It is well established that alterations in the gut microbiota can modulate the development of respiratory disease[41].

In patients with gut dysbiosis such as patients with an established intestinal inflammatory disease or obese patients, the intestinal microbiota may be a secondary risk factor for the development of severe COVID-19[7]. Besides, patients with COVID-19 may develop a dysbiosis in the gastrointestinal microbiota[21] and a reduction in short-chain fatty acid-producing bacteria[42].

GUT MICROBIOTA DYSBIOSIS

Disruption of the gut microbiota can trigger inflammatory events that are associated with metabolic dysfunction, obesity, cancer, and neurological disorders[43,44]. The proliferation or reduction in certain microorganisms can increase the stimulation of innate immune receptors, like nucleotide-binding oligomerization domain-like receptors and Toll-like receptors[45]. The stimulation of this receptor triggers several pro-inflammatory signals and the production of cytokine and chemokine, which modulate the adaptive immune system, influencing both local and systemic immune response[43,44].

The activation of Toll-like receptors on immune cells by the microbiota can generate a low-grade systemic inflammation in the host that is associated with a change in metabolic and immunological responses[46]. Alterations in the microbiome are related to the development of diseases such as obesity, inflammatory bowel disease, and cancer[47]. Therefore, SARS-CoV-2 gastrointestinal infections and alteration of gut homeostasis may be implicated in the development of disease and impact immune response to oral vaccines and medicines and the pathogen immune response[48,49].

NUTRITIONAL INTERVENTION

Several reports have highlighted the potential role of nutrients in the modulation of the immune response to SARS-CoV-2 or a direct anti-viral and/or anti-SARS-CoV-2 properties[50-53]. During this pandemic, nutritional aspects such as obesity[7,54], malnutrition[55], and micronutrient deficiency[56,57] have been postulated as risk factors for severe COVID-19. Nevertheless, the composition of the human microbiota is influenced by many factors, including dietary components[41]. Some bacteria can ferment nondigestible carbohydrates (prebiotics), like soluble fibers, to produce short-chain fatty acids (SCFAs). SCFAs can stimulate the growth and/or activity of commensal bacteria and are associated with health benefits. SCFAs can induce the regulation of the intestinal barrier, reduce oxidative stress, control diarrhea, and modulate intestinal motility and also induce a local and systemic anti-inflammatory effect[58,59].

High-fiber diets can induce the proliferation of beneficial commensal microbes, such as *Lactobacillus* spp. and *Bifidobacterium* spp. in the gastrointestinal tract[60]. In fact, high-fiber diets may increase immunoglobulin A production and modulate the secretion of interferon-gamma and interleukin (IL)-10[61-63], which could aid in the control of gastrointestinal infections.

Prebiotics may alter the microbiota composition by a mechanism called cross-feeding, when the product of a prebiotic's fermentation by a microorganism in the microbiota can be used as a substrate by another microorganism[64-66]. Another mechanism that prebiotics can alter the microbiota is through pH alterations. The fermentation products are predominantly acids, which may cause a decrease in the intestinal pH, restraining the growth of acid-sensitive bacteria, such as *Bacteroides* spp., and promoting butyrate-producing bacteria[67].

SCFAs are divided into acetate, propionate, and butyrate. All SCFAs have potential anti-inflammatory effects with the reduction of prostaglandin E2 and inflammatory cytokines[68]. Acetate can curb the activation of the NLR family pyrin domain containing 3 inflammasome[69]; propionate can inhibit histone deacetylase and reduce lipopolysaccharide-induced inflammation[70]. Butyrate has been associated with anti-cancer properties and reduces pulmonary inflammation[71,72].

Overall, research has demonstrated a potential anti-inflammatory role for SCFAs in both local (intestinal) and non-local inflammation *via* direct anti-inflammatory effects or modulation of the microbiota[71,73,74].

SCFAs can induce the release of anti-inflammatory cytokines such as IL-10[75,76], promoting the regulation of Th cells and inflammatory diseases[77], including

inflammatory bowel disease[78].

Another intervention for the modulation of the gastrointestinal microbiome is *via* the consumption of probiotics. Probiotics are bacteria that can be ingested and provide a beneficial interaction to the host[79]. Several studies have investigated the effects of probiotics on the gut microbiota[80], with conflicting results involving their ability to graft on the commensal microbiota[81-84]. However, probiotics can produce metabolites that can modify and influence the commensal microbiota, intestinal barrier, and immune system[85,86].

Probiotics can also aid in the prevention or treatment of bacterial[87] and viral infections[88]. The administration of probiotics increases the survival of mice infected with the influenza virus[87]. Besides the influenza virus, studies have demonstrated beneficial protection against respiratory syncytial virus infection[89].

The heath benefit of probiotics in respiratory viral infections is due to the modulation of cytokine production and oxidative stress[90]; therefore, they may possibly be an adjuvant treatment for the aberrant release of pro-inflammatory cytokines, chemokines, and oxidative stress during severe COVID-19[91].

The most used probiotics are *Lactobacillus*, *Bifidobacterium*, and *Enterococcus*[92]. Although there is extensive research demonstrating their health benefits, currently there is a gap in knowledge involving the ideal dosage and comparison among strains of probiotics[93].

DISCUSSION

COVID-19 is a potentially deadly disease, which can infect intestinal cells[13]. SARS-CoV-2 gastrointestinal infections[16] can generate diarrhea, pain, and vomiting[19]. To date, few reports have investigated the possible consequences of gastrointestinal infection by SARS-CoV-2; nevertheless, viral infections can alter the gastrointestinal microbiota[20]. A report by Xu *et al*[94] identified a reduction in *Lactobacillus* and *Bifidobacterium* in fecal samples from COVID-19 patients[94]. Also, the microbiome of COVID-19 patients can be disturbed by the necessary or unnecessary use of antibiotics[34].

Yeoh *et al*[95] identified that the alteration on the gastrointestinal microbiome in COVID-19 patients was independent of medications. The alterations on the gut microbiome included a reduction in *Faecalibacterium prausnitzii*, *Eubacterium rectale*, and *bifidobacteria* for up to 30 d after SARS-CoV-2 clearance[95].

The microbiota dysbiosis in COVID-19 may be involved in the inflammatory response and may be a persistent problem after COVID-19 resolution, indicating a possible role for nutritional interventions to curb the inflammatory response and reestablish the gastrointestinal homeostasis of COVID-19 patients.

Dietary and nutritional intervention can modulate the immune response, increasing or dampening the anti-viral response[59-62]. Western-style diets (low fiber content) can increase *Bacteroidetes* and reduce *Firmicutes*[96] and are linked to the development of obesity[97], a risk factor for severe COVID-19[7]. Although reports have identified an increase in SCFAs in fecal samples from obese individuals[96], SCFAs have been associated with control of appetite[98] and increase energy expenditure[99].

In addition, very low fiber-diets can lower mucus production on the intestine and increase the susceptibility to gastrointestinal infections[39]. Importantly, a change in diet can modify the microbiota composition[100]. The microbial communities are in constant change and are also affected seasonally by food consumption[101]. In fact, a reduction in the consumption of fiber can change the microbiota in as little as 1 d, reducing SCFAs production[102].

In opposition, high fiber-diets increase *Firmicutes* and *Actinobacteria* on the gut microbiota[103] and increase the production of SCFAs, which can aid in the reduction of pulmonary inflammation, *via* the gut-lung axis[41,104,105] and promote a local and systemic anti-inflammatory response *via* IL-10 production and Treg cells[75,76,106]. The ingestion of probiotics may stabilize or alter the gastrointestinal microbiome, especially after a perturbation of the microbiota such as post usage of antibiotics or gastrointestinal infections[107].

Probiotic treatments with *Bacillus subtilis* and *Enterococcus faecalis* have been demonstrated to reduce ventilator-associated pneumonia[108]. Treatment with *Lactobacillus rhamnosus* can reduce ventilator-associated pneumonia and *Clostridium difficile*-associated diarrhea in mechanically ventilated patients[109], making it a possible addition to the treatment of patients with severe COVID-19 in intensive care units with assisted mechanical ventilation. Treatment with *Lactobacillus* may be of particular

importance, because respiratory infections may cause a reduction in *Lactobacillus*, and an increase in *Enterobacteriaceae* and intestinal IL-17 inflammation[110].

Targeting IL-17 has been postulated as a treatment for COVID-19[111] because of the increase in IL-17 in severe COVID-19 patients compared to moderate COVID-19 patients[111]. IL-17 and IL-17-producing T helper cells (Th17), type three innate lymphoid cells, invariant natural killer cells, and γδ T cells are involved in the immune response of COVID-19[112]. IL-17 receptor is expressed on the surface of many different cells such as neutrophils, eosinophils, epithelial cells, keratinocytes, and fibroblasts[112]. In addition, IL-17 can directly influence the expression of ACE2, SARS-CoV-2 entry's receptor[113].

The usage of IL-17 blockade, such as monoclonal antibodies against IL-17A and/or IL-17 receptor A, may represent a possible therapeutic option for COVID-19[112]. Nevertheless, IL-17 is an important cytokine in the immune response against *Streptococcus pneumoniae* and *Pseudomonas aeruginosa*, common pathogens in respiratory and intestinal tract infections[112,114]. Secondary bacterial infections can occur in the respiratory system following SARS-CoV-2 infection, especially in patients with invasive mechanical ventilation[34]. IL-17 is especially important for intestinal homeostasis[115]. Therefore, treatment with anti-IL-17 should consider the possible risk for an increase in susceptibility for bacterial infections both respiratory and intestinal.

COVID-19 patients may also develop a cytokine storm syndrome, which may induce multi-organ failure and lead to death or long-term consequences[91]. In this context, probiotics or prebiotics treatment have been previously demonstrated anti-inflammatory effects in respiratory infections *via* the increase in SCFAs[71,73,74,88,116].

SCFAs production and health benefit can be increased by the ingestion of highly fermentable fiber diets[117], probiotics[73], oral administration of drugs like tributyrin (a prodrug of butyrate)[118], or SCFAs directly[119-121].

In this context, the intake of prebiotics and/or probiotics can represent a significant prophylactic intervention and/or recovery of COVID-19 patients.

CONCLUSION

The SARS-CoV-2 infection on the gastrointestinal tract and the long-term consequences of COVID-19 in gastrointestinal homeostasis still needs further investigations. It is clear that SARS-CoV-2 can infect the gastrointestinal tract and impact the intestinal immune response and the gut microbiome. Currently, there is no specific treatment for COVID-19, but investigations on the impact of nutritional intervention *via* modulation of the immune response or *via* microbiota are been investigated and may represent a significant prophylactic intervention and/or recovery of COVID.

Abstract

Hepatitis C virus (HCV) infection is a systemic disease that is implicated in multiple extrahepatic organ dysfunction contributing to its protean manifestations. HCV is associated with diverse extrahepatic disorders including atherosclerosis, glucose and lipid metabolic disturbances, alterations in the iron metabolic pathways, and lymphoproliferative diseases over and above the traditional liver manifestations of cirrhosis and hepatocellular carcinoma. The orchestration between HCV major proteins and the liver-muscle-adipose axis, poses a major burden on the global health of human body organs, if not adequately addressed. The close and inseparable associations between chronic HCV infection, metabolic disease, and cardiovascular disorders are specifically important considering the increasing prevalence of obesity and metabolic syndrome, and their economic burden to patients, the healthcare systems, and society. Cellular and molecular mechanisms governing the interplay of these organs and tissues in health and disease are therefore of significant interest. The coexistence of metabolic disorders and chronic hepatitis C infection also enhances the progression to liver fibrosis and hepatocellular carcinoma. The presence of metabolic disorders is believed to influence the chronicity and virulence of HCV

leading to liver disease progression. This comprehensive review highlights current knowledge on the metabolic manifestations of hepatitis C and the potential pathways in which these metabolic changes can influence the natural history of the disease.

Key Words: Chronic hepatitis C infection; Insulin resistance; Metabolic syndrome; Cardiovascular diseases; Fatty liver; Diabetes mellitus

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Available evidence proves a strong association between hepatitis C virus (HCV) and metabolic complications such as hyperlipidemia, hepatic steatosis, insulin resistance, metabolic syndrome, and diabetes mellitus. *De novo* development of insulin resistance and hepatic steatosis in chronic HCV infection influences the disease progression in the liver and enhances overall morbidity and mortality. The influence of metabolic diseases on HCV infection can increase disease severity. The interplay between HCV major proteins and the liver-muscle-adipose axis is complex and still not fully elucidated. Coexistence of metabolic diseases such as diabetes mellitus and HCV infection are also known to result in adverse outcomes of both disorders. There is evidence that successful treatment halts the progression of liver disease, but more studies are required on how treatment influences the metabolic manifestations.

INTRODUCTION

Hepatitis C virus-beyond a hepatotropic infection

Hepatitis C virus (HCV) is a major cause of liver disease worldwide, with 130-170 million people infected according to the World Health Organization[1]. Approximately 10%-20% of chronically infected patients experience persistent inflammation and develop liver cirrhosis and eventually hepatocellular carcinoma[1]. Well recognized extrahepatic manifestations include but not limited to; glucose and lipid metabolic disorders, atherogenic disease, mixed cryoglobulinemia, lymphoproliferative disorders, renal disease, insulin resistance (IR), type 2 diabetes (T2DM), sicca syndrome, rheumatoid arthritis-like polyarthritis, and autoimmune diseases[2,3]. Moreover, patients with chronic HCV are at an increased risk of developing metabolic bone disease and osteopenia as it was observed in more than 50% of infected subjects[4]. The deleterious effects of metabolic complications as a result of HCV infection is mainly due to impairments in glucose and lipid metabolism[5]. Independent of the stage of hepatic fibrosis, IR and DM are more prevalent in the course of HCV infection and post liver transplantation in chronic HCV (CHC) infected patients[6-8]. Interestingly, prevalence of HCV infection among diabetic patients is higher than in the age-matched general population[9]. CHC induces systemic and hepatic inflammation that contribute to the development of atherosclerosis through elevated levels of pro-atherogenic cytokines and chemokines[10]. Atherosclerosis is also found to be related to the high tumor necrosis factor alpha (TNF-α)/adiponectin ratio that is found in HCV-infected patients and is related to IR[11].

The systemic burden of hepatitis C infection surpasses its liver disease burden due to its metabolic spectrum and it is plausible that, the virus, through disruptions of glucose and lipid homeostasis, stimulates other mechanisms of liver damage and contributes to the pathogenesis of extrahepatic disorders[12]. Therefore, it is imperative to have thorough understanding on the metabolic impact of this enigmatic disease on human body for optimal management of the disease and its consequences. This evidence-based review highlights the current understanding on CHC infection and its metabolic complications.

IMPACT OF CHRONIC HEPATITIS C ON MAJOR METABOLIC ORGANS

Most HCV infected people are unaware of their condition due to its asymptomatic nature. About one-third of infections resolve spontaneously in the first year, the remaining infections persists and become chronic. CHC infection can progress to end-stage liver disease, including cirrhosis and hepatocellular carcinoma (HCC). HCV can also cause serious problems in organ systems other than the liver, including cryoglobulinemic vasculitis, metabolic bone disease, kidney disease, cardiovascular disease, and hematologic malignancies. In the United States, HCV is one of the leading causes of end-stage liver disease requiring liver transplantation, and the mortality attributed to HCV is expected to continue rising during the next 10 years. Figure 1 illustrates the HCV-related metabolic disturbances mainly targeting the liver, skeletal muscle and adipose tissue as current evidence suggests[13].

METABOLIC EFFECTS OF CHRONIC HEPATITIS C INFECTION ON LIVER

Hepatic steatosis in the setting of HCV viral infection is considered as a distinct entity with specific clinical and prognostic implications. The prevalence of hepatic steatosis in patients with HCV infection is 55.54%, which remains higher than that in non-infected individuals[14]. Contrary to non-alcoholic fatty liver disease being associated with hyperlipidemia, CHC is linked with hypolipidemia including hypo-cholesterolemia, hypo-triglyceridemia and lower low-density lipoprotein (LDL) cholesterol levels. Co-existence of non-alcoholic fatty liver disease in HCV infected patients is associated with features of metabolic syndrome (MetS), and is an independent risk factor for advanced liver fibrosis[15-17].

In patients with CHC, genotype 3 has the highest prevalence of hepatic steatosis (40%-86%) while patients with other genotypes is around 50%[18,19]. A direct association exists between genotype 3 HCV (G3-HCV) and the development of steatosis, while in non-genotype 3 CHC, IR plays a key role in the pathophysiology of hepatic steatosis[20,21].

The term "viral steatosis" is used particularly with G3-HCV infection when hepatic steatosis is related with viral load and not MetS and "metabolic steatosis" occurs secondary to IR/MetS in the genotypes G1, G2, and G4[22-24]. Studies in patients infected with G3-HCV have demonstrated that steatosis can improve and even disappear following successful antiviral treatment with interferon and ribavirin; but data from directly acting antivirals (DAAs) are limited[25,26]. The risk of progression of fibrosis is increased with pre-existing steatosis, and a reduced rate of response to antiviral treatment[27-29]. CHC is implicated in the development and progression of non-alcoholic steatohepatitis (NASH). NASH is a chronic state of liver injury that can be caused by CHC infection or coexist with HCV and biopsies have proven that the association leads to advanced fibrosis and is a predictor of liver disease progression in patients with CHC regardless of the genotype[30,31]. Both "viral" and "metabolic" steatosis, stimulates the progression of fibrosis and liver disease influenced by actions of increased insulin levels and inflammatory cytokines on hepatic stellate cells (Figure 2).

HEPATITIS C VIRUS AND IRON METABOLISM

Iron is a central component for HCV virus replication and translation, though it is debatable whether iron promotes or suppresses HCV viral replication. High serum ferritin levels, associated with hepatic iron overload, were evident in CHC patients and considered an independent risk factor for advanced liver fibrosis[32,33]. Alterations of iron metabolism in CHC is believed to be caused by a reduction in the level of hepcidin. Hepcidin, a peptide hormone, is critical in the strict regulation of iron levels under homeostatic states. Though the underlying mechanisms remains unclear, the current opinion propose that all HCV proteins regulates hepcidin expression through signal transducer and activator of transcription 3, mitogen-activated protein kinase, or bone morphogenetic protein/Sma and Mad proteins signaling pathways, and the altered expression of other related genes[34]. Due to the ability of different factors influencing the levels of serum ferritin levels, it serves as an important indicator of hepatic iron overload but only a liver biopsy can confirm the diagnosis. It is vital to further our understanding on how HCV affects iron metabolism and whether it can be used as a therapeutic tool to prevent disease progression.

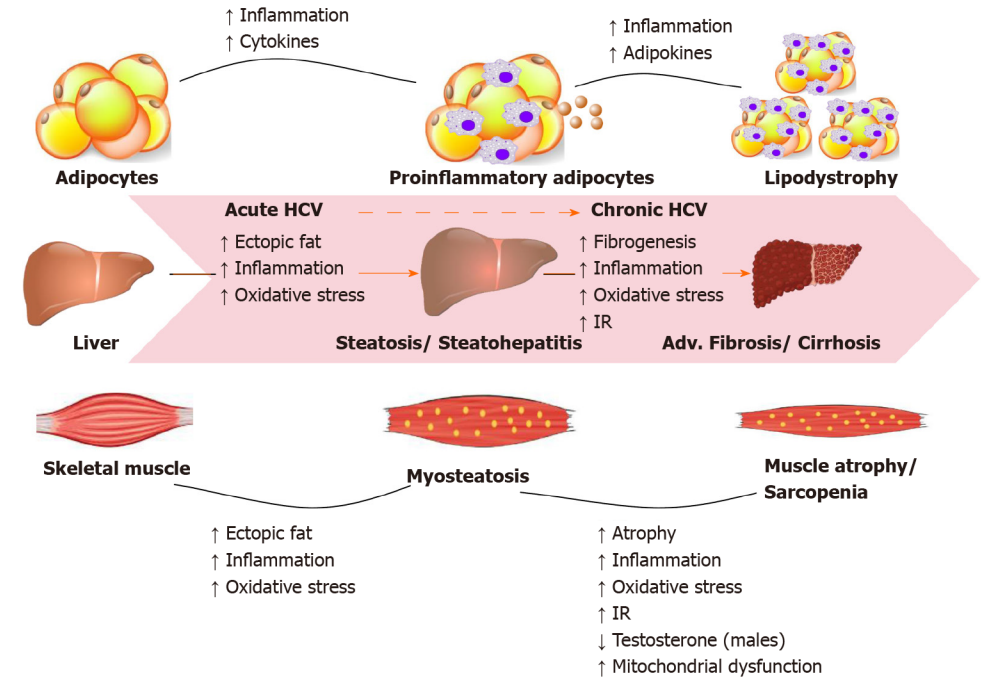

Figure 1 Changes in liver, adipose tissue, and muscle with hepatitis C virus infection. Adv: Advanced; HCV: Hepatitis C virus; IR: Insulin resistance.

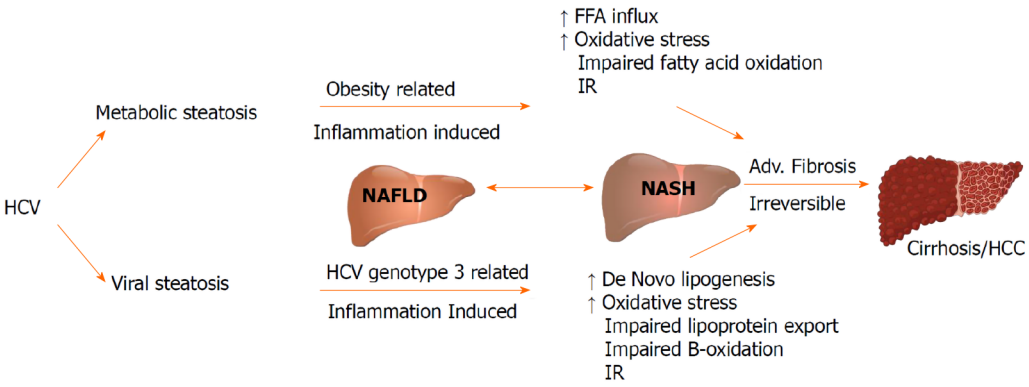

Figure 2 Hepatic steatosis development in hepatitis C virus infection. Adv: Advanced; HCV: Hepatitis C virus; NAFLD: Non-alcoholic fatty liver disease; FFA: Free fatty acid; IR: Insulin resistance; HCC: Hepatocellular carcinoma.

EFFECTS OF CHRONIC HEPATITIS C INFECTION ON SKELETAL MUSCLE

CHC infection is associated with skeletal muscle mass loss, sarcopenia, increased intramyocellular lipid deposition, myosteatosis, and low muscle strength[35-37]. A recent Japanese study by Fukui *et al*[38] demonstrated that skeletal muscle mass decreases in accordance with liver disease progression in male patients with CHC. Sarcopenia, loss of muscle mass and function, has a high incidence rate in patients with cirrhosis (30%-70%) favoring atrophy of type II fast-twitch glycolytic fibers[39,40]. Myosteatosis, is characterized by increased lipid accumulation within muscle fibers and is a complication of hepatitis C Cirrhosis predisposing individuals to muscle atrophy over time[41]. High BMI, IR, diabetes, steatosis, inflammation, increased oxidative stress and lipotoxicity are all independent risk factors that predispose CHC patients to skeletal muscle disorders[42-47]. Therefore, a comprehensive sarcopenia evaluation assessing skeletal muscle mass, muscle strength and physical performance can provide clinicians the optimal risk assessment tools and therapeutic strategies for improving patient's quality of life and to halt the disease progression.

It is widely recognized that testosterone is highly associated with increased muscle

strength and mass[48]. Chaudhury *et al*[49] demonstrated that male CHC patients with hepatic dysfunction/cirrhosis suffered from low levels of free and total testosterone regardless of the treatment regimens (interferon and ribavirin (6%); interferon, ribavirin, and DAAs (18%); ribavirin and DAAs (14%); and DAAs only (62%)) received by patients[50]. The decrease in testosterone was sustained after viral clearance suggesting that testosterone metabolism in the liver is most likely impaired by liver dysfunction in these patients. Neff *et al*[51] was able to show that administration of testosterone hormone to HCV-patients suffering from liver failure increases muscle strength, enhance albumin synthesis, and improve survival post-liver transplant[49,52-54].

The association between CHC infection of the liver as well as hepatic dysfunction and muscle loss is well documented, though not fully understood. The triad complex association can be linked through increased inflammation, oxidative stress, alterations in the endocrine system (IR, testosterone levels), hepatic steatosis, and multiple factors involved in muscle depletion. A better understanding of the etiology of sarcopenia and skeletal muscle mass loss in HCV infected patients and the appropriate management strategies are expected to improve patient outcomes.

HEPATITIS C VIRUS INFECTION AND ADIPOSE TISSUE

Following liver and skeletal muscles, adipose tissue is another major site of IR in CHC infections[51]. Adipose tissue is considered as an important endocrine organ which releases biologically active polypeptides including adipose tissue specific adipokines like leptin and adiponectin and non-adipose tissue specific adipokines such as plasminogen activator inhibitor I (PAI-1)[55]. Adiponectin (an insulin-sensitizing hormone in muscle and liver) and leptin are most abundant in subcutaneous fat while PAI-1 is found in high levels in extracellular matrix[56,57]. Together, leptin, adiponectin and PAI-1 are the abundant adipokines which regulate the body lipid and glucose metabolism *via* the adipo-insular axis[58]. Alterations in adipokine levels/function are a major culprit for multiple complications including the risk of developing T2DM, cardiovascular disease and neurodegenerative disorders.

An interplay between HCV virion and adipocytes is suggested by a strong relationship between HCV viral load and subcutaneous (not visceral) fat[59]. Patients with CHC have significant subcutaneous adipose tissue insulin resistance in comparison with BMI-matched controls. Lim *et al*[58] suggested that that viral eradication improves global, hepatic, and adipose tissue insulin sensitivity. Serum levels of adiponectin and leptins even though associated with IR, HCV associated IR is predominantly a cytokine-independent direct virus-specific effect[60].

Though data is limited, new adipokines have an important role in the regulation of insulin sensitivity in CHC. Vaspin (visceral adipose tissue-derived serpin; seroinA12) has been found to improve insulin sensitivity and glucose tolerance and down regulate TNF-α synthesis[61-63]. The levels of serum vaspin are significantly decreased in chronic HCV infected patients without advanced fibrosis and increased in cases of advanced fibrosis suggesting vaspin to be a compensatory mechanism switch in HCV associated IR. However, no such association was found between serum vaspin level and viral load or homeostatic model assessment of IR values[64]. The level of another adipokine, visfatin, also increases in CHC and is inversely associated with inflammatory activity[65]. Visfatin exerts insulin like effect stimulating insulin receptor substrate-1 (IRS-1) phosphorylation and the peroxisome proliferator-activated receptors (PPARγ) expression but it also potentiates expression of interleukin-6 and TNF-α like adhesion molecules[65,66]. Chimerin, another adipokine thought to be related to IR in CHC infection, inhibits the synthesis of TNF-α and interleukin-6 and ameliorates IRS-1 phosphorylation, to improve insulin sensitivity of adipocytes and to enhance adiponectin synthesis[67,68].

HEPATITIS C VIRUS AND LIPID METABOLISM

HCV regulates the host factor diacylglycerol acyltransferase-1 to promote the biogenesis of lipid droplets, and the HCV core protein recruit nonstructural protein 5A (NS5A) that carries HCV ribonucleic acid from the replication complex on the endoplasmic reticulum-derived membranous web to lipid droplets[69]. The enveloped viral particles may be simultaneously packaged into endoplasmic reticulum luminal lipid droplets in the very low-density lipoprotein cholesterol (VLDL) precursor and eventually the VLDL-dependent pathway secretes it into the circulation as lipo-viral

particles[70,71]. Therefore, HCV infection is implicated in disrupted lipoprotein homeostasis due to impairment of the VLDL-releasing pathway which is one of the driving mechanisms of hepatic steatosis[72]. Derangement of lipid metabolism in HCV infection plays a role in hepatic steatosis, dyslipidemia, and hypobetalipoproteinemia. The HCV core and NS5A proteins interact with apolipoprotein (apo) A, apo A II and apo E. An increased levels of ApoC-III has been found in HCV lipo-viral particles that may inhibit the activity of lipoprotein lipase, disturbing the intravascular catabolism of triglyceride-rich lipoproteins[73-75]. HCV may modulate lipid metabolism and promote the synthesis of saturated fatty acids by regulating the enzymes involved in lipid synthesis[76,77]. Poly-unsaturated fatty acids supplementation counteracts the effects of HCV-induced lipid alterations and inhibits HCV formation[78]. Previous treatment with interferon-based antiviral therapy could reverse the hypocholesterolaemia induced by HCV. It has been shown that cholesterol and low-density lipoprotein cholesterol (LDL-C) levels rapidly recover following viral clearance or sustained virologic response indicating that large amounts of lipids released from the liver into blood circulation may increase levels of cholesterol and LDL-C, resulting in the hydrolysis of triglycerides[79]. More studies are needed to delineate the pathways and potential therapeutic targets.

CHRONIC HEPATITIS C VIRUS AND GLUCOSE METABOLISM

CHC infection is closely associated with alterations of glucose metabolism from the early stages of infection, prior to the development of significant hepatic fibrosis[80]. In patients infected with HCV, total serum fasting blood glucose levels are found to be higher than that in healthy controls[81]. Clinical studies, both prospective and retrospective, showed a two-fold increased risk of developing insulin resistance and T2DM in HCV-infected patients even after correction of confounding factors[82].

The mechanism by which HCV causes glucose metabolism derangement resulting in T2DM is not fully understood. The proposed mechanisms from experimental studies in mice suggest downregulation of glucose transporter 2 receptors causing impaired hepatic glucose uptake, down-regulation of insulin receptor substrate 2 expression [suppression of cytokine signaling (SOCS)-3-dependent mechanism] causing altered hepatic insulin receptor cascade and impaired insulin-driven hepatic neoglucogenesis switch to glycolysis, as well as a defective insulin-driven shutdown of gluconeogenesis resulting in higher endogenous glucose production. Also alterations of the forkhead box O1 phosphorylation and nuclear exclusion by HCV proteins is implicated in T2DM development[83].

There is some evidence to suggest that HCV infected individuals are at risk of developing Type 1 diabetes mellitus through autoimmunity with some studies pointing towards pancreatic autoimmunity developing after Interferon treatment[84]. Many epidemiologic studies have found an association between T2DM and HCV infection possibly due to an interplay of multiple factors including direct viral effects, cytokine milieu, IR *etc*.[85] T2DM can accelerate the natural course of HCV-induced liver disease causing higher risk of fibrosis, cirrhosis, and hepatocellular carcinoma[86]. In patients with CHC infection and T2DM, significant improvement was noted in their diabetes status after HCV eradication with treatment[87-90]. The patients who did not achieve sustained virological response had a higher risk of T2DM[91-96]. Figure 3 illustrates the deleterious effects of HCV on glucose and lipid metabolism.

HEPATITIS C VIRUS AND INSULIN RESISTANCE: CENTRAL AND PERIPHERAL PATHWAYS

HCV proteins that are mainly involved in IR include core proteins, Serine protease and nonstructural viral proteins NS5A and NS5B that contribute to the formation of capsid, down-regulation of interferon-stimulated genes and polymerase activity. HCV induces IR both through multiple pathways and appears to depend on viral load and specifically genotypes G 1, 2 and 4[97].

In the direct mechanism, HCV proteins interact with various components of the insulin signaling pathway disrupting the signaling process of insulin in the hepatocytes. This leads to overexpression of protein phosphatase 2A and SOCS-3, and down regulates the expression of PPAR and IRS causing IR directly. HCV infection enhances hepatic gluconeogenesis through forkhead box O1-dependent pathway and

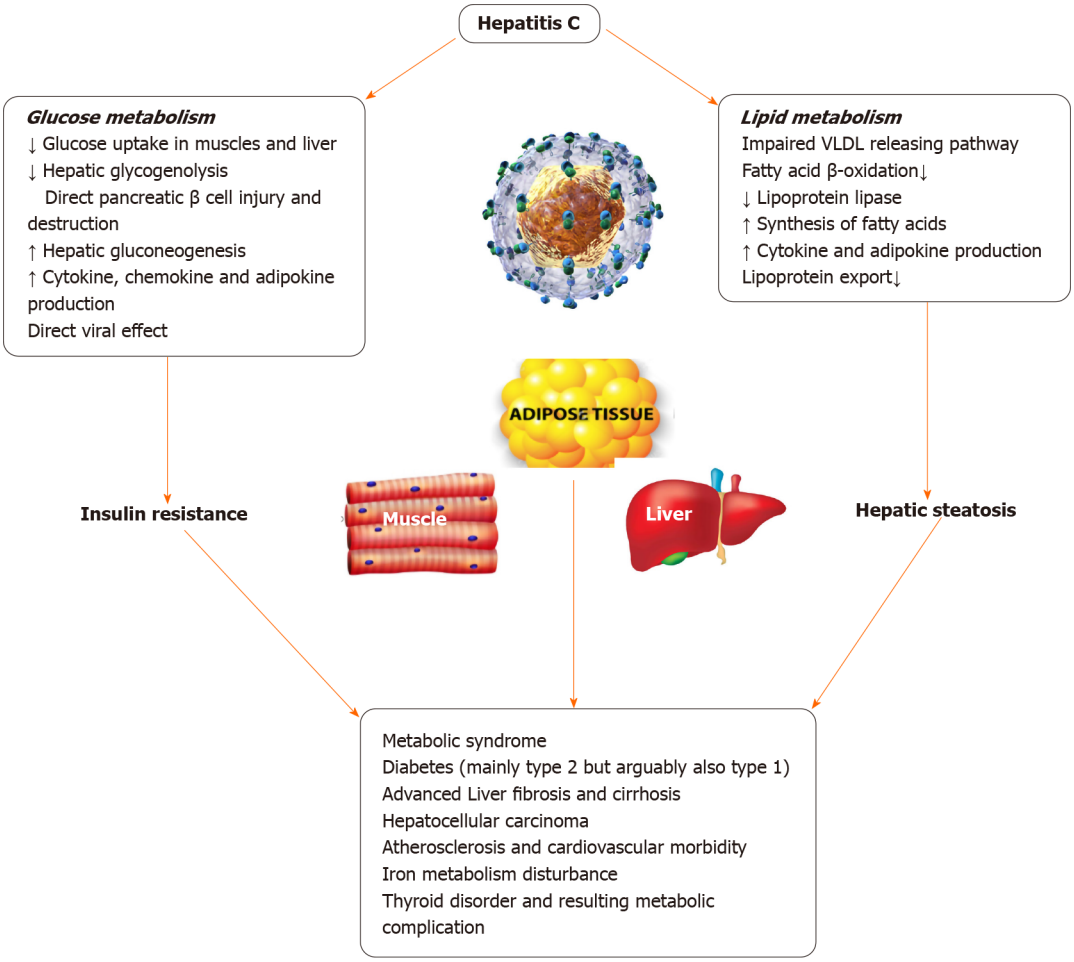

Figure 3 Impact of hepatitis C virus on glucose and lipid metabolism.

suppresses the cell surface expression of glucose transporter 2, resulting in reduced glucose uptake with the help of HCV NS5A protein that plays important roles in these two independent pathways. Any disruption in insulin signaling results in various pathophysiological changes, including glucose intolerance, obesity, dyslipidemia, hypertension, and development of T2DM[98-100]. The mechanism of insulin impairment appears HCV genotype specific, as core protein expression of G3 led to upregulation of SOCS-7 and downregulation of PPARγ, while the core protein from G1 activated mammalian target of rapamycin and induced phosphorylation of IRS-1 at inhibitory serine residues[101]. However, activation of SOCS family appeared to be common mechanism for all major genotypes to induce IR, including genotype 1 as the mammalian target of rapamycin activating variant appeared to be infrequent among known isolates[102-107].

Peripheral IR is the deficits in insulin induced glucose uptake into target tissues (adipose and muscle tissues). IR in CHC infection is thought to primarily affect muscle tissue making it a notable paradigm of IR. Mangia *et al*[106] showed that peripheral insulin resistance and resulting T2DM does not develop for at least first 5 years of infection with HCV suggesting the role of chronic infection in the development of IR rather than acute infection[107]. The pathways of lipid metabolism derangements and IR induced by HCV proteins and host cells opens up potential future treatment options scope for more studies[107,108].

The main PPAR nuclear receptors expressed in the liver that regulates glucose and lipid metabolism, influence cellular differentiation and proliferation as well as regulate the inflammatory process, include PPARα and PPARγ alongside retinoid X receptor. PPARα gene expression in the liver is decreased by 86% in the course of CHC infection[109]. Studies demonstrated a sharp decrease in the hepatic PPARγ expression in G3 CHC patients compared to those with G1 HCV[109-114].

The major pathways by which CHC infection induce insulin resistance are shown in the Table 1.

Table 1 The role of major hepatitis C virus proteins in insulin resistance development

HCV core protein	Nonstructural protein 3 (NS3)	Nonstructural protein 5 (NS5)
Activates members of SOCS family; Genotype 1: Activates mTOR and induces phosphorylation of IRS-1; Genotype 3: Upregulates SOCS-7 and downregulates PPARγ	NOX2 activation	Increasing the ROS within the mitochondria
↓ PPARα gene expression in the liver	↑ ROS	Induces ER stress → ↑ protein phosphatase 2A (PP2A)
↓ Assembly of VLDL	Through ROS → Activation of transcriptional factors such as NF-κB and STAT-3 → more advanced stages of chronic hepatitis → oncogenesis	Dephosphorylation and inactivation of Akt
Induces lipogenesis and gluconeogenesis		Stimulates the NF-κB-mediated increase in proinflammatory cytokines
↓ IFN-α production; ↓ IFN-α stimulated genes		Up-regulation of PP2Ac → hypomethylation of STAT-1 → ↑ association of STAT-1 with PIAS1PIAS1 → impairing the transcriptional activation of IFN-stimulated genes
Activation of the pattern-recognition receptor TLR2 → ↑ production of profibrotic factors. *i.e.* TGF-β, procollagen 1, and MMPs		Stimulates the NF-κB → increase in proinflammatory cytokines (*i.e.* IL-6, TNF-α)
Activates the PA28γ → ↓ IRS-1 tyrosine phosphorylation and IRS-2 expression and TNF-α promoter activation		Dephosphorylation of PKB/Akt → inhibition of insulin signaling
Induces TNF α → portal or periportal inflammation		
Impedes insulin-mediated FoxO1 translocation affecting glucose metabolism		

Akt: Protein kinase B; PKB: Protein kinase B; ER: Endoplasmic reticulum; FoxO1: Forkhead box protein O1; IFN-α: Interferon alpha; IL-6: Interleukin-6; IRS-1: Insulin receptor substrate 1; IRS-2: Insulin receptor substrate 2; MMPs: Matrix metalloproteinases; mTOR: Mammalian target of rapamycin; NF-κB: Nuclear factor kappa light chain; NOX2: NADPH oxidase 2; NS3: Serine protease; NS5: Nonstructural viral proteins NS5A and NS5B; PA28γ: Proteasomal activator; PIAS1: Protein inhibitor of activated STAT 1; PP2Ac: Catalytic subunit of protein phosphatase 2A; ROS: Reactive oxygen species; SOCS: Suppressors of cytokine signaling; SOCS-7: Suppressor Of cytokine signaling 7; STAT-1: Signal transducer and activator of transcription 1; TGF-β: Transforming growth factor beta; TNF-α: Tumor necrosis factor a; TLR2: Toll-like receptor 2; VLDL: Very low density lipoprotein.

HEPATITIS C VIRUS AND METABOLIC SYNDROME

According to the Joint Scientific Statement in 2009, patients who exhibit three of the five following characteristics are diagnosed with the metabolic syndrome (MetS): (1) Abnormal waist circumference as population and country-specific definitions; (2) Systolic blood pressure ≥ 130 mmHg or diastolic blood pressure ≥ 85 mmHg or currently taking blood pressure-lowering agents; (3) High-density lipoprotein of cholesterol < 40 mg/dL in males or < 50 mg/dL in females; (4) Fasting blood sugar ≥ 100 mg/dL or currently taking diabetes medications; and (5) Triglyceride ≥ 150 mg/dL[115,116]. Both CHC infection and the MetS have common basic pathogenesis which is glucose metabolic derangement and IR resulting in close association and overlapping manifestations[117]. Amongst HCV infected patients, particularly older subjects, the prevalence of MetS ranges from 13.2% to 31.5%[118]. The prevalence increases in patients with CHC, older than 60 years of age, having an odds ratio of eight times of developing MetS than those under 40 years of age. A study by Lonardo *et al*[118] exploring the association between HCV genotypes and MetS prevalence found no significant difference compared to controls[119]. This could be due to the small sample size and patient selection criteria.

More studies show that African Americans infected with HCV are more prone to develop MetS than other ethnic groups[120,121]. An aggressive and severe liver disease is common in CHC patients with MetS. Liver fibrosis is notably more advanced in CHC patients with MetS than those without[122]. The prevalence of liver cirrhosis in CHC-MetS patients was 30% compared to 18.4% in CHC patients without MetS[123,124]. As MetS may worsen the progression of liver diseases in HCV infected patients, further research is needed to assess the impact of viral clearance and sustained virologic response on MetS.

IMPACT OF METABOLIC DISEASE ON CHRONIC HEPATITIS C DISEASE PROGRESSION

It is crucial to understand the impact of underlying metabolic diseases on the natural history of CHC infection as much as to understand the risk of developing metabolic complications from CHC. Given the rising prevalence of obesity and metabolic syndrome observed in the United States and globally, recognition of the impact of obesity and IR in disease progression among patients with CHC is particularly important[125].

In a recent systemic review by Dyal *et al*[124] 20 cohort studies were identified to evaluate the impact of metabolic diseases on disease progression among patients with CHC[125]. The authors evaluated the effect of obesity, diabetes, and steatosis as risk factors for developing advanced fibrosis in patients with chronic HCV infection and demonstrated that the presence of concurrent diabetes among patients with CHC infection was associated with a significantly higher risk of developing advanced fibrosis, with effect measures ranging from odds ratios of 2.25 to 9.24. Hepatic steatosis was also strongly associated with an increased risk of developing advanced fibrosis, with odds ratios of 1.80 to 14.3[126]. However, further studies are needed to assess the association between obesity and advanced fibrosis in CHC patients.

Available evidence aimed to better clarify the impact of concurrent metabolic diseases on disease progression and the natural history of chronic HCV infection; however, several limitations while interpreting the results must be acknowledged. The standard method for exploring the effects of metabolic diseases on disease progression would be to recognize patients with pre-existing metabolic diseases who eventually acquired HCV infection. However, a number of these studies were observational in nature and either utilized a case-control or retrospective cohort study design, which inherently limit the true ability to understand causal links. Significant advancements in HCV therapy were introduced subsequent to these studies which may influence the metabolic milieu and disease progression differently and we need more evidence before we extrapolate the current data to the presently available regimens.

The presence of metabolic diseases may influence the sequela of HCV infection. Patients with diabetes, hepatic steatosis, NASH, and insulin resistance were at more risk of developing CHC compared to patients without underlying metabolic disorders[127,128]. These patients were also found to have a faster progression to liver fibrosis through the same mediators that are inducing inflammation. A study by Paradis *et al*[129] investigated the risk of developing HCC in patients with underlying metabolic syndrome disorders and found there is a profound role of MetS in HCC development and progression. This can be further aggravated by the presence of HCV. The presence of NASH is a major contributor to liver cirrhosis in the presence/absence of HCV[130,131]. These findings elucidate the strong association between MetS disorders, HCV and their complex involvement in liver disease progression. This evidence contributes to a shift in HCC etiology which signifies further research.

MANAGEMENT OF METABOLIC COMPLICATIONS IN CHRONIC HEPATITIS C

Advances in treatment options with highly effective DAAs therapy for CHC aimed for eradication of HCV will not only improve HCV-related liver disease but will most likely impact the incidence and prevalence of HCV-related metabolic diseases, given the strong association between the two conditions. The efficacy of current regimens for CHC has improved the sustained virologic response reaching almost > 95%-100%. It is important to know whether the patient is treatment naïve or experienced, the genotype, the fibrosis level, and underlying comorbidities for personalized medicine and best tailored treatment options.

Concurrent management of coexistent metabolic disorders is also important for optimal control of CHC related liver injury and complications such as HCC as mentioned earlier. However, a detailed discussion of management of these conditions is beyond the scope of this review.

CONCLUSION

Hepatitis C infection has emerged as a systemic infection with impacts beyond the primary site of infection, causing a wide range of clinical manifestations in patients. It is crucial to understand the systemic effects of CHC along with its hepatic complications as it relates to metabolic manifestations and complications. HCV virion exploits the multiple functions of lipid droplets to sustain its multiplication and replication within host cells. The orchestration between HCV major proteins and the liver-muscle-adipose axis, poses a major burden on all the health systems of human body if not adequately addressed. The close and inseparable associations between chronic HCV infection, metabolic disease, and cardiovascular disorders are specifically important considering the increasing prevalence of obesity and metabolic syndrome and their economic burden to patients, the healthcare systems, and society. Cellular and molecular mechanisms governing the interplay of these three organs in health and disease are therefore of significant interest. As indicated by the extent of the metabolic comorbidities discussed, HCV increases the disruption in the liver–muscle–adipose triangle resulting in myriad clinical outcomes in patients. Further studies are needed to assess the association between metabolic derangement and patient quality of life. Physicians are encouraged to pay close attention to the metabolic parameters in HCV patients especially cirrhotics and patients listed for liver transplant.

Abstract

Pancreatic ductal adenocarcinoma (PDAC) is a worldwide public health concern. Despite extensive research efforts toward improving diagnosis and treatment, the 5-year survival rate at best is approximately 15%. This dismal figure can be attributed to a variety of factors including lack of adequate screening methods, late symptom onset, and treatment resistance. Pancreatic ductal adenocarcinoma remains a grim diagnosis with a high mortality rate and a significant psychological burden for patients and their families. In recent years artificial intelligence (AI) has permeated the medical field at an accelerated pace, bringing potential new tools that carry the promise of improving diagnosis and treatment of a variety of diseases. In this review we will summarize the landscape of AI in diagnosis and treatment of PDAC.

Key Words: Pancreatic adenocarcinoma; Artificial intelligence; Neural network; Future perspectives; Early diagnosis; Improved performance

INTRODUCTION

Current modalities for the diagnosis and treatment of pancreatic ductal adenocarcinoma (PDAC) remain disappointing. With an overall survival rate of 3%-15%, it is one of the deadliest malignancies in the world[1]. Although currently it is the 7th leading cause of cancer death worldwide, recent trends suggest that in North America and Europe PDAC will soon become 2nd and 3rd respectively[2,3]. Several factors contribute to the poor survival statistics of PDAC: Lack of adequate screening tests, delayed diagnosis, and sub-optimal treatment options. Consequently, improvements in all these areas are desperately needed.

Recent technological advances have led to the increased application of artificial intelligence (AI) in different disciplines. Because computers can store and analyze larger amounts of data than the human brain, AI has the potential to achieve unmet needs in medicine. Since improving outcomes for PDAC is an area of urgent need, this review will provide a summary of current and future applications of AI in the diagnosis and management of PDAC.

AI, MACHINE LEARNING, AND ARTIFICAL NEURAL NETWORKS

AI is a branch of computer science dedicated to developing models aimed at performing functions comparable to those accomplished by the human brain. Machine learning (ML) is the area of AI that deals with developing computer models capable of learning specific tasks through the repetition of calculations derived from large amounts of data[4]. These computer models analyze data through repetitive calculations using mathematical self-derived algorithms that are constantly adjusted until the model produces the desired outcome. Once the combination of adjustments necessary to achieve the outcome has been discovered, the computer then "learns" how to perform that specific task[5].

Broadly speaking, ML can be either supervised or unsupervised. The difference lies in whether the desired outcome of interest is previously known by the computer. In supervised learning, a computer is first introduced to a training dataset (the "input") as well as the desired outcome of interest (the "output"). The computer then analyzes the input making the necessary adjustments to the algorithm until it consistently produces the desired output[6]. This type of learning requires large amounts of training data that has been pre-labeled ("curated") by a human operator. Once the training of the machine is completed, a different dataset is used to test its performance (testing data). In unsupervised learning, the computer is introduced to unlabeled data. The machine then sorts it using the algorithm to identify features within it that can be grouped and analyzed further to reach a specific outcome[7]. Because the data in unsupervised ML is not curated, larger amounts of training data are required than for supervised ML.

To date, most of the ML used in medicine has been supervised; and it has been made possible due to the emergence of a relatively new discipline called radiomics. Radiomics studies the conversion of digital medical images into data that can be then subjected to statistical analysis[8]. Using computer technology, predefined quantitative features are extracted from computed tomography (CT), magnetic resonance Imaging (MRI) or other imaging modalities. An essential step prior to this data extraction however, is lesion "segmentation". Segmentation is in simple terms, delineation of the lesion within an image. In supervised ML a human operator delineates the lesion prior to the algorithm operating on the data. In unsupervised ML, the algorithm learns how to segment the lesion of interest by itself.

Once the quantitative information of the lesion in the image is extracted, it is

analyzed utilizing artificial neural networks (ANN). An ANN is a group of interconnected computers with a structure similar to a neural network in the human brain. Each computer represents a neuron or "node", and each connection a synapse or "weight" (Figure 1). ANNs are organized in "layers" (groups of nodes) and the most basic model contains three: (1) Input layer (which receives the data), (2) Hidden layer (which performs the calculations and analyses), and (3) Output layer (which produces the final output)[9]. Deep neural networks contain more than one hidden layer and therefore can learn to analyze data with higher complexity levels; this is termed "deep learning"[10]. The different layers work in a hierarchical structure to produce the desired output.

AI-ASSISTED ANALYSIS OF ENDOSCOPIC ULTRASOUND IMAGES

Endoscopic ultrasound (EUS) is currently one of the most useful imaging modalities in the diagnosis of PDAC. The overall sensitivity of EUS guided biopsies for the diagnosis of PDAC reaches 98%, but its specificity can be as low as 20%[11]. The accuracy of EUS depends on both operator and lesion-related factors. The most important operator-related factor is the amount of experience performing EUS. On occasions, variations in gastroduodenal anatomy, (*i.e.* after partial gastric resection, or presence of a duodenal stricture) can significantly limit the ability of operator to visualize the pancreas. On the other hand, lesion-related factors include patient's body habitus, the presence of acute inflammation (when EUS is done immediately after an episode of acute pancreatitis) or the presence of chronic pancreatitis (CP), particularly in the presence of parenchymal calcifications. Sensitivity of EUS for PDAC in the presence of CP can be as low as 54%[12,13]. In addition, CP and autoimmune pancreatitis can occasionally form pseudotumors, which may complicate image analysis by the endosonographer.

Several studies have reported on the application of AI in the analysis of EUS images of pancreatic diseases[14-22] (Table 1). For the most part, these studies have focused on evaluating the accuracy of ANNs in differentiating CP from PDAC. Norton *et al*[14] analyzed still EUS images previously selected by experts who did not perform the procedure and were blinded to the final diagnosis using an ANN. A total of 21 patients with PDAC and 14 with CP were included. Four features were analyzed in each image by the ANN, achieving an overall accuracy of 89%.

In a similar study, Das *et al*[17] retrospectively analyzed the performance of an ANN in differentiating PDAC from normal pancreas and CP. A total of 56 patients (22 normal, 12 CP and 22 PDAC) were studied. Their AI algorithm identified PDAC with an area under the curve of 0.93. The differences in accuracy in this study may have been secondary to the more stringent criteria in the definition of CP and the higher number of image features analyzed by the ANN. A larger study performed by Zhu *et al*[18], analyzed 262 patients with PDAC and 126 with CP and reported that their algorithm reached an overall accuracy of 94%.

Elastography is an imaging method developed to establish the differences in consistency ("strain") between normal and abnormal tissue during EUS. Such differences are portrayed in a color-coded overlay on the EUS image, with red correlated with softer tissue and blue with harder[19]. A multicenter study reported an overall accuracy, sensitivity and specificity of 84%, 88% and 83% respectively in differentiating PDAC from CP[20]. This study used ANN analysis of histograms from elastography images previously selected by experts blinded to the patients' diagnoses. Another similar small study of 68 patients reported an accuracy rate of 90%[21].

Contrast agents have also been developed to aid in the differentiation between PDAC and CP. Săftoiu *et al*[22] reported that ANN analysis of contrast-enhanced EUS images could establish a difference with an area under the curve of 94%. Few studies have focused on using standard EUS B mode images to diagnose pancreatic tumors in the absence of CP. These have reported accuracies up to 99%[15,16].

AI-ASSISTED ANALYSIS OF COMPUTERIZED TOMOGRAPHY IMAGES

Computerized tomography (CT) is perhaps the most common medical imaging modality being explored with AI. The analysis of CT images of neoplastic lesions involves three main steps: detection, characterization and monitoring of change over time[23]. Most of the available studies have focused on AI-assisted characterization of lesions, which is equivalent to the previously defined concept of segmentation. Three

Chu *et al*[29], 2019	Retrospective	CT	ANN	456	Segmentation of PDAC *vs* Nl	94%
Devi *et al*[32], 2019	Retrospective	MRI	ANN	168	Nl *vs* Abnormal pancreas	96%
Gao *et al*[33], 2020	Retrospective	MRI	ANN	504	Identify pancreatic disease	77%
Liang *et al*[34], 2020	Retrospective	MRI	ANN	27	Segmentation of panc tumors	Not explicitly stated
Muhammad *et al*[42], 2019	Retrospective	Clinical variables	ANN	800114	PDAC prediction	85%
Klein *et al*[43], 2013	Retrospective	Clinical variables	Computer derived model	7003	PDAC risk	61%
Hsieh *et al*[45], 2018	Retrospective	Clinical variables	ANN	> 1 million	NOD predicting PDAC	72%
Zhao *et al*[46], 2011	Retrospective	Clinival variables + Pubmed data	Bayesian network inference	N/A	PDAC prediction	85%
Sanoob *et al*[47], 2016	Retrospective	Clinical variables	ANN	120	PDAC detection	Not explicitly stated
Momeni-Boroujeni *et al*[56], 2017	Retrospective	FNA samples	ANN	75	PDAC diagnosis	77%
Bhasin *et al*[58], 2016	Retrospective	PDAC genes	Computer vector model	5[2]	PDAC detection	92%
Almeida *et al*[59], 2020	Retrospective	PDAC genes	ANN	40[2]	PDAC detection	86%

[1]Sensitivity.

[2]Genes. AI: Artificial intelligence; ANN: Artificial Neural Network; CT: Computerized tomography; EUS: Endoscopic ultrasound; MRI: Magnetic resonance imaging; FNA: Fine needle aspiration; PDAC: Pancreatic ductal adenocarcinoma; CP: Chronic pancreatitis; NOD: New onset diabetes.

studies have applied AI to the analysis of CT images in PDAC for diagnostic purposes[24-26]. In a small study of 15 healthy patients and 44 with a variety of pancreatic tumors, Fu *et al*[24] reported that their algorithm achieved an overall sensitivity of 76%. In a retrospective case control study of 380 patients (190 cases and 190 controls) Chu *et al*[25] reported an accuracy of 99% in their computer-derived algorithm. Meanwhile, a prospective study by Liu *et al*[26] reported an accuracy of 76%. AI has also been utilized to establish correlations between the CT images of PDAC and their subsequent biological behaviors[27,28].

Two important ongoing projects are worth mentioning. The Felix Project funded by the Lustgarten Foundation is a multidisciplinary study carried out by a group at Johns Hopkins University. Using deep learning computer models with manually segmented images from 156 PDAC cases and 300 normal controls, the group reported a sensitivity

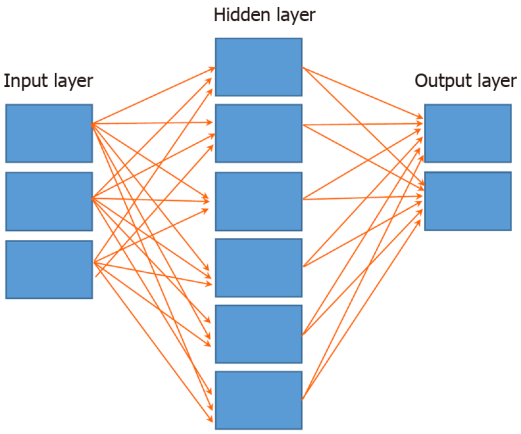

Figure 1 Basic anatomy of an artificial neural network. Input layer, hidden layer (may have more than one) and output layer. All nodes are interconnected through wieghts (arrows).

and specificity of 94% and 99% respectively in their initial report[29]. Based on these encouraging results, the group's next step is to expand their analysis to 575 normal and 750 PDAC patients. The group's ultimate goal is to fine tune the performance of their algorithm prior to expanding it to larger externally derived datasets.

The second ongoing study is being conducted by the Alliance of Pancreatic Cancer Consortium Imaging Working Group (2). Their objective is to collect pre- and post-diagnosis CT, magnetic resonance imaging (MRI) and transabdominal ultrasound images from patients ultimately diagnosed with PDAC. These images will be used to create a repository that will later be shared and analyzed. The ultimate goal of the project is to develop AI models that can predict the appearance of PDAC and diagnose the disease in its early stages.

AI-ASSISTED ANALYSIS OF MAGNETIC RESONANCE IMAGES

Segmentation of MRI images by AI has been reported to be more technically challenging than CT images[30,31]. A few studies have reported that ML models can be trained to accurately identify pathology in the pancreas, although the literature on PDAC is scarce. Devi *et al*[32] reported that an ANN could accurately identify a variety of abnormal pancreatic findings with a 96% accuracy. Similarly, Gao *et al*[33] reported that an AI model differentiated normal from abnormal pancreas at a level comparable to humans (77% *vs* 82% respectively). In the only published study aimed specifically at identifying PDAC in MR images, Liang *et al*[34] reported that a convoluted neural network (a variety of ANN) performed similarly to humans in identifying the lesion.

Artificial Intelligence processing of MRI images has been also applied in the context of PDAC therapy. Spieler *et al*[35] reported that an ANN accurately delineated pancreatic tumors prior to radiotherapy. Zhao *et al*[36] reported similarly positive results. In a study utilizing AI aiming to automatically calculate the dose of stereotactic body radiation therapy, Campbell *et al*[37] demonstrated that an ANN-calculated dose was comparable to a human-calculated one. By applying radiomics to MRI images, investigators have reported that their quantitative data can be correlated with aspects such as tumor subtype, survival and response to chemotherapy[38,39]. This same technology has made possible other studies showing that MR images data can be used to predict relapse after PDAC treatment[40,41].

AI ANALYSIS OF CLINICAL DATABASES

The evolution of AI has resulted in models with the capacity of analyzing data beyond quantitative image features. This type of ML requires a higher complexity in the architecture of the neural networks given the broad range of variables analyzed at any given point in time. These models have been applied in the development of algorithms that can accurately identify patients with or at risk of developing PDAC based on several clinical variables.

Muhammad *et al*[42] utilized an ANN to analyze a large patient population derived from the National Health Interview Survey and the Prostate, Lung, Colorectal and Ovarian trial. The authors developed and trained the ANN with > 800000 patients of which 898 had PDAC. Analyzing variables such as demographics, comorbidities, race and family history, the model predicted the development of PDAC with an AUC of 0.85. In a similar manner, albeit with a lower accuracy, Klein *et al*[43] utilized data from the PanScan Consortium to develop a model that predicted high risk of PDAC among patients of European ancestry with an AUC of 0.61.

New onset diabetes has been adopted as a marker for patients with high risk of developing PDAC within the following 3 years[44]. As such, it has been the subject of analysis by AI techniques. Hsieh *et al*[45] compared the PDAC prediction accuracy of new onset diabetes when analyzed by a regular logistic regression or an ANN. A total of 3092 PDAC cases were identified from a population of > 1000000 patients. Interestingly, the logistic regression slightly outperformed the ANN (AUROC 0.7 and 0.64% respectively). In a complex study combining PubMed data and clinical information, Zhao *et al*[46] utilized an innovative weighted Bayesian network that accurately predicted PDAC with an AUROC of 0.91. In a similar but simpler study, Sanoob *et al*[47] reported that an ANN can accurately diagnose PDAC based on a combination of signs and symptoms[47]. ANNs that analyze clinical data have also been used in determining patient survival and performance after PDAC treatment[48,49].

AI-ASSISTED ANALYSIS OF PATHOLOGICAL AND MOLECULAR FEATURES OF PDAC

Currently, pathologists are responsible for interpretation of histology specimens, and this process is dependent on their previous training, level of experience and individual skills. In an attempt to standardize interpretation and reduce human bias, AI techniques have been applied to pathology specimen analysis[50].

Application of AI in pathology is dependent on creation of a high-resolution digital image from the glass slide. This step is called "whole slide imaging" (WSI). WSI is accomplished by use of glass slide scanners and the technology to support them[51]. WSI and the necessary IT infrastructure to support its clinical use is referred to as "digital pathology". It is expected that eventually, pathology workflow will move away from pathologists looking at glass slides through a microscope to pathologists reviewing digital images of slides on high resolution computer screens. Food and Drug Administration clearance for these devices is relatively new (2017), and widespread adoption of digital pathology technology is still in its early phases. There is an increasing amount of data on validation of WSI compared to microscope viewing of glass slides, for example a recent study showed good concordance of slide interpretation of frozen sections done with glass slides/microscope compared to WSI/digital pathology workstation[52] Similar excellent intraobserver concordance between glass slides and digital pathology has been shown for routine clinical workload in surgical pathology[53].

There is already significant work and available commercial devices that can bring AI computing power to aid in the interpretation and screening of biopsies, although commercial expansion of this is in its infancy[54]. Much of the work regarding AI in pathology concerns prostate and breast malignancy, since the incidence of these malignancies is fairly high, and the clinical need and potential commercial applications present a more attractive corporate opportunity for device sales. However, with continued digitization of glass slides, particularly of pancreatic malignancy (both FNA specimens and surgical pathology) it is hoped that an enlarging curated group of cases can serve as a training set for AI analysis regarding pancreatic cancer.

There has been only a limited number of investigations of AI in pathology for the diagnosis of pancreatic cancer. Although the sensitivity and specificity of EUS guided FNA samples is in average > 90%[55], some specimens still fall under the "atypical cells" category, posing a considerable diagnostic dilemma. In a recent study, Momeni-Boroujeni *et al*[56] studied the performance of an ANN in reclassifying EUS-FNA specimens originally labeled as "atypical" by pathologists. Among a group of 31 patients in whom the final diagnosis had been previously established by other diagnostic methods, the ANN's overall accuracy for adequately reclassifying the specimen as malignant or benign was 77%.

Two of the main factors driving the high mortality of PDAC are suboptimal understanding of its malignant behavior and its unpredictable treatment response rate.

Advances in AI-assisted genetic and molecular profiling of PDAC have recently broadened insight on these factors[57]. Recent data showed that early diagnosis could be possible through AI analysis of the transcription products of certain PDAC genes. These studies have reported sensitivity and specificity ranging from 88%-95% and 83%-95% respectively[58,59]. AI has also been utilized to match PDAC biological information with chemical properties of specific drugs in order to develop models capable of predicting response to these specific agents[60,61].

FUTURE CONSIDERATIONS

Technological advances in the last 50 years have exponentially increased the amount and quality of data available for medical decision making. Hence, it is becoming increasingly evident that new methods for storage and analysis of it are necessary. Although the concept of AI or its applications in medicine may still seem foreign for most practitioners, it is rapidly positioning itself as an indispensable tool to reduce human error. As sophisticated and elegant our diagnostic and therapeutic capacities may be currently, they remain inevitably limited by our subconscious and conscious bias, as well as our wide range of intellectual and technical skills. William Osler's famous quote: "medicine is a science of uncertainty and an art of probability" will likely never be proven false.However the degree of uncertainty and probability considered tolerable in modern medicine is constantly shrinking. The advent of AI brings, in theory, the promise of reducing and even eliminating these shortcomings

Nevertheless, this promise is one that needs to be taken cautiously. There are several hurdles that must be overcome before AI can see widespread adoption in medical care. One limitation is the current lack of adequate standardization. Uniform protocols for data collection, processing, storage, reproduction and analysis must be established and standardized. Furthermore, different types of data may require different AI technologies. For example, ANNs trained to adequately classify histologic slides of pancreatic biopsies which have been fixed and stained with a specific method, may underperform, or not perform at all, when presented with slides prepared in a different manner. Creating such universal protocols, although possible, will be laborious and expensive.

Another concern is with the ethical handling of information. AI systems require vast amounts of data, and therefore, its implementation demands reliable methods of patient data de-identification. This is indispensable to ensure patient confidentiality, since one of the pillars of AI is data sharing. On the other hand, de-identified data needs to maintain its traceability, in order to allow individual practitioners to retrieve it and make the necessary decisions at the bedside. Three different models have been developed for data sharing in AI, and all have their advantages and disadvantages[2,62-65].

Centralized models require sharing of large amounts of data by different sources (*i.e* institutions). This data is uploaded into a central server that carries out the algorithmic adjustments. Once trained, the central server shares the finalized algorithm with the individual sources for internal use. The main drawback of this model is that centralization of the information in the server may increase the risk of a security breach, as the individual source no longer controls the information (Figure 2). In distributed or federated models, each source develops and adjusts its own algorithm with internal data. Once each source has fine-tuned their algorithm, they share its parameters with a central server. The central server then utilizes all the individual parameters to develop a centralized algorithm that later gets returned to the source for internal use (Figure 3). The main advantage of this model is that data is not shared with the central server. In hybrid models features of both models are present. A data repository is created to be shared by both data providers and the central server. The data repository then develops an algorithm using each individual institution's data before it gets sent to the central server. The central server then updates the master algorithm before it gets sent back to the data repository (Figure 4).

The quality of data currently utilized in AI needs to be improved. Most of the AI systems used in data analysis so far have been trained and tested with rather small datasets originating from within local institutions. This raises the issue of information bias. These datasets lack the degree of diversity necessary to mirror the scenarios human providers face during routine clinical practice. For AI systems to perform adequately, the datasets need to be sufficiently diverse in all the possible variables that come into play when making clinical decisions (demographics, medical and/or family history, physical and laboratory findings and others). Therefore, datasets need to

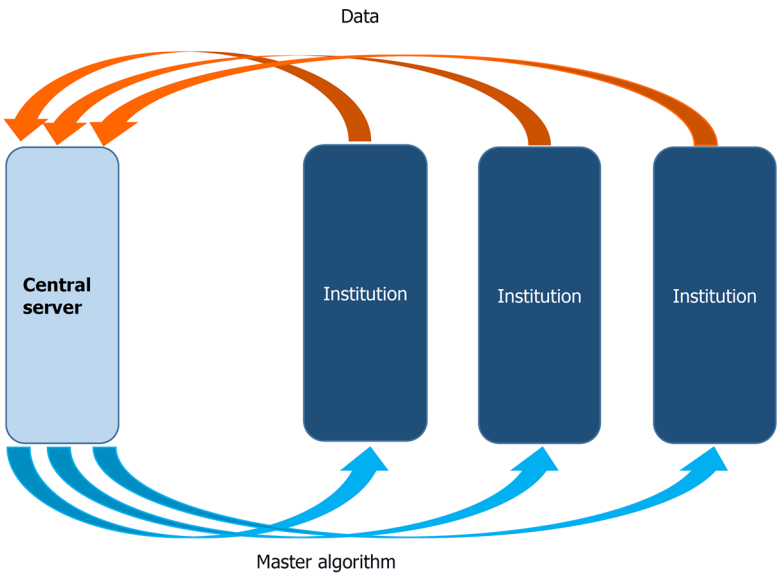

Figure 2 Centralized artificial intelligence information sharing system. Each individual institution provides data to the central server. The server analyzes all the data and develops and algorithm that is sent to each institution. This algorithm is then used by each institution to analyze its own internal data in the future.

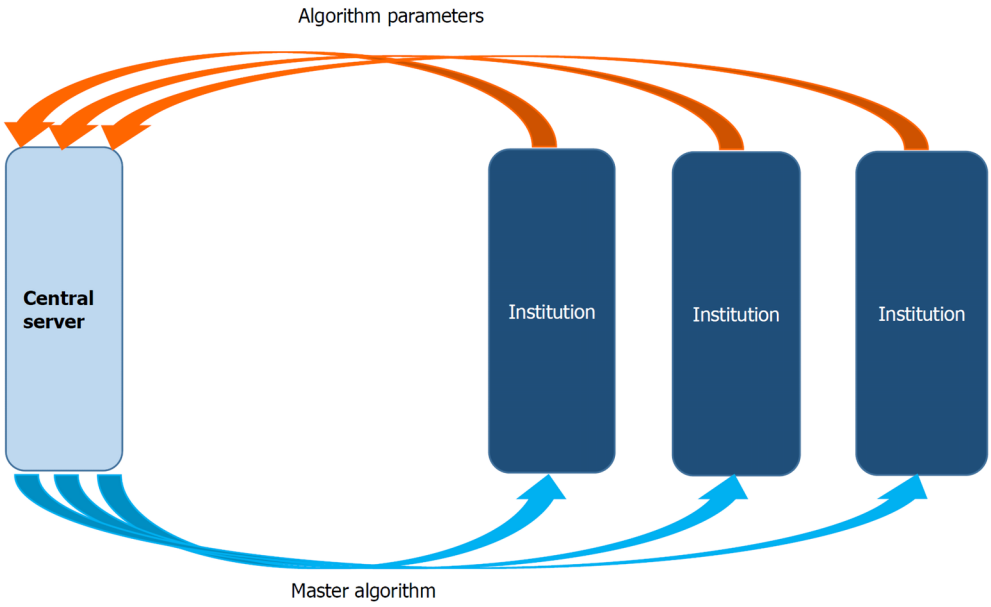

Figure 3 Federated artificial intelligence information sharing system. Each individual institution develops its own algorithm with internal data. Once the algorihms are developed, their parameters are shared with the central server. The server then develops a master algorithm using all the individual parameters. The master algorighm is sent back to the institutions for its internal use.

originate from a variety of sources for them to be representative and inclusive, not from a limited number of large academic medical centers or research institutions.

Another shortcoming is the fact that the average ANN functions as a "black box"[66]. As such, how a specific variable in a dataset is weighted by specific nodes in the network is currently uninterpretable. When evaluating the performance of any ANN, clinicians, mathematicians and computer scientists need to understand the "reasoning" that occurs within the hidden layers. Although questioning of ANNs is possible through mathematical reasoning, it does not reflect clinical decision making. Understanding the way in which ANNs analyze information is paramount for improving their performance and correcting errors that can lead to fatal consequences.

Finally, much of the promise of applying AI in medical image analysis depends on the ability to get actionable results rapidly. The current need for multiple intricate post-processing steps prior to its analysis, indicates that much more work must be

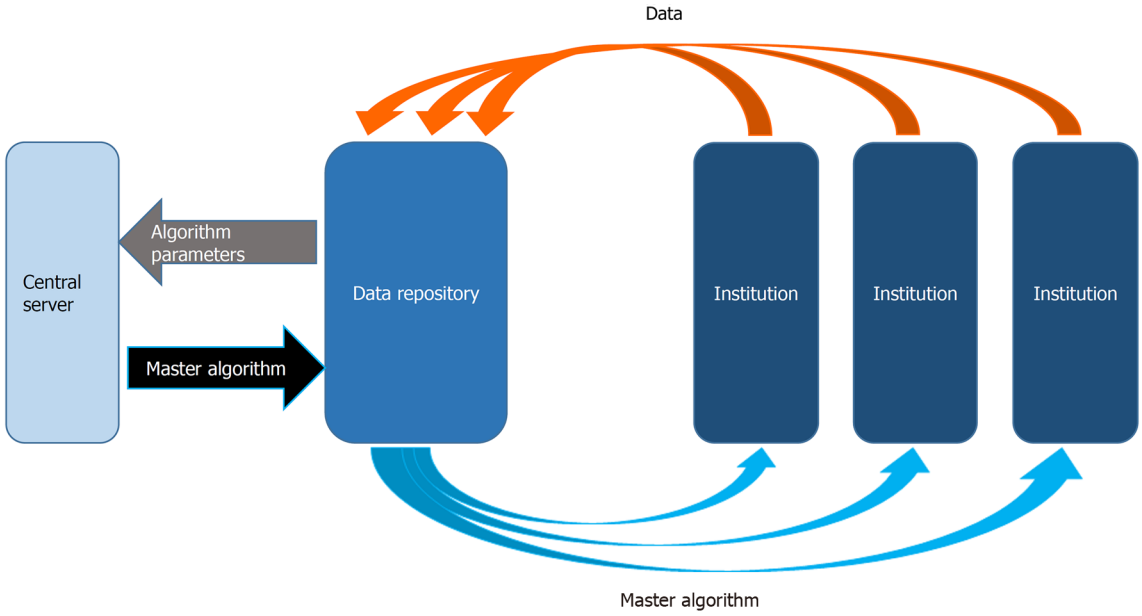

Figure 4 Hybrid artificial intelligence infromation sharing system. A data repository is created as an intermediary between the institutions and the central server. The data repository develops one or more algorithm(s) with the data. The parameters of these algorithms are then shared with the central server to create a master algorithm which is then returned to the repository. New data coming from the institutions is then used by the repository to create new parameters that are then sent to the central server to renew the master algorithm.

done to develop this into a technology that provides "on-the-fly" results[63].

Because of the limitations enumerated above, it is clear that major improvements to the technology need to occur before AI can support everyday activities in clinical practice. It is evident however, that medicine has reached a "point of no return" regarding application of AI. Overcoming these hurdles will require collaboration between academic centers, industry, computer scientists, venture capitalists, regulating organizations and governments (Figure 5). The main goals of this collaboration should be streamlining development of standard data platforms, lowering technology costs and making the technology more "user friendly" so that any provider can use it in real time.

CONCLUSION

With further research, AI could have a large impact on the diagnosis and treatment of PDAC in the future. Novel screening methods are needed, and AI analysis of large comprehensive clinical datasets may yield opportunity for early detection or even predict development of PDAC before a visible lesion can be seen on imaging. An AI protocol which prescreens computed tomography or magnetic resonance imaging prior to a radiologist reading the study could ensure that lesions will not be missed due to human error. "On the fly" AI assistance with endoscopic ultrasound imaging could help the endosonographer optimally target a needle biopsy of a mass. The pathologist can be assisted by an AI algorithm that analyzes the biopsy on the slide that is being read. And AI could prove very useful for following response to treatment and even in suggesting optimal treatment regimens, with personalized treatment strategies based on biological profiling. While AI applications in PDAC are still in the very early stage of development, further investment in research could lead to substantial improvements in screening, early diagnosis, and treatment.

Abstract

The worldwide outbreak of coronavirus disease 2019 (COVID-19) has challenged the priorities of healthcare system in terms of different clinical management and infection transmission, particularly those related to hepatic-disease comorbidities. Epidemiological data evidenced that COVID-19 patients with altered liver function because of hepatitis infection and cholestasis have an adverse prognosis and experience worse health outcomes. COVID-19-associated liver injury is correlated with various liver diseases following a severe acute respiratory syndrome-coronavirus type 2 (SARS-CoV-2) infection that can progress during the treatment of COVID-19 patients with or without pre-existing liver disease. SARS-CoV-2 can induce liver injury in a number of ways including direct cytopathic effect of the virus on cholangiocytes/hepatocytes, immune-mediated damage, hypoxia, and sepsis. Indeed, immediate cytopathogenic effects of SARS-CoV-2 *via* its potential target, the angiotensin-converting enzyme-2 receptor, which is highly expressed in hepatocytes and cholangiocytes, renders the liver as an extra-respiratory organ with increased susceptibility to pathological outcomes. But, underlying COVID-19-linked liver disease pathogenesis with abnormal liver function tests (LFTs) is incompletely understood. Hence, we collated COVID-19-associated liver injuries with increased LFTs at the nexus of pre-existing liver diseases and COVID-19, and defining a plausible pathophysiological triad of COVID-19, hepatocellular damage, and liver disease. This review summarizes recent findings of the exacerbating role of COVID-19 in pre-existing liver disease and vice versa as well as international guidelines of clinical care, management, and treatment recommendations for COVID-19 patients with liver disease.

Core Tip: The clinical menace of coronavirus disease 2019 (COVID-19)-related comorbidities of hepatic diseases and severe acute respiratory syndrome-coronavirus type 2 (SARS-CoV-2) tropism for the liver result in liver impairment with increased liver injury markers and cytokine storm. SARS-CoV-2 aggravates liver injury *via* coagulative and fibrinolytic pathways, cytokine-mediated liver injury, ischemia-hypoxia, and immune-mediated cell death pathways owing to adverse outcomes of liver disease such as nonalcoholic steatohepatitis, drug-induced liver injury, nonalcoholic fatty liver disease, metabolic associated fatty liver disease, and hepatocellular carcinoma. This review summarizes diagnostic approaches, therapeutics, clinical guidelines, and vaccines for COVID-19 and liver disease comorbidities.

INTRODUCTION

Coronavirus belongs to family *Coronaviridae*, subfamily *Orthocoronavirinae*, and order Nidovirales[1]. All over the world, coronaviruses are responsible for causing enteric, neurologic, and hepatic diseases in humans, animals, and other mammals[2]. On the basis of genome and phylogenetic analysis, the subfamily contains four genera named *Alphacoronavirus*, *Betacoronavirus*, *Gammacoronavirus*, and *Deltacoronavirus*[3]. Coronaviruses caused epidemics of severe acute respiratory syndrome coronavirus (SARS-CoV) in 2003 and Middle East respiratory syndrome coronavirus (MERS-CoV) in 2012[2]. The novel coronavirus 2019 (SARS-CoV-2)- belongs to genus *Betacoronavirus*. It is an enveloped virus with a positive-sense, single-stranded RNA genome. SARS-CoV-2 has affected more than 65.8 million people with 1.5 million deaths globally.

In early December 2019, the first documented pneumonia case of unknown origin in Wuhan city of China was confirmed by high-throughput sequencing analysis as a novel *Betacoronavirus* that is currently named SARS-CoV-2. A sudden worldwide outbreak of this virus was declared as health emergency and pandemic of international concern by the World Health Organization (WHO)[4]. In previous epidemics of SARS-CoV and MERS-CoV, bats were considered as the natural host and potential reservoir. Different studies evidenced bats as a reservoir of SARS-CoV-2, however, pangolin species were also considered as natural reservoir of SARS-CoV-2[5].

In the SARS pandemic, the virus was found in patient's stool sample[6], which indicates that fecal samples could be a possible source of transmission of SARS-CoV-2[7]. After clinical recovery, prolonged shedding of SARS-CoV-2 in feces highlighted the possibility of fecal-oral transmission[8]. Positive semen samples containing SARS-CoV-2 have also been observed in two patients who were in recovery and in four who were in the acute stage of infection[9]. Recently, an ocular route of transmission has also been identified in SARS-CoV-2[10].

Symptoms of coronavirus disease 2019 (COVID-19) vary from mild respiratory symptoms to acute respiratory distress syndrome along with multiple organ failure[11] and death, mainly in elderly patients having several comorbidities. The WHO provided timely, effective, and safe supportive management guidelines for COVID-19 patients, which revealed that clinical syndromes associated with SARS-CoV-2 include uncomplicated illness, mild-to-severe pneumonia, acute respiratory distress syndrome, sepsis, and septic shock[12]. However, gastrointestinal symptoms[13] and several extra-pulmonary signs such as liver injury have also been associated with COVID-19[14].

In COVID-19 patients, markers of liver injury may be abnormal[15]. As shown in Table 1, disturbed alanine transaminase (ALT), aspartate transaminase (AST) levels and increased bilirubin have been seen in 14%-53% of COVID-19 patients[16]. A recent study of 1100 patients reported that 18% patients with nonsevere and 56% with severe COVID-19 had elevated serum AST levels. Increased ALT levels were observed in 20% of patients with nonsevere and 28% with severe COVID-19 infection[17]. Moreover, it has been noted that COVID-19 patients with gastrointestinal symptoms showed a high

Table 1 Prevalence of coronavirus disease 2019 patients with altered manifestations of hepatic injury markers

Salient findings	Country	Ref.
Of 417 COVID-19 patients, 76.3% had altered values of liver function tests and 21.5% had liver injury during hospitalization. The use of lopinavir/ritonavir increased the risks of liver injury by 4-fold.	China	Cai *et al*[32], 2020
The prevalence of patients with GI symptoms and elevated level of liver enzymes was 18.6%. The severity of disease increased in patients with digestive symptoms.	China	Pan *et al*[81], 2020
Abnormal liver function tests are common in COVID-19 patients. Of 115 patients, 9.57% had increased ALT levels and 14.78% had increased AST levels.	China	Zhang *et al*[82], 2020
Liver dysfunction at an early stage increases the mortality risk in COVID-19 patients. A total of 151 patients (42.5%) were reported with cholestasis and 101 (28.5%) had hepatocellular injury. Liver dysfunction was more common in critically ill patients.	China	Fu *et al*[83], 2020
About 48.4% of patients with normal liver function had abnormal liver function tests after receiving lopinavir/ritonavir. Liver injury biomarkers (LDH, ALP, GGT, TBiL, prealbumin, and albumin) were dysregulated in a cohort of 288 COVID-19 patients, suggestive of potential as markers of liver injury and a prognosis of severe of COVID-19 disease.	China	Fan *et al*[37], 2020 and Fan *et al*[84], 2020
The presence of acute liver injury was linked with high risk of COVID-19 morbidities and admission to an ICU.	United States	Hajifathalian *et al*[85], 2020
Serum liver enzymes were increased in from 14% to 53% of hospitalized COVID-19 patients.	United States	Fix *et al*[68], 2020
Increased bilirubin level was seen in 16.7% and increased ALT and AST were seen in 15% of COVID-19 patients.	United States	Sultan *et al*[86], 2020

ALP: Alkaline phosphatase; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; COVID-19: Coronavirus disease 2019; GGT: Gamma-glutamyl transferase; GI: Gastrointestinal; ICU: Intensive care unit. LDH: Lactate dehydrogenase; TBiL: Total bilirubin.

prevalence of liver injury compared with patients with no gastrointestinal symptoms. Correspondingly, the prevalence of chronic liver disease (CLD) was high in patients with gastrointestinal symptoms of COVID-19[18].

Liver cancer is the fourth most common cause of cancer-associated death worldwide[19]. The most common type is hepatocellular carcinoma (HCC), and patients with HCC have underlying CLD, which includes alcoholic liver injury, nonalcoholic fatty liver disease (NAFLD), and chronic hepatitis B or C virus infection[19]. It has been reported that cancer patients are at high risk of COVID-19. A study of three hospitals in Wuhan reported 1276 confirmed cases of COVID-19, among which 28 patients had different types of cancer and two of them had HCC[20]. NAFLD, also called metabolic associated fatty liver disease (MAFLD), is highly prevalent globally[21]. A study reported that patients with NAFLD had increased ALT levels following COVID-19 infection[22]. A study from China showed that patients with NAFLD had an increased risk of COVID-19 compared with patients without it[23]. However, more studies are required to understand the mechanism of liver injury caused by NAFLD and COVID-19. It has been observed that use of immunosuppressant drugs in post liver transplant patients more prone them to SARS-CoV-2 infection. Additionally, the use of these drugs were found to enhance the cytokine storm in COVID-19 patients[18,24].

COVID-19-associated liver injury is manifested by entry of SARS-CoV-2 into the liver that can progress during COVID-19 treatment in patients with or without pre-existing liver disease[25]. SARS-CoV-2-related liver injury can occur by multiple factors, including direct cytopathic effect of the virus on cholangiocytes/hepatocytes, immune-mediated damage, hypoxia[19], sepsis[26], and drugs (*e.g.*, acetaminophen, ritonavir/lopinavir, interferon, Chinese herbs, and antibacterial agents) used in treating COVID-19[27]. However, there is no proof that patients with chronic hepatitis are at risk of COVID-19 unless other comorbidities (*e.g.*, cardiovascular disease, diabetes, and hypertension) that can increase the risk of liver disease are present[26]. The angiotensin-converting enzyme 2 (ACE2) receptor is associated with entry of SARS-CoV-2 and is highly expressed (about 80%) in alveolar cells of the lungs[28], the gut, and the kidneys[29]. The expression of ACE2 receptor has also been observed in myocardial cells, nephron proximal tubule cells, absorptive enterocytes of the ileum and colon, bladder urothelial cells; and the oral, nasal and nasopharyngeal mucosal epithelia [30]. It has been reported that ACE2 cell surface receptors are highly expressed in cholangiocytes and hepatocytes, which indicates tropism of SARS-CoV-2 in the liver[31].

COVID-19-ASSOCIATED LIVER INJURY AND ITS CLINICAL IMPLICATIONS IN A GLOBAL SCENARIO

Abnormal levels of liver injury markers such as AST and ALT or abnormal liver function tests (LFTs) in COVID-19 patients place an additional disease burden on clinicians as well as to scientists in terms of treatment regimens and defining the association of COVID-19-linked hepatic diseases. The data that document liver impairment in COVID-19 patients reveal variable levels of liver injury markers across the globe, as shown in Figure 1[32-36]. In this context, the preliminary data were reported by Cai *et al*[32] from Shenzhen, China from January 11 to February 21, 2020 and followed-up to March 7, 2020. The data in the report was from a local hospital that found 318 of 417 COVID-19 patients (76.3%) with abnormal LFT values and 90 of 417 (21.5%) with liver injury during hospitalization. The incidence of liver injuries in Asia was further evaluated by Vespa *et al*[34] in a cohort of 292 COVID-19 patients until March 30, 2020. Compared with Cai *et al*[32], a cholestatic pattern of liver injury with an increased level of alkaline phosphatase (ALP) > 150 U/L was observed in 9.6% of the selected population. Another study of cholestatic liver injury conducted from January 20 to 31, 2020 at the Shanghai Public Health Clinical Center reported abnormal liver functions as increased levels of ALT and AST, gamma-glutamyl transferase (GGT), ALP, and total bilirubin[37]. Thus, the documented reports describe data related to predictive markers of COVID-19 and associated liver injury, but the underlying causes of liver injury associated with worse outcomes are still elusive.

The clinical significance of COVID-19-associated liver disease needs to be described. Some studies have addressed the clinical challenges. Of relevance is a report by Vespa *et al*[34] of an increase in ALP values because of SARS-CoV-2 liver tropism *via* the ACE2 receptor on hepatocytes and cholangiocytes. Furthermore, they correlated the ALP elevation as a marker of patient frailty or as representing an increased systemic inflammatory response to SARS-CoV-2 infection[34]. The prevalence of altered liver injury markers is highly associated with drug-induced liver injury (DILI) during the COVID-19 pandemic. Several studies[32,38-40] have reported potential harms related to pharmacotherapy with lopinavir/ritonavir in COVID-19 patients and the vulnerability of patients in developing severe pneumonia *via* increased LFTs. Moreover, the pathological characteristics of liver injury *via* autopsy analysis of COVID-19 patients provides evidence in support of DILI. A study revealed moderate microvesicular steatosis with mild hepatic inflammation, indicating the possibility of hepatic injury. However, this pattern of histological injury could be correlated with either DILI or SARS-CoV-2 infection[41].

Several risk factors can be linked to the incidence of COVID-19-associated liver injury. A retrospective study in a French population found a marked prevalence of obesity in confirmed COVID-19 patients. The study included 340 COVID-19 patients, 230 (68%) with noncritical COVID-19 and 110 (32%) with critical COVID-19. It was found that 85 of 340 patients with severe COVID-19 (25%) were obese compared with 15.3% of the general French population. Following standardization by age and sex, the prevalence rates of obesity were 1.35% and 1.89% times higher in patients with severe COVID-19 and in those admitted to intensive care units, respectively, than in the general French population[42]. Likewise, Zheng *et al*[43] reported the key association of obesity with the severity of COVID-19 in MAFLD patients, which provides a rationale for the likelihood of the importance of obesity-related comorbidities of liver diseases[44,45].

PRE-EXISTING LIVER DISEASE AND COVID-19: AN INTERLINKED SETUP AND ITS RELATED CONSEQUENCES

CLDs are an existing threat that accounts for the leading causes of liver-related mortality worldwide[46-48]. The major CLDs, including hepatitis B virus or C virus infection, alcohol-induced liver damage (ALD), and NAFLD, lead to prolonged liver damage and increased incidence of CLD-associated cancers, particularly, HCC[49,50]. Underlying liver diseases were one of the crucial causative factors in the previous SARS outbreak, with high mortality rates in adults and elders[51]. The Centers for Disease Control and Prevention recently included liver diseases as a comorbidity and predisposing factor for contracting SARS-CoV-2 infection. Moreover, the American Association for the Study of Liver Diseases (AASLD) endorses COVID-19 testing on a priority basis for patients who manifest symptoms of liver disease[52]. The COVID-19

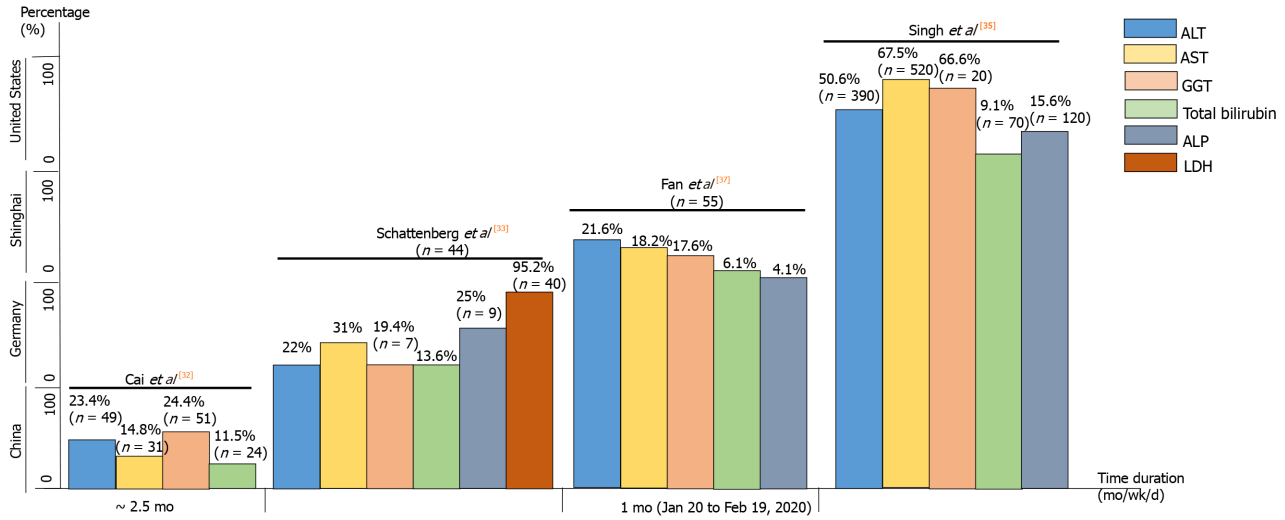

Figure 1 Overview of a global perspective related to incidence of coronavirus disease 2019-associated alterations in liver function tests.
The figure presents only data published in peer-reviewed journals. ALP: Alkaline phosphatase; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; GGT: Gamma-glutamyl transferase; LDH: Lactate dehydrogenase.

pandemic together with the global prevailing menace of CLD further complicates the care of pre-existing liver disease patients as a result of failure of screening, and follow-up. Therefore, the intricate link between pre-existing liver disease and COVID-19 requires additional study and specific disease management. It has to be expected that patients with underlying liver diseases are more vulnerable to exacerbating COVID-19-related effects and vice versa[53] that may account for the high morbidity and mortality rates in the current COVID-19 pandemic.

Relevant to pre-existing liver diseases, alcohol use disorder or ALD is the CLD with the highest hospitalization burden and has seen a more than 2-fold increase in China. The effect is likely to be repeated in the United States, with 12.7% estimated hospitalization rate associated with COVID-19. A gradual increase in the incidence of ALD was accompanied by an increase in patients indicated for liver transplantation prior to COVID-19 pandemic. The direct clinical implications of COVID-19 on ALD are still unknown, but it can be suspected that SARS-CoV-2 infection can serve as a major host-compromising factor with underlying ALD and subsequently results in acute-on-chronic liver failure. The high proportion of ALD among CLD patients is reflected in the number of patients with decompensated ALD during COVID-19 pandemic[52].

Growing evidence of COVID-19-related liver disease comorbidities suggests that MAFLD patients are at higher risk of COVID-19 disease progression[43,54,55]. A retrospective study conducted by Fondevila *et al*[56] described a mechanistic approach in the context of a higher risk of SARS-CoV-2 infection in obese patients. They assessed the hepatic mRNA expression of SARS-CoV-2 cell entry molecules, ACE2 and the cellular transmembrane protease serine 2 (*TMPRSS2*) in obese patients with NAFLD and/or diabetes mellitus type-2. Based on liver mRNA expression of both ACE2 and *TMPRSS2* in obese patients, the results revealed that SARS-CoV-2 entry factors are differently affected in diabetes and NAFLD. Moreover, major alterations in the expression of SARS-CoV-2 entry molecules in in men and women suggest a lower susceptibility of women to liver injury. While obese women with diabetes have unexpectedly lower levels of ACE2 and *TMPRSS2* than obese normoglycemic women, obese patients with nonalcoholic steatohepatitis had a higher expression of those genes, suggesting that advanced stages of NAFLD might predispose to COVID-19.

COVID-19 patients with comorbidities of advanced hepatic complications are generally at an increased risk of infection because of cirrhosis-associated immune dysfunction[57]. A retrospective study by Iavarone *et al*[58] documented a substantial 30-d mortality rate of 34% in a cohort of 50 cirrhotic patients with COVID-19, which was higher than the rate in cirrhotic patients with bacterial infections. Overall COVID-19 mortality from the medical consequences of respiratory failure was correlated with the worsening of liver dysfunction. Other categories of COVID-19 patients with hepatic diseases that are of great concern are liver transplant recipients and patients with autoimmune liver diseases receiving immunosuppressant drugs[57]. However, COVID-19-associated effects in recipients of living donor allografts are still unclear[59]. A case reported by The American Society of Transplantation and the American Society of

Transplant Surgeons described the impact of COVID-19-associated hepatitis during liver transplantation. A patient underwent ABO-incompatible living donor liver transplantation without knowing that the liver donor was infected with COVID-19 during the donation procedure. In that case, donor-derived transmission to the recipient was not identified, and the liver donor was found to be recovering from COVID-19 infection. Donor-derived transmission was not identified[60].

A PLAUSIBLE PATHOPHYSIOLOGICAL TRIAD OF COVID-19, HEPATOCELLULAR DAMAGE AND LIVER DISEASES

Epidemiological studies have described liver dysfunction and the effects of SARS-CoV-2 infection on the liver cells in COVID-19 patients by elevated levels of liver injury markers such as ALT, AST, and bilirubin[32,33,57,61,62]. It has been stated previously that the SARS-CoV and MERS-CoV viruses primarily affect the upper respiratory tract but also affect the liver[62,63]. Despite the immediate and direct action of SARS-CoV-2 *via* potential targets on the epithelial cells of lung alveoli as well as the respiratory tract, emerging evidence suggests that the high expression of ACE2 receptors in the liver renders it susceptible to the pathogenicity of SARS-CoV-2[36,64]. Pathological examination of COVID-19 patients has confirmed cytopathic injury in the lungs[41] and has recently confirmed SARS-CoV-2 infection as an etiology of liver disease. The proposed mechanisms associated with COVID-19-induced liver injury include direct viral insult-linked hepatic derangements, cytokine storm-prompted liver injury, and ischemia related to COVID-19-induced hypoxia as shown in Figure 2[52,65-68].

Liver impairment in COVID-19 might be directly correlated with SARS-CoV-2 infection of liver cells. Approximately 2%-10% COVID-19 patients with diarrhea have confirmed SARS-CoV-2 RNA in stool and blood samples, which implies the possibility of viral exposure in the liver. The affinity of SARS-CoV-2 and SARS-CoV for the ACE2 receptor indicates respective target sites, mainly the upper respiratory tract, lung tissue, and cholangiocytes of the liver, where the virus replicates and manifests COVID-19 associated symptoms[61]. In that context, Zhao *et al*[69] studied a SARS-CoV-2 infection model in human liver ductal organoids. They reported genomic evidence that SARS-CoV-2 virus infection resulted in dysregulation of barrier and bile-acid transporting functions of the cholangiocytes. The study found that altered cholangiocyte functions of could have been the result of a direct SARS-CoV-2 cytopathogenic effect on target cell that expressed ACE2 and *TMPRSS2*.

Cytokine storm is one of the hallmarks of infectious and noninfectious diseases that are capable of causing severe multiple organ injuries. Establishment of the cytokine environment is a multifactorial network that involves an immunological response to an invading antigen along with interplay of activated host immune and inflammatory cells. In line with the concept of cytokine storm in COVID-19 patients, Han *et al*[65] performed a prospective cohort study at a local hospital in Wuhan, China that enrolled 102 COVID-19 confirmed patients and 45 healthy control volunteers. They analyzed the serum profiles of inflammatory cytokines, including tumor necrosis factor-, interferon-, interleukin (IL)-2, IL-4, IL-6, IL-10, and C-reactive protein (CRP) by immunoassays. Significant increases in the levels of the inflammatory markers and CRP were seen in COVID-19 patients compared with the healthy volunteers. Moreover, the levels of IL-6 and IL-10 were significantly higher in critical than severe or moderate COVID-19 patients, suggesting that increased IL-6 and IL-10 may allow rapid diagnosis of patients with increased risk of lethal disease. Furthermore, Wang *et al*[70] reported COVID-19-associated conspicuous cytopathy. The severity of SARS-CoV-2 infection is associated with disturbed levels of liver enzymes, increased alveolar-arterial oxygen gradient and GGT level, and decreased albumin and circulating $CD4^+$ T cells and B lymphocytes. The predominant histological features of COVID-19 liver infection are substantial apoptosis and binuclear hepatocytes[70].

Hepatic dysfunction in severe COVID-19 is accompanied by aberrant activation of the coagulative and fibrinolytic pathways[71], moderately decreased platelet counts, increased neutrophil counts and neutrophil-to-lymphocyte ratios, and high ferritin levels. Such laboratory findings are perceived as nonspecific inflammatory markers, but the altered levels can coincide with a failure of innate immune regulation during progression of severe COVID-19. Indeed, alteration of immune balance activates coagulation and NETosis, and subsequently affects systemic iron metabolism secondary to macrophage activation[38].

DIAGNOSTIC APPROACHES FOR COVID-19

SARS-CoV-2 infection is confirmed by serologic tests that measure the antibody response or antibody titer in the patient. In COVID-19 patients, antibodies are produced in the days to weeks after SARS-CoV-2 infection. Thus, the presence of antibodies indicates that a person was infected with SARS-CoV-2, irrespective of whether the infection caused severe or mild disease or even an asymptomatic infection. Surveillance of antibody seropositivity allows inferences to be made about the extent of infection and the cumulative incidence of infection in the population. Serologic Enzyme-linked immunosorbent assays can be used for COVID-19 serosurveillance and to determine the extent of infection in the population. A confirmed case of SARS-CoV-2 infection is declared by a positive result from nasal and pharyngeal swab specimens by high-throughput sequencing or real-time reverse transcriptase polymerase chain reaction (RT-PCR)[17]. Molecular testing (RT-PCR) confirms infection, often in patients with severe disease, as they are individuals who seek and require health care. A percentage of patients with mild or asymptomatic infections who do not require medical attention may not be tested, and as a result, the full spectrum of the disease will not be known[72]. SARS-CoV-2 infection is associated with epidemiological characteristics, clinical signs, and symptoms of COVID-19 that can be accessed from electronic medical records and laboratory findings. Radiological assessments of COVID-19 patients include chest X-rays or computed tomography. Whereas, laboratory assessments that help to indicate the prognosis of COVID-19 include complete blood counts, blood chemistry, coagulation tests, assays of liver and renal function markers, electrolytes, CRP, procalcitonin, lactate dehydrogenase, and creatine kinase[17].

RECOMMENDATIONS OF THERAPEUTICS FOR COVID-19: VACCINES, LABEL AND OFF-LABEL MEDICATIONS FOR PATIENT CARE

The COVID-19 pandemic has prompted the scientific community and clinicians to develop COVID-19-related therapeutics and vaccines to mitigate as well as control the pathogenicity of SARS-CoV-2. Previous investigations on genomic sequencing of

SARS-CoV and MERS have contributed to vaccination strategies in developing current vaccines against SARS-CoV-2[73]. The characteristics of vaccines in clinical testing are based upon inactivated or live-attenuated viruses, protein subunits, virus-like particles, replicating and nonreplicating viral vectors, and DNA and RNA that may provoke protective immunity to SARS-CoV-2 infection[74,75]. Since July 2, 2020, the global landscape of SARS-CoV-2 vaccine development reported 163 vaccine candidates, 135 of the 163 are in preclinical or exploratory stages of development. Currently, mRNA-1273 (Moderna), Ad5-nCoV (CanSino Biologicals), INO-4800 (Inovio, Inc.), LV-SMENP-DC, a Pathogen-specific aAPC (ShinzenGeno-Immune Medical Institute), ChAdOx1 (Oxford University) BioNtech (Pfizer), Sputnik V (Gamaleya, Russia), and Sinovac (China) have been approved by the WHO under emergency use authorization[76]. India has started mass vaccination with its locally produced Covaxin vaccine. A prolonged time period for approval of vaccines is needed for validation of efficacy and adverse effects in target populations before post-market surveillance. However, adverse reactions to vaccines including fatigue, chills, aches, skin rashes, muscle pain, fever, and joint pain could be a barrier in the global rollout of COVID-19 vaccines[77]. In April, 2020, the Access to COVID-19 Tools accelerator was launched by the WHO and its partners to cooperate in fighting against the COVID-19 pandemic. Moreover, a global collaboration aims to accelerate development, production, and equitable access to COVID-19 tests, treatments, and vaccines among countries, particularly low-to-middle income countries (SAGE; http://www.who.int/).

In terms of therapeutics, COVID-19 medications fall into two categories: Those that target the viral replication cycle and those that aim to control the symptoms of the disease. The aminoquinolines chloroquine and hydroxychloroquine are polymerase inhibitors classically used as antimalarial medications. In malaria, it inhibits heme polymerase, causing the accumulation of toxic heme in the parasite that leads to its death. In COVID-19, it is thought that the drugs keep the virus out of host cells by blocking glycosylation of host receptors and blocking the production of viral proteins by inhibiting endosomal acidification. The WHO recommends the off-label use of hydroxychloroquine or chloroquine and lopinavir/ritonavir for treatment of COVID-19 with any disease severity and any duration of symptoms. Remdesivir and systemic corticosteroids are potential candidates for conditional recommendation of use in hospitalized COVID-19 patients for usual care regardless of disease severity (WHO/2019-nCoV/therapeutics/2020.1). The WHO considers off-label use of medication as country-specific. In many countries, doctors are giving COVID-19 patients medicines that have not been approved for this disease (MEURI; http://www.who.int/). Thus, COVID-19 patients have received off-label and compassionate-use therapies, such as interferon- combined with the repurposed drug Kaletra, an approved combination of the human immunodeficiency virus protease inhibitors ritonavir and lopinavir, chloroquine, azithromycin, favipiravir, remdesivir, steroids, and anti-IL-6 inhibitors, based on either *in vitro* antiviral or anti-inflammatory properties[78]. It is unclear if COVID-19 therapeutics protect against liver injury or disease. It would be interesting to look into protective effects in future.

RECOMMENDATIONS FOR MANAGEMENT OF COVID-19 PATIENTS WITH PRE-EXISTING LIVER DISEASES

The WHO has approved comprehensive guidelines to strengthen the care and management of COVID-19 patients and to provide up-to-date guidance to clinicians and physicians. That report addresses the best practices to manage severe acute respiratory infection (SARI), including infection prevention and control measures and supportive care for COVID-19 patients. Furthermore, the prime considerations focus on recognizing and treating patients with SARI through appropriate diagnosis, early supportive therapy, management of acute respiratory distress and septic shock, prevention of complications, and use of specific COVID-19 treatments[79]. Indeed, patients with CLD do not appear to be over-represented in cohorts of patients with COVID-19, where they make up less than 1% of reported cases. These observations suggest that patients with CLD may have a decreased risk of contracting severe SARS-CoV-2. However, the risk of infection and/or the risk of a severe course of COVID-19 may be different depending on the nature of the CLD and the presence or absence of advanced fibrosis or cirrhosis. In that context, the European Association for the Study of the Liver, European Society of Clinical Microbiology and Infectious Diseases and AASLD provided comprehensive guidance for physicians and clinicians for the care of

patients with CLD during the early stages of the COVID-19 pandemic[68,80]. The salient guidelines are summarized in Table 2 for clinical relevance and management of COVID-19 and liver patients.

CONCLUSION

The chaotic conditions of the global spread of COVID-19 necessitate clinical care and management of patients with pre-existing morbidities, especially highly prevalent liver diseases in developed and developing countries to decrease the economic and health losses globally. Understanding the pathophysiological mechanisms of COVID-19 and its associated adverse effects in hepatic diseases is indispensable for the development of therapeutics and vaccines as well as mitigation of risks factors of disease. The WHO guidelines and associations for the study of liver diseases are timely and helpful in decreasing burden of disease and health education. The WHO needs to play a vital role in equitable and global availability (rollout) of COVID-19 vaccines to low-to-middle income countries to prevent COVID-19 pandemic and associated comorbidities.

Table 2 Summary of specific European Association for the Study of the Liver, European Society of Clinical Microbiology and Infectious Diseases and American Association for the Study of Liver Diseases guidelines and recommendations for the clinical care and management of patients with liver diseases during coronavirus disease 2019 pandemic

	Hospitalization and severe COVID-19	Alterations to standard treatment strategies		Progression of liver disease
	Early administration, laboratory findings and risk of SARS-CoV-2 infection	Treatment of higher risk groups	Resumption of targeted treatment and surveillance	Patient education and intensive lifestyle advice
NAFLD	High prevalence risk of SARS-CoV-2 infection in NAFLD patients with COVID-19 suggest an early admission to the hospital	No side effects related to ACE inhibitors or AR blockers to date, thus, arterial hypertension treatment should continue in accordance to prescribed guidelines	Not well known	Intensive lifestyle interventions including nutritional guidance, weight loss and diabetes management may prevent the risk of severe COVID-19 complications
Chronic Viral Hepatitis	Patients on chronic HBV or HCV medications with poor compliance should observed treatment protocols, directly	(1) In HBV and COVID-19 patients, an alternative agent should be considered rather than interferon-α therapy; (2) COVID-19 patients with high risk of severe acute HCV should consider for an appropriate antiviral therapy on case-by-case basis under the full consultation; and (3) COVID-19 patients with resolved HBV infection, receiving corticosteroids, tocilizumab, or other immunosuppressant agents should be considered for appropriate antiviral therapy to prevent viral reactivation under full consultation	(1) Without COVID-19, the patients should continue the HBV or HCV medications in accordance to general guidelines; and (2) in COVID-19 patients, initiation of HBV or HCV medication should be deferred until full recovery from COVID-19 or on case-by-case basis under the full consultation	Use of telemedicine for patients of on-going chronic HBV or HCV treatment without COVID-19
Autoimmune hepatitis	(1) Immunocompromised patients on corticosteroid treatment during COVID-19 requires respiratory support; And (2) patients on respiratory support may be considered for addition of, or conversion to, dexamethasone treatment	(1) Patients on high doses of corticosteroid may show more susceptibility to SARS-CoV-2 infection or severe COVID-19; (2) Low doses may be considered under special circumstances (*e.g.*, drug-induced lymphopenia, or bacterial/fungal superinfection with severe COVID-19) under consultation with specialist; (3) or may consider budesonide as an alternative first line agent in patient without cirrhosis to induce remission who have a flare of autoimmune hepatitis	Immunocompromised patients with COVID-19 may be considered for dosing of corticosteroid, sufficient for adrenal insufficiency	All patients should receive vaccination of *Streptococcus pneumoniae* and influenza
Alcohol-related liver hepatitis	Alcohol-induced severe hepatitis patients on corticosteroid treatment with COVID-19 require respiratory support	Not well known	Not well known	Increased probability of higher alcohol consumption during social distancing, so, preemptive strategies including patient outreach and telephone alcohol liaison, should be considered
Cirrhosis	(1) Cirrhotic patients with COVID-19 should be considered for early hospitalization; and (2) to avoid admission and to prevent decompensation, guidelines on prophylaxis of spontaneous bacterial peritonitis, gastrointestinal hemorrhage and hepatic encephalopathy should be followed	Vasoconstriction therapy should be considered with great caution for critically ill cirrhotic patients with COVID-19	Cirrhotic patients are vulnerable to both SARS-CoV-2 infection and altered standards of patient care during pandemic. Thus, the best efforts should be made for care of cirrhotic patients according to general guidelines	All patients should receive vaccination of *Streptococcus pneumoniae* and influenza
Hepatocellular carcinoma	Specific risk of HCC patients with COVID-19 remains undefined	In COVID-19 patients, initiation of HBV or HCV medication should be deferred until full recovery from COVID-19 or on case-by-case basis under the full consultation	Full HCC surveillance should resume under specific circumstances	Consider virtual patient visits to discuss diagnosis and management of HCC and other liver tumors
Liver	Patients on the liver transplant	Precautions should be followed to make	Not well known	Patients should

transplant candidates	waiting list with decompensated cirrhosis are at high risk of severe COVID-19 and death following SARS-CoV-2 infection	COVID-19 free liver transplantation process		avoid attending in-person community recovery support meetings, such as Alcoholics Anonymous, and provide alternative telephone or online resources
Liver transplant recipients	Early admission should be considered for all liver transplant recipients who develop COVID-19	Drug levels of calcineurin inhibitors and mechanistic target of rapamycin inhibitors should be closely monitored on administration with COVID-19 medications, particularly hydroxychloroquine, protease inhibitors or new trial drugs for COVID-19	Reduction of immunosuppressant dosing may be considered under special circumstances (*e.g.*, drug-induced lymphopenia, or bacterial/fungal superinfection with severe COVID-19) under consultation with specialist	All patients should receive vaccination of *Streptococcus pneumoniae* and influenza

ACE: Angiotensin-converting enzyme; AR: Adrenoreceptor; COVID-19: Coronavirus disease 2019; HBV: Hepatitis B virus; HCC: Hepatocellular carcinoma. HCV: Hepatitis C virus; NAFLD: Nonalcoholic fatty liver disease; SARS-CoV-2: Severe acute respiratory syndrome-coronavirus type 2.

Abstract

BACKGROUND

Non-responsive celiac disease (NRCD) is defined as the persistence of symptoms in individuals with celiac disease (CeD) despite being on a gluten-free diet (GFD). There is scant literature about NRCD in the pediatric population.

AIM

To determine the incidence, clinical characteristics and underlying causes of NRCD in children.

METHODS

Retrospective cohort study performed at Boston Children's Hospital (BCH). Children < 18 years diagnosed with CeD by positive serology and duodenal biopsies compatible with Marsh III histology between 2008 and 2012 were identified in the BCH's Celiac Disease Program database. Medical records were longitudinally reviewed from the time of diagnosis through September 2015. NRCD was defined as persistent symptoms at 6 mo after the initiation of a GFD

Gastroenterologues du Quebec; and Phase 2 Award from the Fonds de Recherche Sante Quebec.

Institutional review board statement: This study was reviewed and approved by the Institutional Review Board of Boston Children's Hospital.

Informed consent statement: Patients were not required to give informed consent to the study because this study presented no more than minimal risk to patient privacy and confidentiality.

Conflict-of-interest statement: Leffler DA is employed by Takeda Pharmaceuticals International Co. Kelly CP has acted as a scientific advisor to companies attempting to develop new diagnostic and management approaches for Celiac disease including Cour Pharma, Glutenostics, Innovate, Immunogenx and Takeda. He also acts as Principal Investigator on a research grant on Celiac disease supported by Aptalis. Silvester JA has served on an advisory board for Takeda Pharmaceuticals and has received research funding from Biomedal S.L., Cour Pharma and Glutenostics.

Data sharing statement: No additional data are available.

STROBE statement: The authors have read the STROBE Statement-checklist of items, and the manuscript was prepared and revised according to the STROBE Statement-checklist of items.

Open-Access: This article is an open-access article that was selected by an in-house editor and fully peer-reviewed by external reviewers. It is distributed in accordance with the Creative Commons Attribution NonCommercial (CC BY-NC 4.0) license, which permits others to distribute, remix, adapt, build upon this work non-commercially, and license their derivative works on different terms, provided the original work is properly cited and the use is non-commercial. See: http://creativecommons.org/License

and causes of NRCD as well as symptom evolution were detailed. The children without symptoms at 6 mo (responders) were compared with the NRCD group. Additionally, presenting signs and symptoms at the time of diagnosis of CeD among the responders and NRCD patients were collected and compared to identify any potential predictors for NRCD at 6 mo of GFD therapy.

RESULTS

Six hundred and sixteen children were included. Ninety-one (15%) met criteria for NRCD. Most were female (77%). Abdominal pain [odds ratio (OR) 1.8 95% confidence interval (CI) 1.1-2.9], constipation (OR 3.1 95%CI 1.9-4.9) and absence of abdominal distension (OR for abdominal distension 0.4 95%CI 0.1-0.98) at diagnosis were associated with NRCD. NRCD was attributed to a wide variety of diagnoses with gluten exposure (30%) and constipation (20%) being the most common causes. Other causes for NRCD included lactose intolerance (9%), gastroesophageal reflux (8%), functional abdominal pain (7%), irritable bowel syndrome (3%), depression/anxiety (3%), eosinophilic esophagitis (2%), food allergy (1%), eating disorder (1%), gastric ulcer with *Helicobacter pylori* (1%), lymphocytic colitis (1%), aerophagia (1%) and undetermined (13%). 64% of children with NRCD improved on follow-up.

CONCLUSION

NRCD after ≥ 6 mo GFD is frequent among children, especially females, and is associated with initial presenting symptoms of constipation and/or abdominal pain. Gluten exposure is the most frequent cause.

Key Words: Celiac disease; Non-responsive celiac disease; Children; Gluten-free diet; Constipation; Abdominal pain

Core Tip: This is a retrospective chart review study of children < 18 years of age diagnosed with celiac disease (CeD) by positive serology and biopsies showing Marsh III histology to characterize non-responsive CeD (NRCD). NRCD was attributed to a wide variety of diagnoses with gluten exposure (30%) and constipation (20%) being the most common causes. Most (64%) patients improved on follow-up. Our study highlights the importance of performing a diligent search for etiologies of NRCD when there are persistent symptoms despite following a gluten-free diet and reinforces the need for close follow up in the first year of the diagnosis of CeD.

INTRODUCTION

Celiac disease (CeD) is a chronic immune-mediated enteropathy precipitated by exposure to gluten in genetically predisposed individuals[1]. CeD is diagnosed based on clinical symptoms and serological markers in conjunction with specific histological changes found in the duodenum, including villous atrophy, crypt hyperplasia and intraepithelial lymphocytosis[2].

Strict elimination of gluten is currently the only effective treatment for CeD[2,3]. A gluten-free diet (GFD) leads to significant improvement in most people with CeD within weeks[4]. Failure to respond after six to twelve months of a GFD is defined as non-responsive CeD (NRCD), and may occur in both adults and children[5]. NRCD incorporates a range of specific and distinct underlying diagnoses, such as other food intolerance, small intestinal bacterial overgrowth, microscopic colitis, and irritable bowel syndrome[6,7]; nevertheless, the most common etiology of NRCD is continued

gluten exposure[6,8]. Studies suggest that 7% to 52% of adult CeD patients may have NRCD[2,5,6]. A recent retrospective study showed that 34% of children adhering to a GFD still report at least one symptoms more than 24 mo after their diagnosis[5]; however, little is known about the spectrum and etiologies of NRCD in children.

The objective of this study was to determine the incidence, clinical characteristics and underlying causes of NRCD in children.

MATERIALS AND METHODS

In this retrospective cohort study, we used the Boston Children's Hospital (BCH) Celiac Disease Program database to identify children less than 18 years of age with an initial biopsy-confirmed CeD diagnosis at BCH between January 1, 2008 and December 31, 2012. Celiac antibodies included tissue transglutaminase (tTG) immunoglobulin (Ig) A, deamidated gliadin peptide (DGP) IgG and endomysial antibody (EMA) IgA. Included patients had Marsh III lesions, defined by increased intraepithelial lymphocytes, villous atrophy, and crypt hyperplasia[2]. Children diagnosed elsewhere and seen for a second opinion, and those who were asymptomatic at the time of diagnosis were excluded.

Data extracted from medical records included demographics, clinical presentation, serologic results, comorbidities, family history of CeD and number of dietitian visits at BCH within 120 d of CeD diagnosis. Medical records were reviewed longitudinally from the time of diagnosis through September 2015.

Adherence to the GFD was determined from review of medical records, primarily from dietician documentation/notes of their clinical assessment which included a dietary interview and is reported using a previously published assessment scale graded as follows: (1) Excellent = patient never ate gluten intentionally and/or had rare exposure, (2) Good = inadvertent exposure once per month, (3) Fair = exposure 2-3 times per month, (4) Poor = exposure 1-2 times per week, (5) Noncompliant = not on a GFD, or (6) Unable to assess GFD adherence from the medical record[9].

NRCD was defined as persistent clinical symptoms six months or more after the initiation of a GFD. Children with clinical improvement while on a GFD were considered as responders and compared with the NCRD group. This study was approved by the BCH Institutional Review Board.

Statistical analysis

Categorical data were summarized as frequency (percentage) and comparisons between responders and children with NRCD made with Fisher's exact test. Continuous data were presented as median with interquartile range (IQR) and compared across groups by Wilcoxon rank-sum test. A stepwise logistic regression model was used to investigate symptoms at the time of diagnosis that are independently associated with NRCD signs and symptoms included abdominal pain, constipation (hard or infrequent stools), nausea/vomiting, diarrhea, weight loss or poor weight gain, fatigue, short stature, gassiness, abdominal distension, loss of appetite, arthritis/arthralgia, rash, and mouth ulcers. $P < 0.20$ was required for a symptom to enter the model, and $P < 0.05$ was required for the symptom to remain in the model. All comparisons were two-sided, with statistical significance established a priori as $P < 0.05$. Data analysis was performed with SAS v9.4 (Cary, NC, United States).

RESULTS

A total of 659 children under 18 years of age were diagnosed with biopsy-confirmed CeD at BCH between January 1, 2008 and December 31, 2012 (Figure 1). All had elevated serum tTG IgA except for nine subjects. These nine were diagnosed with CeD according to the presence of other celiac serology, HLA typing compatible with CeD or response to a GFD. Forty-three who did not have symptoms at the time of the diagnosis (evaluated for CeD because of type 1 diabetes, family history of CeD or short stature) were excluded from the primary analysis. Of the remaining 616 children included, 525 (85%) subjects showed complete response as determined by resolution of clinical symptoms in the 6 (± 2) mo following the initiation of the GFD (responders). Ninety-one children (15%) met the criteria for NRCD, with persistent symptoms 6 mo after the diagnosis.

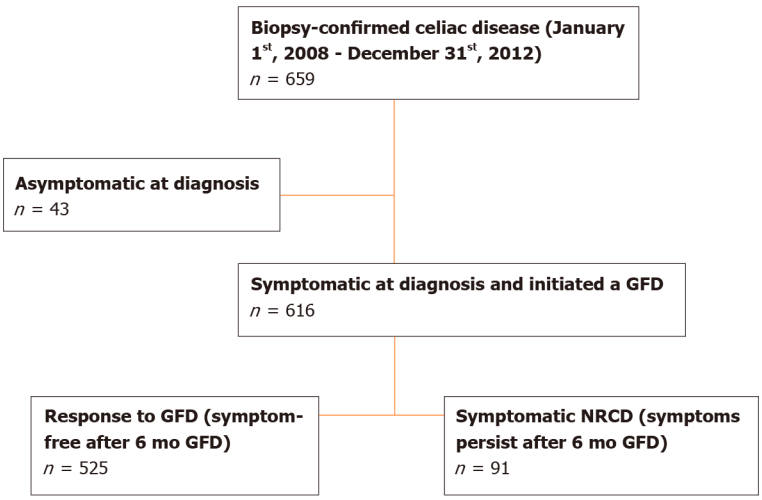

Figure 1 Patient selection flowchart. GFD: Gluten-free diet; NRCD: Non-responsive celiac disease.

Characteristics of responders (n = 525) and NRCD (n = 91) groups are shown in Table 1. Significantly more subjects with NRCD were female (77% *vs* 65%, respectively; P = 0.02). There was no difference in age at time of biopsy, and subjects of all ages were included: < 3 year (9%), 3-6 year (25%), 7-11 year (31%), and 12-17 year (35%). There was a trend towards more Hispanic patients among NRCD subjects compared to responders (5% *vs* 1%, respectively; P = 0.06). Family history of CeD (27%) was less common than family history of other autoimmune disorders (46%), but the incidence for each was similar between NRCD subjects and responders. Finally, at the time of CeD diagnosis, subjects with NRCD had lower body mass index (BMI) z-score compared to responders (median 0.00 (IQR -1.12, 0.58) *vs* 0.18 (IQR -0.48, 0.82); P = 0.02) (Table 1).

Abdominal pain was the most common presenting symptom at diagnosis and was more likely in children with NRCD compared to responders (70% *vs* 54%, P < 0.006). Constipation (hard or infrequent stools) was the second most common presenting symptom and was also more frequent with NRCD (54% *vs* 28%, P < 0.0001). Psychiatric manifestations (anxiety and restrictive eating disorder) were also more prevalent at diagnosis among children with NRCD compared to responders (Table 2).

Symptoms at the time of diagnosis that were determined by stepwise logistic regression to be independently associated with NRCD included constipation, lack of abdominal distension, and abdominal pain. The odds of NRCD were 3.1 (95% confidence interval (CI) 1.9-4.9) times higher for subjects with constipation compared to those with normal bowel movements. Likewise, absence of abdominal distension (odds ratio (OR) for abdominal distension 0.4, 95%CI 0.1-0.98) and presence of abdominal pain (OR 1.8, 95%CI 1.1-2.9) were independently associated with NRCD.

When examining serum tTG IgA antibody levels, 14 (15%) of NRCD patients had a less than 20% decrease in tTG IgA at 6 mo, 11 of whom continued to have tTG IgA levels greater than 1.5 × the upper limit of normal (ULN) at 1 year after diagnosis.

Formal evaluation and counselling by a dietitian within the first 120 d following CeD diagnosis was performed for 75 (82%) of patients with NRCD, compared to 342 (67%) of responders (P = 0.001). Additional nutrition counselling after the first 120 d occurred for 41% (n = 255) children and was more common among NRCD patients than responders (55% *vs* 39%, P < 0.006). GFD adherence was classified as excellent in 54 (66%) of symptomatic NRCD patients and poor in 12 (15%). We were unable to assess adherence to the diet in 9 patients based on medical record review. Seventeen of the 91 patients (19%) had repeat endoscopy as part of their evaluation, a median of 18.9 (IQR 9.5-25.4) months after their initial endoscopy. The majority showed normal villous architecture (82%, n = 14). Two children with persistent villous atrophy had on-going gluten exposure; a third one had follow-up biopsies only 2.8 mo after CeD diagnosis (to follow-up on coexisting eosinophilic esophagitis).

An etiology of NRCD was identified for 88/91 children. Gluten exposure was the most common cause (30%, n = 27) (Figure 2). These children had similar rates of elevated tTG IgA at 6 mo (52% *vs* 46%) and tTG IgA > 1.5 × ULN at one year (15% *vs* 11%) to the rest of the cohort.

Chronic constipation was the underlying cause of NRCD in 18 (20%) patients, and

was already present (*n* = 15) and treated with laxatives (*n* = 14) at the time of CeD diagnosis. Other causes for NRCD which were identified are detailed in Figure 2.

Forty-three (64%) of the 67 NRCD children with follow-up had eventual resolution of their clinical symptoms, whereas the remainder (*n* = 24, 26%) were lost to follow-up before symptoms resolved. Of the 11 patients for whom the etiology of NRCD was unclear, 4 were lost to follow-up, and 5 resolved with time. Only 2 children had persistent symptoms of undetermined etiology lasting 3 years or longer. Symptom resolution was frequent in patients with NRCD secondary to gluten exposure (*n* = 14, 67%) and constipation (*n* = 10, 71%). Those with functional abdominal pain (*n* = 6), irritable bowel syndrome (IBS) (*n* = 3), depression or anxiety (*n* = 3) fared worse. Only 1 patient in each group had resolution of symptoms at 3 years of follow-up despite treatment.

DISCUSSION

We report the incidence, etiology, and clinical characteristics of 91 children with NRCD who were diagnosed and treated at BCH between January 2008 and December 2012. The incidence of symptomatic NRCD 6 mo after initiation of a GFD was 15%. Pediatric NRCD was more prevalent in females and associated with a lower BMI *z*-score, greater abdominal pain, constipation and absence of abdominal distension at diagnosis. Etiologies of NRCD mirrored those reported in adults, with gluten exposure as the most common cause; however, there were no cases of refractory CeD.

Although definitions may vary, our results were consistent with previously published data on NRCD in adults of the same geographic region[6]. We found a lower incidence of NRCD than in a recent pediatric cohort study, in which 34% of children had at least one symptom of CeD more than 24 mo after initiating a GFD[5]. It is unclear whether the prevalence of NRCD increases with time, or if the apparently higher rate of NRCD at 24 mo reflects that the responders were lost to follow-up. Our experience

Table 2 Signs and symptoms at diagnosis of celiac disease among responders to the gluten-free diet and non-responsive celiac disease patients

	Responders (*n* = 525)	NRCD (*n* = 91)	*P* value
Abdominal pain, *n* (%)	286 (54)	64 (70)	< 0.006

with a pediatric population followed at an academic center that had persisting symptoms six months after the initiation of a GFD may also differ from children who had recurrence of symptoms 12 mo or 18 mo after the diagnosis. Although resolution of symptoms may be slow after starting the GFD, our clinical conclusion is that most children are generally symptom-free after six months on a GFD. Accordingly, 85% of pediatric patients diagnosed at BCH had a good clinical response to the GFD.

Some definitions of NRCD include isolated elevation of tTG[2,6]; however, we did not include such children if they were asymptomatic because tTG is not a reliable proxy

for intestinal histology on a GFD[10]. Coexisting disorders, GFD adherence, the initial degree of tTG elevation and severity of villous atrophy all affect time to normalization of tTG which frequently takes longer than 1 year in children[11,12]. Moreover, the presence of villous atrophy is not a sine qua non for NRCD, since the formal definition is based on signs and symptoms and not histology results[2,6]. On the other hand, by only selecting children with positive serology at the time of the diagnosis of CeD, we may have missed some seronegative NRCD[13]. However, seronegative CD is rare, accounting for less than 1% of cases of pediatric biopsy-confirmed (Marsh III) CD in a recent study, so whether they have a different course than seropositive CD remains unclear[14].

As in previous adult and pediatric studies, females were more likely to be diagnosed with NRCD[5,6]. This trend has also been reported among children with functional abdominal pain, but not constipation[14,15]. Females may be more likely to experience, or report GI symptoms. We did not observe any difference in the age at the time of CeD diagnosis. Intriguingly, an association between longstanding symptoms before the diagnosis of CeD and the risk of NRCD was recently reported[5]. Due to the retrospective design of our study, we unfortunately do not have access to this information; however, we did observe lower BMI *z*-scores at CeD diagnosis among the NRCD group. Lower BMI may be a marker of disease severity, thus explaining a prolonged clinical recovery. This underscores the need to monitor CeD patients after diagnosis because malabsorption due to persistent disease and decreased food intake in relation to GI symptoms may further affect BMI and growth. Moreover, the NRCD group had significantly more symptoms at diagnosis which may reflect visceral hypersensitivity or portend a functional gastrointestinal disorder. Although these manifestations are frequently described among pediatric CeD patients[5], the rate and response to a GFD is variable[16]. Identification of a cause other than gluten exposure for NRCD in most of our patients highlights the importance of considering a coexisting disorder.

Gluten exposure was the most common cause of NRCD in our cohort, as previously reported in adults[6,8]. A strict GFD is the only current treatment for CeD. Consultation with a registered dietitian for specialized GFD education at the time of CeD diagnosis is recommended in clinical practice guidelines and standard practice at our institution[2,3]. Nonetheless, only 65% of the responder group and 82% of the NRCD group had a dietitian visit at our institution within the first 4 mo after diagnosis of CD. Due to the retrospective nature of this study, we were unable to ascertain whether some individuals received GFD education outside of our institution, or if families opted out of dietitian visits because a family member had received GFD education. Nevertheless, additional nutrition counselling after the first 120 days was also more common among NRCD patients than responders, perhaps because ongoing symptoms prompt families to seek out additional education/support. Recent American College of Gastroenterology guidelines recommend reevaluation of diet as a first step in the management of NRCD[2].

Eliminating gluten ingestion, both intentional and unintentional, is a significant challenge for many pediatric CeD patients. Even with specialized GFD education, a sizable number of patients had ongoing gluten exposure. Avoiding gluten cross-contact, which occurs during processing, preparation and serving of foods, is especially difficult. Non-adherence to a strict GFD in children and teenagers has been estimated at 8% when disclosed openly[5], but may be nearer 30% when stools are assessed for gluten immunogenic peptides[17] and may increase with GFD duration[18]. Interestingly, 82% of symptomatic NRCD patients in our study appeared to have excellent or good GFD adherence. This is likely an overestimate due to the inherent challenges associated with assessing GFD adherence through dietary recalls and interviews compared to objective measures such as fecal gluten immunogenic peptides[17].

Fourteen (67%) of the 21 symptomatic NRCD patients with suspected ongoing gluten exposure experienced resolution of their symptoms with improved GFD adherence. It is unclear whether the remaining 7 patients were unsuccessful at fully excluding dietary gluten or if healthcare providers erroneously suspected continued gluten exposure as the cause of NRCD. This cohort was prior to the development of the technology allowing the identification of gluten immunogenic peptides in urine and stools. While these technologies appear promising, currently there is no validated measure of gluten exposure other than dietitian assessment. Although the second step in the management algorithm of NRCD in adults after excluding gluten exposure or food intolerance is to proceed to duodenal biopsies to assess for villous atrophy[2], most patients in this pediatric NRCD cohort did not undergo repeat endoscopy. Moreover, some degree of villous atrophy 6 mo to 12 mo after CeD diagnosis is not uncommon

among patients in clinical remission[19].

The second most common cause of NRCD was constipation, which was also an initial manifestation of CeD for most of these patients. Constipation is a common presenting symptom among children with CeD[5,20]. 196 children included in this cohort were constipated at the time of diagnosis, but only 18 had persisting constipation that was deemed to be the cause of NRCD. The GFD is inherently low in fibers which may precipitate constipation in CeD patients[21]. Thus, some patients with constipation as a cause of NRCD may have had either initially treated constipation that recurred on the GFD after stopping laxative (n = 7), new constipation probably caused by the GFD (n = 3) or persisting constipation despite initial laxative therapy (n = 7) or noncompliance to laxative therapy (n = 1). The latter may have been suffering from functional constipation unrelated to CeD, as it is a quite common disorder in children[22]. Nevertheless, many of these patients subsequently improved, highlighting that early and intensive strategies in addition to the GFD can be effective and may avoid persistent symptoms in children.

Notably, constipation is not typically reported as an etiology of NRCD in adults, possibly because they are diagnosed with IBS. Functional abdominal pain and IBS were the cause of NRCD in 10% of our cohort. In comparison, 18% of adult NRCD patients may have IBS[6]. Other less common etiologies include lactose intolerance, present in 9% of our cohort and 7% of adults with NRCD[6]. Upper GI conditions, including gastroesophageal reflux, peptic ulcer disease, *Helicobacter pylori* infection and eosinophilic esophagitis were also responsible for persistent symptoms in pediatric NRCD. Finally, anxiety and eating disorders were responsible for NRCD and may be associated with gastrointestinal dysmotility. This underscores the need to consider the patient as a whole, and how conditions other than CeD may contribute to symptoms on a GFD.

While most children with NRCD had resolution of their symptoms over the follow-up period, symptoms persisted in 36%. Patients with constipation had higher rates of resolution than those with diagnoses such as functional abdominal pain or IBS. Functional abdominal pain is frequent among children with and without CeD, with a recent multicenter study finding a prevalence of 2.1% to 8.2%[23]. The prevalence of IBS is somewhat lower, from 1.2% to 2.9%[15,24].

Strengths and limitations

This large cohort of children with CeD provides epidemiologic data on the characteristics, causes and evolution of pediatric NRCD thereby addressing an important knowledge gap. Chart reviews conducted by either one of two authors (GV and MD) were reviewed by an expert clinical pediatric gastroenterologist; however, the retrospective nature of this study limited our ability to perform a standardized evaluation of each patient. The large number of clinicians at our institution contributed to variability in documentation and differences in approach to medical evaluation. Also, many etiologies of NCRD are diagnosed based primarily on clinical history. Although inclusion of only children who were diagnosed at BCH reduces referral bias, our cohort may differ from populations in other geographic areas.

CONCLUSION

In summary, NRCD after six months of GFD is frequent among children, especially females. Initial presentation with constipation, abdominal pain and absence of abdominal distension is associated with subsequent diagnosis of NRCD. Although gluten exposure was the most frequent cause, a wide variety of diagnoses are also found among NRCD patients. Our study highlights the importance of performing a diligent search for the above etiologies for NRCD in any celiac child with persistent clinical symptoms despite being on GFD and reinforces the need for close follow up in the first year of a CeD diagnosis.

ARTICLE HIGHLIGHTS

Research background

Non-responsive celiac disease (NRCD) is defined as the persistence of symptoms in individuals with celiac disease (CeD) despite being on a gluten-free diet (GFD). There is scant literature about NRCD in the pediatric population.

Research motivation

Addressing an important knowledge gap, this study examines a large cohort of children with CeD providing data on the characteristics, causes and evolution of pediatric NRCD. By characterizing this sub-population of individuals with CeD, we are better equipped to provide clinical guidance and follow-up in those with persistent symptoms.

Research objectives

Through this retrospective cohort study, we sought to determine the incidence, clinical characteristics, and underlying causes of NRCD in children. Additionally, symptom evolution was detailed and compared to identify any potential predictors for NRCD.

Research methods

Retrospective cohort study performed at Boston Children's Hospital (BCH). Children < 18 years diagnosed with CeD by positive serology and duodenal biopsies compatible with Marsh III histology between 2008 and 2012 were identified in the BCH's Celiac Disease Program database. Medical records were longitudinally reviewed from the time of diagnosis through September 2015. NRCD was defined as persistent symptoms at 6 mo after the initiation of a GFD, and causes of NRCD as well as symptom evolution were detailed and compared to identify any potential predictors for NRCD.

Research results

Six hundred and sixteen children were included in this retrospective study, of which 91 (15%) met criteria for NRCD, and of this, most were female (77%). Abdominal pain [odds ratio (OR) 1.8 95% confidence interval (CI) 1.1-2.9], constipation (OR 3.1 95%CI 1.9-4.9) and absence of abdominal distension (OR for abdominal distension 0.4 95%CI 0.1-0.98) at diagnosis were associated with NRCD. NRCD was attributed to a wide variety of diagnoses with gluten exposure (30%) and constipation (20%) being the most common causes. 64% of children with NRCD improved on follow-up.

Research conclusions

NRCD after ≥ 6 mo of GFD is frequent among children, especially females, and is associated with initial presenting symptoms of constipation and/or abdominal pain. Gluten exposure is the most frequent cause. Our study highlights the importance of performing a diligent search for the etiologies for NRCD in any celiac child with persistent clinical symptoms despite being on GFD and reinforces the need for close follow up in the first year of a CeD diagnosis.

Research perspectives

Although the use of a large pediatric cohort positively contributes to the breadth of knowledge surrounding NRCD, and inclusion of only children who were diagnosed at BCH reduces referral bias, our cohort may differ from populations in other geographic areas. As such, a future direction of note is to extend this project to include pediatric Celiac Disease Programs across the United States, to assess if geographic location is a factor in the manifestation and characterization of NRCD.

Abstract

BACKGROUND

Hyperplastic polyps are considered non-neoplastic, whereas sessile serrated lesions (SSLs) are precursors of cancer *via* the ''serrated neoplastic pathway''. The clinical features of SSLs are tumor size (> 5 mm), location in the proximal colon, coverage with abundant mucus called the ''mucus cap'', indistinct borders, and a cloud-like surface. The features in magnifying narrow-band imaging are varicose microvascular vessels and expanded crypt openings. However, accurate diagnosis is often difficult.

AIM

To develop a diagnostic score system for SSLs.

METHODS

We retrospectively reviewed consecutive patients who underwent endoscopic resection during colonoscopy at the Toyoshima endoscopy clinic. We collected

data on serrated polyps diagnosed by endoscopic or pathological examination. The significant factors for the diagnosis of SSLs were assessed using logistic regression analysis. Each item that was significant in multivariate analysis was assigned 1 point, with the sum of these points defined as the endoscopic SSL diagnosis score. The optimal cut-off value of the endoscopic SSL diagnosis score was determined by receiver-operating characteristic curve analysis.

RESULTS
Among 1288 polyps that were endoscopically removed, we analyzed 232 diagnosed as serrated polyps by endoscopic or pathological examination. In the univariate analysis, the location (proximal colon), size (> 5 mm), mucus cap, indistinct borders, cloud-like surface, and varicose microvascular vessels were significantly associated with the diagnosis of SSLs. In the multivariate analysis, size (> 5 mm; $P = 0.033$), mucus cap ($P = 0.005$), and indistinct borders ($P = 0.033$) were independently associated with the diagnosis of SSLs. Size > 5 mm, mucus cap, and indistinct borders were assigned 1 point each and the sum of these points was defined as the endoscopic SSL diagnosis score. The receiver-operating characteristic curve analysis showed an optimal cut-off score of 3, which predicted pathological SSLs with 75% sensitivity, 80% specificity, and 78.4% accuracy. The pathological SSL rate for an endoscopic SSL diagnosis score of 3 was significantly higher than that for an endoscopic SSL diagnosis score of 0, 1, or 2 ($P < 0.001$).

CONCLUSION
Size > 5 mm, mucus cap, and indistinct borders were significant endoscopic features for the diagnosis of SSLs. Serrated polyps with these three features should be removed during colonoscopy.

INTRODUCTION

Recent molecular biology studies have supported the classification of colorectal serrated lesions into hyperplastic polyps (HPs), sessile serrated lesions (SSLs), and traditional serrated adenomas (TSAs)[1]. HPs are considered non-neoplastic, whereas SSLs and TSAs are both precursors of cancer *via* the "serrated neoplastic pathway", which is responsible for up to 20% of all sporadic colorectal cancers[2]. The features of serrated neoplastic pathways include high microsatellite instability and the potential for rapid conversion to malignancy[3,4]. This implies that all SSLs should be accurately diagnosed and endoscopically removed[5], whereas HPs do not need to be removed. Therefore, it is essential to differentiate SSLs from HPs.

SSLs typically occur in the proximal colon[6]. Endoscopically, SSLs usually measure > 5 mm, are frequently covered by mucus called ''mucus cap'', and have indistinct borders and a cloud-like surface[7]. The features of SSLs under magnifying narrow-

band imaging (NBI) are varicose microvascular vessels and expanded crypt openings[8]. The feature of SSLs on chromoendoscopy is a type II open-shape pit pattern. In contrast, HPs commonly occur in the distal colon or rectum and are often ≤ 5 mm in size. However, differential diagnoses are often difficult[9]. We hypothesized that well-designed combination of endoscopic features might be useful for the diagnosis of SSLs. Therefore, the present study aimed to develop a diagnostic score system for SSLs.

MATERIALS AND METHODS

Ethics

This retrospective study was approved by the Ethical Review Committee of the Hattori Clinic on September 4, 2020 (approval No. S2009-U04). Written informed consent was obtained from all participants. All clinical investigations were conducted according to the ethical guidelines of the Declaration of Helsinki.

Patients

We retrospectively reviewed consecutive patients who underwent polypectomy or endoscopic mucosal resection during colonoscopy between July and September 2019 and between January and March 2020 at the Toyoshima Endoscopy Clinic. Colonoscopy was performed to evaluate symptoms such as hematochezia, rectal bleeding, abdominal symptoms, abnormal bowel habits, anemia, or positive fecal immunochemical test findings or for colorectal polyp surveillance. We used an electronic endoscopy reporting system (T-File System; STS Medic, Japan) that was integrated into the clinic's patient record systems.

Endoscopic procedures

The colonoscopies were performed using an Elite CF290 endoscopy system (CV-290 and CLV-290, Olympus, Japan) with a 290 series colonoscope (CF-HQ290Z, CF-HQ290, or PCF-H290Z, Olympus, Japan) or a 260 series colonoscope (PCF-PQ260)[10]. The patients underwent colonoscopies while under conscious sedation with midazolam and/or pethidine hydrochloride. Pancolonic chromoendoscopy was performed by spraying 0.05% indigo carmine[10,11]. All polyps detected by white light imaging during colonoscopy were washed with water, and also assessed by NBI with and without magnification. The colonoscopies were performed by three expert endoscopists (Nishizawa T, Sakaguchi Y, and Toyoshima O).

Endoscopic diagnosis was performed based on the Workgroup on Serrated Polyps and Polyposis classification[12]. We removed lesions diagnosed as adenomas or clinically significant serrated polyps. A clinically significant serrated polyps was defined as any SSL, TSA, or HP measuring ≥ 1 cm anywhere in the colon or HP measuring ≥ 5 mm located proximal to the sigmoid colon[13-15]. We included polyps measuring 15 mm or more in diameter.

The location, size, morphology, and endoscopic diagnosis for each detected polyp were recorded. The location of the polyps was specified as the cecum; ascending, transverse, descending, or sigmoid colon; or rectum. The distal side from the splenic flexure was defined as the distal colon, while the proximal side to the splenic flexure was defined as the proximal colon. The polyp size was estimated by comparison with a closed snare or forceps. The morphology and presence of a mucus cap, indistinct borders, cloud-like surface, varicose microvascular vessels, and expanded crypt opening were also recorded. The mucus cap was defined as coverage with abundant mucus (Figure 1A). Indistinct borders were defined as vague demarcations of the lesion border (Figure 1B). A cloud-like surface appeared granular, nodular, or bumpy and like the surface of a cumulus cloud. Varicose microvascular vessels were defined as vessels thicker than meshed capillary vessels that meandered similar to varicose veins. Expanded crypt opening was defined as the heterogeneous expansion of nearby crypts.

The pathological findings were evaluated by hematoxylin and eosin staining and histological diagnoses were made by an expert gastrointestinal pathologist (H. W.). Serrated lesions were classified as HP, SSL, and TSA according to the World Health Organization classification[16,17]. We collected data on polyps with endoscopic or pathological diagnosis of serrated polyps.

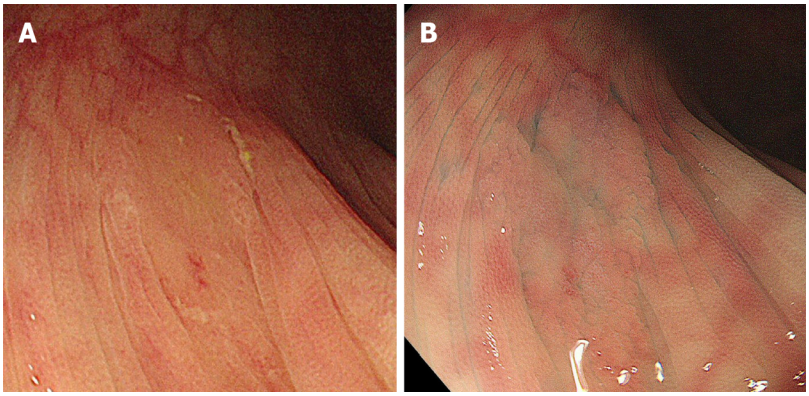

Figure 1 Endoscopic findings regarding sessile serrated lesions. A: "Mucus cap" was defined as coverage with abundant mucus; and B: Indistinct borders were defined as vague demarcations of the lesion border.

Statistical analysis

The significant factors for the diagnosis of SSLs were assessed using logistic regression analysis. The univariate and multivariate analyses included the location (proximal colon) and size (> 5 mm) and presence of mucus cap, indistinct borders, cloud-like surface, varicose microvascular vessels, and expanded crypt opening. Each item that was significant in the multivariate analysis was assigned 1 point and the sum of these points was defined as the endoscopic SSL diagnosis score. The optimal cut-off endoscopic SSL diagnosis score was determined by receiver-operating characteristic (ROC) curve analysis. The calculations were performed using StatMate software, version IV (ATOMS, Tokyo, Japan) and Ekuseru-Toukei 2015 (Social Survey Research Information company, Limited, Tokyo, Japan).

RESULTS

A total of 629 patients underwent colonoscopies with polypectomy or endoscopic mucosal resection. Among 1288 polyps removed from these patients, we identified 232 polyps as endoscopically or pathologically diagnosed serrated polyps. A study flowchart of the included polyps was presented in Figure 2.

The characteristics of the polyps are shown in Table 1. The pathological diagnoses included 72 SSLs, 130 HPs, 1 TSA, 7 adenomas, 20 normal mucosa, and 2 others.

Table 2 shows the results of the univariate and multivariate analyses for the diagnosis of SSL. In the univariate analyses, the location (proximal colon), size > 5 mm, mucus cap, indistinct borders, cloud-like surface, and varicose microvascular vessels were significantly associated with the diagnosis of SSL. On the other hand, expanded crypts opening was not significant in the univariate analysis. In the multivariate analysis, size > 5 mm (P = 0.033), mucus cap (P = 0.005), and indistinct borders (P = 0.033) were independently associated with the diagnosis of SSL. Size > 5 mm, mucus cap, and indistinct borders were each assigned 1 point and the sum of the points was defined as the endoscopic SSL diagnosis score. The minimum and maximum endoscopic SSL diagnosis scores were 0 and 3, respectively. In the ROC curve analysis, the area under the curve was 0.806 and the optimal endoscopic SSL diagnosis score cut-off was 3 (Figure 3A), which corresponded to 75% sensitivity, 80% specificity, and 78.4% accuracy for the prediction of pathological SSL. The ROC curves of the three predictors (size, mucus cap, and indistinct borders) were presented in Figure 3B-D, respectively.

Figure 4 shows the pathological SSL rates for each endoscopic SSL diagnosis score. The pathological SSL rate for an endoscopic SSL diagnosis score of 3 was significantly higher than that for an endoscopic SSL diagnosis score of 0, 1, or 2 (P < 0.001).

DISCUSSION

We found that size > 5 mm, mucus cap, and indistinct borders were independent predictors for SSLs. The combination of these three features in serrated polyps allowed the diagnosis of SSLs with 75% sensitivity, 80% specificity, and 78.4% accuracy.

Various studies have sought to clarify the features of SSLs. Hasegawa *et al*[18] investigated 107 SSLs to discriminate them from other serrated lesions, reporting that the mean lesion size of SSLs was larger than that of HP (14.2 *vs* 6.2 mm; $P < 0.01$). Moreover, SSL was preferentially located in the proximal rather than the distal colon (81.8% *vs* 18.2%), whereas HP was located less often in the proximal colon than in the distal colon.

Hazewinkel *et al*[19] investigated 150 polyps, including 50 SSLs, 50 HPs, and 50

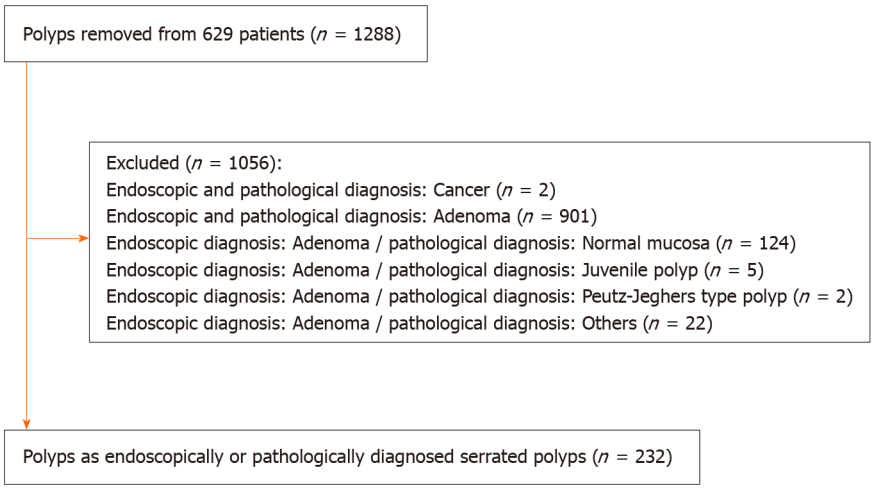

Figure 2 Flowchart of polyp enrollment.

adenomas. Their multivariate analysis demonstrated that indistinct borders [odds ratio (OR): 3.11, P = 0.001] and cloud-like surface (OR: 2.65, P = 0.015) were independent diagnostic factors for SSLs on white-light imaging.

Uraoka *et al*[1] investigated 89 Lesions, including 38 SSLs and 41 HPs. Their multivariate analysis showed that varicose microvascular vessels (OR: 8.2, P = 0.001), size ≥ 10 mm (OR: 7.2, P = 0.002), and proximal location (OR: 6.1, P = 0.004) were independent diagnostic factors for SSLs.

Pereyra *et al*[20] investigated 440 polyps, including 34 SSLs, 135 HPs, and 249 adenomas. Their multivariate analysis showed that flat morphology (OR: 3.81, P = 0.002), red-colored surface (OR: 12.97, P <0.001), right-sided location (OR: 22.21, P <0.001), and mucus cap (OR: 8.77, P < 0.001) were independent diagnostic factors for SSLs.

Murakami *et al*[7] summarized the features of SSLs in their review report, indicating that SSLs were > 5 mm, frequently covered by a mucus cap, and more commonly located in the proximal colon. The features also included small dark spots and varicose microvascular vessels on magnifying NBI and type II open pit patterns on magnifying chromoendoscopy. The small dark spots are nearly synonymous with expanded crypt openings and these are considered to correspond to type II open pit patterns. This phenomenon is likely due to mucin overproduction, which could also lead to the mucus cap[19].

The results of our univariate analysis showed that proximal colon, size > 5 mm, mucus cap, indistinct borders, cloud-like surface, and varicose microvascular vessels were significant factors for the diagnosis of SSLs. Multivariate analysis revealed that size > 5 mm, mucus cap, and indistinct borders were independent predictors for SSLs in our clinical setting.

A combination of endoscopic features has also been previously proposed for the diagnosis of SSL. For instance, Yamada *et al*[21] evaluated the combination of three endoscopic features for SSLs. The combination of dilated and branching vessels (synonymous with varicose microvascular vessels), proximal location, and size (≥ 10 mm) resulted in an area under the curve of 0.7832. The best cut-off point was 2, which corresponded to 79% sensitivity and 81% specificity.

The endoscopic SSL diagnosis score consists of size (> 5 mm), mucus cap, and indistinct borders. The area under the curve in this study was 0.806. The optimal cut-off point was 3, which resulted in 75% sensitivity and 80% specificity. Our score is simple and does not require magnifying NBI. Thus, it may be useful in busy clinical settings or examinations with a scope without a magnifying function.

The present study has several limitations. First, this retrospective study was conducted at a single institution; however, the recording of medical data was well controlled. Second, our study did not perform magnifying chromoendoscopy. A follow-up study is needed to verify the validity of the endoscopic SSL diagnosis score.

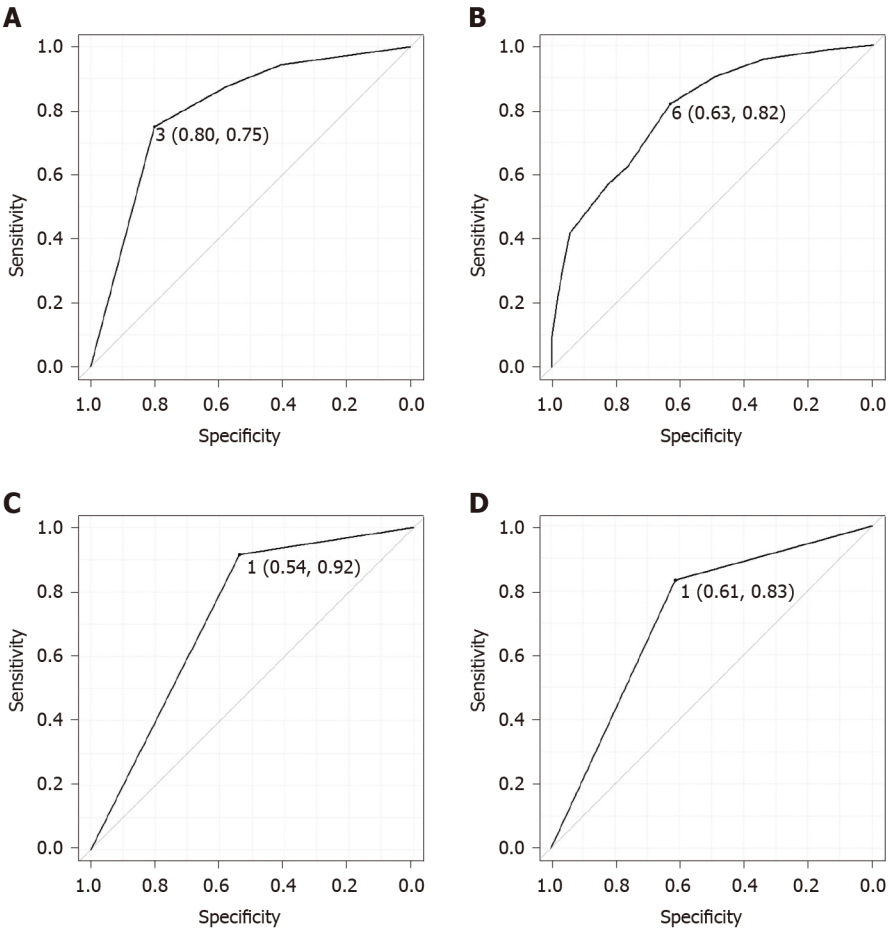

Figure 3 Receiver-operating characteristic curve for predicting sessile serrated lesions. A: Receiver-operating characteristic (ROC) curve for predicting sessile serrated lesion (SSL) based on the endoscopic SSL diagnosis score: The area under the curve (AUC) was 0.806. The optimal cutoff value was 3, for which the endoscopic SSL diagnosis score predicted pathological SSLs with 75% sensitivity and 80% specificity; B: ROC curve for predicting SSL based on polyp size: AUC was 0.801. Size ≥ 6 mm predicted pathological SSLs with 82% sensitivity, and 63% specificity; C: ROC curve for predicting SSL based on mucus cap: AUC was 0.727. The presence of mucus cap predicted pathological SSLs with 92% sensitivity, and 54% specificity; and D: ROC curve for predicting SSL based on indistinct borders: AUC was 0.723. The presence of indistinct borders predicted pathological SSLs with 83% sensitivity, and 61% specificity.

CONCLUSION

In conclusion, size (> 5 mm), mucus cap, and indistinct borders were significant endoscopic features for the diagnosis of SSLs. Serrated polyps with these three features should be removed during colonoscopy.

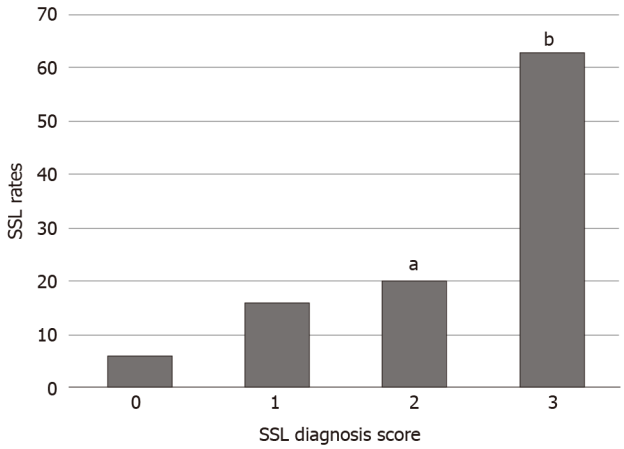

Figure 4 Sessile serrated lesion diagnosis rates based on the endoscopic sessile serrated lesion diagnosis score. [a]*P* < 0.05 compared to an endoscopic Sessile serrated lesion diagnosis score of 0; [b]*P* < 0.001 compared to an endoscopic sessile serrated lesion diagnosis score of 0, 1, or 2. SSL: Sessile serrated lesion.

ARTICLE HIGHLIGHTS

Research background

The serrated neoplastic pathway is responsible for up to 20% of all sporadic colorectal cancers. Sessile serrated lesions (SSLs) should be accurately diagnosed and endoscopically removed.

Research motivation

Various findings have been proposed as features of SSLs. However, accurate diagnosis is often difficult.

Research objectives

This study developed a scoring system to predict the diagnosis of SSLs.

Research methods

We retrospectively reviewed patients who underwent endoscopic resection at the Toyoshima Endoscopy Clinic. We collected data on 232 polyps that were endoscopically or pathologically diagnosed as serrated polyps. The significant factors for the diagnosis of SSLs were assessed using logistic regression analysis.

Research results

In the multivariate analyses, size (> 5 mm; $P = 0.033$), mucus cap ($P = 0.005$), and indistinct borders ($P = 0.033$) were independently associated with a diagnosis of SSL. The endoscopic SSL diagnosis score consisted of three features. An endoscopic SSL diagnosis score of 3 predicted pathological SSLs with 75% sensitivity, 80% specificity, and 78.4% accuracy.

Research conclusions

Size (> 5 mm), mucus cap, and indistinct borders were significant endoscopic features for the diagnosis of SSL. Serrated polyps with these three features should be removed during colonoscopy.

Research perspectives

A follow-up study is needed to verify the validity of the endoscopic SSL diagnosis score.

Abstract

BACKGROUND

The factors affecting the short-term and long-term prognosis of hepatocellular carcinoma (HCC) patients with portal vein tumor thrombosis (PVTT) receiving transarterial chemoembolization (TACE) are still unclear.

AIM

To clarify the predictors correlated with the short-term and long-term survival of HCC patients with PVTT who underwent TACE.

METHODS

The medical records of 181 HCC patients with PVTT who underwent TACE at the Second Affiliated Hospital of Chongqing Medical University from January 2015 to July 2019 were retrospectively analyzed. We explored the short-term and long-term prognostic factors by comparing the preoperative indicators of patients who died and survived within 3 mo and 12 mo after TACE. Multivariate analyses were conducted using logistic regression. The area under the receiver operating characteristic curve (area under curve) was used to evaluate the predictive ability of the factors related to the short-term and long-term prognosis.

RESULTS

The median survival time was 4.8 mo (range: 2.5-8.85 mo). The 3 mo, 6 mo, and 12 mo survival rates were 68.5%, 38.7%, and 15.5%, respectively. In multivariable analysis, total bilirubin, sex, and aspartate aminotransferase (AST) were closely linked to short-term survival. When AST ≥ 87 U/L and total bilirubin ≥ 16.15 μmol/L, the 3-mo survival rate after TACE was reduced significantly ($P < 0.05$). AST had the best predictive ability, followed by total bilirubin, while sex had the worst predictive ability for short-term survival area under curve: 0.763 (AST) *vs*

0.707 (total bilirubin) *vs* 0.554 (sex)]. The long-term survival outcome was significantly better in patients with a single lesion than in those with ≥ three lesions (P = 0.009). Patients with massive block HCC had a worse long-term survival than patients with nodular and diffuse HCC (P = 0.001).

CONCLUSION
AST, total bilirubin, and sex are independent factors associated with short-term survival. The number of tumors and the gross pathological type of tumor are related to the long-term outcome.

Key Words: Transarterial chemoembolization; Hepatocellular carcinoma; Portal vein tumor thrombosis; Survival; Prognostic factors

Core Tip: It is unclear which factors affect the short-term and long-term prognosis of hepatocellular carcinoma patients with portal vein tumor thrombosis receiving transarterial chemoembolization. In our research, we clarified the predictors correlated with the short-term and long-term survival of hepatocellular carcinoma patients with portal vein tumor thrombosis who underwent transarterial chemoembolization by analyzing preoperative indicators. Results showed that aspartate aminotransferase, sex, and total bilirubin were independent factors associated with short-term survival. The number of lesions and the gross pathological type of tumor were related to the long-term outcome.

INTRODUCTION

Primary liver cancer is currently one of the most common malignant tumors, and it is among the top five causes of death and morbidity from malignant tumors around the world[1]. Hepatocellular carcinoma (HCC) is the most common pathological type, accounting for approximately 90% of all primary liver cancers. Because of its biological and anatomical characteristics, HCC easily invades the portal vein during the progression of liver cancer and forms portal vein tumor thrombosis (PVTT). Some reports have proposed that the incidence of HCC with PVTT is approximately 44%-62.2%[2]. HCC accompanied by PVTT is closely associated with a poor prognosis and is likely to lead to intrahepatic metastasis, liver function damage, portal hypertension, upper gastrointestinal bleeding, and other complications. The median overall survival time of HCC patients with PVTT who receive no treatment is only 2.7 mo[3].

There is still controversy about the treatment of HCC with PVTT in Eastern and Western countries. Previous studies have suggested that HCC with PVTT should be classified as stage C of Barcelona Clinic Liver Cancer and is no longer suitable for surgical treatment[4]. Some researchers have mentioned that compared with conservative treatment, TACE is a safe and effective therapy for selected HCC patients with PVTT[5-7]. However, some patients die in the short term after TACE, and patients who have expected postoperative survival times of less than 3 mo may not be suitable for TACE.

At present, the factors affecting the short-term (3 mo) and long-term (12 mo) prognosis of HCC patients with PVTT treated with TACE are still unclear. We aimed to identify the preoperative factors related to the short-term and long-term prognosis by comparing the preoperative clinical data of patients who died in the short-term (< 3 mo) with those who survived into the long-term (> 12 mo) after TACE. The area under the curve (AUC) was utilized to assess the predictability of the factors related to short-term and long-term survival to provide some help for doctors when screening HCC

patients with PVTT to identify those who can benefit from TACE.

MATERIALS AND METHODS

Patient

We enrolled a total of 181 HCC patients with PVTT who received TACE in the Second Affiliated Hospital of Chongqing Medical University from January 2015 to July 2019. The inclusion criteria were as follows: (1) Histopathology confirmed as HCC or clinically diagnosed as HCC; (2) Abdominal color Doppler ultrasound, digital subtraction angiography, contrast-enhanced computerized tomography, or magnetic resonance imaging showed signs of PVTT; (3) No treatment, such as surgery, radiotherapy, chemotherapy, liver transplantation, targeted, or biological therapy, was administered before and after TACE; (4) Age ≥ 18 years; and (5) Complete clinical data were available. Patients with other malignancies or severe heart and lung diseases were eliminated. The follow-up endpoint was July 2020 or the date of death, whichever came first. The follow-up was conducted by telephoning or outpatient visits. During our follow-up, 14 patients received other treatments, such as targeted therapy and High Intensity Focused Ultrasound, and one patient was diagnosed with and treated for a hematologic malignancy. Twenty-six patients were lost to follow-up. The above patients were not included in the study. The study complied with the ethical guidelines of the Declaration of Helsinki in 1964 and passed the review of the Review Committee of the Second Affiliated Hospital of Chongqing Medical University.

Data collection

We collected the basic data of the patients, including sex, age, cause of hepatitis, ascites, hepatoportal arteriovenous fistula, liver cirrhosis, cavernous transformation of the portal vein, Child-Pugh grade, the model for end-stage liver disease score, the Eastern Cooperative Oncology Group score, and albumin-bilirubin grade (ALBI grade). The biochemical parameters included the following indicators: Prealbumin, serum albumin (ALB), total bilirubin, alanine aminotransferase (ALT), aspartate aminotransferase (AST), alpha-fetoprotein, activated partial thromboplastin time, prothrombin time, international normalized ratio, hemoglobin, platelet count, white blood cell count, serum cholinesterase, and gamma-glutamyl transpeptidase. The characteristics of the tumors included the number and size of tumors, the type of PVTT, gross pathological type, invasion of the left and right liver lobes and inferior vena cava tumor thrombus. Cheng's classification of PVTT was applied[8]. The formula for calculating the ALBI score was as follows: ALBI = log10 bilirubin × 0.66 + albumin × (-0.085)[9]. Gross pathological types of liver cancer included the massive block type, the nodular type, and the diffuse type. The clinical diagnostic criteria for patients with HCC are in line with the European Society for Medical Oncology Clinical Practice Guidelines[10].

TACE procedure

The puncture of the artery used Seldinger technology. The right femoral artery was often selected. The catheter was delivered to the celiac trunk and the common hepatic artery, and arteriography was performed to identify the tumor's nutrient artery. The catheter was sent into the tumor-feeding artery and injected with chemotherapy drugs. Chemoembolization drugs commonly included lipiodol, polyvinyl alcohol particles, cisplatin, bleomycin, gelatin sponge particles, *etc*.

Statistical analysis

The mean ± SD or median were used to express the continuous variables. Categorical variables are presented as *n* (%). Two groups of data were compared using independent-samples *t* tests, Mann-Whitney *U* tests, χ^2 tests or Fisher's exact tests. The statistically significant indicators in the univariate analysis ($P < 0.05$) were selected in multivariate analysis in the study. The independent predictors for survival were determined by logistic regression analysis. The predictive ability of the independent predictors for short-term survival was assessed by the AUC. The cutoff value was calculated by the receiver operating characteristic (ROC) curves. The Kaplan-Meier method was used to plot the survival curves. SPSS 25.0 software (Armonk, NY, United States) was used to perform all statistical analyses. When $P < 0.05$, the statistical results were considered significant.

RESULTS

Patient basic characteristics

A total of 181 HCC patients with PVTT who underwent TACE were enrolled in our study. Their baseline data are shown in Table 1. The average age of the patients was 52.16 ± 9.73 years. The 3 mo, 6 mo, and 12 mo survival rates were 68.5%, 38.7%, and 15.5%, respectively. In our study, 159 patients (87.8%) were men and 22 patients (12.2%) were women, hepatitis B patients accounted for 90.1%, and 133 (73.5%) patients had a background of cirrhosis. According to the type of PVTT, 29 (16%) patients, 77 (42.5%) patients, 68 (37.6%) patients, and 7 (3.9%) patients were classified as having type I, II, III and IV PVTT, respectively. For the Child-Pugh grade, 123 (68%) had grade A, 55 (30.4%) had grade B, and 3 (1.6%) had grade C. Patients with greater than or equal to 3 lesions accounted for 48.1%. The median survival time was 4.8 mo.

Short-term survival outcome

Of the 181 patients, 56 patients died within 3 mo after interventional therapy, and 125 patients survived. The clinical data of patients who died and survived within 3 mo after treatment were compared. The results of the univariate analysis are shown in Table 2. Multivariate analysis showed that total bilirubin [odds ratio (OR): 1.027, 95% confidence interval (CI): 1-1.054 P = 0.046), sex (OR: 2.832, 95%CI: 1.025-7.828, P = 0.045] and AST (OR: 1.014, 95%CI: 1.006-1.021, P < 0.01) were significant independent predictors of short-term survival (Table 3).

The AUC was used to evaluate the predictive ability of these indicators for short-term survival. AST (AUC: 0.763, 95%CI: 0.686-0.841) had the best predictive ability, followed by total bilirubin (AUC: 0.707, 95%CI: 0.627-0.788), while sex (AUC: 0.554, 95%CI: 0.461-0.648) had the worst predictive ability (Figure 1).

The cutoff values of the above indicators were calculated by using ROC curves, and the 3-mo cumulative survival rates of patients with AST < 87 U/L and AST ≥ 87 U/L were 84.6% and 40.6% (Figure 2A), respectively. The difference was significant (P < 0.001). The 3-mo cumulative survival rates of the patients with total bilirubin < 16.15 μmol/L and bilirubin ≥ 16.15 μmol/L were 86.9% and 53.6% (Figure 2B), respectively, and the difference was statistically significant (P < 0.001). The 3-mo cumulative survival rates of men and women were 71.1% and 50% (Figure 2C), respectively. The discrepancy was statistically significant (P = 0.019).

Long-term survival outcome

Of the 181 patients, 150 died within 12 mo after interventional therapy, and 31 survived. Univariate analysis showed that the number of tumors, invasion of the left and right liver lobes, pathological type, platelet count, and gamma-glutamyl transpeptidase were correlated with the long-term survival of patients (Table 4), and logistic regression analysis showed that the number of lesions and pathological type were independent predictors of long-term survival (Table 3). The long-term survival outcome was significantly better in patients with a single lesion than in those with ≥ three lesions (OR: 5.809, 95%CI: 1.563-21.594, P = 0.009). Patients with massive block HCC had a worse long-term survival than patients with nodular and diffuse HCC (OR: 0.197, 95%CI: 0.075-0.521, P = 0.001).

We used ROC curves to evaluate the predictability of the number of tumors and pathology for long-term survival. Number of tumors (AUC: 0.665, 95%CI: 0.568-0.763) had the best predictive ability, followed by gross pathology (AUC: 0.620, 95%CI: 0.510-0.730) (Figure 3).

DISCUSSION

In this paper, we found that sex, AST, and total bilirubin were independent influential factors for short-term survival. The incidence and mortality of HCC in men were higher than in women[11]. This was different from the conclusion in our article. The main reason was the imbalance of gender ratio in the article. The AUC of sex was not high (AUC: 0.554, 95%CI: 0.461-0.648, P > 0.05), which showed that although sex was an independent factor influencing short-term prognosis, its predictability was not well.

Total bilirubin was a biochemical indicator of liver metabolic function. Carr *et al*[12] believed that high levels of serum bilirubin can increase the risk of death in HCC patients with PVTT. In our study, it was also found that elevated bilirubin levels were associated with poor short-term survival in HCC patients with PVTT who underwent TACE. According to the AUC of bilirubin, we thought that this indicator had good

Table 1 Characteristic of the 181 patients

Parameters	Patients, *n* = 181
Age in yr	52.16 ± 9.73

MELD score	7.67 (6.08-9.54)
Overall survival time, mo	4.8 (2.5-8.85)

AFP: Alpha fetoprotein; ALBI: Albumin-bilirubin; ALT: Alanine aminotransferase; APTT: Activated partial thromboplastin time; AST: Aspartate aminotransferase; CTPV: Cavernous transformation of the portal vein; ECOG: Eastern Cooperative Oncology Group; GGT: Gamma-glutamyl transpeptidase; INR: International normalized ratio; MELD: Model of end-stage liver disease; PLT: Platelets; PVTT: Portal vein tumor thrombosis; WBC: White blood cell.

predictive power. When total bilirubin was greater than 16.15 μmol/L, the patients' mortality within 3 mo after TACE was significantly increased. This suggested that for patients with preoperative total bilirubin greater than 16.15 μmol/L, the treatment of lowering the bilirubin level may be beneficial in reducing the short-term postoperative mortality.

AST level is elevated in patients with liver disease, reflecting the degree of liver

Table 2 Univariate analysis of survivors *vs* non-survivors at 3 mo after transarterial chemoembolization

Parameters	Survivors, *n* = 125	Non-survivors, *n* = 56	*P* value

damage[13]. In this study, AST was found to be closely related to short-term survival after TACE, while ALT was not found to be associated with short-term survival after interventional treatment.

Xie *et al*[14] suggested that the total cause mortality rate, liver disease mortality and liver cancer mortality rate of those with elevated AST were higher than those of the correspondingly elevated ALT patients. This may mean that patients with

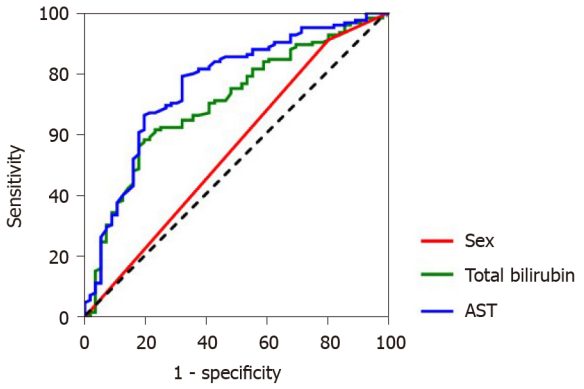
AST: Aspartate aminotransferase; CI: Confidence interval; OR: Odds ratio.

preoperative high levels of AST do not obtain good short-term survival from TACE. When AST ≥ 87 U/L, the 3-mo mortality rate after TACE increased significantly, which indicated that correcting high levels of AST before TACE may be an effective measure to reduce short-term mortality.

In long-term survival analysis, we found that patients with only one lesion had better long-term survival than those with ≥ three lesions. Liu *et al*[15] obtained the same conclusion. Second, patients with massive block liver cancer had a worse long-term outcome than patients with nodular and diffuse liver cancer. This study used the gross pathological type of liver cancer because some patients were clinically diagnosed with liver cancer, and it was not possible to obtain liver tissue biopsy results. The gross pathological type could be judged by imaging, and its clinical applicability was better. However, in this research, the sample size of patients with the diffuse type of liver cancer was small, and this conclusion may need to be further validated in a larger sample size.

In addition, most patients had a background of viral hepatitis in the study, which was different from some areas. This may limit the application of our findings in regions where the cause of liver cancer was non-viral hepatitis. Therefore, research in other countries or regions may be needed to make up for the shortcoming of our study. Because patients with viral hepatitis accounted for the majority, model for end-stage liver disease scores in our study were higher than those of patients whose cause of liver cancer was alcohol or cholestasis.

The following limitations existed in this study. First, this study was a single-center, retrospective study, and it was difficult to avoid selection bias. Second, perhaps because of the small sample size, AUC value was not high, but the AUC value was still statistically significant. The larger and multicenter studies are needed to validate further the results in the future.



CONCLUSION

In summary, sex, AST, and total bilirubin were associated with the short-term survival outcomes in HCC patients with PVTT who underwent TACE. According to the AUC, AST was the best predictor of short-term survival, followed by total bilirubin. Multiple tumor lesions and massive block types of liver cancer were closely related to long-term adverse survival outcomes in HCC patients with PVTT who underwent TACE. In the future, multi-center, prospective and large sample studies are needed to verify these results.

ARTICLE HIGHLIGHTS

Research background

Hepatocellular carcinoma (HCC) patients with portal vein tumor thrombosis (PVTT) have poor prognosis. Transarterial chemoembolization (TACE) is an effective treatment for HCC patients with PVTT. The factors affecting the short-term and long-term prognosis of HCC patients with PVTT receiving TACE are still unclear.

Research motivation

The main aim of this study was to clarify the predictors correlated with the short-term and long-term survival of HCC patients with PVTT who underwent TACE.

Research objectives

We can provide some guidance to clinicians for selecting suitable patients for TACE by analyzing preoperative indicators.

Research methods

A total of 181 HCC patients with PVTT who underwent TACE were enrolled in this retrospective study. We explored the short-term and long-term prognostic factors by comparing the preoperative indicators of patients who died and survived within 3 mo and 12 mo after TACE. Multivariate analyses were conducted using logistic regression. The area under the receiver operating characteristic curve was used to evaluate the predictive ability of the factors related to the short-term and long-term prognosis.

Research results

Total bilirubin, sex, and aspartate aminotransferase (AST) were closely linked to short-term survival. When AST ≥ 87 U/L and total bilirubin ≥ 16.15 μmol/L, the 3-mo survival rate after TACE was reduced significantly. In long-term survival analysis, we found that patients with only one lesion had better long-term survival than those with ≥ three lesions. Patients with massive block liver cancer had a worse long-term outcome than patients with nodular and diffuse liver cancer.

Research conclusions

Sex, AST, and total bilirubin were associated with short-term survival outcomes in HCC patients with PVTT who underwent TACE. According to the area under the curve, AST was the best predictor of short-term survival, followed by total bilirubin. Multiple tumor lesions and massive block types of liver cancer were closely related to long-term adverse survival outcomes in HCC patients with PVTT who underwent TACE.

Research perspectives

Larger and multicenter studies are needed to validate further the results in the future.

Abstract

BACKGROUND

Irritable bowel syndrome (IBS) is a common functional gastrointestinal disorder. Dysregulation of the gut–brain axis plays a central role in the pathophysiology of IBS. It is increasingly clear that the microbiome plays a key role in the development and normal functioning of the gut–brain axis.

AIM

To facilitate the identification of specific areas of focus that may be of relevance to future research. This study represents a bibliometric analysis of the literature pertaining to the microbiome in IBS to understand the development of this field.

METHODS

The data used in our bibliometric analysis were retrieved from the Scopus database. The terms related to IBS and microbiome were searched in titles or abstracts within the period of 2000–2019. VOSviewer software was used for data

open-access article that was selected by an in-house editor and fully peer-reviewed by external reviewers. visualization.

RESULTS
A total of 13055 documents related to IBS were retrieved at the global level. There were 1872 scientific publications focused on the microbiome in IBS. There was a strong positive correlation between publication productivity related to IBS in all fields and productivity related to the microbiome in IBS ($r = 0.951$, $P < 0.001$). The United States was the most prolific country with 449 (24%) publications, followed by the United Kingdom ($n = 176$, 9.4%), China ($n = 154$, 8.2%), and Italy ($n = 151$, 8.1%). The h-index for all retrieved publications related to the microbiome in IBS was 138. The hot topics were stratified into four clusters: (1) The gut–brain axis related to IBS; (2) Clinical trials related to IBS and the microbiome; (3) Drug-mediated manipulation of the gut microbiome; and (4) The role of the altered composition of intestinal microbiota in IBS prevention.

CONCLUSION
This is the first study to evaluate and quantify global research productivity pertaining to the microbiome in IBS. The number of publications regarding the gut microbiota in IBS has continuously grown since 2013. This finding suggests that the future outlook for interventions targeting the gut microbiota in IBS remains promising.

Core Tip: This is the first study to evaluate and quantify the global research productivity pertaining to the microbiome in irritable bowel syndrome (IBS). We present a holistic picture of this emerging topic and explore future research directions. A number of abnormalities have been described within the microbiome of patients with IBS. The relationships of these abnormalities to the causality of dysfunction and associated symptomatology have not been clearly elucidated. Our finding, while preliminary, suggests that the future outlook for interventions targeting the gut microbiota in IBS remains promising.

INTRODUCTION

Irritable bowel syndrome (IBS) is a term used to describe a group of symptoms, including abdominal pain and altered bowel habits, that arises because of disturbances of the interactions between the diet, the brain, the gut, and the microbiome. IBS poses a significant disease burden, with 20% of adults estimated to develop IBS symptoms in any given year. Symptoms arise as a consequence of abnormal visceral sensation and or motility as a result of abnormalities within the enteric or central nervous systems, or both[1]. This usually occurs in the absence of 'organic' disease, but the association with other gastrointestinal diseases is common. Many patients experiencing gastrointestinal inflammation due to infection or inflammatory bowel disease develop IBS symptoms[2]. Nearly a quarter of patients with IBS without identifiable 'organic' disease appear to have low-grade intestinal inflammation as judged by faecal inflammatory markers (calprotectin)[3]. Inflammation may lead to sensitization of peripheral nerves. Most inflammation within the gastrointestinal tract settles, but in susceptible individuals sensitization of peripheral afferents may persist. Such sensitization may be driven by ongoing mast cell activation and increased epithelial

permeability associated with low-level inflammation[4].

The onset of symptoms in IBS is often associated with psychological stressors. A high proportion of people with IBS have psychological comorbidities. Chronic stress is associated with stress-induced hyperalgesia. This hyperalgesia is mediated *via* corticotrophin-releasing hormone and the hypothalamic–pituitary axis (HPA)[5]. Dysfunction within these systems is well documented in patients with functional gastrointestinal disorders and other chronic pain syndromes. Furthermore, many patients have histories of traumatic events in early life. These events may result in changes that profoundly affect the microbiome and brain development, predisposing patients to visceral pain syndromes[6-8]. In addition to direct effects on neurons proximal to the bowel, bacteria and their products have a profound effect on the development and activity of the central nervous system and, consequently, upon the psychological state and behaviors[9]. Within the enteric nervous system, certain bacterial strains may directly promote sensitization or downregulation of peripheral afferents. Of note, low-grade inflammation seen in a proportion of patients with IBS may result from the ability of specific bacteria to enhance the production and the effects of proinflammatory cytokines. Bacteria may also be able to transmit signals *via* the enteric nervous and immune systems to the central nervous system[10].

Although several bibliometric studies have been conducted to evaluate research productivity regarding various research aspects in the medical field[11-18], and some bibliometric studies have focused on microbiota science[19-25], there has not been an assessment of the research output regarding the microbiome in IBS. This study undertakes a bibliometric analysis of the literature within this field to understand the development of the literature pertaining to the microbiome in IBS and to facilitate the identification of specific areas of focus that may be of relevance to future research. This study evaluates data that will help to address the research gaps in this field. The current bibliometric study plays a significant role for researchers interested in the relationship between the microbiome and IBS, because it offers a quick reference guide for interdisciplinary researchers to know how this field has been assessed by scientific experts in previous years.

MATERIALS AND METHODS

The data used in our bibliometric analysis were retrieved from Scopus, which is a multidisciplinary database owned by Elsevier and is considered the largest and most widely used database[26-28]. Most of the publications in this field were published between 2000 and 2019. The following term combinations were searched in the title or abstract within this period: Terms related to IBS, *i.e.*, 'adaptive colitis' OR 'colon spasm' OR 'functional bowel disease' OR 'irritable bowel' OR 'irritable colon' OR 'membranous colitis' OR 'mucous colitis' OR 'spastic colitis' OR 'spastic colon' OR 'spastic bowel' OR 'functional colonic disease' OR 'colon irritable' OR 'colon neurosis' OR 'bowel neurosis' OR 'functional colopathy' OR 'functional colonopathy' OR 'chronic catarrhal colitis' OR 'colica mucosa' OR 'colonic enterospasm' OR 'dyskinesia of the colon' OR 'dyssynergia of the colon' OR 'functional enterocolonopathy' OR 'functional diarrhea' OR 'Glarry enteritis' OR 'glutinous diarrhea' OR 'intestinal croup' OR 'irritable gut syndrome' OR 'lienteric diarrhea' OR 'Membranous catarrh of the intestine' OR 'mucomembranous colic' OR 'myxoneurosis' OR 'nervous diarrhea' OR 'neurogenic mucous' OR 'nonspecific diarrhea' OR 'tubular diarrhea' OR 'unhappy colon' OR 'unstable colon', and terms related to microbiome, *i.e.*, 'microbiome' OR 'microflora' OR 'microbiota' OR 'flora' OR 'probiotic' OR 'Saccharomyces' OR 'Lactobacillus' OR 'Bifidobacterium' OR 'Escherichia coli'. The terms were selected from related reviews on IBS[29,30] and the microbiome[19,20,31-33].

Data analysis

Microsoft Excel was used to analyze the retrieved data to calculate frequencies and percentages. The current bibliometric study included quantitative data about document types, language, country of the publications with their h-index and collaboration pattern, authors of the publications, journals that published papers on IBS, microbiome documents, and citation reports. In addition, we used the Statistical Package for the Social Sciences 16.0 software for Windows to assess the correlation between yearly quantitative distributions of publications related to IBS in all fields and publications related to the microbiome in IBS by using the Pearson correlation test. Analysis with $P < 0.05$ is considered statistically significant. In addition, the VOSviewer program[34,35] was used for mapping and clustering terms according to their

occurrence in both titles and abstracts to determine hot topics in this field. Furthermore, network visualization maps for collaboration among the most productive countries and the most prolific authors in this field were prepared using VOSviewer.

RESULTS

A total of 13055 documents related to IBS in titles and abstracts were retrieved over the period of 2000–2019 at the global level. There were 1872 scientific publications focused on the microbiome in IBS. The research findings showed that English was the main research language of documents indexed in Scopus, accounting for 48.8% of the documents, followed by German (3.9%) and Chinese (2.9%). Articles were the main type of document for publications related to the microbiome and IBS, accounting for 51.9% of documents, followed by reviews (35.3%).

The number of publications related to the microbiome in IBS has increased year by year. The quantity of documents has increased each year, from 9 documents in 2000, to 84 documents in 2009, to 219 documents in 2019 (Figure 1). Published papers during the last 5 years (2015 to 2019) accounted for 47.0% of the total publications. There was a strong positive correlation between the publication productivity related to IBS in all fields and the productivity related to the microbiome in IBS ($r = 0.951$, $P < 0.001$).

In total, authors from 105 countries published their work on the microbiome and IBS topics. Table 1 lists the top 10 most prolific countries. The United States was the most prolific country with 449 (24%) publications, followed by the United Kingdom ($n = 176$, 9.4%), China ($n = 154$, 8.2%), and Italy ($n = 151$, 8.1%). The h-index for all retrieved publications related to the microbiome in IBS was 138. Figure 2 shows the network visualization map for the collaboration among the 40 most productive countries. This includes countries that published more than 5 papers on microbiome and IBS research according to the number of publications in the last two decades (2000–2019). The United States and the United Kingdom can be referred to as central countries for this network because they published research in collaboration with 40 and 31 countries, respectively. In total, 5960 authors published their work on the microbiome and IBS topics. Figure 3 shows the network visualization map for the collaboration among the 32 most productive authors (authors who published more than 10 papers) on the microbiome in IBS research according to the number of publications in the last two decades (2000–2019). EMM Quigley (United States), G Barbara (Italy), JF Cryan (Ireland), and TG Dinan (Ireland) can be considered the prolific authors of this network due to the fact that they published 61, 25, 25, and 23 documents, respectively.

Terms were extracted from the titles and abstracts of all retrieved publications related to the microbiome in IBS and analyzed by the VOSviewer software to identify the current state and hot topics in this field. Terms appearing more than 10 times were included in the map (Figure 4) and were stratified into four clusters: IBS related to the gut–brain axis (yellow cluster), clinical trials related to IBS and the microbiome (red cluster), drug-mediated manipulation of the gut microbiome (blue cluster), and the role of the altered composition of intestinal microbiota in IBS prevention (green cluster).

The top 10 journals accounted for 19.98% of all articles (Table 2). The four journals that published the most studies related to microbiome and IBS were *World Journal of Gastroenterology* ($n = 70$), *Alimentary Pharmacology and Therapeutics* ($n = 54$), *Neurogastroenterology and Motility* ($n = 52$), and the *Journal of Clinical Gastroenterology* ($n = 39$).

The sample presents an average citation rate of 42 citations per publication. However, 16.6% of the publications have never been cited. Table 3 lists the information on the top ranking of publications in terms of the highest number of citations[36-55]. The article 'Prebiotic Effects: Metabolic and Health Benefits" is the most cited article with 1147 citations; it was authored by Roberfroid *et al*[49] and published in the *British Journal of Nutrition* in 2010. This study reported that a substantial number of studies about human intervention have shown that dietary intake of food products/ingredients/supplements results in statistically important improvements in the faecal gut microbiota composition. The second most highly cited article is 'Lactobacillus and Bifidobacterium in IBS: Symptom Responses and Relationship to Cytokine Profiles' by O'Mahony *et al*[44] and published in *Gastroenterology* in 2005. This study showed that intake of *Bifidobacterium infantis* over 8 wk was associated with symptomatic improvement in IBS.

Table 4 presents the top 10 most productive institutions on the microbiome in IBS research, ranked by the total number of publications. The four institutions that have published the most studies related to microbiome and IBS are the University College Cork (n = 87), APC Microbiome Ireland (n = 84), McMaster University (n = 45), the Mayo Clinic (n = 32), and Alma Mater Studiorum Università di Bologna (n = 38) (Table 4).

DISCUSSION

This bibliometric study was carried out using data from Scopus for the period of 2000–2019. It presents a comprehensive review of research progress on the microbiome and IBS, identifies hot topics within this field, and indicates potential directions for future research. It is apparent that the research productivity in this field has progressively increased due to the increasing recognition of the role of the gut microbiota[56,57]. In addition, this increase is probably linked to the growing number of

researchers who are interested in the fields of neurology and gastroenterology [*e.g.*, EMM Quigley (the United States), JF Cryan (Ireland), TG Dinan (Ireland), G Barbara (Italy), Y Ringel (the United States), M Simrén (Sweden), M Camilleri (the United States), A Palva (Finland), M Pimentel (Canada), NJ Talley (Australia), and others]. Over the last two decades, advances in our understanding of the enteric and central nervous systems have led to an evolving understanding of their interactions and how the gastrointestinal microbiome influences their function. Disturbances in the gastrointestinal microbiome have been identified in patients with functional gastrointestinal disease, like IBS, and it is often the case that symptoms may be triggered by events that lead to changes in the microbiome, where the emotional context and the enteric nervous system function in tandem[1].

The results of this study indicate that the United States has been the most prolific country in this field. These findings are consistent with many previous bibliometric studies[12,58]. Research productivity in the United States is likely associated with

overwhelming support in terms of research, the wide range of researchers with an interest within this field, several well-resourced research environments, and greater availability of a well-trained workforce. In addition, the economic strength of the United States has led to a substantial amount of financial support for researchers and has enhanced the mobility of researchers[59,60]. Furthermore, in 2013, the United States launched an exceptional research project on the gut microbiota–brain axis[61], thus contributing to the increasing number of publications regarding the microbiome in IBS.

Our study demonstrates that the gut–brain axis has become the most prolific area for research within IBS and the microbiome globally, and several studies in a range of journals are proof of this emerging trend. According to these data, we can infer that central pain amplification occurs through a wide variety of mechanisms within the

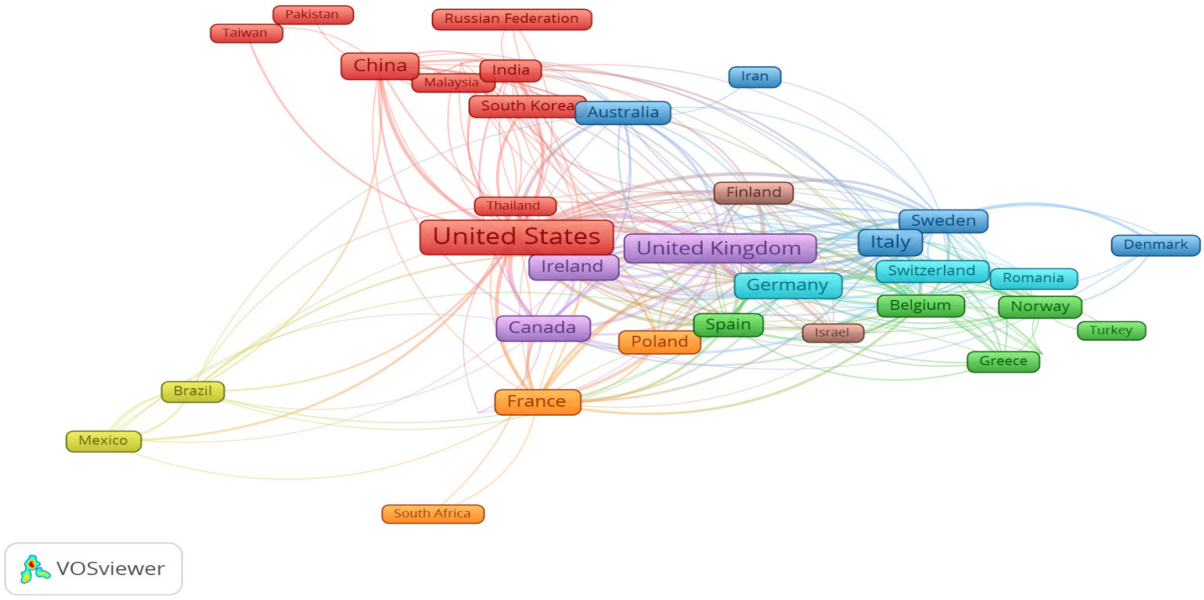

Figure 2 Network visualization map for the collaboration among the 40 most productive countries on the microbiome in irritable bowel syndrome research according to the number of publications in the last two decades (2000–2019).

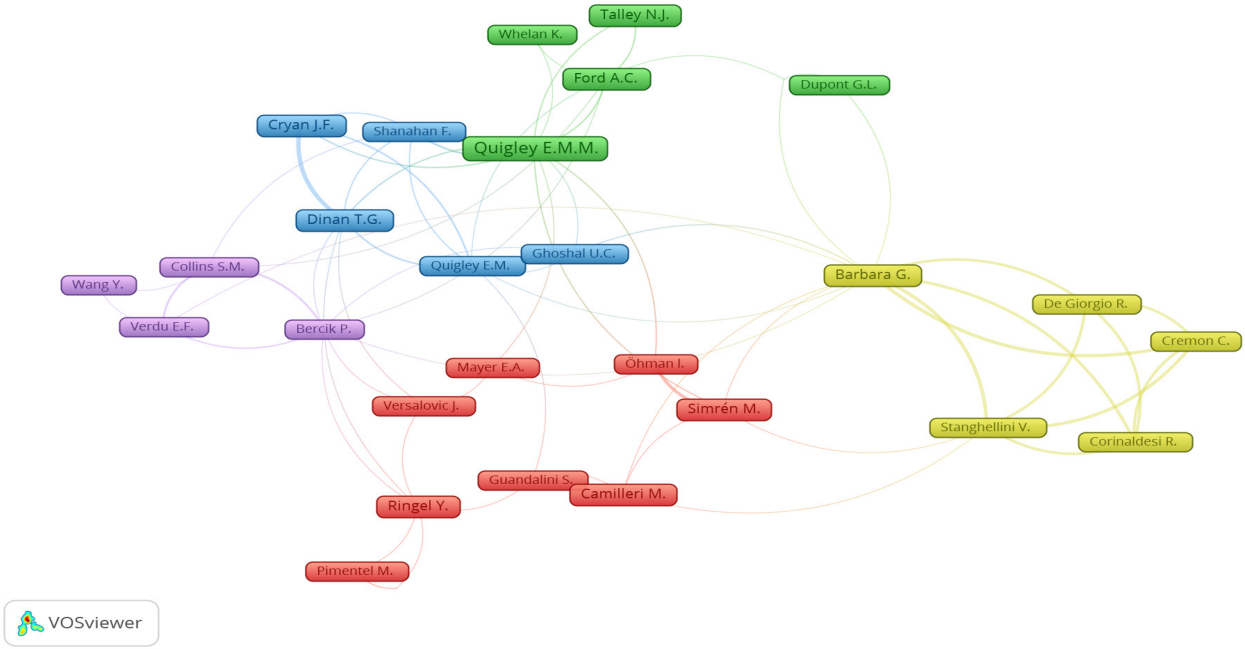

Figure 3 Network visualization map for the collaboration among the 32 most productive authors on the microbiome in irritable bowel syndrome research according to the number of publications in the last two decades (2000–2019).

central nervous system and mediates the effects of mood, emotional context, and environmental circumstances upon our central pain perception. Functional magnetic resonance imaging (fMRI) studies have demonstrated that patients with IBS often display an exaggerated response of arousal circuits associated with the HPA and activation of endogenous pain pathways in response to visceral stimulation. Similarly, studies have shown enhanced anticipation of pain in response to conditioning stimuli in patients with functional gastrointestinal disease[62]. Neuro-immune activation within the central nervous system is associated with altered astrocyte and microglial activity that further enhances central sensitisation.

Early deprivation in patients with IBS can have profound effects on the microbiome, and researchers recognise that these factors may predispose susceptible individuals to more severe IBS[8,63-66]. Changes in central nervous system function arise as a result of

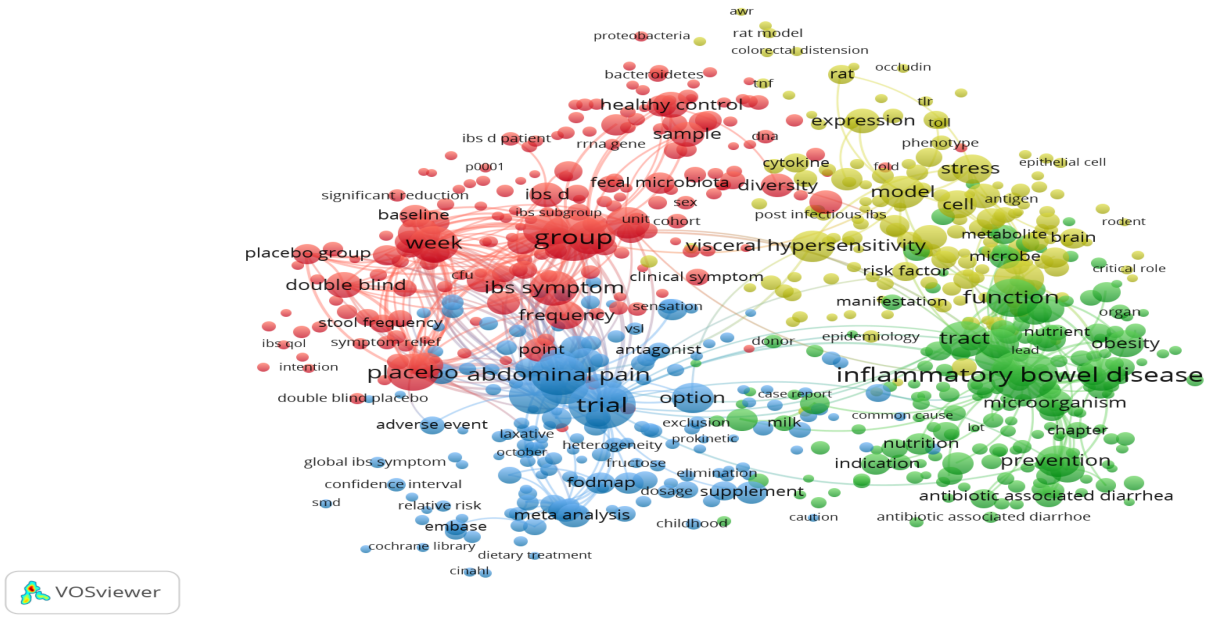

Figure 4 Network visualization map for the terms with high co-occurrence frequencies, based on the titles and abstracts of documents related to the microbiome in irritable bowel syndrome research published in the last two decades (2000–2019).

microbial products, which then influence astrocyte, microglial, and central nervous system inflammatory responses[67]. Certain bacterial strains, possibly as a result of being able to modulate these effects, may influence behaviour. Offspring of mice fed a high-fat diet display disordered behaviour and socialisation. These behavioural changes appear to be manifested by alterations in the microbiome. Correction of 'bacterial deficits' or their metabolic sequelae leads to improvements in behaviour. Specific bacterial strains have been demonstrated to increase resilience in individuals with anxiety, and these behavioural changes have neurological correlates in fMRI studies. Those factors known to provoke IBS have profound effects on the microbiome function; gastroenteritis can deplete the microbiome, and psychological stress can lead to significant changes in the representation of different phyla within the microbial flora. These potentially detrimental changes may facilitate feedback from the gut and, consequently, permit the gut to have effects on mood, behaviour, and cognitive functions.

Limitations

There are some limitations in our study that are similar to previous bibliometric studies. First, although Scopus is the most recognized and the largest database for peer-reviewed literature, our study is restricted to only the Scopus database as a source of data collection. Second, some authors or institutions have different name formats in the Scopus database, and their research count might be scattered; therefore, their names might not show in the active list. Despite these limitations, we still consider that the findings of our analysis were adequate to characterize accurately the state of IBS and microbiome research at the global level.

CONCLUSION

This is the first study to evaluate and quantify the global research productivity pertaining to the microbiome in IBS to present a holistic picture of this emerging topic and explore future research directions. The number of publications regarding the gut microbiota in IBS has continuously grown since 2013. The United States, the United Kingdom, Italy, and Ireland have been the most productive regions. Currently, the main hot topics regarding the gut microbiota in IBS are the gut–brain axis related to IBS, clinical trials related to IBS and the microbiome, drug-mediated manipulation of the gut microbiome, and the role of the altered composition of intestinal microbiota in IBS prevention. A number of abnormalities have been described within the microbiome of patients with IBS. The relationship between these abnormalities and the causality of dysfunction and associated symptomatology have yet to be clearly

elucidated. Our findings, while preliminary, suggest that the future outlook for interventions targeting the gut microbiota in IBS remains promising.

ARTICLE HIGHLIGHTS

Research background

The ability of specific bacteria to boost the development and the effects of proinflammatory cytokines can result in low-grade inflammation seen in a proportion of patients with irritable bowel syndrome (IBS).

Research motivation

The current bibliometric analysis plays an important role for researchers interested in the relationship between the microbiome and IBS. It provides a simple reference guide for interdisciplinary researchers to learn how scientific experts have examined this area in previous years.

Research objectives

This study aimed to carry out a bibliometric review of the IBS and the microbiome literature to explain the growth of this field and assist the identification of unique focus areas that may be important for future research.

Research methods

The information used in our bibliometric research was derived from the Scopus database. Terms related to IBS and the microbiome were searched in titles or abstracts during the period of 2000–2019. For data visualization, VOSviewer software was used.

Research results

Since 2013, the number of publications on gut microbiota in IBS has continuously increased. This result indicates that the future outlook remains optimistic for treatments targeting the gut microbiota in IBS.

Research conclusions

This is the first study to analyze and measure the global research productivity of IBS and microbiome research to provide a holistic view of this evolving subject and explore future research directions. It is evident that, due to the growing understanding of the role of the gut microbiota, research productivity in this area has steadily increased. Currently, the key hot topics are the gut–brain axis related to IBS, clinical trials related to IBS and the microbiome, drug-mediated modulation of the gut microbiome, and the role of the altered composition of the intestinal microbiome in the prevention of IBS.

Research perspectives

Our results indicate that the future outlook for IBS therapies targeting the intestinal microbiota remains promising.

Abstract

BACKGROUND

Rectal subepithelial lesions (SELs) are commonly seen in endoscopic examination, generally manifested as bumps with a smooth surface. Precise preoperative diagnoses for rectal SELs are difficult because abnormal tissues are not easily to be obtained by regular endoscopic forceps biopsy. Traditional guidance modalities of preoperative biopsy, including endoscopic ultrasound, computed tomography, and transabdominal ultrasound, are often unsatisfactory. An updated, safe, and effective biopsy guidance method is required. We herein report a new biopsy guidance modality—endorectal ultrasound (ERUS) combined with contrast-enhanced ultrasound (CEUS).

CASE SUMMARY

A 32-year-old woman complained of a mass inside the rectovaginal space for 9 years, which became enlarged within 1 year. A rectal SEL detected by endoscopy was suspected to be a gastrointestinal stromal tumor or exophytic uterine fibroid. Pathological diagnosis was difficult because of unsuccessful transabdominal core needle biopsy with insufficient tissues, as well as vaginal hemorrhage. A second biopsy was suggested after multiple disciplinary treatment discussion, which referred to a transperineal core needle biopsy (CNB) guided by ERUS combined with CEUS. Adequate samples were procured and rectal gastrointestinal stromal tumor was proved to be the pathological diagnosis. Imatinib was recommended for first-line therapy by multiple disciplinary treatment discussion. After the

tumor shrunk, resection of the rectal gastrointestinal stromal tumor was performed through the posterior vaginal wall. Adjuvant therapy was applied and no recurrence or metastasis has been found by the last follow-up on December 13, 2019.

CONCLUSION

Transperineal CNB guided by ERUS and CEUS is a safe and effective preoperative biopsy of rectal SELs yet with some limitations.

Key Words: Transperineal core needle biopsy; Endorectal ultrasound; Contrast-enhanced ultrasound; Rectal subepithelial lesion; Case report

Core Tip: Rectal subepithelial lesions (SELs) often manifest as bumps with a smooth surface on endoscopy. An efficient biopsy strategy is crucial to sampling for differentiation of pathological types. The transperineal core needle biopsy guided by endorectal ultrasound combined with contrast-enhanced ultrasound overcomes the limitations of previous guidance, such as sampling inadequacy, high risk of complications, and exposure to radiation. In our case, unsuccessful transabdominal biopsy led to failure of pathological diagnosis. The patient underwent this new biopsy modality then, and a diagnosis was finally made. No complications occurred. We recommend this new strategy as a promising tool for rectal SEL biopsy.

INTRODUCTION

Rectal subepithelial lesions (SELs) vary in types and there have been many studies on the diagnostic value of ultrasound (US). Pelvic lipomas, gastrointestinal stromal tumors (GISTs), carcinoid tumors, leiomyomas, schwannomas, and lymphomas often originate from the anorectum[1,2]. These tumors are apt to manifest as rectal SELs on endoscopy. Traditional biopsy guidance methods include endoscopy, endoscopic US (EUS), transabdominal ultrasound, and computed tomography (CT), which have been reported with many disadvantages[1-4] to achieve successful biopsies. By application of endorectal US (ERUS) in anorectal and pelvic diseases in our daily work, we found a novel guidance method for rectal SELs biopsy, which is safer and more effective. Out of several preoperative biopsy approaches for rectal SELs, this case report focuses on transperineal core needle biopsy (CNB)[5] guided by contrast-enhanced US (CEUS) combined with ERUS. We present the following case in accordance with the CARE reporting checklist.

CASE PRESENTATION

Chief complaints

A 32-year-old woman was admitted to our hospital with a progressively enlarged mass in the rectovaginal space for 9 years.

History of present illness

The mass was found during a routine examination 9 years ago and no obvious progression was seen in following annual examinations until a year ago. The maximum diameter of the mass had significantly grown from 4.0 cm to 9.7 cm in a year, with dents in stools, which was caused by tumor compression. The patient had a

submucosal protrusion demonstrated by endoscopy in a local hospital. However, no absolute tumor tissue but only inflammation was found after several times of endoscopic biopsies in the latest 2 years, which was not consistent with clinical estimation. Therefore, she came to our hospital for further diagnosis (Table 1).

History of past illness

The patient had no previous medical history.

Personal and family history

The patient and family had no history of previous similar illness.

Physical examination

The patient's mental status, appetite, sleep, and weight were normal without any obvious symptoms of abdominal distension, tenesmus, prolapse, diarrhea, or constipation. The anterior rectum wall was plump during digital rectal examination without tenderness or blood stain on the fingertip.

Laboratory examinations

Laboratory examinations were normal, including routine blood analysis, carcinoembryonic antigen, α-fetoprotein, carbohydrate antigen (CA) 19-9, and CA125.

Imaging examinations

Contrast-enhanced CT (CECT) showed a mass with liquefaction necrosis (low density area) inside the rectovaginal space, with an obscure margin (Figure 1A). Transabdominal US was performed. A heterogeneous hypoechoic mass with a maximum diameter of 9.7 cm was also seen in the rectovaginal space (Figure 2A), which was suspected to be a rectal GIST or exophytic uterine fibroid.

Further diagnostic work-up

Transabdominal CNB (MG1522 BARD MAGNUM Biopsy Instrument; Tempe, AZ, United States; disposable core tissue biopsy needle, gauge size and needle length: 16 G and 16 cm) was performed to make a definite diagnosis (Figure 2B). Before the operation, written informed consent was obtained from the patient, and her preoperative regular laboratory examinations were normal, including routine blood test, coagulation function, and blood transfusion set. Some hemorrhage occurred from the vagina, causing premature end of the biopsy, and spontaneously relieved several days later. Strips of greyish shattered tissue (Figure 3A) were obtained, with the largest diameter smaller than 0.3 cm. Pathology indicated inadequate biopsy tissue for diagnosis. Another biopsy after ERUS assessment was recommended by multiple disciplinary treatment (MDT).

First, ERUS was performed with the MyLab Twice US system (Esaote, Genoa, Italy) equipped with a biplane endoscopic probe (TRT33, linear frequency of 4–13 MHz, convex frequency of 3-9 MHz), recording the location, size, stratification, adjacence, and echogenicity of the tumor. Then CEUS was performed with a bolus injection through the elbow vein of 2.4 mL SonoVue (Bracco, Milan, Italy) (Figure 4). Because of the heterogeneity of the tumor, it was difficult to recognize the necrotic from non-necrotic part in B mode, which can be clearly depicted by CEUS as nonenhanced *vs* enhanced area. As previous CECT has pointed out necrosis, CEUS was performed right before puncture to confirm the substantial part of the tumor for biopsy guidance for the second time, avoiding the failed samples inside presumptive solid area, which turned to be non-enhanced after CEUS. This guarantees the precision and efficiency of biopsy samples.

The probe was switched to linear mode. The transperineal puncture site and path were decided, and disinfection as well as drape were also completed. After local anesthesia, a freehand biopsy of the lesion was performed with the guidance of in-plane needle. The needle tip and its movements were continuously monitored in real time by ERUS during the whole puncture procedure[6] to procure the tissue of lesion from enhanced area of the tumor on CEUS (Figure 5). Several strips of greyish tissue were obtained with a length of 0.3-1.2 cm (Figure 3B and C). No complications occurred.

Table 1 Timeline of diagnosis and treatment process

Time	Events
January 2018	A mass in the rectovaginal space found 9 years ago had significantly grown in a year, with several times of negative endoscopy biopsy results
January 31, 2018	Transabdominal biopsy failed to provide qualified tissues to make well-defined pathological result
February 8, 2018	The patient underwent transperineal biopsy guided by ERUS and CEUS, diagnosed as rectal GIST
July 23, 2018	The tumor shrunk after 5-mo imatinib treatment, and was completely resected through the posterior vaginal wall
October 13, 2019	Fifteen months after tumor resection, no obvious sign of recurrence was found

ERUS: Endorectal ultrasound; CEUS: Contrast-enhanced ultrasound; GIST: Gastrointestinal stromal tumor.

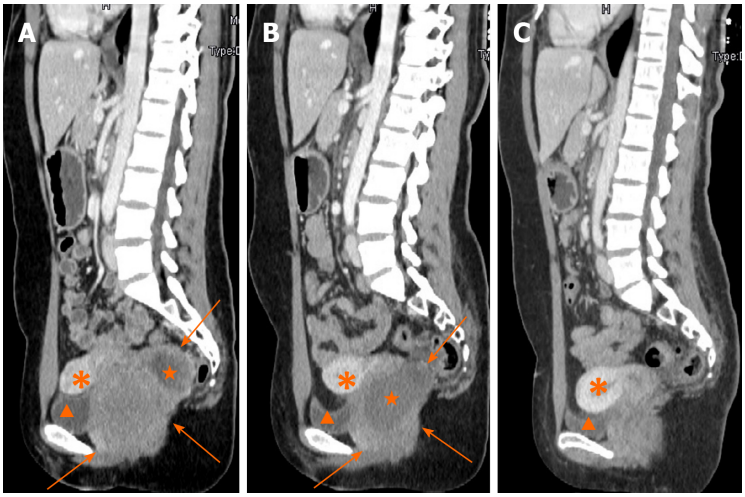

Figure 1 Contrast-enhanced computed tomography in sagittal section. A: A rectovaginal space mass of 8.0 cm in maximum diameter with non-enhancing liquefaction necrosis at the time of admission; B: The mass significantly shrunk to 6.4 cm in maximum diameter after 5 mo of imatinib treatment and non-enhanced liquefaction area enlarged clearly; C: No obvious sign of tumor recurrence in rectovaginal space 15 mo after tumor resection. Arrows: The mass; pentagrams: Liquefaction necrosis area; arrow heads: Bladder; asterisks: Uterus.

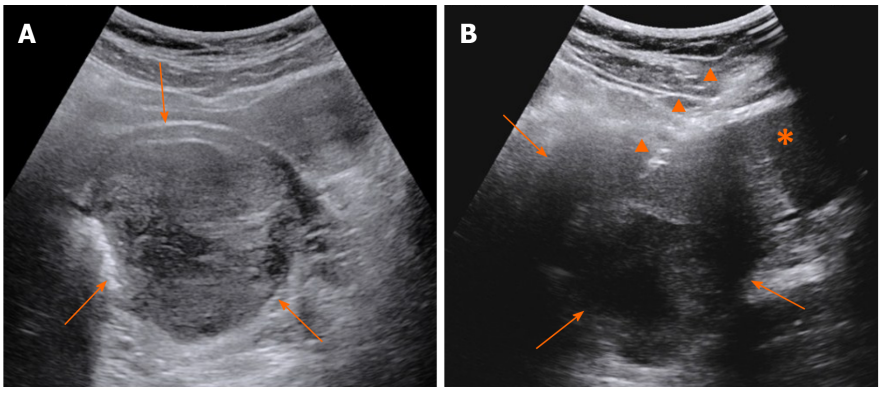

Figure 2 Grey scale ultrasound. A: A mass was demonstrated inside the rectovaginal space in the grey scale images; B: Transabdominal core needle biopsy of the mass. Arrows: The mass; arrow heads: Core needle; asterisk: Uterus cervix.

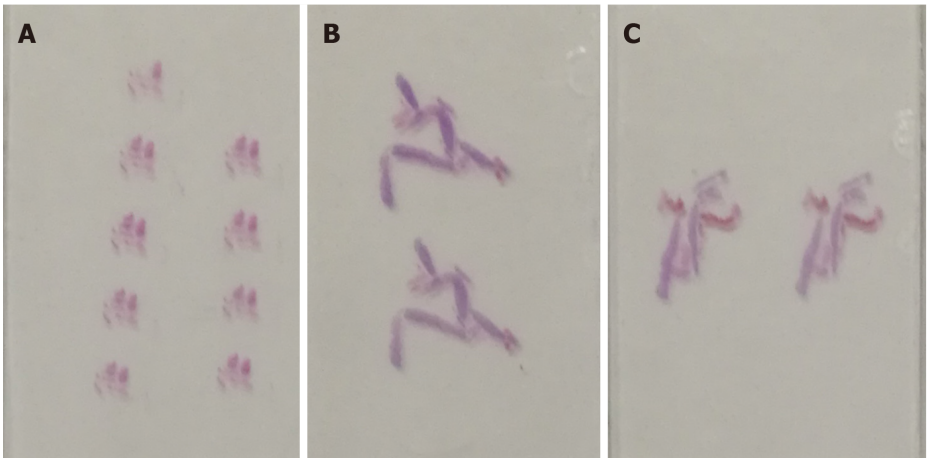

Figure 3 Slide samples. A: The shattered slide samples from transabdominal ultrasound-guided biopsy; B and C: The slide samples from transperineal biopsy guided by endorectal ultrasound, which were abundant and intact.

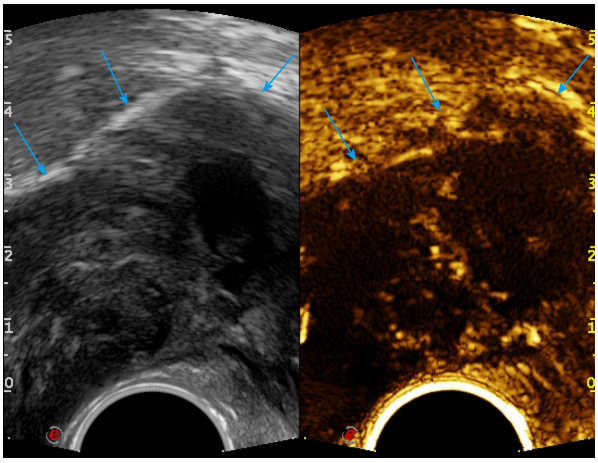

Figure 4 Endorectal ultrasound performed with the convex probe of TRT33. Liquefaction necrosis and cellular appearance were found inside the tumor in transverse sections, and the solid part of the tumor was either hypo- or iso-enhancing. Arrow: Rectal stromal tumor.

FINAL DIAGNOSIS

According to the post-operation immunohistochemical (IHC) staining, CD117, Dog-1, CD34, and succinate dehydrogenase B subunit were positive, and spinal muscular atrophy, Des, and S-100 were negative. The proliferation index of Ki-67 was 2%. The diagnosis was finally settled as GIST with post-therapeutic reaction (Figure 6).

TREATMENT

After the second MDT discussion, imatinib (Gleevec; Novartis, Basel, Switzerland) was decided as first-line therapy. It was suggested to wait for the treatment reaction before making a further therapeutic schedule. After 5 mo, CECT showed that the tumor had significantly shrunk (Figure 1B). The patient underwent complete GIST resection through the posterior vaginal wall. During the surgery, the tumor was found to originate from the rectal muscular layer, close to the posterior vaginal wall, with a smooth capsule, 5.5 cm in maximum diameter. It was greyish white on the cut surface with an interlaced appearance. The postoperative pathology findings were as follows: A suspected spindle cell tumor, interstitial and fibrous tissue proliferation, focal glassy degeneration area accompanied by a few lymphocyte reactions, remote hemorrhage with hemosiderin deposition, and a negative surgical margin.

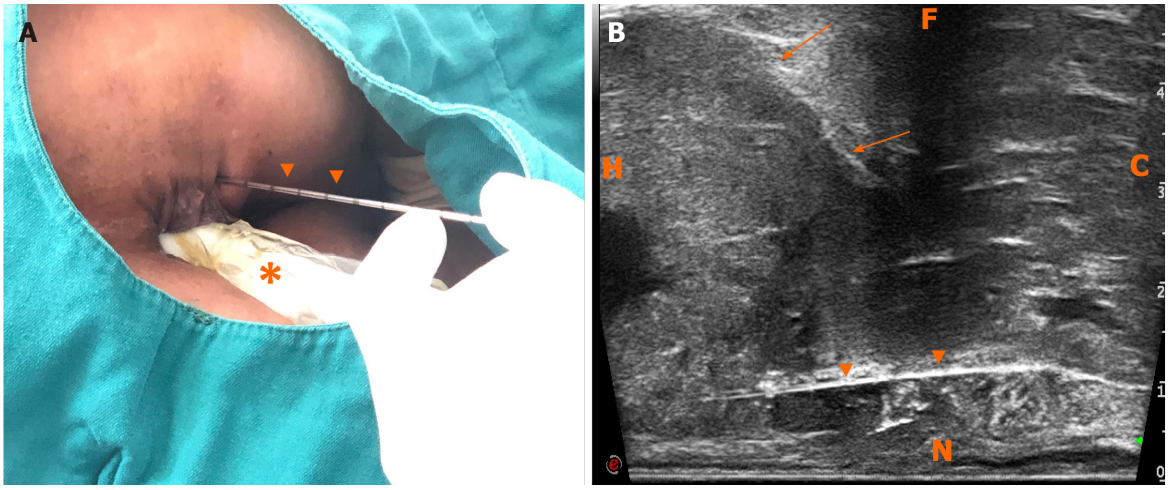

Figure 5 Freehand transperineal biopsy of the rectal subepithelial mass guided by endorectal ultrasound. A: The patient in left lateral decubitus, and the freehand transperineal biopsy was performed, guided by endorectal ultrasound (ERUS); B: Longitudinal sectional image of transperineal core needle biopsy guided by ERUS obtained with the linear probe of TRT33. H: Head; C: Caudal; N: Near field; F: Far field; arrows: Rectal stromal tumor; triangular arrowheads: Core needle; asterisk: TRT33 probe.

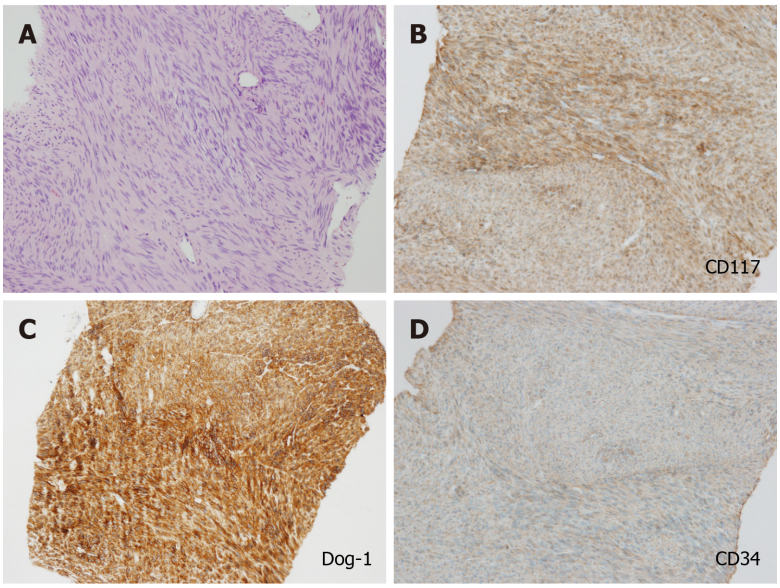

Figure 6 Pathological results. A: A mass consisting of spindle-shaped cells in hematoxylin and eosin staining; B-D: Immunohistochemical staining of the rectal stromal tumor: CD117, Dog-1, and CD34 were strongly positive (low power field).

OUTCOME AND FOLLOW-UP

Fifteen months after resection, CECT of the pelvic cavity on October 26, 2019 (Figure 1C) indicated no obvious sign of tumor recurrence. No recurrence or metastasis has been found either by the last follow-up in December 13, 2019.

DISCUSSION

GISTs are nondirectional differentiated mesenchymal neoplasms that arise anywhere along the digestive tract with an incidence of 3% in the rectum[7]. Approximately 25% of GISTs were found accidently during surgery or by imaging and about 5% at autopsy[8].

Rectal GISTs are often concealed, accompanied by long disease duration, thus symptoms often appear in the late phase of the disease. Common imaging findings include a well-circumscribed tumor with nonannular and exophytic growth pattern, without causing perirectal lymphadenopathy or bowel obstruction in most cases[9].

Rectal GISTs are of increasing concern because of the rare site and post-treatment implications for lifestyle. Targeted therapy has been successful compared with conventional chemotherapy and radiotherapy. Surgery is still the main approach to cure GISTs[10,11]. Preoperative diagnosis is crucial for GISTs, because they differ from other rectal SELs in treatment and prognosis.

GISTs have malignant potential and treatment depends on accurate pathological diagnosis by IHC staining, which requires adequate tissue samples. Endoscopic biopsy only samples mucosal tissue, yet rectal GISTs often present as submucosal growths, which forms a barrier for endoscopic biopsy. EUS-guided fine needle aspiration (EUS-FNA) is considered for preoperative diagnosis of submucosal lesions. In our case, the results of several times of EUS-FNA from the local hospital were negative. Inadequate tissue samples were mentioned by Yegin and Duman[1] in approximately one third of cases. A multicenter retrospective study[3] of EUS-FNA of suspected GISTs gave cytopathological yield, IHC yield, and diagnostic yield of 46%, 41%, and 37%, respectively. In addition, EUS-FNA has been limited in its inability to procure intact and adequate samples that are vital for histopathological and IHC analysis, causing difficulties in pathological diagnosis of GISTs[2,4]. EUS-guided fine needle biopsy (EUS-FNB) is still the commonest biopsy mode for GISTs. However, it requires adequate preoperative bowel preparation, and the risks of infection and hemafecia are higher in transrectal approach than in transperineal approach[12,13]. Also, the technique of EUS-FNB is more difficult, and it requires complex instruments, leading to unavailability in primary hospital.

We performed CNB guided by transabdominal US at first. Post-urination procedure was taken in order to avoid bladder injuries. Compression of the pelvic cavity by the probe was made to protect the surrounding bowel. The needle still went through the vagina and caused vaginal hemorrhage. Eventually, we were not able to obtain a pathological diagnosis because of the conflict between high risk of complications and inadequate sampling.

Then we performed transperineal freehand biopsy under the guidance of ERUS and CEUS, and it succeeded. We consider that ERUS guided transperineal biopsy is a reliable and safe method for preoperative pathological diagnosis of rectal SELs. And CEUS does help in the location of sampling. This method possesses advantages of both high resolution and low risk of infection[14], allowing acquirement of adequate tissue through a short puncture path. And it can be carried out under local anesthesia in outpatient department, with a lower cost of time and money[12]. The needle does not go through the rectal wall, so there is no need for bowel preparation. This method also reduces the application of antibiotics due to a low risk of infection[15].

For patients manifesting as rectal SELs and suspected tumors, to obtain preoperative diagnosis is difficult. ERUS guided transperineal biopsy can be one of the supplementary methods to routine biopsy work-up, especially for the difficult cases after several times of failure for insufficient sampling and risk of puncture complications. In addition, freehand biopsy is more suitable for underdeveloped areas because it does not need needle guide kit and costs less.

There are some limitations of this approach. For patients with stenosis in the rectum or anal tube, or those with high-position lesions beyond the display limit of the probe, the transperineal CNB guided by ERUS combined with CEUS would not be able to carry out.

CONCLUSION

Transperineal CNB guided by ERUS ensures adequate samples with a shorter puncture path, avoiding injuries to the bladder, bowel, uterus, vagina, and prostate. It also protects patients from infection caused by transrectal puncture. CEUS of the lesion can make it clear which points are the most appropriate for sampling. Transperineal CNB guided by CEUS combined with ERUS could be a supplement to traditional biopsy guidance method and it has the potential to be an important tool for preoperative biopsy of rectal SEL. The application could be limited by anorectal stenosis or with high-position lesions.

ACKNOWLEDGEMENTS

The authors thank Dr. Chen HJ for providing the pathological data.

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, and Scopus. The 2020 edition of Journal Citation Report® cites the 2019 impact factor (IF) for *WJG* as 3.665; IF without journal self cites: 3.534; 5-year IF: 4.048; Ranking: 35 among 88 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2019 is 7.1 and Scopus CiteScore rank 2019: Gastroenterology is 17/137.

Abstract

Colorectal cancer (CRC) is among the most prevalent cancers worldwide, and its prevention and reduction of incidence is imperative. The presence of diabetes has been associated with a 30% increased risk of CRC, likely through the mechanism of hyperinsulinemia, which promotes tumorigenesis *via* the insulin receptor in the epithelium or by insulin-like growth factor pathways, inflammation, or adipokines, inducing cancer cell proliferation and cancer spread. Metformin, the first-line agent in treating type 2 diabetes, has a chemopreventive role in CRC development. Additionally, preclinical studies suggest synergistic effects of metformin with oxaliplatin in inhibiting *in vitro* models of colon cancer. Although preclinical studies on the post diagnostic use of metformin were promising and suggested its synergistic effects with chemotherapy, the data on the possible effects of metformin after surgery and other CRC treatment in the clinical setting are less conclusive, and randomized controlled trials are still lacking.

Key Words: Metformin; Type 2 diabetes mellitus; Colorectal cancer; Chemoprevention; Recurrence-free survival; Surgery

Core Tip: Metformin is one of the oldest oral antidiabetic agents used to treat type 2 diabetes mellitus. While there is substantial evidence that metformin may have a chemopreventive role in colorectal cancer (CRC) development, the data on the possible effects of metformin after surgery and other CRC treatment is much less conclusive.

INTRODUCTION

Colorectal cancer (CRC) is one of the most prevalent cancers worldwide, irrespective of gender. Factors contributing to the risk of development of CRC include lifestyle, genetics, and chronic diseases such as diabetes mellitus and obesity[1-3]. Although patient survival has increased over the years due to more effective treatments, there is still a problem with adverse effects and therapy costs. The prevention and reduction of CRC incidence is imperative. Several agents with chemopreventive effects have emerged. Cyclooxygenase-2 inhibitors offered the most promising results in CRC prevention, but their use was associated with elevated cardiovascular risk. Considering that CRC patients often have diabetes mellitus and obesity, which also confers cardiovascular risk, novel targets for CRC chemoprevention are needed. Accumulating data indicates that metformin, the first-line treatment for type 2 diabetes mellitus, may be a candidate chemoprevention agent for cancer, including CRC.

METFORMIN-CLINICAL USE AND MODE OF ACTION

Metformin is one of the oldest oral antidiabetic agents used to treat type 2 diabetes mellitus alone or in combination with other oral or injectable agents. It lowers blood glucose levels by reducing hepatic glucose production, stimulating glucose uptake by peripheral tissues (muscle and fat), and lowering intestinal glucose absorption[4]. The presence of diabetes has been associated with a 30% increased risk of CRC. This potentially occurs through the mechanism of hyperinsulinemia accompanying insulin resistance, which promotes tumorigenesis *via* action on the insulin receptor in the epithelium or by influencing insulin-like growth factor pathways, inflammation, or adipokines inducing cancer cell proliferation and metastasis[5-7]. Therefore, metformin might provide preventive effects by reducing insulin resistance and lowering hyperinsulinemia[8] (Figure 1). Additionally, the use of metformin in various cancer models provided anticarcinogenic action by inhibiting angiogenesis or through antimetabolic and radio-chemosensitizer effects[9]. This is mediated by the synergistic regulation of metformin on adenosine monophosphate-activated protein kinase (AMPK), glycogen synthase kinase-3β, and proliferator-activated receptor-γ as observed in the case of pancreatic cancer[10].

The mechanistic target of rapamycin (mTOR) pathway, with complex multiple feedback loops, plays a central role in coordinating cell growth and proliferation in CRC carcinogenesis. Different mTOR inhibitors have been extensively studied for preventing and/or treating CRC, but no single agent has shown a significant therapeutic efficacy towards CRC potentially because many of the genetic pathways involved in CRC development lie upstream of mTOR and elicit the oncogenic effect through the mTOR signaling pathway[11]. According to the contemporary understanding, the mTOR pathway is continuously activated by various hormones, inflammation, and energy-related factors such as glucose, insulin, and insulin-like growth factor 1. The hypothesis to combine inhibition of these pathways seems promising in providing more effective tumor suppression[12]. Metformin inhibits mitochondrial mammalian respiratory chain complex I followed by activation of liver kinase B1 and downstream target AMPK that results in an inhibition of mTOR activity[13,14]. Metformin also exerts its metabolic effects by improving insulin resistance, hyperinsulinemia, and glycemia. Metformin has apoptotic effects on cancer

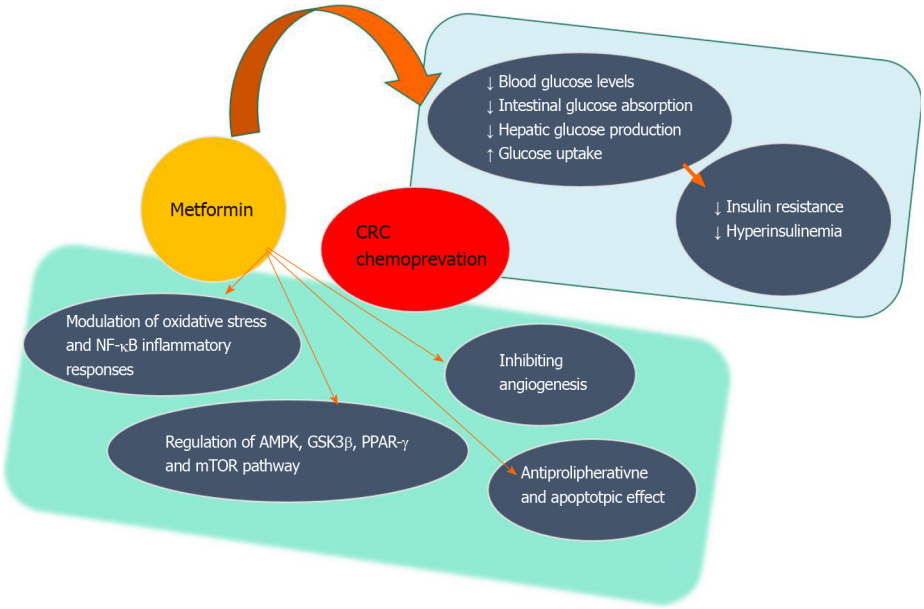

Figure 1 Metformin mode of action including chemopreventive potential in colorectal cancer development. CRC: Colorectal cancer; NF-kB: Nuclear factor kB; AMPK: Adenosine monophosphate-activated protein kinase; GSK3β: Glycogen synthase kinase-3β; PPAR-γ: Proliferator-activated receptor-γ; mTOR: Mechanistic target of rapamycin.

stem cells and potentially has a synergistic effect with other chemotherapeutics[15,16].

Animal and *in vitro* studies indicate that the role of metformin as an antiproliferative agent on CRC cells is through the activation of AMPK[17,18]. One of the first reports on anticancer effect of metformin in a CRC cell model showed the concentration and time-dependent effects on AMPK activation and the reduction of cancer cell proliferation[19]. Other research provided further evidence of the apoptotic effects of metformin by modulating oxidative stress and nuclear factor-κB inflammatory responses[20-22]. In the *in vitro* models, metformin was used either alone or in combination with other agents, primarily fluorouracil (commonly referred to as 5-FU)[20,23-25], which is similar to its use in clinics.

CHEMOPREVENTIVE EFFECTS OF METFORMIN IN CRC TREATMENT

Previous studies have indicated that metformin may decrease the risk of development of colorectal carcinoma[26,27]. Observational data indicates lower tumor incidence in diabetic patients taking metformin, and results from interventional studies show a reduction in the incidence of colorectal adenomas in patients without diabetes taking low-dose metformin[28-30]. Specifically, in a phase 3 randomized trial, a 1-year treatment with low-dose metformin reduced the number and prevalence of premalignant colorectal lesions, such as polyps and adenomas, in patients without diabetes post polypectomy[30]. A recently published retrospective cohort study including 47351 people found an inverse association between long-term (> 5 years) exposure to metformin in diabetic patients and the risk of CRC[31], suggesting its chemopreventive potential. This finding was substantiated with the meta-analysis results of 58 studies showing that metformin usage significantly reduced the incidence of colorectal adenoma and CRC, improving overall and CRC-specific survival rates[32].

On the other hand, data on the role metformin plays in CRC carcinogenesis in nondiabetic patients are not extensive. According to the randomized placebo-controlled trial results, metformin has the chemopreventive potential in nondiabetic patients with a high risk for CRC development[33]. Although metformin therapy was usually well tolerated by patients with different cancers and side effects did not differ from those seen in diabetic patients (dose-related gastrointestinal adverse effects, rarely lactic acidosis, and vitamin B12 deficiency), more data are needed on the optimal dose, schedule, route of administration, treatment duration, and combinations with other chemotherapeutic agents for CRC patients (especially nondiabetic patients) to be able to minimize the potential side effects[34-36].

METFORMIN AND SURVIVAL OF PATIENTS UNDERGOING TREATMENT FOR CRC

While there is substantial evidence that metformin may have a chemopreventive role in CRC development, the data on the possible effects of metformin after surgery and other CRC treatments are much less conclusive.

Lee *et al*[37] first observed a protective effect of metformin after CRC diagnosis in a single institution cohort of 595 patients. Metformin use showed a lower risk of overall mortality [hazard ratio (HR) = 0.66; 95% confidence interval (CI): 0.476-0.923] and CRC-specific mortality (HR = 0.66; 95%CI: 0.45-0.975) in patients with diabetes. However, this analysis suffered from immortal time bias, which may have influenced the results[38]. Fransgaard *et al*[39] examined the association between metformin and overall survival after resection for CRC in patients from the national Danish CRC database. They found better overall survival of patients treated with metformin compared to patients treated with insulin. However, cancer-specific mortality was not differentiated from diabetes-specific mortality, and it is not clear what their respective roles were in all-cause mortality. Therefore, it is impossible to ascertain whether better overall survival in the metformin-treated group can be attributed to metformin or the antitumor effects of other factors. Interestingly, in a recent paper, the same group found no association between metformin use and recurrence-free survival or disease-free survival in patients with surgically treated CRC[40]. The findings of a large population-based analysis from the United Kingdom also do not support a protective association between post-diagnostic metformin use and survival in a cohort of CRC patients with type 2 diabetes mellitus[41].

Several meta-analyses have been published on the topic, and most of them have reported a reduction in CRC-specific mortality with metformin use compared with nonuse in CRC patients[42-45]. However, the studies included in these meta-analyses are very heterogeneous regarding their design and inclusion criteria (*e.g.*, analyzing patients with different CRC stages). Also, information is often not available on the types of surgeries and administered chemotherapy in the included studies.

Evidence exists that metformin in combination with adjuvant therapy may be associated with a better prognosis in CRC patients treated with metformin post-surgery. In preclinical studies, metformin has shown synergistic effects with oxaliplatin in inhibiting *in vitro* models of colon cancer[46]. Based on such evidence, it was hypothesized that metformin combined with adjuvant chemotherapy might be associated with a better prognosis in patients with resected CRC. This was not confirmed in the setting of a randomized study in patients with resected high-risk stage II or stage III CRC who received FOLFOX-4/XELOX adjuvant therapy[47]. Another study exploring the impact of metformin on overall survival and recurrence-free survival in a homogenous group of stage III CRC patients receiving FOLFOX adjuvant therapy failed to find a significant association[48].

These findings stand in contrast to the findings of studies that found an association between metformin use and improved outcomes. However, these were the studies that considered patients with stages I-IV treated with different chemotherapy regimens, including both patients with low stages without adjuvant chemotherapy and patients with advanced stages who received multiple chemotherapeutics[37,49,50]. Therefore, the effect of metformin on overall survival and recurrence-free survival in patients with CRC receiving chemotherapy after resection remains uncertain. Extensive prospective studies that include homogenous patient populations, ideally within randomized trials, with longer follow-up would provide more evidence on the possible association of metformin use and improved survival of patients after CRC treatment.

CONCLUSION

Mounting evidence suggests a chemopreventive role of metformin on CRC development, but the data on its role in diagnosed CRC in adjunct to surgery and chemotherapy are still inconclusive. Additional evidence from prospective, randomized controlled trials are required.

Abstract

Infection with the hepatitis B virus (HBV) is still a major global health threat as 250 million people worldwide continue to be chronically infected with the virus. While patients may be treated with nucleoside/nucleotide analogues, this only suppresses HBV titre to sub-detection levels without eliminating the persistent HBV covalently closed circular DNA (cccDNA) genome. As a result, HBV infection cannot be cured, and the virus reactivates when conditions are favorable. Interferons (IFNs) are cytokines known to induce powerful antiviral mechanisms that clear viruses from infected cells. They have been shown to induce cccDNA clearance, but their use in the treatment of HBV infection is limited as HBV-targeting immune cells are exhausted and HBV has evolved multiple mechanisms to evade and suppress IFN signalling. Thus, to fully utilize IFN-mediated intracellular mechanisms to effectively eliminate HBV, instead of direct IFN administration, novel strategies to sustain IFN-mediated anti-cccDNA and antiviral mechanisms need to be developed. This review will consolidate what is known about how IFNs act to achieve its intracellular antiviral effects and highlight the critical interferon-stimulated gene targets and effector mechanisms with potent anti-cccDNA functions. These include cccDNA degradation by APOBECs and cccDNA silencing and transcription repression by epigenetic modifications. In addition, the mechanisms that HBV employs to disrupt IFN signalling will be discussed. Drugs that have been developed or are in the pipeline for components of the IFN signalling pathway and HBV targets that detract IFN signalling mechanisms will also be identified and discussed for utility

Core Tip: Hepatitis B virus (HBV) infection remains an incurable disease affecting millions worldwide. Treatment with interferons (IFNs) can eliminate the virus by clearing its persistent genome, covalently closed circular DNA (cccDNA), from infected cells. However, its clinical efficacy is limited as HBV proteins antagonize IFN signalling. Other current therapeutics do not target cccDNA thus cannot eliminate HBV. Therefore, new drugs based on the knowledge of how IFNs cause cccDNA degradation and silencing, as well as insights into how HBV antagonizes IFN-mediated mechanisms are needed. This review summarizes what is known about these processes and highlights drugs and developing therapeutics targeted against them for HBV eradication.

INTRODUCTION

Chronic hepatitis B (CHB) is a major global health problem affecting about 250 million people worldwide, resulting in 800000 deaths per year[1]. It is the main etiological factor and cause of mortality for liver cirrhosis and hepatocellular carcinoma (HCC). Despite the availability of a prophylactic vaccine and antiviral therapies, the very high numbers of chronic carriers for the causative hepatitis B virus (HBV) indicates that current treatment regimens are inadequate in eliminating HBV. The primary reason for this is due to the stability and persistence of its genomic DNA[2,3], the covalently closed circular DNA (cccDNA), even under long-term therapy. This pivotal viral DNA template is solely responsible for generating all HBV transcripts[4] and viral proteins. Therefore, sub-detection levels of continually present cccDNA in infected cells and tissues act as template reservoirs for HBV to reactivate and persist long after achieving the treatment endpoint of expressing sub-detection levels of HBV antigens in patient sera. Given its importance in maintaining chronicity of HBV infection, experts in the field have come to a consensus that a curative regime can only be achieved through cccDNA elimination or permanently silencing cccDNA[5,6].

Of the 2 treatment options available, oral administration of nucleoside/nucleotide analogues (NAs) that target the HBV polymerase/reverse transcriptase (pol/RT) are better tolerated in patients to achieve reduced HBV titres[7]. However, NAs do not directly target cccDNA and therefore HBV reactivation persists. In contrast, the less tolerated interferon (IFN) treatment has been shown to be directly efficacious in promoting cccDNA clearance or epigenetically silencing cccDNA[8-10]. This is not surprising, as IFNs are a group of cytokines released from host cells as natural defence against external stimuli such as viral pathogens[11]. IFNs bind to their cognate receptors to elicit an intracellular signalling cascade that activates a set of IFN-stimulated genes (ISGs) with antiviral, immunomodulatory and anti-proliferative functions[12]. As such, IFNs are often used to treat viral infections against a range of viruses including HBV[13], hepatitis C virus[14], and West Nile virus[15]. Multiple lines of evidence have shown that IFN treatment effectively inhibits cccDNA function and eliminates cccDNA with great potency *in vitro* and in selected CHB patients[16,17]. However, the underlying mechanisms of its antiviral functions, especially on cccDNA are poorly understood. This is further compounded by the myriad of adverse effects associated with IFN treatments, such as neuropsychiatric disorders and neutropenia[18,19], greatly

limiting its use in HBV therapy. Moreover, HBV has multiple mechanisms that counteract IFN signalling, dampening the antiviral effect of IFN treatment[20,21] to result in poor antiviral response in some patients[22,23]. To overcome and enhance the sub-optimal antiviral response from direct IFN administration, a better understanding of the precise mechanisms of how IFNs target cccDNA and how HBV can overcome these is necessary. By targeting host factors and HBV products that modulate intracellular IFN signalling and its antiviral and anti-cccDNA effectors, curative therapies with fewer undesirable pleiotropic adverse effects can be developed. This review will highlight these mechanisms and targets for which therapeutic agents can be and have been developed.

cccDNA in HBV life cycle

cccDNA is a stable non-integrated mini chromosome formed in the nucleus of HBV-infected cells[24]. HBV enters cells by engaging the sodium taurocholate cotransporting polypeptide (NTCP) receptor[25] and utilizing epidermal growth factor receptor for internalization[26]. Following cell entry, HBV releases its core nucleocapsid into the cytoplasm while the genomic material carried within, the partially double-stranded relaxed circular DNA (rcDNA) is transported into the nucleus where it is converted into cccDNA through a series of biochemical steps involving multiple host proteins[27-29]. cccDNA contains 4 overlapping open reading frames from which all HBV transcripts are transcribed. These include the 0.7 kb mRNA for the HBx protein, 2.4 kb and 2.1 kb mRNAs that encode three different forms (L, M, and S) of envelope surface proteins (HBs), 3.5 kb pre-Core mRNA that codes for the p22 pre-core protein, a precursor for HBe and another multi-functional 3.5 kb pre-genomic RNA (pgRNA) that is both the template for rcDNA synthesis and also encodes components of the core particle, the core protein (HBc) which forms the viral capsid and the HBV pol/RT[30]. pgRNA and pol/RT are encapsidated by HBc to form the core particle, where reverse transcription takes place within to form the full-length (-) strand of rcDNA, followed by the incomplete synthesis of (+) strand to generate the partially double-stranded rcDNA. This newly synthesized rcDNA can then be recycled into the nucleus to generate more cccDNA, maintaining nuclear cccDNA pool and contributing to cccDNA persistence. Alternatively, core particles can be enveloped for secretion to generate progeny virions[31]. Since cccDNA plays a central role in this replicative cycle, it is clear to see that HBV would cease to replicate or persist when cccDNA is eliminated.

cccDNA copy number and persistence

cccDNA exists in low copies and persists long after antiviral treatment, accounting for HBV reactivation after cessation of treatment[32]. cccDNA is found in every phase of the natural course of HBV infection, even in patients who underwent HBs seroconversion to produce protective anti-HBs antibodies after effective antiviral treatment. Seroconversion or the loss of HBs is an important end goal of HBV therapy as it is associated with positive long-term clinical outcomes such as improvement in liver function and reducing the risk of HCC[33]. Surprisingly, there is currently no international standard for HBV cccDNA quantitation, and a universally endorsed HBV cccDNA assay is also lacking. Thus, the kinetics and amount of cccDNA in infected cells are not clearly defined as the cccDNA copy numbers reported merely reflect the assay used in a publication and does not facilitate comparison between studies. Cell culture models suggest that cccDNA persists up to 40 d in infected HepG2 cells, at up to 12.5 copies per infected cell[31]. Studies in human liver biopsies show that the copies of cccDNA per cell varies greatly by >5000-fold, from very low copies of 0.03 copies per cell to very high levels of 173.1 copies per cell, and that this is correlated with HBV reactivation status[3]. Consistent with the correlation between high cccDNA copies and CHB status, HBe-positive patients have a higher level of cccDNA compared to HBe-negative patients. Moreover, very low cccDNA copies of 1.5 copies per infected hepatocyte is sufficient to cause virus persistence[34]. High cccDNA levels has also been shown to be associated with increased risk of liver inflammation[35]. Collectively, high cccDNA levels is associated with greater HBV titres, increased risk of HBV reactivation and higher risk of developing HBV-associated liver diseases, emphasizing the need for cccDNA elimination to achieve a complete cure from HBV infection.

CURRENT HBV TREATMENT STRATEGIES

Nucleoside/nucleotide analogues

The standard of care for hepatitis B is based on two therapeutic strategies: the use of NAs and IFN-α or its pegylated form (PEG-IFN)[36,37]. To date, six NAs have been approved for treatment, including lamivudine, adefovir, entecavir, telbivudine, tenofovir, and tenofovir alafenamide. As NAs are taken orally, they are easy to administer hence promote patient compliance. NAs suppress viral replication by targeting HBV pol/RT activity to disrupt rcDNA synthesis[38]. By suppressing HBV load, NAs can alleviate HBV-associated liver diseases, regress fibrosis[39] and reduce the risk of developing HCC[40]. However, NAs cannot cure HBV infection as loss of virological markers such as HBs is rarely achieved, and seroconversion rates are negligible (Table 1). As a result, HBV reactivation rate is high, with >50% patients showing flares in virological markers (*e.g.* HBV DNA) and biochemical markers for liver damage [*e.g.* alanine aminotransferase (ALT)]. This is often accompanied with irreversible liver decompensation, resulting in death even when re-introduced to lamivudine[41]. Thus, to avoid HBV reactivation, CHB patients are often put on long-term (often >10 years) or even life-long NA therapy.

However, long-term administration of NAs leads to drug resistance, with nearly 65% of CHB patients becoming resistant when treated with lamivudine for 5 years[42]. This is because NAs target the error-prone HBV pol/RT, generating progeny virions that may carry escape mutations such as rtM204V/I, rtL180M, rtA181T/V, or rtL80V/I in the pol/RT protein sequence, preventing the mutant pol/RT to incorporate NAs into the nascent rcDNA hence escape rcDNA chain termination. As a result, prolonged treatment with NAs allows these "fitter" escape mutants to accumulate, generating drug resistant HBV strains[43,44]. As such, new generations of NAs need to be designed to tackle the problem of HBV mutation. Entecavir and tenofovir are such new generation NAs that are currently favoured over first-generation lamivudine and adefovir due to their higher potency and lower occurrence of drug resistance[45]. Only time will tell if the lower drug resistance rates indeed hold true for these newer NAs. It is more important to note that, NAs do not target cccDNA as the established cccDNA pool does not require HBV pol/RT for maintenance. Therefore, NAs cannot cure HBV infection.

IFNs

IFN-α and PEG-IFN are immunomodulators that augment cell-mediated immunity, part of which includes intracellular antiviral activities that can be executed without the aid of immune cells[46]. The use of PEG-IFN has superseded standard IFN-α as pegylation improves IFN-α half-life, requiring less frequent dosing[47]. More importantly, PEG-IFN-α is more effective in reducing cccDNA levels and also leads to greater rates of ALT normalization with lower HBV reactivation rates (Table 1). When compared to NAs, treatment with IFN and PEG-IFN leads to higher rates of HBe and HBs seroconversion with greater reduction in HBV markers indicative of lower HBV replication rates. Of note, HBs seroconversion is rarely achieved with the use of NAs. Recent clinical studies[48,49] have also confirmed that switching from NA therapy to IFN therapy sustains more significant HBe and HBs losses for longer periods, demonstrating the potency of IFNs in the suppression of HBV replication. However, the use of IFNs in the clinical setting is limited due to the need for high dosage and unpredictably variable patient response, which depends on the status of immune cells, HBV titre and type of HBV. It is also less tolerated in patients due to pleiotropic off-target effects from IFN signalling.

At the tissue level, immune tolerance from chronic infection significantly reduces clinical efficacy of IFN treatment. The extracellular arm of the IFN-mediated antiviral response depends on the activation of HBV-specific $CD4^+$ helper T-cells and $CD8^+$ cytotoxic T-cells to produce cytokines such as IFN-γ and tumour necrosis factor-alpha (TNF-α) that lead to the elimination of HBV-infected cells[50]. However, constant exposure to HBV leads to T-cell exhaustion and an immunotolerant environment[51]. While IFN-γ also induces intracellular antiviral properties, its continued elevation upregulates programmed death-1 (PD-1) immune checkpoint protein on T-cells and also induces its ligand PD-ligand 1 on hepatocytes, leading to immune tolerance as HBV-specific T-cells fail to act on infected cells[52,53]. IFN-γ also promotes the secretion chemokines from hepatic macrophages that retain $CD4^+$ T-cells in the liver and induce apoptosis of HBV-specific T-cells, further contributing to HBV evasion of immune clearance. Many other mechanisms of how HBV-specific immune cells' antiviral activities have been augmented in chronic HBV infection have been documented and

reviewed[54-56], together showing very clearly that IFN treatment alone cannot induce effective clearance of HBV, allowing HBV to persist. Indeed, strategies aimed at restoring extracellular anti-HBV immunity in CHB patients such as with anti-PD-1 therapeutics[57] and adoptive T-cell therapy[58] are being investigated. Since immune tolerance in CHB patients render immune cells non-responsive to IFN therapy, the efficacy of IFN therapy lies heavily on the intracellular arm of IFN-mediated immunity brought about by induction of intracellular antiviral proteins from IFN signaling.

IFNs induce the production of antiviral proteins that specifically disrupt HBV replication and degrade cccDNA. However, HBV has devised multiple strategies that antagonize IFN signalling. These strategies are so effective that even when coupled with NAs, the inability of NAs to reduce the amount of HBV products allows them to continue disrupting IFN signalling, rendering combination therapy efficacious only in selected patients[59,60] but redundant in others[61]. Multiple factors including type of combination therapy, HBV genotype and level of HBV replication greatly affect IFN treatment efficacy[62]. Some studies suggest that sequential NA and IFN therapy is more effective than simultaneous combination therapy[63], a phenomenon which warrants further confirmatory clinical investigation to enhance clinical response rates. HBV itself also significantly affects patient response to IFN therapy, as treatment outcomes are more efficacious in patients carrying the genotype A virus than the genotype D virus[64], and patients are also thrice more responsive to IFN treatment if they carry the genotype B virus than genotype C virus[65]. As further proof to the extent in which HBV alters patient sensitivity to IFN treatment, 30.4% of patients with low end-of-treatment HBs levels (< 10 IU/mL) achieve HBs clearance in a 5-year follow-up, in stark contrast to < 10% of patients achieving HBs clearance[66] when end-of-treatment HBs levels are ≥ 10 IU/mL. This is further supported by the association of greater PEG-IFN response in patients with HBV DNA levels of < 9 Log_{10} copies/mL sera[67]. Clearly, the full potential of IFN therapy has yet to be harnessed and directed towards HBV and its cccDNA. To achieve this, a strong understanding of how IFNs target cccDNA specifically and how HBV overcomes such mechanisms is necessary. New therapeutic agents and strategies can then be developed to prevent HBV from interfering with IFN signalling and enhance the anti-HBV and anti-cccDNA activities of IFNs to bring about HBV elimination.

IFN SIGNALLING

IFNs are key mediators of immunity, comprising a group of cytokines with antiviral properties against a wide range of pathogens. There are 3 types of IFNs (Type I, II, III) (Figure 1) based on the distinct receptors used for signal transduction[68]. Amongst them, only type I IFN-α2a and IFN-α2b are used clinically in the treatment of HBV infections[69,70], although the mechanisms underlying its clinical efficacy remain poorly understood. IFNs from all 3 types have been shown to possess anti-HBV properties (Table 2), but many have poorer patient tolerability than IFN-α. IFNs also differ in anti-HBV potency, but the underlying reasons for such differences are not clear. At high doses, IFNs non-cytolytically purge or silence cccDNA from infected hepatocytes.

Activation of ISGs

The antiviral effects of IFNs are achieved through ISGs[46,68], which are induced through the IFN signalling pathway that activates janus kinase/signal transducers and activators of transcription (JAK/STAT) signalling (Figure 1). After IFNs engage their specific IFN receptors, tyrosine kinase 2 (TYK2) transduces the activating signal to result in phosphorylation of STAT1 and STAT2 transcription factors by protein kinase C-delta (PKC-δ) necessary for nuclear translocation. The heterodimer interacts with IFN regulatory factor 9 (IRF9) to form the ISG factor 3 (ISGF3) transcription factor complex which translocates into the nucleus by importin-dependent mechanisms. ISGF3 can then induce the expression of antiviral ISGs through IFN-stimulated response elements (ISRE) cis regulatory elements with the consensus sequence "AGTTTCNNTTTCN" in ISG gene promoters. Alternatively, phosphorylated STAT1 may homodimerize to form the IFN-gamma-activated factor (GAF) complex that binds to another cis-element, the IFN-gamma activated site with the "TTCN$_{2-4}$GAA" conserved sequence motif and induce ISG expression in the absence of IRF9[71]. As will be further elaborated, each ISG functions differently to bring about the destruction or silencing of cccDNA and other antiviral effects, accounting for pleiotropic effects of IFN treatment. There are a variety of IFN subtypes, each targeting the activation of different sets of ISGs with antiviral properties that may suppress HBV replication (Table 2). By specifically activating these ISGs relevant for cccDNA degradation or silencing, new drugs can be developed that specifically eliminate HBV. In doing so, adverse effects of IFNs that are not well-tolerated in patients may be eliminated as the activation of ISGs that are irrelevant for suppressing HBV replication are by-passed.

Regulators of IFN signalling

As JAK/STAT signalling is critical for the expression of ISGs, it is tightly regulated by several proteins[72]. Suppressor of cytokine signalling (SOCS) 2 and SOCS3 inhibit the IFN signalling cascade by preventing TYK2 activation and hence STAT1 phosphorylation. STAT1 methylation by protein arginine methyltransferase 1 (PRMT1) prevents its binding to the inhibitor protein inhibitor of activated STAT1 (PIAS1), where PIAS1 functions to sequester STAT1 away from its DNA-binding motifs[73]. The methylation of STAT1 is in turn negatively regulated by protein phosphatase 2A (PP2A), which inhibits PRMT1 activity[74]. These factors can be targeted by HBV to disrupt and dampen the IFN signalling and will be discussed later.

ANTI-cccDNA MECHANISMS

Degradation by APOBECs

Many of the IFN subtypes with anti-HBV properties induce APOBEC family genes[75], which are cytidine deaminases that perform RNA editing[76]. They have also been well-documented to act directly on cccDNA to result in degradation. IFN-α, which is used in clinical therapy of CHB, has been shown to reduce the expression of cccDNA, HBV RNA, HBs and HBe in primary human hepatocytes (PHH) and HepRG liver cells. The IFN-α mediated loss of cccDNA was found to last up to 15 d[8]. Induced expression of APOBECs can be seen after IFN treatment in liver biopsies of hepatitis B patients, and in HBV-infected chimpanzees[77]. The importance of APOBECs in mediating cccDNA clearance is supported by the fact that the expression of APOBECs correlates with clinical response to IFN.

Besides IFN-α and IFN-γ, other pathways induced by pro-inflammatory cytokines including TNF-α and lymphotoxin-β (LT-β) have also been shown to induce APOBECs and affect the stability of cccDNA. In agreement with its anti-cccDNA functions[78], APOBECs induced through LT-β signalling with LTβR agonist antibody was shown to

clear 90% of cccDNA in HBV-infected cultured liver cells with good *in vivo* tolerability[8]. As the clinical dose of IFN-α used to achieve cccDNA clearance is relatively high, this suggests that inducing expression of APOBECs through LT-β signalling is an alternative means for cccDNA clearance with potentially fewer adverse effects. While its clinical efficacy and safety remain to be studied, upregulation of natural ligands for LTβR in HBV-infected liver tissues have been reported[79]. IFN-γ and TNF-α also exhibit anti-cccDNA effects to degrade cccDNA[80] levels without causing cell death in HBV-infected chimpanzees, PHH and cultured liver cells.

Following IFN receptor or LTβR activation, the upregulated IFN-α induced APOBEC3A (A3A) and LTβR activation-induced APOBEC3B (A3B) are brought to cccDNA by HBc (Figure 2). Similarly, IFN-γ induced the expression of both A3A and A3B while TNF-α induced the expression of A3B only, whereas knockdown of A3A and A3B abrogated the antiviral effects of IFN-γ and TNF-α. HBc amino acids 77-149 are crucial for this interaction, which brings the APOBECs into close proximity with cccDNA for deamination[8]. cccDNA deamination generates apurinic/apyrimidinic (AP) sites that are recognized by endonucleases[81], which ultimately degrade cccDNA. The dependence on AP sites for cccDNA degradation was confirmed by reduced intact DNA amount when DNA extracted from IFN-γ or TNF-α treated cells were digested with recombinant APE1, an AP endonuclease which specifically recognizes and cleaves AP sites[9]. Surprisingly, knockdown of APE1 in IFN-γ and TNF-α treated HBV infected cells did not show a reduction in cccDNA clearance, suggesting the redundancy of endonucleases in clearing cccDNA. While AP sites can be repaired by the host cells' DNA repair machinery, this is not observed with IFN-mediated AP site formation in cccDNA. This is most likely due to the concurrent downregulation of the base excision repair enzymes such as thymine DNA glycosylase and Nei-like DNA glycosylase after IFN treatment[77]. These studies indicate that A3A and A3B are key proteins responsible for IFN and LTβR mediated cccDNA clearance. APOBECs also have other important roles in clearing HBV cccDNA. APOBEC3F (A3F) and APOBEC3G (A3G) were also found to have anti-HBV properties[82]. A3G for example inhibits pgRNA packaging to reduce virion formation[83]. The mechanism of action for A3F has not been well-characterized.

Epigenetic silencing and transcriptional repression

Apart from eliminating cccDNA, permanently silencing cccDNA is another strategy for the development of anti-HBV therapy. Several studies have shown that IFNs control the epigenetic silencing of cccDNA[84,85], spurring growing interest in

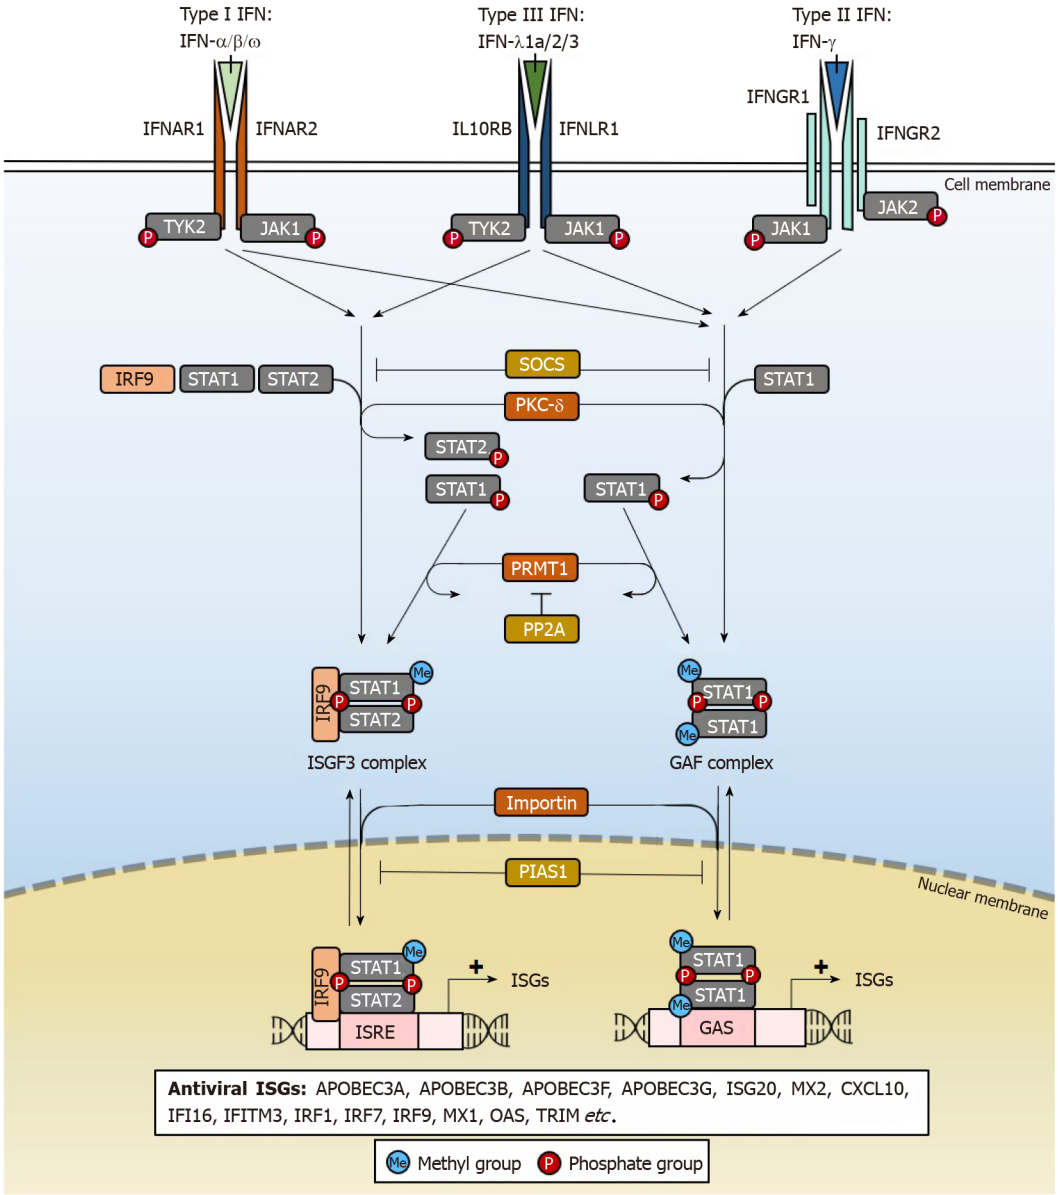

Figure 1 Activation of antiviral interferon-stimulated genes by different interferon subtypes. Different subtypes of interferons (IFNs) bind to their cognate receptors to trigger IFN signalling pathways. The activate janus kinase/signal transducers and activators of transcription-dependent signalling results in the formation of transcription complexes that induce the expression several IFN-stimulated response elements-dependent and gamma activated site-dependent antiviral IFN-stimulated genes (ISGs), which target covalently closed circular DNA (cccDNA) stability and function through a variety of mechanisms. The potency of IFN subtype for cccDNA degradation or silencing is dependent on the types and number of ISGs induced. IFN: Interferon; TYK2: Tyrosine kinase 2; SOCS: Suppressor of cytokine signalling; PKC-δ: Protein kinase C-delta; IRF: Interferon regulatory factor; JAK: Activate janus kinase; STAT: Signal transducers and activators of transcription; ISGF: Interferon-stimulated gene factor; GAF: Gamma-activated factor; ISGs: Interferon-stimulated genes; ISRE: Interferon-stimulated response elements; GAS: Gamma activated site.

controlling cccDNA transcriptional activity through epigenetic modifications[86]. HBV cccDNA exists as episomal chromatin wound around cellular histones that undergo post-translational modifications (PTMs)[87], altering cccDNA chromatin compaction hence accessibility to transcription regulators (Figure 2). Some of the histone marks associated with active cccDNA transcription include H3K4me3, H3K27ac, H3K122ac, and repressive PTMs include H3K27me3. Of note, the distribution of these histone marks varies across different types of HBV-producing samples[10]. In the HepG2-NTCP cell model, histone PTM enrichment is mainly confined to the pre-core/core promoter (CP) region whereas in PHH, they are found throughout the genome with the greatest modifications at the X and pre-S1 promoter regions. In contrast, HBV-infected liver tissues have few PTMs at the CP but accumulate them near pre-S2 and the X promoter regions. The reason and basis for this variability is at present unclear.

cccDNA transcription activity is heavily influenced by the state of epigenetic modification by host cellular factors and PTMs. The cccDNA mini chromosome is

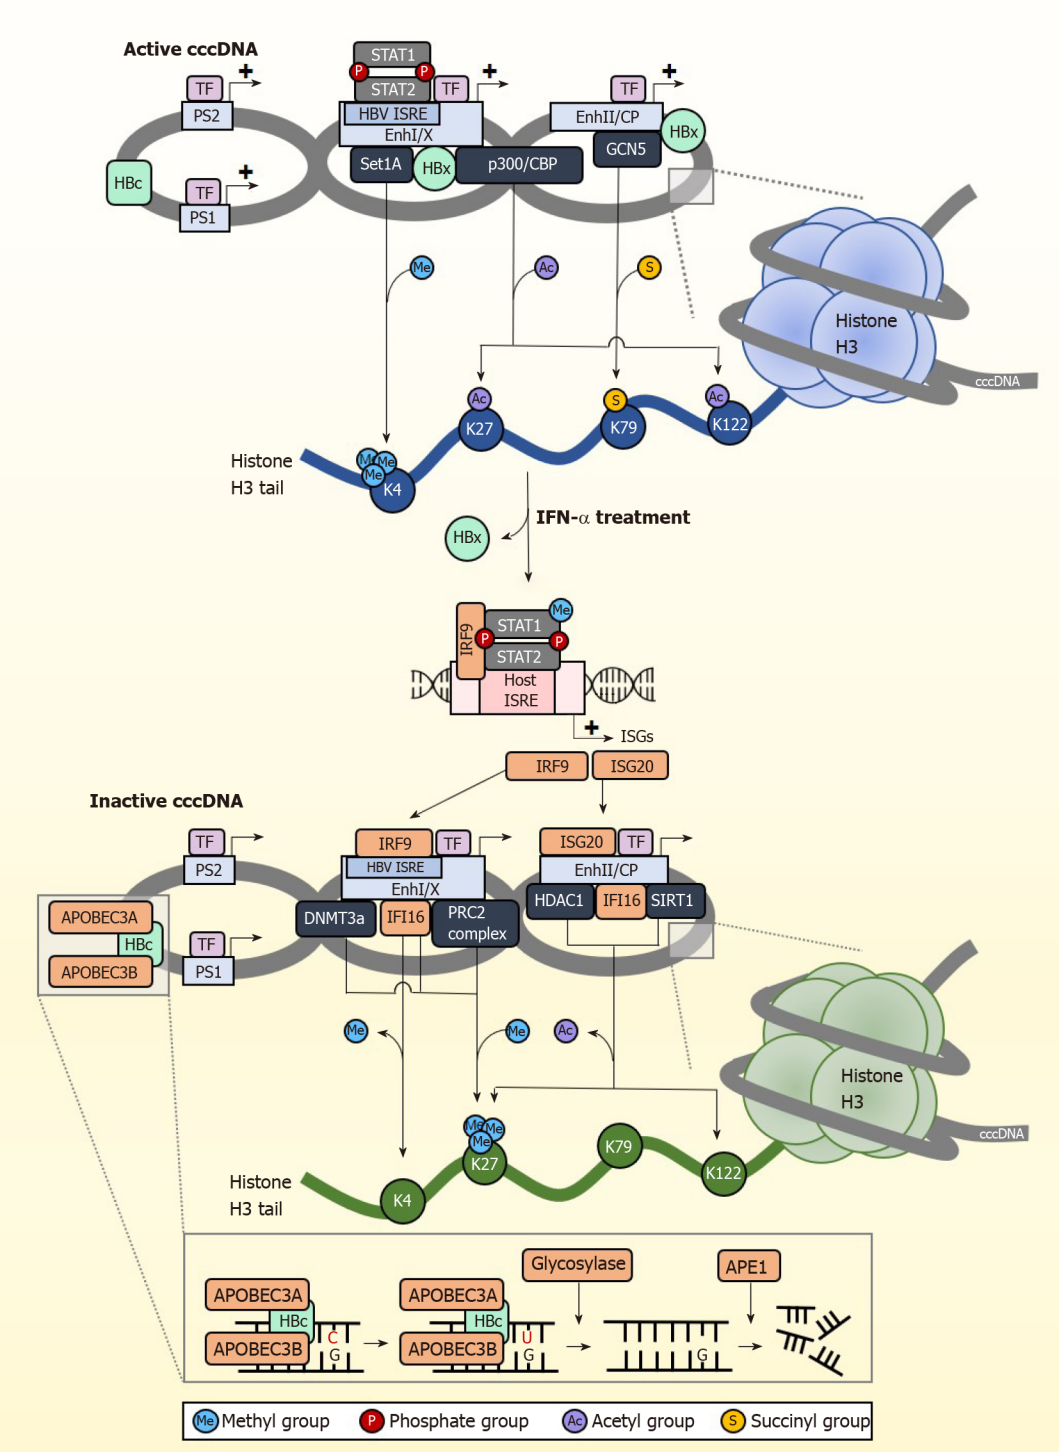

Figure 2 Interferon treatment silences covalently closed circular DNA transcription and recruits APOBECs to actively degrade covalently closed circular DNA. Covalently closed circular DNA (cccDNA) exists as an episomal mini chromosome that is epigenetically modified to support active transcription. Interferon (IFN)-α treatment results in the recruitment of histone modifying complexes that remove activating transcription post-translational modifications (PTMs), and add repressive PTMs that silence cccDNA function. These complexes can be recruited by IFN-stimulated genes (ISGs) such as IFI16. ISGs may also bind directly to cccDNA to repress transcription. Other ISGs such as APOBECs induced by IFN signalling are also recruited by HBc, generating AP sites which lead to cccDNA degradation. HBV: Hepatitis B virus; IFN: Interferon; IRF: Interferon regulatory factor; JAK: Activate janus kinase; STAT: Signal transducers and activators of transcription; ISGs: Interferon-stimulated genes; ISRE: Interferon-stimulated response elements; cccDNA: Covalently closed circular DNA.

heavily modified by various activating PTMs under normal circumstances (Figure 2). H3K4 methyltransferase Set domain containing 1A (Set1A) is recruited to cccDNA promoter sites by HBx, depositing the activating PTM H3K4me3 to drive active transcription[88]. By modulating the expression of Set1A, the relative expression of H3K4me3 can be fine-tuned. IFN treatment disrupts cccDNA transcription activity by

downregulating these epigenetic PTMs that support transcription. In studies using PHH, IFN-α specifically reduced trimethylation of H3K4 and acetylation of H3K27 and H3K122 on cccDNA chromatin to inhibit transcription of HBV RNA, but had negligible effect on epigenetic modification for the control promoters of ACTB and Nanog in the host genome[10].

IFNs also result in cccDNA transcriptional repression through active recruitment of complexes that confer transcription inhibitory epigenetic modifications. The repressive H3K27me3 PTM is induced by IFN-α through increased binding of polycomb repressive complex 2 (PRC2) to cccDNA[84]. The importance of H3K27me3 in inhibiting cccDNA transcription was also confirmed in a separate study showing that upregulation of DNA methyltransferase 3a hypermethylates HBV cccDNA to repress transcription[89]. IFNs have also been recently shown to inhibit succinylation of cccDNA histones, adding on to the transcriptionally repressed state brought about by hypoacetylation and/or methylation[90]. This involves the succinylation of H3K79 by GCN5 histone succinyltransferase (also known as lysine acetyltransferase 2A), which corresponds to higher HBV replication. They further showed that low levels of succinylated H3K79 from GCN5-specific knockdown resulted in significantly reduced cccDNA levels, and that expression of GCN5 and cccDNA correlate well in HBV-infected individuals. More importantly, IFN-α treatment could overcome the effects of overexpressed GCN5 to reduce the levels of succinylated cccDNA, indicating that IFNs act upstream to control GCN5 function and repress cccDNA transcription, the specific mechanism of which remains to be elucidated. Taken together, IFNs epigenetically silence cccDNA function through the recruitment of epigenetic factor complexes that add repressive PTMs or remove activating PTMs so that cccDNA enters a transcriptionally repressed chromatin structural state. Importantly, IFNs can also do so by inducing ISGs that bring about both the removal of activating PTMs and the addition of suppressive PTMs. For example, IFI16 reduces cccDNA transcription activity[91] by recruiting histone deacetylase 1 (HDAC1) and Sirtuin 1 (SIRT1) to increase repressive H3K27me3 PTMs on cccDNA, and concurrently impairs the recruitment of p300/CBP to prevent the addition of activating PTMs on cccDNA.

Interestingly, cccDNA also carries the ISRE cis-element, and this is critical for establishing IFN-mediated epigenetic changes on cccDNA. The HBV ISRE is located at the enhancer I/X promoter region[92,93], and is recognized by the ISGF3 complex and the ISGs IRF1 and IRF7. In transcriptionally active cccDNA, the HBV ISRE is bound by phosphorylated and unphosphorylated STAT1 and STAT2 transcription factors to active cccDNA (Figure 2). IFN treatment induces redistribution of the STAT proteins from the HBV ISRE towards the IFN signalling pathway, resulting in antiviral effects against HBV cccDNA by the upregulation of cccDNA-targeting ISGs. One of these ISGs is IRF9, which binds directly to the HBV ISRE element to suppress cccDNA transcription[94]. When the HBV ISRE is mutated, loss of IRF9 binding was shown to abrogate IFN-induced suppression of cccDNA transcription. This is clinically significant, as mutations in the HBV ISRE affects CHB patient response to IFN treatment[95] to render IFN treatment less effective. In addition, the HBV ISRE sequence is HBV genotype dependent, thus its sequence-dependent functionality partially accounts for differences in patient responder rates between carriers of HBV genotypes B and C[96]. Another ISG, ISG20, also directly inhibits transcription from cccDNA by direct binding to the enhancer II/CP region[97]. Higher ISG20 expression level also correlates to better response to IFN-α treatment in CHB patients[98] and viral clearance in HBV-infected chimpanzees[99]. With the withdrawal of activating transcription factors from cccDNA and binding of specific transcription repressors induced by IFN treatment, cccDNA transcription is further suppressed by epigenetic modifications of histones such as histone hypoacetylation which occurs through the recruitment of the HDAC1 and SIRT1, and hypermethylated by the PRC2 complex. Thus, in addition to epigenetic silencing of cccDNA, IFNs also suppress cccDNA transcription activity by generating IFN-induced transcription repressors specific to cccDNA.

Inhibition of cccDNA synthesis

IFNs are also known to directly inhibit cccDNA synthesis. The antiviral ISG myxovirus resistance protein 2 has been shown to reduce cccDNA formation when overexpressed[100]. Its specific knockdown abrogates the loss of cccDNA induced by IFN-α, providing confirmation for its role in IFN-α induced reduction in cccDNA levels. It has been proposed that this occurs through inhibiting cccDNA synthesis from rcDNA, as well as from downregulated HBV transcripts.

HBV DISRUPTION OF IFN SIGNALLING

HBV is not without its defences. It generates multiple factors that dampen the IFN signalling pathway. Inter-individual variability in the balance of these against antiviral IFN-mediated mechanisms could explain why CHB patients do not respond equally well to IFN-treatment. By understanding how HBV proteins antagonize IFN action, therapeutic approaches that interrupt the anti-HBV functions of IFNs can be developed to improve the response and efficacy of IFN treatments.

HBV disrupts the IFN signalling cascade at various steps. HBx[21] and HBe[20] downregulate the expression of IFN receptors, IFNAR1 and IL10RB, disrupting the initiation of type I and type III IFN signalling (Figure 3). HBe and HBx achieve this by upregulating SOCS2 and SOCS3 respectively, suppressing the IFN signalling cascade and inhibiting TYK2 activation (Figure 1). As SOCS2 also prevents STAT1 phosphorylation, STAT1 is prevented from entering the nucleus to induce ISG expression. Since SOCS2 and SOCS3 are the most direct upstream inhibitors of the IFN signaling pathway, their increased expression significantly attenuates IFN-dependent transcription of ISGs to compromise the therapeutic efficacy of IFNs. It was found that overexpression of HBe alone leads to 6-fold reduction in phosphorylated STAT1 nuclear translocation, hence downregulating protein kinase R (PKR) and oligo-adenylate synthetase (OAS) gene expression by 50%[20]. Similarly, HBx overexpression alone doubled SOCS3 expression and increased PP2A expression by 5-fold, significantly reducing PKR and OAS expression by 3-fold[101]. It is thus clear to see, that the combined effects of expressing HBx and HBe in infected cells, especially in cells with high viral titre and virological markers, will compromise the clinical efficacy of direct IFN therapy. Other HBV proteins act further down the IFN signalling cascade to prevent STAT1 nuclear translocation, further disrupting ISG expression. HBV pol/RT inhibits PKC-δ, preventing STAT1 phosphorylation and competitively binding to importin[102,103]. HBV pol/RT also significantly reduces the induction of IRF9 critical for the generation of ISGs through formation of the ISGF3 complex. p22 also binds importin[104] to prevent STAT1 nuclear translocation. In the nucleus, HBx and HBs upregulate PP2A, which inhibits PRMT1 hence reduces STAT1 methylation, enabling PIAS1 to sequester phosphorylated STAT1 away from its DNA-binding elements *in vitro* and in liver tissues from HBV infected patients[105]. As HBV proteins specifically target multiple regulatory elements of IFN signalling to block ISG expression, the expression of anti-cccDNA and antiviral ISGs would therefore be significantly reduced in the presence of HBV, rendering the effort to eliminate HBV by direct IFN administration futile. Therefore, to circumvent HBV mechanisms that antagonize IFN signalling, therapies aimed at targeting HBV molecules and components of the IFN-signalling pathway would greatly enhance the efficacy of IFN treatment for the elimination and suppression of cccDNA and HBV.

THERAPEUTIC AGENTS AND STRATEGIES AGAINST cccDNA

IFNs may eliminate and suppress cccDNA formation for a therapeutic cure of HBV infections, but IFN therapy has not been particularly efficacious due to the adverse effects from pleiotropic off-target effects and the existence of multiple HBV mechanisms that antagonize the IFN signalling pathway and downstream effector functions. As these greatly limit the clinical use of IFNs for treating HBV infections, alternative approaches that specifically enhance the anti-HBV effects of IFNs and suppress the antagonistic effects of HBV proteins can be developed to achieve cccDNA elimination and suppression without adverse effects from IFN signalling. Multiple classes of drugs that are in development or have been developed, that act on such targets may have the beneficial effect by downregulating HBV cccDNA (Figure 3). They act by modulating the functions of IFN signalling pathway components or HBV proteins that antagonize IFN signalling and its anti-cccDNA effector functions. Of note, as HBV disruption of IFN response is multi-factorial, combination therapy may be necessary to achieve cccDNA elimination for a true HBV cure.

Inducers of APOBECs

Perhaps the most obvious strategy to eliminate cccDNA is to enhance and sustain the expression of APOBECs which actively result in cccDNA degradation. While APOBEC mimics are not yet available, APOBEC expression can be induced through multiple pathways including activation of IFN signalling using other IFN sub-types such as IFN-γ and IFN-λ, and alternative pathways involving TNF-α and LTβR activation.

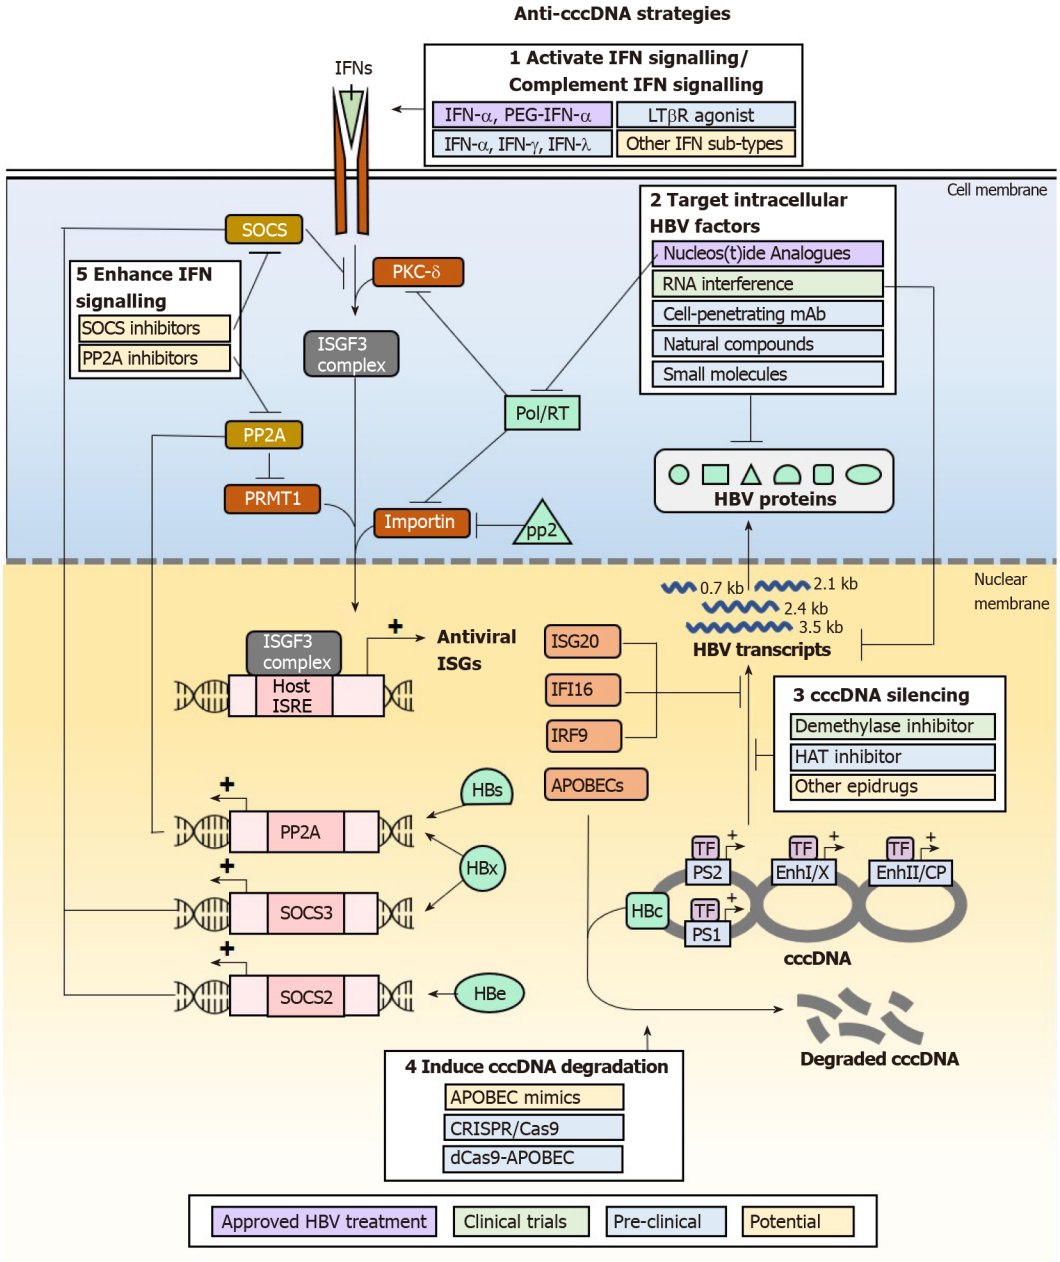

Figure 3 Anti-covalently closed circular DNA strategies and antagonistic hepatitis B virus proteins that modulate the interferon signalling pathway. Hepatitis B virus (HBV) has developed multiple mechanisms that target different parts of the intracellular interferon (IFN) signalling pathway to avert elimination by IFN treatment. Therapeutic agents that counter HBV anti-IFN signalling activities or enhance the strength of host cell IFN signalling may be beneficial to increase the efficiency of IFN treatment for the elimination or silencing of covalently closed circular DNA. HBV: Hepatitis B virus; IFN: Interferon; PEG: Pegylated form; SOCS: Suppressor of cytokine signalling; PKC-δ: Protein kinase C-delta; IRF: Interferon regulatory factor; JAK: Activate janus kinase; STAT: Signal transducers and activators of transcription; Pol/RT: Polymerase/reverse transcriptase; TNF: Tumour necrosis factor; ISGs: Interferon-stimulated genes; ISRE: Interferon-stimulated response elements; cccDNA: Covalently closed circular DNA.

IFN-λ3 was found to be specifically upregulated in patients treated with adefovir or tenofovir, and further shown in cell culture models to be effective in reducing HBs by inducing ISGs[106]. Studies in HepaRG differentiated hepatocytes also show that IFN-β, IFN-λ1 and IFN-λ2 induce longer-lasting APOBEC expression than IFN-α2, and are just as efficient in mediating cccDNA degradation[107]. IFN-γ and TNF-α have also been shown to upregulate APOBEC expression. In particular, the utility of IFN-γ in the treatment of HBV infections can be explored as it is currently used clinically for the treatment of hepatic fibrosis[108]. An LTβR agonist antibody has already been developed and was shown to be safe in mice at lower dosing requirements than clinical IFN-α. This could be further developed and tested in clinical settings for efficacy and safety in the treatment of HBV infections.

The IFN response may also be strengthened by reducing the action of negative regulators of the IFN signalling pathway, primarily by acting on SOCS2 or SOCS3 and

PP2A. This directly inhibits the degradation of IFN signaling, allowing ISGF3 and GAF complexes to form hence carry out transcription of ISGs. Thiazolidinediones such as pioglitazone and rosiglitazone are known to reduce the expression of SOCS proteins[109], and consequently would prevent the loss of IFN signalling transduction hence upregulate APOBEC expression in the presence of appropriate IFNs. They are currently used in the treatment of type II diabetes, thus may be readily re-purposed for the treatment of HBV infections to reduce cccDNA levels. The first-in-class small molecule inhibitor of PP2A, LB-100, would theoretically achieve similar effects of inducing APOBEC expression. It was found to be well-tolerated in patients with solid tumours in phase I clinical trials[110].

Epidrugs

As cccDNA function is highly dependent on its epigenetic PTM status, "epidrugs" are also being investigated for their efficacy in silencing cccDNA function. HAT inhibitor C646, which is widely used in cancer studies, has been shown to reduce H3K27ac and H3K122ac thus silence cccDNA for reduced HBV transcription[10]. The pro-drug GS-5801 (Gilead), which specifically inhibits KDM5 (lysine demethylase 5) has been shown to suppress cccDNA transcription by removing H3K4me3[111]. Given the importance of other epigenetic modifiers such as GCN5 and p300/CBP for cccDNA transcriptional activation, and SIRT1, HDAC1 for transcriptional repression and silencing, other unexplored epidrugs that inhibit the transcription activation group or activate the transcription repression and silencing group may also be tested for efficacy in directly silencing cccDNA. While epidrugs directly silence cccDNA *in vitro*, their greatest challenge in utility as an anti-HBV therapeutic depends on their ability to specifically target cccDNA in infected cells while sparing host genome to avoid carcinogenesis and toxicity[112,113]. In addition, due to compromised functionality of HBV-infected livers, many drugs that have safe profiles in the treatment of non-liver diseases are contraindicated in CHB. For example, the Food and Drug Administration-approved DNMT inhibitor, 5-azacytidine commonly used in the treatment of hematologic malignancies is contraindicated in patients with advanced liver cancer to control HBV infection due to hepatotoxicity[114]. Thus, epidrugs need to be carefully evaluated for safety and suitability in the treatment of HBV infections.

Targeted degradation of HBV products

To avoid drug-induced toxicity, approaches that directly target HBV products (cccDNA, RNA and proteins) are being developed. One such approach is to directly degrade cccDNA using CRISPR/Cas9 (clustered regularly interspaced short palindromic repeats)/CRISPR-associated protein 9) DNA editing machinery, where guide RNA-directed gene editing of cccDNA specifically results in its erroneous repair by non-homologous end-joining which cleaves and/or mutates cccDNA. This has been shown to effectively reduce cccDNA copies and is followed by concomitant clearance of HBs, HBc and HBe expression in mice with humanized liver[115,116] and multiple human liver cell lines[117,118]. While the cccDNA-targeting system is being developed and improved for clinical use, a major concern for this strategy is the generation of off-target double-strand breaks in the host genome that may facilitate HBV genomic integration to cause liver cancer. A suggested solution for this is to tether impaired Cas9 to APOBECs so that cccDNA may be mutated by base-changes instead of strand-breaks[119], highlighting again the importance of APOBECs in the role of targeted cccDNA degradation.

Another approach that has potentially fewer off-target effects is to specifically destroy HBV proteins that disrupt the IFN signalling pathway. Cell-penetrating monoclonal antibodies (mAb) have been developed for such purpose. For example, the genetically engineered antibody 9D11-Tat, formed by fusing a cell-penetrating peptide on the C-terminus of the heavy chain of a mAb specific to HBx, can target HBx for proteosomal degradation[120]. Alternatively, the transcripts for HBV proteins may be targeted for degradation by small interfering RNA (siRNA) duplexes[121]. siRNA therapeutics are already in clinical trials and currently assessed for efficacy and safety. siRNA candidates ARC-520, JNJ-3989 (Arrowhead Pharmaceuticals), and GSK3389404 (Ionis/GlaxoSmithKline)[122-124] have displayed promising efficacy in clearing viral transcripts to reduce HBs and HBV DNA production. Small molecules may also achieve the same effect by reducing HBV transcripts. Of note, the small molecule RG7834 was found to be even more potent than using the current clinical therapeutic agent entecavir in reducing HBs levels in cell culture model and HBV-infected human liver chimeric uPA-SCID mice[125,126]. With increased interest in natural compounds and their potential antiviral functions, curcumin was shown to reduce the expression of HBe and HBs[127] which antagonizes the IFN signalling cascade. Another natural

compound, Dicoumarol, can enhance HBx degradation. It inhibits NQO1 to destabilize its interaction with HBx, rendering it susceptible to the action of proteasomes[128]. With such promising new candidate drugs for tackling HBV, combination therapy that couples IFN treatment with these HBV protein-targeting drugs have been proposed to be hopeful for achieving cccDNA elimination without giving HBV the chance to evade the IFN response.

Clinical updates on the use of IFNs

Neither NAs nor IFNs alone can achieve effective HBV elimination in majority of HBV carriers. However, their mechanisms of action complement one another to potentially achieve viral elimination. NAs are effective in suppressing viral titre in most patients, allowing IFNs to effectively mount a cellular immune response in a less immunotolerant environment when HBV titre is decreased, and concurrently allow IFN-mediated intracellular antiviral mechanisms to effectively act against HBV and its cccDNA with less antagonistic effects from decreased HBV titre. As such, combination therapy is increasingly explored, with many experimenting the types of combinations that can be administered (Table 3). Combinations explored include NA monotherapy followed by IFN monotherapy or vice versa, periods of monotherapy followed by periods of IFN and NA co-administration, or co-therapy followed by monotherapy. Interestingly, the efficacies of combination therapy differ greatly. When NA monotherapy is switched to IFN monotherapy, higher rates of HBe and HBs seroconversion are observed together with lower relapse rates. Simultaneous administration of NAs and IFNs for more than 24 wk, followed by sustained NA treatment gives very high HBe seroconversion rate of 50%, accompanied by the loss of HBs expression in 16% patients. This is a remarkable feat considering the loss of HBs is usually less than 5% with NA or IFN monotherapy (Table 1). In contrast, multiple reports show that simultaneous administration of NAs and IFN yield conflicting results, with many studies showing little benefit from adding IFNs into the regime of NA treatment[129,130]. Further large-scale clinical studies are needed to ascertain the differences in these findings.

CONCLUSION

It is widely accepted that elimination or silencing of cccDNA is necessary to cure HBV infections so that no active template remains for HBV to reactivate. It is possible for IFNs to achieve this through induction of ISGs, primarily APOBECs that specifically target cccDNA for degradation. IFN signalling also results in the recruitment of epigenetic modifiers that render cccDNA in a transcriptionally repressed and silent state. However, HBV prevents these by inhibiting IFN signalling through upregulating negative regulators of IFN signal transduction such as SOCS2, and sequestration of factors that transduce IFN signalling. Thus, to achieve an anti-HBV response that targets cccDNA specifically, drugs that enhance and sustain the anti-cccDNA effects of IFN signalling and drugs that target HBV products that disrupt these IFN-mediated mechanisms need to be developed. Fortunately, many of the anti-cccDNA mechanisms are not unique to HBV infection. Drugs known to modulate these IFN-mediated pathways can be re-purposed and tested for efficacy in suppressing HBV replication and cccDNA levels. These include LTβR agonists and other cytokines that serve as alternative pathways to strengthen IFN-mediated APOBEC expression, inhibitors in the treatment of type II diabetes that act on SOCS proteins to prevent dampening of IFN signalling transduction, and epidrugs that render cccDNA transcriptionally silent. These drugs may be used together with current HBV therapies, new anti-HBV drugs in the pipelines such as cell-penetrating antibodies, cccDNA-targeting CRISPR/Cas9 systems and even natural compounds that directly target HBV proteins that disrupt IFN signalling for degradation. Hopefully, the success of these novel strategies would materialize for the eradication of HBV.

Table 3 Updates on combination therapy

Abstract

Esophageal cancer (EC) is a common malignant tumor of the digestive tract and originates from the epithelium of the esophageal mucosa. It has been confirmed that early EC lesions can be cured by endoscopic therapy, and the curative effect is equivalent to that of surgical operation. Upper gastrointestinal endoscopy is still the gold standard for EC diagnosis. The accuracy of endoscopic examination results largely depends on the professional level of the examiner. Artificial intelligence (AI) has been applied in the screening of early EC and has shown advantages; notably, it is more accurate than less-experienced endoscopists. This paper reviews the application of AI in the field of endoscopic detection of early EC, including squamous cell carcinoma and adenocarcinoma, and describes the relevant progress. Although up to now most of the studies evaluating the clinical application of AI in early EC endoscopic detection are focused on still images, AI-assisted real-time detection based on live-stream video may be the next step.

Key Words: Early esophageal cancer; Artificial intelligence; Endoscopy; Diagnosis; Trend

INTRODUCTION

Esophageal cancer (EC) is one of the most common malignant tumors of the digestive tract and originates from the epithelium of the esophageal mucosa[1]. In 2018, the global incidence of EC was ranked seventh among malignant tumors (6.3/100000), and the mortality rate ranked sixth (5.5/100000)[2]. There are significant differences in the incidence and patterns of EC among different countries and regions, with the highest incidence in East Asia, which is twice the world average (12.2/100000). The main pathological type is esophageal squamous cell carcinoma (ESCC), while esophageal adenocarcinoma (EAC) is the main pathological type in relatively low-incidence areas such as Europe and America. Experiences in Japan and South Korea have confirmed that early EC lesions can be cured by endoscopic therapy. The curative effect is equivalent to that of surgical operation, and the 5-year survival rate of patients can reach 95%[3]. Therefore, early detection of EC and timely endoscopic treatment are the only ways to reduce EC mortality.

Upper gastrointestinal endoscopy is still the gold standard for EC diagnosis. After years of research and practice, the current upper gastrointestinal endoscopy diagnosis technology has made considerable progress. In terms of diagnostic methods, the original single ordinary white light imaging (WLI) has gradually developed into a variety of technologies such as pigment endoscopy, confocal laser endomicroscopy (CLE), electronic staining, magnifying endoscopy (ME), and autofluorescence imaging (AFI) endoscopy[4]. Among them, narrow band imaging (NBI) and blue laser can improve the sensitivity (SEN) of early EC diagnosis to more than 90% compared with ordinary white light endoscopy. CLE, also known as optical biopsy, can be comparable to pathological slices. The diagnostic specificity (SPE) of AFI is 50%, and the SEN is 100%[5]. At present, NBI, blue laser, *etc.* have been widely used in clinical practice, but clinical applications such as CLE and AFI are not universal.

British and American gastroenterologists have developed a series of guidelines for the screening and surveillance of Barrett's esophagus (BE) and EAC[6,7]. In China, gastroenterologists recommend endoscopic screening of key populations to improve the diagnosis rate of early EC. Endoscopic iodine staining and indicative biopsy screening programs implemented in high-risk areas in China can effectively reduce the incidence and mortality of esophageal cancer[8]. It is recommended that 40 years of age is the starting age for screening for EC, and screening should be terminated when the age of 75 or life expectancy is less than 5 years. Early EC and intraepithelial neoplasia (or dysplasia) are the main screening targets[9].

As we all know, the accuracy (ACC) of endoscopic examination results largely depends on the professional level of the examiner. Studies have shown that the use of proton pump inhibitors, less experienced endoscopists (< 5 years and < 1000 cases of endoscopy), and smaller lesions are significantly related to missed diagnosis of EC[10]. A great amount of needs in EC-related endoscopic screening increase the burden of clinical work, and the increase in staff fatigue may in turn affect the efficiency and ACC of the examination. How to solve the problem of the drastic increase in endoscopy workload has plagued clinical work managers.

Artificial intelligence (AI), machine learning (ML), and deep learning (DL) have relatively specific meanings, but they are usually widely used to refer to any modern processing method related to big data. AI is not "new". When Turing first designed his test, the phrase was mainly reserved for a technology that could broadly imitate human intelligence. Today, AI is widely and universally used to refer to any kind of ML program. At the most basic level, ML refers to any type of computer program that can "learn" on its own without having to be explicitly programmed by humans. ML includes supervised learning, unsupervised learning, and semi-supervised learning, which combines supervised and unsupervised approaches. In supervised learning,

algorithms generate answers based on known and labeled data sets. Classification and regression algorithms, such as random forests and support vector machines (SVM), are commonly used in supervised learning. In unsupervised ML, algorithms generate answers to unknown and unlabeled data.

DL is a form of ML that can use supervised or unsupervised algorithms, or both. Through the hierarchical learning process to extract high-level and complex abstractions as data representations, DL models produce results faster than standard ML methods. Convolutional neural network (CNN) can be composed of many layers of models. Each layer takes input from the previous layer, processes it, and then outputs it to the next layer in a daisy chain.

The emergence of AI has gradually emerged in clinical work, and a large number of verifications have been obtained in medical imaging, especially the screening and diagnosis of lung cancer[11], and the analysis of pathological characteristics[12]. Some AI technologies have also been applied in the screening of early EC and have shown their advantages. This article will review the application status of AI in the screening of early EC under endoscopy and discuss its future development trends.

AI IN ENDOSCOPIC DETECTION OF ESCC

In 2002, experts of digestive endoscopy summarized the Paris classification of early digestive tract lesions[13]. Among them, the endoscopic morphology of superficial ESCCs roughly divided into three categories: Protruded, flat, and depressed types. However, in squamous epithelium, the microvascular pattern of intrapapillary capillary loops (IPCLs) is the only reliable indicator of tissue atypia[14]. In diagnostic criteria of the Japanese Esophageal Society (JES) classification, the microvascular irregularity is evaluated for the presence or absence of each of the following morphological factors: Weaving (*i.e.* tortuosity), dilatation, irregular caliber, and different shape (*i.e.* various shapes). Currently, clinical endoscopists generally use the AB classification proposed by JES. If microvessels have three or fewer factors, they are classified as type A; if they have four factors, they are classified as type B[15].

At present, NBI-ME has become the first choice clinical method for the diagnosis of early ESCC. With the help of NBI-ME, endoscopists can clearly observe the morphology of the diseased IPCL and guide the selection of targeted biopsy and clinical treatment strategies. However, the ACC of NBI-ME in diagnosing early ESCC is limited by the experience and level of endoscopists. The diagnostic ACC of experienced experts is as high as 90%, while for inexperienced or non-expert endoscopists, the diagnostic ACC is only 78.6%[16]. AI may help those inexperienced endoscopists to analyze medical images intelligently, detect and/or classify lesions, and improve the ACC of diagnosis by using variant algorithms[17] (Table 1).

ESCC diagnosis

In 2015, Shin *et al*[18] developed a class 2 Linear classification algorithm to identify squamous high-grade dysplasia (HGD) or ESCC by using nuclear-related features of high-resolution microendoscope (HRM) images. The area under the curve (AUC), SEN, and SPE of the test and validation data sets were 0.95, 87%, and 97% and 0.93, 84%, and 95%, respectively. In order to reduce equipment costs, Quang *et al*[19] developed a small tablet-interfaced HRM with real-time algorithms. The algorithm can automatically identify ESCC, and its AUC, SEN, and SPE were 0.937, 95%, and 91%, respectively. It was believed to be especially beneficial in lower-resource settings for operators with less experience interpreting HRM images.

In 2016, Liu *et al*[20] designed an algorithm called Joint Diagonal Principal Component Analysis (JDPCA) for detection of EC. In their research, a novel image feature extraction method was established through combining the algorithm of ML based on JDPCA and conventional feature extraction algorithm without learning. Then a computer-aided method was proposed to identify the endoscopic images obtained from conventional gastroscopy and wireless capsule endoscopy containing lesions. The algorithm can correctly detect 90.75% EC, and the AUC reached 0.9471 as a result. Although ESCC is the main pathological type in China, the specific classification of EC was not mentioned in the study.

Horie *et al*[21] first tried to use DL to diagnose ESCC through a large number of endoscopic images in 2019. The CNN took 27 s to analyze 1118 test images captured using WLI and NBI and correctly detected EC cases with a SEN of 98%. It could distinguish superficial EC from advanced cancer with ACC of 98%. Subsequently, Cai *et al*[22] proposed a novel computer-aided diagnosis (CAD) system using a deep neural

Although no detailed information about the classification of esophageal cancer (EC) was found in the research of Liu *et al*[20] and Luo *et al*[31], I prefer to summarize the data in this table because most EC patients in China suffer from esophageal squamous cell carcinoma. AI: Artificial intelligence; AUC: Area under the curve; SEN: Sensitivity; SPE: Specificity; ACC: Accuracy; PPV: Positive predictive value; NPV: Negative predictive value; HRM: High-resolution microendoscopy; 2-class LDA: Two-class linear discriminant analysis; NA: Not available; WCE: Wireless capsule endoscopy; JDPCA: Joint diagonalization principal component analysis; CCV: Color coherence vector; n-fold-CV: n-fold cross-validation; WLI: White light imaging; NBI: Narrow-band imaging; CNN: Convolutional neural network; SSD: Single-Shot Multibox Detector; DNN: Deep neural network; DL: Deep Learning; BLI: Blue Laser Imaging; ME: Magnifying endoscopy; FCN-CAD: Full convolutional network computer-aided detection; ECS: Endocytoscopic system; GRAIDS: Gastrointestinal Artificial Intelligence Diagnostic System.

network (DNN). Two thousand four hundred twenty-eight (1332 abnormal, 1096 normal) esophagoscopic images from 746 patients were collected to set up a novel DNN-CAD system in two centers, and a validation dataset containing 187 images from 52 patients was prepared. Only standard WLIs were used to train the model. The DNN-CAD model can detect 91.4% of early ESCC, which is higher than that of advanced endoscopists.

Ohmori *et al*[23] evaluated ME and non-ME images [including WLI and NBI/Blue Laser Imaging (BLI)] using Single-Shot Multibox Detector (SSD) based CNN to identify ESCC. The ACC of ME, non-ME+WLI, and non-ME+NBI/BLI was high SEN and moderate SPE, respectively, 77%, 81%, and 77%. It was proved in the study that no significant difference existed in diagnostic performance between AI and experienced endoscopists.

Endocytoscopic diagnosis

Zhao *et al*[24] conducted another CAD model to evaluate the feasibility of automated classification of IPCLs to improve the detection of ESCC. ME-NBI images were collected, and a double-labeled full convolutional network was developed for image segmentation. In the research, it was shown that the diagnostic ACC of senior observers was much higher than that of mid-level and junior observers. When this model distinguished the lesions A, B1, and B2 IPCL, the diagnostic ACC rates of the lesion and pixel level reached 89.2% and 93%, respectively, similar to the seniors. Specifically, the model was more sensitive to type A IPCL than clinicians (71.5% *vs* 28.2%-64.9%), which can avoid unnecessary radical treatment. A total of 7046

sequential HD ME-NBI images from 17 patients were used to train a CNN in another study conducted by Everson *et al*[25]. IPCL patterns were also classified according to the JES classification. This CNN differentiated abnormal from normal IPCL patterns with 93.7% ACC.

The endocytoscopic system (ECS) provides magnified endoscopy, which can be stained with methylene blue to observe surface epithelial cells[26,27]. The optical magnification of ECS is 500 ×, which can be increased to 900 × by using the digital magnification in the video processor[26]. Kumagai *et al*[27] used a CNN-based AI system based on GoogLeNet and trained using 4715 ECS images of the esophagus (1141 malignant and 3574 non-malignant images) to diagnose ESCC using ECS images. An independent set of 1520 images, collected from 55 consecutive patients (27 ESCCs and 28 benign esophageal lesions) were tested. The AI correctly diagnosed 25 of the 27 ESCC with an overall SEN of 92.6%, SPE of 89.3%, and an overall ACC of 90.9%.

Depth of invasion diagnosis of ESCC

The study conducted by Nakagawa *et al*[28] did not determine the IPCL pattern but aimed to predict the depth of cancer invasion by using a DL system based on the CNN-SSD architecture. For all, non-ME and ME images, the system's ability to distinguish correctly pathologic mucosal/submucosal microinvasive (EP/SM1) cancers from submucosal deep invasive (SM2/3) cancers was 91%, 92.9%, and 89.7%, respectively, with comparable performance to experienced endoscopists.

In Tokai *et al*[29] research, AI's ability to measure the depth of ESCC invasion was demonstrated. They collected 1751 ESCC training images obtained by WLI and NBI from the Japan Cancer Institute Hospital and developed a CNN-SSD diagnosis system. The magnified images obtained *via* ME were excluded. Subsequently, 291 test images from 55 patients confirmed by pathological findings were used to compare the AI system with 13 board-certified endoscopists. The AI system detected 95.5% of the ESCC in the test images in 10 s and correctly estimated the ESCC infiltration depth in 6 s, with a SEN of 84.1% and an ACC of 80.9%. The ACC score of this system exceeded 12 of 13 endoscopists, and its AUC was greater than the AUC of all endoscopists. It was indicated that the AI system could potentially be used for ESCC diagnosis and measuring depth of invasion.

Real-time diagnosis of ESCC

Guo *et al*[30] developed a CAD system based on SegNet architecture that can perform real-time automatic diagnosis of precancerous lesions and early ESCC under non-ME and ME. Data from four medical centers in three countries including China, the United States, and India were collected and used for CAD model training. Four sets of data from early ESCC and noncancerous endoscopy including still images and real-time videos were used to verify their effects. The SEN and SPE of the system were 98.04% and 95.03%, respectively, for still images. In 27 non-magnifying videos, the per-frame and the per-lesion SEN were 60.8% and 100%, respectively. In 20 magnifying videos, the per-frame and the per-lesion SEN were 96.1% and 100%, respectively. Unaltered full-range normal esophagus videos included 33 videos (per-frame SPE 99.9%, per-case SPE 90.9%).

In another multi-center, case-control, diagnostic study, Luo *et al*[31] developed and validated the Gastrointestinal Artificial Intelligence Diagnostic System (GRAIDS) for the diagnosis of upper gastrointestinal cancers through analysis of imaging data from clinical endoscopies. Six hospitals of different levels with varying experience in the endoscopic diagnosis of upper gastrointestinal cancer in China participated in the study. The GRAIDS algorithm was based on the concept of DeepLab's V3+ [released by Google (Mountain View, CA, United States) in 2018]. In total, 1036496 endoscopic images from 84424 individuals were used to develop and test GRAIDS. GRAIDS achieved a diagnostic SEN similar to that of expert endoscopists {0.942 [95% confidence interval (CI): 0.924-0.957] *vs* 0.945 (0.927-0.959); $P = 0.692$}. The SEN was higher than that of qualified endoscopists [0.858 (0.832-0.880), $P < 0.0001$] and trainees [0.722 (0.691-0.752), $P < 0.0001$]. In this big data study, the number of EC in the training set and verification set reached about 27% of the total, but the proportion of early EC and the detection effect were not explained. More detailed data on early EC are to be expected.

The latest research results on real-time detection of early EC are from Fukuda *et al*[32]. They used 23746 images of 1544 cases of superficial ESCC confirmed by pathology and 4587 images of 458 cases of non-cancerous and normal tissues to construct a deep CNN-SSD model. NBI or BLI technology was used to collect 5-9 s video clips of 144 patients as a verification data set. The SEN, SPE, and ACC for the AI were 86%, 89%, and 88%, respectively, and 74%, 76%, and 75% for the experts,

respectively. This is an important study that paves the way for the development of better models to detect EC lesions in a real-time clinical environment, but randomized prospective clinical trials are needed for verification.

Another research team from Japan developed an AI system to calculate ESCC invasion depth[33]. In total, 23977 images, including WLI and NBI/BLI images of pathologically proven ESCC from endoscopic videos and still images, were obtained as a learning dataset. An independent validation dataset of 102 video images of ESCC was taken in research. Two types of videos, non-ME with WLI and ME with NBI/BLI of 4-12s, were included. The CNN model was compared with 14 experts in endoscopic field. ACC, SEN, and SPE performance for AI were superior to those for experts in both types of videos. The AI model was concluded to be effective in real-time measurement of ESCC invasion depth.

AI IN ENDOSCOPIC DETECTION OF BE AND EAC

BE is the precursor of EAC. The prevalence of EAC is rising rapidly, and the prognosis of advanced cases is poor. However, early detection of cases can be promptly treated with endoscopic treatment, which has a chance of cure. Due to the difficulty in detecting early neoplasms under endoscopy, early lesions are often missed[34]. This is because early Barrett tumors are usually flat, with only subtle changes in the color and texture of the mucosa. These changes can be visible in the HD-WLI performed by experts. However, due to the low progression rate of tumor formation (< 1% per patient year), many general-level endoscopists rarely encounter the early formation of Barrett's tumor, so that they are not familiar with its endoscopic morphology and cannot recognize the lesions[35]. In order to improve EAC screening and increase the SEN and speed of the examination, AI-assisted endoscopy has important value. In addition, it can also provide convenience for endoscopists facing challenges and anxiety, so as not to miss early lesions (Table 2).

EAC diagnosis

In 2013, van der Sommen *et al*[36] first proposed a SVM algorithm for detecting early cancer in the EAC using HD endoscopic images, color histograms ,and simple statistical data of Gabor features, with a classification ACC of 95.9% and an AUC of 0.992. Later, they found that the system detected 36 from 38 lesions with a recall of 0.95 and a precision of 0.75 through clinical validation. In 2016, van der Sommen *et al*[37] tested a computer algorithm (automated image recognition system) that employed specific texture, color filters, and ML for detecting early neoplastic lesions on BE based on specific imaging details. All images were of high perceptual quality. The algorithm was developed and tested using 100 endoscopic images of 44 BE patients. Early tumor lesions were identified in the per-image analysis, with a SEN and SPE of 0.83. At the patient level, the SEN and SPE of the system were 0.86 and 0.87, respectively.

Swager *et al*[38] conducted the first study based on volume laser endoscopy (VLE) images with direct histological correlation in 2017, which developed a clinically inspiring computer algorithm for BE neoplasia[39]. VLE is an advanced imaging system that can scan the esophagus wall up to 3 mm deep with near-microscopic resolution. A total of 60 VLE images from a high-quality *ex vivo* VLE histological correlation database were used in the study, including 30 nondysplastic BE and 30 HGD/early EAC images. The algorithm of the feature "layering and signal decay statistics" showed good performance in detecting BE neoplasia (AUC = 0.95), and thus it might possible to assist endoscopists in detecting early neoplasia on VLE. van der Sommen *et al*[40] also compared the performance of the CAD methods with the classification ACC of two VLE experts, with a maximum AUC in the range of 0.90-0.93 for the ML method *vs* an AUC of 0.81 for the medical experts.

Horie *et al*[21] proved that the diagnosis ACC for EAC of the CNN was 90% (19/21). Four lesions of EAC were missed, which may be because educational images for EAC were not enough. Only eight were used in the study. In another study about CNN, four methods including Regional-based CNN (R-CNN), Fast R-CNN, Faster R-CNN, and SSD were adapted to detect abnormal regions in the esophagus HD-WLE images automatically[41]. A total of 100 images from 39 patients that have been manually annotated as ground truth by five experienced clinicians were tested. The SSD outperformed other methods achieving SEN of 0.96, SPE of 0.92, and F-measure of 0.94. Hashimoto *et al*[42] conducted a pilot study on the endoscopic detection of early esophageal neoplasia on BE using a CNN system. They pre-trained the system on ImageNet, then received training on 1853 images, and finally tested it with 458 images.

Table 2 Artificial intelligence application for esophageal adenocarcinoma

AI: Artificial intelligence; AUC: Area under the curve; SEN: Sensitivity; SPE: Specificity; ACC: Accuracy; PPV: Positive predictive value; NPV: Negative predictive value; WLI: White light imaging; CAD: Computer-aided diagnosis; SVM: Support vector machines; LOOCV: Leave-one-out cross-validation; NA: Not available; VLE: Volume laser endoscopy; NBI: Narrow-band imaging; CNN: Convolutional neural network; DL: Deep learning; SSD: Single-Shot Multibox Detector; n-fold-CV: n-fold cross-validation; MICCAI: Medical Image Computing and Computer Assisted-Intervention; IRIS: Intelligent real-time image segmentation.

The size of the tumor lesions in the image data they selected was between 3 mm and 20 mm, and most of the lesions were not significant, so that endoscopists with less training were likely to miss the diagnosis. The CNN accurately detected 95.4% of early lesions, including 96.4% of SEN and 94.2% of SPE, and the running speed of the algorithm was allowed for real-time implementation.

Progress on CAD development was made by de Groof *et al*[43] for BE detection. All WLIs recorded in 40 cases of neoplastic Barrett lesions and 20 cases of non-dysplastic BE were collected through WLE in full HD format (1280 × 1024 pixels). Experts delineated the images of neoplasm. The CAD system had received training in color and texture features. The ACC, SEN, and SPE for detection were 92%, 95%, and 85%, respectively, which were evaluated by leave-one-out cross-validation. In the randomized controlled trial (No: NTR7072.) reported in 2019, de Groof *et al*[44] developed a hybrid ResNet-UNet model CAD system using five independent endoscopy data sets. Compared with general endoscopists, the ACC of the CAD system was 88% *vs* 73%, the SEN was 93% *vs* 72%, and the SPE was 83% *vs* 74%. This report details the first externally validated DL-CAD system for early BE neoplasia.

In the study of Ebigbo *et al*[45], two databases [Augsburg data and the 'Medical Image Computing and Computer Assisted-Intervention' (MICCAI) data] were used to train and test a CAD system on the basis of a CNN with a residual net (ResNet) architecture. Based on still images, the diagnosis of EAC by CAD-DL reached SEN/SPE of 97%/88% (Augsburg data) and 92%/100% (MICCAI data) for WLIs and 94%/80% for NBIs (Augsburg data), respectively.

Depth of invasion diagnosis of EAC

Several studies questioned whether surgery should always be used to treat EAC with deep submucosal invasion. However, it is accepted that the depth of invasion is at least one of the biggest risk factors for metastasis[46]. In the searching item related to the word "depth of invasion/ infiltration of EAC", no article published was found. Fortunately, research on AI's infiltration depth measurement of gastric cancer and

colon cancer has been published, which may be worth learning for research of invasion depth of EAC. In the study of Zhu *et al*[47], a total of 790 WLIs served as a development dataset and another 203 images as a test dataset, and a CNN-CAD system, developed from ResNet50, was used to determine the invasion depth of gastric cancer. At a threshold value of 0.5, the SEN was 76.47%, SPE was 95.56%, and the overall ACC was 89.16%. The AI system achieved significantly higher ACC than human endoscopists. Scholars from Japan analyzed endocytoscopic images by using CAD-SVM, and the algorithm obtained after extracting 5543 images from 238 lesions can diagnose invasive colorectal cancer in 200 test images with an ACC of 94.1%[48].

Real time diagnosis of EAC

Ebigbo *et al*[49] developed a real-time DL system based on deep CNN and ResNet architecture with the latest encoder/decoder network DeepLab V.3+. The endoscopy was performed by an expert endoscopist. The system captured random images from real-time camera livestream and provided global prediction (classification) and dense prediction (segmentation), which can accurately distinguish between normal BE and early EAC. The ACC of the AI system for 14 cases of early EAC was 89.9%. The AI-based CAD was indicated to improve the quality of BE assessment, especially for non-expert endoscopists.

In 2019, Trindade *et al*[50] reported an AI software termed intelligent real-time image segmentation for endoscopic surveillance of BE. The intelligent real-time image segmentation identified three established VLE features previously associated with histologic dysplasia and displayed them using different color schemes superimposed over the VLE image. A multi-center randomized controlled trial (NCT03814824) is underway to validate further the AI system. In another study, de Groof *et al*[51] evaluated the preliminary diagnostic ACC of a CAD system in detecting Barrett's neoplasm during live endoscopic procedures. The test dataset composed of the live endoscopy procedure of 10 patients with nondysplastic Barrett's esophagus and 10 patients with confirmed Barrett's neoplasm. WLIs at every 2 cm level of the Barrett's segment were obtained and analyzed. The ACC, SEN, and SPE of the CAD system were 90%, 91%, and 89%, respectively. This result revealed that the CAD system was ready to be tested in larger multi-center trials.

LIMITATION OF AI APPLICATION IN EARLY EC DETECTION

AI is becoming rapidly integrated into modern gastroenterology with the expansion of diagnostic images and treatments. Among the three common tumor diseases of the digestive tract, esophageal cancer, gastric cancer, and colon cancer, the value of AI has been fully demonstrated. Multiple AI algorithms have been developed to run real-time during gastroscopy and colonoscopy for cancerous detection, diagnosis, or invasion depth measurement[48,52,53]. The application of AI in the field of gastric cancer and colon cancer seems to be earlier and more comprehensive than that in the field of esophageal cancer.

It can be seen from the above review that the clinical application of AI in early EC is still in its infancy. The vast majority of studies are retrospective studies, and only two clinical trials have been reported, one of which is still in research progress. The above-mentioned research mainly focused on AI algorithms, training and verification and compared with the detection ACC, SEN, and SPE of different levels of endoscopists. There has not been a large-scale clinical application of AI, whether for surveillance or detection. It is foreseeable that the difficulties in applying AI to clinical practice are manifold, and there are still many obstacles before large-scale implementation.

First of all, the current AI applications mainly focus on files such as images, pictures, and videos. The establishment of an AI model requires a sufficiently large training set labeled by experts for AI learning. This training set requires the participation of a number of expert-level staff, and experts are obviously scarce resources, which makes it difficult for the quantity and quality of the training set to meet sufficient demand. As natural persons, experts are also likely to make mistakes. This may lead to incorrect diagnostic information in the training set. Secondly, a large amount of medical imaging data, especially endoscopy data related to EC, need to be obtained during manual examination. The quality of the data depends not only on the level of the endoscopist but also on the function of the endoscopic instrument. Not all endoscopists can complete a qualified endoscopy, and not all endoscopy equipment can provide the best images. Most medical units can only use their own data, which can be considered a selection bias. AI must be applied to external multi-centers for

validation to explore its ACC. At present, only a multi-center study from China had conducted external verification[31]. Third, the subject of AI use in early EC detection is currently mainly focused on retrospective research. It is difficult to use AI technology for prospective clinical research, especially blinded randomized controlled trials, although this type of research is the most reliable "gold standard" in medical science. To conduct such a trial, it requires medical ethics approval. Fourth, the current generation of AI is numerous but proprietary. Costs including equipment and person training may become a limiting factor for widespread implementation. Fifth, the acceptance and approval of AI by governmental and professional organizations are needed. For each country, any legal issues related to the use of AI in endoscopes must be resolved before widespread implementation.

FUTURE OF AI APPLICATION IN EARLY EC DETECTION

Papers on AI in the diagnosis of early EC are gradually increasing, but except for a few, they basically discuss AI algorithms and clinical validation. The training data and verification data used are also still images. In the study on EAC , the authors also used still images for real-time analysis during endoscopy[49], which may be useful for evaluating EAC and other situations because the area of BE is limited. It is more useful to use real-time video for detection, because the detection can be performed immediately without the need to capture pictures frequently. In order to investigate whether AI is useful for preventing missed cancerous diagnosis, validation videos should not be limited to slow observation videos but include fast videos. However, this high accuracy comes from high-resolution videos, and it is not easy to provide accurate and high-quality images in videos containing low-resolution. As a guarantee of computing speed, the improvement of graphics processing unit and other hardware needs to be synchronized.

Existing papers discuss the still images of the esophageal surface and the depth of invasion, indicating that endoscopic equipment can not only improve the image quality but also become three-dimensional. When combined with other sensing technologies, it is eager to perform three-dimensional mapping of esophageal lesions through an endoscope. If AI technology is combined with three-dimensional endoscopy, what will happen in the future? There is no ending.

The AI system is expected to become a qualified assistant, but not a substitute, for inexperienced endoscopists to get similar judgment capabilities as experts. In order to establish an AI training database applicable to the whole world, it is necessary to establish a gold standard for AI diagnosis. This requires endoscopy experts from different countries and regions to label accurately and supplement the database.

Even though AI is helpful for diagnosis during endoscopy, it is temporarily difficult for AI to perform endoscopy operations on behalf of humans because the shape of the digestive tract varies from person to person. Therefore, for endoscopists, efforts to improve the technology used to operate endoscopes will continue to be indispensable.

CONCLUSION

This review summarizes the current status of research and development of AI in endoscopes related to early EC detection and the application prospects of AI. The use of AI-based endoscopes will enable detection accuracy of early EC and improve prognosis. As the diagnosis ability and accuracy of early EC vary greatly among endoscopists, AI may have better diagnostic capabilities and will help endoscopists to reduce missed diagnosis of early EC in the near future. Maybe only a step is needed to move for AI application in such a clinical field, but the step needs efforts from multiple fields including medicine, AI, optics, legislation, ethics, *etc*. We might as well look forward to this step as soon as possible.

Abstract

Gastrointestinal (GI) symptoms have been described in a conspicuous percentage of coronavirus disease 2019 (COVID-19) patients. This clinical evidence is supported by the detection of viral RNA in stool, which also supports the hypothesis of a possible fecal-oral transmission route. The involvement of GI tract in severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection is corroborated by the theoretical assumption that angiotensin converting enzyme 2, which is a SARS-CoV-2 target receptor, is present along the GI tract. Studies have pointed out that gut dysbiosis may occur in COVID-19 patients, with a possible correlation with disease severity and with complications such as multisystem inflammatory syndrome in children. However, the question to be addressed is whether dysbiosis is a consequence or a contributing cause of SARS-CoV-2 infection. In such a scenario, pharmacological therapies aimed at decreasing GI permeability may be beneficial for COVID-19 patients. Considering the possibility of a fecal-oral transmission route, water and environmental sanitation play a

Core Tip: Coronavirus disease 2019 (COVID-19) patients may suffer from gastrointestinal symptoms that are associated with gastrointestinal dysbiosis. Even though the exact role of gut microbiome perturbation as a either a cause or a consequence of the disease is still to be elucidated, pharmacological interventions aimed at containing intestinal permeability may be of support in COVID-19 patients.

INTRODUCTION

In December 2019, in Wuhan, one of the largest cities in the Chinese province of Hubei, a new coronavirus appeared that was responsible for a pneumonia epidemic that was named by the World Health Organization (WHO) on February 11, 2020 as coronavirus disease 2019 (COVID-19), and declared as a dangerous threat to public health and an international health emergency[1,2]. Indeed, COVID-19 infections rapidly spread and was declared a pandemic by the WHO one month later on March 11, 2020. In a short time, the pandemic involved all continents, and at the time of writing this review, accounts for more than 100 million confirmed cases worldwide, also becoming a serious threat to the global economy[3,4].

At the beginning of January 2020, the new coronavirus responsible for this pandemic was named "severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2)" by the International Committee on Taxonomy of Viruses[5]. It is a single-stranded RNA virus with positive polarity and is closely related to the B-line of beta-coronaviruses, which are typically responsible for severe and lethal respiratory syndromes[2,6]. Phylogenetic analysis showed that the viral sequence of this new coronavirus has a strong similarity (89%) with two other coronaviruses similar to SARS and deriving from bats, namely bat-SL-CoVZC45 (GenBank access n. MG772933.1) and bat-SL-CoVZXC21 (GenBank access n. MG772934.1). Similarities were also found with SARS-CoV, the virus that caused the SARS pandemic in 2002/2003, and the Middle East Respiratory Syndrome (MERS-CoV) pandemic of 2012, with which SARS-CoV-2, shares sequence homologies (79% with SARS-CoV and 50% with MERS-CoV)[7-9] as well as zoonotic transmission and several clinical features.

MECHANISM OF INFECTION

Studies carried out so far suggest that the human angiotensin converting enzyme 2 (ACE2) is the main target receptor for the virus to gain access into human host cells. Binding occurs between the ACE2 binding domain located at the C-terminal end of the viral spike protein and the ACE2 target receptor located on the surface of the host cell membrane[10]. After binding to ACE2 receptors on human cells[11], the SARS-CoV-2 spike protein is cleaved by two mucosa-specific serine proteases, namely TMPRSS2 and TMPRSS4, to facilitate viral cellular infection[12].

Tissues with the highest expression of ACE2, and therefore a high sensitivity to infection are present in both the respiratory and the gastrointestinal (GI) tracts. The receptor is present in the pulmonary epithelium, in type 2 pneumocytes that are present in the alveoli where the exchange between oxygen and carbon dioxide takes

place, in the nose, mouth, stratified epithelial cells in the upper esophagus, and absorbent enterocytes of the ileum and colon. Other receptors that are known to allow entry of SARS-CoV-2 are DC-SIGN (CD209), CD147 and L-SIGN (CD209L)[13-15]. Transmission of the virus can take place through direct contact with respiratory droplets from infected subjects or indirectly from contaminated objects and surfaces[16].

CLINICAL SYMPTOMS

Clinical manifestations associated with COVID-19 infection range from complete absence of symptoms (asymptomatic subjects) to serious and even fatal infections. In most cases, the disease is mild to moderate, so that symptoms can be managed safely at home without the need for hospitalization. The main target of the infection is the respiratory tract, and therefore, the clinical manifestations associated with the disease are mostly respiratory. The most common symptoms are similar to those of seasonal flu and include fever, dry cough, dyspnea, sore throat, headache, muscle aches, and asthenia. Severe respiratory distress, chest pain, pneumonia, and pulmonary insufficiency can also be found in severe cases[17-19]. In SARS-CoV-2 pneumonia, lung computed tomography scans shows bilateral, subpleural ground-glass opacity lesions[20-22]. In addition to pulmonary clinical manifestations, heart damage can also occur in infected patients. Shi *et al*[23] in a study conducted in Wuhan on 400 patients, found that about one-fifth experienced heart disease as a risk factor for worse outcome. Heart damage essentially consists of sudden and severe myocardial inflammation leading to heart failure and arrhythmias[24]. For this reason, hypertensive patients, and in general all individuals with a positive history of cardiovascular disease, are more at risk of experiencing a poor prognosis than other patients[25]. SARS-CoV-2 can also damage the central nervous system, with symptoms that range from mild (anosmia, dysgeusia) to severe (viral encephalitis). Moreover, COVID-19 infection, like other pulmonary infectious diseases, may represent a risk factor for acute cerebrovascular events. The observed D-dimer elevation in COVID-19 patients may indicate additional risk of cerebrovascular events[26]. Kidney and liver damage have also been reported. Proteinuria, hematuria, increased aspartate transaminase (AST, also known as aspartate aminotransferase or glutamic oxaloacetic transaminase), alanine aminotransferase (ALT, also known as alanine transaminase or glutamic-pyruvic transaminase), and bilirubin have been found in about half of infected patients[27,28].

The virulence of microorganisms determines the damage to host cells before the microorganisms are cleared by host immunity[29]. Yet, the virulence of the infective microorganism does not fully account for the virulence of the disease, the majority of which results from inflammation produced by the immune response[29]. That has been demonstrated for many infective diseases and is particularly true for SARS-CoV-2. Most viral and bacterial infections in humans are self-limiting[29,30], and infecting microorganisms become commensal if they can coexist with the human host. The SARS-CoV-2 virus infection is no different[31], and that could explain why most COVID-19 cases are asymptomatic or mild.

COVID-19 AND THE GI TRACT

Although, as reported, SARS-CoV-2 infection mainly affects the respiratory system[32], leading to breathing difficulties, dry cough, and nasal congestion to respiratory failure, this novel coronavirus can be found in the GI tract as well[33]. Furthermore, SARS-CoV-2 RNA has been isolated from stools. Viral nucleocapsid protein can be observed in duodenal and rectal glandular epithelial cells by laser scanning confocal microscopy. The available results provide evidence of the activity of this virus in the GI tract[34].

GI SYMPTOMATOLOGY

GI symptoms are present in approximately 50% of COVID-19 patients, consisting mainly of diarrhea, nausea, vomiting, and abdominal discomfort[35]. Moreover, several studies have shown that SARS-CoV-2 is able to interact with ACE2 receptors on ileal enterocytes and colon epithelial cells, so that a trophism for the GI tract has been hypothesized as well[27,36]. Further evidence supporting the possibility that both the

small and large intestines may be susceptible to SARS-CoV-2 infection, was the isolation of viral RNA from the GI epithelium and staining of the viral nucleocapsid protein in these cells[34]. In addition, viral RNA was also isolated in stool samples from COVID-19 patients, and it was presumed that the viral components originated from infected enterocytes[34,36]. Considering the overall evidence, several reports have expressed concerns of possible fecal-oral transmission of SARS-CoV-2[37,38]. Nevertheless, the findings were not unexpected as other well-known coronaviruses, including those causing the MERS and SARS epidemics, have shown to infect enterocytes, leading to several GI symptoms[39].

Several reports have focused on the GI symptomatology in COVID-19 patients, underlining clinical outcomes that varied widely in terms of frequency. Nine of those studies that included a total of 4177 patients found that the incidence of GI symptoms varied from 4.9% to 61.3%. The most frequent symptoms were diarrhea (8.4%) and lack of appetite (7.4%); 4.1% of patients complained about nausea-related disorders, while vomiting was reported in 2.4% and abdominal pain in 1.7% of the cases[40-48]. Interestingly, the frequency of diarrhea, nausea, and abdominal pain in COVID-19 patients was shown to be higher among women than men[49]. Finally, Yang *et al*[50] examined 50 COVID-19 patients by dividing them in two groups by the presence of either initial pulmonary or initial GI symptoms. They found that patients with GI manifestations as initial symptoms had more severe clinical outcomes, leading to longer hospitalization.

As stated above, and similar to SARS-CoV-1, SARS-CoV-2 infection is mediated by ACE2, which allows the virus to enter the cells and replicate by taking advantage of the host synthesis apparatus[51]. A recent study has shown that the binding affinity of the spike protein of SARS-CoV-2 is about 10-20 times higher than that of SARS-CoV-1[52]. ACE2 receptors are widely expressed in the epithelia of both the respiratory and GI tracts. A recent multiomic *in vitro* study has shown that expression of these membrane enzymes is higher in intestinal cell lines than lung cell lines[36].

The pathophysiology of GI symptoms is not entirely clear, but it seems that they originate as a result of several phenomena. ACE2 performs an essential function in the intestine by regulating amino acid homeostasis and microbiome balance[53]. It is possible that the binding of SARS-CoV-2 to these membrane receptors reduces their availability, giving rise to an alteration of physiological function that induces a dysbiosis that leads to diarrhea, one of the most frequent symptoms reported during SARS-CoV2 infection[54]. The development of a cytokine storm could be indeed the cause of damage to the GI tract. Autopsies of SARS patients found increased expression of proinflammatory cytokines in ACE2-expressing cells compared with those that do not express this enzyme on their membranes[55]. It is fair to think that this happens following SARS-CoV-2 infection. Inflammation could also stimulate the gut microbiota to release molecules that increase the inflammatory state of the intestine and subsequently spread from the intestine into the circulatory system to cause systemic damage with more severe consequences than the viral infection itself[56]. In addition to locally occurring phenomena, the gut-lung axis seems to have a pivotal role in the development of GI symptoms as well. This axis represents a link between two organs that share a common mucous immune system[57]. Its influence has been hypothesized as a result of studies that have described COVID-19 patients with GI symptoms but without SARS-CoV-2 RNA-positive stool samples[54].

The impact of GI comorbidities on the development of symptoms in COVID-19 patients is yet to be defined. While the relationship between disorders such as diabetes, cardiovascular diseases, and hypertension and COVID-19-related severity was proven by several studies[58]. There are not yet sufficient studies to demonstrate a causal link between the presence of previous GI conditions and the onset of COVID-19-related symptomatology.

Indeed, existing studies do not provide indisputable results. A study carried out in China found that pre-existing GI disorders represent a third comorbidity in COVID-19 patients[59]. Another study carried out in Wuhan reported a relatively high percentage of COVID-19 patients with GI disorders[60]. Conversely, other studies carried out in the United States[61] and in Italy[62] have not found a significant correlation between SARS-CoV-2 infection and the presence of inflammatory bowel disease. On the contrary, Papa *et al*[63] observed a better clinical outcome in patients presenting with digestive comorbidities, as presumably they do not hinder the immune response against SARS-CoV-2. However, the authors point out that the number of cases observed was small[63].

FECAL-ORAL TRANSMISSION OF SARS-COV-2

A potential fecal-oral transmission route of SARS-CoV-2, in addition to respiratory droplets, person-to-person contact, or indirect infection following contact with contaminated surfaces, has been proposed by several authors[37,38,64,65]. The presence of common GI symptoms in the COVID-19 patients mentioned above is evidence that the GI tract is involved in SARS-CoV-2 infection.

Viral RNA has been detected in esophagus, stomach, duodenum, and rectum tissue from patients with severe SARS-CoV-2 infections[66]. Notably, the first COVID-19 patient in the United States tested positive for SARS-CoV-2 in loose stool specimens by real-time reverse transcription polymerase chain reaction[67]. Several studies report detection of viral RNA in stool samples in adults[34,68-72] and children[73-75] diagnosed with COVID-19. Interestingly, two studies confirmed that SARS-CoV-2 was detectable in fecal samples even after negative testing of respiratory swabs[70,72], and in patients who did not present GI symptoms[66,69,71]. In addition to SARS-CoV-2 RNA detection in stool samples, positive staining of viral nucleocapsid protein in gastric, duodenal, and rectal epithelia might demonstrate the infection of GI glandular epithelial cells[34]. Wang *et al*[68] found a high content of viral RNA in fecal specimens from COVID-19 patients, and electron microscopy confirmed the presence of living viral particles in those samples. Wölfel *et al*[69] could not isolate living SARS-CoV-2 from stool samples despite the presence of high concentrations of viral RNA, but did detect cells in a few stools that contained subgenomic mRNA, which suggests active replication of the virus in the intestinal tract. The presence of viral subgenomic mRNA indicates actively infected cells because such mRNA is transcribed only in infected cells and is not found packaged into virions[69]. As in adults, SARS-CoV-2 in children might persist in the GI tract longer than in the respiratory system. Actually, a high percentage of children diagnosed of COVID-19 tested positive on rectal or anal swabs, and some were positive after nasopharyngeal or throat swabs became negative[73-75].

Other evidence that supports an alternative fecal-oral transmission of COVID-19 is the expression of SARS-CoV-2 entry-genes in the cells of intestinal tissues. Mucosal cells of the lower intestine can be infected by other coronaviruses, resulting in diarrhea and other enteric symptoms. In this case, SARS-CoV-2 could be carried by saliva and secretions into the digestive tract, where it would infect the ACE2-expressing enterocytes. It has been confirmed that SARS-CoV-2 can infect enterocytes present in human small intestine organoid models, which supports virus replication and a GI route of infection[76]. However, another study demonstrated that human GI secretions were able to inactivate SARS-CoV-2, which suggests that although virus infection and pathogenesis is enhanced in the intestine, it is not clear if it would be a primary site of infection and possible route of transmission[77]. An alternative route of transmission that acts together with the respiratory route might explain the rapid spread of disease.

GUT MICROBIOME ROLE IN COVID-19 SEVERITY

COVID-19 symptomatology is strictly related to both a physiological and an aberrant activation of immune system, leading in very severe cases to a cytokine storm[78]. Based on this premise, it is not surprising that the gut microbiome, which is closely linked to the immune status of the host, may play a role in COVID-19 severity. A gut microbiome imbalance has been associated in COVID-19 patients with elevated concentrations of inflammatory cytokines, and blood markers, including C-reactive protein (CRP), lactate dehydrogenase, and aspartate aminotransferase[79]. Yeoh *et al*[79] examined blood and fecal samples from 100 young (mean age of about 36 years) confirmed positive COVID-19 patients in two Hong Kong hospitals. They also analyzed samples from patients for up to 30 days after clearance of SARS-CoV-2. All patients had slight or moderate symptomatology, with only 5% with severe and 3% with critical conditions. Compared with a group of healthy adult controls, COVID-19 patients had higher fecal populations of *Ruminococcus gnavus*, *Ruminococcus torques*, and *Bacteroides dorei* species. This imbalance seemed not to depend on the pharmacological therapy administered. The same investigators reported a stratification of gut microbiota composition associated with disease severity in hospitalized COVID-19 patients. Cytokine (IL-10 and tumor necrosis factor-), enzyme (AST, -glutamyl transferase, lactate dehydrogenase), CRP, N-terminal proB-type natriuretic peptide levels, and erythrocyte sedimentation rate were previously reported as associated with increased COVID-19-related symptomatology[80-82]. Those parameters were also significantly associated with microbiota composition in COVID-19 patients.

Remarkably, the levels of those molecules increased in parallel with changes in the microbiota composition, representing more severe disease states[79]. Overall, the results suggest that the gut microbiota composition might be linked to the extent of the immune response to COVID-19 and subsequent tissue damage, thus playing a role in regulating disease severity. The persistence of gut microbiota dysbiosis even 30 days after clearance of SARS-CoV-2 might also be linked to the persistence of COVID-19 related symptoms, such as fatigue, dyspnea, and joint pain.

Moreover, Yu[83] suggested that nutritional disorders impair immunity, causing hyperinflammation and leading to an overload of cytokines in COVID-19 patients. Autophagy induced by restrictive eating could be an efficient strategy to prevent COVID-19-related symptomatology. Indeed, it inhibits overgrowth of the microbiota and partially reduces excessive nutrition for replication. Autophagy also attenuates inflammation. On that basis, Yu[83] recommended restoration of good nutritional status together with restriction of food intake, especially in older subjects, to reduce the risk of developing severe symptomatology if infected by COVID-19.

On the other hand, as inflammation can be considered as a physiological response of the immune system to damaged tissues[84], it is a protective reaction to remove the injurious stimuli and to initiate the healing of damaged tissues[84]. Nutrition excess slows tissue healing, indeed nutrition derived from the degradation of the damaged tissue coupled with excess nutrition intake will be mostly turned into lipid intermediates and deposited in nonadipose tissue, lipotoxicity and further tissue damage. Thus, in a state of overnutrition, inflammation can become chronic. In this regard, undernutrition might be beneficial in fighting viral infection, as anorexia nervosa patients seem to be free of common viral infections[85,86].

ROLE OF THE GI TRACT IN COVID-19 COMPLICATIONS

Multisystem inflammatory syndrome in children (MIS-C) is defined by the Centers for Disease Control and Prevention[87] as a severe illness requiring hospitalization that occurs in individuals < 21 years of age with evidence of current or recent SARS-CoV-2 infection, or recent exposure to an individual with COVID-19. Children with MIS-C have fever, laboratory evidence of inflammation, and multiorgan involvement without an alternative plausible diagnosis. Ninety-two percent of children with MIS-C report GI symptoms[88] and 80% develop cardiac pathology. MIS-C is characterized by a superantigen-mediated hyperinflammatory response with a unique T-cell profile and multiple autoantigens[89-91]. It has been recently shown that the spike protein of SARS-CoV-2 contains sequence and structural motifs similar to a *Staphylococcal Enterotoxin B* superantigen[92], and superantigen-induced skewing of the T-cell repertoire in MIS-C patients with expansion of the T-cell receptor beta variable gene correlates with the cytokine storm and hyperinflammation seen in MIS-C[91]. Inflamed expansion of antibodies for multiple non-COVID-19 pathogens, including common coronaviruses, influenza and respiratory syncytial virus[93] plus numerous self-antigens[89,90] also correlates with the severe cardiac complications of MIS-C. Immune complexes stimulate monocytes/macrophages, eliciting phagocytosis, macrophage activation and cytokine storm[94,95] (Figure 1). The instigating factor for MIS-C has not been elucidated, but prominent GI symptoms suggest an intestinal source. The upper or lower respiratory tract are unlikely sources of antigens triggering this hyperinflammatory response, given the relative lack of respiratory symptoms in MIS-C, low/undetectable viral load in respiratory secretions[93], and the 2-4 wk delay between initial infection/exposure and development of MIS-C. Rather, ongoing antigen exposure is much more likely to be from the GI tract as has been shown in Kawasaki disease (KD), a similar illness with a hyperinflammatory profile leading to fever, rash, elevated inflammatory markers resulting in vasculitis, coronary aneurysms, and cardiac pathology. In KD, increased intestinal permeability secondary to upregulation of zonulin, a molecule that regulates paracellular molecule trafficking, has been associated with increased circulating immunoglobulin A and cardiac complications in children with KD[96].

PHARMACOLOGICAL IMPLICATIONS OF FECAL-ORAL TRANSMISSION

A study by Yeoh *et al*[79] was not designed to determine whether dysbiosis is the consequence of patient immune response rather than a contributing cause in disease onset and severity. Nevertheless, the reported association seems to be sufficiently

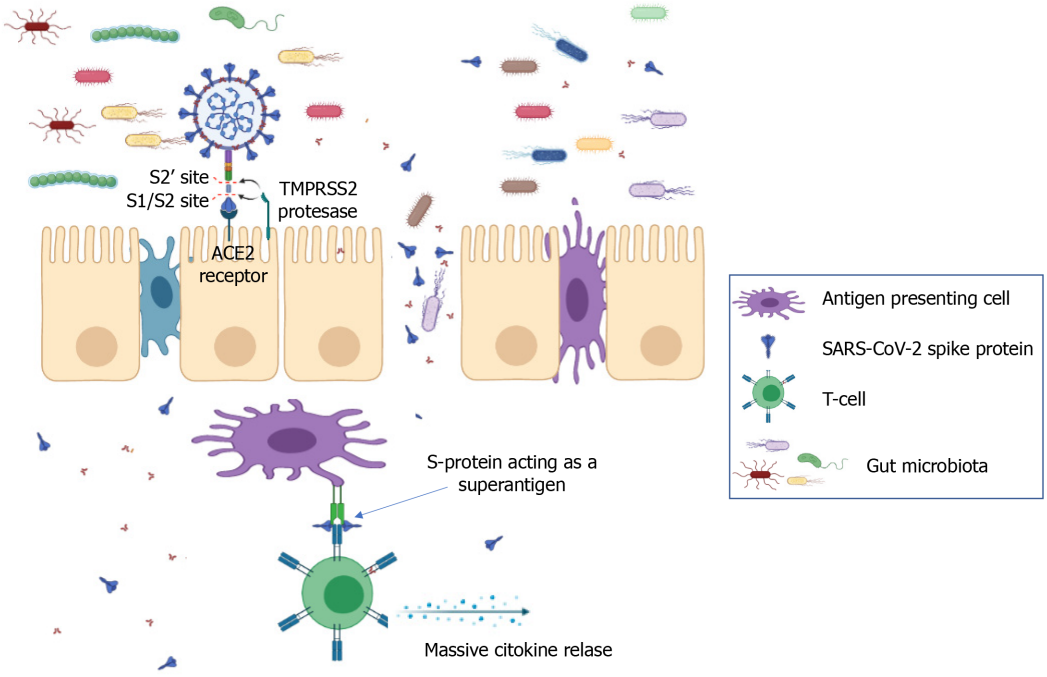

Figure 1 Gut dysbiosis induced by the immune response to severe acute respiratory syndrome coronavirus 2 in the gastrointestinal tract increases gut permeability, which in turn increases spike protein trafficking. Spike protein was reported to act as a superantigen that links the T-cell receptor and major histocompatibility complex II on antigen-presenting cells. ACE2: Angiotensin converting enzyme 2; S-protein: Spike protein; SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2.

robust to support the benefit of pharmacological intervention aimed at decreasing gut permeability for COVID-19 GI symptoms management, and potentially to reduce the risk of its complications, including MIS-C. Such a strategy could both reduce GI tract inflammation and help accelerate naturally occurring dysbiosis correction. Larazotide acetate, a synthetic octapeptide designed as a specific zonulin receptor antagonist, was successfully and safely used to modulate gut permeability and the related inflammation[97,98]. Di Micco *et al*[99] recently proposed an additional role for larazotide in COVID-19 patients. Based on an in-silico evaluation, they reported the ability of larazotide to inhibit the N3 protease of SARS-CoV-2. As larazotide was specifically designed as an oral drug able to reach the lower GI tract, it might be useful both for its direct anti-SARS-CoV-2 effect and to prevent antigen trafficking of SARS-CoV-2-derived molecules, including spike protein from the gut lumen to the bloodstream, which could trigger a cytokine storm leading to MIS-C.

CONCLUSION

In summary, whether digestive symptoms are a direct response to SARS-CoV-2 infection of the GI tract, or a secondary outcome of COVID-19, is still to be completely understood. The presence of viral RNA in the GI tract might partially explain GI symptoms even if it does not mean that there is infection in the intestine. In either case, robust evidence supports GI tract involvement in COVID-19 as well as a potential fecal-oral transmission route. The GI seems to be not only a reservoir of SARS-CoV-2, but also an active battlefield in which virus, innate and adaptive immune system responses, epithelial cells, and gut microbiota play critical roles. The interventions for managing GI-related issues should be twofold. From a patient perspective, pharmacological treatment to reduce the severity of GI symptoms and support a quick re-establishment of eubiosis should be evaluated. Moreover, interventions to ensure water sanitation should be added to the current policies for COVID-19 pandemic control. Considering that many people worldwide lack access to clean drinking water and good sanitation, the possible containment of COVID-19 through water treatment should be carefully taken into account to reduce the actual and future magnitude of the pandemic.

Abstract

BACKGROUND

Exosomes play an important role in metabolic-associated fatty liver disease (MAFLD), but the mechanism by which exosomes participate in MAFLD still remain unclear.

AIM

To figure out the function of lipotoxic exosomal miR-1297 in MAFLD.

METHODS

MicroRNA sequencing was used to detect differentially expressed miRNAs (DE-miR) in lipotoxic exosomes derived from primary hepatocytes. Bioinformatic tools were applied to analyze the target genes and pathways regulated by the DE-miRs. Quantitative real-time PCR (qPCR) was conducted for the verification of DE-miRs. qPCR, western blot, immunofluorescence staining and ethynyl-20-deoxyuridine assay were used to evaluate the function of lipotoxic exosomal miR-1297 on hepatic stellate cells (LX2 cells). A luciferase reporter experiment was performed to confirm the relationship of miR-1297 and its target gene *PTEN*.

RESULTS

MicroRNA sequencing revealed that there were 61 exosomal DE-miRs ($P < 0.05$) with a fold-change > 2 from palmitic acid treated primary hepatocytes compared with the vehicle control group. miR-1297 was the most highly upregulated according to the microRNA sequencing. Bioinformatic tools showed a variety of target genes and pathways regulated by these DE-miRs were related to liver fibrosis. miR-1297 was overexpressed in exosomes derived from lipotoxic hepatocytes by qPCR. Fibrosis promoting genes (*α-SMA*, *PCNA*) were altered in LX2 cells after miR-1297 overexpression or miR-1297-rich lipotoxic exosome incubation *via* qPCR and western blot analysis. Immunofluorescence staining and

animals and approved by the Ethical Committee of the Shanghai General Hospital.

Conflict-of-interest statement: The authors hereby declare that no conflict of interest exists.

Data sharing statement: No additional data are available.

ARRIVE guidelines statement: The manuscript was prepared and revised according to the ARRIVE guidelines.

ethynyl-20-deoxyuridine staining demonstrated that the activation and proliferation of LX2 cells were also promoted after the above treatment. *PTEN* was found to be the target gene of miR-1297 and knocking down *PTEN* contributed to the activation and proliferation of LX2 cells *via* modulating the PI3K/AKT signaling pathway.

CONCLUSION

miR-1297 was overexpressed in exosomes derived from lipotoxic hepatocytes. The lipotoxic hepatocyte-derived exosomal miR-1297 could promote the activation and proliferation of hepatic stellate cells through the PTEN/PI3K/AKT signaling pathway, accelerating the progression of MAFLD.

Key Words: Metabolic-associated fatty liver disease; miRNA-1297; Exosome; Hepatic stellate cell; PTEN; Liver fibrosis

Core Tip: In this study, the expression of miR-1297 was increased in exosomes derived from primary hepatocytes. Exosomal miR-1297 from lipotoxic LO2 (a hepatocyte cell line) could promote LX2 (a hepatic stellate cell line) activation and proliferation by regulating the PTEN/PI3K/ATK pathway. Currently, the study between exosomes and metabolic-associated fatty liver disease is very limited. This is the first time that exosomal miR-1297 from lipotoxic hepatocytes was confirmed to accelerate liver fibrosis, and the new mechanism may become a promising treatment target for metabolic-associated fatty liver disease.

INTRODUCTION

Metabolic-associated fatty liver disease (MAFLD), which was formerly called nonalcoholic fatty liver disease, is highly prevalent worldwide and affects approximately 25% of the global adult population[1]. Recently, a consensus of international experts proposed the terminology change from nonalcoholic fatty liver disease to MAFLD in order to better demonstrated the etiological features of this disease[2]. The incidence of MAFLD has been rising rapidly in recent years, and in China the incidence of MAFLD is 15%-30%[3]. MAFLD is characterized by fatty degeneration of the liver due to different metabolic conditions, such as obesity and type 2 diabetes, leading to fatty deposition in the liver[4]. Lipid deposition will increase the oxidative stress of cells in the liver, damage normal cell function and finally lead to liver fibrosis[5]. Hepatic stellate cell (HSC) activation was regarded as the core part of all kinds of liver fibrosis. The abnormal activation and proliferation of HSCs will cause them to produce more cellular extracellular matrix, destroy the normal structure of liver lobules and eventually result in cirrhosis[6]. However, the exploration of the specific pathogenesis underlying MAFLD is still in the preliminary stages.

Exosomes are circular or cup-shaped lipid bilayer vesicles with diameters of 30-150 nm, which are secreted by the host cells and transfer a variety of compounds, including miRNAs, mRNAs, lncRNAs, DNA and proteins[7]. Exosomes derived from lipotoxic hepatocytes could accelerate the activation of HSCs and lead to fibrosis[8]. However, to date, studies on the exact mechanism of exosomal miRNA and MAFLD are still very limited. In this study, we perform exosomal miRNA profiling from lipotoxic hepatocytes and further determine the potential mechanism by which exosomal miRNAs participate in the progression of MAFLD.

MATERIALS AND METHODS

Cell culture

Hepatocytes (HCs), including primary HCs (PHCs), a normal human HC cell line (LO2) and a human HSC cell line (LX2) were used in this study. PHCs from male wild-type mice were isolated by pronase perfusion and cultured as reported previously[9]. LO2 cells and LX2 cells were cultured in Dulbecco's modified Eagle's medium (Gibco, Grand Island, NY, United States) supplemented with 100 mg/mL streptomycin (Gibco), 100 IU/mL penicillin (Gibco) and 10% fetal bovine serum (Gibco). PHCs were used to obtain exosomes for microRNA sequencing (miRNA seq) and quantitative real-time PCR (qPCR) verification. LO2 cells were used to obtain exosomes for cell incubation, and LX2 cells were used for other experiments. These procedures for PHC isolation were approved by the Ethical Committee of the Shanghai General Hospital.

Human sample collection

There were 20 MAFLD patients who shared similar demographic features and personal histories enrolled in this study. Among the 20 MAFLD patients with similar liver fibrosis severity, 10 patients were diagnosed as mild fatty liver while the other 10 patients were diagnosed as severe fatty liver depending on the hepatic steatosis. FibroScan (Echosens, Paris, France) analysis was applied to assess the controlled attenuation parameter and liver stiffness measurement of these patients according to the 2017 ASSLD guidelines[10]. The liver stiffness measurement value of these patients showed no significant difference. Patients with controlled attenuation parameter values from 265 dB/m to 295 dB/m were regarded as mild fatty liver, while patients with controlled attenuation parameter values over 295 dB/m were defined as severe fatty liver. Serum exosome samples from these patients were collected for miRNA qPCR. The study was approved by the Ethical Committee of the Shanghai General Hospital, and written informed consent was provided by all patients. The clinical features of the patients enrolled in this study are shown in Supplementary Table 1.

Exosome isolation and incubation

Exosomes from PHCs, LO2 cells and human serum samples were isolated using an ultracentrifugation method that was reported in a previous study[11]. To obtain the lipotoxic exosomes, we treated PHCs and LO2 cells with 200 μmol/L palmitic acid (PA, Sigma-Aldrich, St. Louis, MO, United States) or 5% BSA (Sigma-Aldrich) (diluted in phosphate buffered saline, Sigma-Aldrich) as the vehicle control for 24 h. Then, exosomes were isolated from the cell culture medium. For experiments related to exosome incubation, LX2 cells were treated with 50 μg/mL LO2 exosomes for 48 h.

Transmission electron microscopy observation of exosomes

To observe the exosome morphology, transmission electron microscopy (JEOL, Tokyo, Japan) was used. The experimental procedures were performed with assistance from Shanghai Bohao Biotechnology Co., Ltd. (Shanghai, China).

Nanoparticle tracking analysis for exosomes

To analyze the particle diameter distribution, nanoparticle tracking analysis was performed using a NanoSight NS300 system (Malvern Instruments, Worcestershire, United Kingdom) as in a previous study[12].

Exosome uptake experiment

For the exosome uptake experiment, 50 μg/mL LO2-derived exosomes (LO2-exosomes) diluted in phosphate buffered saline were labelled using the red fluorescent dye PKH26 Kit (Sigma-Aldrich) After incubating LX2 with PKH26 labelled LO2-exosomes for 6 h, a fluorescence microscope (Leica, Wetzlar, Germany) was used to observe the exosomes that were absorbed by LX2 cells.

miRNA high-throughput sequencing and data analysis

The miRNA seq experimental procedures were performed with the assistance of Bohao Biotechnology Co., Ltd. (Shanghai, China). The miRNA library was constructed using a TruSeq miRNA Library Prep Kit (Illumina, San Diego, CA, United States) following the standard procedures of the manufacturer's instructions.

Low-quality reads and adapters were filtered out from the raw reads to obtain clean reads. The clean reads were aligned against the miRBase database, and the expressions of miRNAs in each sample were determined. Differentially-expressed miRNAs were

screened using edgeR, under the following criteria: |log2 (fold-change)| ≥ 1 and $P < 0.05$. Heatmaps of gene expression were generated with MeV software (MeV Ltd., Stockport, United Kingdom).

Target gene bioinformatic analysis

Target gene prediction was performed for the significant differentially expressed miRNAs (DE-miRs). GO and pathway enrichment analyses were performed for the target genes using the Gene Ontology Database and Kyoto Encyclopedia of Genes and Genomes.

Cell transfection

For cell transfection, negative control mimics (mi-NC) and miR-1297 mimics (mi-miR) were used to overexpress miR-1297. Small interfering RNA for the negative control (si-NC) and small interfering RNA for PTEN were used to knock down PTEN. Cell transfection was conducted using Lipofectamine 2000 Regent (Invitrogen, Carlsbad, CA, United States) according to the manufacturer's instructions. All of the above vectors were purchased from GenePharma Co., Ltd. (Shanghai, China).

Luciferase reporter assay

The luciferase reporter assay experiment was conducted using the pGL3-basic luciferase vector (Promega, Madison, WI, United States). The 3'-UTR sequence of PTEN predicted to interact with miR-1297, together with a corresponding mutated sequence within the predicted target sites, were synthesized and inserted into the luciferase reporter (Promega, Madison, WI, United States) to generate PTEN wild-type or PTEN mutant (primers shown in Supplementary Table 2). The pGL3-basic luciferase vector containing PTEN wild-type or PTEN mutant were cotransfected with miR-1297 mimics or negative control mimics using Lipofectamine2000 (Invitrogen). After transfection, cells were incubated in suitable conditions for 24 h. The Luciferase Reporter Assay Kit (Promega) was used to assess the relative luciferase activity in accordance with the manufacturer's instructions. Firefly luciferase values were normalized to those of Renilla luciferase.

qPCR analysis

Total RNA was extracted using TRIzol reagent (Invitrogen). qPCR was performed using Hieff qPCR SYBR Green Master Mix (Applied Biosystems, Foster City, CA, United States) and Hieff First Strand cDNA Synthesis Super Mix (Applied Biosystems). β-actin was used as the internal reference to measure the mRNA expression of specific genes. U6 was used to normalize the expression of specific miRNA. Primers used in this research were fully listed in Supplementary Table 2.

Western blot analysis

These included antibodies were used for western blotting analysis: anti-TSG101 (1:1000, Santa Cruz Biotechnology, Santa Cruz CA, United States), anti-CD63 (1:1000, Abcam, Cambridge, MA, United States), anti-PCNA (1:500, Abcam), anti-α-SMA (1:1000, Abcam), anti-PTEN (1:1000, Abcam), anti-TGFβ1 (1:1000, Abcam), anti-SMAD3 (1:1000, Abcam), anti-p-SMAD3 (1:1000, Abcam) and anti-GAPDH (1:2000, Abcam). HRP-conjugated IgG (1:5000, Abcam) was used as the secondary antibody.

Immunofluorescence staining

Antibodies against α-SMA (1:100, Abcam) and 4' 6-diamidino-2-phenylindole (Abcam) were used for immunofluorescence staining. Alexa Fluor 594 AffiniPure goat anti-rabbit IgG (H+L) (Santa Cruz Biotechnology) was used as the secondary antibody. The laser microscope (Leica, Wetzlar, Germany) was used to capture the representative images.

Ethynyl-20-deoxyuridine staining

The proliferation of HSCs was detected by an ethynyl-20-deoxyuridine staining (EdU) cell lighting kit (RiboBio, Shanghai, China). The cell nuclei were stained using Hoechst (Beyotime, Shanghai, China). The laser microscope (Leica, Wetzlar, Germany) was used to capture the representative images.

Statistical analysis

The SPSS software (version 22.0; SPSS, Inc., Chicago, IL, United States) and GraphPad Prism version 8.0 (GraphPad Software, San Diego, CA, United States) were applied to

analyze all the data presented in this study. Data are expressed as the mean ± SD for at least three independent experiments for each group. Continuous variables showing a normal distribution were analyzed by an independent-samples *t*-test or one-way ANOVA. A P value < 0.05 was considered statistically significant.

RESULTS

Identification of exosomes derived from PHCs

Many studies have clarified that exosomes can participate in a variety of metabolic diseases, but the function of exosomes in MAFLD remains unclear. First, the morphology of exosomes derived from PA-treated (Exo-PA) PHCs or vehicle-treated (Exo-CN) PHCs was observed by transmission electron microscopy. Exosomes were small, quasi-circular vesicles with an intact membrane structure (Figure 1A). Then, exosome size and particle concentration were assessed *via* nanoparticle tracking analysis. Exosomes with a diameter of 50-150 nm accounted for 87.50% (Exo-PA) and 81.70% (Exo-CN) of all vesicles, which met the standard of high-quality exosomes (Figure 1B). In addition, the concentration of Exo-PA was significantly higher than that of Exo-CN (P < 0.05, Figure 1C). Finally, the exosomal markers CD63 and TSG101 could be observed in both Exo-PA and Exo-CN (Figure 1D). These results indicated that the method we used could obtain high-quality exosomes for follow-up research.

miRNA seq profiling and bioinformatic analysis of lipotoxic HC-secreted exosomes

To explore the differentially abundant exosomal miRNAs of lipotoxic HCs, we detected the miRNA expression profiles in Exo-PA and Exo-CN using miRNA seq. According to the results, 61 miRNAs were differentially expressed (P < 0.05) with a fold change > 2 (defined as DE-miR) in the Exo-PA group compared with the Exo-CN group. Among the 61 miRNAs, 20 were upregulated, and 41 were downregulated (Supplementary Table 3). In addition, three upregulated miRNAs had a fold change > 5 (hsa-miR-1297, hsa-miR-708-5p, hsa-miR-671-5p), while two downregulated miRNAs had a fold change > 5 (hsa-miR-718, hsa-miR-193a-3p). miR-1297 was the most highly upregulated miRNA (a 7.81-fold change), and miR-718 was the most highly downregulated miRNA (a 6.62-fold change) in the Exo-PA group. Heatmaps and the volcano map of gene expression are shown based on the expression of these DE-miRs (Figure 2A and 2B).

GO functional enrichment analysis was performed for the DE-miRs to explore the target gene function. The results revealed that these DE-miRs were associated with ten cell components, ten molecular functions and ten biological processes. Among these functions, seven functions were related to ubiquitin activity, which plays an important role in liver fibrosis. The results of the level 2 GO term enrichment analysis are presented in Figure 2C.

According to the Kyoto Encyclopedia of Genes and Genomes pathway enrichment analysis, there were 20 significantly enriched pathways. Based on a literature review, four pathways, the AMPK, PI3K-AKT, Hippo and Ras pathways, were highly correlated with liver fibrosis (Figure 2D).

Based on the miRNA seq results, 61 DE-miRs were found to be abnormally expressed in the Exo-PA group compared to the control group. miR-1297 was the top upregulated miRNA among these DE-miRs. Furthermore, seven gene functions and four pathways regulated by these DE-miRs were found to be highly correlated with fibrosis.

Expression levels of exosomal miR-1297 from lipotoxic HCs were significantly upregulated

To verify the results of miRNA seq, we measured exosomal DE-miRs with a fold change > 3 in cell culture samples and human serum samples. For cell culture samples, Exo-PA and Exo-CN were used. For human serum samples, exosomes derived from the serum of patients with severe fatty liver or mild fatty liver were selected in order to clarify the actual change of miR-1297 during the pathogenesis of MAFLD.

In cell culture samples, miR-1297 was the top upregulated candidate with a 5.83-fold change in the Exo-PA group compared to the Exo-CN group, while miR-718 was also the top downregulated miRNA with a 3.62-fold change, which was consistent with the results of miRNA seq. The detailed expression levels for the DE-miRs are shown in Figure 3A.

In human serum exosomal samples from exosomes derived from the serum of

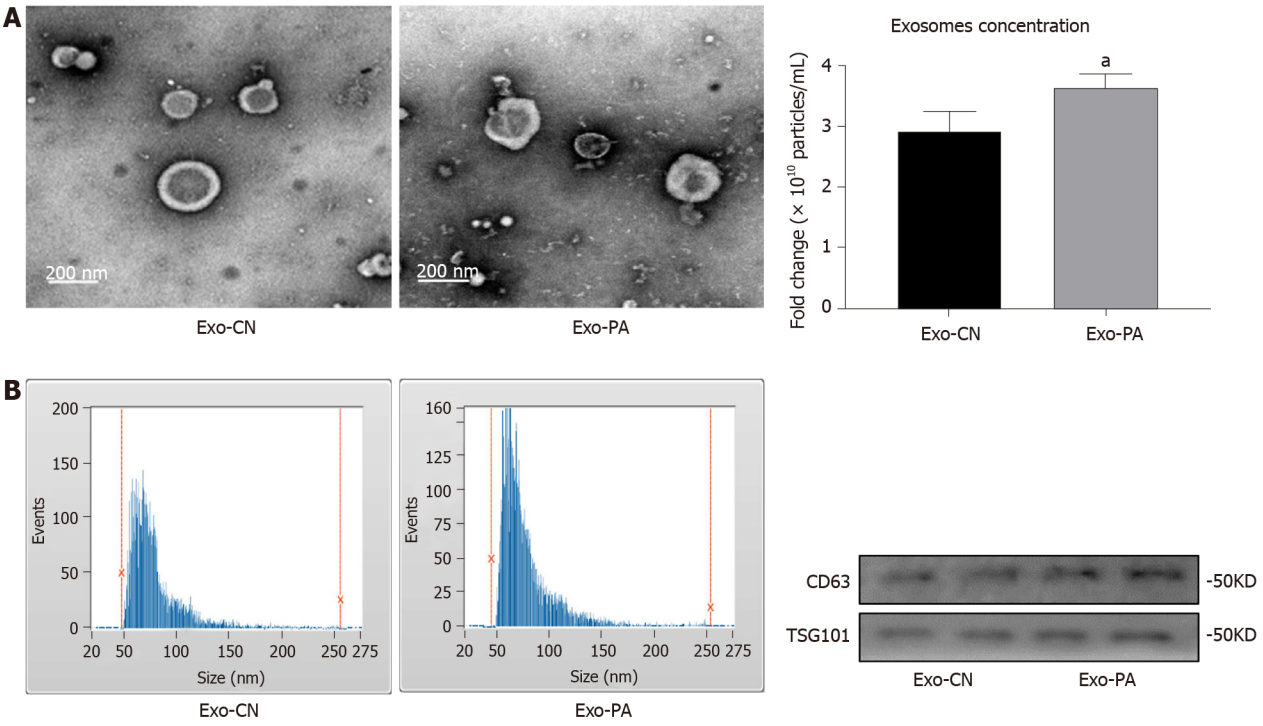

Figure 1 Identification of exosomes derived from primary hepatocytes. A: Exosomes derived from primary hepatocytes (Exo-PHC) were visualized by electronic microscopy (× 30000); B: Nanoparticle tracking analysis for Exo-PHC; C: The concentration of Exo-PHC was measured. Exosomes derived from vehicle control (Exo-CN) treated PHC: 2.92 ± 0.32 × 10^{10} particles/mL *vs* exosomes derived from palmitic acid (Exo-PA) treated PHC: 3.62 ± 0.22 × 10^{10} particles/mL; D: Exosomal markers CD63 and TSG101 were detected by western blot in Exo-PHC. Statistical significance, $^{a}P < 0.05$.

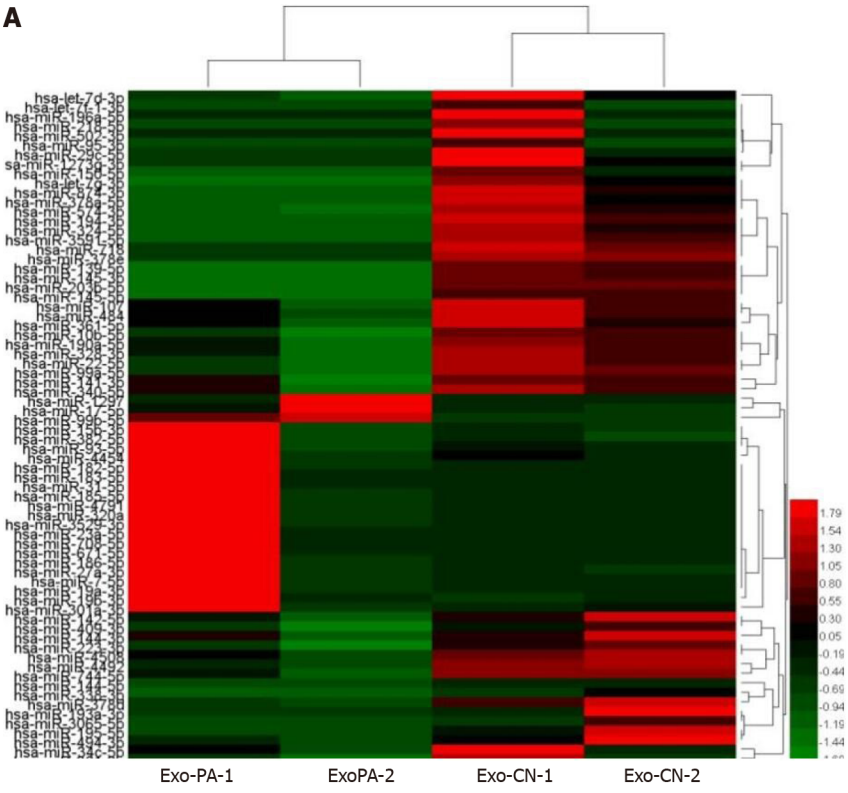
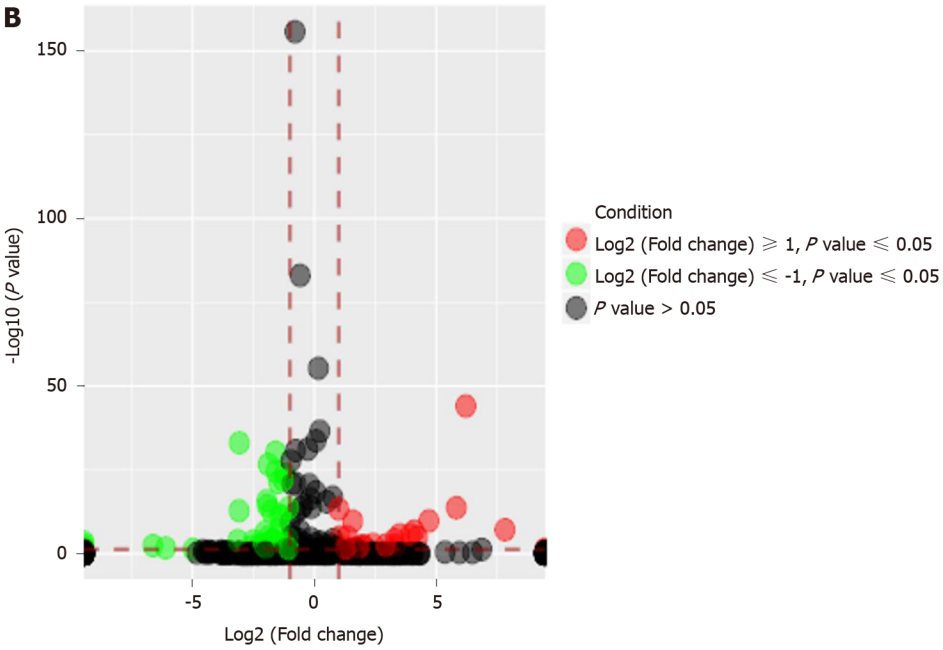


patients with mild fatty liver, miR-1297 had the greatest upregulation (a 3.32-fold change) compared to exosomes derived from the serum of patients with severe fatty liver among all the DE-miRs, while miR-193a was the top downregulated miRNA with a 2.96-fold change. The detailed expression levels for the DE-miRs are shown in Figure 3B.



Although the results of cell culture samples did not completely parallel the results of human serum samples, miR-1297 showed a higher expression level in both groups. Therefore, miR-1297 was finally selected for follow-up research. The above findings suggested that the expression levels of exosomal miR-1297 from lipotoxic HCs were significantly upregulated.

miR-1297 accelerated HSC activation and proliferation

Currently, there is no research related to miR-1297 and liver fibrosis. To explore the effect of miR-1297 on HSCs, we first transfected the hepatic stellate cell line LX2 with miR-1297 mimics (mi-miR) or miRNA negative control mimics (mi-NC). After transfection, the expression was upregulated approximately 1400 times in the mi-miR LX2 cells (Figure 4A). Because α-SMA is an activation marker of HSCs, the expression of α-SMA could reflect collagen production when HSCs are activated. After miR-1297 overexpression in LX2, the mRNA and protein levels of α-SMA were increased (Figure 4B and 4C). In addition, immunofluorescence analysis further revealed that the relative red fluorescence intensity of α-SMA (red fluorescence) was markedly increased in the mi-miR LX2 cells compared to the mi-NC cells (mi-miR: 1.87 ± 0.15 *vs* mi-NC: 1.00 ± 0.22, Figure 4D). During the process of liver fibrosis, the activation and proliferation of HSCs play a central role. PCNA is a proliferation marker of HSCs. The mRNA and protein levels of PCNA were found to be significantly elevated in the mi-miR LX2 cells compared to the mi-NC LX2 cells (Figure 4B and 4C). In addition, an EdU assay was conducted to evaluate the proliferation of HSCs. As shown in Figure 4E, 32.10% of the mi-miR LX2 cells incorporated EdU, while only 24.15% of the mi-NC LX2 cells were EdU positive, which revealed that miR-1297 could promote the proliferation of LX2 cells as well.

These results proved that miR-1297 could accelerate HSC activation and proliferation.

miR-1297 exerted its function by regulating the PTEN/PI3K/AKT pathway in HSCs

As miR-1297 was found to promote HSC activation and proliferation in LX2 cells, we tried to find the target gene it may regulate to exert its function. In the TargetScan database (http://www.targetscan.org/, Figure 5A), a total of three fibrosis-related genes, *COL10A1*, *PTEN* and *TRAF3*, were selected. A previous study suggested that PTEN was found to be the target gene of miR-1297 in human cervical carcinoma

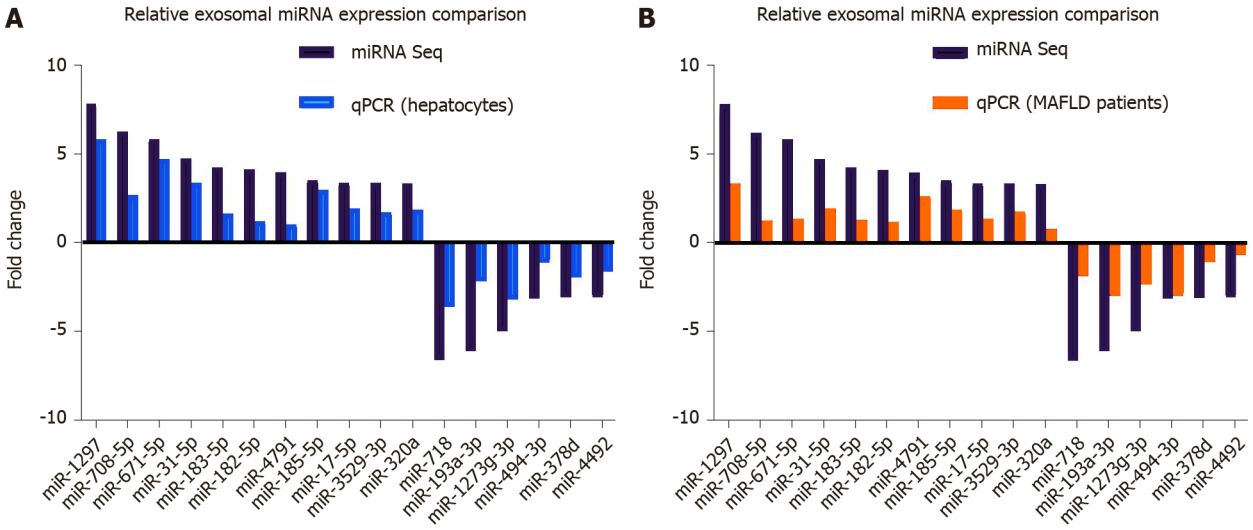

Figure 3 Quantitative real-time PCR analysis verification for differentially expressed microRNAs in exosomes derived from primary hepatocytes and patient serum samples of metabolic-associated fatty liver disease. A: Quantitative real-time PCR was performed on exosomes derived from vehicle control treated primary hepatocyte and palmitic acid treated primary hepatocyte. The fold change ratio of microRNA (miRNA) in the Exo-PA group was compared to the result of differentially expressed miRNAs in the miRNA sequencing (miRNA seq). Detailed data of individual miRNA expression could be seen Supplementary Table 2; B: Quantitative real-time (q)PCR was performed between mild and severe fatty liver human serum exosome samples. The fold change ratio of miRNA in severe fatty liver were compared to the result of the differentially expressed miRNAs of the miRNA sequencing. Detailed data of individual miRNA expression could be seen Supplementary Table 2. MAFLD: Metabolic-associated fatty liver disease.

cells[13], so a luciferase reporter assay was conducted to determine the relationship of miR-1297 and PTEN in LX2 cells. In the PTEN wild-type group, the relative luciferase activity in the mi-miR LX2 cells was decreased compared with that in the mi-NC LX2 cells (mi-NC: 1.00 ± 0.14 *vs* mi-miR: 0.56 ± 0.12) (Figure 5B). However, in the PTEN mutant group, there were no obvious luciferase activity changes between the mi-miR and mi-NC LX2 cells (Figure 5B), which confirmed that PTEN was the target gene of miR-1297 in LX2 cells. Then, the mRNA and protein levels of PTEN were also found to be significantly inhibited after miR-1297 mimic transfection, which indicated that miR-1297 could negatively regulate the expression of PTEN (Figure 5C and 5D).

Previous studies have shown that PTEN could negatively regulate the downstream PI3K/AKT pathway and accelerate liver fibrosis[14-16]. Therefore, PTEN was knocked down to evaluate its function in HSCs. The protein expression of PI3K and p-AKT (Figure 5D and 5E) was markedly elevated in both the miR-1297 and small interfering RNA for PTEN LX2 cells compared to their control cells, while α-SMA and PCNA were also significantly upregulated (Figure 5E), which revealed that PTEN could negatively regulate the PI3K/AKT pathway and HSC activation. These findings suggested that miR-1297 could modulate the PTEN/PI3K/AKT pathway, accelerating the activation and proliferation of HSCs.

Lipotoxic HC-secreted exosomes could transfer exosomal miR-1297 to HSCs and contribute to HSC activation through the PTEN/PI3K/AKT pathway

Given the observed effects, miR-1297 was found to promote the activation and proliferation of LX2. To further determine the function of lipotoxic HC-secreted exosomes (HC-Exos) on HSCs, we incubated LX2 cells with exosomes from PA-treated LO2 cells or exosomes from CN-treated LO2 cells. Through the exosome uptake experiment, both Exo-PA and Exo-CN were observed to be engulfed by LX2 cells, suggesting that HC-Exos were successfully taken up by the recipient HSCs (Figure 6A).

miR-1297 was overexpressed after Exo-PA treatment (Exo-PA: 3.95 ± 0.18 *vs* Exo-CN: 1.00 ± 0.11), while the mRNA and protein levels of PTEN were obviously decreased (Figure 6B and 6D). In addition, the expression of PI3K and p-AKT was significantly increased in the Exo-PA-treated LX2 cells, indicating that miR-1297 modulated the PTEN/PI3K/AKT pathway after lipotoxic HC-Exo treatment (Figure 6D).

In addition, the expression of α-SMA was found to be significantly upregulated in the Exo-PA LX2 group (Figure 6C and 6D). Immunofluorescence analysis revealed a remarkable overexpression of α-SMA (red fluorescence) in the Exo-PA-treated LX2

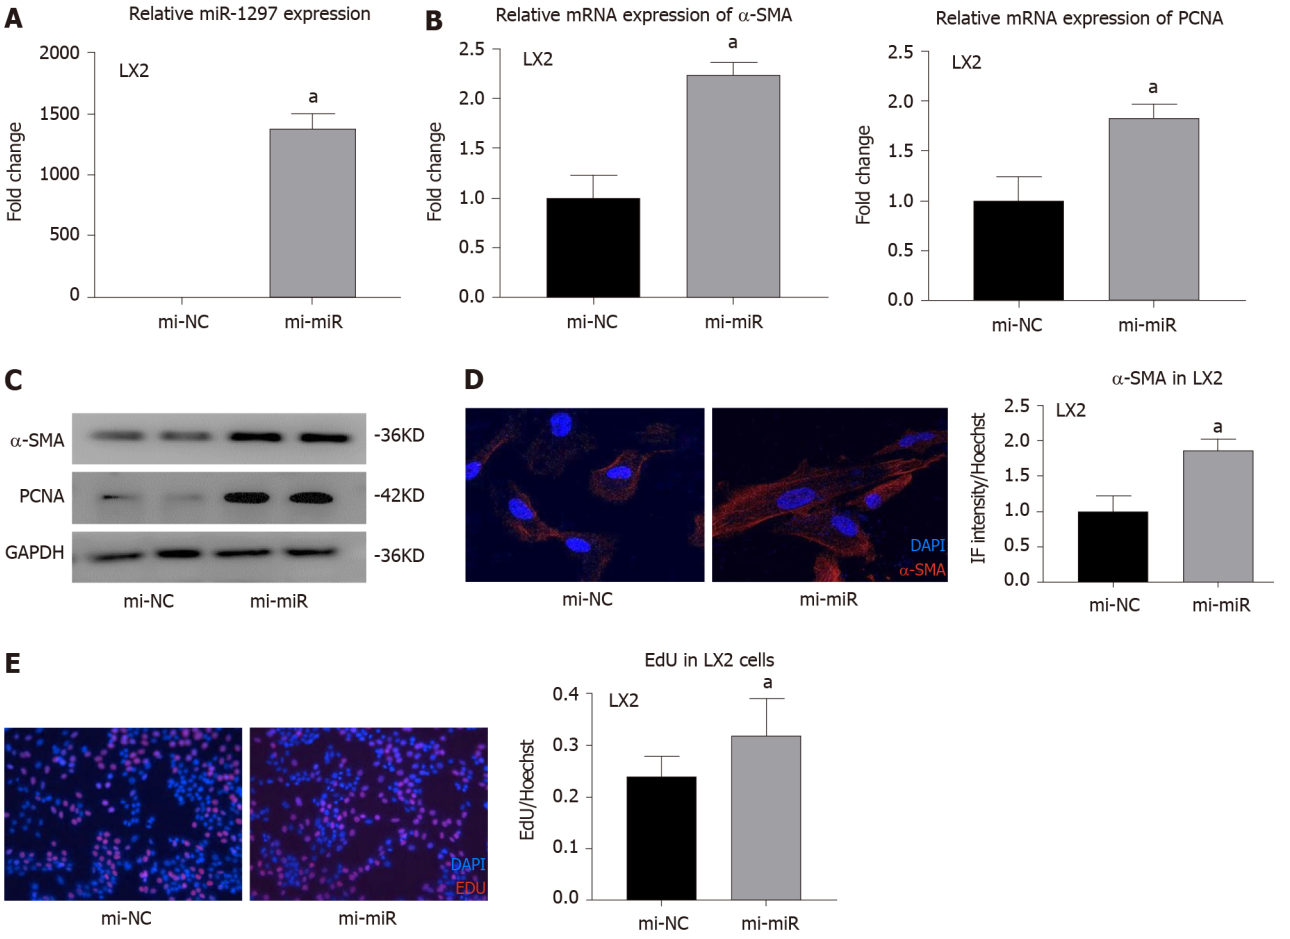

Figure 4 MicroR-1297 promoted hepatic stellate cell activation and proliferation by targeting the PTEN signaling pathway. A: The transfection efficiency of 50 nM miR-1297 mimics in LX2 cells was assessed by quantitative real-time PCR. microRNA mimics of negative controls (mi-NC): 1.00 ± 0.12 *vs* miR-1297 mimics (mi-miR): 1380.25 ± 121.16; B: Relative mRNA expression of *α-SMA* (the activation marker of hepatic stellate cells) and PCNA (the proliferation marker of hepatic stellate cells) were assessed by quantitative real-time PCR. α-SMA: mi-NC: 1.00 ± 0.23 *vs* mi-miR: 2.24 ± 0.12; PCNA: mi-NC: 1.00 ± 0.25 *vs* mi-miR: 1.83 ± 0.14; C: Relative protein expression of α-SMA, PCNA, PTEN, PI3K, AKT and p-AKT were assessed by western blot after treatment of 50 nmol/L miR-1297 mimics for 48 h; D: Immunofluorescence staining of α-SMA was performed to evaluate the activation of LX2 cells after 50 nmol/L miR-1297 mimics for 48 h. mi-NC: 1.00 ± 0.22 *vs* mi-miR: 1.87 ± 0.15, Bar = 200 μm; E: Ethynyl-20-deoxyuridine test was performed to evaluate the proliferation of LX2 cells after 50 nmol/L miR-1297 mimics for 48 h. mi-NC: 0.24 ± 0.04 *vs* mi-miR: 0.32 ± 0.07, Bar = 50 μm. Statistical significance, $^{a}P < 0.05$. DAPI: 4'6-Diamidino-2-phenylindole; EdU: Ethynyl-20-deoxyuridine.

cells (Exo-PA: 1.68 ± 0.21 *vs* Exo-CN: 1.00 ± 0.16) (Figure 6E). The mRNA and protein levels of PCNA were markedly elevated in the Exo-PA group as well (Figure 6C and 6D). The proportion of EdU-incorporated LX2 cells was dramatically elevated (Exo-PA: 0.41 ± 0.06 *vs* Exo-CN: 0.21 ± 0.04) (Figure 6F).

Taken together, these results demonstrated that lipotoxic HC-Exos could transfer exosomal miR-1297 to recipient HSCs, thus promoting HSC activation and proliferation by modulating the PTEN/PI3K/AKT pathway.

DISCUSSION

MAFLD is highly prevalent worldwide and may become the leading cause of end-stage liver disease in the coming decades[17]. Because the majority of MAFLD patients do not show any symptoms, MAFLD may further evolve into liver fibrosis or even hepatocellular carcinoma[18]. Recently, an increasing number of studies focused on the relationship between exosomes and MAFLD-related fibrosis[12], but the exact mechanisms by which exosomes participate in fibrosis remain unclear. In our present research, we observed that the exosomal miR-1297 expression was significantly upregulated in lipotoxic HCs. Furthermore, a novel mechanism through which exosomal miR-1297 mediates cellular communication between HCs and HSCs, subsequently contributing to HSC activation *via* the PTEN/PI3K/ATK pathway, was confirmed.

Exosomes have been identified as important mediators for cell-cell communication by transferring various biological components, such as miRNAs, lncRNAs and proteins[19]. The evidence that exosomes played an important role in the process of liver fibrosis, acting as a means of communication among different hepatic cells, have been confirmed by multiple studies[20]. Exosomal miR-223 from natural killer cells and exosomal miR-181-5p from mesenchymal stem cells were found to inhibit HSC activation by modulating autophagy[21,22]. Lipopolysaccharide-activated THP-1 macrophages could release exosomal miR-103-3p to induce the activation of HSCs[23]. Exosomes derived from human bone marrow mesenchymal stem cells could alleviate liver fibrosis through the Wnt/β-catenin pathway[24]. However, research on HC-HSC crosstalk is very limited. To determine the effect of lipotoxic HC-Exos on HSCs, we performed exosomal miRNA seq for an MAFLD HC-Exo model in our research. A total of 61 miRNAs were found to be abnormally expressed in the lipotoxic HC-Exo group compared to the control group, and seven gene functions and four pathways regulated by these DE-miRs were found to be highly correlated with fibrosis.

Then miR-1297 was found to be the most highly upregulated miRNA in both

lipotoxic PHC-derived exosomes and severe fatty liver patient serum exosomes compared to their control groups *via* qPCR verification. Cellular exosomes were isolated from cell culture media and could represent an MAFLD cell model progression. We found miR-1297 was significantly upregulated in lipotoxic PHC-derived exosomes. However, sometimes the experimental results were not parallel with the actual disease progression. Therefore, we measured the expression of miR-1297 in serum exosome samples of MAFLD patients. Exosomes derived from serum usually originated from different organs and could reveal a rather complicated but more real condition during the disease progression. In serum exosome samples we also found miR-1297 was markedly overexpressed in severe MAFLD patients. Both results revealed that miR-1297 was obviously upregulated during MAFLD progression, and miR-1297 was finally chosen for the follow-up study.

Previous studies have confirmed the role of miR-1297 in liver diseases. miR-1297 promoted the progression of liver cancer by inhibiting the expression of RB1[25]. Liu *et al*[26,27] found that miR-1297 could negatively regulate hepatocellular carcinoma progression by modulating EZH2 and HMGA2. But currently, the role of miR-1297 has not been reported in liver fibrosis. To determine the function of miR-1297 in liver fibrosis, the human hepatic stellate cell line LX2 was treated with miR-1297 mimics and miR-1297-rich lipotoxic exosomes in our research. Upregulation of miR-1297 was found to suppress the expression of its target gene *PTEN* and contribute to the activation and proliferation of LX2 cells.

PTEN is a well-known regulatory gene to suppress tumors and fibrosis, and many studies have demonstrated that it can prevent the development of various fibrotic-related diseases, such as renal, lung and liver fibrosis[28-30]. The loss of PTEN induced by hypoxia inducible factor-1 promoted HSC activation by regulating the P65 signaling pathway[30]. miR-1273g-3p modulated the activation and apoptosis of HSCs by directly targeting PTEN in HCV-related liver fibrosis[31]. In addition, PTEN inhibited macrophage activation by regulating the PI3K/Akt/STAT6 signaling pathway in hepatic Kupffer cells and alleviated liver fibrosis[32]. In the present study, *PTEN* was confirmed to be the target gene of miR-1297. High expression levels of miR-1297 induced by miR-1297 mimics and miR-1297-rich lipotoxic HC-Exos could

negatively regulate PTEN in LX2, inhibiting its function in preventing liver fibrosis. Therefore, the expression of fibrosis-related genes (*α-SMA* and *PCNA*) was found to be increased after miR-1297 overexpression, miR-1297-rich lipotoxic HC-Exo incubation or *PTEN* knockdown, which was hypothesized to explain why miR-1297 could promote HSC activation.

The progression of liver fibrosis is a complex physiological process, including the regulation of multiple signaling pathways, such as the TGFβ1/SMAD, MAPK and PI3K/ATK pathways[33]. The PI3K/ATK pathway is a classic pathway regulated by PTEN that participates in a variety of biological functions, including cell growth, proliferation and differentiation[34]. It has been reported that PTEN could hydrolyze PI3K protein, thereby phosphorylating AKT and stimulating fibroblast accumulation and myofibroblast differentiation[35,36]. Our results demonstrated that the low expression of PTEN induced by miR-1297 or small interfering RNA could promote the protein expression of PI3K and p-AKT, thus elevating the expression of fibrosis-related genes (*α-SMA* and *PCNA*), which may explain the downstream molecular mechanism by which miR-1297 regulates PTEN and activates HSCs.

CONCLUSION

Taken together, our research is the first to clarify that exosomal miR-1297 originating from PA-treated HCs could promote the activation and proliferation of HSCs by targeting the PTEN/PI3K/AKT pathway and accelerate the progression of liver fibrosis. This molecule may become a new target for the treatment of MAFLD in the future.

ARTICLE HIGHLIGHTS

Research background

Accumulating evidence has revealed that exosomes play an important role in the progression of metabolic-associated fatty liver disease, but the exact mechanism remains unclear.

Research motivation

Previous studies demonstrated that exosomes from lipotoxic hepatic cells could contribute to hepatic stellate cell (HSC) activation, but the specific cellular crosstalk interaction was not fully illustrated. We aimed to figure out if exosomal microRNA could participate in this procedure.

Research objectives

To determine the role of exosomal miR-1297 in the metabolic-associated fatty liver disease cell model.

Research methods

miRNA sequencing was conducted to screen differentially-expressed microRNAs. *In vitro* experiments like quantitative real-time PCR analysis, western blot, immunofluorescence and ethynyl-20-deoxyuridine staining were performed to explore the function of exosomal miR-1297 on HSC activation and proliferation.

Research results

miR-1297 was obviously overexpressed in exosomes derived from lipotoxic hepatocytes. The lipotoxic hepatocyte-derived exosomal miR-1297 could promote the activation and proliferation of HSCs through the PTEN/PI3K/AKT signaling pathway.

Research conclusions

The lipotoxic hepatocyte-derived exosomal miR-1297 could accelerate the progression of metabolic-associated fatty liver disease in a cell model.

Research perspectives

This study provided some new evidence on the crosstalk between hepatocyte-secreted exosomes and HSC. miR-1297 may become a potential target for the treatment of

metabolic-associated fatty liver disease.

Abstract

BACKGROUND

Cyanidin-3-O-glucoside (cyan) exhibits antioxidant and anticancer properties. The cell cycle proteins and antimitotic drugs might be promising therapeutic targets in hepatocellular carcinoma.

AIM

To investigate the effect of cyan administration on cell cycle in hepatic precancerous lesion (PCL) induced by diethylnitrosamine/2-acetylaminofluorene (DEN/2-AAF) in Wistar rats.

METHODS

In vivo, DEN/2-AAF-induced hepatic PCL, rats were treated with three doses of cyan (10, 15, and 20 mg/kg/d, for four consecutive days *per* week for 16 wk). Blood and liver tissue samples were collected for measurement of the followings; alpha fetoprotein (AFP) liver function and RNA panel differential expression was evaluated *via* real time polymerase chain reaction. Histopathological examination of liver sections stained with H&E and immunohistochemical study using

glutathione S-transferase placental (GSTP) and proliferating cell nuclear antigen (PCNA) antibodies were assessed.

RESULTS

Cyan administration mitigated the effect of DEN/2-AFF induced PCL, decreased AFP levels, and improved liver function. Remarkably, treatment with cyan dose dependently decreased the long non-coding RNA MALAT1 and tubulin gamma 1 mRNA expressions and increased the levels of miR-125b, all of which are involved in cell cycle and mitotic spindle assembly. Of note, cyan decreased GSTP foci percent area and PCNA positively stained nuclei.

CONCLUSION

Our results indicated that cyan could be used as a potential therapeutic agent to inhibit liver carcinogenesis in rat model *via* modulation of cell cycle.

Key Words: Hepatocellular carcinoma therapy; Hepatocellular-carcinoma growth; Hepatocellular-carcinoma model; Hepatocellular-carcinoma size

Core Tip: Several regulatory RNA networks are important in regulation of liver cell cycle progression and are linked to the pathogenesis of hepatocellular carcinoma. Identification of critical steps involved in hepatocarcinogenesis are likely to lead to the development of new therapeutics that will inhibit tumor proliferation alongside with verification of promising drug targets biomarkers that may lead to improved patient survival. Cyanidin-3-O-glucoside (cyan) has a significant antioxidant and anticancer activities. Cyan could be used as potential agent to inhibit liver carcinogenesis in rat model *via* modulation of cell cycle. Cyan dose dependently decreased the long non-coding RNA-MALAT1 and tubulin 1 mRNA expressions and increased the hsa-miR-125b expression which participate in cell cycle and mitotic spindle assembly.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the commonest primary malignancy of the liver. Its main risk factors include hepatitis B, hepatitis C, and non-alcoholic steatohepatitis. HCC is associated with high mortality and morbidity. Its incidence has increased from 1.4 to 6.2 *per* 100000 cases *per* year within the last 30 years[1]. HCC burden in Egypt is high due to the high prevalence of HCV, where liver cancers account for 11.75% of all gastrointestinal cancers and 1.68% of all malignancies. In addition, over 70% of all liver malignancies in Egypt are HCC[2].

To date, HCC is holding its place as an unresolved dilemma; its resistance to systemic chemotherapy and radiation makes the cure approachable only in very early stages according to Milan criteria, that is, where the tumor size is < 5 cm (when only one lesion is present) or < 3 cm (when 2-3 lesions are present)[3].

Genes involved in cell cycle control are usually mutated in presence of cancer. Dysregulated mitosis results in genomic instability, which leads to tumor aggressiveness[4]. Microtubules are a key component of mitotic spindles, and thus, a crucial part of the process of mitosis. They form an important target in cancer chemotherapy, inducing arrest of mitosis and cell death. On the other hand, while the overexpression of γ-tubulin (γ-TUBG) showed improved survival among small cell lung cancer patients[5], the overexpression of γ-TUBG is found to be characteristic feature of thyroid and breast cancers[6]. Such variation may arise due to differences in gene transcription and check point regulations in different cancer tissues[7].

P-Editor: Wang LL

Cyanidin-3-glucoside (cyan) is a potential chemotherapeutic and chemo-protective agent. Through its antioxidant activity, it scavenges radical oxygen species, which decreases the overall number of tumorous cells (malignant and benign) in *in vivo* studies[8]. Cyan has been implicated in some beneficial health activities[9], including reducing age-associated oxidative stress[10], improving cognitive brain function, and exhibiting anti-diabetic[11], anti-inflammation[12], anti-atherogenic[13], and anti-obesity activities[14]. Previously, it has been reported that cyan mediates caspase-3 cleavage with DNA fragmentation. Cyan has also been associated with induction of autophagy, a key element involved in cancer elimination, *via* induction of autophagy-related gene 5 and microtubule-associated protein 1 light chain 3-II[15]. Cyan has drawn increasing attention because of its potential anti-cancer properties. Cyan may offer a novel avenue for treating HCC. a potential antiproliferative effect on HepG2 cells[16].

The present study was conducted to evaluate the effect of cyan in three different doses on cell cycle progression and mitotic assembly disorder in hepatic precancerous lesion (PCL) *via* assessment of levels of long non-coding RNA (lncRNA) MALAT1, miR-125b, and tubulin 1. We also conducted histopathological and immunohistochemical examination using H&E staining assessment of levels of glutathione S-transferase placental (GSTP) and proliferating cell nuclear antigen (PCNA) antibodies in male Wistar rat model of diethylnitrosamine/2-acetylamino-fluorene (DEN/2-AAF)-induced hepatic PCL.

MATERIALS AND METHODS

Chemicals and drugs

DEN was obtained as 1 g solution in serum bottle diluted in 0.9% NaCl. 2-AAF was obtained as white powder, while cyan was obtained as black powder. Both 2-AAF and cyan were dissolved in 0.9% NaCl. All chemicals were purchased from Sigma-Aldrich, Cairo, Egypt.

Experimental animals

All animal procedures were approved by the Institutional Animal Ethics Committee of Ain Shams University, Faculty of Medicine. Thirty male Wistar rats weighing 200-250 g were purchased from Nile Pharmaceuticals Company (Cairo, Egypt). Animals were housed in an animal room with temperature 25 ± 2 °C and 12 h light/dark cycle controls. An adaptation period of 1 wk was allowed before initiation of the experimental protocol.

Experimental procedures

Induction of hepatic PCL: DEN was injected intraperitoneally (*i.p.*) at a dose of 100 mg/kg once weekly for three consecutive weeks. One week after the last DEN injection, a single dose (300 mg/kg) of 2-AAF was injected.

Animal groups: Rats were divided into five groups (6 rats/each group), including: Naïve group: Rats were injected with a vehicle (0.9% NaCl), PCL group: Rats were injected with DEN and 2-AAF, and three cyan groups (cyan-10, cyan-15, and cyan-20 groups): Rats were injected with DEN and 2-AAF, and orally administered through gastric gavage with cyan in doses of 10, 15, and 20 mg/kg respectively, for four consecutive days *per* week for 16 wk[17].

Assessment of the effects of treatment

Biochemical and molecular studies: After scarifying the animals, blood was withdrawn from each rat from the retro orbital vein and incubated for about half an hour for clotting. Then, the blood sample was centrifuged for 20 min at 5000 RPM to get serum samples. Livers were dissected. The right lobe of the livers was removed, cut into longitudinal sections 2-4 mm in thickness and kept in 10% formalin for histopathological and immunohistochemical examination. The other lobe was kept frozen at -80 °C for molecular analyses. The samples were analyzed for the following parameters: (1) alpha fetoprotein (AFP) levels: AFP level was analyzed using quantitative sandwich rat AFP ELISA kit purchased from MyBiosource Inc. (San Diego, United States) with a sensitivity range of 0.625-20 ng/mL; (2) serum alanine aminotransferase (ALT) levels: The serum ALT was measured according to method described by using kits purchased from Diamond Diagnostic (Cairo, Egypt). ALT catalyzes the transfer of amino groups from specific amino acids to ketoglutaric acid, yielding glutamic acid and oxaloacetic or pyruvic acid, respectively. Ketoacids were

then determined calorimetrically after their reaction with 2, 4- dinitrophenylhydrazine; and (3) determination of serum total bilirubin and direct bilirubin: Alkaline methanolysis of bilirubin followed by chloroform extraction of bilirubin methyl esters, and later, separation of these esters by chromatography and spectrophotometric determination at 430 nm.

Determination of serum albumin

Quantitative determination of serum albumin level was quantified using rat albumin ELISA kit. The absorbance at 450 nm is a measure of the concentration of albumin in the test sample.

Bioinformatics-based selection of cell cycle-microtubule assembly- and HCC-specific RNA panel

The RNA panel was chosen in three steps: (1) *Tubulin, gamma 1* (*TUBG1*) was retrieved as a crucial player in microtubule formation and progression of the cell cycle through gene atlas expression database (available at https://www.ebi.ac.uk/gxa/home) alongside with verification of the chosen gene from protein Atlas database (available at https://www.proteinatlas.org/), followed by analysis of *TUBG1* gene ontology to ensure that it is linked to *G2-M* transition and mitotic spindle assembly, which is closely linked to cancer development through gene card database (available at https://www.genecards.org/); (2) we selected miR-125b-1-3p targeting *TUBG1* mRNA though) miRWALK database available at http://mirwalk.umm.uni-heidelberg.de/), followed by pathway enrichment, which revealed that miR-125b-1-3p is linked to MAP kinase and ubiquitin-mediated proteolysis (strongly correlated with mitotic assembly and cell cycle progression) through (Diana database available at http://diana.imis.athena-innovation.gr/DianaTools/index.php); and (3) lncRNA metastasis-associated lung adenocarcinoma transcript 1, lncRNA MALAT1, was obtained as a lncRNA specific to HCC and targeting miR-125b-1-3p using noncode database available at http://www.noncode.org/ and European Bioinformatics institute database available at https://www.ebi.ac.uk.

Extraction of total RNA, including lncRNA and miRNA from liver tissue

Total RNA was extracted from liver tissues using miRNeasy Mini kit (Cat No. 217004, Qiagen, United States) according to manufacturer's protocol. The extracted RNA concentration and integrity were assessed using [(NanoDrop Technologies/Thermo Scientific, Wilmington, DE, United States)], with RNA purities were 1.8-2. The extracted total RNA was reverse transcribed into cDNA using a miScript II RT kit (Cat No. 218160, 218161, Qiagen, United States) on thermal cycler (Bio-Rad; Hercules, CA, United States), according to the manufacturer's protocol.

Real time-polymerase chain reaction quantification of the RNA panel in liver tissues

The relative expression of TUBG1 mRNA and lncRNA-MALAT1 in liver tissue were measured using a Quantitect SYBR Green Master Mix kit and an RT2 SYBR Green ROX real time-polymerase chain reaction (qPCR) Mastermix (Qiagen), respectively, using a 7500 qPCR Systems (Applied Biosystems, Foster City, CA, United States) detection system) and specific primers (Accession: NM_001128148, NM_003234, NR_002819, and ENST00000534336, respectively) supplied by Qiagen. GAPDH (Accession NM_002046.7) was used as a housekeeping gene. MiR-3163 expression in liver tissue was quantified by PCR using a miScript SYBR Green kit (Qiagen), a miScript universal primer, and a miRNA-specific forward primer (mir-125b-1-3p miScript Primer Assay) (Accession: MIMAT0004592 (5'-ACGGGUUAGG CUCUUGGGAGCU). All steps followed the manufacturer's suggested protocol, and SNORD68 was used as an internal control. Ct values more than 36 were considered as negative. The specificities of the amplicons for the SYBR Green−based PCR amplification were affirmed by the melting curves. The $2^{-\Delta\Delta Ct}$ technique was used to measure the relative expression of the HCC-specific RNA panel.

Histopathological and immunohistochemical studies

Liver sections were cut at 5-μm thickness and stained with H&E. Immunohistochemistry S-P method was used to detect GSTP and PCNA levels. Briefly, the protocol was as follows: (1) the tissues were treated with endogenous peroxidase blocking solution at room temperature for 10 min, and then, incubated in normal nonimmune serum at room temperature for 10 min; (2) mouse anti GSTP or PCNA antibody was added to adjacent tissue sections respectively and incubated overnight at 4 °C; (3) biotin-conjugated second antibody was added to the sections and incubated at

room temperature for 10 min; and (4) S-P complex was added at room temperature for 10 min, and then, 2,4-diaminobutyric acid was used for the color reaction. The tissue sections were washed with Poly (butylene succinate) (PBS) (0.01 mol/L, pH 7.4) between each step. Positive and negative controls were simultaneously used to ensure specificity and reliability of the staining process. A positive section was taken as positive control. In negative control, PBS was used to replace the first antibody. GSTP-positivity was indicated by brown coloration of the cytoplasm. Morphometric analysis of the foci percent area was carried out using Leica Q win V.3 software after capturing the images using a Leica DM2500 microscope (Leica, Wetzlar, Germany). The PCNA labeling indices are represented as the expression of positively-stained nuclei (10 fields/slide at 400 ×) as shown below: +, positive expression found in 1-3 fields; ++, positive expression found in 4-6 fields; and +++, positive expression found in 7-10 fields. Rabbit monoclonal PCNA and GSTP antibodies were purchased from Abcam (San Francisco, United States).

Statistical analysis

All results were expressed as mean ± SD. Statistical analysis was carried out using GraphPad Prism version 6.01. Unpaired t-test was done to compare between naïve and PCL groups. One-way ANOVA, followed by Tukey's test, was carried out to compare between all groups. P values < 0.05 were considered statistically significant.

RESULTS

Effect on AFP levels and liver function tests

As shown in Figure 1, following induction of PCL, rats exhibited a significant increase in AFP levels. AFP levels were significantly decreased in cyan-10, cyan-15, and cyan-20 groups compared to PCL group. There was no significant difference between the AFP levels of the three cyan groups. Liver function tests were affected after receiving DEN/2-AAF in which rats exhibited a significant increase in levels of ALT and total and direct bilirubin, and a significant decrease in the serum albumin (Figure 2). As shown in Figure 2A, rats received cyan. in different doses exhibited a significant decrease in serum ALT compared to PCL group. Cyan-15 group showed significant decrease in serum ALT compared to cyan-10 group. Moreover, cyan-20 group showed significant decrease in serum ALT compared to cyan-10 group. In As depicted in Figure 2B, compared to PCL group, the rats in the three cyan groups exhibited a significant decrease in serum total bilirubin. Furthermore, cyan-20 group showed significant decrease in serum total bilirubin compared to cyan-10 group. Figure 2C: Serum direct bilirubin was significantly decreased in the three cyan groups compared to the PCL group. Moreover, cyan-20 group showed significant decrease in serum direct bilirubin compared to cyan-10 group. Administration of cyan in doses 5, 10 and 20 mg/kg/d produced a significant increase in serum albumin compared to PCL group. However, there was no significant difference between the serum albumin levels of the three cyan groups (Figure 2D).

Effect on expression of lncRNA MALAT1, miR-125b, and TUBG1 (G2/M transition of mitotic cell cycle) in the liver tissue

As shown in Figure 3, induction of PCL resulted in significant increase of lncRNA MALAT a significant decrease in RQ miR-125b and significant increase in RQ TUBG1 expressions in comparison to naïve group. RQ of lncRNA MALAT1 in the liver tissue was significantly decreased in cyan -10,15 and cyan-20 groups compared to PCL group. Furthermore, cyan-20 group showed significant decrease in RQ of lncRNA MALAT1 in the liver tissue compared to cyan-10 group (Figure 3A). On the contrary, RQ of miR-125b in the liver tissue was significantly increased in cyan -10, cyan-15 and cyan-20 groups compared to PCL group. In addition, cyan-20 group showed significant increase in RQ of miR-125b in the liver tissue compared to cyan-10 group (Figure 3B). Furthermore, RQ of TUBG1 in the liver tissue was significantly decreased in cyan-10, cyan-15 and cyan-20 groups compared to PCL group. Also, cyan-20 group showed significant decrease in RQ of TUBG1 in the liver tissue compared to cyan-10 group (Figure 3C).

Histopathological and immunohistochemical studies

Light microscopic examination of H&E-stained sections of naïve rats' liver showed normal hepatic architecture, cords of hepatocytes radiating from central vein, portal

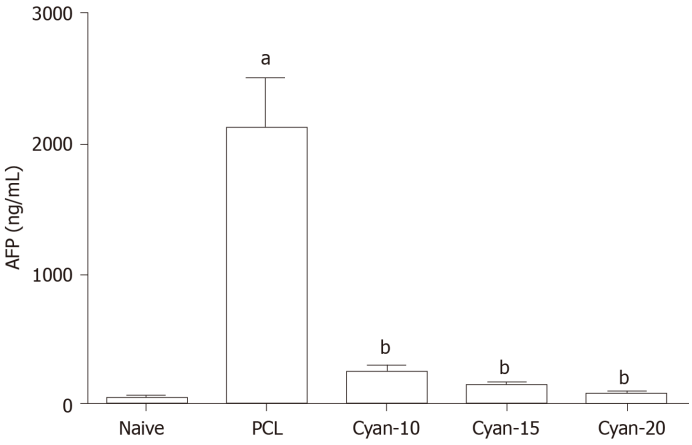

Figure 1 Effect of cyanidin 3-glucoside at different doses (10, 15 and 20 mg/kg/d) on alpha fetoprotein in the serum of rats. Values are mean ± SEM; number of animals = 6 rats/each group. [a]*P* < 0.05 significant differences compared to naïve group, unpaired t test; [b]*P* < 0.05 significant differences compared to precancerous lesion group. PCL: Precancerous lesion; Cyan: Cyanidin-3-O-glucoside; AFP: Alpha fetoprotein.

triads present in between, polygonal hepatocytes with centrally rounded vesicular nuclei, and hepatic sinusoid in between (Figure 4A and B). Liver sections obtained from rats received DEN/2-AAF (Figure 4C-E) showed disruption of normal hepatic lobular architecture along with presence of large, discriminated dysplastic nodules compressing the surrounding liver tissue, with high-grade dysplastic cells displaying increased nuclear: Cytoplasmatic ratio (Figure 4E), nuclear hyperchromatosis, and basophilic cytoplasm. Liver sections of rats treated with different doses of cyanidin (10, 15, and 20 mg/kg) respectively, showed small and less discriminated dysplastic nodules (Figure 4F-H).

Immunohistochemical examination with GSTP antibody appeared as large hyperplastic nodules were demonstrated by the brown color. Figure 5A and B shows the liver sections of naïve group, while Figure 5C shows large-positively stained GSTP foci demonstrated in PCL group. Liver sections from rats of all cyan-treated groups exhibited small GSTP-positive small hepatic foci of different sizes scattered in-between negatively-stained hepatic parenchyma (Figure 5D-F). The percent area of GSTP foci was significantly increased in the PCL group compared to naïve group, while all cyan-treated groups showed significant decrease in the GSTP percent area. Furthermore, cyan-15 and -20 showed significant decrease in the GSTP percent area over cyan-10 (Table 1). PCNA immunohistochemical analysis showed an elevated expression of PCNA in the group that received DEN/2-AAF as compared to naïve group (Figure 6A and B). Liver sections obtained from rats received cyan. in its three doses showed decrease in PCNA-positively stained nuclei (Figure 6C-E and Table 1).

DISCUSSION

Altered expression of mitotic spindle assembly genes has been detected in many cancers. For example, *MAD2* gene levels are downregulated in breast carcinoma[18], while mitotic checkpoint serine/*BUB1* gene expression is dysregulated in colorectal carcinoma[19]. The impairment of spindle assembly genes are frequently detected in HCC[20,21]. Moreover, inhibition of the mitotic assembly genes has been found to be lethal to cancer cells, and has promising therapeutic effect in cancer treatment[22,23].

In this study, we used several public microarray databases for the construction of simple genetic-epigenetic network specific to HCC and linked to cell cycle and mitotic spindle formation. We assessed the antiproliferative effect of cyan in HCC animal model *via* modulation of lncRNA-MALAT1-miR-125b-TUBG1 mRNA axis expression.

Microtubules are involved both in maintenance of cell shape and motility and in mitotic spindle formation[24]. γ-TUBG is a major player that supports microtubule nucleation. γ-TUBG acts as a binding site for the α/β-tubulin dimer and it has two *γ-TUBG* genes, TUBG1 and TUBG2 in mammals only[25]. The TUBG levels in the centrosome change during cell cycle progression and usually increases at the start of mitosis. At the end of mitosis, TUBG levels are decreased to interphase levels[26]. Overexpression and altered compartmentalization of γ-TUBG may lead to carcinogenesis[27-29]. Interestingly, γ-TUBG associates interact with tumor suppressor

protein C53 in mammalian interphase cells of different cellular origins[30]. Interestingly, γ-TUBG interacts with E2F transcription factors, resulting in upregulation of E2F target genes PCNA and CDKB1[31] and glutathione S transferase activity[32]. On the other hand, the mRNA and protein levels of TUBA1C are upregulated in HCC. Clinically, it affects the survival of patients and the level of metastatic burden along with portal vein thrombosis. In addition, it activates cellular proliferation and migration and is a potential therapeutic target for HCC[33]. Recent studies have shed light on the efficacy of microtubule-binding agents in the treatment of HCC, especially

in combination with mammalian target of rapamycin inhibitors[34].

One of the few miRNAs that regulate Spindle Assembly Checkpoints (SAC) is miR-125b. It suppresses the expression of Mad1 (a core SAC protein) that is responsible for inhibiting entry into anaphase till metaphase defects are corrected[35]. Importantly, miRNA-125b has been found to be associated with colorectal cancer[36], multiple myeloma[37], and breast cancer[38]. Song *et al*[39] demonstrated that the expression of miR-125b in hepatocytes was protective and reflected better survival in HCC tissue samples due to restoration of SIRT6 expression[39]. miR-125b-5p inhibits HCC proliferation by targeting TXNRD1, the terminal step of biosynthesis of nucleotides[40].

Deregulation of lncRNAs has been shown to be crucial in cancer progression, especially HCC[41,42]. Hung *et al*[43] demonstrated the involvement of lncRNAs in regulation of the expression of cell cycle-related genes, p53 gene regulatory pathway, and apoptosis[43,44]. The lncRNA MALAT1 is overexpressed in several solid tumors and is linked with tumor recurrence[45-47]. MALAT1 coordinate RNA polymerase II transcription, pre-mRNA splicing, and mRNA export[48]. Thus, this lncRNA holds great potential in influencing the local concentration of a specific splicing factor during specific stages of the cell cycle. Depletion of MALAT1 in cancer cells inhibits tumorigenicity[49]. MALAT1 regulates E2F1 transcription factor activity, highlighting its pro-proliferative function[50]. MALAT1 is upregulated in many cancer types, including breast cancer[51], cervical cancer, lung cancer[52], and hepatocarcinoma[53-55]. In a previous study, hypoxia enhanced MALAT1 expression, leading to increase in proliferating and invading activity of Hep3B cells due to negative interaction with miR200a[56]. Huang and his group explored the role of specificity protein 1/3 in regulation of MALAT1 expression in HCC cells[57].

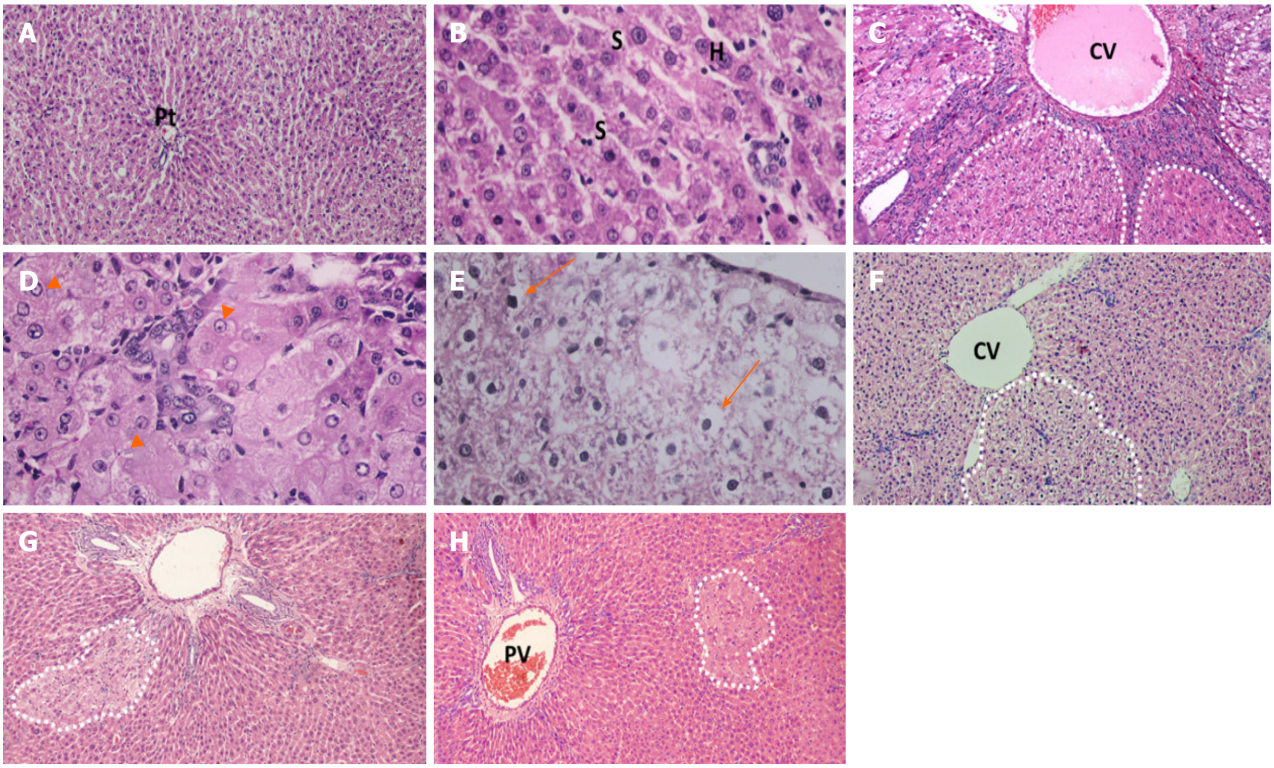

Figure 4 Photomicrographs of liver sections stained with H&E staining. A and B: Naïve group liver sections showed normal hepatic architecture, cords of hepatocytes radiating from central vein and portal triads present in-between and polygonal hepatocytes with central rounded vesicular nuclei, and hepatic sinusoid in-between; C-E: Liver sections of rats received diethylnitrosamine/2-acetylaminofluorene (DEN/2-AAF) showed larger, discriminated dysplastic nodules (doted shapes) compressing the surrounding liver tissue with disruption of normal hepatic lobular architecture; D: Liver sections of rats received DEN/2-AAF showed eosinophilic foci of cellular alteration consisting of enlarged hepatocytes with increased acidophilic staining and vaculated nuclei (arrow head); E: Liver sections of rats received DEN/2-AAF showed foci of Clear cell formed of hepatocytes showing variable degrees of cytoplasmic vacuolations and ballooning with pyknotic nuclei (arrow); F-H: Liver sections of rats treated with different doses of cyanidin (10, 15, 20 mg/kg) respectively, showing small and less discriminated dysplastic nodules (doted shapes). Cyanidin or anthocyanin (a polyphenolic pigment found in plants) confers several pharmacological benefits, including anticancer properties[58-62]. Cyan mediates cytotoxicity against human monocytic leukemia cells *via* G2/M phase arrest and induction of apoptosis[63]. Tsai *et al*[64] evaluated anthocyanins as promising anticancer or chemopreventive agents to induce G2/M arrest in HAs-induced leukemia cell cycle arrest *via* ATM-Chk1/2-Cdc25C axis modulation[64]. They also found that anthocyanin inhibits the proliferation of HCC cells[65,66].

In our study, the effect of cyan on cancerous tissue was dose-dependent (10, 15 and 20 mg/kg/d), that is, increasing its effect with increasing the concentration of the drug. This was proved also, with the correlated significant decrease in the percent area of GSTP foci, PCNA expression which are the target of TUBG1 mRNA and the molecular epigenetic markers associated with HCC (lncRNA MALAT1 and miR-125b-1-3p) in the liver tissue of rats in our study (Figure 7). Thus, we can hypothesize that administration of cyan in PCL may result in downregulation of lncRNA MALAT1 with subsequent release of free miR-125b-1-3p that binds to TUBG1 mRNA and downregulate its expression[65]. The changes in the epigenetic-genetic network affect their target genes PCNA and GSTP.

Lastly, the cyan-mediated modulation of cell cycle and mitotic spindle assembly that regulate HCC proliferation might affect the capability of the HCC cells to overcome oxidative stress[66,67]. Our data confers the rationale for designing antimitotic approach combining the conventional cytotoxic drugs with phytochemical extracts to inhibit cell cycle progression in cancer. More *in vitro* functional studies are required to explore the functional mechanism of the chosen RNA panel and validate their role as drug target biomarkers.

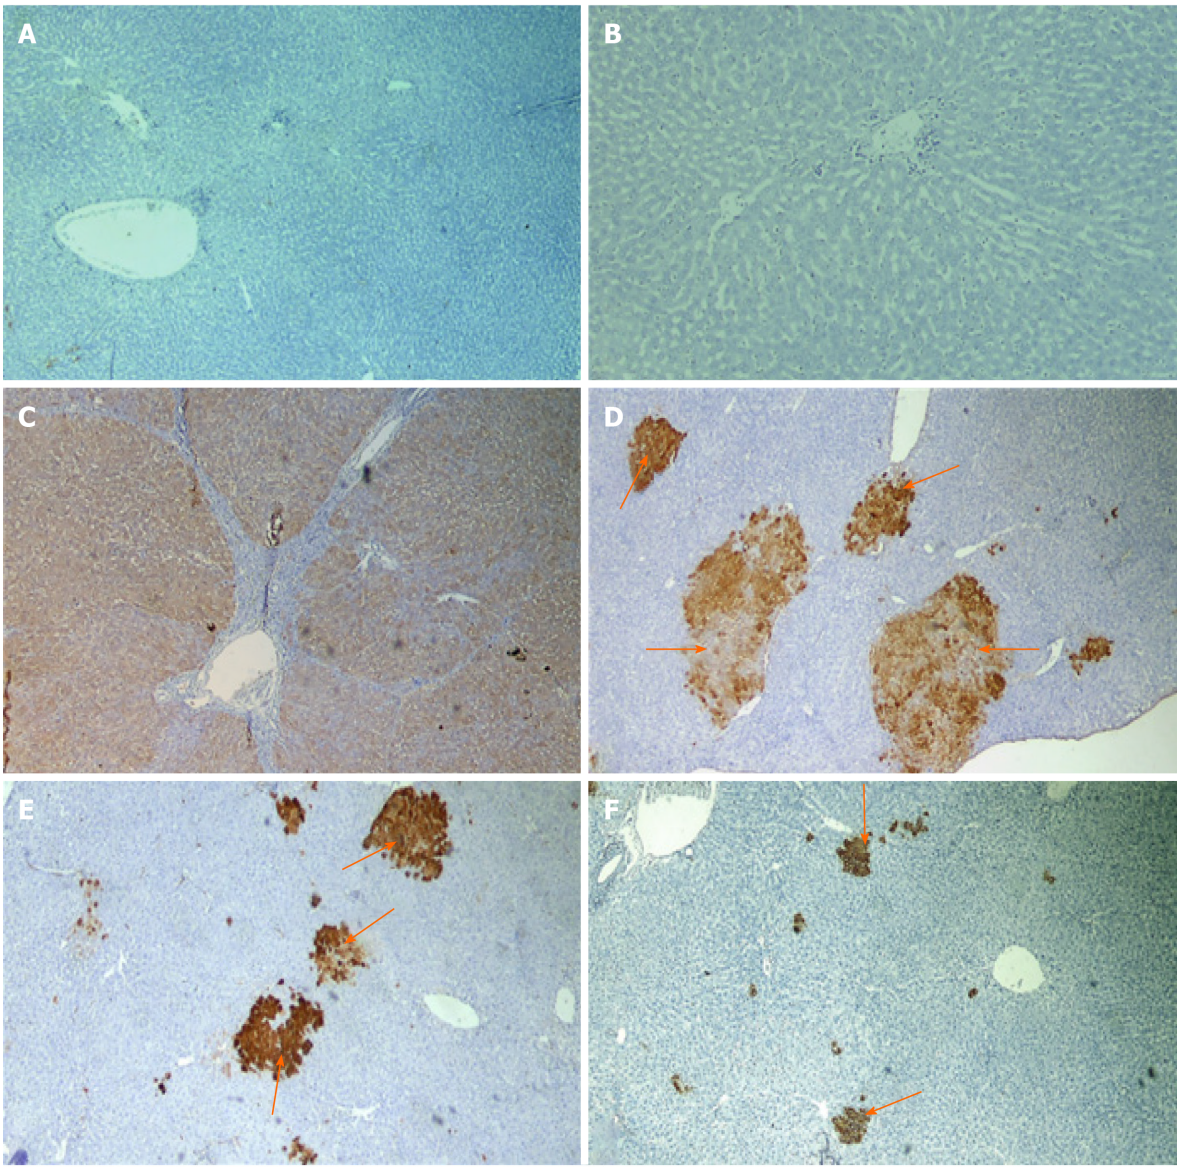

Figure 5 Photomicrographs of liver sections of rats immunohistochemical stained with glutathione S-transferase placental antibody. A and B: Naive group; C: Precancerous lesion group showing multiple glutathione S-transferase placental (GSTP)-positive large hepatic nodules (brown stained nodules) occupying most of section; D-F: Liver sections of rats treated with different doses of cyanidin (10, 15, 20 mg/kg) showing GSTP positive small hepatic foci (brown stained cells = arrow) of different size scattered in-between negatively stained hepatic parenchyma. (Magnification: × 40)

CONCLUSION

Cyanidin is a natural molecule that holds great potential in unraveling the mystery of cytotoxic pharmacy in the future. It can be used to devise novel antimitotic drugs that can target cell cycle in HCC. Our results also indicated great potential of the TUBG1 mRNA- miR-125b-lncRNA MALAT1 and -1-3p axis as potential drug target biomarker for further investigations.

ARTICLE HIGHLIGHTS

Research background

Several regulatory RNA networks are important in regulation of liver cell cycle progression.

Research motivation

Cyanidin-3-glucoside (cyan) is a potential chemotherapeutic and chemo-protective agent.

Research objectives

The present study aimed to investigate the effect of cyan administration on cell cycle in hepatic precancerous lesion induced by diethylnitrosamine/2-acetylaminofluorene in Wistar rats.

Research methods

We used bioinformatic analysis followed by experimental validation.

Research results

Cyan dose dependently decreased the long non-coding RNA-MALAT1 and tubulin gamma 1 mRNA expressions and increased the hsa-miR-125b expression which participate in cell cycle and mitotic spindle assembly. Cyan administration decreased alpha-fetoprotein and improved liver function. Cyan decreased glutathione S-transferase placental foci percent area and proliferating cell nuclear antigen positively stained nuclei.

Research conclusions

Cyanidin may offer a natural molecule to unravel the mystery a cytotoxic pharmacy for the future.

Research perspectives

Further larger *in vitro* and *in vivo* studies are needed to elucidate the mechanism of cyanidin cytotoxicity in hepatocellular carcinoma.

Abstract

BACKGROUND

Currently, rectovaginal fistula (RVF) continues to be a surgical challenge worldwide, with a relatively low healing rate. Unclosed intermittent suture and poor suture materials may be the main reasons for this.

AIM

To evaluate the efficacy and safety of stapled transperineal repair in treating RVF.

METHODS

This was a retrospective cohort study conducted in the Coloproctology Department of The Sixth Affiliated Hospital of Sun Yat-sen University (Guangzhou, China). Adult patients presenting with RVF who were surgically managed by perineal repair between May 2015 and May 2020 were included. Among the 82 total patients, 37 underwent repair with direct suturing and 45 underwent repair with stapling. Patient demographic data, Wexner faecal incontinence score, and operative data were analyzed. Recurrence rate and associated risk factors were assessed.

RESULTS

The direct suture and stapled repair groups showed similar clinical characteristics for aetiology, surgical history, fistula features, and perioperative Wexner score.

University, Guangzhou, China (No. E2018012).

Informed consent statement: Patients underwent sutured or stapled repair surgery after each agreed to treatment by written consent.

Conflict-of-interest statement: The authors declare having no conflicts of interest related to this study or its publication.

Data sharing statement: No additional data are available.

The stapled repair group did not show superior results over the suture repair group in regard to operative time, blood loss, and hospital stay. However, the stapled repair group showed better postoperative Wexner score (1.04 ± 1.89 *vs* 2.73 ± 3.75, $P = 0.021$), less intercourse pain (1/45 *vs* 17/37, $P = 0.045$), and lower recurrence rate (6/45 *vs* 17/37, $P = 0.001$). There was no protective effect from previous repair history, smaller diameter of fistula (< 0.5 cm), better control of defecation (Wexner < 10), or stapled repair. Direct suture repair and preoperative high Wexner score (> 10) were risk factors for fistula recurrence. Furthermore, stapled repair gave better efficacy in treating complex RVFs (*i.e.*, multiple transperineal repair history, mid-level fistula position, and poor control of defecation).

CONCLUSION

Stapled transperineal repair is advantageous for management of RVF, providing a high primary healing rate and low recurrence rate.

Key Words: Rectovaginal fistula; Surgical repair; Transperineal approach; Stapled technique; Recurrence

Core Tip: This retrospective cohort study evaluated efficacy and safety of the novel usage of stapling in repairing rectovaginal fistula (RVF). The overall recurrence risk of patients treated by staple repair was significantly lower than that of patients who underwent the conventional direct suture transperineal repair, especially for cases of complex RVFs, including multiple repair history, ≥ 10 preoperative Wexner score, or mid-level RVF status. According to the 5-year follow-up experience, stapled repair appears to be a promising surgical option for treating RVF, with high efficacy and safety.

INTRODUCTION

Rectovaginal fistula (RVF) continues to be a surgical challenge worldwide, presenting with a variety of symptoms, which include the passage of air and/or stool from the vagina or development of urinary and/or vaginal sepsis. The aetiology of RVF is mixed, but it most commonly results from obstetric trauma (with 3rd or 4th degree perineal lacerations), perianal Crohn's disease[1], radiation damage or malignancy, and complication of anorectal or gynaecological surgery[2]. Each among the range of RVF-related symptoms exerts a significant negative impact on the patient's quality of life and may substantially limit social interaction and even independence[3].

The vast majority of RVF cases require surgical treatment; despite a variety of surgical approaches being in use, primary healing rates in many series remain variable and low[4-8]; moreover, the risk of a poor longer term outcome and the need for more than one surgical repair remain appreciable[9,10]. Rupture of the incisions in the rectum and perineal diaphragm is a major cause of recurrence, with the incision dehiscence largely owing to the high local pressure exerted on the incision itself[9]. In conventional repair, the intermittent suture method often results in inadequate tight closure of the incision. The intervals of stitches are vulnerable to be pressed open by the rapid increase of local pressure when defecation. In addition, the silk thread suture is not reliable to withstand local high pressure, as it cracks easily. Therefore, looking for stronger suture materials and adopting a continuous suture to stabilize the incision may effectively reduce the risk of incision fracture. The stapled cartridge used in stapler operation is both continuous and close in its closure arrangement, facilitating

achievement of tight closure in our experience.

Given the range of surgical approaches, both the surgeon and the patient may be left unsatisfied with the result and with the occasional consequences of stoma, diminished sphincter function, poor perineal healing, and dyspareunia. It is accepted that outcomes for RVF repairs are influenced by many factors, including the primary aetiology, the type and times of prior repair, the use of a temporary diverting stoma, the time interval between recurrence of symptoms and a subsequent repair, the underlying integrity of the sphincter and the perineal body, any prior history of irradiation, and patient comorbidity[11-13]. Patients with Crohn's disease represent a particular group with uniformly worse results, wherein a combination of medical and surgical treatment by a healthcare management team is required[14-16].

Patients may be classified into anovaginal and RVFs, with sub-categorization of the RVF cases into low *vs* high and simple *vs* complex[17]. The location of the fistula defines the operative approach (*i.e.*, anal, perineal, or vaginal). Low RVF is typically located through or distal to the anal sphincter complex, with communication to the vaginal introitus above the dentate line. High RVF has its vaginal opening near the cervix, with a mid-level RVF defined as situated at a point between that of a low and a high case. Complicated cases are more likely to require some form of interposition graft and/or faecal diversion. Simple fistulas are typically small in size (< 2.5 cm in diameter), more distally located, and have either a traumatic or cryptoglandular origin. In contrast, complex fistulas include cases with an inflammatory bowel disease origin, relation to cancer or radiation treatment, and a recurrent RVF following an unsuccessful prior repair. The wide range of options for RVF repair reflect these varying aetiologies and the armamentarium available for recurrent cases. Beyond primary repair, these options selectively include a mucosal advancement flap (with or without sphincteroplasty), muscle or soft-tissue interposition (Martius grafting, graciloplasty, and biologic mesh interposition), fibrin glue, fistula plugs, ligation of the intersphincteric fistula tract (known as LIFT) procedure, and faecal diversion[18].

Our group has previously reported the safety of the novel use of a stapled transperineal repair by means of the Echelon Flex 60 Endopath (Ethicon Endo-Surgery Inc., Cincinnati, OH, United States) over a medium-term follow-up, as determined in a pilot series of obstetric-related non-Crohn's disease cases, showing a high success rate[19]. We have now assessed a retrospective cohort of patients presenting with low- and mid-level RVF, comparing outcomes and the probability of recurrence between those undergoing either a direct sutured or stapled fistula closure.

MATERIALS AND METHODS

Study design

Ethical permission for conduct of the study was provided by the Ethics Committee of The Sixth Affiliated Hospital of Sun Yat-sen University (Guangzhou, China). Patients presenting with an RVF who were surgically managed by perineal repair between May 2015 and May 2020 were included in the analysis. Patients were identified from a prospectively maintained database, crosschecked with operating theatre records of The Sixth Affiliated Hospital of Sun Yat-sen University (a university-affiliated 1383-bed tertiary referral centre, with 800 dedicated beds for coloproctology).

For comparison, patients undergoing standard direct suture repair were classified as Group 1 and those who underwent stapled transperineal repair were included in Group 2. In the event of a repeat repair, a minimum waiting period of 6 mo posto-perative from the previous repair was needed. All patients underwent a consultant clinical examination, colonoscopy, anorectal manometry (Manoscan™360; Sierra Scientific Instruments, Los Angeles, CA, United States), and magnetic resonance imaging (Optima MR360, 1.5 T; GE Healthcare, Waukesha, WI, United States) of the anal sphincter[6].

Patients with only a low-level or mid-level RVF (as defined) were included in the analysis. The exclusion criteria were < 18 years of age, underlying inflammatory bowel disease or diagnosed Crohn's disease, malignant cases of RVF, and cases where the RVF was associated with active perianal sepsis and/or an undrained perianal abscess (Figure 1).

Surgical procedure

Our group has previously described the stapled RVF repair[19]. Briefly, all patients underwent a preoperative rectal and vaginal lavage with a Betadine wash. One hour prior to surgery, ciprofloxacin and/or metronidazole was administered intravenously.

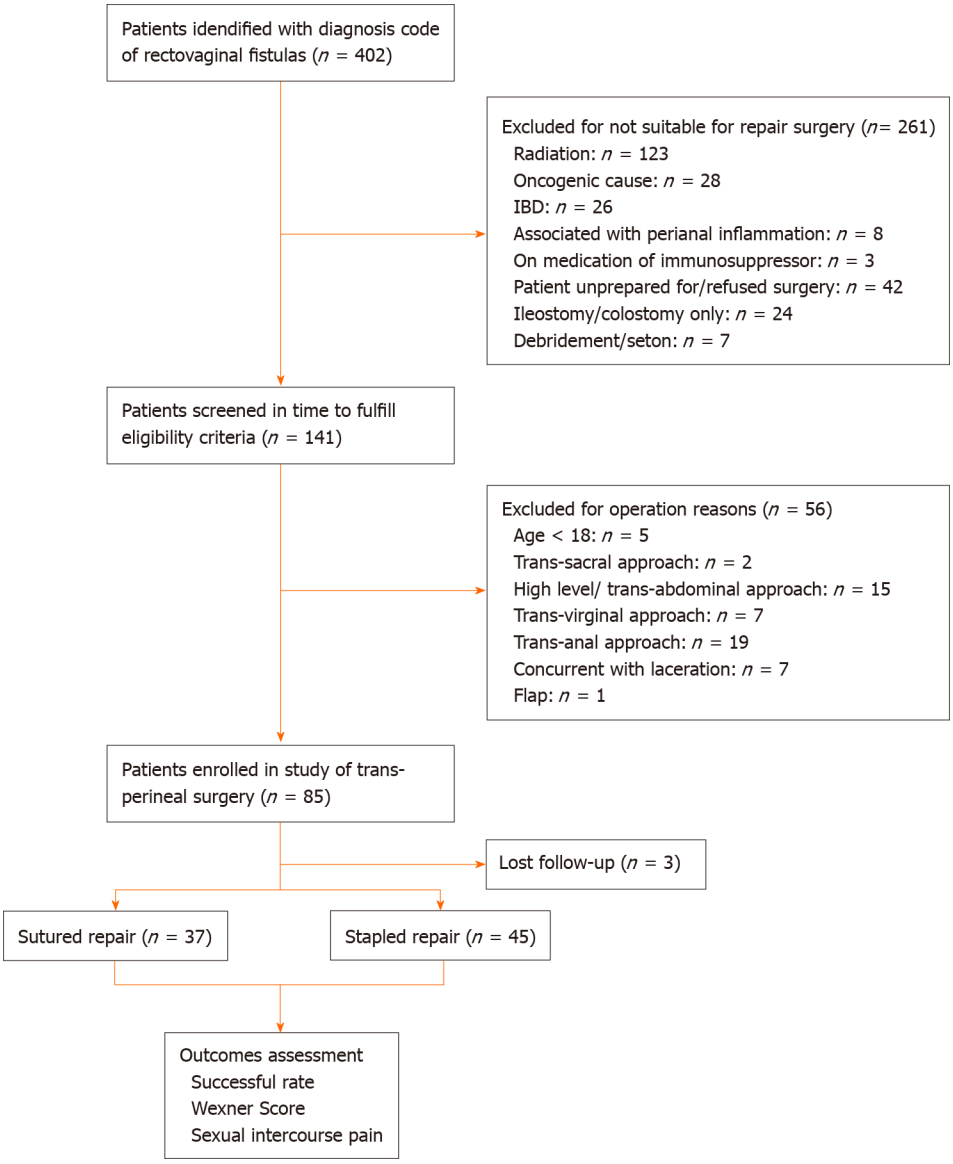

Figure 1 Participant enrolment and follow-up. A total number of 402 rectovaginal fistula patients were treated at The Sixth Affiliated Hospital of Sun Yat-sen University between May 2015 and May 2020. Among them, 85 were treated by stapled or sutured transperineal repair in our hospital. Apart from three patients who were lost to follow-up, 82 patients were included in this study. The clinical data for each were collected and analysed retrospectively. A total of 37 patients underwent conventional direct sutured transperineal repair and were classified as Group 1, and 45 patients who underwent stapled repairs were included in Group 2. Basic characteristics, perioperative details, and surgical outcomes were evaluated. IBD: Inflammatory bowel disease.

Following induction of the anaesthesia, a urinary catheter was inserted with the patient in the lithotomy position. A Lonestar retractor (Saisheng Medical Technology Co., Ltd, Changzhou, Jiangsu Province, China) was used for exposure, with insertion of a No. 6 Fr Nelaton tube into the fistula, so as to identify the fistula during the dissection. A "U-shaped" incision was then made in the region, mid-way between the vagina and the rectum, with dissection of the rectovaginal septum and injection in the dissection area of a 1:200000 epinephrine-saline solution in order to facilitate a bloodless dissection. Slight traction on the Nelaton tube assisted in identification of the fistula from surrounding normal tissues.

For those patients in Group 1, the fistula was sharply severed with a scalpel, after which the rectum and vagina were closed separately with interrupted 2/0 or 3/0 Vicryl (Ethicon Endo-Surgery Inc.) sutures. No specific attempt was made to reduce the suture line tension or to interpose tissue to support the rectovaginal septum. In Group 2 patients, the Echelon Flex 60 Endopath (Ethicon Endo-Surgery Inc.) stapler was used for fistula closure by means of a stapled cartridge (3.5 mm staple height, 1.5 mm when closed). The staples left on the vaginal wall side were removed, after which the defect in the vaginal wall was closed by direct suture. After clear identification of the edges of the external anal sphincter, those cases where an external anal sphincter defect had been demonstrated by preoperative imaging underwent an attendant anal

sphincteroplasty. Equally, if there was any tension on the suture line, a levatorplasty was also performed using a continuous absorbable monofilament barbed Stratafix (Ethicon Endo-Surgery Inc.) suture. The skin was closed over a suction drain, with a gauze roll pack inserted in the vagina. Both antibiotics were continued for 72 h postoperatively, with removal of the gauze roll in the ward after 48 h and removal of the drain usually till the drainage less than 5 mL during a 48-h period.

Assessment parameters and outcome

Patient demographic data collected included age, fistula aetiology, fistula duration, the measured distance of the lower edge of the fistula from the anal and vaginal margins, and the fistula diameter. The Wexner faecal incontinence score was determined before surgery[20]. Operative data collected included the operative time (interval between the beginning of the operation and commencement of application of the dressing) and the degree of intraoperative blood loss (based on the number of gauze pads used). Postoperative complications (*e.g.*, wound infection, wound dehiscence, and anal canal stenosis) were recorded, along with the use of a diverting stoma and the length of hospital stay (referred to as LOHS). Patients were routinely followed with clinical examination and performance of Wexner scoring at 1 mo after surgery, as well as with recording of any reported dyspareunia in sexually active patients. Recurrence of a fistula was specifically assessed in patients who reported vaginal flatus or faecal discharge undergoing repeat imaging.

Statistical analysis

Statistical analyses were performed using the SPSS statistical software package (version 26.0; IBM Corp., Armonk, NY, United States). All statistical methods used in this study were evaluated by an expert in Biomedical Statistics (Department of Medical Statistics, Sun Yat-sen University). Student's *t*-test was used for comparisons where data were normally distributed and with Wilcoxon's rank sum test for non-normally distributed data. Categorical data were assessed by either a chi-squared test or a Fisher's exact test, where appropriate. Groups 1 and 2 were compared using the log rank test, with significant variables on univariate analysis inserted into a multivariate Cox regression model. Risk factors for fistula recurrence were identified with graphic construction of a projected risk using the Kaplan-Meier method[21]. *P* values < 0.05 were considered statistically significant.

RESULTS

A total of 82 patients with mid- and low-level RVF were included in the analysis, with 37 patients in Group 1 (direct sutured repair) and 45 patients in Group 2 (stapled repair). The overall mean age was 37.82 ± 12.63 years, with division of the groups into those < 60 and ≥ 60 years of age. Given the exclusion criteria, the commonest aetiologies of RVF in the cohort included post-obstetric (n = 39; 47.56%), congenital-related (n = 18; 21.95%), post-anorectal surgical (n = 24; 29.27%), and other (traumatic, n = 1; 1.22%) causes. The overall mean duration of disease was 110.38 ± 141.4 mo, with the fistula opening located a mean distance of 2.26 ± 1.33 cm from the anal margin and 1.76 ± 1.22 cm from the vaginal introitus. The mean fistula width was 0.69 ± 0.46 cm, with overall 0.48 ± 0.83 prior attempts at RVF repair. The mean preoperative Wexner score for the entire cohort was 6.77 ± 3.45, with sub-categorization of the groups by < 10 or ≥ 10 on the scale. The mean follow-up period was 13.7 mo (range: 1.0-54.7 mo).

Table 1 shows the clinical characteristics of the patients. The etiological distribution of patients was quite different between the two groups, but the majority of cases were secondary to surgery, particularly conventional surgery. Other parameters showed no statistical difference between the two groups. Table 2 shows the intraoperative factors, where there was no statistical difference noted between Group 1 and Group 2 cases in operative time, intraoperative blood loss, or LOHS. Compared with Group 1, the postoperative Wexner score was significantly lower in Group 2. Otherwise, the Wexner score was largely improved within both of the two groups after surgery. There was no difference in the incidence of postoperative dyspareunia, with one patient from each group complaining of new-onset painful intercourse. There were 17 recurrent cases in Group 1 and significantly less in Group 2 (n = 6; P = 0.001).

As shown in Table 3, univariate analysis of factors affecting recurrence showed significance for previous repair history, fistula diameter, surgical technique, and preoperative Wexner score, with a non-significant effect noted for obstetrical fistulas, occurrence secondary to surgery, and existing intestinal stoma. In multivariate

RVF: Rectovaginal fistula.

Kaplan-Meier curves generated for the postoperative recurrence-free period are shown in Figure 2 and demonstrate a significantly higher risk of recurrence if a sutured rather than a stapled repair was performed and if the preoperative Wexner score in the cohort was ≥ 10. The effect of the preoperative Wexner score was particularly evident in the first 1 mo following surgery (Figure 2B). Figure 3 shows a generated Kaplan-Meier curve comparing the effects of surgical repair (sutured *vs* stapled) with the preoperative Wexner score, demonstrating an overall significant effect of an interaction of the mode of surgery with the Wexner score recorded 1 mo after surgery ($P = 0.031$). In this regard, for those patients with a preoperative Wexner score of < 10, the recurrence rate for conventional sutured repair was 38.71% (12/31) but only 8.57% (3/35) for those managed by stapled repair (Figure 3B). For those patients presenting with a preoperative Wexner score of ≥ 10, a higher recurrence rate was predicted for patients undergoing sutured repair compared with stapled repair (83.33% *vs* 30%, respectively) (Figure 3C).

Despite the fact that failed prior repair history and fistula location were not found to

be significant for recurrence in the Cox proportional hazards model, we redrew the Kaplan-Meier curves with separation of different groups to develop the latent advantages of the stapled technique. The effect of prior repairs significantly impacted those cases undergoing multiple sutured repairs (Figure 4). There was no difference noted in the recurrence rate between Groups 1 and 2, if there was a single prior RVF repair experience [4/8 (50%) *vs* 2/7 (28.57%), respectively; $P = 0.466$], whereas the risk of recurrence in patients who had not undergone a prior repair was higher in Group 1 than in Group 2 [10/26 (38.46%) *vs* 2/31 (6.45%), respectively; $P = 0.005$] (Figure 4B and C). Meanwhile, the stapled technique largely resolved the risk of recurrence in patients who had undergone multiple prior repairs [3/3 (100%) *vs* 2/7 (28.57%), respectively; $P = 0.016$] (Figure 4D). Furthermore, the recurrent risk of sutured repair cases was significantly higher than that of stapled repair cases among both the low-level subgroup [11/27 (40.74%) *vs* 4/28 (14.29%), respectively; $P = 0.04$] and the mid-level subgroup [6/10 (60%) *vs* 2/17 (11.76%), respectively; $P = 0.009$] (Figure 5).

DISCUSSION

This retrospective comparative study showed that the stapled closure of RVF is safe and efficient, with a significantly lower fistula recurrence rate. Multivariate analysis showed the surgical approach and the preoperative Wexner incontinence score to be independent predictors of postoperative success, with predicted recurrence risk greatest in the first postoperative year. There was also an interactive effect on recurrence risk between high-grade preoperative incontinence and the use of a stapled repair.

Our group had recently reported on the safety of the Echelon Flex 60 Endopath stapler, as determined in a pilot study of 7 RVF cases, showing its relative ease of use and low morbidity[19]. As far as we are aware, our latest study (presented herein) is the first to compare stapled RVF closure with a direct sutured repair. Outside of separated local rectal and vaginal sutures, given the high rate of RVF recurrence over time, alternative techniques have included the use of augmentations, such as the Martius

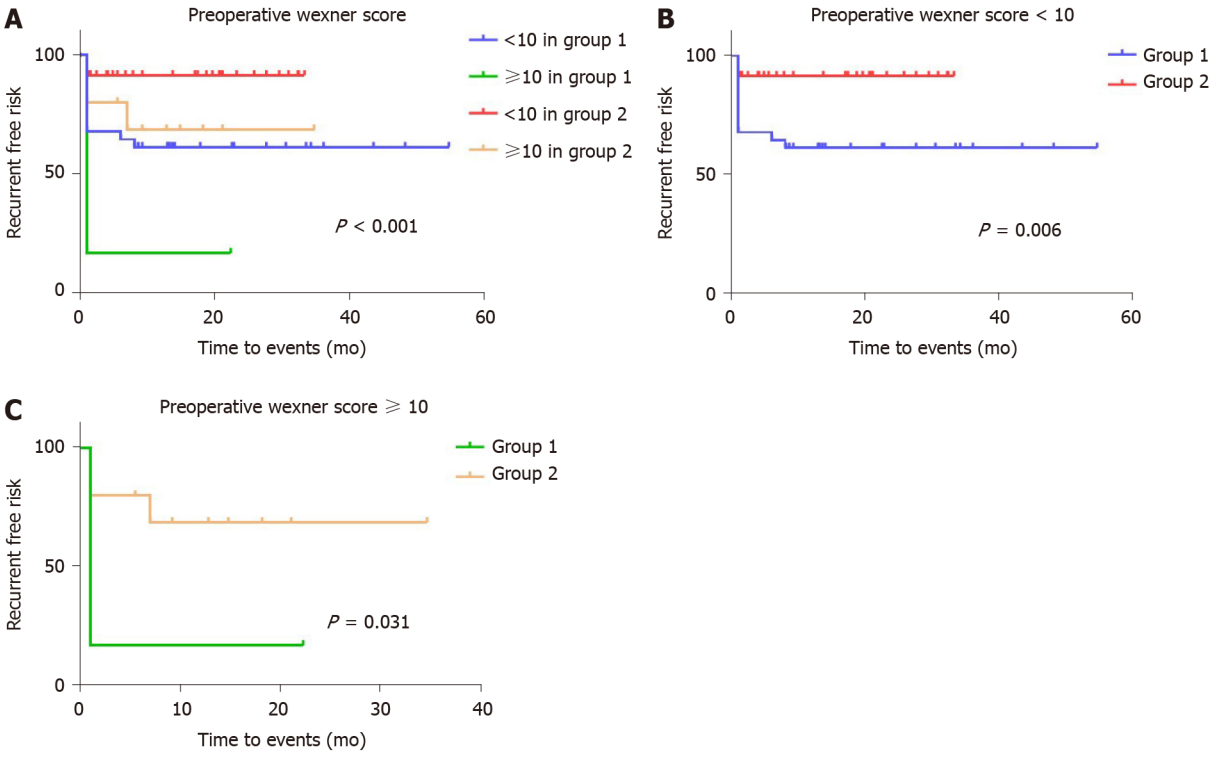

Figure 3 Kaplan-Meier curves assessing recurrence-free risk combining the mode of surgery (sutured *vs* stapled repair) with the preoperative Wexner score. A: Preoperative Wexner score categorized as < 10 or ≥ 10 in each group; B: Patients with preoperative Wexner score < 10 in each group; C: Patients with preoperative Wexner score ≥ 10 in each group.

labial fat pad replacement[22,23], interposition graciloplasty[24,25], ometoplasty or fat instillation[26,27], and the insertion of absorbable biocompatible mesh[28]. Despite these newer augmented techniques, the surgical management of RVF remains a major challenge, with recurrence rates ranging widely in the literature (from 0% to 80%)[4,7,10]. The principal clinical features associated with recurrence after an initial repair include the number of prior repairs[11], the fistula aetiology, and a history of cigarette smoking[4]; there has been no demonstrable effect of age, body mass index, presence of comorbidities, or steroid use[29].

Our present study showed advantage for the stapled fistula closure with the groups assessed (well matched for the number of multiple previous fistula repairs). In this regard, Lowry *et al*[11] showed a reduction in success rate (from 88% down to 55%) between the first repair and those patients who had undergone two prior failed attempts. Since there is a correlation between the number of surgical attempts and the ultimate rate of failure, future investigations need to prospectively assess the stapled RVF closure in cases with higher risk of recurrence. Otherwise, the recurrence rate of each aetiology in Group 1 was higher than that in Group 2, especially in secondary-to-surgery patients [9/16 (56.25%) *vs* 1/8 (12.5%), respectively]. Given that secondary-to-surgery patients had a history of more than or equal to one repair operation, this finding also indicates that patients with multiple operations are not optimally suitable for another sutured repair. The relative high healing rate in mid-level fistulas also suggests stapled repair as a potential surgical option for treating complex RVF. Data concerning the value of a protective stoma in RVF repair remain controversial[30]. Our stoma use in both cohorts was comparatively low, with the two groups being well matched. Outside of more complicated cases or those excluded from our analysis[13], diversion of stomas is more likely to be used in RVF cases with coincident sepsis or after multiple failed repairs.

It is important to recognize that our results are biased towards lower and simpler cases, wherein most specialist interventions should have a moderately high success rate. In this regard, our study merely confirmed the feasibility of the stapled procedure, with a very low attendant perioperative morbidity. Our results may also depend upon factors which lie outside of the particular repair method. In this respect, Lo *et al*[7], in a combined 12-mo follow-up study of patients from Taiwan, Malaysia, and the Philippines, showed a worse overall outcome after simple local RVF repair when the women were older and of lower socioeconomic status or when their fistula

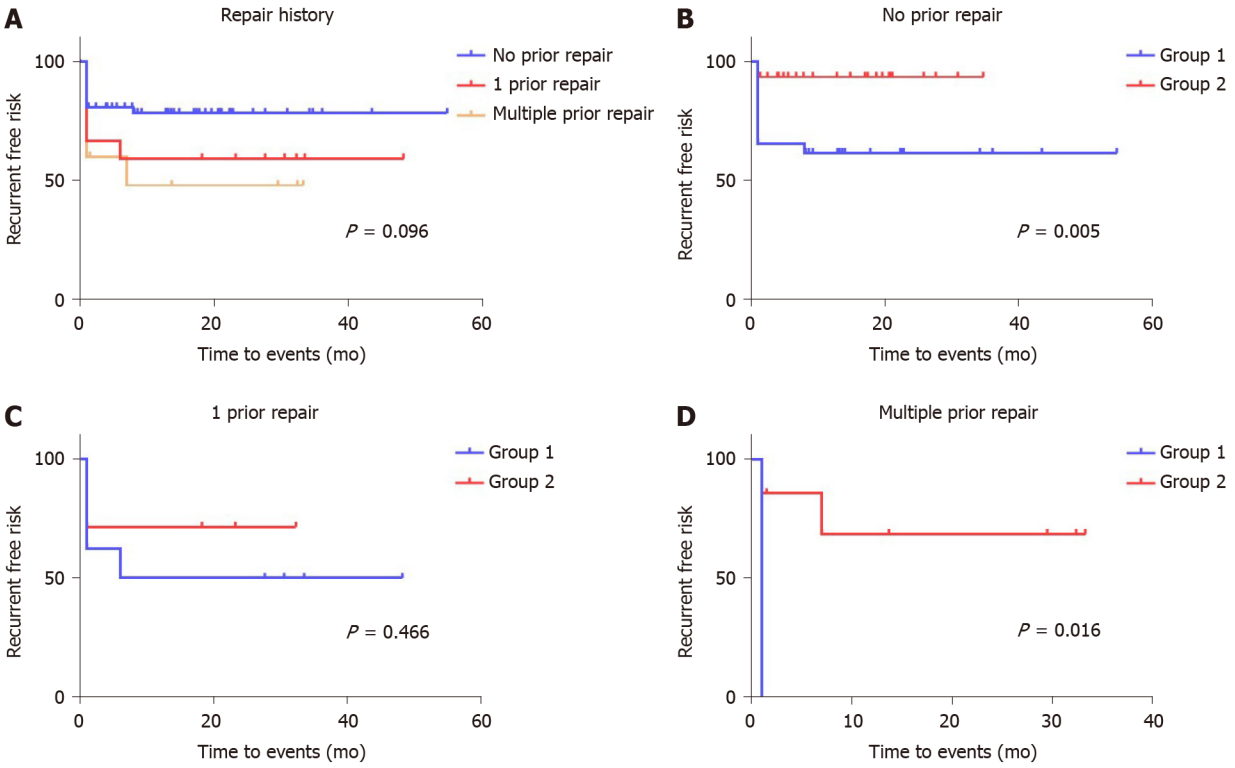

Figure 4 Kaplan-Meier curves of risk of recurrence and the effect of prior rectovaginal fistula repair history, according to the mode of surgery (sutured *vs* stapled repair). A: Transperineal repair categorized as no prior repair, single, and multiple prior repair(s) in each group; B: Patients who had no prior repair history in each group; C: Patients with a single prior repair in each group; D: Patients who had more than one prior repair in each group.

resulted from non-obstetric-related causes. In our practice, the majority of our cases were post-obstetric, even though RVF is an uncommon sequel of vaginal delivery[31]. The success of surgery depends upon the integrity of the local tissues, the absence of active inflammation and infection, the amount of scar tissue available, and the degree of attenuation of the perineal body. We postulate that failure after local repair is consequent to tension within the soft-tissues, an effect which may be diminished with the use of a stapled closure.

Given the differential forces across a high-pressure rectum to a comparatively low-pressure vaginal circuit[32], spontaneous healing of an RVF is rare[33]. We consider it appropriate to perform a coincident sphincteroplasty and levatorplasty in cases with demonstrable sphincter defects, where there has been a prior third or fourth degree perineal laceration. This is an added advantage of the transperineal repair (however performed) that readily permits an anterior levatorplasty, which acts as a bulwark against the high-pressure rectal side of the repair. This is consistent with results from other studies that have used different types of repair; for example, Tsang *et al*[12] showed that with advancement mucosal anoplasty, there was a substantial improvement in success for those cases presenting with preoperative incontinence and a visible external anal sphincter defect if combined with both a sphincteroplasty and a levatorplasty. Besides, the additional separation towards the fistula helps alleviate local tension. In our experience, the plane in the rectovaginal septum should be expanded sufficiently around the entire fistula. It represents the cornerstone for tension-free cutting closure of the fistula when the stapler is applied. Second, the levator ani muscle should be exposed bilaterally for consequent continuous suturing. This facilitates a better reinforcement of levatorplasty and closure of the fistula, to withstand future tension.

For the different local RVF repair method in the present study, preoperative incontinence in the stapled group appeared to be a predictor of a better outcome, whereby the interposition of well-vascularised tissue between the rectum and the vagina can lead to improved healing. In our opinion, a preoperative Wexner score exceeding 10 strongly indicates a dysfunctional anal sphincter. Therefore, the surgeon should dissociate enough space to reconcile the use of the stapler and sphincter repair or levatorplasty. It seems that having adequate space exposed in order to place the stapler and perform levatorplasty or sphincteroplasty during the stapled repair process in patients with a high Wexner score will greatly alleviate the local pressure on

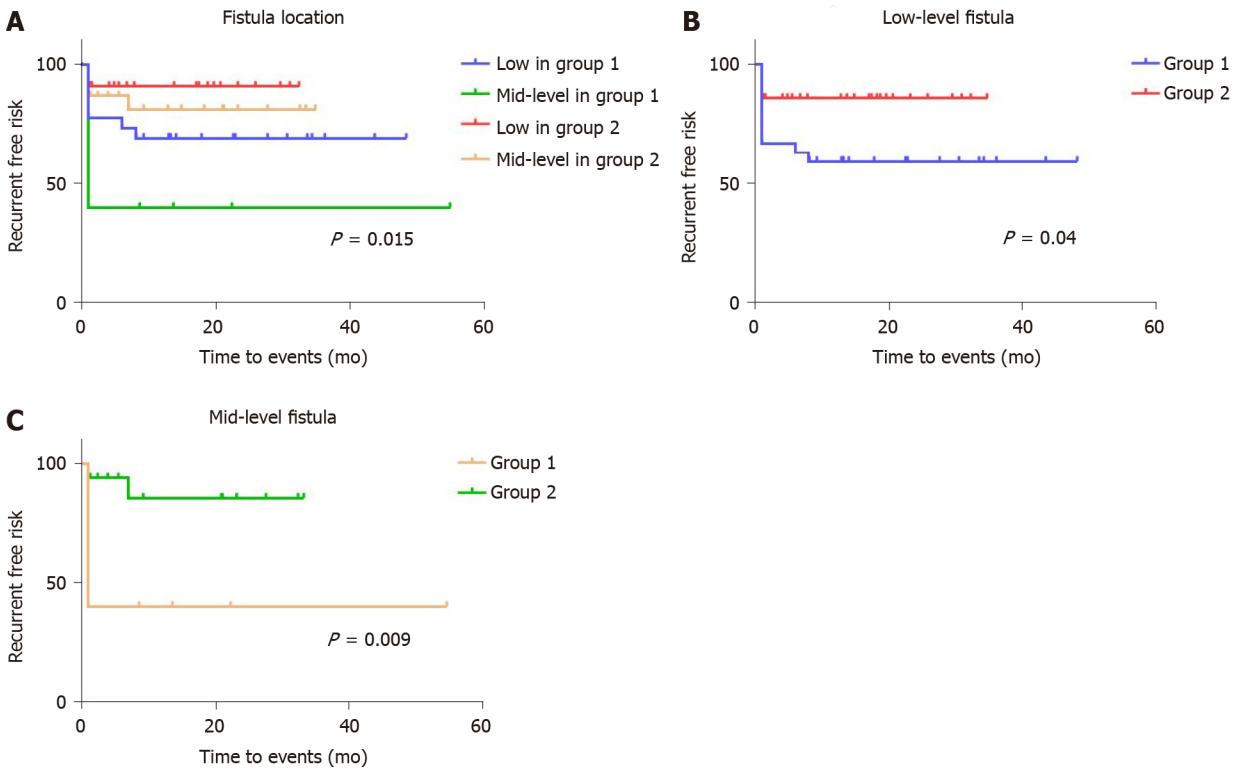

Figure 5 Kaplan-Meier curves of risk of recurrence and the effect of height of the fistula, according to the mode of surgery (sutured *vs* stapled repair). A: Fistula location categorized as low- and mid-level in each group; B: Patients with low-level fistula in each group; C: Patients with mid-level fistula in each group.

the incision, which may have contributed to the lower recurrence rate.

Our study has several limitations. The retrospective design with focused consideration of low- and mid-level fistulas introduces biases towards particular types of surgery in less complicated cases. In addition, our median follow-up was relatively short, with the expectation of later recurrent fistulas in both groups over time. The overall low incidence of inflammatory bowel disease in China can also influence the outcome of RVF repair, limiting the ability to translate our experience to other countries. Further, in China, patients with congenital RVF quite commonly wait to present to an adult Coloproctology Unit until after marrying age, to request repair. Another potential limitation of our study lies in the fact that, although Wexner scoring was performed preoperatively, the true prevalence and severity of incontinence may be greater since some symptoms can be inaccurately attributed to the fistula rather than to pre-existing incontinence. This emphasizes the importance of a thorough physical examination and preoperative sphincter imaging for successful functional outcome and patient satisfaction following treatment, reflecting not only fistula healing but also continence improvement.

Our study has shown the advantage of management of non-inflammatory RVF using a stapled repair over a direct suture, with reduced recurrence rates over a short- to medium-term follow-up.

CONCLUSION

In conclusion, the stapled transperineal repair technique shows better efficacy and acceptable safety in surgical treatment of low- and mid-level RVFs.

ARTICLE HIGHLIGHTS

Research background

Currently, rectovaginal fistula (RVF) continues to be a surgical challenge worldwide, on account of low primary healing rates and uncertainty regarding secondary repair.

Research motivation

Based on findings from a preliminary pilot study of the safety of stapled transperineal repair on low- and mid-level RVF, we designed a retrospective study to compare outcomes and recurrence rates between sutured and stapled transperineal repair.

Research objectives

Patient demographic data, Wexner faecal incontinence score, and operative data were analyzed. Recurrence rate and associated risk factors were specifically assessed.

Research methods

This was a retrospective cohort study conducted on patients from the Coloproctology Department of The Sixth Affiliated Hospital of Sun Yat-sen University. In total, 82 adult patients presenting with RVF who were surgically managed by perineal repair between May 2015 and May 2020 were included. Among them, 37 patients were repaired with direct suture and 45 patients with stapler.

Research results

The two treatment groups shared similar clinical characteristics, such as aetiology, surgical history, fistula features, and Wexner score. The stapled repair group did not show superior results over the sutured repair group in regard to operative time, blood loss, and length of hospital stay. However, the patients in the stapled repair group showed a better postoperative Wexner score (1.04 ± 1.89 *vs* 2.73 ± 3.75, $P = 0.021$), less intercourse pain (2.22% *vs* 2.7%, $P = 0.045$) and, most important, lower recurrence rate (13.33% *vs* 45.95%, $P = 0.001$). No previous repair history, smaller diameter of fistula (Wexner < 0.5 cm), better control of defecation (Wexner < 10), and stapled repair showed protective effects on healing. Direct suture repair and preoperative high Wexner score (≥ 10) were further demonstrated to be risk factors for fistula recurrence.

Research conclusions

Stapled transperineal repair shows an advantage for management of non-inflammatory, low- and mid-level, or even with prior failure of repair of RVF, with high primary healing rate and low recurrence rates.

Research perspectives

Our retrospective analysis of only low- and mid-level fistulas introduces biases towards particular types of surgery in less complicated cases. In addition, our median follow-up was relatively short, with the expectation of later recurrent fistulas in both groups over time. The long-term efficacy of stapled repair needs further prospective, randomized controlled trials to fully understand and capitalise on its advantages in clinic.

Abstract

BACKGROUND

Integrative multi-omic approaches have been increasingly applied to discovery and functional studies of complex human diseases. Short-term preoperative antibiotics have been adopted to reduce site infections in colorectal cancer (CRC)

Institute, No. P20 CA192994; National Cancer Institute, No. P20 CA192996; and Simons Foundation, No. 415604.

Institutional review board statement: This study was approved by the Stony Brook University Institutional Review Board (approval No. 163184).

Informed consent statement: All study participants, or their legal guardian, provided informed written consent prior to study enrollment.

Conflict-of-interest statement: All authors declare no conflicts-of-interest related to this article.

Data sharing statement: All de-multiplexed, paired-end 16S rRNA gene sequence files and RNA-sequence data along with associated metadata were deposited into the Gene Expression Omnibus, which is a public repository that archives and freely distributes comprehensive sets of microarray, next-generation sequencing, and other forms of high-throughput functional genomic data submitted by the scientific community data base under project accession number GSE165255. All the tissues analyzed were collected from patients that gave informed consent for sharing results of the analysis of their anonymized tissues on public databases, where the risk of identification is very low. The statistical code used in this study is available from the corresponding author at ellen.li@stonybrookmedicine.edu.

STROBE statement: The authors have read the STROBE Statement-checklist of items, and the manuscript was prepared and revised according to the STROBE Statement-checklist of items.

Open-Access: This article is an open-access article that was selected by an in-house editor and fully peer-reviewed by external reviewers. It is distributed in accordance with the Creative Commons Attribution

resections. We hypothesize that the antibiotics will impact analysis of multi-omic datasets generated from resection samples to investigate biological CRC risk factors.

AIM

To assess the impact of preoperative antibiotics and other variables on integrated microbiome and human transcriptomic data generated from archived CRC resection samples.

METHODS

Genomic DNA (gDNA) and RNA were extracted from prospectively collected 51 pairs of frozen sporadic CRC tumor and adjacent non-tumor mucosal samples from 50 CRC patients archived at a single medical center from 2010-2020. The 16S rRNA gene sequencing (V3V4 region, paired end, 300 bp) and confirmatory quantitative polymerase chain reaction (qPCR) assays were conducted on gDNA. RNA sequencing (IPE, 125 bp) was performed on parallel tumor and non-tumor RNA samples with RNA Integrity Numbers scores ≥ 6.

RESULTS

PERMANOVA detected significant effects of tumor *vs* nontumor histology (P = 0.002) and antibiotics (P = 0.001) on microbial β-diversity, but CRC tumor location (left *vs* right), diabetes mellitus *vs* not diabetic and Black/African Ancestry (AA) *vs* not Black/AA, did not reach significance. Linear mixed models detected significant tumor *vs* nontumor histology*antibiotics interaction terms for 14 genus level taxa. QPCR confirmed increased *Fusobacterium* abundance in tumor *vs* nontumor groups, and detected significantly reduced bacterial load in the (+)antibiotics group. Principal coordinate analysis of the transcriptomic data showed a clear separation between tumor and nontumor samples. Differentially expressed genes obtained from separate analyses of tumor and nontumor samples, are presented for the antibiotics, CRC location, diabetes and Black/AA race groups.

CONCLUSION

Recent adoption of additional preoperative antibiotics as standard of care, has a measurable impact on -omics analysis of resected specimens. This study still confirmed increased *Fusobacterium nucleatum* in tumor.

Key Words: Colorectal cancer; Antibiotics; African Continental Ancestry Group; Diabetes mellitus; 16S rRNA gene; RNA-sequencing

Core Tip: This pilot study explored the effect of five variables [tumor histology, preoperative antibiotics, laterality of colorectal cancer (CRC) location, diabetes mellitus, Black/African Ancestry (AA) race] on analysis of microbiome and host transcriptome among archived frozen CRC resection samples. The introduction of short-term preoperative antibiotics as standard of care has a measurable effect on the analysis. Despite the small sample size and variable exposure to preoperative antibiotics, it was still possible to use the data for discovery studies. Fusobacterium abundance was increased in tumor *vs* nontumor regions. Expression of VBP1 was decreased in expression in both Black/AA tumor and nontumor samples.

INTRODUCTION

Imbalances in mucosal associated microbiota (dysbiosis) have been reported in human colorectal cancer (CRC)[1]. The increased risk of CRC in patients with inflammatory bowel diseases and in animal models of intestinal inflammation support the concept that bacteria promoting colonic inflammation may be proto-oncogenic[2]. According to the driver and passenger hypothesis, there are key pathogens that can drive tumorigenesis and support other bacteria as passengers to proliferate and exacerbate disease in sporadic CRC[3]. Similarly, the keystone hypothesis states that certain low abundance pathogens can promote inflammation by altering a normal microbiota into a dysbiotic one[4]. There are certain pathogens that are associated with CRC including increased abundances of *Peptostreptococcus, Bacteroides fragilis, Fusobacterium nucleatum* (*F. nucleatum*), and *Escherichia coli* and decreased abundances of *Clostridium, Bifidobacterium, Faecalibacterium* and *Roseburia*[1-6]. The potential mechanisms at which these particular bacteria may affect the adenoma-carcinoma sequence, include gene expression alternations, promotion of chronic inflammation and release of carcinogenic metabolites[1-6]. The approach of collecting and integrating multi-omic host and microbiome data has been increasingly applied to discovery and functional studies of human gastrointestinal diseases[7,8]. In an ongoing multi-omic analysis of archived frozen mucosal samples of tumor and adjacent nontumor regions of CRC surgical resection specimens (2010-2020), we discovered that a major change was made in the preoperative antibiotic protocol as of January 2017. Prior to that time, the standard of care was to administer only intravenous antibiotics within 30 min of incision, and only a few CRC resection patients were placed on short-term oral antibiotics within a month of the surgery, for various clinical indications. However, after this time, the standard operating protocol for preoperative antibiotics was to prescribe outpatient oral neomycin and metronidazole 24 h in advance of the procedure, in order to reduce surgical site infections[9-11]. The use of antibiotics can shift the microbiome depending on the dosage and duration of the antibiotic exposure. Several studies have shown that tumorigenesis and tumor growth can be attenuated with different antibiotic cocktails and timing of antibiotic exposure with duration of inflammation. On the other hand, early exposure to antibiotics increased risk of CRC and interfered with chemotherapy efficacies due to microbial dysbiosis[5]. With these conflicting findings and this change in protocol at our institution, it allowed us to examine how differential use of antibiotics, along with other clinical/demographic factors influences integrative, multi-omic analyses of CRC.

The five following variables were included in the analysis of the microbiome and host transcriptome datasets generated in this pilot study: (1) Tumor histology (tumor *vs* nontumor); (2) Preoperative antibiotics (yes/no); (3) Laterality of CRC location (left *vs* right); (4) Diabetes mellitus (yes/no); and (5) Black/African Ancestry (AA) race (yes/no). The rationale for comparing tumor *vs* nontumor histology is based on multiple previous reports of differences between tumor and nontumor regions of CRC resection specimens[1,12,13]. Since antibiotics clearly have an effect on the human microbiome[14], it was crucial to assess the impact of the change in antibiotic protocol on the metagenomic and transcriptomic data, before making the commitment to expand the pilot study by analyzing more CRC resection samples. Because molecular differences have been previously reported right sided and left sided CRCs[15], laterality of CRC location was included in the analysis.

The original targets of this pilot discovery and functional study were two biological CRC risk factors: (1) Diabetes mellitus; and (2) Black/AA race. Diabetes mellitus has been associated with increased CRC risk and poorer survival[16,17], and has been implicated in CRC pathogenesis[18]. Several studies have described alterations in the fecal microbiome of patients with diabetes mellitus compared to those without diabetes mellitus in the absence of a CRC diagnosis[19-21]. Transcriptomic profiling of CRC resection tumor and adjacent nontumor samples suggested evidence of diabetic "field cancerization" of the nontumor region[22].

CRC incidence and mortality has been persistently higher in Black/AA compared to all other races in the United States[23,24]. Paredes *et al*[25] recently reported that transcriptomic profiling of Black/AA compared to White/European Ancestry (EA) revealed reduced immune related gene expression in tumor samples and plasma cytokine levels collected from Black/AA CRC patients. We report here the results of this pilot study to investigate the effects of the tumor histology, preoperative antibiotics, laterality of CRC location, diabetes mellitus status and Black/AA race on microbiome and human transcriptomic data of CRC patients.

MATERIALS AND METHODS

Patient samples

Sequencing analysis of 51 pairs of tumor and nontumor frozen mucosal samples collected from 50 treatment-naïve sporadic CRC subjects (excluding samples collected after neoadjuvant therapy), archived in the Stony Brook Cancer Center Tissue Analytics Shared Resource, was approved by the Stony Brook Institutional Review Board (IRB, IRB2019-00682) and by the Cold Spring Harbor Laboratory IRB (IRB 1467912). All the archived samples were collected prospectively from CRC patients scheduled between 2010-2020 for surgical resection for clinical care, who had given their informed consent for banking of surgical remnant for possible genomic sequencing, collection of longitudinal clinical metadata and access to clinical formalin-fixed paraffin embedded (FFPE) tissues for possible genomic sequencing under a protocol approved by the Stony Brook University IRB (No. 163184). CRC samples collected from individuals diagnosed with hereditary CRC syndromes or inflammatory bowel diseases and individuals who received neoadjuvant treatment, were excluded from this analysis. The clinical metadata included age at the time of tissue collection, self-identified race and ethnicity, family history of a first degree relative with CRC, tumor location (right, cecum-transverse colon; left, splenic flexure-rectum), pathologic cancer stage, smoking status (current, past, never), body mass index, diabetes mellitus status, preoperative antibiotics within a month of surgery (yes/no), cancer stage (0, 1, 2, 3, 4). Participants who enrolled in the study after 2017 were automatically assumed to be exposed to preoperative antibiotics as the new protocol prescribes oral neomycin (1 g × 3 doses) and metronidazole (500 mg × 3 doses) to the patient 24 h prior to surgery. DNA and RNA were extracted from the archived frozen tissues using the Qiagen Allprep DNA/RNA/miRNA kits (Qiagen, Hilden, Germany) according to the manufacturer's protocol. DNA and RNA were extracted from 5 μm sections of FFPE tumor and non-tumor samples using the Qiagen Allprep DNA/RNA FFPE (Qiagen, Hilden, Germany) kits according to the manufacturer' protocol except that xylene was used to de-paraffinize the FFPE samples.

16S rRNA gene sequencing

The 16S rRNA libraries were constructed by generating broad-range polymerase chain reaction (PCR) amplicons using barcoded primers that target the V3V4 variable region of the 16S rRNA gene: Primers 338F (5'-ACTCCTACGGGAGGCAGCAG-3') and 806R (5'-GGACTACHVGGGTWTCTAAT-3'), as previously described from 51 paired tumor and nontumor DNA samples[22]. Illumina paired-end sequencing was performed on the Miseq platform with versions v2.4 of the Miseq Control Software and of MiSeq Reporter, using a 600-cycle version 3 reagent kit. Illumina Miseq paired-end reads were aligned to human reference genome hg19 with bowtie2 and matching sequences were discarded as previously described[25]. All de-multiplexed, paired-end 16S rRNA gene sequence files along with associated metadata were deposited into the Gene Expression Omnibus under project accession number GSE165255. The paired end reads were assembled, aligned and classified using the SINA/SILVA classifier as previously described[26-28]. Operational taxonomic units (OTUs) were produced by binning sequences with identical taxonomic assignments.

Taqman quantitative PCR analysis of mucosal genomic DNA

Real time Taqman PCR analyses were conducted using established specific primers and probe for the *F. nucleatum* nusG gene[29,30] and broad range primers and probe bacterial 16S rRNA gene[31] shown in Table 1. The Taqman primers and probe for the human solute carrier family 21 or *SLCO2A1* also termed prostaglandin cotransporter or *PGT* gene[29], a single copy autosomal gene located on human chromosome 3, were from Taqman assay ID Hs00194554_m1 (Thermo Fisher Scientific, Waltham, MA, United States). The probes and primers were custom ordered as two separate Taqman assay kits (Thermo Fisher Scientific, Waltham, MA, United States). The first kit combined the *F. nucleatum* NUS gene assay (FAM probe) with the total bacterial 16S rRNA gene assay (VIC probe). The second kit combined the *F. nucleatum* nus gene (FAM probe) with the human *SLCO2A1* gene assay (VIC probe). The PCR assays were carried out in triplicate with 80 hg of sample DNA in 20 μL in each well. The thermal conditions were 10 min at 95 °C and 45 cycles of 15 s at 95 °C and 1 min at 60 °C. *F. nucleatum* subsp. *nucleatum* Knorr ATCC 25586 genomic DNA (gDNA) purchased from ATCC (Manassas, VA, United States) and a gene block was synthesized using the predicted PCR amplicon from the *F. nucleatum* subsp. *animalis 4_8* genome reference

Table 1 Specific Taqman polymerase chain reaction primer and probe sequences for the *Fusobacterium nucleatum* nusG gene and broad range Taqman primer and probe sequences for the bacterial 16S rRNA gene

F. nucleatum: *Fusobacterium nucleatum*.

sequence for the Human Microbiome Project (Assembly: GCA_000400875, Integrated DNA Technologies, Coralville, IA, United States) were used as positive controls. The 80 hg of DNA template was used in each 20 μL reaction and with either *F. nucleatum* (FAM probe)/*SLCO2A1* (VIC probe) or the *F. nucleatum* (FAM probe) broad-range 16S rRNA gene (VIC probe) in triplicate.

RNA sequence analysis

RNA-sequencing was conducted on a subset of tumor and nontumor RNA samples with RIN scores ≥ 6 at the CSHL Cancer Center Sequencing Technologies and Analysis Shared Resource and unpaired tumor RNA samples at the New York Genome Center. At both sequencing centers, the RNA sequence libraries were prepared with the Kapa RNA kit with RiboErase (Roche Sequencing and Life Science Kapa Biosystems, Wilmington, MA, United States) according to the manufacturer's protocol and Illumina 125 bp PE sequencing was conducted on HiSeq2500 instruments with a targeted depth of 20 million. The sequences were aligned using Salmon in Patro *et al*[32]. The sequences were deposited in NCBI's Gene Expression Omnibus database with accession number GSE165255.

Statistical analysis

Statistical analysis was performed utilizing the Biostatistics and Bioinformatics Shared Resource at the Stony Brook University Cancer Center. Patient demographics were compared between the subset of samples analyzed and the total set of samples archived in the Stony Brook Cancer Center Tissue Analytics Shared Resource (2010-2020) using either Wilcoxon rank sum test for continuous variables, and chi-square test using GraphPad Prism. Alpha diversity indices [*e.g.*, Sobs, Shannon complexity (H), Shannon Evenness (H/Hmax)] were calculated on samples yielding a total OTU count inferred through 1000 replicate resamplings using Explicet[33]. Linear mixed models were used to compare alpha-diversity (Sobs, ShannonH, ShannonE) between different groups of histology, antibiotics, location, diabetes and Black/AA race. Log-transformation was applied if the normality assumption was not satisfied. Compound symmetry (CS) covariance structure was utilized to model the correlation among measurements from the same patient. β-diversity was assessed by calculating distance matrices based on the Morisita-Horn dissimilarity index and visualized by principal coordinate analysis (PCoA). A PERMANOVA analysis[34] was performed to assess the statistical significance of differences in β-diversity with the following five variables: (1) Tumor histology (tumor/nontumor); (2) Pre-operative antibiotics (yes/no); (3) Anatomic location (left/right); (4) Diabetes mellitus (yes/no); and (5) Black/AA race (yes/no). These analyses were conducted using the vegan 2.56 package of R 3.6.1, and the default setting for number of permutations (n = 999). To compare relative abundance of each OTU between tumor *vs* nontumor, generalized linear mixed model (GLMM) or generalized estimating equation (GEE) models were used by using the actual counts of each OTU as the outcomes, which were assumed to follow a negative binomial distribution[26]. CS covariance structure was utilized to model the correlation among measurements from the same patient. The log overall count for each individual in each group was considered as an offset in order to normalize for differences in sequencing depth of coverage. When models had a fitting issue because of excessive 0 counts, all sample's counts+1 were used as the outcome and log (overall count+1) was used as the offset. The two-way interaction term between tumor histology

(tumor/nontumor) and preoperative antibiotics (yes/no) was first added in each model to estimate the difference between tumor *vs* normal within patients with or without pre-operative antibiotics. For OTUs that had model fitting difficulty and OTUs with non-significant interaction, the two-way interaction term was removed and the aforementioned models were fit again. Univariate linear mixed models were used to estimate the coefficient of correlation and the *P* values for the log transformed relative abundances of selected OTUs. The *P* values were based on the *t*-test for GLMM and the *Z*-test for GEE. The Bonferroni adjusted *P* values < 0.05 were considered as statistically significant. These analyses were performed using SAS 9.4 (SAS Institute Inc., Cary, NC, United States).

Differentially expressed genes (DEGs) ($\log_2$ fold change ≥ 1, adjusted *P* value < 0.05 were identified using DESeq2[35] for the five groups: (1) Tumor histology (tumor *vs* nontumor); (2) Preoperative antibiotics within a month of the surgery (yes/no); (3) Anatomic location of the CRC and adjacent nontumor region (left *vs* right); (4) Diabetes mellitus status (yes/no); and (5) Black/AA self-declared race (yes/no). For the latter four variables, the tumor and nontumor samples were analyzed separately. The DEG lists were also deposited in NCBI's Gene Expression Omnibus database with accession number GSE165255.

RESULTS

Patient characteristics of samples analyzed

The characteristics of the patients for the subset of samples analyzed compared to that of the total collection of archived sporadic CRC samples (2010-2020) are shown in Table 2. Since the samples in the subset were originally selected to provide Black/AA samples and "matched" White/EA samples for another transcriptomic profiling performed at a separate sequencing facility[25], there was significantly higher representation of Black/AA samples in this pilot study. Left-sided CRCs were also more highly represented in the subset compared to the overall collection. Because most of the subset samples were collected prior to January 2017, (when the protocol adding preoperative oral antibiotic prophylaxis was first introduced), there was a lower representation of samples collected from patients who had preoperative antibiotic treatment compared to the total sample collection. Of the 18 diabetic patients, only one had type 1 diabetes mellitus and the remaining 17 patients were diagnosed with type 2 diabetes mellitus.

Colonic mucosal microbiome analysis

We generated 5706758 16S rRNA gene sequences from 51 pairs of CRC tumor and nontumor samples. After excluding sequence libraries with total counts < 1000, the remaining 89 sequence libraries (41 tumor, 48 nontumor, 26 preoperative antibiotics, 63 no preoperative antibiotics, 55 left, 34 right, 32 diabetic, 57 not diabetic, 21 Black/AA, 68 not Black/AA) had an average sequencing depth of 64752 (minimum 1032; maximum 248838). As shown in Table 3, no significant differences were detected in any of the three alpha diversity indices between the following five groups: (1) Preoperative antibiotics (yes/no); (2) Tumor *vs* nontumor histology; (3) Anatomic location of sample (left *vs* right); (4) Diabetes mellitus status (yes/no), and (5) Black/AA race *vs* not Black/AA race. Exploratory PERMANOVA using the Morasita Horn index for β-diversity was performed with the same five groups (see Table 4). Tumor histology and preoperative antibiotics demonstrated significant *F* statistics, but anatomic location, diabetes and Black/AA race did not reach significance. The PCoA comparisons using these indices for these five groups are displayed in Figure 1.

Because PERMANOVA identified tumor histology and preoperative antibiotics as significant, fitted linear mixed models were used to measure the effect of preoperative antibiotics and tumor histology along with first order preoperative antibiotics*tumor histology interactions on the relative abundances of individual genus-level taxa. For this analysis, we included those OTUs with average relative abundances greater than 0.001% and that were observed in at least 25% of the samples. Because of model convergence issues, 4 OTUs (*Firmicutes/Eubacterium, Firmicutes/Acidaminococcus, Proteobacteria/Neisseriaceae, Proteobacteria/Desulfovibrio)* were also excluded because of failure of their models to converge. Of the 106 OTUs included in the relative abundance regression analysis, 14 exhibited significant first order tumor histology*preoperative antibiotics interaction terms (see Table 5). The estimated differences in tumor *vs* nontumor samples were analyzed separately for those 14 OTUs depending on whether the patients were prescribed additional preoperative

antibiotics. One of 14 OTUs, *Fusobacteria/Leptotrichia,* was associated with increased relative abundance in tumor *vs* nontumor, regardless of preoperative antibiotic exposure (adjusted $P < 0.0001$ after Bonferroni correction = unadjusted P value*28 with antibiotics, and adjusted $P = 0.01$ after Bonferroni correction with no antibiotics). Of the 92 OTUs without significant first order preoperative antibiotic*tumor histology interaction terms, 19 OTUs, including *Fusobacterium* spp. demonstrated significant differences in tumor *vs* nontumor samples with adjusted $P < 0.05$ after Bonferroni correction (see Table 6).

Taqman quantitative PCR confirmation of increased F. nucleatum relative abundance in tumor vs non-tumor samples

*F. nucleatum (*both subspecies *nucleatum* and subspecies *animalis)* were enumerated in tissues specimens by quantitative PCR (qPCR) of the nusG gene, while total bacterial load was assayed by broad-range 16S rRNA gene qPCR. The human *SLCOA2* gene was assayed in parallel in order to normalize results. QPCR assays were performed on 37 paired tumor/nontumor mucosal gDNA samples, (10 pairs, +preoperative antibiotics; 27 pairs, -preoperative antibiotics). DNA samples were depleted in 7 tumor samples and 1 nontumor samples of the 51 paired tumor/nontumor samples and were therefore excluded from the analysis. *F. nucleatum* nusG was undetectable

rRNA and human *SLCOA2* assays are shown in Figure 2A-C . Pairwise comparisons of the mean tumor *F. nucleatum* nusG gene Ct ± SD with nontumor samples (32.2 ± 4.8 *vs* 34.0 ± 4.2, $P = 0.0125$), confirmed that there was a higher abundance of *F. nucleatum* in tumor samples compared with their paired adjacent nontumor samples. The mean 16S rRNA gene Ct was significantly higher in the (+)antibiotics group compared with the (-)antibiotics group (24.8 ± 3.7 *vs* 22.3 ± 3.4, $P = 0.0085$, missing 1 tumor (+)antibiotics and 1 tumor (-)antibiotics Ct value). This suggests that the preoperative antibiotics significantly reduced mucosal associated bacteria load. The difference in the mean *F. nucleatum* Ct between the (+)antibiotics group and the (-)antibiotics group (34.1 ± 3.7 *vs* 32.7 ± 4.8, $P = 0.24$) did not reach significance. The difference in the mean human *SLCOA2* Ct between the (+)antibiotics group and the (-)antibiotics group also did not reach significance (34.5 ± 0.8 *vs* 34.4 ± 2.3, $P = 0.74$, missing 2 nontumor (-)antibiotics Ct values).

In this current study the detection rates for the detection of *F. nucleatum* nusG gene were 84% and 93% respectively for the frozen tumor and nontumor samples. Of note, the Taqman probe used in the current study differed from the probe used in the previous FFPE studies, in that the probe in the current study did not overlap the reverse primer. The mean Ct values for each of the three qPCR assays performed on paired FFPE tumor/nontumor samples were compared with the Ct values obtained on the parallel pairs of frozen tumor/nontumor samples collected from the same two CRC patients (see Table 7). The broad range 16S rRNA gene Ct values were significantly higher in the FFPE samples compared to the paired frozen mucosal samples (30.6 ± 1.6 *vs* 22.7 ± 1.7, $P = 0.0034$, $n = 4$), despite using 80 hg of gDNA in all assays. The differences in the mean *F. nucleatum* nusG Ct values did not reach

Table 7 Comparison of the mean quantitative polymerase chain reaction mean threshold cycles ± SD between genomic DNA extracted from paired frozen and formalin-fixed paraffin embedded samples

	F. nucleatum nusG		16S rRNA		Human SLCO2A1	
	Frozen	FFPE	Frozen	FFPE	Frozen	FFPE
Tumor A	25.9 ± 1.2	35.4 ± 0.1	21.8 ± 0.1	31.4 ± 0.1	32.6 ± 2.5	39.3 ± 0.6
Nontumor A	37.2 ± 0.6	39.9/ND	22.2 ± 0.1	31.7 ± 0.3	34.8 ± 0.5	ND
Tumor B	26.0 ± 1.0	27.5 ± 1.0	21.6 ± 0.2	28.3 ± 0.1	33.2 ± 1.0	32.5 ± 1.3
Nontumor B	31.5 ± 1.4	35.1 ± 0.7	25.2 ± 0.1	31.2 ± 0.6	34.6 ± 0.9	38.2 ± 0.1

significance, but one of the FFPE samples bordered on being not detectable (ND). The differences in the mean human *SLCOA2* Ct values did not reach significance although one of the FFPE samples was ND.

Effect of tumor histology and preoperative antibiotics on human RNA-sequencing data

Since significant effects of tumor histology and preoperative antibiotics were noted in the microbiome analysis, we were particularly interested in the potential effect of preoperative antibiotics on the human transcriptomic profiles generated in parallel. RNA-seq data was obtained from CSHL for 33 paired tumor/nontumor RNA samples and 4 unpaired tumor RNA samples at CSHL. RNA-sequencing was completed on an additional 11 unpaired tumor RNA samples at the NYGC sequencing center. PCoA demonstrated a clear separation between the tumor and nontumor transcriptomic profiles (see Figure 3). Out of a total of 31052 genes, 1235 DEGs were decreased in tumor (n = 48) *vs* nontumor (n = 33, Log_2 fold change ≤ -1, adjusted P value < 0.05) and 1229 DEGs were increased.

No clear separation was observed on PCoA for the remaining four variables: Preoperative antibiotics (see Figure 3), left *vs* right CRC location (not displayed), diabetic *vs* not diabetic (not displayed), or Black/AA race *vs* not Black/AA race (not displayed). DESeq2 analyses were conducted on the tumor samples separately from the nontumor samples for these four variables. For the (+)antibiotics (n = 15) *vs* the (-)antibiotics (n = 33) group of tumor samples, 30 DEGs were decreased and 188 DEGs were increased. For the (+)antibiotics (n = 13) *vs* (-)antibiotics (n = 20) nontumor samples, no DEGs were decreased and 32 DEGs were increased. Six upregulated DEGs were common with the same polarities in both tumor and nontumor (+)antibiotics/(-)antibiotics DEG lists (see Table 8).

For the left (n = 30) *vs* right (n = 18) CRC location groups of tumor samples, 12 DEGs were decreased and 7 DEGs were increased, and for the left (n = 18) *vs* right (n = 15) CRC location groups of nontumor samples, 72 DEGs were decreased and 36 DEGs were increased. However, no DEGs were common to both tumor and nontumor left *vs* right DEG lists. For the diabetic (n = 18) *vs* nondiabetic (n = 30) groups of tumor samples, 52 DEGs and 9 DEGs were increased, and for the diabetic (n = 12) *vs* nondiabetic (n = 21) groups of nontumor samples, 2 DEGs were decreased and 6 DEGs were increased. No DEGs were common to both tumor and nontumor diabetic/nondiabetic DEG lists.

In the analysis of the Black/AA (n = 11) *vs* not Black/AA (n = 37) groups of tumor samples, 5 DEGs were decreased and 11 DEGs were increased in Black/AA samples. For the Black/AA (n = 10) *vs* not Black/AA (n = 33) groups of nontumor samples, 42 DEGs were decreased and 5 DEGs were increased in Black/AA samples. Three DEGs were common to both tumor and nontumor Black/AA *vs* not Black/AA groups (see Table 9).

DISCUSSION

The results of this pilot study illustrate the need for thorough curation of the clinical metadata linked to archived gastrointestinal resection specimens for discovery and functional studies on CRC pathophysiology. Even after prospectively interviewing

research subjects for antibiotic exposure prior to surgical resection and carefully reviewing the electronic medical record for prescribed medications, it was difficult to assess this potentially important confounding variable. Further discussion with the colorectal surgery service revealed that a major change in pre-operative antibiotics was established as standard of care as of January 2017 to reduce site infections. This change in protocol was made, because there was accumulating evidence that the addition of short term perioperative oral antibiotics reduced intra-abdominal surgical site infections[9-11]. The reduced mucosal associated bacterial abundance based on our 16S rRNA broad range PCR assays, may contribute to the reduced incidence of postoperative intra-abdominal infections. Our results indicate that there is a measurable effect not only on the host mucosal-associated microbial communities but also on the host colonic mucosal transcriptomic profiles. Reviewing the literature, while some studies clearly excluded CRC subjects who had received additional preoperative antibiotics[13], it is not clear in a number of published reports, whether exposure to preoperative antibiotics was taken into consideration in the analysis. Though the effect of the antibiotics is transient, and the baseline microbiome is shown to recover within 1.5 mo with the most potent antibiotics[36], the impact of preoperative antibiotics has a measurable effect on the mucosal transcriptomic profiles generated from the resection specimens.

A major limitation of this pilot study is the small number of subjects who were analyzed and potential selection bias with respect to the five variables included in the analyses. We detected significant differences in microbial β-diversity between tumor *vs* nontumor histology groups and (+)antibiotics *vs* (-)antibiotics. However, failure to detect differences with respect to CRC location, diabetes or Black/AA race could be because this study was underpowered to detect a significant effect of these three variables. Despite heterogeneity in pre-operative antibiotic protocols, qPCR analysis confirmed previous reports showing that *F. nucleatum* abundance was increased in tumor compared to paired nontumor samples[29,37-41]. Lower detection rates of *F. nucleatum* nusG gene by PCR were previously reported on archived FFPE CRC tissues, ranging from 13%-45%[37,38] while our study reports 84% and 93% detection rates for tumor and non-tumor fresh frozen regions respectively. Furthermore, *F. nucleatum* has been detected in advanced adenomas but not in early adenomas, which are precursor stages along the adenoma-carcinoma sequence[39,41]. *F. nucleatum* abundance has been associated with poor prognosis and resistance to chemotherapy[37,41,42]. In xenograft models of human CRC, antibiotic treatment for three weeks reduced *Fusobacterium* load, cancer cell proliferation and overall tumor growth, however treatment for only

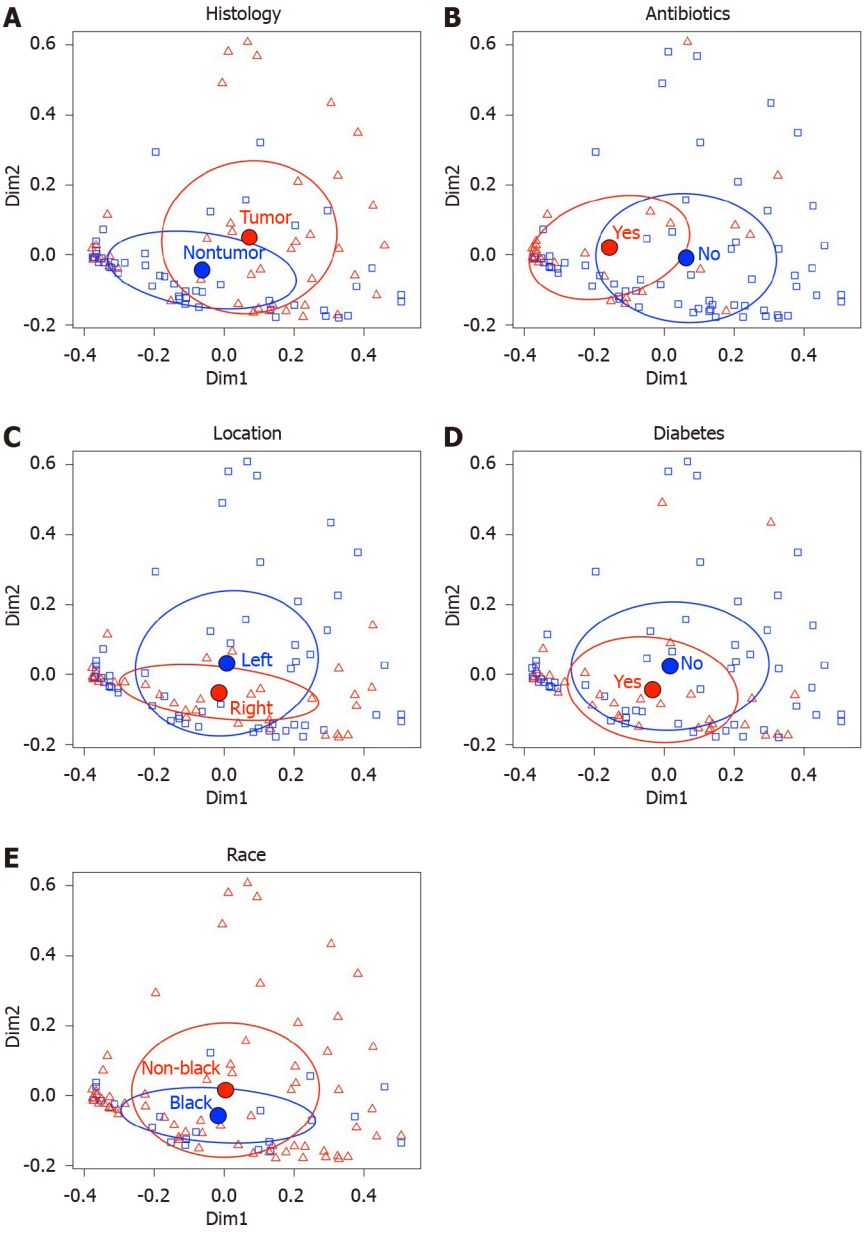

Figure 1 Principal coordinate analysis plots for Morita Horn dissimilarity indices. A: Preoperative antibiotic treatment (yes/no); B: Tumor *vs* nontumor histology; C: Anatomic location of sample (left *vs* right); D: Diabetes mellitus status (yes/no); E: Black/African Ancestry race (yes/no). The filled circles and surrounding ovals indicate the mean ± SD centroid for each group.

24 h had no significant effect[38]. There has been one report that *F. nucleatum* abundance is higher in colonic effluents collected from Black/AA male veterans compared to White/EA male veterans undergoing screening colonoscopy[43].

Despite the small sample size and variable exposure to preoperative antibiotics, it was still possible to use the data for discovery studies. Expression of the von Hippel-Landau binding protein 1 or *VBP1* in Black/AA CRC tumors (n = 64) was observed to be significantly lower compared to White/EA CRC tumors (n = 284, P = 0.026) in The Cancer Genome Atlas (TCGA) database and in a recently published transcriptomic profiling study[21]. The polarity observed for differences in proprotein convertase subtilisin/kexin type 1 inhibitor or *PCSK1N* Black/AA *vs* White/EA CRC tumors in the TCGA database however, was opposite to what was observed in this pilot study. The *MTND1P23* gene was not present in the TCGA database. We are particularly intrigued by the results indicating reduced *VBP1* expression in Black/AA tumor *vs* not Black/AA tumor and Black/AA nontumor *vs* not Black/AA nontumor, because of a recent report that *VBP1* suppresses HIF-1α-induced epithelial□mesenchymal transition *in vitro* and tumor metastasis *in vivo*[44].

Given that the new preoperative antibiotic protocol adopted at this medical center is 24 h of oral antibiotics in addition to current IV antibiotics administered within 30 min

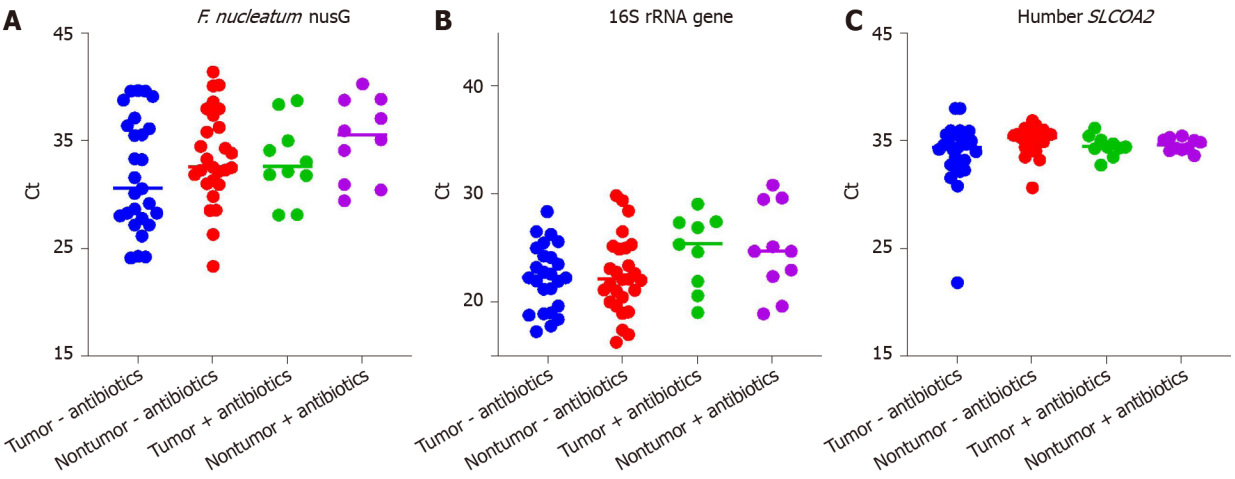

Figure 2 Scatter plots of threshold cycle values. A: *Fusobacterium nucleatum* nusG gene; B: Broad range 16S rRNA gene; C: Human *SLCOA2* gene quantitative polymerase chain reaction assays. *F. nucleatum*: *Fusobacterium nucleatum*.

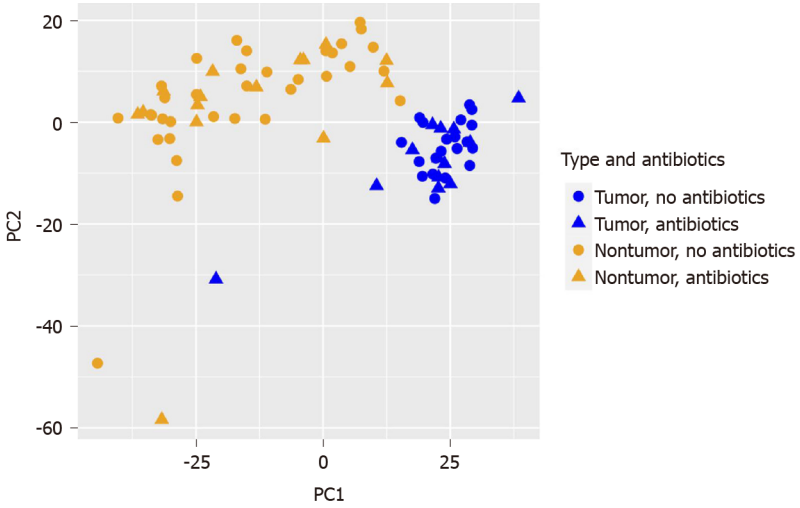

Figure 3 Principal coordinate analysis of human colorectal cancer RNA-seq data with respect to tumor histology (tumor *vs* nontumor) and preoperative antibiotics (yes/no).

of incision for colorectal resections, a relevant question is how to further pursue the findings of this initial discovery and functional study. Going forward, probably the best solution is to perform targeted PCR assays on archived FFPE CRC and advanced adenoma tissues collected prior to the change in preoperative antibiotics protocol in order to sufficiently power the analysis of evaluating the effect of laterality, diabetes status and race on microbiome and transcriptomic data of CRC patients. In particular, utilizing the targeted PCR to detect *Fusobacterium*, it can possibly be used as a clinical prognostic biomarker for diabetic CRC patients. We also plan to shift our prospective collection of colonic tissues away from surgical resections to prospective collection of colonoscopic biopsy samples.

CONCLUSION

The recent addition of preoperative oral antibiotics 24 h to the standard administration of IV antibiotics within 30 min of incision has a measurable effect on colonic mucosal gene expression in addition to its effect on the amount and composition of mucosal associated bacteria in the resected specimen. Despite heterogeneity in the preoperative antibiotics in this study cohort, increased abundance of *F. nucleatum*, was observed in tumor *vs* nontumor regions of the resected specimen. This study identified the *VBP1* gene, which may suppress CRC metastasis, as having decreased RNA expression in

both tumor and nontumor regions of the resected specimen collected from Black/AA subjects.

ARTICLE HIGHLIGHTS

Research background

Imbalances in mucosal associated microbiota (dysbiosis) have been reported in human colorectal cancer (CRC). There are certain pathogens that are associated with CRC including increased abundances of *Peptostreptococcus, Bacteroides fragilis, Fusobacterium nucleatum,* and *Escherichia coli* and decreased abundances of *Clostridium, Bifidobacterium, Faecalibacterium* and *Roseburia.* The approach of collecting and integrating multi-omic host and microbiome data has been increasingly applied to discovery and functional studies of human gastrointestinal disease.

Research motivation

A major change was made in the preoperative antibiotic protocol at this hospital as of January 2017. Prior to that time, the standard of care was to administer only intravenous antibiotics within 30 min of incision, and only a few CRC resection patients were placed on short-term oral antibiotics within a month of the surgery, for various clinical indications. However, after this time, the standard operating protocol for preoperative antibiotics was to prescribe outpatient oral neomycin and metronidazole 24 h in advance of the procedure, in order to reduce surgical site infections. The use of antibiotics can shift the microbiome depending on the dosage and duration of the antibiotic exposure. Several studies have shown that tumorigenesis and tumor growth can be attenuated with different antibiotic cocktails and timing of antibiotic exposure with duration of inflammation. On the other hand, early exposure to antibiotics increased risk of CRC and interfered with chemotherapy efficacies due to microbial dysbiosis. With these conflicting findings and this change in protocol at our institution, it allowed us to examine how differential use of antibiotics, along with other clinical/demographic factors influences integrative, multi-omic analyses of CRC.

Research objectives

To examine the effect of the five following variables were included in the analysis of the microbiome and host transcriptome datasets generated in this pilot study: (1) Tumor histology (tumor *vs* nontumor); (2) Preoperative antibiotics (yes/no); (3) Laterality of CRC location (left *vs* right); (4) Diabetes mellitus (yes/no); and (5) Black/African Ancestry (AA) race (yes/no).

Research methods

Genomic DNA (gDNA) and RNA were extracted from prospectively collected 51 pairs of frozen sporadic CRC tumor and adjacent non-tumor mucosal samples from 50 CRC patients archived at a single medical center from 2010-2020. 16S rRNA gene sequencing (V3V4 region, paired end, 300 bp) and confirmatory quantitative polymerase chain reaction (PCR) assays were conducted on gDNA. RNA sequencing (IPE, 125 bp) was performed on parallel tumor and non-tumor RNA samples with RNA Integrity Numbers scores ≥ 6.

Research results

Exploratory PERMANOVA using the Morasita Horn index for β-diversity was performed with each of the five groups. Tumor *vs* nontumor histology (P = 0.002) and preoperative antibiotics (P = 0.001) demonstrated significant F statistics, but anatomic location, diabetes and Black/AA race did not reach significance. Differences in α-diversity did not reach significance between the five groups. Fourteen taxa at the genus level exhibited significant tumor*preoperative antibiotic interactions. Of the taxa without tumor*preoperative antibiotic interactions, 7 taxa were significantly increased in tumor *vs* nontumor, including *Fusobacterium*, and 11 taxa were significantly decreased. The increase in *Fusobacterium nucleatum* (*F. nucleatum*) abundance was confirmed by Taqman PCR assays. Additional preoperative antibiotics significantly reduced mucosa-associated total bacterial abundance, which may contribute to reduction of intra-abdominal surgical site infections. Analysis of a subset of parallel formalin-fixed paraffin embedded (FFPE) samples retained polarity of the observed trends but impaired signal strength. Principal coordinate analysis of the

transcriptomic data showed a clear separation from tumor and nontumor samples. Consequently, differentially expressed genes were analyzed separately for the other four variables separately in tumor and nontumor samples. Differentially expressed genes common to the tumor and nontumor groups were identified for additional preoperative antibiotics and Black/AA race. The *VBP1* gene, which may suppress CRC metastasis, exhibits reduced expression in Black/AA subjects compared to not Black/AA subjects.

Research conclusions

The recent addition of preoperative oral antibiotics 24 h to the standard administration of IV antibiotics within 30 min of incision has a measurable effect on colonic mucosal gene expression in addition to its effect on the amount and composition of mucosal associated bacteria in the resected specimen. Despite heterogeneity in the preoperative antibiotics in this study cohort, increased abundance of *F. nucleatum,* was observed in tumor *vs* nontumor regions of the resected specimen. This study identified the VBP1 gene, which may suppress CRC metastasis, as having decreased RNA expression in both tumor and nontumor regions of the resected specimen collected from Black/AA subjects.

Research perspectives

Given that the addition of preoperative antibiotics to the standard administration of IV antibiotics within 30 min of incision has a measurable effect on colonic mucosal gene expression, in addition to its effect on the amount and composition of mucosa-associated bacteria in the resected specimen, is being widely adopted as standard of care, we plan to perform targeted PCR assays on archived CRC FFPE tissues to confirm our results collected prior to when the change in protocol was adopted (January 2017). Because patients undergoing colonoscopy are not routinely prescribed antibiotics before the procedure, we also plan to shift prospective collection of colonic neoplastic and normal tissues away from surgical resections to prospective collection of research colonoscopic biopsy samples.

ACKNOWLEDGEMENTS

We want to thank the colorectal cancer (CRC) patients who have donated their remnant surgical specimens and clinical data to the GI Clinical Resource Core and to the surgeons in the Division of Colon and Rectal Surgery, (Drs. Genua J, Lee K, Smithy W and Leiboff AR) for participating in the collection of CRC specimens for the Stony Brook Cancer Center Tissue Analytics Shared Resource. We want to thank Ji P and Dr. Williams J with assistance in extracting nucleic acids from the tissue samples. We want to thank Dr. Goodwin S for coordinating the RNA sequencing at Cold Spring Harbor Laboratory. The authors wish to acknowledge the Stony Brook Cancer Center Biostatistics and Bioinformatics Shared Resource for expert assistance on processing and analyzing the 16S rRNA sequence, the RNA-seq and clinical data. The authors also wish to acknowledge the Cold Spring Harbor Cancer Center Sequencing Technologies and Analysis Shared Resource, and the New York Genome Center for expert assistance.

Abstract

BACKGROUND

It has been suggested that apolipoprotein E (*APOE*) polymorphisms are associated with the risk of developing inflammatory bowel disease (IBD) and the early age of disease onset. However, there are no reports regarding the relationship with clinical characteristics and disease severity.

analysed data; All authors approved the final version of the article.

Supported by The National Science Centre, Poland, No. 2017/25/B/NZ5/02783 (to Walkowiak J).

Institutional review board statement: The study obtained the approval of the Bioethical Committee at Poznań University of Medical Sciences (960/15 with the associated amendments).

Informed consent statement: Patients gave informed consent to the study. The analysis used anonymous clinical data after each patient agreed to participate by written consent.

Conflict-of-interest statement: We have no financial relationships to disclose.

Data sharing statement: No additional data are available.

AIM

To summarise that APOE polymorphisms are associated with the risk of developing IBD and the early age of disease onset.

METHODS

In total, 406 patients aged 3-18 with IBD (192 had ulcerative colitis and 214 had Crohn's disease) were genotyped using the TaqMan hydrolysis probe assay. Clinical expression was described at diagnosis and the worst flare by disease activity scales, albumin and C-reactive protein levels, localisation and behaviour (Paris classification). Systemic steroid intake with the total number of courses, immunosuppressive, biological, and surgical treatment with the time and age of the first intervention were determined. The total number of exacerbation-caused hospitalisations, the number of days spent in hospital due to exacerbation, the number of relapses, and severe relapses were also estimated.

RESULTS

Ulcerative colitis patients with the *APOEε4* allele had lower C-reactive protein values at diagnosis (P = 0.0435) and the worst flare (P = 0.0013) compared to patients with the *APOEε2* allele and genotype *APOEε3/ε3*. Crohn's disease patients with the *APOEε2* allele scored lower on the Pediatric Crohn's Disease Activity Index at diagnosis (P = 0.0204). IBD patients with *APOEε2* allele spent fewer days in the hospital due to relapse (P = 0.0440).

CONCLUSION

APOE polymorphisms are associated with the risk of developing IBD and the clinical expression of IBD. However, the clinical relevance of the differences identified is rather modest.

Key Words: Apolipoprotein E polymorphism; Crohn's disease; Ulcerative colitis; Immunosuppression; Surgery; Disease severity

INTRODUCTION

Heritability and disease risk can only be partly explained by genetic factors alone[1-4]. Inflammatory bowel disease (IBD) has a strong genetic makeup. To date, 240 risk gene loci have been associated with the disease[1]. Several genetic variations are linked to specific IBD phenotypes. For instance, *NOD2*, *IRGM*, *ATG16L1*, and *NCF4/NCF2* are related to segmental, structuring, or early-onset disease[5-10]. Genetic testing for these and other variants may prove useful in predicting the disease course for future clinical use.

One of the well-known genetic determinants of some diseases other than IBD is apolipoprotein E (*APOE*), most commonly known for its role in Alzheimer's disease[11]. Although first recognised for its role in lipoprotein metabolism, APOE is involved in several biological processes not directly related to lipid transport function[12]. Importantly, APOE is a key player in immunoregulation[13-15] and

associated with autoimmune disorders such as multiple sclerosis, rheumatoid arthritis, and psoriasis[16-18]. It has been reported that APOE has several immune-related functions such as suppressing T-cell proliferation[19-21], possibly by downregulating DNA synthesis and reducing phospholipid turnover in T cells[22-24], neutrophil activation[25], and modulation of macrophage assisted[26-28] antigen presentation[14,15].

APOE is a polymorphic protein present in three major isoforms that differ only by two single amino acid substitutions, APOEε4 (arg112, arg158), APOEε3 (cys112, arg158), and APOEε2 (cys112, cys158). The amino acid replacement causes profound functional changes at the cellular and molecular level as well as in the immune system. APOE suppresses the production of proinflammatory cytokines such as tumour necrosis factor-α in microglia in an isoform-dependent manner (ε2 > ε3 > ε4)[29]. In turn, inflammatory cytokines can promote APOE synthesis and release or downregulate the production of APOE in different tissues[30,31]. However, interactions between APOE and cytokines are occasionally conflicting, highlighting the complex roles of APOE and cytokines in various disorders[15].

In IBD, inflammation alters lipid, apolipoprotein, and lipoprotein profiles in subjects with active disease[32,33] and patients with limited response to infliximab[34]. A previous study from Saudi Arabia showed that the genetic distribution of *APOE* polymorphisms in IBD seems to be altered compared to healthy subjects[35]. The study also suggested that the *ε4* allele increased the risk of IBD and was associated with an early onset of the disease. Similarly, *APOEε4* has been associated with severity in another immunologic disorder: rheumatoid arthritis[16]. For these reasons, this study aimed to investigate the relationship between *APOE* variants with disease severity in IBD.

MATERIALS AND METHODS

Patients

Patients recruited to the study belonged to the Polish Paediatric Crohn's and Colitis cohort and involved 406 paediatric IBD patients: 214 with Crohn's disease (CD; 86 females, 128 males) and 192 with ulcerative colitis (UC; 87 females, 105 males) (Table 1). Patients were recruited in the course of hospital treatment or during scheduled visits at outpatient clinics (Department of Pediatric Gastroenterology and Metabolic Diseases, Poznań University of Medical Sciences; The Department of Gastroenterology, Hepatology, Feeding Disorders and Paediatrics; The Children's Memorial Health Institute, Warsaw; Department of Pediatric Gastroenterology and Nutrition, Medical University of Warsaw; Department and Clinic of Pediatrics, Gastroenterology and Nutrition, Wroclaw Medical University; Department of Pediatrics, Faculty of Medical Sciences in Zabrze, Medical University of Silesia, Katowice; Department of Pediatrics, Faculty of Medical Sciences, Medical University of Silesia in Katowice and Department of Pediatric Endoscopy and Gastrointestinal Function Testing, Collegium Medicum in Bydgoszcz, Nicolaus Copernicus University in Toruń, Bydgoszcz, Poland). The diagnosis of IBD was confirmed by experienced gastroenterologists using standard diagnostic criteria[36,37]. The inclusion criteria were a diagnosis of CD or UC and aged 3-18. Patients in life-threatening, severe general condition were excluded from the study. The study obtained the approval of the Bioethical Committee at Poznań University of Medical Sciences (960/15 with the associated amendments).

Disease severity evaluation

Disease activity was assessed using appropriate scales at diagnosis and the worst flare [Pediatric Ulcerative Colitis Activity Index and Pediatric Crohn's Disease Activity Index (PCDAI)][38], which was defined by the highest Pediatric Ulcerative Colitis Activity Index and PCDAI scales in their medical history. Albumin (g/dL) and C-reactive protein (CRP; mg/L) concentrations at diagnosis and the worst flare were obtained from medical records (CRP reference range 0-5 mg/L). The treatment domain included data regarding systemic steroid intake with the total number of courses, immunosuppressive treatment with the time and age of the first intake, biological therapy with time and age of first admission, and operative treatment with time and age of first surgery. The localisation and behaviour of the disease were defined by the Paris Classification at the diagnosis and worst flare[39]. Most CD patients presented with an ileocolonic location and nonstricturing behaviour of the disease (Supplementary Table 1), while most UC patients presented with pancolitis and were never severe (S0: > 65 on the Pediatric Ulcerative Colitis Activity Index scale;

[1]C-reactive protein reference range 0-5 mg/L.
[2]Systemic steroid therapy included: methylprednisolone, prednisone, hydrocortisone.
[3]Immunosuppressive and anti-inflammatory agents included: Azathioprine, methotrexate, mercaptopurine, cyclosporine, mycophenolate mofetil, tacrolimus, sulfasalazine.
[4]Biological agents included: infliximab, adalimumab, golimumab, vedolizumab.
[5]Only surgery related to inflammatory bowel disease-specific problems (*e.g.*, colectomy, resection, fistula, perforation, abscess) was included. CRP: C-reactive protein; IBD: Inflammatory bowel disease; IQR: Interquartile range; PCDAI: Pediatric Crohn's Disease Activity Index; PUCAI: Pediatric Ulcerative Colitis Activity Index.

Supplementary Table 2). Based on medical records, the total number of exacerbation hospitalisations, the number of days spent in hospital due to exacerbation, the number of relapses, and severe relapses from diagnosis were estimated and calculated per year of the disease duration. The associated extraintestinal symptoms and concomitant diseases were collected from the medical history.

Genotyping

DNA was isolated from whole blood using the Blood Mini (A and A Biotechnology). A hydrolysis probe assay (TaqMan assay) was used with the following probes, C_904973_10 and C_3084793_20, to genotype patients (Life Technologies Corp. Carlsbad. California, United States). The genotyping was performed on the CFX-96 thermocycler system with allele discrimination plots provided by CFX Manager Software (Bio-Rad, Hercules, CA, United States).

Statistical analysis

Differences in categorical variables were compared with two-tailed Fisher's exact test. Differences in continuous variables were evaluated by the Mann Whitney *U* test and Kruskal-Wallis test. Post hoc comparisons were performed with Dunn's test, and the significance level for the time-to-treatment analysis was evaluated by Gehan's test. The explanatory factor analysis was used to analyse the underlying factors in the questionnaire. The significance level was set at $P < 0.05$, and statistical analyses were performed using Statistica 13.1 software (StatSoft Inc, Tulsa, OK, United States), JASP 0.10.2 (University of Amsterdam, Amsterdam, the Netherlands), and G*Power (Dusseldorf University, Germany). Comparisons between groups with less than ten patients were not included.

RESULTS

Genotyping

The most prevalent genotype in UC and CD was *APOEε3/ε3* (Table 2). No differences in the distribution of alleles and genotypes between UC and CD were documented.

The distribution of the *APOE* genotypes was compared to previous studies in the Polish population (Supplementary Table 3). Pooling available data[40-42] to obtain a similar sample size (n = 425) showed a significantly lower frequency of *APOEε3/ε3* genotype in IBD patients compared to controls (62.3% *vs* 71.5%; P = 0.0051; odds ratio = 0.66; 95% confidence interval: 0.49-0.88) and simultaneously higher frequency of *APOEε3/ε4* genotype (21.7% *vs* 15.1%; P = 0.0153; odds ratio = 1.56; 95% confidence interval: 1.09-2.23) with no difference in other genotypes or for the *APOEε3* allele (P = 0.8625). However, in the study of Bojar *et al*[43] (postmenopausal women; n = 402), the distribution of *APOEε3/ε3* genotype was similar to the present study (62.9% *vs* 62.3%; P = 0.8555; odds ratio = 0.97; 95% confidence interval: 0.73-1.30).

UC patients with *APOEε3ε3* had higher CRP values, and the *APOEε2/ε3* genotype were predisposed to left-sided colitis (E2) at diagnosis (Table 3). Concomitant diseases in CD patients occurred at different frequencies in major *APOE* genotypes, and children with *APOEε2ε3* genotype had significantly lower PCDAI scores at diagnosis than patients with the remaining genotypes (Table 4). UC patients with *t*he *APOEε4* allele had significantly lower CRP levels than the patients with *APOEε3ε3* genotype and *APOEε2*-positive, both at diagnosis and at the worst flare (Table 5). There were also differences in age at first biological treatment. Additionally, *APOEε2*-positive patients with IBD spent significantly fewer days in the hospital due to relapse per year of disease duration than *APOEε4*-positive patients and with the *APOEε3/ε3* genotype (Table 5). Patients with CD and *APOEε3ε3* genotype had lower values of standardised body height at diagnosis (Table 5). No difference was observed in the frequency of systemic steroids, immunosuppressive, and biological treatment between *APOE* genotypes in UC and CD patients. Supplementary Table 4 shows the results for the whole group of IBD patients.

DISCUSSION

The present study investigated the relationship between *APOE* genotype and disease severity in IBD, suggesting that the *APOE* genotype might be associated with some indices of disease course such as CRP and albumin levels at the worst flare, age at surgery and numbers of hospitalisation days. UC patients with the *APOEε4* allele had the lowest values of CRP, both at diagnosis and the worst flare. The median age at first biological therapy in UC was lowest in patients with the *APOEε4* allele, whereas left-side colitis was more frequent among patients with the *APOEε2* allele. In CD patients, the *APOEε4* allele was associated with higher albumin at worst flare and higher standardised body height at diagnosis. Moreover, patients with the *APOEε2* allele scored lower on the PCDAI. This study is the largest to show the genetic distribution of *APOE* polymorphisms in IBD to date.

APOE is known to be associated with inflammation indicators[13]. The findings of the present study confirm this relationship as the CRP levels differed between *APOE* genotypes. Patients with the *APOEε4* allele and *APOEε3ε4* genotype had lower CRP values at diagnosis and the worst flare, while patients with the *APOEε3ε3* genotype had higher levels of CRP at the worst flare. These results are similar to those obtained in healthy adults, which showed that subjects with *APOEε3ε3* had the highest plasma

levels of CRP and individuals with *APOEε4ε4* and *APOEε2ε4* had the lowest levels[13]. A similar pattern has also been observed in other diseases such as coronary artery disease[43-46]. März *et al*[47] proved that in coronary artery disease, both white cell count and fibrinogen were not related to the *APOE* genotype, suggesting that the underlying mechanism is not associated with inflammation[46] but rather to the mevalonate/cholesterol synthetic pathway, which may be downregulated in patients with *APOEε4* in response to altered lipoprotein metabolism and hepatic uptake[46]. In another study, the *APOEε4* allele was also associated with lower CRP but not white blood cell count[47]. Further mechanistic studies are needed to explain the link.

Our study is the first to report that in CD patients, the *APOEε4* allele is associated with higher median levels of albumins at the worst flare. Albumin level is negatively correlated with the extent of the inflammatory response, which is caused by a hypercatabolic state and a decrease of albumin synthesis in the liver[48]. Tumour necrosis factor-α inhibits albumin expression causing hypoalbuminemia[48] , a state associated with IBD activity, unresponsiveness to treatment, and increased risk of colectomy in UC. Patients with hypoalbuminemia had a higher likelihood of having more than two courses of corticosteroids, thiopurine, or anti-tumour necrosis factor treatment[49]. In CD, albumin levels were reported as a marker of postoperative complications[50] and active clinical disease[51]. Low albumin level together with high CRP may correlate with an increased inflammatory response[52]. In the study of Sayar *et al*[53], the area under the curve values for severe UC were 0.883 for albumin levels (cut-off 3.6 g/dL) and 0.941 for CRP/albumin ratio (cut-off 0.6)[52]. Given these data, the results of our study may suggest that the *APOEε4* allele is associated with a milder disease course of CD. The association of the *APOEε2* allele with lower PCDAI scores and fewer days of hospitalisation due to relapse might suggest a protective role of this allele on disease severity. However, this relationship is more complicated as we found that the *APOEε2* allele is also associated with a younger age at first surgery. This finding should be verified, preferably in a group of adult patients with a longer disease course and higher surgery rates.

The biology of APOE in IBD has not been fully elucidated, but recent studies have shown that the *APOE* transcript is overexpressed in paediatric IBD patients[53]. Studies in colonic epithelial cells in a mouse model showed that the apoE-mimetic peptide (COG112) inhibited the inflammatory response to *Citrobacter rodentium*[54], a bacterium known to cause colitis in mice[55]. The authors suggested this occurred by preventing the activation of nuclear factor κB[54]. Therefore, further mechanistic studies of APOE action are warranted.

A previous study on *APOE* in IBD in a group with a different genetic background (Saudi Arabia) did not focus on disease severity. Therefore, any comparisons are difficult[35]. In that study, the *APOEε4* allele was associated with the risk of developing IBD and early onset, whereas our study did not identify significant differences between *APOE* genotypes and age at diagnosis. The frequencies of *APOEε3ε3* genotype were lower in IBD patients in comparison to controls, which is consistent with the above-mentioned report[35].

The present study involved a large multicentre paediatric cohort, including a comprehensive clinical description, which allowed a detailed genotype-phenotype analysis. However, defining the global severity of the disease course remains challenging, especially in diseases with such a differentiated clinical presentation. The major limitation of this study is related to the retrospective character of the data collection regarding diagnosis and the worst flare. Need for surgery, which is one of

[1]Systemic steroid therapy included: methylprednisolone, prednisone, hydrocortisone.
[2]Immunosuppressive and anti-inflammatory agents included: azathioprine, methotrexate, mercaptopurine, cyclosporine, mycophenolate mofetil, tacrolimus, sulfasalazine.
[3]Biological agents included: Infliximab, adalimumab, golimumab, vedolizumab.
[4]Only surgery related to inflammatory bowel disease-specific problems (*e.g.*, colectomy, resection, fistula, perforation, abscess) was included.
[5]*e.g.*, celiac disease, bronchial asthma, obesity, gastroesophageal reflux disease, epilepsy, hypothyroidism. CRP: C-reactive protein; IBD: Inflammatory bowel disease; IQR: Interquartile range; PUCAI: Pediatric Ulcerative Colitis Activity Index.

the most crucial measures of disease course, would require longer follow-up in order to describe disease severity. Although we did not include a control group, *APOE* polymorphisms in healthy subjects have been studied in the Polish population[40-42,56], which allowed us to estimate whether there was any frequency distribution difference.

CONCLUSION

APOE polymorphisms are associated with the risk of developing IBD and seem to be associated with the clinical expression of the disease and applied treatment (with inflammatory markers and nutritional status, disease activity and localisation, hospitalisations). However, the clinical relevance of the differences identified is relatively modest.

ARTICLE HIGHLIGHTS

Research background

Apolipoprotein E (*APOE*) polymorphisms were previously reported to be linked with the risk of developing inflammatory bowel diseases (IBD).

Research motivation

No data on the relationship between *APOE* polymorphisms and disease severity are available.

Research objectives

This study aimed to investigate the link between *APOE* variants and disease severity in IBD.

Research methods

The TaqMan hydrolysis probe assay was used to genotype 406 patients with IBD (192 had ulcerative colitis and 214 had Crohn's disease). Clinical expression involved disease activity scales, albumin and C-reactive protein levels, disease localisation and behaviour, and treatment with the time and age of the first intervention. The number of hospitalisations and days spent in hospital due to exacerbation as well as the number of relapses and severe relapses were also estimated.

Research results

Ulcerative colitis patients with the *APOEε4* allele had the lowest C-reactive protein values both at diagnosis ($P = 0.0435$) and the worst flare ($P = 0.0013$) compared to patients with the *APOEε2* allele and genotype *APOEε3/ε3*. Crohn's disease patients with the *APOEε2* allele scored lower on the Pediatric Crohn's Disease Activity Index at diagnosis ($P = 0.0204$). All IBD patients with the *APOEε2* allele spent fewer days in the hospital due to relapse ($P = 0.0440$).

Research conclusions

The *APOE* genotype seems to be associated with some indices of disease course such

as inflammatory markers, disease activity, and applied treatment. However, the clinical significance of the differences identified remains modest.

Research perspectives

Further mechanistic studies of APOE action in IBD are warranted.

Abstract

BACKGROUND

Nucleos(t)ide analogs (NAs) cessation in chronic hepatitis B (CHB) patients remains a matter of debate in clinical practice. Current guidelines recommend that patients with hepatitis B e antigen (HBeAg) seroconversion discontinue NAs after relatively long-term consolidation therapy. However, many patients fail to achieve HBeAg seroconversion after the long-term loss of HBeAg, even if hepatitis B surface antigen (HBsAg) loss occurs. It remains unclear whether NAs can be discontinued in this subset of patients.

AIM

To investigate the outcomes and factors associated with HBeAg-positive CHB patients with HBeAg loss (without hepatitis B e antibody) after cessation of NAs.

METHODS

We studied patients who discontinued NAs after achieving HBeAg loss. The Cox proportional hazards model was used to identify predictors for virological relapse after cessation of NAs. The cut-off value of the consolidation period was confirmed using receiver operating characteristic curves; we confirmed the cut-off value of HBsAg according to a previous study. The log-rank test was used to

reviewed and approved by the Second Hospital of Shandong University Institutional Review Board (Approval No. KYLL-2015(LW)-0002).

Informed consent statement: Written informed consent was obtained from all patients.

Conflict-of-interest statement: All authors have no conflicts of interest.

Data sharing statement: No additional data are available.

STROBE statement: The authors have prepared the manuscript according to the STROBE Statement-checklist of items.

compare cumulative relapse rates among groups. We also studied patients with CHB who achieved HBeAg seroconversion and compared their cumulative relapse rates. Propensity score matching analysis (PSM) was used to balance baseline characteristics between the groups.

RESULTS

We included 83 patients with HBeAg loss. The mean age of these patients was 32.1 ± 9.5 years, and the majority was male (67.5%). Thirty-eight patients relapsed, and the cumulative relapse rate at months 3, 6, 12, 24, 36, 60, 120, and 180 were 22.9%, 36.1%, 41.0%, 43.5%, 45.0%, 45.0%, 45.0%, and 52.8%, respectively. Twenty-six (68.4%) patients relapsed in the first 3 mo after NAs cessation, and 35 patients (92.1%) relapsed in the first year after NAs cessation. Consolidation period (≥ 24 mo *vs* < 24 mo) (HR 0.506, $P = 0.043$) and HBsAg at cessation (≥ 100 IU/mL *vs* < 100 IU/mL) (HR 14.869, $P = 0.008$) were significant predictors in multivariate Cox regression. In the PSM cohort, which included 144 patients, there were lower cumulative relapse rates in patients with HBeAg seroconversion ($P = 0.036$).

CONCLUSION

HBeAg-positive CHB patients with HBeAg loss may be able to discontinue NAs therapy after long-term consolidation, especially in patients with HBsAg at cessation < 100 IU/mL. Careful monitoring, especially in the early stages after cessation, may ensure a favorable outcome.

Core Tip: A considerable proportion of patients fail to achieve hepatitis B e antigen (HBeAg) seroconversion after the long-term loss of HBeAg, even if hepatitis B surface antigen loss occurs. It remains unclear whether nucleos(t)ide analogs (NAs) can be discontinued in this subset of patients. The current study included patients who discontinued NAs after achieving HBeAg loss (without hepatitis B e antibody) for long periods since 2001. It was concluded that these patients may be able to discontinue NAs therapy after long-term consolidation. HBsAg at cessation < 100 IU/mL predicts sustained virological response after NAs cessation. Careful monitoring, especially in the early stages after cessation, may ensure a favorable outcome.

INTRODUCTION

Nucleos(t)ide analogues (NAs) are primary therapeutic agents for hepatitis B virus (HBV) infection; they significantly improved outcomes in patients with chronic hepatitis B (CHB)[1-3]. However, taking these medicines for life presents a substantial obstacle to compliance among patients with CHB. Therefore, NAs withdrawal is being studied[4-6].

Hepatitis B e antigen (HBeAg) has been proved to be associated with several immunomodulatory functions in HBeAg-positive patients with CHB, including replication of HBV and responses of the host to the virus[7,8]. Current guidelines recommend that patients with HBeAg seroconversion discontinue NAs after relatively long-term consolidation therapy[1-3]. Although only a small number of patients achieved a loss of hepatitis B surface antigen (HBsAg), our previous study showed acceptable cumulative relapse rates for HBeAg-positive patients who achieved HBeAg seroconversion[5].

A considerable proportion of patients fail to achieve HBeAg seroconversion after

the long-term loss of HBeAg, even if HBsAg loss occurs[9,10]. It remains unclear whether NAs can be discontinued in this subset of patients[1-3,11,12]. In an outcome study of patients with CHB and HBeAg loss after NAs cessation, 17 of 25 patients maintained sustained virological response (SVR)[10]. Another study also included CHB patients with HBeAg loss and the off-treatment virologic responses remained poor[13]. However, these studies were not explicitly designed for this subpopulation; furthermore, the sample sizes were small, and the consolidation periods were short[10,13]. Therefore, the persuasiveness of the conclusions was limited.

Some patients in our previous cohort[5,14] discontinued NAs after achieving HBeAg loss for long periods because of personal decisions and were not included in our previous analyses, while some maintained SVR. Therefore, the purpose of the present study was to determine the outcomes and related factors in patients with HBeAg-positive CHB with HBeAg loss [without hepatitis B e antibody (HBeAb)] after NAs cessation.

MATERIALS AND METHODS

Patients and methods

Patients: In our previous observational cohort, including CHB patients who discontinued NAs therapy and underwent regular follow-up, some discontinued NAs after achieving HBeAg loss (without HBeAb) for long periods. We included them in the current study (Cohort A). Before the decision to discontinue NAs, we informed all patients of the current guidelines, and we carefully evaluated all patients for potential risks. The patients decided to discontinue NAs according to their values and the state of their illness. We closely monitored them during follow-up after NAs cessation. Cumulative relapse rates were compared between HBeAg-positive patients with CHB who achieved HBeAg seroconversion (Cohort B) and Cohort A. Figure 1 describes the flowchart of patient inclusion. We recruited all patients from The Second Hospital, Cheeloo College of Medicine, Shandong University, between December 2001 and January 2020. All patients provided written informed consent. The Ethical Committee of The Second Hospital, Cheeloo College of Medicine, Shandong University, approved the study protocol. The study followed the principles of the Helsinki Declaration.

We previously published treatment criteria for NAs[5]. Cessation criteria required that patients in Cohort A receive at least 6 mo consolidation therapy after achieving HBeAg loss, with undetectable HBV DNA and normal alanine aminotransferase (ALT), and total therapy duration should last at least 18 mo. Patients in Cohort B should receive at least 6 mo consolidation therapy after achieving HBeAg seroconversion, with undetectable HBV DNA and normal ALT, and total therapy duration should be at least 12 mo. As per updated guidelines, consolidation therapy in these groups extended to at least 12 mo.

Exclusion criteria were signs of cirrhosis or decompensated liver disease and NAs resistance.

Data collection

We retrospectively collected pretreatment baseline data. After NAs cessation, the patients were followed-up at months 1, 2, 3, 4, 6, 9, and 12, and every 6 mo thereafter. The follow-up evaluation included liver biochemistry, serology of HBV, and quantification of HBV DNA.

The current study's observational endpoint was virological relapse, which was defined as serum HBV DNA > 10^4 copies/mL after NAs cessation confirmed 2 wk apart.

Statistical analyses

Variables were expressed as mean ± SD, median [interquartile range (IQR)], or number (percent) and were compared using the *t*-test, Mann–Whitney *U* test, chi-squared test, or Fisher's exact test. Cox proportional hazards model was used to identify predictors for response status after NAs cessation. The cut-off value of the consolidation period was confirmed using receiver operating characteristic curves; we confirmed the cut-off value of HBsAg according to a previous study[15]. The log-rank test was performed to compare cumulative relapse rates across groups. Propensity score matching (PSM) analysis was used to balance baseline characteristics between patients with HBeAg loss (Cohort A) and HBeAg seroconversion (Cohort B). We used 1:1 nearest-neighbor matching and a match tolerance of 0.10. All statistical analyses were performed using IBM SPSS version 22.0 (IBM Corp., Armonk, NY, United States). The statistical

procedure was reviewed by a biomedical statistician (Zhang Y).

RESULTS

Characteristics and virological response in patients with HBeAg loss (Cohort A)

There were 83 patients in Cohort A. The mean age of these patients was 32.1 ± 9.5 years, and the majority was male (56 patients, 67.5%). We treated patients for a median of 49 (IQR 36–61) mo. The median follow-up period for patients with SVR was 72 (IQR 36–108) mo. Patients received single NAs, including lamivudine in 45 patients, adefovir dipivoxil in 24 patients, telbivudine in nine patients, entecavir in four patients, and tenofovir in one patient. Table 1 displays the baseline characteristics of the patients. Figure 2 describes the distribution of ages and consolidation periods.

Thirty-eight patients relapsed and the cumulative relapse rates at month 3, 6, 12, 24, 36, 60, 120, and 180 were 22.9%, 36.1%, 41.0%, 43.5%, 45.0%, 45.0%, 45.0%, and 52.8%, respectively. Twenty-six (68.4%) patients relapsed in the first 3 mo after NAs cessation, and 35 patients (92.1%) relapsed in the first year after NAs cessation. The latest relapse occurred at month 129 after NAs cessation. Table 1 displays the baseline characteristics of relapsed patients and patients with SVR. All relapsed patients received close follow-up or salvage treatments according to their condition and treatment history. No liver failure or hepatic decompensation occurred.

Univariate and multivariate Cox regression determined predictors for virological relapse. Only consolidation period (≥ 24 mo *vs* < 24 mo) (HR 0.506, P = 0.043) and HBsAg at cessation (≥ 100 IU/mL *vs* < 100 IU/mL) (HR 14.869, P = 0.008) were significant predictors in multivariate regression (Table 2).

Among the 19 patients with HBsAg at cessation < 100 IU/mL, only one patient relapsed at month 3 after NAs cessation, and the cumulative relapse rates were significantly lower than those of patients with HBsAg at cessation ≥ 100 IU/mL (log-rank test, P < 0.001, Figure 3A). For the 51 patients with longer consolidation periods (≥ 24 mo), the cumulative relapse rates at month 3, 6, 12, 24, 36, 60, 120, and 180 were 17.6%, 27.5%, 31.4%, 31.4%, 33.8%, 33.8%, 33.8%, and 44.9%, respectively, which maintained significantly lower relapse rates than patients with shorter consolidation periods (< 24 mo) (log-rank test, P = 0.012, Figure 3B).

Patients with functional cure in Cohort A

Six of 83 patients achieved functional cure (HBsAg loss) at cessation. All these patients maintained SVR and HBsAg loss during follow-up. The other 11 patients, although they had detectable HBsAg at cessation, also achieved HBsAg loss during follow-up

after cessation and maintained SVR. The median follow-up period of these 11 patients was 108 (IQR 78–180) mo.

Comparison of cumulative relapse rates between CHB patients with HBeAg loss (Cohort A) and HBeAg seroconversion (Cohort B)

We preliminarily screened 83 patients in Cohort A and 190 patients in Cohort B for PSM. We included 144 patients (72 pairs) in the PSM cohort (Figure 1). The baseline characteristics remained comparable between the two groups (Table 3). The log-rank test revealed lower cumulative relapse rates in patients with HBeAg seroconversion (P = 0.036, Figure 4).

DISCUSSION

The response status of patients with HBeAg-positive CHB with HBeAg loss after NAs cessation was evaluated. Despite the absence of HBeAb, these patients maintained

acceptable virological response after relatively long-term consolidation therapy, especially in patients with HBsAg at cessation < 100 IU/mL. After PSM, the cumulative relapse rates were higher than those in patients with HBeAg seroconversion. More extended consolidation periods (≥ 24 mo) and low HBsAg at cessation (< 100 IU/mL) predicted better response after NAs cessation.

NAs cessation remains a matter of debate in clinical practice. Although a functional cure has been recognized as a feasible goal and an acknowledged treatment endpoint of NAs therapy[12,16,17], the low incidence rates are an essential obstacle to its clinical application. Furthermore, a considerable proportion of HBeAg-positive patients with CHB stopped NAs before achieving HBsAg loss; nevertheless, the response status remained acceptable[5,14]. For these reasons, NAs cessation following HBeAg seroconversion plus more than 1–3-year consolidation therapy is recommended by current guidelines for HBeAg-positive patients with CHB[1-3]. Because some patients in our cohort discontinued NAs after achieving HBeAg loss (without HBeAb) for long periods, the current study compared cumulative relapse rates between CHB patients with HBeAg loss and those with HBeAg seroconversion. Although the cumulative relapse rates remained acceptable in patients with HBeAg loss (45.0% at year 10), better outcomes were observed in patients with HBeAg seroconversion.

To achieve better outcomes for CHB patients with HBeAg loss, we recommend sufficient consolidation periods. In the present study, the consolidation period (≥ 24 mo) was considered an independent predictor for SVR. There were similar conclusions in previous studies exploring factors predicting drug withdrawal for patients with

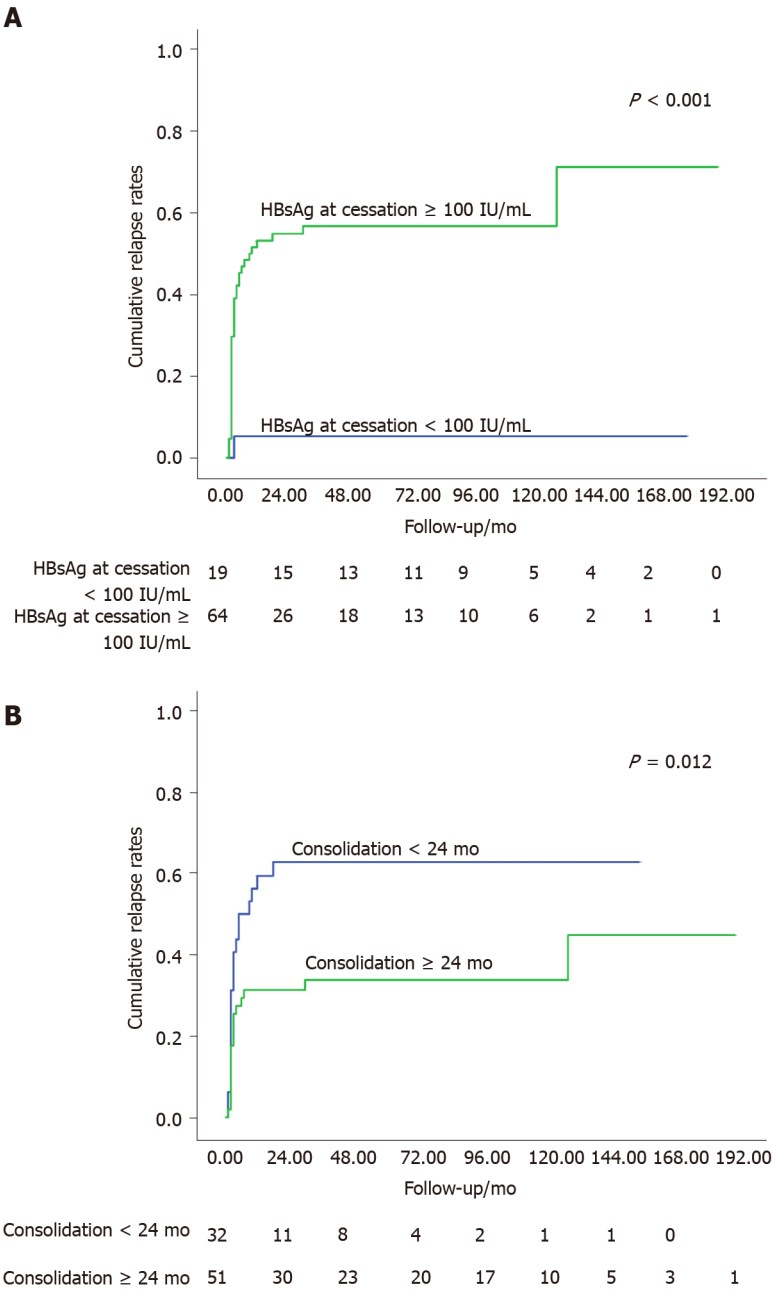

Figure 3 Cumulative virological relapse rates. Cumulative virological relapse rates in A: Hepatitis B e antigen (HBeAg) loss patients with hepatitis B surface antigen at cessation ≥ 100 IU/mL and < 100 IU/mL; B: HBeAg loss patients with consolidation periods ≥ 24 mo and < 24 mo. HBsAg: Hepatitis B surface antigen.

CHB achieving HBeAg seroconversion[5,10,18-21]. Nevertheless, the consolidation periods remain controversial. The three cut-off values (12 mo, 18 mo, and 36 mo) adopted by different cohorts might be attributed to various sample size distributions in different consolidation periods. In the current study, more than one-third of patients received consolidation for more than 36 mo (Figure 2), which ensured the cut-off value's credibility (≥ 24 mo). In addition, according to recommendations of early guidelines, three patients in Cohort A discontinued NAs with consolidation periods less than 12 mo. All these patients relapsed and were re-treated with good outcomes.

In addition to lengthier consolidation, several other factors in Cohort A patients may help obtain better outcomes. As mentioned above, HBsAg is an essential predictor of response status after NAs cessation[15]. Lower HBsAg at cessation predicted better outcomes[15], and our present results corroborate this finding. In Cohort A, seventeen patients achieved HBsAg loss (six patients at cessation and another 11 patients during follow-up) in the present study, a relatively high percentage (20.5%). All these patients maintained HBsAg loss and SVR during follow-up. Second, younger age predicted SVR in both HBeAg-positive and HBeAg-negative

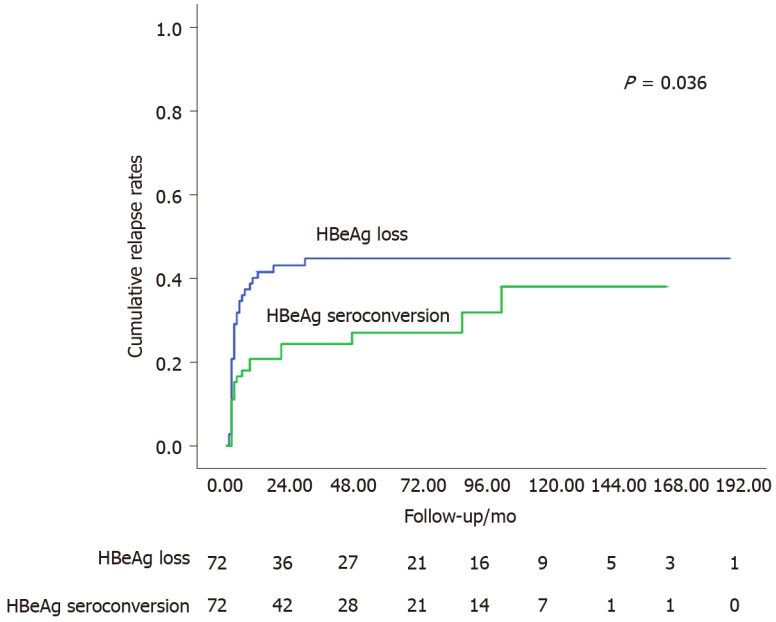

Figure 4 Cumulative virological relapse rates in patients with hepatitis B e antigen loss and seroconversion. HBeAg: Hepatitis B e antigen.

CHB patients[5,10,13,22,23]. However, age was not a predictor in the current study. The mean age of the patients in Cohort A was 32.1 ± 9.5 years, a relatively young sample. Furthermore, 82 patients (98.8%) were under 50 years old, while 65 patients (78.3%) were under 40 years old (Figure 2). The narrow age spectrum may also conceal the role of age in prognosis after cessation. Third, we excluded patients with cirrhosis and decompensated liver disease. The current guidelines recommend indefinite antiviral therapy for these patients[1-3]. We also excluded patients with NAs resistance to obtain better outcomes.

We followed patients in the current study regularly to identify relapse as early as possible. Most patients (92.1%) relapsed in the first year after NAs cessation, especially during the first 3 mo (68.4%), suggesting that more careful monitoring is critical in the early stages after cessation. These characteristics were similar to those in patients achieving HBeAg seroconversion[5,14].

There are some limitations to the current study. First, most patients did not receive first-line NAs because of their enrollment in a relatively early period (since 2001), and we followed them for relatively long periods. We excluded patients with NAs resistance to minimize the influence of low-genetic barrier NAs. Second, as an exploratory study, some features of the included patients made them more likely to achieve a sustained response, which might decrease the representativeness of the current study.

CONCLUSION

In conclusion, HBeAg-positive CHB patients with HBeAg loss may be able to discontinue NAs therapy after long-term consolidation. HBsAg at cessation < 100 IU/mL predicts SVR after NAs cessation. Careful monitoring, especially in the early stages after cessation, should be adopted to ensure favorable outcomes

ARTICLE HIGHLIGHTS

Research background

Nucleos(t)ide analogs (NAs) cessation in chronic hepatitis B (CHB) patients remains a matter of debate in clinical practice, especially in patients who fail to achieve hepatitis B e antigen (HBeAg) seroconversion after the long-term loss of HBeAg. Few studies were explicitly designed for this subpopulation.

Research motivation

To determine whether chronic hepatitis B patients with HBeAg loss could discontinue NAs after long-term consolidation.

Research objectives

We investigated the outcomes and factors associated with HBeAg-positive CHB patients with HBeAg loss [without hepatitis B e antibody (HBeAb)] after cessation of NAs.

Research methods

Patients who discontinued NAs after achieving HBeAg loss (without HBeAb) for long periods were included and predictive factors were explored. CHB patients who achieved HBeAg seroconversion were also included for controls.

Research results

HBeAg-positive CHB patients with HBeAg loss maintained acceptable virological response after NAs cessation, especially in patients with hepatitis B surface antigen (HBsAg) at cessation < 100 IU/mL. After PSM, the cumulative relapse rates were higher than those in patients with HBeAg seroconversion. More extended consolidation periods (≥ 24 mo) and low HBsAg at cessation (< 100 IU/mL) predicted better response after NAs cessation.

Research conclusions

HBeAg-positive CHB patients with HBeAg loss may be able to discontinue NAs therapy after long-term consolidation, especially in patients with HBsAg at cessation < 100 IU/mL.

Research perspectives

HBeAg-positive CHB patients with HBeAg loss may be able to discontinue NAs therapy after long-term consolidation and lower HBsAg at cessation is preferred. Careful monitoring, especially in the early stages after cessation, may ensure a favorable outcome.

ACKNOWLEDGEMENTS

We thank Dr. Yuan Zhang for the statistical review of the study.

Abstract

BACKGROUND

Whether to use a T-tube for biliary anastomosis during orthotopic liver transplantation (OLT) remains a debatable question. Some surgeons chose to use a T-tube because they believed that it reduces the incidence of biliary strictures. Advances in surgical techniques during the last decades have significantly decreased the overall incidence of postoperative biliary complications. Whether using a T-tube during OLT is still associated with the reduced incidence of biliary strictures needs to be re-evaluated.

AIM

To provide an updated systematic review and meta-analysis on using a T-tube during adult OLT.

METHODS

In the electronic databases MEDLINE, PubMed, Scopus, ClinicalTrials.gov, the Cochrane Library, the Cochrane Hepato-Biliary Group Controlled Trails Register, and the Cochrane Central Register of Controlled Trials, we identified 17 studies (eight randomized controlled trials and nine comparative studies) from January 1995 to October 2020. The data of the studies before and after 2010 were separately extracted. We chose the overall biliary complications, bile leaks or fistulas, biliary strictures (anastomotic or non-anastomotic), and cholangitis as outcomes. Odds

ratios (ORs) with 95% confidence intervals (CIs) were calculated to describe the results of the outcomes. Furthermore, the test for overall effect (Z) was used to test the difference between OR and 1, where $P \leq 0.05$ indicated a significant difference between OR value and 1.

RESULTS

A total of 1053 subjects before 2010 and 1346 subjects after 2010 were included in this meta-analysis. The pooled results showed that using a T-tube reduced the incidence of postoperative biliary strictures in studies before 2010 ($P = 0.012$, OR = 0.62, 95%CI: 0.42-0.90), while the same benefit was not seen in studies after 2010 ($P = 0.60$, OR = 0.76, 95%CI: 0.27-2.12). No significant difference in the incidence of overall biliary complications ($P = 0.37$, OR = 1.41, 95%CI: 0.66-2.98), bile leaks ($P = 0.89$, OR = 1.04, 95%CI: 0.63-1.70), and cholangitis ($P = 0.27$, OR = 2.00, 95%CI: 0.59-6.84) was observed between using and not using a T-tube before 2010. However, using a T-tube appeared to increase the incidence of overall biliary complications ($P = 0.049$, OR = 1.49, 95%CI: 1.00-2.22), bile leaks ($P = 0.048$, OR = 1.91, 95%CI: 1.01-3.64), and cholangitis ($P = 0.02$, OR = 7.21, 95%CI: 1.37-38.00) after 2010. A random-effects model was used in biliary strictures (after 2010), overall biliary complications (before 2010), and cholangitis (before 2010) due to their heterogeneity ($I^2 = 62.3\%$, 85.4%, and 53.6%, respectively). In the sensitivity analysis (only RCTs included), bile leak ($P = 0.66$) lost the significance after 2010 and a random-effects model was used in overall biliary complications (before 2010), cholangitis (before 2010), bile leaks (after 2010), and biliary strictures (after 2010) because of their heterogeneity ($I^2 = 92.2\%$, 65.6%, 50.9%, and 80.3%, respectively).

CONCLUSION

In conclusion, the evidence gathered in our updated meta-analysis showed that the studies published in the last decade did not provide enough evidence to support the routine use of T-tube in adults during OLT.

Key Words: Orthotopic liver transplantation; T-tube; Biliary tract reconstruction; Biliary complications; Biliary strictures; Meta-analysis

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: This is the first meta-analysis that compared the postoperative outcomes with or without a T-tube in biliary reconstruction during orthotopic liver transplantation (OLT) before and after 2010. Before 2010, T-tube was favorable for biliary stricture and had no influence on overall biliary complications, bile leaks, and cholangitis. After 2010, not using a T-tube was good for overall biliary complications and cholangitis; however, using a T-tube was not associated with biliary strictures and showed an unbeneficial trend for bile leaks. Therefore, the studies published in the last decade did not provide enough evidence to support the use of T-tube during adult OLT.

INTRODUCTION

Orthotopic liver transplantation (OLT) is an effective treatment for end-stage liver diseases[1,2]. Although the overall outcome of OLT has improved significantly during the last decades, biliary complications, such as biliary strictures and bile leaks, remain the major causes of morbidity and mortality[3]. Biliary anastomosis was thought to be

the Achilles' heel of liver transplantation[4].

T-tube has been routinely used for biliary anastomosis during conventional hepatobiliary surgery[5,6]. However, its use in biliary reconstruction during OLT remains controversial. Several randomized controlled trials (RCTs) and comparative studies have been conducted to evaluate the value of using a T-tube in biliary reconstruction during OLT. The results, however, remained inconclusive. Even meta-analyses on this issue have provided different suggestions; Sun *et al*[7] indicated that T-tube was an excellent tool for biliary tract reconstruction while Sotiropoulos *et al*[8] suggested that abandonment of T-tube was better.

Some surgeons chose to use a T-tube during OLT because they believed that it reduces the incidence of biliary strictures. Recent advances in surgical techniques have significantly decreased the overall incidence of postoperative biliary complications. Whether using a T-tube during OLT is still associated with the reduced incidence of biliary strictures needs to be re-evaluated. Therefore, we performed this updated systematic review and meta-analysis to compare biliary complications with and without a T-tube during OLT in studies conducted before and after 2010[7-27]. We tried to find the current value of using a T-tube for biliary reconstruction during adult OLT.

MATERIALS AND METHODS

Search strategy and selection criteria

To find relevant studies, the electronic databases MEDLINE, PubMed, Scopus, ClinicalTrials.gov, the Cochrane Library, the Cochrane Hepato-Biliary Group Controlled Trails Register, and the Cochrane Central Register of Controlled Trials were used to retrieve papers in English literature from January 1995 to October 2020. The search terms included "OLT" (or "Liver Grafting" or "Liver Transplantations" or "Liver Transplant" or "Hepatic Transplantations") and "T-tube" (or "Stents") and "Biliary Tract Reconstruction" (or "Bile Ducts Reconstruction" or "Bile Duct"). Relevant comparative studies and RCTs on biliary tract reconstruction during OLT were identified. Manual search was still needed to seek further data from the article list.

Inclusion criteria

The inclusion criteria were: (1) Trails including OLT recipients (≥ 18 years); (2) Trials with primary reports of overall biliary complications and at least one biliary complication (bile leaks or fistula, anastomotic or non-anastomotic strictures, and cholangitis); and (3) Trials using choledochocholedochostomy (CCS) to reconstruct the bile duct. RCTs and comparative studies were considered, while news, commentaries, and case reports were excluded. The other exclusion criteria were as follows: (1) Liver recipient age less than 18 years; (2) Retransplantations; (3) Significant donor and recipient duct size mismatch; and (4) Diagnosis of some autoimmune diseases (*e.g.*, primary sclerosing cholangitis).

Data extraction

The data of the studies before and after 2010 were separately extracted. Three authors did a literature search of the above databases in parallel and reached consensus on most items. The differences in opinion were discussed by all authors and came to an agreement finally. The following variables were considered: Authors, year of publication, number of patients, sex, mean age of subjects, and cold ischemia time (CIT) (min). The following outcomes were evaluated: Overall biliary complications, bile leaks or fistulas, biliary strictures (anastomotic or non-anastomotic), and cholangitis.

Intervention and outcome definition

In case that a T-tube was used, a T-tube was inserted into the bile duct after the biliary tract reconstruction of end-to-end or side-to-side CCS. In case that T-tube was not used, there was not any T-tube used in the end-to-end or side-to-side CCS. The main outcomes were defined as bile leaks, biliary strictures, and cholangitis. Bile leaks were suspected in patients with abdominal pain and fever. Biliary strictures were indicated by the biochemical elevations of alkaline phosphatase and total bilirubin levels in patients without allograft rejection or hepatic artery thrombosis[28]. Bile leaks and biliary strictures were diagnosed by percutaneous transhepatic cholangiography, endoscopic retrograde cholangio-pancreatography, and T-tube cholangiogram[29]. In

addition, biliary strictures can also be diagnosed by computed tomography and magnetic resonance imaging. Cholangitis was suspected when the infectious symptoms with cholestatic parameters occurred, and the Charcot triad (right upper quadrant pain, jaundice, and fever) was also a characteristic of cholangitis[30].

Quality assessment

The quality of the studies in the systematic review and meta-analysis was determined using the Jadad composite scale[31]. The following parameters were evaluated: Randomized study, description of randomization, description of withdrawals and dropouts, double-blinded study, and description of double blinding. Each of these was scored as one point. The maximum of points was five. A greater score indicated better quality of selected studies.

Data analysis

This systematic review and meta-analysis were performed with STATA software (StataCorp. 2017. Stata Statistical Software: Release 15. College Station, TX: StataCorp LLC.). Outcomes evaluated were: Overall biliary complications, bile leaks or fistulas, biliary strictures, and cholangitis. Odds ratios (ORs) with 95% confidence intervals (CIs) were calculated to describe the results of dichotomous outcomes. Furthermore, the test for overall effect (Z) was used to test the difference between OR and 1, where $P \leq 0.05$ indicated a significant difference between OR value and 1. Statistical heterogeneity was assessed with the statistics I^2, where $P \leq 0.05$ or $I^2 > 50\%$ were considered as having significant heterogeneity[32]. A fixed-effects model was suitable to estimate the cases with homogeneity ($I^2 \leq 50\%$) while a random-effects model should be used when significant heterogeneity ($I^2 > 50\%$) was detected. The Egger test (bias, P) was used to detect the publication bias, where $P \leq 0.05$ indicated a significant publication bias[33]. Sensitivity analysis based on ten RCTs was used to test the stability of the results of meta-analysis including all studies.

RESULTS

Characteristics of selected studies

There were 267 studies published between 1995 and 2020, of which 109 were excluded because they did not mention the use of a T-tube during OLT. Fourteen reviews, five case reports, and one letter were also excluded. After the full texts of the potential studies had been retrieved, only 20 studies met the inclusion criteria. A study was excluded because it was the preliminary result of a RCT while the final result of the RCT was already included[34]. Two studies were excluded because of the lack of no reference to patient selection or confounding variables[35] or the use of a T-tube in patients without a T-tube[36]. Finally, eight RCTs and nine comparative studies with 2199 subjects were included in our meta-analysis (Figure 1). Among them, 1053 subjects were from studies conducted before 2010 and 1146 were from studies conducted after 2010. Five RCTs got 3 points on the Jadad scale while three RCTs got only 2 points. The mean Jadad score of RCTs was 2.63 points. Seven comparative studies are retrospective, whereas two comparative studies are prospective. The observation period was at least 3 mo except for one with only 2 mo. In most studies, the T-tube was removed 3 mo after the biliary reconstruction operation, but in one comparative study, the T-tube was removed only 9 wk after operation. One study had selection bias for the use of a T-tube and another study was biased on the intention-to-treat[13]. There were no significant differences in age, CIT, and gender (data not shown). Detailed data and results are summarized in Tables 1 and 2, respectively.

Results of meta-analysis including all studies

The pooled resulted showed that in studies conducted between 1995 and 2010, the use of a T-tube appeared to reduce the incidence of biliary strictures ($P = 0.012$, OR = 0.62, 95%CI: 0.42-0.90, Figure 2A and Table 3), while for studies conducted after 2010, there was no significant difference between the "with T-tube" group and the "without T-tube" group in the occurrence of biliary strictures ($P = 0.60$, OR = 0.76, 95%CI: 0.27-2.12, Figure 2B). No significant differences in the incidences of overall biliary complications ($P = 0.37$, OR = 1.41, 95%CI: 0.66-2.98, Figure 3A), bile leak ($P = 0.89$, OR = 1.04, 95%CI: 0.63-1.70, Figure 4A), and cholangitis ($P = 0.27$, OR = 2.00, 95%CI: 0.59-6.84, Figure 5A) were observed between using and not using a T-tube in studies conducted before 2010. However, using a T-tube appeared to increase the incidences of

complications (in studies before 2010), and cholangitis (in studies before 2010) due to their heterogeneity (I^2 = 62.3%, 85.4%, and 53.6%, respectively). Unfortunately, we failed to figure out the source of heterogeneity. Sensitivity analysis failed to reveal the main cause of the heterogeneity. Funnel plots detected a publication bias for bile leaks (Egger: Bias = 2.43, P = 0.003) and for cholangitis (Egger: Bias = 2.97, P = 0.02).

Results of sensitivity analysis including only RCTs

The meta-analysis with only RCTs showed that except for bile leaks which lost the significance in studies after 2010 (P = 0.66), the rest outcomes remained unchanged. Overall biliary complications and cholangitis were not evaluated because only one RCT was available to provide the information and the publication bias tests were not applicable (Table 4). A random-effects model was used in overall biliary complications (in studies before 2010), cholangitis (in studies before 2010), and biliary strictures (in studies after 2010) because of their heterogeneity (I^2 = 92.2%, 65.6%, 50.9%, and 80.3%, respectively). Funnel plots did not detect any publication bias among the outcomes.

DISCUSSION

Whether to use a T-tube or not during OLT remains a challenging question for today's transplant surgeons. The advantages of using a T-tube are the real-time monitoring of the color and quantity of bile. Therefore, using a T-tube can get the condition of transplanted liver and an access of the radiographic imaging of the biliary tree[10,12,14]. And the use of a T-tube has been thought to reduce intraductal pressure to protect biliary anastomosis[12,37]. However, the use of a T-tube may also contribute to the development of biliary leaks and cholangitis[15,16,25]. Although, in the period from 1995 to 2010, the data showed that the use of a T-tube could reduce the incidence of biliary strictures, the use of a T-tube had no influence on the occurrence of overall biliary complications, cholangitis, and bile leak. However, in the current updated (from 2010 to 2020) meta-analysis, we documented that the use of a T-tube did not reduce the incidence of biliary strictures and it appeared to increase the development of overall biliary complications and cholangitis and showed an unfavorable trend for bile leaks.

Reduction of the postoperative development of anastomotic or non-anastomotic strictures is considered an inherent trait of using a T-tube during OLT. Indeed, inserting a T-tube is still a useful way to decrease the use of invasive diagnostic techniques like endoscopic retrograde cholangiography[26,38], when a patient is suspected with bile leaks, just as the past decade data showed. However, unlike most studies, there was no significant difference between the "with T-tube" group and the "without T-tube" group in the occurrence of biliary strictures in the period from 2010 to 2020 in our analysis. Biliary stricture could occur in the non-anastomotic part due to the lack of the blood supply[39,40]. And bile leak, infection, and wound contraction may contribute to anastomotic biliary stricture[41-43]. The inflammatory reaction and fibrosis processes may occur in the biliary tract wall contacting with the T-tube due to the foreign body reaction to a T-tube[44,45]. If a T-tube was placed on the biliary tract for a long time, T-tube will alter the local host defense mechanism to increase the susceptibility to infection which may induce biliary fibrosis[46,47]. Fortunately, the recent advancement in surgical techniques has significantly improved the short-term outcomes after OLT[48,49].

Bile leaks commonly complicate liver transplantation. They usually occur in the early postoperative period or after the T-tube removal. And bile leaks prolonged the hospital stay, increased the medical costs, and disturbed the postoperative recovery[50]. Some physicians thought that the use of a T-tube plays an important role in development of bile leaks in recipients[51]. In the results of our study, there was no significant difference in the incidence of bile leaks between the "with T-tube" group and the "without T-tube" group in the period from 1995 to 2010. Nevertheless, we found that the use of a T-tube increased the risk of developing bile leaks in biliary reconstruction during OLT in the period from 2010 to 2020. Unfortunately, in the sensitivity analysis, bile leaks lost the significance, which lowered the statistic power of the results. Therefore, at least in part, our data demonstrated that T-tube showed an unbeneficial trend for bile leaks. Previous studies showed that 5% to 15% of patients suffered from bile leaks after T-tube removal[52,53]. And the biliary anastomosis or T-tube exit site was a major source of the bile leakage[54,55]. The delayed formation of a fibrous trajectory to allow safe removal of T-tube may play an important role in the incidence of bile leak[56]. In addition, multiple biliary reconstructions also contributed to the occurrence of the bile leaks and were associated with a poor prognosis of

Table 4 Sensitivity analysis of outcomes (only randomized control trials included)

Period	Outcome	Studies	participants	Effect size OR, 95%CI (fixed/random)	Heterogeneity	Test for overall effect (fixed/random)	Publication bias	Study quality[1]	Favors
1995-2010	Overall biliarycomplications	5	639	1.15 [0.28, 4.72]	I^2 = 92.2% ([b]P = 0.001)	Z = 0.19/(P = 0.85)	Egger: Bias = 2.63; P = 0.71	3 × 4, 2 × 1	None
	Bile leak	5	639	0.56 [0.28, 1.13]	I^2 = 0.0% (P = 0.72)	Z = 1.62/(P = 0.11)	Egger: Bias = 1.72; P = 0.08	3 × 4, 2 × 1	None
	Biliary stricture	5	639	0.45 [0.24, 0.85]	I^2 = 0.0% (P = 0.46)	Z = 2.47/([a]P = 0.014)	Egger: Bias= -2.78; P = 0.10	3 × 4, 2 × 1	With T-tube
	Cholangitis	4	541	1.83 [0.36, 9.41]	I^2 = 65.6% ([a]P = 0.03)	Z = 0.72/(P = 0.47)	Egger: Bias = 3.39; P = 0.054	3 × 4	None

patients[57].

Cholangitis always seems to be a direct outcome of usage of T-tube in biliary reconstruction during OLT. Our study documented that the development of cholangitis had a significant difference between the "with T-tube" group and the "without T-tube" group in the period from 2010 to 2020. However, in the period from 1995 to 2010, we found that cholangitis did not reach the significance between the two groups. There was a trend that T-tube increased the risk of cholangitis. A T-tube was a bridge between the abdominal cavity and external environment to facilitate entry of bacteria into human body. And the surface of a T-tube is a good platform for bacteria to implant so bacteria could form biofilm which help bacteria proliferate better[58,59]. The biofilm in T-tube plays an important role in occurrence of cholangitis[60,61]. If the T-tube was broken by the patient carelessly, the bile may flow out of the biliary tree to induce bacterial infection. Most patients were immunocompromised because of immunosuppressors after OLT, which made patients vulnerable to bacterial or viral infection. In another words, it is fatal for some patients suffering from infections such

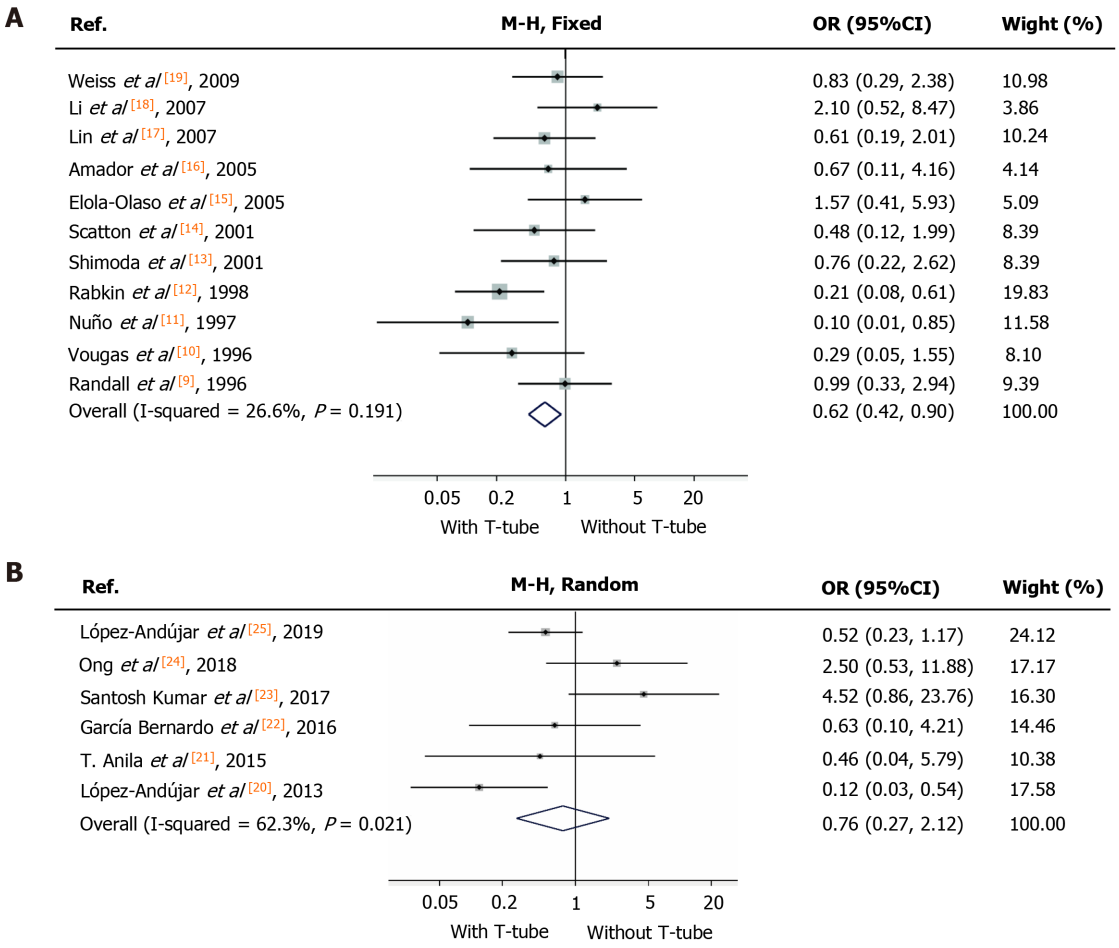

Figure 2 Biliary strictures. A: In the period from 1995 to 2010, odds ratio (OR) for biliary strictures between "T-tube" group and "without T-tube" group was calculated with a fixed-effects model. The shape of diamond represents the overall effect of OR with 95% confidence interval (CI). The use of T-tube decreased the incidence of biliary strictures; B: In the period from 2010 to 2020, OR for biliary strictures between "T-tube" group and "without T-tube" group was calculated with a random-effects model. The shape of diamond represents the overall effect of OR with 95%CI. There was no significant difference between the two groups. OR: Odds ratio; CI: Confidence interval.

as cholangitis. T-tube inserting also increased the risk of long-term biliary inflammation and biliary tract fibrosis[47].

As for overall biliary complications, there was no significant difference between the two groups in the period from 1995 to 2010. Interestingly, our document showed that the use of a T-tube did play a role in development of all kinds of biliary complications in the period from 2010 to 2020. The modern diagnostic devices and the advanced endoscopic technique revealed many latent complications (small thrombosis, local infections, mild internal hemorrhage, and so on), which were difficult to be detected in the past[10,13,14].

There may be a potential bias because several outcomes had significant publication bias. Since our meta-analysis contained nonrandomized studies and some comparative studies that had selection bias, both contributed to the article's limitation. Although we reduced the heterogeneity of the selected studies *via* using random-effects models, the inherent bias still partially existed. And almost all the comparative studies got just 1 point on the Jadad scale; however, the five RCTs got 3 points on the Jadad scale while three RCTs got 2 points, which indicated that the quality of the selected studies was not very high. In addition, the retrospective design of the comparative studies may introduce recall bias and reporting bias.

CONCLUSION

In conclusion, the data in our study showed that the use of a T-tube is a beneficial factor for biliary strictures before 2010, whereas no benefit was observed for overall biliary complications, biliary leak, and cholangitis in the same period. According to the

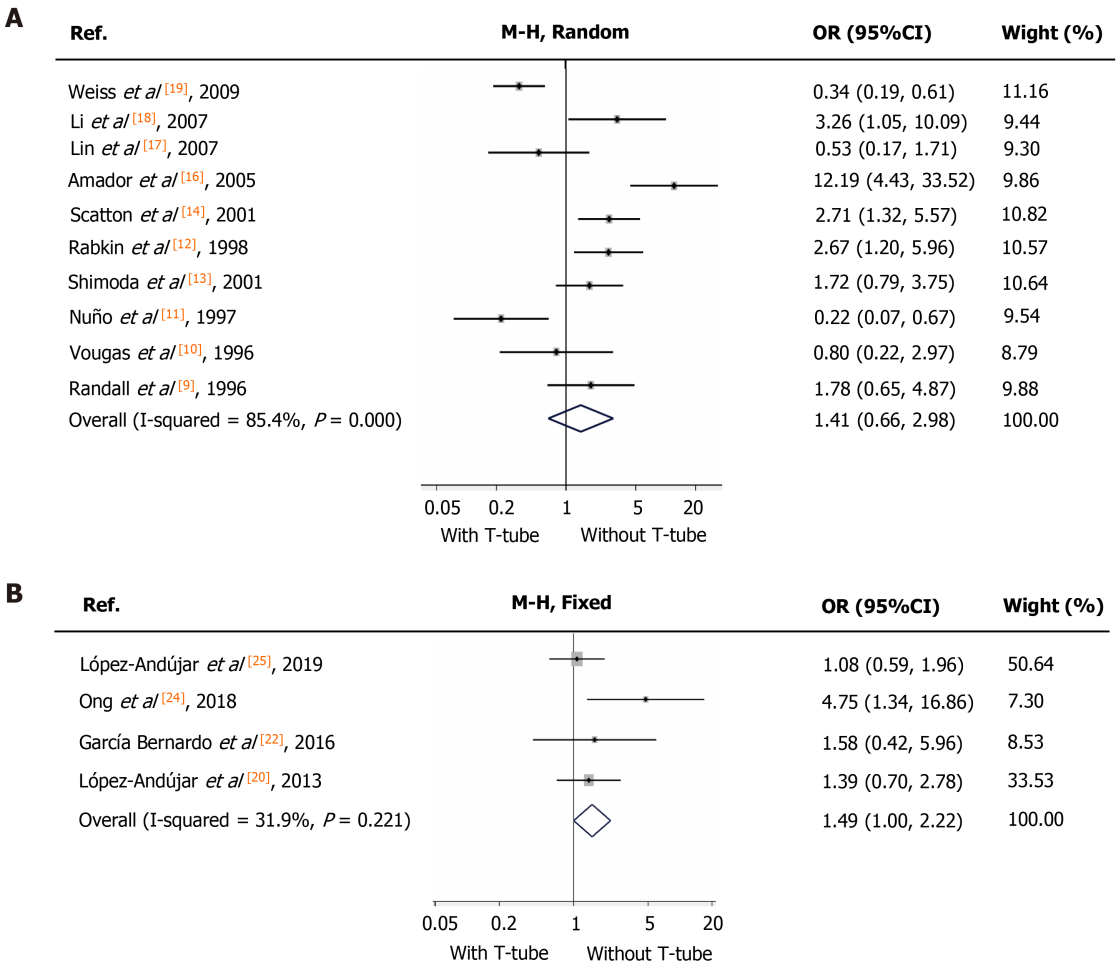

Figure 3 Overall biliary complications. A: In the period from 1995 to 2010, odds ratio (OR) for overall biliary complications between "T-tube" group and "without T-tube" group was calculated with a random-effects model. The shape of diamond represents the overall effect of OR with 95% confidence interval (CI). The use of T-tube had no influence on occurrence of overall biliary complication; B: In the period from 2010 to 2020, OR for overall biliary complications between "T-tube" group and "without T-tube" group was calculated with a fixed-effects model. The shape of diamond represents the overall effect of OR with 95%CI. The occurrence of overall biliary complications was significantly higher in "T-tube" group. OR: Odds ratio; CI: Confidence interval.

studies after 2010, not using a T-tube is beneficial in terms of overall biliary complications and cholangitis; however (after sensitivity analysis), the use of a T-tube is not associated with biliary strictures and shows an unbeneficial trend for bile leaks. Therefore, the evidence gathered in our updated meta-analysis showed that the studies published in the last decade did not provide enough evidence to support the routine use of T-tube in adults during OLT.

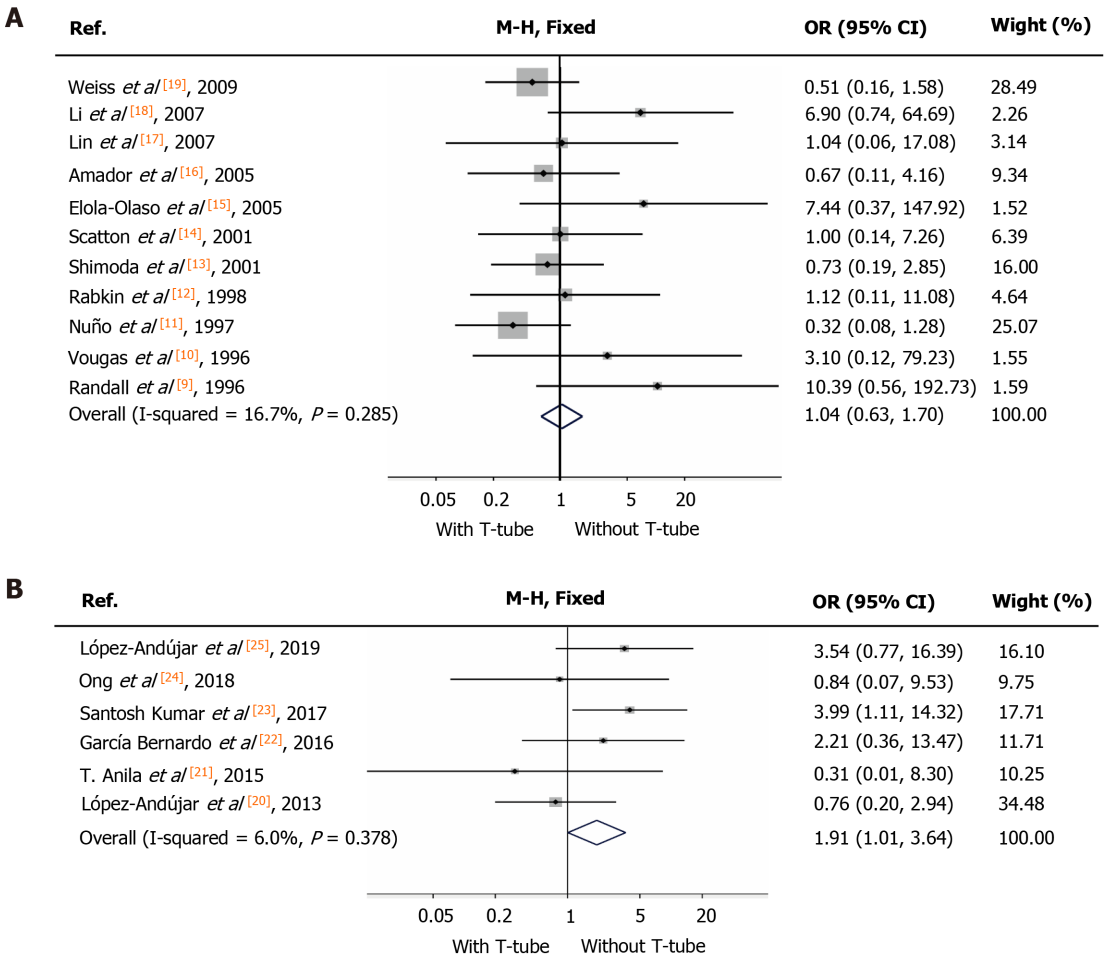

Figure 4 Bile leaks. A: In the period from 1995 to 2010, odds ratio (OR) for peritonitis between "T-tube" group and "without T-tube" group was calculated with the fixed model. The shape of diamond represents the overall effect of OR with 95% confidence interval (CI). There was no significant difference between the two groups; B: In the period from 2010 to 2020, OR for peritonitis between "T-tube" group and "without T-tube" group was calculated with the fixed model. The shape of diamond represents the overall effect of OR with 95%CI. The incidence rate of bile leaks was significantly higher in "T-tube" group. OR: Odds ratio; CI: Confidence interval.

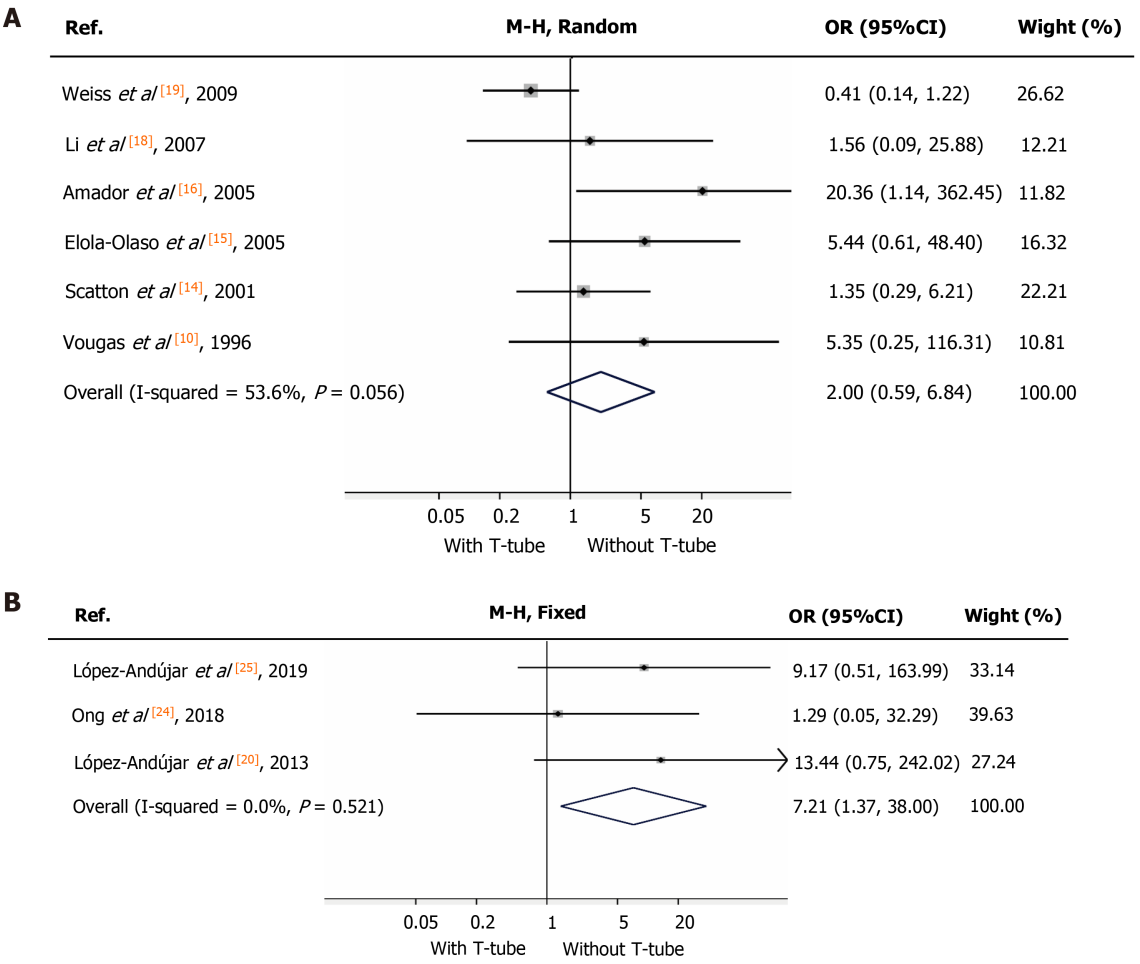

Figure 5 Cholangitis. A: In the period from 1995 to 2010, odds ratio (OR) for cholangitis between "T-tube" group and "without T-tube" group was calculated with a random-effects model. The shape of diamond represents the overall effect of OR with 95% confidence interval (CI). There was no significant difference between the two groups; B: In the period from 2010 to 2020, OR for peritonitis between "T-tube" group and "without T-tube" group was calculated with a fixed-effects model. The shape of diamond represents the overall effect of OR with 95%CI. The incidence rate of bile leaks was significantly higher in "T-tube" group. OR: Odds ratio; CI: Confidence interval.

ARTICLE HIGHLIGHTS

Research background

The use of the T-tube in the reconstruction of the biliary tree during orthotopic liver transplantation (OLT) is still debatable.

Research motivation

Biliary complications after OLT, including bile leaks, cholangitis, and biliary strictures, prolonged the hospital stay, impaired the postoperative recovery, and increased the medical costs. T-tube was involved in the occurrence of these biliary complications. Therefore, it is helpful to identify the role of T-tube in the incidence of the biliary complications.

Research objectives

We performed a meta-analysis to evaluate whether patients benefit from the use of a T-tube during OLT.

Research methods

We calculated odds ratios with 95% confidence intervals to identify the role of a T-tube in the incidence of the overall biliary complications, bile leaks, cholangitis, and biliary strictures.

Research results

We discovered that T-tube had no influence on the risk of the overall biliary complications, bile leaks, and cholangitis and reduced the incidence of biliary strictures in the period from 1995 to 2010. However, in the recent decade (from 2010 to 2020), we found that T-tube did not affect the occurrence of biliary strictures and increased the incidence of overall biliary complications and cholangitis. And the use of a T-tube showed an unbeneficial trend for bile leak after 2010.

Research conclusions

In conclusion, the evidence gathered in our updated meta-analysis showed that the studies published in the last decade did not provide enough evidence to support the routine use of T-tube in adults during OLT.

Research perspectives

More T-tube-related outcomes should be included in the future meta-analysis so the advantages and disadvantages would be evaluated better.

ABOUT COVER

Editorial Board Member of *World Journal of Gastroenterology*, Halina Cichoż-Lach, MD, PhD, Professor, Department of Gastroenterology with Endoscopic Unit, Medical University of Lublin, Jaczewskiego 8, Lublin 20814, Poland. halina.lach@umlub.pl

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, and Scopus. The 2020 edition of Journal Citation Report® cites the 2019 impact factor (IF) for *WJG* as 3.665; IF without journal self cites: 3.534; 5-year IF: 4.048; Ranking: 35 among 88 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2019 is 7.1 and Scopus CiteScore rank 2019: Gastroenterology is 17/137.

RESPONSIBLE EDITORS FOR THIS ISSUE

Abstract

The concept of textbook outcome (TO) has recently gained popularity in surgical research and has been used to evaluate the quality or success of different surgical procedures, including hepatopancreatobiliary (HPB) operations. TO consists of individual outcome parameters that each reflect different domains of care including structure, process, and individual outcomes; in turn, the composite TO metric represents the optimal course after a surgical episode. TO can be used to assess patient-level outcomes, hospital performance, center designation and quality metrics. In addition to being an outcome measurement, TO may also be linked to healthcare costs. Future efforts should be directed towards establishing a universal definition of TO in HPB surgery so that surgeons and hospitals can assess and compare outcomes, identify shortcomings and improve real world patient outcomes.

Key Words: Textbook; Outcome; Hepatopancreatobiliary; Surgery

INTRODUCTION

Traditionally, quality assessment of complex surgery has focused on analyzing and evaluating individual outcome parameters, mainly complications, length of stay (LOS), in-hospital mortality, as well as 30-, 90-d mortality and readmission[1]. More recently, there has been a shift in quality assessment from individual outcome parameters to composite outcomes, which have been considered superior to assess patient outcomes and hospital performance[2-5]. A recently introduced concept, "textbook outcome" (TO) represents the optimal course following surgery that is better aligned with patient expectations around "optimal" care[2-5]. TO uses an "all-or-none" approach in which the optimal or "textbook" outcome is not achieved unless patients achieve all of the individual parameters comprising a TO[2-5].

The concept of TO has gained popularity in surgical clinical research and has been advocated as a measure to assess quality or success of complex surgical procedures, including abdominal aortic aneurysm repair, as well as hepatopancreatic, esophageal, gastric, sarcoma, colon cancer resection and transplantation[2-10]. Specifically, TO is a composite measure that aggregates various clinically important perioperative outcomes included in the definition of an "optimal" surgical episode. Such a composite measure encompasses determinants of quality of care from different domains including structure, process, and individual outcomes[2]. Indeed, each individual outcome may capture different domains of quality (*e.g.*, perioperative mortality might be related to operative volume, failure-to-rescue may be related to structure or processes of perioperative care, while LOS or readmissions may be related to discharge planning processes in place for each institution)[5]. In turn, TO is particularly relevant in the care of complex cancers, including hepatopancreatobiliary (HPB) malignancies, which require coordination across a number of specialties and through various phases of multidisciplinary treatment to achieve the best possible outcome[3,5,11]. In addition, TO can be used as a "benchmark" to track the quality of care delivered to patients and compare hospital performance across different institutions or health systems[12-14]. In this article, we highlight the existing and emerging literature on TOs in HPB surgery.

ASSESSING PATIENT-LEVEL OUTCOMES USING TO

Although the concept of TO was initially described in 2013 by a group of colorectal surgeons in Netherlands[2], it was used for the first time to assess outcomes of patients undergoing hepatopancreatic surgery in 2018[4]. Merath *et al*[4] first assessed TO rates after hepatopancreatic surgery among Medicare beneficiaries from 2013 to 2015[4]. TO was defined no postoperative complications, no prolonged LOS (*i.e.*, ≤ 75th percentile), no 90-d readmission and no 90-d postoperative mortality[4]. The study analyzed patients with all surgical indications (*i.e.*, both benign and malignant diseases) and demonstrated that TO was achieved in 44% of individuals undergoing hepatopancreatic surgery[4]. Of note, among patients who underwent pancreatic resection, TO was achieved in 47.8% following minor pancreatic resection (*i.e.*, distal pancreatectomy or other partial pancreatectomy) and 24.7% following major pancreatic resection (*i.e.*, proximal pancreatectomy, pancrea-ticoduodenectomy, total pancreatectomy)[4]. Similarly, while TO was achieved in 46.8% of patients undergoing minor hepatectomy, the incidence of TO decreased to 33.3% among patients who had undergone a major liver resection[4]. These data highlighted the fact that less than one-half of patients overall experienced an optimal or "textbook" outcome after hepatopancreatic surgery; in particular, achievement of TO was markedly lower among patients undergoing major pancreatic or liver resections.

Due to the inherent limitations of administrative billing databases, several important perioperative outcomes were not captured and assessed in the initial study by Merath *et al*[4]. Rather, the use single- or multi-center institutional databases that contain more granular data to provide more clinically important information and allow for a more thorough assessment of postoperative outcomes was needed. To this

end, Merath *et al*[3] published a subsequent study that assessed the incidence of TO following resection of intrahepatic cholangiocarcinoma (ICC) using a multi-institutional database that incorporated data from 15 major HPB centers[3]. In this study, the authors defined TO as R0 resection, no perioperative transfusion, no postoperative complications, no prolonged LOS, no 30-d readmission and no 30-d mortality[3]. Among 687 patients analyzed, TO was achieved only in 25.5% of patients undergoing curative-intent resection for ICC. Younger patient age (age < 60 years), absence of preoperative jaundice, earlier T-category disease (*i.e.*, T1a, T1b), node-negative disease, and no bile duct resection were independent predictors of TO[3]. Although 30-d mortality was less than 5%, a TO was achieved in only one-fourth of patients largely due to high rates of complications and LOS, highlighting the need for further improvements in managing patients undergoing complex HPB procedures[3].

Another study examined TO after curative-intent resection of hepatocellular carcinoma (HCC)[5]. TO was defined as R0 resection, no reoperation, no severe postoperative complications (Clavien-Dindo ≥ III), no prolonged LOS, no 90-d readmission and no 90-d mortality[5]. In analyzing 605 patients, the incidence of TO was 62.3% after curative-intent resection of HCC[5]. Patients with BCLC-0 HCC and albumin-bilirubin grade grade 1 (*i.e.*, good liver function) had higher odds of achieving a TO[5]. In addition to examining perioperative outcomes, the impact of TO on long-term outcomes was also assessed. Of note, patients who experienced a TO had a better 5-year overall survival (OS) of 69.6% compared with a 5-year OS of 56.9% among individuals who did not achieve a TO[5], which was in line with previous studies on esophageal and gastric cancer[6]. Similarly, Heidsma *et al*[15] reported an incidence of TO that was 49.3% among patients undergoing resection for pancreatic neuroendocrine tumors; the odds of TO varied based on the type of procedure performed[15]. In fact, the highest TO rates were noted among individuals undergoing distal pancreatectomy (56.7%) followed by those undergoing enucleation (52.0%) and then pancreatoduodenectomy (32.5%)[15]. TO was also an independent predictor of long-term outcomes, with 3-year disease-free survival ranging from 91.7% among patients who achieved a TO to 85.2% among patients who did not[15]. These data validated the clinical relevance of TO among cancer patients, aligning the importance of surgical quality (and outcomes) with the primary goal of achieving a potentially curative operation. As more investigators integrate TO into the field of surgical oncology, TO may evolve to incorporate other variables representing domains of multidisciplinary care delivery (*i.e.*, negative margin resection, adequate lymph node sampling, receipt of neoadjuvant/adjuvant chemotherapy) to create an oncologic composite outcome measure [*i.e.*, textbook oncologic outcome (TOO)][16,17]. Although consensus as to which individual components should define a TOO has not been reached (Table 1), the use of a TOO might be a better way to characterize patient and hospital-level outcomes among cancer patients.

ASSESSING HOSPITAL PERFORMANCE, DESIGNATIONS AND QUALITY METRICS USING TOs

Hospital performance remains an important topic among patients and stakeholders, such as insurance and pharmaceutical companies as well as the government. To date, different designations and ranking systems are available to evaluate hospital performance. Of note, teaching hospitals have been assigned with the mission to teach the next generation of physicians, support research and provide excellent patient care[18,19]. Previous studies had demonstrated contradictory results when examining individual outcome parameters (*i.e.*, mortality, morbidity, readmissions) relative to teaching hospital status[18,19]. To this point, Mehta *et al*[12] investigated the impact of teaching status on TO among Medicare beneficiaries undergoing hepatopancreatic surgery[12]. Of note, patients undergoing surgery for pancreatic cancer at a major teaching hospital were more likely to achieve a TO *vs* patients treated at a minor teaching hospital[12]. When assessing only high volume hospitals, the odds of a TO were comparable among patients treated at major *vs* minor teaching centers, highlighting that the beneficial effect of teaching hospital status was largely mediated by procedural volume and not necessarily by teaching status itself[12].

Another study investigated a commonly used ranking system, the United States News & World Report (USNWR) Best Hospital rankings, relative to TO[13]. Although the USNWR rankings are commonly used by patients and are thought to influence patient decision-making and choice of hospital to undergo treatment, a recent study demonstrated similar odds of achieving a TO among patients undergoing complex

Table 1 Existing literature around textbook outcome in hepatopancreatobiliary surgery

Ref.	Study period	Database	Indication	Components of TO	TO rates
Merath *et al*[3], 2019	2013-2015	Medicare	Benign and malignant hepatopancreatic lesions	No complications. No prolonged LOS. No 90-d mortality. No 90-d readmission	44.0%
Merath *et al*[4], 2020	1993-2015	Multi-institutional ICC database	Intrahepatic cholangiocarcinoma	R0 resection No transfusion. No complications. No prolonged LOS. No 30-d mortality. No 30-d readmission	25.5%
Tsilimigras *et al*[5], 2020	2000-2015	Multi-institutional HCC database	Hepatocellular carcinoma	R0 resection No reoperation. No complications (Clavien-Dindo ≥ III) No prolonged LOS. No 90-d mortality. No 90-d readmission	62.3%
Heidsma *et al*[15], 2020	2000-2016	US Neuroendocrine Tumor Study Group database	Pancreatic neuroendocrine tumors	R0 resection No complications (Clavien-Dindo ≥ III). No prolonged LOS. No 90-d mortality. No 90-d readmission	49.3%

TO: Textbook outcome; LOS: Length of stay; ICC: Intrahepatic cholangiocarcinoma; US: Ultrasonography; HCC: Hepatocellular carcinoma.

cancer surgery (*i.e.*, lung, colorectal, esophageal, liver and pancreatic resections) at honor roll (top 20 institutions) *vs* non-honor roll hospitals[13]. These data suggested that the USNWR ranking had only a minor impact on the likelihood of achieving a TO and, thus, should not necessarily been used to choose institutions to undergo complex cancer surgery. In addition, these data suggested that composite outcomes such as TO should perhaps been taken into consideration among policymakers to establish the methodology of hospital ranking systems for complex cancer surgery.

For oncologic patients, quality of care is of particular importance as patients seek a holistic, multidisciplinary care in the battle against cancer. To date, there are only 10 dedicated cancer centers (DCCs) that provide care to cancer patients[20]. Another important designation for hospitals providing cancer care is the National Cancer Institute cancer center (NCI-CC) designation, which approximately 70 institutions in the United States hold for outstanding efforts related to prevention, diagnosis and treatment of cancer[21]. In another study by Mehta *et al*[20], the authors compared outcomes of patients undergoing hepatopancreatic surgery at DCC *vs* NCI-CC for cancer[20]. Of note, patients who underwent hepatopancreatic surgery had increased odds of achieving a TO when treated at a DCC *vs* NCI-CC (pancreatic resections: 22% higher chance of a TO; liver resection: 31% higher chance of a TO), despite the fact that DCCs more frequently cared for patients with multiple comorbidities[20]. Higher TO rates translated into reduced Medicare expenditures at DCCs, which suggested a higher value proposition of DCC *vs* NCI-CC in the treatment of patients with hepatopancreatic malignancies[20].

Several other national quality metrics have been proposed to assess quality of care provided to patients. For example, hospital magnet recognition, established by the American Nurses Credentialing Center has been used to identify institutions with a focus on improving nursing care and, in turn, quality of care delivered to patients[22]. In addition, the Leapfrog Group has set a minimum annual hospital surgical volume for certain operations–including pancreatic resection (*i.e.*, > 20 pancreatic resections)–associated with improved outcomes[23]. Another quality indicator made available by the Leapfrog group is the Leapfrog safety grade which is solely focused on patient safety[23,24]. In analyzing data from 4853 Medicare beneficiaries, Merath *et al*[14] examined all 3 quality indicators (*i.e.*, leapfrog minimum volume standards, safety grade and magnet status) relative to TO following hepatopancreatic resections[14]. Of note, patients undergoing pancreatectomy at hospitals meeting all 3 quality metrics (*i.e.*, quality trifactor) had 28% higher odds of experiencing a TO compared with individuals undergoing pancreatectomy at non-trifactor hospitals[14]. When examining each of the quality indicators separately, magnet status and safety grade A were alone not enough to confer high TO rates. Rather, the positive effect of the quality trifactor was largely mediated by the compliance with the Leapfrog minimum volume standards that were associated with lower odds of mortality and serious complications and, in turn, greater odds of TO[14].

ASSESSING TRENDS IN TOs OVER TIME

TO has also been assessed relative to changes in practice and outcomes in HPB surgery over time. By analyzing the American College of Surgeons National Surgical Quality Improvement Program database, Beane *et al*[25] reported an increase in optimal or "textbook" outcomes after pancreatic surgery in North America[25]. There was a decrease in postoperative morbidity, mortality and LOS between 2013-2017 that resulted in an increase in the incidence of TO by 3% to 5% after pancreatic surgery on a nationwide level[25]. A number of reasons might be responsible for this improvement. First, there was a decrease in superficial and deep surgical site infections, and a decrease in the rates of shock/sepsis after pancreatic resection[25]. In addition, an increase in minimally invasive pancreatic resection was noted over time (mainly robotic resection) that may have contributed to a decrease in LOS. The broad dissemination and implementation of enhanced recovery after surgery protocols over the past 5 to 10 years likely also contributed to the observed reduction in LOS[26,27]. Furthermore, the increase in TO incidence over time may also have been to centralization of pancreatic cancer care at specialized centers and increased access to multidisciplinary oncologic teams. In turn, the modest improvement in the incidence of TO noted over time may be a reflection of the varied distribution of pancreatic cancer cases, and not an actual improvement in the majority of centers throughout the nation[25].

Indeed, by combining two multi-institutional datasets, Tsilimigras *et al*[11] analyzed the trends in TO rates after curative-intent resection of primary liver malignancies (*i.e.*, ICC and HCC) at major HPB centers over a 12-year period[11]. Overall, 62.0% of patients achieved a TO after ICC or HCC resection at major HPB centers. In assessing the trends of TO over the years, no significant improvement was noted over the study period examined (2005-2017) (P_{trend} = 0.90)[11]. When analyzing the individual components comprising TO, no specific factor demonstrated an increasing trend over time (all P_{trend} > 0.05). Perhaps more surprisingly, no increasing trends in TO rates were noted among patients undergoing either major (2005 to 2009: 49%; 2014 to 2017: 48%) or minor liver resection (2005 to 2009: 71%, 2014 to 2017: 71%) over the study period (both P_{trend} > 0.05)[11]. Apart from TO itself, the year of surgery was also not associated with improved long-term outcomes among patients with either ICC or HCC[11]. These data highlight the fact that despite advances in surgical techniques and perioperative care, only modest improvements in the outcomes of HCC and ICC patients occurred over the last decade. In turn, there is still a long way to optimize real world outcomes among patients with HPB malignancies.

FINANCIAL IMPACT OF TOs

Besides representing a quality outcome measure, TO may also have financial implications. In fact, the financial impact of TO has been investigated and data have suggested that a disproportionate amount of money is spent on patients who do not achieve a TO after hepatopancreatic surgery. For example, Merath *et al*[4] noted that among patients who achieved a TO, Medicare payments were approximately $11000 less following minor hepatopancreatic resections and $14000 less for patients undergoing major resection when compared with individuals who did not achieve a TO[4]. Similarly, Mehta *et al*[12] suggested that TO resulted in an average of $5000 less in Medicare expenditures after hepatopancreatic surgery at teaching hospitals (TO: $19191, *vs* no TO: $24165, $P < 0.001$)[12]. The association of decreased overall costs with the achievement of a TO was consistent across major and minor teaching hospitals, as well as among high and low volume institutions, highlighting that TO has financial implications irrespective of the hospital setting[12]. Collectively, the data suggest that TO might be a composite metric that reflects value—*i.e.*, high quality combined with lower costs. In turn, improving TO rates after hepatopancreatic surgery may not only optimize the quality of care provided to patients, but also decrease health care costs and lead to cost-effective and high-value care.

ADVOCATING FOR WIDER IMPLEMENTATION OF TO IN HPB SURGERY

Advocates of TO note that this composite metric provides a more comprehensive estimate of quality of perioperative care[28]. However, a primary criticism of TO is that there is no consensus in the literature as to what should be considered an "optimal"

outcome after a specific operation. Moreover, patient risk factors strongly influence outcomes and require comprehensive risk adjustment in order to make valid comparisons. With the thoughtful implementation of composite quality metrics in HPB surgery, surgeons and centers will hopefully gain a better understanding of the perioperative processes of care and develop insights to improve patient outcomes. Moreover, the optimization of expectation management will be facilitated, especially in high-risk patients. Improved understanding of these gaps through the use of TO can allow systems to identify patients who are high risk of failure to achieve optimal short- and long-term outcomes after surgery and redirect resources accordingly. Thus, fundamentally the concept of TO aligns with the patient best interest, which is the ideal outcome after surgery.

CONCLUSION

TO provides a more realistic assessment of patient-centered perioperative care and represents the optimal experience around a surgical episode. TO should be the ideal outcome that surgeons should strive to achieve for their patients. The use of TO in cancer populations is of paramount importance as a measure of both short- and long-term outcomes. TO can be used to assess performance across different institutions as well as assess quality metrics or hospital designations. Future efforts should be directed towards establishing a universal definition of TO in HPB surgery so that surgeons and hospitals can assess and compare outcomes, as well as identify shortcomings and improve real-world patient outcomes.

Abstract

Coronavirus disease 2019 (COVID-19) is a devastating worldwide pandemic infection caused by a severe acute respiratory syndrome namely coronavirus 2 (SARS-CoV-2) that is associated with a high spreading and mortality rate. On the date this review was written, SARS-CoV-2 infected about 96 million people and killed about 2 million people. Several arguments disclosed the high mortality of COVID-19 due to acute respiratory distress syndrome or change in the amount of angiotensin-converting enzyme 2 (ACE2) receptor expression or cytokine storm strength production. In a similar pattern, hepatic impairment patients co-infected with SARS-CoV-2 exhibited overexpression of ACE2 receptors and cytokine storm overwhelming, which worsens the hepatic impairment and increases the mortality rate. In this review, the impact of SARS-CoV-2 on hepatic impairment conditions we overviewed. Besides, we focused on the recent studies that indicated cytokine storm as well as ACE2 as the main factors for high COVID-19 spreading and mortality while hinting at the potential therapeutic strategies.

Core Tip: Implications of fast coronavirus disease 2019 (COVID-19) outbreak are huge annoying problems that affected countries' health and economies around the world. Patients associated with hepatic impairment are considered at a high-risk target for severe acute respiratory syndrome namely coronavirus 2 severity and mortality. A good understanding of virus machinery provides excellent ideas about how to combat this monster. We provide detailed information about the recent mechanisms of COVID-19 pathogenesis, implications on several hepatic disorders, and potential therapeutic strategies.

INTRODUCTION

Coronaviruses are classified into four categories, namely α, β, γ, and δ type. The α- and β-coronaviruses could infect mammals, while γ- and δ- coronaviruses appear to infect birds[1]. Six coronaviruses reported as human-affected viruses include α-coronaviruses NL63 and 229E, low-pathogenic β-coronaviruses OC43 and HKU1, these viruses cause mild respiratory symptoms as common cold[2]. The remaining two types were identified as β-coronavirus, which unusually induced fatal respiratory tract infections[3]. Between 2002 and 2003, severe acute respiratory syndrome (SARS) resulted in the outbreak of SARS0[4]. In 2012 the Middle East respiratory syndrome (MERS) originated and circulated in camels[5].

In 2019, a newly discovered coronavirus is a SARS coronavirus 2 (SARS-CoV-2), which induces a contagious disease coronavirus disease 2019 (COVID-19) and is currently spreading nationwide[6]. Consequently, the third identified zoonotic coronavirus detected after SARS and MERS cause potentially fatal respiratory tract infections[7,8]. The early cases of COVID-19 were linked to the Huanan seafood market, Wuhan, China[9,10].

On January 12, 2020, the World Health Organization (WHO) temporarily named this new virus the 2019 novel coronavirus (2019-nCoV)[11]. On January 30, 2020, the WHO declared the 2019-nCoV epidemic a public health emergency of international burden[11]. After that February 11, 2020, the WHO formally named the disease caused by 2019-nCoV as COVID-19[12]. On the same day, the international committee of taxonomy named this virus as SARS-CoV-2 and classified it as coronavirus under the family Coronaviridae, subfamily Orthocoronavirinae, based on the genotypic and serological characterization[11,13,14].

SARS-CoV-2 is a new generation of β-coronavirus which shares 79% and 50% genome sequencing with SARS and MERS, respectively[15]. This information confirmed some of the available evidence that SARS-CoV-2 was generated from bats and pangolins[14]. Other studies suggest that SARS-CoV-2 was a chimeric virus obtained from the fusion of a bat's coronavirus and a coronavirus of unknown origin[16]. In the same context, the study conducted by Sun *et al*[17] showed that the structure of SARS-CoV-2 was similar to the coronavirus isolated from Chinese chrysanthemum-headed bats in 2015. So far, no confirmation has been made of the zoonotic source of SARS-CoV-2 yet[18].

SARS-CoV-2 has a 29891-nucleotide genome (encoding 9860 amino acids)[19] with a diameter of about 50-200 nm[20]. Two-thirds of viral RNA, primarily in the first open reading frames (ORFs) (ORF1a/b), converts into two non-structural polyproteins pp1a, pp1ab, and encodes 16 non-structural proteins (NSP). In contrast, the remaining ORFs encode structural and accessory proteins[21,22]. Six ORFs of functions are arranged between 5′ to 3′ (ORF1a/ORF1b), spike glycoprotein (S), a small envelope protein (E), matrix protein (M), and nucleocapsid protein (N)[21]. Moreover, seven putative ORFs encoding accessory proteins are disseminated between the structural genes[23,24]. The glycoprotein S is responsible for the receptor-binding site and membrane fusion[25]. The envelope protein E has essential roles in releasing and accumulating viruses[26], besides protein M[27]. Additionally, a NSP plays many functions during the viral cycle[28].

SARS-CoV-2 AND ANGIOTENSIN-CONVERTING ENZYME 2

Only specific and permissive cells inside the host may be infected. Specifically, cells that generate proteins and viral factors which are required for virus replication. As soon as the virus enters the cell, the virus recruits cells to produce essential viral encoded proteins involved in replicating the virus's genetic material[29]. The viral replication process generally known as cytopathic effects, could induce biochemical changes resulting in cellular damage. Interestingly, SARS-CoV-2 relies on specific cellular receptors to invade the cells that carry these factors like other types of coronaviruses[30].

The surface of SARS-CoV-2 is covered by several types of glycosylated S proteins that facilitate the virus's attachment to the host angiotensin-converting enzyme 2 (ACE2), hence mediating the entry of the virus into the host cells[31]. This action could activate S protein by a specific type of serine protease located on the host cell membrane called TM protease serine 2. After the virus recruited the host cell, it releases its RNA and uses the host cells to replicate and synthesize its functional proteins[32].

SARS-CoV-2 is predicted to have organ tropism beyond the respiratory tract, also including the kidney, heart, skeletal muscle, central nervous system, liver, and gastrointestinal tract. The spread of infection through the body is reasonable for developing COVID-19 systemic symptoms and exacerbating pre-existing disorders[33,34]. Therefore, patients with severe COVID-19 illness show multiple organ damage, such as acute kidney injury, acute pulmonary injury, heart injury, and liver injury[35].

SARS-CoV-2 may induce liver injury *via* a similar mechanism. Furthermore, we cannot neglect angiotensin II's action; once SARS-CoV-2 binds to ACE2 receptors it stimulates angiotensin II to mediate the tissue injury[36]. These findings confirm that angiotensin II levels are increased in healthy patients with COVID-19 and are directly correlated with viral load[37].

Hepatic sharing of ACE2 receptors is unreasonable; it is widely distributed in the endothelial layer but not in the sinusoidal endothelium[38]. On the surface of cholangiocytes, ACE2 receptors have more significant expressions than hepatocytes[39]. Cholangiocytes ACE2 receptors expression was close to that of type II alveoli cells in the lungs, indicating that the liver may be a strong candidate for SARS-CoV-2[40]. In Contrast, Immunohistochemical stains for Kupffer cells and lymphocytes T and B for ACE2 are negative[41]. In fact, in patients with COVID-19, SARS-CoV-2 has been detected in their liver and can induce liver injury through different pathways[42]. The general mechanism of ACE2 mediated SARS-CoV-2 infection is outlined in Figure 1.

SARS-CoV-2 and devastating cytokine storm

Cytokine storm is an augmented cytokine output attributable to an irregular immune response to various stimuli like viral infections, rheumatic disorders, cancer, sepsis, multiple organ failure, and drugs that contribute to unnecessary immune cell activation[43]. Consequently, the rising aggressive systemic hyperinflammatory reaction is associated with the release of many pro-inflammatory cytokines responsible for critical illness[43,44]. Cytokine storm has been found in various viral infections, including influenza H5N1, H1N1 viruses, and two SARS-CoV and MERS-CoV coronaviruses[45-48]. Recent data reported that patients infected by SARS-CoV-2 show massive levels of cytokines and chemokines and are implicated with COVID-19 severity and high mortality rate[49].

The growing cytokine storm results in the continuous activation and expansion of innate and adaptive immune cells to produce a harmonized cascade of inflammatory responses, resulting in a devastating cytokine storm[50]. Indeed, the result of a mixture of several immune active molecules is the cytokine storm's product. The main components involved in forming the cytokine storm are interferons (IFNs) and interleukins (ILs)[51]. However, other inflammatory biomarkers such as c-reactive protein (CRP), fibroblast growth factor, macrophage-colony stimulating factor (M-CSF), interferon gamma-induced protein 10, monocyte chemoattractant protein-1 (MCP-1), macrophage inflammatory proteins-1α and 1β, platelet-derived growth factor, tumor necrosis factor-alpha (TNF-α), and vascular endothelial growth factor (VEGF) are markedly detected in the COVID-19 sever case-patients[52-54]. Hence, the uncontrolled response in severe COVID-19 patients is correlated with unfavorable clinicopathological consequences.

During COVID-19 illness, several pathological factors have been reported to participate in the initiation and propagation of SARS-CoV-2-induced cytokine storm (Figure 2).

Renin angiotensin-aldosterone system

The Renin-angiotensin-aldosterone system (RAAS) is a significant regulator of several physiology and pathophysiology conditions such as maintenance of fluid and electrolyte homeostasis with the maintenance of vascular tone[55,56]. Recent evidence implies that RAAS has autocrine and paracrine effects in addition to the classical circulating endocrine effects. Hence, RAAS plays pivotal roles in cellular growth, migration, differentiation, apoptosis, inflammation, thrombosis, and fibrosis[11,57-59].

When renin is secreted directly into the bloodstream by juxtaglomerular cells, this secreted renin cleaves the liver-released substrate, angiotensinogen, to generate the inactive peptide, angiotensin (Ang) I, which is then converted by endothelial ACE to Ang II[56,60]. On the other hand, ACE2 cleaves Ang I to produce Ang (1-9) peptide. Besides, Ang II and Ang (1-9) can metabolize by ACE or other peptidases to form Ang 1-7[61,62].

The RAAS is a double-edged sword that acts through two distinct opposing arms: the ACE/Ang II/AT1 receptor axis, which is responsible for main actions, and the ACE-2/Ang-(1-7) /Mas receptor axis, the counter-regulatory arm[63,64]. The ACE catalytic activity contributes to an increase of Ang II levels and an increase in Ang-(1-7) catabolism, while ACE2 catalytic activity is primarily based on Ang I and Ang II and leads to the formation of Ang (1-7)[64,65]. Ang II plays a central role in the RAAS *via* angiotensin II type 1 and 2 receptors (AT1R and AT2R); thus, stimulating the ACE/Ang II/AT1 receptor axis which results in regulating vasoconstriction, fibrotic remodeling, inflammatory response, and production of reactive oxygen species (ROS)[66]. Ang II itself will directly activate the nuclear factor-kappaB (NF-κB) pathway through the phosphorylation of the p65 subunit of NF-κB; therefore, increases the output of IL-6, IL-1β, TNF-α, and IL-10[67,68]. Ang II also affects mitogen-activated protein kinases (MAPKs; extracellular signal-regulated kinases 1/2, c-Jun N-terminal kinases, p38-MAPK), which have a high impact on pro-inflammatory cytokines release[68,69]. Besides, a spontaneous association of Ang II with host immune cells, *e.g.*, neutrophils, T and B lymphocytes, and tissue-resident cells results in the release of pro-inflammatory cytokines, including prostaglandins, IL-6, IL-1β, TNF-α, VEGF, and IFN-γ, as well as the activation of kinase plethora [*e.g.*, Janus kinase (JAK) and p38 MAPK][70,71].

As soon as the SARS-CoV-2 spike (S)-protein binds to ACE2[72], the serum level of Ang II was significantly increased, which in turn mediated trans-signaling of the IL-6/soluble IL-6 receptor-a complex in to finally activate of signal transducer and activator of transcription 3 (STAT3)[73]. STAT-3 has been reported to up-regulated

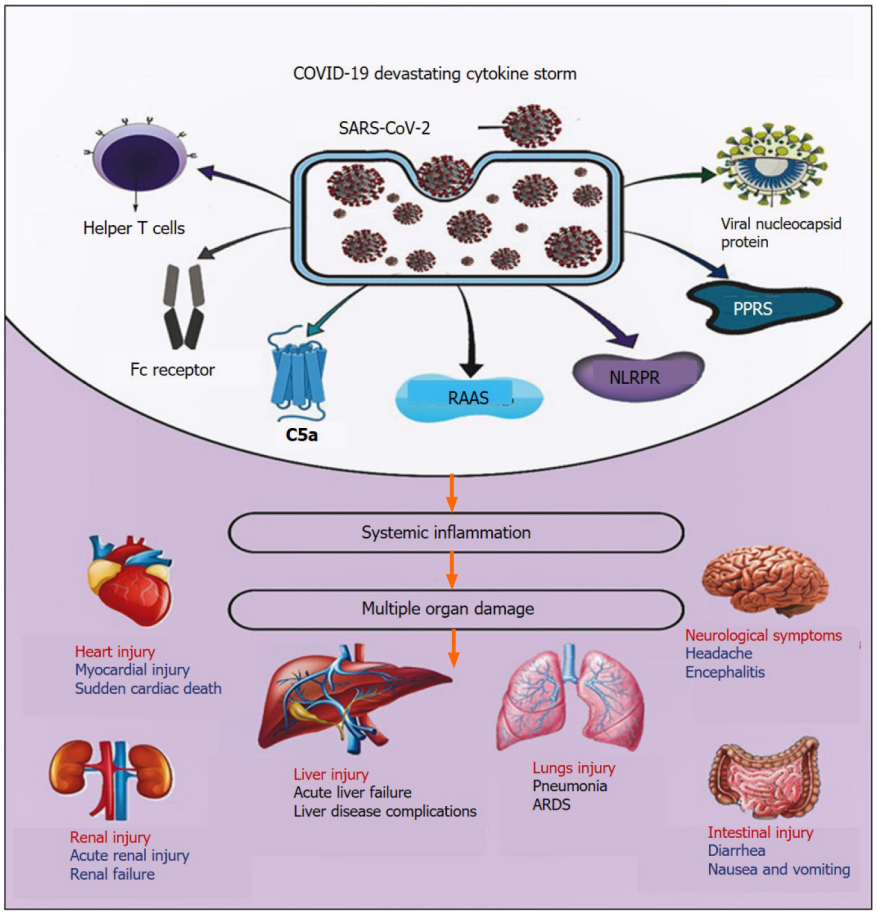

Figure 2 Coronavirus disease 2019 and devastating cytokine storm. COVID-19: Coronavirus disease 2019; SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2; C5a: Complement component 5a; RAAS: Renin-angiotensin-aldosterone system; NLRPR: Nucleotide-binding oligomerization domain, Leucine-rich repeat and pyrin domain-containing receptor; PPRs: Pattern recognition receptors; ARDS: Acute respiratory distress syndrome.

several inflammatory genes like NF-κB. Besides activation of NF-κB by SARS-CoV-2 mediated STAT3 activation, SARS-CoV-2 itself can activate NF-κB by binding with pattern recognition receptors (PRRs). The net results trigger a cytokine storm accompanied by acute respiratory distress syndrome (ARDS) and multiple organ damage[68,74]. During COVID-19, ACE2 depletion and ACE/Ang II/AT1R axis activity are highly augmented[75]. Therefore, a therapeutic modality by administering exogenous ACE2 to patients with COVID-19 can potentially impact COVID-19 severity[76]. On the other hand, targeting the ACE/Ang-II/AT1R axis downstream, such as the IL-6/STAT3 axis, should be considered to avoid ARDS inflammation and end-organ damage induced by cytokine storm[68,76].

In contrast to the ACE/Ang II/AT1R pathway, the Ang (1-7) interacts with the Mas receptor to provide vasodilation and antiproliferative effects[77]. Indeed, activating Mas receptors induce activation of phospholipase A, phosphoinositide 3 kinases/protein kinase B axis, endothelial nitric oxide synthase, and intracellular calcium accumulation[78]. Additionally, Ang (1-7) down-regulates p38 MAPK and NF-κB expression harmony with the suppression of inflammatory markers such as IL-6, IL-8, and TNF-α[68]. Furthermore, Ang (1-7) *via* the Mas receptor activation attenuated Ang II-induced intercellular adhesion molecule-1, vascular cell adhesion molecule-1, and MCP-1[68,79]. Together, activation of these pathways suggests that Ang (1-7) has antiproliferative, anti-thrombotic, and anti-inflammatory functions and ameliorates tissue damages[70,78].

Interestingly, down-regulation of the ACE-2/Ang (1-7)/Mas receptors axis was proposed to be increased during COVID-19; since the virus uses the enzyme's peptidase domain to enter into the cells, there is a down-regulation of ACE-2 with ACE up-regulation[63]. Thus, it contributes to a massive release of cytokines and inflammatory responses. Since Ang (1-7) plays a critical role in counteracting the pro-inflammatory activity of RAAS, it has been proposed that Ang (1-7) or one of its associated agents could be administered to patients with COVID-19 since it protects against activation of inflammatory mediators in a cytokine outbreak[68]. Additionally,

Ang (1-7) was previously reported to inhibit liver fibrogenesis[80]. Thus, it may be helpful to attenuate liver injury in patients with liver impairments infected with SARS-CoV-2.

Fc receptor

SARS-CoV-2 is a specific antibody with the Fc receptor. Indeed, SARS-CoV-2 recruits several immune cells, *e.g.*, granulocytes, monocytes, and macrophages, and activates the complement cascade, resulting in high virus reproduction and violent infection[81,82]. Since the liver includes several cells related to the immune response, so, antibody-dependent, ACE2-independent pathway was activated[83]. As a result, SARS-CoV-2 infection overactivated and secreted excessive amounts of cytokines and chemokines such as TNF-α, IFN-γ, IL-6, IL-8[82].

Viral nucleocapsid proteins

Viral nucleocapsid proteins fused with the infected cells' host cell membrane, which permits the viral nucleocapsid protein to stay on the surface of the cell membrane[84]. This fusion makes the proteins easily recognizable by antigen-presenting cells that activate the immune response[83]. The normal antigen-presenting cells are dendritic cells, macrophage cells, monocytes, plasma cells, *etc.*, introduced to viral particles CD8+ cytotoxic and CD4+ regulatory T lymphocytes, the major histocompatibility complexes[85].

PRRs

Several PRRs are the first line receptors that detect pathogenic infection like SARS-CoV-2. After the virus enters the body, it produces pathogen-associated molecular patterns (PAMPs), which recognizes by PRRs and fires the standard innate immune system[86]. The membrane-bound toll-like receptor (TLR) family among PRRs, predominantly recognizes PAMPs in the extracellular system and to a lesser degree in the intracellular milieu[87]. Activation of this signal contributes to increasing the expression of transcription factors that induce pro-inflammatory cytokine production, such as NF-κB, and activate immune defense against viral infection *via* the IFN type I pathway[85,88].

Nucleotide-binding oligomerization domain, Leucine-rich Repeat and Pyrin domain-containing (nod-like receptor protein) receptor

Another family of pathogenic detecting receptors is nod-like receptor protein (NLRP) receptors (NLRP1, NLRP3, NLRP7, and NLRC4), which are the cytosol of endogenous danger-associated molecular patterns expressed inside the cell[89,90]. The activation of these receptors by SARS-CoV-2 has been reported to associate with the adhesion of molecules' activation, inflammatory response, and triggering innate immune cells[91]. This reaction contributes to the activation of pro-inflammatory mediators cytokines production such as TNF-α, IL-1, IL-6, IL-10, or type 1 interferons[92,93].

T-helper type 1 cell

The T-helper type 1 (Th1) cell response can be triggered by the elevation of inflammatory cytokines, which plays a significant role in providing a memory response against the virus and adaptive immunity. It is essential to coordinate humoral and cytotoxic T cell responses during viral infections[94]. Besides, elevated levels of Th2 cells secrete cytokines in patients with COVID-19, *e.g.*, IL-4 and IL-10, which inhibit inflammatory responses[95]. Furthermore, there was a significant increase in cytokines secreted by Th1 and Th2 cells, such as TNF-α, IL-6, IL-18, IL-4, and IL-10. Additionally, IL-2 and IL-6 are significantly elevated in patients with COVID-19 and correlate with the disease's seriousness[96]. Interestingly, hepatocytes, Kupffer cell, and hepatic stellate cells after being infected with SARS-CoV-2 immune cells after overactivation and secretion of excessive cytokines, *e.g.*, IL-6, IL-8, TNF-α, IFN-γ, which are involved in severe cytokine storm and causes tissue damage[85,97]. Compared to a reduced level of naive B cells, plasma B cells significantly increased in COVID-19 patients, several naive B-cell receptor isotypes [immunoglobulin heavy chain (IGHV) 3-15, IGHV3-30, and IGHV3-11] were previously used in the manufacture of other virus vaccines which were also reported and identified in patients[98]. Furthermore, the novel target genes in cytokine storm are IL-1β, IL-6, and the granulocyte-macrophage colony-stimulating factor (GM-CSF), while TNFSF13, IL-18, IL-2, and IL-4 seemed to help patients' recovery from COVID-19[99].

Complement activation

Viral infection has been reported to stimulate the complement cascade and consequently, initiate specific inflammatory responses[100]. Among these complements, complement factor 5a (C5a) is the most potent inflammatory peptide in the complement cascade, which increases the production of pro-inflammatory cytokines such as IL-6, IL-1, and TNF-α from macrophages under the effect of TLR-2, TLR-4, and TLR-9[101,102]. Terminal complement variable C5b-9 stimulates the release of IL-6 from vascular smooth muscle cells by stimulating the redox-sensitive transcription factor NF-κB, activator protein 1, and MCP-1[68,100]. Besides, C3a overexpression results in increased production of IL-1, IL-6, and TNF-α[103].

The complement cascade plays aberrant pivotal roles in the pathogenesis of SARS-CoV-2. It promotes viral nucleocapsid protein-mediated auto-activation of mannan-binding lectin serine peptidase-2 (MASP-2)[104]. Indeed, MASP-2 is considered the main serine protease in the lectin pathway. It binds to the mannose-binding lectin pathway to induce the downstream complement cascade, which in turn accelerates inflammatory responses. In two patients with COVID-19 who received an anti-C5a antibody, a positive clinical response was improved as evidence by enhancing lung oxygenation and alleviating systemic inflammation[105,106]. Hence anti-C5a antibodies could be a new therapeutic option for combating COVID-19 severity.

COVID-19 and hepatic dysfunction

Patients with digestive issues and co-infected with SARS-CoV-2 show a higher risk of mortality than patients without digestive problems. In severe cases of COVID-19, liver dysfunction was observed and associated with extensive activation of coagulative and fibrinolytic pathways as well as alteration of platelets, neutrophils, and lymphocytes profiles[8]. In parallel, patients with chronic liver disease (CLD), hepatitis viruses [hepatitis B virus (HBV), hepatitis C virus (HCV), hepatitis D virus, and hepatitis E virus], hepatotropic viruses infection, non-alcoholic fatty liver disease, and non-alcoholic steatohepatitis are more susceptible to COVID-19 and may present worse outcomes from ARDS compared with the other critically ill patients[82,107]. Alqahtani *et al*[108] performed a meta-analysis that showed that patients with a previous history of liver disease have a 57.33% chance of severing COVID-19 infection and a 17.65 % higher mortality rate than other patients[108]. A recent multicenter cohort study showed that hepatic decompensation was positively associated with COVID-19 disease, which increasing the risk of death from 26.2% to 63.2%[109]. This rate could be related to low platelets and lymphocytes in those patients or due to cirrhosis-related immune dysfunction[97]. Besides, COVID-19 is markedly distinguished by an increase in cytokine secretion, which induces hepatocytes injury, contributing to the loss of hepatic regeneration and worse clinical outcome, especially in patients with CLD[97,110]. In contrast, Lippi *et al*[111] indicated that CLD plays a minor role in affecting patients' progression, severity, or mortality[111].

The pattern of liver damage in COVID-19 is essentially considered during COVID-19. The liver injury can be associated with the virus's immediate cytopathic effect, unregulated immune response, sepsis, hypoxia, and drug-inducing liver injury[112,113]. Also, COVID-19 causes underlying chronic hepatic disorders to exacerbate and contributes to liver decompensation with higher mortality[114]. Recent general studies show that about 2%-11% of COVID-19 patients have underlying CLD, and 14%-53% developed hepatic dysfunction with COVID-19[8,14,115,116]. In patients with severe COVID-19, the ratio of hepatic injury is highly set in contrast to mild patients' rate. Hence, hepatic injury frequency can represent 58.06%, 51%, and 78% in patients' death from COVID-19[14]. Cai *et al*[117] conducted a study on 417 patients with COVID-19 which showed that about 76.3% of patients had abnormal liver test results and 21.5% exhibited liver injury during hospitalization[117]. Li *et al*[118] indicated that patients with abnormal liver activity (58.8% and 66.7%) could be more likely to have moderate to severe COVID-19[118].

It is understood that cholangiocytes play an essential role in liver regeneration and immune response, and cholangiocytes ACE2 expression is greater than that of hepatocytes[38,116,119]. Thus, it was proposed that the liver injury that resulted in SARS-CoV-2 infection could be due to the damage caused by virus infection to bile duct cells and not liver cells[113]. The expression of ACE2 in cholangiocytes was also observed, it is about 20 times higher than in hepatocytes[13]. Additionally, gamma-glutamyl transferase, a diagnostic biomarker for cholangiocyte injury, has also been identified to be highly up-regulated in severe cases of COVID-19[120,121]. However, aspartate aminotransferase (AST) and alanine aminotransferase (ALT) are elevated predominantly in COVID-19. Generally, it is 1-2 times more than the normal range,

which averages to modestly elevated total bilirubin (TBIL) levels early in the disease process[112,115,116]. On the contrary, the study conducted by Chen *et al*[122] showed an elevation of ALT and AST serum levels to 7590 U/L and 1445 U/L, respectively, in patients with severe COVID-19[122].

Several studies have found that AST, ALT, and TBIL were substantially higher in the intensive care unit (ICU) patients than in non-ICU patients[123,124]. A retrospective cohort study performed by Hundt *et al*[125] reported abnormal liver tests [AST, ALT, Alkaline phosphatase (ALP), and TBIL] in the patients with COVID-19. Most patients with abnormal liver tests had an elevation limit of 1-2 times more than the normal limits. It has also been reported that abnormal liver tests were directly proportionated with poorer clinical outcomes[125].

Hypothesizes of hepatic injury during COVID-19 illness

Hepatic injury in COVID-19 patients could result from a cytokine storm rather than direct cytopathic effects of the virus itself[112,113,126]. The direct cytopathic effects of SARS-CoV-2 can induce stress on endoplasmic reticulum and mitochondrial dysfunction[127]. Moreover, the human body can initiate immune-mediated inflammation, such as cytokine storm resulting in liver damage or hepatic failure in critical COVID-19 patients[128-130]. Hypoxia is also a common characteristic of extreme COVID-19 illness that promotes ROS production and initiates the release of multiple pro-inflammatory factors to induce more liver damage[82]. Electron microscope examination of liver obtained from patients infected with SARS-CoV-2 revealed that SARS-CoV-2 causes endoplasmic reticulum tension that induces de novo lipogenesis. Lipogenesis could also contribute to the production of non-specific inflammatory changes, including hepatocyte swelling and steatosis, mild hepatic sinus cell proliferation, and Kupffer cell hyperplasia[82].

Effect of SARS-CoV-2 on several types of liver disorders

As we mentioned before, SARS-CoV-2 is remarkably impactful on patients with chronic diseases, including chronic hepatic impairments. The impact of SARS-CoV-2 on several types of liver disorders is outlined in Table 1.

Non-alcoholic fatty liver disease and COVID-19

Several studies have documented that obesity is a significant mortality factor in COVID-19 patients. The need for overall survival and mechanical ventilation correlated with obesity[131]. Typically the ACE2 expression level in adipose tissue is greater than that of lung tissue[97]. These clarify adipose tissue's susceptibility to invasion by SARS-CoV-2, and then the virus can spread to other organs[132]. Obese patients are at high risk for non-alcoholic fatty liver disease (NAFLD), which in turn has a higher chance of developing severe COVID-19 with a higher probability of abnormal liver function and a more extended viral shedding period[133]. NAFLD is associated with the development and severity of COVID-19[97,133]. NAFLD patients also elevate cytokine levels, rendering them more vulnerable to COVID-19 related to excessive cytokine production[134]. Experimentally, it has been shown that ACE2 expression increases in chronic liver damage and NAFLD[135]. Patients with COVID-19 exhibit increased serum levels of MCP-1, which exacerbate steatohepatitis; thus, the virus can increase NAFLD progression to Non-alcoholic steatohepatitis (NASH)[136]. Multicenter retrospective by Hashemi *et al*[137] study the clinical outcome of COVID-19 and CLD. Patients with high NAFLD require ICU admission and mechanical ventilation. There is no overall mortality among CLD patients mainly due to NAFLD[137]. According to the evidence available, NAFLD is an independent risk factor for extreme COVID-19, but most studies did not separate NAFLD from its more extreme NASH[138].

Liver cirrhosis and COVID-19

Patients with liver cirrhosis have a potentially higher risk of SARS-CoV-2 infection, a higher risk of a severe condition, and a higher risk of liver decompensation[139]. Liver cirrhosis in SARS-CoV-2 infected patients is described as a predictor of mortality[140,141]. A decrease in ACE2 *via* SARS-CoV-2 induced internalization is predicted to exacerbate liver fibrosis and augment the disease's severity, especially in the long term. Therefore, the impact of COVID-19 on long-term liver-related outcomes is also worth considering in patients with cirrhosis[142]. A multicenter matched cohort study by Kushner and Cafardi[139] patients with cirrhosis plus COVID-19 were observed to have mortality equal to cirrhosis patients alone higher than those with COVID-19 alone[139]. Sarin *et al*[143] The APCOLIS study of pre-existing liver disease indicated that in CLD patients,

Table 1 Implication of severe acute respiratory syndrome coronavirus 2 on patients with hepatic disorders

Hepatic disorders	Main findings of the study	Ref.
NAFLD	NAFLD is associated with a higher risk of symptomatic, severe, and progressive COVID-19	Hashemi *et al*[137], 2020
	SARS-CoV-2 infection in patients with NAFLD required ICU admission and mechanical ventilation concomitant with increased NAFLD progression to NASH	Sachdeva *et al*[212], 2020
Liver cirrhosis	Patients with liver cirrhosis and COVID-19 are related to worse clinical outcomes and a high mortality rate than patients with COVID-19 alone	Kushner and Cafardi[139], 2020
	SARS-CoV-2 co-infection augmented liver injury as evidenced by worsens decompensated clinical status	Sarin *et al*[143], 2020
	Cirrhotic patients with COVID-19 had a higher risk of mortality than COVID-19 patients alone, but they are equally mortality rate with cirrhosis patients without COVID-19	Bajaj *et al*[144], 2021
HCC	Patients with HCC consider a risk group, and HCC is positively related to deterioration symptoms and bad outcomes in COVID-19	Zhang *et al*[213], 2020
	Patients with cancer are more susceptible to infection and poorer prognosis of COVID-19	Liang *et al*[147], 2020
Hepatitis B	Patients infected with HBV tend to have a more severe form of COVID-19	Chen *et al*[150], 2020
	SARS-CoV-2 and HBV co-infection showed monocytopenia, lymphopenia, and thrombocytopenia, as well as metabolic disorders	Liu *et al*[151], 2021
	COVID-19 may induce HBV reactivation, but it rarely occurs	Aldhaleei *et al*[152], 2020
Hepatitis C	Patients infected with HBV or HCV showed a high risk of mortality and morbidity if co-morbid with COVID-19	Mirzaie *et al*[155], 2020
	Patient with hepatic c and COVID-19 has an undesirable clinical outcome	Mostardeiro *et al*[156], 2020
	HCV pre-existing was associated with high mortality	Mangia *et al*[157], 2020

NAFLD: Non-alcoholic fatty liver disease; HCC: Hepatocellular carcinoma; NASH: Non-alcoholic steatohepatitis; SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2; COVID-19: Coronavirus disease 2019; HBV: Hepatitis B virus; HCV: Hepatitis C virus; ICU: Intensive care units.

SARS-CoV-2 infection causes severe liver damage, decompensating one-fifth of the cirrhosis and worsening the already decompensated clinical status[143]. Bajaj *et al*[144] multicenter North American contemporaneously enrolled study, compared to patients with cirrhosis alone or cirrhosis and COVID-19 patients had similar mortality rate, but higher than patients with COVID-19 alone[144].

Hepatocellular carcinoma and COVID-19

In general, cancer patients, especially those who have recently received cancer treatment, have a greater chance of infection and a worse outcome. Besides, epidemiological data suggest that patients with cancer are more vulnerable to SARS-CoV-2 infection[145]. Hepatocellular carcinoma (HCC) is the sixth most prevalent cancer globally, accounting for about 6% of all cancer incidences[146]. HCC patients are more susceptible than other cancers to the consequences of the COVID-19 pandemic since the liver damage caused by SARS-CoV-2 could complicate current hepatitis in most HCC patients[146]. A retrospective cohort study by Yang *et al*[96] confirmed that cancer patients had deteriorating symptoms and bad results from SARS-CoV-2 infection[96]. Besides, these patients have poor nutritional status-related anemia and hypoproteinemia that impair their immunity, rendering them more vulnerable to severe disease[96].

A prospective nationwide cohort study in China on cancer patients, including HCC patents and COVID-19, was more vulnerable to severe disease. They had an increased chance of mortality and ICU admission. Recent chemotherapy within a month also increased the risk of severe disease[147]. Most HCC and CLD patients fall into a high-risk group and are expected to have worse outcomes[114]. Vigorous screening for COVID-19 disease should be prescribed in cancer patients undergoing antitumor therapy, and medications that induce suppression of immunity should be stopped, or their dosages decreased in the event of COVID-19[148].

Hepatitis B and COVID-19

For patients with chronic hepatitis B and are in the immune tolerance phase, further tests are required to confirm whether these patients have active viral replication and repeated liver damage after co-infection with SARS-CoV-2[82]. Several Chinese clinical

trials have found patients with hepatitis B infection are also present among patients with severe COVID-19 cases. That suggests that patients infected with HBV tend to have a more severe form of SARS-CoV-2[85,149]. Chen *et al*[150] found that 47% of patients with HBV are observed with severe COVID-19 cases[150]. However, other studies have shown that chronic viral hepatitis does not seem to be proportional to the severity of COVID-19[115]. Liu *et al*[151] retrospective study reported that COVID-19 was not substantially affected by co-infection with HBV. However, at the onset of COVID-19, patients co-infected with SARS-CoV-2 and HBV showed more severe monocytopenia, thrombocytopenia, hypoalbuminemia, and hepatic deficiency in lipid metabolism[151]. SARS-CoV-2 and HBV co-infection produces lymphopenia that can cause HBV reactivation. However, it has been reported just in one case of a patient with potential HBV reactivation, which seems to be an unusual event[152]. Chinese medical association and Chinese society of hepatology indicated that patients with hepatitis B administrated antiviral therapy, discontinuation of anti-HBV drugs, or failure to receive anti-HBV treatment can lead to the reactivation of HBV, especially during SRSA-CoV-2 infection following high-dose hormone therapy[82].

Hepatitis C and COVID-19

HCV infection is a dominant factor for liver diseases, including liver cirrhosis, hepatocellular carcinoma, and a common liver transplantation cause[153]. All over the world, HCV infection is the primary cause of liver-related mortality and morbidity[154]. Similarly, the symptoms of hepatic impairments are widespread among patients with COVID-19 and HCV[155]. Therefore, the American associations of liver disease evaluated the underline liver diseases' status, *e.g.*, hepatitis A, hepatitis B, and hepatitis C, in COVID-19 patients and found that co-infection between HCV and SARS Cov-2 increased liver enzyme levels, especially in pediatric[112]. Besides, a systematic preprint review by Mirzaie *et al*[155] suggested that patients with hepatitis B and/or hepatitis C present a high risk of morbidity to COVID-19 and require further investigation to overcome a significant marker of mortality due to co-infection[155]. Mostardeiro *et al*[156] reported that in a case study patient with hepatitis C and COVID-19 co-morbidity has an undesirable clinical outcome[156]. Correspondingly, a cohort study by Mangia *et al*[157] has been elucidated that HCV pre-existing associated with high mortality; meanwhile, HCV antibodies suggestive as a protective agent against COVID-19[157].

On the other hand, countries co-operated and adapted to develop a screening model to detect HCV as a hepatitis elimination program[158]. Nowadays, due to the spreading of the COVID-19 pandemic, it extends beyond the direct morbidity and mortality associated with coinfection COVID-19 may act as a barrier to reduce hepatitis C care, result in a decrease in HCV serological testing and identification[159]. Hence, Blach *et al*[160] based on their mathematical models, predicted scenario of the 1-year delay which resulted in an additional 44800 liver cancers and 72300 deaths from HCV globally by 2030[160]. Thus, rapid HCV testing in the context of SARS-CoV-2 screening programs may be the only solution for achieving the WHO's 2030 HCV elimination target[161].

Therapeutic approaches for aborting COVID-19 cytokine storm

As mentioned before, SARS-CoV-2 infections may cause cytokine storm to result in hyperactivation of T lymphocytes and release massive amounts of cytokines such as IL-6, IL-1β, TNF-α, and others[162]. Neutralization of these cytokines offer an excellent therapeutic avenue in combating the COVID-19 outbreak. Here, several therapeutic options can be used for terminating SARS-CoV-2-induced cytokine storm.

IL-6 inhibitors

IL-6 acts as a critical catalyst during cytokine storm, specifically during COVID-19[163]. Hence, IL-6 may be the main accused acute phase response, including fever, the elevation of CRP and ferritinemia, ARDS, multiorgan damage in cases of severe COVID-19[90,164]. Anti-IL-6 biologics targeted the IL-6 receptor or IL-6 itself with anti-inflammatory properties[44]. So, anti-IL-6 agents like tocilizumab, siltuximab, and sarilumab are all humanized monoclonal antibodies that are generated to the IL-6 receptor[165,166]. Currently, tocilizumab (TCZ) is used in active rheumatoid arthritis, juvenile idiopathic arthritis, autoimmune rheumatic diseases[165,167], temporal arteritis, and giant-cell arteritis[168]. Recently, TCZ is used to attenuate the adverse effects of the cytokine storm-induced by chimeric antigen receptor T cell treatment[169,170]. Giving TCZ a potential therapeutic option for critically ill patients with COVID-19 who have a significant elevation in the level of IL-6[171]. However, the treatment of COVID-19 with TCZ is an off-label use[172]. However, based on existing evidence, it could be a right and

safe choice to compete with cytokine storm during COVID-19. A retrospective study by Nasonov and Samsonov[172] indicated that tocilizumab directly enhances clinical outcomes in severe and critical COVID-19 patients, no noticeable adverse reactions were observed, and it is effectively reducing mortality[172]. Another retrospective study by Luo *et al*[173] reported that in COVID-19 patients with a risk of cytokine storm, TCZ is an excellent treatment choice. They are also recommended a repeat dose of TCZ for severe COVID-19 patients with elevated IL-6[173]. Because of its common uses in rheumatoid arthritis and other auto-inflammatory disorders, TCZ hepatic side effect is well known. Typically mild elevations of serum aminotransferase are observed[174]. In contrast, TCZ may be correlated with HBV reactivation. Hence, HBV serological test could be a part of routine pretreatment work-up[175].

IL-1 inhibitors

IL-1 is an active pro-inflammatory cytokine secreted during cytokine storm[49]. It can lower pain thresholds, on the other hand it is one of the cytokines playing a dominant role in tissue damage[176,177]. The IL-1 receptor antagonist, anakinra, canakinumab, and Rilonacept are already indicated in conditions characterized by sustained fevers and systemic inflammatory response such as rheumatoid arthritis, familial Mediterranean fever, and cryopyrin-associated periodic syndrome[169]. Anakinra is the first biologic recombinant IL-1R antagonist. Anakinra inhibits both IL-1α and IL-1β *via* competitively IL-1R binding[178]. As previously reported, anakinra is effective in attenuating cytokine storm[169,178]. These promising results suggest the role of anakinra in combating CS in patients with COVID-19[179]. A retrospective cohort study by Huet *et al*[180] showed that in patients with COVID-19, anakinra decreased both the need for invasive mechanical ventilation in the ICU and mortality rate without significant side effects[180]. Anakinra is not a hepatotoxic agent but is more likely to indirectly trigger acute liver damage through activity against IL-1 or the immune system. Moreover, it has not been related to hepatitis B reactivation[181].

TNF-α inhibitors

The viral spike protein of SARS-Cov2 induced a TNF-α converting enzyme-dependent shedding of the ACE2 ectodomain, facilitating viral penetration into cells and promoting tissue injury *via* increased TNF-α production[90,182]. TNF-α is a crucial cytokine produced in all inflammatory conditions, and autoimmune diseases stimulate inflammation and oxidative stress production. TNF-α is mainly produced by monocytes, macrophages, B cells, and other tissues[93,183]. Activation of TNF-α increases IL-1 and IL-6 release[49]. TNF-α inhibitors such as adalimumab, etanercept, and infliximab are used to manage several conditions like rheumatoid arthritis, ankylosing spondylitis, psoriatic arthritis, and inflammatory bowel disease[88,169]. Consequently, attenuate IL-6, IL-1, and VEGF levels as well as adhesion molecules and angiogenic factors. In patients with COVID-19, both plasma and tissues show an excessive amount of TNF-α[184]. Therefore, the anti-TNF-α antibody markedly reduces TNF-α in the blood, indicating that anti-TNF-α antibody could have potential anti-inflammatory benefits during COVID-19[185]. Additionally, it may cause downregulation of ACE2 expression and shedding[186,187]. So far, in treating patients with COVID-19, TNF-α blockers have not been proposed, but TNF-α blockers' effectiveness in treating patients with COVID-19 needs more priority[188,189].

JAK/STAT inhibitors

The JAK family and the adaptor-associated protein kinase 1 (AAK1) is a member of the numb-associated kinase family that plays a role in viral particles endocytosis, which act as a regulator of clathrin-mediated endocytosis[190,191]. Inhibitors of AAK1 can prevent viral particles entry into the cell[40,50]. Phosphorylated cytokine receptors recruit STAT transcription factors that modulate gene transcription. Furthermore, inhibiting activated cytokine receptors' phosphorylation through Janus kinase inhibitors, which could suppress cytokine signaling pathways[165]. Thus, AAK1 inhibitors have been suggested as possible candidates for the treatment of COVID-19. By inhibiting the JAK-STAT pathway, and cellular viral entry in COVID-19[192,193]. Janus kinase inhibitors such as baricitinib, filgotinib, fostamatinib, peficitinib, tofacitinib, and upadacitinib are previously indicated in managing the treatment of rheumatoid arthritis and autoimmune diseases[194,195]. Baricitinib is a JAK inhibitor with an extreme affinity to AAK1-binding[190]. Therefore, it inhibits the JAK-STAT pathway, that is used to suppress pro-inflammatory cytokine and attenuate the risk of cytokine storm[191,196]. Baricitinib is supposed to have dual effects in COVID 19 patients *via* reducing viral cell entry and inflammation[190]. One consideration related to the use of Baricitinib could be

superior to other JAK-STAT signaling inhibitors, as it is relatively safe[190,197]. However, baricitinib is in harmony with increased thromboembolic events, which affect the risk of developing these events in patients with COVID-19[198]. However, it is also probable that the JAK inhibitors might affect the activity of numerous cytokines, *e.g.*, INF-α, a potent mediator of antiviral response, may be impaired by JAK inhibitors[199]. Data by Bronte *et al*[200] suggests that baricitinib prevented the progression of COVID-19 by regulating patients' immune response, accordingly improving clinical outcomes[200].

Corticosteroids

Corticosteroids have a broad spectrum of cellular immune responses, different pharmacological activity, and wide therapeutic applications[201,202]. Glucocorticoids can inhibit innate and adaptive immune responses which are significantly used in inflammatory conditions and autoimmune disorders[203]. These anti-inflammatory and immunosuppressive effects occur in different mechanisms through direct actions on gene expression, transcription factors, and glucocorticoids' receptors' second messenger cascades[203]. Corticosteroids receptor complex induces gene transcription of many anti-inflammatory genes, involving IκB, which have immunosuppressive effects by inhibiting the activation of NF-κB signaling resulting in downregulation of IL-1β, IL-4, IL-10, IL-13, GM-CSF, TNF-α, and transforming growth factor-β[165,204,205].

Additionally, Corticosteroids reduce T cells and macrophages proliferation, activation, differentiation, and survival. Corticosteroids diminishes Th1 and macrophage pro-inflammatory cytokines IL-1β, IL-2, IL-6, TNF-α, and IL-17[206,207]. The uses of corticosteroids suppress the immune response, reduce viral clearance, and provoke viral replication[202]. Corticosteroids are widely used in critically ill patients with SARS and MERS infections[44]. Evidence has shown that corticosteroids' delayed their viral clearance[201]. The controversy on the use of corticosteroids remains far from definitive in COVID-19 patients. Corticosteroids decrease the pro-inflammatory cytokine's transcription, thus avoiding prolonged cytokine reaction and cytokine storm[208]. It allows corticosteroids in low doses and short duration and specific conditions with COVID-19 and requiring respiratory support the wat to survive[209]. In patients with COVID-19, trials indicated that dexamethasone in low dose, *i.e.*, 6 mg once daily orally for ten days reduced the death rate by one-third in patients who undergo ventilation and one-fifth in patients with oxygen supplementation[210]. Today, dexamethasone is widely used in severe COVID-19, including in patients with pre-existing CLD[211].

CONCLUSION

The outbreak of COVID-19 disease is the most annoying problem all over the world. This situation was developed due to a mutant version of the SARS virus called the SARS-CoV-2 virus. Studying the virus structure, mode of infection, and pathogenesis mechanism provided excellent hints about how we can fight it. In this review, we concluded that the most destructive power of the virus is the generation of violent cytokine storm, which is probably the cause of high mortality rates in hepatic and non-hepatic patients. Moreover, this review concluded that the possible ways to combat aggressive cytokine chaos might be a potential therapy for the COVID-19 patient co-morbid with liver disorders. Finally, this review encourages the scientists to study the SARS-CoV-2 virus cytokine storm in deep to find more effective and promising therapy for COVID-19 illness.

Abstract

Faecal incontinence (FI) is a debilitating common end result of several diseases affecting the quality of life and leading to patient disability, morbidity, and increased societal burden. Given the various causes of FI, it is important to assess and identify the underlying pathomechanisms. Several investigatory tools are available including high-resolution anorectal manometry, transrectal ultrasound, magnetic resonance imaging, and electromyography. This review article provides an overview on the causes and pathophysiology of FI and the author's perspective of the stepwise investigation of patients with FI based on the available literature. Overall, high-resolution anorectal manometry should be the first investigatory tool for FI, followed by either transrectal ultrasound or magnetic resonance imaging for anal internal sphincter and external anal sphincter injury, respectively.

Key Words: Incontinence; Manometry; Ultrasound; Rectal; Magnetic resonance imaging; Faecal

Core Tip: Faecal incontinence (FI) is a debilitating symptom, which causes severe disability that deeply affect patients' quality of life. Given the various causes of FI, it is important for clinicians to recognize the available diagnostic investigatory tools and be familiar with the clinical approach for FI. Herein, we provide a concise overview of FI and recommend a stepwise algorithm for FI investigation.

INTRODUCTION

Faecal incontinence (FI) is defined as the recurrent involuntary passage of rectal contents (solid or liquid stool) through the anal canal, and the inability to delay evacuation until socially convenient. Crucial factors to consider when defining FI include the duration of symptoms for at least 1 mo and age of onset of at least 4 years with previously attained control[1-3]. FI is considered to be a prevalent disorder with a considerable economic burden, but due to embarrassment, it is generally underreported; hence, its true prevalence is challenging to assess[4]. The prevalence of FI in the adult population of the United States is estimated to be 0.8%-6.2%[5]. The prevalence of FI increases with age from approximately 3% in the age group of 20 to 29 years to 16% in people aged ≥ 70 years[6]. A systematic review by Sharma *et al*[7] of over 30 studies estimated a prevalence of 1.4% to 19.5%. This discrepancy was clarified by variance in data collection methods applied and FI definition. Unsurprisingly, lower rates of FI were reported in personal interviews compared with anonymous questionnaires. The prevalence of FI is similar in both males and females, while the pathogenesis is often dissimilar between sexes.

FI has important consequences on social activities and quality of life as well as significant economic burden attributable to diagnostics, medications, instruments, procedures, and reduced work ability[8]. FI is regularly classified from a clinical point of view as: urge incontinence (discharge despite active efforts to constrict anal sphincters), passive incontinence (involuntary discharge with no awareness), and faecal seepage (leakage of stool with normal continence and evacuation)[2].

Numerous causes and associated conditions are linked to FI such as anal sphincter dysfunction, rectal disorders, neurological diseases, malignant diseases, psychiatric conditions, and other disease[8]. One major challenge in the management of FI is the hitch in correlating objective with subjective parameters.

In this review article, we shed light on the clinical evaluation and workup of patients with FI, from history taking to diagnostics including high-resolution anorectal manometry (HRAM), transrectal ultrasound (TRUS), perineal ultrasound, magnetic resonance imaging (MRI) of the pelvic floor including MR proctography, and nerve studies such as anal sphincter electromyography (EMG). The purpose of the review is to provide a practical tool box for clinicians to use when evaluating patients with FI.

CAUSES AND RISK FACTORS OF FAECAL INCONTINENCE

FI represents a final pathway of several traumatic and non-traumatic disorders. The most non-traumatic causes include anal sphincters and rectal dysfunctions as well as various inflammatory, congenital, structural, metabolic, neurological, muscular, psychological and functional diseases (Table 1). Alterations in bowel habits, such as diarrhoea for any reason (including inflammatory bowel disease, irritable bowel disease) and constipation with paradoxical diarrhoea and overflow incontinence are considered to be among the most established risk factors for FI[9]. The most common anal sphincters structural traumatic causes leading to FI are related to obstetrical trauma during vaginal delivery, anorectal surgical procedures including anorectal dilation, haemorrhoidectomy, fistulotomy, fistulectomy, sphincterotomy, rectal prolapse repair, and after ileo-anal reconstructive surgeries[10-12]. Many patients with neurological disorders affecting the brain, spinal cord or peripheral nervous system have FI because of impaired anal sphincter control, reduced or absent anorectal sensibility or abnormal anorectal reflexes. Patients with diabetes may have neuropathy of the anal canal and some have chronic diarrhoea. Connective tissue diseases, remarkable scleroderma, myopathy and atrophy of the internal anal sphincter (IAS) may lead to FI. Rectal surgery may disturb the reservoir function of the rectum as seen in patients after anterior resection surgery. Additionally, pelvic radiotherapy may lead to FI.

Table 1 Organic causes of faecal incontinence

Congenital neurological	**Spina bifida**
Acquired neurological	Pudendal neuropathy; Spinal injury/surgery; Demyelinating diseases; Degenerative diseases; Neurological malignancy
Congenital structural disease	Imperforate anus; Cloacal anomalies
Acquired structural disease	Vaginal delivery; Obstetric trauma; Ano-rectal surgery; Ano-rectal trauma
Gastrointestinal diseases	Inflammatory bowel disease; Irritable bowel syndrome; Radiation proctitis; Microscopic colitis; Malabsorption
Neoplastic	Hypersecretory tumours; Colorectal cancer; Ana cancer
Psychiatric	Psychiatric diseases
Medications	Diarrheal agents; Chemotherapy

INVESTIGATION FOR FAECAL INCONTINENCE

History taking and physical examination

It is important in the early stages of FI evaluation to search for possible causes and risk factors during careful detailed history taking in order to route diagnostics accordingly. The main symptoms of faecal incontinence are the progressive loss of control of rectal contents including solids stool and liquids. Urge incontinence is specified by the patient's awareness to defecation call but inability to constrict the external anal sphincter (EAS) sufficiently until reaching the toilet, and many patients report "accidents" within a few seconds or minutes. Involuntary discharge without awareness is categorized as passive incontinence and generally caused by disturbed sensation capability of the rectum and anal canal. It is imperative to identify discrete disparities in relation to various triggers such as daytime *vs* night time, physical activity, cough, stress, stool consistency, or food intake. Other secondary symptoms of FI may arise due to stool leakage including pruritus, perianal skin irritation, and infection as well as urinary tract infections. Notably, these secondary symptoms may be the chief complaints prompting patients to seek medical care without mentioning FI. Moreover, FI may have other important related conditions, which mandates direct exploration with the patient such as urinary incontinence, vaginal bulging (rectocele, cystocele), rectal prolapse, altered bowel habits, defecation disorders, and rectal bleeding.

Physical examination of the anorectal region is of paramount importance and starts with a visual inspection to search for leaked stool, skin irritation and infections, haemorrhoids, fistulas opening, and anal fissures[13]. During digital rectal examination, the experienced index finger is capable of affording a general estimation of the anal resting and squeeze pressures. Moreover, coordinated relaxation of the pelvic floor muscles during straining can be addressed as well during Valsalva manoeuver to search for possible defecation disorders (*i.e.* functional anismus)[14-16].

HRAM

According to American College of Gastroenterology guidelines, in cases of FI, it is worth testing with AM[17]. HRAM is an important diagnostic tool for the assessment of anorectal motor and sensory function[18]. The utilization of HRAM is a necessary diagnostic key tool in the evaluation of FI, as it enhances the understanding of the underlying pathophysiological bases of FI, permitting the delivering of optimal therapy for each specific patient. HRAM, which provides a dynamic recording of the anal sphincters and intraluminal rectal pressures, is considered to be the best-established diagnostic tool that permits an objective evaluation of several factors of anal and rectal function including basal tone and contractility, recto-anal coordination, and reflex function (such as recto-anal inhibitory reflux) as well as rectal sensation thresholds[18,19], which is an important predictor of response to biofeedback training[19]. The recently established international anorectal physiology working group published a consensus guideline paper that proposes a practical standardized protocol for the performance and analysis of anorectal manometry, named the London Classification[20]. Several manometric findings may be linked to FI such as impaired anal sphincter resting pressure tone (hypotension) and impaired squeeze pressure (hypo-contractility) (Figures 1 and 2). Moreover, HRAM enables the assessment of abnormal rectal sensitivity both hypersensitivity and hyposensitivity, two conditions that may cause FI in different manners. Rectal sensation is assessed by inflating a balloon in the rectum and recording balloon volumes needed to produce the first

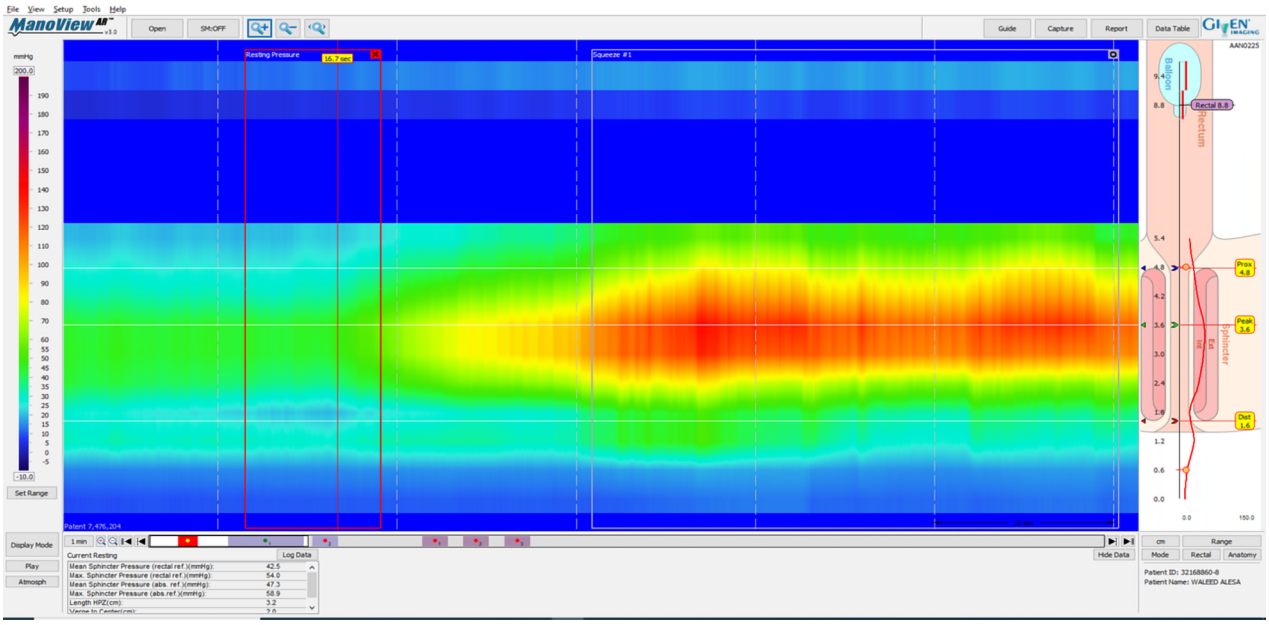

Figure 1 High-resolution anorectal manometry demonstrating normal resting and squeeze anal pressures. Supplied from the Gastroenterology and Endoscopy United, The Nazareth Hospital, EMMS, Nazareth, Israel.

sensation, urge, and discomfort[20]. Rectal hyposensitivity can be caused by neuropathy, mucosal inflammation, or fibrosis and may lead to patient unawareness to the presence of stool in the rectum leading to accumulation of stool and incontinence. Rectal hypersensitivity may lead to urge incontinence and is common among patients with irritable bowel syndrome[13].

Pelvic floor and anal canal imaging

In incontinent patients with reduced anal pressures, especially when surgery is being considered, the anatomic integrity of the anal sphincters, rectal wall, and puborectalis muscle region should be evaluated by either endoscopic ultrasound or MRI[17]. Although, both tests are considered overlapping in identifying abnormalities including scars, defects, marked focal thinning or atrophy however, every test has its

uniqueness and diagnostic capabilities. While ultrasound is superior in identifying IAS tears, EAS atrophy is more identified by MRI[21,22]. Additionally, discriminating between an external anal sphincter tear and scar is better with MRI[17].

Endoscopic ultrasound: TRUS or endoanal ultrasound (EAUS) is a simple, well tolerated, widely available examination considered the gold standard in investigating the anal sphincter integrity[23,24] (Figure 3). However, its sensitivity and accuracy in identifying sphincter injuries is debated and operator-dependent[25]. Gold *et al*[26] reported that the interobserver agreement in diagnosing sphincter defects and IAS measurements by EAUS is very good, and better than EAS measurements. Common structural pathologies in patients suffering from FI that are easily identified by EAUS include IAS discontinuity (defect), IAS atrophy (identified by diffuse thinning of the sphincter to less than 1 mm thickness (Figure 4)[27], and EAS discontinuity (defect) or scar manifested as focal thinning (Figure 5)[19,28]. On the other hand, precise determination of EAS atrophy is difficult with EAUS due to its inferiority in determining the EAS boundaries and its inability to distinguish between normal muscle tissue and fatty infiltration[29]. Indeed, EAS atrophy is defined by diffuse reduction in muscle bulk on serial images below the level of the puborectalis, to the point where the muscle is barely identifiable[21]. The leading cause of FI is anal sphincter injury originating from vaginal delivery in females, and it may result from direct anal sphincter laceration or indirectly from sphincter innervation damage[29].

Two-dimensional EAUS, which allows cross sectional images only in the axial plane, remains the mainstay of sphincter inspection[24]; however it does not achieve accurate longitudinal measurements necessary for planning complete surgical intervention. On the other hand, three-dimensional EAUS enables the determination of length, thickness, area, and volume measurements by producing a digital volume that can be seen from any plane[29], and is displayed as either multiplanar images or tomographic slicing, thus allowing more accurate defect visualization[24].

MRI: MRI is expensive, not readily available, and not tolerated by claustrophobic patients and is unsuitable in patients with pacemakers, defibrillators, and other metal implants[29]. Two modalities of MRI are available in clinical practice: the invasive endoanal MRI using endoluminal coils and the non-invasive external phased-array. Both modalities are comparable in identifying EAS defects[30] and atrophy[31]. Compared to EAUS, the accuracy of endoanal MRI in diagnosing IAS defects is lower[32]. Several studies have reported that EAUS and endoanal MRI are equivalent in diagnosing EAS injuries[22,32,33]; however, endo-anal MRI allows better distinction between fat and muscle and in identifying scars[27]. This property underscores the diagnostic ability of EAUS in detecting focal EAS thinning and structural lesions[34-37]. Interestingly, only moderate agreement between EAUS and external phased-array MRI in diagnosing obstetric injuries, which represent the main aetiology for FI, has been reported[38]. Recently, magnetic resonance defecography has gradually emerged as a modern modality substituting the traditional X-ray based defecography. It is non-invasive test that uses MRI to obtain images at various stages of defecation to evaluate how well the pelvic muscles are working and provide insights into rectal function. Magnetic resonance defecography can provide important functional disorders related to the defecation process as well as various important structural abnormalities associated with FI and other pelvic floor disorders. These structural abnormalities include rectocele, enterocele, anorectal descent, and descending perineum[39]. The identification may impact the kind of surgical treatments[40].

Electromyography

A neurophysiological assessment of the anorectum includes an assessment of the conduction of the pudendal and spinal nerves using EMG examination of the sphincter. This test is of particular significance when surgery is being considered; however its availability is mainly reserved for research purposes and its clinical application has been declining recently in many countries[41,42]. However, EMG use has been advocated in patients with refractory symptoms, suspected to originate from neurogenic sphincter weakness especially when it is assumed to result from sacral root injury, it is advocated to assess rectal sensation and compliance by needle EMG of the anal sphincter[43].

CONCLUSION

FI is considered to be a prevalent disorder with a considerable economic burden, but due to embarrassment it is generally underreported. FI impacts severely patients' quality of life, leading to various organic and psychological comorbidities. Detailed history taking and anamnesis by physician is mandatory to define the patient's main complaints with a focus on risk factors for FI and whether passive or urge FI is dominant. Moreover, digital rectal examination is of paramount importance to assess anorectal sensation, anal sphincter resting and importantly the squeeze pressures as well. HRAM is an important initial diagnostic modality to start with, as it can provide crucial information about the anal sphincter functions and can evaluate rectal sensation capability using balloon dilation in the rectum. The anatomic integrity of the anal sphincters, rectal wall, and puborectalis muscle region should be evaluated by either TRUS or MRI. Although, both tests are considered overlapping in identifying abnormalities including scars, defects, marked focal thinning or atrophy, every test has its own uniqueness and diagnostic capabilities. While TRUS is superior in identifying internal anal sphincter tears, external anal sphincter atrophy is more identified by MRI. Additionally, discriminating between an external anal sphincter tear and scar is better with MRI. Figure 6 demonstrates the authors' perspective of the structured, step-by-step approach for the evaluation and diagnosis of FI. Still, the place of EMG in the evaluation of FI needs to be explored. Finally, this recommended approach should aid clinicians in the stepwise management of patients with FI.

Abstract

Endoscopic removal of large (≥ 20 mm) non-pedunculated colorectal lesions (LNPCLs) may result in major adverse events, such as delayed bleeding (DB) and delayed perforation (DP), despite closure of the mucosal defects with clips. Topical application of a coverage agent refers to the creation of a shield with a biocompatible medical device (tissue or hydrogel) with proven bioactive properties. Coverage of the eschar after endoscopic resection provides shielding protection to prevent delayed complications. The aim of the present review was to systematically collect and review the currently available literature regarding the prevention of DB and DP with coverage agents after endoscopic mucosal resection or endoscopic submucosal dissection of LNPCLs.

Key Words: Large colorectal lesions; Delayed bleeding; Topical application; Endoscopic mucosal resection; Endoscopic submucosal dissection

INTRODUCTION

Endoscopic resection of precancerous colorectal lesions is one the most frequently performed medical interventions, which significantly decreases the risk of colorectal cancer incidence and death. Large (20 mm) non-pedunculated colorectal lesions (LNPCLs) show the highest cancer risk and their careful, complete, and timely removal is especially critical. Endoscopic removal of these lesions may result in major adverse events, such as delayed bleeding (DB) and delayed perforation (DP), especially in high-risk patients with a Spanish Endoscopy Society Endoscopic Resection Group score 6 or deep mural injury signs II-V, despite closure of the mucosal defects with clips[1-3]. Complete clip closure is not possible in 40% cases due to large size or poor accessibility[4]. The risk of DB ranges from 1% to 12% (1.5% with complete closure, 9% with partial closure and 12% with failed closure), whereas the risk of DP is around 1%[5,6]. The routine use of prophylactic clipping does not reduce the risk of post-procedural bleeding overall[7]. On the other, prophylactic endoscopic coagulation of visible vessels is not effective in the prevention of clinically significant DB[8].

Topical application of a coverage agent refers to the creation of a shield with a biocompatible medical device (tissue or hydrogel) with proven bioactive properties. Coverage of the eschar after endoscopic resection provides shielding protection to prevent delayed complications[9]. A comprehensive understanding of the pathogenic mechanisms of action involved is mandatory to address these challenges. The aim of the present review was to systematically collect and review the currently available literature regarding the prevention of DB and DP with coverage agents after endoscopic mucosal resection (EMR) or endoscopic submucosal dissection (ESD) of LNPCLs.

SEARCH STRATEGIES

A comprehensive search of PubMed was performed to identify articles in English. Search strategies and key words were as follows: (1) ("Endoscopy" [All Fields] AND ("topical application" [All Fields]); (2) ("Large colorectal lesions" [All Fields] AND "EMR" [All Fields] OR "ESD" [All Fields]); and (3) ("Delayed bleeding" [All Fields] OR "delayed perforation" [All Fields]). In addition, manually inspected relevant articles that were missed by the above search strategy were also included.

CLINICAL DATA

Following our search, 8 studies were identified with 191 patients included in case series, which are summarized in Table 1. Tested agents were: Polyglycocolic acid sheets with fibrin glue (PGA-FG), Surgicel, platelet-rich plasma (PRP), Purastat and cyanoacrylate. All these measures present biological safety after experience in clinical practice. The first report was published in 2014 to evaluate the shielding technique after ESD in 10 patients with LNPCLs, placing PGA sheets on the mucosal defect with biopsy forceps and then spraying FG through a special double-lumen tube[10]. PGA is an absorbent and hydrophilic suture reinforcement material, hydrolysed *in vivo*, with a degradation and absorption period within approximately 15 wk[11]. To perform this technique, soft and elastic PGA sheets were cut into small pieces, held with biopsy forceps, and transported to the mucosal defect through the channel of the scope.

Table 1 Outcome of coverage agents to prevent delayed bleeding and perforation after endoscopic resection of colorectal lesions

Ref.	Year	Design	*n*	Size (mm)	Agent	Primary endpoint	Follow-up	Outcomes
Tsuji *et al*[10]	2014	SA	10	39.7	PGA-FG	Prevent late complications	2 wk	0% DB/0% DP

Subramanian *et al*[21]	2021	RCT	43	33.7	Purastat	Prevent late complications	4 wk	5.5% DB
Martines *et al*[22]	2020	TA	15	25	NBCA-MS	Prevent delayed bleeding	-	0% DB

SA: Single-arm interventional case series study; TA: Two-arm interventional case series study; RCT: Randomized clinical trial; PGA-FG: Polyglycocolic acid sheet with fibrin glue; PRP: Platelet-rich plasma; NBCA-MS: N-butyl-2-cyanoacrylate with methacrylosulfolane (Glubran 2); DB: Delayed bleeding; DP: Delayed perforation; MHR: Mucosal healing rate.

Fibrinogen first and then thrombin were sprayed with different spray tubes to fix the sheets to the ulcer and to enhance the coating effect[12]. The use of PGA-FG in LNPCLs achieved a success rate of 100%, but required a long-procedure time (a mean of 19 min). During follow-up colonoscopy, 80% of patients showed persistence of PGA sheets at 2 wk.

Surgicel Fibrillar, an oxidized regenerated cellulose that swells into a gelatinous mass, was the second substance investigated to reduce late complications in a large case-series of 49 patients with colorectal ESD[13], using one layer of this agent diluted in 10 mL of normal saline through a special spraying catheter. Surgicel aids in clot formation after blood saturation, serving as a haemostatic adjunct, and has a localized bactericidal effect due to a low pH of 3.4-3.7[14]. To assess the effectiveness of Surgicel application, a retrospective comparison with another 52 patients with LNPCLs who underwent conventional ESD was performed. All lesions were successfully covered, and the covering procedure was less time-consuming (5 min). During the follow-up period, rebleeding occurred in 0 (0%) patients and 4 (7.7% in the control group) patients. Postpolypectomy syndrome (PPS) was observed in three patients (6.1%) who were treated with Surgicel, compared with 17 (32.7%) in the non-Surgicel group. In 20 patients treated with this product, a follow-up colonoscopy was performed the next day, and Surgicel remained on the defect in all cases. Based on this, the authors speculated that the reduction in the inflammatory reaction was associated with the shielding effect and reduced endotoxemia due to the bactericidal property of this agent, which acidifies the environment.

PRP, also known as autologous platelet gel, has confirmed robust healing properties over the eschar after EMR in preclinical models[15]. Platelets play a fundamental role in haemostasis and are a natural source of growth factors. PRP fluid contains at least a 2-fold peripheral blood platelet count and a large amount of pivotal growth factors for reepithelization, which are released from the alpha granules of activated platelets[16]. The use of PRP is justified in the exponential release of multiple pleiotropic factors, which enhances the physiological and haemostatic healing processes, with a very low risk of fibrotic healing or strictures. In clinical practice, PRP was used as a coverage agent to prevent late complications in a limited number of patients with very large lesions located in the rectum (mean size 54 mm)[17]. PRP was obtained from a sample of patient's blood (18-36 mL) drawn at the time of endoscopy. DB occurred in 1 of 4 lesions with blood transfusion or endoscopic treatment not required. PRP also showed a very high mucosal healing rate after 4 wk (79%), the time to apply PRP was very quick (2 min), and the force required to pass the composition was appropriate, comparable to saline. Nevertheless, patient number is too small to draw any conclusions on efficacy, and controlled data are lacking.

PuraStat has also been tested to prevent DB after endoscopic resection of LNPCLs. This agent is a fully synthetic matrix scaffold built from a chain of three types of amino acids than bond together to form a peptide. It forms a transparent gel when it comes into contact with blood or tissue fluids, comprising a network of nanofibers that form an extracellular matrix, providing a physical barrier to stop bleeding by blocking blood vessels. Three case series (single-arm interventional studies) and one randomized clinical trial have been reported in 113 patients with LNPCLs[18-21]. Total lesion surface was completely covered with a dose of 3 mL in a median time of 2 min. Clinically significant DB occurred in 4.4% of patients (range 0%-12%). The concerns with this gel are that it has to be applied through a special catheter, it is affected by gravity, and slowly slides from the ulcer bed after covering. Exsufflation after application seems to be effective in applying the gel to the whole area with less migration.

Recently, cyanoacrylate has been evaluated in a two-arm study[22]. Two groups of fifteen patients with LNPCLs were compared to evaluate early and DB after EMR in association with a modified cyanoacrylate glue (N-butyl-2-cyanoacrylate + methacryloxysulfolane-Glubran 2®) *vs* EMR alone. Cyanoacrylate is a strong and fast-acting synthetic glue with sealing, adhesive and haemostatic properties, which rapidly polymerizes in the presence of water to form long and strong chains. Based on these properties it has been widely used in surgery, and for primary and secondary prophylaxis of bleeding from gastric varices[23]. This substance has been applied using a 7 Fr spray Teflon catheter. No case of early bleeding was reported in both groups. Two cases (13.3%) of DB with readmission to hospital and redo endoscopy with apposition of haemostatic clips were performed in patients with EMR alone, as compared with no cases of DB in the shielded group (P = 0.48).

DISCUSSION

Endoscopic shielding with coverage agents is a very promising method to prevent late complications in patients with LNPCLs, especially in proximal lesions with an increased risk of bleeding of at least 2-fold. The protective effect of clips is limited to those cases where complete closure was achieved (57% of cases), and the median number of clips to completely close the resection defect was four[4-6]. The absence of efficacy in many cases of the clipping technique, with its cost and technical difficulties, induced the appearance of new endoscopic approaches to solve this unmet need.

The use of coverage agents is the quickest and simplest technique to cover large mucosal defects, and published data seem to confirm their efficacy in the prevention of late complications. However, most of the reports are case series, without a control arm and with a relatively short follow-up. There is a lack of randomized controlled trials and of head-to-head comparative studies of shielding products. Moreover, none of the published series can incorporate blinding, with considerable bias therefore inevitable.

Regarding the type of active treatment used, there is no ideal treatment, and all have pros and cons (Table 2). As options developed to prevent DB and DP it is important to consider the cost-effectiveness of each treatment. The overall rate of delayed adverse events is assessed as 10%, and the cost for management of these complications, including admission and additional therapies, is estimated at 5000 $ per patient. The cost for an economical prophylactic measure for each patient without adding to the overall financial cost is around 500 $ per cushion. Commercially available data show the price range per 1 mL to be 10-150 $; thus, it is necessary to consider the economics, the upfront cost for the added prophylactic intervention, and the downstream cost savings for an avoided hospitalization. If the mean used volume is 3 mL, we can estimate the cost-effectiveness of each tested agent, from PRP, the cheapest, to cyanoacrylate, the most expensive.

Apart from efficacy, mucosal healing activity is another important issue to consider. All these prophylactic measures help and accelerate mucosal reepithelialisation, but the healing process has only been measured with PRP. The ideal coverage agent should have a chemical structure and physical properties showing an appropriate adhesion capacity to avoid migration against gravity and adherence failure, some refractoriness to bacterial degradation in order to increase the bioactive period and reduce the incidence of PPS, and healing activity to increase mucosal healing rate. Application should be straight with minimal force to pass the agent, ideally using standard devices accessible to all endoscopy units, inducing a small increase in the time of the resection procedure and with a short learning curve. Ideally, it should also be able to release bioactive drugs to treat specific conditions such as colorectal cancer

Table 2 Pros and cons of coverage agents based on ideal properties

Property	PGA-FG	Surgicel	PRP	Purastat	Cyanoacrylate
Appropriate adhesion capacity	+	+	+	+	+
Absence of special device	-	+	+	-	+
Not time-consuming	-	+	+	+	+
Refractory to bacterial degradation	+	+	-	-	+
Healing activity	+	+	+	+	+
Price range of 1 mL ($)	20-25	15-20	10-12	100-150	150
Drug-release	-	-	-	-	-

PGA-FG: Polyglycocolic acid sheet with fibrin glue; PRP: Platelet-rich plasma.

or inflammatory bowel disease. All these properties are still to be confirmed in proof of concept studies with robust data.

To obtain the ideal agent, larger prospective studies with control groups and a comparison of the different substances are needed.

CONCLUSION

The use of coverage agents is the quickest and simplest technique to cover large mucosal defects, and published data seem to confirm their efficacy in the prevention of late complications. However, most of the reports are case series, without a control arm and with a relatively short follow-up. There is a lack of randomized controlled trials and of head-to-head comparative studies of shielding products. Moreover, none of the published series can incorporate blinding, with considerable bias therefore inevitable.

Abstract

Bile duct epithelial tumours showing papillary neoplasm in the bile duct lumen are present in the intrahepatic and extrahepatic bile ducts. Clinicopathological images of these tumours are distinctive and diverse, including histological images with a low to high grade dysplasia, infiltrating and noninfiltrating characteristics, excessive mucus production, and similarity to intraductal papillary mucinous neoplasm (IPMN) of the pancreas. The World Health Organization Classification of Tumours of the Digestive System in 2010 named these features, intraductal papillary neoplasm of the bile duct (IPNB), as precancerous lesion of biliary carcinoma. IPNB is currently classified into type 1 that is similar to IPMN, and type 2 that is not similar to IPMN. Many of IPNB spreads superficially, and diagnosis with cholangioscopy is considered mandatory to identify accurate localization and progression. Prognosis of IPNB is said to be better than normal bile duct cancer.

Key Words: Intraductal papillary neoplasm of the bile duct; Intraductal papillary mucinous neoplasm of the pancreas; Peroral cholangioscopy; Cholangioscopy

INTRODUCTION

Presence of intraductal tumours showing a pattern of spurring papillary neoplasm has been known since before[1-4]. Although the names of these tumours varied depending on the country and region, it is known that the tumours have a better postoperative prognosis than normal infiltrating bile duct cancer. Also known are the facts that quite a few pre-infiltrating phases can be found in these tumours; cases with a low grade dysplasia are present; and some cases have excessive mucus production. Many similarities with intraductal papillary mucinous neoplasm (IPMN) of the pancreas are also pointed out. A recommendation has been made in recent years to call these tumours intraductal papillary neoplasm of the bile duct (IPNB)[1]. Diagnosis of IPNB and the current status of its treatment are hereby reported.

HISTORY OF IPNB

Epithelial tumours demonstrating a variety of images develop in the bile duct. Of these tumours, bile duct epithelial tumours indicate papillary neoplasm in the bile duct lumen[1-4]. These tumours have better prognosis than normal bile duct cancer, and often present with distinguishing and diverse clinical pathophysiology. Yet, no specific name was given to these tumours. In the United States and Europe, these tumours are called biliary papilloma if they are solitary, and biliary papillomatosis if they are multiple[5,6]. These are slow growing, low grade tumours with potential malignancy, and some cases of infiltration and metastasis have been also reported. Separately, hepatobiliary cystadenoma and adenoma also exist, and differences among these diseases were not necessarily clear-cut.

Intrahepatic stone-related intrahepatic bile duct cancer was examined in 2001. There are quite a few bile duct epithelial tumours showing papillary growth in the bile duct, with excessive mucus production. These tumours are morphologically and characteristically similar to IPMN of the pancreas; thus, we consider these cases as neoplastic lesion and reported it as intraductal papillary neoplasm of the liver[7]. As similar tumours were also noted thereafter in the extrahepatic bile duct, the tumours were renamed IPNB[8]. This lesion was officially named IPNB in the revised World Health Organization Classification of Tumours of the Digestive System in 2010[9].

PATHOLOGICAL DIAGNOSIS OF IPNB

IPNB is epithelial tumour with intraductal papillary proliferation, and defined as having a histologically thin fibrovascular stem[1-4]. Excessive mucus production is often noted but this is not a decisive element for diagnosis of IPNB. IPNB is reported to be a lesion similar to IPMN. Specific lesions are: (1) Papillary proliferation of tumours in the bile duct lumen or in the bile duct; (2) Intestinal, gastric, pancreatobiliary, and oncocytic subtypes noted in IPMN are also common in IPNB; (3) As in IPMN, cancerous cells show intraepithelial and intramucosal progression along the intraductal wall adjacent to the primary site, and some are multiple cases with asynchronous and simultaneous tumours; (4) IRNB has better prognosis compared with normal bile duct cancer or normal pancreatic carcinoma; (5) Some IPNB cases show excessive mucus production; however, the incidence is lower than that of IPMN. In some cases, no clear excessive mucus production is noted. Patients with excessive

mucus production often show cystic expansion of the bile duct at the main site of papillary growth; and (6) In the case of infiltrating growth of IPNB, either normal tubular adenocarcinoma or bile duct mucinous adenocarcinoma may result. Similar infiltrating images are also known in IPMN.

The World Health Organization Classification of Tumours of the Digestive System in 2010 added the definition of IPNB as one of precancerous, pre-infiltrating lesions of the bile duct cancer[9]. However, studies since then have revealed that some cases with intraductal noninfiltrating papillary tumours are slightly different from those cases similar to IPMN. These different cases include biliary papillary adenocarcinoma that has been previously reported by Albores-Saavedra[10,11]. Based on these results, IPNB was classified into two types. Type 1 is IPNB similar to IPMN, and mostly classified into gastric and intestinal subtypes. Type 1 shows homogeneous tissue image, and often occurs in the intrahepatic bile duct, with excessive mucus production often experienced by patients. Many of type 1 IPNB is considered a high grade dysplasia; however, some regions often show a low grade dysplasia, and some cases have only a low grade dysplasia. Type 1 includes many of patients undergoing resection in noninfiltrating phase, and those who show cystic expansion in the bile duct with lesion. Type 2 IPNB is slightly different from IPMN; however, it is experienced as IPMN in rare cases. Type 2 IPNB includes lesions previously reported by Albores-Saavedra as bile duct papillary adenocarcinoma and papillary bile duct cancer[7,8]. Tissue images of type 2 IPNB are slightly more complicated, showing some solid sites. Almost all cases are considered a high grade dysplasia, often occurring in the extrahepatic bile duct. Many cases already show infiltrating images at the time of resection, but some cases show noninfiltration. Most of the cases are classified into intestinal and pancreatobiliary subtypes, with few cases of excessive mucus production. Examination of IRNB with macroscopic mucus production revealed that many of tumours with mucus production are noninfiltrating, similar to IPMN, and those with no mucus production tended to show infiltration[12]. IPNB classification is still far from perfect. After classifying into two types, we find it difficult to classify into type 1 IPNB and type 2 IPNB in some cases, or to differentiate progressed papillary bile duct cancer from type 2 IPNB. Further consideration is necessary.

IPNB DIAGNOSIS

Image diagnosis plays an important role in giving a diagnosis of IPNB. If clinical symptoms show abdominal pain, pyrexia, and elevation of hepatobiliary enzymes in a blood test, an image diagnosis of the abdominal region will be made. In this case, abdominal ultrasonography, contrast computed tomography (Figure 1), Magnetic resonance imaging (Figure 2), and endosonography will enable us to identify the main focus[13]. However, these modalities may not ensure an accurate diagnosis because the presence of mucus, which is characteristics of IPNB, must be verified, and superficial expansion and progression of IPNB are often to the extent beyond our expectation. This is where direct cholangiography, intraductal ultrasonography (IDUS), and cholangioscopy come in[14-16]. The presence of mucus can be identified by checking papillary dilation and emission of mucus with endoscopy, or by outlining the mucous plug with cholangiography (Figure 3). Even when cholangiography contrasts the bile duct dilated with mucus, it is difficult in some cases to identify the main focus itself owing to mucus, let alone superficial expansion and progression. Meanwhile, IDUS enables us to identify the main focus and depict mucus; it can be easily conducted at the time of ERCP by following the guide wire; and it allows us to capture a wide scope of the region for observation. The presence of mucus, however, makes it difficult to evaluate the bile duct wall in IDUS. Thus, cholangioscopy plays a central role in the diagnosis of IPNB[14-16]. Cholangioscopy enables us to observe with narrow band imaging in addition to usual white light imaging, and is considered useful for the diagnosis of benignancy and malignancy as well as progression staging[14-16]. As mentioned earlier, the main focus of papillary bulge may be captured by computed tomography and magnetic resonance imaging, but the evaluation of superficial spread and progression from the main focus is difficult. Cholangioscopy allows us to directly observe the superficial spread and progression and to perform an open biopsy, thereby enabling accurate diagnosis of the progression (Figure 4). Depending on a route of approach, percutaneous transhepatic cholangioscopy (PTCS) and peroral cholangiosccopy (POCS) are available in cholangioscopy. Generally, PTCS where percutaneous biliary drainage is performed, has a bigger channel diameter and a shorter effective length. These features make it easy to wash and superior in removing

Figure 1 Contrast computed tomography revealed a 70-mm cystic lesion with a papillary bump in the lumen of left hepatic lobe.

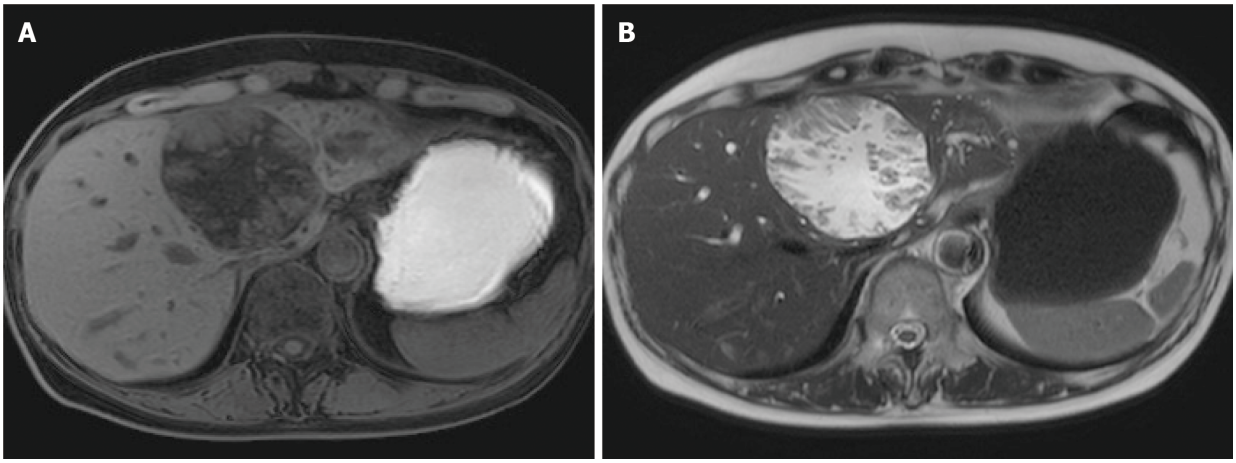

Figure 2 Magnetic resonance imaging. A: T1-weighted image; and B: T2-weighted image papillary solid lesion protuberating from cystic wall is noted and the cystic component showed the same signals as water. Transportation between the cyst and the root of left hepatic duct is noted.

Figure 3 Translucency caused by mucus is noted from hepatic portal region to lower bile duct.

mucus. With great operability, PTCS ensures a sufficient visual field and enables a wider scope of observation and more detailed monitoring. Weak points of PTCS are that it takes time until we can observe as time to fistula formation is required, and that dissemination *via* fistula has been also reported[15]. Therefore, the current indications for PTCS are limited, and POCS is mostly performed except for the following cases:

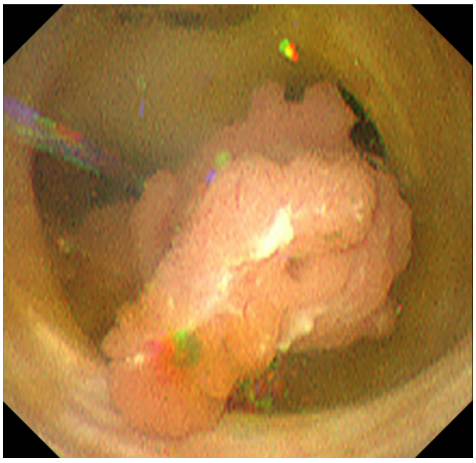

Figure 4 The lesion originates from the root of left hepatic duct, and pedunculated and elevated lesion protruded toward the extrahepatic bile duct, with no clear superficial spread.

Difficulty in biliary cannulation with ERCP; difficulty in reaching duodenal papilla after Billroth-2 method or Rou-X-en Y anastomosis; and difficulty in removing mucus with POCS. Benefits of POCS are that it does not require fistula formation, allows direct observation from the initial ERCP, and entails no risk for fistula dissemination. On the other hand, POCS may limit the scope of observation since its approach route is longer and operation is cumbersome and difficult. Nonetheless, sufficient evaluation with POCS is possible because the resection line of distal site of the tumour is important in determining the scope of resection at the time of operation on IPNB (Figures 5 and 6).

RESULTS OF SURGICAL TREATMENT OF IPNB

Treatment results in dysplasia

Kubota *et al*[17] examined 119 patients with intrahepatic IPNB, and reported the 5-year survival: 84.6% in low or intermediate-grade neoplasia group, 90.9% in high-grade neoplasia group, and 79.2% in invasive carcinoma group. When complete resection was performed, no statistical significance was noted in overall survival between the group of infiltrating cancer and the other group of noninfiltrating cancers. As further examinations of infiltrating cancer, Onoe *et al*[18] reported the ratio of infiltrating site relative to the lesion and its prognosis on 184 patients with intrahepatic and extrahepatic bile duct cancer exhibiting intraductal papillary proliferation. The 5-year survival in four groups: Noninfiltrating cancer, infiltrating site < 10%, infiltrating site = 10%-50%, and infiltrating site > 50%, were 92%, 74%, 64%, and 33%, respectively. The former three groups showed no statistical between-group differences; however, the infiltrating site > 50% group showed significantly poor prognosis, almost equivalent to the 5-year survival of 35% in 460 patients with non-papillary bile duct cancer. Onoe *et al*[18], pointed out that there still was a moot point in the disease concept of IPNB but indicated that if bile duct cancer exhibiting intraductal papillary proliferation was an infiltrating cancer, with an infiltrating site accounting for not more than 50% of the entire cancer, its good prognosis was more significant than non-papillary bile duct cancer. Rocha *et al*[19] reported that 29 of 39 IPNB patients (74%) had infiltrating cancer. Significantly poor prognostic factors were infiltration exceeding 5 mm, and infiltration beyond the bile duct wall, exceeding 10% of the entire tumour. The ratio of infiltrating cancer in IPMN is 21%-48%[19,20] , while that in IPNB is 70%-80%, slightly higher[21,22]. It is reported that prognoses of IPMN-derived infiltrating cancer and infiltrating pancreatic ductal carcinoma are almost the same[23,24], or prognosis of IPMN-derived infiltrating cancer is slightly better[25,26]. Meanwhile, better prognosis is reported in IPNB as compared with normal bile duct cancer[27]. This is due to characteristics of IPNB tumour itself, and because of relatively early diagnosis that is possible with obstructive jaundice caused by its proliferation into the intraductal lumen.

Figure 5 Resected specimen. Left lobectomy, caudal lobectomy, resection of extrahepatic bile duct, and choledochojejunostomy were performed.

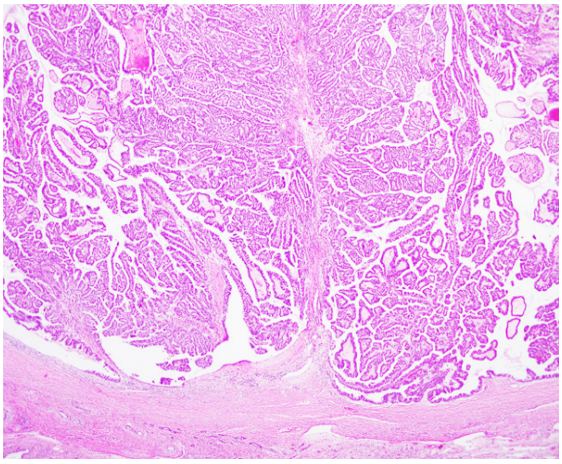

Figure 6 Pathological diagnosis is intraductal papillary neoplasm of the bile duct with an associated invasive carcinoma (Hematoxylin-Eosin Stain) with no superficial spread.

PROGNOSTIC FACTORS

Presence or absence of complete resection is an important prognostic factor, and reported in great numbers[18,19,28,29]. Luvira *et al*[28] reported that the bile duct resection stump tested positive for invasive carcinoma, and overall survival significantly decreased, while testing positive for dysplasia and carcinoma in situ did not impact prognosis. In contrast, Jung *et al*[29] reported that overall survival and recurrence-free survival of the group in which the bile duct resection stump tested positive for a low to intermediate grade dysplasia, significantly decreased to the extent similar to the overall survival of carcinoma in situ and invasive carcinoma, as compared with the group that tested negative. International consensus guidelines for the management of IPMN specifies that additional resection is indispensable if a clear high grade dysplasia or infiltrating cancer is present in the pancreatic resection stump while additional resection is not necessary even when a low grade dysplasia is present on the stump[30]. In IPNB, no guideline is available for a low grade dysplasia in the bile duct resection stump. Unlike IPMN where total pancreatectomy is therapeutic option depending on a patient, there is a resection limit for the bile duct, and thus, additional resection is performed as much as possible at each institution.

Presence or absence of metastases to lymph nodes is a major prognostic factor along with complete resection[18,28,29]. Luvira *et al*[28] reported that the 5-year survival of patients tested negative for metastases to lymph nodes was 51.2% while that of those tested positive was 11.1%, suggesting significantly poor prognosis. Of all 124 patients with IPNB, 98 patients underwent lymph node dissection. No difference in prognosis

was noted between these 98 patients and 26 patients without lymph node dissection, and thus, the results failed to support the usefulness of lymph node dissection. Patients with infiltrating cancer include those patients with lymph node dissection, and lymph node dissection may seem necessary. However, metastases to lymph node rarely occur in an intraductal growth type of intrahepatic bile duct cancer. As there are type 1 and type 2 for IPNB, more meticulous consideration may be needed to discuss the necessity of lymph node dissection in the future.

RECURRENCE OF IPNB AFTER SURGICAL TREATMENT

IPNB is known to recur in the bile duct after surgical resection. Despite that the initial resection stump of the bile duct tested negative, intraductal papillary tumour presenting with tissue image similar to the initial resection recurred. This is the characteristics similar to IPMN. IPNB recurs after more than 10 years in some cases, appearing as if it were new carcinoma. This suggests a multicentric growth of IPMN[31]. Therefore, observation of clinical course is necessary, with postoperative intraductal recurrence in mind.

CONCLUSION

IPNB is classified into type 1 that is similar to IPMN and type 2 that is not similar to IPMN. Prognosis of IPNB is said to be better than normal bile duct cancer. Cholangioscopy is useful for diagnosis of localization and progression. It is important to determine an operative method based on information obtained through cholangioscopy and to observe clinical course.

Abstract

BACKGROUND

Colon cancer cell lines are widely used for research and for the screening of drugs that specifically target the stem cell compartment of colon cancers. It was reported that colon cancer carcinoma specimens contain a subset of leucine-rich repeat-containing G protein-coupled receptor 5 (LGR5)-expressing stem cells, these so-called "tumour-initiating" cells, reminiscent in their properties of the normal intestinal stem cells (ISCs), may explain the apparent heterogeneity of colon cancer cell lines. Also, colon cancer is initiated by aberrant Wnt signaling in ISCs known to express high levels of LGR5. Furthermore, *in vivo* reports demonstrate the clonal expansion of intestinal adenomas from a single LGR5-expressing cell.

AIM

To investigate whether colon cancer cell lines contain cancer stem cells and to characterize these putative cancer stem cells.

METHODS

A portable fluorescent reporter construct based on a conserved fragment of the LGR5 promoter was used to isolate the cell compartments expressing different levels of LGR5 in two widely used colon cancer cell lines (Caco-2 and LoVo). These cells were then characterized according to their proliferation capacity, gene expression signatures of ISC markers, and their tumorigenic properties *in vivo* and

in vitro.

RESULTS

The data revealed that the LGR5 reporter can be used to identify and isolate a classical intestinal crypt stem cell-like population from the Caco-2, but not from the LoVo, cell lines, in which the cancer stem cell population is more akin to B lymphoma Moloney murine leukemia virus insertion region 1 homolog (+4 crypt) stem cells. This sub-population within Caco-2 cells exhibits an intestinal cancer stem cell gene expression signature and can both self-renew and generate differentiated LGR5 negative progeny. Our data also show that cells expressing high levels of LGR5/enhanced yellow fluorescent protein (EYFP) from this cell line exhibit tumorigenic-like properties *in vivo* and *in vitro*. In contrast, cell compartments of LoVo that are expressing high levels of LGR5/EYFP did not show these stem cell-like properties. Thus, cells that exhibit high levels of LGR5/EYFP expression represent the cancer stem cell compartment of Caco-2 colon cancer cells, but not LoVo cells.

CONCLUSION

Our findings highlight the presence of a spectrum of different ISC-like compartments in different colon cancer cell lines. Their existence is an important consideration for their screening applications and should be taken into account when interpreting drug screening data. We have generated a portable LGR5-reporter that serves as a valuable tool for the identification and isolation of different colon cancer stem cell populations in colon cancer lines.

Core Tip: The intestinal epithelium harbors two distinct pools of putative stem cells, the leucine-rich repeat-containing G protein-coupled receptor 5$^+$(LGR5) stem cell population and the B lymphoma Moloney murine leukemia virus insertion region 1 homolog$^+$ stem cell population. Colon cancer cell lines such as Caco-2 and LoVo are extensively used in colon cancer research, and express high levels of LGR5. Here, we aimed to investigate whether colon cancer cell lines contain cancer stem cells and characterized these cells. Using an LGR5 reporter, we characterized LGR5$^+$ cells and revealed that Caco-2 cell line contains a classical intestinal stem cell-like population (LGR5$^+$). However, in LoVo cell lines, stem cell-like population is more akin to the B lymphoma Moloney murine leukemia virus insertion region 1 homolog$^+$ stem cells.

INTRODUCTION

Colorectal cancer (CRC) remains a leading cause of morbidity and mortality worldwide[1], highlighting the need for more effective therapeutics. It is now well established that both blood and solid cancers are initiated and propagated from a subset of rare cells, called cancer stem cells (CSCs), which are resistant to chemotherapy or radiation[2-4]. Current evidence indicates that CRC is indeed a disease of colon stem cells[2,5,6] that are resistant to current therapeutics and can rapidly proliferate to re-establish the tumor[7]. The intestinal crypt-villous structure harbors two distinct pools of putative stem cells[8]. One pool is located at the crypt base and is characterized by the expression of leucine-rich repeat-containing G protein-coupled receptor 5 (LGR5), and the other pool resides at +4 position and consists of B lymphoma Moloney murine

P-Editor: Ma YJ

leukemia virus (Mo-MLV) insertion region 1 homolog (Bmi-1) and telomerase reverse transcriptase (TERT) expressing cells[9-11]. The hierarchy of these stem cell pools in the normal crypt and their respective contributions to colon cancer and relapse following therapy is under debate. Some suggest both pools contribute equally to maintenance of the crypt, following a pattern of neutral drift[12], while others propose that Lgr5$^+$ stem cells (SCs) comprise the active population of the crypt and that Bmi-1$^+$ or TERT$^+$ cells are quiescent SCs that represent a reserve pool of SCs with the ability to replace Lgr-5$^+$ cells in case of loss or injury[8,13]. The existence of CSCs within intestinal tumors was most elegantly demonstrated by Schepers *et al*[14] using lineage re-tracing with a multicolor Cre-reporter R26R-confetti targeted to a single adenomatous polyposis coli allele in mouse intestinal stem (LGR5$^+$) cells, demonstrating that these intestinal adenomas were maintained by CSCs that exist in a cellular hierarchy. LGR5 is a receptor for R-spondins and activates potent Wnt signal enhancers such as Rnf43 and Znrf3[15]. LGR5 is present in various stem cell compartments throughout the body[16], including the intestine, and is an exquisite marker of intestinal stem cells (ISCs) capable of forming the entire intestinal mucosa[9]. LGR5$^+$ ISCs persist in adenoma and can initiate CRC through the activation of the Wnt/β-catenin signaling pathway[17].

Human colon cancer cell lines such as Caco-2 and LoVo are extensively used in drug screening and colon cancer research and express high levels of LGR5[18-20]. To establish criteria for the selection of suitable cell lines for drug discovery, several studies have investigated variability between the colon cell lines, identifying characteristic differences in gene expression signature, epigenetic and genetic make-up, migratory abilities, and proliferative capacities between different intestinal cancer and cell lines, including Caco-2 and LoVo[21,22]. However, the CSC population(s) within these cell lines remains to be fully characterized. This is important since anticancer drugs often attempt to target these CSCs[23,24].

To isolate the CSC compartment from colon cancer cell lines we constructed a reporter based on a conserved promoter fragment of the *LGR5* gene. After validating the fidelity of this LGR5 reporter, we showed that it can be used as a genetic tool to isolate LGR5-expressing CSCs from Caco-2 and LoVo human colon cancer cell lines. Surprisingly, our data revealed that these two widely used colon cancer lines possess different stem cell compartments. We conclude that this portable LGR5 reporter constitutes a valuable tool for the development of colon cancer therapeutics specifically designed to ablate these CSCs.

MATERIALS AND METHODS

Cell culture

Human colon cancer cell lines (LoVo, Caco-2, and SW480), a human fibroblast cell line (CRL-2429), a mouse fibroblast cell line (3T3), and a mouse motor neuron cell line (NSC-34) were obtained from ATCC and maintained in Dulbecco's Modified Eagle Medium (DMEM, Invitrogen, Carlsbad, CA, United States) supplemented with fetal bovine serum (FBS, Bovogen Biologicals, Keilor East, Australia) to a final concentration of 10% and passaged every 3-4 d at 80% confluency. The human neuroblastoma cell line (SH-SY5Y from ATCC) was maintained in DMEM supplemented with 20% FBS and passaged every 2-3 d. All cell lines used for experiments were at early (a maximum of 20-25) passage number.

Construction of LGR5 promoter-based reporter constructs

Conservation of the *LGR5* gene and its promoter was assessed using evolutionary conserved region browser and multiple alignments of several vertebrate genomes. The human *LGR5* gene is located on chromosome 12 and has a conserved region upstream of the main promoter. This gene segment [LGR5 promoter element (983 bp)] was amplified from RP11-59F15 bacterial artificial chromosome clones (obtained from the Australian Genome Research Facility, Ltd., Melbourne, Australia) by polymerase chain reaction (PCR) (Supplementary Figure 1A) using a set of primers (Table 1). Sequences for specific restriction sites (*Nde* I, *Nhe* I, *Sac* I, and *Xho* I) were added to allow the insertion of the amplicon into the pEYFP-N1 vector (Clontech, Mountain View, CA, United States). Subsequently, this purified deoxyribonucleic acid (DNA) fragment was A-tailed and ligated into pGEM®-T Easy Vector System I (Madison, WI, Promega). White colonies were selected and plasmid DNA isolated, purified, and sequenced. Verified plasmids containing the DNA of interest, which is also free of PCR-introduced mutations, were then digested and ligated into the pEYFP-N1 vector. A negative control clone was constructed by the deletion of the promoter insert from the

promoter-pEYFP-N1 clone. The original pEYFP-N1 vector (Clontech) with the CMV promoter was used as a positive control.

Transient transfection

Cell lines at 50%-60% confluence was transfected with LGR5 promoter-pEYFP-N1 DNA using FuGENE® HD Transfection Reagent (Roche, Basel, Switzerland) following the manufacturer instructions. LoVo, Caco-2, SW480, human fibroblast CRL2923, 3T3, 4T1, and EMT6 cell lines were transfected in 3:1 transfection reagent to DNA ratio in serum-free medium. For the SY5Y cell line, the ratio was 3:2. Eight to ten hours post-transfection, serum was added to the culture medium. All cultures were kept at 37 °C in a 5% CO_2 atmosphere until microscopic analyses were performed using an inverted fluorescence microscope (IX51, Nikon, Tokyo, Japan) 24-48 h post-transfection to examine enhanced yellow fluorescent protein (EYFP) expression levels.

Flow cytometry

For flow cytometry and fluorescence-activated cell sorting (FACS), cultured cells were harvested by incubation in a non-enzymatic cell dissociation buffer (Gibco® Life Technologies, Waltham, MA, United States) for 7-10 min. Next, cells were washed in phosphate buffer saline (PBS) and resuspended in 0.5 mL PBS for analysis. Flow cytometric analysis of EYFP expression of live cells was conducted using an Accuri flow cytometer (BD Biosciences, San Jose, CA, United States). FACS sorting was performed using an Influxcell sorter (BD Biosciences). Negative controls were used in every analysis to set the background fluorescence. Propidium Iodide Staining Solution (Invitrogen) was added to discriminate dead cells. Data analysis was performed on at least 10000 cells per sample as assessed by CFlow software (BD Biosciences). Fluorescence gates for positive cells were set to attain the false-positive rates of < 1%.

Colony PCR

A single colony of bacterial cells was suspended in a reaction volume of 50 µL, containing 1 µL of PCR primers (10 µmol/L each), 5 µL of 10 × PCR Buffer Minus Mg^{2+}, 1 µL of 10 mmol/L dNTP mixture, 1.5 µL of 50 mmol/L $MgCl_2$, and Milli-Q water. The cycle parameters of the reaction were as follows: Initial denaturation 95 °C for 3 min; 35 cycles of 30 s for denaturation at 95 °C, 30 s for annealing at 58 °C, and 1 min for the extension at 72 °C then final elongation at 72 °C for 2 min.

Quantitative real-time PCR

RNA extraction and complementary DNA (cDNA) synthesis: RNA was extracted from approximately 5 × 10^6 cells using RNeasy mini kit (Qiagen, Valencia, CA, United States) following the manufacturer's instructions. DNAse I treatment (on column) was performed during the extraction procedure as recommended by the kit manual. RNA quantification was performed using Nanodrop 1000. One microgram of RNA was used for cDNA synthesis using iScript™ cDNA Synthesis Kit (Bio-Rad Laboratories, Inc., Hercules, CA, United States) following the manufacturer's instructions. As a control for genomic DNA contamination, a 'no reverse transcriptase reaction' was carried out for every batch of cDNA synthesized.

Quantitative real-time PCR analysis: SsoFast™ EvaGreen® Supermix was used as the Master-mix and quantitative real-time PCR (qPCR) was carried out with a C1000™ Thermal Cycler (Bio-Rad Laboratories, Inc.). Each gene was amplified in triplicate in a reaction volume of 10 µL, containing 10 µL qPCR primers (Table 1), 5 µL of 2 × SsoFast EvaGreen Supermix, 0.2 µL cDNA, and Milli-Q water. The cycling parameters of the reaction were as follows: 95 °C for 3 min for enzyme (Sso7-fusion polymerase)

activation; 40 cycles of 10 s for denaturation at 95 °C, and 30 s for annealing and extension at 60 °C followed by a Melt Curve analysis to ensure reaction specificity. Glyceraldehyde-3-phosphate dehydrogenase was amplified in parallel and used for normalization. The amplification product was then analyzed using the 2-ΔCt method. 'No reverse transcriptase' and water controls were included in each qPCR run to exclude genomic DNA or sample cross-contamination.

Soft agar assay

To test anchorage-independent growth in soft agar, a layer of 0.6% agar (Agar Noble; Difco Laboratories, Detroit, MI, United States) in 2 × DMEM containing 20% FBS was plated in 35-mm dishes and placed in the fridge overnight. The next day, Geneticin resistant (400-500 μg/mL of Geneticin) cells were sorted for EYFP expression into high, low, and no-EYFP expressing cells using the Influxcell sorter (BD Biosciences). Cells were next washed with PBS and pelleted by centrifugation at 300 *g* for 3 min. Cells (2×10^4) were suspended in 2 mL of equal volumes of 0.6% agar (Agar Noble; Difco Laboratories) and 2 × DMEM containing 20% FBS and overlaid as a second layer. This was overlaid over a layer of 3 mL of 0.3% agar in the same medium, in 35 mm dishes. Once a week, 300 μL of medium containing 0.3% agar was added. After 21 d, plates were stained with 0.5 mL of 0.005% Crystal Violet for an hour. Colonies larger than 0.25 mm in diameter were then counted using ImageJ software.

In vivo tumorigenicity assay

Six- to eight-week-old non-obese diabetic (NOD)/severe combined immunodeficient (SCID) mice were obtained from Animal Resources Centre (Perth, Australia) and were housed in the animal house facility of the Australian Institute for Bioengineering and Nanotechnology, The University of Queensland. All procedures were approved by the University of Queensland Animal Ethics Committee (UQCCR/115/13/NHMRC) and conformed to the Animal Care and Protection Act Qld (2002) and the Australian Code of Practice for the Care and Use of Animals for Scientific Purposes (8th edition, 2013). Sorted cells were suspended in a 1:1 mixture of medium and Matrigel (BD Biosciences) and injected subcutaneously into NOD/SCID mice (2×10^5 cells per animal in a total volume of 50 μL) into the ventral side of the flank (n = 3 animals per group). Tumor growth was monitored and measured with calipers daily. Three weeks after the injection, mice were anesthetized by CO_2 inhalation, and tumors were excised, measured, weighed, and fixed in 4% paraformaldehyde for paraffin embedding. Tissue sections were stained with hematoxylin-eosin.

RESULTS

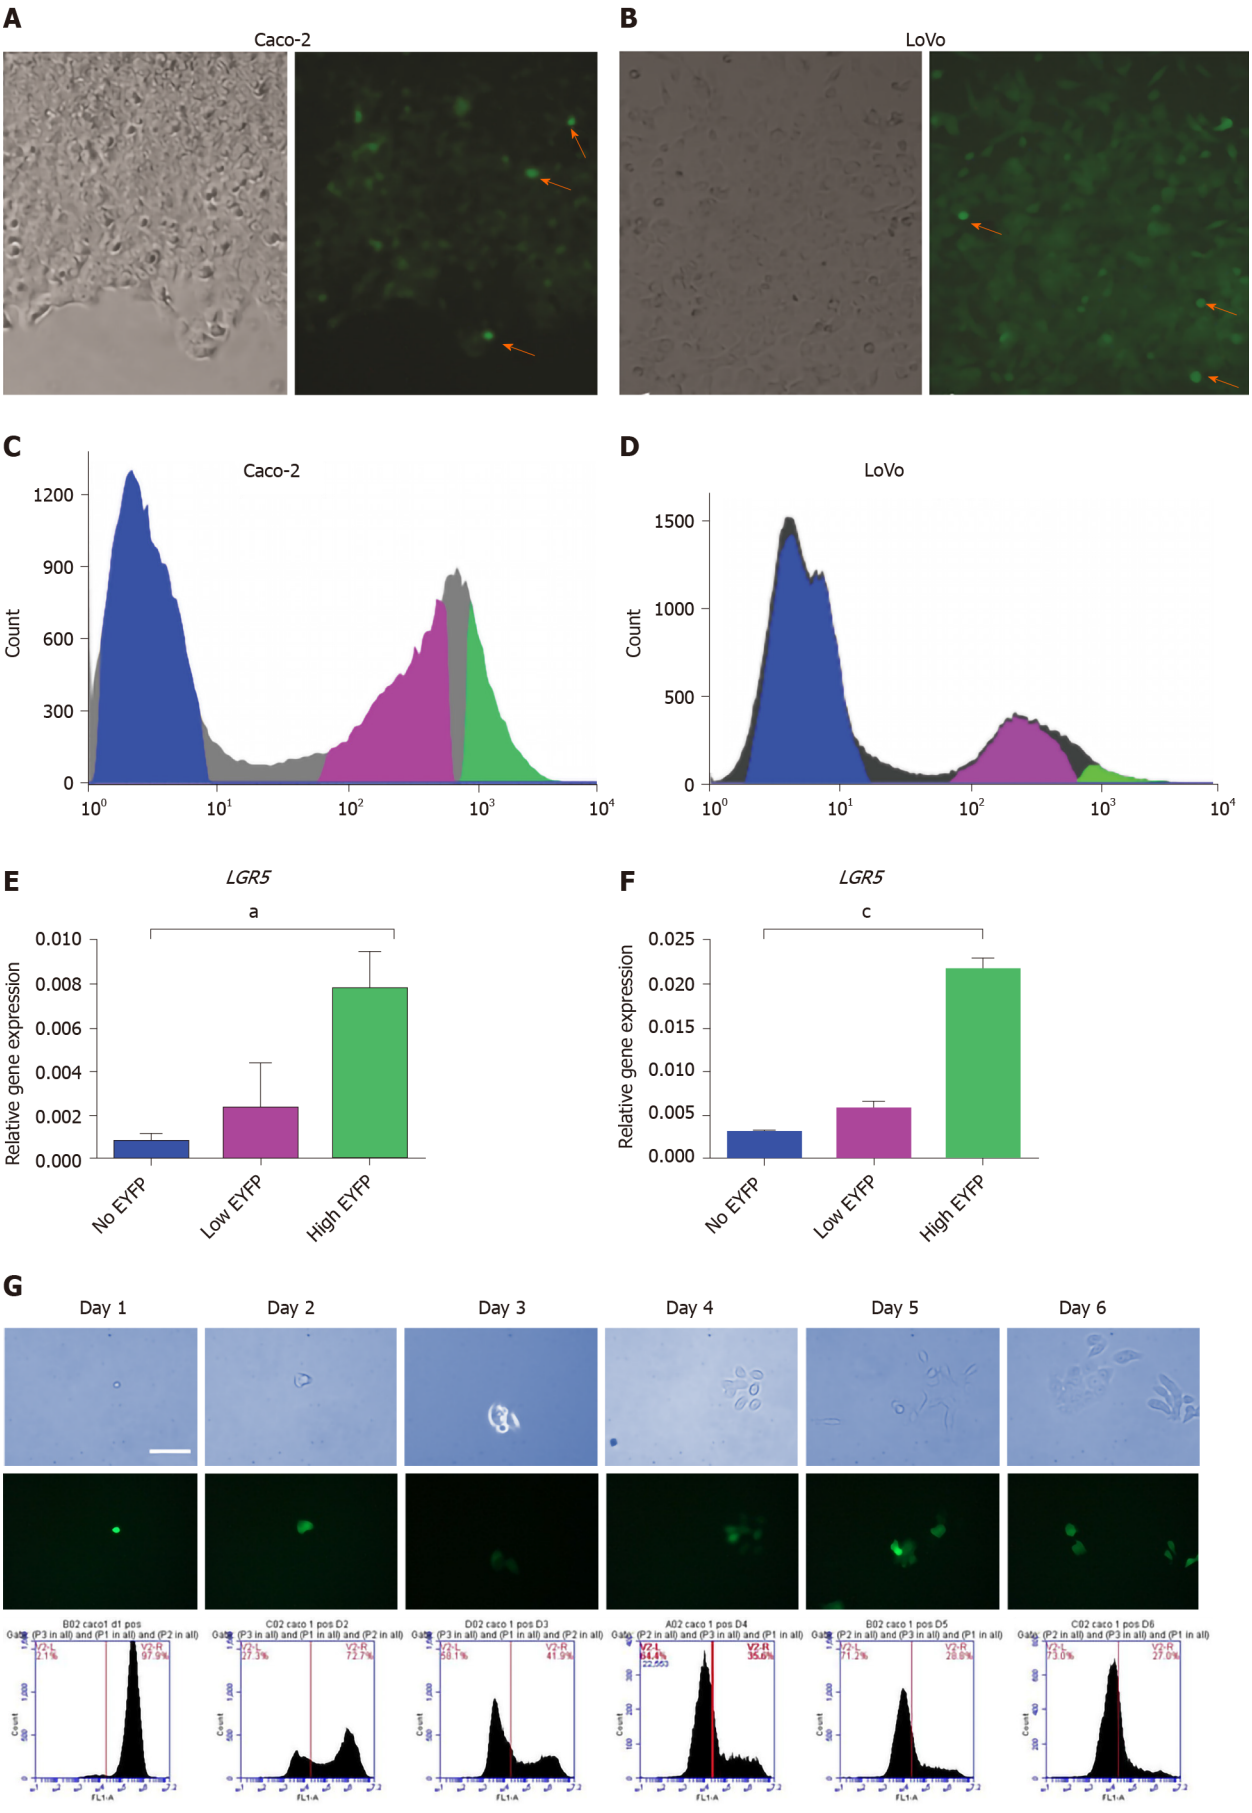
A conserved LGR5 enhancer-based promoter fragment recapitulates endogenous LGR5 expression

Due to the lack of a reliable anti-LGR5 antibody, isolation of LGR5 expressing cells *via* FACS or magnetic-ACS was not possible in our hands. We, therefore, constructed an EYFP reporter driven by a conserved LGR5 promoter fragment (Supplementary Figure 1A). To test whether the *LGR5* promoter-based construct correctly reported on LGR5 expression, we transiently transfected the LGR5-EYFP reporter as well as a negative control vector (promoter-less vector or empty-EYFP vector) and a positive control vector (CMV-EYFP) into colon cancer cell lines Caco-2, LoVo, and SW480 that display a high endogenous expression of *LGR5* and into CRL2429, 3T3, NSC-34 and SH-SY5Y cells that do not express LGR5 messenger RNA (mRNA). Transient transfection of the LGR5 reporter construct in these LGR5-expressing and LGR5-negative cell lines revealed that EYFP expression correlated well with endogenous LGR5 mRNA expression level (Supplementary Figure 1B). As expected, transfection of the promoter-less construct (empty-EYFP vector) did not result in YFP expression, whereas the CMV-driven EYFP vector showed widespread (30%-60% of cells) expression (Supplementary Figure 1B), indicating that the absence of fluorescence in LGR5 negative lines was not due to ineffective delivery of plasmid DNA.

To generate stably expressing reporter lines, Caco-2 and LoVo cell lines were transfected with a linearized LGR5 reporter vector, single-cell seeded, and maintained under Geneticin selection (400 μg/mL for LoVo cell line and 500 μg/mL for Caco-2 cell line) for 1 mo. Two single cell-derived clones from each cell line were picked, expanded, and cryopreserved. Fluorescence microscopy analysis revealed that these clonal LGR5/EYFP Caco-2 and LGR5/EYFP LoVo cultures contained a subset of cells

with a range of EYFP fluorescence, including small EYFP fluorescence bright cells (Figure 1A and B; orange arrows), which was validated using FACS (Figure 1C and D). Cells transfected with promoter-less plasmid showed no EYFP expression in any of the surviving clones, whereas the majority of CMV-promoter transfected clones homogeneously expressed EYFP, as expected. We hypothesized that cells expressing high levels of LGR5/EYFP in the colon cancer cell lines would constitute the stem cell compartment of Caco-2 and LoVo cell lines. To test this hypothesis, we sorted the cells into three populations according to their EYFP expression (EYFP^{negative}, EYFP^{low}, and EYFP^{high} cells). As anticipated, the qPCR analysis showed that LGR5 mRNA expression was 8-fold higher in EYFP high cells than in the EYFP negative fraction in both LGR5/EYFP Caco-2 and LGR5/EYFP LoVo clonal lines (Figure 1E and F, respectively).

In agreement with the idea that LGR5 marks a stem cell compartment, flow cytometric analysis of sorted EYFP^{negative}, EYFP^{low}, and EYFP^{high} cells from each of the lines revealed that over the course of several days, EYFP^{high} cells gave rise to EYFP negative "daughter" cells (Figure 1G and H). Time-lapse immunofluorescence and phase-contrast images of cultured EYFP^{high} sorted Caco-2 cells confirmed that EYFP negative cells emerged from the small EYFP^{high} cells over time (Figure 1G). No cells acquired EYFP expression amongst derivatives of FACS-sorted EYFP-negative cells (Figure 1I). LGR5-EYFP LoVo clones exhibited identical behaviors (Figure 1H and J). We interpreted these data to mean that LGR5^{high} (EYFP^{high}) cells possess stem cell-like properties, given they are capable of self-renewal and generate a distinct EYFP-negative cell population, incapable of re-acquiring expression of the LGR5 reporter.



EYFP^{high}-expressing cells of Caco-2 and LoVo CRC cell lines show an ISC gene expression signature

If LGR5/EYFP^{high} cell populations in Caco-2 and LoVo clones represent an ISC compartment, then these cells should show higher mRNA expression of typical ISC marker genes compared to LGR5/EYFP^{low} and LGR5/EYFP^{negative} fractions. Our data (Figure 2A) show that EYFP^{high} cells in the Caco-2 cell line indeed display significantly increased expression of the stem cell markers LGR5, olfactomedin 4 (OLFM4), TERT, leucine-rich repeated and immunoglobulin-like domains 1 (LRIG1), AFAP1I1, TNFRF19, organic cation transporter 1 (OCT1), and achaete-scute complex homolog 2 as compared to cells with low or no EYFP expression, but conspicuously do not express B lymphoma Moloney murine leukemia virus insertion region 1 homolog (Bmi1). Surprisingly, in the LoVo cell line (Figure 2B) EYFP^{high} cells expressing high LGR5 reporter activity possessed low levels of OLFM4, AFAP1I1, and LRIG1 compared to EYFP^{low} and EYFP^{negative} fractions. EYFP^{high} cells in the LoVo cell line instead robustly express Bmi1 as compared to EYFP^{negative} cells but exhibit lower hTERT as compared to EYFP^{negative} and EYFP^{low} fractions. These data suggest that in the LoVo cell lines LGR5 marks a different cancer cell compartment than in Caco-2 cells. Collectively, our data indicate that the LGR5/EYFP reporter faithfully marks a population of LGR5 expressing CSCs in the Caco-2 cell line but that this stem cell population is distinct from the EYFP^{high} fraction in the LoVo cell line that appears to mark a Bmi1^{high}/LGR5 TERT^{low} expressing a subset of cells.

LGR5/EYFP^{high} cells in Caco-2 colon cancer cell line exhibit increased colony-forming ability

To assess whether LGR5 expressing subsets in the Caco-2 and LoVo lines exhibit functional differences we employed the anchorage-independent tumor stem cell colony-forming assay[25]. Using this assay, we assessed the *in vitro* anchorage-independent growth of LGR5/EYFP^{high}, LGR5/EYFP^{low}, and LGR5/EYFP^{negative} cell populations of the LGR5/EYFP Caco-2 and LGR5-EYFP LoVo lines (Figure 3A and B). Our data showed that after 3-wk culture in soft agar, the number of colonies formed by the three cell populations of Caco-2 and LoVo cell lines was comparable (Figure 3C and E) but that the colony sizes of the LGR5/EYFP^{high} cell populations in Caco-2 line were considerably larger (> 0.25 mm in diameter) than those in LGR5/EYFP^{low} and LGR5/EYFP^{negative} cell populations (Figure 3D and F), suggesting LGR5^{high} cells in Caco-2 cell line exhibit increased proliferation and/or reduced cell death rates.

To assess further the tumorigenicity of the LGR5/EYFP^{high} cell compartments of Caco-2 and LoVo lines, LGR5/EYFP^{high} and EYFP^{negative} sorted cells were injected subcutaneously into the right and left flanks, respectively, of NOD-SCID mice (n = 3), and tumor growth was monitored daily before excision of tumors after 3 wk. As shown in Figure 4A, LGR5/EYFP^{high} Caco-2 cells were able to form tumors when injected into NOD-SCID mice. LGR5/EYFP^{high} formed larger tumors than the LGR5/

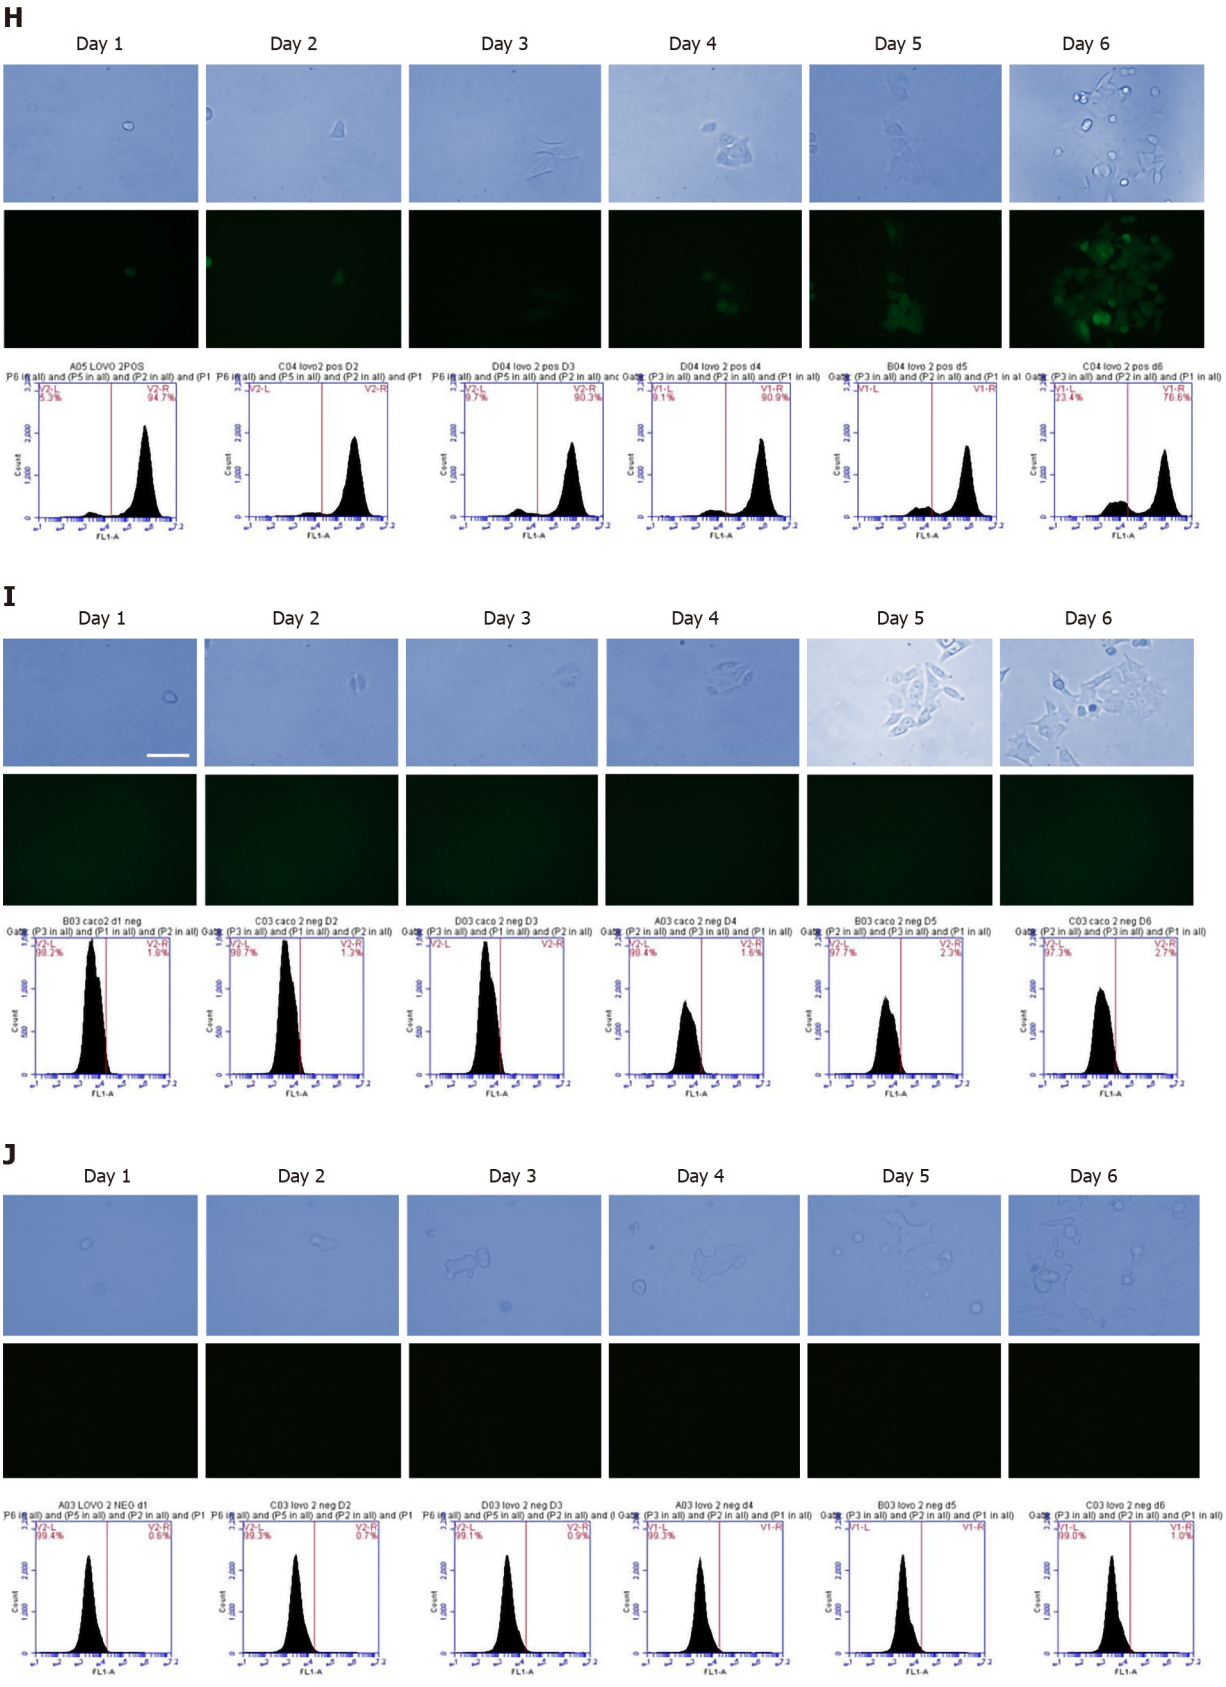

Figure 1 Proliferation and differentiation analysis of the stem cell compartment in stably transfected clones. A and B: Phase contrast and fluorescence images show colonies of stably transfected Caco-2 (A) and LoVo (B) cells expressing the enhanced yellow fluorescent protein (EYFP) reporter (red arrows show small cells expressing high level of enhanced yellow fluorescent protein, EYFP); C and E: Fluorescence-activated cell sorting (FACS) sorting of leucine-rich repeat-containing G protein-coupled receptor 5 (LGR5)/EYFP expression in Caco-2 clone (C) and LoVo clones (E) into EYFP^{high}, EYFP^{low}, and EYFP^{negative} populations; D and F: Quantitative real-time polymerase chain reaction analysis of *LGR5* messenger ribonucleic acid expression in EYFP^{high}, EYFP^{low}, and

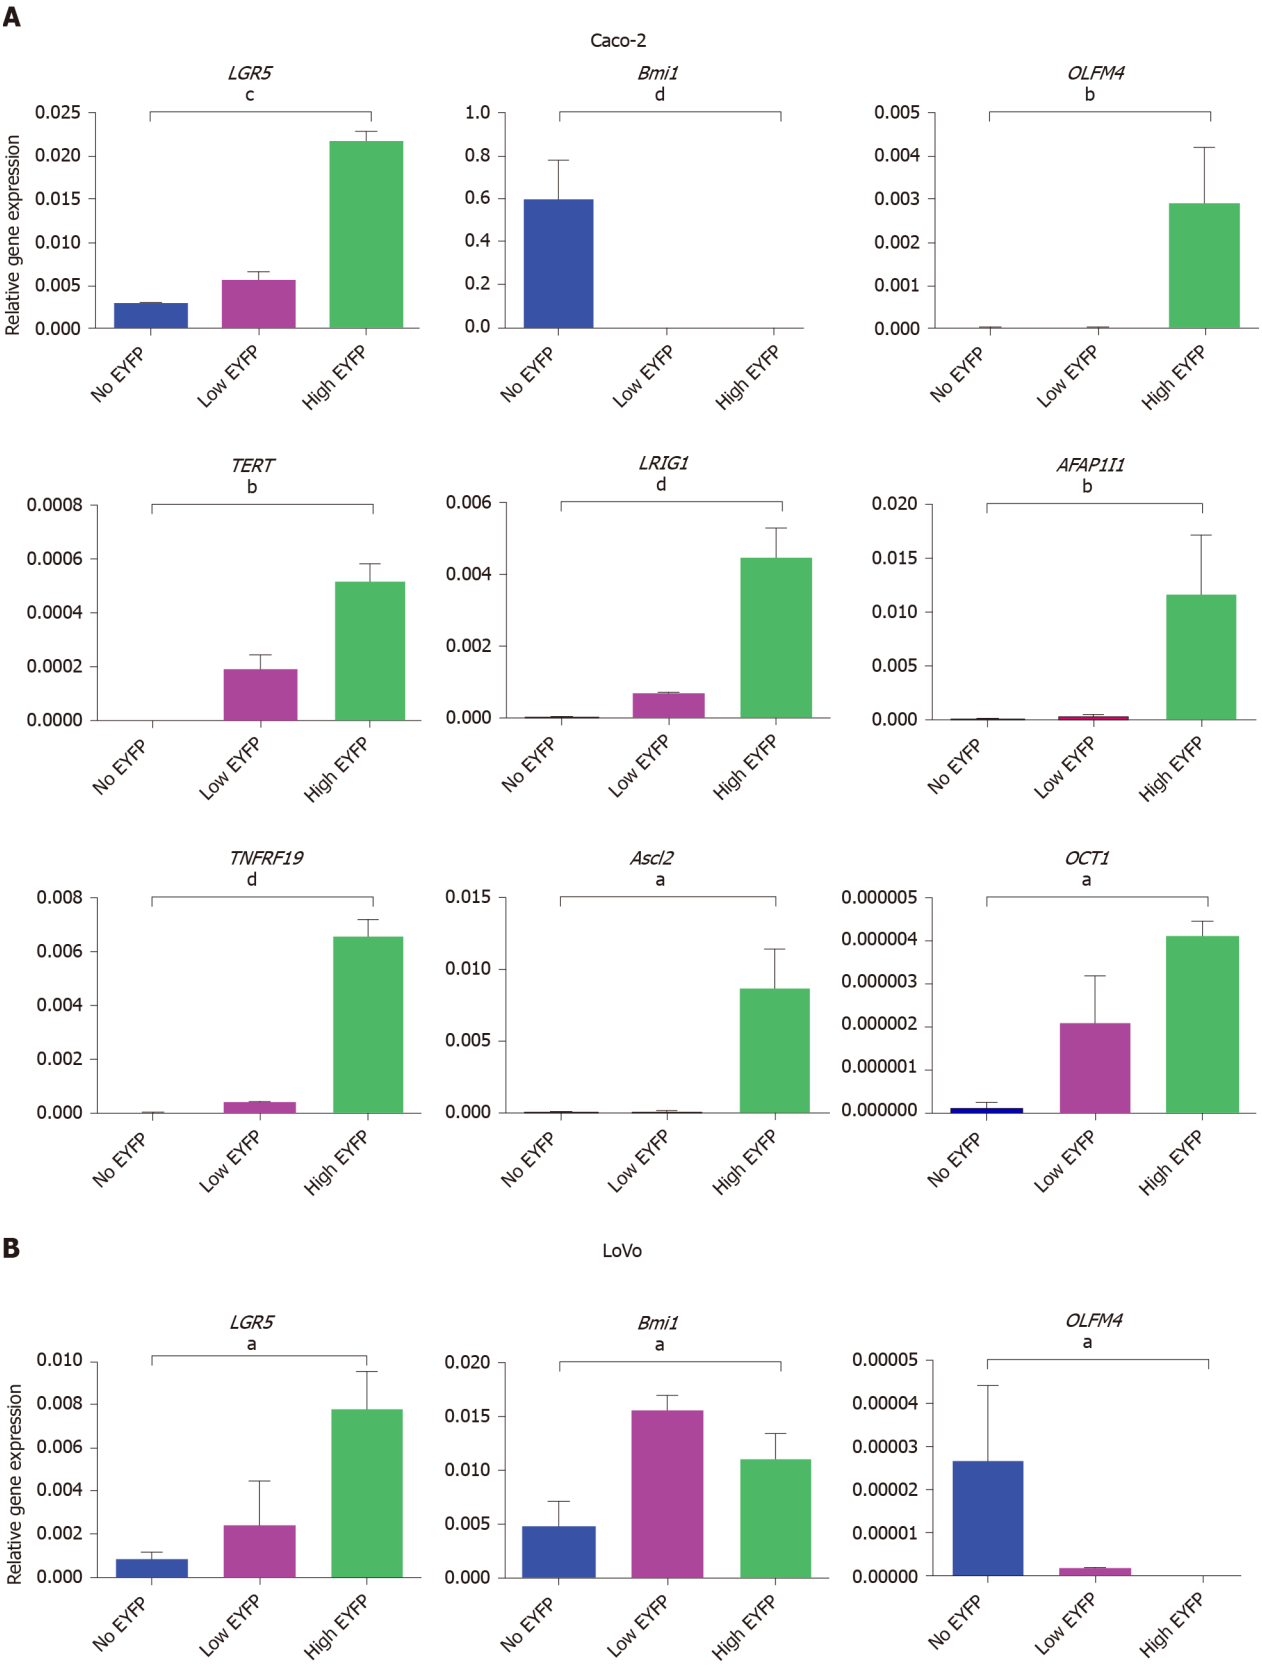
EYFP^{negative} cells relative to glyceraldehyde-3-phosphate dehydrogenase gene in Caco-2 clones (D) and LoVo clones (F); G: Phase contrast images show proliferation of EYFP^{high} cells from LGR5/EYFP Caco-2 clone; fluorescence images show self-renewal of LGR5/EYFP stem cells and down-regulation of LGR5/EYFP in differentiated progeny in LGR5/EYFP Caco-2. Sequential FACS analysis shows EYFP expression in LGR5/EYFP Caco-2 clone over 6 d in culture; H: Phase contrast images show proliferation of EYFP^{negative} and cells from LGR5/EYFP Caco-2 clone; fluorescence images show self-renewal of LGR5 stem cells and down-regulation of LGR5 in differentiated progeny in LGR5/EYFP Caco-2. Sequential FACS analysis shows EYFP expression in LGR5/EYFP Caco-2 clone over 6 d in culture; I and J: Phase contrast images show proliferation of EYFP^{high} (I) and EYFP^{negative} (J) cells from LGR5/EYFP LoVo clone; fluorescent pictures showing self-renewal of LGR5 stem cells and down-regulation of LGR5/EYFP in differentiated progeny in LGR5/EYFP LoVo; sequential FACS analysis of EYFP expression in LGR5/EYFP LoVo clone over 6 d in culture. LGR5: Leucine-rich repeat-containing G protein-coupled receptor 5; EYFP: Enhanced yellow fluorescent protein.

EYFP^{negative} cells (Figure 4B and C).



In the LoVo cell line, on the other hand, both LGR5/EYFP^{high} cells and LGR5/EYFP^{negative} sorted cells had almost comparable tumorigenic properties (Supplementary Figure 2).

DISCUSSION

The heterogeneity of cancer cell lines has been recognized, but it was not until the 1980s that it was shown that the human DLD-1 colon cancer cell line, originally established from a single human colon carcinoma[26], contains subpopulations of cells with different morphology, karyotype, and cloning efficiency in soft agarose that produce histologically distinct tumors when injected into athymic mice. Recent studies have explained this apparent heterogeneity of colon cancer cell lines when it was discovered that colon cancer carcinoma contains a subset of stem cells expressing LGR5, termed "tumor-initiating" cells specimens[27]. This was strongly supported by lineage tracing studies[28] showing that colon cancer is initiated by aberrant Wnt signaling in ISCs, known to express high levels of LGR5. Furthermore, *in vivo* lineage tracing experiments on intestinal adenomas demonstrated the clonal expansion of these adenomas from a single LGR5-expression cell[14].

In light of this evidence, we decided to investigate whether colon cancer cell lines widely used for drug-screening[21] contain CSCs and developed a reporter that would allow their isolation and characterization. Here, we showed that a 983 bp fragment of the LGR5 promoter faithfully reports on endogenous LGR5 expression in the colon cancer cell lines LoVo and Caco-2. Interestingly, we revealed that the ISC populations in these two cell lines exhibit different gene expression and functional properties. Our data show that the Caco-2 cell line contains a population of highly proliferative cells that exhibit a classic intestinal CSC gene expression signature that is marked by a high expression of LGR5, in agreement with previous findings[28,29]. These cells can both self-renew and generate more differentiated LGR5 negative progeny and also exhibit an *in vitro* tumorigenic potential. In support of the notion that LGR5/EYFP^{high} cells within Caco-2 colon cancer cell line represent the CSC compartment, our limited gene expression analysis revealed that LGR5/EYFP^{high} cells display a transcriptional signature very similar to that of the ISC, including *LGR5*, *Olfm4*, and *Ascl2*[29-31]. Our data are also in agreement with Sato *et al*[9] who showed that only very high LGR5-expressing cells are the ISCs in normal intestinal tissue. In agreement with a study by Maddox *et al*[32], our data further show that the LGR5/EYFP^{high} fraction of the Caco-2 cell line exhibits a high expression of OCT1, a known ISC marker. The LGR5/EYFP^{high} fraction of the Caco-2 colon cancer cells also showed the highest telomerase expression (TERT), which is a characteristic of most CSCs, associated with the ability to proliferate indefinitely[33,34]. Conspicuously, the LGR5/EYFP^{high} fraction of the Caco-2 acquires Bmi1 expression upon loss of LGR5 expression, in agreement with the proposed cellular differentiation hierarchy of the intestinal crypt[10]. Collectively, these data suggest that the LGR5/EYFP^{high} fraction of the Caco-2 colon cancer cell line indeed represents a CSC-like population. These data are in close agreement with a similar study in SW480 and HT-29 human colon cancer cell lines in which LGR5 was also found to mark a CSC population[35].

In contrast to the Caco-2 cell line, in the LoVo colon cancer cell line, LGR5/EYFP^{high} cells showed the lowest expression of the ISC markers hTERT, LRIG1, AFAP1I1, and , and low expression of the CSC marker OCT1, suggesting that in LoVo cells LGR5 marks a different cell population, *i.e.* not a stem cell-like population. Indeed, our data show that in the LoVo cell line, cells with high LGR5/EYFP expression possess a gene expression signature more akin to Bmi-expressing stem cells of the crypt. In LoVo cells it is rather the LGR5^{negative} fraction that highly expresses ISC marker OCT1[32],

OLFM4[36,37], and Bmi1[10], suggesting that this cell line originated from a CSC population other than LGR5^{+}cells. Supporting this suggestion, in a recent review on the intestinal hemostasis and plasticity in humans, the writer argued that there is a wide range of cell types in the intestinal epithelium that can revert to stem cell fate and regenerate the epithelium post-injury[38]. Moreover, Bmi1 marks a distinct pool of ISCs that mainly reside above the crypt base[39]. Lineage tracing has shown that this Bmi1^{+} stem cell pool, the so-called reserve stem cell pool, is able to regenerate intestinal epithelial tissue in the absence of LGR5^{+} ISCs[10,39] and also give rise to LGR5^{+} cells in normal and injured intestinal epithelium[40]. In support of this idea, a number of other human colon cancer cell lines (such as LIM1899, LIM1215, LIM2537, and LIM1863)[41] have previously been shown to exhibit increased anchorage-independent growth and enhanced tumorigenicity in xenograft experiments upon ablation of LGR5.

CONCLUSION

We conclude that we have generated a portable LGR5-reporter that should prove a valuable tool for the identification and isolation of different colon CSC populations in colon cancer lines. The characterization of such populations is important for drug screening and design. Since LGR5 marks adult stem cell populations in a number of tissues throughout the body[42], it will be interesting to determine whether our LGR5 promoter reporter can also be used to isolate such LGR5 expressing CSCs from other human cancer cell lines such as glioblastoma[43], esophageal adenocarcinomas[44], ovarian primary tumors[45], gastric tumors[46], and hepatomas[47-50] that are also marked by high LGR5 expression.

Our data further indicate that LGR5/EYFP^{high} expression marks two different intestinal crypt stem cell population in the Caco-2 and LoVo cell lines. Since Caco-2 and LoVo cell lines are widely used for screening of colon cancer drugs[51], our findings of different stem cell populations in these lines likely has important implications for

Columns and error bars represent means ± SD of two independent experiments using duplicate measurements for each experiment. neg: Negative; LGR5: Leucine-rich repeat-containing G protein-coupled receptor 5; YFP: Yellow fluorescent protein.

ARTICLE HIGHLIGHTS

Research background

The intestinal crypt-villus structure harbors two distinct pools of putative stem cells, the active [leucine-rich repeat-containing G protein-coupled receptor 5 (LGR5)$^+$ cells] and the quiescent stem cell populations (B lymphoma Moloney murine leukemia virus insertion region 1 homolog$^+$ or telomerase reverse transcriptase$^+$ cells). Current evidence indicates that CRC is indeed a disease of colon stem cells that are resistant to current therapeutics and can rapidly proliferate to re-establish the tumor. Furthermore, it was reported that colon cancer carcinoma specimens contain a subset of LGR5-expressing stem cells. Human colon cancer cell lines, such as Caco-2 and LoVo, are extensively used in drug screening and colon cancer research and express high levels of LGR5.

Research motivation

To establish criteria for the selection of suitable cell lines for drug discovery and reveal potential variability between colon cell lines, we here identify the cancer stem cell (CSC) population(s) within colon cancer cell lines, quantify differences in gene expression signatures in these cells, and assess their proliferative and tumorgenicity capacities.

Research objectives

The present study aimed to isolate cells expressing LGR5 in Caco-2 and LoVo colon cancer cell lines and investigate whether these cells constitute the CSC compartments

in these cell lines. This was achieved through the creation of a transgenic proliferating stem cell-specific reporter construct based on the proximal promoter of *LGR5* gene.

Research methods

Using a portable fluorescent reporter construct based on a conserved fragment of the LGR5 promoter, subpopulations of cells from the colon cancer cell lines (Caco-2 and LoVo) were sorted into three cell compartments expressing different levels of LGR5 (high-, low-, and no-expression of LGR5). Next these cell compartments were characterized based on their gene expression signatures, proliferation, and tumorgenicity properties.

Research results

Cells expressing high levels of LGR5 with Caco-2 colon cancer cell line appear to represent a CSC-like population. In contrast, in the LoVo cell line, the LGR5 negative fraction possessed some features of the intestinal stem cells, *e.g.*, a specific gene expression signature, suggesting that this cell line was likely derived from a CSC population other than LGR5$^+$ cells.

Research conclusions

LGR5 marks the stem cell compartments of the Caco-2, but not LoVo, cell lines. Thus, it would appear that different colon cancer lines possess properties of different stem cell compartments. The portable LGR5 reporter outlined in this study constitutes a valuable tool for the identification and purification of LGR5-expressing cells from mixed cell populations.

Research perspectives

The portable LGR5 reporter described in this study constitutes a valuable tool for the identification and purification of LGR5-expressing cells from mixed cell populations.

ACKNOWLEDGEMENTS

We thank Professor McGuckin M (MMRI, Brisbane) for providing human colon cancer cell lines (Caco-2, LoVo, and SW480) and Dr. Rolfe B (AIBN, Brisbane) for providing mouse NSC-34 cells.

Abstract

BACKGROUND

Expression of the full-length isoform of Abelson interactor 1 (ABI1), ABI1-p65, is increased in colorectal carcinoma (CRC) and is thought to be involved in one or more steps leading to tumor progression or metastasis. The ABI1 splice isoform-L (ABI1-SiL) has conserved WAVE2-binding and SH3 domains, lacks the homeodomain homologous region, and is missing the majority of PxxP- and Pro-rich domains found in full-length ABI1-p65. Thus, ABI1-SiL domain structure suggests that the protein may regulate CRC cell morphology, adhesion, migration, and metastasis *via* interactions with the WAVE2 complex pathway.

AIM

To investigate the potential role and underlying mechanisms associated with

Hospital Institutional Review Board (No. 2020-11).

ABI1-SiL-mediated regulation of CRC.

METHODS

ABI1-SiL mRNA expression in CC tissue and cell lines was measured using both qualitative reverse transcriptase-polymerase chain reaction (RT-PCR) and real-time quantitative RT-PCR. A stably ABI1-SiL overexpressing SW480 cell model was constructed using Lipofectamine 2000, and cells selected with G418. Image J software, CCK8, and transwell assays were used to investigate SW480 cell surface area, proliferation, migration, and invasion. Immunoprecipitation, Western blot, and co-localization assays were performed to explore intermolecular interactions between ABI1-SiL, WAVE2, and ABI1-p65 proteins.

RESULTS

ABI1-SiL was expressed in normal colon tissue and was significantly decreased in CRC cell lines and tissues. Overexpression of ABI1-SiL in SW480 cells significantly increased the cell surface area and inhibited the adhesive and migration properties of the cells, but did not alter their invasive capacity. Similar to ABI1-p65, ABI1-SiL still binds WAVE2, and the ABI1-p65 isoform in SW480 cells. Furthermore, co-localization assays confirmed these intermolecular interactions.

CONCLUSION

These results support a model in which ABI1-SiL plays an anti-oncogenic role by competitively binding to WAVE2 and directly interacting with phosphorylated and non-phosphorylated ABI1-p65, functioning as a dominant-negative form of ABI1-p65.

Key Words: Colon cancer; Abelson interactor 1 isoform-L; Cell adhesion; Cell migration; WAVE2

Core Tip: The purpose of this study was to investigate the role and mechanism of Abelson interactor 1 splice isoform-L (ABI1-SiL) in the metastatic behavior of colorectal carcinoma cells. Our results showed that ABI1-SiL played a key role in cell surface area, adhesion, and migration, but not in proliferation and apoptosis in SW480 cells. ABI1-SiL may have anti-oncogenic roles by competitively binding to WAVE2, and directly interacting with phosphorylated and non-phosphorylated ABI1-p65, functioning as a dominant-negative molecule towards ABI1-p65.

INTRODUCTION

Globally, colorectal carcinoma (CRC) is the third most commonly diagnosed cancer and the fourth most common cause of cancer death[1]. Despite treatment advances for CRC over the past two decades, novel molecular therapeutic strategies are required to generate informative biomarkers and identify new targets[2,3].

Abelson interactor protein-1 (ABI1) is increased and/or phosphorylated in many malignant tumors and has been proposed as a potential tumor promoter[4-11]. By forming complexes with Eps8-Sos1[6], NWasp[12], and WAVE2[13,14], ABI1 has been shown to play critical roles in the regulation of cell proliferation, apoptosis, adhesion, and migration in breast cancer, Bcr-Abl-induced leukemia, and melanoma, both *in vitro* and *in vivo*[4-15]. Recent findings have indicated that ABI1-p65 is increased and involved in colonic tumorigenesis and that it mediates the invasive properties of

CRC[7,8]. Recently, using a CRC tissue chip, we showed that increased expression of ABI1-p65 is significantly correlated with infiltration and associated with shorter overall survival[16]. Taken together, this evidence strongly suggests that ABI1 is involved in one or more of the steps leading to tumor progression or metastasis.

Alternative splicing is one of the main engines that drive proteome diversity, and up to 94% of genes are estimated to be alternatively spliced in humans[17,18]. There are many abnormal mRNA splice isoforms specifically associated with cancer progression and metastasis, some of which exert antagonistic functions[2,19,20]. Numerous structurally distinct isoforms of ABI1 exist in mammalian cells[12,21]. The ABI1-p65 isoform is increased in CRC and is thought to be involved in one or more of the steps leading to tumor progression and metastasis. However, the specific role, if any, that other splice isoforms of ABI1, such as ABI1 splice isoform-L (ABI1-SiL), play in CRC development remains unknown. As Figure 1 shows, ABI1-SiL is a splice isoform of ABI1 resulting from the alternative splicing of exons III, IV, and VIII through X. ABI1-SIL has conserved WAVE2-binding and SH3 domains, as well as several phosphorylated sites, such as pY213, pY421/pY435, and pY506, but lacks the homeodomain homologous region (HHR) and the majority of the PxxP- and Pro-rich domain[16,21]. The domain structure of ABI1-SiL suggests that it might regulate cell morphology, adhesion, migration, and even metastasis of CRC cells, similar to the ABI1-p65 isoform, by interacting with WAVE2 or other proteins.

In this study, we generated polymerase chain reaction (PCR) primers capable of specific detection of the ABI1-SiL isoform. We demonstrated that, compared with ABI1-p65, the expression of ABI1-SiL was significantly decreased in CRC tissues and cell lines, and overexpression of ABI1-SiL repressed migration and adhesion in SW480 colon cancer cells. We showed that both ABI1-p65 and ABI1-SiL were able to interact and co-localize with WAVE2 and ABI1-p65 in SW480 cells. Taken together, this evidence is the first to demonstrate that ABI1-SiL is an antagonistic splice isoform of ABI1-p65 that functions as a potential anti-oncogene.

MATERIALS AND METHODS

Cell lines and reagents

The CRC cell lines HCT-116, HT-29, LoVo, LS174T, SW480, and SW620 (the Type Culture Collection of the Chinese Academy of Sciences, Shanghai, China.), as well as the normal colon cell line CRL-1541 (ATCC, Rockville, MD, United States), were cultured in DMEM (HyClone, Beijing, China) supplemented with 10% fetal bovine serum (FBS) (Sigma, St. Louis, MO, United States). HEK-293T cells (ClonTech, Mountain View, CA, United States) were grown in DMEM (HyClone, Beijing, China) supplemented with 10% FBS. Plasmid-mediated transfection of SW480 cells with pCMV6 and pCMV6-ABI1-GFP (green fluorescence protein) transcript variant 12 (ABI1-Tv12) was performed as previously described using Lipofectamine (Invitrogen, CA, United States)[4,22]. Both pCMV6 and the vector containing human ABI1 cDNA (NM_001178125.1, ABI1-Tv12, encoding ABI1-SiL) were purchased from OriGene Technologies, Inc. (Rockville, MD, United States). G418 (500 μg/mL) was used to select stable cell lines overexpressing ABI1-SiL.

Patient tissue collection

CRC and matched adjacent tissue samples were obtained from 24 patients. All CRC cases were diagnosed using enteroscopy, and primary carcinoma of the colon-rectum was histologically identified. All samples were anonymized prior to this study. The local ethics committee of the Peking University, People's Hospital approved the study.

Qualitative and quantitative PCR analysis

Tissue samples, as well as the cell lines described above, were analyzed for the expression of transcript variant-12 (ABl1-SiL)[21]. Total RNA was isolated from patient samples, CRC cell lines, and transfected SW480 cells using an RNeasy mini kit (QIAGEN, Valencia, CA, United States) as previously described[23]. cDNA was subsequently generated using oligo-(dT) primers and the SuperScript III First-strand Synthesis System (Invitrogen, Carlsbad, CA, United States). PCR was performed to confirm the expression of ABI1-SiL[21] using the following primers: Forward, 5'-CCTCTCAGCTTCGGAGAATGG-3' and reverse, 5'-AGGAGGATTTGT TCTCGACAGTGT-3'. A 101 bp-amplified fragment in the PCR products was shown to be ABI1-SiL (confirmed by DNA sequencing). Quantitative PCR (qPCR) was performed using either human ABI1 universal 1 (ABI1-U1) (transcript variant 1-12)

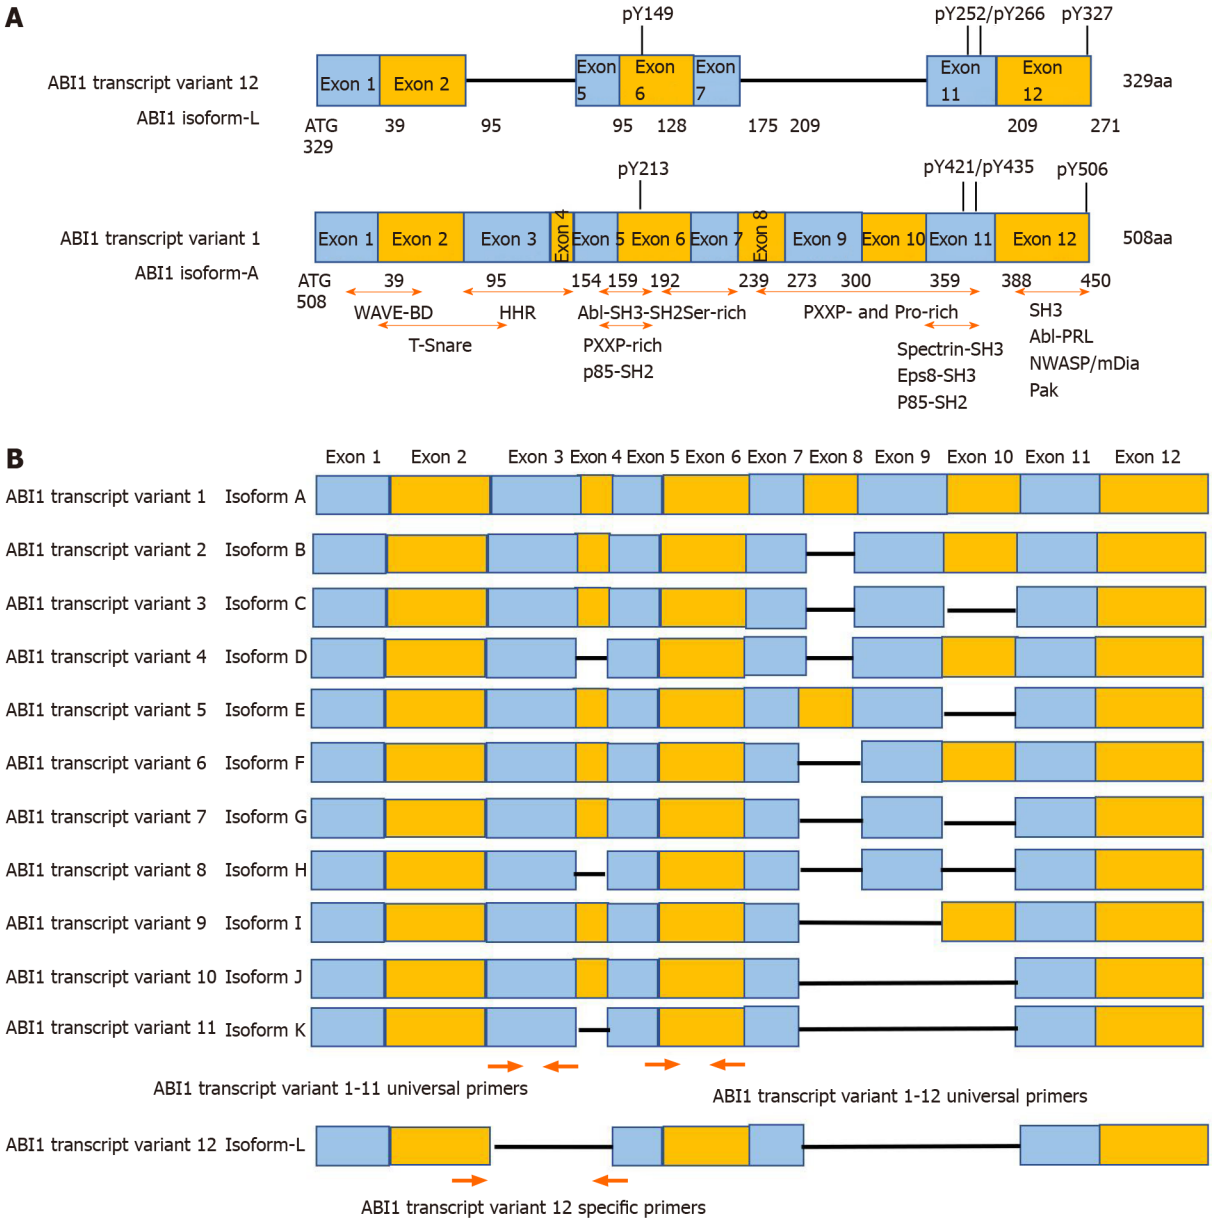

Figure 1 Diagram of Abelson interactor 1 isoforms and polymerase chain reaction primers used to measure expression levels of Abelson interactor 1. A: Schematic comparison of the exons and functional domains of two major isoforms of Abelson interactor 1 (ABL1): ABL1 splice isoform L (ABI1-SiL) and ABL1 splice isoform A (ABI1-p65). ABI1-SiL has conserved WAVE2-binding and SH3 domains, but lacks the homeo-domain homologous region and the majority of the PxxP- and Pro-rich domain; B: Schematic showing locations of ABI1 universal 1 (ABI1-U1)-, ABI1 universal 2 (ABI1-U2)-, and ABI1-SiL-specific primers. Primers were selected to target exon 3, as it represents a major structural difference between ABI1-SiL and other ABI1 variants. Three sets of primers were designed to analyze the expression of ABI1-SiL in colorectal carcinoma cells and tissues. Transcript variant 12-specific primers were used for qualitative analysis, while transcript variant 1-12 universal (ABI1-U1) and transcript variant 1-11 universal (ABI1-U2) primers were used for quantitative analysis of ABI1-SiL expression. ABI1: Abelson interactor 1; HHR: Homeo-domain homologous region.

primers (forward: 5′-ACACTGGGACGGAATACTCCTTAT-3′; reverse: 5′-CTACCACTGTTTTCTCGACTTCCA-3′) or human ABI1 universal 2 (ABI1-U2) (transcript variant 1-11) primers (forward: 5′-AGTGGCACGAAGAGAGATTGG-3′; reverse: 5′-CTGTGTAATCGATAGGTTTCCGAAT-3′) and SYBR Green Master Mix (Applied Biosystems, Foster City, CA, United States). PCR reactions began with a 10 min incubation at 95 °C for AmpliTaq Gold activation, followed by 40 cycles at 95 °C for 15 s for the denaturation step and 60 °C for 1 min for the primer annealing and extension step. qPCR was performed using the DNA Engine Option 2 System (Bio-Rad, CA, United States). Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was used as an endogenous housekeeping control for relative quantification of transcription (forward primer: 5′-AACGACCCCTTCATTGAC-3′, reverse primer: 5′-TCCACGACATACTCAGCAC-3′). The percentage of ABI1-SiL among all variants was calculated as $(1\text{-}2^{-[\text{Ct-ABI1-U2-Ct-ABI1-U1}]}) \times 100\%$.

To examine the potential roles of ABI1-SiL overexpression on differentiation and invasion of SW480 cells, a series of additional genetic markers (including POU, CD44, KRT20, MMP1-4, and WAVE2) were also analyzed by qPCR (primers sequences are not shown).

Cell culture and transfection

Lipofectamine-mediated transfection of SW480 cells was performed as previously described[4]. Cells were plated in six-well plates 24 h prior to transfection, and 2 μg of plasmid DNA was used for each transfection. To overexpress ABI1-SiL, a pCMV6 vector specifically coding for ABI1-SiL or a control pCMV6 empty vector was used for stable transfection of SW480 cells or transient transfection of 293T cells. Forty-eight hours after transfection, transfected cells were treated with G418 (500 μg/mL). Individual G418-resistant clones were picked after 3-4 wk. Clones were analyzed by qPCR and Western blot for ABI1-SiL expression, and clones with the highest ABI1-SiL expression were chosen for further studies. Clones 3 and 6 overexpressing ABI1-SiL were named SW480-ABI1-SiL3 and SW480-ABI1-SiL6, respectively. SW480 cells transfected with the empty pCMV6 vector were named SW480-V.

To analyze the subcellular localization of ABI1-SiL in SW480 cells and to test for co-localization with ABI1-p65 and/or WAVE2, a pCMV6 vector encoding a GFP-ABI1-SiL fusion protein was used for both transient and stable transfections. In transient experiments, 48 h after transfection, the 293T cells underwent subcellular localization studies by fixing the cells in 4% paraformaldehyde in phosphate buffer saline (PBS) for 10 min, followed by fluorescence microscopy analysis.

Western blot and co-immunoprecipitation

Western blot analyses were performed as previously described[4]. We used the following antibodies: GAPDH (1:2000 dilution; #CB100999, Proteintech, IL, United States), ABI1-p65 (1:1000 dilution; D147-3, BML, MA, United States), WAVE2 (1:500 dilution; 07-410, Upstate, NY, United States), GFP (1:200 dilution; 1G6; Pregene Co. Beijing, China), and NAP-1 (1:1000 dilution; #12140-1-AP, Proteintech, IL, United States) protein A/G (Sc-2003, Santa Cruz, CA, United States). The protease inhibitor cocktail was purchased from Sigma (St. Louis, MO, United States). Cells were lysed in lysis buffer (20 mmol/L HEPES, pH 7.2; 150 mmol/L NaCl; 1% Triton X-100; and 10% glycerol). Total protein lysates (150 μg each) from all tested cell lines were separated on sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) gels, transferred to a nitrocellulose membrane, and immunoblotted with appropriate antibodies. Immunoprecipitation analysis was performed as described previously[4]. Briefly, SW480-V and/or SW480-ABI1-SiL6 cells were lysed as described above and incubated with appropriate antibodies bound to sepharose beads. Immunoprecipitates were resolved by SDS-PAGE, transferred to nitrocellulose, and immunoblotted with appropriate antibodies. Membranes were then washed with TBST buffer and incubated with secondary antibodies conjugated to HRP (horseradish peroxidase) (Jackson ImmunoResearch Laboratories Beijing, China). Bound antibodies were detected using the SuperSignal West Pico Trial Kit (Thermo Scientific, Rockford, IL, United States), and images were acquired using an ImageQuant 350 system (GE Healthcare, Piscataway, NJ, United States) and analyzed using ImageJ software (NIH, Bethesda, MD, United States).

Cell surface area assay

To measure the surface area, all four tested cell lines were routinely cultured and images were captured using a Cannon EOS600D camera. ImageJ was used to measure the cell surface area of 100 cells per condition. The measured values were normalized to the mean value of the SW480 parental cells.

Cell adhesion, migration, and invasion assays

For adhesion assays, 2.5×10^5 cells from each cell line were plated in a six-well plate (2.5 mL/well) coated with or without either 0.2% BSA or 0.1% gelatin, or fibronectin (5 μg/mL) (BD Biosciences, Bedford, MA, United States) and incubated at 37 °C/5% CO_2 for 6 h. Non-adherent cells were removed, and adherent cells were washed three times with 1 mL pre-warmed DMEM medium. To determine the number of adherent cells, the number of adherent cells within five randomly selected microscopic fields was counted in three independent experiments.

Cell migration assays were performed using a 24-well transwell chamber (Corning, New York, NY, United States) with 8.0-μm pore polycarbonate filter inserts, and cell invasion assays were performed using inserts of Transwell plates (8.0-μm pores,

Corning Costar Corp., Cambridge, MA, United States) coated with Matrigel (Costar, Cambridge, MA, United States)[22]. Cells (2.5×10^4 cells/well) suspended in serum-free DMEM containing 0.2% BSA were placed in the upper chamber of each transwell. In each lower chamber, 600 μL of DMEM supplemented with 10% FBS was added. The inserts were then incubated at 37 °C in a humidified atmosphere containing 5% CO_2 for 24 h (migration) and 48 h (invasion), respectively. Cells that had not penetrated the filters were removed using cotton swabs. Cells that migrated to the bottom of the insert were fixed in 4% paraformaldehyde for 10 min and stained with 0.1% crystal violet for 30 min, followed by rinsing with PBS and examination under a bright-field microscope equipped with a 100 × objective. Migratory or invasive activity was expressed as the average number of migrated cells per microscopic field over five fields in each assay from three independent experiments.

Cell proliferation and apoptosis assays

Cell proliferation assays were performed using Cell Counting Kit-8 (CCK-8; Dojindo, Rockville, MD, United States) according to the manufacturer's instructions. All tested cell lines were seeded at 2.5×10^4 cells per well of a 96-well plate and cultured in 100 μL of DMEM supplemented with 10% FBS. At the indicated time points, culture medium was exchanged for 110 μL of DMEM supplemented with CCK-8 reagent (10 μL CCK-8 and 100 μL DMEM), and cells were incubated for an additional 2 h. Absorbance was measured for each well at a wavelength of 450 nm, with the reference wavelength set at 600 nm. An increase or decrease in absorbance values at 450 nm in the experimental wells relative to the initial value was indicative of cell growth or death, respectively. Cell growth was monitored at 24 h, 48 h, 72 h, and 96 h, and was repeated in replicates of three wells per time point.

Apoptosis assays were performed immediately after selection with G418. Cells were washed twice and seeded at a density of 2×10^5 cells/mL in DMEM and 10% FBS in the presence of G418 (for SW480-V, SW480-ABI1-SiL3, and SW480-ABI1-SiL6). After 48 h of culture, apoptosis was monitored using the Annexin V-FITC Apoptosis Detection Kit (KeyGen Biotech, #KGA107, Shanghai, China). For FACS analysis, 1×10^5 cells were co-stained with Annexin V-EGFP and with the fluorescent dye propidium iodide (PI). Cells that stained negative for both PI and annexin V were considered viable cells; PI-negative and annexin V-positive stained cells were considered early apoptotic cells; PI-positive and annexin V-positive stained cells were considered to be in the later stages of apoptosis. All assays were carried out independently, in triplicate.

Immunofluorescence microscopy

Samples of 293T cells were cultured on fibronectin-coated coverslips and transiently transfected with either the ABI1-SiL-GFP plasmid or a control plasmid, as well as SW480-ABI1-SiL6. The cells were fixed in 4% paraformaldehyde in PBS for 10 min and permeabilized with 0.2% Triton X-100 in PBS for 8 min. Non-specific binding was blocked by incubation of the coverslips with 3% bovine serum albumin in PBS, followed by incubation with primary antibodies (anti-ABI1-p65 and or anti-WAVE2) in 1% bovine serum albumin/PBS. After extensive washing with PBS, cells were incubated with appropriate Alexa-conjugated secondary antibodies. Cytoskeleton was detected by Phalloidin staining. The slides were examined under a Nikon Eclipse TE2000-U fluorescence microscope, and images were captured and analyzed using Nikon NIS Elements imaging software.

Statistical analysis

SPSS version 16.0 software (SPSS Inc., Chicago, IL, United States) was used for statistical analyses. Data from all quantitative assays are expressed as the mean ± SD and were analyzed statistically using one-way analysis of variance (ANOVA) followed by Dunnett test and general linear model analysis (univariate). *P* values less than 0.05 were considered statistically significant.

RESULTS

Establishment of qualitative and quantitative real-time reverse transcriptional polymerase chain reaction assays for detection of ABI1-SiL

The *ABI1* gene encodes a member of the Abelson interactor family of adaptor proteins. At least 12 alternatively spliced transcript variants encoding multiple isoforms have been observed for this gene[21]. There are significant differences in the exons and

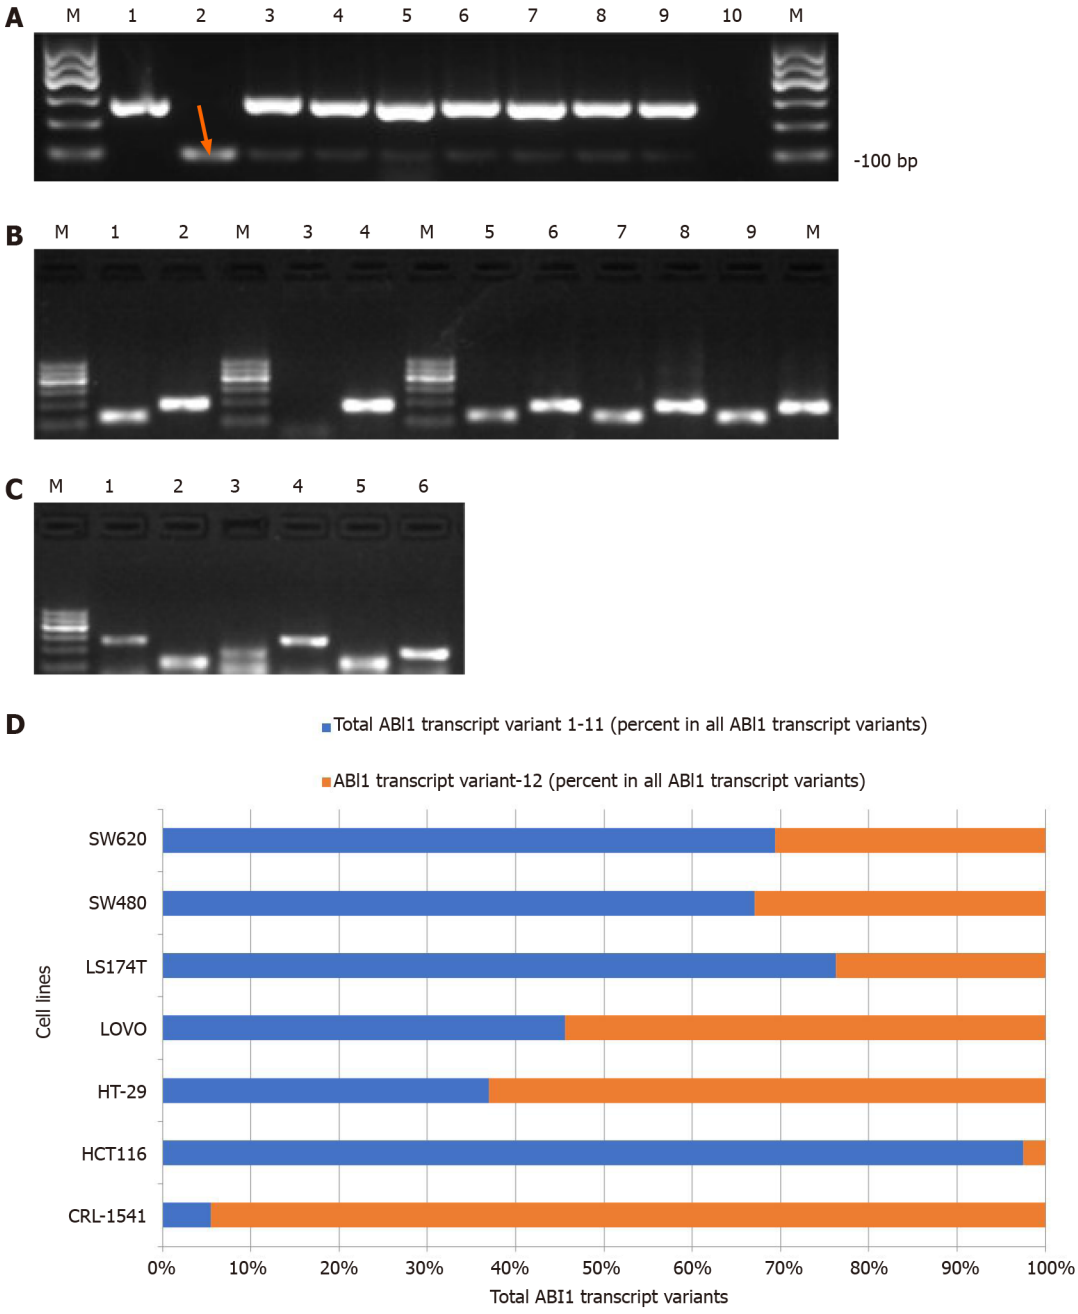
functional domains contained in the different isoforms of *ABI1*, which may result in structural differences in the proteins that lead to differing functions between ABI1-SiL and other transcript variants (Figure 1A). To detect the expression of ABI1-SiL, we designed a set of qualitative primers and two sets of universal quantitative primers that detect this isoform specifically, as shown in Figure 1B. Using qualitative PCR, two visible bands were amplified, and we verified through sequencing that the 101-bp band represents the transcript variant-12 specific PCR product (Figure 2A). We demonstrated that ABI1-SiL was expressed in all tested CRC cells and control CRL-1541 cells.

Next, we tested the reliability of the primers designed for quantitative analysis of ABI1-SiL expression. ABI1-SiL and 12 plasmids (single and/or mixtures), as well as the cDNA from CRL-1541 cells and HCT116 cells, were used as templates to perform qPCR. PCR amplified products were examined by 1.5% agarose gel electrophoresis (Figure 2B). Taken with the analysis of the amplification curve, the melting curve, and the sequencing data for the PCR products (data not shown), these observations indicated that we have successfully established a quantitative assay specific for detection of ABI1-SiL.

The proportion of ABI1-SiL isoform is significantly decreased, relative to other ABI1 splice isoforms, in colon cancer tissues and cell lines

In previous studies, we and other groups have shown that the full-length isoform of ABI1 (ABI1-p65) is increased in colon cancer cells and tissues and involved in the progression and development of colon cancer[7,8,22]. To analyze the potential role of ABI1-SiL in colon cancer, we examined the expression level of ABI1-SiL in CRC cells and tissues using qPCR. As Figure 2D and E shows, the ratio of the ABI1-SiL isoform to other ABI1 splice isoforms was significantly decreased in all CRC cells compared with control CRL-1541 cells and was also decreased in 16 of 24 CRC tissues compared with adjacent tissues. These observations indicated that ABI1-SiL may play an anti-oncogenic role in colorectal tissues.

Successful creation of a human colon cancer SW480 cell model stably overexpressing ABI1-SiL



To test the function of ABI1-SiL in cellular phenotypes of colon cancer, we overexpressed ABI1-SiL in SW480 colon cancer cells. The full-length cDNA of ABI1-SiL, or an empty vector control plasmid, was introduced into SW480 by Lipofectamine-mediated transfection. We confirmed ABI1-SiL expression in two stable cell lines, SW480-ABI1-SiL3 and SW480-ABI1-SiL6 (Figure 3A and B). As shown in Figure 3C, the expression of the cDNA in SW480 cells resulted in a significant increase in the proportion of the ABI1-SiL isoform relative to other isoforms by about 30%, as compared to the parental SW480 and SW480-V cell lines. We also demonstrated through Western blot that the ABI1-SiL-GFP fusion protein was expressed in SW480-ABI1-SiL3 and SW480-ABI1-SiL6 cells, but not in parental SW480 and SW480-V cells (Figure 3D). These data confirm that we successfully constructed a SW480 colon cancer cell model overexpressing ABI1-SiL.

Overexpression of ABI1-SiL increases the surface area of human colon cancer SW480 cells

We observed that the SW480-ABI1-SiL3 and SW480-ABI1-SiL6 stable cell lines were substantially larger and were more similar in morphology to epithelial cells than the parental and empty vector transfected cells (Figure 4A-D, see arrows). To quantitatively assess this difference in cellular morphology, Image J and SPSS software were used to examine the cell surface area of the transfected and control cell lines. As Figure 4E shows, the cellular surface area was significantly increased by about 40% in SW480-ABI1-SiL3 and SW480-ABI1-SIL6 cells compared with the parental and control SW480 cells ($P < 0.01$). To determine whether ABI1-SiL-induced changes in cellular morphology are due to effects on differentiation of SW480 cells, we used qPCR to analyze the expression of POUS, CD44, and KRT20, but we observed no difference in the expression of these genes, except for KRT20 in SW480-SiL3 (Figure 4E).

Overexpression of ABI1-SiL inhibits adhesion and migration, but not invasion, of SW480 human colon cancer cells

We performed adhesion, migration, and invasion assays to test whether ABI1-SiL overexpression activated these cellular mechanisms. In the adhesion assay, we discovered that ABI1-SiL overexpression significantly impaired the adhesive

capability in all tested conditions (0.2% BSA, gelatin, fibronectin, and no coating) (P < 0.01, Figure 5A). Among the tested coating conditions, the adhesion assay showed that ABI1-SiL had the strongest inhibitory effect on adhesion in the presence of fibronectin. In the migration assay, ABI1-SiL overexpression also greatly inhibited the migration of SW480 cells *in vitro* (P < 0.01) (Figure 5B-F). Interestingly, ABI1-SiL overexpression showed no inhibitory effect on invasion of SW480 cells (P > 0.05; Figures 5G-K). Furthermore, expression analysis using qPCR revealed that ABI1-SiL overexpression had no effect on expression of matrix metalloproteases 1, 2, 3, or 4 (Figure 5L).

Overexpression of ABI1-SiL does not alter either proliferation or apoptosis of the human colon cancer cell line SW480

It has been reported that the full-length isoform of ABI1 (ABI1-p65) promotes proliferation and inhibits apoptosis of colon cancer cells[24-26], but the action of ABI1-SiL in colon cancer cells is unknown. To further determine the effect of ABI1-SiL overexpression on the proliferation and apoptosis of SW480 cells, we performed CCK-8 cell viability and apoptosis assays. As Figure 6A and B shows, overexpression of ABI1-SiL had no effects on proliferation or apoptosis of SW480 cells. These observations confirmed that changes in migration and invasion did not result from alterations in cell proliferation and apoptosis.

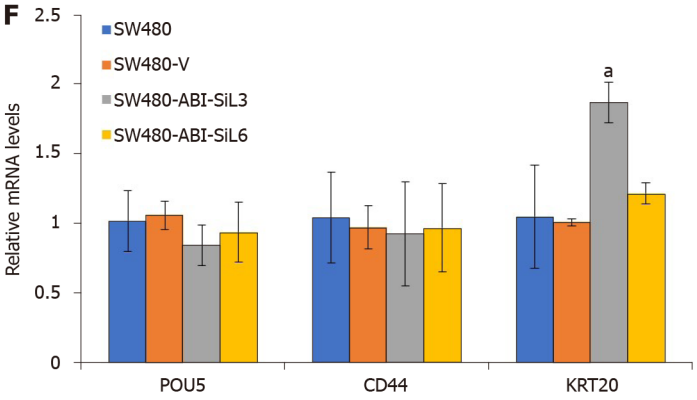
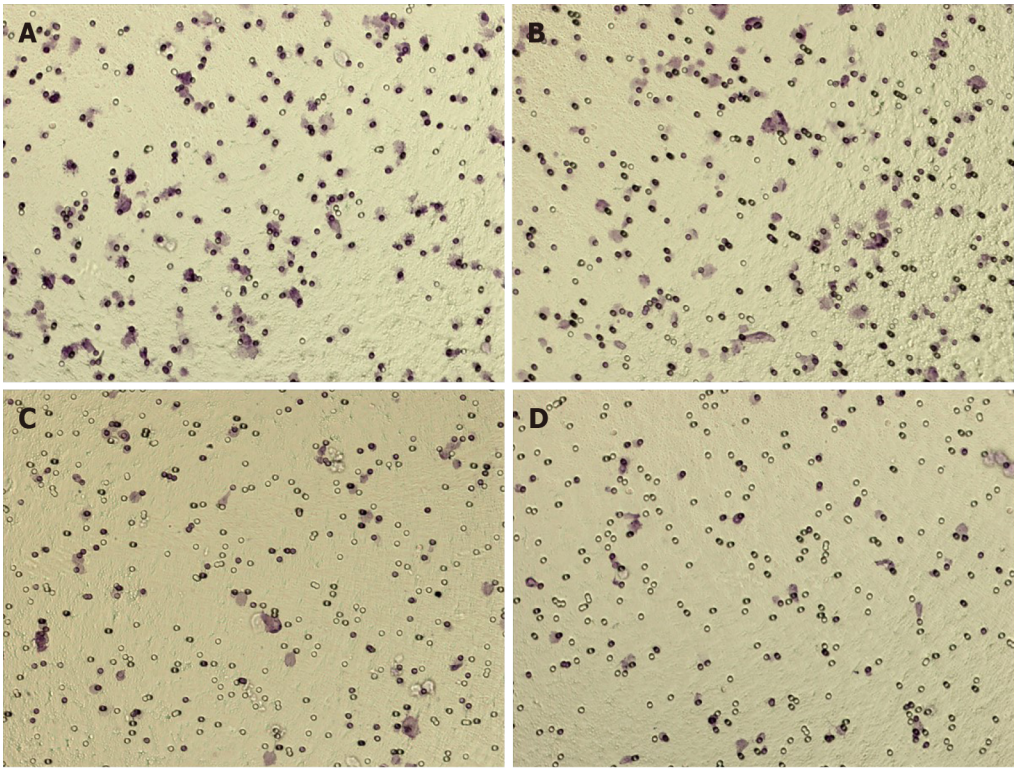
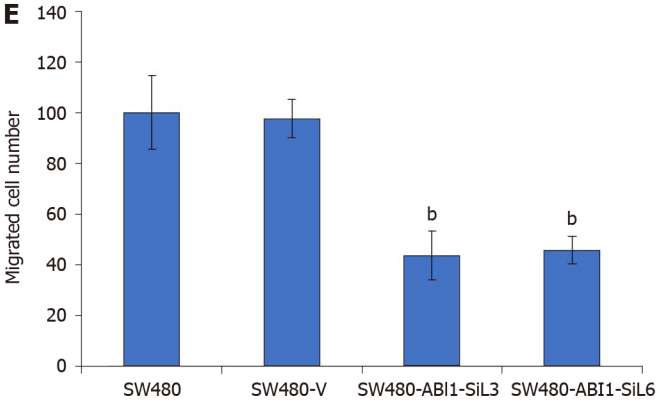
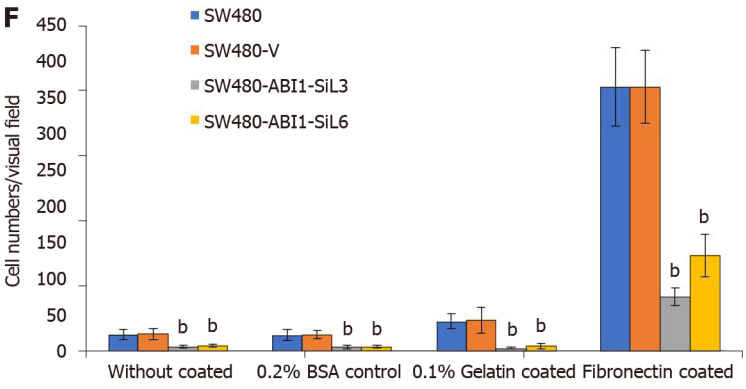
Potential mechanism underlying the effects of ABI1-SiL on cell morphology, adhesion, and migration of SW480 cells

It has been widely accepted that ABI1 regulates cancer cell morphology, adhesion, and migration by directly interacting with WAVE2 and forming the ABI1-WAVE2-NAP-1 complex[27-29]. We confirmed the expression of ABI1-p65, WAVE2 and NAP-1 in all tested cell lines. As Figures 3D, 7A, and 7B demonstrate, ABI1-SiL overexpression did not alter the expression of ABI-p65 and WAVE2 at either the mRNA or protein level, as well as NAP-1 at the protein level. The SW480-Vector and SW480-ABI1-SiL6 cell lines were used to analyze potential mechanisms underlying the effect of ABI1-SiL expression on cell morphology, adhesion, and migration of SW480 cells. Western blot









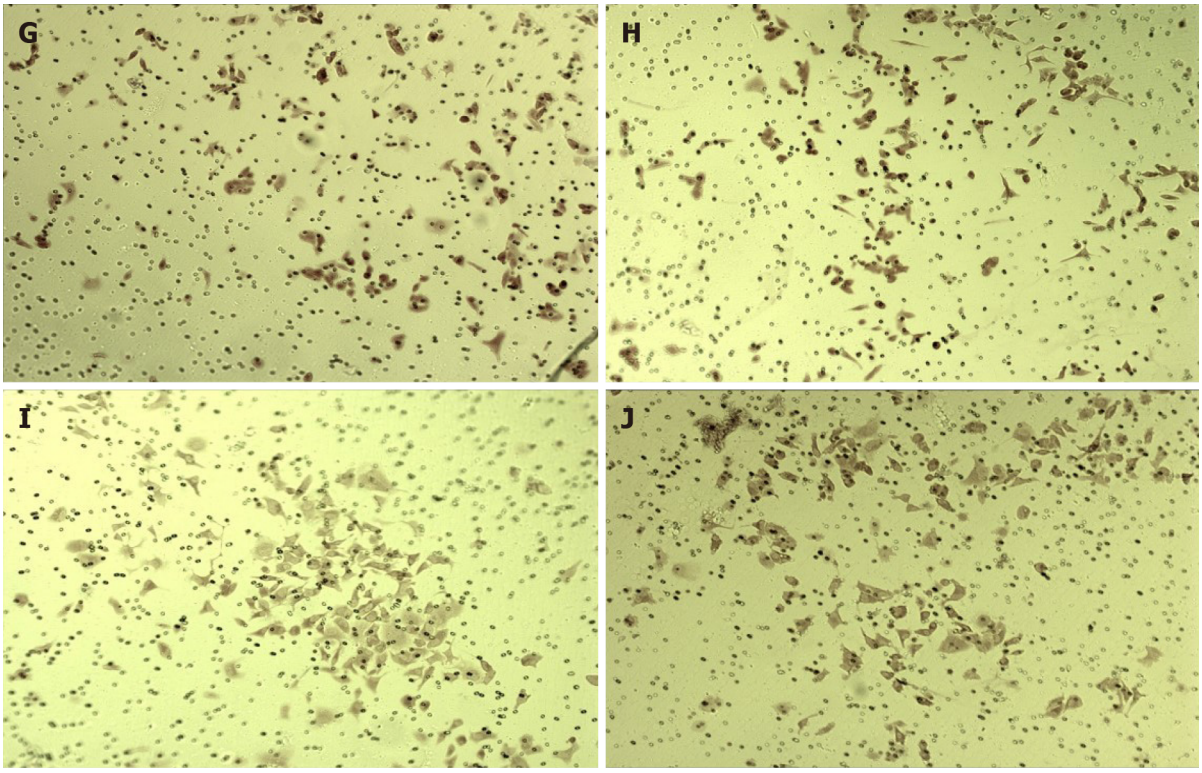


Figure 4 Alterations in cellular morphology occur with exogenous Abelson interactor 1 splice isoform-L expression in SW480 colon cancer cells. Figure 5 Overexpression of Abelson interactor 1 splice isoform-L inhibits migration and adhesion, but not invasion, of SW480 human colon cancer cells. A-F: Effect of Abelson interactor 1 splice isoform-L (ABI1-SiL) overexpression on migration of SW480 cells *in vitro*. A migration assay was conducted over 24 h with 2.5 × 10^4 cells using a transwell chamber. Cells on the lower surface of the filter were imaged. SW480 (A), SW480-V (B), SW480-ABI1-SiL3 (C), and SW480-ABI1-SiL6 (D) were used. The number of migrating cells that penetrated the transwell chamber is expressed as the mean number of cells from five random fields. Representative results from one experiment of three are shown (E). The effects of ABI1-SiL overexpression on SW480 cell adhesion on 0.2% BSA, 0.1% gelatin, or fibronectin-coated surfaces were assessed (F). All tested cell lines were cultured in 0.2% BSA, 0.1% gelatin, or 5 μg/mL fibronectin-coated six-well plates (2.5 × 10^5 cells per well) for 6 h. The total number of cells that were adherent in each condition were counted. The vertical axis shows the number of the

adherent cells per field (from five random fields) and is expressed as the mean ± SD of triplicate wells; G-L: Effect of ABI1-SiL overexpression on invasion of SW480 cells *in vitro*. An invasion assay was conducted over 48 h with 2.5 × 10 ^{4} cells using Matrigel filters. Results shown here are for one representative experiment. Cells on the lower surface of the filter were imaged. SW480 (G), SW480-V (H), SW480-ABI1-SiL3 (I), and SW480-ABI1-SiL6 (J) were used. The number of migrated cells that penetrated through Matrigel-coated filters is expressed as the mean number of cells in five random fields (K). ABI1-SiL overexpression in SW480 cells has no effect on the mRNA expression of MMPs (L). $^aP < 0.05$ and $^bP < 0.01$ indicate significant differences between SW480, SW480-V, SW480-ABI1-SiL3, and SW480-ABI1-SiL6 cells. ABI1-SiL: Abelson interactor 1 splice isoform-L.

D). Interestingly, we also observed evidence of a direct interaction between ABI1-p65, phosphorylated ABI1-p72, and ABI1-SiL-GFP (Figure 7D). Additionally, we showed that ABI1-SiL does not bind to NAP-1, but ABI1-p65 and phosphorylated ABI1-p72 do in SW480-ABI1-SiL6 cells (Figure 7E). Finally, 293T cells, transfected with ABI1-SiL-GFP and stable SW480-ABI1-SiL6, were used to examine the co-localization of ABI1-SiL-GFP and WAVE2 or ABI1-p65. As shown in Figures 8 and 9, ABI1-SiL co-localizes with both WAVE2 and ABI1-p65. These observations suggested that the ABI1-SiL isoform inhibits the adhesion and migration of SW480 cells *in vitro* by competitively interacting with WAVE2 and directly binding to ABI1-p65. These results provide a novel molecular mechanism explaining the functions of distinct ABI1 isoforms in CRC cells.

DISCUSSION

In this study, we have identified a novel function for ABl1-SiL in adhesion and migration of colon cancer SW480 cells and propose a mechanism underlying this function. Our model is based on a combination of gene expression and mechanistic studies of ABI1-SiL in colon cancer cells and tissues. We and other groups have previously shown that overexpressed non-phosphorylated ABI1-p65 functions as a pro-oncogene in development and progression of CRC[7,8,22]. Now, we wanted to address the question of whether there are other ABI1 isoforms that exist in colon tissues and cells that play additional roles in colon cancer. Identification of novel alternatively spliced isoforms with dysregulated expression in cancer could lead to the development of tumor-specific molecular targets for prognosis and therapy[30].

At present, there is no commercial antibody available that can detect the ABI1-SiL protein. Here, we report a set of PCR-based methods that can specifically measure ABI1-SiL mRNA expression. Unlike the full-length ABI1-p65 isoform, ABI1-SiL was significantly decreased in colorectal tissues and cells compared with the adjacent tissues and CRL-1541 normal colon cells (Figure 2). This observation, coupled with the structural differences between ABI1-SiL and other isoforms, especially ABI1-p65 (Figure 1A), led us to postulate that ABI1-SiL might function as an anti-oncogene.

ABI1-SiL mRNA expression was significantly decreased in SW480 cells, so we selected this cell line to investigate the effects of ABI1-SiL expression on cellular phenotypes in colon cancer cells. We successfully constructed SW480 cell lines that stably overexpress ABI1-SiL. We observed that ABI1-SiL overexpression in SW480 cells resulted in enlarged cell size and impaired adhesion and migration, but had no effect on invasion, proliferation, apoptosis, or transcriptional regulation (Figures 3-6). ABI1-SiL overexpression did not alter the mRNA expression levels of ABI1-p65, WAVE2, MMPs, POU, CD44, or KRT20. In combination with its decresion in CRC tissues and cells, these observations suggest that ABI1-SiL could function as an anti-oncogene and that the underlying mechanism needs to be explored.

It is widely accepted that an ABI1-WAVE2 complex is involved in epithelial morphogenesis[31], adhesion, migration, and invasion of cancer cells[13,28,32]. As shown in Figure 1A, the conserved WAVE2-binding and SH3 domains of ABI1-SiL provide the same sites as ABI1-p65 to competitively bind to WAVE2 and/or the proline-rich domain (PRD) of other molecules, including the PRD of ABI1-p65, but the lack of the HHR and the majority of the PxxP- and Pro-rich domain makes it likely to function as a native dominant negative that suppresses the pro-oncogenic functions of ABI1-p65. Bidirectional co-IP experiments confirmed interactions between ABI1-SiL, WAVE2, and ABI1-p65. In control SW480 cells, ABI1-p65 interacts with WAVE2, while in SW480 ABI1-SiL6 cells, both ABI1-p65 and ABI1-SiL are able to bind to WAVE2 (Figure 7C and D). These observations suggested a possible mechanism by which ABI1-SiL competitively binds to WAVE2. Increased ABI-SIL expression could inhibit ABI1-p65-WAVE2 complex formation, resulting in reduced adhesion and migration. Competitive binding of WAVE2 to ABI1 isoforms suggests the possibility of fine

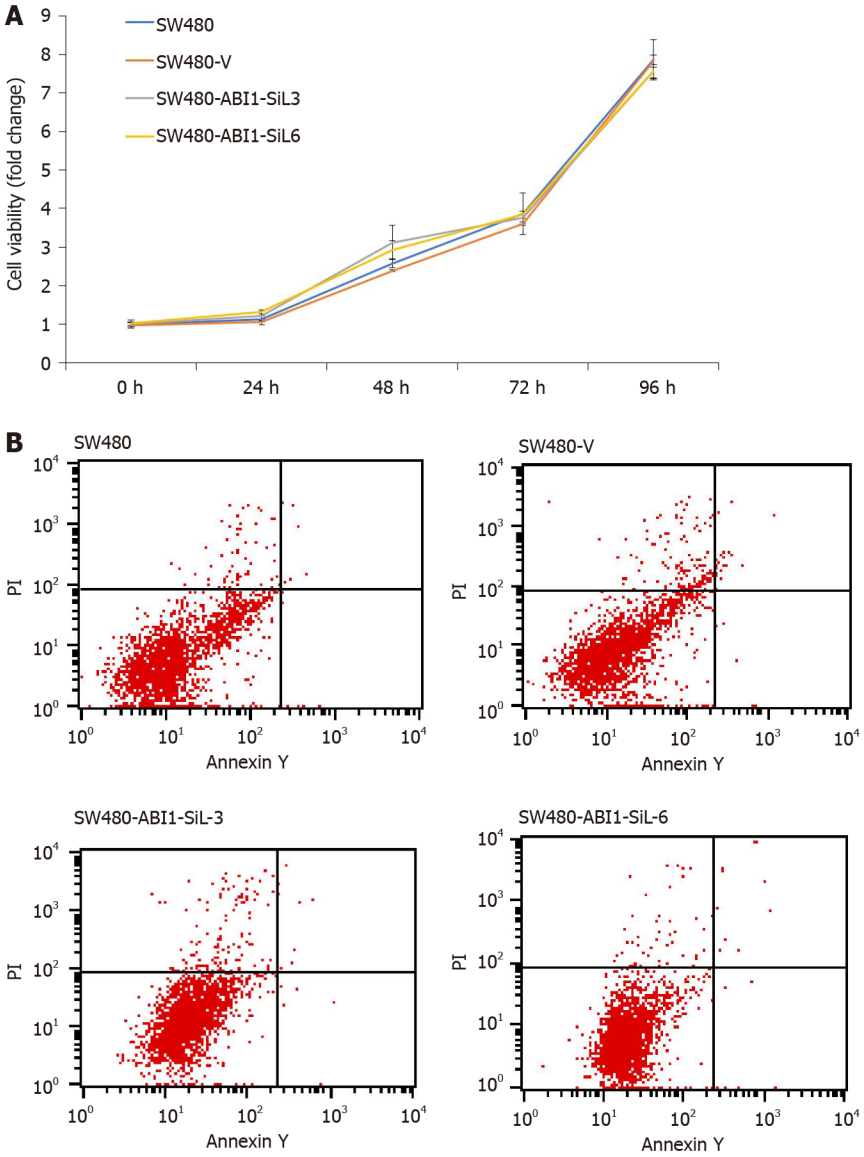

Figure 6 Overexpression of Abelson interactor 1 splice isoform-L does not alter proliferation or death of SW480 cells. Abelson interactor 1 splice isoform-L (ABI1-SiL) overexpression did not impair the proliferation of SW480 cells *in vitro*. Proliferative assay was performed with a Cell Counting Kit-8. A: Cell viability (fold change) is shown in the vertical axis as the mean ± SD of triplicate wells (n = 3). ABI1-SiL overexpression did not induce the apoptosis of SW480 cells *in vitro*; B: Cell apoptosis was assessed by Annexin-V assay. ABI1-SiL: Abelson interactor 1 splice isoform-L.

regulation of WAVE2 complex function in an ABI1 isoform-dependent manner. Interestingly, we also found that ABI1-SiL might interact directly with ABI1-p65, thus indirectly decreasing the formation of the ABI1-p65-WAVE2 complex. These intermolecular interactions were further confirmed by the co-localization of ABI1-SiL-GFP with WAVE2 and ABI1-p65 (Figures 8 and 9). WAVE2, ABI1, and NAP-1 are required for the WAVE regulatory complex (WRC) which activates the Arp2/3 complex to control branched actin polymerization in response to Rac activation[33-35]. As Figure 7E shows, the fact that ABI1-SiL (lacks a HHR domain required for binding to Nap1) does not bind to NAP-1, but ABI1-p65 and phosphorylated ABI1-p72 do in SW480-ABI1-SiL6 cells, suggests that ABI1-SiL overexpression disturbed WRC assembly and further impaired SW480 adhesion and migration. Additionally, all of the above observations were also observed in leukemia K562 and gastric cancer NCI-N87 cells (data not shown).

The present results indicate possible functions of ABI1-SiL in the regulation of SW480 morphogenesis, adhesion, and migration through interactions with WAVE2 and ABI1-p65, respectively. Although the overexpression of ABI1-SiL results in increased cell surface area and a more epithelial-like morphology, we did not find alterations in expression levels of any mRNA involved in differentiation of SW480 cells. Future studies will explore correlations between ABI1 splicing-isoform expression and *KRAS* or *BRAF* mutations or *MSI* in patients with colon cancer.

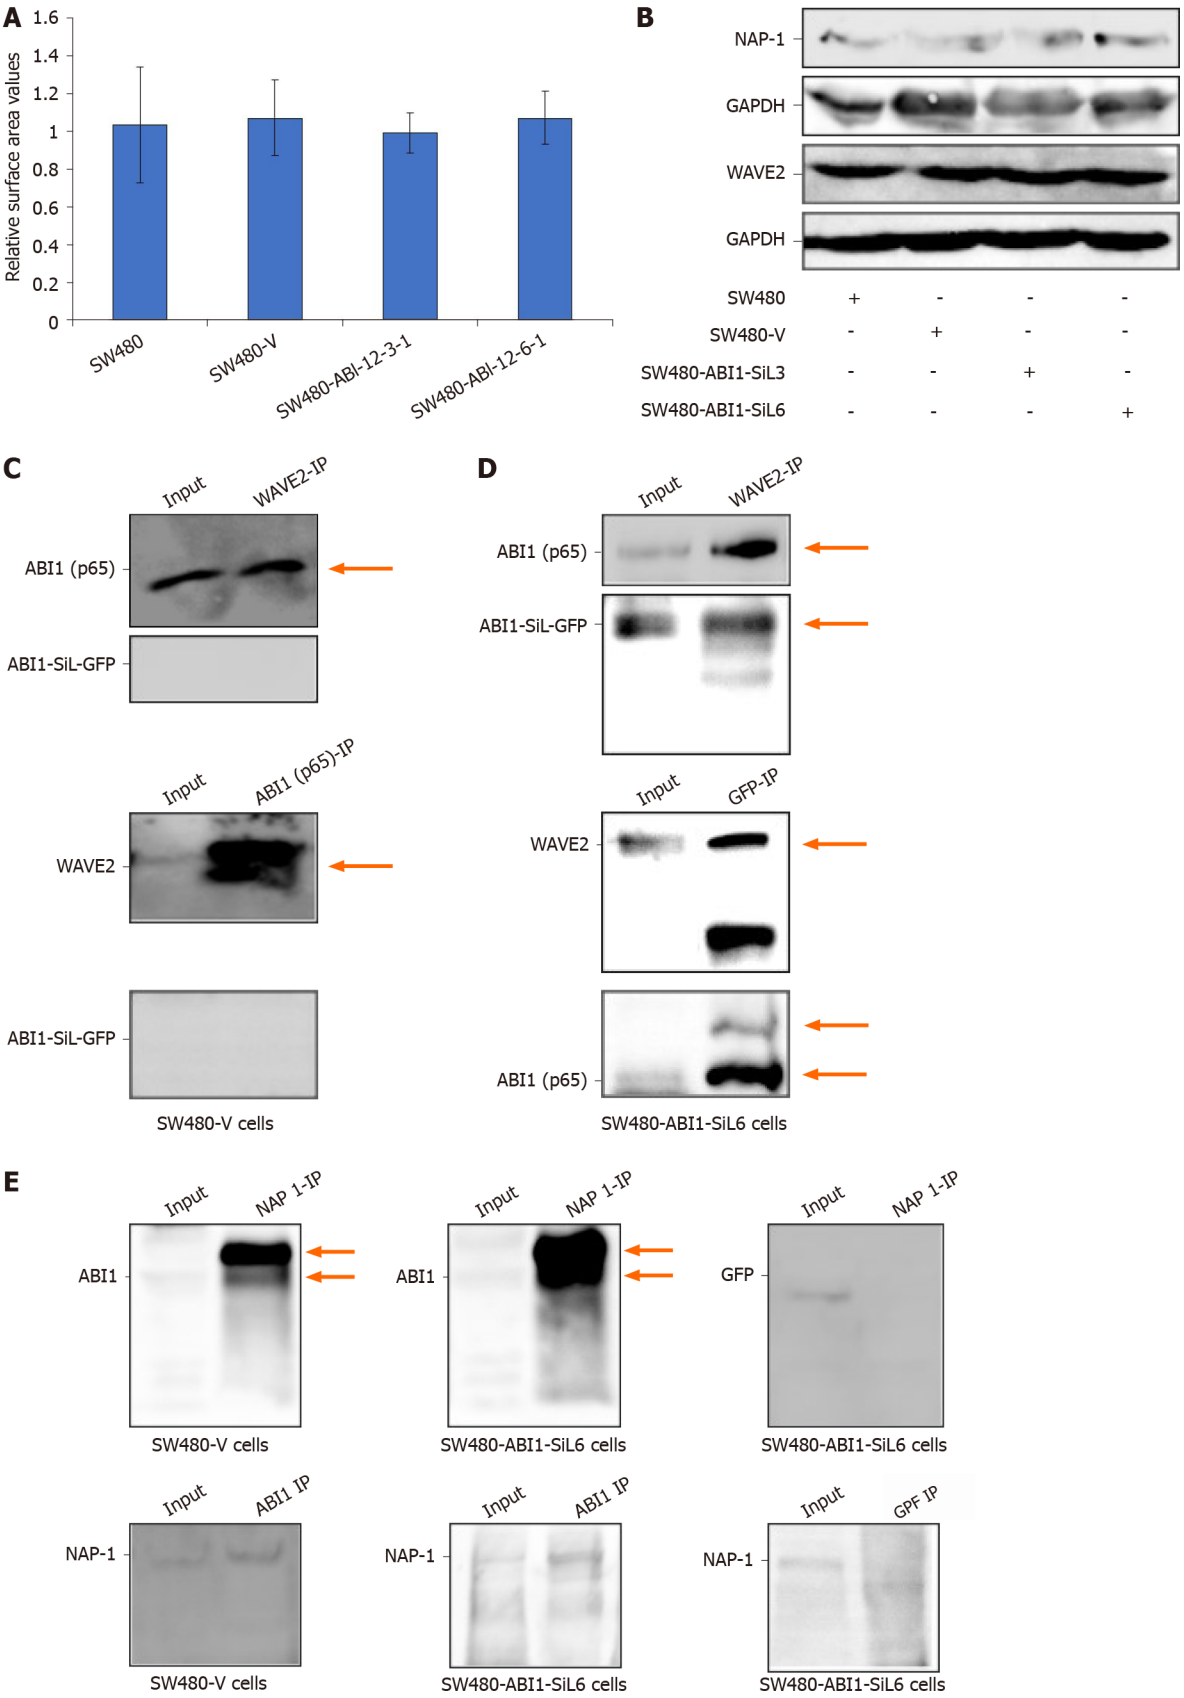

Figure 7 Abelson interactor 1 splice isoform-L interacts with WAVE2, phosphorylated or non-phosphorylated Abelson interactor 1-p65, and NAP-1 in SW480 cells. A and B: Abelson interactor 1 splice isoform-L (ABI1-SiL) overexpression does not change the mRNA (A) or protein (B) expression of WAVE2; C and D: Co-immunoprecipitates (IP) were subjected to Western blot using the indicated antibodies. Bidirectional co-IP and Western blot analysis show that both ABI1-p65 and ABI1-SiL bind to WAVE2 in SW480-V (C) and SW480-ABI1-SiL6 cells (D); E: ABI1-SiL interacts with phosphorylated and non-phosphorylated ABI1-p65 in SW480 cells (arrows). ABI1-SiL does not bind to NAP-1, but ABI1-p65 does. ABI1-SiL: Abelson interactor 1 splice isoform-L; ABI1: Abelson interactor 1; GFP: Green fluorescence protein; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

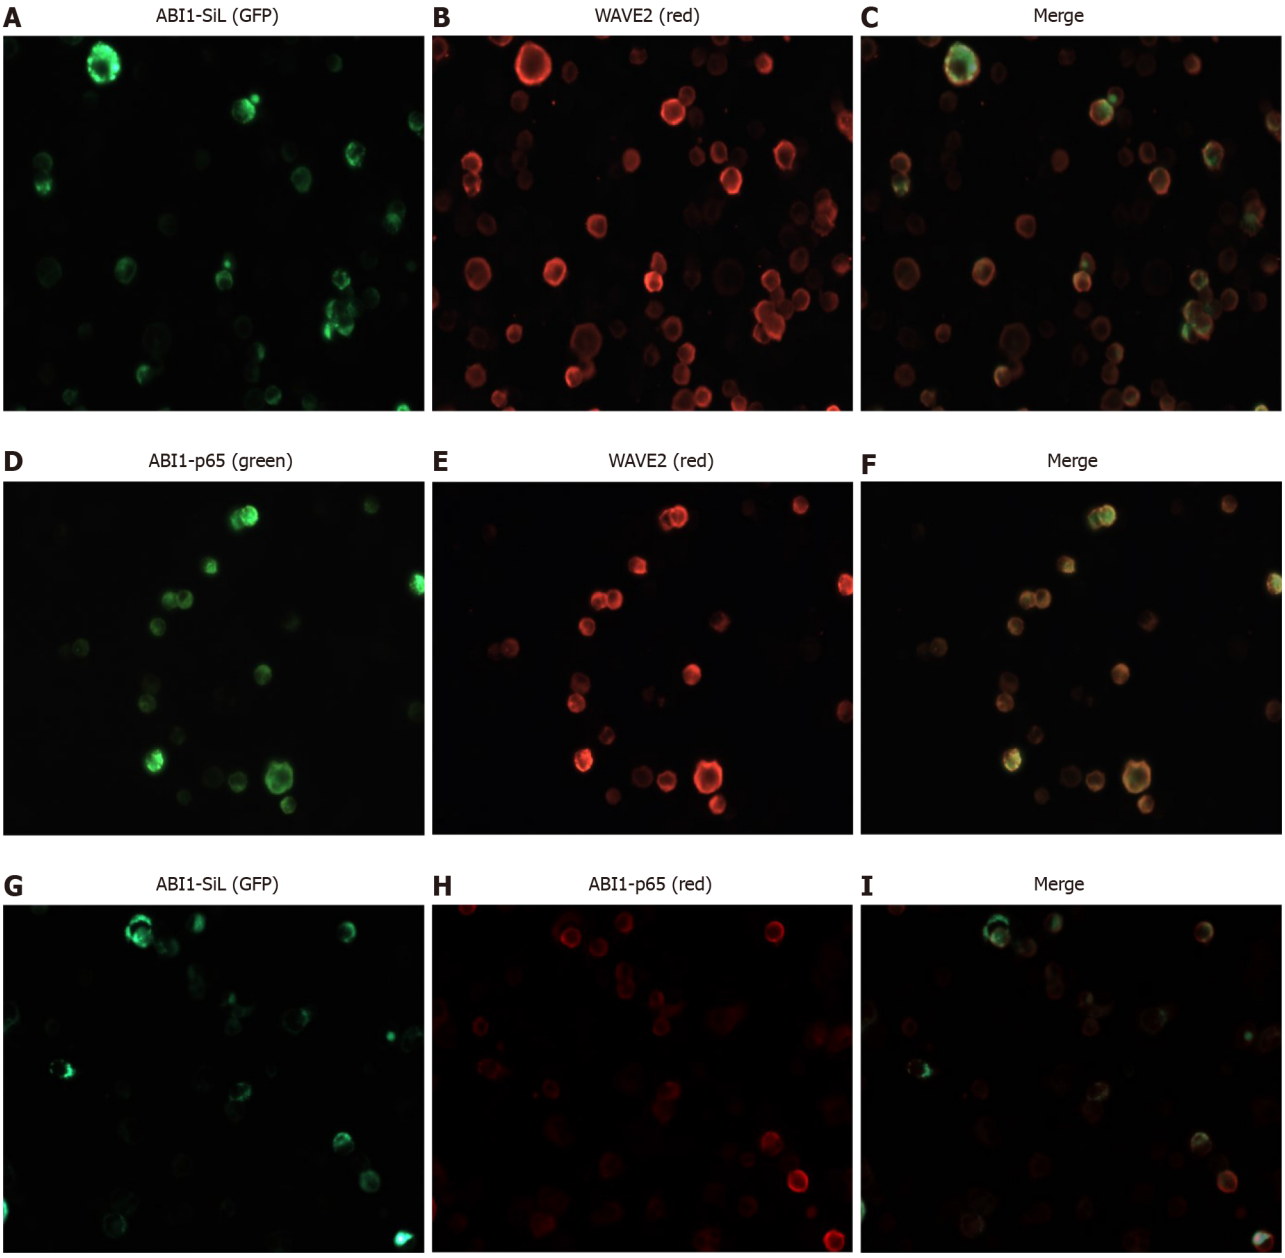

Figure 8 Abelson interactor 1 splice isoform-L co-localizes with WAVE2 and Abelson interactor 1-p65 in 293T cells. A-I: Abelson interactor 1 splice isoform-L-GFP (green fluorescence protein) co-localizes with WAVE2 and ABI1-p65. Samples of 293T cells transiently transfected with Abelson interactor 1 splice isoform-L were probed with WAVE2 (A, B, and C) and Abelson interactor 1-p65 (G, H, and I) antibodies, respectively, while 293T cells were probed for WAVE2 and Abelson interactor 1-p65 (D, E, and F). Magnification × 400. ABI1-SiL: Abelson interactor 1 splice isoform-L; ABI1: Abelson interactor 1; GFP: Green fluorescence protein.

Similarly, relationships and underlying mechanisms will be investigated to connect ABI1-SiL overexpression with mesenchymal-epithelial transition, and determine the roles of other ABI1 isoforms in the cellular and molecular phenotypes underlying colon cancer. Furthermore, ABI1 is present in several intrinsic protein complexes that regulate actin cytoskeletal remodeling, and the existence of several ABI1 isoforms raises the possibility of isoform-specific roles in other ABI1-specific functions[36]. In conclusion, we have shown for the first time herein that ABI1-SiL regulates adhesion and migration in SW480 cells *via* a mechanism involving fine regulation of WAVE2 complex activity, providing a putative biomarker and novel therapeutic target for colon cancer.

In addition, there are still some other limitations in the current study. First, we need more specific and accurate quantitative methods[37,38] to investigate the expression pattern of ABI1-SiL in a large-scale population in the future, and evaluate its potential application value as a clinical molecular diagnostic marker. Second, we need to systematically analyze the exon sequences of all ABI1 transcriptional variants, and use

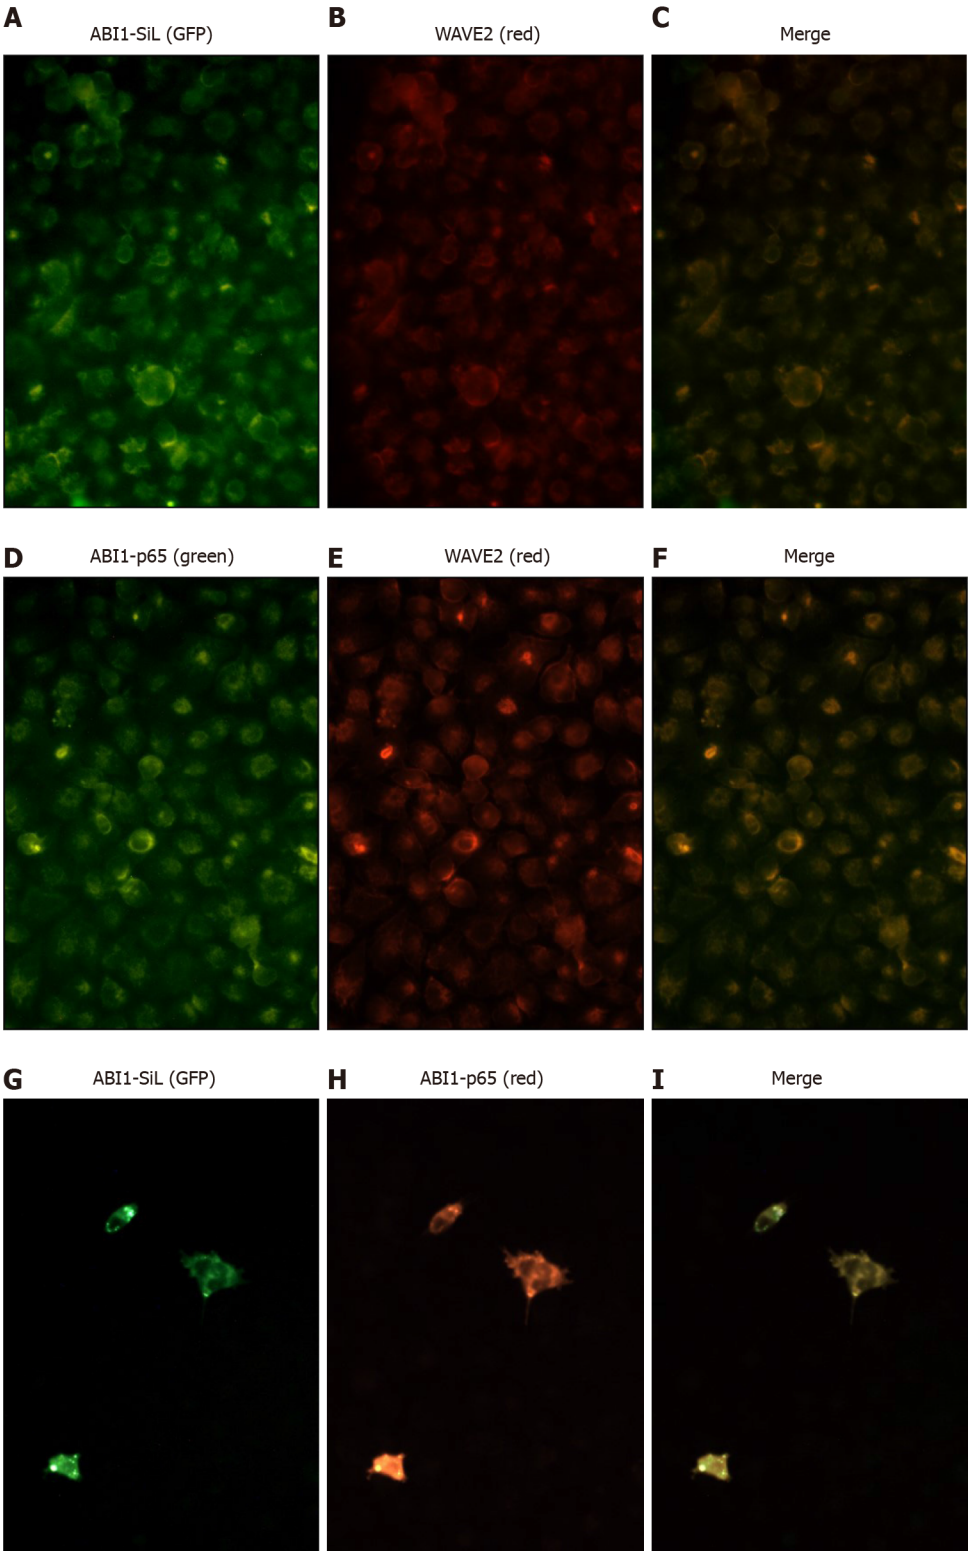

Figure 9 Abelson interactor 1 splice isoform-L co-localizes with WAVE2 and Abelson interactor 1-p65 in SW480-ABI1-SiL6 cells. A-I: Abelson interactor 1 splice isoform-L (ABI1-SiL)-GFP (green fluorescence protein) co-localizes with WAVE2 and ABI1-p65. SW480-ABI1-SiL6 cells were probed with WAVE2 (A, B, and C) and ABI1-p65 (G, H, and I) antibodies, while SW480 cells were similarly probed for WAVE2 and ABI1-p65 (D, E, and F). Magnification × 400. ABI1-SiL: Abelson interactor 1 splice isoform-L; ABI1: Abelson interactor 1; GFP: Green fluorescence protein.

splice switching oligonucleotides[39] and/or gene modification techniques[40] to explore clinical interventions targeting ABI1-SiL. Finally, we also need to rely on animal models to further verify the underlying mechanism of the anti-oncogenic role of ABI1-SiL.

CONCLUSION

These results support a model in which ABI1-SiL plays an anti-oncogenic role by competitively binding to WAVE2 and directly interacting with phosphorylated and non-phosphorylated ABI1-p65, functioning as a dominant-negative form of ABI1-p65.

ARTICLE HIGHLIGHTS

Research background

Abnormally expressed and/or phosphorylated Abelson interactor 1 (ABI1) participates in the metastasis and progression of colorectal carcinoma (CRC), but the roles of ABI1 splice isoforms (ABI1-SIs) are unknown. Exploring the roles and underlying mechanism of ABI1-SIs has important theoretical and practical significance for molecular diagnosis and targeted therapy of CRC.

Research motivation

ABI1-SIs-L (ABI1-SiL) plays an anti-oncogenic role in CRC, and it may be a potential molecular marker and therapeutic target in CRC.

Research objectives

To exploring the roles and underlying mechanism of ABI1-SiL in CRC.

Research methods

We report a set of polymerase chain reaction-based methods that can specifically measure ABI1-SiL mRNA expression and constructed an ABI-SiL overexpressing SW480 cell model. CCK8, transwell, immunoprecipitation, Western blot, and co-localization assays were used to identify the anti-oncogenic role of ABI-SiL and the underlying mechanism in CRC.

Research results

ABI-SiL had a potential anti-tumor effect in CRC. Overexpression of ABI-SiL did not affect the proliferation and invasion of SW480 cells, but can increase the surface area and migration of SW480 cells by competitively binding WAVE2 and ABI1-p65.

Research conclusions

ABI1-SiL plays an antioncogenic role in CRC cells by competitively binding WAVE2 and ABI1-p65.

Research perspectives

Targeting ABI1-SIL expression is a potential treatment for colorectal cancer metastasis.

ACKNOWLEDGEMENTS

We are very grateful to Dr. Dai ZH for his reasonable suggestions and comments on the revision of the manuscript.

Abstract

BACKGROUND

Pancreatic ductal adenocarcinoma (PDAC) is the fourth leading cause of death among cancers, it is characterized by poor prognosis and strong chemoresistance. In the PDAC microenvironment, stromal cells release different extracellular components, including CXCL12. The CXCL12 is a chemokine promoting the communication between tumour and stromal cells. Six different splicing isoforms of CXCL12 are known (α, β, γ, δ, ε, θ) but their role in PDAC has not yet been characterized.

AIM

To investigate the specific role of α, β, and γ CXCL12 isoforms in PDAC onset.

METHODS

We used hTERT-HPNE E6/E7/KRasG12D (Human Pancreatic Nestin-Expressing) cell line as a pancreatic pre-tumour model and exposed it to the α, β, and γ CXCL12 isoforms. The altered expression profiles were assessed by microarray analyses and confirmed by Real-Time polymerase chain reaction. The functional enrichment analyses have been performed by Enrichr tool to highlight Gene Ontology enriched terms. In addition, wound healing assays have been carried out to assess the phenotypic changes, in terms of migration ability, induced by the α, β, and γ CXCL12 isoforms.

RESULTS

Microarray analysis of hTERT-HPNE cells treated with the three different CXCL12 isoforms highlighted that the expression of only a few genes was altered. Moreover, the α and β isoforms showed an alteration in expression of different genes, whereas γ isoform affected the expression of genes also common with α and β isoforms. The β isoform altered the expression of genes mainly involved in cell cycle regulation. In addition, all isoforms affected the expression of genes

associated to cell migration, adhesion and cytoskeleton. In vitro cell migration assay confirmed that CXCL12 enhanced the migration ability of hTERT-HPNE cells. Among the CXCL12 splicing isoforms, the γ isoform showed higher induction of migration than α and β isoforms.

CONCLUSION
Our data suggests an involvement and different roles of CXCL12 isoforms in PDAC onset. However, more investigations are needed to confirm these preliminary observations.

Key Words: CXCL12; Splicing isoforms; Pancreatic cancer; Microarray; Migration; Wound healing assay

Core Tip: In the microenvironment of pancreatic ductal adenocarcinoma (PDAC), stromal cells release different extracellular components, including CXCL12, in order to communicate with cancer cells. Here, we investigated the specific role of α, β, and γ CXCL12 splicing isoforms in PDAC onset, by using a pre-tumour model. Microarray analysis suggested a role of CXCL12 in cell migration, and wound healing assays confirmed this hypothesis. In particular, γ isoform showed the highest promotion of migration. Our results shed light on the molecular basis of PDAC onset and progression.

INTRODUCTION

Pancreatic ductal adenocarcinoma (PDAC) is one of the most aggressive gastrointestinal tumours with a 5-year survival rate of 7%[1]. Due to the lack of early symptoms and specific diagnostic markers of early-stage disease, PDAC is often diagnosed at an advanced stage. At the time of diagnosis, the 90% of patients already presents advanced tumour progression and distant metastasis, therefore the surgical treatment is no longer applicable. This tumour also shows a high resistance rate to anti-tumour drugs, so chemio- and radio-therapy are not effective[2,3]. Progressive accumulation of genetic mutations, causing activation of different signalling pathways, drives tumour growth and development[4]. The earliest genetic event in the progression of the normal ductal epithelial cells to premalignant pancreatic intraepithelial neoplasia (PanIN) is the mutation of the K-Ras oncogene[5]. The activation of K-Ras protein triggers various downstream effector proteins which promote proliferation, metabolic reprogramming, anti-apoptosis, evasion of the immune response and remodelling of the microenvironment[6]. Recently, increasing interest has been focused on the PDAC microenvironment. The PDAC microenvironment is composed of a large portion of stroma surrounding cancer cells and contains cells such as cancer-associated fibroblasts (CAFs), T cells, stellate cells, macrophages, regulatory T cells, endothelial cells and others[7-9]. To maintain a favourable microenvironment for cancer cell survival, stromal cells secrete extracellular components, such as extracellular matrix (ECM), matrix metallo-proteinases, growth factors, transformation growth factor-β and cytokines.

One of the above-mentioned molecules is the chemokine CXCL12 (C-X-C motif chemokine ligand 12), a low molecular weight protein (about 12 kDa), belonging to the CXC chemokine family. In PDAC, CXCL12 is a key messenger in the intercellular communication between tumour and stromal cells[10]. In fact, CXCL12 promotes tumour proliferation, epithelial to mesenchymal transition, metastases, angiogenesis and immunosurveillance[10,11]. In PDAC setting, it acts through highly expressed

receptors namely CXCR4 and CXCR7[11]. Although six different CXCL12 splicing variants have been described (α, β, γ, δ, ε, θ), only some properties of α, β and γ isoforms are known[12]. The sequence of the isoforms differ significantly one from another, thus also the function of the isoforms which are not yet characterized could be different or even contrary[12,13]. In breast cancer the role of the isoforms α, β, γ, and to a lesser extent δ, was studied[14,15], whereas in PDAC no information is available about the specific role played by each isoform of CXCL12. Moreover, often the papers focusing on CXCL12 role in PDAC actually report the results without stating which isoform in particular is under investigation[12].

The hTERT-HPNE E6/E7/KRasG12D (Human Pancreatic Nestin-Expressing) is a pancreatic pre-tumour cell line. These cells derive from normal pancreas duct epithelial cells and harbour the classical KRas (G12D) mutation, furthermore it bears inactivated p53 and Rb tumour suppressor genes. This status mimics the cells that have acquired the cancer predisposing mutations, but are not yet fully transformed. The phenotype of this cell line is similar to the third phase of the premalignant lesions, called PanIN-3[5,6,16].

Here, we investigated the transcriptomic alterations induced by treatments with the α, β and γ CXCL12 isoforms (the only ones commercially available) in a pancreatic pre-cancerous model in order to study PDAC onset. To this aim, we treated hTERT-HPNE cells with different CXCL12 isoforms, and assessed the gene expression profiles of these cells by microarray analyses. Since microarray analyses indicated several deregulated genes involved in cell migration, we also performed wound healing assays.

MATERIALS AND METHODS

Cell culture

The human pancreatic pre-tumour cell line hTERT-HPNE E6/E7/K-RasG12D (ATCC® CRL-4038™) was purchased from American Type Culture Collection. These cells are adherent and have an epithelial-like morphology. Furthermore, they lack fundamental features of malignant pancreatic cancer cells, such as the anchorage independent growth in soft agar and the ability to engraft as tumours in athymic mice. This cell line was developed from human pancreatic duct cells by transduction of human telomerase gene (*hTERT*) in order to escape from cellular senescence. Further immortalization steps included the introduction of the human papillomavirus 16 E6 and E7 proteins, which are able to impair the function of key tumour suppressors p53 and Rb. In these cells, the KRAS *G12D* mutation is sufficient to induce formation of PanIN lesions, without inducing a fully malignant phenotype. Cells were maintained in high glucose Dulbecco's Modified Eagle's Medium (Lonza, Milan, Italy) supplemented with 10% fetal bovine serum, 1% L-Glutamine and 1% Penicillin/Streptomycin (EuroClone, Milan, Italy). Cells were maintained at 37 °C in a humidified atmosphere of 5% CO_2 in air.

Cell treatments

A total of 2 × 10^6 hTERT-HPNE cells were seeded in p100 dishes for cell treatments. Once cells reached the right confluence, they were treated for 24 h with 100 ng/mL of each of the following isoforms: Human recombinant CXCL12-α (PHC1346, Thermo Fisher Scientific, Milan, Italy), human recombinant CXCL12-β (2716-SD, R&D Systems) and human recombinant CXCL12-γ (6448-SD-025, R&D Systems, Minneapolis, MN, United States). Cells cultured similarly for 24 h have been used as control. All experiments were carried out in biological triplicates.

RNA isolation and cDNA synthesis

Total RNA was isolated from harvested cells (12 samples in total) using the RNeasy Protect Cell Mini Kit (Qiagen, Milan, Italy) according to the manufacturer's instructions. The RNA concentration in isolated samples was determined by ultraviolet absorption at 260 nm. The quality of total RNA was first assessed using an Agilent Bioanalyzer 2100 (Agilent Technologies, Palo Alto, CA, United States). Biotin-labelled cDNA targets were synthesized starting from 150 ng of total RNA. Double stranded cDNA synthesis and related cRNA was performed with GeneChip® WT Plus Kit (Affymetrix, Thermo Fisher Scientific, Milan, Italy). Same kit was used to synthesize the sense strand cDNA before fragmenting and labelling. All steps of the labelling protocol were performed as suggested by Affymetrix, starting from 5.5 μg of ssDNA.

DNA microarray hybridization and image acquisition

Hybridization was performed using the GeneChip® Hybridization, Wash and Stain Kit (Affymetrix, Thermo Fisher Scientific, Milan, Italy). In particular, fragmented and labelled sscDNA were diluted in hybridization buffer at a concentration of 23 ng/μL for a 2.3 μg total and denatured at 99 °C for 5 min, incubated at 45 °C for 5 min and centrifuged at maximum speed for 1 min prior to introduction into the GeneChip® cartridge. A single GeneChip® Human Clariom S was then hybridized with each biotin-labelled sense target (12 samples in total). Hybridizations were performed for 16 h at 45 °C in a rotisserie oven (60 rpm). GeneChip® cartridges were washed and stained with GeneChip® Hybridization, Wash and Stain Kit in the Affymetrix Fluidics Station. GeneChip arrays were scanned using an Affymetrix GeneChip® Scanner 3000 7G using default parameters. Affymetrix GeneChip® Command Console software was used to acquire GeneChip® images and generate .DAT and .CEL files, which were used for subsequent analysis.

Bioinformatics analysis of microarray data

Analyses of the raw expression data (probe-level .CEL files) were carried out within R/Bioconductor environment (version 3.6 and 3.9, respectively). In particular, we applied the background correction and quantile normalization by employing the Robust Multi-array Average method available in the *oligo* R package[17]. Then, ComBat function from *sva* R package[18] was used to remove potential batch effects. Principal component analysis was used for the data quality control, before and after batch effect correction. For differential expression analysis, *genefilter* and *limma* R packages have been used[19]. In particular, for the identification of differentially expressed genes (DEGs), we considered the Benjamini-Hochberg corrected *P* value cut-off (FDR), set at 0.05, and a $\log_2$ Fold Change $|\log_2 FC| > 0.7$.

Functional and pathway enrichment analyses

Enrichr tool (http://amp.pharm.mssm.edu/Enrichr/)[20] was used to perform functional enrichment analysis of the DEGs, *i.e.*, the identification of the most over-represented (enriched) Gene Ontology (GO) terms. In this tool, we selected the panels GO Biological Process, GO Molecular Function and GO Cellular Component. Only statistically significant results are reported ($P < 0.05$).

Real-Time polymerase chain reaction

To confirm the microarray results, we assessed the expression of some DEGs by Real-Time polymerase chain reaction (PCR). We selected six genes (CXCL8, RRP12, ADH1B, UBA7, FEM1C, and CASP1) based on the commonly used criteria, that is their fold-changes in relative expression and *P* values[21]. For this purpose, we isolated RNA from hTERT-HPNE cells as described previously for microarray analysis. Then, RNA was reverse transcribed with HyperScript First Strand Synthesis Kit (GeneAll Biotechnology, Korea) using random primers to obtain complementary DNA (cDNA). The selected genes were run in duplicate by Real-Time PCR, using SYBR Green chemistry. The primer sequences are reported in Supplementary Table 1. All samples were tested in triplicate using GAPDH (glyceraldehyde-3-phosphate dehydrogenase) as the reference gene for data normalization to correct for variations in RNA quality and quantity. Threshold cycle (C_T) values of genes of interest were normalized against C_T values of GAPDH, and a relative fold change in expression with respect to a reference sample was calculated by the $2^{-\Delta\Delta Ct}$ method.

Monolayer wound healing assay

To evaluate the cell migration capacity, hTERT-HPNE cells were seeded into a 24-well plate (2×10^4 cells/well) and allowed to attach and grow until reaching the 90%-100% confluence. Cell monolayers were scratched with a sterile 1000 μL pipette tip to make a wound. Then, wounded cell monolayers were washed with phosphate-buffered saline 1× to remove cell debris, and incubated for 24 h in DMEM with 100 ng/mL of each CXCL12 isoform. Cells were monitored under the Eclipse Ti2E microscope (Nikon, Tokyo, Japan) equipped with a camera (Hamamatsu Photonics, Japan) and photographed at 0 h, 12 h and 24 h. Each experiment was performed in triplicate and the data were presented as mean ± SD.

Statistical analysis

For Real-Time PCR and migration assays, differences in gene expression levels between the treated and untreated cells or difference in cell migration ability were determined using the *t*-test. *P* values less than 0.05 were considered statistically

significant. All statistical analyses were performed by using the Stat6 Software for Windows (Stat6 Software, San Diego, CA, United States).

RESULTS

Identification of DEGs

Gene expression alterations in pancreatic hTERT-HPNE cells treated with α, β or γ CXCL12 isoforms, compared to the untreated cells, have been assessed by microarray analyses on Affymetrix Human Clariom S Array. After data processing (*i.e.*, quality control, normalization, batch effect removal), only a few genes resulted to be differentially expressed between treated and untreated cells. Indeed, pairwise comparisons between each treatment and the controls highlighted 17, 24 and 16 DEGs for α, β and γ isoforms, respectively (Table 1). This observation suggests that treatments with CXCL12 did not dramatically alter the gene expression of hTERT-HPNE cells and that, among tested isoforms, the β isoform may induce the highest effect on the transcriptome. Among DEGs regulated by α isoform, 7 were overexpressed and 10 were underexpressed; regarding β isoform, 12 genes were upregulated and 12 were downregulated; finally, for γ isoform, 2 genes were overexpressed and 14 were underexpressed. By hierarchical clustering, the expression levels of these DEGs allow to easily highlight control samples, but homogeneous clusters of samples treated with each CXCL12 isoform are not so clearly distinguishable (Figure 1). This result suggests that, although CXCL12 treatments alter gene expression in hTERT-HPNE cells, the specific effect of each isoform is quite difficult to identify. Therefore, we compared DEGs among different treatments, revealing common and exclusive genes (Figure 2). In particular, 10, 11 and 1 (*i.e.*, LGR5) DEGs were exclusive for α, β and γ isoforms, respectively, suggesting that the effects on the transcriptome of γ isoform is intermediate between those induced by α and β isoforms. Indeed, α and β isoforms induced expression alteration in many different genes, whereas γ isoform affected the expression of genes also common with α and β isoforms (Figure 2).

Quantitative PCR validation

Real-Time PCR analysis was carried out on treated and control samples in order to validate microarray data. Among significant DEGs identified by microarray analysis, we chose 3 up-regulated (UBA7, FEM1C, CASP1) and 3 down-regulated (CXCL8, RRP12 and ADH1B) genes for Real-Time PCR validation. As reported in the Figure 3, the selected genes showed no discrepancies in their expression profiles, for each CXCL12 isoform, between microarray and Real-Time PCR. Indeed, for all isoforms, CXCL8, RRP12 and ADH1B genes resulted to be downregulated also in Real-Time PCR results. In particular, CXCL8, RRP12 and ADH1B genes showed an average fold change reduction of 2.01, 1.78 and 1.72, respectively. Regarding UBA7, FEM1C and CASP1 genes, Real-Time PCR confirmed that they were upregulated, on average, of 1.74, 1.55 and 1.60 times, respectively, after all CXCL12 isoform treatments.

Functional and pathway enrichment analyses

The three lists of DEGs (*i.e.*, for each CXCL12 isoform) have been submitted to Enrichr tool in order to provide an interpretation of the biological processes associated with these genes. This gene enrichment analysis has been performed considering GO terms, regarding GO Biological Process, GO Molecular Function and GO Cellular Component (Supplementary Table 2-4). Our analyses showed that β isoform seems to alter, more than α and γ isoforms the expression of genes involved in cell cycle regulation, DNA replication, G2/M checkpoints, p53 signalling pathway, regulation of apoptosis and senescence. In addition, enrichment analyses highlighted that, for all CXCL12 isoforms, most enriched GO terms involved cell migration and adhesion. Indeed, we often found terms such as "intermediate filament", "cytoskeleton", "microtubule", "kinesin complex", "motor activity", "tubulin binding", " positive chemotaxis", "hemidesmosome assembly", "cell-substrate junction assembly", "microtubule polymerization or depolymerisation", "regulation of cell motility", "regulation of actin filament depolymerisation" (Supplementary Tables 2-4). Since these terms seem to be uniformly distributed among the three CXCL12 isoforms, we decided to carry out *in vitro* assays to evaluate better the specific effect of each CXCL12 isoform on cell migration.

Only significant differentially expressed genes are reported (adjusted *P* values < 0.05). FC: Fold change.

Monolayer wound healing assay

To assess the biological influence of each CXCL12 isoform on cell migration, hTERT-HPNE cells have been subjected to monolayer wound healing assay. Compared with untreated control, the migration ability of treated hTERT-HPNE cells significantly ($P < 0.05$) increased at 12 h and 24 h time-points after CXCL12 isoforms administration. In particular, the γ isoform increased (37% at 24 h) the hTERT-HPNE migration more than α (16% at 24 h) and β (22% at 24 h) CXCL12 isoforms (Figure 4). Our results confirmed the functional enrichment analyses on DEGs identified by microarray experiments.

DISCUSSION

The strong interaction between stroma and tumour cells is a typical characteristic of PDAC microenvironment. CAFs, representing the 50% of PDAC stroma, are involved in malignant progression, by releasing several chemokines such as CXCL12[12]. In cancer cells presenting the CXCL12 receptor (CXCR4), numerous signalling pathways are activated, which promote cell growth, proliferation, migration, invasion, metastasis and drug resistance[12]. In this study, we investigated the potential role of three different CXCL12 splicing isoforms in a pancreatic pre-tumour model. In particular, we used immortalized, epithelial-like pancreatic duct cells bearing a mutation in the KRAS gene (*G12D*), which is known to be present in 90% of low-grade PanIN-1 lesions. The *G12D* mutation triggers conformational changes that result in KRAS protein activation, which, in turn, can constitutively stimulate several effector pathways involved in tumour development. However, in pancreas, it leads only to a pre-malignant phenotype; indeed, further mutations, amplifications or inactivation of other genes are necessary for the tumour formation[5,6,16]. Therefore, this model has a great value as control in functional *in vitro* assays.

Our microarray data identified some DEGs in hTERT-HPNE cells upon treatment with different CXCL12 isoforms. The DEGs of each isoform were associated with cell migration, adhesion, and cytoskeleton. In vitro wound healing assays confirmed these gene expression results for all isoforms. Our data also showed that the treatment with

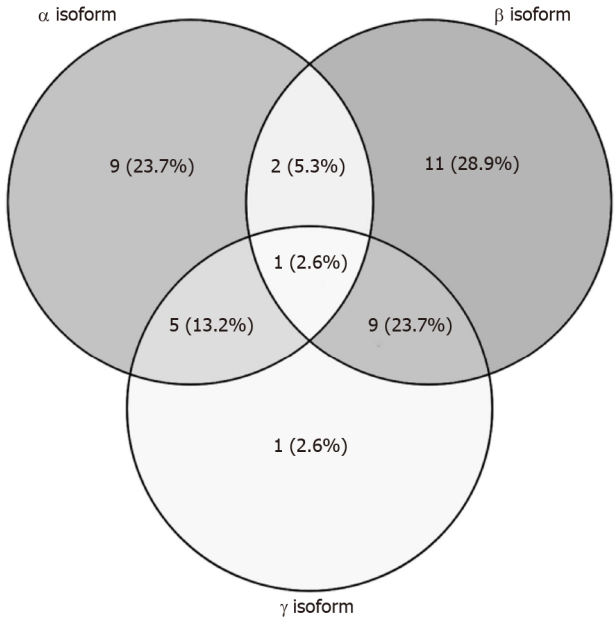

Figure 2 Comparison of the number of differentially expressed genes in all treatment conditions (α, β and γ CXCL12 isoforms) in hTERT-HPNE cells. Differentially expressed genes were detected using an FDR-corrected *P* value threshold of $P < 0.05$.

CXCL12 γ isoform on hTERT-HPNE cells caused enhanced wound healing repair than α and β isoforms.

Similar previous results are not available, since the different CXCL12 isoforms have been usually evaluated in terms of their chemoattractant abilities, that is in *in vitro* chemotaxis assays with a CXCL12 gradient. In a study of Yu *et al*[22], β isoform was more efficient than the others, while in some other studies the isoform with the highest attractant ability was α isoform[23,24]. Furthermore, there are in other studies which determined that γ isoform induced greater migration than other isoforms[25,26]. In

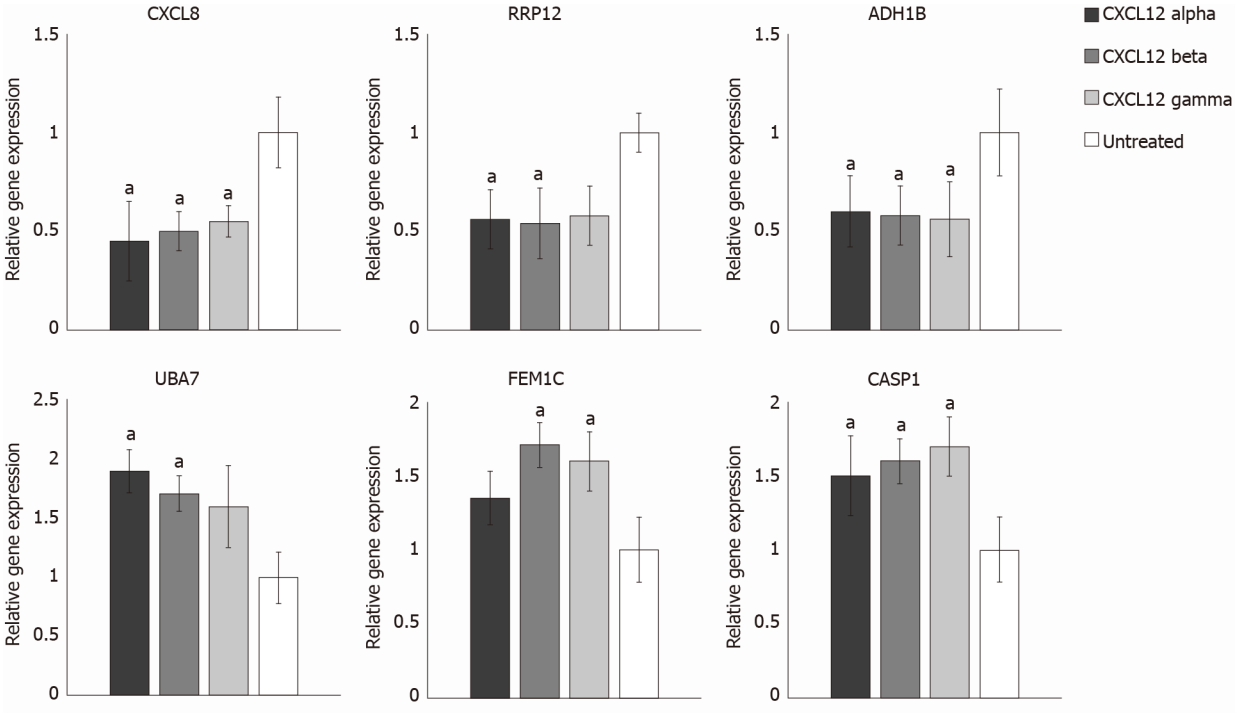

Figure 3 Real-Time polymerase chain reaction analysis of differentially expressed genes. Expression levels of CXCL8, RRP12, ADH1B, UBA7, FEM1C, and CASP1 in treated and untreated hTERT-HPNE cells. All values are expressed as the mean ± SD. Values were considered to be significantly different respect to the control at $^{a}P < 0.05$.

another *in vitro* chemotaxis assay, the use of different concentrations allowed to realize that α isoform induced greatest migration at low concentrations, whereas γ isoform at high concentrations[27]. It was also observed that the chemotactic responses of cells toward CXCL12 can be drawn as a bell-shaped curve with very low effects at both high and low concentrations of CXCL12 isoforms, maybe due the CXCR7 scavenging which alters the CXCL12 gradient to facilitate migration[25]. On the contrary, γ isoform drives chemotaxis to a much greater extent than α and β in *in vivo* studies. Indeed, γ isoform binds to the ECM components, with an extremely greater affinity than α isoform, allowing its local increase and so its activation by oligomerization[26,27].

Among genes with significantly altered expression upon treatments with the different CXCL12 isoforms, there are many genes already known to be involved in cell migration. Interestingly, this is the first study highlighting the possible genes targeted by different CXCL12 isoforms. For example, all CXCL12 isoforms were able to reduce the expression of DOCK10 gene, involved in several cellular processes, including the cellular migration. In particular, it regulates amoeboid motility[28] and it is able to induce filopodia and membrane ruffles[29]. In many tumour types, the overexpression of the receptor GFRA1 Leads to enhanced cancer cell proliferation and migration[30]. The GFRA1 downregulation caused by α and γ CXCL12 isoforms could highlight their potential anti-tumoral role. Both β and γ isoform affect the expression of the alcohol dehydrogenase gene (*ADH1B*), known to take part in several pathways promoting ovarian cancer cell infiltration[31]. Since CXCL12 β and γ isoform downregulate ADH1B gene, it suggests their possible anti-tumoral effect. Also JAM2 expression is downregulated by CXCL12 β and γ isoforms and, interestingly, JAM2 is known to affect cell invasion and migration abilities in pancreatic cancer cells[32]. GAS6-AS1 (GAS6 antisense RNA 1), overexpressed only upon treatments with the α isoform, promotes cancer cell growth, migration, and invasion ability in breast[33] and gastric cancer[34]. The CXCL12 β treatment induced overexpression of GDF9, CKAP2 and KIF2C. While GDF9 overexpression is correlated with a loss of the invasiveness, growth, and migration in human kidney cancer[35], CKAP2 overexpression increased cell proliferation, migration and invasion in HeLa cells[36]. Similarly to CKAP2, KIF2C mediates the cell migration in gastric cancer[37] and hepatocellular carcinoma[38]. Moreover, in KRas mutated cells, the knock down of KIF2C reduced the cell migration[39]. Our results showed that only CXCL12 γ isoform reduced the expression of LGR5. It is able to alter actin cytoskeleton, and in turn, reduce cell migration[40]. However, other studies demonstrated the central role of LGR5 in the tumour

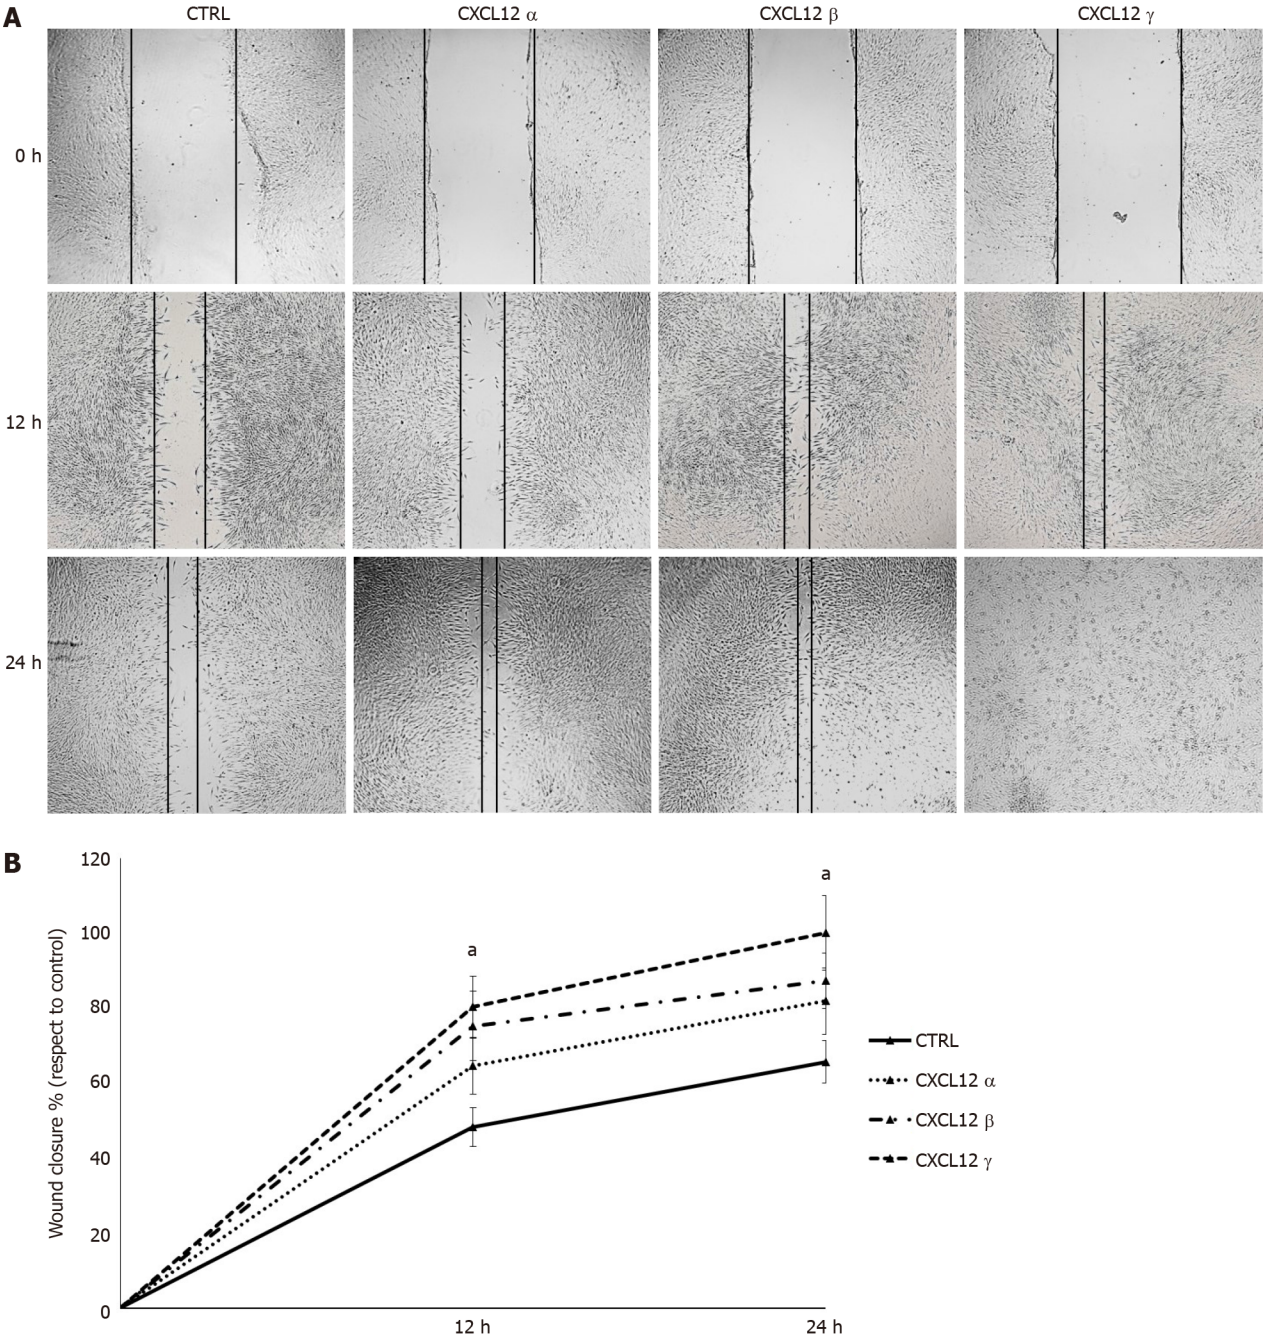

Figure 4 Migration ability of hTERT-HPNE cells. Wound healing assay was used to assess the effect of CXCL12 isoform treatments on cell migration. A: The cells were photographed immediately (0 h) after wounding by a pipette tip and at different time points (12 h and 24 h); B: The migration ability of the treated cells was evaluated by measuring their efficiency in wound repair compared with that of the control. All values are expressed as the mean ± SD. Values were considered to be significantly different respect to the control at $^{a}P < 0.05$.

physiopathology, although its utility as a marker of cancer stem cells is still controversial[41].

Besides cell migration, CXCL12 treatments affected the expression of genes involved in cell cycle regulation, genome integrity, stroma remodelling, and inflammation. For example, only the CXCL12 β treatment induced overexpression of *E2F3* and *ATR* genes. The upregulation of *E2F3* gene, involved in regulation of cell cycle, promotes proliferation and progression of pancreatic cancer cells[42]. The DNA damage sensing by the *ATR* kinases plays critical role in the resistance to chemotherapeutic drugs. Indeed, the inhibition of ATR increased pancreatic cancer cells' sensitivity to gemcitabine and radiation *in vitro*[43,44]. The *SERPINB2* gene expression is downregulated only upon treatments with α isoform. Interestingly, since *SERPINB2* mediates the remodelling of PDAC stroma, leading to the suppression of tumour growth and local invasion[45], α isoform may have a pro-tumoral activity in our hTERT-

HPNE cell model. The expression of the pro-tumour *KSR1* (Kinase suppressor of Ras-1) gene in our KRAS mutated pancreatic cells was downregulated upon treatments with CXCL12 α and γ isoforms. Interestingly, deletion of *KSR1* prevented cell signalling, leading to the block of the transformation induced by mutated KRAS[46]. The inhibition of *KSR1* gene determined a significant growth reduction of pancreatic tumours in vivo, as observed after injection of Panc-1 cells, a cellular model of KRAS-dependent PDAC, in nude mice[47]. Finally, CXCL12 β and γ isoforms downregulated the expression of the major metastasis-promoting inflammatory chemokine CXCL8 (also known as interleukin-8, IL-8). Indeed, KRAS mutation induces overexpression of CXCL8, which is necessary for cancer growth, vascularization and stromal remodelling[48]. Unlike CXCL12 β and γ isoforms, tumor necrosis factor-α, leukemia inhibitory factor, IL-1β, IL-6, and interferon-β induced the expression of CXCL8 in PDAC cells[49]. On the contrary, Matsuo *et al*[50] demonstrated that CXCL8 secretion by pancreatic cancer cell lines was significantly induced by CXCL12. However, unlike our experiments, these authors performed assays in a tumour model and without information about the involved CXCL12 isoform.

CONCLUSION

In conclusion, we showed that treatments with different CXCL12 isoforms prompt cell migration to different extents, probably due to different genes identified by our microarray analysis. Our results may facilitate the elucidation of the role of some CXCL12 isoforms in pancreatic cancer onset, and its underlying molecular mechanisms. In addition, the identified genes may represent novel candidates for diagnostic biomarkers and therapeutic targets for pancreatic cancer.

ARTICLE HIGHLIGHTS

Research background

Pancreatic ductal adenocarcinoma (PDAC) is a highly lethal cancer type, since it is usually diagnosed late, it has a very poor prognosis and strong chemoresistance. In the tumour microenvironment, cancer cells and other cell types co-exist and communicate by exchanging several molecules, including the chemokine CXCL12.

Research motivation

CXCL12 pre-mRNA can be alternatively spliced into different isoforms (α, β, γ, δ, ε, θ). However, their specific roles in PDAC have not yet been fully described.

Research objectives

Here, we aim to evaluate the specific roles of the main CXCL12 isoforms (α, β, and γ) in PDAC onset.

Research methods

We administered α, β, and γ CXCL12 isoforms to a pre-tumour model of PDAC, *i.e.*, the hTERT-HPNE E6/E7/KRasG12D cells. Then, we performed microarray analysis and Real-Time polymerase chain reaction validation in order to evaluate the global gene expression alterations. We also carried out wound healing assays in order to evaluate the effect of α, β, and γ CXCL12 isoforms on the cell migration ability.

Research results

The transcriptomic analyses showed that the expression of only few genes was affected by the treatment with the three isoforms. In particular, α and β isoforms affect different genes, whereas γ isoform altered the expression of genes already affected by the other isoforms. Since many genes affected by all isoforms are involved in cell migration and cytoskeleton remodelling, we performed cell migration assays, which confirmed the role of CXCL12 in migration, mainly caused by the γ isoform.

Research conclusions

Our results suggest that α, β and γ CXCL12 isoforms can trigger different responses in a pancreatic pre-tumour model. The γ isoform induced the highest level of cell migration.

Research perspectives

Although our data shed light on the molecular basis of PDAC onset and progression, further studies are necessary for a deeper characterization of CXCL12 isoforms.

ACKNOWLEDGEMENTS

We thank the Microarray Unit of Cogentech S.R.L. Benefit Corporation (Milan, Italy) for their assistance in the experimental microarray analyses.

Abstract

BACKGROUND

Recurrent acute pancreatitis (RAP) may be a presenting feature of and an indication for resection of pancreatic cysts, including intra-ductal papillary mucinous neoplasm (IPMN). Few data are available regarding the prevalence of malignancy and post-operative RAP in this population.

AIM

To study the role of resection to help prevent RAP and analyze if presentation as RAP would be a predictor for malignancy.

METHODS

This retrospective study assessed 172 patients who underwent surgical resection of pancreatic cystic neoplasms at a university hospital between 2002 and 2016. The prevalence of preoperative high-risk cyst features, and of neoplasia was compared between patients with and without RAP. To identify the cause of pancreatitis, all the patients had a detailed history of alcohol, smoking, medications obtained, and had cross-sectional imaging (contrast-enhanced computed tomography/magnetic resonance imaging) and endoscopic ultrasound to look for gallstone etiology and other structural causes for pancreatitis. The incidence of RAP post-resection was the primary outcome.

RESULTS

IPMN accounted for 101 cases (58.7%) {[branch duct (BD) 59 (34.3%), main duct (MD) 42] (24.4%)}. Twenty-nine (16.9%) presented with RAP (mean 2.2 episodes): 15 had BD-IPMN, 8 MD-IPMN, 5 mucinous cystic neoplasm and 1 serous cystic neoplasm. Malignancy was similar among those with *vs* without RAP for all patients [6/29 (20.7%) *vs* 24/143 (16.8%)] and IPMN patients [6/23 (26.1%) *vs* 23/78 (29.5%)], although tended to be higher with RAP in BD-IPMN, [5/15 (33.3%) *vs* 3/44 (6.8%), $P = 0.04$]. At mean follow-up of 7.2 years, 1 (3.4%) RAP patient had post-resection RAP. The mean episodes of acute pancreatitis before *vs* after surgery were 3.4 *vs* 0.02 ($P < 0.0001$).

CONCLUSION

Malignancy was not increased in patients with pancreatic cystic neoplasms who have RAP compared to those without RAP. In addition, specific cyst characteristics were not clearly associated with RAP. The incidence of RAP was markedly decreased in almost all patients following cyst resection.

Key Words: Pancreatic cyst; Pancreatic neoplasm; Pancreatitis; Malignancies

Core Tip: Our findings from this original study support international consensus guidelines recommendations for surgical resection of pancreatic cystic neoplasms presenting with acute pancreatitis but more for the effective treatment of recurrent acute pancreatitis (RAP) rather than for the identification of malignancy. The objective of this research was to study the role of resection to help prevent RAP and analyze if presentation as RAP would be a predictor for malignancy.

INTRODUCTION

Acute pancreatitis is among the most frequent gastrointestinal causes of hospital admission in the United States with nearly 280000 hospitalizations annually[1]. While pancreatic cysts in the setting of pancreatitis are frequently assumed to be pseudocysts, neoplastic pancreatic cysts are recognized as a cause of acute pancreatitis. Intra-ductal papillary mucinous neoplasms (IPMN) are the most common cystic pancreatic neoplasms. They arise within the main pancreatic duct or side-branches and are characterized by production of thick mucinous fluid. Additional pancreas cystic neoplasms include mucinous cystic neoplasm and serous cystic neoplasm. Pancreatic cysts may cause acute pancreatitis by compression of the pancreatic duct or by obstruction of the pancreatic duct with mucus. The reported rate of acute pancreatitis among patients with IPMN varies between 7% and 67%[2-5]. A careful clinical history could help to differentiate such neoplastic cysts from a mature, encapsulated fluid collection without necrosis (pseudocyst) or with necrosis (walled-off necrosis, WON) that may occur as a cystic lesion after 4 wk from the onset of acute pancreatitis[6]. The presence of a pancreatic cyst in imaging at diagnosis of index pancreatitis is probably a neoplastic cyst, while the detection of a cyst in the follow-up of pancreatitis with a normal first imaging exam likely a post inflammatory pseudocyst or WON.

The diagnosis of acute pancreatitis is based on the presence of two of the following three features: (1) Abdominal pain consistent with acute pancreatitis (acute onset of a persistent, severe, epigastric pain often radiating to the back); (2) Serum lipase activity (or amylase activity) at least three times greater than the upper limit of normal; And (3) Characteristic findings of acute pancreatitis on contrast-enhanced computed

tomography (CECT) or magnetic resonance imaging (MRI) or transabdominal ultrasonography[6]. Recurrent acute pancreatitis (RAP), defined as two or more definite episodes of acute pancreatitis, occurs in approximately 17% to 29% of patients who present with a first episode of acute pancreatitis[5,7-9]. Approximately 80% of RAP is related to alcohol and gallstones. Other etiologies include medications, pancreas divisum, sphincter of Oddi dysfunction, pancreatic cancer, hypertriglyceridemia, hypercalcemia, infections, and genetic predisposition[10,11].

Few data are available regarding the prevalence of malignancy and on the course of RAP associated with pancreatic cystic neoplasms, such as IPMN, and the potential benefit of surgical resection in patients with acute pancreatitis due to pancreatic cysts. We, therefore, performed a retrospective study to assess the characteristics of patients with pancreatic cystic neoplasms who present with unexplained RAP and the effect of surgical resection on the natural history.

MATERIALS AND METHODS

We conducted a retrospective cohort study at the Yale-New Haven Hospital to identify patients who underwent surgical resection of pancreatic cystic neoplasms between January 1, 2002 and December 1, 2016. Those who had RAP, defined as 2 or more episodes of acute pancreatitis without an identifiable cause prior to resection[12], and imaging [computed tomography, magnetic resonance imaging, and/or endoscopic ultrasound (EUS)] documenting the cyst pre-operatively were defined as the RAP cohort. To identify the cause of pancreatitis, all the patients had detailed history of alcohol, smoking, medications obtained and had cross-sectional imaging (CECT/MRI) and EUS to look for gallstone etiology and other structural causes for pancreatitis. The diagnosis was double-checked. Patients with resection who did not have prior RAP served as the control cohort. Patient follow-up extended until September 2018. The study was approved by the institutional review board at Yale University.

Preoperative classification was based on preoperative imaging and results of fine-needle aspiration, if performed. Cysts were classified as IPMNs and non-IPMNs. The IPMNs were sub-classified as main-duct (MD) and branch-duct (BD). Mixed-type IPMNs were included in the MD group. Preoperative diagnosis of IPMNs were based on clinical findings from the images obtained. Histopathology from post-surgical resection specimens was used as the gold standard to ascertain the final diagnosis. The pathological classification and pre-surgical classification were made on the basis of World Health Organization criteria and current literature[13-16]. Performing metastatic urothelial cancer (MUC) staining or gene sequencing

Malignancy was defined as the presence of invasive carcinoma or high-grade dysplasia on final surgical pathology. Patients with no follow-up data post-operatively, known pseudocysts and predominantly solid pancreatic masses were excluded. Patient demographic, clinical, radiographic, and pathologic data were extracted from the medical record. In patients with multiple cysts, the features of the largest cyst or the cyst with the most concerning high-risk features (*e.g.*, mural nodules) were the characteristics recorded for the patient. Patient data post-resection were also extracted, with the primary goal of identifying episodes of acute pancreatitis. On surgically resected specimens, MUC staining, histologic examination and gene sequencing were used for pathologic subclassification[17,18].

Statistical analysis

The primary analysis involved a comparison of the number of episodes of acute pancreatitis pre- and post-resection of pancreas cyst in patients who had RAP. We also compared baseline patient and cyst characteristics between patients with RAP and those without RAP. Comparisons between the RAP cohort and control (non-RAP) cohort and between the preoperative and post-operative time period were performed with the Mantel-Haenszel risk difference calculation for continuous variables and Mantel-Haenszel risk ratio for proportions. Statistical analysis was performed by using the statistical algorithms in Cochrane Review Manager Software 5.3.

RESULTS

A total of 172 patients with pancreatic cysts underwent surgery between 2002 and

2016. The indication for surgery was RAP along with cyst characteristics in 11 patients and among all other patients, the indication for surgery was based on the cyst morphology. IPMNs accounted for 101 (58.7%) of these 172 cases {BD-IPMN [59 (34.3%)] and MD-IPMN [42 (24.4%)]} (Table 1 and Figure 1). The next most common types of lesions were mucinous cystic neoplasms [32/172 (18.6%)] and serous cystic neoplasms [16/172 (9.3%)] (Table 1). Since preoperative diagnosis on cysts were made using radiologic findings, the final diagnosis might have varied based on surgical findings. Twenty-nine (16.9%) patients had RAP without other identifiable cause prior to resection, while the remaining 143 (83.1%) patients had no episodes of acute pancreatitis prior to resection. No patient had evidence of chronic pancreatitis. Among the 29 patients with RAP with cystic neoplasms, the surgical procedure performed was pancreaticoduodenectomy (n = 18) or distal pancreatectomy (n = 11) with surgical mortality 0%, morbidity 3/29 (10%) (one patient had mesenteric bleeding requiring immediate exploratory laparotomy, one had afferent limb syndrome 2 wk later required exploratory laparotomy for adhesion lysis, and other with a delayed abscess in left upper quadrant managed with external drainage.

Comparison of pre-resection and post-resection period in the RAP cohort

The mean number of pancreatitis episodes *per* patient prior to resection in the RAP cohort was 2.2 (range 2-32 episodes). The median elapsed time between the first episode of acupuncture (AP) and surgery was 17 mo (range 1.5 mo to 7 years). The mean follow-up after surgery was 7.2 years (range 1.9-13.8 years).

Only 1 (3%) of 29 RAP patients (with BD-IPMN) had acute pancreatitis documented post-resection. The mean number of recurrent episodes of acute pancreatitis *per* patient-year before *vs* after surgery was 3.40 *vs* 0.02 (absolute difference = 3.38, 95%CI 1.76 to 5.00; $P < 0.0001$)). All the episodes were mild acute pancreatitis and none of the patients in this cohort had severe acute pancreatitis[3]. A marked decrease was seen in all types of cysts (Table 2). The one patient with recurrent pancreatitis after resection had BD-IPMN; he had 8 episodes before resection and 32 after resection and progressed to chronic pancreatitis with ductal calcification at 6 years after resection. No patient without prior RAP developed acute pancreatitis after resection.

Comparison of RAP and control cohort

Selected characteristics of the RAP and control cohorts are shown in Table 3. Median age and proportion who were male were comparable. No clear differences were identified between the cohorts in characteristics of the cystic lesions, including in size, or proportion with malignancy except for location in the tail of pancreas where most cyst patients were without RAP. IPMNs tended to be more common among patients with RAP than in those without RAP (79.3% *vs* 54.5%; risk difference = 0.25; 95%CI: 0.08, 0.41, $P = 0.004$) with most of the difference seen in the BD-IPMN patients.

Table 4 shows the results for the RAP and control cohorts in all patients with IPMN. Patients with RAP were more likely to have intestinal and less likely to the gastric IPMN cysts (intestinal: 34.8% *vs* 12.8%; risk difference: 0.22 (95%CI: 0.01, 0.43); $P = 0.04$; gastric: 13% *vs* 53.9%; risk difference: -0.41 (95%CI: -0.58, -0.23); $P < 0.0001$). The pathological subtypes of 21.8% of RAP patients and 10.3% of non-RAP patients was unknown.

Table 5 is restricted to patients with BD-IPMN. Again, no clear differences were seen between cohorts in patient or cyst characteristics with the possible exception of a tendency to a higher prevalence of malignancy in the RAP group *vs* non-RAP group with BD-IPMNs {33.3% *vs* 6.8%, [risk difference = 0.27 (95%CI: 0.02, 0.52); $P = 0.04$]} although the numbers in each cohort were small. A similar difference in pathological subtypes were noted. Patients with RAP were more likely to have BD-IPMN of an intestinal subtype and less likely to have a gastric subtype *vs* the control cohort [intestinal: 46.7% *vs* 9.1%; risk difference = 0.38 (95%CI: 0.11, 0.64); $P = 0.006$; gastric: 0% *vs* 68.2%; risk difference = -0.68 (95%CI: -0.84, -0.52); $P < 0.001$]. However, it should be noted that the pathological subtype of 26.7% of BD-IPMNs was not recorded. Based on the significant results from Univariate analysis, multivariable analysis logistic regression performed, however, the results did not vary in any significance (Tables 6-8).

DISCUSSION

Surgical resection has been recommended for patients with pancreatic cystic neoplasms who present with acute pancreatitis[16], regardless of cyst type. Reasons for

Table 1 Types of pancreatic cysts

IPMN cysts (total)	101

Non-IPMN (n = 6)	7.52 (8.53)	0 (0)[1]	7.52 [0.69, 14.35]	0.03

[1]In order to calculate mean differences and risk ratios, a standard deviation of 0.0001 was substituted for zero. IPMN: Intra-ductal papillary mucinous neoplasm; MD-IPMN: Main duct-IPMN; BD-IPMN: Branch duct-IPMN; SD: Standard deviation; CI: Confidence interval.

resection include identification and removal of underlying malignancy, prevention of the development of malignancy, and prevention of additional attacks of pancreatitis[16]. The characteristics of cystic neoplasms associated with acute pancreatitis and the impact of surgical resection on the prevention of malignancy and future episodes of RAP, however, have not been well defined. We found that cyst characteristics, such as location, size, the proportion with solid component, and prevalence of malignancy were not clearly different between patients with *vs* without RAP. IPMN was the most common cystic neoplasm among patients with a history of RAP undergoing surgical resection. Although a prior report found MD/combined type IPMN to be more frequently associated with RAP (%)[3] and another study found no difference[5], we found that among patients with IPMN, RAP was more often associated with BD-IPMN (65%) than MD-IPMN (35%). Our results are different from Jang *et al*[3] where MD/combined IPMN resulting more RAP was thought to be due to mechanical obstruction of the main pancreatic duct by thick mucin, resulting in ductal hypertension, thereby premature activation and release of pancreatic enzymes[3]. However, BD-IPMN leading to AP/RAP is assumed primarily due to the obstruction of the main pancreatic duct by the migration of mucin from the BD or may not be related to mucin but just to the viscosity of cyst fluid[3]. Patients with RAP also were more likely to have intestinal histological subtype *vs* the control cohort, although histologic subtype was unknown in a third of patients.

Malignancy was present in approximately one-fifth of patients undergoing surgical resection of pancreatic cysts, with similar proportions in those with and without RAP. Malignancy tended to be more common in BD-IPMN patients with RAP (33.3% *vs* 6.8% without RAP), although given relatively small numbers and multiple comparisons, this finding must be viewed as hypothesis-generating. Prior studies vary

in the reported association of malignancy within pancreatic cysts in patients presenting with acute pancreatitis[19]. Some report no increased risk[20-22]. However, a recent study identified IPMN presenting with acute pancreatitis to be associated with an increased risk of malignancy as compared to IPMN without pancreatitis on multivariable analysis[23]. Morales-Oyarvide *et al*[23] also identified a significant association of AP with IPMN of intestinal subtype (OR = 4.7, 2.5-8.8)[23]. The intestinal phenotype of IPMN has a propensity for mucin hypersecretion, which may promote AP due to ductal obstruction[24-27]. In addition, the intestinal phenotype has been associated with an increased risk of malignancy and with colloid carcinoma[25].

Among the 15 BD-IPMN patients with RAP who had surgical resection in our study, pre-operatively only 1 (6.7%) demonstrated all 3 high-risk features for malignancy (dilated main pancreatic duct > 10 mm, size > 3 cm, solid component)[28] and 3 (20%) had 2 high-risk features. One-third, however, had malignancy identified on surgical pathology. Based on the presence of high-risk stigmata/worrisome features alone, *per* international revised consensus guidelines of 2017[16,29] or European guidelines[30], resection would not have been indicated in 14 of the 15 BD-IPMN patients if they had not presented with acute pancreatitis. And based on American Gastroenterological Association guidelines, if these patients did not have RAP, only 3 of 15 would have had EUS based on the requirement for at least 2 high-risk features[28]. American College of Gastroenterology guidelines recommends EUS or referral to a multidisciplinary team for pancreatic cystic lesions in the presence of pancreatitis regardless of high-risk

RAP: Recurrent acute pancreatitis; IQR: Interquartile range; CI: Confidence interval.

features[31]. While observational studies have suggested an increased risk of pancreatic cancer in all patients presenting with acute pancreatitis[19,32], further studies are needed to evaluate whether acute pancreatitis may be an independent predictor of malignancy within pancreatic cysts.

The primary goal of our study was to determine the post-resection course of patients with RAP associated with pancreatic cystic neoplasms. We found that episodes of RAP are rare following surgical resection of pancreatic cystic neoplasms, suggesting that the pancreatic cystic neoplasms were indeed the cause of RAP in almost all cases. Only 1 (3%) of 29 patients presenting with RAP had RAP after resection, and the rate of acute pancreatitis *per* patient-year decreased from 3.4 to 0.02 ($P < 0.0001$), with marked reductions in all types of pancreatic cystic lesions. It is also important to note that as the pancreatic exocrine function decreases after pancreas resection, the mere resection itself may reduce the frequency of RAP[33]. Pancreatic surgery for an indication of RAP alone is a very invasive procedure and therefore, risk/benefits should be considered while making the decision. In such cases, since the pancreatic ductal occlusion at the site of the papilla has been postulated to be the main reason for RAP in IPMN, performing an endoscopic pancreatic sphincterotomy with or without stenting may be effective in preventing pancreatitis recurrence[34].

We recognize several limitations to this study, including the retrospective review of data. In addition, this cohort is limited to patients who have undergone surgical resection of pancreas cystic neoplasms, which makes it a selected population not representative of the overall group of patients with pancreatic cystic neoplasms. For example, most patients with BD-IPMN or serous cystic neoplasms do not undergo resection. Patient cases were reviewed to exclude other identifiable causes of acute pancreatitis; however, given the study's retrospective nature, the evaluation was not standardized. All of the patients in our surgical cohort had RAP, with 2 or more episodes. This is reflective of clinical practice for BD-IPMN, as resection in the absence of multiple high-risk features is typically not pursued following a single episode of idiopathic pancreatitis. Although, this study clearly shows the risk reduction of RAP after the pancreatic resection, further investigation with large population prospective study is needed to prove causal relationship between the cause of RAP and pancreatic resection.

RAP: Recurrent acute pancreatitis; IQR: Interquartile range; NA: Not available; CI: Confidence interval.

CONCLUSION

In conclusion, we found that malignancy is not increased in patients with pancreatic cystic neoplasms who have RAP compared to those without RAP. In addition, specific cyst characteristics were not clearly associated with RAP, although intestinal histological subtype appeared to be more common in patients with RAP. Most importantly, episodes of RAP were markedly reduced after cyst resection, with only one of 29 patients having recurrent episodes. Our findings support international consensus guidelines recommendations for surgical resection of pancreatic cystic neoplasms presenting with acute pancreatitis but more for the effective treatment of RAP rather than for the identification of malignancy[16].

ARTICLE HIGHLIGHTS

Research background

Pancreatic cystic neoplasms may present recurrent acute pancreatitis (RAP). Little is known on the role of resection for preventing RAP and if any correlation of higher prevalence of malignancy is seen among these patients.

Research motivation

Predicting malignancy among the pancreatic cystic neoplasms and management of RAP is challenging.

Research objectives

The objective of this research was to study the role of resection to help prevent RAP and analyze if presentation as RAP would be a predictor for malignancy.

Research methods

We adopted a retrospective cohort study model, enrolling all the patients with pancreatic cystic neoplasms who underwent surgical resection and compare between those who presented with RAP and without RAP. Incidence of RAP after resection and prevalence of malignancy among those who presented with RAP were the primary outcomes.

Research results

Malignancy was similar among those with *vs* without RAP for all patients 20.7% *vs* 16.8%. The mean episodes of acute pancreatitis before *vs* after surgery were 3.4 *vs* 0.02 ($P < 0.0001$). These findings clearly contribute much to this area of science. Although, this study clearly shows the risk reduction of RAP after the pancreatic resection, further investigation with large population prospective study is needed to prove a causal relationship between the cause of RAP and pancreatic resection.

Research conclusions

When patients with RAP are noted to have pancreatic cysts, it should be emphasized to differentiate if those cysts are the cause or the effect of RAP, *i.e.*, if cystic neoplasms are causing the RAP or if cysts are pseudocysts as a result of RAP. Larger data is needed to see if there exists a causal relationship. Similar to the presentation of jaundice as a predictor for malignancy among pancreas cystic neoplasms, RAP may have a role as a predictor of high-risk cysts.

Research perspectives

Future research to be focused on a larger prospective cohort to answer the above two questions.

Abstract

BACKGROUND

In the early stage of acute pancreatitis (AP), a large number of cytokines induced by local pancreatic inflammation seriously damage the intestinal barrier function, and intestinal bacteria and endotoxins enter the blood, causing inflammatory storm, resulting in multiple organ failure, infectious complications, and other disorders, eventually leading to death. Intestinal failure occurs early in the course of AP, accelerating its development. As an alternative method to detect small intestinal bacterial overgrowth, the hydrogen breath test is safe, noninvasive, and convenient, reflecting the number of intestinal bacteria in AP indirectly. This study aimed to investigate the changes in intestinal bacteria measured using the hydrogen breath test in the early stage of AP to clarify the relationship between intestinal bacteria and acute lung injury (ALI)/acute respiratory distress syndrome (ARDS). Early clinical intervention and maintenance of intestinal barrier function would be highly beneficial in controlling the development of severe acute pancreatitis (SAP).

AIM

To analyze the relationship between intestinal bacteria change and ALI/ARDS in the early stage of SAP.

METHODS

A total of 149 patients with AP admitted to the intensive care unit of the Digestive Department, Xuanwu Hospital, Capital Medical University from 2016 to 2019 were finally enrolled, following compliance with the inclusion and exclusion criteria. The results of the hydrogen breath test within 1 wk of admission were collected, and the hydrogen production rates at admission, 72 h, and 96 h were calculated. The higher the hydrogen production rates the more bacteria in the small intestine. First, according to the improved Marshall scoring system in the 2012 Atlanta Consensus on New Standards for Classification of Acute

Pancreatitis, 66 patients with a PaO_2/FiO_2 score ≤ 1 were included in the mild AP (MAP) group, 18 patients with a PaO_2/FiO_2 score ≥ 2 and duration < 48 h were included in the moderately SAP (MSAP) group, and 65 patients with a PaO_2/FiO_2 score ≥ 2 and duration > 48 h were included in the SAP group, to analyze the correlation between intestinal bacterial overgrowth and organ failure in AP. Second, ALI (PaO_2/FiO_2 = 2) and ARDS (PaO_2/FiO_2 > 2) were defined according to the simplified diagnostic criteria proposed by the 1994 European Union Conference. The MSAP group was divided into two groups according to the PaO_2/FiO_2 score: 15 patients with PaO_2/FiO_2 score = 2 were included in group A, and three patients with score > 2 were included in group B. Similarly, the SAP group was divided into two groups: 28 patients with score = 2 were included in group C, and 37 patients with score > 2 were included in group D, to analyze the correlation between intestinal bacterial overgrowth and ALI/ARDS in AP.

RESULTS

A total of 149 patients were included: 66 patients in the MAP group, of whom 53 patients were male (80.3%) and 13 patients were female (19.7%); 18 patients in the MSAP group, of whom 13 patients were male (72.2%) and 5 patients were female (27.8%); 65 patients in the SAP group, of whom 48 patients were male (73.8%) and 17 patients were female (26.2%). There was no significant difference in interleukin-6 and procalcitonin among the MAP, MSAP, and SAP groups (P = 0.445 and P = 0.399, respectively). There was no significant difference in the growth of intestinal bacteria among the MAP, MSAP, and SAP groups (P = 0.649). There was no significant difference in the growth of small intestinal bacteria between group A and group B (P = 0.353). There was a significant difference in the growth of small intestinal bacteria between group C and group D (P = 0.038).

CONCLUSION

Intestinal bacterial overgrowth in the early stage of SAP is correlated with ARDS.

Key Words: Acute respiratory distress syndrome; Hydrogen breath test; Intestinal bacterial overgrowth; Severe acute pancreatitis; Interleukin-6; Acute lung injury

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Our retrospective study included 149 patients with acute pancreatic disease. The changes in intestinal flora were detected by the hydrogen breath test. We found that the change in intestinal flora in patients with severe acute pancreatitis was related to acute respiratory distress syndrome, which can aggravate the disease. The results of the hydrogen breath test can be used as a warning signal for severe acute pancreatitis.

INTRODUCTION

Acute pancreatitis (AP) is a common form of acute abdomen. The mortality rate of severe AP (SAP) with early organ failure can be as high as 36%-50%[1]. The earliest SAP-related organ dysfunction occurs in the respiratory system with the main symptoms of acute lung injury (ALI) and acute respiratory distress syndrome (ARDS)[2,3]. In the early stage of AP, a large number of cytokines is induced by local pancreatitis to enter the bloodstream, causing systemic inflammatory response syndrome (SIRS) through the cytokine cascade reaction; the large number of released cytokines can seriously damage the intestinal barrier function and increase intestinal wall permeability, intestinal microbial flora imbalance, intestinal bacterial overgrowth, and intestinal bacterial translocation. When intestinal bacteria and endotoxins enter

the blood, leading to multiple organ failure (multiple organ dysfunction syndrome), the end result is death[4].

The results of animal experiments have shown that when intestinal ischemia occurs in SAP, the mechanical barrier of the intestinal tract is damaged, the permeability of small intestine and colon mucosa is increased, and damage in the small intestine becomes more obvious; at that time, small intestine peristalsis decreases or even disappears, and the number of bacteria in the small intestine and colon rapidly increases, leading to small intestinal bacterial overgrowth (SIBO)[5]. Cen *et al*[4] established a model of intestinal motility disorder in AP rats, indicating that gastrointestinal motility disorder is the early cause of SIBO. Intestinal motility disorder is caused by neurohormone-mediated intestinal motility reduction induced by AP[6]. *Escherichia coli* and other bacteria grow excessively due to stagnation of substances in the cavity.

The gold standard for SIBO evaluation is quantitative culture of duodenal or jejunal aspiration under aerobic and anaerobic conditions, and a study found colony formation higher than 10^3 CFU/mL (colony-forming unit/mL)[7]. Because of the high cost and invasive nature of small intestinal fluid aspiration culture, the hydrogen breath test, as an alternative method for SIBO testing, has been suggested as an inexpensive, safe, and noninvasive alternative. It is widely used in the clinic as an important method to diagnose SIBO. However, the sensitivity range of the hydrogen breath test is 20%-90%, possibly because of the lack of uniform diagnostic criteria, which has been resolved by the recently published North American breath test consensus[8].

The lactose hydrogen respiration test is a noninvasive semi-qualitative test, originally designed to measure the oral-cecum passage time; it is currently used for many diseases of the digestive system, such as lactose intolerance, irritable bowel syndrome, dyspepsia, and non-alcoholic fatty liver[9,10]. The premise of the hydrogen breath test to detect SIBO is that the human metabolism does not produce hydrogen or methane. Methanogens are not bacteria, but belong to the category of archaea, mainly present in the colon, accounting for 10% of all anaerobic organisms[7]. Since the production of methane requires hydrogen metabolism, the hydrogen and methane concentrations can be simultaneously detected with the carbohydrate breath test. The lactulose hydrogen respiration test involves oral lactulose (non-absorbent sugar) to the cecum, fermentation with coliform bacteria to produce hydrogen and methane, absorption into the systemic circulation, and then exhalation to detect the concentration of hydrogen/methane in the breath; when the concentration of hydrogen/methane in the breath exceeds the baseline, a SIBO diagnosis can be reached[11].

This study aimed to examine the change in intestinal bacteria measured using the hydrogen breath test in the early stage of AP to elucidate the relationship between intestinal bacteria and ALI/ARDS. Early clinical intervention and maintenance of intestinal barrier function will be very beneficial in controlling the development of SAP.

MATERIALS AND METHODS

Research object and grouping

We retrospectively analyzed the data of 456 patients with AP who met the diagnostic criteria of the 2012 "Consensus on New Atlanta Classification Standards for Acute Pancreatitis" and who were admitted to the intensive care unit (ICU) of the Department of Digestive Department, Xuanwu Hospital of Capital Medical University from 2016 to 2019. A total of 152 patients were admitted with SIRS or organ failure and could cooperate with the hydrogen breath test within 1 wk of admission. According to the 2012 "Consensus on New Atlanta Classification Standards for Acute Pancreatitis" improved Marshall scoring standard[1], 1 patient had circulatory failure, 2 patients had renal failure, 66 patients had no organ failure, and 83 patients had respiratory failure. One patient with circulatory failure and 2 patients with renal failure were excluded. A total of 149 patients were finally included. General data including age, sex, body mass index (BMI), Acute Physiology and Chronic Health Evaluation (APACHE)-II score, and mediators of inflammation were collected.

Inclusion criteria: (1) admission within 48 h after onset; (2) admission to the hospital with SIRS; (3) organ failure within 1 wk after admission; (4) age older than 18 years; and (5) clear mind, understanding ability normal, ability to communicate with the

physician.

Exclusion criteria: (1) chronic pancreatitis; (2) history of immune-related diseases, immune deficiency, and AIDS; (3) malignant tumors; (4) inability to cooperate and complete the hydrogen breath test; (5) incomplete case data; or (6) circulatory failure or renal failure.

Grouping

According to the improved Marshall score standard in the 2012 "Consensus on New Atlanta Classification Standards for Acute Pancreatitis"[1]: $PaO_2/FiO_2 \geq 301$ mmHg was scored as 1 point, 201 mmHg ≤ $PaO_2/FiO_2 \leq 300$ mmHg was scored as 2 points, 101 mmHg ≤ $PaO_2/FiO_2 \leq 200$ mmHg was scored as 3 points, and $PaO_2/FiO_2 \leq 101$ mmHg was scored as 4 points.

Methods: 66 patients with a PaO_2/FiO_2 score ≤ 1 were included in the mild AP (MAP) group, 18 patients with a PaO_2/FiO_2 score ≥ 2 and duration < 48 h were included in the moderately SAP (MSAP) group, and 65 patients with a PaO_2/FiO_2 score ≥ 2 and duration > 48 h were included in the SAP group (Figure 1).

ALI and ARDS: ALI and ARDS were defined according to the European Union Conference[12]. The simplified criteria recommended by the meeting included defining arterial hypoxia $PaO_2/FiO_2 < 300$ mmHg as ALI and $PaO_2/FiO_2 < 200$ mmHg as ARDS, excluding cardiogenic pulmonary edema. In this study, a PaO_2/FiO_2 score = 2 was used to define ALI, and a PaO_2/FiO_2 score > 2 was used to define ARDS.

Methods: The MSAP group was divided into two groups according to the PaO_2/FiO_2 score: 15 patients with PaO_2/FiO_2 score = 2 were included in group A, and 3 patients with score > 2 were included in group B. Similarly, the SAP group was divided into two groups: 28 patients with score = 2 were included in group C, and 37 patients with score > 2 were included in group D (Figure 1).

Treatment

MAP: (1) abrosia, gastrointestinal decompression, saline enema; (2) fluid resuscitation, water maintenance, electrolyte and acid-base balance; and (3) lactulose to improve intestinal function, proton pump inhibitors for gastric acid secretion, ulinastatin and/or gabexate to improve pancreatic microcirculation.

MSAP/SAP: (1) abrosia, gastrointestinal decompression, saline enema; (2) fluid resuscitation, water maintenance, electrolyte and acid-base balance; and (3) lactulose to improve intestinal function, proton pump inhibitors for gastric acid secretion, ulinastatin and/or gabexate to improve pancreatic microcirculation; octreotide to inhibit pancreatic exocrine function, and parenteral nutrition support.

When ARDS appeared it was treated with a mechanical ventilator. When renal failure appeared it was treated with CRRT (continuous renal replacement therapy). Vasoactive drugs were used to increase blood pressure when circulatory failure could not be corrected. Peri-pancreatic and extra-pancreatic infections were treated with anti-infection therapy.

Outcome: After treatment, when there was no abdominal pain, abdominal distension, or fever, and when there were active bowel sounds, spontaneous defecation, and the abdominal computed tomography re-examination showed marked improvement, the patient could be discharged from the ICU (Figure 2).

Hydrogen breath test

Test methods: The patient remained awake and quiet during the examination and did not exercise vigorously. For the detection process, the fasting breath was collected twice, and the highest value was used as the basic exhaled hydrogen concentration (H_0). The subjects were asked to quickly consume a lactulose solution including 10 g of lactulose in 100 mL of room-temperature pure water. Subjects then exhaled every 20 min 9 times (H_1-H_9). The hydrogen concentration in the exhalation was measured and recorded at each time point.

Data processing: Hydrogen production at admission, 72 h and 96 h was measured. The average hydrogen production rate was calculated as follows: $[H_n\text{-}H_{(n-1)}]/H_0$, ($0< n \leq 9$).

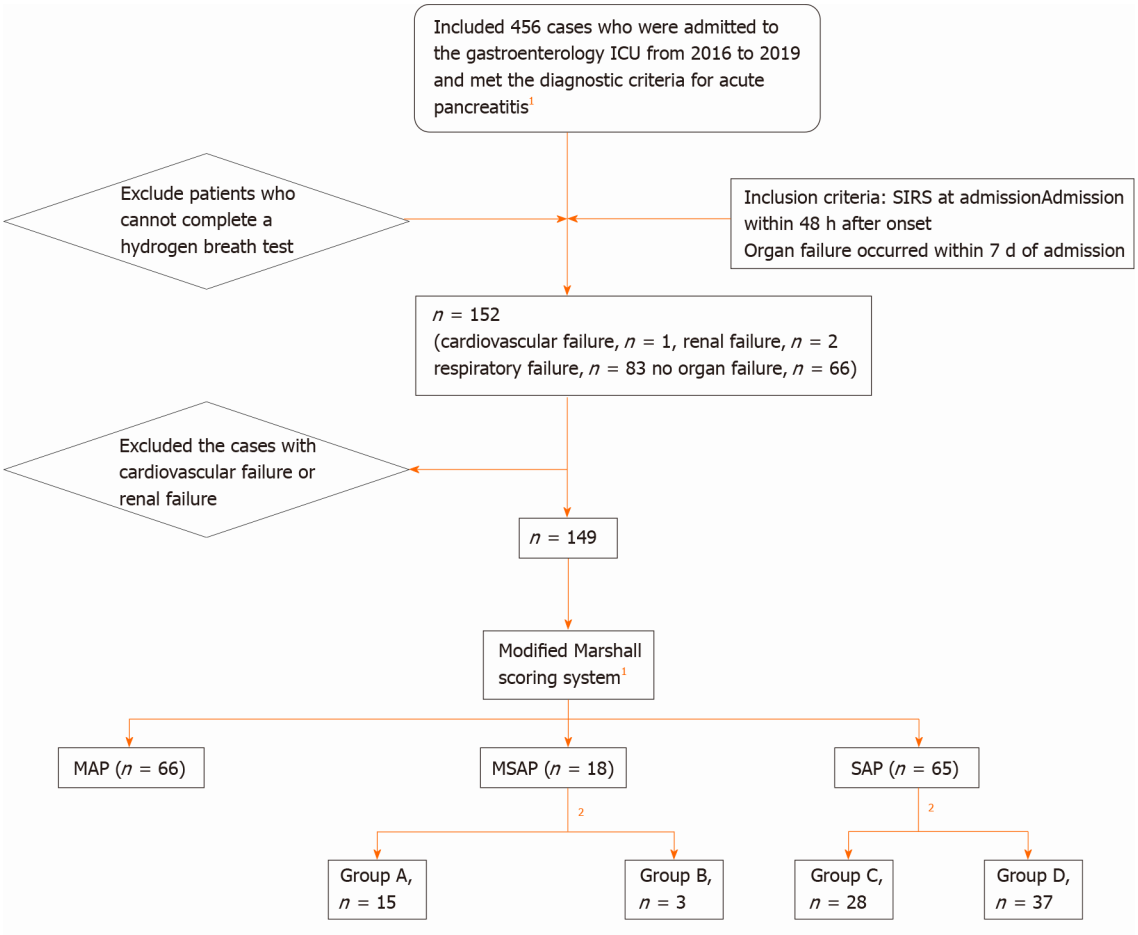

Figure 1 Research sample screening and grouping process. [1]Classification of acute pancreatitis 2012: revision of the Atlanta classification and definitions by international consensus. [2]Report of the American-European Consensus conference on acute respiratory distress syndrome in 1994. Simplified standard: PaO_2/FiO_2 < 300 mmHg is defined as acute lung injury and PaO_2/FiO_2 < 200 mmHg is defined as acute respiratory distress syndrome, and excludes cardiogenic pulmonary edema. Group A: PaO_2/FiO_2 = 2; Group B: PaO_2/FiO_2 > 2; Group C: PaO_2/FiO_2 = 2; Group D: PaO_2/FiO_2 > 2; ICU: Intensive care unit; SIRS: Systemic inflammatory response syndrome; MAP: Mild acute pancreatitis; MSAP: Moderately severe acute pancreatitis; SAP: Severe acute pancreatitis.

Statistical analysis

SPSS 25.0 (IBM Corp., Armonk, NY, United States) was used for data analysis, $P < 0.05$ was considered statistically significant. Age, BMI, APACHE-II score, and mediators of inflammation were measured, and the data are expressed as mean ± SD; and one-way analysis of variance (ANOVA) was used to compare the two groups. The hydrogen breath test data are expressed as the average hydrogen production rate ± SD, and the repeated-measures ANOVA was used in the comparison between the two groups. The number and percentage of counting data were expressed, and the chi-square test was used for comparison between the groups.

RESULTS

Clinical characteristics

A total of 149 patients were included: 66 patients in the MAP group, of whom, 53 patients were male (80.3%) and 13 patients were female (19.7%); 18 patients in the MSAP group, of whom 13 patients were male (72.2%) and 5 patients were female (27.8%); 65 patients in the SAP group, of whom 48 patients were male (73.8%) and 17 patients were female (26.2%) (Table 1). There was a significant difference in age, sex, and APACHE-II score among the MAP, MSAP, and SAP groups (both, $P < 0.001$) (Table 1).

Correlation between inflammation indicators and ALI/ARDS

There was no significant difference in interleukin (IL)-6 and procalcitonin among the MAP, MSAP, and SAP groups ($P = 0.445$ and $P = 0.399$, respectively) (Table 2). There

was no significant difference in IL-6 and procalcitonin among the MAP and MSAP groups (P = 0.306 and P = 0.683, respectively) (Table 3). There was no significant difference in IL-6 and procalcitonin among the MAP and SAP groups (P = 0.879 and P = 0.311, respectively) (Table 4). There was no significant difference in IL-6 and procalcitonin among the MSAP and SAP groups (P = 0.455 and P = 0.150, respectively) (Table 5).

Correlation between changes in the intestinal bacteria and ALI/ARDS

There was no significant difference in the number of intestinal bacteria among the MAP, MSAP, and SAP groups (P = 0.649) (Table 6). There was no significant difference in the number of intestinal bacteria among the MAP and MSAP groups (P = 0.196) (Table 7). There was no significant difference in the number of intestinal bacteria among the MAP and SAP groups (P = 0.494) (Table 8). There was no significant difference in the number of intestinal bacteria among the MSAP and SAP groups (P = 0.784) (Table 9). There was no significance difference in the number of intestinal bacteria and ALI/ARDS between group A and group B (P = 0.353) (Table 10). There was a significant difference in the number of intestinal bacteria and ALI/ARDS between group C and group D (P = 0.038) (Table 11, Figure 3). The changes in intestinal bacteria in the early stage of SAP were correlated with ARDS.

DISCUSSION

In this study, we used the hydrogen breath test to detect changes in intestinal bacteria in the early stage of AP and demonstrated that there was a correlation between ARDS and SIBO in the early stage of SAP.

This study also had some limitations. The results of the hydrogen breath test are easily affected by the number of aerogenes and the enzymatic activity of fructase. The number of gas-producing bacteria in the intestinal tract is affected by individual factors, including the environment and dietary habits, resulting in varying numbers of gas-producing bacteria among individuals. Abrosia and the use of antibiotics[13] also affect the number of gas-producing bacteria. The higher the enzymatic activity of fructase, the more gas is produced[11]. Routine lactulose treatment can improve the intestinal acid-base environment, reduce intestinal bacteria, and inhibitory activity[14];

there is also the catharsis effect of reduced intestinal bacteria; long-term lactulose treatment is equivalent to increasing the dose of lactulose in the hydrogen breath test, resulting in higher or lower results. In this study, quantitative analysis and the growth ratio were used to neutralize the influence of the basic value on the qualitative results.

As early as 2017, Zhang *et al*[15] and others were using the qualitative standard of the hydrogen breath test to examine the relationship between SAP and SIBO. The results showed that damage of intestinal barrier function is already present in the early stage of SAP; the positive SIBO rate was higher in patients with SAP, and SIBO mainly occurred within 72 h from onset. Finally, we found that there was a correlation

between ARDS and SIBO in the early stage of SAP ($P < 0.05$) in line with the results of previous studies. ALI/ARDS are the earliest organ-dysfunction symptoms in SAP. In this study, it was concluded that the occurrence of ARDS was related to SIBO within 72 h of admission. Studies have shown that SAP intestinal failure appears early, consistent with the results of our study. SAP-induced ALI/ARDS is mainly due to lung injury mediated by inflammatory factors[16]. Both infectious and non-infectious factors can lead to a large number of inflammatory factors. In the early stage of AP, inflammatory factors produced by pancreatic digestion damage intestinal barrier function, leading to persistent SIRS and SIBO, with SIBO leading to harmful metabolite accumulation in the intestinal tract, especially endotoxins and pathogenic intestinal bacteria[17]; subsequently, a large number of endotoxins and bacteria enter the bloodstream, flow through the pulmonary capillaries, activate neutrophils, damage the pulmonary vascular endothelium, leading to diffuse alveolar injury and type I alveolar necrosis, and eventually to ALI/ARDS[18,19]. Zhang *et al*[20] found that serum endotoxins

and intestinal mucosal permeability in patients with SAP were higher than in normal controls. Wang *et al*[3] found that lung bacteria were rich in intestine-related bacteria in mice with AP, sepsis, and ARDS. This study only showed the translocation of intestinal bacteria when sepsis and ARDS occurred simultaneously but did not explain the relationship between intestinal bacteria and ARDS when only ARDS occurred. Unfortunately, we could not locate animal experimental data on the correlation between ARDS and intestinal bacteria in the early stage of AP. The results of this clinical study showed that ARDS was correlated with intestinal bacteria, which should be further explored using animal models. However, although animal test support is lacking, in a clinical study on the relationship between the onset time and treatment time window of AP[21], the researchers concluded that the key time window for AP treatment is within 1 wk after the onset of AP; otherwise, the disease will worsen, the clinical course will be prolonged, and the mortality rate will increase; in terms of time, this study completely agrees with the previous research results. Therefore, the results of this study are of high guiding significance for clinicians who manage patients with AP. Early attention to the changes in intestinal bacteria can prevent the occurrence of SAP and high mortality.

This study also explored the correlation between IL-6 and ALI/ARDS. At present, the research results show that IL-6 is related to SAP. IL-6 can be used as an early predictor of complications[22]. The specificity of serum IL-6 > 160 pg/mL in the

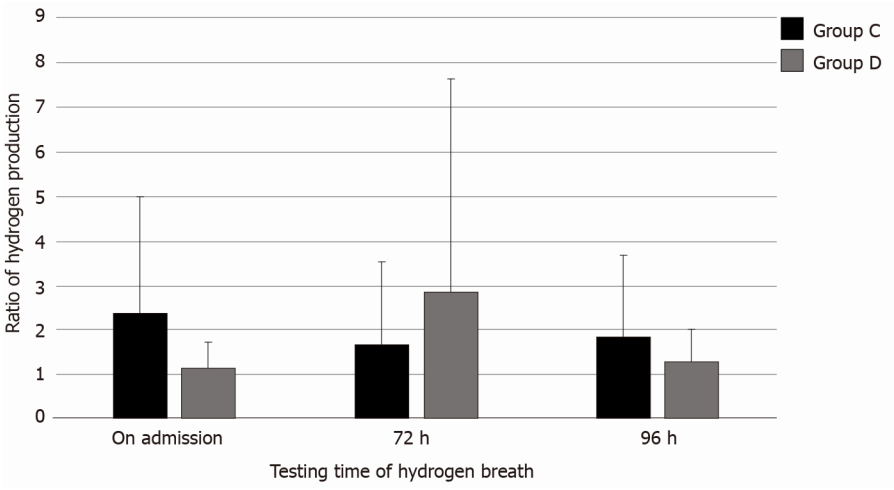

Figure 3 The correlation between changes in intestinal bacteria and acute lung injury/acute respiratory distress syndrome in the severe acute pancreatitis group. Group C: $PaO_2/FiO_2 = 2$; Group D: $PaO_2/FiO_2 > 2$.

diagnosis of SAP was 95%[23]. Relevant animal experiments have shown that when pancreatic injury occurs, IL-6 is rapidly synthesized to play an anti-inflammatory and protective role. When IL-6 continues to be synthesized and accumulates in large quantities, it mainly plays a pro-inflammatory role, leading to the occurrence and development of SAP[22]. In a clinical study conducted by Rezaie *et al*[13], it was found that the content of IL-6 in the blood was positively correlated with the abundance of *Enterobacteriaceae* and *Enterococci*, but negatively correlated with the abundance of *Bifidobacteria*. That study also compared the characteristics of intestinal bacteria between patients with AP and healthy controls. The results showed that the intestinal bacteria of patients with AP and healthy controls differed, and the abundance of *Enterobacteriaceae* and *Enterococci* and other potentially pathogenic bacteria differed from the abundance of beneficial bacteria such as *Bifidobacteria*, which decreased significantly. Although the final results of this study did not show a correlation between IL-6 and SAP, it is considered that this may be related to the treatments administered after admission.

CONCLUSION

Early organ failure in SAP was found to be closely related to the intestinal bacteria. Importantly, this study also determined the timing of SIBO, which is of great guiding significance for the clinical treatment of AP.

ARTICLE HIGHLIGHTS

Research background

In the early stage of acute pancreatitis (AP), a large number of cytokines induced by local pancreatic inflammation seriously destroy the intestinal barrier function, resulting in intestinal bacteria and endotoxins in the blood, causing inflammatory storms, and leading to multiple organ failure. Hydrogen breath testing is currently used for many diseases of the digestive system, such as lactose intolerance, irritable bowel syndrome, dyspepsia, and non-alcoholic fatty liver. This test, as an alternative method to detect small intestinal bacterial overgrowth (SIBO), was used to indirectly reflect the number of intestinal bacteria in AP. This study aimed to examine the change in intestinal bacteria measured using the hydrogen breath test in the early stage of AP to elucidate the relationship between intestinal bacteria and acute lung injury (ALI)/acute respiratory distress syndrome (ARDS). Early clinical intervention and maintenance of intestinal barrier function will be very beneficial in controlling the development of severe AP (SAP).

Research motivation

Clinical trials showed that intestinal bacteria in AP patients were different to those in healthy people and the abundance of potential pathogenic bacteria such as *Enterobacteriaceae* and *Enterococcus* increased significantly while the abundance of beneficial bacteria such as *Bifidobacterium* decreased significantly. Animal experiments showed that not only the changes in intestinal bacteria in patients with AP were verified, but also there was a correlation between the changes in intestinal bacteria and organ failure. However, neither of them showed a relationship between intestinal bacteria and organ failure in the early stage of AP. If we can understand the change in intestinal bacteria using the hydrogen breath test in the early stage of AP, in order to understand the relationship between intestinal bacteria and ALI/ARDS, we can intervene and maintain the stability of intestinal barrier function as soon as possible, which will be very beneficial in controlling the development of SAP.

Research objectives

Maintaining intestinal barrier function and reducing and preventing intestinal bacteria translocation have become the key to controlling the occurrence and development of SAP. This reduces complications in the early stage of the disease. We performed the present study to investigate the changes in organ function and intestinal bacteria in AP, and to explore the correlation between SIBO and AP organ function.

Research methods

Principle of the hydrogen breath test: after taking lactulose (nonabsorbable sugar), it reaches the cecum and is fermented with coliform bacteria to produce hydrogen and methane, which are absorbed into the systemic circulation and exhaled through the lung. When the hydrogen concentration in the exhaled breath exceeds the baseline, it is diagnosed as SIBO. In this study, a portable hydrogen expiratory detector was used to detect the patients' expired hydrogen concentration to diagnose SIBO. The change in exhaled hydrogen concentration can reflect the number of bacteria in the small intestine.

Research results

The results showed that in 37 SAP patients with ARDS, the average hydrogen production rate at admission was 1.15 ± 0.58, at 72 h was 2.85 ± 4.79 and at 96 h was 1.31 ± 0.71. In 28 SAP patients without ARDS, the average hydrogen production rate at admission was 2.39 ± 2.61, at 72 h was 1.68 ± 1.85, and at 96 h was 1.84 ± 1.86. The increase in intestinal bacteria in patients with SAP within 72 h after admission was related to the occurrence of ARDS. How to effectively maintain the stability of intestinal barrier function in the early stage of the disease and prevent the overgrowth of intestinal bacteria is a problem to be solved.

Research conclusions

In this study, intestinal bacterial overgrowth in the early stage of SAP was associated with ARDS. Moreover, the occurrence of ARDS was related to SIBO within 72 h of admission. It is of guiding significance to maintain the stability of intestinal barrier function in the early stage in order to reduce the complications of early organ failure and late infection.

Research perspectives

How to effectively maintain the stability of intestinal barrier function and prevent the excessive growth of intestinal bacteria in the early stage of disease, in order to reduce the occurrence and development of SAP, is the future research direction.

Abstract

BACKGROUND

Gastrointestinal cytomegalovirus (CMV) disease occurs commonly in immunocompromised/immunodeficient patients with advanced human immunodeficiency virus infection, neoplasm, solid organ transplantation, hematopoietic stem cell transplantation, or treatment with immunosuppressants, but is rarely reported in association with measles infection.

CASE SUMMARY

We describe a case of extensive gastrointestinal CMV disease secondary to measles infection in a 9-mo-old boy who presented with persistent fever and bloody diarrhea. His condition was improved after ganciclovir treatment. Serological analysis of CMV showed negative immunoglobulin (Ig) M and positive IgG. Blood CMV-DNA was 9.26×10^3 copies/mL. The diagnosis of gastrointestinal CMV disease was confirmed by histopathological findings of intranuclear and intracytoplasmic inclusions and Owl's eye inclusion. This case highlights the differential diagnosis and histopathological characteristics of gastrointestinal CMV infection and laboratory tests.

CONCLUSION

Extensive gastrointestinal CMV lesions can be induced by the immune suppression secondary to measles infection. Rational, fast, and effective laboratory examinations are essential for suspected patients.

Core Tip: We report a case of gastrointestinal cytomegalovirus (CMV) disease secondary to measles infection in a 9-mo-old Chinese boy who had extensive gastrointestinal lesions; the diagnosis was confirmed by histopathological analysis. His condition was improved by ganciclovir treatment. This case highlights the differential diagnosis and histopathological characteristics of gastrointestinal CMV infection and laboratory tests and sheds light on the difficulty in diagnosing gastrointestinal CMV disease due to its nonspecific clinical presentation and the weak diagnostic value of serologic antibody detection.

INTRODUCTION

Cytomegalovirus (CMV) is an intracellular virus, and CMV infection of the gastrointestinal tract is commonly documented in immunocompromised/immunodeficient patients. Measles infection induces immune suppression and is associated with an increased susceptibility to secondary infections[1], and this effect has typically been thought to last from a few weeks to a few months[2]. The Th2 response during convalescence of measles might inhibit Th1 responses, increasing susceptibility to other infections in children with measles[3]. The morbidity from diarrhea, one of the most common complications of measles, is reported to increase in the acute phase of measles[4]; however, gastrointestinal CMV infection is rarely reported as a causative etiology of persistent diarrhea secondary to measles infection.

CMV disease of the gastrointestinal tract is associated with significant mortality, mostly resulting from considerable bleeding and perforation when the patient is in an immunodepressed status[5]. However, it is not so common for the lesions to be very large. Limitations of the serologic assay of CMV and nonspecific clinical manifestations that mimic many other infectious diseases present a significant challenge to early and accurate diagnosis in clinical practice. Clinicians should consider CMV infection as a differential diagnosis even in immunocompetent patients with common alimentary symptoms, particularly intractable diarrhea, hematochezia, or vomiting in conjunction with fever. Here, we describe a case of gastrointestinal CMV disease secondary to measles infection that involved vast lesions, and we review the differential diagnosis, histopathological diagnosis, and treatment of gastrointes-tinal CMV infection.

CASE PRESENTATION

Chief complaints

A 9-mo-old Chinese boy was admitted to Shenzhen Children's hospital because of a persistent high fever and diarrhea that lasted for 17 d.

History of present illness

After 3 d of fever, he had a rash extending from his face to his trunk and limbs, and 5 d later, he suffered watery and bloody diarrhea. Positive immunoglobulin (Ig) M on the 10th day of fever confirmed a diagnosis of measles. Peripheral white blood cells, neutrophils, and C-reactive protein were elevated. Many leukocytes were found in his stool. Cefoperazone-sulbactam was administered intravenously for 4 d before admission, but the frequency of diarrhea increased, along with abdominal distension.

History of past illness

The patient had two episodes of pneumonia 40 d before this admission.

Personal and family history

The patient was born by cesarean section after full-term gestation, without complications during gestation or delivery. He had met physical and developmental milestones. Routine childhood immunizations were administered except for the measles vaccine.

Physical examination

On admission, the patient was weak but alert with a dehydrated appearance and typical measles skin (pigmentation and desquamation all over his body). The abdomen was soft and distended, with no tenderness or masses. The remainder of the physical examination was normal. Rapid intravenous rehydration was applied before further evaluation.

Laboratory examinations

Serological analysis for CMV showed negative IgM and positive IgG. PCR blood assay showed an elevation of CMV-DNA. The other laboratory results are shown in Tables 1 and 2.

Imaging examinations

Abdominal radiography (Figure 1) revealed upper gastrointestinal obstruction, while abdominal ultrasonography showed no obvious dilatation of the intestine or free effusion. Enhanced computed tomography demonstrated obstruction in the horizontal duodenum.

Further diagnostic work-up

On the 23rd day, gastroscopy (EG-99WR; Fujinon, Tokyo, Japan) and colonoscopy (GIF-XQ240; Olympus, Tokyo, Japan) were performed. Gastroscopy (Figure 2) revealed gastroduodenal mucosal edema and hyperemia, lymphoid hyperplasia, focal ulceration, pseudotumor formation, and stenosis in the horizontal duodenum. Incomplete colonoscopy (Figure 3) displayed diffuse mucosal edema and roughness, stiffness, friability, and white membranoid substances in the descending colon, sigmoid colon, and rectum. The histopathological examination revealed characteristic inclusions suggestive of CMV.

FINAL DIAGNOSIS

The final diagnosis of the presented case was gastrointestinal CMV disease.

TREATMENT

After admission to the hospital, suspected bacterial infection was treated with intravenous vancomycin and meropenem without improvement. On hospital day 12, diarrhea was aggravated with persistent high fever and episodes of vomiting and abdominal distension. Fasting and gastrointestinal decompression did not improve his condition. After the diagnosis of gastrointestinal CMV disease was made, intravenous ganciclovir was administered at 5 mg/kg every 12 h on the 30th hospital day for 2 wk and then reduced to 5 mg/kg each day for 1 wk.

OUTCOME AND FOLLOW-UP

The patient's condition improved after treatment with IV ganciclovir and he was discharged on the 54th hospital day. He was followed regularly to 4.5 years old, and he is doing well.

DISCUSSION

This 9-mo-old Chinese boy had persistent fever and diarrhea after measles infection; ensuing vomiting, abdominal distension, and hematochezia presented at a later stage.

All of these symptoms are indicative of digestive system diseases. Fever and diarrhea are common signs of different diagnoses in infants and children, including gastrointestinal infectious and noninfectious causes. In complicated cases with a prolonged course, there are difficulties in distinguishing pathogens; thus, detailed clinical data, exposure history, and pertinent laboratory tests can provide valuable assessment information.

Bacteria are reported as predominant pathogens of measles associated with diarrhea. However, this patient failed to respond to various antibiotics. Some distinct pathogens were considered. Enteroaggregative *Escherichia coli* (*E. coli*) and enteropatho -genic *E. coli* are the most commonly implicated bacterial pathogens in persistent infections in developing countries, especially among children[6]. The patient was a breastfed infant who had no ingestion of contaminated food, water, or unpasteurized milk, no exposure to sick contacts, no contact with infected pets or fowl, no travel history, and a negative result from stool culture, all of which indicated a low possibility of *shigella, salmonella, campylobacter* or other enteric infections[7].

While asymptomatic colonization of *Clostridium difficile* (*C. difficile*) is prevalent in infants, for patients with recent exposure to hospitals and antibiotics, microbiological evaluation should focus on the diagnosis of *C. difficile* infection[8]; however, *C. difficile* should be sensitive to vancomycin, together with repeated negative bacterial separation and culture and enzyme immunoassay tests for toxins A and B and glutamate dehydrogenase. There was no support for the diagnosis of *C. difficile* infection in this patient.

The patient lives in China, a country that ranks 3rd in the world for high tuberculosis

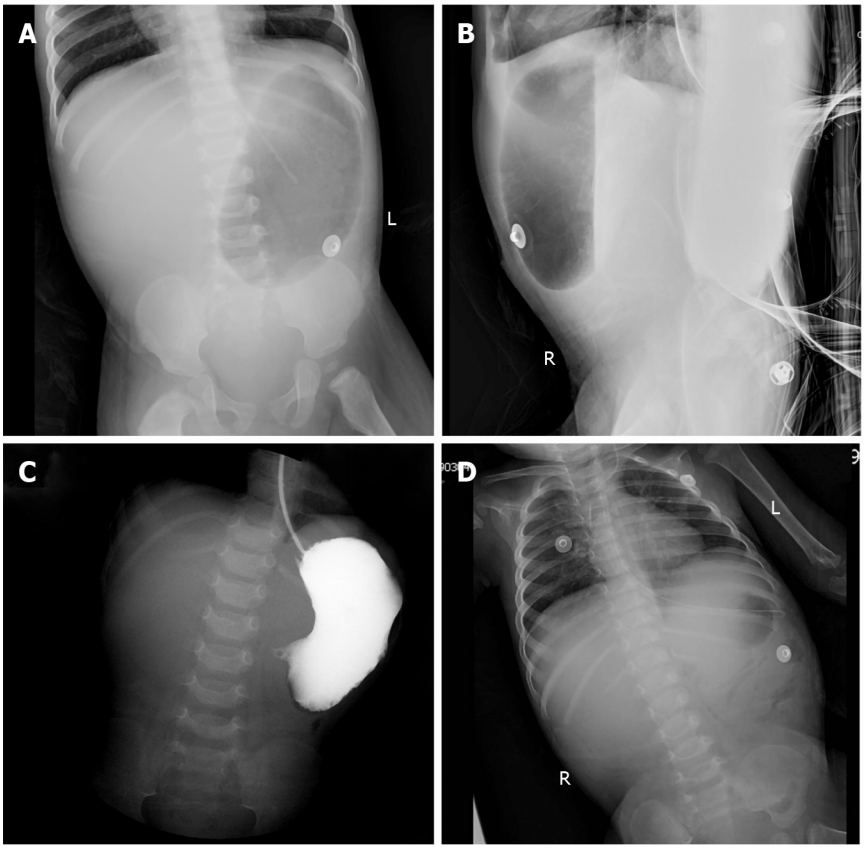

Figure 1 Abdominal plain. A and B: Supine (A) and lateral (B) abdominal plain films showed a large stomach, and no free gas was found in the small intestine, colon, or rectum. A nasogastric tube was coiled in the stomach; C: The iopromide administered by gastric tube did not enter the duodenum; D: Re-examination of abdominal film revealed decreased gas in the stomach and a few inflatable intestines.

(TB) morbidity; thus, intestinal TB (ITB) should be considered even though it is more likely to cause miliary TB in infants. ITB is characterized by low-grade fever, abdominal pain, loss of weight, altered bowel habits, and night sweats[9]. The absence of exposure to *Mycobacterium tuberculosis* and negative chest X-ray and interferon-γ release assay for TB revealed no direct evidence of TB in this patient.

As a noninfectious disease, inflammatory bowel disease (IBD) should be included in the differential diagnosis when lacking evidence of clear pathogenic microorganism infection[7]. The typical clinical presentations of infantile-onset IBD are intermittent fever and bloody diarrhea[10]; some cases are also associated with oral ulcers and

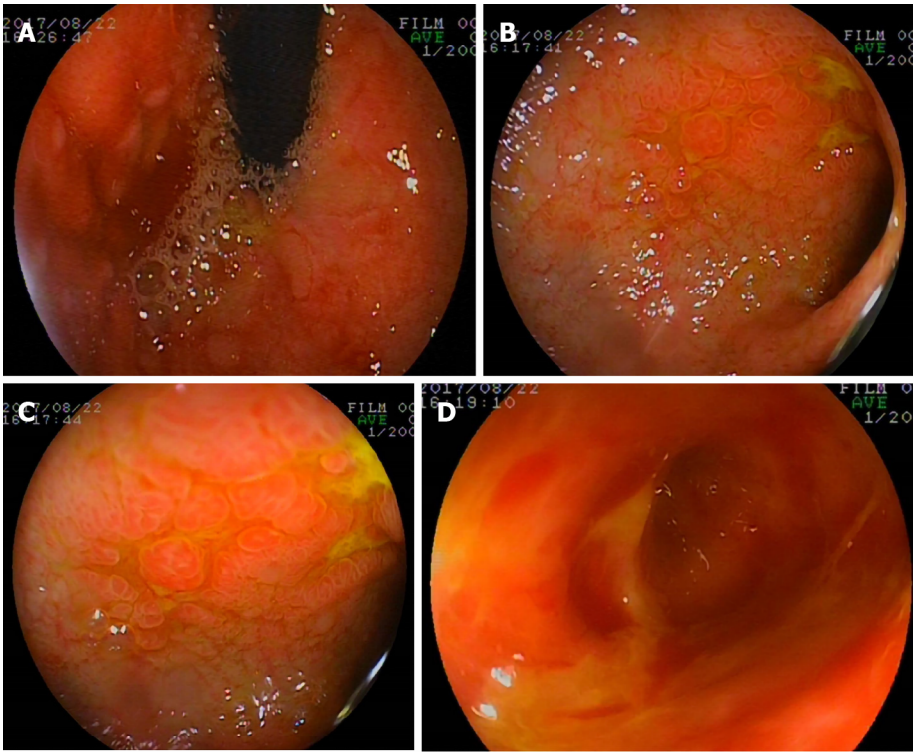

Figure 2 Gastroscopic findings. A gastroscope was inserted into the horizontal part of the duodenum. Hyperemia, edema, lymphoid hyperplasia, focal ulceration, and pseudotumor formation were seen in the stomach and duodenum. A: Gastric fundus; B and C: Duodenal bulb; D: Dilatation of proximal duodenum.

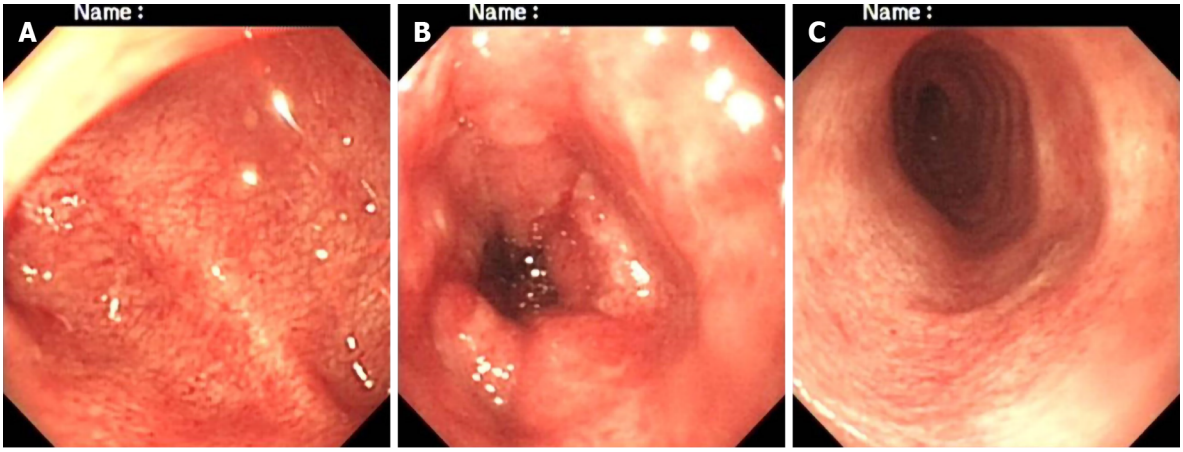

Figure 3 Colonoscopic findings. A colonoscope reached the splenic flexure of the colon. It showed hyperemia, roughness, stiffness, friability, and easy bleeding of the mucosa. A: Rectum; B: Sigmoid colon; C: Descending colon.

perianal abscess and fistula. The diagnosis relies on endoscopic evaluation and histopathological findings of mucosal biopsy other than on clinical characteristics and history. Macroscopic features revealed no contiguous or skip linear ulceration, aphtha ulceration, cobblestoning, fistula, abscesses, or other changes, and microscopic features showed no crypt architectural changes or noncaseating granuloma, so the evidence supporting IBD was insufficient[11]. Granting that very-early onset IBD may have heterogeneous or atypical symptoms and signs, endoscopy and mucosal biopsy were of great benefit to exclude IBD in this patient. There was no evidence of indigestion, malabsorption, autoimmune enteropathy, hemolytic uremic syndrome, allergic or neoplastic disorders, drug- or poison-induced diarrhea, structural diseases, or functional enteropathy in this case (Table 3).

Multiple factors may contribute to several weeks of measles-induced immune suppression[1]. There is an epidemiologically detectable long-term increase in susceptibility to infectious diseases in those who survive measles[12]. Measles infection contributes to transient lymphopenia with decreased numbers of T cells and B cells in

circulation during the acute phase of infection. As viral RNA persists, suppression of lymphocyte proliferation is induced. During recovery, the later Th 2 CD4+ T-cell response may suppress macrophage activation and Th 1 responses to new infections. Moreover, measles-infected dendritic cells induce lymphocyte unresponsiveness. The suppression of interleukin (IL)-12 production, lymphocyte expression of CD30, and elevation of IL-4, IL-10, and IL-13 might contribute to immune suppression. Deficiencies of both innate and adaptive immune responses can render individuals with measles more susceptible to secondary bacterial and viral infections[13]. The susceptibility to CMV is considered to be due to impaired cell-mediated immunity and a reduction in the levels of IgM[14].

Any part of the alimentary tract can be impacted by CMV infection but the typical CMV lesions are limited to either the upper or the lower gastrointestinal tract, while both the upper and the lower gastrointestinal tracts are rarely involved simultaneously[15]. Gastrointestinal CMV disease with complex and diverse but nonspecific symptoms is a remediable disease with a high mortality; delayed diagnosis, misdiagnosis, and missed diagnosis greatly increase fatality. To the best of our knowledge, in both immunocompetent and immunodeficient patients, intractable diarrhea and fever seem to be the most common presentations of gastrointestinal CMV disease, so differentiating CMV infection from infectious diarrhea as early as possible is vital in clinical practice.

In addition to broad clinical presentations and signs, confirmation of the virus *via* laboratory methods is indispensable in diagnosing CMV disease. In this patient, CMV-IgM was negative, and the absence of evidence of active infection led to an uncertain causal relationship between CMV infection and various symptoms, which demanded histopathology detection for further verification. Nonetheless, the positive CMV-IgG titre was more than 4-fold in 2 wk, and elevated CMV DNA copies provided clues for diagnosis. Nevertheless, false negative IgM results can be obtained in immunocompromised patients and infants. Positive measles IgM was detected in this patient because the immune status was not affected by measles infection at the early stage. However, due to an immunocompromised status secondary to measles infection later, the negative IgM significantly limits its clinical application in the early diagnosis of CMV infection, which may delay diagnosis and treatment[16].

Negative results of CMV PCR do not rule out CMV disease[17]. As a marker of early diagnosis, CMV pp65 antigen is not able to differentiate between latent infection and active disease. Viral culture is the diagnostic gold standard, but its poor sensitivity and slow turn-around time limit its clinical utility, while histopathology assays can provide confirmatory information for invasive disease which is highly specific[18] (Figure 4). Therefore, when gastrointestinal CMV infection is suspected, endoscopy and biopsy must be performed to obtain positive evidence for diagnosis.

The macroscopic features of gastrointestinal CMV disease vary from normal mucosa, focal erythematous, erosion, and pseudotumor formation to deep ulceration, lacking specificity[19]. Based on the patchy distributions and diverse endoscopic findings, biopsy location and number are important to assess CMV[20]. Gastroduodenoscopy and incomplete colonoscopy were performed in this patient due to the risk of intestinal perforation and massive hemorrhage. The outcome of the histopathology assay confirmed invasive CMV disease.

CMV disease requires evidence of parenchymal organ damage before it can be diagnosed and treated with antiviral therapy. Anti-CMV treatment in immunocom-

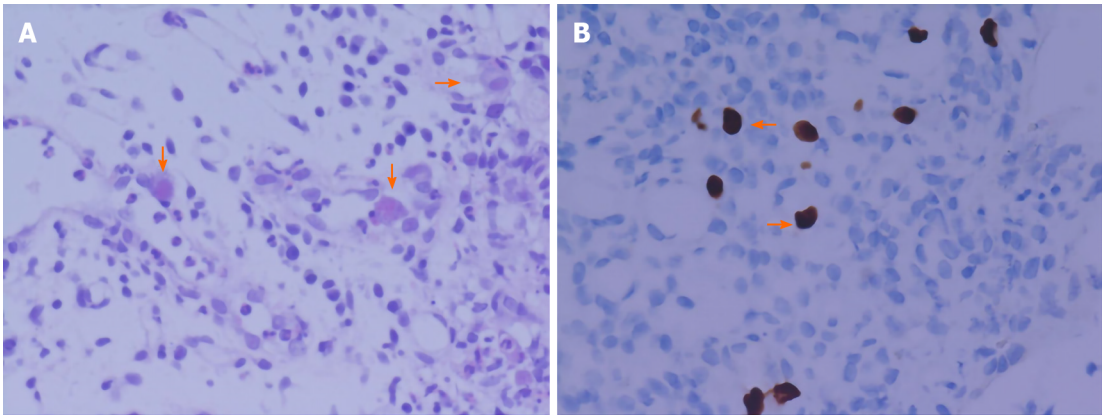

Figure 4 Gastrointestinal histopathologic findings. Histopathologic photomicrographs of gastric, duodenal, descending colony-like, sigmoid colony-like, and rectal specimens. promised patients is of vital importance to improve prognosis. Ganciclovir is recommended as the first-line pharmacological treatment for CMV infection, which comprises induction and maintenance. The initial dose must be adjusted for renal function and it is commonly advised to be 5 mg/kg every 12 h for at least 2 wk to 3 wk in the induction stage[21]. The course of treatment varies with therapeutic reactions, including symptoms, quantitative detection of viral load, whole blood counts, hepatic function and renal function. When patients cannot tolerate side effects or diseases worsen with the use of ganciclovir, foscarnet is generally used as a substitution drug, whereas which can result in renal toxicity and electrolyte disturbances[22]. After the diagnosis of CMV disease, the auditory, ophthalmic, and neurodevelopmental assessments of the patient were normal. His temperature decreased, vomiting disappeared, and the bowls recovered after intravenous ganciclovir administration. Inflammation biomarkers and CMV DNA copies decreased. An obvious improvement in imaging was shown on re-examination (Figure 1). The amelioration after antiviral therapy helped exclude IBD completely. Undoubtedly, this patient was fortunate. For immunocompromised patients with severe CMV infection, surgical treatment is required when medical treatment is ineffective.

In conclusion, we sought to review the differential diagnosis for similar clinical outcomes in a young child with diarrhea, hematochezia, and fevers, and to clarify endoscopic and histopathological findings as well as outline treatment options for CMV colitis. We highlighted the diagnostic challenges of gastrointestinal CMV disease due to its nonspecific clinical presentation and the weak diagnostic value of serologic antibody detection. We hope to help clinicians improve the understanding of the importance of considering this disease in immunocompromised patients, as well as to consider it in otherwise healthy patients with a prolonged course characterized by fever, diarrhea, and hematochezia who may become immunocompromised due to measles infection.

CONCLUSION

This is the first case of gastrointestinal CMV infection due to transient immunosuppression secondary to measles infection in a presumably immunocompetent child. Gastrointestinal CMV disease should be taken into considera-tion in patients with persistent fever and diarrhea followed by measles infection. Rational, fast, and effective laboratory examinations are essential for a timely diagnosis, avoiding inappropriate treatment and reducing mortality in suspected patients.

ABOUT COVER

Editorial Board Member of *World Journal of Gastroenterology*, Eiji Miyoshi, MD, PhD, Professor, Chairman, Department of Molecular Biochemistry & Clinical Investigation, Osaka University Graduate School of Medicine, 1-7 Yamada-oka, Suita, Osaka 565-0871, Japan. emiyoshi@sahs.med.osaka-u.ac.jp

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, and Scopus. The 2020 edition of Journal Citation Report® cites the 2019 impact factor (IF) for *WJG* as 3.665; IF without journal self cites: 3.534; 5-year IF: 4.048; Ranking: 35 among 88 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2019 is 7.1 and Scopus CiteScore rank 2019: Gastroenterology is 17/137.

Abstract

Originally proposed by John McCarthy in 1955, artificial intelligence (AI) has achieved a breakthrough and revolutionized the processing methods of clinical medicine with the increasing workloads of medical records and digital images. Doctors are paying attention to AI technologies for various diseases in the fields of gastroenterology and hepatology. This review will illustrate AI technology procedures for medical image analysis, including data processing, model establishment, and model validation. Furthermore, we will summarize AI applications in endoscopy, radiology, and pathology, such as detecting and evaluating lesions, facilitating treatment, and predicting treatment response and prognosis with excellent model performance. The current challenges for AI in clinical application include potential inherent bias in retrospective studies that requires larger samples for validation, ethics and legal concerns, and the incomprehensibility of the output results. Therefore, doctors and researchers should cooperate to address the current challenges and carry out further investigations to develop more accurate AI tools for improved clinical applications.

Core Tip: Artificial intelligence (AI) technologies are widely used for medical image analysis in the gastroenterology and hepatology fields. Several AI models have been developed for accurate diagnosis, treatment, and prognosis based on images of endoscopy, radiology, pathology, achieving high performance comparable to experts. However, we should be aware of the certain constraints that limit the acceptance and utilization of AI tools in clinical practice. To use AI wisely, doctors and researchers should work together to address the current challenges and develop more accurate AI tools to improve patient care.

INTRODUCTION

Originally proposed by John McCarthy in 1955, artificial intelligence (AI) which involves machine learning (ML) and problem solving, has achieved a breakthrough and revolutionized the processing methods of clinical medicine with the increasing workloads of medical records and digital images. In clinical practice, AI consists of several overlapping technologies such as ML, artificial neural networks (ANNs), deep learning (DL), convolutional neural networks (CNNs), and recurrent neural networks[1,2] (Figure 1). Since the 1980s, ML has been performed to construct a mathematical model and predict outcomes based on input data, and it is roughly divided into supervised (labeled data), unsupervised (unlabeled data), and semi-supervised (both labeled and unlabeled data) learning techniques[3]. Recently, as a subset of ML, ANNs have received increased interest because they can identify and learn input data by themselves instead of being labeled by experts[4]. In the last decade, DL, a new model of ML, holds great promise in clinical medicine. DL is particularly suitable for enormous complex or highly dimensional medical image analysis and predictive modeling tasks using the multilayers of ANNs, including CNNs and recurrent neural networks[5,6]. Notably, given that convolutional and pooling layers can extract distinct features and fully connected layers can make a final classification, CNNs have demonstrated excellent performance in image recognition such as endoscopy, radiology, and pathology[7,8].

In the fields of gastroenterology and hepatology, doctors are paying attention to AI technologies for the diagnosis, treatment, and prognosis of various diseases due to the heterogeneous expertise levels of doctors (majoring in endoscopy, radiology, and pathology), time-consuming procedures, and increasing workloads. Specifically, doctors usually assess medical images visually to detect and diagnose diseases based on personal expertise and experience. As the maturity of digitalization increases, a quantitative assessment of imaging information has become the reality instead of relatively inaccurate qualitative reasoning[9,10]. Although a lot of time is necessary to review and check image analysis traditionally, little information can be obtained. For example, using AI technologies to process pathology images can assess the histopathological classification and predict gene mutations in liver cancer[11], while only the mass nature can be identified by conventional pathology assessment. As a country with a high population, China has produced rapidly increasing medical records, which result in the high workloads[12]. Despite the progression of AI, gastroenterologists and hepatologists should always be aware of its limitations such as the retrospective manner of included studies and the utilization of not particularly suitable databases. In addition, it demands that doctors prepare for the effects and changes of AI on clinical practice in the real world.

In this review, we aim to (1) introduce how AI technologies process input data, learn from input data, validate the established model; (2) summarize the AI applications in endoscopy, radiology, pathology for accurate diagnosis, treatment, and prognosis; and (3) discuss the current limitations and future considerations of AI

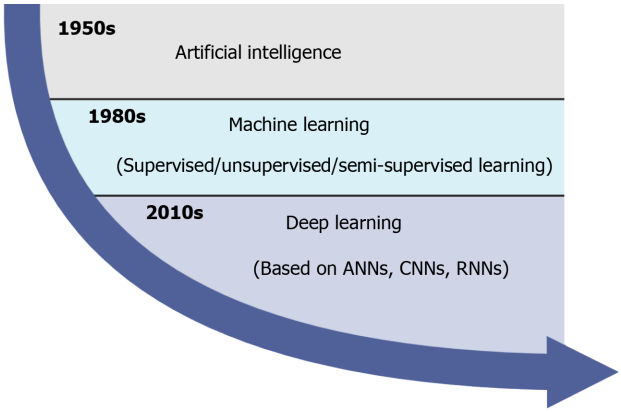

Figure 1 Timeline and related technologies of artificial intelligence. AI: Artificial intelligence; ANN: Artificial neural network; CNN: Convolutional neural network; RNN: Recurrent neural network.

applications in the fields of gastroenterology and hepatology (Figure 2).

METHODS IN DEEP LEARNING

As the most suitable approach for medical image analysis, the DL approach does not require shaped regions of interest on images to complete feature selection and extraction based on a neural network structure[13,14]. After data collection and processing, the correct neural network is chosen to establish a model, followed by model validation to assess its true generalizability.

Data processing

Raw data are collected and analyzed, and corrupt data are identified and cleaned in the processing phase. Data selection methods are provided in Scikit-Learn[15], a Python machine learning library, which consist of univariate selection, feature importance, correlation matrix, and recursive feature elimination or addition. Other programming languages such as R Studio (http://www.r-project.org) or MATLAB software (University of New Mexico, New Mexico, United States) also offer a successful environment for AI, and they provide similar approaches to address specific tasks. Useful data and relevant variables from multiple data sources, which are applied to predict outcomes, are selected and divided into an initial training set and a testing set that allow training and internal validation of the model. Data in the training set should be different and nonredundant from that in the testing set. Notably, for small datasets, a higher proportion of data should be included in the testing set to measure the performance of the trained model accurately through cross-validation or in a bootstrapping procedure.

Modeling

After transforming the data into an appropriate format, different tools are developed for implementing ML. Although several programming tools such as Python, R Studio, and MATLAB vary among themselves, they provide similar options and algorithms to adjust the parameters based on specific tasks. The major classification algorithms for testing are Naive Bayes, Decision Trees, Support Vector Machine, K-Nearest Neighbor, and Ensemble Classifiers. Oversampling or undersampling of the unbalanced training data can be utilized to improve the representation of classes and prevent model bias during the modeling stage. Currently, as the calculation workload of the batch learning process is heavy, minibatch learning is more popularized with repeating epochs, which usually decreases errors for the training and testing phases. However, an early stopping technique would be adopted to address the overfitting problem if repeating epochs cannot ensure error reduction. Based on the evaluations of model performance, developers conduct feature engineering again to manipulate the features and approve the predictive values of the model. After the optimization phase, selection for the model is primarily based on trial-and-error and the best performance for specific problem-solving. Finally, model optimization is performed with adjusted parameters by testing different configurations.

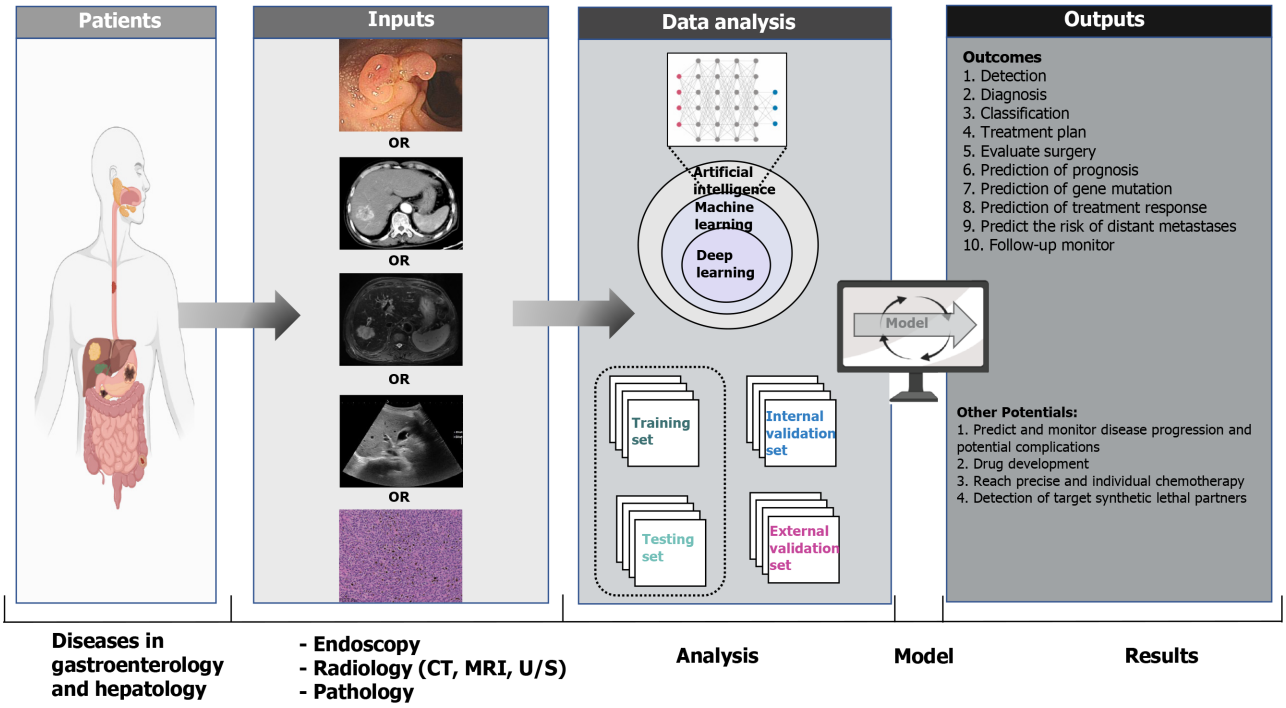

Figure 2 Artificial intelligence-assisted endoscopy, radiology, and pathology applications for medical image analysis in the fields of gastroenterology and hepatology, including detecting and evaluating lesions, facilitating treatment, and predicting treatment response and prognosis, and other potentials, using several deep learning models. CT: Computed tomography; MRI: Magnetic resonance imaging.

Model validation

To evaluate the AI approaches, one of the most significant requirements is external validation, which is called the blind test. Any model developed within one dataset will merely reflect its idiosyncrasies, and will have poor performance in analyzing new settings. In addition, models can also be validated by internal data testing (*e.g.*, *k*-fold cross-validation). In *k*-fold cross-validation, the dataset is separated into *k* subsets, including one subset for testing and the remaining (*k*-1) subsets for training a model. With all data used in both training and testing sets, the cross-validation process is repeated *k* times. The model performance is finally calculated as the average value of all *k* iterations. The *k* varies depending on the size of the dataset. For example, leave-one-out validation may be used in a small training set (< 200 data points), which means that *k* is equivalent to the dataset size. The appropriate and robust predictive model should have consistent performance between training and testing sets, preventing overfitting discrepancies.

ARTIFICIAL INTELLIGENCE IN ENDOSCOPY

With the advent and continuous improvement of fiberoptics, endoscopy has been playing a significant role in the diagnosis and treatment of gastrointestinal diseases. However, gastrointestinal diseases remain an enormous economic burden and lead to high mortality worldwide. AI is applicable in the gastroenterology fields within endoscopy[16-18], such as identification of esophageal and gastric neoplasia in esophago-gastroduodenoscopy (EGD), detection of gastrointestinal bleeding in wireless capsule endoscopy (WCE), and polyp detection and characterization in colonoscopy, *etc*[19-63] (Table 1).

EGD

Inadequate examination of the upper gastrointestinal tract is one of the reasons for misdiagnosing several EGD diseases. Based on AI-assisted EGD, the upper gastrointestinal tract can be divided into the pharynx, esophagus, stomach (upper, middle, lower), and duodenum with high values of the area under the curve (AUC)[19]. Furthermore, several AI technologies have classified the images of the stomach within EGD to significantly monitor the blind spots, and their accuracy has reached the ability

Table 1 Summary of key studies on artificial intelligence-assisted endoscopy in gastroenterology fields

AI: Artificial intelligence; CNN: Convolutional neural network; EN: Early-stage neoplasia; BE: Barrett's esophagus; SVM: Support vector machine; NA: Not available; EAC: Esophageal adenocarcinoma; ESCC: Esophageal squamous cell carcinoma; EGC: Early-stage gastric cancer; GC: Gastric cancer; ANN: Artificial neural network; GI: Gastrointestinal; GIA: Gastrointestinal angioectasia; DNN: Deep neural network; CRC: Colorectal cancer.

of experienced endoscopists[20,34].

Endoscopic surveillance for Barrett's esophagus (BE) is the potential risk factor for esophageal adenocarcinoma (EAC), of which the prognosis is related to disease staging[64,65]. However, accurate detection of esophageal neoplasia and early EAC remains difficult for experienced endoscopists[66]. An AI system developed by Ebigbo *et al*[24] enabled early detection of EAC with high sensitivity and specificity, they subsequently designed a real-time system for neoplasia classification in magnification. Both accurate detection of early EAC is important in BE images and the novel system of high invasion accuracy also deserves clinical attention[23]. In esophageal squamous cell carcinoma (ESCC), these tumors are often diagnosed at advanced stages, while early ESCC seems to be detected based on endoscopists' experience because they are almost impossible to visualize with white light endoscopy. Fortunately, with AI technologies, small esophageal lesions (< 10 mm) are recognized, and there is an AI system showing diagnostic accuracy of 91.4%, which is higher than that of high-level (with experience of > 15 years, 88.8%), mid-level (with experience of 5-15 years, 81.6%), and junior-level (with experience of < 5 years, 77.2%) endoscopists[28]. In addition, the prognosis of ESCC can be proved by differentiating tumor invasion depth[29,30].

The prognosis of gastric cancer (GC) mainly depends on the early detection and invasion depth of the disease. It is extremely difficult for endoscopists to recognize early gastric cancer (EGC), which is often accompanied by gastric mucosal inflammation, and the false-negative rate of EGC in EGD has reached nearly 25.0%[67,68]. AI-assisted EGD has the potential to address tough tissues. However, the first reported CNNs-based AI system for detection of EGC had a low positive predictive value of 30.6%, leading to misdiagnosis of gastritis and misinterpretation of the gastric angle as GC[69]. In 2019, Wu *et al*[34] examined the detection of GC by AI and

validated 200 endoscopic images, with increased accuracy, sensitivity, and specificity values (92.5%, 94%, and 91%, respectively). Furthermore, the AI system, named GRAIDS, has achieved diagnostic sensitivity close to that of expert endoscopists (94.2% *vs* 94.5%), and it demonstrated a robust performance showing high diagnostic accuracy in a multicenter study[37]. Besides detection, one of the most important criteria for curative resection is the invasion depth. The invasion depth prediction of GC by AI was first developed by Kubota *et al*[70], and the model showed the accuracy of T-stages (T1 = 77%, T2 = 49%, T3 = 51%, T4 = 55%, respectively). Considering that endoscopic mucosal resection is appropriate for intramucosal cancers (M) and submucosal cancers (invasion < 500 μm) (SM1), a more detailed classification is urgently needed. Therefore, an AI system was developed to differentiate the depths of M or SM1 and SM2 (submucosal invasion ≥ 500 μm) for GC with significantly higher sensitivity, specificity, and accuracy than those of skilled endoscopists[38].

WCE

AI-assisted WCE enables endoscopists to highlight suspicious regions on examination of the digestive tract noninvasively, including detection of small bowel bleeding, ulcers, and polyps, celiac disease, *etc*. Based on specific AI classifiers and validation techniques (mainly *k*-fold cross-validation), these models utilized still frames, pixels, or real-time videos to identify patients with small bowel bleeding with accuracy above 90% for most studies[40,41,43,44]. A CNNs-based algorithm, established in a retrospective analysis of 10000 WCE images (8200 and 1800 in the training and testing set, respectively) and validated by 10-fold cross-validation, was proposed for automatic detection of small bowel bleeding. The model was performed with a high *F*-1 score of 99.6% and precision of 99.9% for both active and inactive bleeding frames[40]. Besides detection, several emerging AI tools have been developed to stratify patients for the possibility of recurrent bleeding, treatment requirement, and mortality estimate to prevent repeated endoscopies in a significant proportion of patients with potential recurrent upper or lower gastrointestinal bleeding[39,42].

Colonoscopy

Colorectal polyp detection and appropriate polypectomy during colonoscopy is the standard way to prevent colorectal cancer (CRC). Since missed colorectal polyps can potentially progress into CRC, AI-assisted colonoscopy has been developed for polyp detection and characterization, and predicting the prognosis of CRC. In terms of polyp detection, an automated AI system using an energy map was developed in 2016, and it showed barely satisfactory performance[47]. Urban *et al*[52] used 8641 labeled images and 20 colonoscopy videos as the training and testing set to establish a CNNs model to identify colonic polyps, and the model had an accuracy of 96.4%[52]. Notably, the models should be validated to improve accuracy. After validating the model developed by Wang *et al*[54] with 27113 newly collected images from 1138 patients, the model showed acceptable performance (sensitivity = 94.38%, specificity = 95.2%, and AUC = 0.984). In addition, polyp characterization with magnifying endoscopic images is useful for identifying pit or vascular patterns to improve performance. AI tools with narrow-band imaging[51] or endoscopic videos[56] can be used to differentiate diminutive hyperplastic polyps and adenomas with high accuracy. Specifically, diminutive polyps (≤ 5 mm) may also be identified during colonoscopy[55]. In addition, AI may assist doctors in predicting the prognosis of CRC. An ANNs model, which was developed from a dataset of 1219 CRC patients, may predict patient survival and influential factors more accurately than a Cox regression model[59], and it also enables doctors to predict the risk of distant metastases[60].

ARTIFICIAL INTELLIGENCE IN RADIOLOGY

There is a disproportionate growing rate between radiological imaging data and the number of trained radiologists, and it has forced radiologists to compensate by increasing productivity[71]. The emergence of AI technologies has eased the current dilemma and dramatically advanced radiology image analysis, including ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI) in the fields of gastroenterology and hepatology. In addition, the rise of radiomics, which is a new technology in radiology and cancer, can extract abundant quantifiable objective data to evaluate surgical resection and predict treatment response[72-112] (Table 2).

Table 2 Summary of key studies on artificial intelligence-assisted radiology in hepatology fields

Ref.	Country	Disease studied	Design of study	Application	Number of cases	Type of machine learning algorithm	Outcomes (%)	
							Accuracy	Sensitivity/Specificity

Abdominal ultrasound

AI technologies have been applied to abdominal ultrasound-based medical images for the assessment of liver diseases, such as hepatic fibrosis and mass lesions. A support vector machine-derived approach was developed by Gatos *et al*[72] to detect and classify chronic liver disease (CLD) based on abdominal ultrasound. After quantifying 85 ultrasound images (54 healthy and 31 with CLD), the proposed model showed superior results (accuracy = 87.0%, sensitivity = 83.3%, and specificity = 89.1%), which greatly improved the diagnostic and classification accuracy of CLD. Furthermore, CNNs are employed to identify and isolate regions of different stiffness temporal stability under ultrasound to explore the impact on CLD diagnosis. The updated detection algorithm has augmented the accuracy to 95.5% after excluding unreliable areas and reducing interobserver variability[76]. Detecting and classifying hepatic mass lesions as benign or malignant is equally important. Schmauch *et al*[83] performed supervised training (367 ultrasonic images together with the radiological reports) to build a DL model, and the resulting algorithm had high receiver operating characteristic curves of 0.93 and 0.916 in lesion detection and characterization, respectively. Although the model could increase the diagnostic accuracy and detect potential malignant mass lesions, it should be further validated. In addition, combining AI technologies with contrast-enhanced ultrasound may improve the performance to identify and characterize liver cancer. For example, after AI-assisted contrast-enhanced ultrasound was applied to detect liver lesions in the arterial, portal, and late phases, the accuracy, sensitivity and specificity of the examination were markedly increased[82]. Due to the misty demonstration of gastroenterology within ultrasound, an AI-assisted ultrasound tool was limited.

CT/MRI

Liver diseases often present indeterminate behaviors on abdominal CT, and a biopsy is

recommended according to the European Association for the Study of the Liver guidelines[113]. Based on a large dataset of CT images (7461 patients diagnosed with liver fibrosis), a CNNs model was developed and it outperformed the radiologists' interpretation[85]. Furthermore, depending on ANNs-based contrast-enhanced CT images from 460 patients, Yasaka *et al*[90] conducted a retrospective study to classify liver masses into five categories with high accuracy, including (1) primary hepatocellular carcinoma (HCC); (2) malignant tumors apart from HCC; (3) early HCC, indeterminate masses, or dysplastic nodules; (4) hemangiomas; and (5) cysts. For patients diagnosed with liver tumors or pancreatic cancer, it is crucial to complete the liver or pancreas segmentation to assess the lesions and make the ideal treatment plan. Instead of conventional manual segmentation, a CNNs model was proposed to segment liver tumors based on CT images, with an accuracy of more than 80.0%, favoring suitable decision-making[101]. Additionally, a CNNs model was also developed for pancreas localization and segmentation using CT images[102]. Furthermore, monitoring tumor recurrence plays an important role in follow-up CT. Vivanti *et al*[89] collected and integrated the initial appearance of tumors, CT behaviors, and quantification of the tumor loads throughout the disease course, and then they designed an automated detection model of tumor recurrence with an accuracy of 86%.

Besides depending on CT images, a DL approach for pancreas segmentation can also be designed from MRI images. Several AI-assisted studies have shown promising results in classifying MRI liver lesions with/without risk factors and patients' clinical data, improving the accuracy and yields of reference models[93,96,98,102].

Radiomics

Currently, radiomics has received great interest from doctors because this AI-assisted technology can extract indiscoverable quantifiable objective data of the radiological images and reveal the association with potential biological processes[114,115]. Preoperative stratification of patients at different risk of recurrence and prediction of survival after resection is fundamental to improve prognosis. As an independent risk factor of recurrence, microvascular invasion (MVI) cannot be provided in conventional radiological techniques[116]. Several studies have managed to use radiomic algorithms based on ultrasound, CT, or MRI to elaborate radiomic signatures for preoperative prediction of MVI[106-108]. Besides the prediction of recurrence, radiomics may also be utilized to predict survival after surgical resection. However, compared to the excellent AI models based on pathologic images, radiomics-based predictive models merely attain a low value of 0.78[109].

Beyond recurrence and survival prediction purposes, radiomics can also be utilized for prediction of patients' response to transarterial chemoembolization (TACE) and radiofrequency ablation (RFA), and post-radiotherapy hepatotoxicity. A CNNs model developed from 105 HCC patients' CT images had higher accuracy in predicting response to TACE than the Barcelona Clinic Liver Cancer stages[94]. In addition, Chen *et al*[112] designed an excellent clinical-radiomic model to predict objective response to first TACE based on 595 HCC patients' CT images, which could assist the selection of HCC patients for TACE. Another study used radiomics of MRI images with clinical data to perform prediction of TACE response[105]. For HCC in the early stages, RFA is a recommended option. Based on radiomics, Liang *et al*[103] designed a model to predict the RFA response and HCC recurrence after RFA, obtaining high AUC, sensitivity, and specificity. Additionally, post-radiotherapy hepatotoxicity should be monitored to adjust the position and dose of radiotherapy. A CNNs model not only identified that irradiation of the proximal portal vein was associated with poor prognosis, it also predicted post-radiotherapy hepatotoxicity with an AUC of 0.85[91]. Ibragimov *et al*[91] applied a CNNs model to determine the consistent patterns in toxicity-related dose plans, and the AUC of the model for dose planned analysis was increased from 0.79 to 0.85 after the combination with some pre-treatment clinical features, showing that the combined framework can indicate the accurate position and dose of radiotherapy.

ARTIFICIAL INTELLIGENCE IN PATHOLOGY

Pathological analysis is considered the gold standard for the diagnosis of diseases in the fields of gastroenterology and hepatology. Currently, there is a shortage of pathologists around the world, which has become an obstruction for maintaining the accuracy of pathological analysis[117]. With the development of the whole-slide imaging (WSI) scanner and AI technologies, a combination of both technologies can ease the medical burden, improve the diagnosis accuracy, and even predict gene mutations and

prognosis[118-147] (Table 3).

Basic AI-assisted pathology: diagnosis

The basic role of pathology is disease diagnosis. In the fields of gastroenterology, there is an increasing need for automatic pathological analysis and diagnosis of GC. Based on the virtual version of pathological slices, several studies were performed to identify and classify GC automatically with high AUCs[120-122,126]. For example, a CNNs model was developed to distinguish gastric mass lesions including gastric adenocarcinoma, adenoma and non-neoplastic lesions, and it has achieved the highest AUC of 0.97 for the identification of gastric adenocarcinoma[126]. With regard to colorectal lesions, Wei *et al*[128] trained an AI-assisted model to classify colorectal polyps on WSIs, and notably, the performance of the model was similar to that of local pathologists whether in a single institution or other institutions. Besides diagnosis, a model based on more than 400 WSIs was developed to differentiate five common subtypes of colorectal polyps with accuracy of 93%[127]. In CRC, Shapcott *et al*[129] performed a retrospective study to develop a CNNs model for diagnosis based on 853 hand-marked images with an accuracy of 84%.

In the fields of hepatology, AI-assisted pathology is applied in patients with hepatitis B virus (HBV), metabolic associated fatty liver disease, HCC, *etc*. An automated, stain-free AI system can quantify the amount of fibrillar collagen to evaluate the degree of HBV-related fibrosis with the AUC > 0.82[132]. For patients with metabolic associated fatty liver disease, AI-assisted pathology tools were used to identify and quantify pathological changes including steatosis, macrosteatosis, lobular inflammation, ballooning, and fibrosis[133], and the algorithm output scores for quantitative comparison with experienced pathologists achieved good agreement. However, limited AI-assisted pathology tools have been built for HCC diagnosis. Notably, the MFC-CNN-ELM program was designed for nuclei grading of biopsy specimens from HCC patients, which revealed high performance in classifying tumor cells of different differentiation stages[134].

Advanced AI-assisted pathology: prediction of gene mutations and prognosis

Apart from AI-assisted pathology tools in diagnosis, it is no surprise that many tools have been developed for the prediction of gene mutations and prognosis in the fields of gastroenterology and hepatology. In CRC, AI tools have shown great effectiveness in predicting prognosis across all tumor stages based on WSIs[139,140], and several prospective multicenter studies have further validated the high prognosis performance[142]. Notably, a subset of genetic defects occurring in gastroenterology is related to some morphological features detected on WSIs. Among screened genetic defects, microsatellite instability and mismatch-repair deficiency are associated with the survival of gastrointestinal and colorectal cancer patients receiving immunotherapy. Therefore, an AI tool was designed to predict microsatellite instability and mismatch-repair deficiency directly from pathology, and it finally showed reasonably good performance in assisting immunotherapy[138,141]. Notably, Kather *et al*[140] further validated the above model's performance in predicting overall survival from CRC pathology slides with a hazard ratio of 2.29 in CRC-specific overall survival (OS) and an hazard ratio of 1.63 in OS, respectively. However, besides the above-mentioned studies that have focused on tumor detection of CRC, few studies were designed to predict gene mutations and prognosis due to the more complicated and heterogeneous histomorphology in gastric diseases than that in the colon[136,137].

In the fields of hepatology, AI tools are mainly used to predict gene mutations and prognosis in HCC. For example, a model has higher accuracy in predicting survival postoperatively than using a composite score of clinical and pathological factors in HCC. In addition, the model may generalize well after validating the performance in an external dataset with different staining and scanning methods[146]. Chen *et al*[11] investigated a CNN (Inception V3) for automatic classification (benign/malignant classification with 96.0% accuracy, and differentiation degree with 89.6% accuracy) and gene mutation prediction from WSIs after resection of HCC. It was found that *CTNNB1, FMN2, TP53,* and *ZFX4* could be predicted from WSIs with external AUCs from 0.71 to 0.89. Currently, after integrating clinical data, biological data, genetic data, and pathological data, the novel model may also be a promising approach. The first multi-omics model combined ribonucleic acid (RNA) sequencing, miRNA sequencing and methylation data from The Cancer Genome Atlas, and then employed AI technologies to predict and differentiate survival of HCC patients[145]. Other attempts have been made to develop models that can predict gene mutations directly based on WSIs of HCC. Using AI-assisted pathology, some approaches can predict gene expression and RNA sequencing, which may have the potential for clinical

Table 3 Summary of key studies on artificial intelligence-assisted pathology in the gastroenterology and hepatology fields

Ref.	Country	Disease studied	Design of study	Application	Number of cases	Type of machine learning algorithm	Outcomes (%)	
							Accuracy	Sensitivity/Specificity
Basic AI-based pathology: diagnosis								
Tomita *et al*[118], 2019	United States	BE and EAC	Retrospective	Detection and classification of cancerous and precancerous esophagus tissue	Training: 379 images with 4 classes: normal, BE-no-dysplasia, BE-with-dysplasia, and adenocarcinoma; Testing: 123 images with 4 classes: normal, BE-no-dysplasia, BE-with-dysplasia, and adenocarcinoma	CNNs	Mean: 83; BE-no-dysplasia: 85; BE-with-dysplasia: 89; Adenocarcinoma: 88	Normal: 69/71 BE-no-dysplasia: 77/88; BE-with-dysplasia: 21/97; Adenocarcinoma: 71/91

translation[147]. Interestingly, some gene expression such as PD-1 and PD-L1 expression, inflammatory gene signatures, and biomarkers of inflammation did trend with improved survival and response in HCC patients[148].

LIMITATIONS AND FUTURE CONSIDERATIONS

This review retrospectively summarized some key and representative articles with the possibility of missing some publications in AI-related journals. Although various studies have shown promising results in the fields of AI-assisted gastroenterology and

hepatology, there are still several limitations to be discussed and resolved. One of the major criticisms is the lack of high-quality training, testing, and validation datasets for the development and validation of AI models. Due to the retrospective manner of most studies, selection bias must be considered at the training stage, meanwhile, overfitting and spectrum bias may result in overestimation of the model accuracy and generalization. According to the rigorous "six-steps" translation pipelines[149], doctors and AI researchers should join the calls that advocate for developing interconnected networks of collecting raw acquisition data which was shifted from processed medical images over the world and training AI on a large scale to obtain robust and generalizable models. Furthermore, the black-box nature of AI technologies has become a barrier to clinical practice, because developers and users do not know the details about how computers output the conclusion. Explainable AI for reliable healthcare is worth investigating to reach clinical interpretability and transparency. In addition, from the perspective of ethics and legal liabilities, AI models may potentially cause errors and challenge the patient-doctor relationship despite the fact that they improve the clinical workflow with enhanced precision. Especially in the fields of gastroenterology and hepatology, cancer discrimination may mean a completely different treatment. If misdiagnosis occurs during AI application, who should take responsibility- the doctor, the programmer, the company providing the system, or the patient? Issues such as ethics and legal liabilities should be demonstrated in the early phase to maintain the balance between minimal error rates and maximal patient benefits[150,151].

There have been an increasing number of studies applying AI to gastroenterology and hepatology over the past decade. In the future, the trend will continue and larger studies will be carried out to compare the performance of medical professionals with AI *vs* professionals without AI to highlight the importance of AI assistance. AI technologies will be utilized to develop more accurate models to predict and monitor disease progression and potential complications, and these models may ameliorate the insufficiency of medical resources in the remote underserved or developing regions. Besides, AI-assisted personalized imaging protocols and immediate three-dimensional reconstruction may further improve the diagnostic efficiency and accuracy. Researchers will be able to realize the mechanism of disease progression and treatment response through the combination of multi-modality images or multi-omics data. In addition, there is an emerging trend applying AI to drug development, such as prediction of compound toxicity, physical properties, and biological activities, which may assist chemotherapy for digestive system malignancy. Furthermore, AI could be used to process the data generated from the tissue-on-a-chip platform which could better summarize the tumor microenvironment, thus reach precise and individual chemotherapy in gastroenterology and hepatology. As synthetic lethality becomes a promising genetically targeted cancer therapy[152,153], AI could also be used for the detection of target synthetic lethal partners of overexpressed or mutated genes in tumor cells to kill cancers. Finally, AI tools could not replace endoscopists, radiologists, and pathologists in the near and even distant future. Computers would make predictions and doctors would make the final decision, in other words, they would always work together to benefit patients.

CONCLUSION

AI is rapidly developing and becoming a promising tool in medical image analysis of endoscopy, radiology, and pathology to improve disease diagnosis and treatment in the fields of gastroenterology and hepatology. Nevertheless, we should be aware of the constraints that limit the acceptance and utilization of AI tools in clinical practice. To use AI wisely, doctors and researchers should cooperate to address the current challenges and develop more accurate AI tools to improve patient care.

ACKNOWLEDGEMENTS

We thank Yun Cai for polishing our manuscript. We are grateful to our colleagues for their assistance in checking the data of the studies.

Abstract

Viral infections affecting the liver have had an important impact on humanity, as they have led to significant morbidity and mortality in patients with acute and chronic infections. Once an unknown etiology, the discovery of the viral agents triggered interest of the scientific community to establish the pathogenesis and diagnostic modalities to identify the affected population. With the rapid scientific and technological advances in the last centuries, controlling and even curing the infections became a possibility, with a large focus on preventive medicine through vaccination. Hence, a comprehensive understanding of hepatitis A, B, C, D and E is required by primary care physicians and gastroenterologists to provide care to these patients. The review article describes the epidemiology, pathogenesis, clinical presentation, diagnostic tools and current medication regimens, with a focus on upcoming treatment options and the role of liver transplantation.

Key Words: Hepatitis A; Hepatitis B; Hepatitis C; Hepatitis D; Hepatitis E; Treatment

INTRODUCTION

Viral hepatitis has been a formidable challenge eliciting epidemic dating back to ancient times, with documented outbreaks 5000 years ago in China and similar jaundice descriptions by Hippocrates in the fifth century BC in the island of Thassos[1,2]. Technological advancements over the modern era allowed for the viruses to be identified and subsequent scientific inquiry revolutionized the morbidity and mortality caused by these viral pathogens. We aim to provide an overview of viral hepatitis with discussion of current and prospective therapies. Though most remain dominant in certain parts of the world, globalization demands a fundamental understanding of each virus as we all have the daily potential of encountering any of them at our doorstep.

HEPATITIS A

Epidemiology

First discovered in 1973 by Feinstone, a spherical 27 nanometer particle was seen on immune electron microscopy in the fecal sample of hepatitis A patients[3]. A member of the picornavirus family, the hepatitis A virus (HAV) is an RNA virus responsible for 1.4 million cases per year globally[4], with an estimated 7134 deaths in 2016; almost half of these cases were reported in Asia[5]. In the United States, the annual incidence rate was reported to be 2 cases per 100000 people, in 2006. Recent outbreaks of the disease have shown a 294% increase in infections between 2016-2018 compared to 2013-2015[6,7].

Recent outbreaks

In 1988, about 300000 people in Shanghai reported symptoms of HAV after consumption of raw clams, described as one of the largest outbreaks in the modern era[8,9]. Several outbreaks related to specific food products affecting over 300 patients from multiple states in the United States have been reported in the recent years (2013-2019). The outbreaks have been related to consumption of fresh blackberries, frozen strawberries, raw scallops, and pomegranate seeds. A recent study in 2017 conducted over 4 states (California, Kentucky, Michigan, and Utah) has shown evidence for shift towards large community outbreaks with person-to-person transmission. The majority of these infections have been reported among persons with injection or non-injection drug use and/or persons experiencing homelessness[10].

Current data from state health departments shows, over 37000 new outbreak related cases with greater than 22600 hospital admissions and approximately 350 HAV deaths reported between July 2016 and December 2020[11].

On the contrary, 19947 cases of HAV from 24 European Union countries have been reported between January and December 2017, which is four times higher when compared to similar time periods between 2012 and 2015[12]. The number of outbreak related cases from 22 European Union countries was 4475 in 2016 and most outbreaks were related to men who have sex with men.

Pathogenesis

The transmission of HAV occurs *via* fecal-oral route, which includes consumption of contaminated food or water and person to person contact. Polymerase chain reaction testing for blood donors is performed as transmission through blood transfusion is noted on rare occasions[13]. The dissemination of the HAV into the liver occurs *via* the portal vein after the virus traverses the mucosa of the small intestinal wall. The virus particles subsequently replicate and are secreted into the biliary canaliculi, reaching back to the small intestine through the bile ducts and being re-excreted in the feces. Until the body responds with appropriate immune reaction in antibodies, the HAV enterohepatic cycle continues. Human leukocyte antigen-restricted, HAV-specific CD8+ T lymphocytes and natural killer cells have been implicated in the damage and destruction of infected hepatocytes[14-16].

Clinical presentation

The usual HAV incubation period is about 2-4 wk[17]. Fever, malaise, jaundice have been described as the most common presenting symptoms for HAV infection[18]. Other common symptoms include weakness, fatigue, nausea, vomiting, abdominal pain, arthralgias, myalgias, diarrhea and anorexia[12]. Patients rarely enter a prolonged cholestatic phase through recovery, while relapsing infections have been described as well[19].

About 10%-15% of patients present with a relapsing course within a 6-mo period of the initial infection[20]. The symptoms during the relapse are usually less severe than the initial infection. Notably, on extremely rare occasions a type 1 autoimmune hepatitis has been observed in genetically predisposed patients[21]. The spectrum of infections can range from asymptomatic patients without jaundice, symptomatic patients with jaundice, cholestasis with prolonged jaundice, to relapsing infections or acute liver failure[19].

Serum aminotransferases above 1000 U/dL are usually noted, with total bilirubin typically ≤ 10 mg/dL, and alkaline phosphatase below 400 U/L. Usually the serum alanine aminotransferase (ALT) is higher than the aspartate aminotransferase (AST)[22,23]. In general, older patients are more likely to have severe hepatocellular derangements, hospital admissions and higher mortality[24]. These findings can be attributed to an impaired regeneration capacity of the liver and a relatively weaker immune system in the older population[25]. In addition to old age, higher mortality has been reported in males[26]. Old age, underlying liver pathology and chronic viral hepatitis are reported risk factors for acute liver failure. In patients who develop acute liver failure, higher mortality has been associated with creatinine > 2 mg/dL (strongest predictor) total bilirubin > 9.6 mg/dL and albumin < 2.5 g/L[18].

Diagnosis

Specific antibodies against HAV (anti-HAV) in the serum can be detected. The diagnosis is confirmed by the presence of immunoglobulin (Ig) M anti-HAV. The antibodies can be detected at the time of onset of symptoms. Serum IgM levels peak during the acute infection and remain positive for up to 4 mo on an average from the onset of symptoms[27]. Immunity is usually tested with HAV total antibody to determine HAV natural exposure or secondary to vaccination[28]. The presence of IgM antibodies without any clinical symptoms is indicative of HAV infection in the past with persistent antibodies, asymptomatic infection or false positive test[29].

Liver biopsy or imaging studies are not required to make a diagnosis. If performed, a liver biopsy may show marked portal inflammation with typically a lesser degree of necrosis, Kupffer cell proliferation, acidophil bodies, or ballooning when compared to non-HAV viral hepatitis[30].

Management

No specific treatment is available for HAV and the management is mainly symptomatic. The primary focus remains on improving sanitary conditions to minimize the transmission in the community. Historically, immunoglobulins have been used in the prevention of HAV infections. With the availability of an effective vaccine, the use of immunoglobulins has been largely abandoned except in infants below the age of 12 mo. Post exposure prophylaxis with hepatitis A vaccine has been approved since 2007 for immunocompetent patients without chronic liver disease, who are between the ages of 12 mo and 40 years of age[11].

An inactivated HAV vaccine has been licensed in Europe since 1991, while a live attenuated hepatitis A vaccine has been in use in China since 1992[31]. The inactivated virus vaccine was first approved for use in United States in 1995. The vaccine is given in 2 to 3 dose series at least 6 mo apart, depending on the vaccine formulation used. In 1996, the Advisory Committee on Immunization Practices (ACIP) recommended vaccination for people at high risk for HAV infection or adverse consequences of the infection[32]. In 2006, ACIP recommended routine vaccination of all children 12-23 mo of age; and in 2019, the committee recommended routine HAV vaccination of people experiencing homelessness[33,34]. Other recommendations for groups that would benefit from vaccination are described in Table 1[35].

The vaccine has had significant effect on the decrease in HAV infections, although coverage rates remain lower when compared to other childhood vaccines. These rates were noted to be around 87% for first dose and 57% for the second dose. Long term immune response up to 40 years in noted in over 90% patients who receive both doses of the 2-vaccine series[36].

Table 1 Centers for Disease Control and Prevention recommendations for hepatitis A vaccination

	Recommendations
Children	Children age 12-23 mo
	Age 2-18 yr who have not received the vaccine (catch up vaccination)
High risk population	International travelers
	Men who have sex with men
	Illicit drug users
	People at occupational risk of exposure
	People anticipating close personal contact with international adoptee
	People experiencing Homeless
Population at high risk of severe hepatitis A	People with chronic liver disease
	HIV+ people
Others	Pregnant women at high risk or at risk of severe hepatitis A
	Any person requesting the vaccine

HIV: Human immunodeficiency virus.

Role of liver transplant

Acute liver failure occurs in less than 1% of acute HAV infections[6]. From these patients, only 31% require emergent liver transplant for treatment of fulminant disease, while the remaining patients recover spontaneously with symptomatic management[37]. In a study comparing liver transplant outcomes in patients with HAV *vs* hepatitis B infection, the patients with HAV were found to have lower 1- and 5-year survival rates. Presence of acute pancreatitis and HAV recurrence in this population was identified as risk factors for shorter graft and patient survival. Following transplant, patients should be carefully monitored for HAV recurrence as it is common and is associated with poor outcomes[38].

HEPATITIS B

Epidemiology

Chronic hepatitis B virus (HBV) infection had an estimated prevalence of 257 million people in 2015 worldwide, with the highest proportion of cases in Western Pacific and African regions (68% of the cases) and with the lowest prevalence in North America[39]. An estimated 29% of cirrhosis-related deaths worldwide were due to HBV in 2017[40], while also contributing to the majority of liver cancer-deaths the same year. There are ten identified HBV genotypes (A-J) collectively, with 35 identified sub-genotypes; the distribution of the genotypes varies broadly worldwide (Figure 1)[41]. The variation in the genotype distribution and risk factors relies on common factors in high-risk populations, such as vertical transmission which is associated to higher risk of chronic disease and hepatocellular carcinoma (HCC)[42]. Risk factors for HBV transmission include a history of blood transfusion, intravenous drug or paraphernalia use[43], contaminated piercing instruments[44], sexual intercourse with an infected person and organ transplantation from HBV positive donors[45].

Pathogenesis

The HBV is a double-stranded DNA virus belonging to the *Hepadnaviridae* family, first identified in 1963 and named the Australian Antigen due to the protein reacting to antibodies from a hemophiliac patient. The virus has a special trophism for hepatocytes, to which it adheres and integrates upon initial infection[46]. After viral uncoating, the DNA integrates to the host nucleus as a covalently closed circular DNA (cccDNA) that can persist indefinitely in the hepatocytes; this explains the possibility of HBV reactivation in chronic inactive disease[47]. Ultimately, through a process driven by reverse transcriptase, new viral molecules are assembled from the cccDNA and are released by exocytosis. This process leads to immune-mediated liver injury as antigens

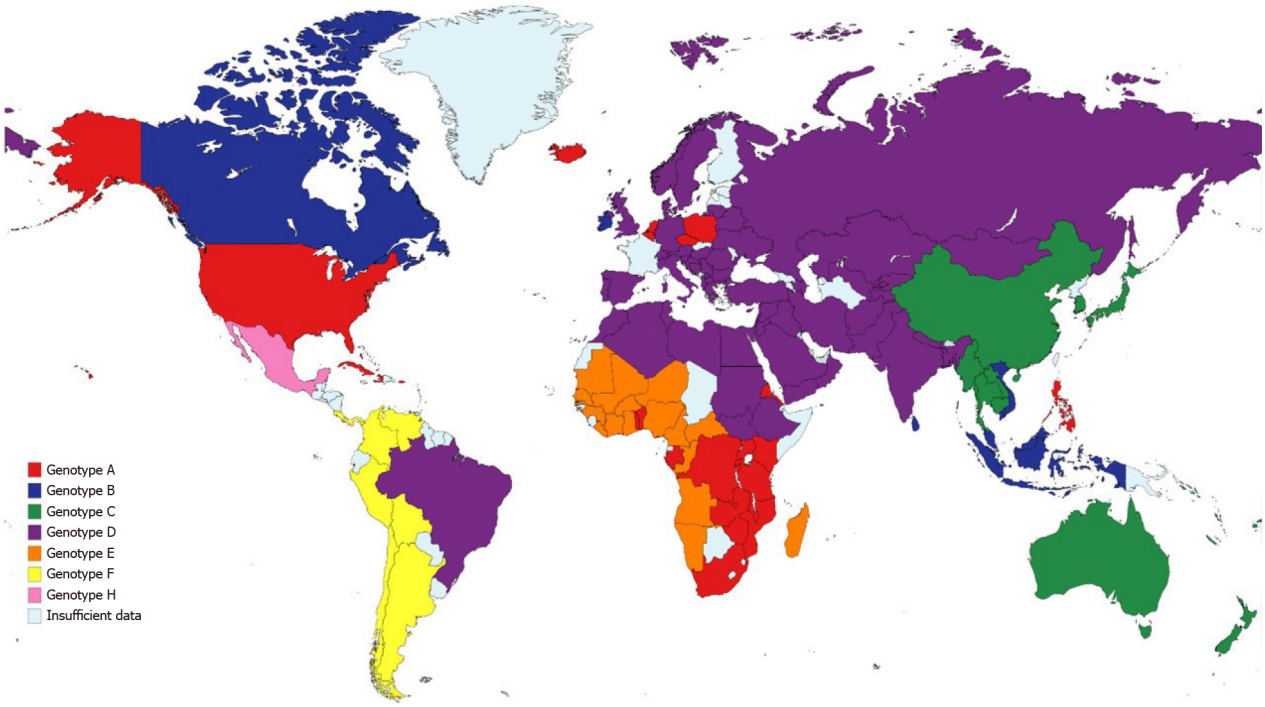

Figure 1 Global geographic distribution of most common hepatitis B virus genotypes per country.

are recognized by the immunologic system, with a lesser effect from direct viral cytotoxicity. Importantly, the DNA expresses important proteins for its survival including two capsid core proteins—core antigen and e antigen (hepatitis B e antigen, HBeAg), and the surface antigen (hepatitis B surface antigen, HBsAg), all of which are relevant for diagnosis and surveillance. Variations in genotypes have been described, with differences clinically relevant for pegylated (PEG)-interferon response and HCC risk[48].

Clinical presentation

Acute HBV infection can range from a subclinical disease to an icteric hepatitis, the former being the most common presentation[49]. Patients may present fatigue, nausea, vomiting and right upper quadrant pain before or during jaundice onset. Notably, less than 1% of cases may present fulminant hepatitis. During the acute phase, there is a rapid HBV viral load increase in the 10000-100000 ng/mL range, along with ALT and AST elevation in the 1000-2000 IU/L range, and total bilirubin elevation[50]. At this point, HBsAg and IgM core antibody (HBcAb) become positive, supporting an acute HBV diagnosis. Although a subset of acute HBV can have resolution of the infection with liver enzyme normalization, if the ALT remains elevated after 6 mo from initial presentation, a chronic HBV phase is established.

Chronic HBV may develop in patients exposed at a younger age[51], with genetic predisposition or in those that did not develop symptoms when acute HBV infection occurred[52]. These patients are usually asymptomatic for years, unless there is HBV exacerbation[53] or development of complications[54]. The occurrence of HBV exacerbations is best explained by four phases reflecting the disease activity[55]. The first phase (known as immune tolerant) shows markedly elevated HBV titers and positive HBeAg, without ALT elevation or liver inflammation for which patients are asymptomatic. The second phase (immune clearance) is characterized by activation of the immune system, leading to elevation of ALT at least five-fold the upper limit, HBV DNA decrease and histological evidence of inflammation, possibly leading to fatigue, jaundice, and right upper quadrant pain. The third phase (immune control) shows negative HBeAg, as there is seroconversion to positive HBeAb (hepatitis B e antibody) and undetectable to low HBV DNA titers. The fourth phase (immune active) is characterized by ALT and HBV DNA elevation due to triggers such as hepatitis D virus (HDV) superinfection or immunosuppression, leading to similar symptoms seen in the immune clearance phase with potential risk for acute liver failure. Importantly, the disease can fluctuate between the third and fourth phases.

Diagnosis

Patients that present with acute HBV present with serologies as previously discussed. However, some patients will be in the "window period", where the immune system has cleared the HBsAg, but no HBV surface antibody (HBsAb) is present; in this scenario, the only positive marker is an elevated IgM HBcAb. Ultimately, once the patient clears the infection, both positive IgG HBcAb and HBsAb will be present. On the other hand, if the patient develops chronic HBV infection, no HBsAb will be detected and HBsAg will persist, even if IgG HBcAb is present. Also, the HBeAg status, HBV DNA and aminotransferases level help determining the phase of the disease and tailor treatment considerations. Finally, the population that has been vaccinated and has never been exposed to HBV will only show positive HBsAb[56].

Complications

Due to parenchymal inflammation and fibrosis with long-term disease, patients with chronic HBV are predisposed to develop liver cirrhosis. Also, patients with HBV have an increased risk to develop HCC, regardless of the presence of cirrhosis; this risk is well established, but the mechanisms of carcinogenicity are hypothesized to be multifactorial including length[57] and severity[58] of HBV DNA elevation, ethnicity of the patients and more recently has been associated to the actual genome strain of the virus, especially patients with genotype C[59].

Current treatment options

Based on consensus from multiple societies, treatment with viral suppression therapy is recommended if patients have extrahepatic manifestations, pregnancy, family history of HCC, hepatitis C virus (HCV)/HDV co-infection, immunosuppression prophylaxis, compensated/decompensated liver cirrhosis[60], or if in the immune active phase and meeting specific criteria established by liver society guidelines (Table 2)[61-63].

Current HBV treatments include nucleoside/nucleotide analogs and PEG-interferon. Overall, the HBsAg seroconversion is higher with PEG-interferon regimen compared to other medications, but its efficacy is limited due to poor patient tolerance[64]. Available nucleoside/nucleotide analogs include lamivudine, adefovir, telvidudine, entecavir, tenofovir fumarate and tenofovir alafenamide[61,63]. From these medications, the first line regimen for treatment consists of entecavir, tenofovir fumarate or tenofovir alafenamide monotherapy due to high genetic resistance barrier, while the other medications can be considered as options based on medication availability and poor access to first line agents.

Role for liver transplant

Patients with HBV that develop acute liver failure, decompensated liver cirrhosis or HCC can potentially undergo liver transplantation as ultimate therapy. In the setting of posttransplant immunosuppression, the rate of HBV recurrence is high with survival rates < 50% after 2 years if no preventive measures are taken[65]. Hence, based on donor and recipient serologies different strategies have been developed including the use of combination of HBV immunoglobulin during the anhepatic and postoperative phase when indicated, with indefinite use of high-genetic barrier nucleoside/nucleotide analogs demonstrating the lowest rates of HBV recurrence and post-transplant decompensation[66].

Ongoing research and future directions

Current treatment options have changed the prognosis for HBV patients, but have been limited by its low cure rates. Hence, other targets in the viral life cycle have been evaluated to improve HBsAg seroconversion and potential cure. For example, inhibition of the HBV entry into the uninfected hepatocytes by blockage of the sodium taurocholate co-transporting peptide (NTCP) receptor in the HBV capsid has been studied with three drugs in different trial stages. Bulevirtide is a NTCP antagonist found to inhibit infection in mice injected with HBV[67]; in a phase 1 study it showed to be safe without occurrence of serious side effects in 36 healthy subjects at a max dose of 20 mg[68]. Subsequently, a multicenter phase 2b randomized trial in 60 HBV/HDV patients receiving PEG-interferon, bulevirtide 2 mg or both with bulevirtide at 2 mg and 5 mg dosing for 48 wk showed a higher proportion of HBsAg decline or loss in patients with combination therapy[69]. Other potential NTCP inhibitor are the cyclosporin derivatives such as SCY450 and SCY995[70], which have been found to inhibit hepatocyte HBV entry *in vitro* without affecting bile acid uptake, opening a new therapeutic window. Other experimental medications from the cyclophilin inhibitor family like alisporivir[71] and CRV431[72], have shown reduction of HBV DNA and

Table 2 Treatment criteria in patients with chronic hepatitis B virus and immune active phase per society guidelines

Criteria	American Association for the Study of Liver Disease[61]	European Association for the Study of the Liver[63]	Asian Pacific Association for the study of Liver Diseases[62]
ALT	≥ 2 times ULN—males 35 U/L, females 25 U/L	> 1 time ULN—40 U/L	> 2 times ULN—40 U/L
HBV DNA viral load	> 2000 IU/mL if HBeAg negative or > 20000 IU/mL if HBeAg positive	> 2000 IU/mL, regardless of HBeAg status	> 2000 IU/mL if HBeAg negative or > 20000 IU/mL if HBeAg positive
Degree of liver fibrosis/inflammation	Liver biopsy with moderate-severe inflammation or advanced liver fibrosis (F3-F4). Liver elastography or serum markers showing advanced liver fibrosis (F3-F4)	Liver biopsy, liver elastography or non-invasive testing consistent with moderate-severe fibrosis (F3-F4)	Liver biopsy with moderate-severe inflammation or advanced liver fibrosis (F3-F4). Fibroscan or serum markers showing advanced liver fibrosis (F3-F4)

ALT: Alanine aminotransferase; HBV: Hepatitis B virus; HBeAg: Hepatitis B e antigen; ULN: Upper limit of normal.

HBsAg in lab models possibly through a similar mechanism with promising results.

Another potential target is at the level of capsid assembly, where core assembly modulators have been found to disrupt the assembly by producing abnormal capsid proteins (Type I) or virions without DNA (Type II)[73]. *In vitro* evaluation of infected hepatocytes showed a decrease in HBV DNA with different investigational molecules such as JNJ-6379, RO7049389, EDP 514, GLS4 and BAY 41-4109. From these, JNJ-6379, R07019389 and GLS4 have advanced to phase 2 and 3 clinical studies[64].

High interest has focused on the use of interfering RNA molecules. These are small molecules administered intravenously, with the capacity of covalently binding to RNA before assembly and leading to RNA degradation, which could decrease the HBV DNA, HBeAg, HBsAg and HBcAg titers while increasing the seroconversion rates. A few molecules have advanced to phase 2 studies with no delivery method concern, with most of the studies presented at major hepatology conferences. The use of GSK3389404 in a phase IIa study showed a dose-dependent reduction in HBsAg, with an adequate safety profile in 66 patients[74]. Similarly, JNJ-3989 Led to sustained HBsAg reduction in 56% of 39 patients in a phase II study[75]. Also, a phase 2a randomized study evaluating GSK3228836 showed several log HBsAg reduction among 17 HBV patients[76]. Further phase 3 studies are needed to evaluate the seroconversion and functional cure rates in larger populations.

Other relevant target has been the inhibition of HBsAg release from infected hepatocytes to decrease the immunogenic tolerance induced by this molecule. A phase 2 trial study evaluating the combination of PEG-interferon and REP 2139 in 12 patients with HDV coinfection showed a titer reduction to < 50 IU/mL in 6 subjects and HBV DNA suppression in 10 subjects[77]. A second study on REP 2139 and a derivative (REP 2165) in combination with tenofovir and PEG-interferon showed functional cure rates up to 40% in HBeAg negative HBV patients[78].

Lastly, newer nucleoside/nucleotide analogs affecting the HBV life cycle have been developed. Besifovir is a molecule with similar chemical structure to tenofovir fumarate. These two medications were compared in a phase 3 randomized trial including 197 HBV patients receiving the medications for 48 wk. There was no difference in HBV DNA suppression rate with the use of besifovir (80.9%) compared to tenofovir (84.9%), showing equivalence in treatment rates between both arms[79].

On another hand, modulation of the immune system to increase HBV clearance has been a hot topic since the introduction of interferon-based treatments. Recently, the use of immune checkpoint inhibitor *via* programmed death receptor 1 (PD-1) blockage has been explored as a mechanism to overcome the T-cell anergy seen in chronic HBV. Nivolimumab is a PD-1 inhibitor that was studied in a phase I trial along with and without a therapeutic vaccine in 24 patients with HBeAg negative chronic HBV, showing a significant HBV DNA log reduction but no significant HBsAg seroconversion rates (only seen in one patient)[80]. Other studied mechanisms include the innate immunity stimulation through stimulation of toll-like receptors (TLR). However, in phase 1 studies neither TLR-7 nor TLR-8 agonists have shown to decrease significantly the HBsAg titers in the short term[81]; further phase 2 studies with longer treatment duration may help elucidate its role in HBV treatment.

Finally, HBV vaccination has become revolutionary in public health infection prevention by reducing vertical transmission and decreasing HCC incidence in younger populations[82]. While the currently widespread regimen with recombinant HBsAg (Engerix-B/Recombivax HB) includes three doses for immunization, a recent regimen utilizing an adjuvant in conjunction with recombinant HBsAg (Heplisav) has

shown to be as efficacious after two doses, with consideration to administer in non-compliant patients or patients with HBsAb titers < 10 IU/mL. Special interest has been directed to therapeutic vaccines to achieve functional HBV cure. Even though different therapeutic vaccines have been studied, the HeberNavac HBsAg-HBcAg is the only vaccine that has shown significant HBeAg seroconversion rates compared to PEG-interferon in a randomized phase III trial[83]. Although promising, immunotherapy remains a territory to be explored and similar to HCV the goal of viral eradication remains at the core of research efforts.

HEPATITIS C

Epidemiology

Greater than 71 million persons worldwide are infected with HCV[84]. Prevalence has increased from 1990 to 2010[85]. The Eastern Mediterranean region has an HCV prevalence greater than 2%, considered to be the highest in the world. The continents of Africa and Europe have a prevalence of 1%-2%. North and South America and the Western Pacific region have a prevalence of less than 1% (Figure 2)[84].

There are seven main genotypes and 67 subtypes. HCV genotype 1 represents about half of all HCV infections, making it the most prevalent genotype in the world. The second most common is HCV genotype 3, involving approximately one-third of HCV infections; it is found more commonly in south Asia, Australia, and several European countries. Genotypes 2 is found in Asia and West Africa, while genotype 4 is found in central and eastern sub-Saharan Africa, North Africa, and the Middle East. Genotypes 2 and 4 represent about 9%-13% of all HCV cases. Genotypes 5, 6, and 7 are restricted to South Africa, South-east Asia, and Democratic Republic of Congo, respectively[86-88] (Figure 3).

Pathogenesis

Hepatitis C is a small, enveloped, positive single-stranded RNA virus that was first discovered in 1989 as a member of the *Flaviridae* family and is the only member of genus *Hepacivirus*. It enters the body percutaneously through needlestick injuries (including healthcare or intravenous drug use) containing contaminated blood. It may also enter non-percutaneously through organ transplantation, blood transfusions, sexual intercourse, perinatal transmission, hemodialysis, religious scarification, body piercings, tattoos, and immunoglobulin injection[89]. There are 4 host-derived factors that facilitate the entry of HCV into the bloodstream: Scavenger receptor class B type I, Occludin, Claudin-I and CD81[90]. Additionally, CD81 binds with the viral particle, either through viral envelope protein (E)2 or other molecules and facilitates its entry into the hepatocyte[91].

Although it is considered a non-cytopathic virus, once HCV enters the hepatocyte, it replicates and causes cell necrosis *via* immune-mediated cytolysis (innate immunity and adaptive immunity) and metabolism-mediated inflammation (hepatic steatosis, oxidative stress, and insulin resistance)[90].

Non-structural protein 5A (NS5A) and E2 regions of HCV also play an important role in the pathogenesis. NS5A inactivates RNA dependent protein kinase (PKR) in hepatocytes, inhibiting the apoptotic pathway and inducing anti-inflammatory interleukin secretion, allowing for viral replication. E2 protein inhibits PKR, allowing the evasion of HCV. The role that different HCV genotypes play in the progression of liver disease is still controversial, but genotype 1b seems to have a more aggressive course, as it has been more associated to cirrhosis progression and liver disease decompensation requiring transplantation[92].

HCV core proteins leads to insulin resistance by direct receptor effect or through increased secretion of tumor necrosis factor-alpha; this leads to further hepatic steatosis, inflammation, and fibrosis. HCV associated oxidative stress is mainly caused by HCV-core protein which induces oxidation of glutathione and increase in reactive oxygen species[93]. NS5A promotes production of reactive oxygen species in the membrane of the endoplasmic reticulum[94]. NS3 is also thought to directly induce oxidative stress[95]. Finally, HCV causes steatosis through impaired secretion of lipids from liver cells, increased production of free fatty acids, and impaired fatty acid breakdown[90].

Clinical presentation

Chronic HCV infection can occur in 50%-85% of patients, while 15%-45% of patients may present spontaneous clearance of the virus[96]. Most patients with HCV infection

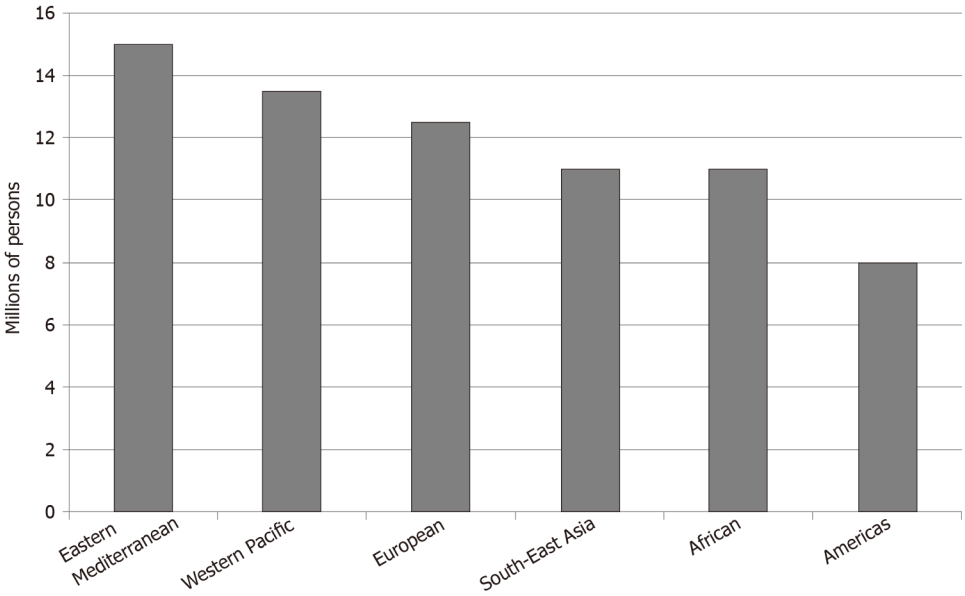

Figure 2 World Health Organization estimated chronic hepatitis C infection prevalence worldwide per region in 2015.

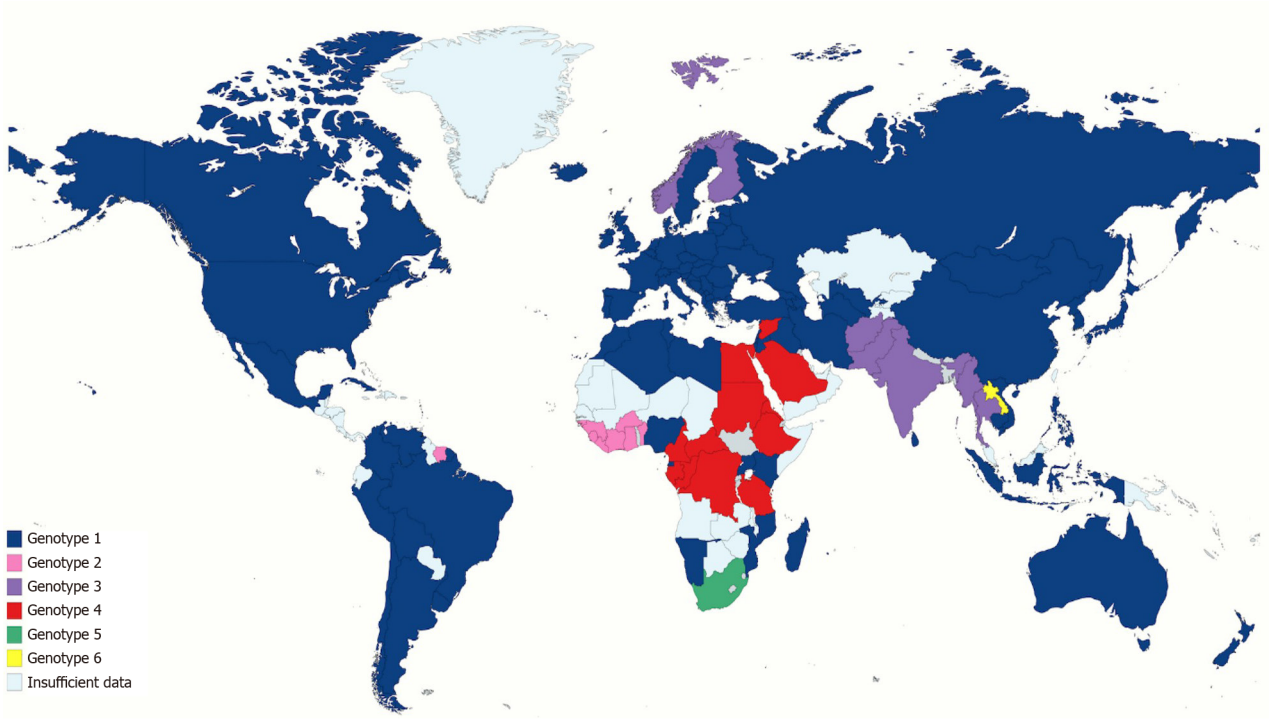

Figure 3 Global geographic distribution of most common hepatitis C virus genotype per country.

are asymptomatic or have nonspecific symptoms. These may include fatigue, sleep disturbances, nausea, diarrhea, abdominal pain, anorexia, myalgia, arthralgia, weakness, depression, anxiety, and weight loss[97]. Patients who develop cirrhosis may develop jaundice, ascites, and other stigmata of cirrhosis.

Serum aminotransferase levels remain relatively stable over time in chronic HCV patients. One in three patients have a normal ALT; only one fourth have a serum ALT more than twice the upper limit of normal; the rest of patients have slight enzyme elevations, usually less than twice the upper limit of normal. Rarely, ALT elevations more than 10-fold the upper limit of normal may occur[98]. There is little correlation between aminotransferase levels and liver histologic findings[99].

On the other hand, it is estimated that acute HCV accounts for 15%-20% of cases of acute hepatitis[100]. More than two thirds of acute HCV infections are usually asymptomatic[101]. Symptomatic patients present similarly to other acute hepatitis, with

jaundice, nausea, dark urine, and right upper quadrant pain. These symptoms develop 2-26 wk after exposure and lasts 2-12 wk[102]. Aminotransferase levels tend to be greater than 10 times to 20 times the upper limit of normal but fluctuate widely and may even normalize[103]. Acute liver failure due to acute HCV infection is extremely rare, but patients with chronic HBV[104] or other underlying chronic liver conditions may be predisposed to this outcome.

Extrahepatic manifestations are found in up to 38% of patients with chronic HCV[105]. These may include hematologic abnormalities, such as essential mixed cryoglobulinemia and lymphoma; glomerular renal disease, most notably membranoproliferative glomerulonephritis and cryoglobulinemia; dermatologic disorders such as porphyria cutanea tarda and lichen planus; rheumatologic complaints such as arthralgias/myalgias; neurological involvement with sensory or motor neuropathy; and autoimmune conditions such as thyroiditis. Resolution of these manifestations can be expected with treatment.

Complications

Spontaneous clearance of HCV occurs in about one fourth to one half of patients[106]. This usually occurs within 12 wk of exposure. A C/C type allele polymorphism in the chromosomal locus close to interleukin-28B has been associated with higher spontaneous clearance (50%) compared to the 15% rate of spontaneous viral clearance seen with the T/T allele[107]. Other favorable factors associated with higher rates of clearance include HLA-DRB1 and DQB1 alleles, white race, female sex, childhood infection, symptomatic acute infection, and high titers of neutralizing antibodies[106].

Rate of progression of chronic HCV infection to cirrhosis varies widely among the literature, but pooled data estimates that 16% of patients develop cirrhosis within 20 years[108]. It estimated that an HCV infected liver develops cirrhosis after approximately 20-30 years[109,110] with approximately 700000 deaths annually worldwide[111]. Risk factors for progression of hepatic fibrosis in patients with chronic HCV infection include age > 40 years[110], alcohol consumption, HBV coinfection human immunodeficiency virus coinfection, immunosuppressed stage, marijuana use, obesity, diabetes mellitus[112], schistosomiasis, severe hepatic necroinflammation, smoking, male sex[113], and white race[114]. The viral load has not correlated with risk of progression to cirrhosis. Studies have described a 3.9% risk of decompensation per year with ascites presence representing the most common form of decompensation[115]. Once patients develop cirrhosis, there is a 1.4%-4.9% yearly incidence rate of HCC[115-117]. It is estimated that HCV accounts for 25% of HCC cases worldwide[118].

Diagnosis

Third generation enzyme immunoassays (EIAs) detect antibodies against different HCV antigens, including HCV core, NS3, NS4, and NS5 as early as 8 wk, with sensitivity and specificity of 99% after 2-6 mo after exposure[119]. False negatives may arise in patients on hemodialysis and immunocompromised patients. These are considered indirect assays.

Quantitative, HCV RNA tests are a type of direct immunoassays that may detect HCV viremia in patients with at last 10-15 IU/mL[120]. HCV core antigen immunoassay is an alternative to HCV RNA testing but cannot be used to monitor response to antiviral therapy as it has limitations in sensitivity[121].

In patients with low pre-test probability for HCV infection, a negative EIA for anti-HCV antibody effectively excludes HCV infection. However, in patients suspected acute HCV infection, HCV RNA viral load by polymerase chain reaction (PCR) must also be obtained as antibodies may not become positive until 2-6 mo on average. A positive HCV antibody and positive HCV RNA confirms HCV infection but cannot distinguish between acute and chronic infection. Acute infection can be confirmed if a patient previously tested negative in the 6 mo prior to infection and has not tested positive for both RNA and antibody, or if the RNA and antibody become negative within 6 mo. Chronic HCV infection is defined as positive HCV RNA of at least 6 mo duration.

For patients with suspected exposure to HCV, HCV RNA, anti-HCV antibody, and serum aminotransferases are obtained within 48 h to obtain baseline values. If HCV RNA is positive, infection is confirmed, and acuity will depend on whether HCV antibody is positive (chronic) or negative (acute). However, if HCV RNA is negative, it should be rechecked in 4 wk and if positive it is considered an acute HCV infection. If HCV RNA is negative 4 wk after exposure, it should be re-checked at 12-16 wk. If negative again, HCV should be checked once more at 6 mo.

Currently available treatments

Antiviral therapy should be contemplated for almost all patients with HCV. Clinicians should consider withholding treatment in patients with decompensated cirrhosis listed for liver transplant with a high Model for End-Stage Liver Disease (MELD) score, pregnant patients, and patients with less than 12 mo of life expectancy.

The intent of HCV treatment is to eradicate the virus to mitigate cirrhosis and associated complications, such as portal hypertension, HCC, need for liver transplantation, and death. The goal is to obtain sustained viral remission (SVR), which is the absence of virus in the blood 12 wk after treatment completion. SVR has been associated with improvement in elastography fibrosis scores[122], while decreasing hepatic decompensation[123], HCC[124], and liver-related deaths[125].

The major groups of therapy include interferon-alpha, ribavirin, and direct acting antivirals (DAAs). Interferon was the first treatment available for HCV in the 1980s. More recently, interferon has been bound to PEG, which increases its half-life and has increased SVR rates[126]. Ribavirin, an oral guanosine analog, may be used in a synergistic combination interferon to increase response and reduce relapse. Ribavirin is usually well tolerated but may produce hemolytic anemia, especially in patients with renal disease given its excretion in the kidney. It should be avoided in patients with a creatinine clearance less than 50 mL/min. In addition, ribavirin is teratogenic[127].

DAAs inhibit replication of HCV by targeting the NS3/NS4 protease, NS5A protein, and the NS5B polymerase. NS3/NS4 protease inhibitors end in the suffix "-previr" and include boceprevir, telaprevir, simeprevir, paritaprevir, grazoprevir, glecaprevir, and voxilaprevir. NS5A inhibitors end in suffix "-asvirs" and include daclatasvir, ledipasvir, ombitasvir, and elbasvir, velpatasvir, and pibrentasvir. NS5B polymerase inhibitors end in "-buvirs" and are either nucleoside, nucleotide (sofosbuvir), or non-nucleoside (dasabuvir).

The classes of DAAs are typically used in combination: sofosbuvir/lepidasvir, elbasvir/grazoprevir, sofosbuvir/velpatasvir, sofosbuvir/velpatasvir/voxilaprevir, and glecaprevir/pribrentasvir. The choice of regimen and duration depend on the patient's genotype, renal function, and concurrent medications. The genotypic coverage provided by each regimen is outside of the scope of this review, but importantly sofusbuvir/velpatasvir and glecaprevir/pibrentasvir are considered pangenotypic regimens. Protease inhibitors are primarily hepatically excreted and thus are contraindicated in Child-Pugh B and C cirrhosis. Nucleoside NS5B inhibitor sofosbuvir is primarily renally excreted and should be avoided in patients an estimated glomerular filtration rate less than 30 mL/min per 1.73 m^2.

Role of liver transplant

Liver transplantation frequently provides destination treatment for HCV decompensated cirrhosis or HCC in candidates who are not deemed appropriate for surgical resection. HCV infection remains one of the leading etiologies for liver transplantation worldwide[128]. Since 2012, the percentage of liver transplants allocated for chronic HCV infection has steadily decreased in United States[129] due to the use of DAAs. The use of liver transplant for acute liver failure secondary to HCV infection has not been a common phenomenon.

Virtually all recipients who are serologically positive for HCV at the time of transplant develop recurrent HCV infection during reperfusion of the transplanted liver graft[130]. The main consequence is the development of post-transplant liver injury in the form of fibrosis in up to 40%[130], recurrent cirrhosis in up to 30% after 5 years[131], and fibrosing cholestatic HCV in up to 10%[132]. This has been associated with lower overall survival in HCV infected recipients in comparison to HCV negative recipients[133]. To counteract this, therapy with DAAs have been used and have increased post-transplant one-year survival rates in HCV viremic recipients from 90%-92%[129]. DAAs may be used to cure HCV prior to transplant, eliminating the chance of HCV recurrence[134], or can be used post-transplant. Reasons why HCV treatment with DAAs may be delayed until after transplant include: improvement of MELD score leading to de-listing or increased wait time on transplant list, lower likelihood of SVR, and limited access to available regimens for advanced cirrhosis[135].

Utilization of HCV infected organs has been one of the major advancements aimed at increasing the donor organ pool and decreasing waitlist time. Initially, this was primarily performed in recipients already infected with chronic HCV. Between 2010 to 2015, the proportion of HCV positive livers transplanted into HCV seropositive recipients increased 2.4-fold[136]. More recently, the transplantation of HCV infected organs including livers into HCV seronegative recipients has been utilized with

similarly good outcomes[137,138]. Donors positive for HCV RNA have a high risk of transmitting infection to HCV negative recipients but this may also occur with HCV antibody positive HCV RNA negative donors in up to 16% of cases[139].

HCV negative recipients who receive HCV positive organs may receive DAA therapy prophylactically or reactively after they are found to be positive for HCV. In liver transplantation, DAA therapy is typically given for at least 12 wk to recipients once they are found to have positive HCV RNA, usually within 3 mo. Thus far, studies have shown SVR of up to 100%[140,141]. Questions are easing surrounding the concern whether the risk of rejection is increased in recipients of HCV organs, either from HCV or DAA therapy[140]. Initial 2-year outcomes of HCV positive organ transplantation in HCV negative recipients have shown promising similar patient and graft survival[138]. Short duration of DAA has been considered but not extensively studied in HCV positive liver transplantation.

In non-hepatic transplantation, prophylactic DAA therapy is favored before viremia to reduce the chances of complications and the duration of DAA therapy[142]. Some authors have even limited duration of DAA therapy to as few as 8 d, but this is not currently recommended outside a clinical trial setting[143]. A pangenotypic regimen is typically utilized if prophylactic DAA therapy is used. Thus far, outcomes of transplantation of HCV positive nonhepatic organs in HCV negative patients have been promising, but data is limited. There is still some concern regarding risks such as DAA treatment failure with evolution of resistance associated substitutions and fibrosing cholestatic hepatitis[144].

Ongoing research and future directions

Much of the future research and guidelines will aim to answer questions regarding the safety, ethical, and practical concerns regarding the transplantation of HCV viremic organs into HCV negative recipients. Several factors related to the HCV donor organ remain nebulous. It is unclear whether duration of HCV infection, viral load, genotype, and failed prior treatment of the donor will affect SVR rates post-transplant in this patient population as studies have not controlled for these factors[145]. In addition, several optimal donor factors, specifically age and fibrosis grade, are not clear. Previous studies showed that HCV infected livers of donors 50 years or older have been found to have increased fibrosis progression and worse graft survival[146], but this data is prior to the advent of DAAs and should be re-examined. Similarly, data prior to the widespread use of DAAs showed that HCV positive donor kidneys had worse outcomes; because of this, the kidney donor profile index includes HCV status as a relevant factor but more recent data from the DAA era shows similar outcomes in these HCV positive donor kidneys[147]. Further studies are needed to establish its effects in the outcomes and limit the number of discarded HCV infected organs.

Recipient selection to match donor characteristics when utilizing HCV organs need further investigation to establish best practice guidelines for HCV organ utilization. For now, HCV infected donor allografts are used mainly in patients whose waitlist duration is expected to exceed their duration of transplant-free survival, but no studies have explicitly examined this. Another scarcely studied but relevant risk is how healthy the recipient's liver condition factors to receive an HCV infected non-liver organ, and what the long-term outcomes of this are. Timing of DAA therapy, optimal regimen, duration, cost effectiveness of different strategies, interactions between DAAs and calcineurin inhibitors, and other drug interactions with DAAs will also need to be investigated. Finally, data on long-term outcomes, specifically efficacy and safety, following transplantation of HCV viremic organs into HCV negative recipients is lacking, as current data is limited to 1-2 years.

The ongoing pursuit for a HCV vaccine remains prudent, especially since DAAs do not prevent against reinfection. To date, there have been a few clinical trials studying different methods for active immunity, including viral vectors[148], DNA-plasmid, recombinant proteins, and prime-boost vaccination strategies[149]. However, thus far, many of these trials are still in the early phases or have not conferred consistent long-term immunity.

In 2020, the United States Center for Disease Control and Prevention increased the previous screening expanse by recommending one-time universal screening for all adults at least 18 years of age. Similarly, the United States Preventive Services Task Force recommended one-time universal screening for patients 18-79 years old. The World Health Organization (WHO), the American Association for the Study of Liver Diseases/Infectious Diseases Society of America joint guideline group, the European Association for the Study of the Liver, the National Health Service in the United Kingdom, the Canadian Task Force on Preventive Health Care, the Canadian

Association for the Study of the Liver, and other groups have yet to recommend universal screening.

Given the vast prevalence of HCV infections worldwide, there has been an increased effort in the last five years to encourage primary care physicians to treat HCV. This has been aided by the ease of using DAAs and the advent of pangenotypic drugs. However, studies have shown that up to 59% of primary care physicians still refer all of their HCV patients to specialists, citing needing additional training to feel comfortable treating the infection[150]. Thus, further studies investigating the best methods in educating and involving primary care physicians to treat HCV are needed.

HEPATITIS D

Epidemiology

In a recent large meta-analysis by Chen *et al*[58] with 182 articles included from 61 countries, it was estimated that 62-72 million individuals around the globe are infected with HDV. Approximately 10.58% of HBsAg carriers were coinfected with HDV, which is two-fold higher than what has been estimated previously[150,151]. Areas of highest HDV infection carriage include western and middle Africa, the Amazon Basin, eastern and Mediterranean Europe, the Middle East, and parts of Asia. Notably, a recent epidemiological study examining a cohort of HBV-positive intravenous drug users revealed an alarming increase in HDV seroprevalence from 29% in 1988-1989 to 50% in 2005-2006[152]. Nonetheless, the lack of HDV RNA validation in many of these studies hinders a true estimation of HDV prevalence.

Pathogenesis

HDV is a single-stranded RNA virus, considered a defective virus that requires the existence of HBV for full expression and replication. It was first described in 1977 by Rizzetto *et al*[153] in Italy, when they detected a new antigen-antibody system associated with but immunologically distinct from HBV by direct immunofluorescence. Although there are 8 different described HDV genotypes, HDV-1 is responsible for most cases in North America, Europe, and the Middle East[154].

Like HBV, HDV is transmitted *via* the parenteral route through exposure to infected blood or body fluids with an exceedingly small inoculum needed to transmit infection[155].

Clinical presentation

The clinical spectrum of HDV infection ranges from inactive asymptomatic carrier to acute liver failure[156]. Concomitant infection of HBV and HDV typically leads to mild self-limited disease or less likely severe acute hepatitis with spontaneous resolution of both infections[157]. In contrast, HDV superinfection in chronic HBV carriers usually results in a protracted clinical course[158]. Nevertheless, patients exhibit heterogeneous clinical presentations with more severe disease reported in genotypes 1 and 3[159], intravenous drug users, and older patients in European cohorts. This could be due to the variable direct cytotoxic effect and immunogenic response to HDV on the host hepatocytes[160-162].

Screening for HDV should be considered in all HBsAg-positive patients especially those presenting with worsening liver disease. Initially, testing for total anti-HDV antibody (IgM and IgG) should be attempted by EIAs or radioimmunoassays. A positive test warrants confirmation by serum reverse transcriptase-PCR assays for HDV RNA. Quantification of serum HDV RNA is important in evaluating the need for and efficacy of antiviral therapy.

Currently available treatments

Current evidence supports treating chronic HDV infection in those with detectable viral RNA and evidence of biochemical or histological active liver disease, particularly if significant fibrosis exists[61]. On the contrary, asymptomatic patients with normal liver enzymes do not require therapy.

With nearly 34 years lapsed since the introduction of interferon for the treatment of chronic HDV infection, it remains the only available treatment option of proven benefit[163]. Nonetheless, sustained virologic response is low even with the newer PEG-interferon and rarely exceeds 25%[164]. A meta-analysis of five trials comparing standard 48-wk PEG-interferon with no treatment confirmed not only a modest benefit to PEG-interferon but such benefit was not sustained[165].

Ongoing research and future directions

The past decade has witnessed the evolution of multiple novel antiviral agents that target various critical steps of HDV life cycle. Three new drugs have emerged for the treatment of chronic HDV infection. Among them is the specific inhibitor of HDV prenylation lonafarnib which showed promising results as a monotherapy or when combined with ritonavir or PEG-interferon. Reduction in viral RNA load and improvement in liver enzymes were observed at variable endpoints[166]. Although observed therapeutic benefits correlated with lonafarnib dose used, that was challenged by its universal limiting adverse effects like nausea, diarrhea, abdominal bloating, and weight loss.

Other new therapies included HDV entry inhibitors such as bulevirtide. As mentioned above, this medication was evaluated in patients with HBV coinfection for 24 wk as a monotherapy or in combination with PEG-interferon or tenofovir. The majority of bulevirtide treated patients experienced a > 1 log10 reduction in HDV RNA after 24 wk of therapy with combination therapy being more effective than monotherapy. Finally, as mentioned in the hepatitis B section, REP 2139 was introduced as an inhibitor of virion secretion with potential for viral load suppression in patients with HBV-HDV coinfection. However, marked ALT elevations were noted in these studies[77,78]. Combination of inhibitors over an enduring treatment regimen are likely required. These novel agents are being considered in combination with PEG-interferon, which carries known side effects that may be prohibitive in its use with HDV cirrhosis.

Animal studies suggest that vaccine strategies for preventing HDV superinfection may be feasible[167,168]. Those studies used groundhogs as animal models and focused on inducing active immunity by injecting the animal with a full-sized HDV antigen or synthetic peptides. These investigations, although promising, were limited by their small size and heterogenous results. As of today, vaccination against HBV remains the most cost-effective means to prevent HDV infection.

Role of liver transplant

Liver transplantation is indicated in patients with fulminant liver failure. Communication and arrangement for transfer to a transplant facility are paramount in the ability to rescue these individuals. Post liver transplantation recurrence of HDV infection despite appropriate medical therapy was estimated to be 13.4%[169] with comparable outcomes between patients with and without recurrence.

HEPATITIS E

Epidemiology

The WHO reported an estimated 20 million new hepatitis E virus (HEV) infections every year globally, leading to 3.3 million symptomatic cases of acute hepatitis and in another report to over 44000 deaths in 2015[39]. Although the use of current antibody assays in seroprevalence studies remains debatable, the overall seroprevalence of the HEV in the United States between 1988 and 1994 was projected to be 21%[170]. Other more recent analyses reported a lower but rising overall seroprevalence in the United States born individuals from 4.5% in 2013-2014 to 8.1% in 2015-2016, with increasing age, female sex, and Asian ethnicity being significant predictors of HEV seropositivity[171].

Pathogenesis

The HEV is a small, single-stranded RNA virus that is considered one of the most common, yet underdiagnosed etiologies of acute viral hepatitis with the earliest epidemic going back to 1955 in New Delhi[172]. While it stands as the only member of the genus *Hepevirus* in the family *Hepeviridae*a, a plethora of genotypes were identified to date with four of particular clinical significance; genotypes 1 and 2 being confined to humans, while genotypes 3 and 4 can infect humans and animals largely *via* the fecal-oral route[173,174].

Clinical presentation

Most HEV infected patients are either asymptomatic or may develop mild, self-limited, HAV-like illness. Typically preceded by an incubation period ranging between 2 wk to 10 wk[175]. This is essentially true of HEV genotypes 1 and 2. However, the zoonotic genotypes HEV 3 and 4 have been increasingly reported as causes of

chronic hepatitis almost exclusively in those who are immunocompromised[176,177]. Less than 5% of acutely infected HEV patients will progress to acute liver failure and those patients are more likely to be pregnant, malnourished, or have a preexisting liver condition[178,179].

Although a uniform diagnostic approach for HEV infection is limited by the lack of standardized antibody assays, patients with consistent clinical presentation should be tested for anti-HEV IgM antibody assay with a confirmatory HEV RNA viral load if positive.

Currently available treatments

Similar to HAV infection, the majority of patients with acute HEV infection require no specific treatment and the management is mostly supportive. However, patients who develop acute liver failure may warrant liver transplantation[180]. A rising body of literature investigated the role of ribavirin in treating chronic HEV infection in immunosuppressed patients with variable success[181]. Whenever possible, treatment should be accompanied by reducing immunosuppressive therapy and followed by testing for clearance to confirm eradication[182]. A 3-mo course of ribavirin has been proposed for the above indication, while its use in acute fulminant hepatitis appear promising[183], more robust evidence is yet awaited.

Prevention remains the most effective approach to combat HEV-related disease. This can be achieved by maintaining quality standards for public water supplies and maintaining hygienic practices as per the WHO recommendation[175].

In 2011, a recombinant vaccine to prevent HEV infection was registered in China. Although it is not approved yet in other countries, few studies have emerged to evaluate efficacy and safety of this vaccine. In a large, randomized trial from China including 112604 healthy adults that evaluated different doses of HEV vaccine compared to placebo, a protective effect of 100% was reported at 1 year following 30 d from the last dose received. Another trial revealed a protective efficacy of the vaccine against HEV to be 86.8% after 4.5 years of the first vaccination[184]. Other preventive options such as immune globulin remain experimental[185].

Ongoing research and future directions

For chronic HEV patients who fail ribavirin therapy, some alternatives such as PEG-interferon[186] and sofosbuvir are being considered pending more evidence[187]. Their routine use is being hindered by the lack of safety and efficacy profile in this setting besides the perceived higher risk of acute rejection with PEG-interferon due to its immunostimulatory effect in organ transplant recipients.

Role of liver transplant

Although liver transplant recipients may develop chronic HEV in the setting of prolonged immunosuppression, acute HEV infection may rarely result in acute liver failure necessitating liver transplant. Accumulating epidemiologic evidence described significant heterogeneity in HEV infection prevalence and outcomes. For example, HEV remains the most common cause of acute viral hepatitis and acute liver failure (up to 44%) in some Asian countries such as India and Bangladesh[187,188]. This contrasts with Western Europe and the United States where it is a rare cause of acute liver failure[189].

CONCLUSION

The recognition of the epidemiological and clinical features of hepatitis A, B, C, D and E is crucial to guide the diagnosis of these conditions. Fortunately, the medical advances in the last centuries have allowed to effectively diagnose them and comprehensively establish its multisystemic impact in this population. With the advent of new therapies, the possibility of achieving control of the disease is a reality, while reaching the cure and eradication of chronic hepatitis B, C and D is around the corner.

Abstract

The coronavirus disease 2019 (COVID-19) pandemic is a threat worldwide for individuals of all ages, including children. Gastrointestinal manifestations could be the initial presenting manifestation in many patients, especially in children. These symptoms are more common in patients with severe disease than in patients with non-severe disease. Approximately 48.1% of patients had a stool sample that was positive for severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) viral RNA. Children typically form 1%-8% of all laboratory-confirmed cases of SARS-CoV-2. Gastrointestinal manifestations of COVID-19 in children are not rare, with a prevalence between 0 and 88%, and a wide variety of presentations, including diarrhoea, vomiting, and abdominal pain, can develop before, with or after the development of respiratory symptoms. Atypical

manifestations such as appendicitis or liver injury could also appear, especially in the presence of multisystem inflammatory disease. In this review, we discussed the epidemiology of COVID-19 gastrointestinal diseases in children as well as their implications on the diagnosis, misdiagnosis, prognosis, and faecal-oral transmission route of COVID-19 and the impact of gastrointestinal diseases on the gut microbiome, child nutrition, and disease management.

Key Words: COVID-19; SARS-CoV-2; Gastrointestinal diseases; Children; Dysbiosis; Faecal-oral transmission

Core Tip: Coronavirus disease 2019 (COVID-19) presents with different manifestations, including gastrointestinal inflammation, especially in children. Gastrointestinal effects of COVID-19 have a significant impact on the diagnosis, misdiagnosis, prognosis, faecal-oral transmission route, gut microbiota, and child nutrition. The presence of gastrointestinal symptoms in children with COVID-19 should not be ignored.

INTRODUCTION

The rise of coronavirus disease 2019 (COVID-19) at the end of 2019 became a real and significant challenge to humanity, especially as the outbreak escalated to a global pandemic in March 2020. The challenge was related not only to the rapid transmission of COVID-19 but also to the dilemma and conflict in the clinical presentations, rate of mutation, laboratory diagnosis, and management of the disease. COVID-19 is caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), a virus that is related to a large group of enveloped, positive-stranded RNA viruses called coronaviruses because of the crown-like spikes on their surface. There are four subgroups (genera) of coronaviruses, named alpha, beta, gamma, and delta; the alpha and beta subgroups can cause disease in humans, causing respiratory infections, gastrointestinal infections, and hepatic and central nervous system diseases[1]. The most recent outbreaks of coronavirus belong to beta coronaviruses and include the SARS-CoV outbreak, the Middle East respiratory syndrome coronavirus outbreak, and the recent SARS-CoV-2 pandemic. In humans, coronaviruses primarily affect the upper respiratory tract, causing different manifestations of respiratory infections. However, gastrointestinal manifestations could be the initial presenting manifestation in many patients, especially in children. These manifestations could also be the sole manifestations in a small percentage of patients. This article will review the different gastrointestinal disorders in association with SARS-CoV-2 infection (COVID-19) and discuss their epidemiological and clinical implications[2].

EPIDEMIOLOGY OF COVID-19 AND GASTROINTESTINAL DISORDERS IN CHILDREN

Although it predominantly affects adults of higher age groups, SARS-CoV-2 can infect children at any age, even during the neonatal period; intrauterine or perinatal transmission of the virus is uncertain, and vertical transmission is not yet proven[3]. Children typically form 1%-8% of all laboratory-confirmed cases of COVID-19: 7% in neonates, 29% in infants less than 1 year old, 10% in the 2nd year of life, 11% between 2 and 5 years old, 16% between 5 and 10 years old, and 34% between 10 and 18 years of

age[4]. However, the percentage of the disease in children may differ from one country to another and from one ethnic group to another according to the underlying health, social, and economic status of individuals[5]. As the number of children infected is currently increasing, studies have shown that most infected children have mild disease. However, approximately 4.4% of infected children have severe disease, with a mortality rate of 0.2%, with no deaths reported below the age of 9 years. Infants less than 1 year old and children who have other underlying comorbidities are more prone to severe COVID-19. There was no sex difference in the infected children, unlike that observed in adults with a male to female ratio of 1.1:1. The source of infection was usually an infected family member as a part of a family cluster outbreak[6].

The low prevalence of COVID-19 in children is multifactorial. Children have few outdoor activities, especially with school shutdowns, lower travelling rates than adults, and less exposure to smoking and air pollution; hence, children are less likely to be exposed to infection. Their immune status plays an important role in modifying their risk of infection with SARS-CoV-2. Children have a more active innate immune response and a healthier respiratory system than adults, especially children less than 10 years of age. They also respond with a normal or high lymphocytic count in response to infection with SARS-CoV-2, in contrast to adults, who respond with a decreased lymphocytic count. Coinfection with other viruses may limit the replication of SARS-CoV-2 *via* direct virus-to-virus interactions and competitive inhibition and may be a possible mechanism like what is observed with the common cold and influenza. However, the main factor for the low incidence of COVID-19 in children is related to the age-dependent immaturity of angiotensin-converting enzyme 2 (ACE2) receptors in children and their different distribution and function compared to adults. These receptors serve as a binding site for SARS-CoV-2 and a portal of entry to the inside of the cell by the binding of the viral spike proteins to ACE2 receptors. The degree of cell susceptibility to viral infection is correlated with the number of ACE2 receptors on those cells. However, ACE2 has dual effects on cell infection by the virus. In addition to ACE2 receptors acting as a binding site for the virus, they have a very important pulmonary protective role, as they protect against severe lung injury caused by the virus. Therefore, this dual role of ACE2 pushes us to perform more research to confirm its implication in COVID-19 pathogenesis[7-10]. The low number of children infected with SARS-CoV-2 does not necessarily mean a high resistance to the infection. Another possible theoretical reason is related to Bacillus Calmette-Guérin (BCG) vaccination in children. BCG may provide some protection against COVID-19 as it modulates cell-mediated immunity, including innate cells such as macrophages, monocytes, and epithelia, and many children are vaccinated with BCG[11]. However, the protective effects of BCG against COVID-19 are still unknown. As more than 95% of children infected with SARS-CoV-2 are asymptomatic and less likely to be tested, epidemiological surveillance may be inadequate, and children may still contribute to viral transmission.

Although fever and respiratory manifestations are the most common features of COVID-19, approximately 17.6% of patients present with gastrointestinal symptoms that usually appear 1-2 d before respiratory symptoms. Verified cases of COVID-19 with the sole gastrointestinal manifestation have been described in both adults and children. Gastrointestinal manifestations were more common in patients with severe disease (17.1%) than in patients with non-severe disease (11.8%). Approximately 48.1% of the patients had stool that was positive for viral RNA, even in stool samples collected after the respiratory samples turned negative for the virus. The exact rate of gastrointestinal symptoms is a matter of debate, with various incidences among the different studies. Anorexia and poor appetite were the most common gastrointestinal symptoms (a range between 347% and 67% and a mean of 47%), followed by diarrhoea (range between 2.1% and 32.5% and a mean of 11.6%), abdominal pain and discomfort (range between 1% and 11.9% and a mean of 5.2%), and nausea and vomiting (range between 1% and 11.7%, and a mean of 5.1%), while the incidence of liver damage ranged from 15% to 53%[12-18]. Liver damage is doubled in the presence of gastrointestinal manifestations compared to in the absence of gastrointestinal manifestations. Gastrointestinal manifestations usually deteriorate with disease progression, and severe gastrointestinal bleeding has been reported in some cases[19].

Gastrointestinal manifestations of COVID-19 in children are not rare, with a prevalence between 0 and 88%, and a wide variety of presentations, including diarrhoea, vomiting, and abdominal pain, that can develop before, with or after the development of respiratory symptoms. Atypical manifestations such as acute appendicitis or liver injury could also appear, especially in the presence of multisystem inflammatory disease[20]. An American study including 44 children showed that gastrointestinal manifestations were present in 84.1% of children

admitted to the hospital and were most often associated with fever and rash[21]. In a meta-analysis including 280 children from 9 studies, the pooled prevalence of gastrointestinal manifestations was 22.8%. Diarrhoea was the most common presentation (12.4%), followed by vomiting (10.3%) and abdominal pain (5.4%)[22]. In a prospective study including 992 healthy children of healthcare workers in the United Kingdom, approximately 7% tested positive for SARS-CoV-2 antibodies, half of them were asymptomatic, and 19% had gastrointestinal symptoms, including diarrhoea, vomiting, and abdominal cramps[23]. Another study in Wuhan, China showed that gastrointestinal manifestations were observed in 15.2% of children infected with SARS-CoV-2 (diarrhoea 8.8% and vomiting 6.4%). In contrast to adults, gastrointestinal manifestations in children were associated with less severe disease and less need for oxygen therapy[24].

Pathogenesis of gastrointestinal infection in COVID-19

The exact mechanism of gastrointestinal symptoms caused by SARS-CoV-2 infection is still unclear. The detection of SARS-CoV-2 RNA in the stool suggests faecal-oral transmission. The presence of gastrointestinal manifestations before respiratory symptoms in a group of patients, along with the presence of viral shedding from the gastrointestinal tract in cases with a more aggressive clinical course, may indicate the role of the gastrointestinal tract in modifying the course of COVID-19 and help in predicting prognosis[25]. Several studies suggest that the virus actively infects the cells of the gastrointestinal tract, replicating itself in the epithelium of the small and large intestine and producing an excessive immunological reaction in the host[26]. ACE2 is highly expressed in lung alveolar type II cells and the upper oesophagus, in absorptive enterocytes from theileum and colon, and in hepatocytes and cholangiocytes. The ACE2 receptor is an important receptor on the cell membrane of host cells. The interaction between the S protein of SARS-CoV-2 and ACE2 promotes the invasion of host cells by SARS-CoV-2. Abundant expression of ACE2 throughout the endothelial surface of the gastrointestinal tract, especially in enterocytes, may act as a secondary entry site for SARS-CoV-2 infection. The magnitude of ACE2 expression in the gut may ameliorate or worsen gut dysbiosis and gastrointestinal leakage[27]. Dysbiosis and the consequent leaky gut further impair the gut-lung axis and are related to the onset of pulmonary hypertension as well as the hyperactivation of the ACE/Ang II/AT1R (angiotensin II type 1 receptor) axis from ACE2 Loss. At the same time, infection with SARS-CoV-2 causes infiltration with many plasma cells and lymphocytes and potentially induces interstitial oedema and the degeneration of the gut-blood barrier, leading to the spread of viruses, bacteria, endotoxins, and microbial metabolites into the systemic circulation, affecting the host's response to SARS-CoV-2 infection and inducing multisystem dysfunction and septic shock[28]. Persistent viral faecal shedding alters the gut into a base for sustained viral replication and consequently may explain the associated poor prognosis. On the other side of the gut-lung axis, SARS-CoV-2-infection-induced respiratory lesions impair the respiratory tract microbiota, which adversely compromises the digestive tract through immune dysregulation[29].

Failure to detect viral RNA in the stool in some patients infected with SARS-CoV-2 that have gastrointestinal manifestations suggests the presence of other mechanisms of indirect gastrointestinal injury in COVID-19 patients. Disturbed cellular immunity has a significant impact on gastrointestinal health in patients with COVID-19. Lung-derived C-C chemokine receptor type 9-CD4- T cells were significantly increased in patients infected with SARS-CoV-2 compared to healthy individuals. These cells are important for mucosal immunity and have a significant role in the development of chronic enteritis by intestinal immune damage and the disruption of the intestinal flora[30]. The resulting dysbiosis will further promote the polarization of Th17 cells in the small intestine, and the production of excessive interleukin (IL)-17A leads to the recruitment of neutrophils, causing more intestinal immune damage, and inducing diarrhoea and other gastrointestinal symptoms[31]. The induced intestinal inflammation impairs the intestinal mucosal barrier, allowing easy access of the bacteria and its toxin to circulate in the blood and affect other organs, including the liver (gut-liver axis). Intestinal inflammation-induced host and microbial metabolites can reach the liver through the portal vein, impairing liver function[32]. Consequently, the inflamed liver releases bile acids and other bioactive materials into the biliary and systemic circulation, reaching the intestines and causing more intestinal lesions (bidirectional effect). The liver could also be affected by the adverse effects of various drugs used to treat COVID-19 (Figure 1).

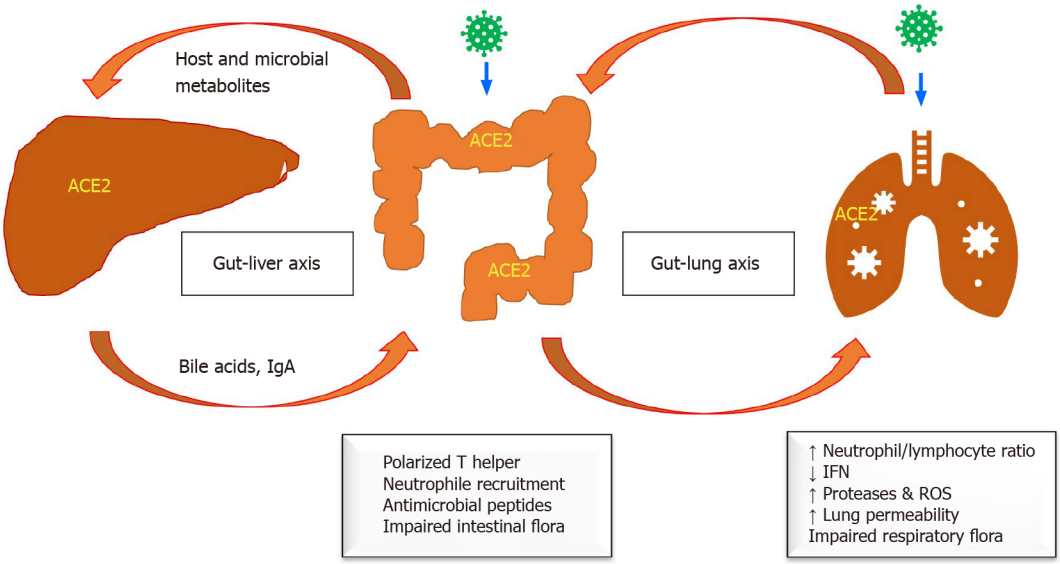

Figure 1 Pathogenesis of gastrointestinal infection in coronavirus disease 2019. ACE2: Angiotensin-converting enzyme 2; IFN: Interferon; IgA: Immunoglobulin A; ROS: Reactive oxygen species.

Diagnosis

Gastrointestinal manifestations are present in more than half (57%) of the patients infected with commonly circulating coronaviruses, especially in children. These manifestations are considered a warning in the presence of other medical comorbidities[33]. Children infected with SARS-CoV-2 usually have milder clinical manifestations of the disease than adults, and occasionally, they act as asymptomatic carriers. Gastrointestinal symptoms are common in children with COVID-19; approximately 25% of them exhibit at least one gastrointestinal symptom. These symptoms may occur in the absence of respiratory symptoms. The most common gastrointestinal symptoms in children are diarrhoea, followed by vomiting and abdominal pain. The manifestations usually come in combination. Gastrointestinal bleeding was reported in adults, but no data were reported in children. Abdominal pain is sometimes severe enough to be mistaken with acute abdomen such as acute appendicitis or systemic sepsis[20].

Infants less than one year of age may present with food intolerance or feeding difficulties. These atypical presentations, especially as initial symptoms, may be misleading and lead to delayed diagnosis of COVID-19. Diagnosis is usually based on the detection of viral nucleic acids in respiratory tract specimens, while faecal nucleic acid detection is often neglected. Therefore, children with gastrointestinal symptoms as the predominant manifestation of COVID-19 are often misdiagnosed[34]. Gastrointestinal manifestations are a prominent presenting feature of multisystem inflammatory syndrome in children (MIS-C). When presenting with MIS-C, COVID-19 could be confused with gastrointestinal infections or even inflammatory bowel disease. Therefore, any child with a history of recent SARS-CoV-2 exposure or infection and prominent gastrointestinal symptoms should be considered to have MIS-C, especially in the presence of other clinical comorbidities and extremely high inflammatory markers[21].

Diagnostic tools

The initial diagnostic tools to monitor infected children are the same as those used for adults, *i.e.*, tracing the history of contact with any infected individuals. Real-time reverse transcription-polymerase chain reaction (RT-PCR) testing of nose and throat swabs for the detection of SARS-CoV-2 nucleic acid is the gold-standard confirmatory test for COVID-19. The virus can be detected from the stool until 12 d after disease onset. Stool can still give positive results despite negative respiratory tests. Patients who present with gastrointestinal symptoms may have a longer duration between symptom onset and viral clearance and may have increased faecal virus positivity compared with those who present with respiratory symptoms[35]. Children have a higher nucleic acid positivity rate of faeces and prolonged faecal viral shedding compared to adults[34]. SARS-CoV-2 RNA can be found in stool specimens and anal/rectal swabs, often with more positivity than oral samples, in the late phase of

the disease. Next-generation sequencing is utilized to identify SARS-CoV-2 strains and mutations for epidemiological and research purposes. Rapid antigen detection tests depend on the detection of the viral antigen in the nose and throat swab in cases with high viral load and in pre-symptomatic and early symptomatic cases up to five days from symptom onset. These tests offer multiple benefits in comparison to RT-PCR tests, including shorter turnaround times, easier techniques, and reduced costs, especially in situations with limited RT-PCR testing capacity. However, there is a high chance of cross-reactivity with other coronavirus families. Additionally, rapid antigen detection tests have lower sensitivity and specificity than RT-PCR. Therefore, positive results should be confirmed with RT-PCR. On the other hand, antibody detection tests are usually negative during the first 7–10 d of infection, with a high risk of missing cases of SARS-CoV-2 infection[36,37].

There are relatively lower rates of lymphopenia and higher inflammatory markers in children than in adults, and thrombocytopenia may occur. Monitoring the lymphocyte count and C-reactive protein level as signs of severe infection while using procalcitonin levels to detect potential bacterial coinfection is encouraged. Patients with severe infection may have high plasma levels of IL-2, IL-7, IL-10, granulocyte colony-stimulating factor, interferon-gamma-inducible protein 10, monocyte chemoattractant protein 1, macrophage inflammatory protein 1-alpha and tumour necrosis factor alpha. Levels of bilirubin and hepatic enzymes are excellent markers for the severity of infections. Elevated lactate dehydrogenase levels, abnormal coagulation, elevated D-dimers, and progressively decreased lymphocytic count may also be observed in severe cases[6,38,39].

Positive faecal occult blood testing indicates upper gastrointestinal bleeding. Endoscopy may show mucosal damage to the oesophageal, gastric, duodenal, and colonic mucosa. Biopsy could show numerous infiltrating plasma cells and lymphocytes, as well as interstitial oedema in the lamina propria of the stomach, duodenum, and rectum. Viral-induced gastrointestinal inflammation causes elevated serum IL-6 levels and elevated levels of faecal calprotectin with significantly higher concentrations in patients with COVID-19 suffering from diarrhoea[26]. The ACE2 protein, used by the virus as a receptor for entry, could be stained mainly in the cytoplasm of gastrointestinal epithelial cells. Immunofluorescence testing may show abundant expression of ACE2 in the glandular cells of the gastric, duodenal, and rectal epithelia[40]. Lung imaging examination has been considered a complimentary confirmation method. Chest X-ray findings in children appear to be nonspecific. However, children with mild disease should not routinely have computed tomography chest imaging in view of high radiation exposure[13].

IMPLICATIONS OF GASTROINTESTINAL INFECTION IN COVID-19

Faecal-oral transmission

Oral gastrointestinal infection with SARS-CoV-2 alters the gastrointestinal tract into a reservoir for viral replication, leading to virus spread to other organs, as well as viral shedding in the stool. Faecal viral shedding could continue for 1 wk after clearance from the respiratory tract. This was observed to be more prevalent in children than in adults, with possible long-term faecal-oral transmission, increasing the potential risk for stools to become a source of the contamination of airdrops and several environmental surfaces and may play an important role in viral spread. Therefore, negative nasopharyngeal or oral samples for the virus may not be sufficient to confirm "non-infectivity", as the virus might still be intermittently shed in body fluids and excreta, including stool. Adding one negative stool sample may increase the negativity yield, especially in patients with gastrointestinal symptoms. However, intermittent shedding should also be considered. The risk of faecal-oral transmission of SARS-CoV-2 is suspected to increase, especially with studies reporting that viral particles in environmental settings may remain viable in aerosols for up to 3 h and for 72 h on solid surfaces. When combined with poor hygiene, including poor handwashing techniques, children have a high risk of transmitting the disease to their contacts. Children should be taught the importance of proper hygiene in an easily understandable language. They should also avoid contact with elderly people if they test positive for COVID-19[41-43].

Impact on the gut microbiome

The gut microbiome is the collection of microorganisms (bacteria, yeast, fungi, archaea, protozoa, and viruses) found in the gastrointestinal tract, mostly in the large bowel,

and it performs many beneficial functions, including immune modulation, with pro-/anti-inflammatory effects. The relation between infection with SARS-CoV-2 and the microbiota is bidirectional. Infection with SARS-CoV-2 is well known to cause the dysbiosis of both the respiratory and gastrointestinal microbiota, which negatively impacts gastrointestinal health and contributes to the development of gastrointestinal disease. The dysbiosis of the gut microbiota creates a suitable environment for SARS-CoV-2 replication and subsequent effects. The inflammatory proteins, cytokines and other mediators that are released because of gut dysbiosis will be augmented with coronavirus infection, which may induce a "cytokine storm" causing more damage than the virus alone, which can ultimately result in multiorgan injury[44]. Zuo *et al*[45] examined the effect of infection with SARS-CoV-2 on the gut microbiome. They found that the virus induces dysbiosis, an effect that begins even before the start of antiviral therapy. They observed the enrichment of opportunistic pathogens and the depletion of beneficial commensals, an effect that could persist even after the clearance of SARS-CoV-2 from the body, suggesting a more long-lasting detrimental effect on the gut microbiome. They observed a decline in beneficial microbes such as *Lactobacillus*, *Bifidobacterium* and *Faecalibacterium prausnitzii*, which are inversely correlated with the severity of the disease. They also observed the enrichment of *Clostridium hathewayi, Clostridium ramosum,* and *Coprobacillus*, which are positively correlated with disease severity[45]. Zuo *et al*[46] also found heterogeneous configurations of the faecal mycobiome, with the enrichment of fungal pathogens from the genera *Candida* and *Aspergillus,* during the hospitalization of patients with COVID-19 compared with controls. This effect persisted even after nasopharyngeal clearance of SARS-CoV-2[46]. Other factors could also play a role in inducing dysbiosis in patients with COVID-19, including the presence of other comorbidities that negatively affect the gut microbiota, such as diabetes mellitus, hypertension, and old age; the use of antibiotics, antivirals, antifungals, and steroids; and other intensive care units milia that could negatively affect and alter the gut microbiome[47].

Impact on patient nutrition

COVID-19 affects the nutrition of patients in many aspects. The poor appetite found in a significant number of patients with COVID-19 makes it difficult to achieve the desired nutrition goals with an oral diet alone, causing undernutrition and sarcopenia. Diarrhoea and vomiting, which are common presentations in children with COVID-19, play an important role in undernutrition development. Anosmia may impair taste perception and interfere with nutritional supplementation or food intake. At the same time, the disruption of normal intestinal mucosal integrity by SARS-CoV-2 could compromise the digestion and absorption of nutrients and may even prevent trophic enteral nutrition[48]. Mechanical ventilation that may be needed in the management of children with severe respiratory disease causes excessive swallowing of air and further gastric distention, which predisposes them to gastroesophageal reflux. Pneumonia and respiratory distress may also cause delayed gastric emptying and intestinal hypomotility, leading to constipation, which is an important factor able to interfere with proper nutritional therapy[49].

Impact on patient management

Gut dysbiosis is an important cause of/and results from gastrointestinal inflammation in patients with COVID-19. Gut microbiota diversity and the presence of beneficial microorganisms in the gut may play an important role in determining the course of the disease. The restoration of gut microbiota diversity could help ameliorate the severity of the disease. Since the gut microbiota is malleable and can be modulated by dietary modification, the addition of specialized pre-/probiotics such as fructooligosaccharides, galactooligosaccharides and various *Lactobacillus* strains to the diet could help to improve gut dysbiosis, especially for patients presenting with diarrhoea, thereby improving the overall immune response in these patients[50]. Fermented food with probiotics can produce bioactive peptides able to inhibit ACE enzymes by blocking the active sites. Furthermore, fragments of dead probiotic cells can also serve as ACE inhibitors. Consequently, probiotics could have the potential to block the ACE receptor, which acts as an entryway for SARS-CoV-2 to attack gastro-intestinal cells[51]. At the same time, prebiotics, probiotics, or symbiotics could be supplied as a prophylactic measure to high-risk groups, such as front-line caregivers and healthy contacts with a suspected case of COVID-19[50]. However, microbiota modulation as a method of treatment of patients with COVID-19 is based on indirect evidence and needs further study.

Dietary management plays an important role in patients with COVID-19. Oral intake is the preferred method of nutrition if the patient condition allows. Oral intake is of paramount importance, as a lack of nutrient contact with intestinal mucosa could lead to the atrophy of lymphoid tissue and functional decline of the immune system, as well as the intensification of bacterial translocation. The patients are advised to take a high-calorie and high-protein diet (1-2.5 g/kg/d) to maintain adequate metabolic functions and proper body weight. If the nutrition targets are not met by the oral diet, oral nutrition supplements are recommended and should be started within 1-2 d of hospitalization. Supplementation with digestive enzymes can be given for patients with poor general conditions and impaired digestion. Breast milk is a true immune nutrient, and breastfeeding should be encouraged[52]. If oral intake fails or is not tolerated, enteral nutrition is still the preferred method of nutrition therapy, as it stimulates the gut. Gastric feeding is preferred to optimize digestive activity, and the post-pyloric route (preferably jejunal) is recommended in the presence of a high risk of reflux aspiration, intolerance, or the failure of nasogastric tube feeding. Prokinetic agents may be used to enhance motility prior to this intervention. As enteral feeding (especially when using post-pyloric tubes) carries a high risk of aerosol generation, healthcare professionals should use proper personal protective equipment during insertion of the tubes. Enteral nutrition ensures adequate anthropometric progression and decreases the length of hospital stay, costs, mortality rate, and septic complications compared with parenteral nutrition. Overfeeding should be avoided in patients with COVID-19 and severe respiratory disease, as this can increase the risk of hypercapnia. The prone position during enteral feeding is permitted and may lead to a better prognosis. Parenteral nutrition is indicated when nutrition targets cannot be met by enteral nutrition or gastrointestinal intolerance is present despite different measures to address intolerance[53-55].

Occasionally, children with severe gastrointestinal symptoms may need endoscopy. This procedure could stimulate excessive saliva and other digestive secretions that increase the risk of choking, vomiting, or diarrhoea with a greater risk of transmission of infection during digestive endoscopy, biopsy, and treatment *via* an airborne route, including the aspiration of oral and faecal material *via* endoscopes. Therefore, these procedures should be performed in a specialized endoscopic operation room, if possible, with negative pressure with standard level-three protection and strict disinfection procedures[56,57].

Impact on misdiagnosis and prognosis

Children with COVID-19 have been reported to present as asymptomatic or with only mild symptoms of the respiratory or gastrointestinal system. Infants are more likely to present with atypical clinical symptoms than older children. A study reported five infants diagnosed with COVID-19 who presented with isolated fever and reduced oral intake without associated respiratory symptoms[58,59]. The characteristics of gastrointestinal symptoms in COVID-19 are more insidious than the characteristics of respiratory symptoms, making them easy to overlook. However, some patients might have only gastrointestinal symptoms during the whole course of the disease, and some continue to shed the virus in faeces, despite respiratory samples testing negative[60]. An awareness of these insidious or atypical presentations will allow appropriate investigation and help to decrease the risk of misdiagnosis and consequently decrease the risk of the spread of the disease in the community.

Compared to patients without digestive symptoms, those presenting with digestive symptoms have a longer time from onset to admission and a worse prognosis[61]. A study by Chen *et al*[62] showed that the presence of gastrointestinal symptoms was associated with a high risk of adult respiratory distress syndrome, non-invasive mechanical ventilation, and tracheal intubation, but not mortality, in patients with COVID-19[62]. Another study by Zhou *et al*[63] showed that patients with gastrointestinal symptoms have a similar rate of complications, treatment, and clinical prognosis as patients without gastrointestinal symptom in medical and nonmedical staff[63]. However, these studies were performed in the adult population and cannot be extrapolated in children.

CONCLUSION

COVID-19 has a wide variety of clinical presentations, and gastrointestinal effects are not rare. Gastrointestinal manifestations could be the initial presenting manifestation in many patients, especially in children, and are more common in patients with severe

disease. Gastrointestinal inflammation associated with COVID-19 greatly affects diagnosis and may increase the rate of misdiagnosis, with a significant impact on prognosis, faecal-oral transmission, the gut microbiome, and patient nutrition and management.

Abstract

Hepatitis C virus (HCV) elimination by 2030, using direct-acting antiviral treatments, has been promoted by the World Health Organization. This achievement is not attainable, however, particularly after the 2020 pandemic of the coronavirus disease 2019. Consequently, the more realistic objective of eliminating HCV from population segments for which targeted strategies of prevention and treatment are easily attained has been promoted in Europe, as a valid alternative. The underlying idea is that micro-elimination will ultimately lead to macro-elimination. The micro-elimination strategy may target different specific populations and at-risk groups. Different settings, including prisons and hospitals, have also been identified as micro-elimination scenarios. In addition, dedicated micro-elimination strategies have been designed that are tailored at the geographical level according to HCV epidemiology and individual country's income. The main elements of a valid and successful micro-elimination project are reliable epidemiological data and active involvement of all the stakeholders. Community involvement represents another essential component for a successful program.

Key Words: Hepatitis C virus antibodies; Hepatitis C virus elimination; Hepatitis C virus epidemiology; Hepatitis C virus RNA; Hepatitis C virus diagnosis; Hepatitis C virus infection

Core Tip: Achievement of hepatitis C virus (HCV) elimination using direct-acting antiviral drugs treatment by 2030 promoted by World Health Organization is hardly attainable especially amidst the coronavirus disease 2019 pandemic. The smaller goal of eliminating HCV from population segments for which tailored strategies of prevention and treatment can be easily implemented appears more realistic. Different

INTRODUCTION

Chronic hepatitis C is a major public health problem, affecting approximately 71 million people worldwide[1]. In 2016, the World Health Organization (WHO) published a document highlighting their global strategy aiming to achieve viral hepatitis elimination by 2030[2,3]. The objectives of this strategy for hepatitis C virus (HCV) infection-as a public health problem-are 90% reduction of new infections, 65% reduction in mortality, 90% increase in HCV diagnosis, and 80% increase in treatment rates.

The availability of low cost and highly efficient pangenotypic regimens for HCV treatment has led to the treatment of 5 million infected persons across the world. However, all the steps along the HCV care cascade need to be enhanced, starting with the proportion of infected people screened, followed by the number of patients testing positive for HCV antibodies and diagnosed with HCV RNA, and finishing with the consequent proportion of patients linked to care and treatment[4]. While safety improvements and harm reductions can be achieved and will ensure a reduction in incidence, HCV diagnoses remain largely suboptimal, with less than 20% of the estimated 71 million chronic HCV-infected individuals identified globally. Razavi *et al*[5]. reported that, among high-income countries, only 11 are on track to eliminate HCV by 2030 and 5 more countries are on track for elimination by 2040; all the remaining are expected to eliminate HCV by 2050 or later. This is mostly due to an insufficient number of patients diagnosed, linked to care and treated, across the majority of countries.

A low level of community awareness as well as stigma and fears related to special populations, such as people who use intravenous drugs (PWID), prevent an expanded screening. Referral of patients already diagnosed represents another major challenge. Even more critical are geographical and transportation barriers. Long wait times before the start of treatment and reimbursement policies in some countries account for additional obstacles. Although pre-treatment evaluations, including viral load confirmation and liver disease staging, can be simplified using the pangenotypic and panfibrotic regimens currently available[4], treatment restrictions related to the stage of fibrosis remain a limiting factor in several countries.

More recently it has become evident that a key aspect in improving the results of treatment strategies is patient engagement. In addition, the coronavirus disease 2019 (COVID-19) pandemic is having a deep impact on management of chronic liver diseases in general. Screening campaigns appear more difficult to implement, and testing and access to treatment have been reduced[6]. Moreover, modeling the global impact of COVID-19 on global HCV elimination efforts has shown that a 1-year delay scenario could result in an excess of incidence of HCV cases and liver-related events among such cases, as well as an excess of cases with the infection's consequent hepatocellular carcinoma development[7].

Thus, it is clear that a one-size-fits-all strategy would be unsuccessful to achieve global elimination and that different populations with chronic HCV infection require dedicated programs[8,9]. Achievement of elimination in a well-defined group or context currently appears more feasible and checkable than a macro-elimination plan[10]. The inclusion of key interventions and the adoption of test-and-treat strategies and simplified treatment regimens were then considered more tangible and achievable milestones. In particular, since 2017, the European Association for Study of the Liver

adopted a micro-elimination strategy as a stepwise, savvy approach in the fight against HCV. The goal of macro-elimination was accordingly adjusted in order to pursue micro-elimination in defined subgroups of patients, such as patients with human immunodeficiency virus (HIV)/HCV coinfection or hemophilia, and prisoners or PWID[10].

Micro-elimination requires involvement of all the different stakeholders, including administrative local representatives, health providers, and patients representatives. This strategy is based on different criteria that allow stakeholders to adapt to different situations. The key aspect is to individualize access to the services on the basis of the patients' needs in order to overcome barriers and to achieve higher rates of diagnosis and treatment in a given population of interest during an established period of time. It is important that the progress attained is publicly announced and analyzed using adequate performance indicators[11]. One of the advantages of this strategy is that once results are achieved in a given context, the success translates into leverage for new initiatives. Of course, stakeholders' engagement is key to successful micro-elimination, together with funding, advocacy efforts and ability to scale, and most importantly involvement of the community. The approaches to micro-elimination may differ and they might be based on different locations, different settings, or different populations[11].

AVAILABLE HCV TREATMENT REGIMENS

Current developments in the treatment of chronic hepatitis C are dramatic. Indeed, several direct-acting antiviral drugs (DAA) have been approved from 2013 to 2017 for treatment of HCV-infected patients, with high rates of sustained virological response (Table 1). The arrival of these highly effective treatment regimens has improved prospects for the eradication of HCV worldwide. DAA are well tolerated. The first approved DAA was sofosbuvir a once-daily pangenotypic oral nucleotide analog polymerase inhibitor as a component of combination antiviral regimens. It was approved on December 2013[4]. The protease inhibitor simeprevir was used as a two pills combination with sofosbuvir for all the different HCV genotypes but 2 and 3 on 2014[4]. Sofosbuvir was later in the same year used as a single pill fixed dose combination with the NS5A inhibitor, ledipasvir for genotype 1 and 4 treatment[4]. Simultaneously, on 2014 the three compounds combination of ombitasvir, paritaprevir /ritonavir boosted and dasabuvir not including polymerase inhibitor was approved for genotype 1 treatment[4]. Daclatasvir another NS5A inhibitor was approved for genotype 2 and 3 on 2015[4]. The combination of NS5 and NS3 protease inhibitor elbasvir and gazoprevir with or without ribavirin for GT1 and 4 infection was approved on 2016[4]. However, the true revolution was the approval on January 2016 of sofosbuvir/velpatasvir (SOF/VEL). Velpatasvir is a second generation NS5A inhibitor administered with sofosbuvir as single pill fixed combination[4]. This was the first pangenotypic regimen to be used without ribavirin for 12 wk regardless of severity of liver disease even in patients with compensated cirrhosis[4]. The other pangenotypic regimen based on glecaprevir and pibrentasvir without the inclusion of a polymerase inhibitor to be administered as three pills daily initially for a variable duration of treatment of 8 or 12 wk and later for only 8 wk in patients with or without cirrhosis infected with genotypes 1, 2, 4 and for no cirrhotic genotype 3 and for 12 wk in patients with cirrhosis of genotype 3 was approved on 2017. The use of easy to manage and safe pangenotypic regimens provide not only effective treatment options but also the most powerful opportunity to achieve HCV elimination.

MICRO-ELIMINATION IN DIFFERENT GEOGRAPHICAL LOCATIONS

Egypt has a very high burden of HCV infections and severe HCV-related liver diseases. In 2015, the reported prevalence of HCV chronic infection in the general population was 7%[12]. The national plan involved testing of 35 million Egyptians for HCV antibodies, over a 6-mo period. As a result, over 2.4 million Egyptians had been treated by 2019. This is an example of strong political commitment and industry support, allowing barriers to be removed. However, implementation of systems to track patients who were treated and cured, and to monitor the achievement of HCV elimination have not been properly developed. Pilot projects conducted at community level were recently completed[12]. From 2018, a test-and-treat strategy was started, targeting each individual aged 18-80 years in 73 villages under the auspices of 7

governates. Free testing was offered, and patients were linked to care and offered free treatment during an educational and prevention campaign. Of the 200000 early tested individuals, 34000 tested positive for HCV antibodies and 14500 were treated. Of those, 99.9% completed the assigned treatment and 97% achieved viral clearance[13].

Another example of a well-conducted HCV micro-elimination campaign comes from Iceland, where the HCV prevalence before the direct-acting antivirals revolution was low. Of 1000 persons infected with HCV in the country, nearly all have been diagnosed within a test-and-treat campaign started in 2016. Treatment was supported by pharmaceutical companies. So far, the island is on track to eliminate HCV by 2021[14].

Georgia was the first European country that started an active national hepatitis elimination program tailored to local needs, based on the 5.4% HCV prevalence in the country. A nationwide case-finding integrated program was designed according to previous experiences in HIV prevention and a control program was initiated for HCV[15]. The HCV testing was integrated in the country's healthcare services for substance users, patients with mental health disorders, and HIV-coinfected subjects. The initial program expanded its scope in 2016, aiming for complete HCV elimination. Of the 150000 estimated HCV-infected subjects, 58% were diagnosed and 80% initiated the HCV treatment; the cure rate was 98.8% for those who completed it. Identification of HCV infection among the remaining population appears to be challenging. According to a recent model based on the Georgia data, in 2019, mortality was reduced by 14% and both prevalence and incidence were reduced by 37%[16].

Among the other European countries, Scotland raised awareness on the impact of HCV through strong campaigns. This led to political support in scaling up the issue, with consequent reduction in HCV incidence and prevalence as well as in mortality. The improvements in harm reduction settings were mainly driven by the use of rapid and accurate diagnosis through dried blood spot testing. Given that there remain undiagnosed subgroups, the next challenge will be involving primary care physicians to increase the diagnosis rate and treatment access[17]. In Spain, with 46.9 million inhabitants and an HCV prevalence of 0.22%, a nationwide plan was initiated in 2016. According to the national data, while HCV testing has been performed in 90% of the general population, testing and linkage to care in at-risk groups remain suboptimal[18].

In other countries, including some from Europe and the United States, the lack of comprehensive data on local situations in terms of prevalence and incidence, or the lack of good quality data in given high-risk groups-other than the lack of affordable tests or harm reductions programs-seem to be affecting achievement of the WHO's goal.

In particular, HCV elimination in low- and middle-income countries has been considered prohibitive until recently. Low-cost screening and drop of drug cost attained only recently are the cornerstone of a published experience involving Cambodia, India, Indonesia, Myanmar, Nigeria, Rwanda and Vietnam by intensive screening and decentralized programs this program has led to cure over 120 people with cure rate higher than 90%. This initiative-supported by Clinton Health Access-proves that the combination of political will, modest financial investment and adequate training pave the way for viral elimination even in the presence of limited

infrastructures[19].

Exploring worldwide progresses in the path to achieve a testing cure protocol for HCV, special attention needed to be reserved to Pakistan. Pakistan has the second highest global burden of HCV infection worldwide with very low level of infection awareness[20]. The Government launched a National Hepatitis Framework for 2017-2021 planning to cure 95% of infected people with DAA (generic sofosbuvir in combination with ribavirin). This initiative resulted in a doubled number of treatments. Despite this success, the country should develop an extensive monitoring and evaluation system and should further implement the national plan[21].

Moving to other countries, low testing rate and poor linkage to care are barriers to treatment in China. Due to its large population a considerable number of infected patients have not yet been discovered. In order to curb the spread of HCV infection and relate morbidity hospitals conduct blood-borne virus screening for inpatients[22]. In addition, several projects are exploring the impact of social media in increasing HCV infection awareness. Among them an interesting randomized controlled study based on crowdsourcing is ongoing in Shenzhen in the setting of primary care. This study aims at enrolling more than 1000 subjects older than 30 years. Subjects randomized into the active arm will receive promotional material by social media campaigns and their HCV testing uptake will be compared to those of the control group just attending the primary care departments and not involved in crowdsourcing activities[23]. A model of targeted HCV screening in past PWID has been adopted in Hong Kong since 2012. Although based on a limited number of subjects, this project represents the first example of targeted screening in Asia[24].

MICRO-ELIMINATION IN DIFFERENT SETTINGS

Prisons' and hospitals' emergency departments are considered appropriate settings for universal screening programs. HCV is common in prisons and guidelines recommend that HCV treatment should be offered to all HCV-infected prisoners. However, a significant proportion of incarcerated patients remain untreated and, once released, contribute to the spread of HCV through the local community. The incidence of HCV infection among prisoners is consequent to drug use and has been estimated globally as 16 *per* 100 person-years (1-34 years)[25]. Prisoners are difficult to engage, due to established high-risk behaviors and psychological disorders[26]. On the other hand, the specific context of prisons allows, after a rapid testing, a quick treatment plan implementation and completion, with the only limiting factor being a short permeance in the same prison[27]. A study conducted in Australia showed that of 562 HCV RNA-positive patients, 416 started treatment with different direct-acting antiviral agents. A sustained virological response (SVR) at 12 wk of 72% was attained, with patients lost to treatment after release accounting for this particular SVR rate. For patients able to complete treatment, per protocol analysis revealed higher SVR at 12 wk (SVR12) rates, up to 96% and comparable to those for the general population[28]. This study was based on a nurse-centered strategy.

Other models based on multidisciplinary networks and telemedicine have been explored in the United Kingdom[29]. Initiatives based on telemedicine were promoted and associated with a high number of treatments and treatment responders in Spain, in a large experiment conducted in "El Dueso" prison between May 2016 and July 2017. Overall, 847 inmates agreed to participate. Among them, 110 were HCV antibodies-positive and 86 HCV RNA-positive. Only 69 patients were treated and 66 of those competed the treatment, yielding a 96.9% SVR rate by intention-to-treat analysis[30]. In the United Kingdom, 128 of 266 individuals who started treatment based on telemedicine had available follow-up data. Of them, 87% achieved SVR; however, the proportion of patients who experienced reinfection was high[31].

The feasibility of a test-and-treat strategy in incarcerated subjects has been highlighted recently in a study by Wong *et al*[32] This study was based on a pangenotypic regimen, with minimal monitoring required. Of the 526 incarcerated adults treated with SOF/VEL in different countries across the world, SVR12 was attained by 437, representing 98.9% of those who completed treatment. A non-virological failure was reported in 82 individuals.

Another example of micro-elimination in a dedicated setting is provided by various interventions implemented in hospital emergency or surgical departments. Examples of these strategies are provided by studies conducted in Spain, in Italy and, more recently, in the United States. In a Spanish study conducted at the emergency department of Hospital Val d'Hebron on 5000 subjects, it was shown that the rate of

HCV antibodies positivity was 4%, higher than that in the general population; in contrast, the rate of active infections was low, with only 16% being HCV RNA-positive. Interestingly, the study showed that in 40% of cases, patients were unaware of their infectious condition[33].

An Italian survey evaluated 11000 patients from the Venetian area. Each patient was tested upon admission to the surgery department[34]. Overall, 2% showed HCV antibodies positivity. Again, the rate was slightly higher than in the general population. Unfortunately, in this study, the results from HCV RNA data were not available for all and estimating active infections was not possible.

In the United States, an automated emergency department cohort screening for viral hepatitis was started in 2018 in New Jersey. The strategy was based on testing Baby Boomers until 2019 and was implemented by extending screening to at-risk in-patients from 2019 to 2020, with further expansion of the screening according to the Centers for Disease Control (CDC) screening guidelines form 2020 onwards. With the aid of a patient navigator, subjects testing HCV RNA-positive were linked to treatment. Universal screening results showed a 3.4% rate for HCV antibodies positivity and 0.9% of HCV RNA positivity among missed Baby Boomers subjects; the rates among non-Baby Boomers were 0.8% and 0.2%, respectively. Rates were higher for subjects aged 55-75 years. The combined cohort and universal screening led to identification of 195 infected individuals among the 37000 subjects who were screened to be linked to care[35].

MICRO-ELIMINATION IN DIFFERENT POPULATIONS

As reported by Degenhardt *et al*[36], the estimated prevalence of PWID by country is variable, with the highest rates reported in United States, Russia, Australia, Brazil, and the European Union. In the United States, PWID account for 60% of new HCV infections (60%) (CDC 2018), while in the European Union, 53.2% of PWID are reportedly HCV antibodies-positive. In the United Kingdom, 80% of individuals infected with HCV are PWID. Therefore, PWID are a key population for targeted micro-elimination strategies. In this population, pangenotypic regimens are associated with high rates of SVR, regardless of the recent use of substances[37].

A large number of studies have investigated different strategies to eliminate HCV in this target population. Integrated approaches based on harm reduction in community settings to enable scale-up and use of simplified models based on low-cost diagnostics have been shown successful in improving screening, linkage to care, treatment access, and response. Studies have suggested that scale-up treatment in this population is mandatory[38]. A study conducted in Scotland in Tayside, a region with a population of 400000 and with an HCV prevalence of 0.55%-0.56%, explored enhanced testing and treatment service focusing on the HCV/HIV coinfection subpopulation. Of the total 2700 subjects, 2300 were diagnosed. In comparison to the pegylated-interferon treatment era, higher rates of patients were linked to treatment and cured. Multidisciplinary involvement included pharmacies, drug treatment centers and prisons, and was based on dedicated educational programs. Of the positive patients, 76% were treated[39].

Multidisciplinary involvement has been pursued by other groups, including ours. In late 2019, our center launched a program promoting ad hoc transportation from "SERDS" (*i.e.*, Centers Taking Care of People with Substance Disorders) to prescribing centers, fast-track baseline evaluation at our center, and a close on-treatment monitoring at 15 different SERDS by the SERDS physician. Of 1500 patients screened, 239 (16%) were HCV RNA-positive, and all were linked to care and started treatment. Of them, 30% were active drug users and 70% were past drug users. High SVR12 rates were reported overall, being 98%. No reinfection was experienced during a short follow-up[40].

Other initiatives, within substance users disorders programs, have targeted their efforts to decentralization. Among them, one-within a continuum program adopted in Philadelphia, United States to compare navigator *vs* embedded treatment models-recently showed that navigators are not sufficient to link HCV PWID to HCV cure[41]. By contrast, embedding HCV treatment within a substance use disorders (SUD) treatment program increases the number of patients linked to care.

The feasibility of HCV eradication in intravenous drug use in Italy has been evaluated within the San Patrignano Therapeutic community. Results showed that one-third of the resident patients were unaware of their HCV infection status. The rate of HCV antibodies-positive patients was 65%, and 238 of the 293 patients who tested

HCV RNA-positive started treatment. As in our study, no case of reinfection was experienced after a short follow-up[42]. The SVR rate was 96.6%. In both these studies, patients were treated with a pangenotypic regimen of SOF/VEL for 12 wk.

Decentralization of the confirmatory testing in harm-reduction sites has been recently implemented. Test-and-treat in point-of care at harm-reduction and addiction centers was proposed as a strategy to treat patients monitored at these centers or at addiction centers in Catalonia, Italy[43]. In both cases, an increase in the number of treatments was registered (+ 57% and + 19%, respectively), although SVR remained suboptimal and associated with a reinfection rate of 6% in harm-reduction centers[43]. In Georgia, a decentralizing screening strategy was shown to be associated with an increase in every step of the HCV care cascade[44]. In the United States, decentralization was implemented with an internist addiction medicine specialist evaluating opiate-dependent patients in a hepatology clinic. This co-localization model was associated with an improvement in the number of patients taking treatment, with an adherence rate of 87.4% and SVR of 98.9%[45].

Among the higher risk groups, MSM cannot be forgotten. Data from population based on systems evaluating the progress through the cascade of care in this group are limited. In France, incidence continue to rise. Among 21.519 HIV positive, HCV negative patients followed between 2012 and 2016 in 16 centers, 218 first HCV infections occurred. Simultaneously, among 3392 patients with cured HCV infection, 74 reinfections were registered[46]. This data show why this is a target population for micro-elimination even despite the high uptake of DAA. As shown in a study from Switzerland, DAA use was able to halve HCV incidence in HIV positive MSM[47].

Very recently a study was designed to compare progress in care and treatment in MSM and non-MSM with HCV infection living in British Columbia[48]. Slightly more MSM *vs* non-MSM received HCV RNA confirmatory testing (83% *vs* 82%) and initiated treatment. In 2019 as compared to 2012, treatment uptake among MSM increased significantly (63% *vs* 37%). SVR rates of 91% and 90% were registered among MSM and non-MSM, respectively. These results suggest that DAAs were associated with substantial improvement in progression across the different HCV care cascade steps.

COVID-19 CHALLENGES CAN HELP HCV SCALE-UP

COVID-19 emergency is demonstrating a greater impact in HCV testing and diagnosis. In United States, at Boston Medical Center, testing decreased by 50, while new diagnoses decreased by more than 60%[49]. Consequently, nontraditional methods of preventive healthcare delivery as telemedicine and technology need to be used in order to emphasize the importance of prevention.

In African Countries integration of diagnostics platforms and implementation of digital technologies were rapidly promoted during the pandemic. Testing and treatment services are facilitating the continuation of essential prevention and are ensuring that people are not further marginalized. Although prevention interventions that require mass gathering are suspended, internet and postal systems may ensuring treatment distribution and help is assisting patients with self-testing[50].

CONCLUSION

The simplification of treatment access, and treatments tailored to the different settings are key aspects towards achieving HCV elimination. All the described interventions have demonstrated an ability to increase in one or more of the HCV cascade steps. The success of micro-elimination initiatives relies on correct targeting of a patient population or appropriate geographical context identification and patient setting.

The COVID-19 pandemic is affecting the results of some of these initiatives, requiring an extension of the timelines and further adjustments to reduce interpersonal contacts. However, it may also result in opportunities to spread awareness of the risks related to infectious disease and of the chances of combined screening programs for HCV and COVID-19.

As the WHO goal for HCV elimination seems hard to reach in the proposed timeframe, micro-elimination is a key alternative strategy. Provided that community involvement represents a free pass for a successful program, micro-elimination will ultimately lead to macro-elimination.

Abstract

The coronavirus disease 2019 (COVID-19) outbreak has drawn the scientific community's attention to pre-existing metabolic conditions that could aggravate the infection, causing extended viral shedding, prolonged hospitalization, and high death rates. Metabolic dysfunction-associated fatty liver disease (MAFLD) emerges as a surrogate for COVID-19 severity due to the constellation of metabolic alterations it entails. This review outlines the impact MAFLD exerts on COVID-19 severity in obese subjects, besides the possible mechanistic links to the poor outcomes. The data collected showed that MAFLD patients had poorer COVID-19 outcomes than non-MAFLD obese subjects. MAFLD is generally accompanied by impaired glycemic control and systemic arterial hypertension, both of which can decompensate during the COVID-19 clinical course. Also, MAFLD subjects had higher plasma inflammatory marker concentrations than non-MAFLD subjects, which might be related to an intensified cytokine storm syndrome frequently associated with the need for mechanical ventilation and death. In conclusion, MAFLD represents a higher risk than obesity for COVID-19 severity, resulting in poor outcomes and even progression to non-alcoholic steatohepatitis. Hepatologists should include MAFLD subjects in the high-risk group, intensify preventive measurements, and prioritize their vaccination.

Core Tip: It is notorious that obesity represents a risk for coronavirus disease 2019 (COVID-19) severity. However, COVID-19 often causes liver alterations or provokes the progression of pre-existing liver diseases. This review outlines the role of metabolic dysfunction-associated fatty liver disease in COVID-19 severity. The evidence available thus far supports the notion that metabolic dysfunction-associated fatty liver disease represents a more intense risk than obesity for hospitalization, extended viral shedding, and death. A pro-inflammatory state with inflammasome activation, implying increased susceptibility to cytokine storm syndrome, underlies these findings and emerges as, in addition to massive vaccination of subjects with liver diseases, potential targets for therapeutic strategies.

INTRODUCTION

The infection caused by the coronavirus severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) [coronavirus disease 2019 (COVID-19), *Beta-coronavirus* genus, *Coronaviridae* family] was declared as a pandemic in March 2020 by the World Health Organization and caused an unprecedented burden to health systems worldwide because of its harmful evolution to severe acute respiratory syndrome[1,2]. Although most cases are asymptomatic, this fact facilitated the rapid viral spread worldwide, resulting in overloaded hospitals due to the extended hospitalizations and the frequent need for mechanical ventilation that severe COVID-19 requires[3,4]. From December 2019 to February 14, 2021, COVID-19 caused almost 2.4 million deaths, and more than 108 million confirmed cases in 222 countries or territories[1].

The SARS-CoV-2 relies on binding to the angiotensin-converting enzyme 2 (ACE2) receptor to enter target cells and start viral shedding[5]. Much as the infection frequently happens through the nasopharyngeal epithelium and has the lungs as the chief target with respiratory commitment, COVID-19 represents a systemic disease with adverse cardiac, circulatory, and cerebral outcomes after hematogenic propagation and virus neurotropism for the vagus nerve that links lungs to the central nervous system[6-8]. Of note, the presence of ACE2 receptors in the brush border of intestinal enterocytes and cholangiocytes makes possible the occurrence of gastrointestinal symptoms and aggravation of pre-existing metabolic diseases[9,10]. Figure 1 summarizes the most common infection and propagation pathways of SARS-CoV-2 with adverse effects in the human body.

In this regard, overweight emerged as a high-risk factor to hospitalization due to COVID-19, surpassed only by age ≥ 65 in the New York population[11], emphasizing the high risk of severe COVID-19. Body mass gain yields metabolic alterations that start in the adipose tissue, with hypertrophy and hyperplasia as attempts to buffer excessive energy intake by fat storage[12]. In the long run, adipogenesis capacity exhausts, and the existing enlarged adipocytes trigger lipolysis to manage a continuous lipid accumulation through lipogenesis[13,14]. At this stage, excessive non-esterified fatty acids (NEFAs) are diverted to other organs like the liver and drive steatosis[15].

Hepatic steatosis is known as the hepatic manifestation of metabolic syndrome. Hence, metabolic disturbances such as insulin resistance, systemic arterial hypertension, and meta-inflammation, typical from obesity, coexist with this hepatic impairment[15,16]. Therefore, it was recently renamed metabolic dysfunction-associated fatty liver disease (MAFLD) as it represents better the constellation of metabolic impairments involved in its etiology than the former acronym non-alcoholic fatty liver disease[17].

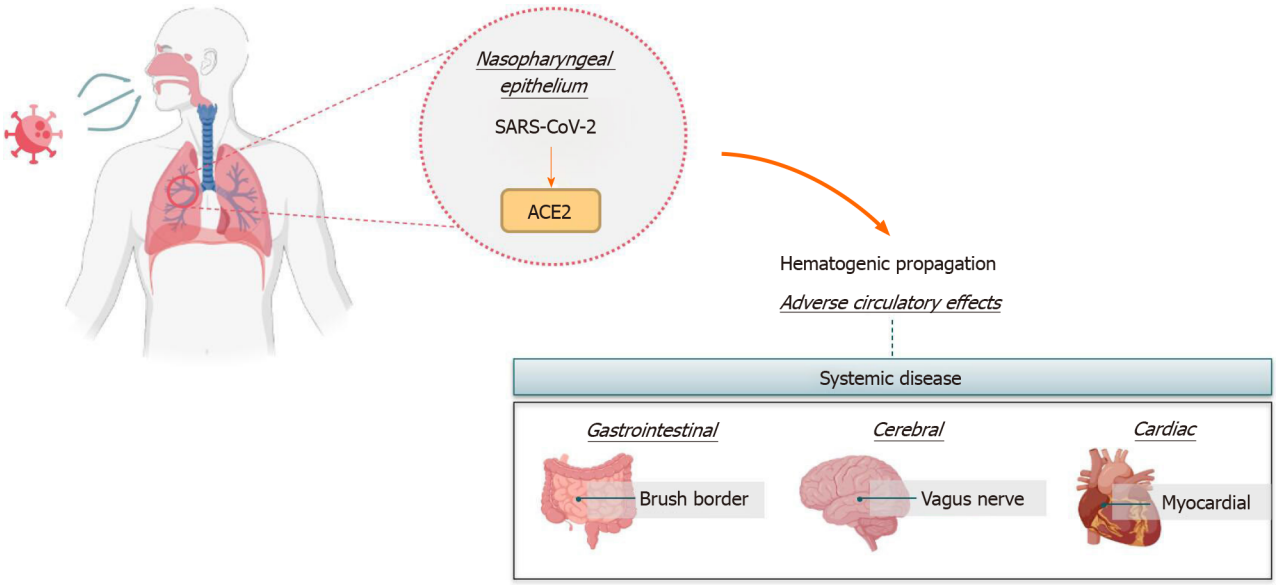

Figure 1 Most common infection and propagation pathways of severe acute respiratory syndrome coronavirus 2 in the human body.
SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2; ACE2: Angiotensin-converting enzyme 2.

MAFLD in obesity comprises lipotoxic effects on the liver by proinflammatory adipokines that influence hepatic energy metabolism in an endocrine fashion[18]. The inflamed adipose tissue has been linked to enhanced viral systemic spread, entry, and viral shedding in COVID-19 obese subjects[19]. This hypothesis complies with an intensified cytokine storm in obese patients with COVID-19, explaining the poor outcomes[20].

Among the metabolic impairments caused by excessive body fat, pre-existing MAFLD can result in COVID-19 patients being more prone to hospitalization and worsening metabolic conditions[21]. This review outlined the impact MAFLD exerts on COVID-19 severity in obese subjects in addition to the possible mechanistic links to poor outcomes. The information gathered relating to COVID-19 was that available on PubMed from the beginning of the pandemic until the end of 2020.

OBESITY AND FATTY LIVER: EPIDEMIOLOGY AND PATHOGENESIS

MAFLD is the most common chronic hepatic disease worldwide. Its global prevalence is around 25%, with the highest prevalence in the Middle East (31.79%) and South America (30.45%)[22]. MAFLD is not a disease exclusive of obesity, but obese subjects fall victim to fatty liver more frequently, as their insulin-resistant and pro-inflammatory adipokine profile converge to the accumulation of ectopic fat[18,23]. Recent evidence shows the presence of obesity among 51.34% of MAFLD patients and 81.83% of patients with non-alcoholic steatohepatitis (NASH)[22]. Although MAFLD silently initiates without symptoms, its harmful progression towards NASH (with hepatic fibrosis), cirrhosis, or hepatocellular carcinoma challenges the scientific community to understand its metabolic basis.

The pathogenesis of fatty liver is multifactorial and linked to diet, metabolic factors, intestinal microorganisms, and genetics. Exposure of hepatocytes to high levels of lipids and carbohydrates, usually included in the diet of obese individuals, leads to glucolipotoxicity and predisposes to MAFLD. Excessive circulating NEFAs come from accelerated lipolysis and reduced fatty acid uptake in subcutaneous adipose tissue, triggering ectopic fat accumulation (in the liver, skeletal muscle) and, therefore, insulin resistance in multiple organs[24]. The release of NEFAs from dysfunctional and insulin-resistant adipocytes causes lipotoxicity, induced by the ectopic accumulation of toxic metabolites stemmed from triglycerides. Hence, inflammatory pathways are activated, and cellular dysfunction occurs with liver incapacity to eliminate excessive NEFAs, ending up in lipoapoptosis, an essential feature of NASH[18].

Hepatic steatosis comprises approximately 60% of hepatic triglycerides from adipose tissue, 25% from *de novo* lipogenesis and 15% from dietary lipids[25]. Moreover, visceral adipose tissue is more closely related to the fatty liver than subcutaneous

adipose tissue, possibly because the former is more resistant to insulin than the latter[26]. Increasing evidence shows that during adipose tissue expansion in obesity, there are changes in the expression and secretion of adipokines, favoring pro-inflammatory mediators for the development of MAFLD, progression to NASH, and possible development of liver cirrhosis[27]. Leptin and adiponectin are the adipokines widely described in the literature as influences on fatty liver development.

In animal models of MAFLD, leptin seems to have a double action: It can protect from hepatic steatosis, at least in the early stages of the disease, but it also can act as an inflammatory and fibrogenic factor when the disease persists or progresses, that is when the mechanisms of counterweight do not limit it[28-30]. In this sense, leptin can directly increase the production of pro-inflammatory cytokines, such as tumor necrosis factor (TNF)-α, interleukin (IL)-6, IL-12, and IL-18, the chemokines IL-8 and monocyte chemoattractant protein 1, and the lipid mediators prostaglandin E2, leukotrienes, and LTB4, being responsible for the noxious MAFLD progression[26]. Persisting hyperleptinemia promotes liver inflammation and fibrosis as the disease progresses to NASH.

On the contrary, adiponectin decreases as the fat mass increases. At physiological conditions, adiponectin exerts an anti-steatotic effect on hepatocytes by increasing beta-oxidation, while decreasing gluconeogenesis, fatty acid input to the liver, and *de novo* lipogenesis. Furthermore, high molecular weight adiponectin isoform has anti-inflammatory properties like TNF-α blockade and downregulation, resulting in insulin resistance alleviation[29]. In the case of positive energy balance and overweight onset, this critical balance is disrupted towards the side of TNF-α, contributing to chronic low-grade inflammation, insulin resistance, and MAFLD[26]. In humans, patients with fatty liver exhibit low adiponectin concentrations, whereas control subjects show high adiponectin concentrations. However, the adiponectin concentrations are even lower in patients with NASH than in MAFLD. It can be argued that, initially, adipokine actions can limit hepatic steatosis, but as adipose tissue expands, adipokine changes become harmful and contribute to MAFLD progression[18].

An innovative concept proposes that the gut-liver axis plays a crucial role in the pathogenesis and progression of MAFLD[31]. Although there are some controversies, animal and human studies show that gut microbiota from obese subjects comprises an increase in the relative abundance of firmicutes followed by a decrease of bacteroidetes[32]. Moreover, a higher prevalence of gram-negative bacteria, such as proteobacteria, and reduced phylum-level diversity are usual features in non-alcoholic fatty liver disease patients[33]. Changes in the gut microbiota in obesity disrupt the intestinal endothelial barrier, eliciting systemic bacterial translocation and hepatic inflammation by microbiota-related endotoxins and short-chain fatty acids that reach the liver through the portal vein[26].

Concerning a possible genetic predisposition to MAFLD, the adipose tissue of obese patients with fatty liver has upregulation of pro-inflammatory genes and macrophages-producing cytokines compared to obese subjects that do not develop MAFLD[34]. This observation raises the hypothesis of a genetic polymorphism that explains why some obese individuals develop MAFLD, while others do not[35]. Briefly, an allele in the *PNPLA3* gene is a surrogate for the MAFLD onset and hepatic inflammation[36]. Other genes like *FDFT1*, *TM6SF2*, *GCKR*, and *MBAT7* have already been linked to the progression of MAFLD[37]. However, the complete identity of "MAFLD related to genetics" still needs to be further investigated.

CORONAVIRUS DISEASE 2019 PROGNOSIS IN METABOLIC DYSFUNCTION-ASSOCIATED FATTY LIVER DISEASE PATIENTS

Hepatic outcomes of COVID-19

The clinical course of COVID-19 encompasses elevated aspartate aminotransferase and alanine aminotransferase combined with a mild rise in bilirubin levels[38]. A study in China found that 37.3% of patients had an abnormal liver function at hospital admission[39]. In Mexico, 96.8% of patients (n = 150) had a liver impairment but without an association between abnormal liver function tests and mortality[40]. A Chinese study has suggested aspartate aminotransferase as a promising marker to predict hospital stay, with higher values suggestive of prolonged periods. However, this information might not apply to different populations and should be better addressed[41].

Concerning histological liver changes, a post-mortem study in Belgium revealed histological alterations in all 14 deceased COVID-19 patients, with central lobular necrosis and portal inflammation as the most frequent hepatic histological damages[42].

In agreement with this, COVID-19 patients with acute respiratory distress syndrome showed mild microvesicular steatosis and lobular and portal activity in China[43]. The most common post-mortem histological findings in 40 North Americans that died from COVID-19 were fatty liver (75%), mild acute hepatitis (50%), and portal inflammation (50%). However, the fat distribution pattern was not typical of MAFLD and might stem from the administration of steroids during hospitalization[44].

In line with these previous findings, a Chinese study showed 96% of hepatocellular liver injury among COVID-19 hospitalized subjects, with 50% of them presenting liver injury at hospital admission and 75.2% showing liver injury during hospital stay[45]. This observation emphasizes that not only could the pre-existing hepatic disease produce a severe form of COVID-19, but the virus itself can trigger liver damage. Indeed, it is hard to distinguish whether liver injury during hospital stay stemmed from the COVID-19 infection or some drugs used as attempts to stop viral replication[45,46]. Hepatotoxic effects of paracetamol, lopinavir/ritonavir, remdesivir, chloroquine, tocilizumab, and uminefovir can cause microvesicular steatosis and mild hepatic inflammation[47]. These findings are depicted in Figure 2.

METABOLIC DYSFUNCTION-ASSOCIATED FATTY LIVER DISEASE IN CORONAVIRUS DISEASE 2019 PATIENTS: INCREASED SEVERITY WHEN COMPARED TO OBESITY?

MAFLD is considered a pre-existing condition that turns individuals more vulnerable to COVID-19 infection and virus-related complications. Furthermore, these patients may have an increased risk of MAFLD to NASH progression, a long-term consequence of viral infection[48]. As MAFLD is frequently associated with overweight/obesity, it is sometimes hard to separate the single effect each one exerts on COVID-19 severity. Herein, we outlined the most recent evidence after almost 1 year from the beginning of the pandemic.

The presence of MAFLD could predict severe COVID-19 (more than 2-fold prevalence) and critical illness in patients younger than 60 years old in China[49], in addition to longer viral shedding time (17.5 d *vs* 12.1 d on average)[45]. Furthermore, Chinese MAFLD patients without type 2 diabetes showed a 4-fold high risk for severe COVID-19, and a 12% increase in the risk for severe COVID-19 for each 1-unit augmentation in body mass index[50]. Obesity conferred a 6 times greater risk of severe infection in Chinese patients with MAFLD [odds ratio (OR) did not adapt 5.77, P = 0.029]. The association of obesity with COVID-19 severity remained after adjusting for many factors (age, sex, smoking habits, diabetes, hypertension, and dyslipidemia, OR compatible 6.32, P = 0.033)[51].

Conversely, a study considering a large sample in the United States pointed out MAFLD/NASH as a greater risk for hospitalization than obesity itself[52]. In line with this, increased rates of COVID-19 clinical severity among MAFLD patients have been observed even after controlling for obesity, suggesting that the effect of MAFLD on disease severity may be more expressive than increased body mass index[53]. MAFLD/NASH might have a significant role in maximizing chronic inflammation and hypercoagulability, emerging as a pivotal surrogate for severe COVID-19 cases[52].

A study in Brazil showed that hepatic steatosis was found in computed tomography (CT) among 31.9% of COVID-19 positive patients, while only 7.1% of COVID-19 negative subjects showed hepatic steatosis. The OR was 4.698 after adjusting for age and sex, but they did not evaluate the severity or poor clinical outcomes[54]. In this context, a meta-analysis carried out with six Chinese studies with 1293 participants revealed that patients with COVID-19 showed a high percentage of MAFLD and increased risk of COVID-19 severity, indicating a need for intensive monitoring of MAFLD patients with COVID-19[55].

In agreement with this, MAFLD entails a constellation of metabolic abnormalities that can be aggravated during viral infection. Through univariate analysis, it was shown that metabolic syndrome leads to a higher cumulative incidence of COVID-19, with liver damage being the most associated with this outcome[56]. Moreover, COVID-19 can cause hypoglycemia or hyperglycemia, compromising glycemic control due to sedentarism, anxiety, or viral tropism to pancreatic tissue[57]. Continuous monitoring of blood glucose is encouraged as hypoglycemia should be avoided, and glycemia should not exceed 180 mg/dL or 10 mmol/L in COVID-19 patients. MAFLD patients commonly show hypertension, and surveillance of medication and blood pressure levels can avoid shock in severe COVID-19 cases[58].

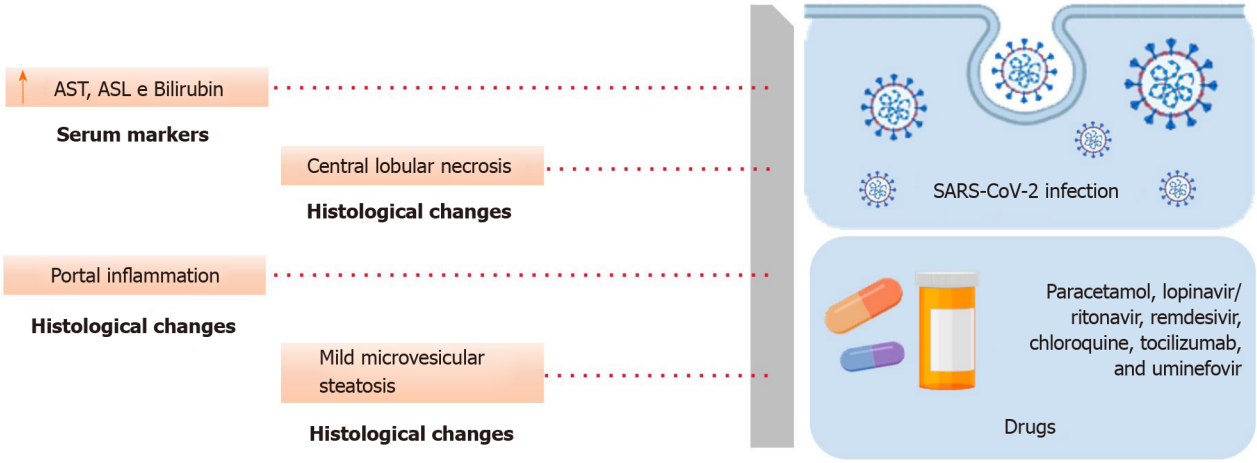

Figure 2 Clinical features and hepatological changes due to severe acute respiratory syndrome coronavirus 2 infection (upper panel) and hepatotoxic effects of some drugs used as an attempt to treat coronavirus disease 2019 (lower panel). SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2; AST: Aspartate aminotransferase.

Despite showing similar COVID-19 symptoms to non-MAFLD, fever in 66.8% and cough in 55.7% of patients[39], MAFLD patients showed higher chances of intensive care unit admission (intensive care unit, OR: 1.60), intubation (2.51), need for vasopressors (1.22), and alanine aminotransferase > 5 times upper limit of normal (2.12)[59]. In univariate analyses, when compared with patients without chronic liver disease, subjects with MAFLD had significantly higher rates of intensive care unit admission (50.9% *vs* 35.2%, $P = 0.0095$) and need for mechanical ventilation (49.1% *vs* 30.4%, $P = 0.006$)[53].

A possible explanation for increased COVID-19 severity due to MAFLD includes higher C reactive protein (CRP) (107 *vs* 91.2 mg/L, $P = 0.05$) concentrations in COVID-19 patients with MAFLD than controls without MAFLD in London[60]. This favored pro-inflammatory state can result in high death rates, as MAFLD patients who died during hospitalization had higher concentrations of inflammatory markers like ferritin[61], prothrombin time, and lactate dehydrogenase than patients with MAFLD who survived hospitalization[60]. Notably, the combination of high CRP levels with low lymphocyte count predicted prolonged hospital stay (median 23 *vs* 18 d; $P = 0.037$) and a higher proportion of severe COVID-19 (33.3% *vs* 14.7%, $P = 0.007$) compared to non-obese patients[50]. Figure 3 outlines the mild symptoms and the factors that lead to severe forms of COVID-19.

Concerning imaging exams and COVID-19 prognosis in MAFLD patients, a CT study in the Mexican population proposed the liver to spleen ratio (CTL/S) as a surrogate for the diagnosis of MAFLD in COVID-19 patients, given that spleen does not store fat. Both organs are visualized in the CT performed to evaluate the degree of pulmonary commitment because it shows the upper abdomen, and the CTL/S ≤ 0.9 indicated the presence of fatty liver. Hepatic steatosis was associated with severe COVID-19 pneumonia, and CTL/S could be a substantial aid to estimate the prognosis of COVID-19 in MAFLD patients[62].

A recent systematic review evaluating clinical studies from China, Israel, and the United States showed that the presence of hepatic steatosis is a predictor for symptomatic and severe COVID-19, even after the adjustment for obesity presence (OR: 2.358, $P < 0.001$)[63]. Moreover, COVID-19 infection in pre-existing chronic liver disease patients from 13 different Asian countries caused decompensation in 20% of the cirrhotic patients with high mortality. Among MAFLD patients, the presence of comorbidities like obesity and type 2 diabetes entailed a risk of liver injuries due to COVID-19 infection[64]. In agreement, a recent Indian study using non-COVID-19 cirrhotic patients as controls showed that COVID-19 infection resulted in a 100% mortality rate in patients with acute-on-chronic liver failure in comparison with 53.3% in acute-on-chronic liver failure controls. The poor outcome that COVID-19 imposes on cirrhotic patients includes the need for mechanical ventilation and urges physicians and hepatologists to consider patients with chronic liver diseases as a high-risk group for COVID-19 and guarantee rigorous preventive measures[65].

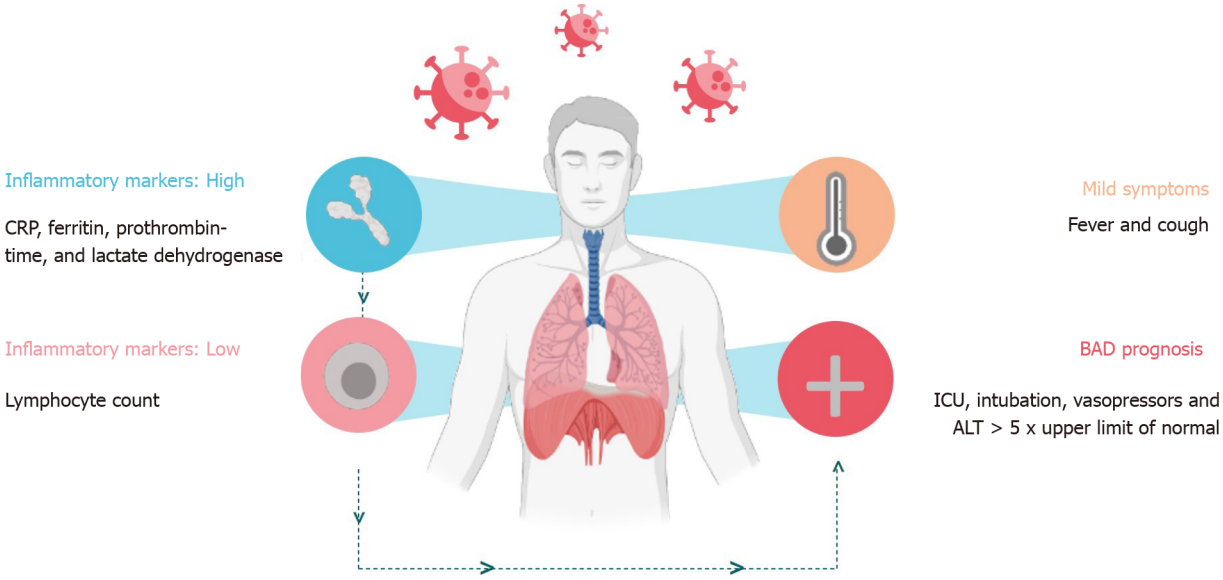

Figure 3 Mild symptoms, inflammatory markers, and serious developments of coronavirus disease 2019. ALT: Alanine aminotransferase; CRP: C reactive protein; ICU: Intensive care unit.

INVOLVED PATHWAYS IN INCREASED SEVERITY OF CORONAVIRUS DISEASE 2019 IN OBESE SUBJECTS WITH METABOLIC DYSFUNCTION-ASSOCIATED FATTY LIVER DISEASE

The post-mortem evaluation of the livers from people that died of COVID-19 often reveals that the virus causes inflammatory and immune-mediated liver damage rather than cytopathic harm[43]. The observation of different immune cell exudates near the portal area reinforces this hypothesis and links hepatic damage to the cytokine storm syndrome (CSS), which emerges as a promising explanation for the increased severity of COVID-19 in obese patients with MAFLD[66,67].

To put it simply, CSS comprises the activation of inflammasomes and the following release of pro-inflammatory cytokines like IL-1β and IL-6[68,69]. The inflammasomes are complexes of proteins that reside in macrophages, activated by tool-like receptors binding to a pathogen-associated molecular pattern or damage-associated molecular patterns[70,71]. The liver has the largest macrophage reservoir in the body (the Kupfer cells); and, therefore, the activation of the NLR family pyrin domain containing 3 (NLRP3) inflammasome can damage this organ and acts as a promising marker of COVID-19 severity in obese patients[43,72].

The adipose tissue expansion in obesity triggers fatty liver and inflammasome activity by lipotoxicity[73]. The dramatic changes that adipose tissue macrophages undergo during weight gain (polarization to M1 state) reflect in the Kupfer cells that produce inflammatory chemokines and cytokines, generating hepatic insulin resistance and inflammation[74,75]. In this context, IL-6 emerges as a pivotal marker of COVID-19 worsening as it can trigger the CSS[76], besides being generally high in obese and MAFLD subjects[77].

It can be supposed that the obese patient with MAFLD before catching COVID-19 could show a maximized CSS, which might be linked to the increased need for longer hospitalizations and intensive care. Consistent with this suggestion, inflammasome activation elicits massive augmentation of pro-inflammatory cytokine concentrations and induces pyroptosis[78]. Cell death mediated by pyroptosis in macrophages relies on NLRP3 activation and provokes severe acute respiratory syndrome in COVID-19 patients, picturing a frame of aggravated disease by the CSS in MAFLD patients[79]. Furthermore, severe obese subjects can show serious infections in the lower respiratory tract due to mechanical dysfunction, which also makes them more prone to secondary infections[80].

Additional mechanisms related to the intensification of COVID-19 in MAFLD obese patients include the hepatocellular hypoxia in chronic liver diseases that leads to ACE2 overexpression[81]. Hence, these changes can cope with MAFLD progression towards NASH by the overexpression of ACE2 in endothelial cells and the consequent

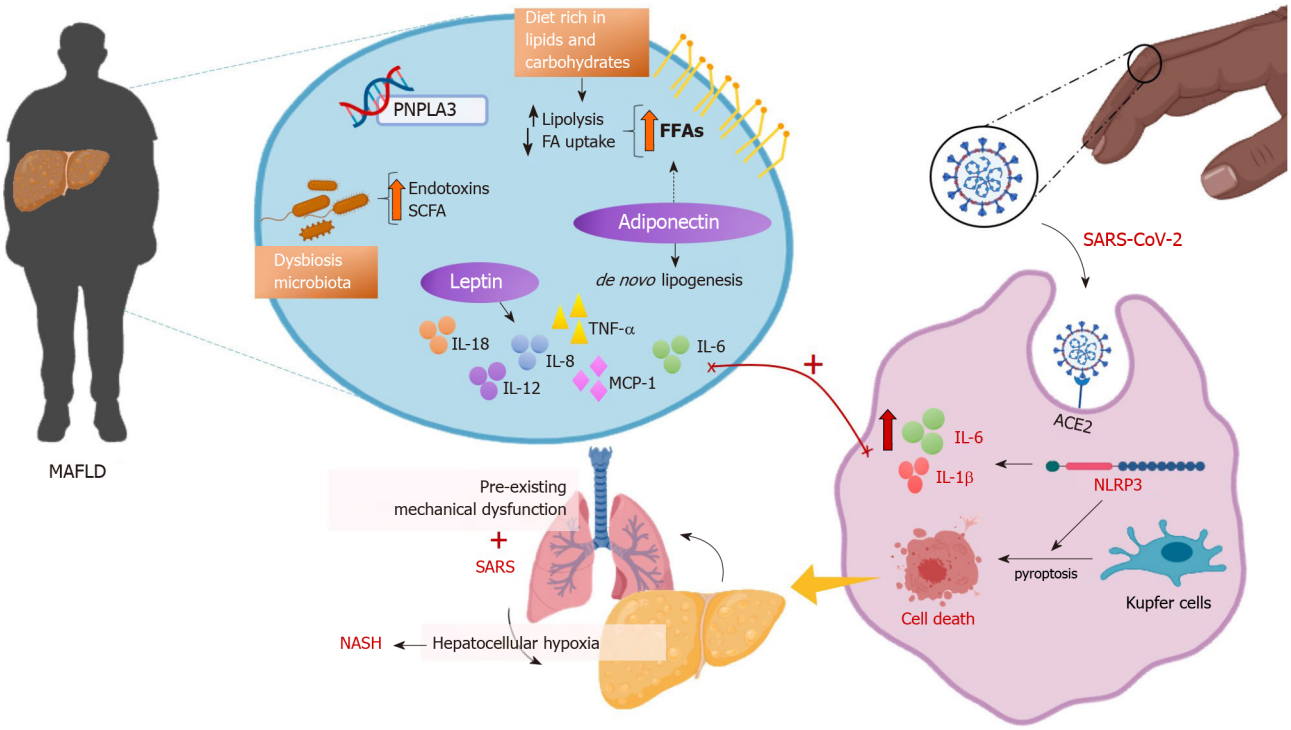

Figure 4 Graphical abstract. Metabolic dysfunction-associated fatty liver disease (MAFLD) patients usually show a constellation of metabolic impairments that include altered adipokine profile, glucolipotoxicity with ectopic lipid accumulation, and gut dysbiosis, besides a genetic background that favors these hepatic alterations and pre-existing mechanical lung dysfunction when obese. These clinical conditions before coronavirus disease 2019 (COVID-19) infection can aggravate the cytokine storm syndrome, with activation of macrophages that reside in the liver (Kupffer cells), resulting in inflammasome activation and cell death by pyroptosis. MAFLD patients are at high risk of complications and severe COVID-19 clinical course, with frequent mechanical ventilation, prolonged hospitalizations, and extended viral shedding. Upon survival, COVID-19 may act as a surrogate for MAFLD-non-alcoholic steatohepatitis progression, and hepatocellular hypoxia seems to underlie this process. ACE2: Angiotensin-converting enzyme 2; FFA: Free Fatty Acid; IL: Interleukin; MAFLD: Metabolic dysfunction-associated fatty liver disease; MCP1: Monocyte chemoattractant protein 1; NASH: Non-alcoholic steatohepatitis; NEFAs: Non-esterified fatty acids; NLRP: NLR family pyrin domain-containing; SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2; SCFA: Short-chain fatty acid; TNF-α: Tumor necrosis factor.

increased reactive oxygen species production, inflammatory pathways activated in the Kupfer cells, and peroxisome proliferator-activated receptor-alpha down-regulation with pro-lipogenic gene expression and steatosis maximization[82,83]. In this regard, the presence of hepatic steatosis before viral infection can amplify the symptoms of COVID-19 as the lipotoxicity sustains the activation of Kupfer cells and allows the progression to liver fibrosis. The main pathways involved with the severity of COVID-19 in MAFLD patients are depicted in Figure 4.

CONCLUSION

In conclusion, pre-existing MAFLD increases the risk of severe COVID-19 that requires hospitalization. MAFLD itself can represent an increased predisposition to CSS, and high CRP concentrations, NLRP3 activation, and IL-6 concentrations emerge as likely surrogates for the need for mechanical ventilation, with high death rates or evolution to NASH among survivors.

It is urgent to consider that MAFLD surpassed obesity as a risk factor to COVID-19 severity in populations with diverse genetic backgrounds. Therefore, MAFLD subjects should be ranked high-risk to catch COVID-19, submitted to rigorous preventive measurements, and classified as a prioritized group for vaccination.

ACKNOWLEDGEMENTS

The authors would like to thank all physicians, health professionals, and researchers for working uninterruptedly during pandemics. Your dedication helped to gather the information that saved millions of lives and resulted in vaccines in an unprecedented

minimal time.

Abstract

Gastroesophageal reflux disease (GERD) is one of the most commonly encountered digestive diseases in the world, with the prevalence continuing to increase. Many patients are successfully treated with lifestyle modifications and proton pump inhibitor therapy, but a subset of patients require more aggressive intervention for control of their symptoms. Surgical treatment with fundoplication is a viable option for patients with GERD, as it attempts to improve the integrity of the lower esophageal sphincter (LES). While surgery can be as effective as medical treatment, it can also be associated with side effects such as dysphagia, bloating, and abdominal pain. Therefore, a thorough pre-operative assessment is crucial to select appropriate surgical candidates. Newer technologies are becoming increasingly available to help clinicians identify patients with true LES dysfunction, such as pH-impedance studies and high-resolution manometry (HRM). Pre-operative evaluation should be aimed at confirming the diagnosis of GERD, ruling out any major motility disorders, and selecting appropriate surgical candidates. HRM and pH testing are key tests to consider for patients with GERD like symptoms, and the addition of provocative measures such as straight leg raises and multiple rapid swallows to HRM protocol can assess the presence of underlying hiatal hernias and to test a patient's peristaltic reserve prior to surgery.

Key Words: Gastroesophageal reflux disease; Fundoplication; High resolution manometry; pH-impedance; Anti-reflux surgery; Pre-operative assessment

Core Tip: The goal of this review is to discuss recent technological advancements that have utility for patients with gastroesophageal reflux disease (GERD) as a pre-operative assessment for anti-reflux surgery. Surgical treatment of GERD is centered around improving the integrity of the lower esophageal sphincter, therefore it is crucial to rule out other esophageal pathologies that may present with GERD-like symptoms. Advances in pH-impedance studies allow for assessment of patients with weak acid reflux of non-erosive reflux disease. High resolution manometry with the addition of provocative measures can uncover underlying esophageal motility disorders with GERD-like symptoms.

INTRODUCTION

Gastroesophageal reflux disease (GERD), defined as an abnormal reflux of gastric contents with associated symptoms, is one of the most common digestive diseases in the world, and currently affects up to 30% of individuals in North America[1,2]. While the disease is commonly encountered in the outpatient setting, the true number of individuals with GERD could be even higher, as some patients may self-treat with over-the-counter medications[3]. Studies have also found the number of patients with GERD continues to rise, which may be due to the growing obesity epidemic[1]. Additionally, GERD is one of the costliest digestive diseases in the United States, with up to half of the cost attributed to the long term use of proton pump inhibitor (PPI) therapy[4].

The American College of Gastroenterology (ACG) guidelines state that a presumptive diagnosis of GERD can be made in patients with classical symptoms such as heartburn or regurgitation, with further diagnostic evaluation such as an upper endoscopy recommended for patients with alarm symptoms[5]. The ACG recommends management of these patients begin with lifestyle modifications, including weight loss and dietary changes, along with an 8-week course of PPI therapy[5]. While this approach is effective for most patients, a subset of patients may require further management including surgical options such as fundoplication. Surgical treatment of GERD is as effective as medical management in appropriate candidates and is currently recommended for reasons including complications from PPIs, medication non-compliance, and large hiatal hernias[3,5]. Additionally, the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) recommends surgical therapy for patients with GERD who: have failed medical management, request surgery due to quality of life issues related to long term medication use, have complications such as Barrett's esophagus, or have extra-esophageal symptoms related to their GERD[6].

While surgical treatment of GERD may be as effective as medical therapy, complications are also possible. The most commonly reported side effects of surgery include dysphagia, belching, and increased abdominal bloating, though it is also possible to develop more severe complications requiring repeat surgery[7]. A total 360° Nissen Fundoplication is the most common surgical treatment for GERD, but variations also exist involving differing degrees of wrapping. Studies have found partial fundoplication to be similarly effective for reducing reflux symptoms, and may also have less post-operative dysphagia and bloating[8]. This is supported by a level 1 recommendation from the SAGES that partial fundoplication is associated with less dysphagia and similar patient satisfaction[6]. Additionally, newer techniques such as the Linx procedure [which uses a circlet of magnets to augment the lower esophageal sphincter (LES)] have shown similar short-term outcomes for the treatment of GERD when compared to fundoplica-tion. More research is needed on the long-term outcomes[9].

While surgical treatment of GERD can successfully relieve symptoms in up to 90% of patients[10], a thorough pre-operative assessment is necessary to identify appropriate surgical candidates. The underlying mechanism of anti-reflux surgery is to improve the integrity of the LES. Therefore, in order to achieve the best post-operative outcomes, it is crucial to confirm a patient's symptoms are due to GERD and not another underlying pathology. Otherwise, a patient would likely continue experiencing symptoms post-operatively along with potentially developing complications such as dysphagia.

Newer technologies are becoming increasingly available for the assessment of patients with reflux symptoms and can help confirm the diagnosis of GERD. Improvements in pH studies with the inclusion of impedance measurements may help identify patients with non-erosive reflux disease (NERD). Additionally, advancements in high resolution manometry (HRM) help further classify esophageal pathologies and identify patients as having disorders with GERD like symptoms (Table 1). In this review, we aim to provide a guide for the pre-operative assessment and evaluation of patients with reflux. We will focus on newer technologies that can be used to identify appropriate candidates for anti-reflux surgery by confirming the diagnosis of GERD and ruling out other esophageal diseases.

The ACG guidelines state that a presumptive diagnosis of GERD can be made in patients with classical symptoms such as heartburn or regurgitation, with further diagnostic evaluation such as an upper endoscopy recommended for patients with alarm symptoms[5]. The ACG recommends management of these patients begin with lifestyle modifications, including weight loss and dietary changes, along with an 8-wk course of PPI therapy[5]. While this approach is effective for most patients, a subset of patients may require further management including surgical options such as fundoplication. Surgical treatment of GERD is as effective as medical management in appropriate candidates and is currently recommended for reasons including complications from PPIs, medication non-compliance, and large hiatal hernias[3,5]. Additionally, the SAGES recommends surgical therapy for patients with GERD who: have failed medical management, request surgery due to quality of life issues related to long term medication use, have complications such as Barrett's esophagus, or have extra-esophageal symptoms related to their GERD[6].

While surgical treatment of GERD may be as effective as medical therapy, complications are also possible. The most commonly reported side effects of surgery include dysphagia, belching, and increased abdominal bloating, though it is also possible to develop more severe complications requiring repeat surgery[7]. A total 360° Nissen fundoplication is the most common surgical treatment for GERD, but variations also exist involving differing degrees of wrapping. Studies have found partial fundoplication to be similarly effective for reducing reflux symptoms, and may also have less post-operative dysphagia and bloating[8]. This is supported by a level 1 recommendation from the SAGES that partial fundoplication is associated with less dysphagia and similar patient satisfaction[6]. Additionally, newer techniques such as the Linx procedure (which uses a circlet of magnets to augment the LES) have shown similar short-term outcomes for the treatment of GERD when compared to fundoplication. More research is needed on the long-term outcomes[9].

While surgical treatment of GERD can successfully relieve symptoms in up to 90% of patients[10], a thorough pre-operative assessment is necessary to identify appropriate surgical candidates. The underlying mechanism of anti-reflux surgery is to improve the integrity of the LES. Therefore, in order to achieve the best post-operative outcomes, it is crucial to confirm a patient's symptoms are due to GERD and not another underlying pathology. Otherwise, a patient would likely continue experiencing symptoms post-operatively along with potentially developing complications such as dysphagia.

Newer technologies are becoming increasingly available for the assessment of patients with reflux symptoms and can help confirm the diagnosis of GERD. Improvements in pH studies with the inclusion of impedance measurements may help identify patients with NERD. Additionally, advancements in HRM help further classify esophageal pathologies and identify patients as having disorders with GERD like symptoms (Table 1). In this review, we aim to provide a guide for the pre-operative assessment and evaluation of patients with reflux. We will focus on newer technologies that can be used to identify appropriate candidates for anti-reflux surgery by confirming the diagnosis of GERD and ruling out other esophageal diseases.

Table 1 Esophageal disorders with gastroesophageal reflux disease-like symptoms

Diagnosis	Definition	Clinical symptoms	Pathophysiology	Diagnostic evaluation
Structural disorders				
GERD	Symptoms and complications secondary to the reflux of gastic contents above the lower esophageal sphincter[5]	Regurgitation, reflux, dysphagia, retrosternal non-cardiac chest pain, globus sensation, extra esophageal symptoms	Abnormal transient LES relaxation, LES dysfunction secondary to anatomic abnormality such as hiatal hernia	Upper endoscopy, high resolution manometry, ambulatory pH testing, ambulatory impedance testing
Weak acid reflux	Symptoms secondary to reflux of gastric contents above the LES with pH ranging from 4-7[32]	Reflux, regurgitation, non-cardiac chest pain	Persistent reflux with pH from 4-7 due to transient LES relaxation	pH studies - on maximum PPI therapy
Eosinophilic esophagitis	Presence of symptoms of esophageal dysfunction such as reflux or dysphagia, eosinophilic inflammation on esophageal biopsy with ≥ 15 eosinophils per high power field, and exclusion of other disorders with similar presentations[81]	Dysphagia, reflux, non-cardiac chest pain	Eosinophil mediated inflammatory response in the esophagus secondary to allergenic antigens	Upper endoscopy with biopsy
Motility disorders				
Achalasia	Elevated IRP > 15 mmHg and absence of normal peristalsis[44]	Dysphagia, regurgitation, non-cardiac chest pain	Failure of LES relaxation and absence of normal peristalsis	High resolution manometry, upper endoscopy, barium studies
Absent peristalsis	Systemic symptoms with aperistalsis with failed peristalsis on 100% of swallows[49]	Reflux, dysphagia, non-cardiac chest pain	Lower esophageal collagen deposition leading to LES dysfunction	High resolution manometry, autoimmune antibody workup
Distal esophageal spasm	Normal IRP and ≥ 20% premature contractions with DCI > 450 mmHg[44]	Dysphagia, regurgitation, reflux, non-cardiac chest pain	Impaired inhibition and coordination of esophageal muscle contraction	High resolution manometry, Barium swallow "corkscrew esophagus"
Hypercontractile esophagus	Minimum of 2 swallows with DCI > 8000 mmHg[44]	Retrosternal non-cardiac chest pain, dysphagia, regurgitation	Increased contraction of esophageal smooth muscle	Upper endoscopy, barium studies, high resolution manometry
Esophagogastric junction outflow obstruction	Elevated median IRP > 15 mmHg with evidence of peristalsis on swallows[44]	Dysphagia, reflux, regurgitation	Impairment of esophagogastric junction relaxation with normal or weakened esophageal peristalsis	High resolution manometry, needs to be confirmed with further studies such as barium swallow or endoflip, must rule out artifact that can be seen with a hiatal hernia
Opioid induced esophageal dysfunction	Presence of symptoms of esophageal dysfunction with manometric evidence of esophageal dysmotility in the presence of chronic opioid use[55]	Regurgitation, dysphagia, reflux	Opioid induced blocking of esophageal inhibitory signals leading to increased spastic contraction and decreased LES relaxation	Clinical history, high resolution manometry
Gastroparesis	Presence of symptoms such as nausea, vomiting, and early satiety with mechanical obstruction ruled out and evidence of delayed gastric emptying on testing[82]	Nausea, reflux, regurgitation, early satiety, abdominal pain and bloating	Multiple etiologies caused slowed peristalsis and delayed gastric emptying	Gastric emptying study
Functional disorders				
Functional heartburn	Presence of burning retrosternal discomfort, no symptoms relief on optimal therapy, absence of GERD or EOE as cause of symptoms, and absence of major motility disorder[83]	Reflux, regurgitation, globus sensation	Potentially secondary to increased esophageal sensitivity	Upper endoscopy, high resolution manometry, pH-impedance studies
Reflux hypersensitivity	Presence of retrosternal chest pain, normal endoscopy and absence of EOE, absence of major motility disorder, and symptom association with reflux events with normal acid exposure on pH-impedance tests[83]	Reflux	Hypersensitization of esophageal nerve endings leading to pain secondary to physiologic esophageal stimuli	Upper endoscopy, high resolution manometry, pH-impedance studies
Rumination	Must include both persistent regurgitation of recently ingested food with subsequent spitting or re-mastication, and regurgitation that is not preceded by retching[83]	Regurgitation (frequently after meals), reflux	Behavioral contraction of abdominal muscles leading to increased intragastric pressure and reflux	Clinical history, high resolution manometry, pH-impedance studies
Supragastric	Presence of frequent repetitive	Frequent belching, reflux,	Behavioral swallowing of air	Clinical history, high

belching	belching, no established clinical correlate for gastric belching, and evidence of supragastric origin on impedance testing[83]	regurgitation, globus sensation	without LES relaxation	resolution manometry, pH-impedance studies

LES: Lower esophageal sphincter; GERD: Gastroesophageal reflux disease; IRP: Integrated relaxation pressure; DCI: Distal contractile integral; EOE: Eosinophilic esophagitis.

HISTORY TAKING

The most important step in evaluating a patient's candidacy for anti-reflux surgery is to confirm the diagnosis of GERD. This starts with careful history taking to assess the signs and symptoms a patient is suffering from. While the presence of typical GERD symptoms is enough for a presumptive diagnosis[5], these symptoms can also be present in a wide range of diseases and do not confirm the diagnosis of GERD. One recent systematic review found that classic symptoms such as heartburn and regurgitation had a varying degree of sensitivity, ranging from 30%-76%, for the presence of underlying GERD[11]. Additionally, the researchers found the studied symptoms were associated with a wide range of specificities (62%-96%)[11]. It is also important to identify if patients are suffering from extra-esophageal symptoms of GERD, as they are less likely to find symptom relief with surgery. One randomized control study compared patients with asthma on medical *vs* surgical therapy for reflux. While all patients experienced clinical improvement of their symptoms, researchers found no significant difference between the two modalities[12]. Overall, while a patient may display classic symptoms of GERD, further assessment must be completed to determine their appropriateness for surgery.

Another important aspect of the patient's history is to assess their response to PPI therapy, which may be a good predictor of outcomes after anti-reflux surgery[13]. One recent study involving 370 patients undergoing laparoscopic Nissan fundoplication found patients who responded well to PPI therapy had a significantly greater reduction in reflux symptoms after surgery[14]. Previous studies have also indicated that patients with symptoms refractory to PPI therapy may have a higher likelihood of poor surgical outcomes[15]. However, while PPI effectiveness may help predict surgical outcomes, it should not be used to confirm or rule out a diagnosis. One meta-analysis found that a successful response to PPI therapy was only 78% sensitive and 54% specific for an underlying diagnosis of GERD[16].

When assessing a patient for anti-reflux surgery, it is also important to understand the role of obesity in surgical outcomes. It is known that GERD is more common in obese patients, as greater central adipose tissue may lead to increased intraabdominal pressure stressing the LES[17]. While some studies indicated the morbidly obese are at a higher risk for surgical failure, more recent studies found similar outcomes of fundoplication in obese patients[18,19]. An alternative surgical option for obese patients includes Roux-en-Y gastric bypass surgery. The SAGES currently recommends bypass surgery for morbidly obese patients with GERD, as it can help decrease GERD symptoms in addition to the weight loss benefits for the patient[6]. However, evidence is still unclear regarding the optimal surgical treatment for patients with class I obesity, and while anti-reflux surgery is a safe option, these patients should be evaluated on a case-by-case basis. Additionally, it is still important to fully assess the reflux symptoms of patients undergoing weight loss surgery. While obese patients are more likely to have GERD, they may also have an underlying esophageal motility disorders, and the use of HRM can help distinguish between these conditions[20].

ESOPHAGEAL PH TESTING

After thorough history taking to identify patients with GERD like symptoms, a upper endoscopy can help make a diagnosis by directly visualizing esophageal lesions such as esophagitis. However, a subset of patients may still have gastric reflux without evidence of any erosions[5]. In these patients with NERD, further testing is required to accurately diagnose reflux and confirm if a patient might be a good candidate for surgical correction. Esophageal pH testing can be a useful modality to identify acidic reflux above the LES[21,22]. Standard ambulatory pH monitoring involves placement of a trans-nasal probe 5 cm above the LES[23]. The probe then measures acid exposure time (AET) by recording any drops in pH below 4 over a 24-h period (Figure 1). The

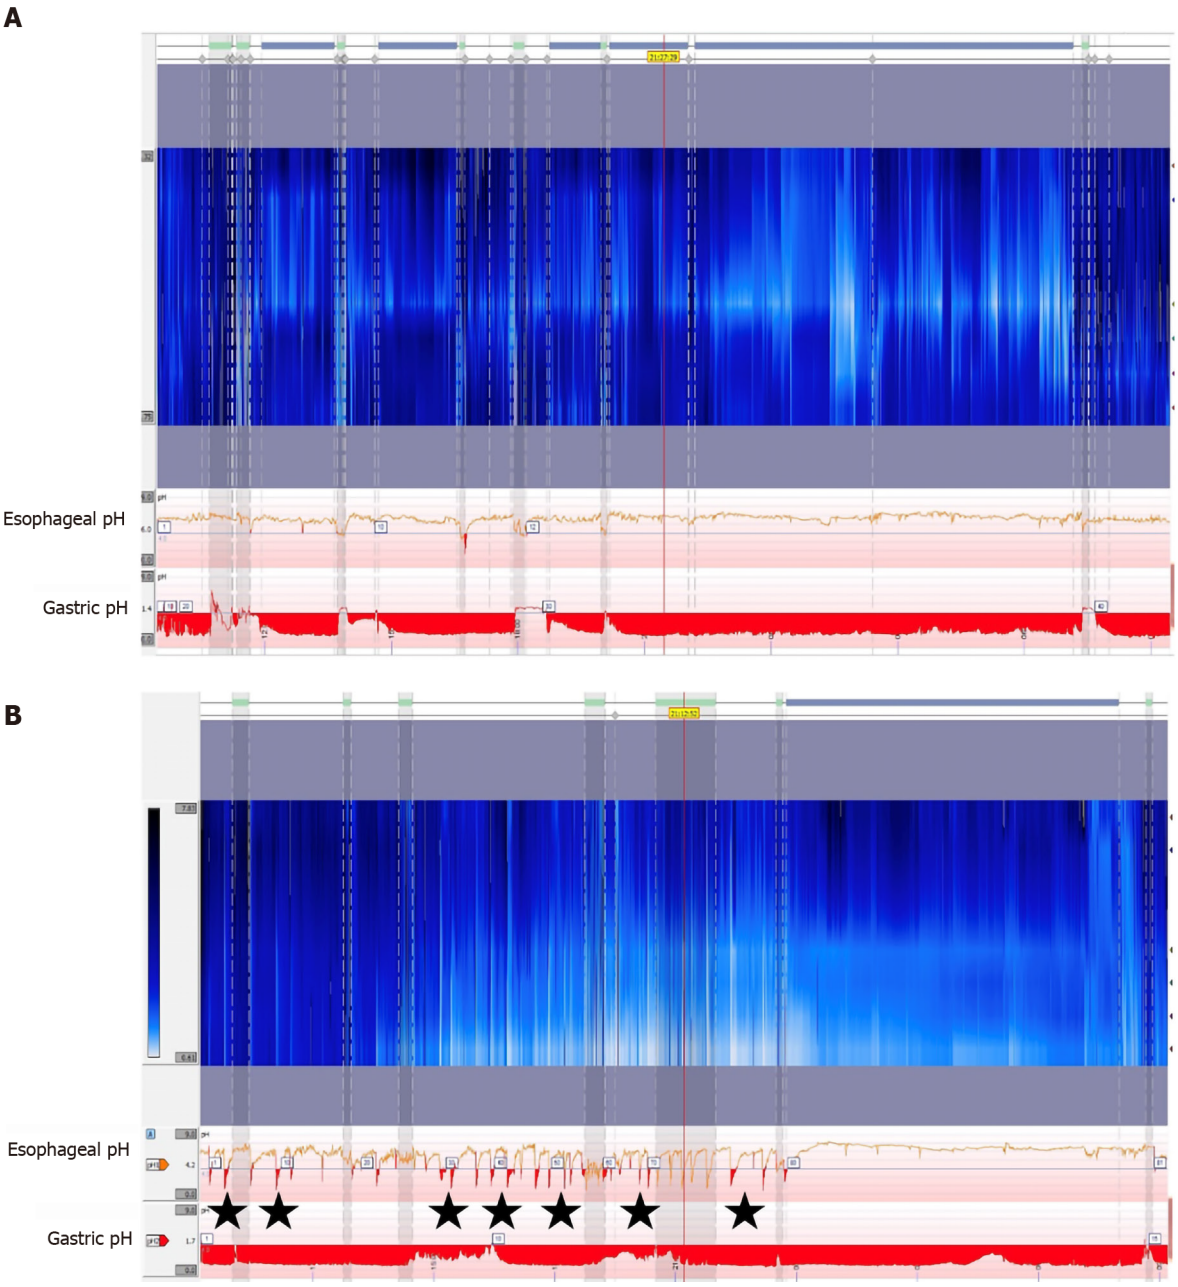

Figure 1 Twenty-four hours pH studies. A: Normal 24 h pH study showing acid in the stomach without acid reflux events in the esophagus; B: Abnormal 24 h pH monitoring test with multiple acid reflux events in the esophagus (star indicating reflux events).

DeMeester score was a system developed in the 1970's to categorize a patient's reflux based on parameters including the number and timing of reflux events as well as supine *vs* upright positioning during these periods[24]. More recently, the Lyon consensus recommends using only AET when determining GERD, and defined pathologic reflux as having greater than 6% AET[22]. Although there is debate regarding which method is more reliable, both have similar strengths and weaknesses, and there is no current evidence that one method is superior to the other[25]. In general, the ACG recommends pH monitoring for all patients with NERD as a pre-operative assessment, and more recent studies have also found utility in measuring AET for patients with LA grade A or B esophagitis prior to surgery[5,26]. Additionally, pH testing has utility for confirming reflux in patients with GERD or NERD who are unresponsive to PPI therapy[21].

One drawback of ambulatory pH monitoring is the discomfort patients may experience from the trans-nasal catheter, with some studies showing patients tend to decrease typical daily activities that might promote reflux after the probe is placed[27]. Wireless capsule pH monitoring is also available, and while it must be placed endoscopically, it is often better tolerated than the catheter probe and may provide

better measurements of physiologic reflux (Figure 2)[28]. In addition to improved patient tolerance, the capsule can record AET for 48-96 h depending on battery life, improving the sensitivity of the test[29]. However, both catheter and capsule pH monitoring are limited by the fact that they only measure acidic reflux. Studies have shown up to 30% of patients with pathologic reflux may have normal pH measurements on ambulatory monitoring[30]. This indicates up to 1/3 of patients with LES dysfunction who may benefit from surgery are missed with this form of testing (Table 2).

pH-impedance testing

Multichannel intraluminal impendence pH monitoring (MII-pH) is a newer technology that measures changes in electrical conductivity between multiple points on the probe[23]. This data is combined with the pH probe to measure reflux of any material above the LES, independent of pH (Figure 3)[30]. The Lyon consensus defines physiologic reflux as 40 or less reflux events, with pathologic defined as greater than 80 episodes of reflux[22]. This definition allows for patients to continue PPI therapy during testing, as pH does not factor into the diagnosis[31]. MII-pH testing also has utility in identifying patients with weak acid reflux (pH 4-7). Up to 30% of patients with GERD may continue to have symptoms refractory to acid suppression therapy[32]. While these symptoms could potentially be secondary to any of the diagnoses seen in Table 1, MII-pH testing can identify patients with weak reflux by independently measuring reflux and pH (Figure 3). Treatment of patients with weak acid reflux is controversial, especially because previous studies have shown failure of PPIs is an indicator for poor outcomes after anti-reflux surgery[15]. However, if clinicians can confirm refractory GERD is secondary to weak acid reflux and not alternative diagnoses such as functional heartburn, they can identify patients who would still be good surgical candidates[33].

Limitations of MII-pH testing include using a trans-nasal catheter and required manometry testing for all patients prior to placement[29]. Additionally, visual analysis of the data is time consuming, but computerized electronic review software can be imprecise. One study found that computer interpretation of results identified only 74% of reflux events confirmed by visual analysis[34]. The authors suggested visual review of the data may be necessary to confirm test accuracy[34]. There also remains a potential for patients to have increased AET and reflux events secondary to other esophageal pathologies not related to LES dysfunction or GERD. This is important to keep in mind during pre-operative assessment for anti-reflux surgery, as patients without underlying LES dysfunction would not be good candidates for surgical treatment. Patients with rumination syndrome can have false positives on pH testing due to frequent regurgitation, not transient LES relaxation[35]. Increased AET can also be secondary to a hypomotility disorders, such as in patients with achalasia or scleroderma. This is not limited to only pH testing, as impedance studies may also have inconclusive or misleading results in patients with achalasia, scleroderma, or rumination syndrome[29]. Due to these possibilities, the ACG recommends that all patients undergo manometry as part of their pre-operative assessment to rule out any motility disorders that may cause reflux[5].

Another important aspect of utilizing pH or pH-impedance testing is the measurement of any associated symptoms during testing (Figure 4). Since there is still the potential for false positives when looking at AET or number of reflux episodes during testing, it is also important for a patient to log any symptoms they experience during testing[36]. This also has utility with extra-esophageal symptoms and can help in identifying if symptoms are causing reflux or are secondary to reflux, such as coughing[36], The Symptoms Association Probability (SAP) is one example of a methods to assess the association of symptoms with reflux events. This involves using a 2 × 2 table assessing the presence of symptoms and reflux events in 2-min blocks over a 24 h period[37]. Analysis then allows the determination of whether the symptoms were more likely secondary to reflux events or caused by chance. While there are other methods to assess symptom association, a SAP can provide a probability of symptom association and is thought to have the best clinical utility[36].

MANOMETRY AND MOTILITY TESTING

Another important aspect of the pre-operative assessment is to rule out major esophageal motility disorders with HRM (Figure 5). Patients with GERD often have findings of decreased LES pressures on HRM, indicating an impaired ability for the

Table 2 Esophageal pH measurement options

	Overview	Benefits	Limitations
Twenty-four hours ambulatory catheter	Trans-nasal catheter placed 5 cm above the LES. Measures time of pH < 4	Can be placed in office	Catheter may cause discomfort; Patients may deviate from daily routine; Patients should refrain from taking PPI therapy during testing; False positives secondary eating/drinking acidic food
Wireless capsule	Small probe that is placed endoscopically in esophagus 5-6 cm above LES. Measures time of pH < 4	Little patient discomfort; Battery life of 48-96 h allows for better measurement of physiologic acid exposure	Must be placed endoscopically; Patients should refrain from taking PPI therapy during testing; False positives secondary eating/drinking acidic food
MII-pH catheter	Trans-nasal catheter placed 5 cm above LES. Contains pH probe along with electrodes to measure reflux episodes	Can be done on or off PPI; Measures pH and reflux independently; Patients can continue taking PPIs; Can identify patients with weak acid reflux	Catheter may cause discomfort; Patients must have prior manometry testing; False positive possible in patients with rumination, achalasia, and scleroderma

LES: Lower esophageal sphincter; PPI: Proton pump inhibitor.

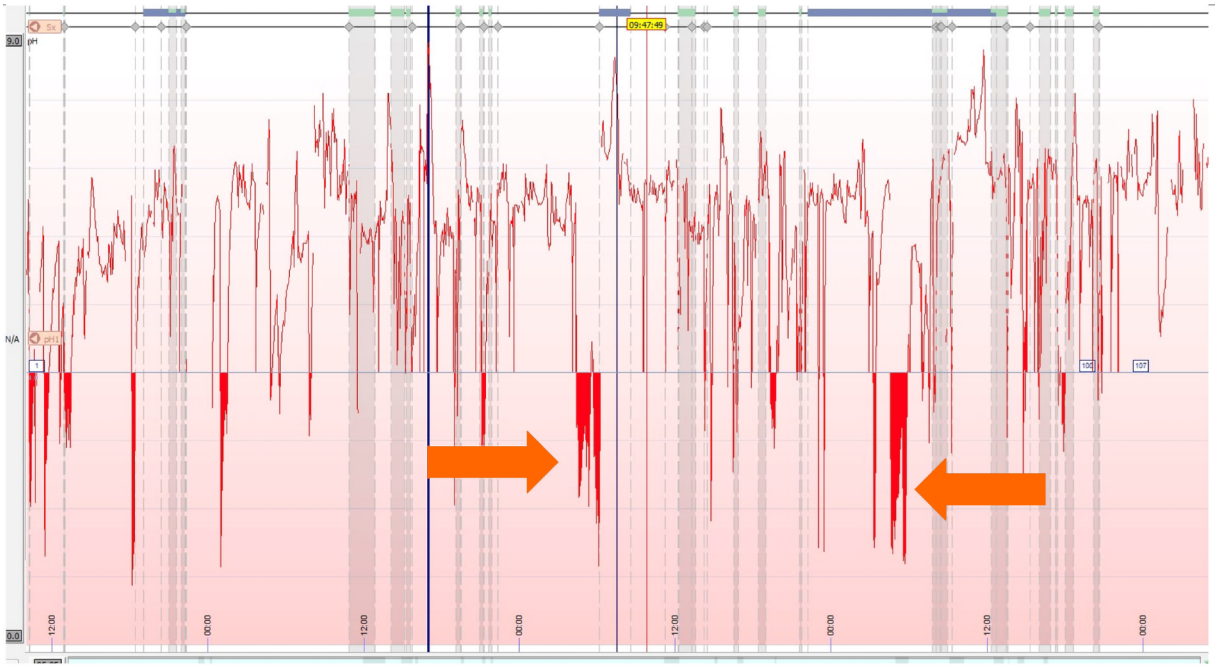

Figure 2 Abnormal wireless capsule pH study (arrows indicating prolonged reflux events).

LES to act as an anti-reflux barrier and prevent gastric contents from entering the esophagus[38]. The smooth muscle in the LES is also augmented by pressure generated from the crural diaphragm, and because HRM utilizes an increased number of sensors, these pressures can be differentiated when evaluating the LES strength[39]. The esophagogastric junction contractile integral can also be quantified on HRM and may identify patients with severe reflux, but further research is needed to create a standardized metric for evaluating patients[22]. Additionally, LES physiology can be altered in the presence of a hiatal hernia, and HRM can be used to assess and measure the size of a patient's hiatal hernia[40]. While esophageal manometry is not a confirmatory test for diagnosing GERD, HRM is useful in identifying any underlying motility issues (Figure 6)[41,42]. While there is limited data to support mandatory pre-operative manometry testing, the ACG still recommends manometry to specifically rule out achalasia and absent peristalsis seen in conditions such as scleroderma[5]. In the 2019 ICARUS guidelines, 94% of experts also strongly agreed with pre-op HRM testing, but this could only be supported with grade D evidence[42]. Additionally, HRM can be used to assess baseline esophageal physiology to predict the risk of post-operative dysphagia.

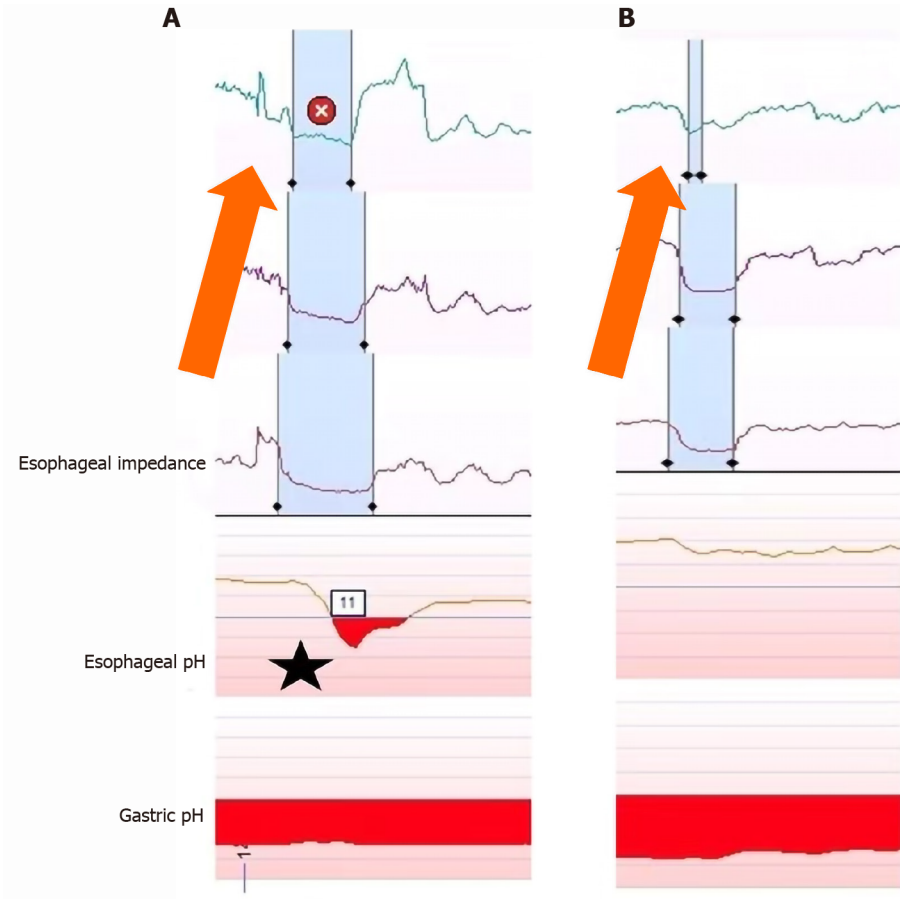

Figure 3 Examples of pH-impedance measurements. A: Reflux event recorded during 48 h pH-impedance study; B: Weak acid reflux event in the esophagus without acid exposure in the stomach detected on pH-impedance study (arrows indicating impedance events, star indicating pH drop and acid event).

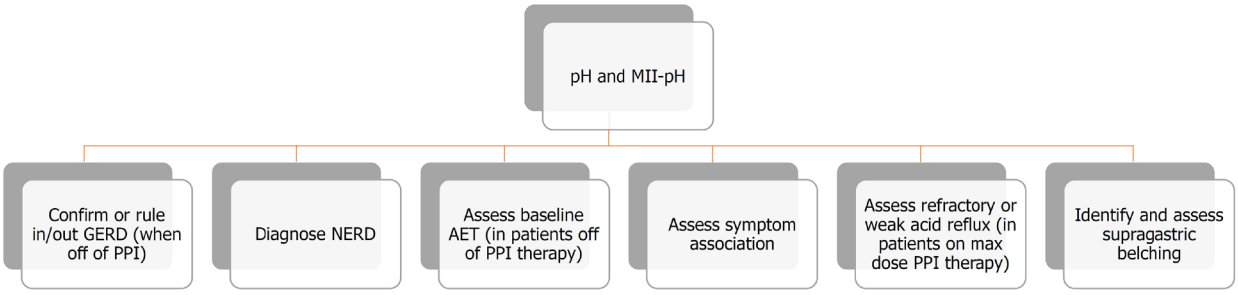

Figure 4 Utility of pH and multichannel intraluminal impendence pH testing for pre-operative assessment. GERD: Gastroesophageal reflux disease; NERD: Non-erosive reflux disease; PPI: Proton pump inhibitor; AET: Acid exposure time; MII-pH: Multichannel intraluminal impendence pH monitoring.

Ruling out major motility disorders

The main indication for HRM should be used to rule out major motility disorders, as these may be the underlying cause of a patient's reflux symptoms, and may also be a contraindication for fundoplication[6].

Achalasia: Abnormal esophageal peristalsis can manifest as GERD-like symptoms in patients with achalasia. The integrated relaxation pressure (IRP) is an important measurement during manometry that assesses esophageal pressures and transit across the esophagogastric junction[43]. According to the Chicago Classification (CC), type I achalasia is diagnosed in patients found to have an IRP > 15 mmHg and 100% failed peristalsis on HRM, with type II having the same characteristics as well as panesophageal pressurization in ≥ 20% of swallows[44]. Type III achalasia is defined as an elevated IRP > 15 mmHg, the absences of any normal peristalsis, and spastic contractions greater > 450 mmHg on ≥ 20% of swallows (Figure 7)[44]. As previously

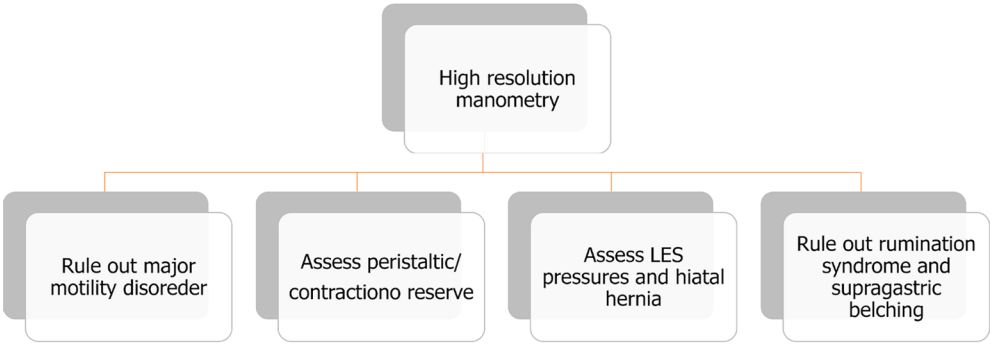

Figure 5 Utility of high-resolution manometry for pre-operative assessment. LES: Lower esophageal sphincter.

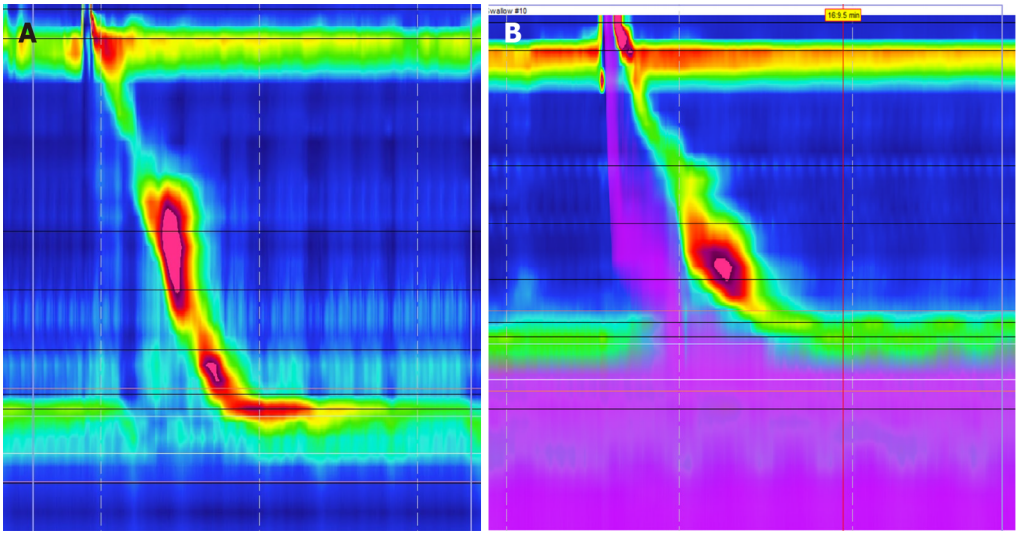

Figure 6 Normal peristalsis and lower esophageal sphincter relaxation on high-resolution manometry. A: Example of normal swallow on high-resolution manometry; B: Normal swallow with complete esophageal clearance by impedance.

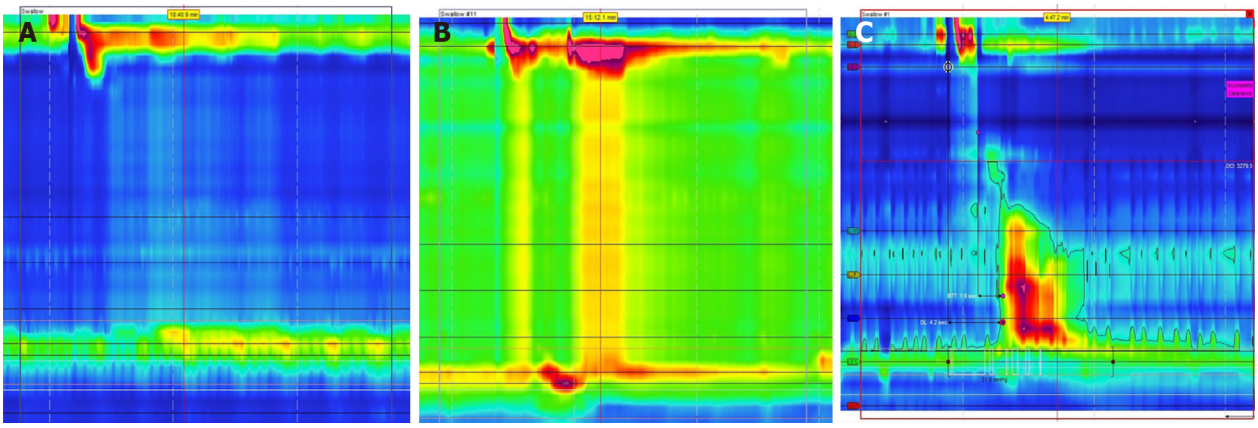

Figure 7 Examples of achalasia diagnosed on high-resolution manometry. A: Type I achalasia with failure of lower esophageal sphincter relaxation and absence of peristalsis; B: Type II achalasia with panesophageal pressurization; C: Type III achalasia with abnormal peristalsis (spastic/premature contractions).

discussed, the goal of fundoplication is to improve the integrity of the LES, but patients with achalasia suffer from impaired LES relaxation along with esophageal aperistalsis. While these patients may also have underlying GERD, surgical treatment revolves around addressing the LES with myotomy[42,45]. However, after myotomy weakens the LES, GERD can become a common side effect. While these patients would benefit from fundoplication, there is debate regarding the risk of post-operative

dysphagia[46]. One prospective randomized study compared outcomes of myotomy alone *vs* myotomy with fundoplication for 43 patients with achalasia. Researchers found that patients receiving myotomy with fundoplication had significantly less GERD and AET, with no significant difference in dysphagia between the two groups[47]. The group also followed patients long-term and concluded there was no significant differences in post-op dysphagia in patients who received myotomy with fundoplication[48]. Current guidelines from both the ACG and the SAGES recommend patients with achalasia undergo both myotomy and fundoplication for the best outcomes[45,46].

Absent peristalsis: Conflicting data also exists regarding fundoplication for patients with absent peristalsis. Evidence of aperistalsis, defined as failed peristalsis with 100% of swallows, on HRM can indicate patients with scleroderma-like esophagus (Figure 8)[49]. Older studies have confirmed anti-reflux surgery can lead to improved symptoms, but more recent studies indicated these patients might have a higher risk for post-operative dysphagia[42,50]. Additionally, studies have shown that alternative surgeries such as a Roux-en-Y bypass may lead to better outcomes. A 2018 study followed patients with systemic sclerosis undergoing surgical treatment for their GERD and compared fundoplication *vs* Roux-en-Y bypass. While the sample size was small, researchers found patients had better GERD symptom relief after Roux-en-Y compared to fundoplication[51].

Esophagogastric junction outflow obstruction: Esophagogastric junction outflow obstruction (EGJOO) is another esophageal motility disorder that can present with GERD like symptoms. In this disorder, patients have normal or weakened esophageal peristalsis on HRM with an elevated IRP[44]. While the current CC provides a guideline on making a diagnosis with HRM, it is important to remember that other factors can lead to an increased IRP. In some patients with hiatal hernias, the manometry catheter may be incorrectly positioned due to the underlying anatomical abnormality, which can contribute to increased IRP measurements[52]. These patients require confirmatory testing, and some centers have adopted the use of upright HRM measurements with an IRP > 12 mmHg as a cutoff[53]. Additionally, other esophageal abnormalities such as Schatzki's ring can lead to altered HRM results[54]. Data is currently limited regarding the outcomes of fundoplication in patients with EGJOO, but an accurate diagnosis is still important as it identifies esophageal dysmotility as the cause of a patient's GERD like symptoms.

Opioid induced esophageal dysfunction is increasingly being recognized as a potential cause of esophageal dysmotility. Just as chronic opioid use can lead to bowel hypomotility, it is theorized that opioids may block esophageal inhibitory signals leading to increased contractions and decreased LES sphincter relaxation[55]. This can in turn lead to findings of EGJOO, esophageal spasm, and hypercontractile esophagus on HRM (Figure 9)[56]. It is important to recognize the effect of chronic opioid use on esophageal motility, as cessation of opioid drugs may lead to resolution of GERD like symptoms.

Hypercontractile disorders: In addition to uncovering evidence of esophageal hypomotility, HRM can also identify hypercontractile patterns such as jackhammer esophagus and esophageal spasm (Figure 10). While the pathophysiology behind these diseases is still under investigation, both involve impaired inhibition and coordination of esophageal peristalsis and can present with dysphagia, non-cardiac chest pain, and reflux[57,58]. Jackhammer esophagus can be diagnosed on HRM if at least 20% of swallows have a distal contractile integral (DCI) of greater than 8000 mmHg[44]. According to the 2019 ICARUS guidelines, 64% of experts agreed that patients with jackhammer esophagus are still good candidates for anti-reflux surgery, but this assertion is only supported by grade D evidence[42]. Data is limited regarding outcomes of patients with jackhammer esophagus after anti-reflux surgery, but one retrospective study found no difference in outcomes when compared to patients with physiologic esophageal motility[59]. Distal esophageal spasm is diagnosed in patients with a normal IRP but ≥ 20% of premature contractions with a DCI of > 450 mmHg[44]. 64% of experts agreed that these patients were not good surgical candidates, but this again was only supported with grade D evidence[42]. Instead, the authors suggested specific therapeutic measures for esophageal spasm such as botulinum injections and myotomy instead of anti-reflux surgery[42].

Utility of provocative maneuvers during HRM

Provocative studies such as multiple rapid swallow (MRS) or rapid drink challenge

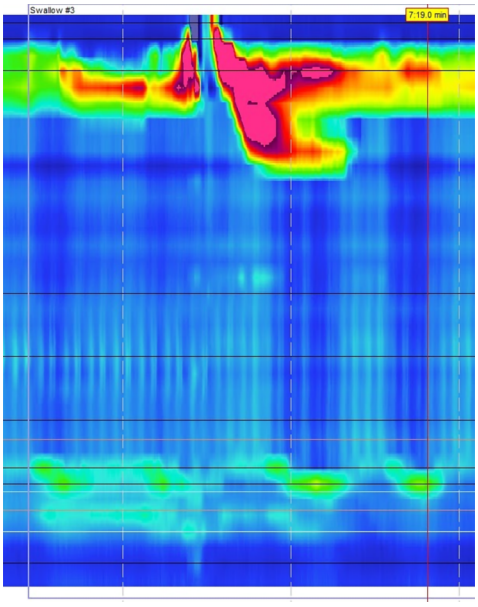

Figure 8 Scleroderma esophagus with absent peristalsis and hypotensive lower esophageal sphincter.

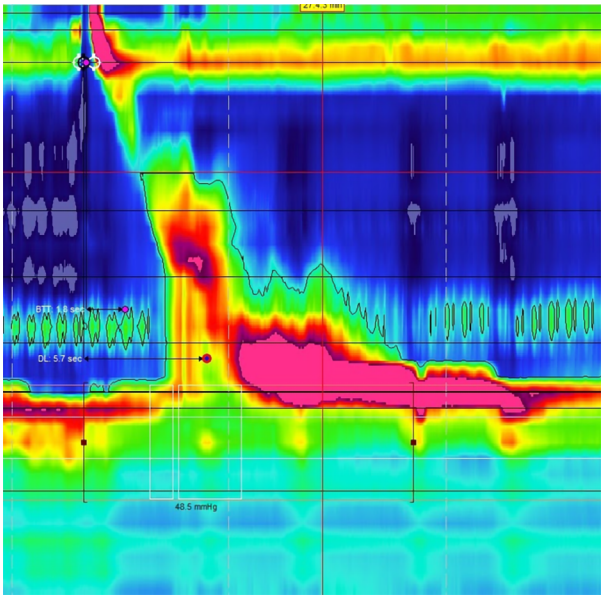

Figure 9 Outflow obstruction with elevated residual pressure and distal pressurization from chronic opioid use.

(RDC) tests can also be added to HRM to further evaluate esophageal physiology. MRS testing involves swallowing small amounts of water over a quick period of time which stresses the coordination of esophageal contraction and LES relaxation[60]. Recent studies have found the addition of MRS during HRM can help uncover pathologies that might have been missed on manometry alone such as distal esophageal spasm and achalasia variants[61]. MRS also allows for visualization of esophageal pressurization patterns which can help identify hypercontractility and EGJOO[62,63]. RDC is also a simple test that can be added to HRM to stress the esophagus and uncover motility disorders. RDC is a similar test to MRS, but involves drinking a larger total amount of water. A recent study in 2017 compared HRM and RDC results between healthy individuals and a cohort of patients with dysphagia and reflux. They found that the addition of RDC improved the sensitivity and specificity of HRM for identifying esophageal motility disorders to 85% and 95% respectively[64].

Another provocative test that can be added to HRM is apple viscous swallows (AVS). AVS involves patients swallowing apple sauce during manometry, and the increased viscosity may help better simulate physiologic swallowing of food. A study from 2011 Looked at patients with dysphagia and compared results of HRM with AVS

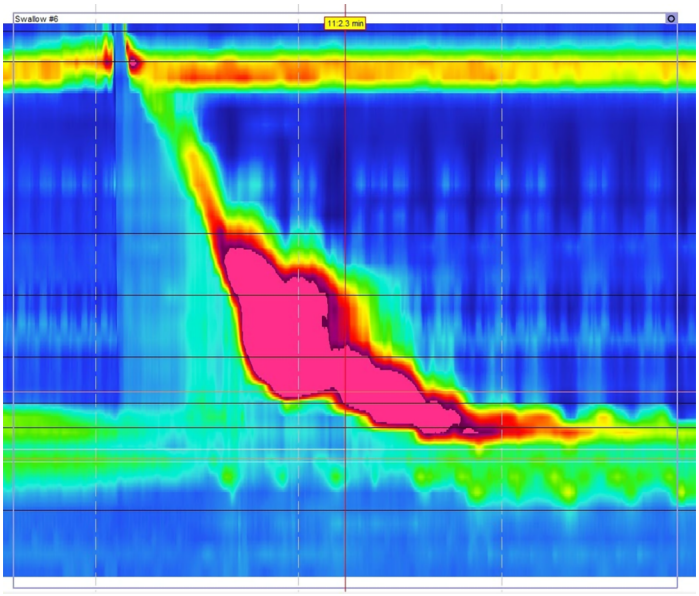

Figure 10 Example of hypercontractile esophagus with distal contractile integral > 8000 mmHg.

and standard water swallows. The researchers found that 4% of patients had abnormal results with water swallows, but this increased to 30% with AVS[65]. Overall, the additions of provocative maneuvers such as MRS, RDC, and AVS to HRM are quick and simple and can help identify esophageal motility disorders in patients with GERD like symptoms.

Provocative testing also has important utility as a pre-operative assessment by predicting the risk of post-operative dysphagia. The DCI is another measurement that can be used to assess the strength of esophageal contractions during HRM[63]. According to the CC, a DCI ratio can be calculated from standard manometry and MRS testing to assess peristaltic or contraction reserve (Figure 11)[44]. This can help indicate the ability of the esophageal body to augment contractions and may be predictive of multiple pathologies in patients with impaired esophageal motility[22,66]. Patients with weak contractions on HRM with MRS may have low peristaltic reserve and a DCI ratio cutoff of > 0.85 was found to be 67% sensitive and 64% specific for identifying late post-operative dysphagia in patients with GERD[67]. Additionally, a lack of manometric response can identify patients with esophageal involvement of their systemic sclerosis, as peristaltic reserve is typically absent in this population[68].

It is known from previous studies that impaired LES pressures are associated with increased esophageal acid exposure[69]. A 2012 retrospective study included over 2000 patients who underwent manometry and pH testing and found that patients with incompetent LES pressures had significantly higher DeMeester scores[70]. A hiatal hernia is one example of why the LES can be compromised in patients and lead to lower closing pressures[71]. The straight leg raise is another simple provocative maneuver that can be completed during HRM to assess patients with a hiatal hernia (Figure 12). Previous studies have indicated the size of a hiatal hernia is the best predictor for the severity of GERD[72]. Straight leg raises during HRM can increase intraabdominal pressure and stress the LES. A recent study measured trans-esophagogastric junction gradient pressures during straight leg raises on HRM and found a significant decrease in peak pressure gradient in patients with a hiatal hernia of 3 cm or greater[73]. Straight leg raises are a simple provocative maneuver to add during HRM and can identify patients that could benefit from surgical treatment for both their GERD and hiatal hernia with good outcomes[74] (Table 3).

Ruling out supragastric belching and rumination syndrome

Patients with GERD may also commonly complain of increased belching[75]. Supragastric belching is another disorder with many GERD-like symptoms, and is common in patients with GERD, NERD, reflux hypersensitivity, and functional dyspepsia[76,77]. Distinguishing between the two disorders is important, as both are due to different underlying pathologies requiring specific treatment approaches. Supragastric belching is seen as a learned behavioral disorder where air is pulled into the esophagus, but there is no transient relaxation of the LES as seen in physiologic

Table 3 Key measurements on high resolution manometry

Measurement	Utility
Integrated relaxation pressure	Measures esophageal pressures during transit and passage through esophagogastric junction. Can be used to diagnose achalasia and other hypomotility disorders
Distal contractile integral	Measures strength of esophageal contractions. Can diagnose hypercontractile disorders such as jackhammer esophagus
Distal latency	Measurement of esophageal transit and contraction time. Can indicate impaired or spastic peristalsis
DCI ratio	Ratio of DCI on normal swallows and MRS testing. Used to assess peristaltic reserve. This can be used to predict risk of post-operative dysphagia

DCI: Distal contractile integral; MRS: Multiple rapid swallow.

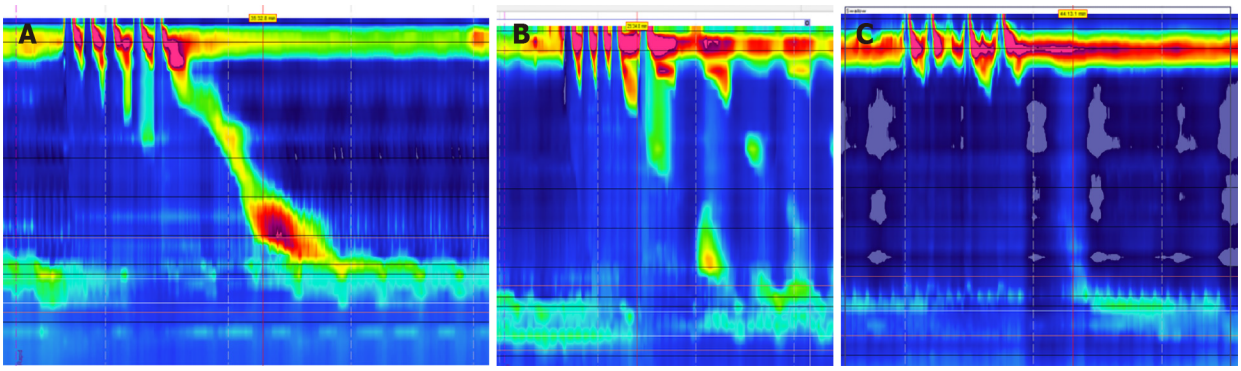

Figure 11 Findings on high-resolution manometry with multiple rapid swallow. A: Normal multiple rapid swallow (MRS) with good contraction distal contractile integral; B: Weak esophageal contractions with MRS; C: Failed esophageal contractions with MRS.

belching[78]. Even though these patients present with symptoms of reflux, the treatment is directed at behavioral therapy to decrease bringing air into the esophagus. These patients would not be good candidates for anti-reflux surgery. Recent improvements in high resolution impedance manometry (HRIM) allow for clinicians to measure both esophageal pressure and flow during swallows[79]. While supragastric belching can induce GERD, HRIM can identify episodes of supragastric belching with no LES relaxation and confirm only esophageal air is released instead of gastric air[80].

Rumination syndrome is another functional disorder involving patients suffering with GERD-like symptoms of frequent reflux and regurgitation. Like supragastric belching, HRM can be useful in identifying the underlying mechanism of the dysfunction. A recent study found that different subtypes of rumination can be identified on HRM, with some having pathophysiologies similar to supragastric belching, and others showing evidence of gastric contents refluxing above the LES[35]. While the first line treatment of rumination syndrome involves cognitive behavioral therapy, HRM can help identify patients with gastric rumination as the cause of their reflux symptoms, and these patients may benefit from further treatments such as anti-reflux surgery[35].

CONCLUSION

Fundoplication is a safe and effective treatment for individuals with GERD, but a thorough pre-operative assessment is critical to achieving good surgical outcomes. Newer technologies continue to become more widely available and can help clinicians in selecting appropriate surgical candidates. By accurately diagnosing GERD, assessing peristaltic reserve, and ruling out major motility disorders and diseases with GERD-like symptoms, clinicians can confidently identify patients with true LES dysfunction who would benefit from surgical intervention.

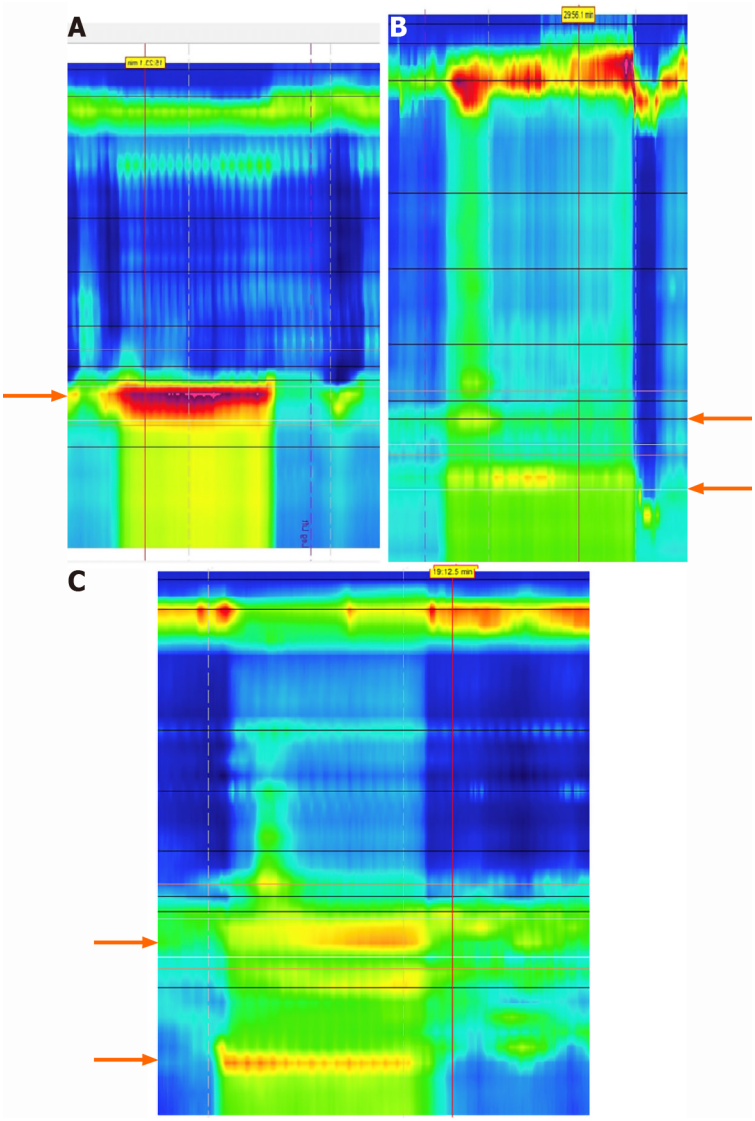

Figure 12 Examples of straight leg raise testing during high-resolution manometry. Abstract

BACKGROUND

Sulongga-4 (SL-4) is a herbal formula used in traditional Mongolian medical clinics for the treatment of peptic ulcers and gastroenteritis, even though its pharmacological mechanism has not been well characterized.

AIM

To evaluate the protective effect and identify the mechanisms of action of SL-4 on gastroduodenal ulcer induced by pyloric ligation (PL) in rats.

METHODS

PL was performed to induce gastric and duodenal ulcers in rats, which were then treated with oral SL-4 (1.3, 2.6, or 3.9 g/kg per day) for 15 d. PL-induced gastroduodenal ulceration. Therapeutic effects were characterized by pathological and histological evaluations and inflammatory indicators were analyzed by enzyme-linked immunosorbent assay. Microarray analyses were conducted to identify gene expression profiles of gastroduodenal tissue in PL rats with or without SL-4 treatment. The candidate target genes were selected and verified by quantitative reverse transcription polymerase chain reaction (qRT-PCR).

RESULTS

SL-4 decreased histopathological features in the PL-induced ulcerated rats. SL-4

significantly ($P < 0.05$) decreased expression of tumor necrosis factor-α, interleukin (IL)-1β, IL-6, endotoxin, platelet-activating factor, and increased prostaglandin E2 and epidermal growth factor in ulcer tissue. Microarray analysis was used to identify a panel of candidate target genes for SL-4 acting on PL-induced ulceration. Genes included some complement and coagulation cascade and retinol metabolism pathways that are closely associated with inflammatory responses and gastric mucosal protective mechanisms. qRT-PCR showed that altered expression of the selected genes, such as *CYP2b2*, *UGT2b1*, *A2m*, and *MASP1* was consistent with the microarray results.

CONCLUSION

SL-4 exerts protective effects against PL-induced gastroduodenal ulcers *via* reducing inflammatory cytokines and elevating expression of gastric acid inhibitory factors. Downregulation of *CYP2b2* and *UGT2b1* genes in retinol metabolism and upregulation of *A2m* and *MASP1* genes in the complement and coagulation cascades pathways are possibly involved in SL-4-mediated protection against gastroduodenal ulcer.

Key Words: Sulongga-4; Peptic ulcer; Pyloric ligation; Microarray analysis; Inflammatory reaction; Retinol metabolism

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Sulongga-4 (SL-4) is a classic herbal formula used in Mongolian medical clinics for the treatment of peptic ulcers and gastroenteritis. This study investigated the protective effects and molecular mechanisms of SL-4 in pyloric ligation (PL)-induced gastroduodenal ulcers in rats *via* microarray analysis. Our results suggest that SL-4 was strongly protective against PL-induced gastroduodenal ulcers *via* reducing inflammatory cytokines and elevating the expression of gastric acid inhibitory factors. Downregulation of *CYP2b2* and *UGT2b1*, and upregulation of *A2m* and *MASP1* may be involved in the gastroduodenal ulcer protection mechanism of SL-4.

INTRODUCTION

Peptic ulcer disease is the most prevalent chronic disease of the digestive system, with complications resulting in high morbidity and mortality[1]. Many factors can lead to the formation of peptic ulcers, and one of the basic mechanisms is impairment of gastric mucosal barrier function by acidic gastric secretion[2]. Inflammation or injury of the digestive system cause visceral hypersensitivity that can drive the development of chronic pain and patient discomfort[3], while inflammation is a key driver of gastric ulcer formation[4]. For protection against inflammation, cells respond with attenuated production of proinflammatory cytokines such as interleukin (IL)-12, tumor necrosis factor (TNF)-α, IL1β, IL-6, IL-8, and interferon (IFN)[5,6]. These cytokines drive the aggregation and trigger activation of T cells in areas of inflammation. Mediators of inflammation protect against peptic ulcer formation. Although peptic ulcer disease can be treated with drugs such as proton pump inhibitors, H2 receptor antagonists and prostaglandin analogs, most of these drugs have adverse reactions and limitations when used for the long term[7]. Safer and more effective antiulcer agents are therefore needed.

The use of plant extracts as natural medications is well documented, with multifunctional effects reported such as immunostimulatory, anti-inflammatory, antiviral, anticancer, and radioprotective effects[8]. Plant or herbal extracts are also recognized as a source of therapeutics for gastric ulcers[9]. Traditional Mongolian

medicine (TMM) has been used to treat peptic ulcers and is proven to be effective in clinical treatment. The use of TMM is widespread in North China, Mongolia, and the Buryat Republic. The use of TMM is spreading to more Asian countries because of its profound curative effects on some common diseases in the northern region. The Mongolian medicine Sulongga-4 (SL-4) is composed of four medicinal herbs: *Forsythia suspensa*, *Persicaria bistorta*, *Caulis clematidis* armandii, and *Ophiopogon japonicus*. According to ethnopharmacological records, SL-4 has shown good efficacy against Hododenbaoru, a term in TMM referring to peptic ulcer[10]. Modern clinical applications and preliminary studies have shown that SL-4 is generally used for abdominal pain, gastroenteritis, peptic ulcer, and diarrhea. For example, SL-4 has been found to have clinical therapeutic effects against infantile diarrhea and to improve intestinal health[11-13]. Wang *et al*[14,15] reported that SL-4 was protective against acute liver damage induced by pyloric ligation (PL) and CCl_4. To further evaluate the efficacy of SL-4, we investigated whether it had a protective effect on PL-induced gastroduodenal ulcer in a rat model. Additionally, combined microarray analysis and data mining were conducted to uncover the underlying molecular mechanisms of the gastroprotective effects of SL-4.

MATERIALS AND METHODS

Ethics statement

Male Sprague-Dawley rats (200 ± 20 g, 6 wk of age, SPF grade, batch no. SCXK 2015-0001) were purchased from Liaoning Chang-Sheng Biotechnology Co. The experimental procedures were approved by the Committee on the Ethics of Animal Experiments of Inner Mongolia University for Nationalities (approval no. NM-LL-2016-12-15-01), in accordance with the requirements and general guidelines of the Chinese Experimental Animals Administration Legislation. All surgery was conducted under sodium pentobarbital anesthesia, and every attempt was made to alleviate suffering.

Animal treatment

Sixty male rats were housed in environmentally controlled conditions (22 ± 2 °C, relative humidity of 50% ± 5%) with a 12-h light/dark cycle and had free access to food and water for 7 d acclimatization. SL-4 was provided by the Drug Manufacturing section of the Affiliated Hospital of Inner Mongolia University for Nationalities (batch No.: 20190312). Rats were randomly divided into five groups (n = 12) that were treated by a sham operation, PL, and 1.3, 2.6, or 3.9 g/kg SL-4. Rats in the sham operation and PL groups were given 0.5% carboxymethylcellulose sodium (CMC-Na, Sigma). Rats in the three SL-4 groups were given 1.3, 2.6, or 3.9 g/kg SL-4 in 0.5% CMC-Na suspension by gastric lavage once daily. The rats in all five groups were pretreated for 15 consecutive days.

Ulcer model induced by PL

One hour after the last drug administration, all rats were fasted for 24 h with free access to water prior to ulceration. Each rat was anesthetized by intraperitoneal injection of pentobarbital for induction of PL-induced gastric ulcer as previously described[16]. The abdominal cavity was opened and the pylorus was ligated, avoiding injury of the adjacent blood vessels. The stomach was gently replaced and the belly was sutured. After being deprived of food and water for 18 h, the animals were killed and the stomach and duodenum were dissected for subsequent analysis.

Pathological and histological examination

Rats were anesthetized intraperitoneally with sodium pentobarbital and killed. Gastric and duodenal sections were harvested for pathological examination. For histological examination, gastroduodenal ulcer tissue was fixed with 4% paraformaldehyde for 48 h; decalcified in 10% aqueous EDTA solution (Sigma-Aldrich, St. Louis, MO, United States) at room temperature and constant agitation, processed, and embedded in paraffin. The tissues were cut into 4 μm serial sections and dewaxed twice in xylene at 37 °C for 15 min; rehydrated through decreasing concentrations of ethanol, and washed in distilled water at room temperature for 5 min. The tissues were stained with hematoxylin and eosin (H&E, Nanjing Jiancheng Bioengineering Institute, Nanjing, China).

Measurement of tissue cytokine expression

Gastroduodenal tissues were homogenized in Tris buffer on ice and centrifuged at 12 000 *g* at 4 °C for 10 min. The supernatants were used to determine the activities of endotoxin (ET), IL-6, and platelet-activating factor (PAF) in the duodenal tissue and TNF-α, prostaglandin E2 (PGE2), epidermal growth factor (EGF) and IL-1β in the gastric tissue. Enzyme activity was determined with commercial assay kits (Nanjing Jiancheng Bioengineering Institute).

Total RNA extraction

Total RNA was extracted for microarray and qRT-PCR assay from gastric and duodenal tissue with TRIzol reagent (Invitrogen, Gaithersburg, MD, United States) and purified with mirVana miRNA Isolation Kits (Ambion, Austin, TX, United States). RNA was quantified with a Qubit fluorometer (Thermo Fisher Scientific, United States), and RNA integrity was assessed with a Bioanalyzer 2100 (Agilent, CA, United States). Only RNA extracts with an RNA integrity of > 6 were used in subsequent analyses.

Microarray analysis

Microarray hybridization, scanning, and analysis were performed by the Capital Biotechnology Corporation (Beijing, China). Using 100 ng total RNA, double-stranded cDNA containing the T7 RNA polymerase promoter sequence was prepared with CbcScript reverse transcriptase using a cDNA synthesis system (Capitalbio, Beijing, China) with the T7 Oligo(dT). cDNA labeled with a fluorescent dye (Cy5 or Cy3-dCTP) was produced by Eberwine's linear RNA amplification method and subsequent enzymatic reactions. The procedure was improved by using CapitalBio cRNA Amplification and Labeling Kits to produce higher yields of labeled cDNA. The microarray slides were read with an Agilent G2565CA Microarray Scanner to obtain the microarray hybridization images. The array data were analyzed for data summation, normalization, and quality control with GeneSpring V13 (Agilent).

Differentially expressed genes and Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway analysis

Chip signal intensities ≥ 400 were included for comparison. A two-class unpaired algorithm in the CapitalBio expression microarray analyzer software (CBC analyzer) was applied to identify differentially expressed genes in the sham operation and PL groups, and the PL and SL-4 groups in both gastric and duodenal tissues. Differentially expressed genes with fold-change ≥ 2.0 or ≤ 2 and P values ≤ 0.05 were evaluated. KEGG pathways were analyzed with a CaptitalBio Molecule Annotation System integrated with the KEGG database as previously described.

qRT-PCR validation

To validate the microarray results, qRT-PCR was used to validate the expression of the selected genes in the SL-4 (3.9 g/kg), PL and sham groups. The RNA samples used for qRT-PCR were the same samples from individual rats that made up the pools. One microgram of total RNA and an oligo(dT) primer were used for cDNA synthesis following the manufacturer's protocol for SuperScript III reverse transcriptase (Invitrogen, Carlsbad, CA, United States). Primers for the four genes chosen for verification were designed based on sequences published in GeneBank (Table 1). The validated genes were *CYP2b2*, *UGT2b1*, *MASP1*, and *A2m*. qRT-PCR was performed with an ABI PRISM 7900 sequence detection system (PE Applied Biosystems, Foster City, CA, United States) under the following conditions: 50 °C for 10 min, 40 cycles of 95 °C for 1 min, and 60 °C for 1 min. The program was ended with a melting curve from 72 °C to 95 °C and cooling to 40 °C. The *GAPDH* gene was used as a housekeeping control. Relative gene expression (ΔΔct) was calculated and graphed as a fold-change.

Statistical analysis

Pharmacological data were analyzed using SPSS 17.0 and reported as means ± SD. Intergroup comparisons was conducted with *t*-tests, and $P < 0.05$ was taken to indicate a significant difference. Regarding the microarray, a CBC analyzer (expression profile analysis procedures based on R Bioconductor and PERL) was used for the analysis. To select the DEGs, the threshold values were ≥ 2 and ≤ 2 fold-change and a *t*-test P value of 0.05. The data were Log_2 transformed and median centered by genes using the adjust data function of CLUSTER 3.0 software and further analyzed by hierarchical

clustering with average linkage.

RESULTS

SL-4 decreased histopathological features in ulcerated rats

In the PL group, rats showed severe injury and inflammation of the gastroduodenal epithelium and edema of the submucosa. SL-4 improved these alterations dose-dependently, and showed less mucosal damage and milder inflammation than the PL group (Figure 1). H&E staining confirmed the pathological alterations of gastroduodenal tissues. The SL-4-treated groups showed a recovery trend toward normal histology and only superficial lesions. More precisely, the mucosal structure and the epithelium were intact, with normal glandular size, morphology, and distribution in the SL-4 3.9 g/kg group compared with PL untreated rats, which was essentially the same as the control sham group.

SL-4 modulated cytokine expression in the damaged gastroduodenal tissue

The levels of enzymes present in tissue homogenates were determined by enzyme-linked immunosorbent assays. SL-4 pretreatment significantly ameliorated elevation of the inflammatory factors TNF-α and IL-1β in rat gastric tissue and increased the expression of prostaglandin E_2 (PGE2) and EGF hormones that inhibit gastric acid secretion compared with the PL group (Figure 2). In comparison, SL-4 treatment attenuated the expression of IL-6, ET and PAF in ulcerated duodenal tissue compared with the PL group in (Figure 3).

SL-4 altered gene expression in rats with PL-induced gastroduodenal ulcers

DEGs were identified in the ulcerated gastroduodenal tissues by an mRNA fold-change between two experimental groups of ≥ 2 and a *P* value ≤ 0.05. Volcano plot analysis showed that 1415 genes (731 upregulated and 784 downregulated) and 1460 genes (792 upregulated and 668 downregulated) were differentially expressed in gastric tissue from sham and PL, and PL and SL-4 groups (Figure 4A and B), and 2610 (1344 upregulated and 1266 downregulated) and 209 (100 upregulated and 109 downregulated) DEGs were identified in sham *vs* PL and PL *vs* SL-4 in the duodenal tissue (Figure 4C and D).

KEGG pathways analysis

To define the biological pathways associated with PL and SL-4 treatment in rat gastroduodenal ulceration, we analyzed the microarray data using R software, which was based on the KEGG database. The top ten DEG-enriched pathways in the sham *vs* PL and PL *vs* SL-4 groups in gastric and duodenal tissue are summarized in Tables 2 and 3. In gastric tissue, four pathways were engaged in the crosstalk of sham *vs* PL and PL *vs* SL-4, including *Staphylococcus aureus* infection, retinol metabolism, cytokine-cytokine receptor interaction, and the hematopoietic cell lineage pathway. In duodenal tissue, among the top 10 KEGG pathways in the sham *vs* PL and PL *vs* SL-4, two were the same in both groups, which were the complement and coagulation cascade pathways and *S. aureus* infection pathway.

According to the rat phenotype, retinol metabolism in the gastric tissue and complement and coagulation cascade pathways in the duodenal tissue were both closely associated with inflammatory responses and gastric mucosal protection mechanisms. Twelve genes were found to have > 2-fold expression and *P* values ≤ 0.05 in the two pathways. Gene expression pattern variations had the same trends in the PL and SL-4 groups. More precisely, when gene expression associated with retinol

metabolism was upregulated in the PL group, SL-4 downregulated the same genes relative to the PL group. In contrast, the pathways for certain genes in the complement and coagulation cascade were downregulated in the PL group and upregulated in the SL-4 group (Table 4).

qRT-PCR validation

The SL-4-mediated increase or decrease in *CYP2b2* and *UGT2b1* in the retinol metabolism pathway, and *A2m* and *MASP1* in the complement and coagulation cascades pathway were verified by qRT-PCR. Changes in the expression patterns of the four selected genes were consistent with the microarray results (Figure 5). Expression of *CYP2b2* and *UGT2b1* mRNA were increased in the PL group and decreased by SL-4 treatment. In contrast, expression of *A2m* and *MASP1* were decreased in the PL group and increased in the SL-4 group.

DISCUSSION

In Mongolian folk medicine, SL-4 is traditionally used to treat peptic ulcers and gastroenteritis. Previous studies have shown that SL-4 has therapeutic effects against infantile diarrhea and improves intestinal health[13-15]. However, the anti-ulcerogenic effect of SL-4 and its pharmacological mechanism have not been well investigated. Thus, we aimed to study whether SL-4 had a protective effect on PL-induced gastroduodenal ulcers in a rat model and examined its molecular mechanism by microarray analysis.

PL is a well-established methodology to develop gastric ulceration in rats[16]. PL induces accumulation of gastric acid and pepsin, resulting in breakdown of the gastric

mucosal barrier and causes inflammatory injury, which are key drivers of gastric ulcer formation[17]. To protect against inflammation, the cells respond with attenuated production of proinflammatory cytokines such as IL-12, TNF-α, IL-1, IL-6, and IFN[18]. Our findings show that SL-4 significantly improved the protective effects against gastroduodenal mucosal hemorrhage and inflammation, as confirmed by histopathology. Additionally, inflammatory factors such as IL-6, TNF-α and IL-1β were significantly reduced by SL-4 in contrast to the PL group, which indicates that the antiulcer effects of SL-4 can be attributed to anti-inflammatory activity. PAF, a potent phospholipid mediator of leukocyte activation, is a potent mediator of endogenous ulcer formation[19]. ET is a hormone secreted by the endothelial cells of blood vessels that can also promote ulceration[18]. Our data showed that SL-4 suppressed expression of PAF and ET in the gastroduodenal tissues in PL model mice in a dose-dependent manner, suggesting an inhibitory role for SL-4 in the activation of endothelial cells during ulcer maintenance. Additionally, SL-4 increased expression of PGE2 and EGF in gastroduodenal tissue, which indicates that it may effectively inhibit the secretion of gastric acid, enhance the gastric mucosal defensive function, promote the repair of gastric mucosal injury, and reduce recurrence rate of gastric ulcer[20]. A previous study reported that PGE2 was responsible for the production and maintenance of the cellular integrity of the gastric mucosa, and that depletion of PGE2 could cause gastric ulcers[21]. Histological evaluation showed that SL-4 reduced mean ulcer size and minimized ulcer formation, congestion, inflammation, hemorrhage, and necrosis of the gastric mucosa. Together, these findings demonstrated the antiulcer effect of SL-4 in PL rats.

Forsythia suspensa is a major herbal component of SL-4. It has been reported that its active ingredients forsythiaside and forsythin exert potent anti-inflammatory and antibacterial activities, which may have possible use as antiulcer agents[22]. A number of medicinal plants have been reported useful for the treatment of gastrointestinal

Genes involved in the retinol metabolism pathway in gastric tissue and in the complement and coagulation cascade pathways in duodenal tissue with > 2-fold change associated with different experimental treatments were determined by microarray analysis. Fold-induction was calculated as the normalized intensity in the study groups. Positive and negative numbers represent up- and downregulated gene expression. PL: Pyloric ligation; Sham: Sham operation; SL-4: Sulongga-4 decoction.

disorders. Wu *et al*[23] reported that a Chinese medicinal herb, *Pogostemon cablin*, and its main active compound β-patchoulene profoundly inhibited ulcer formation by reducing the inflammatory response and improving angiogenesis. Kumar *et al*[24] studied the antiulcer activity of an Indian medicine *Cedrus deodara* and found that its volatile oil had a potent gastroprotective effect on ulceration and inflammation in PL- and ethanol-treated rats. Al-Wajeeh *et al*[25] reported that a Malaysian medicine *Cibotium barometz* hair protected against ethanol-induced ulceration through regulation of antioxidant enzymes and gastric secretory actions. Consistent with those findings, our data confirmed that the gastroprotective effects of SL-4 components primarily work through modulation of inflammatory and gastric secretory mechanisms.

Microarray techniques are crucial for understanding and interpretating the activity of traditional medicines, particularly in revealing their mechanisms of action and drug targets[26]. To investigate the underlying molecular mechanisms of SL-4, we determined the gene expression profiles of gastric and duodenal tissues obtained from rats with PL-induced ulcers with or without SL-4 treatment. Retinol metabolism was one of the most significantly modified pathways in gastric tissue after SL-4 treatment. Retinoic acid (RA) intake and metabolism change dramatically during the acute-phase response (APR) to inflammation[27]. The APR is a metabolic system responding to infection, trauma, or tissue injury, and the PL method used in this study may have caused a strong APR in the intestinal tract. Inflammation drives decreased retinol usage by a reduction of retinol-binding protein synthesis[28]. RA increases the synthesis of inflammatory cytokines including transforming growth factor (TGF)-β, IL-10, IL-4, IL-5, and IL-6, and enhances white blood cell production[29]. Microarray analysis found that SL-4 decreased the expression of key transcriptomes associated with retinol metabo-lism. RA concentration is controlled by glucuronosyltransferases, including UGT2b1, and P450 cytochromes including CYP26A1, CYP26B1, and CYP26C1. These subfamilies catalyze RA oxidation to forms including 5,8-epoxy RA, 4-oxo RA, 4-hydroxy RA, and 18-hydroxy RA[30,31]. Thus, decreased enzyme activation blocks RA accumulation in the other areas and maintains a suitable physiological RA concentra-

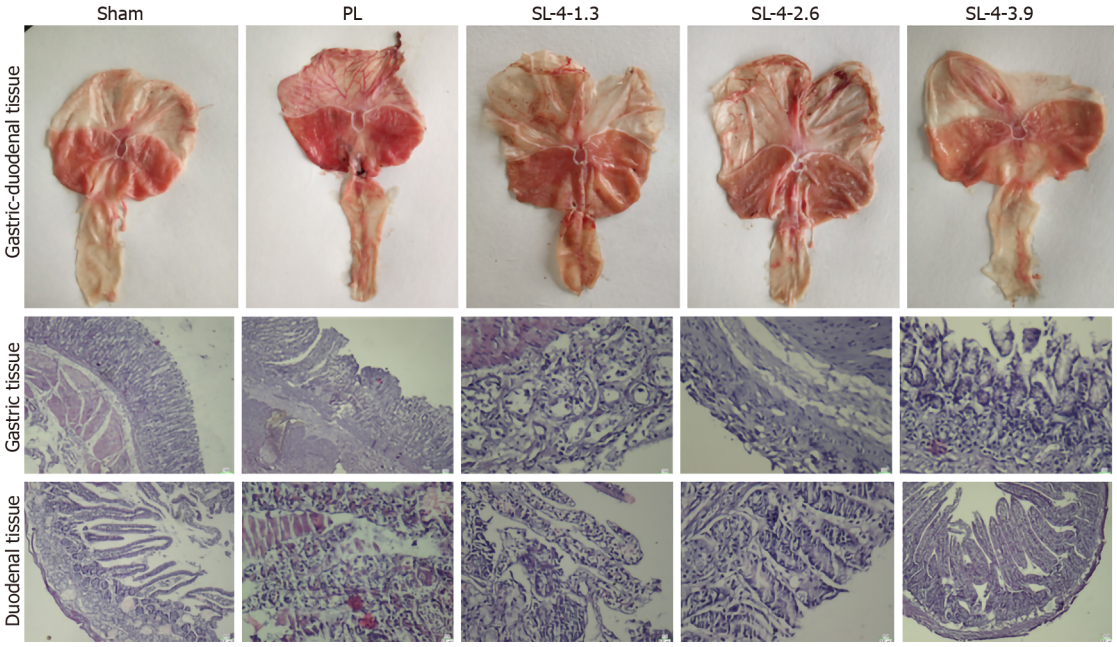

Figure 1 Histopathological assessment of the effects of Sulongga-4 on pyloric ligation-induced gastric and duodenal ulcers in rats. The gastroduodenal tissues were fixed with 4% paraformaldehyde, embedded in paraffin, and sectioned. The tissue sections were dewaxed, rehydrated, and stained with hematoxylin and eosin before observation by light microscopy (10 × 10). PL: Pyloric ligation; Sham: Sham surgery; SL-4: Sulongga-4 decoction.

tion to achieve the anti-inflammatory function of the gastrointestinal tract. Therefore, SL-4 can enhance the role of RA in maintaining homeostasis at the intestinal barrier and equilibrating immunity and tolerance. Together with vitamin A supplementation, SL-4 treatment may improve the protective effect against gastric ulcers in a clinical setting. The current results also suggest that SL-4 accelerates the anti-inflammatory effects of retinol metabolism. This further indicates the therapeutic effect of SL-4 on inflammatory bowel disease and other clinical inflammatory symp-toms.

Additionally, KEGG analysis found significant differences in the complement and coagulation cascade pathways that could have been caused by an inflammatory response. Damage of the intestinal tract activates the coagulation cascade. Fibrin formation provides a physical barrier that can be a potential shield from inflammation[32]. Our microarray results indicated that SL-4 elevated the transcriptome expression of A2m, which acts as a carrier protein to bind numerous growth factors and cytokines, such as platelet-derived growth factor, basic fibroblast growth factor, TGF-β and IL-1β, thus inhibiting inflammation[33]. MASP1 is a serine protease that functions as a component of the lectin pathway of complement systems, which plays a pivotal role in the defense against infection[34]. Elevation of MASP1 expression by SL-4 may be responsible for improving the immune activity and defense against gastric infections. The above results suggest that SL-4 may have several active substances that promote anti-inflammatory responses that prevent peptic ulcer formation *via* retinol metabolism and the complement and coagulation systems.

S. aureus infection was found in both gastric and duodenal tissues, which indicated that PL activated the immune system against *S. aureus* infection. Although our KEGG analysis did not find a direct protective effect, antimicrobial activity for SL-4 has been reported[12]. The intestinal immune system plays a vital role in the prevention of and defense against inflammation caused by harmful pathogens. In our study, PL induced an increase in IL-1β secretion in gastric tissues. Although the IL-1β-mediated immune response to *S. aureus* has not been confirmed, IL-1β is a key cytokine in orchestrating host defenses against the organism[35]. Therefore, the effect of SL-4 on bacterial infection of the intestinal tract should be investigated in a future study.

CONCLUSION

Our data demonstrate that SL-4 protected against PL-induced gastroduodenal ulceration by reducing inflammatory cytokines and increasing the expression of gastric acid inhibitory factors. We propose that regulation of *CYP2b2* and *UGT2b1* gene

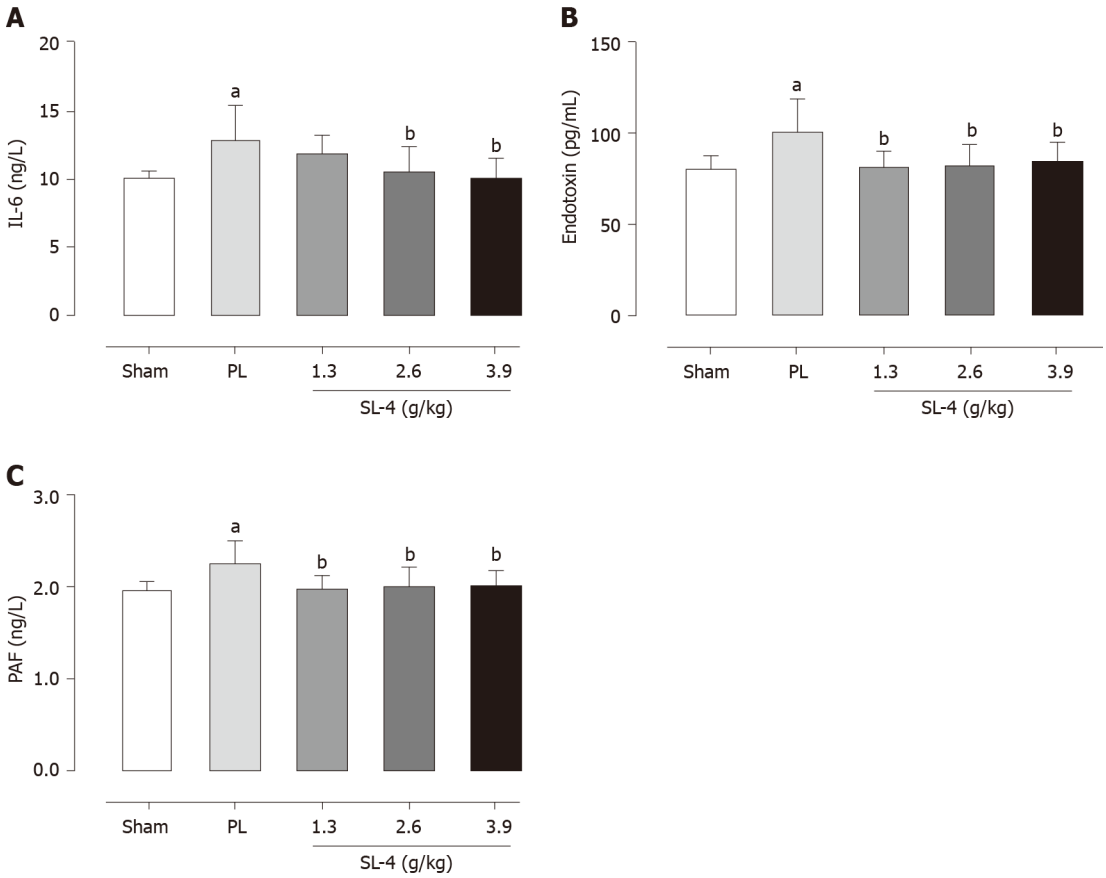

Figure 2 Expression of interleukin-6, endotoxin, and platelet-activating factor in duodenal tissue obtained from rats in different groups, and determined by enzyme-linked immunosorbent assay. Data are reported as means ± standard error (n = 10-12). Sham: Sham surgery; SL-4: Sulongga-4 decoction.

expression in the retinol metabolism pathway and *A2m* and *MASP1* genes in the complement and coagulation cascade pathways are may be involved in mechanism by which SL-4 protects against gastroduodenal ulcers. Most notable are the effects of SL-4 on the transcriptome involved in retinol metabolism, which has not been described previously. The Mongolian folk medicine SL-4 is a promising gastroprotective agent with potential use for treating gastric ulcers in clinical practice.

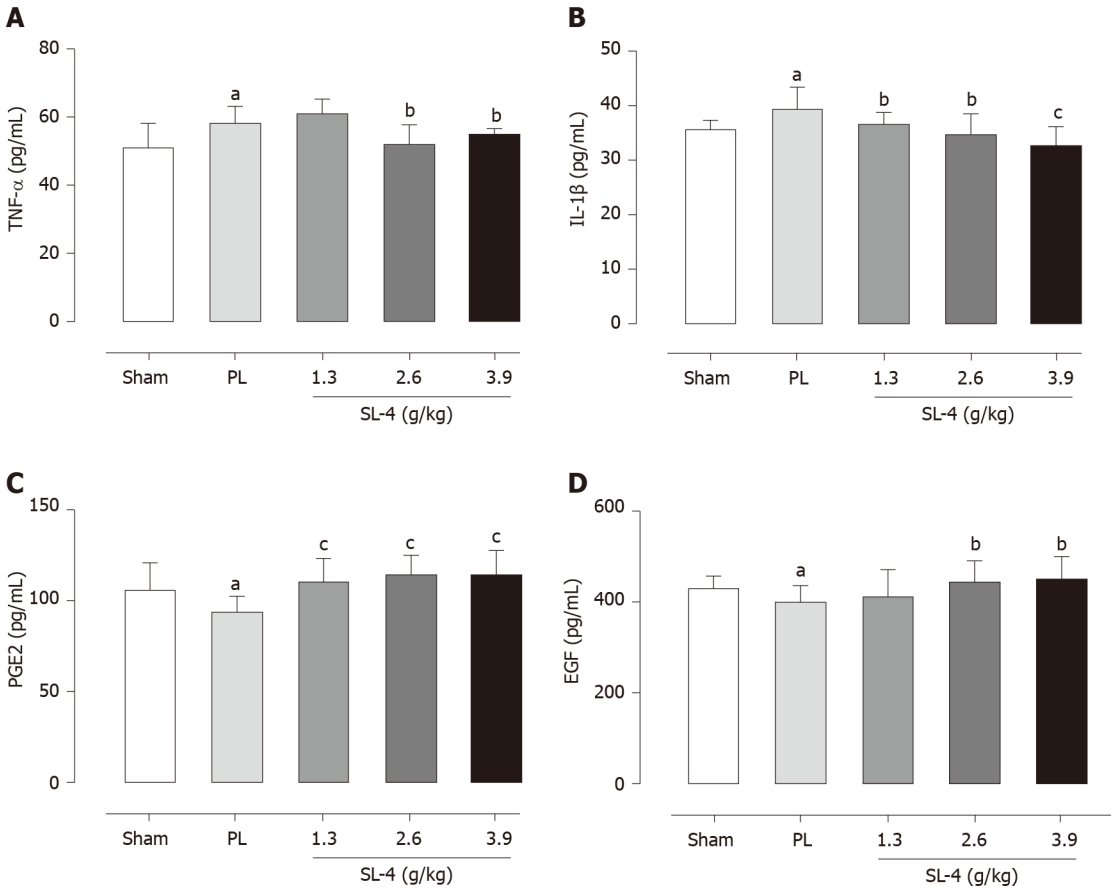

Figure 3 Expression of tumor necrosis factor-α, interleukin-1β, prostaglandin E2 and epidermal growth factor in the gastric tissue from rats in different groups, and determined by enzyme-linked immunosorbent assay. Values are means ± standard error (n = 6). $^{a}P < 0.05$ *vs* sham operation; $^{b}P < 0.05$ *vs* pyloric ligation (PL). Sham: Sham operation; SL-4: Sulongga-4 decoction.

ARTICLE HIGHLIGHTS

Research background

Sulongga-4 (SL-4) is a classic herbal formula used in traditional Mongolian medical clinics for the treatment of peptic ulcers and gastroenteritis, even though its pharmacological mechanism has not been well characterized.

Research motivation

The study objective was to identify the protective effect and mechanism of SL-4 against peptic ulcer disease.

Research objectives

To evaluate the protective effect and identify the mechanisms of action of SL-4 on gastroduodenal ulcer induced by pyloric ligation (PL) in rats.

Research methods

PL was performed to induce gastric and duodenal ulcers in rats that were then treated with oral SL-4 (1.3, 2.6, or 3.9 g/kg per day) for 15 d. PL-induced gastroduodenal ulceration. Therapeutic effects were evaluated by pathological and histological evaluation. Inflammatory indicators were analyzed by enzyme-linked immunosorbent assay. Microarray analyses were conducted to determine the gene expression profiles of gastroduodenal tissue in PL rats with or without SL-4 treatment. The candidate target genes were selected and verified by quantitative reverse transcription polymerase chain reaction (qRT-PCR).

Research results

SL-4 improved the histopathology of the PL-induced ulcers. SL-4 significantly ($P <$ 0.05) decreased the expression of tumor necrosis factor-α, interleukin (IL)-1β, IL-6, endotoxin, PAF, and increased prostaglandin E2 and EGF in ulcer tissue. Microarray

analysis was used to identify a list of candidate target genes for SL-4 acting on PL-induced ulceration. The genes included some that modulate complement and coagulation cascade pathways, and retinol metabolism pathways that are closely associated with inflammatory responses and gastric mucosal protective mechanisms. qRT-PCR showed that altered expression of the selected genes, such as *CYP2b2*, *UGT2b1*, *A2m*, and *MASP1*, was consistent with the microarray results.

Research conclusions

SL-4 exerted protective effects against PL-induced gastroduodenal ulcers *via* reducing inflammatory cytokines and elevating the expression of gastric acid inhibitory factors. Downregulation of the *CYP2b2* and *UGT2b1* genes in retinol metabolism and upregulation of the *A2m* and *MASP1* genes in the complement and coagulation cascade pathways may have been involved in the protection against gastroduodenal ulcers.

Research perspectives

SL-4, a Mongolian folk medicine, is a promising gastroprotective agent with potential clinical use as a treatment of gastric ulcers.

Abstract

BACKGROUND

Gastric carcinoma (GC) is a digestive system disease with high morbidity and mortality. However, early clinical detection is difficult, and the therapeutic effect for advanced disease is not satisfactory. Thus, finding new tumor markers and therapeutic targets conducive to the treatment of GC is imperative. MRPL35 is a member of the large subunit family of mitochondrial ribosomal protein. MRPL35 shows the characteristic of oncogene in colorectal cancer and esophageal cancer, which promotes the exploration of the correlation between MRPL35 and GC. We proposed that the expression of MRPL35 might be critical in GC.

AIM

To study the effect of *MRPL35* knockdown on GC cell proliferation.

METHODS

2020-071).

Peer-review started: December 22,

The expression of *MRPL35* in GC was evaluated based on data from the public tumor database UALCAN (www.ualcan.path.uab.edu). The effect of the expression of *MRPL35* on the prognosis was evaluated with KMplot (www.kmplot.com). The expression of MRPL35 was assessed on the tissue microarray by immunohistochemistry and the level of *MRPL35* mRNA in 25 pairs of clinical GC tissues and matched adjacent tissues was detected by quantitative reverse transcription-polymerase chain reaction. Celigo cell count assay, colony formation assay, and flow cytometry were used to assess the role of MRPL35 in GC cell proliferation and apoptosis *in vitro*. Additionally, tumor formation experiment in BALB/c nude mice was utilized to determine the effect of *MRPL35* on GC cell proliferation. After knockdown of *MRPL35*, related proteins were identified by isobaric tags for relative and absolute quantification analysis, and the expression of related proteins was detected by Western blot.

RESULTS

The expression of MRPL35 was up-regulated in GC ($P = 1.77 \times 10^{-4}$). The Kaplan-Meier plots of the overall survival indicated that high expression of MRPL35 was associated with a poor survival in GC. Compared with adjacent tissues, the expression of MRPL35 in GC tissues was increased, which was related to age ($P = 0.03$), lymph node metastasis ($P = 0.007$), and pathological tumor-node-metastasis stage ($P = 0.024$). Knockdown of *MRPL35* inhibited GC cell proliferation and colony formation and induced apoptosis. Animal experiment results showed that knockdown of *MRPL35* inhibited tumor formation in BALB/c nude mice. Western blotting analysis showed that after knockdown of *MRPL35*, the expression of PICK1 and BCL-XL proteins decreased, and that of AGR2 protein increased.

CONCLUSION

Collectively, our findings demonstrate that knockdown of *MRPL35* inhibits GC cell proliferation through related proteins including PICK1, BCL-XL, and AGR2.

Key Words: Gastric carcinoma; MRPL35; Apoptosis; Proliferation; Tissue microarray; Isobaric tags for relative and absolute quantification

Core Tip: MRPL35 is a member of the large subunit family of mitochondrial ribosomal protein. Our results showed that compared with adjacent tissues, the expression of MRPL35 in gastric carcinoma (GC) tissues was increased significantly, which was related to age, lymph node metastasis, and pathological tumor-node-metastasis stage of GC patients. Knockdown of MRPL35 inhibited GC cell proliferation, clone formation, and tumor formation in BALB/c nude mice, induced apoptosis, reduced the expression of PICK1 and BCL-XL proteins, and increased that of AGR2 protein. These data indicate that MRPL35 might be an oncogene and be used as a new therapeutic target for GC.

INTRODUCTION

Gastric carcinoma (GC) is a common digestive system disease, the fourth most common cancer, and the second leading cause of cancer-related mortality worldwide. About 1033701 new cases of GC and 782685 GC-related deaths occurred worldwide in 2018, accounting for 8.2% of all cancer deaths in this year[1,2]. In China, the incidence of GC has always been high, and the mortality rate of the disease has also increased

gradually, which is threatening human life and health.

At present, the treatment for GC mainly includes surgery, chemotherapy, radiotherapy, and drug treatment[3]. Most patients with early and advanced GC can be treated by surgery. However, the metastasis of GC is a major problem faced by surgery. The surgical treatment cannot cope with the distant metastasis of GC. Chemotherapy and radiotherapy reduce the recurrence and metastasis of GC, treat residual lesions, protect surrounding normal tissues and important organs, and improve survival[4]. During chemotherapy and radiotherapy, patients have to bear a specific degree of discomfort and pain, resulting in lower patient compliance, which in turn, affects the treatment effect. Therefore, finding effective drug treatment target is a major issue in the treatment of GC.

MRPL35, a 39S large subunit, encoded by a nuclear gene, is a member of the large subunit family of mitochondrial ribosomal protein. It is a specific component of mitochondrial ribosomes and plays a key role in the assembly of cytochrome C oxidase, involved in the translation of mitochondrial proteins[5,6]. The *MRPL35* gene is localized on chromosome 2p11.2, and the protein contains 188 amino acids and has a molecular weight of about 25 ku. Survival analysis revealed that high expression of MRPL35 indicated a prolonged survival in patients with glioblastoma[7]. The expression of MRPL35 in colorectal cancer tissues is higher than that of the matched adjacent tissues[8]. Furthermore, down-regulation of MRPL35 leads to increased production of reactive oxygen species and DNA damage and can inhibit cell proliferation, block the G2/M phase cell cycle, reduce the mitochondrial membrane potential, and induce apoptosis and autophagy *in vitro*. After the transfection of esophageal cancer TE-1 cells with lentivirus, compared with shCtrl (negative control virus) group, the expression of MRPL35 was reduced in the shMRPL35 (lentiviral particles of MRPL35) group, and *MRPL35* silencing suppresses the proliferation of esophageal cancer TE-1 cells and promotes apoptosis[9]. Other studies found that MRPL35 was negatively correlated with the survival time of patients after surgery[10]. *MRPL35* knockdown in colorectal cancer HCT116 cell and SW480 cell inhibited cell proliferation, promoted apoptosis, and blocked the G2/M phase of the cell cycle.

The MRP family regulates cells by participating in the transcriptional translation function of ribosomal proteins, which is closely related to tumor genesis and development[11]. Previous studies have confirmed that *MRPS18-2* is an oncogene[12]; *MRPL44* is up-regulated in the tissues of cervical lymph node metastasis of thyroid cancer[13]; *MRPS22*, which is found in large cell lung cancer, is highly expressed in squamous cell carcinoma and adenocarcinoma, and is low in other types of cancer[14]; *MRPL41* is down-regulated in colorectal cancer, pancreatic cancer, and other cancers[15]; *MRPS23*, down-regulated in breast cancer, can activate P21 WAF1/CIP1 and P53, inhibit cell proliferation, and promote apoptosis[16]; and MRPL35 is associated with the occurrence and development of glioblastoma, esophageal cancer, and colorectal cancer. However, the expression and functional role of MRPL35 in GC remain largely unknown. Therefore, we analyzed the correlation between MRPL35 and GC by tissue microarray, cell function experiments, nude mouse tumor formation experiments, and proteomic analysis. The expression of MRPL35 might be critical in GC according to the experimental results, and it could be a potential therapeutic target for GC.

MATERIALS AND METHODS

Patients

GC tissues and matched adjacent tissues were obtained from Department of Hepatobiliary Surgery, General Hospital of Ningxia Medical University. Following surgical removal, the tissue samples were immediately stored in liquid nitrogen before total RNA extraction. All tissues were histopathologically identified as GC or adjacent tissues. None of the patients had received preoperative adjuvant therapy, and all patients provided informed consent in accordance with the protocol approved by the Ethics Committee of Ningxia Medical University.

Immunohistochemistry staining

Immunohistochemistry (IHC) staining was performed on the tissue microarray (TMA)[17,18]. The method of staining is immunohistochemical streptavidin-peroxidase (SP) method. The section contained 64 pairs of GC tissues and matched adjacent tissues. The section was deparaffinized in xylene and washed in 700 mL/L ethanol. The antigen was recovered using citrate buffer (pH 6.0) under high pressure for 10

min. Endogenous peroxidase was blocked with 30 mL/L H_2O_2 (MERCK, Germany) in methanol for 10 min. Then, the section was incubated overnight with primary antibody (mouse polyclonal anti-MRPL35 antibody, HPA026631; Sigma-Aldrich, St. Louis, MO, United States) at 4 °C and secondary antibody successively, and developed with diaminobenzidine (DAB) reagent. The section was washed in TBST three times for 5 min, rinsed with tap water for 5 min, and then counterstained with hematoxylin. A negative control was run by omission of primary antibody (phosphate buffered saline instead of primary antibody) on another slide that was for testing the proper antibody concentration. Subsequently, the TMA was analyzed independently by two pathologists without knowing the patients' clinical information. The areas of the brown-yellow particles are the signs of positively stained tumor cells which represent the MRPL35 protein in the tissues. The staining intensity was scored from 0-3 as negative (0), weak (1), medium (2), or strong (3). The degree of staining was scored by the area of positively stained tumor cells relative to the entire tumor area: 0 (0%), 1 (1%-25%), 2 (26%-50%), 3 (51%-75%), and 4 (76%-100%). The overall protein expression score (the overall score range was 0-12) was calculated by multiplying the intensity and the positive score.

Cell culture and transfection

Human GC cell lines (AGS, NCI-N87, MKN-45, and HGC-27) were purchased from the Cell Bank of the Chinese Academy of Sciences. The cell lines were cultured in a cell incubator at 37 °C and 50 mL/L CO_2 in RPMI-1640 medium (Gibco, New York, United States) containing 100 mL/L fetal bovine serum (FBS, Gibco) and penicillin and streptomycin (Invitrogen, Carlsbad, United States). shMRPL35 and shCtrl were designed and produced by GeneChem (Shanghai, China). Lentiviral transfection and the specific steps were performed according to the manufacturer's instructions.

Quantitative reverse transcription-polymerase chain reaction

Total RNA of the cultured cells was extracted using TRIzol reagent (PuFei, Shanghai, China). PrimeScript RT Master Mix Perfect Real-Time (TaKaRa, Shiga, Japan) was used to synthesize first-strand cDNA from total RNA. Quantitative reverse transcription-polymerase chain reaction (qRT-PCR) was performed using SYBR Master Mixture (TaKaRa) according to the manufacturer's instructions. The primers used are as follows: *MRPL35*: Forward, 5′-TTGGCATCTTCAACCTACCGC-3′ and reverse, 5′-GGAGGAAACAACTGGTGTCTGA-3′; *GAPDH*: Forward, 5′-TGACTTCAACAG CGACACCCA-3′ and reverse, 5′-CACCCTGTTGCTGTAGCCAAA-3′. Data are presented as the mean ± SD for duplicate runs. The relative quantification of *MRPL35* expression was evaluated using the $2^{-\Delta\Delta CT}$ method. All experiments were repeated three times.

Celigo cell count assay

The infected cells were seeded in a six-well plate at a density of 2000 cells/well and cultured at 37 °C and 50 mL/L CO_2. On the following day, the Celigo assay was performed daily for 5 consecutive days according to the manufacturer's instructions. All experiments were repeated three times.

Colony formation assay

The infected cells were inoculated in a six-well plate at a density of 1000 cells/well. The medium was changed every 3 d during the interval. After 2 wk, the colonies were fixed with 4% paraformaldehyde for 40 min and stained with 0.1% crystal violet (Sigma-Aldrich) for 4 min. The visible colonies were counted manually. Triplicate wells were assessed for each treatment group. All experiments were repeated three times.

Flow cytometry analysis of apoptosis

Apoptotic and necrotic cells were evaluated with Annexin V-fluorescein isothiocyanate (FITC) and propidium iodide (PI) (KeyGEN, Jiangsu, China). All the samples were analyzed in triplicate by flow cytometry (BD Bioscience, Bedford, MA, United States). All experiments were repeated three times.

Tumor formation experiment in BABL/c nude mice

Four-week-old male BABL/c nude mice of specific pathogen-free (SPF) grade were purchased from the Animal Experiment Center of Ningxia Medical University. All animals were housed in polypropylene cages and fed standard laboratory chow and water *ad libitum*, and maintained at a temperature of 22 ± 1 °C, with 50% ± 5% relative

humidity and 12:12 h light-dark cycles. First, MKN-45 cells were infected with shMRPL35 and shCtrl (n = 10 per group). A microsyringe was used to extract 200 μL of the infected and uninfected MKN-45 cell suspension at a concentration of 1.25 × 10^7 /mL, and injected into the skin of nude mice. The tumor volume was measured daily using the formula $V = W^2 \times L \times 0.5$ (V, volume; W, width; L, length). The animal protocols (IACUC-NYLAC-2019-083) were approved by the Institutional Animal Care and Use Committee of Ningxia Medical University.

Isobaric tags for relative and absolute quantification analysis

SDT lysis method was used for GC cell sample preparation, and the bicinchoninic acid (BCA) method (Beyotime, Shanghai, China) was used for protein quantification. After protein samples were subjected to sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), Coomassie brilliant blue staining, and filter aided sample preparation enzymolysis, the resulting peptides were quantified using NanoDrop (Thermo Scientific ND2000, Shanghai, China), and the sample peptides were labeled according to the instructions of the isobaric tags for relative and absolute quantification (iTRAQ) labeling kit (AB SCIEX, Framingham, MA, United States). The labeled peptides of each group were mixed and graded using Agilent 1260 infinity II HPLC system, and Easy nLC chromatographic system (Thermo Scientific) analysis and mass spectrometry were performed. The high-resolution mass spectrometer Q Exactive Plus (Thermo Scientific) and Proteome Discoverer 2.1 (Thermo Scientific) software were used for iTRAQ analysis, and the database search was performed on the MASCOT2.5 (Matrix Science, Boston, MA, United States) server. The Protein Database used was Uniprot_HomoSapiens_159615_20170811.fasta (http:// www.uniprot.org). A homology search was first performed for the identified sequences with a localized sequence comparison tool NCBI BLAST+ against the NCBI database, and top 10 aligned sequences were selected according to the E value from the lowest to the highest for subsequent analysis. Then, Blast2GO Command Line was utilized to perform GO (Gene Ontology) annotation on the identified proteins. The enrichment analysis of GO annotation or KEGG pathway annotation was performed on the identified proteins through Fisher's exact test. The expression of identified proteins was analyzed with Cluster 3.0 software, and hierarchical clustering heat map was generated with Java Trewview software.

Western blot analysis

Total protein was extracted using the Whole Cell Lysis Assay (KeyGEN, Jiangsu, China), and the concentration was determined by BCA Protein Quantitation Assay (KeyGEN, Jiangsu, China). The protein was separated by SDS-PAGE (60-100 mL/L gel) with a sample amount of 50 μg and transferred to polyvinylidene difluoride (PVDF) membranes that were probed with specific primary antibodies overnight at 4 °C. Then, the membranes were incubated with secondary antibodies for 1 h. The immune-reactive bands were visualized using ECL Reagent (Affinity Biosciences, Jiangsu, China) and images were analyzed by Bio-Rad Laboratories (Inc., Hercules, United States). All the primary antibodies and secondary antibodies were from Abcam (MA, United States).

Statistical analysis

The statistical methods of this study were reviewed by Sun J from Department of Occupational and Environmental Health and Department of Medical Statistics, Institute of Public Health and Management, Ningxia Medical University. All analyses were performed using GraphPad Prism 7.0. All the data are expressed as the mean ± SE. Statistical significance was analyzed using one-way ANOVA. $P < 0.05$ was considered statistically significant.

RESULTS

The expression of MRPL35 is up-regulated in GC tissues

The expression of MRPL35 between GC tissues and adjacent tissues was compared through the public tumor database UALCAN (www.ualcan.path.uab.edu). The results showed that the expression of MRPL35 was increased in GC tissues in comparison with matched adjacent tissues (P = 1.77 × 10^{-4}; 10-4; Figure 1A). In different pathological grades, the expression of MRPL35 in moderate and well grades was higher than that in matched adjacent tissues (P = 8.25 × 10^{-5}; P = 4.19 × 10^{-5}; 10-5;

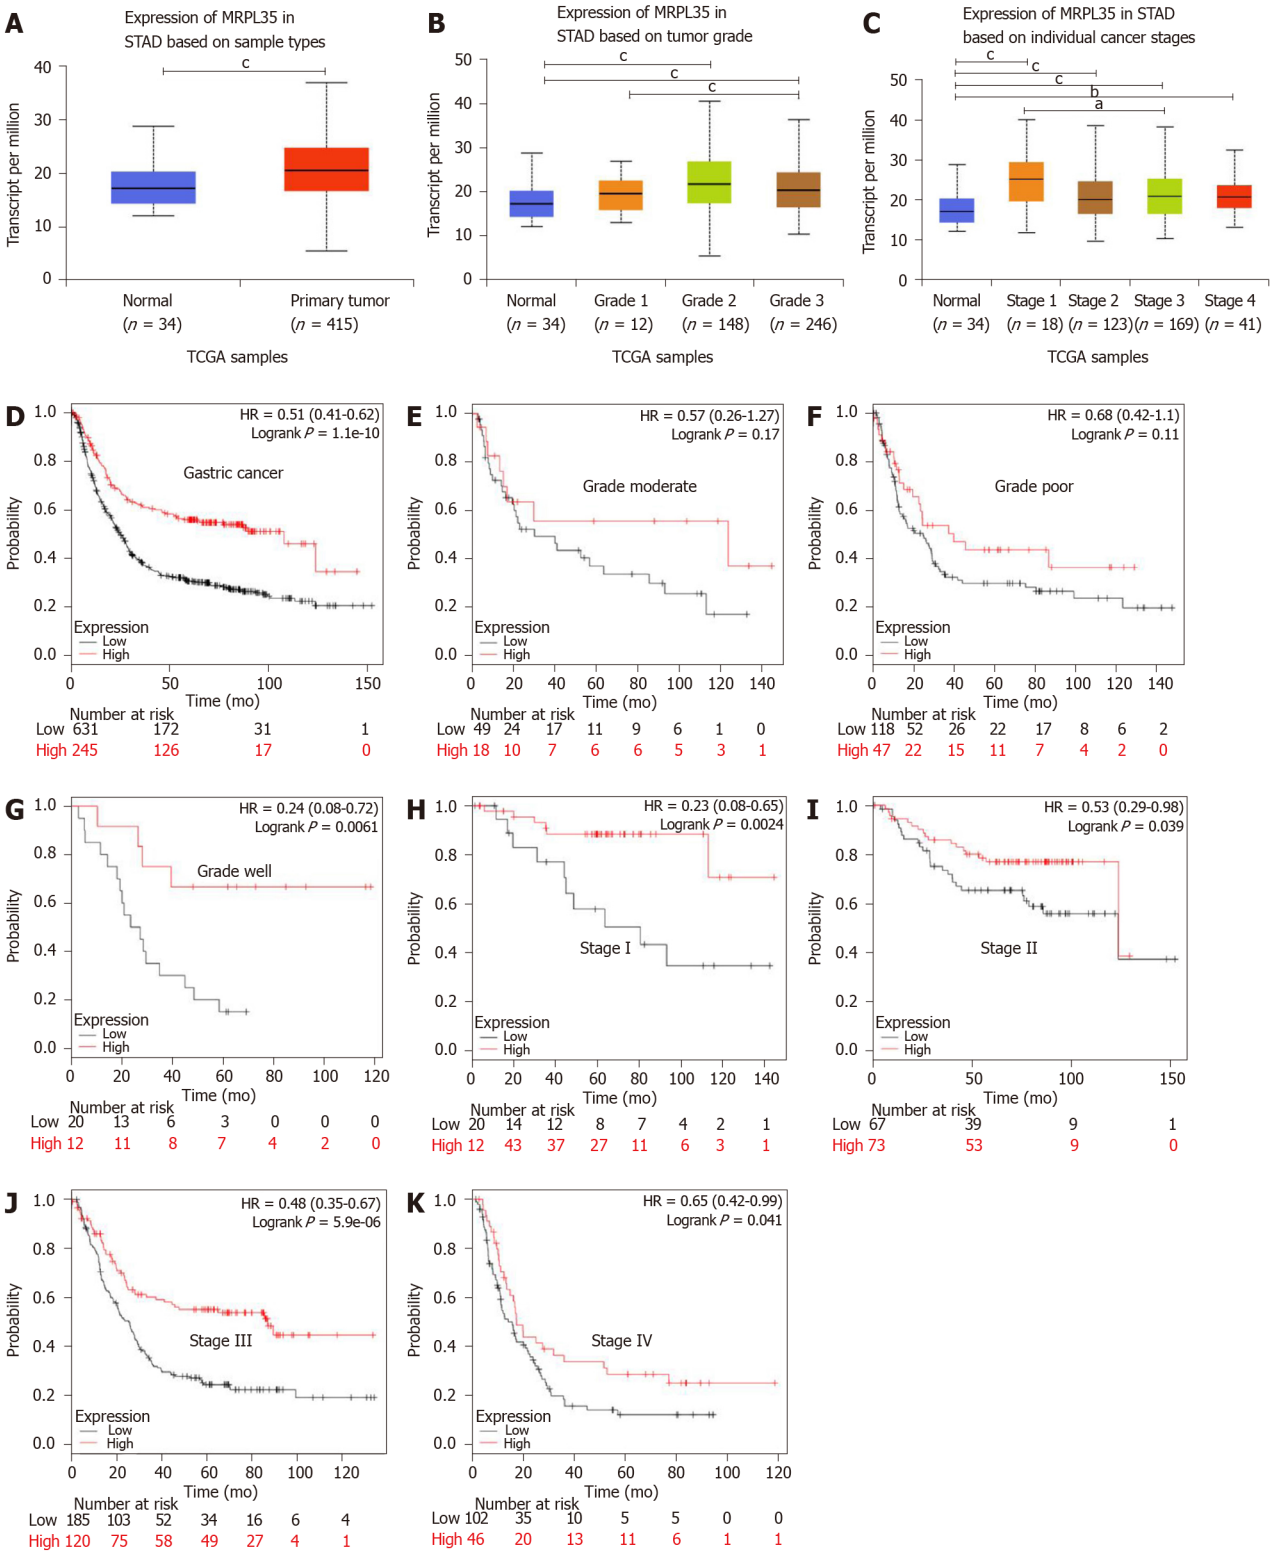

Figure 1 MRPL35 is highly up-regulated in gastric carcinoma. A-C: The expression of MRPL35 in stomach adenocarcinoma based on sample type (A), tumor grade (B), and individual cancer stage (C). The results were based on data from the public database UALCAN (www.ualcan.path.uab.edu); D: Kaplan-Meier overall survival chart. The results were based on data from the public database KMplot (www.kmplot.com); E-G: Overall survival of patients with high and low expression of MRPL35 in different pathological grades of gastric carcinoma (GC) (E, moderate; F, poor; G, well); H-K: Overall survival of patients with high and low expression of MRPL35 in different pathological stages of GC (H, stage I; I, stage II; J, stage III; K, stage IV). The results were based on data from the public database KMplot (www.kmplot.com). $^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$. STAD: Stomach adenocarcinoma; HR: Hazard ratio.

Figure 1B). In different pathological stages, the expression of MRPL35 in stages I, II, III, and IV was higher than that in matched adjacent tissues ($P = 0.0012$, $P < 6.42 \times 10^{-4}$, $P = 4.36 \times 10^{-4}$, and $P = 0.0021$, respectively; Figure 1C). Next, the effect of MRPL35 expression on the prognosis was evaluated with KMplot (www.kmplot.com). The

Kaplan-Meier plots of the overall survival indicated that high expression of MRPL35 was associated with a poor survival in GC (Figure 1D). When stratified according to different histological types and disease stages, patients with high MRPL35 expression had a poor overall survival in well grade and in stage I, stage II, stage III, and stage IV (Figure 1G-K), but not in poor and moderate grades (Figure 1E and F).

Furthermore, the expression of MRPL35 in clinical samples was detected by IHC method in 64 pairs of GC tissues and matched adjacent tissues. The immunostaining of MRPL35 protein was mainly located in the cell (Figure 2A-C). The negative control pictures are shown in the supplementary materials (Supplementary Figure 1). According to the staining site, the MRPL35 protein expression score was calculated by multiplying the intensity and the positive score (total score range 0-12). The expression of MRPL35 protein in GC tissues was higher than that in matched adjacent tissues ($P < 0.05$) (Figure 2D and E). These data indicated that up-regulation of MRPL35 might play an important role in the development of GC. In addition, the expression of *MRPL35* mRNA in 25 pairs of clinical GC tissues and matched adjacent tissues was detected by qRT-PCR, and the expression of *MRPL35* mRNA was up-regulated in GC tissues ($P = 0.009$; Figure 2F and G).

The correlation between the high expression of MRPL35 and clinicopathological factors in patients with GC proved the importance of high expression of MRPL35 in GC patients (Table 1). According to the average expression (staining score), 68 patients were divided into two groups; for the expression of MRPL35, < 6 was defined as low expression and ≥ 6 defined as high expression. The result of statistical analysis showed that high expression of MRPL35 was correlated with age ($P = 0.03$), lymph node metastasis ($P = 0.007$), and pathological tumor-node-metastasis stage (p-TNM stage) ($P = 0.024$). On the other hand, the correlation between the expression of MRPL35 and other clinicopathological features was not significant.

Expression of MRPL35 in GC cells

Next, qRT-PCR analysis was performed to determine the expression of *MRPL35* in four human GC cell lines. The result showed that the expression of *MRPL35* was elevated in AGS and HGC-27 cell lines, but was lower in MKN-45 and NCI-N87 cell lines (Figure 3A). Thus, lentiviral vectors were used to knock down *MRPL35* in both cell lines. At 72 h post-transfection, bright light and fluorescence observation under a microscope showed that the cell transfection rate was > 80% (Figure 3B and C). qRT-PCR data revealed that the expression of *MRPL35* mRNA (PSC32114 and PSC32115) in AGS and HGC-27 cells was inhibited after *shRNA* lentivirus transfection ($P < 0.05$), and the knockdown efficiency reached 73.7% and 76.5% in AGS cells, and 67% and 77.5% in HGC-27 cells (Figure 3D and E). Subsequently, the expression of MRPL35 protein after *MRPL35* knockdown in AGS cells was assessed by Western blot; in contrast with the shCtrl group, the expression of MRPL35 (PSC32114 and PSC32115) was reduced in AGS cells ($P < 0.05$) (Figure 3F).

Effect of MRPL35 knockdown on GC cell proliferation, colony formation, and apoptosis

In contrast with the shCtrl group, the shMRPL35 (PSC32114 and PSC32115) group had inhibited proliferation of the two cell lines as monitored by Celigo cell count assay ($P < 0.01$), indicating that knockdown of *MRPL35* had an inhibitory effect on cell proliferation (Figure 4A and B). In addition, knockdown of *MRPL35* greatly reduced the colony-forming ability of AGS and HGC-27 cells (Figure 4C and D). Finally, the apoptosis was analyzed using flow cytometry. The numbers of apoptosis of AGS cells and HGC-27 cells in the shMRPL35 (PSC32114 and PSC32115) group increased compared with the shCtrl group ($P < 0.01$) (Figure 4E and F). These result indicated that MRPL35 might be essential for the proliferation of GC cells.

Knockdown of MRPL35 inhibits tumor formation in BABL/c nude mice

The tumor volume of the shMRPL35 group was smaller than that of the shCtrl group (Figure 5A and B). Within 3 wk of tumor formation, the tumor growth curve was drawn. Compared with the shCtrl and the NC groups, the tumor growth rate of the shMRPL35 group was lower (Figure 5C) ($P < 0.01$).

Proteomic and bioinformatic analysis identified proteins

Among 5993 proteins, 100 differentially expressed proteins (DEPs) were identified (Figure 6A). In comparison with the shCtrl group, 49 DEPs were up-regulated and 51 were down-regulated in the shMRPL35 group. The DEPs were screened based on the multiple of expression difference > 1.2 times and P value (t-test) < 0.05. The

enrichment analysis was performed through GO functional annotation, describing the differential proteins from a large variety of biological processes, including cellular process, single-organism process, biological regulation, regulation of the biological process, and metabolic process (Figure 6B and C). The significance level of protein enrichment in each pathway was obtained by analyzing DEPs based on the KEGG database pathway annotation analysis (Figure 6D). The result of cluster analysis showed that the expression of all DEPs was different in the groups of shMRPL35 and shCtrl (Figure 6E).

Knockdown of MRPL35 alters the expression of PICK1, BCL-XL, and AGR2 proteins in GC cells

PHLDA1, MAPK8, PICK1, BCL-XL, AGR2, and ZFP36L1 proteins were selected for Western blot verification, and these proteins ranked the top 30 in biological process, molecular function, and cellular component. The expression of PHLDA1, MAPK8, PICK1, BCL-XL, AGR2, and ZFP36L1 proteins in AGS cell was detected by Western blot, and these proteins were contained in DEPs. Compared with the shCtrl group, the expression of PICK1 and BCL-XL proteins was decreased, and that of AGR2 was increased in the shMRPL35 group ($P < 0.01$) (Figure 7A and B). Based on the above result, knockdown of *MRPL35* may inhibit the proliferation of GC cells through PICK1, BCL-XL, and AGR2 proteins.

DISCUSSION

A major finding of this study is that knockdown of *MRPL35* could inhibit the proliferation of human GC cells and promote apoptosis through nude mouse tumor

A
B
C

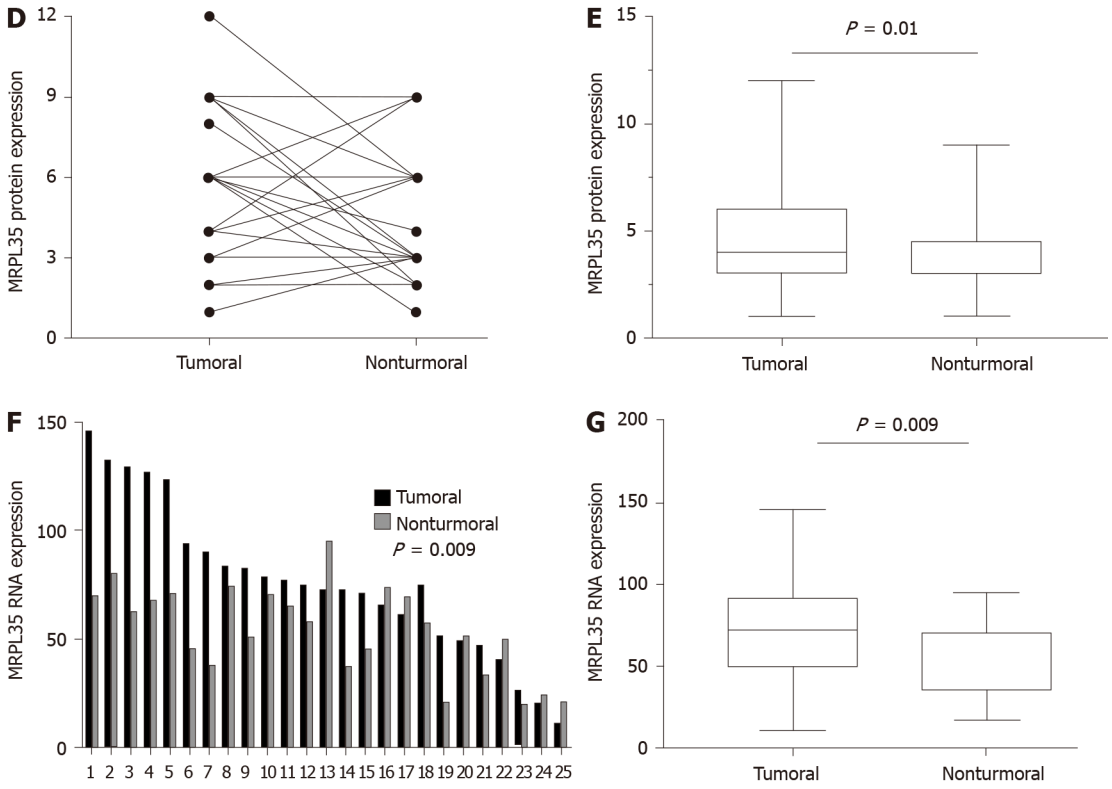

Figure 2 The expression of MRPL35 is up-regulated in gastric carcinoma tissues. A-C: Immunohistochemistry was performed on 64 pairs of gastric carcinoma (GC) tissues and matched adjacent tissues. Magnification: 4 × (A), 40 × (B), 200 × (C); D and E: The relative expression of MRPL35 in GC tissues and matched adjacent tissues; F and G: The relative expression of *MRPL35* mRNA in GC tissues and matched adjacent tissues (n = 25).

formation experiment *in vivo*, together with cell function experiment *in vitro*. In addition, proteomic analysis found that related downstream proteins changed after knockdown of *MRPL35*. And then, the six proteins were assessed by Western blot, which showed that the expression of PICK1 and BCL-XL proteins decreased, while that of AGR2 protein increased. In addition, the expression of MRPL35 was up-regulated in GC tissues, and high expression of MRPL35 was associated with a low survival rate in GC. Sixty-four pairs of clinical samples of GC tissues and matched adjacent tissues were examined for the expression of MRPL35 by IHC. The expression of MRPL35 in GC tissues was increased compared with matched adjacent tissues, and high expression of MRPL35 was correlated with age, lymph node metastasis, and p-TNM stage. Moreover, the results of other studies on MRPL35 in other cancers were similar to those of the current study, suggested that MRPL35 has the potential to serve as a new therapeutic target for GC. It is necessary to explain the number of tissues on the TMA. Originally, there were 75 pairs of GC tissues and matched adjacent tissues on the section, but a few of them were worn out during the IHC process. Finally, the tissues that could present on the slide and be used for analysis included 68 GC tissues and 64 matched adjacent tissues, that is to say, there were 64 GC tissues and 64 matched adjacent tissues, as well as the extra four GC tissues of which the matched adjacent tissues were worn out. We performed clinicopathological feature analysis on the remaining 68 GC tissues, and then obtained the data in Table 1. However, we carried out the IHC analysis on the remaining 64 pairs of GC tissues and matched adjacent tissues, because it should make a comparative analysis between GC tissues and the matched adjacent tissues. So only 64 pairs of tissues are shown in Figure 2A, for there were no matched adjacent tissues to be compared with the extra four GC tissues. The figures of the extra four GC tissues are shown in the supplementary materials (Supplementary Figure 2).

From the previous studies, we noticed that the expression of MRPL35 was decreased and cell proliferation inhibited, while apoptosis was promoted after knockdown of *MRPL35* in esophageal cancer TE-1 cells[9]. This phenomenon was similar to the results of the current study. The expression of MRPL35 in cancer tissues was higher than that in matched adjacent tissues in colorectal cancer, and *MRPL35* knockdown *in vitro* can inhibit cell proliferation and promote apoptosis[8]. The expression of MRPL35 was decreased in the nude mouse xenograft model of colorectal

cancer[19]. Indeed, the tumor growth rate in the experimental group was slow, and the tumor was smaller than that in the control group, which was the same as our experimental results. The gastrointestinal tract contains the mouth, esophagus, stomach, small intestine, and large intestine. The cells contained in these tissues were developed from the endoderm of the early embryo. Perhaps because the esophagus, stomach, and large intestine all come from the endoderm, the inhibitory effects of MRPL35 in GC, esophageal cancer, and colorectal cancer are similar.

Furthermore, the PICK1 protein contains a PDZ domain, which binds to a variety of membrane proteins and organizes the subcellular localization of adaptor protein[20]. It may also participate in receptor aggregation by acting on the level of receptor internalization. Decreased expression of MRPL35 regulates the expression of MRPL27, reducing the expression of PICK1. The protein encoded by *BCL-XL* belongs to the BCL-2 protein family[21]. It can be used as an anti- or pro-apoptotic regulator involved in various cell activities and regulation of the opening of the mitochondrial outer membrane channel (VDAC). MRPL35 regulates the expression of BCL-XL by regulating the family member BAX. AGR2 encodes a member of the disulfide isomerase family of endoplasmic reticulum protein and plays a role in cell migration, cell differentiation, and growth, and is associated with cancer progression[22]. Consequently, the expression of MRPL35 and MRPL2 is altered, which in turn, affects that of AGR2. These results fully indicated that *MRPL35* might be an oncogene, and the correlation between MRPL35 and GC is worthy of in-depth exploration.

In short, the current study suggested that MRPL35 has a causal correlation with GC, and related downstream proteins of MRPL35 have been identified. Nevertheless, the current study has some deficiencies. At present, only a few studies have investigated MRPL35, which is not sufficient to clarify its role as a therapeutic target for GC. On the premise that there are no relevant studies on MRPL35 and GC, follow-up research would be divided into three stages. In the first stage, the correlation between *PICK1*, *BCL-XL*, and *AGR2* genotype and GC phenotype would be explored. In the second stage, the correlation between MRPL35 and its downstream proteins PICK1, BCL-XL, and AGR2 would be examined. In the third stage, the mechanism underlying the interaction between MRPL35 and PICK1, BCL-XL, and AGR2 would be assessed, and two modes of action were considered: Direct and through tool protein. Also, covalent and non-covalent interactions occurred between the proteins. Anyway, our study aimed to provide a scientific basis for the treatment of GC and find effective drug target for the early prevention of GC.

CONCLUSION

MRPL35 is related to esophageal cancer and colorectal cancer, and has not been reported in GC. Our experimental data combined with the data in the public tumor database show that MRPL35 is of extraordinary importance in GC tissues and cells, which has also been verified in nude mice. The expression of MRPL35 in GC tissues is higher than that of the matched adjacent tissues, and knockdown of *MRPL35* can inhibit the proliferation of GC cells and induce apoptosis. This suggests that MRPL35 is a potential target for the treatment of GC, and it is necessary to further study the effect of MRPL35 on GC.

ARTICLE HIGHLIGHTS

Research background

Gastric carcinoma (GC) is one of the most common cancers, and the existing treatment methods cannot meet the treatment needs for GC. At the same time, MRPL35, a member of the large subunit family of mitochondrial ribosomal protein, shows the characteristics of oncogene in certain cancers.

Research motivation

The existing treatment methods for GC mainly include drugs, chemotherapy, and surgery, all of which have certain defects. Finding new therapeutic targets will be of great benefit to patients with GC.

Research objectives

The present study aimed to explore the correlation between MRPL35 and GC, and the effect of knockdown of *MRPL35* on GC cells.

Research methods

The expression of MRPL35 in GC and the effect of MRPL35 on the prognosis of GC were evaluated based on data from public databases. Immunohistochemistry staining and pathological factors analysis were performed on 64 pairs of GC tissues and matched adjacent tissues. The effect of MRPL35 on the proliferation and apoptosis of GC cells was determined by Celigo cell count assay, flow cytometry, and tumor formation experiment in BABL/c nude mice. The related proteins that changed after knockdown of *MRPL35* was identified by proteomic analysis and tested by Western blot.

Research results

The expression of MRPL35 was up-regulated in GC and high expression of MRPL35 was associated with a poor survival in GC. The expression of MRPL35 in GC tissues was increased in comparison with matched adjacent tissues, which was related to age, lymph node metastasis, and pathological tumor-node-metastasis stage. Knockdown of *MRPL35* inhibited GC cell proliferation and colony formation and induced apoptosis. After knockdown of *MRPL35*, the expression of PICK1 and BCL-XL protein decreased, and that of AGR2 protein increased.

Research conclusions

MRPL35 is up-regulated in GC, and knockdown of *MRPL35* could inhibit the proliferation of GC cells and induce apoptosis.

Research perspectives

MRPL35 can be used for targeted therapy of GC, and can also be used as a new biomarker for GC.

Abstract

BACKGROUND

Esophageal cancer is a malignant tumor of the digestive tract that is difficult to diagnose early. CPI-455 has been reported to inhibit various cancers, but its role in esophageal squamous cell carcinoma (ESCC) is unknown.

AIM

To investigate the effects and mechanism of the lysine demethylase 5C inhibitor, CPI-455, on ESCC cells.

METHODS

A methyl tetrazolium assay was used to detect the inhibitory effect of CPI-455 on the proliferation of Eca-109 cells. Apoptosis, reactive oxygen species (ROS), and mitochondrial membrane potential were assessed by flow cytometry. Laser confocal scanning and transmission electron microscopy were used to observe changes in Eca-109 cell morphology. The protein expression of P53, Bax, lysine-specific demethylase 5C (KDM5C), cleaved Caspase-9, and cleaved Caspase-3 were assayed by western blotting.

Compared with the control group, CPI-455 significantly inhibited Eca-109 cell proliferation. Gemcitabine inhibited Eca-109 cell proliferation in a concentration- and time-dependent manner. CPI-455 caused extensive alteration of the mitochondria, which appeared to have become atrophied. The cell membrane was weakly stained and the cytoplasmic structures were indistinct and disorganized, with serious cavitation when viewed by transmission electron microscopy. The flow cytometry and western blot results showed that, compared with the control group, the mitochondrial membrane potential was decreased and depolarized in Eca-109 cells treated with CPI-455. CPI-455 significantly upregulated the ROS content, P53, Bax, Caspase-9, and Caspase-3 protein expression in Eca-109 cells, whereas KDM5C expression was downregulated.

CONCLUSION
CPI-455 inhibited Eca-109 cell proliferation *via* mitochondrial apoptosis by regulating the expression of related genes.

Key Words: Lysine-specific demethylase 5C; CPI-455; Esophageal squamous cell carcinoma; Caspase; P53

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: This study confirmed that the lysine demethylase 5C inhibitor CPI-455 inhibited the proliferation of Eca-109 esophageal squamous cell carcinoma cells. CPI-455 played a role in esophageal squamous cell carcinoma cells proliferation and invasion that may have been associated in part with p53, Bax, Caspase-9, and Caspase-3 expression. CPI-455 induced Eca-109 cell apoptosis *via* a mitochondria-mediated intrinsic apoptotic signaling pathway by regulating the expression of related genes.

INTRODUCTION

Esophageal cancer is a common digestive tract cancer, of which esophageal squamous cell carcinoma (ESCC) and esophageal adenocarcinoma represent the main histological types[1,2]. The incidence of esophageal cancer is relatively high, ranking seventh worldwide. ESCC accounts for more than 90% of esophageal cancers. As it is difficult to diagnose ESCC early due to a lack of specific clinical symptoms and insufficient preventive measures, it is often diagnosed at an advanced stage and has a poor prognosis. In addition, the 5-yr postoperative survival rate is less than 50%[3-5].The lysine-specific demethylase 5C (KDM5C) inhibitor, CPI-455, regulates the apoptosis and proliferation of tumor cells by regulating the methylation state of lysine in KDM5C[6]. CPI-455 activity been reported in cervical[7], gastric[8], and prostate cancer[9], and in other diseases[10,11]; but not in the treatment of esophageal cancer. In this study, human ESCC Eca-109 cells were used as a research model to preliminarily study the effect and mechanism of CPI-455 against ESCC and to explore novel approaches for the treatment and prevention of ESCC.

MATERIALS AND METHODS

Cell lines

Eca-109 human esophageal cancer cells and HPT-1A normal human esophageal epithelial cells were provided by the Cell Resource Center of the Shanghai Life Sciences Institute, Chinese Academy of Sciences (Shanghai, China). Other materials

included CPI-455 (MSDS, 1628208-23-0; Gibco, Ltd., United States), DMEM and RPMI 1640 cell culture media and fetal bovine serum (Gibco, Ltd). Anti-human P53 (cat no. sc-6243), Bax, KDM5C (cat no. sc-81623), Caspase-9 (cat no. 9746), Caspase-3 (cat no. 9502), GAPDH (glyceraldehyde-3-phosphate dehydrogenase, cat no. sc-47778) polyclonal antibody (1:200; Abcam, United Kingdom) were used for western blotting. Annexin V-fluorescein isothiocyanate (FITC)/propidium iodide (PI) apoptosis detection kits (cat no. F7250) were from Sigma-Aldrich (United States). polyvinylidene difluoride (PVDF) membranes were from Biyuntian Biotech (China) and bicinchoninic acid (BCA) protein quantitative detection kits were from Thermo Fisher (United States). An Epics Ultra flow cytometer (Beckman Coulter, United States), JEM-100sx transmission electron microscope (Jeol Ltd., Japan), and a TCS SP2 laser confocal microscope (Leica, Germany) were used.

Cell culture

Eca-109 cells were cultured in DMEM and HET-1A cells were cultured in RPIM-1640 medium. Both were supplemented with 10% pre-inactivated FBS, 100 U/mL penicillin, and 100 U/mL streptomycin. Cells were adherently cultured in a 37 °C constant temperature incubator with a volume fraction of 5% CO_2 and 95% humidity; 0.25% trypsin-EDTA was used for cell digestion and passage. Cell growth in the culture flask was observed every 1-2 d, and the cell culture medium was replaced for passage culture.

Methyl tetrazolium assay

For assay of growth and the logarithmic phase, cells were collected by trypsin digestion and centrifugation and 90 mL of a single cell suspension (3×10^3/mL) were inoculated into 96-well culture plates and cultured at 37 °C in an atmosphere containing 5% CO_2. overnight to ensure adherence. When the cells grew to the appropriate density, the supernatant was discarded and 100 mL of the CPI-455 KDM5C inhibitor was added to each well, giving a final concentration of 15 mmol/L. The plates were cultured in an atmosphere containing 5% CO_2 at 37 °C for 0, 24, 48, 72, and 96 h (5 wells/time point). Following this, the cells were collected and centrifuged at 150 *g* for 10 min. The supernatant was discarded and the precipitate was washed once with phosphate buffered saline (PBS). A total of 200 μL of serum-free RPMI-1640 medium was added, followed by addition of 10 μL of methyl tetrazolium (MTT; 5 mg/mL). Following culture for a further 4 h, the supernatant was removed and 150 μL DMSO was added to each well to dissolve the purple crystals. The optical density (OD) was read at 490 nm after the crystals had completely dissolved. The survival rate was calculated as S% = (OD of the experimental group/OD of the control group) × 100.

Laser confocal scanning microscope assay of the ectropion of membrane phosphatidylserine

The fluorescence of cell smears and suspension cultures after polylysine treatment was observed by confocal microscopy. Red (488/590 + 42 nm) and green (488/530 + 30 nm) dual channel detection and differential interference contrast imaging were performed. A total of 100 fields of vision were screened and 30 typical fields of vision were selected for inclusion in the preliminary statistical analysis. Annexin V-FITC (fluorescein isothiocyanate), PI double staining was performed and the fluorescence of Eca-109 cell membranes and necrotic nuclei was observed and analyzed as described above. DAPI (4', 6-diamidine-2-phenylindole, dihydrochloride) was used to stain the nuclei in cell smears and glycerol patches and analyzed by fluorescence microscopy, as described above.

Terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) assay of nucleation and DNA fragmentation of Eca-109 cells

Eca-109 cells (5×10^6/mL) were seeded in 24-well plates and cultured for 48 h. Cell smears were prepared from 50 μL of cell suspension on polylysine-treated slides that were fixed with 4% paraformaldehyde at room temperature for 30-60 min and washed twice with PBS. After treatment with terminal deoxynucleotidyl transferase and termination, the preparations were washed four times with PBS and incubated with FITC-labeled antibody for 30 min. Nuclei were stained with PI (1.0 g/mL) and the preparations were sealed with glycerin-mounted coverslips and marked. The cells were observed with a confocal laser scanning microscope, with FITC and PI dual channel fluorescence at an excitation wavelength of 490 nm and an emitted wavelength of 520 nm).

Flow cytometry assay of reactive oxygen species (ROS)

Eca-109 cells were cultured in a six-well plates (3×10^3 cells/well), treated with 15 μmol/L CPI-455 for 48 h, and collected. The cells were washed three times in PBS, centrifuged for 5 min, and the supernatant was discarded. The cells were resuspended in serum-free medium, dichloro-dihydro-fluorescein diacetate (DCFH-DA) was added to a final concentration of 10 mmol/L, and the plates were incubated at 37 °C for 40 min. The cells were centrifuged for 10 min, and the pellet was collected, washed, and resuspended in precooled PBS. The cells were centrifuged to obtain a pellet and were stained for fluorescence detection. Each assay was performed in triplicate.

Flow cytometry assay of mitochondrial membrane potential

Cells were harvested (2×10^6/mL) at scheduled times after treatment with 15 μmol/L CPI-455 for 48 h. The Mitocapture dye and antibody incubation solutions were freshly prepared. The cells were washed and centrifuged and the mitochondria were stained. The cells were immediately transferred to collecting tubes for flow cytometry.

Western blotting assay of P53, Bax, KDM5C, cleaved Caspase-9, and cleaved Caspase-3

Eca-109 cells were cultured for 48 h, collected, and centrifuged at 150 *g* for 5 min (r = 6 cm). Total protein was extracted using a protein extraction kit. The supernatant was collected, and the protein concentration was determined using a BCA protein kit. Proteins were separated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and transferred to PVDF membranes. After blocking in 5% skim milk at room temperature for 2 h, anti-human mouse P53, Bax, KDM5C, Caspase-9, Caspase-3, and GAPDH monoclonal antibodies (1:1000; Santa Cruz Biotechnology, Inc., United States) were added and the membranes were incubated overnight at 4 °C and then with horseradish peroxidase (HRP)-labeled mouse secondary antibody (1:3,000; Origene Technologies Inc., China). The films were developed, fixed, scanned and analyzed using Image J software to calculate the gray values. Protein expression of the target protein was reported relative to GAPDH protein expression.

Statistical analysis

GraphPad Prism 6.0 software was used to statistical analyze the data. The data were reported as means ± SD. All assays were repeated independently three times. Between-group differences were compared with independent samples *t*-tests. One-way analysis of variance was used to compare data with normal distributions. Least significant difference (LSD)-*t*-tests were used for pairwise comparisons of multiple groups. The significance level was = 0.05.

RESULTS

CPI-455 inhibits Eca-109 cell proliferation

The MTT results demonstrated that CPI-455 significantly inhibited the proliferation of Eca-109 cells in a time- and a concentration-dependent manner. The CPI-455 LD_{50} was 15 mol/L CPI-455 at 48 h. Therefore, the 48 h concentration of 15 mol/L CPI-455 was selected for the follow-up procedures (Figure 1).

CPI-455 induces Eca-109 cell apoptosis

The laser confocal scanning microscopy results showed that prior to CPI-455 treatment, the Eca-109 cells had developed a complete mitochondrial structure. Mitocapture revealed a bright red color and "pipe-like network" that surrounded the nuclear lobule and was distributed throughout the entire cell. Following treatment with CPI-455 (15 μmol/L) for 48 h, both groups showed the presence of dye in the cytoplasm, with red mitochondrial staining and green cytoplasmic staining. Some cells contained visible "point and flake" red-stained mitochondria scattered in the cytoplasm, not present in clusters surrounding the nucleus, and gradually merging to form a "structureless aggregation". Substantial changes to the mitochondrial structure were observed, which appeared to indicate mitochondrial atrophy. Following CPI-455 treatment, the Eca-109 cell membranes were weakly stained and the internal cytoplasmic structures indistinct and disorganized, with severe cavitation (Figure 2A and B).

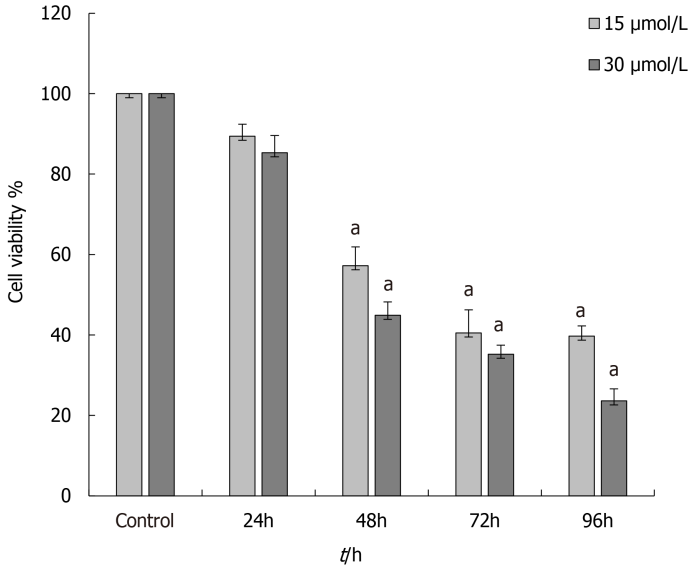

Figure 1 Eca-109 cell viability following treatment with CPI-455 at different times and concentrations. Data are expressed as means ± SE (n = 3). [a]P < 0.05 *vs* control.

TUNEL and laser confocal scanning microscopy showed green fluorescence generated by the combination of FITC and the staining of 3'-OH terminal fragments produced by DNA fragmentation in the nucleus of apoptotic cells. Red fluorescence was emitted by PI-stained nuclei, which revealed the location of cells. Double-positive cells were seen in cells treated with CPI-455. Most Eca-109 cells in the CPI-455 group were double-positive for FITC and PI fluorescence. Most Eca-109 cells in the control group were negative for FITC and positive for PI, indicating that TUNEL assay of the CPI-455-stimulated group was positive. In terms of cell morphology, compared with the control group, most Eca-109 cells in the control group had a lower nuclear staining density, an unclear nuclear boundary, and larger nuclei. However, most ECA-109 cells in gemcitabine group had dense chromatin and small nuclei (Figure 2C and D).

CPI-455 upregulates ROS content, P53, Bax, Caspase-9, and Caspase-3 expression and downregulates KDM5C expression and mitochondrial membrane potential in Eca-109 cells

Flow cytometry was used to detect the effect of CPI-455 on the level of ROS in Eca-109 cells. With an extension of the induction time, the level of intracellular ROS in the Eca-109 cells was increased significantly, with statistically significant differences observed at 24, 48, and 72 h (P < 0.01, Figure 3). Compared with the control group, the mitochondrial membrane potential was depolarized and decreased (P < 0.01, Figure 4). The western blot results found increased expression of p53, Bax, Caspase-9, and Caspase-3 at 24, 48, and 72 h following CPI-455 treatment (Figure 5). However, KDM5C protein expression in the treated cells was significantly decreased compared with the controls (P < 0.01, Figure 6).

DISCUSSION

Esophageal cancer is a digestive tract malignant tumor that is difficult to diagnose early. The most common treatments are surgery, radiotherapy, chemotherapy, and biologically targeted therapy[12]. The prognosis remains poor. The occurrence and development of esophageal cancer is complex and involves multiple gene changes, commonly resulting from histone methylation and epigenetic regulation of tumor-related genes.

CPI-455 is a KDM5C inhibitor that modulates the apoptosis and proliferation of tumor cells by regulating the lysine methylation status KDM5C. Recent reports have confirmed that the anti-tumor effect of CPI-455 in ovarian, breast, stomach, lung, and liver cancer is achieved by inducing the apoptosis and autophagy of tumor cells *via* modulating KDM5C gene transcription and expression[13,14]. In this study, the anti-Eca-109 effect of CPI-455 was studied and the associated mechanism was explored.

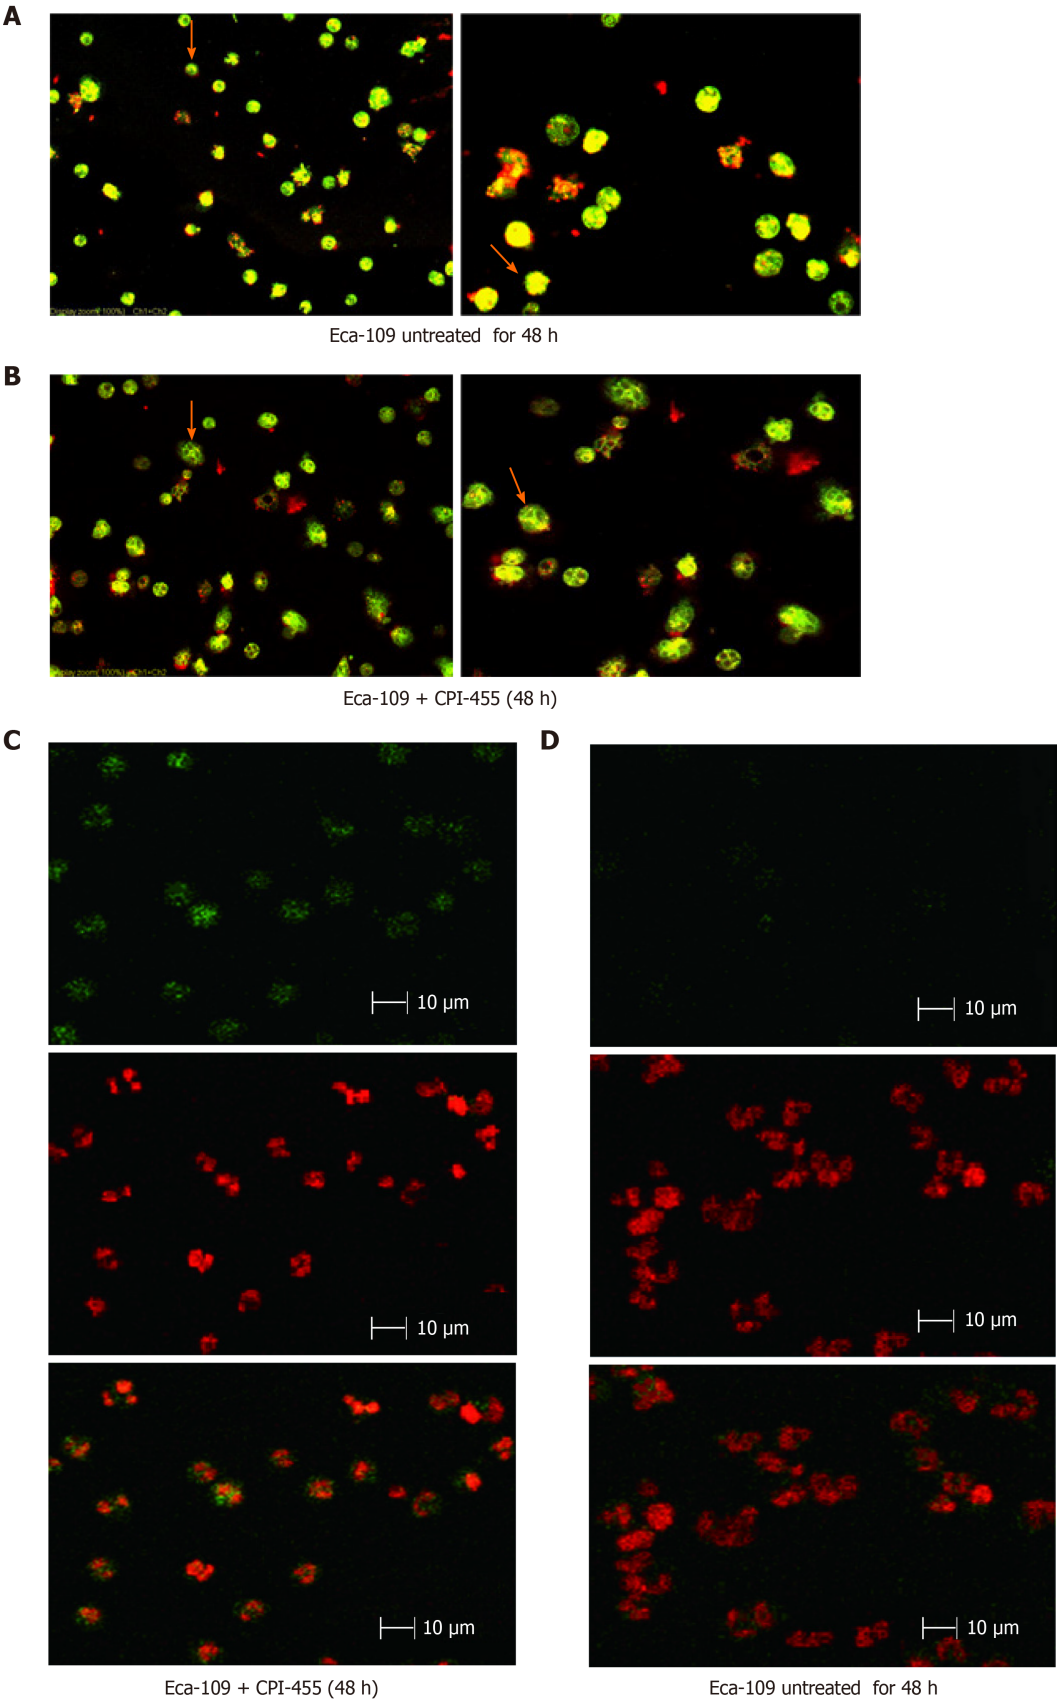

Figure 2 Changes in Eca109 cells after 48 h culture with and without CPI-455 treatment. Left panels show the morphology of the mitochondria of Eca109 cells. A: Arrows indicate mitochondria with complete and clear structure. B: Arrows indicate mitochondria with a fuzzy structure and weak staining of cells. Right panels show TUNEL assay results (bar = 10 μm) and laser confocal scanning microscopy × 600 of nuclear staining and DNA fragmentation of Eca109 cells C: without, and D: with CPI-455 treatment. Data are reported as means ± SE (n = 3).

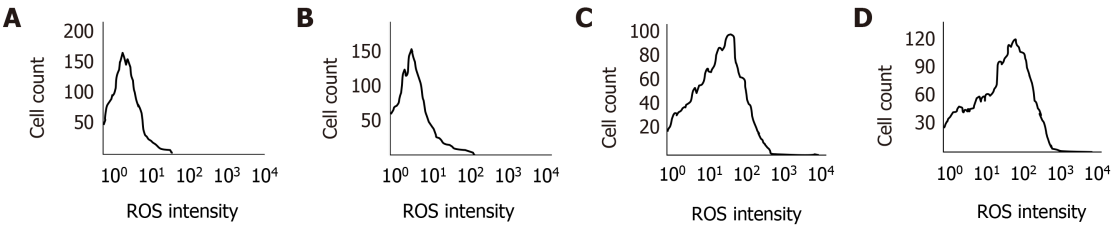

Figure 3 Eca-109 induced by CPI-455 is dependent on the generation of reactive oxygen species. A: Eca109 untreated (0 h); B: Eca-109 induced by CPI-455 for 24 h; C: Eca-109 induced by CPI-455 for 48 h; D: Eca-109 induced by CPI-455 for 72 h. Data are reported as means ± SE (n = 3). ROS: Reactive oxygen species.

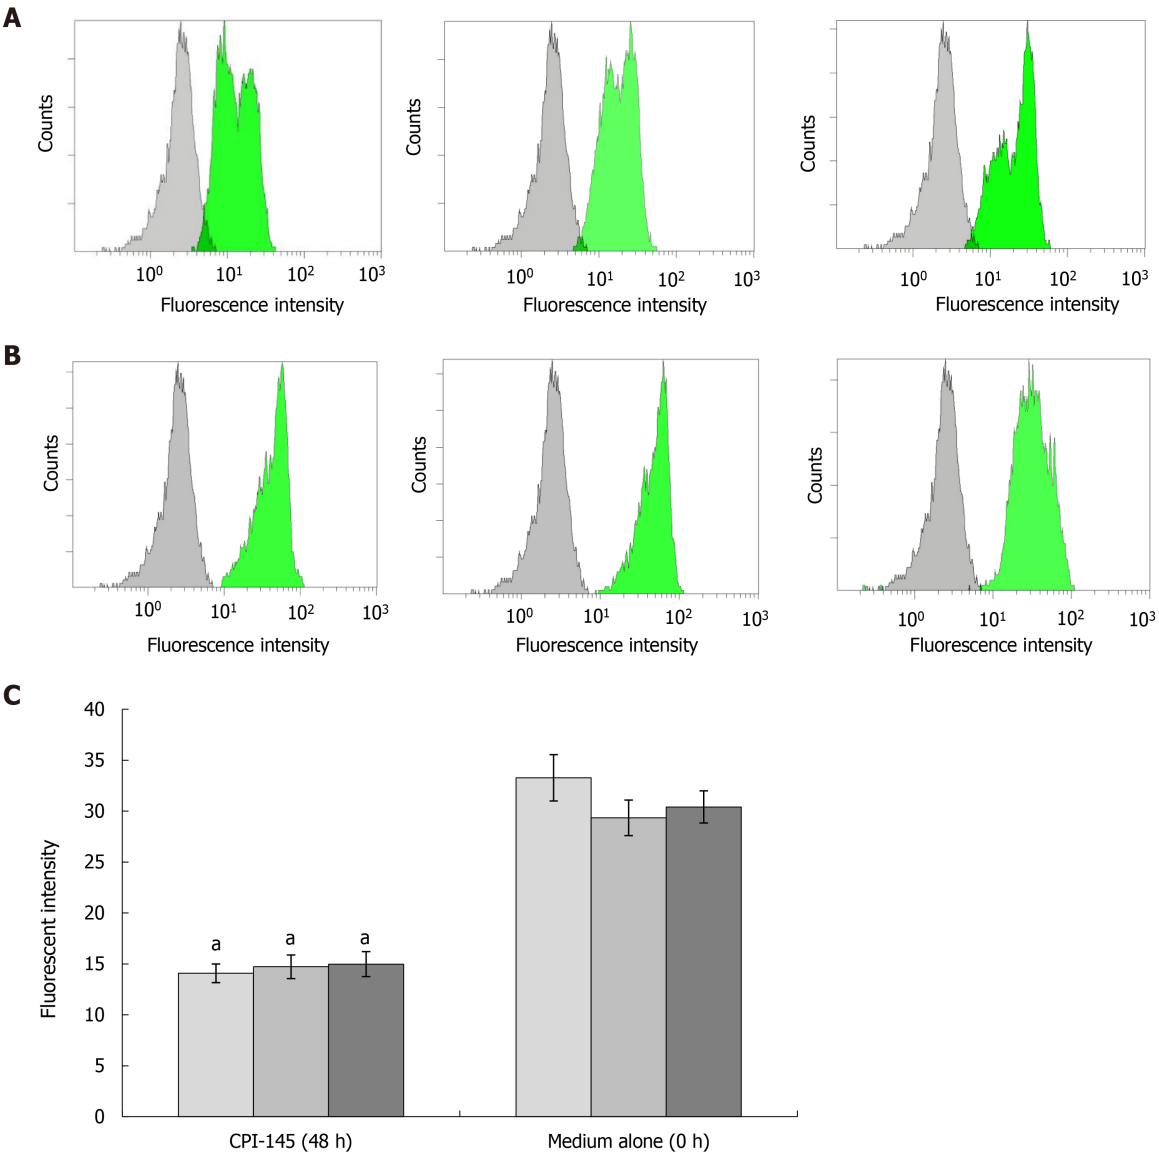

Figure 4 Mitochondrial membrane potential assayed by flow cytometry. A: Eca109 untreated (0 h); B: Eca109 treated with CPI-455 for 48 h; C: Gray scale results of membrane potential energy of mitochondria (Blue: Results of the first assay; Red: Results of the second assay; Green: Results of the third assay). Data are reported as means ± SE (n = 3). $^{a}P < 0.05$ *vs* control.

The study results found that CPI-455 inhibited the proliferation of esophageal cancer cells in a time-and concentration-dependent manner. However, at its effective concentration, CPI-455 was less toxic to normal esophageal cells than to Eca-109 cells. The inhibitory effect of CPI-455 on Eca-109 cell proliferation was confirmed by the assay of cell-membrane permeability by laser confocal scanning microscopy. This finding indicates that CPI-455 has favorable effects by inhibiting Eca-109 cell

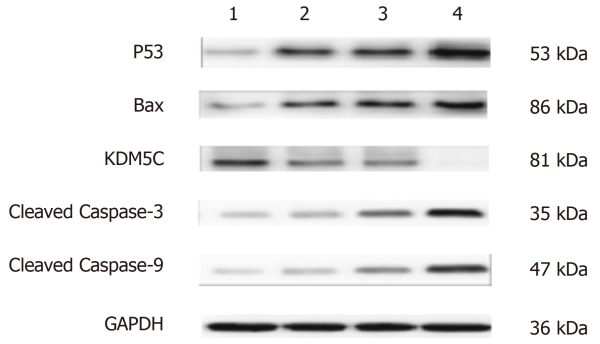

Figure 5 Western blot assays of p53, Bax, lysine-specific demethylase 5C, cleaved Caspase 3, and cleaved Caspase 9 protein expression in Eca-109 cells. Lane 1: Eca109 untreated (0 h); Lane 2: Eca109 induced by CPI-455 for 24 h; Lane 3: Eca109 induced by CPI-455 for 48 h; Lane 4: Eca109 induced by CPI-455 for 72h. KDM5C: Lysine-specific demethylase 5C; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

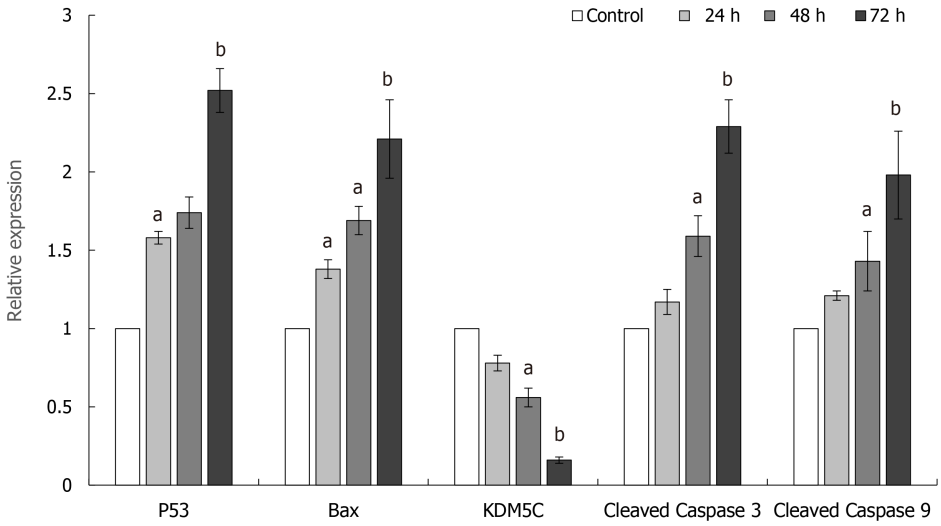

Figure 6 Densitometry analysis of the immunoblotting data of P53, Bax, lysine-specific demethylase 5C, cleaved Caspase 3, and cleaved Caspase 9 proteins in Eca-109 cells. Data are reported as means ± SE (n = 3). $^{a}P < 0.05$ *vs* control; $^{b}P < 0.01$ *vs* control.

proliferation and growth, as well as the selective killing on ESCC cells (Figures 1 and 2).

Flow cytometry was used to determine the ROS content of Eca-109 cells, which is considered to be the by-product of oxygen consumption and cell metabolism. Previous studies have found that various chemotherapy drugs can induce an increase in the ROS content in tumor cells, and that at a certain level, ROS can induce the apoptosis of tumor cells[15-18]. Decrease of the mitochondrial membrane potential is the initial manifestation of the hypoxia apoptosis cascade[19]. In this study, the level of intracellular ROS significantly increased in treated Eca-109 cells (Figure 3), and depolarization of mitochondrial membrane was increased compared with controls (Figure 4). CPI-455 significantly induced the apoptosis of Eca-109 cells.

Previous studies have confirmed that the mechanism by which tumor cell apoptosis is induced varies widely depending on the various pathways that are involved. These includes mitochondrial pathways, which play an important role in the maintenance of stability, and those involving activation of multiple upstream and downstream genes (*e.g.*, p53 and Bax). Activation of Caspase-2, 3, and 9 on the mitochondrial membrane is linked to the activation of mitochondrial apoptotic pathways[22-24].

Therefore, the inhibitory effect of the KDM5C inhibitor, CPI-455, on Eca-109 cell proliferation may be related to the downregulation of KDM5C expression, activation of Caspase-3 and Caspase-9, change in mitochondrial membrane permeability, promotion of ROS production, depolarization of the mitochondrial membrane, release of the proapoptotic proteins, Bax and p53, in the mitochondria into the cytoplasm, and induction of tumor cell apoptosis (Figures 5 and 6). The above results indicate that CPI-455 induced apoptosis through an ROS-dependent mitochondrial signaling

pathway[25].

Our study had some limitations, the mechanism involved in inducing apoptosis of tumor cells is extensive, and the mitochondrial apoptosis pathway is only one of them that plays an important role in maintaining cell stability. The mechanism has not been fully elucidated and needs further study. The results of this study provide a theoretical basis for the application of CPI-455 for the treatment of ESCC.

CONCLUSION

CPI-455 inhibited ECA-109 cell proliferation *via* the mitochondrial apoptosis pathway by regulating the expression of related genes.

ARTICLE HIGHLIGHTS

Research background

Esophageal cancer is a malignant tumor of the digestive tract that is difficult to diagnose early. Although CPI-455 is reported to inhibit various cancers, the role of CPI-455 in esophageal squamous cell carcinoma (ESCC) is unknown.

Research motivation

KDM5C, a lysine-specific demethylase 5C, inhibited ESCC proliferation and invasion, which may be partly associated with the expression of p53, Bax, Caspase-9, and Caspase-3. Mitochondria-mediated intrinsic apoptotic signaling plays an important role in the process of Eca-109 cell apoptosis induced by CPI-455.

Research objectives

The study objective was to investigate the effect and mechanism of the KDM5C inhibitor, CPI-455, on ESCC cells.

Research methods

The changes in proliferation, apoptosis, ROS content, and mitochondrial membrane potential of Eca-109 cells induced by CPI-455 were observed. The expression of P53, Bax, Caspase-9, Caspase-3, and KDM5C in Eca-109 cells was assayed.

Research results

CPI-455 inhibited Eca-109 cell proliferation. P53, Bax, Caspase-9, and Caspase-3 were upregulated in Eca-109 cells, and KDM5C was significantly downregulated, by CPI-455. CPI-455 increased the level of intracellular ROS in Eca-109 cells, and decreased the mitochondrial membrane potential compared with the control group.

Research conclusions

CPI-455 inhibited Eca-109 cell proliferation *via* the mitochondrial apoptosis pathway by regulating the expression of related genes.

Research perspectives

CPI-455 might be a potential candidate for the development of novel chemotherapeutic agents to treat ESCC.

Abstract

BACKGROUND

With improved survival in gastric cancer patients, health-related quality of life has become an important clinical endpoint alongside primary oncological outcomes.

AIM

To investigate health-related quality of life after various surgical procedures for gastric cancer treatment.

METHODS

The validated Slovenian version of the European Organization for Research and Treatment of Cancer Quality of Life Core Questionnaire (QLQ-C30) and its gastric cancer-specific module (QLQ STO-22) was sent for self-completion to patients that underwent curative resection for gastric adenocarcinoma between January 2014 and December 2018 at our centre. In total, 116 patients responded. Scores were compared between patients after subtotal distal *vs* total gastrectomy and patients after subtotal distal gastrectomy with Billroth II *vs* Roux-en-Y reconstruction.

RESULTS

Interestingly, the extent of resection did not influence daily functioning; however, more dysphagia and eating restrictions were reported in patients after total gastrectomy when compared to patients after subtotal distal gastrectomy. Moreover, patients with Billroth II reconstruction after subtotal distal resection experienced worse physical and role functioning and reported more pain, fatigue and reflux compared to Roux-en-Y reconstruction.

CONCLUSION

Based on our results, Roux-en-Y reconstruction after subtotal distal gastrectomy

have read the STROBE Statement-checklist of items, and the manuscript was prepared and revised according to the STROBE Statement-checklist of items.

should be preferred over Billroth II reconstruction. The data obtained from this study will help surgeons when preoperatively informing their patients about expected functional outcomes after gastrectomy and enable them to ensure proper supportive care of their patients in the postoperative period.

Core Tip: Quality of life assessment is an important tool to guide and evaluate treatment interventions, especially after a major surgery like gastrectomy. We conducted a cross-sectional survey among patients with gastric adenocarcinoma treated at our centre to provide insight into overall wellbeing after curative resection. The information provided will guide surgeons in selecting an optimal treatment approach and informing patients about expected treatment outcomes.

INTRODUCTION

Gastrectomy is a major operation that alters the physiological functions of the digestive tract. Consequently, patients that undergo this treatment commonly experience a broad range of metabolic disorders, including malnutrition, weight loss and several postgastrectomy symptoms that negatively impact patients' wellbeing[1]. With modern gastrectomy techniques and other treatment modalities, survival in gastric cancer patients has improved and health-related quality of life (HRQoL) has become an important aspect when evaluating treatment outcomes[2].

Various surgical procedures have been described for achieving oncological radicality in gastric cancer. In previous comparative studies, subtotal distal gastrectomy was associated with shorter operative duration, reduced postoperative complications and better recovery when compared to total gastrectomy[3-6]. On the other hand, total gastrectomy could still be performed safely with low morbidity while reducing the risk of inadequate safety margins or remnant carcinoma[7,8]. Following subtotal distal gastrectomy, there is no consensus regarding the best type of reconstruction[9,10]. Billroth II reconstruction is often performed due to its simplicity, but associated reflux gastritis and esophagitis have been the limiting concerns. Roux-en-Y reconstruction is a recommended alternative, but it can result in delayed gastric emptying, nausea, vomiting and abdominal pain[11]. Selection of the procedure is usually made based on tumour location, preoperative staging, the patient's general physical status and the surgeon's preference. In addition, quality of life assessment has become an increasingly important index for evaluating and selecting treatment interventions. Patient-reported measures regarding their physical and emotional state after treatment as opposed to objectively defined short-term perioperative outcomes should be taken into consideration to achieve optimal care.

We conducted a cross-sectional survey among patients with gastric adenocarcinoma treated at a tertiary referral centre to provide insight into overall wellbeing after curative resection. The European Organization for Research and Treatment of Cancer (EORTC) Quality of Life Core Questionnaire (QLQ-C30) and its gastric cancer-specific module (QLQ STO-22) were used to assess HRQoL[12]. Its various aspects were compared among different surgical procedures.

MATERIALS AND METHODS

Patients

Patients with gastric cancer that underwent curative resection at the Ljubljana University Medical Centre between January 2014 and December 2018 were recruited for the study. Patients were eligible for inclusion if they were older than 18, had undergone curative subtotal distal or total gastrectomy for histologically confirmed adenocarcinoma, and had not undergone previous gastric surgery. We excluded patients that were deemed unable to answer the questionnaires, provided questionnaires with missing items that prevented final scoring, suffered from other gastrointestinal diseases (*e.g.*, chronic inflammatory bowel disease, exocrine pancreatic insufficiency or cholestasis) or other malignant diseases, had undergone emergency or palliative surgery, or had experienced disease recurrence. The study was approved by the National Medical Ethics Committee of Republic of Slovenia (No. 0120-315/2019/3; July 9, 2019). Patients that met the inclusion criteria and provided written informed consent were included for further analysis.

Data collection

Data on the patients included demographics, comorbidities, American Society of Anesthesiologists score, tumour stage, type of resection, type of reconstruction, postoperative complications, hospital stay, histopathological characteristics of the tumour, cancer recurrence and possible (neo)adjuvant therapy and were collected from electronic patient records.

Surgery

All patients underwent open gastrectomy, either subtotal distal or total, depending on the tumour location and preoperatively determined tumor-node-metastasis stage. Gastric adenocarcinoma was confirmed upon histopathological examination of the specimen.

After total gastrectomy, reconstruction was performed with Roux-en-Y esophagojejunostomy in all cases. After subtotal distal gastrectomy, either a Billroth II or Roux-en-Y anastomosis was constructed. Braun enteroenterostomy was routinely performed in all cases of Billroth II gastrojejunostomy. Billroth I reconstruction was not performed in our patient cohort due to the surgeon's preference and lack of early-stage gastric cancer.

HRQoL assessment

To assess postoperative HRQoL of our patient cohort, the validated Slovenian versions of the EORTC QLQ-C30 (version 0.3) and QLQ STO-22 were used[12].

The EORTC QLQ-C30 questionnaire consists of 30 questions divided into five functional scales (physical, role, cognitive, emotional and social), three symptom scales (fatigue, pain, and nausea and vomiting), the global health status/quality of life scale and six single items to report other complaints (dyspnoea, loss of appetite, insomnia, constipation, diarrhoea and financial difficulties).

The EORTC QLQ-STO22 is a gastric cancer–specific module to assess HRQoL of patients with adenocarcinoma of the stomach. It comprises 22 questions divided into five multi-item scales (dysphagia, chest and abdominal pain, reflux, eating restrictions and anxieties) and four single items (dry mouth, taste problems, body image and hair loss).

A study description with an informed consent form plus the EORTC QLQ-C30 and EORCT QLQ-STO-22 questionnaires were sent to the patients for self-completion.

All completed questionnaires were scored and linearly transformed to a 0-100 scale according to the EORTC QLQ-C30 Scoring Manual[13]. On the functional scale higher scores represent better functioning, whereas on the symptom scale higher scores indicate higher symptom burden. Missing values were processed as follows: if at least half of the items from the scale were answered, the missing items were assumed to have values equal to the average of the completed items on the scale.

HRQoL was compared between patients after subtotal distal *vs* total gastrectomy and between patients after subtotal distal gastrectomy with Billroth II *vs* Roux-en-Y reconstruction.

Statistical analysis

Means with standard deviation as well as medians with interquartile ranges of EORTC QLQ-C30 and EORTC QLQ-STO-22 scores were obtained. The Shapiro–Wilk test was used to test the normal distribution of the data.

The time that elapsed from surgery to completion of the questionnaires was compared among different surgical procedures using the Kruskal-Wallis test and Mann-Whitney *U* test.

Scores of EORTC QLQ-C30 and EORTC QLQ-STO-22 of patients after subtotal distal *vs* total gastrectomy and Billroth II *vs* Roux-en-Y reconstruction were compared with the Mann-Whitney *U* test.

To assess the correlation between the type of operation and general health status adjusted for some demographic and clinical characteristics of patients, multiple linear regression was used. The assumptions of absence of multicollinearity (assessed by variance inflation factor), normal distribution of the residuals and homoscedasticity were met.

A double-sided P value of < 0.05 was considered statistically significant. All statistical analyses were performed using SPSS 27.0 (IBM Corporation, Armonk, NY, United States).

RESULTS

Patients

Invitations for study participation were sent to 234 patients. A total of 116 (49.6%) patients that provided informed consent with completed questionnaires were further analyzed. There were 63 men and 53 women 44 to 88 years old. Ten questionnaires had missing items. In six questionnaires, only one item was missing. In four questionnaires, there were two missing items, which were not part of the same scale.

The time that elapsed from surgery to completion of the questionnaires is shown in Table 1 and was not statistically different among different surgical procedures (P = 0.161).

Respondents and non-respondents did not differ significantly according to sex, type of gastric resection, type of reconstructive procedure and postoperative complications. Respondents were younger (P = 0.016) and had a significantly less advanced disease stage (P = 0.001). The baseline characteristics of patients eligible for inclusion are presented in Table 2.

EORTC QLQ-C30 questionnaire evaluation

Patients after total *vs* subtotal distal gastrectomy: No statistically significant differences were observed in HRQoL of patients after total gastrectomy when compared to patients after subtotal distal gastrectomy. The details are shown in Table 3.

Patients after subtotal distal gastrectomy with Billroth II *vs* Roux-en-Y reconstruction: HRQoL of patients after subtotal distal gastrectomy with Billroth II reconstruction was significantly lower on the physical (P = 0.038) and role functioning (P = 0.034) scale when compared to patients with Roux-en-Y reconstruction. Patients with Billroth II reconstruction also reported more pain (P = 0.01) and fatigue (P = 0.028). No differences were observed between the two groups in global health status/quality of life scores (P = 0.635). The details are summarized in Table 4.

Reported scores on different functional scales and the global health status/quality of life scale among various surgical procedures are presented in Figure 1. Patients after subtotal distal gastrectomy with Roux-en-Y reconstruction scored highest on cognitive, role functioning and physical scales when compared to patients after total gastrectomy or subtotal distal gastrectomy with Billroth II reconstruction.

Quality of life and type of surgery: The type of surgery was significantly associated with the stage of the disease (P = 0.002) (Table 5). Patients with stage III gastric adenocarcinoma underwent either total gastrectomy (43.9%) or subtotal distal gastrectomy with Billroth II reconstruction (41.3%) rather than Roux-en-Y reconstruction (22.2%).

When adjusted for demographic data, disease stage and postoperative complications in a multiple linear regression model, no statistically significant differences in the global health status/quality of life scale were observed among different surgical procedures. Global health status/quality of life scores were significantly negatively associated with disease stage (β = -0.21, P = 0.029; Table 6).

Patients with Roux-en-Y reconstruction had significantly higher scores on the emotional (β = 0.24, P = 0.041), role functioning (β = 0.24, P = 0.034) and physical scale (β = 0.23, P = 0.048) when compared to patients after Billroth II reconstruction, even

Table 1 The time elapsed from surgery to completion of the questionnaires among different surgical procedures

	Median (IQR), yr
Total gastrectomy	3 (2-4)
Subtotal distal gastrectomy	3 (2-4)
Billroth II reconstruction	3 (1-4)
Roux-en-Y reconstruction	2.5 (1-4)

The difference among total gastrectomy, subtotal distal gastrectomy with Billroth II reconstruction and Roux-en-Y reconstruction was not statistically significant (P = 0.161, Kruskal-Wallis test), nor was the difference among total and subtotal distal gastrectomy (P = 0.056, Mann-Whitney U test). IQR: Interquartile range.

when adjusted for other variables in a regression model (Table 7).

EORTC QLQ STO-22 questionnaire evaluation

Patients after total *vs* subtotal distal gastrectomy: Patients after total gastrectomy reported more dysphagia (P = 0.020) and eating restrictions (P = 0.017) when compared to patients after subtotal distal gastrectomy. No differences were found in other scales of the EORTC QLQ STO-22 questionnaire (Table 8).

Patients after subtotal distal gastrectomy with Billroth II *vs* Roux-en-Y reconstruction: Patients after subtotal distal gastrectomy with Billroth II reconstruction reported more problems with reflux when compared to patients with Roux-en-Y reconstruction. No differences were found in other scales of the EORTC QLQ STO-22 questionnaire (Table 9).

DISCUSSION

The results of this cross-sectional survey show that the type of gastric resection influences different aspects of HRQoL. Patients after total *vs* subtotal gastrectomy had similar functional scores, but the former experienced more dysphagia and eating

restrictions. At the same time, patients after subtotal gastrectomy with Billroth II (compared to Roux-en-Y) reconstruction reported worse physical and role functioning scores and complained of symptoms such as pain, fatigue and reflux. However, these differences appear to be clinically less relevant because similar global health scores were reported by patients after different surgical procedures. The information provided should guide the surgeon on the optimal treatment approach after considering oncological feasibility of the technique. Moreover, it should be used to inform patients about expected functional sequelae.

Previous studies evaluated longitudinal changes of HRQoL after gastrectomy for gastric cancer and used preoperative scores as a reference[14-21]. However, these scores are highly influenced by circumstances surrounding the diagnosis as well as symptoms associated with the disease itself, such as nausea and vomiting, dysphagia, postprandial fullness, loss of appetite, fatigue due to anaemia and so on, resulting in worse HRQoL[16,17]. In their multicentre study, Brenkman *et al*[22] compared EORTC QLQ-C30 scores of patients after gastrectomy to a Dutch reference population and concluded that global HRQoL is more or less comparable between the two cohorts despite patients' worse scores on several functional and symptom scales. Similarly, Lee *et al*[23,24] found no significant difference in global HRQoL between patients more than 5 years after surgery for gastric cancer and healthy volunteers awaiting a routine screening exam.

A limited number of studies focused on HRQoL after various surgical procedures[5,11,15,16,18,20]. Hence, we opted to conduct a cross-sectional analysis to compare HRQoL after various types of gastric resection and to evaluate the actual life quality deviation caused by surgical treatment. Based on our results, the type of reconstruction appeared to have a greater effect on HRQoL than the extent of gastric resection, which is somehow unexpected. Our data show that proximal gastric preservation has marginal advantages for improving patients' quality of life by reducing dysphagia and eating restrictions postoperatively whereas no differences in daily functioning were found. In line with our finding, subtotal distal gastrectomy was generally better tolerated in several previous studies, especially due to a higher

symptom burden reported with total gastrectomy such as nausea and vomiting, dysphagia, eating restrictions and reflux[16,21]. In subtotal gastrectomy, gastric physiology is at least partly preserved, possibly leading to superior HRQoL. However, several studies found no difference in global HRQoL between the two groups[5,15,18,25]. A possible explanation for this finding is the time interval from the surgical procedure. HRQoL changes over time are well documented. In longitudinal analyses, significantly worse scores on almost all HRQoL scales were observed 1 mo to 6 mo postoperatively compared to the preoperative scores[14-17,20]. Several functional scales recovered to the baseline by 1 year after surgery, however, symptoms such as nausea and vomiting, reflux and eating restrictions persisted even 5 years after surgery[19,23,24]. In a long-term analysis by Lee *et al*[25], HRQoL inferiority of patients after total gastrectomy when compared to subtotal distal gastrectomy generally disappeared beyond 5 years postoperatively, remaining inferior only in eating restrictions. In our study, the median time interval from the surgery to the completion of the questionnaires was 3 years, possibly diminishing some differences between the two groups.

Regarding the type of digestive tract reconstruction after subtotal distal gastrectomy, the choice of the technique is often driven by the surgeon's preferences,

and no clear recommendations exist in the current literature[9-11]. Several studies suggested Roux-en-Y reconstruction to be superior to Billroth II reconstruction in terms of preventing bile reflux and remnant gastritis, thus allowing better quality of life[10,26-28]. However, in a proportion of patients, Roux-en-Y may be associated with a Roux stasis syndrome causing delayed gastric emptying with postprandial pain, nausea and vomiting[29,30]. Our results are partly in line with previous studies reporting reduced HRQoL following Billroth II *vs* Roux-en-Y reconstruction[10,26-28]. Patients after

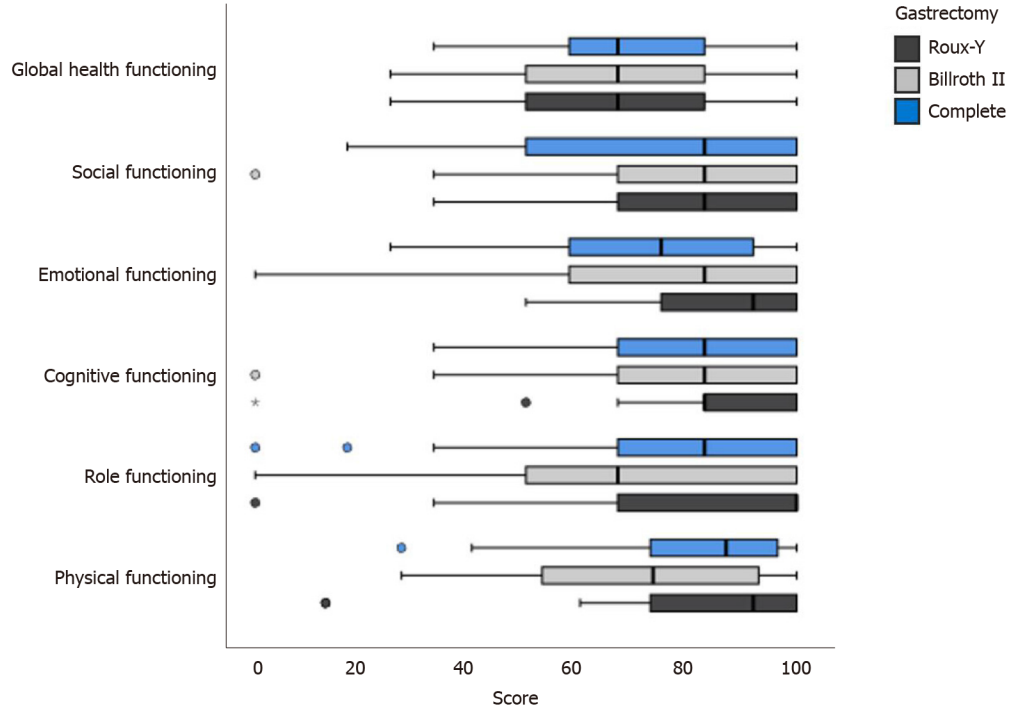

Figure 1 Median scores with interquartile ranges of functional scales and global health status/quality of life scale based on the type of surgery.

Billroth II reconstruction scored lower on some of the functional scales and reported more pain, fatigue and reflux symptoms. This occurred despite routine construction of Braun anastomosis, which supposedly diverts bile from the remnant stomach, relieving reflux symptoms, dumping syndrome or other disturbances in food intake[31]. Although patients after Billroth II reconstruction were more likely to have a higher disease stage than those after Roux-en-Y reconstruction, statistically significant superiority of the Roux-en-Y procedure on the emotional, role and physical functioning scale remained after adjustment for demographic data, disease stage and postoperative complications.

Study limitations

This study has some limitations. First, the cross-sectional nature does not allow

longitudinal assessment of HRQoL. Nonetheless, we believe this kind of design allows us to gain important insight into the overall HRQoL of patients following gastrectomy, which represents the basis for clinical decision making. Second, the number of participating patients is relatively low (116), representing 49.6% of patients that were eligible for study inclusion. Third, mail surveys lack data related to the actual health status of the patient. We did not see the patients to obtain their health status objectively; therefore, their subjective measures could not be compared to their actual physical findings. Nonetheless, HRQoL is a multimodal construct of physical, psychological and social wellbeing in relation to disease treatment. Therefore, objective and subjective measures are not necessarily related. Even if a patient is objectively well, he or she may at the same time be subjectively unwell, which should be addressed separately from objective measures.

CONCLUSION

Our study shows that patients after gastrectomy for gastric cancer experience several functional and symptom complaints affecting quality of life. Based on our results, with regard to HRQoL, subtotal distal gastrectomy with Roux-en-Y reconstruction should be preferred over subtotal distal gastrectomy with Billroth II reconstruction. Patients should be informed preoperatively about expected functional sequelae after surgery and should be regularly monitored postoperatively to ensure proper symptomatic and supportive care.

ARTICLE HIGHLIGHTS

Research background

Gastrectomy is a major operation that alters the physiological functions of the digestive tract. Consequently, these patients experience malnutrition, weight loss and several postgastrectomy symptoms that negatively impact patients' wellbeing.

Research motivation

With improved survival in gastric cancer patients, health-related quality of life has become an important clinical endpoint alongside oncological outcomes.

Research objectives

The aim of this study was to investigate health-related quality of life after various surgical procedures for gastric cancer treatment.

Research methods

Patients that underwent curative resection for gastric adenocarcinoma at a tertiary centre between January 2014 and December 2018 were recruited for inclusion in this cross-sectional survey. The validated Slovenian version of the European Organization for Research and Treatment of Cancer Quality of Life Core Questionnaire (QLQ-C30) and its gastric cancer specific module (QLQ STO-22) were sent to all eligible patients for self-completion. The scores of both questionnaires were compared between patients after subtotal distal *vs* total gastrectomy and patients after subtotal distal gastrectomy with Billroth II *vs* Roux-en-Y reconstruction using the Mann-Whitney *U* test. The association between the type of operation and general health status adjusted for some demographic and clinical characteristics was assessed with multiple linear regression.

Research results

Out of 234 patients that were eligible for study inclusion, 116 (49.6%) patients completed the questionnaires. No statistically significant differences were observed in scores on global or functional scales among patients after total or subtotal distal gastrectomy. However, patients after total *vs* subtotal gastrectomy did experience more dysphagia (P = 0.020) and eating restrictions (P = 0.017). Patients after subtotal distal gastrectomy with Billroth II reconstruction reported significantly worse scores on the physical (P = 0.038) and role functioning (P = 0.034) scales and had more problems with pain (P = 0.010), fatigue (P = 0.028) and reflux (P = 0.001). When adjusted for demographic data, disease stage and postoperative complications, no

differences were observed in reported global health status/quality of life scores among different surgical procedures. However, Roux-en-Y was superior over Billroth II reconstruction in emotional (β = 0.24, P = 0.041), role (β = 0.24, P = 0.034) and physical (β = 0.23, P = 0.048) functioning when adjusted for other variables in a regression model.

Research conclusions

Patients after gastrectomy for gastric cancer experience several functional and symptom complaints. Based on our results, subtotal distal gastrectomy with Roux-en-Y reconstruction should be preferred over subtotal distal gastrectomy with Billroth II reconstruction.

Research perspectives

The data obtained from this study will help surgeons when preoperatively informing their patients about expected functional outcomes after gastrectomy and enable them to ensure proper supportive care for their patients in the postoperative period.

Abstract

BACKGROUND

Mucosal healing (MH) has emerged as a key therapeutic target in inflammatory bowel disease (IBD), and achievement of this goal is documented by endoscopy with biopsy. However, colonoscopy is burdensome and invasive, and substitution with an accurate noninvasive biomarker is desirable.

AIM

To summarize published data regarding the performance of noninvasive biomarkers in assessing MH in IBD patients.

METHODS

We conducted a systematic review of studies that reported the performance of biomarkers in diagnosing MH in patients with IBD. The main outcome measure was to review the diagnostic accuracy of serum and fecal markers that showed promising utility in assessing MH.

RESULTS

We screened 1301 articles, retrieved 46 manuscripts and included 23 articles for full-text analysis. The majority of the included manuscripts referred to fecal markers (12/23), followed by circulatory markers (8/23); only 3/23 of the included manuscripts investigated combined markers (serum and/or fecal markers). Fecal calprotectin (FC) was the most investigated fecal marker for

assessing MH. In ulcerative colitis, for cutoff levels ranging between 58 mcg/g and 490 mcg/g, the sensitivity was 89.7%-100% and the specificity was 62%-93.3%. For Crohn's disease, the cutoff levels of FC ranged from 71 mcg/g to 918 mcg/g (sensitivity 50%-95.9% and specificity 52.3%-100%). The best performance for a serum marker was observed for the endoscopic healing index, which showed a comparable accuracy to the measurement of FC and a higher accuracy than the measurement of serum C-reactive protein.

CONCLUSION
Several promising biomarkers of MH are emerging but cannot yet substitute for endoscopy with biopsy due to issues with reproducibility and standardization.

Key Words: Inflammatory bowel disease; Ulcerative colitis; Crohn's disease; Biomarkers; Serum; Fecal; Mucosal healing

Core Tip: Identification of performant biomarkers that can substitute for repeated and cumbersome invasive procedures is a priority. Although therapeutic success in both Crohn's disease and ulcerative colitis remains to be clearly defined, mucosal healing has been one of the main therapeutic targets stipulated by recent recommendations. In inflammatory bowel disease mucosal healing, several serum- and fecal-based markers have shown promising results; however, a multimarker may improve the diagnostic accuracy of any single independent biomarker.

INTRODUCTION

Endoscopic inspection plays a pivotal role in the diagnosis and monitoring of inflammatory bowel disease (IBD). According to current guidelines and recommendations, each individual patient is likely to undergo several endoscopic evaluations during the course of their disease, sometimes at relatively short intervals. Endoscopy is crucial to establish a diagnosis and to evaluate disease extent and severity. Endoscopic reassessment is recommended on a case-by-case basis in patients not responding to treatment or with frequent relapse and remains the gold standard for confirming the response to treatment[1].

Although therapeutic success in both Crohn's disease (CD) and ulcerative colitis (UC) remains to be clearly defined, mucosal healing (MH) has been one of the main therapeutic targets stipulated by recent recommendations[2]. MH is associated with lower risks of relapse, hospitalization and surgery[3,4]. While there is currently no clear consensus regarding the definition of MH despite the many proposed scoring systems for endoscopic activity in IBD, most experts agree that a Mayo endoscopic subscore of 0 or 1 or a SES-CD (simple endoscopic score for CD) less than 3 constitutes an acceptable measure of MH, both of which have been widely used in recent clinical trials of UC and CD, respectively[5,6].

Invasive procedures, such as colonoscopy, have a great impact on patients. Patients with IBD report significantly more embarrassment and burden from the bowel preparation phase and more pain during the colonoscopy[7]. Although the risk of complications related to colonoscopy in IBD patients is very low (< 1%), it is higher than that in other groups of patients[8,9] and involves significant costs[10]. Therefore, identifying reliable surrogate noninvasive markers for disease activity is desirable to reduce patient burden and costs.

In recent years, a wealth of publications regarding various noninvasive biomarkers in IBD have reported conflicting results on various clinical endpoints. The aim of this

systematic review was to evaluate published data regarding the diagnostic accuracy of biomarkers in assessing MH in IBD patients.

MATERIALS AND METHODS

Rationale

We conducted a systematic review of studies that reported on the accuracy of noninvasive biomarkers in diagnosing MH in patients with colonic IBD with the aim of identifying and assessing the diagnostic accuracy of these biomarkers. Neither imaging markers nor urine-based markers were included in this analysis. Studies investigating the role of C-reactive protein (CRP) in detecting MH were also not included, as a comprehensive analysis regarding this subject was recently published[11]. In this review, 30 eligible publications regarding CRP were included. CRP positively correlated with the endoscopic activity of the disease, yielding correlation coefficients from 0.29 to 0.63 for UC and from 0.31 to 0.71 for CD. At the time of this publication, no new data have emerged; thus, reanalysis of published data is unnecessary at this time.

Literature search

A structured search was conducted on December 12, 2020 of the PubMed (MEDLINE) database. Our search terms included the following medical subject headings (Mesh) and text words: For IBD: inflammatory bowel disease, ulcerative colitis, Crohn's disease; For MH: mucosal healing, endoscopic remission, colonoscopy, sigmoidoscopy, remission induction; For biomarkers: biomarker, predict*, clinical, laborator*, serol*, serum, fecal*, feces, blood, cytokine*. The entire search algorithm was the following: ((((((((((((marker*[tw])) OR (biomarker*[tw])) OR ("Biomarkers"[Mesh])) OR (predict*[tw])) OR (clinical[tw])) OR (laborator*[tw])) OR (serol* [tw])) OR ("Serum"[Mesh])) OR (fecal* [tw])) OR ("Feces"[Mesh])) OR (blood [tw])) OR ("Blood"[Mesh])) OR (cytokine* [tw])) OR ("Cytokines"[Mesh])) AND ("Colonoscopy"[Mesh Terms] OR "Sigmoidoscopy"[Mesh Terms] OR "Remission Induction"[Mesh Terms] OR ("mucosal"[Text])) OR "endoscopic remission"[Text Word])) AND ((((((inflammatory bowel disease [tw]) OR (ulcerative colitis [tw])) OR (Crohn's disease [tw])) OR ("Inflammatory Bowel Diseases"[Mesh])) OR ("Colitis, Ulcerative"[Mesh])) OR ("Crohn's Disease"[Mesh])).

Inclusion criteria

All manuscripts published from January 2010, with the full text version available online, either *via* open access or pay per view, were included in the screening process. To avoid potential bias related to the use of older generation endoscopes and to account for the evolving definition of "mucosal healing", we restricted our review to manuscripts published in the last 10 years.

Exclusion criteria

Manuscripts concerning pediatric patients, veterinary studies, noncolonic CD, unspecified IBD, narrative reviews, case reports and research that did not include an endoscopic evaluation to confirm MH and a clear definition of MH were not included.

Data extraction

These criteria were applied for the title screening process, followed by a full-text read of the filtered results. For all articles that met the criteria, using an a priori designed extraction form, two independent reviewers collected data regarding the type of study that was conducted, the investigated marker and its source (serum, feces) and the marker accuracy in predicting MH and the definition of MH considered for each study. The reference sections of the included studies were analyzed to retrieve relevant studies not identified by the original search.

Articles included in the final analysis were evaluated for quality and risk of bias using the Cochrane Risk of Bias Tool[12] and the Methodological Index for Non-Randomized Studies criteria[13] (Supplementary Tables 1 and 2).

Our review was registered on PROSPERO (December 19, 2020) and is currently awaiting publication on the registry site. Reporting of the review was conducted using the PRISMA guidelines. The statistical methods of this study were reviewed by a biomedical statistician at Colentina Clinical Hospital.

RESULTS

In total, 1301 articles were retrieved with the search strategy, and 46 manuscripts were included for full-text analysis (Figure 1)[14]. After excluding studies that did not provide a clear definition of MH and studies that did not report at least a measure of performance for the investigated markers, 23 articles were included for complete data extraction and final analysis. Another reason for exclusion was reference to unclear characteristics of the study populations (ileal or colonic CD); MH was not one of the stated endpoints.

The selected manuscripts were further categorized by the source of investigated markers (fecal, serum). Studies investigating the performance of combined markers were discussed separately. Of 23 studies, 14 referred to prospective cohorts, with only 2 having a multicentric design. We also included 5 retrospective cohort analyses, 2 cross-sectional cohort studies, one case-control pilot study and a post hoc analysis of a clinical trial. The number of patients included in each study ranged from 20 to 311. The majority of included manuscripts referred to fecal markers (12/23), followed by circulatory markers (7/23), and only 4/23 investigated combined markers (serum and/or fecal markers). Most studies were performed in patients with UC (13/23): 7/12 studies investigated fecal markers, 4/7 studies investigated circulatory markers, and only one of the 3 included studies investigated combined markers. For CD patients, only 2/12 studies investigated fecal markers, and 2 studies referred to combined markers. Seven studies included both UC and CD patients (3/12 studies dedicated to fecal-based markers and 4/7 studies investigating circulatory markers).

For the definition of MH in CU patients, a Mayo endoscopic score (MES) of 0/0-1, UCEIS (UC endoscopy index of severity) of 0 or a Matts score of 1-2 (MH) Matts = 1/MES = 0 (complete MH) was applied. For CD patients, the MH definition was variable among studies: a SES-CD < 2/≤ 2/≤ 3/3-7, CDEIS (CD activity index) ≤ 4, or absence of mucosal lesions was used.

Role of fecal biomarkers in detecting MH

Of the 23 studies included in this analysis, 12 investigated the association between fecal marker levels and MH.

Fecal calprotectin: Calprotectin is an antimicrobial protein mainly secreted by neutrophils that remains stable for several days at room temperature[15] and has been widely investigated in IBD patients for disease activity detection. In 9/12 studies, the authors investigated fecal calprotectin (FC) performance in assessing MH. Two studies compared FC and fecal immunochemical test (FIT) performance, and one investigated immune fecal occult blood test (iFOBT). Most studies were conducted in cohorts of UC patients (6/9) that involved a low number of participants (minimum 44, maximum 128). There was a large variation in the selected optimal cutoff values, and several commercial assays were used (ELISA, QPOCT).

In UC, the reported cutoff levels of FC for MH detection ranged between 58 mcg/g (sensitivity 89.7% and specificity 93.3%) and 490 mcg/g (sensitivity 100% and specificity 62%). For CD, the cutoff levels of FC ranged from 71 mcg/g (sensitivity 95.9% and specificity 52.3%) to 918 mcg/g (sensitivity 50% and specificity 100%) (Table 1).

FIT: Another fecal marker widely investigated for the assessment of IBD patients is FIT, which quantifies the globin (protein) component of hemoglobin found in stool. Quantitative FIT estimates the degree of colonic inflammation by measuring the concentration of hemoglobin in feces using an antibody that targets human hemoglobin[16]. When compared to FC, the specificity for MH in UC was similar, but FIT appeared to be more sensitive than FC for predicting MH (95% *vs* 77% for MES = 0 in a study by Hiraoka *et al*[17], 98.0% *vs* 78.4% for MES = 0, 94.9%, *vs* 74.6% for UCEIS 0-1 in a study by Ryu *et al*[18]). One of the main advantages of using FIT over FC refers to cutoff values of FIT, which are relatively stable and almost equivalent to the cutoff values used in colorectal cancer screening[19].

iFOBT: In addition to FIT, another fecal marker is the iFOBT, which measures the heme (nonprotein) component of hemoglobin from blood in the stool. This method has many limitations that cause false-positive results. Food and medication, as well as blood from dietary sources or upper GI bleeding, can result in a positive test[20]. When compared to FC in a retrospective analysis in UC patients, iFOBT showed higher sensitivity and specificity for assessing MH (80.6% and 100% *vs* 74.1% and 84.2%, respectively)[21].

Table 1 Synthetic presentation of data on fecal marker performance in detecting mucosal healing

Role of circulatory biomarkers in detecting MH

We analyzed 7 studies discussing the role of various serum biomarkers in detecting MH. Four of 7 studies were conducted in UC cohorts; in 3 of the 7 studies, both UC and CD patients were included. We identified 3 studies that investigated the utility of trefoil factor 3 (TFF3) as a marker for MH in patients with UC, but only one study met the inclusion criteria. TTF3 is a mucin-associated peptide that is widely expressed in a tissue-specific manner in the gastrointestinal tract and is predominantly secreted by goblet cells of the small and large intestine[31]. In a study by Nakov *et al*[32], the TFF3

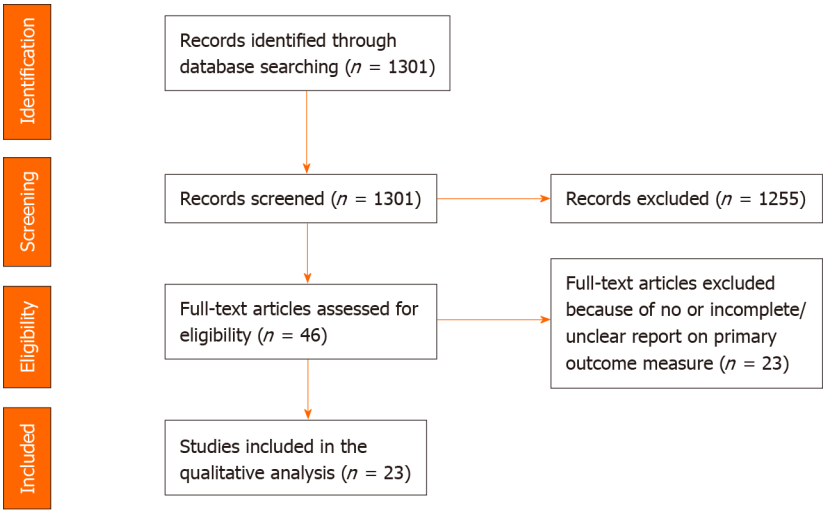

Figure 1 Flow chart of the manuscripts included in the final analysis according to the PRISMA reporting guidelines.

cutoff level of 6.74 ng/mL indicated complete MH (MES = 0; UCEIS = 0), with a sensitivity and specificity of 87.9% and 86.9% in patients with UC, respectively. An interesting aspect is that the area under the receiver operating characteristics (ROC) curve (AUC) of TFF3 + CRP showed higher accuracy than the AUC of TFF3 alone (Z = 2.210, P = 0.027) for predicting complete MH. However, when investigated in CD patients treated with tumor necrosis factor (TNF)-α antagonists, TTF3 was not a convenient or reliable surrogate marker of MH[33].

Budzynska *et al*[34] investigated serum neutrophil gelatinase-associated lipocalin (NGAL), a low-molecular-weight protein released from activated neutrophils and the intestinal epithelium, whose mRNA expression is increased in inflamed intestinal tissue. NGAL performed well in UC patients and was able to distinguish endoscopically active from inactive UC, with an AUC-ROC of 0.758 (sensitivity 96% and specificity 54%). However, NGAL levels showed no significant relationship with either the clinical or endoscopic activity of CD.

In a study by Planell *et al*[35], transcriptional changes in whole-blood samples from UC patients were investigated. A significant correlation with the degree of endoscopic activity was observed in several genes, including *haptoglobin* (*HP*), *CD177*, *GPR84*, and *S100A12*. Within the subset of genes whose expression best correlates with endoscopic disease severity, *HP* was the best gene to predict mucosal lesions. The logistic regression model for endoscopic activity prediction (endoscopic Mayo score: 0 *vs* ≥ 1) demonstrated a significant effect of *HP* (P < 0.001), with an odds ratio of 1.9 [95% confidence interval (CI): 1.35-2.78] and an AUC = 0.75 (95%CI: 0.64-0.85). Defining a cutoff of -2.9 DCt, the sensitivity and specificity were 63.5% and 80.0%, respectively.

Nicotinamide phosphoribosyltransferase (Nampt) is another serum marker showing good potential in assessing MH. Nampt is an intracellular enzyme that is primarily associated with the induction and persistence of inflammatory responses. In a study by Neubauer *et al*[36], serum Nampt in UC positively correlated with its clinical and endoscopic activity as well as with proinflammatory cytokines. Serum Nampt ≤ 1.54 ng/mL was a good indicator of MH (sensitivity 76%, specificity 75%, AUC 0.768).

One recent study proposed serum amyloid A (SAA) as a surrogate marker for MH. Both SAA and CRP are mainly secreted from the liver, but SAA is reported to be more effective than CRP in diseases other than IBD[37]. The diagnostic accuracy of SAA for MH was superior to that of CRP. SAA levels < 5.8 could discriminate mucosal inflammation from MH, with a sensitivity of 72.2%, specificity of 85%, and accuracy of 79.9%. In contrast, CRP levels < 0.060 could distinguish mucosal inflammation from MH, with a sensitivity of 62%, specificity of 75%, and accuracy of 70.4%[38].

Dierckx *et al*[39] investigated glycoprotein acetylation (GlycA) in the serum or plasma of patients with IBD. GlycA is a novel nuclear magnetic resonance biomarker that summarizes the signals originating from glycan groups of certain acute-phase glycoproteins. In this study, GlycA concentration in both CD and UC patients achieving MH dropped back to HC levels (P = 0.90, P = 0.910) and showed potential to identify MH even in patients without elevated CRP. This should therefore be tested in large prospective cohorts.

Serum levels of leucine-rich alpha-2 glycoprotein, investigated in a prospective setting, were significantly higher in endoscopically active patients with UC having extensive and left-sided colitis than in those with MH, although marker performance measures were not clearly reported[40].

A systematic presentation of the data regarding serum marker performance discussed in this review is listed in Table 2.

Role of combined biomarkers in detecting MH

Because of the suboptimal performance of individual noninvasive markers at detecting MH, further combining fecal and serum biomarkers in panels has been attempted to increase accuracy in several studies.

A multicentric international study conducted by D'Haens *et al*[41] aimed to develop and validate a multimarker, serologic, algorithm-based diagnostic test that could reflect the severity of endoscopic inflammation in CD patients. The endoscopic healing index (EHI) model includes serum concentrations of 13 biomarkers: angiopoietin 1 (ANG1) and 2 (ANG2); carcinoembryonic antigen-related cell adhesion molecule 1; CRP; SAA1; interleukin (IL) 7; transforming growth factor α; vascular cell adhesion molecule 1; extracellular matrix metalloproteinase inducer; and matrix metalloproteinases 1 (MMP1), 2 (MMP2), 3 (MMP3), and 9 (MMP9). EHI was constructed as a scale of 0-100 arbitrary units of EHI activity, with a higher score indicating more severe disease activity. The EHI identified patients with resolution of endoscopic disease activity, with good overall accuracy, although with variation between the 2 cohorts assessed. The EHI AUC-ROC values were comparable to the measurement of FC (0.950 *vs* 0.923 $P = 0.147$ in validation cohort 1 and 0.803 *vs* 0.854, $P = 0.298$ in validation cohort 2) and higher than that of serum CRP.

Other serum markers that have shown promising results are anti-inflammatory serum cytokine profiles. Gubatan *et al*[42] reported that the serum cytokine ratio IL-4 + IL-10/IL-17A + TNF-α has the ability to identify UC patients with baseline histologic MH (AUC of 0.641, $P = 0.044$). A serum cytokine ratio IL-4 + IL-10/IL-17A + TNF-α threshold of 0.1522 had the greatest sensitivity (52.6%, 95%CI: 35.8-69.0) and specificity (75.0%, 95%CI: 56.6-88.5), with a positive likelihood ratio of 2.015.

Other authors have tried to evaluate the combined role of serum, fecal and clinical scores in detecting MH. A post hoc analysis from the CALM study[43] reported the performance of the combination of FC, CRP and clinical disease activity index (CDAI) in detecting MH. Using the cutoffs FC < 250 μg/g, CRP < 5 mg/L, and CDAI < 150, it had a sensitivity/specificity of 72%/63% and positive/negative predictive values of 86%/42% for CDEIS < 4 and no deep ulcers 48 wk after randomization. Data regarding the performance of combined biomarkers are listed in Table 3.

Cytokines, such as IL-6 and soluble IL-2 receptor (sIL-2R), have been shown to modulate the intestinal immune system. Mavropoulou *et al*[44] analyzed serum IL-6 and sIL-2R levels in a cohort of IBD patients. They evaluated the correlation between these laboratory markers and clinical and endoscopic disease activity status in IBD patients. In this study, serum levels of sIL-2R ($P < 0.001$) and CRP ($P = 0.003$) as well as FC values ($P < 0.001$) were associated with endoscopic remission in UC patients by univariate analysis. For CD patients, the threshold value for IL-6 to discriminate patients with endoscopic remission or active disease was 5.5 pg/mL, with an AUC-ROC of 0.80 (95%CI: 0.71-0.89).

DISCUSSION

Over the past decade, the standard of care and management of IBD have greatly improved as a result of newly approved drugs as well as a wide array of invasive and noninvasive diagnostic tools. Novel "treat-to-target" strategies have recently been shown to impact disease progression and improve outcomes for IBD patients. MH has been one of the main targets suggested as part of current therapeutic goals[42]. Compared to previous strategies that focused on symptom control, recent studies have shown that achieving MH is associated with lower risks of relapse, hospitalization and surgery[3,4]. However, because MH is objectivated by intrusive colonoscopy, it is becoming increasingly apparent that surrogate noninvasive markers are needed for close and efficient disease monitoring and control. A reliable surrogate marker for MH would have a significant clinical impact, by reducing the number of endoscopic evaluations required during the course of disease.

Based on our findings, other than FC, which has a clear established role in current real-life clinical practice, none of the biomarkers was accurate enough to replace

endoscopy. The most accurate serum marker was a multimarker based on 13 serum proteins, called the EHI, which showed comparable accuracy to the measurement of FC and higher accuracy than the measurement of serum CRP. We observed that most studies focused on assessing individual markers among a small number of patients in a wide variety of study designs and heterogeneous groups of patients.

However, endoscopic activity scores and MH definitions are not homogenous, which could represent an impediment in establishing the performance of various investigated markers. Additionally, there are several commercial assays for FC and other marker measurements available, making the establishment of cutoff values an insurmountable obstacle. Few studies compared the investigated markers to FC, which has been widely investigated and is commonly used in clinical practice.

It is mandatory to assess MH at different key time points during the disease course, especially to gauge the response to therapy or to address newly developed symptoms. FC has emerged as one of the few noninvasive tools commonly used in IBD clinical practice, and there is now considerable evidence confirming the good accuracy of FC in detecting MH[2].

Even though some factors may influence its concentration (*e.g.*, the amount of mucus and blood in stool[45]), FC is one of the most sensitive noninvasive tools in differentiating IBD from functional disorders[46]. For IBD patients, different cutoff levels have been proposed for diagnostic purposes to differentiate between endoscopic active and nonactive disease, histologic healing[47] or prediction of relapse[2], but a consensus has not yet been established. At present, an FC level over 250 mcg/g is considered to indicate active colonic inflammation[48], while levels below 100 mcg/g may indicate endoscopic remission[49].

One major limitation of FC use refers to the so-called "gray zone" level between 100 mcg/g and 250 mcg/g, which is difficult to interpret. Bodelier *et al*[50] investigated the occurrence of indefinite FC levels in a real-life IBD cohort and studied the additional value of a combination of biochemical markers and clinical activity indices. In the studied cohort, 24% of CD and 15% of UC patients had FC in this "gray zone". Finally, if given the option, patients usually prefer blood over fecal tests[51], and this further limits the widespread use of FC in clinical practice.

Some of the circulatory markers investigated in the studies included in this review showed promising results. However, none of the investigated blood- or fecal-based markers showed great accuracy for MH prediction and therefore cannot replace endoscopy at this point.

Table 3 Synthetic presentation of data on combined marker performance in detecting mucosal healing

Ref.	Study type	Investigated marker	MH definition	CU/CD	Number of patients	AUC	95%CI	Sn (%)	Sp (%)	Cutoff level

EHI: Endoscopic healing index measuring 13 proteins in blood [angiopoietin 1 (ANG1) and 2 (ANG2), carcinoembryonic antigen-related cell adhesion molecule 1, C-reactive protein, serum amyloid A1, interleukin 7, transforming growth factor α, vascular cell adhesion molecule 1, extracellular matrix metalloproteinase inducer, and matrix metalloproteinases 1 (MMP1), 2 (MMP2), 3 (MMP3), and 9 (MMP9)]; UC: Ulcerative colitis; CD: Crohn's disease; AUC: Area under the curve; CI: Confidence interval; Sn: Sensitivity; Sp: Specificity; SES-CD: Simple endoscopic score for Crohn's disease; CRP: C-reactive protein; CDAI: Crohn's disease activity index; sIL-2R: Soluble interleukin 2 receptor; MES: Mayo endoscopic subscore; FC: Fecal calprotectin.

An ideal marker or multimarker should be noninvasive, sensitive, disease-specific, easy to perform, cost-effective[52] and ideally patient-friendly; such a marker remains to be identified by future research.

An important observation concerns newly established therapeutic targets in IBD management, which could soon be included as a standard of care achievement of histologic healing. Several studies have already assessed the performance of biomarkers in detecting this endpoint, such as the study conducted by Gubatan *et al*[42], which explored the accuracy of serum cytokines in assessing histologic healing, defined as a Geboes Histologic Grade of < 3. There is evidence that FC levels correlate more closely with histological evaluation than macroscopic findings, suggesting that this biological marker is more sensitive than endoscopy[53].

Widely used serum markers, such as CRP, white blood cell count, and erythrocyte sedimentation rate, combined with clinical activity scores are currently used in IBD monitoring. This approach lacks the diagnostic accuracy needed for decision making in patients with UC, and colonoscopy is still required for proper evaluation of disease activity.

For future research, a combined marker approach benchmarked against a well-investigated marker, such as FC, could be a promising alternative to endoscopic examination.

There are certain limitations to our analysis. We decided not to include data on CRP or imaging markers (magnetic resonance imaging, ultrasound) in detecting MH. A previous comprehensive analysis regarding the role of CRP in this setting was recently published by Krzystek-Korpacka *et al*[11]. In this review of 30 studies, there was a large variation in the selected optimal cutoff values, ranging from 0.4 mg/L to 28 mg/L. CRP performance as an MH marker displayed better sensitivity than specificity for CD, with respective median values of 79.5% *vs* 61%, and better specificity than sensitivity for UC, with respective median values of 82% *vs* 66%[1]. CRP is a widely used marker in clinical practice for IBD monitoring, but it still fails to provide sufficient accuracy to replace endoscopy as an independent marker for MH. Expanding the search to imaging modalities would have diluted the information provided and was beyond the scope of our paper. Both magnetic resonance imaging and ultrasound are indispensable tools in IBD management, but operator-dependent

and costly, limiting their widespread use and accessibility. Our search was we relied exclusively on PubMed (MEDLINE) database for identification of potentially eligible studies.

CONCLUSION

Various biomarkers for MH are currently under investigation and show promising results. However, at present, no biomarker is accurate enough to replace endoscopy. Therefore, it is our strong belief that future high-quality studies should further focus on establishing panels of biomarkers that would have higher predictive values than biomarkers alone.

ARTICLE HIGHLIGHTS

Research background

Mucosal healing (MH) has been one of the main therapeutic targets stipulated by recent recommendations. MH is associated with lower risks of relapse, hospitalization and surgery. In recent years, a wealth of publications regarding various noninvasive biomarkers for MH have reported conflicting results.

Research motivation

MH is objectivated by intrusive colonoscopy, and it is becoming increasingly apparent that surrogate noninvasive markers are needed for close and efficient disease monitoring and control. A reliable surrogate marker for MH would have a significant clinical impact, by reducing the number of endoscopic evaluations required during the course of disease.

Research objectives

We aimed to summarize published data regarding the performance of noninvasive biomarkers in assessing MH in inflammatory bowel disease patients.

Research methods

We conducted a systematic review of studies that reported the performance of biomarkers in diagnosing MH in patients with inflammatory bowel disease. The main outcome measure was to review the diagnostic accuracy of serum and fecal markers that showed promising utility in assessing MH.

Research results

We screened 1301 articles, retrieved 46 manuscripts and included 23 articles for full-text analysis. Fecal calprotectin (FC) was the most investigated fecal marker for assessing MH. The best performance for a serum marker was observed for the endoscopic healing index, which showed a comparable accuracy to the measurement of FC and a higher accuracy than the measurement of serum C-reactive protein.

Research conclusions

Several promising biomarkers of MH are emerging but cannot yet substitute for endoscopy with biopsy due to issues with reproducibility and standardization.

Research perspectives

For future research, a combined marker approach benchmarked against a well-investigated marker, such as FC, could be a promising alternative to endoscopic examination.

Abstract

BACKGROUND

Gastric pull-up (GPU) procedures may be complicated by leaks, fistulas, or stenoses. These complications are usually managed by endoscopy, but in extreme cases multidisciplinary management including reoperation may be necessary. Here, we report a combined endoscopic and surgical approach to manage a failed secondary GPU procedure.

CASE SUMMARY

A 70-year-old male with treatment-refractory cervical esophagocutaneous fistula with stenotic remnant esophagus after secondary GPU was transferred to our tertiary hospital. Local and systemic infection originating from the infected fistula was resolved by endoscopy. Hence, elective esophageal reconstruction with free-jejunal interposition was performed with no subsequent adverse events.

CONCLUSION

A multidisciplinary approach involving interventional endoscopists and surgeons successfully managed severe complications arising from a cervical esophagocutaneous fistula after GPU. Endoscopic treatment may have lowered the perioperative risk to promote primary wound healing after free-jejunal graft interposition.

Checklist (2016), and the manuscript was prepared and revised according to the CARE Checklist (2016).

Core Tip: Gastric pull-up (GPU) reconstruction after esophagectomy may be complicated by leaks, fistulas, and stenoses. In such cases, endoscopic interventions, including endoscopic vacuum therapy, stenting, or dilatation, are the corrective treatments of choice, but surgery is preferred when esophageal reconstruction becomes necessary. Here, we report a case of esophageal reconstruction after a secondary GPU procedure by combining endoscopic and surgical techniques to perform subtotal esophageal resection and reconstruction using a free-jejunal graft interposition.

INTRODUCTION

Gastric pull-up (GPU) procedures may be complicated by leaks, fistulas, and stenoses. In such cases, restoration of the esophagus and adequate recovery of alimentation becomes challenging[1]. Endoscopic interventions, including endoscopic vacuum therapy (EVT), stenting, or dilatation, are the corrective treatments of choice[2], but surgery is preferred when esophageal reconstruction becomes necessary[3]. Here, we report a case of esophageal reconstruction after a secondary GPU procedure by combining endoscopic and surgical techniques.

CASE PRESENTATION

Chief complaints

A 70-year-old male patient underwent emergency esophageal diversion after injury to the cervical esophagus during spinal surgery.

History of present illness

Six months later, retrosternal GPU procedure was performed but postoperative anastomotic leakage occurred. The leakage was successfully managed by endoscopy and the patient was discharged with a fully covered esophageal stent in place. Three weeks later, local cervical infection and sepsis developed. At this time, our tertiary university hospital was contacted for patient transfer.

History of past illness

Notable previous illnesses were arterial hypertonus, non-active smoking status and an ischemic stroke with incomplete senso-motoric hemiparesis. Furthermore, the patient had a thyroidectomy in the past and open prostatectomy due to prostate cancer.

Personal and family history

The patient had no family history that was related to the present illness.

Physical examination

On admission, the patient showed clear signs of malnutrition and systemic inflammation with jugular and cervical phlegmon.

Laboratory examinations

Initial laboratory data revealed a hemoglobin level of 6.7 g/dL, white blood cell count of 6400 cells/μL, and platelet count of 210 × 10^3/μL. The creatinine level was 0.76 mg/dL, unremarkable liver and cholestasis parameters, and albumin level was 2.8 g/dL.

Imaging examinations

A chest computed tomography (CT) scan and endoscopy revealed a dislodged esophageal stent, with the proximal flare abutting an extraesophageal air and fluid-filled cavity (Figure 1). During stent removal, a partially epithelialized esophageal perforation 2 cm distal to the pharynx with an infected cavity (Figure 1B and C) as well as a 5 cm-long stenosis of the remaining esophagus were detected.

FINAL DIAGNOSIS

Diagnosis of cervical esophagocutaneous fistula and anastomotic stenosis after GPU with signs of chronic malnutrition and systemic inflammation.

TREATMENT

The patient received calculated antibiotic treatment and was transferred to the intensive care unit. An immediate endoscopy was carried out, and the dislocated stent (partially covered metal stent, length 80 mm, diameter 18 mm) was removed. Endoscopy showed an old, partially epithelialized and wide esophageal perforation 2 cm distal of the pharynx with an infected cavity behind it. Distal of the fistula, a long-segment (5 cm) stenosis of the esophagus ranging up to the esophago-gastrostomy was confirmed. Notably, the perforation and the fistula cavity were likely to be a secondary injury due to the dislocated cervical stent tulip (diameter 24 mm). After pus evacuation and debridement of the fistula, a fully covered self-expanding metal stent (length 100 mm, diameter 20 mm) was inserted in order to cover the fistula and to treat the stenosis. Due to an expected long-term course, a percutaneous jejunal feeding catheter was surgically inserted to ensure sufficient enteral nutrition. The first re-endoscopy revealed a slippage of the stent so that the cranial fistula ostium was not sufficiently covered. The stent position was successfully corrected but dislocated again during follow-up.

Thus, endoscopic management was switched to EVT. An EsoSponge system (B. Braun Melsungen, Germany) was placed into the esophagocutaneous fistula ostium (cavity). The jugular and cervical phlegmon resolved during EVT within two weeks and repeated endoscopic balloon dilatation was performed to resolve the esophageal stenosis. However, it became obvious that endoscopic management could not resolve the broad and rigid fistula with the concomitant partially obliterated esophagus. The issue was discussed interdisciplinarily and the therapeutic aim of endoscopy was redefined: Profound consolidation of the cervical infection and cleaning of the fistula cavity until salvage surgery (Figure 1D).

The cervical phlegmon resolved within two weeks, allowing subtotal esophageal resection and reconstruction using a free-jejunal graft interposition according to Ott *et al*[4]. Pre-operative work up included CT angiography to establish the feasibility of vascular reconstruction. Partial sternotomy was necessary to provide access to the esophagus and the stomach (Figure 2A). After resection of the cervical esophagus and fistula, the exploration confirmed that the GPU could not be mobilized up to the pharynx. Thus, laparotomy was performed and a suitable jejunal segment was harvested. The left carotid artery and the left jugular vein were used as recipient vessels. The graft was implanted in an isoperistaltic position. The cervical anastomosis was performed in an end-to-end fashion and the upper mediastinal gastro-jejunostomy in a side-to-side fashion (Figure 2B). A part of the upper sternum was resected to avoid any pressure on the graft and gastrojejunostomy. The soft tissue defect was covered with a sternocleidomastoid muscle flap. Abdominal reconstruction was achieved by an end-to-end jejunojejunostomy.

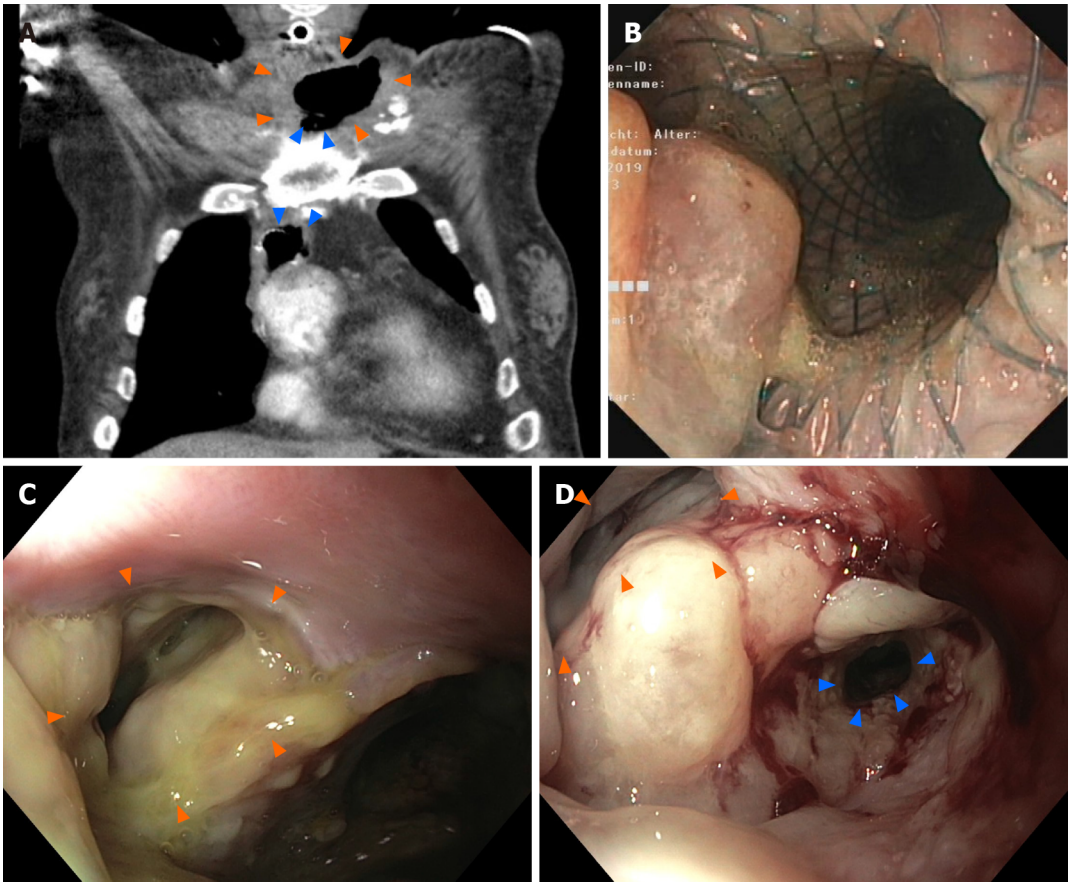

Figure 1 Preoperative findings. A: Contrast-enhanced computed tomography with oral and intravenous contrast application showing the jugular abscess (indicated by orange arrowheads) and the fully covered self-expandable metallic stent with its proximal end in the fistula (indicated by blue arrowheads); B: Endoscopy showing fully covered self-expandable metallic stent placed in the distal stenotic esophagus with the esophagocutaneous fistula directly orally of the stent. The fistula orifice is partially covered by the stent flare; C: Endoscopy after stent extraction with the large prestenotic fistula orifice (indicated by orange arrowheads); fistula filled with pus; D: Endoscopy after endoscopic vacuum therapy with cleaned fistula (indicated by orange arrowhead). The fistula is entirely epithelized. The distal esophagus segment remains stenotic (indicated by blue arrowheads).

OUTCOME AND FOLLOW-UP

The postoperative course was uneventful. Oral alimentation was reestablished accompanied with daily speech therapy. Anastomotic healing was confirmed radiologically and endoscopically and the patient was transferred to a rehabilitation clinic in good clinical condition.

DISCUSSION

Esophagectomy with diversion and later reconstruction of the upper gastrointestinal (GI) tract is reserved for complex esophageal disease[5]. Despite numerous advantages over alternative reconstruction techniques, anastomotic complications following GPU procedures occur in up to 12% of cases[6].

Managing anastomotic leakage or stricture of GPU can be extremely challenging because of local tissue damage from previous surgery or chronic infection[1,7]. Endoscopic management of leaks, fistulas and stenosis in the upper GI tract has therefore not only become a valuable tool, but the standard approach for successful management even in complex situations[8,9]. Here, it is extremely important to carefully consider and constantly evaluate the local tissue and wound conditions. In our case, the constant pressure caused by the stent itself may have further deteriorated the esophageal wall and, thus, may have caused perforation and fistula with abscess formation since no external drainage had been established.

The surgical options available for the management of a complicated GPU procedure are limited and usually contain a high risk of morbidity and mortality[5]. Esophageal reconstruction with a free jejunal graft was introduced by Seidenberg and colleagues

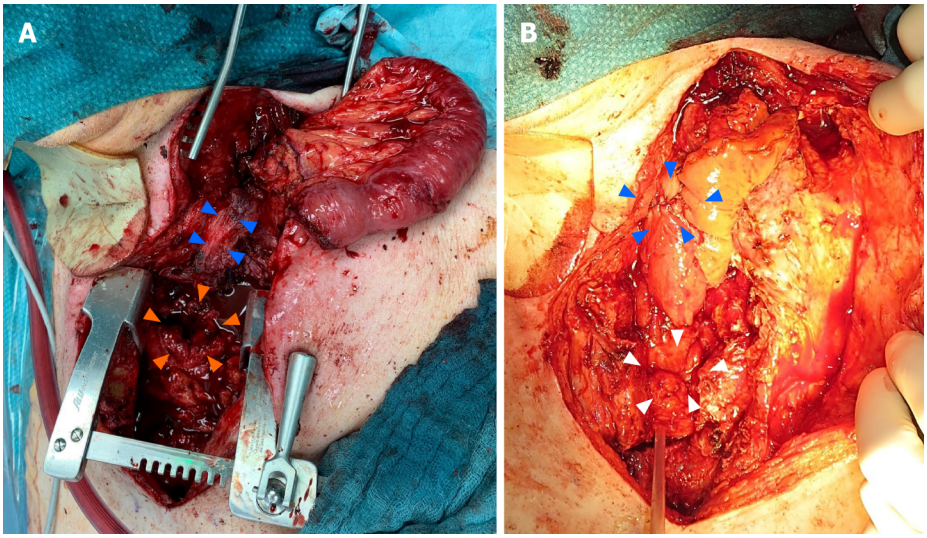

Figure 2 Findings during surgery. A: Free jejunal segment after reperfusion before intestinal anastomosis; orange arrowheads indicating the orifice of the gastric pull-up; blue arrowheads indicating the stenotic distal esophagus; B: Free jejunal segment after intestinal anastomosis; blue arrowheads at the mesentery of the free jejunal graft indicating the proximal esophago-jejunostomy; white arrowheads indicating distal jejuno-gastrostomy.

in 1959 and later modified by Siewert and colleagues in 2008 for treating cancer of the cervical esophagus[4,10]. The use of a salvage option after failed GPU has also been described[12]. Recent data regarding follow-up results in esophageal reconstruction strongly suggest the superiority of intestinal flaps over other reconstructions such as skin flaps.

High failure rates for secondary attempts after failed esophageal reconstruction have been described[1], with a complication rate in excess of 70%[11]. However, free jejunal grafts have considerable advantages. They are usually easy to harvest, provide low donor-site morbidity, have good size approximation to the cervical esophagus, tolerate reflux well, and have a low rate of peptic ulceration incidence[12]. Disadvantages include the need for transient ischemia that requires advanced microsurgical skills for swift revascularization and a challenging surgical site environment because of previous surgery and infection.

CONCLUSION

A multidisciplinary approach involving interventional endoscopists and surgeons was necessary to enable successful salvage management. Despite prior complications, operations and chronic infection, restoration and reconstruction of the esophagus was ultimately achieved (Figure 3). Thus, patients with chronic postoperative fistulas or

stenoses of the esophagus should be referred to specialized centers in a timely manner.

ACKNOWLEDGEMENTS

We would like to thank Mrs. Anna Maria Kellersmann for preparation of Figure 3 and Dr. Mohammed Hankir for proofreading the manuscript.
