These results were somewhat surprising since it might be expected that the loss of Sp1 would be compensated for by Sp3 and Sp4. The functional properties of Sp3 and Sp4 were also determined in Panc1, L3.6pL and MiaPaca2 cells by knockdown and the results showed that like Sp1, knockdown of Sp3 or Sp4 decreased cell proliferation, induced apoptosis (increased Annexin V staining and cleaved PARP) and decreased cell invasion and similar results were observed in lung, breast, kidney and colon cancer cell lines[66]. These results indicated the importance of all three Sp TFs as independent pro-oncogenic factors that regulate pancreatic cell growth, survival and invasion, and related genes and it was suggested that Sp TFs were non-oncogene addiction genes[66].

Genomic analysis of altered gene expression after individual knockdown of Sp1, Sp3 and Sp4 in Panc1 pancreatic cancer cells further demonstrated their pro-oncogenic functions and unique effects of Sp1, Sp3 and Sp4 in this cell line. Figure 2A illustrates the total number of genes that are changed after individual knockdown of Sp1, Sp3

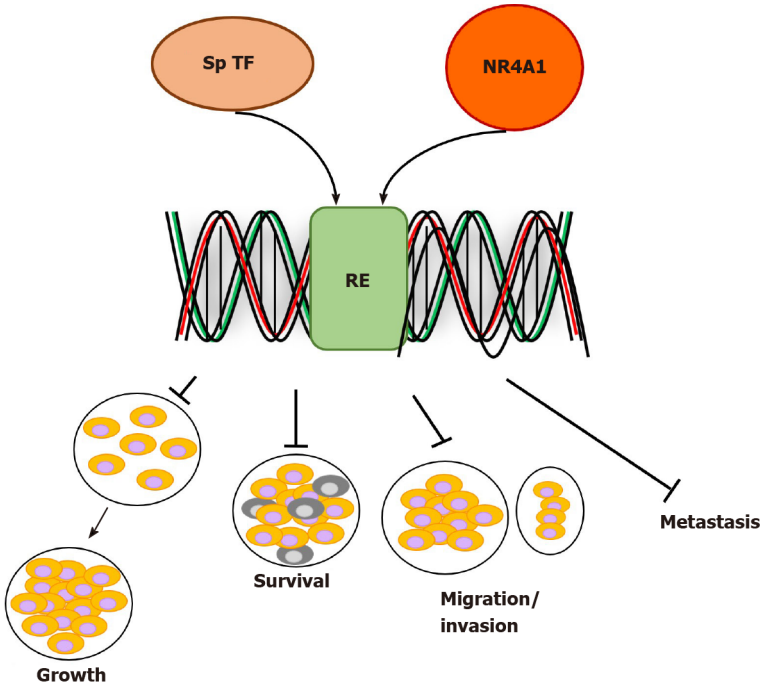

Figure 1 Common functional properties of specificity protein transcription factors and nuclear receptor 4A1 in pancreatic and other cancer cells. Specificity protein (Sp) transcription factors (TFs) (Sp1, Sp3 and Sp4) bind GC-rich gene promoter sequences to activate gene expression associated with enhanced cell proliferation, survival, migration, invasion and metastasis. Nuclear receptor 4A1 (NR4A1) binds as monomer or homodimers to NBRE and NuRE promoter elements and NR4A1 also acts as a cofactor for Sp1 and Sp4-regulated genes and NR4A1/Sp binds GC-rich promoter sequences. Sp: Specificity protein; TFs: Transcription factors; NR4A1: Nuclear receptor 4A1.

and Sp4, the number of uniquely modified genes and the number of genes commonly repressed or induced by Sp1-Sp3, Sp1-Sp4 and Sp3-Sp4. Knockdown of Sp3 and Sp4 resulted in the highest number (and percentage) of commonly induced or repressed genes. Causal Ingenuity Pathway Analysis (IPA) of the genes affected by knockdown were sorted into functional groups and Figure 2B-D illustrate the overlap in affected genes in the Sp1-Sp3, Sp1-Sp4 and Sp3-Sp4 groups associated cell growth, survival and cellular movement (migration and invasion). The overall number and percentage of commonly induced or repressed genes was highest for Sp3 and Sp4 in each functional category and this was similar to that observed for the total number of commonly induced or repressed genes (Figure 2A). Quantitative results from the causal IPA confirmed that the genomic changes observed in the array data were consistent with the functional changes observed after individual knockdown of Sp1, Sp3 and Sp4. This study also confirmed that knockdown of Sp1 alone or Sp1/3/4 (combination) in L3.6pL pancreatic cancer cells also decreased the growth of tumors in athymic nude mice bearing L3.6pL cells as xenografts[66].

In addition to the array studies noted above, there are a number of studies on Sp knockdown or overexpression in pancreatic cancer cells that have identified other Sp-regulated genes that contribute to the pro-oncogenic functions of Sp1, Sp3 and Sp4, and this includes regulation of pro-oncogenic long non-coding RNAs (MALAT1) and microRNAs (Table 1)[20,66-69]. These data were obtained only in pancreatic cancer cells; however, similar results for many of these genes have also been observed in other cancer cell lines[20]. Results summarized in Table 1 were observed in multiple pancreatic cancer cell lines and for some genes, their regulation by Sp TFs is cell context-dependent and there are also differences in the roles of Sp1, Sp3 and Sp4. Some studies used a combination of oligonucleotides targeting the 3 TFs (siSp1/3/4) and the combined knockdown of Sp1, Sp3 and Sp4 by RNA interference in Panc28 and L3.6pL pancreatic cancer cells decreased expression of NFkB-p65 and NFkB-p50 proteins[70]. In the former cell line, individual knockdown of Sp1, Sp3 or Sp4 partially decreased expression of both NFkB subunits. In L3.6pL cells, Sp1 and to a lesser extent Sp3, but not Sp4 knockdown decreased NFkB-p65 whereas Sp4 knockdown was primarily responsible for decreased expression of NFkB-p50 protein.

NR4A1 and pancreatic cancer

The pro-oncogenic role of NR4A1 has been investigated in multiple solid tumor

Table 1 Specificity protein regulated genes in pancreatic cancer cells

Functional	Sp-regulated gene
Cell proliferation and cell cycle progression	*EGFR, IGFR, cyclin D1, PIK3R1, pmTOR, 4-EBP, pS6RP, STAT3, pSTAT3, NFkB-p65/950*
Survival and apoptosis	*Survivin, bcl-2, PARP cleavage, APAF1, ATM, TNFRSF25, COX2, NFkB-p65/5*
Cell migration/movement EMT	*B1-integrin, α2-integrin, MTSS1, vimentin*
Angiogenesis	*VEGF, VEGFR1, VEGFR2, COX2*
Other pro-oncogenic factors	*TNFα, BRCA1, ARHGEF2, Ajuba, MALAT-1, RAS-6TP, FAS*

A detailed analysis of specificity protein (Sp)-regulated genes (Sp1, Sp3 and Sp4) in Panc1 cells based on RNAseq after Sp knockdown has been reported [66] and reviewed[20]. Sp: Specificity protein; EMT: Epithelial-mesenchymal transition.

derived cancer cell lines (rev. in 70), however, the number of publications on the functions of NR4A1 in pancreatic cancer is limited[55,71,72]. Knockdown of NR4A1 in pancreatic cancer cells inhibits cancer cell and tumor growth in athymic nude mouse xenograft studies, induces apoptosis and inhibits migration/invasion. Thus, the pro-oncogenic functions of NR4A1 and Sp TFs in pancreatic cancer cell lines are similar (Figure 1) and comparable results were obtained after their knockdown. For example, knockdown of NR4A1 by RNA interference in pancreatic cancer cells decreased expression of bcl-2 and survivin and this was accompanied by markers of apoptosis including increased TUNEL staining, caspase-3 and PARP cleavage[55,71]. Proteome analysis confirmed that loss of NR4A1 enhanced cell death and decreased gene products associated with cell proliferation and this was accompanied by increased reactive oxygen species (ROS) and ROS-induced endoplasmic reticulum (ER) stress genes including CHOP, Grp78, ATF4 and XBP-1s[71]. In addition, genes such as thioredoxin domain containing 5 (TXNDC5) and isocitrate dehydrogenase 1 (IDH1) that maintain high reductant levels are also NR4A1 regulated genes and their loss after receptor knockdown triggers the ROS-ER stress response. Knockdown of NR4A1 also decreased cell migration and expression of β1- and α5-integrins which play a role in NR4A1-regulated pancreatic cancer cell migration[72]. Thus, there is overlap between the function of Sp TFs and NR4A1 in pancreatic cancer cell lines and studies in other cancer cell lines show that many of the Sp-regulated genes summarized in Table 1 are also regulated by NR4A1[70]. Regulation of the same genes by Sp TFs and NR4A1 was recently reported in breast cancer cells where knockdown of Sp4 or NR4A1 decreased expression of α6- and β1-integrins in MDA-MB-231 and SKBR3 breast cancer cells. The effects of Sp3 and Sp1 knockdown on expression of these integrins was gene- and cell context-specific.

Mechanistic convergence of NR4A1 and Sp TFs

Both NR4A1 and Sp TFs are nuclear proteins that interact with defined cis-elements in their target gene promoters. Mechanistic studies showing cooperative activation of common genes by NR4A1 and Sp1 was first observed in pancreatic cancer cells and subsequently investigated and confirmed in other cancer cell lines[55,72]. The survivin gene has a GC-rich promoter that binds Sp TFs and has been extensively characterized as an Sp-regulated gene[73,74]. Knockdown of NR4A1 or treatment with NR4A1 antagonists decreased expression of survivin protein and mRNA and also decreased luciferase activity in pancreatic cancer cells transfected with GC-rich survivin promoter-luciferase constructs[55]. Further analysis of survivin regulation in pancreatic cancer cells showed that survivin is regulated by a p300/NR4A1/Sp1 complex where Sp1 binds the GC-rich survivin promoter, NR4A1 acts as a cofactor/coactivator and p300 is also part of the complex. The identification of this functional NR4A1/Sp complex is consistent with previous reports showing many other nuclear receptors also activate gene expression through interactions with Sp1. Studies in other cancer cell lines have identified other NR4A1-regulated genes that are regulated by NR4A1/Sp1, NR4A1/Sp4 or NR4A1/Sp1/4 and these include β1-, β3- and β4-integrins, α5- and α6-integrins, TXNDC5 and the PAX3-FOX01 fusion oncogene and the checkpoint gene PD-L1 (rev. in 70). Thus, like Ajuba[75], NR4A1 acts as a cofactor for Sp TFs in pancreatic and other cancer cell lines and they coregulate some of the same genes (EGFR, survivin and IGF1R). The possible interactions of NR4A1 and Ajuba, a coregulator of Sp-regulated genes needs to be further investigated.

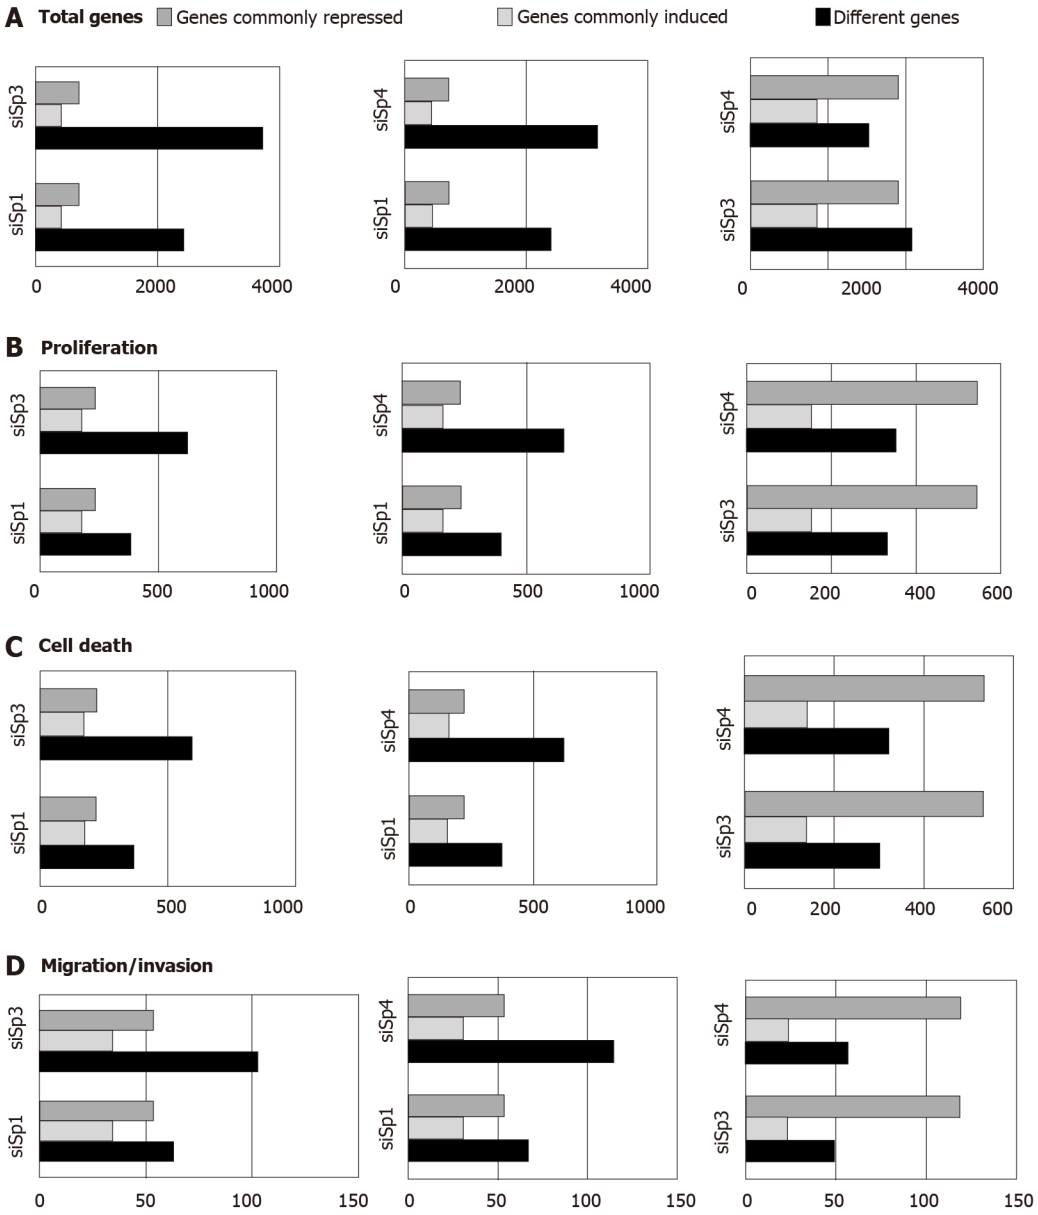

Figure 2 Genomic analysis of Sp1, Sp3 and Sp4 regulated genes in pancreatic cancer cells. A: The number of total genes regulated by specificity protein (Sp) transcription factors (TFs) in Panc1 cell was determined by individual Sp knockdown (siSp1, siSp3 and siSp4) and the number of unique (Different genes) and commonly repressed (Genes commonly repressed) and induced (Genes commonly induced) genes are indicated; B-D: Ingenuity Pathway Analysis analysis of genes that regulate cell proliferation (B), cell death (C) and migration/invasion (D) compares the number of unique and commonly repressed/induced genes by Sp1 and Sp3, Sp1 and Sp4 and Sp3 and Sp4 as described[66].

DRUGS THAT TARGET SP TFS AND NR4A1

Several drugs that target Sp TFs in pancreatic cancer cells have been identified and these include tolfenamic acid and structurally related compounds, COX2 inhibitors curcumin, metformin, piperlongumine, methyl 2-cyano-3,12-dioxooleana-1,9-dien-28-oate (CDDO-Me), benzylisothiocyanate (BITC) and phenethylisothiocyanate (PEITC) (Figure 3)[20]. All of these compounds downregulate Sp1, Sp3 and Sp4 through different pathways. For example, tolfenamic acid and COX2 inhibitors induce proteasome-dependent degradation of Sp1, Sp3 and Sp4 whereas metformin induces the dual specificity phosphatases MPK-1 and MPK-5 which are important for Sp downregulation. The phosphatases downregulate miR-27a which results in upregulation of ZBTB10, a Sp repressor which competitively displaces Sp TFs from GC-rich sites resulting in gene inactivation since ZBTB10 Lacks a transactivation domain. ROS-inducers including PEITC, BITC, piperlongumine, CDDO-Me and curcumin also decrease Sp-regulated gene expression through an ROS-mediated pathway which also involves induction of Sp repressors namely ZBTB4, ZBTB10 and ZBTB34[20] (Figure 4). This pathway involves ROS-dependent remodeling of repressor complexes

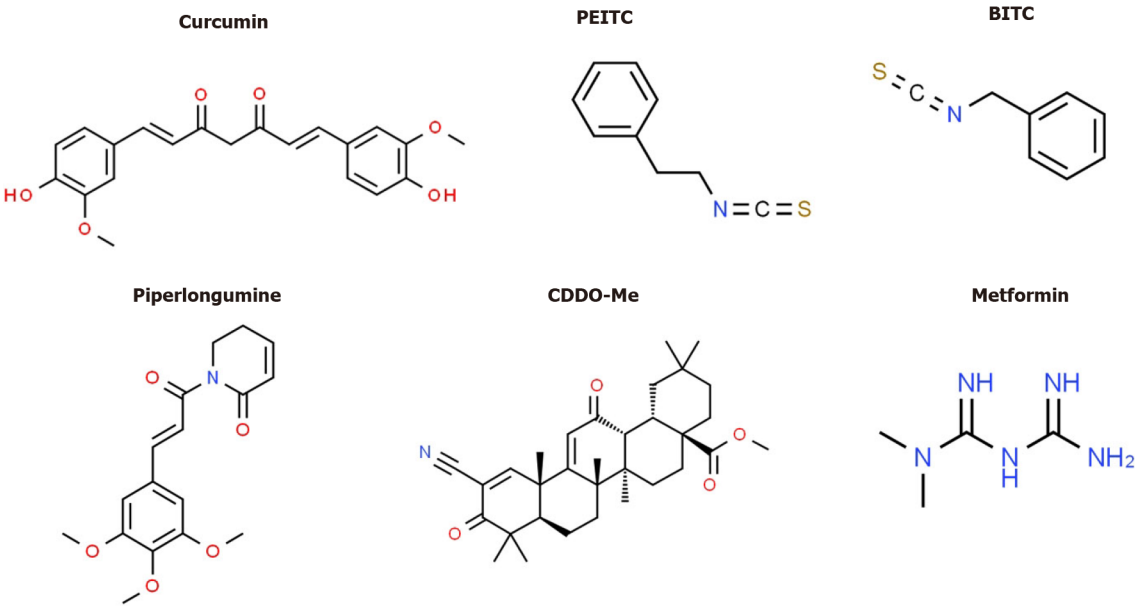

Figure 3 Structures of agents that target downregulation of Sp1, Sp3 and Sp4 in pancreatic and other cancer cell lines[68]. The structurally diverse compounds act through multiple pathways in different cancer cell lines.

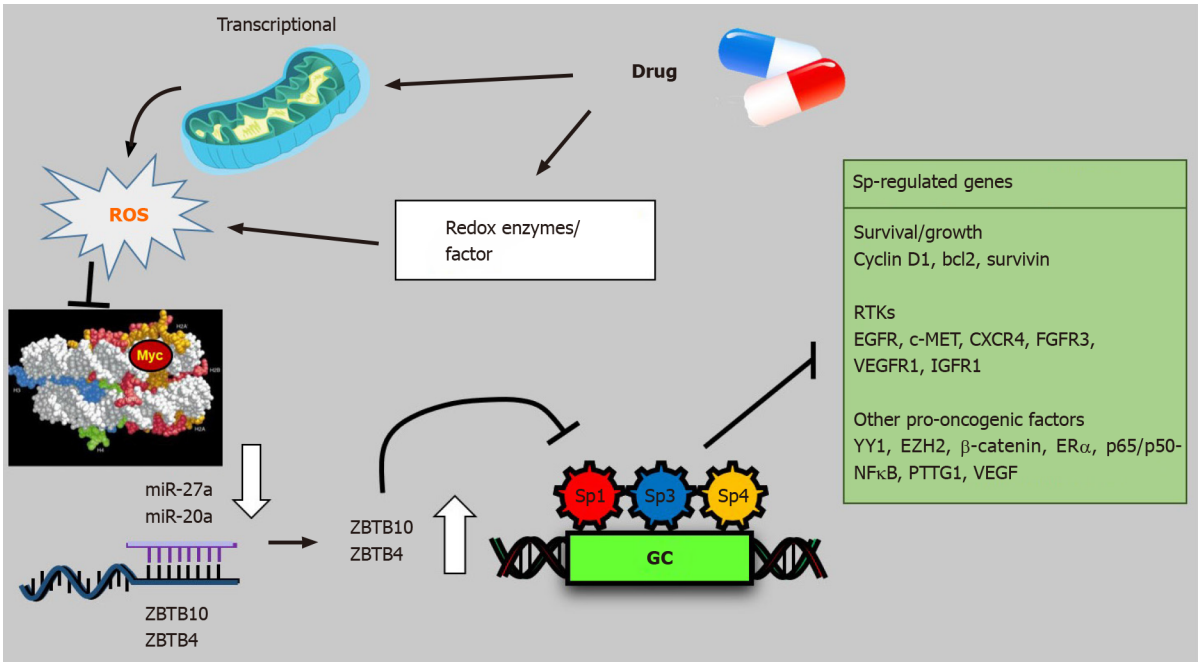

Figure 4 Mechanism of reactive oxygen species-dependent downregulation of specificity protein transcription factors. Induction of reactive oxygen species results in epigenetic suppression of Myc, downregulation of microRNAs, induction of ZBTB suppressors and decreased expression of specificity protein (Sp) transcription factors and Sp-regulated genes[20]. ROS: Reactive oxygen species; Sp: Specificity protein.

which results in downregulation of cMyc and cMyc-dependent microRNAs (miR-27a, miR-17-92) and induction of ZBTBs. These compounds (Figure 4) and others induce similar patterns and mechanisms of Sp downregulation in other cancer cell lines[20], however, there are compound-specific differences in mechanisms that are cell context-dependent.

Bis (3'-indolyl)-1-(p-hydroxyphenyl) methane (DIM-C-pPhOH) (Figure 5) was identified as an NR4A1 Ligand that acts as a receptor antagonist and mimics the effects of NR4A1 knockdown in pancreatic and other cancer cell lines[70]. DIM-C-pPhOH and several 3,5-disubstituted phenyl analogs are inhibitors of cell proliferation, survival and migration/invasion and they inhibit expression of NR4A1/Sp- and other NR4A1-regulated genes. Moreover, many of the 3,5-disubstituted analogs of

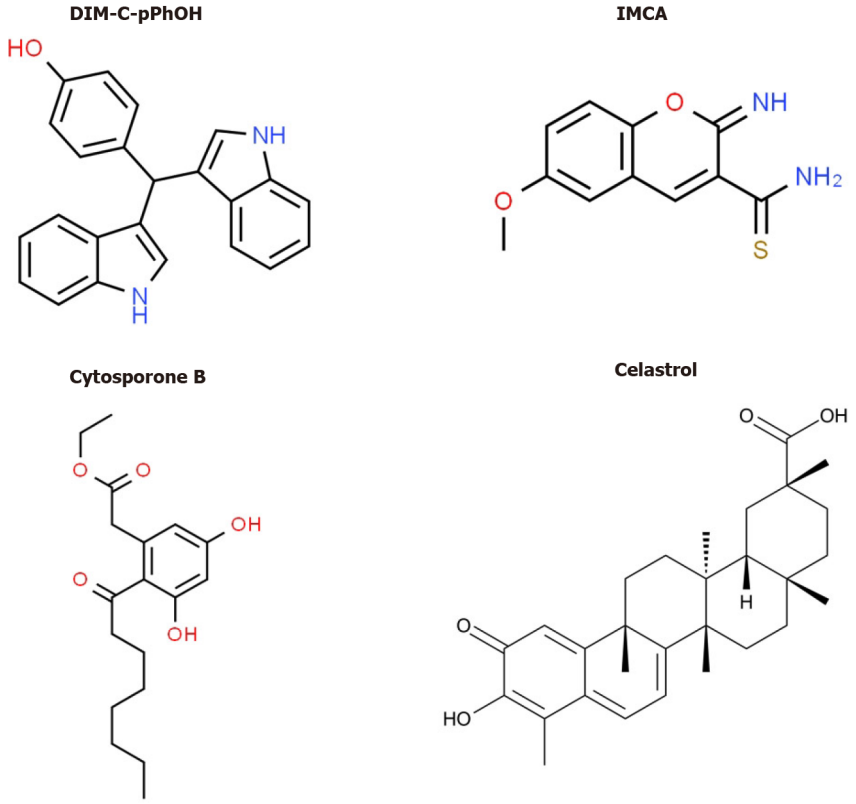

Figure 5 Nuclear receptor 4A1 ligands. Structures of compounds that directly bind nuclear receptor 4A1 include DIM-C-pPhOH, IMCA, cytosporone B and celastrol[76-80].

DIM-C-pPhOH inhibit tumor growth in mouse xenograft models at doses < 5 mg/kg per day and ongoing studies have identified ligands that inhibit tumor growth at doses < 1mg/kg per day. Interestingly, several other classes of compounds bind and modulate NR4A1-dependent pathways/genes and these include cytosporone B and structurally related compounds, IMCA (2-imino-6-methoxy-2H-chromene-3-carbothiomide) and the triterpenoid celastrol and analogs[76-80] (Figure 5). Fascinatingly, celastrol also activates ROS-dependent downregulation of Sp1, Sp3 and Sp4 in bladder cancer cells[80] (*e.g.*, Figure 4) and uniquely acts as a bifunctional agent targeting both Sp TFs and NR4A1. Ongoing studies in this laboratory have identified other dual targeting agents with potential for clinical applications for pancreatic cancer therapy.

CONCLUSION

In summary, it is evident that both Sp TFs and NR4A1 are pro-oncogenic factors that regulate pancreatic cancer cell and tumor growth and interactions of NR4A1 and Sp TFs are also important for regulating many critical genes (Figure 1) involved in pro-oncogenic functions. Although the functional importance of NR4A1/Sp regulated genes in cancer cell growth, survival, migration and invasion has been established in pancreatic and other cancers, clinical applications of drugs targeting Sp and NR4A1 are lacking. Several compounds have been identified that induce Sp downregulation or inhibit/antagonize NR4A1. Current studies in our laboratories are focused on identifying agents like celastrol that act simultaneously as NR4A1 antagonists and Sp downregulators as a new class of drugs that will enhance the effectiveness of current chemotherapies used for clinical treatment of pancreatic and other cancers.

Abstract

Colorectal cancer (CRC) was the second-ranked worldwide type of cancer during 2020 due to the crude mortality rate of 12.0 per 100000 inhabitants. It can be prevented if glandular tissue (adenomatous polyps) is detected early. Colonoscopy has been strongly recommended as a screening test for both early cancer and adenomatous polyps. However, it has some limitations that include the high polyp miss rate for smaller (< 10 mm) or flat polyps, which are easily missed during visual inspection. Due to the rapid advancement of technology, artificial intelligence (AI) has been a thriving area in different fields, including medicine. Particularly, in gastroenterology AI software has been included in computer-aided systems for diagnosis and to improve the assertiveness of automatic polyp detection and its classification as a preventive method for CRC. This article provides an overview of recent research focusing on AI tools and their applications in the early detection of CRC and adenomatous polyps, as well as an insightful analysis of the main advantages and misconceptions in the field.

Key Words: Artificial intelligence; Machine learning; Deep learning; Medical images; Colorectal cancer; Colorectal polyps
