Data-driven radiomics is inherently unable to provide insights into the biological basis of the observed relationship. It is important to note that HCC shows large intra- and inter-tumor heterogeneity at the biological level. With the rapid development and popularization of machine learning, researchers are paying increasing attention to the improvement of prediction ability; however, they are far from understanding the biological significance of the observed research results. This disconnect between the predictive models and their biological significance inherently limits their widespread clinical translation. Therefore, it is necessary to introduce biological significance into the radiomics field through various available biological methods, such as genome association, immunohistochemical analyses, local microscopic pathological image texture analyses, and evaluation of macroscopic histopathological marker expression (Figure 1)[47].

CONCLUSION

Radiomics based on multiple imaging modalities has performed remarkably well in predicting the HCC-MVI status. In future, researchers need to focus on standardizing image segmentation and radiomics processing processes and the optimization of algorithms to further improve the accuracy of

Figure 1 Histology and genomic analysis can provide specific small-scale insights and help validate radiomic results.

individualized prediction. Importantly, it may be possible to provide some new insights through combining deep learning and LI-RADS with radiomics and introducing biological significance.

Abstract

BACKGROUND

Recent studies have emphasized the emerging importance of long noncoding RNAs (lncRNAs) in colorectal cancer (CRC). However, the functions and regulatory mechanisms of numerous lncRNAs in CRC have not been fully elucidated.

AIM

To explore the functional role and underlying molecular mechanisms of lncRNA TNFRSF10A-AS1 in CRC.

METHODS

TNFRSF10A-AS1 expression was measured by quantitative real-time polymerase chain reaction in CRC, and the relationship between TNFRSF10A-AS1 levels and the clinicopathological features of CRC patients was analyzed. The effect of TNFRSF10A-AS1 expression on CRC proliferation and metastasis was examined *in vitro* and *in vivo*. Mechanistically, we investigated how TNFRSF10A-AS1 is involved in CRC as a competitive endogenous RNA.

RESULTS

TNFRSF10A-AS1 was expressed at a high level in CRC and the upregulation of TNFRSF10A-AS1 was associated with advanced T grade and tumor size in CRC patients. A functional investigation revealed that TNFRSF10A-AS1 enhanced the proliferation, migration ability and invasion ability of colon cancer cells *in vitro* and *in vivo*. A mechanistic analysis demonstrated that TNFRSF10A-AS1 acted as a miR-3121-3p molecular sponge to regulate HuR expression, ultimately promoting colorectal tumorigenesis and progression.

CONCLUSION

TNFRSF10A-AS1 exerts a tumor-promoting function through the miR-3121-3p/HuR axis in CRC, indicating that it may be a novel target for CRC therapy.

Key Words: Colorectal cancer; Long noncoding RNA; TNFRSF10A-AS1; miR-3121-3p; HuR

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: TNFRSF10A-AS1 was upregulated in colorectal cancer (CRC) tumor tissues and cell lines, and it was positively correlated with tumor grade and size in patients with CRC. In addition, TNFRSF10A-AS1 facilitated CRC growth and metastasis. Mechanistically, TNFRSF10A-AS1 was predominantly found in the cytoplasm of CRC cell lines and upregulated the level of the downstream target, HuR, by sponging miR-3121-3p, thereby further promoting colorectal tumorigenesis and progression.

INTRODUCTION

Colorectal cancer (CRC) is one of the most commonly diagnosed cancers and the third leading cause of cancer-related deaths around the world[1]. Despite marked advances in CRC diagnosis and therapy in recent years, the prognosis remains poor for many patients due to a lack of timely diagnosis and individualized disease management measures. The 5-year survival rate for CRC patients with distant metastases is approximately 14%[2]. Notably, CRC incidence and mortality rates are rising rapidly in developing countries[3]. In addition, epidemiological studies have shown an increasing incidence in adolescents and adults less than 50 years of age[4]. Genetic factors and poor lifestyle habits are the main predisposing factors for CRC, but the exact pathogenesis is unknown. Therefore, in-depth studies of the pathogenesis of CRC are of great clinical importance.

Recent evidence from studies of CRC-related pathogenesis has suggested that tumor-specific long noncoding RNAs (lncRNAs) may contribute to early diagnosis and prognostic assessment as well as improve disease treatment outcomes. LncRNAs are long (over 200 nucleotides) RNAs[5] that can interact with DNA, RNA and proteins. The function of lncRNAs mainly depends on their subcellular localization. Nuclear lncRNAs tend to bind DNA and proteins to regulate chromatin interactions, transcription and RNA processing, while cytoplasmic lncRNAs modulate mRNA stability or translation to influence cellular signaling cascades and can also act as competing endogenous RNAs (ceRNAs). CeRNAs competitively bind microRNA response elements (MREs) to regulate downstream gene expression[6,7]. In cells, ceRNAs containing the same MREs can competitively bind to the same microRNA (miRNA) and play posttranscriptional regulatory roles. Recent studies have shown that lncRNA/miRNA/mRNA mechanisms are involved in several aspects of CRC, including tumorigenesis, epithelial-mesenchymal transition (EMT), inflammatory processes and chemo-/radio-resistance[8]. For example, lncRNA SNHG6 serves as a ceRNA of miR-26a/b and miR-214, thereby regulating their common target, EZH2, to promote CRC growth and metastasis[9]. However, the functions and mechanisms of a vast majority of CRC-associated lncRNAs remain unclear.

LncRNA TNFRSF10A-AS1 is a novel lncRNA that has been demonstrated to be associated with the mechanism of autophagy in CRC, and Kaplan-Meier survival analysis has indicated that patients with high expression of TNFRSF10A-AS1 have a better prognosis. However, TNFRSF10A-AS1 expression in CRC cell lines is relatively high, which is inconsistent with the above findings[10]. Another study has identified five lncRNAs, including TNFRSF10A-AS1, by the expression of genome-wide lncRNAs in high-throughput RNA sequencing data, which may be useful to predict gastric cancer prognosis[11]. The current evidence on TNFRSF10A-AS1 is all based on The Cancer Genome Atlas (TCGA) data analysis, and the role of TNFRSF10A-AS1 in tumors is inconsistent. Moreover, the exact mechanism of TNFRSF10A-AS1 is unclear. Therefore, clinical and biological studies are needed to validate these findings. Our work is aimed to study the expression, functional roles and exact mechanisms of TNFRSF10A-AS1 in CRC. In the present study, our findings suggested that TNFRSF10A-AS1 was a novel oncogenic lncRNA that promoted CRC progression and might provide new ideas for CRC therapy.

MATERIALS AND METHODS

Database search

The expression of lncRNA TNFRSF10A-AS1 in colon adenocarcinoma (COAD) and rectum adenocarcinoma (READ) was analyzed using Gene Expression Profiling Interactive Analysis (GEPIA). GEPIA is an online analysis tool that is available to provide fast and customizable analysis based on TCGA data. We compared the expression of TNFRSF10A-AS1 between CRC tumor and nontumor tissues by box plots, which used $\log_2$(TPM + 1) for log-scale ($P < 0.05$ compared to control).

Patient tissue samples

We collected 40 pairs of surgically resected CRC tumor tissues and matched adjacent non-tumor tissue samples. These samples were obtained from patients with pathologically diagnosed CRC at the Second Hospital of Hebei Medical University. Patients were required to be free of radiotherapy, chemotherapy and other antitumor treatments prior to surgery, as well as free of any other malignant disease other than CRC. After isolation, some specimens were immediately placed in liquid nitrogen and stored at -80 °C for RNA and protein analysis, and other specimens were fixed in 4% paraformaldehyde for histological examination. All patients who met the above criteria signed informed consent forms. The study was approved by the Ethics Committee of the Second Hospital of Hebei Medical University (2021-R241).

Cell lines

Six human colon cancer cell lines (Caco-2, DLD1, HCT116, HCT15, HT29 and SW480) and one normal colonic epithelial cell line (FHC) were obtained from American Type Culture Collection (ATCC; Manassas, VA, United States). All cell lines were routinely cultured in Dulbecco's modified Eagle's medium (DMEM; Gibco BRL, Grand Island, NY, United States), containing 10% fetal bovine serum (FBS; Gibco BRL).

We conducted cell transfection using Lipofectamine 2000 (Invitrogen, Carlsbad, CA, United States), including small interfering RNA (siRNA), miRNA mimics, miRNA inhibitor and negative control oligonucleotides (Shanghai GenePharma Co., Ltd., Shanghai, China). The stable TNFRSF10A-AS1 overexpression lentiviral vector, TNFRSF10A-AS1 knockdown vector and empty vector were designed and synthesized by GenePharma. And finally, cell lines were screened according to the resistance carried by the lentivirus.

RNA extraction and quantitative real-time polymerase chain reaction

Total RNA was isolated from CRC tissue and cell samples, and then reverse transcribed into complementary DNA (cDNA), and finally quantitative real-time polymerase chain reaction (qRT-PCR) was conducted with cDNA and specific primers. Gene expression was calculated using GAPDH or U6 as internal reference genes. Table 1 lists all the qRT-PCR primer sequences involved in the study.

Cell counting kit-8 proliferation assay

Seeded colon cancer cells into 96-well cell culture plates at 1000 cells/100 μL per well according to the experimental grouping. At 24, 48, 72, 96 and 120 h, 10 μL of Cell Counting Kit-8 (CCK-8) reagent (Shanghai Share-bio Biotechnology Co., Shanghai, China) was added directly to each well. After incubation for 2 h at 37 °C, the optical density (OD) value (450 nm) was estimated.

Colony formation assay

Colon cancer cells were plated in 6-well cell culture plates at 1000 cells per well according to the experimental grouping and routinely cultured in a cell incubator. Cell culture was terminated once colonies were visible. Cells were then washed, fixed, stained, photographed and counted.

Cell cycle and apoptosis assays

Cell cycle analysis was performed using a Cell Cycle and Apoptosis Analysis Kit (Beyotime Biotechnology Co., Shanghai, China) following the manufacturer's protocol. Cells were fixed with ethanol, washed and stained with PI staining solution. Cell apoptosis was assayed using an Annexin V-FITC Apoptosis Detection Kit (Beyotime Biotechnology Co.), in which early and late apoptotic/dead cells were labeled using Annexin-V and PI, respectively.

Transwell assay

The upper chamber of Transwells (Corning, Kennebunk, ME, United States) was seeded with cells in 200 μL of culture medium without serum. The bottom chamber of Transwells was filled with medium supplemented with 10% FBS. The invasion and migration characteristics assay were distinguished by the presence or absence of Matrigel in the upper chamber. Cells in the bottom chambers of Transwells were fixed, stained and photographed following twenty-four hours of routine culture.

Western blot assay

Total protein from tissue and cell samples was extracted and the protein concentrations were tested. Different concentrations of polyacrylamide gels were prepared according to the molecular weight of the protein to be detected. Proteins were then electrophoresed and transferred to polyvinylidene fluoride (PVDF) membranes. Finally, the membranes were first incubated with primary antibodies against cyclin D1, proliferating cell nuclear antigen (PCNA), cleaved caspase-3, cleaved PARP, HuR as well as GAPDH (Cell Signaling Technology, Danvers, MA, United States) at 4 °C overnight and then the proteins were incubated with secondary antibodies (Cell Signaling Technology) for 1 h.

Immunohistochemistry

Tissue samples were fixed in paraformaldehyde, dehydrated in alcohol, embedded in paraffin as well as sectioned. In addition, immunohistochemical staining of tissue sections was carried out according to the experimental steps. Finally, staining of the sections was observed under a microscope.

Luciferase reporter assay

TNFRSF10A-AS1 containing wild-type (WT) or mutant (MUT) miR-3121-3p-binding sequences was designed, synthesized and sub-cloned into the pmiRGLO vector (Shanghai GenePharma Co., Ltd.). DLD1 cells were cotransfected with reporter plasmid, miR-3121-3p mimics or mimics NC. After cotransfection under routine culture conditions for 48 h, the Dual-Luciferase Reporter Assay System (Promega, Madison, WI, United States) was used to evaluate the luciferase activity of all the above reporter vectors.

Subcutaneous xenograft models

We performed animal experiments for *in vivo* validation. BALB/c nude mice at four- to six-week-old were subcutaneously injected with DLD1 cells stably transfected with sh-TNFRSF10A-AS1 (sh-lnc) or sh-negative control vector (sh-NC) (1×10^7, 200 μL) and HCT116 cells stably overexpressing TNFRSF10A-AS1 (oe-lnc) or empty vector (control) (1×10^7, 200 μL) into the right and left dorsal flanks of the nude mice, respectively. After implantation, the tumor volume was observed and measured every 2 d. The tumor volume was calculated using the measured length and width of the tumor according to

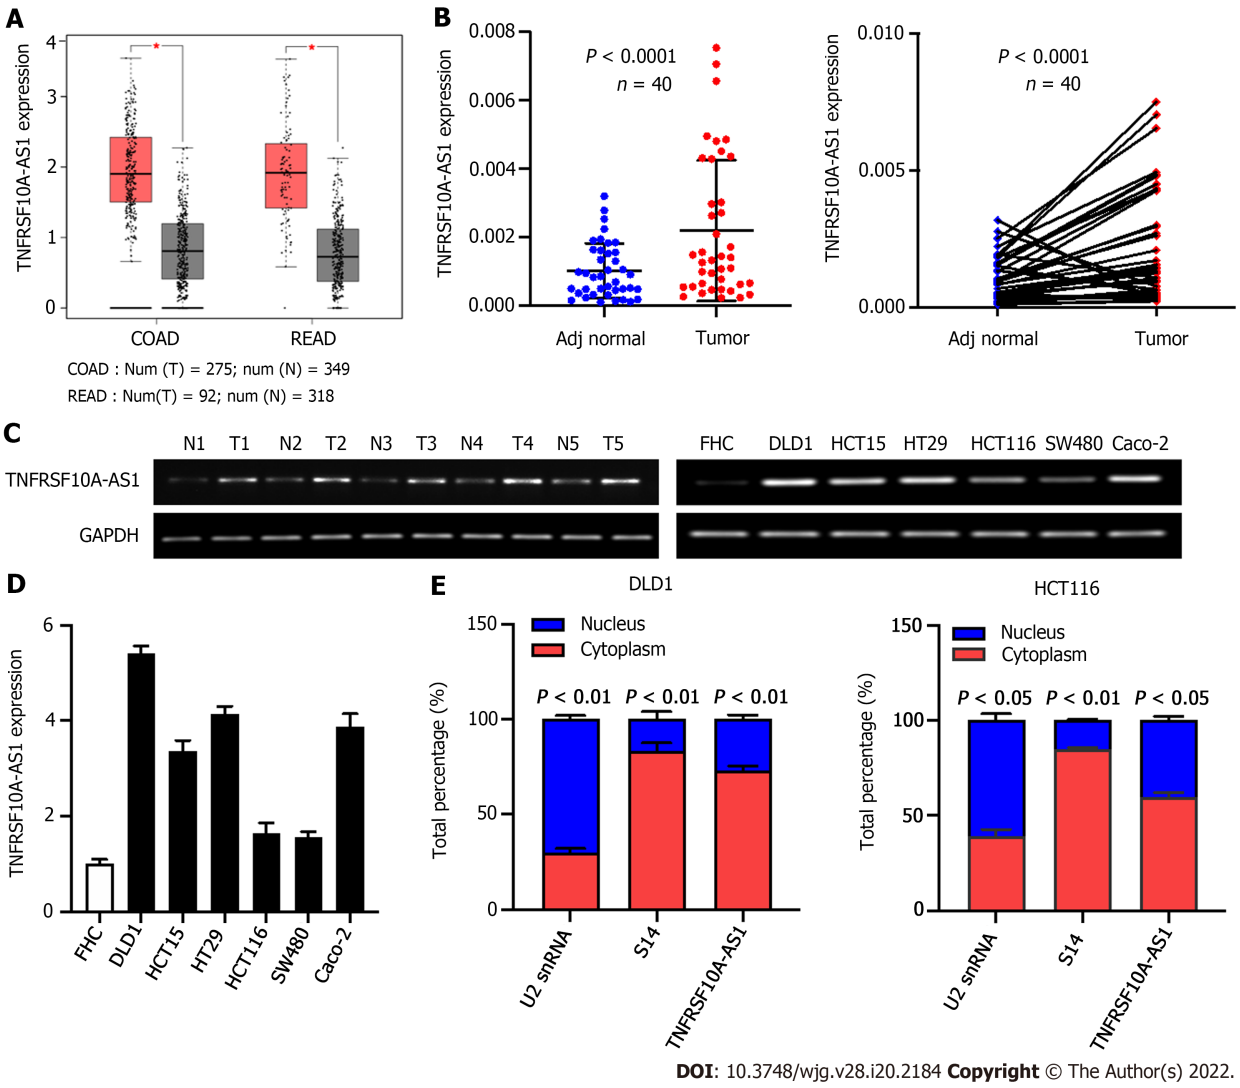
the formula: Tumor volume = (length × width^2)/2. At the end of the animal study, subcutaneous tumors were removed and used to assess tumor volume and weight as well as to perform qRT-PCR, Western blot and histological analyses.



Statistical analysis

Statistical analyses were performed using GraphPad Prism 9 software or SPSS 22.0 software. Data were presented as the mean ± SD. TNFRSF10A-AS1 and miR-3121-3p expression levels in CRC patients were compared using the paired-sample *t* test. Statistical significance between groups was analyzed using the χ^2 test, Fisher's exact probability, Student's *t* test or one-way Analysis of Variance (ANOVA). $P < 0.05$ was considered statistically significant.

RESULTS

TNFRSF10A-AS1 is upregulated in CRC

To identify whether lncRNA TNFRSF10A-AS1 is differentially expressed in CRC, we first analyzed TNFRSF10A-AS1 expression in TCGA database. We used the GEPIA online database to analyze TNFRSF10A-AS1 expression of CRC tissues, and results showed that TNFRSF10A-AS1 was expressed higher in both colon and rectal carcinoma tissues than that of corresponding adjacent normal tissues (Figure 1A). We then examined TNFRSF10A-AS1 expression in 40 pairs of CRC tissue samples. TNFRSF10A-AS1 expression was significantly increased in 34 of 40 (75%) tumor samples compared to the adjacent normal mucosa tissues (Figure 1B). Next, TNFRSF10A-AS1 expression was verified in multiple colon cancer cell lines, namely, DLD1, HCT15, HT29, HCT116, SW480 and Caco-2, and human colon mucosal epithelial FHC cells. TNFRSF10A-AS1 was significantly upregulated in the colon cancer

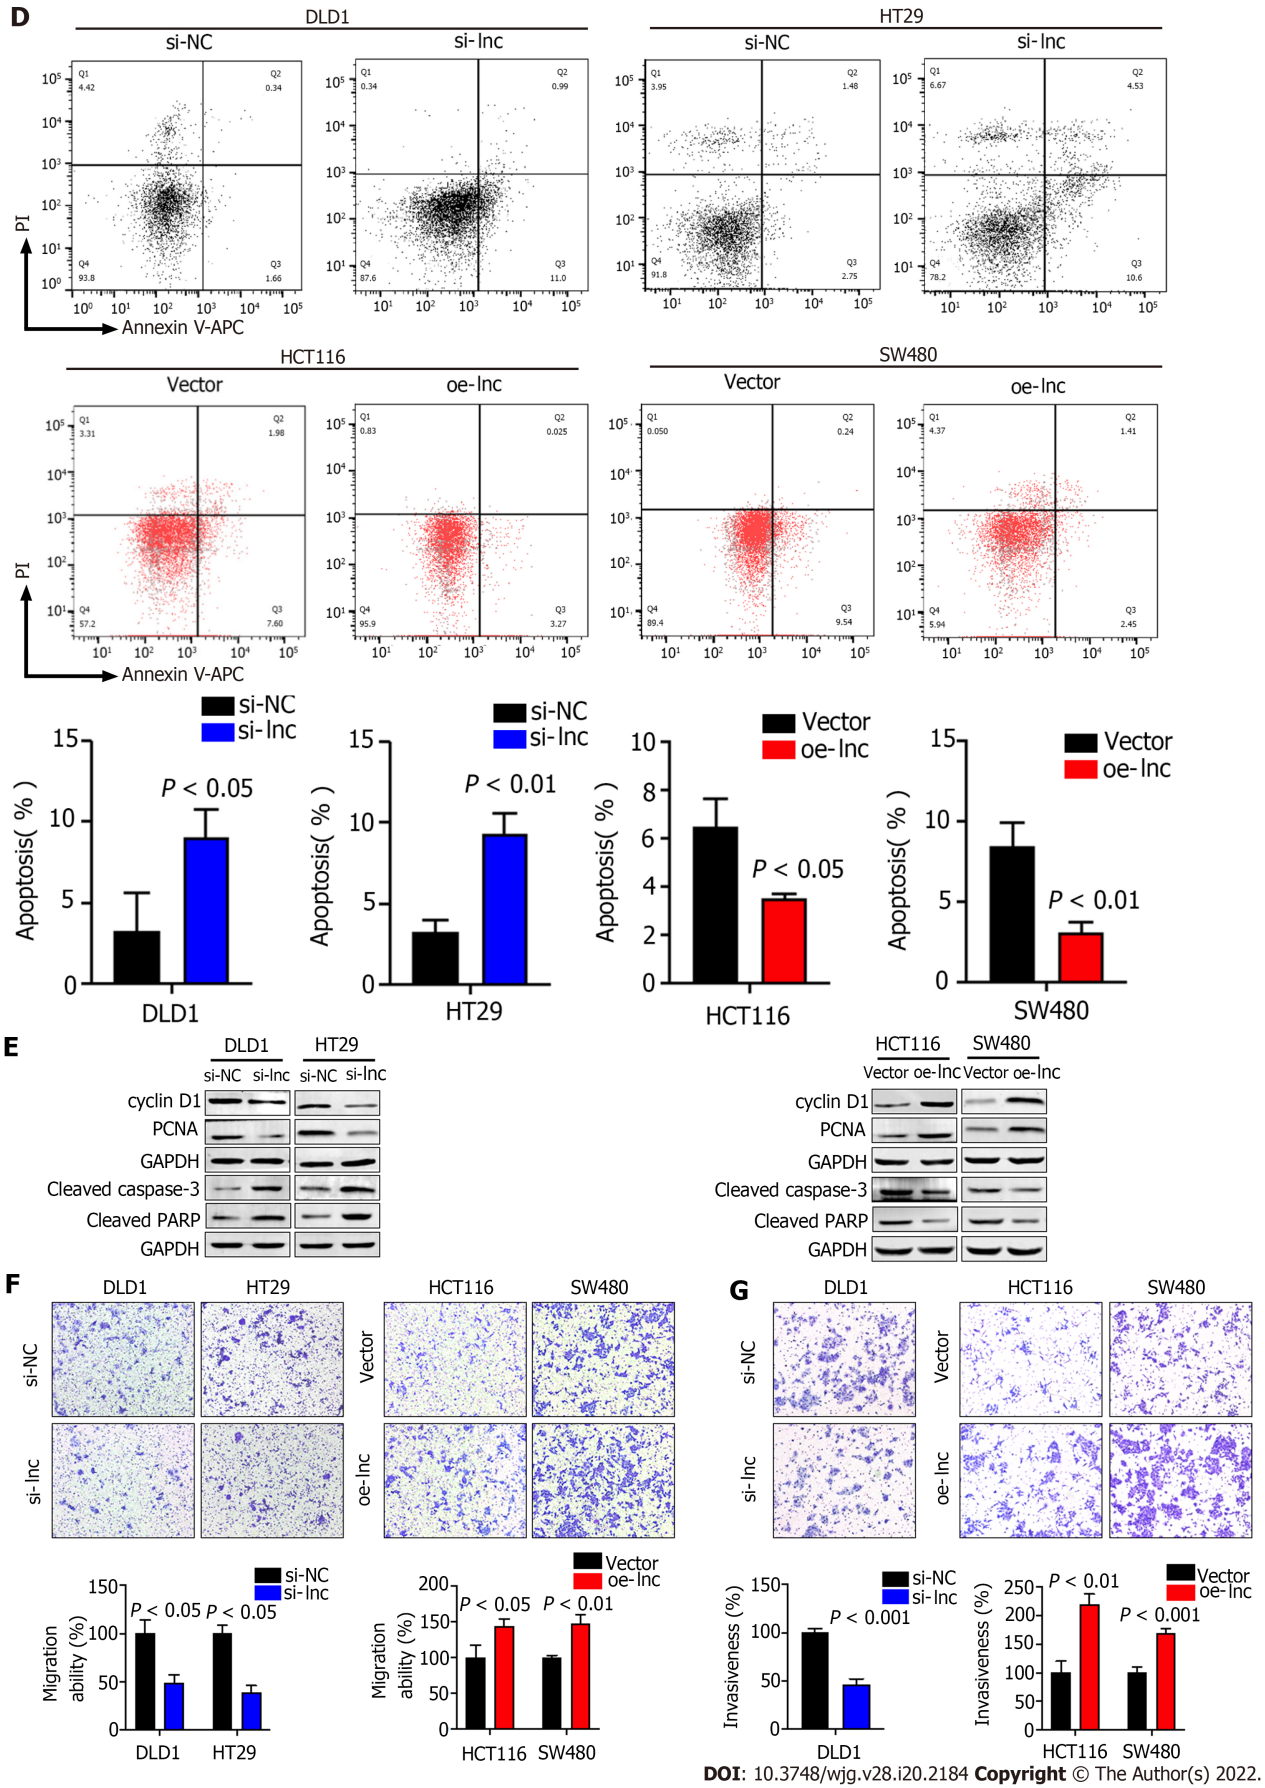

Figure 1 TNFRSF10A-AS1 is upregulated in colorectal cancer. A: TNFRSF10A-AS1 was upregulated in tumor tissues compared to normal tissues in TCGA colorectal cancer (CRC) database; B: TNFRSF10A-AS1 was overexpressed in CRC tumor tissues compared to matched adjacent nontumor tissues (n = 40); C: Levels of TNFRSF10A-AS1 in CRC were measured by reverse transcription-polymerase chain reaction (RT-PCR); D: TNFRSF10A-AS1 was higher in colon cancer cell lines than in colon mucosal epithelial FHC cells; E: The expression levels of TNFRSF10A-AS1 in the cytoplasm and nucleus of DLD1 and HCT116 cells were detected by quantitative real-time polymerase chain reaction (qRT-PCR). U2 snRNA was used as the internal reference for genes expressed in the nucleus, and S14 was used as the internal reference for genes expressed in the cytoplasm. COAD: Colon adenocarcinoma; READ: Rectum adenocarcinoma.

cell lines compared to FHC cells (Figure 1D). RT-PCR also confirmed that TNFRSF10A-AS1 was upregulated in CRC tissues and cells (Figure 1C). We further explored the cellular localization of TNFRSF10A-AS1 in DLD1 and HCT116 cells. qRT-PCR results showed that TNFRSF10A-AS1 was predominantly found in the cytoplasm (Figure 1E), which indicated that TNFRSF10A-AS1 might function in the cytoplasm. In addition, we analyzed associations between TNFRSF10A-AS1 and clinicopathological features of CRC patients and found that the upregulation of TNFRSF10A-AS1 was associated with advanced T grade and tumor size (Table 2). Collectively, the above findings indicated that TNFRSF10A-AS1 was increased in CRC and might be involved in colorectal carcinogenesis as an oncogene.

TNFRSF10A-AS1 promotes colon cancer cell proliferation, migration and invasion as well as inhibits cell apoptosis

To explore the biological function of TNFRSF10A-AS1 in colon cancer cells, we first designed a siRNA against TNFRSF10A-AS1, a short hairpin RNA (shRNA) against TNFRSF10A-AS1 and a lentiviral overexpression vector for TNFRSF10A-AS1. Silencing TNFRSF10A-AS1 in DLD1 and HT29 cells significantly inhibited cell viability and clonogenicity, whereas ectopic expression of TNFRSF10A-AS1 in HCT116 and SW480 cells significantly promoted cell viability and clonogenicity (Figure 2A and B). We also conducted flow cytometry to clarify the role of TNFRSF10A-AS1 in cell cycle distribution. Knockdown of TNFRSF10A-AS1 led to a significant increase in G1 phase cells and a decrease in S-phase cells in both DLD1 and HT29 cells. In contrast, the opposite results were exhibited in both HCT116 and

Figure 2 TNFRSF10A-AS1 promotes colon cancer cell proliferation, migration and invasion as well as inhibits cell apoptosis *in vitro*. A and B: Downregulation of TNFRSF10A-AS1 decreased cell viability and clonogenicity in DLD1 and HT29 cells, whereas upregulation of TNFRSF10A-AS1 greatly

increased cell viability and clonogenicity in HCT116 and SW480 cells; C: Silencing TNFRSF10A-AS1 arrested cells at the G1/S transition, whereas overexpressing TNFRSF10A-AS1 facilitated this transition; D: Downregulation of TNFRSF10A-AS1 enhanced cell apoptosis, whereas upregulation of TNFRSF10A-AS1 inhibited cell apoptosis; E: Western blot analysis showed that TNFRSF10A-AS1 knockdown decreased the expression of cyclin D1 and PCNA but increased the activation of caspase-3 and PARP, whereas TNFRSF10A-AS1 overexpression had the opposite effect; F and G: Silencing TNFRSF10A-AS1 suppressed DLD1 and HT29 cell migration and invasion abilities, whereas these abilities were significantly enhanced by overexpressing TNFRSF10A-AS1 in HCT116 and SW480 cells.

SW480 cells with overexpression of TNFRSF10A-AS1 (Figure 2C). Moreover, Western blot analysis revealed that downregulation of TNFRSF10A-AS1 decreased cyclin D1 and PCNA expression, while the upregulation of TNFRSF10A-AS1 increased cyclin D1 and PCNA expression (Figure 2E). In general, genes that promote proliferation can suppress cell apoptosis. Therefore, we conducted Annexin V-APC/PI staining and Western blot analysis to test the impact of TNFRSF10A-AS1 on the apoptosis of colon cancer cells. The results showed that downregulation of TNFRSF10A-AS1 increased the apoptosis rate and the expression of the cleaved forms of caspase-3 and PARP, which are markers of cell apoptosis, whereas upregulation of TNFRSF10A-AS1 led to the opposite effects (Figure 2D and E).

In addition to malignant proliferation, tumor cells also exhibit migration and invasion abilities. Therefore, we performed Transwell assays with or without Matrigel to explore the impact of TNFRSF10A-AS1 on the migration and invasion properties of colon cancer cells. Downregulation of TNFRSF10A-AS1 markedly suppressed the migration and invasion abilities of DLD1 and HT29 cells, whereas overexpressing TNFRSF10A-AS1 significantly enhanced the abilities of HCT116 and SW480 cells (Figure 2F and G). Therefore, these findings demonstrated that TNFRSF10A-AS1 exerted a cancer-promoting role in CRC, prompting further investigations of its potential regulatory mechanisms.

miR-3121-3p is downregulated in CRC

The above findings suggested that TNFRSF10A-AS1 might play a tumor-promoting role in the cytoplasm. Thus, we explored the potential molecular mechanism of TNFRSF10A-AS1 based on the ceRNA mechanism. We first predicted potential target miRNAs of TNFRSF10A-AS1 by using miRNA target prediction tools, including miRDB, DIANA and LncRNAMAP. The prediction results of the three databases yielded 15 candidate miRNAs (Figure 3A). Among them, miR-3121-3p expression was upregulated in TNFRSF10A-AS1-deficient cells and downregulated in TNFRSF10A-AS1-overexpressing cells, consistent with the ceRNA mechanism theory (Figure 3B). Subsequently, we performed qRT-PCR to evaluate miR-3121-3p expression in CRC tissues, which indicated significant downregulation of miR-3121-3p in colorectal tumor tissues compared to matched nontumor tissues (Figure 3C). We further confirmed the interaction between TNFRSF10A-AS1 and miR-3121-3p using a dual-luciferase reporter assay (Figure 3E). Luciferase activity was reduced in cells cotransfected with TNFRSF10A-AS1-WT and the miR-3121-3p mimics, whereas there was no difference between cells cotransfected with TNFRSF10A-AS1-MUT and the miR-3121-3p mimics and cells cotransfected with TNFRSF10A-AS1-MUT and mimics NC (Figure 3F). Finally, we analyzed the correlation between miR-3121-3p levels and the clinicopathological features of CRC patients and discovered that downregulation of miR-3121-3p was associated with large tumor size (Table 3). These results suggested that miR-3121-3p might be a tumor suppressor and exert an inhibitory effect on CRC.

miR-3121-3p inhibits the proliferation, migration and invasion of colon cancer cells by silencing HuR

Because there are few studies related to miR-3121-3p and no relevant studies in CRC, we set out to investigate the function and mechanism of miR-3121-3p in CRC. We first predicted the downstream proteins of miR-3121-3p using four online databases, *i.e.*, miRDB, TargetScan, miRTarBase and RNA22, and then obtained 3 candidate genes (ELAVL1, PLEKHA6 and ATL3) after taking the intersection (Figure 4A). Of the three candidate genes, ELAVL1 (HuR) has been demonstrated to be involved in CRC progression and may act as an oncogene in CRC. qRT-PCR showed that the expression of miR-3121-3p was relatively lower in DLD1 cells and higher in HCT116 cells (Figure 3D). Thus, we selected DLD1 cells and HCT116 cells for transfection with miR-3121-3p mimics and inhibitor, respectively, to further identify the effects of miR-3121-3p on the malignant phenotype of CRC. Experimental results at both the mRNA and protein levels indicated that upregulation of miR-3121-3p decreased HuR expression, whereas downregulation of miR-3121-3p increased HuR expression (Figure 4B), suggesting that HuR might be a downstream target protein of miR-3121-3p.

We next studied the impacts of miR-3121-3p on the biological function of colon cancer cells. Growth curves based on the CCK-8 assay displayed that upregulation of miR-3121-3p suppressed the proliferation and viability of DLD1 cells, whereas downregulation of miR-3121-3p enhanced the proliferation and viability of HCT116 cells (Figure 4C). The colony number of DLD1 cells transfected with the miR-3121-3p mimics was significantly lower than that of the control group, whereas the colony number of HCT116 cells transfected with the miR-3121-3p inhibitor was significantly higher than the control group (Figure 4D). In addition, Transwell assays indicated that upregulation of miR-3121-3p in DLD1 cells significantly impaired the migration and invasion abilities, whereas downregulation of miR-3121-3p in HCT116 cells significantly enhanced these abilities (Figure 4E). In summary, the above results confirmed

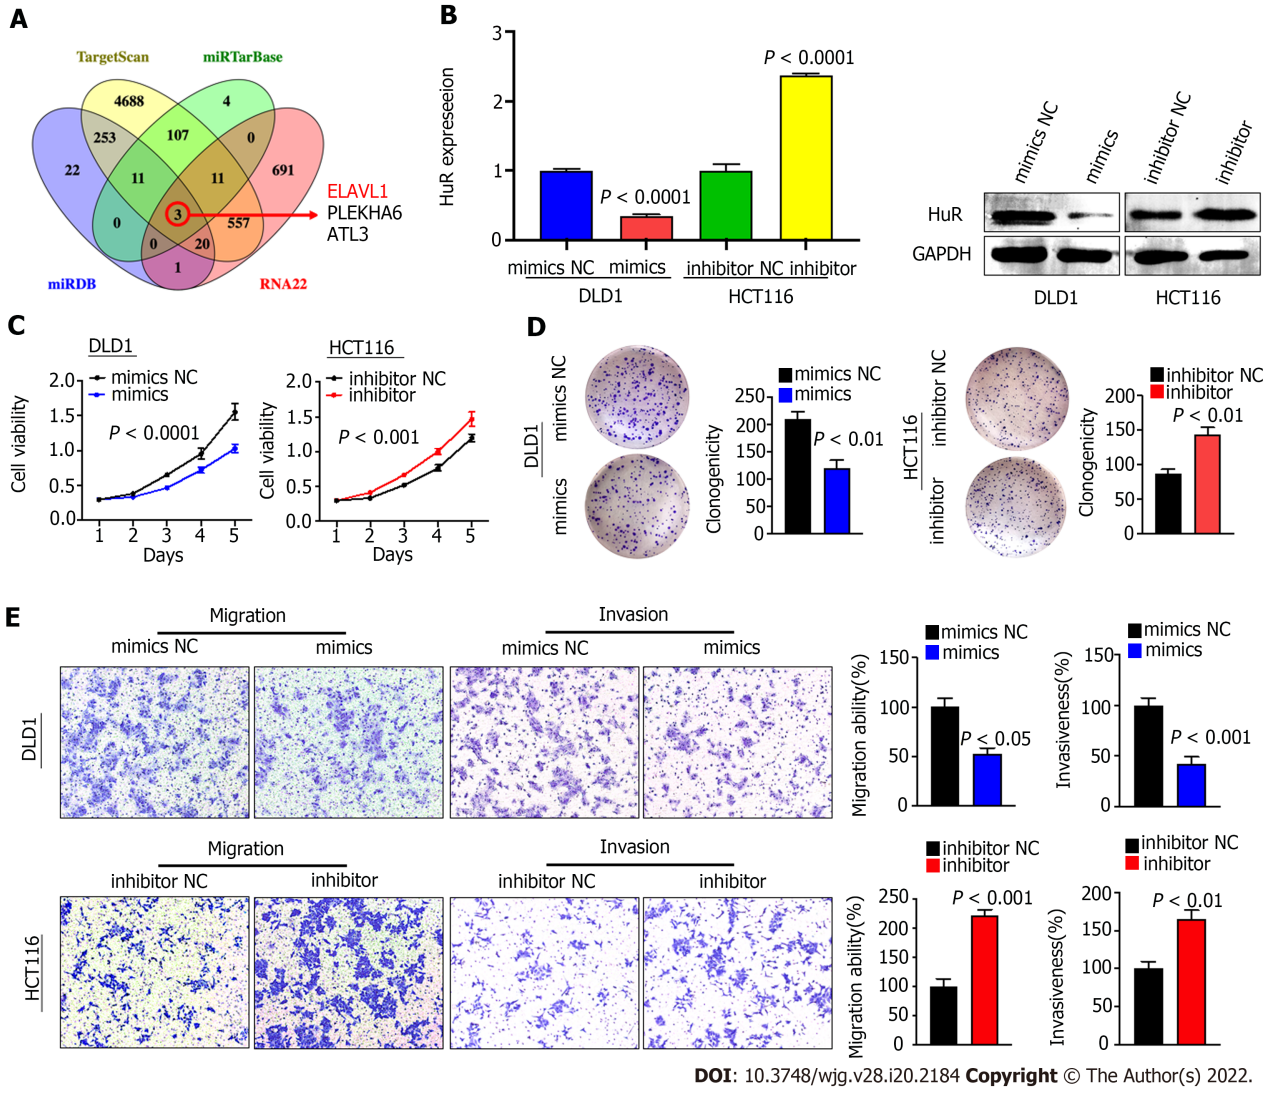
that miR-3121-3p played a suppressive effect in the malignant phenotype of CRC, including aberrant proliferation and metastasis.

TNFRSF10A-AS1 accelerates the proliferation, migration and invasion of colon cancer cells via the miR-3121-3p/HuR axis

We performed rescue experiments using miR-3121-3p mimics and inhibitor with the aim of verifying whether TNFRSF10A-AS1 exerts a tumor-promoting effect through the miR-3121-3p/HuR axis. We first examined HuR expression at the mRNA and protein levels. Silencing TNFRSF10A-AS1 decreased the mRNA and protein levels of HuR in DLD1 cells, whereas overexpressing TNFRSF10A-AS1 in HCT116 cells enhanced HuR expression. In addition, the miR-3121-3p inhibitor and mimics reversed the regulatory effects on HuR expression caused by TNFRSF10A-AS1 silencing and overexpression, respectively (Figure 5A). Furthermore, we sought to clarify whether the miR-3121-3p mimics and inhibitor reverse the impacts of TNFRSF10A-AS1 on CRC biological functions. All the experiments results, including CCK-8, colony formation as well as Transwell assays, indicated that the suppressive impacts on DLD1 cells caused by TNFRSF10A-AS1 knockdown could be balanced by miR-3121-3p inhibitor, while miR-3121-3p mimics could counteract the promoting effect of TNFRSF10A-AS1 overexpression on HCT116 cells (Figure 5B-E). The above results indicated that the miR-3121-3p/HuR regulatory axis might be one of the mechanisms by which TNFRSF10A-AS1 promoted CRC proliferation, migration and invasion.

TNFRSF10A-AS1 promotes CRC growth in vivo

Given that the above *in vitro* experimental results suggested that TNFRSF10A-AS1 had a tumor-promoting effect on colon cancer cells, we selected TNFRSF10A-AS1-deficient DLD1 cells and TNFRSF10A-AS1-overexpressing HCT116 cells for tumor xenograft experiments to verify the effect of TNFRSF10A-AS1 *in vivo*. Consistent with the results of *in vitro* experiments, we found that the downreg-



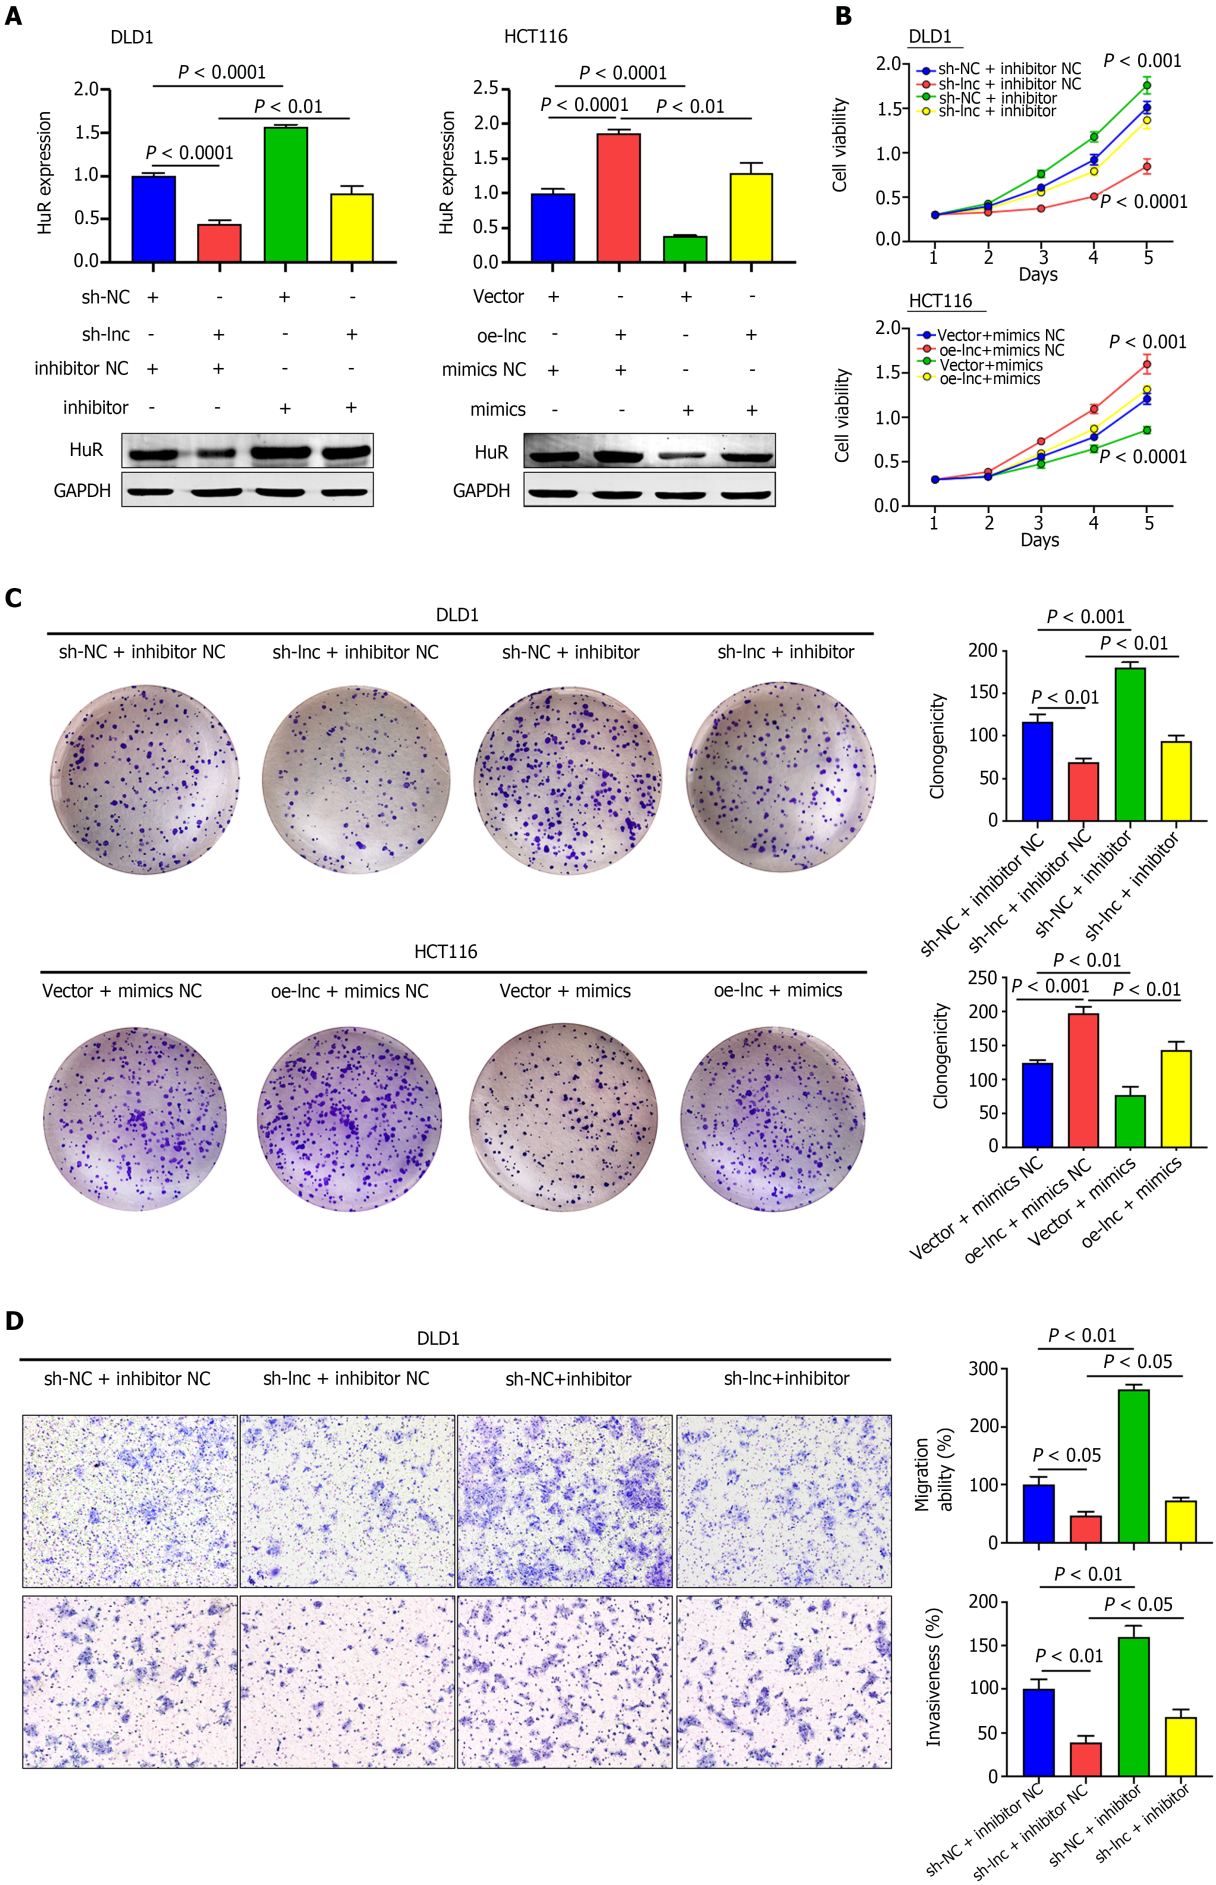
DOI: 10.3748/wjg.v28.i20.2184 **Copyright** © The Author(s) 2022.

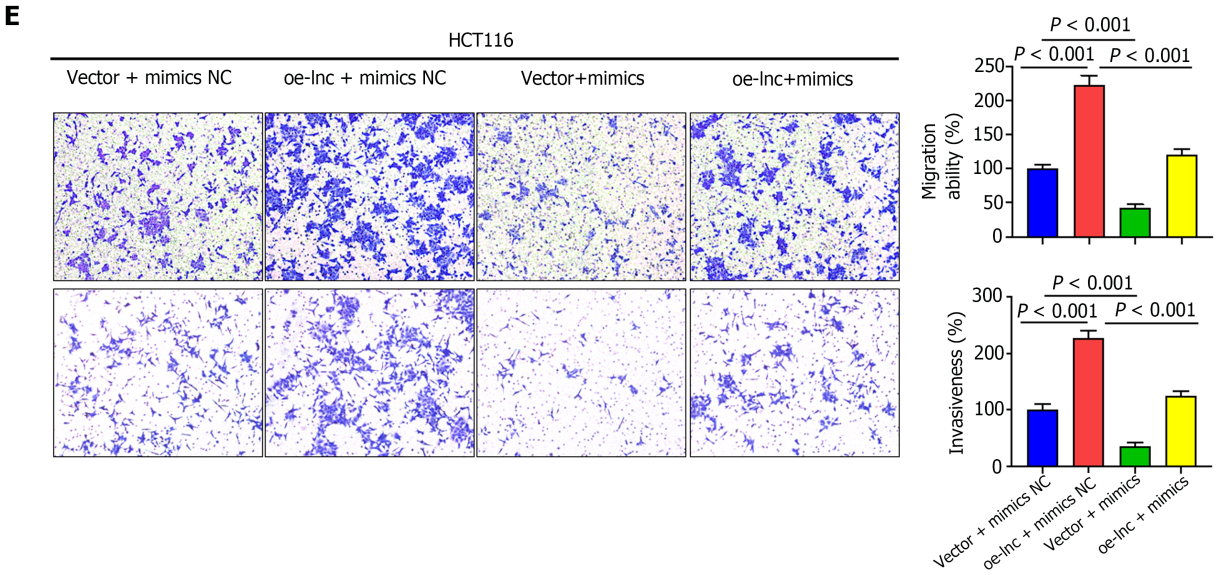
Figure 3 miR-3121-3p is downregulated in colorectal cancer. A: We used three websites (miRDB, DIANA and LncRNAMAP) to predict 15 microRNAs with binding sites for TNFRSF10A-AS1; B: miR-3121-3p expression was increased in cells transfected with si-lnc and decreased in cells transfected with oe-lnc; C: miR-3121-3p was downregulated in colorectal cancer tumor tissues compared to matched nontumor tissues (n = 40); D: Levels of miR-3121-3p in colon cancer cell lines were detected by quantitative real-time polymerase chain reaction; E: Schematic illustration of the predicted binding sites of miR-3121-3p in the TNFRSF10A-AS1 sequence; F: Relative luciferase activities after cotransfection with TNFRSF10A-AS1-WT, TNFRSF10A-AS1-MUT, miR-3121-3p mimics or NC in DLD1 cells. WT: Wild-type; MUT: Mutant.

ulation of TNFRSF10A-AS1 significantly reduced the tumor size and weight of DLD1 xenografts (Figure 6A), whereas upregulation of TNFRSF10A-AS1 markedly promoted HCT116 xenograft growth (Figure 6B). Moreover, IHC assays demonstrated that downregulation of TNFRSF10A-AS1 reduced the expression of the Ki-67 proliferation marker in xenograft tumor tissues, whereas upregulation of TNFRSF10A-AS1 produced the opposite effect (Figure 6C). qRT-PCR, Western blot and IHC analyses all revealed that HuR expression was downregulated in TNFRSF10A-AS1-deficient xenograft tumor tissues but upregulated in TNFRSF10A-AS1-overexpressing xenograft tumor tissues (Figure 6C-E). Western blot analysis of tissue samples from CRC patients also showed that HuR was increased in tumor tissues compared to paired nontumor tissues (Figure 6F). Therefore, these *in vivo* results further supported the tumor-promoting role of TNFRSF10A-AS1 in CRC, which functioned at least in part as a molecular sponge of miR-3121-3p to upregulate HuR expression.

DISCUSSION

In this study, we first uncovered TNFRSF10A-AS1 as an oncogene that participated in colorectal carcinogenesis and progression. Although the available findings have demonstrated that TNFRSF10A-AS1 is involved in the autophagic mechanism of CRC as well as gastric cancer prognosis, the current





DOI: 10.3748/wjg.v28.i20.2184 **Copyright** © The Author(s) 2022.

Figure 4 miR-3121-3p suppresses colon cancer cell proliferation, migration and invasion *in vitro*. A: Four websites (miRDB, TargetScan, miRTarBase and RNA22) were used to predict 3 downstream target mRNAs with binding sites for miR-3121-3p; B: HuR expression was assessed in DLD1 and HCT116 cells transfected with miR-3121-3p mimics, miR-3121-3p inhibitor or NC using quantitative real-time polymerase chain reaction and Western blot assays; C and D: miR-3121-3p mimics inhibited cell viability and clonogenicity, but miR-3121-3p inhibitor enhanced cell viability and clonogenicity; E: Upregulation of miR-3121-3p inhibited cell migration and invasion capabilities, whereas downregulation of miR-3121-3p enhanced these capabilities.

evidence is all based on the analysis of TCGA data, and its functional roles and detailed mechanisms in CRC cannot be determined. Our study showed that TNFRSF10A-AS1 was upregulated in CRC and the upregulation of TNFRSF10A-AS1 was associated with advanced tumor size and T grade. In functional experiments both *in vitro* and *in vivo*, we found that TNFRSF10A-AS1 enhanced the malignant phenotype of colon cancer cells. Regarding the molecular mechanism of TNFRSF10A-AS1, we identified miR-3121-3p by bioinformatics analyses and verified the direct interaction between TNFRSF10A-AS1 and miR-3121-3p by dual-luciferase reporter assays. In contrast to TNFRSF10A-AS1, miR-3121-3p was downregulated in CRC, negatively associated with the tumor size as well as exerted inhibitory effects on the malignant phenotype of colon cancer cells, which is consistent with ceRNA mechanism theory. Mechanistically, one of the ways in which TNFRSF10A-AS1 exerted its pro-cancer effects was through sponging miR-3121-3p. By binding to miR-3121-3p, TNFRSF10A-AS1 attenuated the silencing effect of miR-3121-3p on its downstream target gene, HuR. Taken together, our findings provide evidence for an important role of TNFRSF10A-AS1 and the TNFRSF10A-AS1/miR-3121-3p/HuR axis in CRC progression, thereby providing a theoretical basis for the diagnosis and treatment of CRC.

ceRNA is an important regulatory mode of cytoplasmic lncRNA. Here, after confirming that TNFRSF10A-AS1 was more abundant in the cytoplasm of CRC cell lines, we used online tools to predict potential target miRNAs of TNFRSF10A-AS1. We further validated the expression relationship between TNFRSF10A-AS1 and candidate miRNAs, and we discovered that miR-3121-3p might be a downstream target miRNA of TNFRSF10A-AS1. And the dual-luciferase reporter assay further confirmed that TNFRSF10A-AS1 might function as the molecular sponge of miR-3121-3p. In the lncRNA-miRNA-mRNA network, miRNAs, as intermediate mediators, exert biological effects by modulating

Figure 5 TNFRSF10A-AS1 promotes colon cancer cell proliferation, migration and invasion *via* the miR-3121-3p/HuR axis. A: HuR was evaluated in DLD1 and HCT116 cells transfected with miR-3121-3p mimics, miR-3121-3p inhibitor, NC, sh-lnc or oe-lnc; B and C: Cell proliferation abilities were estimated using Counting Kit-8 and colony formation assays in DLD1 and HCT116 cells transfected with miR-3121-3p mimics, miR-3121-3p inhibitor, NC, sh-lnc or oe-lnc; D and E: Transwell assays were performed to analyze cell migration and invasion abilities in DLD1 and HCT116 cells transfected with miR-3121-3p mimics, miR-3121-3p inhibitor, NC, sh-lnc or oe-lnc.

downstream target proteins. After experimental evidence established that TNFRSF10A-AS1 could sponge miR-3121-3p, we explored its effector genes. Among candidate target genes predicted by target prediction software, only HuR has been shown previously to regulate CRC progression, and our results also verified that miR-3121-3p exerted a negative regulatory effect on HuR expression. Rescue experiments also confirmed that miR-3121-3p mimics and inhibitor counteracted the regulatory effects of TNFRSF10A-AS1 overexpression and knockdown, respectively, on HuR expression, cell proliferation, migration ability and invasion ability. Thus, one of the mechanisms by which TNFRSF10A-AS1 acts may be as a molecular sponge for miR-3121-3p, which upregulates HuR expression and ultimately promotes colorectal carcinogenesis and progression.

HuR, a cancer-associated RNA-binding protein (RBP), is a member of the embryonic lethal abnormal vision (ELAV) family, and it increases mRNA stability by binding to conserved AU-rich elements (AREs) within 3′ untranslated regions (UTRs), thereby preventing gene degradation[12]. HuR expression is upregulated in different tumors, including breast cancer, CRC, gastric cancer and prostate cancer, and it is correlated with advanced clinicopathological parameters, expression of tumor-associated proteins, a low survival rate and poor prognosis[13-16]. CRC-related studies show that HuR is upregulated and promotes colon cancer growth by targeting RNA in the cytoplasm[17]. In addition, increased HuR protein in the cytoplasm is correlated with T stage, and importantly, HuR overexpression increases the growth of colon cancer cells in nude mouse models[18]. A recent study has revealed that miR-22, as a tumor suppressive miRNA, directly binds to HuR and downregulates its expression to inhibit proliferation and migration abilities of CRC, as well as xenogeneic tumor growth [19]. Through our experimental research, we found that the upstream lncRNA TNFRSF10A-AS1 sponged an important tumor suppressive miRNA in CRC, miR-3121-3p, which negatively regulated HuR expression. Consistent with previous studies, HuR was highly expressed in CRC. Our study results further suggested that the expression of HuR might be positively regulated by the upstream molecular TNFRSF10A-AS1, which might be one of the mechanisms by which TNFRSF10A-AS1 exerted a pro-cancer effect in CRC.

Based on the results of comprehensive analyses, including bioinformatics analyses, cell functional experiments and clinical research tools, we have sufficient evidence that TNFRSF10A-AS1 is a novel oncogene that promotes tumor malignancy in CRC. Mechanistically, TNFRSF10A-AS1 regulates the expression of the downstream target, HuR, by sponging miR-3121-3p, which further promotes CRC progression. Targeting the TNFRSF10A-AS1/miR-3121-3p/HuR axis may have potential therapeutic implications for CRC.

DOI: 10.3748/wjg.v28.i20.2184 **Copyright** © The Author(s) 2022.

Figure 6 TNFRSF10A-AS1 promotes the growth of colorectal cancer *in vivo*. A and B: Tumor volume and weight were significantly decreased in the TNFRSF10A-AS1 knockdown group but markedly increased in the TNFRSF10A-AS1 overexpression group; C-E: TNFRSF10A-AS1 enhanced cell proliferation (as assessed by Ki67 staining) and increased HuR expression (as assessed by HuR staining, quantitative real-time polymerase chain reaction and Western blot) in xenograft tumor tissues; F: HuR was upregulated in colorectal cancer patient tumor tissues compared to matched nontumor tissues by Western blot analysis.

CONCLUSION

TNFRSF10A-AS1 as a ceRNA promotes tumor malignancy of CRC through the miR-3121-3p/HuR axis. TNFRSF10A-AS1/miR-3121-3p/HuR axis may provide more effective targets for CRC therapy.

ARTICLE HIGHLIGHTS

Research background

The critical importance of long noncoding RNAs (lncRNAs) to the onset and exacerbation of colorectal cancer (CRC) has been validated in an increasing number of studies. However, numerous lncRNAs associated with CRC remain unidentified and the detailed mechanisms remain poorly understood. TNFRSF10A-AS1 is a new lncRNA, the function in CRC and gastric cancer is inconsistent and the exact mechanism is unclear.

Research motivation

The present study will clarify the oncogenic pathogenesis of TNFRSF10A-AS1 in CRC progression, leading to new ideas for CRC therapy.

Research objectives

To detect TNFRSF10A-AS1 expression in CRC and investigate the functions and potential mechanisms of TNFRSF10A-AS1 in CRC onset and exacerbation.

Research methods

In this study, the authors detected TNFRSF10A-AS1 expression in CRC and clarified the relationship between TNFRSF10A-AS1 levels and clinicopathological features of CRC patients. Furthermore, a series of functional experiments both *in vitro* and *in vivo* were performed to explore the role of TNFRSF10A-AS1. The mechanism of TNFRSF10A-AS1 mainly focused on its role as a miRNA molecular sponge.

Research results

TNFRSF10A-AS1 expression was increased in CRC and positively associated with advanced tumor size and T grade of CRC patients. TNFRSF10A-AS1 enhanced the malignant phenotype of colon cancer cells by promoting CRC proliferation and metastasis. Mechanistically, TNFRSF10A-AS1 was more abundant in the cytoplasm and upregulated the downstream target, HuR, by sponging miR-3121-3p, ultimately promoting CRC progression.

Research conclusions

TNFRSF10A-AS1 upregulates HuR expression by sponging miR-3121-3p, ultimately promoting colorectal tumorigenesis and progression. Therefore, TNFRSF10A-AS1 and the TNFRSF10A-AS1/miR-3121-3p/HuR axis may play an important role in CRC onset and exacerbation.

Research perspectives

Targeting TNFRSF10A-AS1 and the TNFRSF10A-AS1/miR-3121-3p/HuR axis may have potential novel therapeutic implications for CRC.

Abstract

BACKGROUND

Patients with primary sclerosing cholangitis (PSC) are at a high risk of developing cholestatic liver disease and biliary cancer, and endoscopy is crucial for the complex management of these patients.

AIM

To clarify the utility of recently introduced digital single-operator video cholangioscopy (SOVC) for the endoscopic management of PSC patients.

METHODS

In this observational study, all patients with a history of PSC and in whom digital SOVC (using the SpyGlass DS System) was performed between 2015 and 2019 were included and retrospectively analysed. Examinations were performed at a tertiary referral centre in Germany. In total, 46 SOVCs performed in 38 patients with a history of PSC were identified. The primary endpoint was the evaluation of dominant biliary strictures using digital SOVC, and the secondary endpoints were the performance of selective guidewire passage across biliary strictures and the diagnosis and treatment of biliary stone disease in PSC patients.

RESULTS

The 22 of 38 patients had a dominant biliary stricture (57.9%). In 4 of these 22 patients, a cholangiocellular carcinoma was diagnosed within the stricture (18.2%). Diagnostic evaluation of dominant biliary strictures using optical signs

showed a sensitivity of 75% and a specificity of 94.4% to detect malignant strictures, whereas SOVC-guided biopsies to gain tissue for histopathological analysis showed a sensitivity of 50% and a specificity of 100%. In 13% of examinations, SOVC was helpful for guidewire passage across biliary strictures that could not be passed by conventional methods (technical success rate 100%). Biliary stone disease was observed in 17.4% of examinations; of these, in 37.5% of examinations, biliary stones could only be visualized by SOVC and not by standard fluoroscopy. Biliary stone treatment was successful in all cases (100%); 25% required SOVC-assisted electrohydraulic lithotripsy. Complications, such as postinterventional cholangitis and pancreatitis, occurred in 13% of examinations; however, no procedure-associated mortality occurred.

CONCLUSION

Digital SOVC is effective and safe for the endoscopic management of PSC patients and may be regularly considered an additive tool for the complex endoscopic management of these patients.

Core Tip: Endoscopic management of patients with primary sclerosing cholangitis (PSC) is complex; our study is the first to evaluate the utility of single-operator video cholangioscopy (SOVC) with digital imaging quality in these patients. Our data indicate that the use of digital SOVC in PSC patients substantially improves the evaluation of biliary strictures and that SOVC effectively supports interventions, such as stricture dilation and biliary stone treatment, in PSC patients; mild to moderate complications occurred in a minority of cases. Concluding digital SOVC may be effective and safe as an additive tool for the complex endoscopic management of PSC patients.

INTRODUCTION

Primary sclerosing cholangitis (PSC) is an immune-mediated chronic liver disease characterized by inflammatory, fibrotic, and destructive changes of the bile ducts, leading to cholestasis, biliary stricture development and hepatic fibrosis. Because of the chronic disease course, PSC patients are at a high risk of developing liver cirrhosis and cholangiocellular carcinoma (CCC)[1,2]. Although PSC patients do not regularly show clinical symptoms in early disease, those with advanced disease often develop typical clinical symptoms including right upper quadrant pain (20%), pruritus (10%), jaundice (6%) and fatigue (6%)[1]. Endoscopy is crucial for the diagnostic and therapeutic management of PSC patients, as documented by recent guidelines[2,3]. Standard endoscopic management of PSC patients includes endoscopic retrograde cholangiography (ERC) and is often challenging. In particular, standard endoscopic management is required in patients with biliary strictures: Diagnostic assessment of strictures may become necessary to exclude malignancy, and therapeutic interventions, including stricture dilation to improve cholestatic disease, may be needed[2,3]. Despite endoscopic treatment, PSC patients may develop advanced liver cirrhosis requiring organ transplantation[4], revealing the unmet need for additional therapeutic options.

Cholangioscopic techniques have progressed in recent years. In 2015, the first digital single-operator video cholangioscope (SpyGlass™ DS System, Boston Scientific, Marlborough, MA, United States) was released[5]. Compared with the previous fibre-optic system, this digital single-operator video cholangioscopy (SOVC) instrument is armed with digital imaging, enabling up to four-times higher resolution, a 60% wider field of view, improved manoeuvrability, and irrigation capacities to clean the field of view [5-9]. Furthermore, forceps biopsies are available, allowing SOVC-guided tissue sampling[5,6,8,9], guidewires can be selectively passed across biliary strictures to allow subsequent interventions[8], and SOVC-assisted lithotripsy devices are ready to treat biliary stone disease[10]. Recently, digital SOVC was technically updated, leading to further advances in lighting and image resolution (SpyGlassDS 2.0; Boston Scientific, Marlborough, MA, United States).

The latest guidelines state that intraductal cholangioscopy can help to diagnose indeterminate biliary strictures in PSC patients and that cholangioscopy may be useful for tissue sampling[2,3]. However, the data are rare, and no study thus far has reported the use of newly introduced digital SOVC in PSC patients. Considering the superior imaging quality and manoeuvrability of digital SOVC instruments, further research is required to address the question of whether digital SOVC may offer an effective additive endoscopic treatment in these patients.

Therefore, this study aimed to evaluate the efficacy and safety of digital SOVC for the diagnostic and interventional endoscopic management of patients with PSC.

MATERIALS AND METHODS

Study design and inclusion criteria

This retrospective, monocentre study was performed at the Department of Medicine B for Gastroenterology, Hepatology, Endocrinology and Clinical Infectiology of the University Hospital Muenster, Germany. The data from all patients ≥ 18 years of age and with a previously diagnosed PSC who had undergone digital SOVC using the SpyGlass DS System (Boston Scientific, Marlborough, MA, United States) between December 2015 and November 2019 were retrieved from the clinical data systems. PSC diagnosis was previously known and not initially established during performed SOVC examinations. Biliary tract cancer was not previously diagnosed in these patients; likewise, IgG4-related sclerosing cholangitis was not known in our patient cohort. The study conformed to the ethical guidelines of the 1975 Declaration of Helsinki and was approved by the Ethics Board of the Westphalian Wilhelms-University of Muenster and Medical Council of Westphalia-Lippe, Germany. To minimize known sources of bias, this trial was reported according to the STROBE statement, wherever appropriate and applicable[11].

Technical aspects of digital single-operator video cholangioscopy

Cholangioscopies were performed by highly experienced endoscopists according to the generally accepted guidelines using an ERC case volume exceeding 200/year and performing ERC procedures for at least five years[12]. Before examination, all the patients received prophylactic antibiotic treatment; nonsteroidal anti-inflammatory drugs (NSAIDs; *e.g.*, indomethacin) were not regularly administered before the procedure. CO_2 insufflation was used during all examinations. Before cholangioscopy, an endoscopic papillotomy was performed, or one had been previously performed. The cholangioscope (digital SOVC; Boston Scientific, Marlborough, MA, United States) was inserted into the biliary duct in a guidewire-assisted method; targeted biopsies were acquired using SpyBite forceps (Boston Scientific, Marlborough, MA, United States). For biliary stone treatment, electrohydraulic lithotripsy (EHL) was performed using a bipolar lithotripsy 2.4 F catheter probe (Walz Elektrotechnik GmbH, Rohrdorf, Germany) with saline solution irrigation (SSI) controlled over a dedicated irrigation pump. The probe produces high-frequency hydraulic pressure waves, resulting in the fragmentation of biliary stones[10,13].

The primary endpoint of this study was to evaluate the efficacy and safety of digital SOVC to detect malignancy in dominant biliary strictures in patients with PSC, depending on the visual inspection and histological evaluation of SOVC-acquired biopsies. According to the European guidelines, strictures were defined as dominant if they had a diameter smaller than 1.5 mm in the common bile duct and smaller than 1 mm in the right and left hepatic ducts[14]. Visual signs suggesting malignancy were documented if the performing endoscopists classified visual findings as suspicious for malignancy in the presence of irregular vessels, easy bleeding, irregular surfaces and elevated masses protruding into the duct lumen[15,16]. Acquired biopsy material was analysed by an experienced pathologist and classified as suspicious for malignancy if cancer cells or high-grade cell dysplasia were detected. The final diagnosis (reference standard) of biliary stricture dignity was based on a detailed evaluation of all the available data, including clinical information, cross-sectional imaging reports and histopathological analyses, which could be found in the electronic patient chart. The median follow-up time was 12 mo [interquartile range (IQR) 7-27 mo]; during this time, the patients were followed up by repeated checks of the available electronic medical records.

For secondary endpoint analysis, the use of digital SOVC for the diagnosis and treatment of biliary stone disease in PSC patients was documented. Furthermore, the use of digital SOVC for selective guidewire insertion across biliary strictures in cases that were solely performed because of a previous failure of conventional endoscopic methods to treat a biliary stricture *via* selective guidewire placement was evaluated.

Safety analysis

Adverse events following examination were documented as follows: (1) Postinterventional pancreatitis was defined if patients developed abdominal pain and a threefold increase in the serum lipase levels within 48 h of the examination[17]; (2) Postinterventional cholangitis was documented as the presence of new fever (> 38.0 °C) and newly or significantly higher cholestatic and inflammatory markers

requiring antibiotics within three days of the examination[17]; and (3) Severe bleeding was diagnosed if bleeding was observed during intervention that required immediate endoscopic therapy or if haemoglobin level decreased by two points or more[17]. Adverse events were graded as mild, moderate, or severe, depending on the length of additional hospital stay (mild = 1-3 d, moderate = 4-10 d, severe = > 10 d)[17].

Statistical analysis

The data were analysed using IBM SPSS Statistics 27.0 (IBM Corp., Armonk, United States). Additionally, contingency table-derived data were determined using StatPages[18]. Frequencies and percentages were recorded for categorical variables; means and standard errors (SEs) were reported for continuous variables. Missing data are indicated and reported in the text and tables. The statistical methods of this study were reviewed by Arne Bokemeyer.

RESULTS

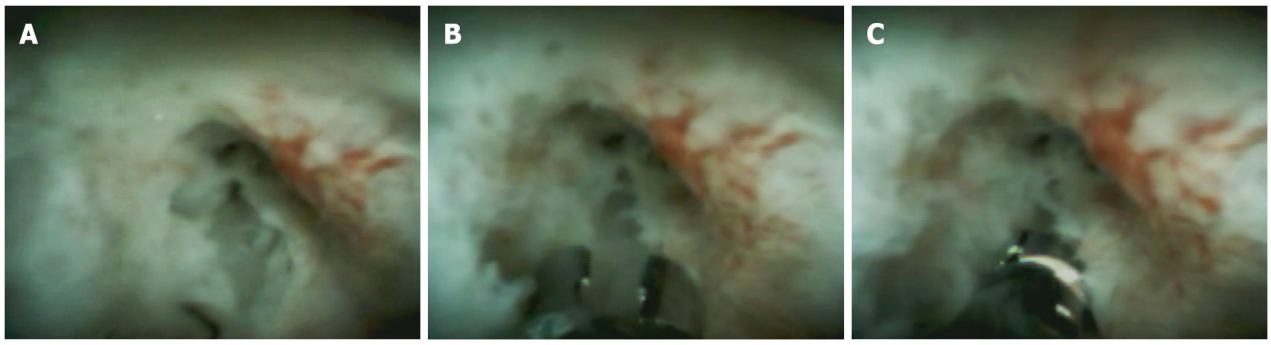
Study population

During the study period, 151 ERCs were performed in 72 patients with PSC, and in 30.5% of these ERCs, digital SOVC was additionally carried out (46/151). These 46 cholangioscopies, conducted in 38 PSC patients, were included in the final dataset (Figures 1 and 2). The main indication for SOVC use was the assessment of biliary strictures (80.4%), followed by selective guidewire placement across biliary strictures (13%) and treatment of biliary stone disease (4.3%). A total of 68.4% of the patients were male, whereas 31.6% of the patients were female. The mean age was 44.8 years (SE: ± 2.1 years). Considering all patients, the mean period from the initial ERC performed for PSC diagnosis to the performance of the first SOVC was 99.9 mo (SE ± 16.6). A total of 52.6% of the patients had liver cirrhosis, and 29% were enrolled for liver transplantation. In 10.5% of patients, a final diagnosis of a malignant biliary tumour was established (Table 1). In these patients, the mean time from initial ERC performed for PSC diagnosis to the digital SOVC, which was sufficient to establish bile duct cancer diagnosis, was 71.3 mo (standard error: ± 16.6) with a range of at least 11 mo up to 150 mo.

Of the cholangioscopies, 38 examinations were initial, and 8 were repeated examinations (Table 2). All the examinations were ERC-based (100%). The median total examination time was 73 min (± 5.2 min; missing data in 6/46 examinations). In one case, the digital SOVC system technically failed during examination and could not be relaunched (2.2%; Table 2).

During SOVC, the main procedures were selective SOVC-assisted guidewire insertions to support diagnostic assessment and therapeutic interventions of the biliary tract in 84.7% of examinations, SOVC-assisted forceps biopsy acquisition in 54.3% of examinations, and the performance of SOVC-assisted EHL for refractory biliary stone disease in 4.3% of examinations. Biliary strictures were dilated in 76.1% of examinations, and endoprostheses were placed in 10.9% of examinations (Table 2).

Diagnostic efficacy of stricture assessment in PSC using SOVC



Dominant biliary strictures were present in 22 of 38 patients (57.9%; Table 3). Dominant strictures were mainly localized intrahepatically (59.1%), followed by strictures at the intra- and extrahepatic passages (27.3%) and extrahepatic strictures (13.6%). In 4 of 22 patients, dominant strictures were of a malignant entity (18.2%). The malignant strictures were localized at the intra- and extrahepatic crossing in three patients, and in one patient the stricture was localized intrahepatically at the left hepatic duct. Using SOVC, visual signs of malignancy could be observed in 18.2% of patients. In 13 of 22 patients, SOVC-assisted forceps biopsies were obtained (59.1%; Figure 1). In 2 of 13 biopsies, histopathological analysis revealed signs of malignancy (carcinoma or high-grade dysplasia; 15.4%). In 1 of 13 patients, insufficient tissue was obtained using forceps biopsies, making an accurate histopathological analysis impossible (7.7%; Table 3). The visual examination of dominant strictures had an accuracy of 90.9% (CI: 72.8%-99.2%), a sensitivity of 75% (CI: 25.2%-97.8%), a specificity of 94.4% (83.4%-99.5%), a positive predictive value of 75% (25.2%-97.8%), and a negative predictive value of 94.4% (83.4%-99.5%; Table 4). Histopathological analysis of SOVC-assisted biopsy acquisition had an accuracy of 83.3% (CI: 57.2%-83.3%), a sensitivity of 50% (10.8%-50%), a specificity of 100% (80.4%-100%), a positive predictive value of 100% (21.7%-100%), and a negative predictive value of 80% (64.3%-80%) (Table 4).

Use of SOVC for biliary stone treatment in patients with PSC

In 8 of 46 examinations (17.3%), biliary stones were found (Table 5). Stones were localized intrahepatically (37.5%), extrahepatically (37.5%) and both intra- and extrahepatically (25%). The stone size ranged between 3 and 20 mm, and the number of stones ranged between 1 and 5 *per* examination. In 3 of 8 cases (37.5%), biliary stones were only visualized using SOVC, and standard fluoroscopy failed to detect biliary stones. In all 8 examinations, biliary stone treatment was finally successful; however, in 2 of 8 examinations (25%), biliary stone disease was refractory to standard ERC methods, including stone extraction with baskets and/or balloon catheters, which was why EHL was applied for stone

Figure 2 Selective guidewire placement across a biliary stricture in a patient with primary sclerosing cholangitis using digital single-operator video cholangioscopy. A: Multiple attempts to pass a biliary stricture in a patient with primary sclerosing cholangitis using conventional selective guidewire insertion failed, which is why digital single-operator video cholangioscopy (SOVC) was used and helped visualize the stricture; B and C: Under SOVC-assisted guidance, a guidewire was successfully placed across the biliary stricture, enabling subsequent endoscopic therapy.

fragmentation. In both cases, EHL successfully led to complete stone fragmentation (100%; Table 5).

SOVC-assisted selective guidewire passage across PSC-associated strictures

The 6 of 46 examinations were solely performed because of a previous failure of conventional endoscopic methods to treat a biliary stricture *via* selective guidewire placement (13%; Figure 2). Of these, 5 were initial SOVC procedures, and one was a repeated procedure. The technical success rate of SOVC-assisted guidewire insertions across biliary strictures was 100%, enabling subsequent dilation of the stricture (Table 5).

Adverse events

In 13% of the procedures, adverse events were documented (Table 6). More specifically, postinterventional pancreatitis was observed in 6.5% of cases, of which 67% had a moderate and 33% a severe disease course. Postinterventional cholangitis occurred in 6.5% of cases, of which all had a moderate disease course (100%). Other procedure-related adverse events, including severe bleeding or organ perforations, did not occur. All procedure-related complications could be successfully managed by conservative therapeutic approaches. No mortality due to procedure-related adverse events occurred. Because of side effects, patients needed to stay in the hospital for 6.5 more days (SE ± 1.5 d) (Table 6).

DISCUSSION

Although a few previous reports evaluated the utility of cholangioscopy in PSC patients in general[19, 20], our study is the first to evaluate the efficacy and safety of SOVC with digital imaging quality in patients with PSC. Digital SOVC is effective and safe as an additive tool for the complex endoscopic

management of these patients. In addition to evaluating biliary strictures, digital SOVC facilitates interventions to the biliary tract because of selective guidewire placements across biliary strictures and helps to diagnose and treat biliary stone disease.

Stricture assessment of biliary strictures in PSC patients is critical to excluding malignancy: PSC patients have a lifetime risk of developing CCC of up to 20%[2]. Clinical judgement, laboratory markers, and cross-sectional imaging are insufficient to exclude malignancy, explaining why endoscopic evaluation, including tissue sampling, becomes necessary[2,3,21]. If a standard work-up including ERC with transpapillary tissue sampling fails to determine stricture aetiology, the performance of peroral cholangioscopy is suggested[21]. Visual interpretation of biliary strictures using cholangioscopy may help diagnose indeterminate biliary strictures: A recent meta-analysis including 283 procedures with digital SOVC in unselected patients found a sensitivity of 94% and a specificity of 95% in detecting malignancy in biliary strictures[22]. In addition to optical evaluation, cholangioscopic-guided biopsies can be obtained: Another recent meta-analysis in unselected patients found a sensitivity of 72% and a specificity of 99% in diagnosing biliary malignancy using cholangioscopy-guided biopsies[23]. Despite these promising results in unselected patients, the results in selected PSC patients might be different: A prospective trial using legacy fibreoptic SOVC in 47 patients with PSC evaluated the use of SOVC-assisted forceps biopsies and found a sensitivity of only 33% and a specificity of 100% in detecting malignant biliary strictures[20]. In our study, visual evaluation of indeterminate biliary strictures identified malignancy with a sensitivity of 75% and a specificity of 94% and histopathological analysis of SOVC-guided biopsies showed a sensitivity of 50% and specificity of 100%. In comparison, our study showed a lower sensitivity and specificity of visual and bioptical stricture assessment than those in

previous studies in unselected patients using SOVC. However, comparing our results to previous studies with fibreoptic SOVC including only selected PSC patients, our sensitivity and specificity rates for the diagnostic evaluation of biliary strictures might be improved. As a limitation, digital SOVCs might only be advanced with difficulties to all intrahepatic strictures due to the decreasing lumen of the proximal bile ducts making proximal intrahepatic ducts partially inaccessible for cholangioscopic assessment. To guide cholangioscopy intrahepatically, the use of guidewires can help to advance the

cholangioscope to more proximal localized strictures.

In conclusion, this study shows that using SOVC with digital imaging quality may significantly improve the diagnostic evaluation of indeterminate strictures in PSC patients. However, validated criteria for optical evaluation of strictures are missing and may be particularly needed in stricture evaluation of PSC patients because inflammatory tissue alterations of the bile ducts hinder easy evaluation of biliary stricture aetiology. Furthermore, no consensus exists concerning the number of biopsies that should be obtained to ensure adequate biopsy material[24]. Speculatively, the sensitivity rates of histopathological evaluation may be improved by a higher number of SOVC-guided biopsies [25]; furthermore, larger forceps biopsies for digital SOVC were recently introduced, promising to further improve cholangioscopic diagnostics in the future. Histopathological analysis is essential for excluding differential diagnoses including Ig4-related sclerosing cholangitis, which may mimic a PSC-like disease. In addition to radiologic and serological assessment, tissue acquisition for histopathological analysis is important for diagnostic assessment[26], and SOVCs might help to gain sufficient histopathological material for correct assessment.

Endoscopic interventions, including stricture dilation, can be performed to improve cholestatic disease in PSC patients and are part of current guideline recommendations[2,3]. Technically, biliary dilation should be preferred to inserting biliary stents[2,3]: Notably, in our cohort, stricture dilation was regularly performed in most patients (76%), whereas only a few received biliary stenting (10.9%). To facilitate biliary dilation or stenting, a guidewire must be placed across the biliary stricture[8,27,28]; however, this selective guidewire placement might fail using standard ERC techniques. A previous trial using fiberoptic SOVCs in 15 patients after liver transplantation showed a technical success rate of 60% of placing a guidewire across a stricture[28]. Another study, which was published by our group, using digital SOVC for selective guidewire insertion in 23 unselected patients showed an overall technical success rate of 70%; notably, the technical success rate was significantly higher in benign strictures than in malignant strictures (88% *vs* 46%; $P = 0.02$)[8]. In the current study, in 6 examinations, conventional ERC techniques failed to pass a guidewire across a biliary stricture, and digital SOVC helped in all cases to perform selective guidewire placement, enabling subsequent stricture dilation (technical success rate: 100%). In conclusion, digital SOVC with improved imaging quality is highly successful in facilitating selective guidewire placement across biliary strictures, even in PSC patients in whom previous attempts to pass a stricture with a guidewire failed using standard ERC techniques.

Patients with PSC may have a high incidence of biliary stone disease[29,30]. In two previous studies, PSC patients had an incidence of biliary stone disease of up to 50%[29,30]. In our cohort, we found a slightly lower incidence of biliary stone disease; however, stones were still frequently found in 17.3% of examinations. A previous trial with 41 PSC patients undergoing fibreoptic cholangioscopy using the mother-baby-technique suggested that 30% of biliary stones were missed by standard fluoroscopy and could only be visualized using cholangioscopy[29]. In our cohort, nearly 40% of biliary stones were missed on fluoroscopy and could only be detected using digital SOVC likely confirming that digital SOVC with improved imaging quality substantially helps detect biliary stones in PSC patients. Although the utility of cholangioscopy for stone detection in PSC patients might be superior using digital SOVC, it might be less likely that a routine use of digital SOVCs for stone detection in PSC patients is cost-effective, which might especially be true for MRCP-negative cases. Sometimes the extraction of biliary stones proximal to biliary strictures might be challenging. Dilation of the distal biliary stricture might substantially help extract stones. Furthermore, EHL might be used for stone fragmentation. In 25% of our cases, SOVC-assisted EHL was used for refractory biliary stone disease and showed complete treatment success (100%). This high technical success rate of biliary stone treatment was similar to that in previous trials, varying from 86% to 100%[9,10,15,16,31] supporting the role of digital SOVC as an effective treatment for refractory biliary stone disease, even in PSC patients.

Additionally, we evaluated the safety of using digital SOVC in PSC patients. In ERC, adverse events occurred in approximately 7% of examinations[32]. Concerning digital SOVC, earlier studies observed complication rates ranging from 0 to 16.4%[9,10,15,16,31], and a recent meta-analysis applying digital SOVC to evaluate biliary strictures found a complication rate of 7%[33]. We found a complication rate of 13%, which is in the upper range of previous trials, although only fully trained endoscopists performed procedures in our cohort. Our cholangitis rate (6.5%) was slightly higher than that of unselected patients (4%), likely because of the complexity of our cases: Only PSC patients were included in our cohort; among these, more than 50% had cirrhotic liver disease, and nearly 30% were enlisted for liver transplantation. The risk of cholangioscopy in PSC patients is controversial: Considering that the stricturing disease course hampers adequate biliary drainage post contrast injection, PSC patients may be at special risk of developing post-ERC cholangitis[34]. Furthermore, our pancreatitis rate (6.5%) was slightly higher than the post-ERC pancreatitis rates observed in unselected patients (2%-4%)[32,35]. Fortunately, all cases of pancreatitis could be managed conservatively, and no surgical management was necessary. In our cohort, rectal NSAIDs were not routinely applied at the start of the study; however, considering our results, rectal NSAIDs should be regularly dispensed in all patients with PSC undergoing digital SOVC, which is the current standard of care in our department and part of recent guideline recommendations[17]. In summary, considering this moderate rate of complications, digital SOVC should be performed in selected cases and by experienced endoscopists at tertiary referral centres.

Our study has several limitations. First, our study was retrospective and is limited by a small sample size comprising only 46 procedures; however, it is the first to exclusively evaluate digital SOVC use in PSC patients; furthermore, PSC is a rare disease, making our number of procedures noteworthy. Second, we included cases at only one hospital in our analysis; however, our centre is a large tertiary referral centre offering special endoscopic experience to perform cholangioscopic procedures, and we could ensure that all endoscopists were fully trained, improving the reliability of our results. Nevertheless, our study results are limited by a lack of validation, making future prospective multicentre studies necessary. Third, our endoscopists were not blinded to patient history, likely biasing their visual impression to determine the biliary stricture dignity; however, digital SOVC was performed because strictures were still indeterminate despite previously performed diagnostics. Fourth, in all our patients, a previous traditional cholangiography was performed before the use of digital SOVC, which might have confounded the rate of cholangitis described in our study. However, this setting was our routine clinical practice. Initially, endoscopists performed traditional cholangiography, which revealed findings making further cholangioscopic assessment instantly necessary.

CONCLUSION

In summary, our data indicate that using digital SOVC in patients with PSC is efficient and safe. In addition to evaluating biliary strictures, which may be substantially improved because of superior image quality, SOVC supports interventions due to selective guidewire placements across biliary strictures and helps diagnose and treat biliary stone disease, explaining why digital SOVC might be frequently used as an additive tool for the complex endoscopic management of PSC patients.

ARTICLE HIGHLIGHTS

Research background

Patients with primary sclerosing cholangitis (PSC) have a high risk of developing cholestatic liver disease, biliary strictures, and biliary cancer, which frequently require endoscopy for diagnostic and therapeutic management.

Research motivation

Recently, digital single-operator video cholangioscopy (SOVC) was introduced, offering superior image quality and manoeuvrability. However, no study thus far has reported the use of newly introduced digital SOVC in PSC patients.

Research objectives

To clarify the efficacy and safety of the recently introduced SOVC for the endoscopic management of patients with PSC.

Research methods

This observational study retrospectively included all patients with a known PSC and in whom digital SOVC (with the SpyGlass DS System) was performed between 2015 and 2019 at a tertiary referral centre. In total, 46 SOVCs performed in 38 patients with PSC were identified. The primary endpoint was the evaluation of dominant biliary strictures using digital SOVC.

Research results

The 22 of 38 patients had a dominant biliary stricture (57.9%), and in 18.2% of these cases, a cholangiocellular carcinoma was diagnosed within the stricture. Diagnostic evaluation of dominant biliary strictures using optical signs showed a sensitivity of 75% and a specificity of 94.4% in detecting malignant strictures, whereas SOVC-guided biopsies to obtain tissue for histopathological analysis showed a sensitivity of 50% and a specificity of 100%. In 13% of examinations, SOVC was helpful for guidewire passage across biliary strictures that could not be passed by conventional methods (technical success rate 100%) and furthermore, in 8 examinations, SOVC helped visualize and treat biliary stone disease (100% success rate). Mild to moderate complications occurred in 13% of examinations.

Research conclusions

Digital SOVC is effective and safe for the complex endoscopic management of PSC patients.

Research perspectives

In the future, digital SOVC might be regularly considered as an additive tool for the endoscopic management of patients with PSC.

Abstract

BACKGROUND

Direct acting antiviral (DAA) therapy has enabled hepatitis C virus infection to become curable, while histological changes remain uncontained. Few valid non-invasive methods can be confirmed for use in surveillance. Gadolinium-ethoxy-benzyl-diethylenetriamine penta-acetic acid (Gd-EOB-DTPA) is a liver-specific magnetic resonance imaging (MRI) contrast, related to liver function in the hepatobiliary phase (HBP). Whether Gd-EOB-DTPA-enhanced MRI can be used in the diagnosis and follow up of hepatic fibrosis in patients with chronic hepatitis C (CHC) has not been investigated.

AIM

To investigate the diagnostic and follow-up values of Gd-EOB-DTPA-enhanced MRI for hepatic histology in patients with CHC.

METHODS

Patients with CHC were invited to undergo Gd-EOB-DTPA-enhanced MRI and liver biopsy before treatment, and those with paired qualified MRI and liver biopsy specimens were included. Transient elastography (TE) and blood tests were also arranged. Patients treated with DAAs who achieved 24-wk sustained

virological response (SVR) underwent Gd-EOB-DTPA-enhanced MRI and liver biopsy again. The signal intensity (SI) of the liver and muscle were measured in the unenhanced phase (UEP) ($SI_{UEP\text{-}liver}$, $SI_{UEP\text{-}muscle}$) and HBP ($SI_{HBP\text{-}liver}$, $SI_{HBP\text{-}muscle}$) *via* MRI. The contrast enhancement index (CEI) was calculated as $[(SI_{HBP\text{-}liver}/SI_{HBP\text{-}muscle})]/[(SI_{UEP\text{-}liver}/SI_{UEP\text{-}muscle})]$. Liver stiffness measurement (LSM) was confirmed with TE. Serologic markers, aspartate aminotransferase-to-platelet ratio index (APRI) and Fibrosis-4 (FIB-4), were also calculated according to blood tests. The grade of inflammation and stage of fibrosis were evaluated with the modified histology activity index (mHAI) and Ishak fibrosis score, respectively. Fibrosis regression was defined as a ≥ 1-point decrease in the Ishak fibrosis score. The correlation between the CEI and liver pathology was evaluated. The diagnostic and follow-up values of the CEI, LSM, and serologic markers were compared.

RESULTS

Thirty-nine patients with CHC were enrolled [average age, 42.3 ± 14.4 years; 20/39 (51.3%) male]. Twenty-one enrolled patients had eligible paired Gd-EOB-DTPA-enhanced MRI and liver tissues after achieving SVR. The mHAI median significantly decreased after SVR [baseline 6.0 (4.5-13.5) *vs* SVR 2.0 (1.5-5.5), $Z = 3.322$, $P = 0.017$], but the median stage of fibrosis did not notably change ($P > 0.05$). Sixty pairs of qualified MRI and liver tissue samples were available for use to analyze the relationship between the CEI and hepatic pathology. The CEI was negatively correlated with the mHAI ($r = -0.56$, $P < 0.001$) and Ishak score ($r = -0.69$, $P < 0.001$). Further stratified analysis showed that the value of the CEI decreased with the progression of the stage of fibrosis rather than with the grade of necroinflammation. For patients with Ishak score ≥ 5, the areas under receiver operating characteristics curve of the CEI, LSM, APRI, and FIB-4 were approximately at baseline, 0.87–0.93, and after achieving SVR, 0.83–0.91. The CEI cut-off value was stable (baseline 1.58 and SVR 1.59), but those of the APRI (from 1.05 to 0.24), FIB-4 (from 1.78 to 1.28), and LSM (from 10.8 kpa to 7.1 kpa) decreased dramatically. The APRI and FIB-4 cannot be used as diagnostic means for SVR in patients with Ishak score ≥ 3 ($P > 0.05$). Seven patients achieved fibrosis regression after achieving SVR. In these patients, the CEI median increased (from 1.71 to 1.83, $Z = -1.981$, $P = 0.048$) and those of the APRI (from 1.71 to 1.83, $Z = -2.878$, $P = 0.004$) and LSM (from 6.6 to 4.8, $Z = -2.366$, $P = 0.018$) decreased. However, in patients without fibrosis regression, the medians of the APRI, FIB-4, and LSM also changed significantly ($P < 0.05$).

CONCLUSION

Gd-EOB-DTPA-enhanced MRI has good diagnostic value for staging fibrosis in patients with CHC. It can be used for fibrotic-change monitoring post SVR in patients with CHC treated with DAAs.

Key Words: Gadolinium-ethoxybenzyl-diethylenetriamine penta-acetic acid-enhanced magnetic resonance imaging; Contrast enhancement index; Hepatitis C virus; Direct acting antiviral; Sustained virological response; Fibrosis regression

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: In this prospective, comparative study, the correlation between the contrast enhancement index (CEI) in the hepatobiliary phase of gadolinium-ethoxybenzyl-diethylenetriamine penta-acetic acid enhanced magnetic resonance imaging and liver pathology measures was analyzed in patients with chronic hepatitis C. It was determined that the CEI has good diagnostic performance and is more useful than serological markers and transient elastography for hepatic-fibrosis monitoring in patients achieving sustained virological response.

INTRODUCTION

Chronic hepatitis C (CHC) remains one of the major etiologies of chronic liver disease, causing

substantial morbidity and mortality globally[1,2]. Remarkably well-tolerated, effective, and short-time direct acting antiviral (DAA) regimens have revolutionized therapy for hepatitis C virus (HCV) infection, achieving a high rate of sustained virological response (SVR). However, it has also been reported that despite achieving SVR, patients may still experience disease progression[3,4]. It is critical to follow up pathological changes in the liver after DAA therapy. A growing number of studies have focused on the use of non-invasive tests to substitute liver biopsy[5-7]. However, there are few validated thresholds for longitudinal assessment that correspond to histologic changes in fibrosis, and there is no definite non-invasive method for diagnosing the stage changes in fibrosis after SVR.

Gadolinium-ethoxybenzyl-diethylenetriamine penta-acetic acid (Gd-EOB-DTPA; Promovist® in Europe and Eovist® in the United States, Bayer Healthcare, Berlin, Germany) is a liver-specific magnetic resonance imaging (MRI) contrast agent[8]. The hepatocyte uptake and biliary excretion of Gd-EOB-DTPA mainly take place *via* organic anion transporting polypeptides OATP1B1/3 on the sinusoidal membrane and multidrug resistance-associated proteins MRP2 on the canalicular membrane. Therefore, after intravenous injection, Gd-EOB-DTPA shows extracellular distribution in the dynamic phase and hepatocyte-specific transportation in the hepatobiliary phase (HBP). Decrease in the number of normal hepatocytes and impaired hepatocyte function may reduce the hepatic enhancement of the HBP[9]. It has been reported using Gd-EOB-DTPA-enhanced MRI to identify hepatocellular carcinoma[10], evaluate liver function[11,12], stage liver fibrosis[13,14], and predict liver failure after hepatectomy[15].

To the best of our knowledge, no studies have used Gd-EOB-DTPA-enhanced MRI to evaluate changes in fibrosis after SVR with paired liver biopsy. The primary aim of our study was to evaluate the diagnostic performance of Gd-EOB-DTPA-enhanced MRI in staging liver fibrosis. The secondary aim was to confirm whether this diagnostic test can be used for longitudinal assessment of liver fibrosis in patients with CHC after achieving SVR treated by DAA regimens.

MATERIALS AND METHODS

Study design

Patients with chronic HCV infection treated with DAAs in our hepatology center between January 2014 and December 2016 were prospectively invited to undergo Gd-EOB-DTPA-enhanced MRI and liver biopsy. Patients with qualified Gd-EOB-DTPA-enhanced MRI data and liver biopsy samples were enrolled. The selection of DAA regimens was based on the genotype and state of liver disease. The patients who achieved SVR after DAA therapy underwent the examinations a second time. Exclusion criterias were: (1) Non-HCV etiology-related chronic liver disease (such as chronic hepatitis B, drug-or alcohol-related liver disease, non-alcoholic steatohepatitis, *etc.*); (2) Clinical hepatic decompensation; (3) Solid organ transplantation; (4) Malignancy; (5) Combined with other systemic disease (immune system disease, blood system disease, *etc.*) and (6) Contraindications for MRI and liver biopsy. SVR was defined as undetectable HCV RNA 24 wk after the end of treatment.

Liver biopsy was performed within 1 mo before treatment and 3 mo after SVR. MRI was performed prior to liver biopsy within 1 mo. MRI with marked motion artifacts and specimens of liver tissue with lengths < 10 mm or < six portal areas under the microscope were regarded as inappropriate[16]. Demographic information, virologic data, and laboratory findings were collected.

MRI protocol

All liver MRI examinations were performed with a Discover 750 3.0 T MR scanner (GE Healthcare, Milwaukee, WI, United States) using a 32-channel torso array coil. Patients were in the supine position during horizontal axis scanning and had received prior training on how to breathe. Gd-EOB-DTPA (Promovist®, Bayer Healthcare) was injected intravenously as a contrast agent at a dose of 0.1 mL/kg body weight with a flow rate of 2 mL/s, followed by a 20-mL 0.09% NaCl flush. Three-dimensional T1-weighted contrast-enhanced MRI was conducted in the unenhanced phase (UEP), arterial phase (AP, 25 s), portal phase (60 s), and HBP (20 min).

Image analysis

The signal intensities (SIs) of the liver parenchyma and paraspinal muscle in the UEP ($SI_{UEP\text{-}liver}$ and $SI_{UEP\text{-}muscle}$) and HBP ($SI_{HBP\text{-}liver}$ and $SI_{HBP\text{-}muscle}$) were independently measured by two professional radiologists with nearly 4 and 6 years of experience in interpreting abdominal MRIs, using regions of interests (ROIs). The radiologists were blinded to the patients' clinical data and pathological changes.

Four ROIs were manually circled (size: 100–150 mm^2) in the posterior and anterior segments of the right hepatic lobe and inner and lateral segments of the left hepatic lobe at the hepatic hilar level. The location of the ROIs had to be at the center of each segment, far from the abdominal wall, and avoiding visible blood vessels, bile ducts, and lesions. The ROI of the paraspinal muscle was mainly circled on the left side.

The contrast enhancement index (CEI) was calculated using the following formula[17]:

$CEI = (SI_{HBP\text{-}liver}/SI_{HBP\text{-}muscle})/(SI_{UEP\text{-}liver}/SI_{UEP\text{-}muscle})$

The change rate in the CEI (Δ CEI%) between pre-treatment (CEI_{pre}) and post-SVR (CEI_{post}) was calculated as ($CEI_{post}/CEI_{pre} \times 100\%$).

Histopathological analysis

Specimens were fixed in formalin immediately after liver biopsy and embedded in paraffin; 4-μm-thick sections were cut and stained with hematoxylin and eosin and Masson's trichrome. Two professional hepato-pathologists, both with nearly 30 years of working experience, assessed the degree and stage of necroinflammation and fibrosis of the specimens using the Ishak scoring system [modified histological activity index (mHAI) and Ishak score][18]. The pathologists were blinded to the imaging results and patient clinical data. The stages of liver fibrosis were divided into three groups according to the Ishak score, 0-2, 3-4, and 5-6, respectively. Necro-inflammatory severity was graded according to the mHAI score as 0-4, 5-8, 9-12, and 13-18[19]. Fibrosis regression was defined as a decrease of at least one point in the Ishak score after SVR[20].

Non-invasive fibrosis measurements

Experienced technicians conducted liver stiffness measurements (LSMs) with FibroScan (Echosens, Paris, France). An effective result should have a successful rate > 60% and interquartile range/median ratio ≤ 30%.

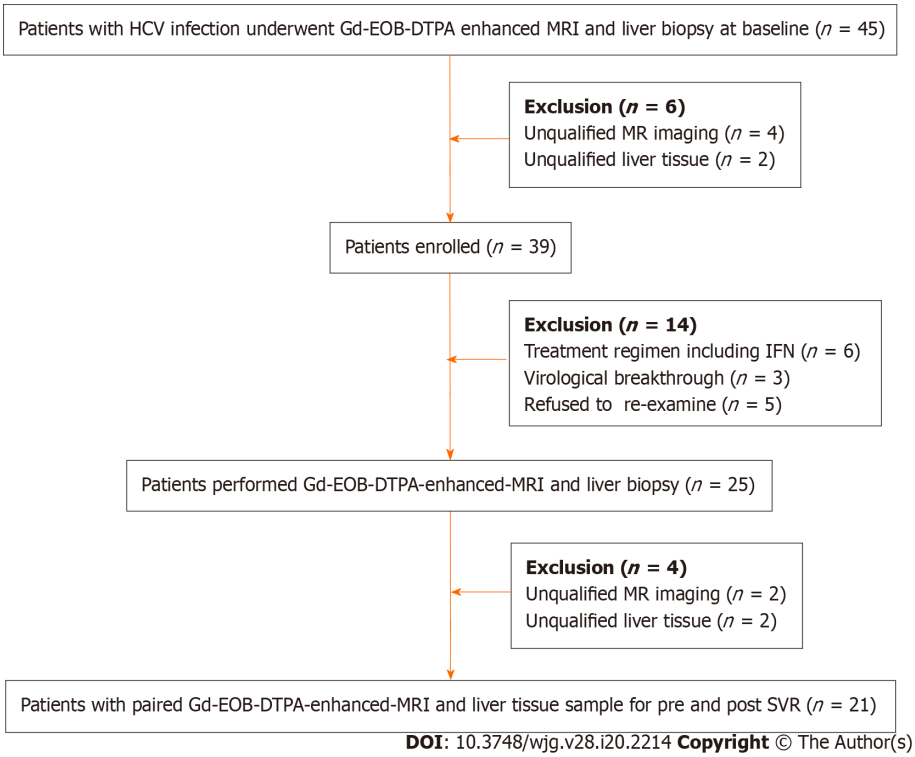
With respect to serologic biomarkers of fibrosis, the aspartate aminotransferase (AST)-to-platelet ratio (APRI) and Fibrosis-4 (FIB-4) were calculated as following:

APRI = [(AST/ULN)/platelet count ($\times 10^9$/L)] × 100[21]; FIB-4 = (age × AST)/[(platelet count) ($\times 10^9$/L) × ALT1/2][22]

The change rates in APRI, FIB-4, and LSM between pre-SVR ($value_{pre}$) and post-SVR ($value_{post}$) were calculated similarly with the CEI calculation.

Statistical analyses

Descriptive analyses were performed for sociodemographic characteristics (age, sex), clinical data [alanine aminotransferase (ALT), AST, total bilirubin (TB), albumin (Alb), platelet (PLT) count, HCV RNA, genotype, FIB-4, APRI, LSM, and CEI], histological grading, and staging.



Descriptive analyses were performed for sociodemographic characteristics, clinical data, histological characteristics, and the CEI. The value of HCV RNA was logarithmically transformed with 10 as the base. Continuous variables are expressed as median (interquartile range) (ALT, AST, TB, PLT, APRI, FIB-4, and LSM) or mean ± SD [age, Alb, international normalized ratio (INR), HCV RNA, mHAI, and CEI]. Categorical variables (sex, numbers of patients in the different mHAI and Ishak score groups) are presented as counts and percentages. The absolute values of the interclass correlation coefficients (ICC) were measured for SIs to confirm the interobserver reliability between reviewers. Student's t-test (age, Alb, INR, HCV RNA, mHAI, and CEI) and Mann-Whitney U test (ALT, AST, TB, and PLT) were used to compare continuous variables, and the chi-square test was used for classified variables (sex, HCV genotype). The comparison between pre-and post-SVR was performed with the Wilcoxon sign rank test (ALT, AST, TB, PLT, FIB-4, APRI, and LSM) and paired sample t-test (Alb, INR, and CEI). Spearman's correlation coefficient was calculated for the CEI, mHAI, and Ishak score. The predictive value of the CEI, APRI, FIB-4, and LSM for liver fibrosis was assessed using the area under the receiver operating characteristic curve (AUROC). Sensitivity, specificity, positive predictive value, and negative predictive value were also calculated. An optimal cut-off value was chosen to maximize the Youden index, which is defined as (sensitivity + specificity-1). P values < 0.05 were considered statistically significant. Statistical analyses were performed using IBM SPSS version 26.0 (IBM Corp., Armonk, NY, United States).

RESULTS

Forty-five patients underwent Gd-EOB-DTPA-enhanced MRI and liver biopsy at baseline and six with unqualified samples were excluded. Among the enrolled patients (n = 39), six were recommended to receive treatment with DAA plus Peg-IFN, and three had virological breakthrough. Twenty-five patients underwent MRI and liver biopsy again after achieving SVR, and 21 pairs of data were eligible. Therefore, there were 60 qualified and pairable MRI images and liver tissue samples available for analyzing correlation between CEI and liver pathology. The study flow chart is shown in Figure 1.

Intraclass correlation coefficients

Two radiologists interpreted the Gd-EOB-DTPA-enhanced MRI images. The ICC for the measured SI values were excellent (greater than 0.9) for before and after achieving SVR. The ICC of the CEI was 0.729 (0.481, 0.858) and 0.886 (0.744, 0.952) pre and post SVR, respectively. Details of the inter-observer agreements of the ROI measurements and CEI are presented in Supplementary Table 1.

Patient characteristics

The 39 patients enrolled had a mean age of (42.3 ± 14.4) years, mean HCV RNA of (6.4 ± 0.7) $\log_{10}$ IU/mL, and 20 (51.3%) were male. The distribution of HCV genotypes (GT) was 1, 2, 3, and 6 in 19 (48.7%), 4 (10.3%), 13 (33.3%), and 3 (7.7%) patients, respectively. Patients with Ishak score of 5-6 were elder, had higher ALT and lower PLT levels than those with Ishak scores of 0–2 ($P < 0.05$) (Table 1).

Of the 21 patients who achieved SVR and had paired MRI and liver tissue samples, 13 (62%) received sofosbuvir/ribavirin therapy, and the other eight (38%) received daclatasvir/asunaprevir regimens. As expected, the values of ALT, AST ($P < 0.001$), and necroinflammation grade ($P = 0.023$) significantly decreased post SVR (Table 2). No significant change in fibrosis stage was observed. Among the noninvasive measurements, the median of LSM, FIB-4, and APRI decreased significantly, the mean of the CEI increased slightly without statistically significant ($P = 0.29$) (Table 2). After achieving SVR, 7 (33%) patients achieved fibrosis regression. No patient with Ishak 5-6 ($n = 7$) achieved fibrosis regression.

The CEI decreased with the progression of liver fibrosis

In patients with CHC, the CEI was negatively correlated with the grade of inflammation ($r = -0.56$, $P < 0.001$) and stage of fibrosis ($r = -0.69$, $P < 0.001$). The CEI decreased significantly among patients with Ishak scores 0–2, 3–4, and 5–6 (1.78 ± 0.11, 1.64 ± 0.11, and 1.50 ± 0.09, respectively, $P < 0.001$) (Figure 2A). To further analyze the relationship between the CEI and liver pathology, we stratified the patients according to the mHAI (0–4, 5–8, 9–12, and 13–18) and Ishak score (0–2, 3–4, and 5–6; the numbers of patients in each subgroup are shown in Table 3).

In patients with a mHAI of 0–4, the CEI in Group 2 ($n = 11$) was significantly lower than that in Group 1 ($n = 14$) [(1.67 ± 0.11) *vs* (1.79 ± 0.11), $P = 0.021$] and the CEI of the only patient in Group 3 was 1.52 (Figure 2B). When the mHAI was 5–8, the CEI decreased in the order of fibrosis Group 1 ($n = 3$), 2 ($n = 13$), and 3 ($n = 9$) at 1.75 ± 0.06, 1.62 ± 0.11, and 1.49 ± 0.12, respectively ($P = 0.032$) (Figure 2C). All patients with an mHAI of 13–18 had liver cirrhosis ($n = 9$), and they were not grouped. In contrast, after subgrouping the patients based on the fibrosis grade, there were no significant differences in the CEI among the inflammation groups (all $P > 0.05$) (Figure 2D–F). Therefore, we believe that decrease in the CEI is mainly associated with the progression of fibrosis.

The CEI is more useful for liver fibrosis diagnosis than the LSM, APRI, and FIB-4

Table 4 shows a comparison of the predictive values between the CEI and other non-invasive methods. According to the AUROCs and cut-off values, we found that the diagnostic efficacy of the CEI, LSM, APRI, and FIB-4 before and after DAA treatment was similar for liver cirrhosis (Ishak score ≥ 5), while

the cut-off values of serological markers such as the APRI and FIB-4 significantly decreased post SVR. The cut-off value of the LSM also showed a similar trend. For significant fibrosis (Ishak score ≥ 3), post SVR, the diagnostic efficacy of the LSM decreased, and the APRI and FIB-4 showed no diagnostic value.

[1]The cutoff values of aspartate aminotransferase-to-platelet ratio index (APRI) and Fibrosis-4 (FIB-4) or the diagnosis of liver cirrhosis decreased dramatically after sustained virological response (SVR).
[2]N: No diagnosis value of APRI or FIB-4 in patients with significant fibrosis after achieving SVR.
APRI: Aspartate aminotransferase-to-platelet ratio index; AUROC: Area under receiver operating curve; CEI: Contrast enhancement index; CI: Confidence interval; FIB-4: Fibrosis-4; LSM: Liver stiffness measurement; SVR: Sustained virological response.

Only dynamic change in the CEI can be used to evaluate fibrosis regression after achieving SVR

Figure 3 shows the change of the CEI and other non-invasive methods in patients with (red column) and without (black column) fibrosis regression. Among the patients with fibrosis regression (n = 7), the CEI increased significantly (from 1.68 ± 0.09 to 1.83 ± 0.18, P = 0.043) after DAA treatment; similarly, the LSM [from 6.6 (2.6) to 4.8 (1.2), P = 0.018] and APRI [from 0.37 (0.22) to 0.20 (0.08), P = 0.018] values decreased significantly. For patients who did not achieve fibrosis regression (n = 14), only the CEI remained stable (P > 0.05), while the LSM, APRI, and FIB-4 decreased significantly (P < 0.05). It is suggested that the decrease in the latter three noninvasive measurements after treatment may not be related to fibrosis regression. By comparing the change ratios of the four noninvasive indexes before and after treatment, only CEI% changed significantly, and CEI% was moderately positively correlated with

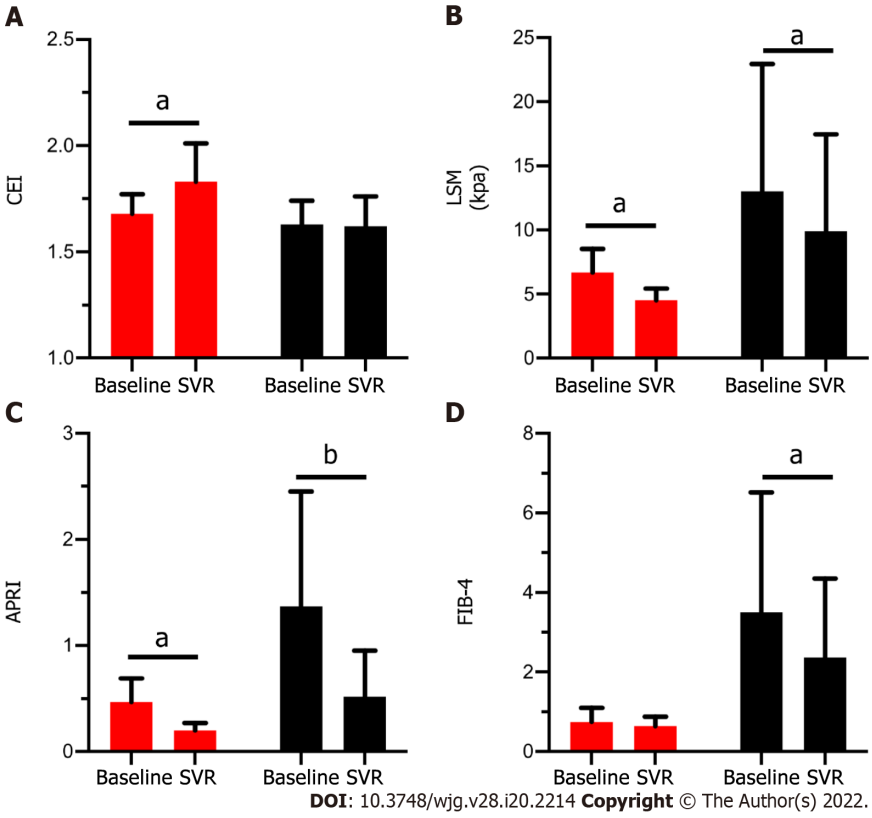
fibrosis regression ($r = 0.50$, $P = 0.021$) (Table 5).

DISCUSSION

In this study, paired liver biopsy and Gd-EOB-DTPA-enhanced MRI data of patients with CHC before and after SVR were reported for the first time. This study concluded that the CEI of Gd-EOB-DTPA-enhanced MRI in the HBP decreased with the progression of liver fibrosis. For patients with CHC, the CEI can be used to distinguish among the different stages of liver fibrosis at baseline and after achieving SVR more effectively than the APRI, FIB-4, and LSM. The change in the CEI between pre and post SVR was related to fibrosis regression. This result increased the options for dynamic assessment of liver fibrosis after achieving SVR.



In our study, patients treated with DAA plus interferon were excluded. Although the combination therapy may have no effect on the evaluation of liver pathology, based on the current situation of CHC treatment, majority of patients can be cured by simple DAAs. So, we pay more attention on correlation between CEI and pathology changes in patients cured by simple DAAs. It is worth mentioning that, HCV RNA was both detected at 12- and 24-wk after the end of treatment. The value of HCV RNA at 12-wk were also undetectable in patients achieving SVR24. Since patients were enrolled between 2014-2016, SVR12 and SVR24 both could be used at that time, while the 24-wk SVR last longer, it was used in our article. We specially agree that the current definition of SVR as an undetectable HCV RNA at 12 wk after the end of treatment.

In the correlation analysis, we found that the CEI was mild negative related to both grade of inflammation and stage of fibrosis. Further hierarchical analysis showed that the CEI mainly decreased with the progression of liver fibrosis, which was consistent with the results of a previous multiple regression analysis[23]. As mentioned above, after achieving SVR, the overall liver fibrosis status was not notably improved, and the CEI also did not change significantly. Therefore, we combined 60 pairs of CEI and liver pathology data before and after treatment for analysis. It should be mentioned that the overall mHAI decreased after treatment, which may have affected the results. However, in our pre-analysis, we

Table 5 Relationship between the changes of contrast enhancement index, aminotransferase-to-platelet ratio index, Fibrosis-4, liver stiffness measurement and fibrosis regression

	Fibrosis regression		*P* value
	Yes (*n* = 7)	No (*n* = 14)

Figure 3 Comparison of four noninvasive methods before and after sustained virological response between patients with fibrosis regression or not. A: Value of contrast enhancement index; B: Value of liver stiffness measurement; C: Value of aspartate aminotransferase-to-platelet ratio index; D: Value or Fibrosis-4 in patients with (Red column) and without (Black column) fibrosis regression at baseline and after achieving sustained virological response (SVR). Red column: Patients had fibrosis regression after achieving SVR (*n* = 7). Black column: Patients didn't have fibrosis regression after achieving SVR (*n* = 14). $^{a}P < 0.05$; $^{b}P < 0.001$. CEI: Contrast enhancement index; SVR: Sustained virological response; LSM: Liver stiffness measurement; APRI: Aspartate aminotransferase-to-platelet ratio index; FIB-4: Fibrosis-4.

found that in the 21 paired MRI and liver biopsy samples after treatment, the correlation between the mHAI and Ishak score ($r = 0.74$, $P < 0.001$) remained significant. This may be because the patients with a mHAI > 13 at baseline had liver cirrhosis. After achieving SVR, there was no significant improvement in fibrosis or in the inflammation status. It was also shown that the correlation between the CEI and fibrosis stage remained relatively stable and was not related to the treatment state.

In patients with liver cirrhosis (Ishak score 5-6), the diagnostic values of the CEI and of the other non-invasive methods were similar, which was also partly previously reported by a cross-sectional comparative analysis[23]. As the inflammatory status improved with antiviral treatment, the cut-off values of the APRI (from 1.05 to 0.24) and FIB-4 (from 1.78 to 1.28) both substantially decreased for the same fibrosis status. The serological biomarkers had no diagnostic value for significant fibrosis after HCV eradication, mainly because with the rapid regression of liver necroinflammation, the ALT and

AST levels returned to normal, reducing the diagnostic accuracy of serological biomarkers. Although accessible and common, the APRI and FIB-4 may not be suitable for the surveillance of patients with CHC post SVR[21,24].

Other than the serological biomarkers, the LSM obtained with TE is currently considered useful for fibrosis monitoring[25-27]. However, several studies have reported a rapid decrease in the LSM mainly related to inflammation regression, and its cut-off values are influenced by liver morphometry. Hence, the decrease in the LSM may be misinterpreted as change in the liver fibrosis stage[6,28]. A longitudinal study of 2 years showed that following SVR attainment, the improvements in the LSM were overstated compared to histologic staging[28]. Therefore, the follow-up value of liver fibrosis regression in patients with HCV SVR needs to be further verified. Our findings strengthened this notion in a relative short follow-up time (median of 6.2 mo). The cut-off value of the LSM decreased slightly in patients with liver cirrhosis (from 10.8 kPa to 7.1 kPa), wherein an LSM value of 7.1 kPa obtained with TE was defined as the threshold for absence of or minimal fibrosis in patients with CHC[29]. The comparative analysis also showed significant decrease in the LSM value in patients without fibrosis regression.

Apart from the CEI, several studies have reported multiple hepatobiliary liver enhancement indexes of Gd-EOB-DTPA-enhanced MRI, including RE (calculated as $[SI_{HBP}-SI_{UEP}]/SI_{UEP}$ of the liver parenchyma), liver-to-portal vein contrast ratio (calculated by dividing the liver parenchyma SI by the portal vein SI on HBP images), and liver-to-spleen contrast ratio (calculated by dividing the liver parenchyma SI by the spleen SI on HBP images)[30-32]. In previous reports, the signals of the portal vein and spleen were integrated with plasma or extracellular extravascular space exposure to the contrast agent, thus showing that the liver-to-portal vein contrast ratio and liver-to-spleen contrast ratio were more strongly related to liver function than to liver fibrosis[12,33]. Adjustment of the signal of the paraspinal muscle for SI_{liver} on the same slice was performed to normalize the shimming influences and correct for technical bias. Compared with other organs, SI_{muscle} was more stable and less influenced by age and liver function. Jang *et al*[23] also validated this view. A few articles have shown similar diagnostic accuracies for RE and the CEI. In our study, RE was mildly negatively associated with liver inflammation (r = -0.57, P = 0.007) and fibrosis (r = -0.44, P = 0.043) (unreported), possibly because the SI of the liver after injecting Gd-EOB-DTPA changes, as the window level and width differ in the images [34].

There were several limitations in our study. First, limited by the inclusion criteria, the sample size was small, and the CEI% of patients with fibrosis regression was close to 1. We will explore further by expanding the sample size. Second, we did not use MR elastography (MRE) or T1-mapping to predict liver fibrosis, which have a superior diagnostic value in predicting liver fibrosis than Gd-EOB-DTPA-enhanced MRI[35,36]. However, except for the influence of body mass index and ascites on TE, the sequencing method in MRE is not unified, and the threshold value changes across different methods [26]. In recent years, MR relaxometry in the form of T1 mapping has been considered promising as a non-invasive method for characterizing hepatic fibrosis using the look-locker technique for measurement. Our patients were enrolled between 2014 and 2016, when T1 mapping was not in use. Third, although histology is a gold standard procedure, the tissues used in our study were all from liver biopsies rather than from hepatectomy, and there may have been misjudgment regarding the histological changes. Fourth, the mean follow-up duration after achieving SVR was only 6.2 mo, and a longer follow-up period is warranted.

CONCLUSION

In conclusion, the CEI of Gd-EOB-DTPA-enhanced MRI can be used to diagnose liver fibrosis in patients with CHC. The change of the CEI can be used to monitor fibrosis regression post SVR by DAA therapy.

ARTICLE HIGHLIGHTS

Research background

The histological change and non-invasive method surveillance after hepatitis C virus (HCV) eradication by direct acting antiviral (DAA) therapy have not been elucidated. As using a liver-specific magnetic resonance imaging (MRI) contrast, whether Gadolinium-ethoxybenzyl-diethylenetriamine penta-acetic acid (Gd-EOB-DTPA) enhanced MRI can be used to diagnose and follow-up the liver fibrosis in patients with chronic hepatitis C (CHC) has not been investigated.

Research motivation

The key issues are whether Gd-EOB-DTPA enhanced MRI can be used in diagnosing and following-up in patients with CHC. The result will provide important information on non-invasive method selection for dynamic assessment of liver fibrosis in patients with CHC and histology change after achieving SVR treated by DAAs.

Research objectives

To investigated the diagnostic and follow-up values of Gd-EOB-DTPA-enhanced MRI for hepatic histology in patients with CHC. We further explore the value of Gd-EOB-DTPA enhanced MRI in evaluating fibrosis regression in patients with CHC after achieving sustained virological response (SVR) treated by DAAs.

Research methods

Chronic HCV infected patients with paired liver biopsy and Gd-EOB-DTPA enhanced MRI before and after DAA treated was included. Contrast enhancement index (CEI) was calculated according with signal intensity *via* MRI, and the correlation between CEI and histology change was evaluated. Fibrosis regression was defined as a ≥ 1-point decrease in the Ishak fibrosis score. The diagnostic and follow-up values of the CEI, liver stiffness measurements (LSM), aminotransferase (AST)-to-platelet ratio (APRI) and Fibrosis-4 (FIB-4) were compared.

Research results

Thirty-nine patients with CHC were enrolled, with average age of 42.3 ± 14.4 years and 20/39 (51.3%) were male. Twenty-one enrolled patients had eligible paired Gd-EOB-DTPA-enhanced MRI and liver tissues after achieving SVR. According to correlation and the hierarchical analysis, the CEI mainly decreased with the progression of liver fibrosis. Compared with LSM, APRI and FIB-4, the CEI is more useful for liver fibrosis diagnosis, the correlation between the CEI and fibrosis stage was relatively stable and was not related to the treatment state. In paired analysis using liver pathology and CEI before and after treatment, only the dynamic change in the CEI can be used to evaluate fibrosis regression after achieving SVR.

Research conclusions

The CEI of Gd-EOB-DTPA-enhanced MRI can be used as a non-invasive method to diagnose liver fibrosis in patients with CHC. The dynamic change of the CEI can be used to monitor fibrosis regression post SVR in patients with CHC after DAA therapy.

Research perspectives

Larger and longer-term prospective studies in patients with CHC should be performed in future studies.

ACKNOWLEDGEMENTS

We are sincerely grateful to the radiologists Dr. Xiao-Xuan Jia and Dr. Xin-Yu Zhang for their involvement in the MRI analysis. We also thank Prof. Aileen Wee and Guang-De Zhou for their involvement in the liver pathology confirmation. We also thank Hui-Xin Liu, MD, for help with the statistical review.

Abstract

BACKGROUND

While capsule endoscopy (CE) is the gold standard diagnostic method of detecting small bowel (SB) diseases and disorders, a novel magnetically controlled capsule endoscopy (MCCE) system provides non-invasive evaluation of the gastric mucosal surface, which can be performed without sedation or discomfort. During standard SBCE, passive movement of the CE may cause areas of the complex anatomy of the gastric mucosa to remain unexplored, whereas the precision of MCCE capsule movements inside the stomach promises better visualization of the entire mucosa.

AIM

To evaluate the Ankon MCCE system's feasibility, safety, and diagnostic yield in patients with gastric or SB disorders.

METHODS

Of outpatients who were referred for SBCE, 284 (male/female: 149/135) were prospectively enrolled and evaluated by MCCE. The stomach was examined in the supine, left, and right lateral decubitus positions without sedation. Next, all patients underwent a complete SBCE study protocol. The gastric mucosa was explored with the Ankon MCCE system with active magnetic control of the capsule endoscope in the stomach, applying three standardized pre-programmed computerized algorithms in combination with manual control of the magnetic movements.

RESULTS

The urea breath test revealed *Helicobacter pylori* positivity in 32.7% of patients. The mean gastric and SB transit times with MCCE were 0 h 47 min 40 s and 3 h 46 min 22 s, respectively. The average total time of upper gastrointestinal MCCE examination was 5 h 48 min 35 s. Active magnetic movement of the Ankon capsule through the pylorus was successful in 41.9% of patients. Overall diagnostic yield for detecting abnormalities in the stomach and SB was 81.9% (68.6% minor; 13.3% major pathologies); 25.8% of abnormalities were in the SB; 74.2% were in the stomach. The diagnostic yield for stomach/SB was 55.9%/12.7% for minor and 4.9%/8.4% for major pathologies.

CONCLUSION

MCCE is a feasible, safe diagnostic method for evaluating gastric mucosal lesions and is a promising non-invasive screening tool to decrease morbidity and mortality in upper gastrointestinal diseases.

Key Words: Bowel diseases; Capsule endoscopy; Diagnostic techniques; Gastrointestinal diseases; Gastric mucosa; *Helicobacter pylori*

Core Tip: We evaluate the feasibility, safety, and diagnostic yield of magnetically controlled capsule endoscopy (CE) system developed by Ankon and AnX robotics that provides non-invasive evaluation of the gastric mucosal surface, which can be performed without sedation or patient discomfort. During gold-standard small bowel CE, passive movement may cause areas of the complex gastric mucosa to remain unexplored, whereas the precision of magnetically controlled capsule endoscopy (MCCE) capsule movements inside the gastrointestinal tract achieves better visualization of the entire mucosa, including the stomach. The Ankon MCCE system is a promising, non-invasive screening tool that achieved ~90% diagnostic yield of mucosal abnormalities in this study.

INTRODUCTION

Capsule endoscopy (CE) is a non-invasive, painless, patient-friendly, and safe diagnostic method. It is currently the gold standard examination for small bowel (SB) diseases, including inflammatory bowel disease, suspected polyposis syndromes, unexplained abdominal pain, celiac disease, and obscure gastrointestinal bleeding (OGIB). Small bowel capsule endoscopy (SBCE) provides excellent diagnostic yield, which has been proven in many clinical trials since its introduction in the late 1990s. Currently, it has a fundamental role in gastrointestinal (GI) endoscopy, especially in patients with suspected SB diseases[1]. Attempts to expand the diagnostic role of CE to areas that are traditionally explored with standard endoscopic procedures (gastroscopy and colonoscopy), *e.g.*, the esophagus, stomach, and colon. These aims have been challenged by significant drawbacks in the past due to a lack of optimal preparation, standardized procedural design, and ability to visualize the entire mucosal surface[2]. A common perception is that the anatomical structures of the stomach and colon are too complex for adequate visualization with a passive capsule endoscope[3-5].

Although the SB seems to be a simple pipe, the more complex gastric anatomy with passive movements may cause unexplored areas of the gastric mucosa when utilizing standard CE. Magnetically controlled capsule endoscopy (MCCE) systems were developed over the past ten years to precisely control capsule movements inside the GI tract and to achieve better visualization of the entire mucosa, especially in the stomach. Different approaches have been developed and studied over time, which have enabled manual steering or active movement of the capsule systems. The external magnetic field seems to be the most adequate and energetically effective method for steering and holding the capsule within the stomach[6,7].

According to recent, prospective studies that were mainly conducted in China, a methodology developed by Ankon and AnX robotics could be an optimal method for non-invasive screening and

early diagnosis of gastric diseases such as gastric cancer and intramucosal high-grade dysplasia. It has the potential to become a valuable and accepted screening method in a population with high gastric cancer risk[8].

The aim of this study was to evaluate the feasibility, safety, and diagnostic yield of the Ankon MCCE system in patients with gastric and SB disorders who were referred to our endoscopy unit for SBCE examination between September 2017 and December 2020. Our secondary aim was to evaluate the overall gastric examinations, SB transit times (TTs) and efficacy of MCCE to achieve complete gastric and SBCE investigation by utilizing the same upper GI capsule.

MATERIALS AND METHODS

Study design

Our present study prospectively enrolled outpatients who were seen at the Endo-Kapszula Endoscopy Unit, Székesfehérvár, Hungary, between September 2017 and December 2020. A combined investigation of the stomach and SB of patients referred to for SBCE was performed with a robotically MCCE system (NaviCam, Ankon Technologies Co, Ltd, Shanghai, China).

The primary endpoint of the recent study was to investigate the diagnostic yield of MCCE in the evaluation of gastric and SB abnormalities. The secondary endpoints were to evaluate the feasibility of performing complete gastric and SB investigation by utilizing the same diagnostic procedure; to address safety parameters, including adverse and severe adverse events, and to calculate the capsule TTs, such as esophageal, gastric, and SB TTs, and the overall procedure time.

Patients

All patients who were referred to our endoscopy unit for SBCE and who agreed to our gastric study protocol were included in the current study. During the study period, we enrolled 284 consecutive, eligible patients, of which there were 149 males (52.5%) and 135 females (47.5 %), with a mean age of 44 years. Detailed patient characteristics are shown in Table 1. The indications of MCCE were iron deficiency anemia, OGIB, suspected/established SB Crohn's disease, suspected/confirmed celiac disease, suspected SB neoplastic disease, carcinoid syndrome, and SB polyposis syndromes.

This study was approved by the Ethical Committee of the University of Szeged (Registry No. 5/17.04.26) and registered in the ClinicalTrials.gov trial registry (Identifier: NCT03234725). The present study was conducted according to the World Medical Association's Declaration of Helsinki provisions in 1995. Patients agreed to undergo capsule endoscopies and *Helicobacter pylori* (*H. pylori*) urea breath tests (UBTs) by written informed consent.

Patient preparation for MCCE

According to the SBCE guidelines, we applied the following patient preparation and study protocol: Patients followed a liquid diet and consumed 2 L of water with two sacks of polyethylene glycol (PEG) the day before the study. First, *H. pylori* C^{13} UBT was performed on the morning of the study, while the patient was in a fasting condition. The UBT requires an average of 30 min, during which time the patient should not consume any fluids or food. During that visit, the patient's medical history was recorded, and a physical examination was performed. After the UBT, the patient ingested 2 dL water with simethicone suspension (80 mg) to reduce mucus in the stomach. Then, to distend the stomach properly, approximately 8-10 dL of clean water consumed by all patients within 10 min. Water ingestion may be repeated as needed to enhance gastric distension during examination. After complete visualization of the total gastric mucosal surface, active pyloric propulsion of the capsule was attempted in all patients with the external magnetic field. If it was unsuccessful, 10 mg intravenous metoclopramide was applied 60 min after the capsule was swallowed.

Contraindications of MCCE were the same as of those of SBCE and magnetic resonance imaging (MRI) examination. In our study, absolute contraindications were the patients with previous abdominal surgery and/or a previous capsule retention; with implanted MRI-incompatible electronic devices (*e.g.*, implantable cardioverter-defibrillator and pacemakers), or magnetic, metal foreign bodies; and who were not competent or refused the informed consent form; who were under age 18 or above age 70; and those who were pregnant. A patency capsule test was initially performed in all patients to determine those with relative contraindications, including known or suspected GI obstruction due to SB Crohn's disease, neoplasia, or SB surgery.

Technical methods of MCCE

Our system involves a special static magnet with robotic and manual guidance, computer workstation with ESNavi software (Ankon Technologies Co, Ltd) (Figure 1), magnetic capsule endoscope, capsule locator, and data recorder. The capsule endoscope sizes 26.8 × 11.6 mm, weighs 4.8 g, and has a permanent spherical magnet inside (Figure 2). The operator can adjust the frequency of captured pictures from 0.5 to 6 frames per second (fps). Capsule functioning can be stopped temporarily and

Figure 1 Robotic C-arm, investigation table, and computer workstation for magnetically controlled capsule endoscopy.

restarted by the operator remotely from the workstation. The picture resolution is 480 × 480 pixels, and the field of view is 140°. The illumination can be automatically adjusted by an automatic picture focusing mechanism, which enables the view depth to shift from 0 mm to 60 mm. Depending on the fps, the battery life can be over 10 h, which allows combined gastric and SB capsule investigations with the same capsule.

The magnetic robotic C-arm generates an adjustable magnetic field outside of the body with a maximum strength of 0.2 T, which allows precise controlled movements in three spatial directions. During the process, the physician guides the magnetic capsule by two joysticks in any chosen, spatial direction or along its axis, and therefore, he can rotate or tilt it. Moreover, the capsule can advance forward 360° by a rotational automatism in the direction of the capsule visual axis, which is helpful for transposition of the capsule from the long axis of the stomach.

The capsule locator is a unique device that activates the capsule by infrared light prior to the patient swallowing it. The presence of the capsule can be detected in the case of suspected capsule retention (Figure 3).

The system is capable of real-time digital transmission of images to the operating system. At the same time, it is continuously obtaining information about the gyroscope, which is built into the capsule

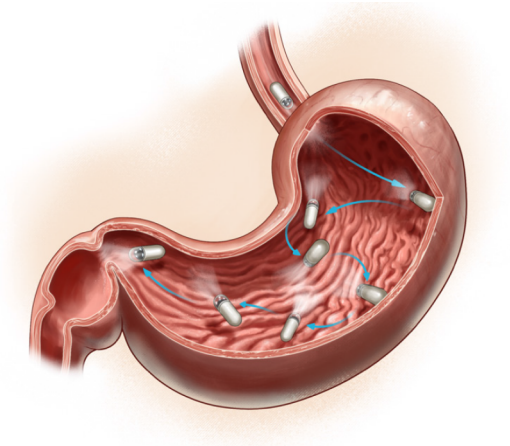
Figure 3 Capsule locator device.

[three-dimensional (3D) motion detector]. It also receives data from the actual spatial location of the camera and localizes the capsule inside the body at any time. The data recorder (Figure 4) may receive all motion information and high-quality pictures *via* wireless transmission from the capsule endoscope. In contrast, the connection between the data recorder and the workstation *via* a USB wire makes visible the real-time pictures and gyroscope information.

Magnetic CE can be transferred along five different axes with the controlling magnet: two rotational and three 3D spaces. To achieve this, there are two joysticks on the workstation desktop: the left one controls the capsule in two rotational axes (horizontal and vertical directions) and the right joystick directs it in the three translational axes (forward/backwards, up/down, left/right). Precise magnetic control is achieved by positioning the examining table, modifying the position of the spherical magnet axis along the 3D space, and dynamically adjusting the strength and direction of the vectorial magnetic fields perpendicular to each other. The above-mentioned robotic systems can also automatically run the magnetic field vector and position it by robotically controlled computer-based software (scripts) in default mode, which can achieve a standardized mucosal scanning during the MCCE procedure without the direct intervention of a physician.



MCCE study protocol and gastric stations

To achieve optimal gastric mucosal visualization and standardization of the MCCE protocol in the stomach, we defined eight different stations with different patient positions to visualize the entire inner gastric surface as during upper GI endoscopy. Changing the patient position from the left lateral decubitus to the supine and right lateral position is necessary to combine gravity and magnetic force, which improve capsule maneuvering (Figure 5). The capsule swallowed by the patients in the left lateral decubitus position (Figure 6).

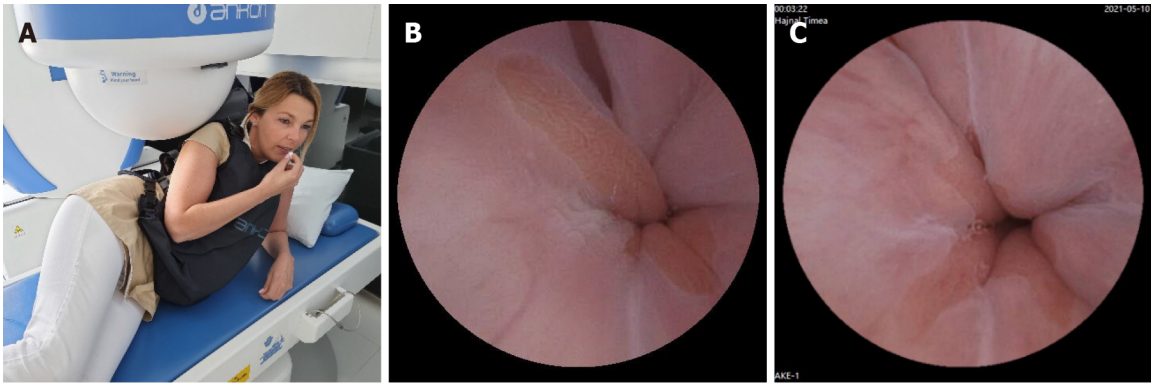
Figure 5 Different magnetically controlled capsule endoscopy stations and capsule camera orientations defined to achieve a complete gastric mucosal surface visualization and mapping (created by Zoltán Tóbiás, MD).

Stations at the left lateral decubitus position: Station I. Visualization of the gastric fundus and subcardial region with the cardia (posterior J type retroflexion).

After entering the stomach, the capsule was lowered into the large curvature at the body of the stomach. The magnetic ball was held high up at the level of the patient's right shoulder. The capsule camera was maintained in an obliquely upward orientation of 45° and then horizontally rotated to observe the gastric fundus and the cardia (Figure 7A-C).

Station II. Moving closer to the cardia and the fundus (anterior J type retroflexion).



While using the right joystick, the ball magnet was lowered and fitted closely to the patient's right arm. Due to the proximity of the magnetic field, the capsule rose to the anterior wall and small curvature of the stomach. The capsule was then rotated with the camera oriented vertically upward to observe the cardia up close, with the fundus at a distance (Figure 7D-F).

Station III. Visualization of the gastric body from the fundus.

With the ball magnet in the same position, using the left joystick, the capsule camera was rotated and tilted downwards, enabling visualization of the proximal body of the stomach (corpus) and the gastric folds at the large curvature with a longitudinal view (Figure 7G-I).

Stations in the supine position: Station IV. Visualization of the angular incisure.

Patients were asked to lie on their back, in a supine position. The capsule was moved and located to the distal body into the angular region due to a change of gravity and stepwise magnetic movements. The magnetic ball was moved to the left upper abdomen (hypochondrium) and then lowered, close to the patient abdomen. In this case, the capsule was raised to the anterior wall of the stomach; therefore, the small curvature and the angular incisure were examined as well (Figure 8A-C).

DOI: 10.3748/wjg.v28.i20.2227 **Copyright** © The Author(s) 2022.

Figure 6 The capsule swallowed by the patients in the left lateral decubitus position. A: Patients and ball magnet position; B and C: Pictures of the Z-line by CE from our database.

Station V. Visualization of the larger curvature of the distal body from the angular incisure (U type of retroversion).

The magnetic ball was moved to the epigastric area, close to the abdomen. Then the capsule camera was oriented upward to observe the anterior wall of the gastric body. In this position, the capsule can be turned and rotated (*e.g.*, towards the cardia), enabling visualization of the distal body of the stomach longitudinally, as in the endoscopic view of U-type retroversion (Figure 8D-F).

Stations at the right lateral decubitus patient position: Station VI. Visualization of the antral canal.

In the next phase, patients were asked to turn to the right lateral decubitus position. Due to the gravity force, the capsule sank and moved spontaneously into the antral region. Then, the ball magnet was positioned over the left kidney. The capsule was brought closer to the large curvature with the camera oriented obliquely downward at 45°, which enabled observation of the antrum. Then, the antral canal could be examined with the pylorus, and the angular incisure became visible from the antrum (Figure 9A-C).

Stations in the supine position: Station VII. Prepyloric view and visualization of the pylorus.

After that, each patients were asked to lie on his or her back in the supine position. The ball magnet was positioned close to the body on the right upper abdomen (hypochondrium). The capsule camera was oriented horizontally and laterally toward the pylorus for closer observation. The magnet position ensured that the capsule remained in the antrum. Using both the right and left joysticks, we moved the capsule closer to the pylorus (Figure 10A-C).

Station VIII: Magnetically controlled transpyloric passage of the capsule.

The magnetic ball was placed at the patient's right side at the level of the duodenal bulb. The capsule was then rotated until the camera faced the pylorus. The capsule was dragged close to the pylorus under the guidance of the magnet robot. As the pylorus was opened, peristalsis assisted the capsule into the duodenum. After transpyloric passage, first we depicted the duodenal bulb, then from the descending and inferior horizontal part of the duodenum, we visualized the ampulla of the Vater by tilting the capsule camera upwards to facilitate the retrograde view (Figure 10D-G).

Examining the small intestine

If the capsule entered *via* the small intestine, patients were asked to drink 1 L of PEG solution, and from then on, they were requested to drink clear fluids (*i.e.*, water). The movement of the capsule in the small intestine was then monitored hourly in real-time visualization mode. The examination ended when the capsule arrives at the colon or stops functioning due to the low battery.

RESULTS

An UBT test revealed *H. pylori* positivity in 32.7% of cases. (Table 2). No significant association with HP status and the type (proximal or distal), distribution (diffuse or focal) and severity (minimal or active, erosive) of the gastritis described on MCCE results were depicted.

The mean gastric, SB, and colon TT with MCCE was: 47 h 40 min (M/F: 44 h 15 min/51 h 14 min), 3 h 46 min 22 s (3 h 52 min 44 s/3 h 38 min 21 s) and 1 h 4 min 34 s (1 h 1 min 16 s/1 h 8 min 53 s), respectively. Average total time of MCCE examination: 5 h 48 min 35 s (5 h 46 min 37 s/5 h 50 min 18 s) (Table 3).

Table 2 The results of *Helicobacter pylori* C13 urea breath tests

	n	*H. pylori* positive	%	*H. pylori* negative	%	χ^2	*P* value	
Normal	30	7	23%	23	77%	0.9775	0.3228	NS
Minor proximalgastritis	19	9	47%	10	53%	1.529	0.2163	NS

Table 3 Mean gastric, small bowel, and overall transit times of magnetically controlled capsule endoscopy

Transit time	All cases	SD	Male	Female
Stomach	0 h 47 min 40 s	0 h 43 min 29 s	0 h 44 min 15 s	0 h 51 min 14 s
Small bowel	3 h 46 min 22 s	2 h 1 min 24 s	3 h 52 min 46 s	3 h 38 min 21 s
Total	5 h 48 min 35 s	1 h 50 min 49 s	5 h 46 min 37 s	5 h 50 min 18 s

The diagnostic yields for detecting any abnormalities in the stomach and SB with MCCE were 81.9%: 68.6% for minor pathologies and 13.3% for major pathologies. 25.8% of the abnormalities were found in the SB, and 74.2% were in the stomach. The diagnostic yield for stomach/SB was 4.9%/8.4% for major pathologies and 55.9%/12.7% for minor pathologies (Table 4). In the stomach, ulcers and polyps were considered major, while signs of gastritis were minor pathologies. In the SB signs of Crohn's and celiac disease were the major and non-specific inflammation, diverticula and angiodysplasia the minor pathologies. Based on findings from MCCE examinations, the distribution of pathologies is depicted in Table 5.

The capsule's active magnetic movement through the pylorus was successful using the magnet in 41.9% of all patients (automatized protocol in 56 patients and active manually controlled magnetic activity in 63 patients) (Table 6).

In 18 (M/F: 6/12) patients (6.3%), SB visualization with MCCE was incomplete. There were 13 occurrences of incomplete examinations as a result of capsule depletion. In 3 of these 13 cases, the capsule was depleted within 5 h of operation, indicating a manufacturing flaw. The average total study time in the remaining 10 cases was 9 h 12 min 9 s. From the pylorus to the last image, the average transit time was 8 h 26 min 4 s. The examination was discontinued sooner than planned in 3 cases due to the patient's request. In 2 cases, there was capsule retention due to Crohn's-like ulceration, accompanied by a narrow bowel lumen (Table 6). These problems were resolved spontaneously without surgery, but with medical treatment. There were no serious adverse events or capsule retention during the study period.

DISCUSSION

There are two main directions in developing capsule endoscopes with active movements: internally and externally guided techniques. Internal guidance means that the locomotive system is integrated into the capsule, but these systems require longer-lasting batteries for full functionality. Its main advantage is a more precise navigation with the help of the internalized locomotive system. External guidance refers to outwardly conducted capsule movements, *e.g.*, with a magnetic control unit or device/moving arm generating the magnetic field. The exceptional advantage of this method is that the magnetic field (and its adjustment) built by the external unit controls the locomotive mechanism, thus making this an energy-saving solution. However, a disadvantage of this technique is that it is limited to more passive, less flexible locomotion. The examining physician controls the capsule outside the body with an external control unit, which decreases the accuracy of the spatial and temporal movements. Locomotion of the capsule endoscope would result in numerous long-term advantages in the diagnostics and therapy of GI diseases (focused biopsies, treatment options, *e.g.*, laser tumor ablation, local targeted release of certain medications, and endoscopic ultrasound applications)[1].

Table 4 Diagnostic yield of magnetically controlled capsule endoscopy

Diagnostic yield	Major	Minor	Total
Total	38 (13.3%)	195 (68.6%)	233 (81.9%)
Gastric	14 (4.9%)	159 (55.9%)	173 (60.8%)
SB	24 (8.4%)	36 (12.7%)	60 (21.1%)

SB: Small bowel.

Table 5 Distribution of pathologies detected by magnetically controlled capsule endoscopy

	Polyp ventriculi	Ulcus ventriculi	Coeliakia	Crohn	Gastritis	Small intestinal diverticula	Angiodysplasia	Aspecific infalmmation in small bowel
Major pathologies	5	9	1	23	159	1	26	9

Table 6 Distribution of different types of transpyloric transit in complete and incomplete small bowel studies

	Cases (*n*)	Mean total transit time	Mean gastric transit time	Mean SB transit time	Transpyloric transit		
					With magnet by automatic protocol	With magnet manually	Without magnet
Total study population	284	5 h 48 min 35 s	0 h 47 min 40 s	3 h 46 min 22 s	56 (19.7%)	63 (22.2%)	165 (58.1%)
Incomplete studies	18 (6.3%)	7 h 13 min 41 s	0 h 52 min 35 s	6 h 19 min 51 s	2	5	11
The capsule depleted (> 5 h)	10 (3.5%)	9 h 12 min 9 s	0 h 46 min 5 s	8 h 26 min 4 s	0	3	7
The capsule depleted (< 5 h)	3 (1%)	2 h 23 min 25 s	0 h 24 min 9 s	1 h 51 min 22 s	1	0	2
The patient requested to terminate	3 (1%)	4 h 45 min 9 s	0 h 50 min 3 s	3 h 55 min 6 s	1	1	1
The capsule stopped because of a disease	2 (0.7%)	8 h 19 min 36 s	2 h 11 min 33 s	6 h 8 min 33 s	0	1	1

SB: Small bowel.

Magnetic assisted capsule endoscopy (MACE) systems have been developed over the past 5-10 years, primarily for research goals. Experiences drawn from previously conducted *in vitro* studies showed that locomotion and precision of the capsule are significantly influenced by the physical characteristics of the generated magnetic field created by the external magnetic unit while travelling in the human body[1].

In 2011, Olympus was the first to introduce a modified MRI machine prototype that moved a MACE system which allowed the operator to successfully guide the capsule in a chosen spatial direction inside the stomach after drinking water. However, the adoption of this diagnostic procedure did not spread worldwide and get medical acceptance[6].

In 2014, IntroMedic developed a navigation (NAVI) magnetic capsule system that could be moved externally with a small, hammer-shaped, external static magnet device. The technology involving a magnet that assisted the physician in manually moving the capsule endoscope appeared viable and valuable in many experimental settings. However, it did not achieve any breakthroughs, as it only allowed sudden and harsh position changes of the capsule. In clinical trials studying the application of the NAVI capsule system using a small cohort, 65%-86% of the mucosal layer of the stomach was visualized accurately using external magnetically controlled locomotion after the ingestion of water. Its diagnostic accuracy was similar to that of traditional gastroscopy[9]. Using a similar type of NAVI capsule system, CE was performed on the large intestines, where magnetic locomotion directed the capsule from the cecum to the sigmoid colon. At the same time, a colonoscopy probe was inserted to monitor capsule movements to provide dilatation[10]. In iron deficiency anemia, after routine colonoscopy of 49 patients, the performance of a MACE system was compared with the IntroMedic Navi system in providing a diagnostic examination of the stomach and small intestine in one sitting.

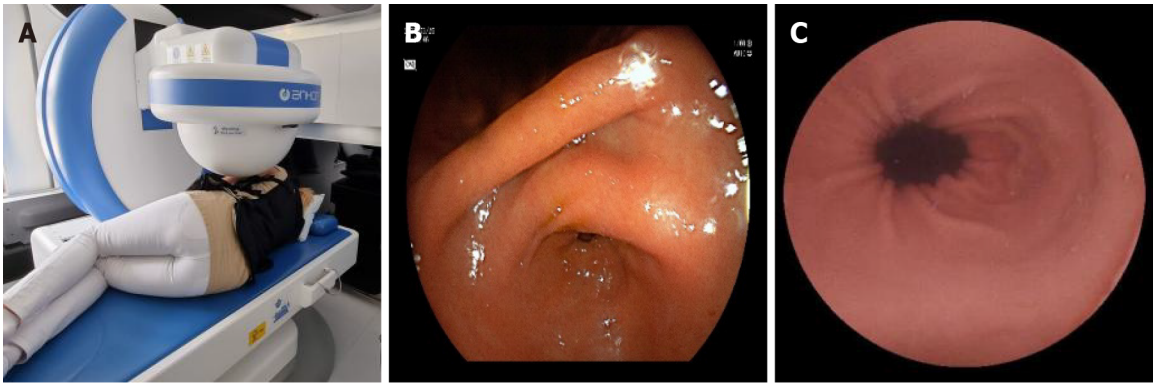
According to the results, MACE detected more pathologies than by gastroscopy alone, and no significant difference in diagnostic sensitivity was found between the methods when examining the upper GI tract[11].



Precise locomotion of the magnetic capsule inside the GI tract by manual control is not possible due to the variable density of tissues and variable distance of the capsule, *e.g.*, in the stomach from the external magnet. Moreover, exact spatial location of the capsule, its relation to the surrounding organs, or the ante-/retrograde orientation cannot be judged accurately. Therefore, a control mechanism is needed alongside the magnetic capsule, which is based on external robotics that enable the physician's input to be executed (*i.e.*, joystick: in forward, backward, upward, downward, and sideways directions). By pre-programming instruction sequences (script) in the computing control unit to examine the stomach from the fundus to the antrum, we created a reproducible examination of the complete inner mucosal lining of the stomach, which lowered the variability among investigations. If the examining physician notices significant pathology, he/she can intervene and move the examination to manual control and revisit the alteration; doing so increases the number of images taken of the lesion and optimizes the diagnostic accuracy of the study.

NaviCam was the first magnetically controlled capsule system that enables bidirectional data transmission and robotic control. The capsule functions at 1-6 fps and its spatial orientation with continuous monitoring of energy levels are transmitted *via* the recording vest to control the data and screen of the computing unit. At the console, we can control the precise locomotion of the capsule, image capturing speed, and brightness, as well as turn it on or off.

We combined manual and automatic, robotic capsule control to optimize the gastric procedure. As we previously published in an *in vitro* setting, complete 100% visualization of the inner surface of a plastic stomach model with the medium and large stomach autoscan program module and with the freehand controlling method could be successfully achieved in all cases. With the small and medium stomach mode, we could observe only 97.5% of the inner surface, because of the incomplete visualization of the prepyloric region. With freehand method, we needed nearly twice as much average time (749 s) to make a complete examination, compared to the robotic maneuvering with autoscan program (390 s). In an everyday praxis, in each patient position, the following stations and capsule positioning were performed after running the 3 different autoscan programs[12,13].

CE is a potentially patient-friendly and noncontact/infection-free diagnostic modality of screening for gastric diseases, which may result in complete and excellent examinations of the stomach. During the coronavirus disease 2019 pandemic, direct contact with the patients in the practice is a potential risk factor for infections. Non-contact medicine is a possibility for further examinations, such as remote control of CE[14]. The prevalence of focal gastric lesions (polyps, gastric ulcers, submucosal tumors, *etc*.)

DOI: 10.3748/wjg.v28.i20.2227 **Copyright** © The Author(s) 2022.

Figure 10 Stations VII and VIII in the supine position. increases with age, and they may be detected with MCCE as effectively as with gastroscopy[8]. The sensitivity is between 90% and 92%, and the specificity is between 94% and 96.7%[15]. Several studies proved that, altogether, reliable preparation (gastric cleanliness), careful examination, and MCCE are pivotal for adequate gastric visualization and, therefore, for the detection of superficial gastric neoplasms[16]. In a large multicenter gastric cancer screening trial conducted in China seven asymptomatic patients out of 3182 were diagnosed with advanced cancer by MCCE. Cancer prevalence was highest in the gastric body (3 cases), followed by 2 cases in the cardia and 2 in the antrum, while 1-1 cases were detected in the region of the angulus, in the fundus and in the esophagus. All were confirmed to be adenocarcinoma pathologically. These results indicate that screening with MCCE may be useful in high family risk populations or people aged over 50 years old as a gastric cancer screening modality[8].

Magnetic steering may also impact TTs, as delayed gastric transit of the CE (especially in patients with gastroparesis) may lead to an incomplete SB exam. This method may increase the papilla detection rate as well. In addition to magnetic steering, there are several other independent factors, such as male gender and higher BMI, which increase gastric TTs and decrease SB TTs, thus impacting the time required for CE completion[10]. Despite the fact that delayed gastric TT may cause incomplete SBCE, we should avoid esophago-gastro-duodenoscopy to resolve temporary gastric capsule retention and instead use MCCE[17].

The visual diagnosis of the presence of *H. pylori* with standard white light endoscopy (WLI) has a relatively low accuracy, especially in population with a low pretest probability. Moreover, WLI endoscopy correlates poorly with histopathological findings of *H. pylori* induced gastritis too. Recently, low quality retrospective studies proposed the theory, that with the application of a special electronic chromoendoscopy, linked color imaging, diffuse reddish appearance of the mucosa in the gastric body and fundic glands correlates with the presence of HP[18].

In our study we found no correlation between the HP status and the activity and type of gastritis observed on MCCE as follows, but not included this into the Table 2, since it would be relevant in another publication, focusing HP status and gastritis on MCCE.

MCCE is an excellent method to visualize the entire gastric mucosal surface up to 100% precision in healthy volunteers[5]. In a previous study of 75 consecutive patients, we demonstrated that with our combined method with automatic and manual control, a complete visualization of the cardia, fundus, corpus, angulus, antrum, and duodenal bulb was 95.4%, 100%, 100%, 100%, 100% and 100%, respectively. The ampulla of Vater was detected and observed in 20 patients (26%). Moreover, the visualization of the distal esophagus and the Z-line was possible in 67/75 patients (89%), which was

assessed as complete in 23, and partially complete in 44 patients. The mean stationary time for MCCE in the distal esophagus was 1 min and 32 s[19].

The use of MCCE needs to be considered in western and eastern countries, as there are two different scenarios, depending on the different levels of prevalence of UGI diseases and gastric cancer in each country. Nowadays, MCCE is mostly used for the detection of malignant and premalignant gastric lesions, which are more prevalent in eastern countries. However, the present technology opens the door to further, new technologies; subsequent developments would allow MCCE technology to be extended to other regions of the GI tract, *e.g.*, the esophagus, which may facilitate the detection of more relevant lesions, such as Barrett metaplasia in western countries as well. With second-generation MCCE, visualization of the esophagus, Z-line, and duodenal papilla would be improved, according to a study by Jiang *et al*[20] Furthermore, the gastric TT could shorten by one-third, which was nearly achieved by conventional endoscopy with an examination of approximately 10 min.

It is known that the current gold standard gastroscopy has some clear disadvantages, as it is commonly uncomfortable for patients, and therefore it is mostly performed under sedation, which carries definite procedure related risks. MCCE, as a patient-friendly, non-invasive test, might be an alternative for patients who refuse to undergo gastroscopy and increase patients' adherence for screening. Furthermore, MCCE of the stomach was recently approved by the Chinese Food and Drug Association for the following diagnostic indications: (1) As an alternative diagnostic tool for patients who refuse to undergo gastroscopy; (2) Screening of gastric diseases as a part of physical examination; (3) Screening for gastric cancer; (4) To diagnose various causes of GI inflammation; (5) To perform follow-up for diseases like gastric varices, gastric ulcer, atrophic gastritis, and polyps after surgical or endoscopic removal[21].

There is no similar study in the literature, as we performed a complete upper GI capsule examination, including the stomach and the SB with the same capsule endoscope during MCCE. Denzer *et al*[22] published a blinded, prospective trial from two French centers with the Intromedic manually controlled MCCE. A total of 189 patients were enrolled into this multicenter study. Lesions were defined as major (requiring biopsy or removal) or minor ones. The final gold-standard was unblinded conventional gastroscopy with biopsy, under sedation with propofol. Twenty-three major lesions were found in 21 patients and in this population, the capsule accuracy was 90.5% as compared to gastroscopy. Of the remaining 168 patients, 94% had minor and mostly multiple lesions; the capsule accuracy was 88.1%. All patients preferred MCCE over gastroscopy[22].

One of the risk factors of incomplete SB capsule endoscopy is a prolonged gastric transit time, which could be considered as a limitation of our combined gastric and SB study protocol. In our patient population, the average gastric transit time with magnetic transpyloric, manual control was 26 min. In contrast, in those cases where the magnetic transpyloric control failed, after examining the stomach, we left the capsule to propel through the pylorus by spontaneous peristaltic activity. In these patient groups, the average gastric transit time took 1 h and 9 min. In 10 cases out of 18 incomplete SB studies caused by battery low energy, this event occurred in 3 patients with manual magnetic passage and in 7 patients with spontaneous transpyloric passage[23].

Visibility and identification of landmarks are important factors to consider in accurate examination of stomach using MCCE. Gastric landmarks and typical stations described in the methods were always forced to achieve during combined automatic and manual maneuvering. For improving the learning curve of our gastroenterologist, we started to train the examinations in a plastic stomach model. In our previously published abstract, we described the improvement of the learning curves with manual magnetic controls both in experts and in trainees[1]. In this study, we find significant differences in the examination time of the complete inner surface mapping between trainees and experts, and moreover automatic protocols were faster and equally accurate as experts to achieve a complete inner surface mapping.

The problem how to minimalize bubbles and mucoid secretions is an existing problem in real life studies. To improve visibility, we established a unique preparation process with a combination of bicarbonate, Pronase B, and simethicone combined with a patient body rotation technique[2]. Moreover, in our described stations, we rotate our patients from left lateral to supine, then from supine top right lateral, and finally from right lateral to supine position during MCCE study. During this protocol, the gastric mucoid secretions also moving into different parts of the stomach due to the gravity making visible all the landmarks and the majority of the mucosal abnormalities. Application of prokinetics or motilin agonist erythromycin might also be an option in future studies to improve the visibility and reduce gastric lake content[24,25].

An inherent limitation of our present study that we performed gastroscopy only in a few patients with major gastric pathologies to accomplish final diagnosis and biopsy; and therefore, we could not assess the accuracy of MCCE in all patients compared to gastroscopy. However, several previous studies demonstrated excellent diagnostic value and high accuracy. In a recent meta-analysis of Zhang *et al*[26] four studies with 612 patients were included, in which the results of blinded MCCE and gastroscopy were compared. MCCE demonstrated a pooled sensitivity and specificity of 91% (95%CI: 0.87-0.93) and 90% (95%CI: 0.75-0.96), respectively. The diagnostic accuracy of MCCE was 91% (95%CI: 0.88-0.94) for assessing gastric diseases.

CONCLUSION

MCCE is an effective and safe diagnostic method for evaluating gastric and SB mucosal lesions while being utilized as a single upper GI capsule endoscope in patients referred for SBCE evaluation. MCCE using the novel Ankon capsule endoscopic technique is a proper diagnostic method for evaluating the gastric mucosa. It is a promising non-invasive screening tool that may be applied in future monitoring of patients with high gastric cancer family risk to decrease morbidity and mortality of benign and malignant upper GI disorders.

ARTICLE HIGHLIGHTS

Research background

While capsule endoscopy (CE) is the gold standard diagnostic method of detecting small bowel diseases and disorders, a novel magnetically controlled capsule endoscopy (MCCE) system provides non-invasive evaluation of the gastric mucosal surface, which can be performed without sedation or discomfort.

Research motivation

During standard small bowel capsule endoscopy (SBCE), passive movement of the CE may cause areas of the complex anatomy of the gastric mucosa to remain unexplored, whereas the precision of MCCE capsule movements inside the stomach promises better visualization of the entire mucosa.

Research objectives

To evaluate the Ankon MCCE system's feasibility, safety and diagnostic yield in patients with gastric or small bowel disorders.

Research methods

Of outpatients who were referred for SBCE, 284 (male/female: 149/135) were prospectively enrolled and evaluated by MCCE. The stomach was examined in the supine, left, and right lateral decubitus positions without sedation. Next, all patients underwent a complete small bowel CE study protocol. The gastric mucosa was explored with the Ankon MCCE system with active magnetic control of the capsule endoscope in the stomach, applying three standardized pre-programmed computerized algorithms in combination with manual control of the magnetic movements.

Research results

The urea breath test revealed *Helicobacter pylori* positivity in 32.7% of patients. The mean gastric and small bowel transit times with MCCE were 47 min 40 s and 3 h 46 min 22 s, respectively. The average total time of upper GI MCCE examination was 5 h 48 min 35 s min. Active magnetic movement of the Ankon capsule through the pylorus was successful in 41.9% of patients. Overall diagnostic yield for detecting abnormalities in the stomach and small bowel was 81.9% (68.6% minor; 13.3% major pathologies); 25.8% of abnormalities were in the small bowel; 74.2% were in the stomach. The diagnostic yield for stomach/small bowel was 55.9%/12.7% for minor and 4.9%/8.4% for major pathologies.

Research conclusions

MCCE is a feasible, safe diagnostic method for evaluating gastric mucosal lesions and is a promising non-invasive screening tool to decrease morbidity and mortality in upper gastrointestinal diseases.

Research perspectives

MCCE is promising as a non-invasive screening tool that may be applied in future monitoring of patients for evaluating gastric mucosal lesions and decreasing morbidity and mortality of benign and malignant upper GI disorders.

Author contributions: Szalai M, Madácsy L and Finta Á performed the capsule endoscopy examinations; Szalai M, Helle K, Finta Á, Oczella L and Madácsy L performed the data collection; Szalai M, Helle K, Lovász BD, Finta Á, Rosztóczy A, Oczella L and Madácsy L drafted the manuscript; Oczella L enrolled participants; Szalai M and Madá csy L reviewed capsule endoscopy images as expert endoscopists with high experience in capsule endoscope; Rosztó czy A and Madácsy L planned the study concept, consulted with the authors, performed manuscript database validation, supervised the manuscript preparation and writing, and acted as the submission's guarantor; All authors finally read and approved the manuscript.

Institutional review board statement: This study was approved by the Ethical Committee of the University of Szeged (registry No. 5/17.04.26) and registered in the trial registry: ClinicalTrials.gov (Identifier: NCT03234725). The present study was conducted according to the World Medical Association's Declaration of Helsinki provisions in 1995.

Informed consent statement: All involved participants gave their informed consent (in written form) prior to study inclusion. Patients agreed to participate in the present study, undergo capsule endoscopy and Helicobacter pylori breaths tests by written informed consent. All details that might disclose the identity of the subjects under study are anonymized. The institutional review board of University of Szeged waived the requirement to obtain informed consents from patients.

Conflict-of-interest statement: No conflict-of-interest.

Data sharing statement: Data (deidentified participant data) are available upon reasonable request. Contact details: endomabt1@gmail.com; László Madácsy (0000-0002-7589-6193). No additional information or data is available.

STROBE statement: The authors have read the STROBE Statement-checklist of items, and the manuscript was prepared and revised according to the STROBE Statement-checklist of items.

Open-Access: This article is an open-access article that was selected by an in-house editor and fully peer-reviewed by external reviewers. Abstract

BACKGROUND

Intramural duodenal hematoma is a rare condition described for the first time in 1838. This condition is usually associated with blunt abdominal trauma in children. Other non-traumatic risk factors for spontaneous duodenal haematoma include several pancreatic diseases, coagulation disorders, malignancy, collagenosis, peptic ulcers, vasculitis and upper endoscopy procedures. In adults the most common risk factor reported is anticoagulation therapy. The clinical presentation may vary from mild abdominal pain to acute abdomen and intestinal obstruction or gastrointestinal bleeding.

CASE SUMMARY

The aim of this case summary is to show a case of intramural spontaneous hematoma with symptoms of intestinal obstruction that was properly drained endoscopically by an innovative system lumen-apposing metal stent Hot AXIOS™ stent (Boston Scientific Corp., Marlborough, MA, United States).

CONCLUSION

Endoscopic lumen-apposing metal stent Hot AXIOS™ stent is a safe and feasible treatment of duodenal intramural hematoma in our case.

Key Words: Duodenal hematoma; Several pancreatic diseases; Endoscopy complication; AXIOS™ stent; Case report

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: The present case explored the feasibility, safety and efficacy of endoscopic ultrasound-guided drainage of spontaneous duodenal hematoma. The new lumen-apposing self-expandable metallic stent Hot AXIOS™ could be considered a valid alternative to conventional endoscopic incision of the hematoma by using a needle-knife, a biopsy forceps or surgical drainage and percutaneous drainage to relieve pain and a persistent duodenal ulcer.

INTRODUCTION

Intramural duodenal hematoma (IDH) is a rare intestinal condition described for the first time at autopsy in 1838[1], and the first source in the PubMed database accessing the MEDLINE database (http://www.ncbi.nlm.nih.gov/pubmed/) dates from 1952[2].

This condition is usually associated with blunt abdominal trauma in children[3] and upper endoscopy procedures (duodenal biopsy or injection therapy for bleeding peptic ulcers) or various non-traumatic conditions in adults (> 70% of cases). These include several pancreatic diseases even if the association remains unclear, such as certain coagulation disorders (anticoagulant therapy, haemophilia, Von Willebrand disease, Henoch-Schönlein purpura), malignancy, collagenosis, peptic ulcers and vasculitis[4-7].

Clinical symptoms for IDH may vary from vague abdominal pain to acute abdomen, intestinal obstruction or gastrointestinal bleeding[3,8], and diagnosis is subsequently confirmed by magnetic resonance imaging or computed tomography (CT) and upper gastrointestinal endoscopy (UGIE).

Most IDH cases resolve spontaneously or with correction of abnormal coagulation. Percutaneous drainage or surgery may be needed in some refractory IDH cases, malignancy, perforation and intestinal tract obstruction.

Here we present the use of the innovative lumen apposing metal stent catheter (LAMS) Hot AXIOS™ (Boston Scientific Corp., Marlborough, MA, United States) in the case of spontaneous IDH with intestinal substenosis, which was non-responsive to conservative management, in a patient without risk factors. This innovative device, with a lumen apposing self-expandable metal stent fitted onto an electrocautery-enhanced tip catheter, is safe and feasible in gallbladder drainage, choledochoduodenostomy and drainage of pancreatic fluid collections. In recent years, Hot AXIOS™ has also been used for off-label indications including gastrojejunostomy, gastro-gastrostomy and drainage of postsurgical collections. Herein we report the use of Hot AXIOS™ in the rare digestive disorder spontaneous IDH.

CASE PRESENTATION

Chief complaints

A 51-year-old man was admitted to the hospital with abdominal pain, bloating and vomiting.

History of present illness

The clinical data suggested a diagnosis of intestinal obstruction.

History of past illness

The patient did not report comorbidities or recent abdominal trauma without relevant previous medical history and in particular without having taken anti-platelet medication.

Personal and family history

He did not have relevant family history.

Physical examination

Physical examination on admission revealed slight tenderness over the epigastric region and right flank.

Laboratory examinations

Initial biochemical analysis indicated neutrophilic leukocytosis (13.07 × 10^9/L) and an increased level of C-reactive protein without alterations of serum haemoglobin, D-dimer, platelet function and

coagulation parameters.

Imaging examinations

A contrast-enhanced abdominal CT scan revealed an IDH (Figure 1A). On admission UGIE and then endoscopic ultrasound (EUS) confirmed submucosal swelling of the second part of the duodenum that measured approximately 90 mm along the long axis with substenosis of the duodenal lumen (Figure 1B).

MULTIDISCIPLINARY EXPERT CONSULTATION

A conservative approach was attempted with clinical observation and empirical antibiotic therapy. The patient was discharged in good clinical condition after 8 d of intravenous antibiotic therapy.

FINAL DIAGNOSIS

Intramural spontaneous duodenal hematoma.

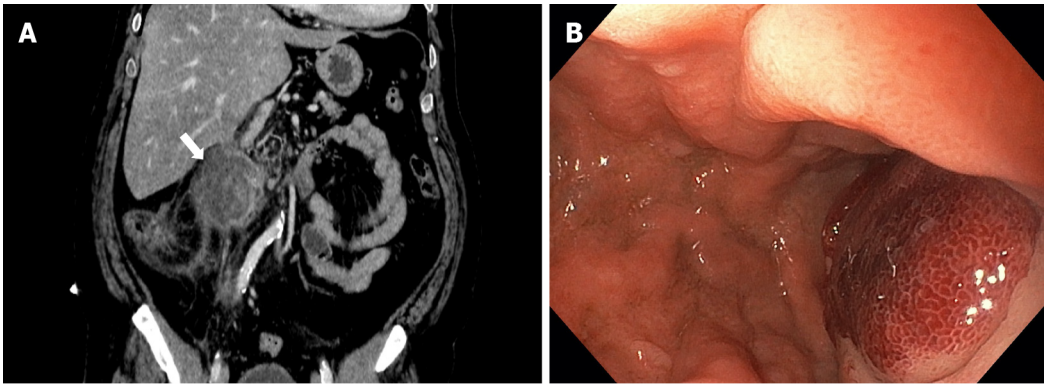
TREATMENT

After 48 h the patient was readmitted to the hospital due to clinical relapse. Biochemical analysis indicated a significant increase of both leukocytosis and C-reactive protein, and the radiological evaluation confirmed the previous diagnosis. After 10 d a multidisciplinary evaluation was performed, and minimally invasive endoscopic treatment was proposed.

EUS-guided drainage was performed with the Hot AXIOS™ system. A direct LAMS 15 mm × 10 mm was inserted into the submucosa lumen with an electrocautery-enhanced tip catheter and released under complete EUS control after the second flange was deployed in the duodenal lumen (Figure 2A). UGIE control confirmed the correct LAMS placement, and hematinic material associated with slightly purulent drainage was observed (Figure 2B).

OUTCOME AND FOLLOW-UP

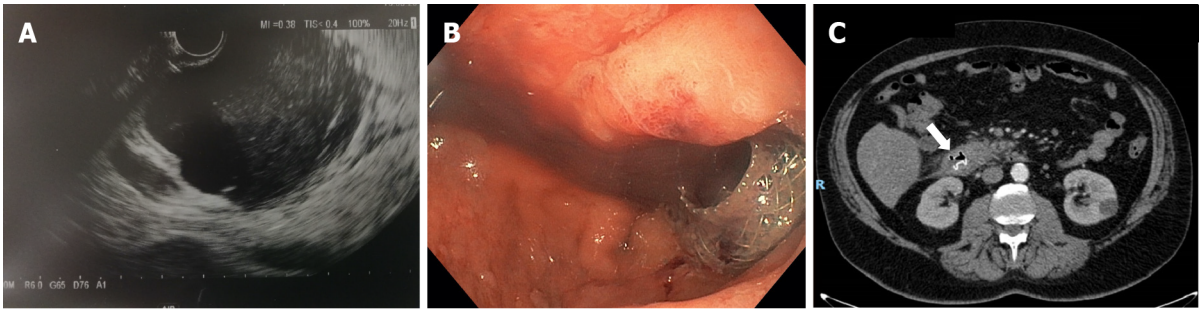
A control CT scan demonstrated the presence of LAMS and the complete drainage of the intramural collection (Figure 2C). The patient was discharged in good clinical condition after 7 d. After an additional 2 wk he repeated UGIE, which revealed a complete resolution of the duodenal bulging, and the LAMS was contextually removed with complete closure of the mucosal defect with a clip. At the 30-d follow-up the patient was completely asymptomatic.



DISCUSSION

IDH is a rare condition usually caused by trauma, anticoagulant therapy, rupture of a duodenal aneurysm or biopsy[4-7,9]. Rare cases of IDH have also been described as a consequence of acute pancreatitis[3] or after endoscopic retrograde cholangiopancreatography procedures[10].

CT and magnetic resonance imaging represent the most sensitive diagnostic exams for IDH. Radiological exams have a role both for diagnosis as well as follow-up of small bowel hematoma within 2 wk[11,12]. Once IDH is confirmed, conservative management with fasting and total parenteral nutrition should be given[13]. Traditionally, in the case of persistent IDH, surgical drainage[14,15] and percutaneous drainage were performed[16], both causing great trauma for the patient. The indications for surgical intervention are not well clarified, certainly in the case of occlusive symptoms over 7-10 d or where there is evidence of perforation with a generalized peritonitis[17].



To date there are few described cases of endoscopic drainage of duodenal hematoma. This consists of endoscopic incision of the hematoma using a needle-knife or a biopsy forceps in order to obtain rapid submucosal decompression[18,19] with improvement of abnormal laboratory findings and abdominal pain in up to 1 wk. The persistence of duodenal ulcer at the site of endoscopic incision has also been described with a complete resolution only after 1 mo[18].

In our case we had a patient with an unremarkable previous medical history, with no risk factors for IDH who presented with intestinal pseudo-obstruction symptoms and leukocytosis without evidence of pancreatitis. We first attempted a conservative approach according to the existing data, but after recurrence of symptoms an endoscopic approach was proposed.

Figure 1 Intramural duodenal hematoma. A: Contrast-enhanced abdominal computed tomography in coronal section; B: Endoscopic visualization with substenosis of duodenal lumen.

DOI: 10.3748/wjg.v28.i20.2243 **Copyright** © The Author(s) 2022.

Figure 2 Intramural duodenal hematoma after endoscopic treatment. A: Endoscopic ultrasonography (EUS) image showed deployment of the distal flange of a cautery-tipped lumen apposing metal stent (LAMS) in the intramural duodenal hematoma under EUS guidance; B: Endoscopic views showed the proximal flange of the LAMS; C: Control abdominal computed tomography confirmed the correct position of the LAMS.

The Hot AXIOS™ lumen-apposing stent is a novel double-flanged covered, self-expanding metal stent, safe and effective in gallbladder drainage, choledochoduodenostomy and drainage of pancreatic fluid collections. In the recent years, Hot AXIOS™ stents have also been used for off-label indications including gastrojejunostomy, gastro-gastrostomy and drainage of postsurgical collections.

Here we present the use of Hot AXIOS™ in a rare but possible digestive disorder with a rapid and complete resolution of this insidious clinical entity, as confirmed by CT scan and with only 7 d length of stay without abnormal laboratory findings and abdominal pain after the procedure.

CONCLUSION

In our experience Hot AXIOS™ is a safe and effective endoscopic procedure for the treatment of IDH, reserved for patients who are not responsive to conservative management. However, it should be performed by expert endoscopists trained in EUS and radiological procedures. To reduce the rate of postoperative complications and improve clinical outcome a previous careful clinical evaluation focusing on coagulopathies is mandatory.

Abstract

Recently, we read the article "Gut microbiome composition can predict the response to nivolumab in advanced hepatocellular carcinoma patients" with interest, and it is preliminary suggested that gut microbiota is closely related to therapeutic effect of nivolumab. Based on the meaningful results of this article, several valuable research directions are proposed to enhance the therapeutic effect of immune checkpoint inhibitors on advanced hepatocellular carcinoma.

Key Words: Gut microbiome; Immunotherapy; Immune checkpoint inhibitor resistance; Probiotics; Faecal microbiota transplantation; Hepatocellular carcinoma; Prognosis

TO THE EDITOR

We read with interest the article "Gut microbiome composition can predict the response to nivolumab in advanced hepatocellular carcinoma patients"[1], in which the authors analyzed and summarized the correlation between gut bacterial composition and the prognosis of nivolumab therapy in hepatocellular carcinoma (HCC) patients. The highlight of this article was that gut microbiota composition and diversity of responders differed significantly from those of non-responders following nivolumab therapy. Several intestinal bacterial species such as *Citrobacter freundii, Azospirillum species*, and *Enterococcus durans* were specific to the responders. Moreover, a higher *Prevotella/Bacteroides* ratio and the presence of *Akkermansia species* can serve as predictive markers of response. Altogether, the study not only demonstrated that the therapeutic effect of nivolumab has something to do with the composition of the gut microbiota in advanced HCC patients, but also provided some inspiration for future research direction.

In our opinion, it is of importance to underline that the relationship between the therapeutic effect of various immune checkpoint inhibitors (ICIs) such as pembrolizumab, nivolumab atezolizumab, durvalumab, and avelumab on HCC and the gut microbiota. At present, the response rates to ICIs are very low in advanced HCC. To be specific, the response rate to ICI monotherapy is merely 15%-23%, which is increased to approximately 30% after combination treatment[2]. How to improve the effectiveness of ICI treatment is essential and has been extensively investigated. While the human gut microbiota has been shown to be associated with clinical responses to ICIs in HCC[3], the available data in this field remain limited and the relevant scientific work is only in the initial stage. Thus, more research is required in the future. First, clinical studies with large sample sizes are needed to further clarify the relationship between the gut microbiota and the therapeutic effect of various ICIs. At the same time, which types of gut microbiota are suitable for which ICIs should also be figured out. Furthermore, construction based on the gut microbiota can function as a prognostic marker for the response to various ICI therapies. These results will provide clinicians with a valuable reference for rational use of ICIs and personalized precision therapy. Second, the mechanism by which the gut microbiota promotes the therapeutic effect of various ICIs needs to be further studied, with the focus on key pathways such as intestinal mucosal barrier function, bacterial metabolites, and microorganism-related molecular patterns, thus being conducive to discovering how to enhance the therapeutic effect of various ICIs by targeting the gut microbiota. Third, probiotics, prebiotics, synbiotics, and antibiotics may represent innovative, safe, and low-cost strategies for promoting the therapeutic effect of various ICIs[4]. In this respect, it is of necessity to determine which beneficial bacteria and harmful bacteria are bound up with the therapeutic effects of which ICIs. Meanwhile, it will also be significant to confirm how probiotics, prebiotics, synbiotics, and antibiotics alter the composition of the gut microbiota and how relevant it is to the therapeutic effect of various ICIs. In other words, these results will contribute to the identification of probiotics, prebiotics, synbiotics, and antibiotics that may increase the efficacy of ICIs when being used in combination. Last but not least, faecal microbiota transplantation (FMT) may be a direct and superior approach to enhancing the therapeutic effect of various ICIs through modulating the gut microbiota in human beings. Considering that, it is extremely valuable to explore the therapeutic method of FMT in combination with ICIs. Besides, the optimal gut microbiota composition for enhancing the therapeutic effect of various ICIs should be recognized. On this basis, it is of great importance to choose the right donors[5].

In summary, based on the meaningful research results of this article, it is expected that readers can pay attention to the relationship between the gut microbiota and therapeutic effect of ICIs on advanced HCC and the method of regulating the gut microbiota to improve the therapeutic effect of ICIs.

ABOUT COVER

Editorial Board Member of *World Journal of Gastroenterology*, Somashekar G Krishna, MD, MPH, AGAF, FASGE, FACG, Professor of Medicine, Director of Clinical Research, Division of Gastroenterology, Hepatology and Nutrition, The Ohio State University Wexner Medical Center, 395 West 12th Avenue, Room 226, Columbus, OH 43210, United States. somashekar.krishna@osumc.edu

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, and Scopus. The 2021 edition of Journal Citation Report® cites the 2020 impact factor (IF) for *WJG* as 5.742; Journal Citation Indicator: 0.79; IF without journal self cites: 5.590; 5-year IF: 5.044; Ranking: 28 among 92 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2020 is 6.9 and Scopus CiteScore rank 2020: Gastroenterology is 19/136.

Abstract

Hepatocellular carcinoma (HCC) is a global health challenge. Due to the high prevalence in low-income countries, hepatitis B virus (HBV) and hepatitis C virus infections remain the main risk factors for HCC occurrence, despite the increasing frequencies of non-viral etiologies. In addition, hepatitis D virus coinfection increases the oncogenic risk in patients with HBV infection. The molecular processes underlying HCC development are complex and various, either independent from liver disease etiology or etiology-related. The reciprocal interlinkage among non-viral and viral risk factors, the damaged cellular microenvironment, the dysregulation of the immune system and the alteration of gut-liver-axis are known to participate in liver cancer induction and progression. Oncogenic mechanisms and pathways change throughout the natural history of viral hepatitis with the worsening of liver fibrosis. The high risk of cancer incidence in chronic viral hepatitis infected patients compared to other liver disease etiologies makes it necessary to implement a proper surveillance, both through clinical-biochemical scores and periodic ultrasound assessment. This review aims to outline viral and microenvironmental factors contributing to HCC occurrence in patients with chronic viral hepatitis and to point out the importance of surveillance programs recommended by international guidelines to promote early diagnosis of HCC.

Key Words: Hepatitis C virus; Hepatitis B virus; Hepatitis D virus; Hepatocellular carcinoma; Cirrhosis; Liver

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Chronic hepatitis B virus (HBV), hepatitis C virus (HCV) and hepatitis D virus (HDV) infection represents a global health burden leading to liver fibrosis, cirrhosis and hepatocellular carcinoma (HCC). Among these complications, HCC accounts for 3.5% of all deaths worldwide. Thus, the understanding of the role of chronic hepatitis virus infection in HCC development is necessary in order to clarify the mechanisms underlying oncogenesis and design future treatments for this cancer. This review outlines pathophysiological and molecular pathways that contribute to carcinogenesis in HBV, HCV and HDV chronic infection focusing on the impact of clinical surveillance and antiviral treatment on the risk of HCC development.

INTRODUCTION

Primary liver cancer is the sixth most common cancer worldwide accounting for 800000 new cases per year and one of the major causes of cancer-related death in men with 745000 deaths per year. It has been estimated that there will be an increased incidence after the year 2025 with more than 1 million cases per year[1]. Hepatocellular carcinoma (HCC) represents the most common histologic type among liver cancers (70%-90%)[2]. According to recent epidemiologic studies, the mortality rate from HCC is increasing in some of the European and North American countries. Indeed, HCC has been recognized as the cause of death in 54%-70% of patients with compensated cirrhosis of different etiologies[3]. Nevertheless, HCC is one of the most prevalent cancers in less developed world regions. About 60%-70% of HCCs have been linked with chronic hepatitis B virus (HBV) or hepatitis C virus (HCV) infection, with a total incidence of 16/100000 cases globally (Table 1)[4], while the linkage with hepatitis D virus (HDV) is less clear[5].

HCC is associated with many risk factors (Table 2) with the highest odds ratio (OR) for viral ones. Cirrhosis precedes most cases of HCC and may exert a promoting effect *via* hepatocyte regeneration and chronic inflammation[4]. There are other environmental and genetic risk factors involved in the pathogenesis of HCC such as excessive alcohol consumption, aflatoxin intake, diabetes, obesity and hereditary hemochromatosis[6]. This review outlines the pathophysiology and molecular pathways that contribute to carcinogenesis in HBV, HCV and HBV/HDV chronic infection and investigates the impact of surveillance programs and antiviral treatments on the risk of HCC occurrence.

HBV INFECTION AND HCC DEVELOPMENT

Epidemiology

HBV infection is the most widespread chronic viral infection in the world. Currently, 2 billion people have been infected and more than 350 million are chronic carriers of the virus[7]. Worldwide HBV surface antigen (HBsAg) seroprevalence is 3.6% with the highest prevalence in Africa (8.83%) and in Western Pacific Asia (5.26%)[8]. In contrast, the prevalence of chronic HBV infection is low in most of European countries and it is estimated to be around 0.5%-0.7%[9]. Underdiagnosis and undertreatment are still unresolved issues and public awareness is largely suboptimal with less than 25% of infected Europeans aware of HBV transmission risk at the moment of their diagnosis[9]. Thus, chronic HBV infection is the tenth leading cause of global deaths accounting for 3.5% of all deaths worldwide (786000 deaths per year). Half of the total liver cancer mortality in 2010 has been attributed to HBV infection[10].

Molecular pathways and HCC development in chronic hepatitis B

Chronic HBV infection is the most important cause of HCC worldwide. Prospective cohort studies show a 5-100-fold increase in the risk of developing HCC among patients with untreated chronic HBV infection[2]. A systematic review estimates a yearly HCC incidence rate of 0.2% in HBV inactive carriers, of 0.6% in those with chronic infection without cirrhosis and of 3.7% in those with compensated cirrhosis[11]. Meta-analyses show a 15-20 times greater relative risk for HCC occurrence in HBsAg positive individuals than in HBsAg negative individuals[2].

Most of HBV-infected individuals (70%-90%) develop HCC related to the onset of cirrhosis and secondary to chronic inflammation[2]. However, in up to one-third of patients, HCC occurs in the absence of cirrhosis[12]. Oncogenesis in HBV infected patients is a complex phenomenon involving

Table 1 Hepatocellular carcinoma incidence and risk factors

HBV: Hepatitis B virus; HCV: Hepatitis C virus; NC: Non cirrhotic; CC: Compensated cirrhosis; a: Lack of proper data in the selected area.

most of the cell cycle regulation molecular pathways (Table 3 and Figure 1). As a noncytopathic virus, the pathogenesis of HBV tissue damage is mainly mediated by cell-mediated immune response to HBV epitopes surface proteins. Persistent HBV replication triggers immune response against the virus leading to genetic damage and perpetrating oxidative stress. In addition to chronic inflammation, other viral mechanisms contribute to HBV carcinogenesis involving the HBs and HBx proteins, the insertional mutagenesis caused by HBV DNA integration into the host genome, which induces chromosomal instability and alters the expression of endogenous genes, the epigenetic modifications through DNA methylation and the regulation of microRNA (miRNA) expression[13].

There are other factors increasing HCC risk among HBV carriers that can be divided into: Viral factors (high rates of HBV replication, long term infection, coinfection with HCV/human immunodeficiency virus/HDV, high risk genotype) and host-related factors, such as genetic or demographic (older ages, male sex, Asian or African origin, family history of HCC), clinical (presence of cirrhosis) and environmental (diabetes, overweight, alcohol abuse, aflatoxin exposure)[14].

VIRAL FACTORS

Role of HBV DNA level

The risk of developing HCC strictly correlates with HBV viraemia. Multiple integrations have been detected in liver tissues and integrated HBV sequences have been observed in almost 90% of HBV-related HCCs[13]. The reveal-HBV study shows increased HCC-related mortality in subjects with baseline HBV DNA higher than 10^6 copies/mL compared to those with baseline DNA lower than 300 copies/mL. A multivariate cyclooxygenase (COX) regression analysis identifies an increase in HBV DNA levels as the strongest independent predictor of death from HCC, after adjusting for age, sex, smoking, alcohol consumption and hepatitis B e antigen (HBeAg) serostatus[15]. Nevertheless, patients previously defined as "inactive carriers" (HBeAg negative, HBV DNA < 10000 copies/mL and normal liver function tests) have a 5-fold higher risk of developing HCC compared to HBsAg negative controls [16].

The integration of HBV DNA into the host genome represents a major pathogenetic pathway. The plasmid-like covalently closed circular DNA (cccDNA), derived from the conversion of HBV DNA soon after the entry into the hepatocyte, is recognized in the nucleus as a damaged product triggering DNA repair pathways such as the activation of cell cycle checkpoints and histone degradation, which enhances DNA recombination rates[17-19]. The integration of HBV DNA can also contribute to hepatocarcinogenesis by altering several cancer-relevant genes[20]. Viral promoter-driven human transcripts have also been identified adjacent to repetitive non-coding sequences, in particular long interspersed nuclear elements or short interspersed nuclear elements[20]. Evidence for fusion proteins have been collected for retinoic acid receptor-β and human cyclin A gene resulting in tumor-specific chimeric proteins endowed with pro-carcinogenic functions[21].

Despite this evidence, HBV integration is random and hardly ever leads to direct oncogene activation or tumor suppressor genes inactivation. However, it is widely accepted that integration contributes to hepatocytes genetic instability leading to clonal proliferation[22]; this can occur in HBV infected patients even before liver tissue damage is clinically evident[23].

Role of HBsAg

A study shows that the presence of HBV-DNA integration increases more than 100 times the risk for HCC occurrence among HBsAg carriers compared with HBsAg negative individuals[13]. HBsAg seems to have effects on the mitochondrial function, as it reduces the lipid b-oxidative activity of enoyl-coenzyme A hydratase short chain 1. On one hand, this interaction induces cell apoptosis by decreasing the mitochondrial membrane potential and reduces the phosphorylation of a serine/threonine protein kinase (Akt). On the other hand, it leads to an increased reactive oxygen species (ROS) production and promotes UDP-glucose ceramide glycosyltransferase which contributes to the alteration of ceramide metabolism[24]. Furthermore, HBsAg can inhibit jumping translocation breakpoints leading to increased cell motility and decreased apoptosis[13].

Table 2 Risk factors for hepatocellular carcinoma development[6,181-183]

Risk factors in hepatocellular carcinoma (other than liver cirrhosis)		OR (95%CI)
Strong risk factors (OR > 10)	**Europe**	
	Untreated chronic HBV/HCV hepatitis	191.0
	Untreated chronic HCV hepatitis	31.2
	Untreated chronic HBV hepatitis	18.8
	East Asia and Africa	
	Untreated chronic HBV/HCV hepatitis	75.6
	Untreated chronic HBV hepatitis	20.8
	Untreated chronic HCV hepatitis	11.5
Moderate risk factors (OR = 2-10)	Aflatoxin B1 exposure	5.9
	Untreated chronic HDV infection	3.9
	Diabetes	3.2
	Asian race	3.2
	Male gender	2.8
	Alcohol intake	2.3
	Severe iron overload	2.1
Weak risk factors (OR < 2)	Obesity (BMI > 30 kg/m^2)	1.9
	Mild iron overload	1.6
	Current smoking	1.6
	HCV genotype 1b	1.6
	PNPLA3 rs738409 single nucleotide polymorphism	1.4

HBV: Hepatitis B virus; HCV: Hepatitis C virus; HDV: Hepatitis D virus; OR: Odds ratio; CI: Confidence interval; BMI: Body mass index.

Role of HBeAg

The association between HBeAg and HCC has been well established by epidemiological studies although the pathophysiological mechanisms of HBeAg-mediated oncogenesis remain unknown. A large study investigates the effect of HBV replication on HCC development risk among 11893 Taiwanese men followed up for a mean of 8.5 years: The incidence rate of HCC is 1169 per 100000 person-years among HBsAg/HBeAg positive men, 324 per 100000 person-years for HBsAg positive HBeAg negative men and 39 per 100000 person-years among HBsAg negative men[25]. HBeAg enhances cell proliferation by means of promotion by a G1/S transition. Data suggests that miR-106b upregulation mediated by HBeAg is involved in the pathogenesis of HBV-related HCC by downregulating retinoblastoma (RB) gene[26].

Role of HBV preS/S proteins, oxidative stress and interaction with endoplasmic reticulum

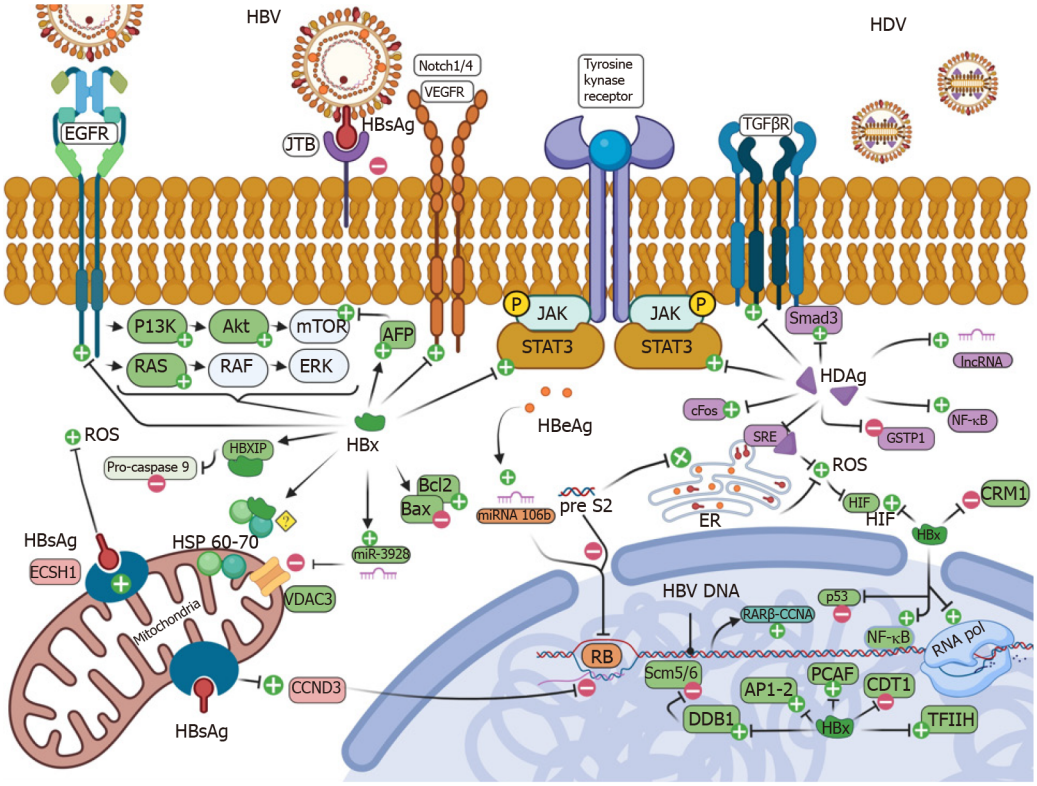
The preS/S open reading frame encodes three envelope proteins (S or HBsAg, M, and L proteins)[27]. Various specific mutations in the preS/S gene may imbalance surface proteins' synthesis and their consequent retention within hepatocytes' endoplasmic reticulum (ER)[13,28]. This process occurs mainly in the presence of HBsAg or pre-S2 mutants: The viral proteins amassed in the ER can lead to oxidative stress, stimulate cell growth and survival signaling pathways and cause mutation through the generation of free radicals. The induced ER stress upregulates the cytoplasmic cyclin A pathway promoting chromosome instability through centrosome over-duplication[29]. Moreover, pre-S2 mutant protein in hepatocytes can directly interact with the c-Jun activation domain-binding protein 1 inducing hyperphosphorylation of the RB tumor-suppressor and its inactivation[13,30].

Role of HBx protein

HBx is a 154 aminoacids long protein which is essential for the HBV viral life cycle. HBx is usually expressed at low levels during the first stages of infection but with the rise of HBV DNA integration frequency during infection, relative HBx expression can increase[31]. HBx is involved in multiple and complex molecular pathways linked to mitogen and apoptotic signaling cascades, resulting in one of the most relevant oncogenic proteins in HBV proteome. It does not interact directly with DNA, but rather it

Table 3 Molecular pathways of hepatocellular carcinoma carcinogenesis in hepatitis B virus infected patients

HBx related pathways
DNA repair impairment and DNA instability
HBx - binds to DDB1 - instability of Scm5/6 - impairment in DNA replication and repair
HBx - interacts with TFIIH - impairment in DNA replication and repair
HBx - blocks BER pathway - impairment in DNA repair
HBx - binds to CRM1 and sequestering it in cytoplasm - aberrant centrosome duplication and chromatin's segregation - chromosome instability
DNA replication increase
HBx - upregulates RLF and CDT1 and downregulates geminin - DNA replication
HBx - binds to cccDNA - recruiting PCAF - histone H3 acetylation - inhibition of chromatin's methylation - DNA replication
Cell cycle deregulation *via* signal pathways
HBx - binds to p53 - impaired function of p53 - cell cycle dysregulation
HBx - induces AFP expression - activation of PTEN and PI3K/mTOR pathway - cell cycle deregulation
HBx - activates Notch1 and Notch4 receptor - cell cycle progression
HBx - upregulates NF-kB, AP-1, AP-2, c-EBP, RNA-polymerase, ATF - altered oncogenes expression and cell cycle deregulation
HBx - upregulates NF-kB - upregulation of EGR1 - upregulation of miR-3928v - downregulation of $VDAC_3$ - tumor suppressor inhibition
HBx - downregulates SFRP1 and SFRP5 - DNMT1 recruitment - inhibition of WNT/β-catenin pathway - epithelial mesenchymal transition
Epigenetic modification impairment
HBx - interacts with MBD2 and CBP - P3 and P4 promoters' activation through hypomethylation - recruitment of IGF2 - oncogenesis
HBx - stimulates deacetylation of IGFBP3 gene - upregulation of IGF1 - mitogenic and anti-apoptotic effects
HBx - upregulates DNMT1 - hypermethylation of RASSF1A - tumor suppressor inhibition
HBx - downregulates DNMT3a/DNMT3L and recruits HDAC1 - hypomethylation of oncogenes promoters including JAK/STAT3 - impairment in cell differentiation
HBx - downregulates CD82, MTA1, PCDH10 through hypermethylation - tumor progression
HBx - inhibits CDH1 through deacetylation - E-cadherin upregulation - metastasis promotion
Apoptosis impairment
HBx - upregulates Bcl2 and Mcl1, inhibits Bax - apoptosis inhibition
HBx - upregulates Foxo4 - increased resistance to ROS damage, avoiding cell death and apoptosis
HBx - upregulates NF-kB - increase of DR5 - TRAIL induced apoptosis
HBx - inhibits caspase-8 inhibitor A 20 - TRAIL induced apoptosis
mi/lnc RNA related pathways
HBx - impairs miRNA regulation and synthesis - cell cycle deregulation
HBx - impairs lncRNA regulation and synthesis - cell cycle deregulation
Oxidative stress
HBx - downregulates NQO1 - mitochondrial injury - ROS production
C-terminal truncated HBx - mitochondrial DNA damage - ROS production
Neoangiogenesis
HBx - upregulates VEGF, HIF1 and ANG2 - neoangiogenesis
Unknown mechanism
HBx - binds to HSP60 and HSP70 - unknown function but involved in HCC carcinogenesis
Pre-S/S related pathways
pre-S2 - retention of HBV proteins in ER - ROS increase - cell DNA damages
pre-S2 - retention of HBV proteins in ER - upregulation of CCNA - chromosome instability and centrosome overduplication



pre-S2 - interacts with JAB1 - RB tumor suppressor inhibition
HBsAg related pathways
HBsAg - binds to ECHS1 - ROS increase - cell DNA damages
HBsAg - binds to JTB - decreased apoptosis and increased cell mobility
HBeAg related pathways
HBeAg - stimulates upregulation of miR-106b - RB tumor suppressor inhibition
HBV DNA related pathways
cccDNA - triggers DNA repair pathways - histone degradation and cell cycle checkpoints activation - enhanced DNA recombination rate
HBV DNA - genome integration - oncogene activation or tumor suppressor inhibition with evidence of fusion proteins
HBV DNA - genome integration - genetic instability - clonal proliferation
Inflammatory pathways
Increased cytokines production (TGF-β, IL-4, IL-10, IL-12, IL-13) - JAK/STAT3 activation - cell proliferation
CD4+ T follicular helper decrease - loss of growth inhibition and death control of cancer cells
CD8+ cell dysfunction - impaired growth inhibition and death control of cancer cells
Functional exhausted CD8+TIM-3+ T cells - increased viral replication - increased viral factors in HCC development
NK cells - increase in IL-4 and IL-13 - activation of HSCs - increased cytokines production - cell cycle deregulation
NK cells - miR-146a increase - reduced cytotoxicity and decreased IFN-γ production - reduction in immunosurveillance
Tregs - PD1 and CTLA4 overexpression - C
Gut microbiota-related pathways
HBV related dysbiosis - circulating LPS - TLR4 activation - cytokines production - JAK/STAT3 activation - cell proliferation

acts on cellular promoters, impairs DNA repair pathways, enhances DNA replication, alters epigenetic processing and inhibits apoptosis mechanisms. HBx effects are proven to contribute to HCC progression as well, by means of angiogenesis upregulation and stimulation of cell motility.

Some preclinical studies show that HBx interacts with cell cycle regulatory pathways activating a plethora of genes involved in mitogen signaling cascades and their downstream transcription factors, including, nuclear factor-κB (NF-κB), phosphatidylinositol 3-kinase (PI3K) and phosphatase and tensin homolog through upregulation of alpha-fetoprotein (AFP), Notch1 and Notch4, wingless-related integration site (WNT)/β-catenin signaling, activator protein 1 (AP-1), AP-2, CCAAT-enhancer-binding protein, RNA polymerase and nuclear factor of activated T cells. The activation of these pathways leads to altered expression of growth-control genes[32]. Other significant targets of HBx are the p53 family genes; The viral protein directly binds to p53 and impairs its function (p53-mediated apoptosis, p53-mediated transactivation properties and cell cycle regulation)[33].

In vitro studies have provided mechanistic insights towards the understanding of the role of HBx in HBV-mediated carcinogenesis showing an interesting effect on DNA replication. Indeed, HBx expressing cells exhibit increased DNA replication licensing factor, chromatin licensing and DNA replication factor 1, as well as reduced expression of geminin. The impairment in these molecules homeostatic balance leads to an increase in DNA replication[34]. Furthermore, HBx impairs DNA repair enzymes, interacting with transcription factor IIH, and deregulating all other proteins involved in the base excision repair pathway[32]. HBx is also involved in HBV transcription from cccDNA in the beginning and maintaining phase of viral replication. This leads to chromatin modulation and chromosomal instability because the HBx bond with cccDNA induces the recruitment of acetyltrans-

ferases P300/CREB-binding protein (CBP)-associated factor and acetylation of histone H3, inhibiting chromatin's methylation[35]. HBx seems to induce multipolar spindle formation, chromosome segregation defects and aberrant centrosome duplication, probably by sequestrating the nuclear transport receptor Chromosomal Maintenance 1 in the cytoplasm[36]. HBx binds to the HBx interacting protein regulating the centrosome duplication or to the UV-damaged DNA binding protein 1 that influences the stability of proteins such as the structural maintenance of chromosome proteins 5 and 6 complex which plays a role in nuclear DNA replication and repair[37,38].

In mitochondria, HBx binds heat shock proteins 60 and 70 (HSP60 and HSP70) and increased levels of the resulting complex have been found in HCC cells, even if the underlying carcinogenetic mechanism has not been understood yet[39]. HBx, through miR-3928v upregulation, downregulates voltage dependent anion channel 3 (VDAC3) expression in mitochondria leading to the loss of its tumor suppression activity[40].

The role of HBx on apoptosis has been controversial. On one hand, HBx upregulates B-cell lymphoma 2 (Bcl-2) and myeloid cell leukemia-1 that exert an anti-apoptotic role and downregulates Bcl-2-associated X protein, a cytosolic protein inducing apoptosis by its interaction with VDAC3 channels on the mitochondrial membrane. On the other hand, HBx stimulates apoptosis by increasing the cell surface concentration of death receptor 5 and inhibits caspase-8 inhibitor A20 that have central roles in tumor necrosis factor (TNF) α-related apoptosis-inducing ligand mediated apoptosis. Moreover, HBx increases resistance to apoptosis through the forkhead box protein 4 avoiding cell death primed by oxidative stress damage[32]. In addition, HBx controls hepatic angiogenesis, upregulating vascular endothelial growth factor (VEGF), hypoxia inducible factor 1 (HIF-1) and proangiogenic growth factor angiopoietin 2 (ANG2)[41].

HBx effects on DNA methylation and acetylation

DNA methylation and acetylation are two of the most studied epigenetic modifications and usually occur in the early stage of HCC development. The genomic hypomethylation/hypoacetylation increases chromosome instability while localized hypermethylation/hyperacetylation decreases the expression of

Table 4 Hepatocellular carcinoma surveillance in hepatitis B virus infected patients

HCC surveillance in HBV-infected patients		
Western medical societies		
EASL, 2017	High-risk-patients: (1) HBV cirrhotic patients; (2) HBV and F3 fibrosis; and (3) HBsAg-positive patient on NA treatment with a PAGE-B of ≥ 18 at the onset of therapy. Medium risk-patients: HBsAg-positive patient on NA treatment with a PAGE-B of 10 - 17 at the onset of therapy	Screening with US examination with or without AFP every 6 mo for medium and high-risk patients. No specific HCC screening needed for low-risk patients
AASLD, 2018	High-risk patients: (1) HBV cirrhotic patients; (2) Special population of HBsAg-positive adults: Asian or African men (> 40 yr) and Asian women (> 50 yr), first-degree family member with a history of HCC, HDV coinfected; and (3) HBsAg-positive children/adolescents with advanced F3 or cirrhosis and first-degree family member with HCC	Screening with US examination with or without AFP every 6 mo; if in areas where US is not readily available, screening with AFP every 6 mo
Eastern medical societies		
JSH, 2014-2021	Extremely-high-risk patients: HBV cirrhotic patients. High-risk patients: Special population of HBsAg positive patients: age ≥ 40, male, alcohol consumption, high HBV load, family history of HCC, HCV/HDV/HIV coinfection, F3 fibrosis, low platelet count associated with advanced fibrosis, genotype C, and core promoter mutation	Screening with US and tumor marker measurements (AFP, protein induced by vitamin K absence or antagonist-II and AFP-lectin fraction 3) every 3-4 mo in the super-high-risk population. A 6-12 mo dynamic CT scan or dynamic MRI should be performed. Screening every 6 mo in high-risk populations
APASL, 2016	High-risk patients: All patients with HBV-related cirrhosis. HBsAg-positive without cirrhosis, based on the economic situation of each country and on the available risk scores	Surveillance by US and AFP should be performed every 6 mo and preferably every 3-4 mo in cirrhotic patients and those at high risk of HCC
KLCSG, 2014-18	High-risk patients: HBV cirrhotic patients; chronic hepatitis B patients	Screening with US examination with or without AFP every 6 mo. If liver US cannot be performed properly, liver dynamic CT or dynamic contrast-enhanced MRI can be performed

HCC: Hepatocellular carcinoma; HBV: Hepatitis B virus; HCV: Hepatitis C virus; HDV: Hepatitis D virus; HIV: Human immunodeficiency virus; EASL: European Association for the Study of the Liver; AASLD: American Association for the Study of Liver Diseases; JSH: Japan Society of Hepatology; APASL: The Asian Pacific Association for the Study of the Liver; KLCSG: Korean Liver Cancer Study Group; US: Ultrasound; AFP: Alpha-fetoprotein; F3: Fibrosis; HBsAg: Hepatitis B virus surface antigen; CT: Computed tomography; MRI: Magnetic resonance imaging.

tumor suppressor genes[13]. DNA hypermethylation in the promoter region of specific oncosuppressor genes has been found in HBV-related HCC mainly due to HBx effect.

HBx upregulates DNA methyltransferases 1 (DNMT1) causing a hypermethylation of rat sarcoma (RAS) association domain family member 1 (RASSF1A), involved in cell cycle maintenance, altering its expression from the very early stages of HCC development[42]. On the contrary, the downregulation of DNA methyltransferases (DNMT) 3A and DNMT 3L and the recruitment of histone deacetylase 1 causes the hypomethylation of intragenic CpG islands resulting in dedifferentiation of liver cells[43]. The upregulation of methyl-CpG binding domain protein 2 and CBP triggers a molecular pathway leading to hypomethylation of promoters 3 (P3) and 4 (P4) of insulin-like growth factor 2 gene that stimulates cell duplication pathways as well as G1/S transition[44]. Hypomethylation has been found in the promoter region of Telomerase Reverse Transcriptase (TERT), increasing the proliferative potential of the cell, and in the promoter region of COX-2, leading to a proinflammatory condition[45]. Hypermethylation has also been found in a cluster of differentiation 82, a metastasis suppressor protein involved in the p53 pathway, metastasis-associated protein 1 and protocadherin 10. Deacetylation of Cadherin-1 promoter leads to E-cadherin upregulation and a progression to metastatic disease[32].

A growing number of studies identify and investigate the role of specific miRNA, small non-coding RNA molecules (up to 25 nucleotides in length) that regulate gene expression at transcriptional and post-transcriptional levels as mediators in the hepatocarcinogenic process. Recent publications, summarized by Sartorius *et al*[46] in a meta-analysis, have found miRNAs that are involved in HBV-related HCC leading to more aggressive cancer phenotypes by means of both tumor suppressor genes inactivation and oncogenes activation.

Role of occult HBV infection

Studies with highly sensitive polymerase chain reaction assays show that HBV DNA may persist in the liver of people who have serologic recovery from acute HBV infection, as an occult HBV infection. A systematic review identifies a modest association between occult HBV infection and the risk of HCC occurrence [risk ratio (RR) = 2.83][47]. Another case-control study performed in Hong Kong shows an increased prevalence of occult HBV infection in cryptogenic HCC[48]. None of these studies is population based and most of them have a small sample size. Thus, the association between HBV occult infection and HCC lacks convincing evidence.

Role of HBV genotypes

HCC is more common in patients with HBV genotype C, D and F than in those with genotype A[49].

The majority of retrospective and case-control studies indicate that patients with genotype C HBV have a more severe course of liver disease and a higher risk of HCC occurrence has been reported. A community-based Taiwanese cohort study shows that genotype C is associated with an increased risk of HCC in HBV carriers [hazard ratio (HR) = 2.35, 95% confidence interval (CI): 1.68-3.30, $P < 0.001$] as well [50]. The Eradicate-B study, by analyzing HBsAg positive patients without evidence of cirrhosis and a mean follow-up of 14.7 years, points out a higher annual incidence rate of HCC in genotype C than genotype B patients[51].

HBV genotype also influences the features of HCC. In genotype B patients, solitary HCC nodules are more frequent than in genotype C (94% *vs* 86%), but are more often associated with satellite nodules (22% *vs* 12%)[52]. Indeed, several reports show that HBV genotype type B is associated with a higher risk of HCC development in youth, whereas genotype C is associated with HCC development in the elderly[53]. Genotype D has been noticed to be prevalent in HCC patients younger than 40 years of age, as compared to other genotypes (63% *vs* 44%; $P = 0.06$). Furthermore, a study carried out among Alaska native HBV infected patients shows that the HCC is more prevalent in genotype F than other genotypes (OR= 7.73, 95%CI: 3.69-16.4, $P < 0.001$)[54]. Data about genotype E, endemic in Africa, are lacking and further studies are needed to outline the carcinogenic role of this genotype. Differently from HBV genotypes, the clinical significance of HBV subtypes is still unclear[55].

Role of HBV variants

Several mutations in the X gene of the HBV genome are frequently found in HBV mutants of individuals with HCC. Some studies show that 3′-end X gene is commonly deleted in HCC cells leading to a C-terminal truncated HBx protein that may have a key role in the carcinogenetic process[56]. In a Taiwanese cohort, genotype C shows a higher prevalence of BCP A1762T/G1764A variant than genotype B. Patients with BCP A1762T/G1764A variant have a higher risk of developing HCC and a long-term follow up study reveals BCP A1762T/G1764A variant as an independent predictor for progression to HCC[57]. Mutations in enhancer II (C1653T) and elsewhere in the basal core promoter (T1753V) have also been found to be associated with HCC development[57].

ENVIRONMENTAL FACTORS

Role of chronic inflammation

Chronic tissue inflammation plays a central part in oncogenesis through various complex mechanisms. In the liver, continuous inflammation and regeneration increases the risk of hepatocarcinogenesis. Cytokines production and inflammation-mediated alteration of key signaling pathways, such as signal transducer and activator of transcription 3 (STAT3) and NF-κB pathways, play an important role as well [13,58]. The most common immune alterations found during HBV infection are: Cytokines production [such as tumor growth factor (TGF-β), interleukin (IL)-4, IL-10, IL-12, IL-13], decreased CD4+ and CD8+ cells function, Treg cells dysfunction and innate immune response suppression[59].

CD4+ Th1 and CD8+ cells play an important role in cell cycle regulation and death control of cancer cells; thus, T cells dysfunction can lead to a higher risk of HCC development[60]. The impairment of HBV-specific CD8+ T cell functions in patients with chronic hepatitis B is mainly shown by the high expression levels of inhibitory receptors such as cytotoxic T-lymphocyte antigen 4, programmed cell death protein (PD) 1 and T cell immunoglobulin and mucin-domain containing (TIM) 3. CD8+TIM-3+ T cells are functionally exhausted because of the continuous immune activation and are unable to effectively produce cytokines and exert anti-viral activity[60]. Additionally, non-specific CD8+ T cells with memory phenotypes secrete interferon (IFN)-γ, recruiting hepatic macrophages which promote HCC through the secretion of TNF-α, IL-6 and Monocyte Chemoattractant Protein 1[61]. The frequency of circulating CD4+ T follicular helper cells decreases and their function results are impaired during disease progression in patients with HBV-related HCC; CD4+ cells infiltrate seems to be significantly reduced in HCC tumor regions compared to non-tumor regions[62].

Natural killer (NK) cells from HCC patients show significant increase in the expression of miR-146a which downregulates NK cell's function and leads to a decreased IFN-γ and TNF-α production. Activation of non-virus-specific cells may result in widespread inflammation promoting HCC development. NK cells promote hepatic stellate cells (HSCs) activation in liver fibrogenesis through the production of the inflammatory cytokines IL-4 and IL-13[63]. HSCs enhance the recruitment of regulatory T cells (Tregs) in the liver increasing the fibrotic processes and therefore hepatocarcinogenesis. Indeed, Tregs show enhanced suppressive function by PD-1 over-expression leading to a more immunosuppressive and exhausted cellular microenvironment in HBV-related HCC compared to non-virus-related HCC[64]. Thus, HBV-induced immune imbalance is a major risk factor in the pathway of HCC development.

Role of the gut microbiota

The link between the gut-liver axis and HCC has been studied in animal models as well as small cohorts of patients and is based on the theories that inflammation related to chronic liver disease causes

dysbiosis and intestinal barrier dysfunction. Translocation of bacterial products in portal and systemic circulation can trigger molecular pathways leading to inflammation, in particular lipopolysaccharide (LPS) from Gram-negative bacteria wall activates the Toll-like receptor (TLR) 4 causing an increase in inflammatory cytokines production. In turn, cytokines are linked to the activation of signaling pathways of cell proliferation, such as Janus kinase (JAK)/STAT3[65]. A well characterized pattern of inflammatory cytokines and chemokines has been associated with cirrhosis and HCC, characterized by increased plasmatic levels of IL-8, IL-13, C-C motif chemokine ligand (CCL) 3, CCL4 and CCL5[66]. This correlates alteration in gut microbiota with replication and immortalization of HCC cells. Indeed, several studies suggest that the gut microbiota might play a key role in the process. The inflammatory role of LPS is in fact mediated by TLR4; TLR4 knock-out mice show a much lower incidence of HCC [67]. Some other studies demonstrate that diethylnitrosamine (DEN)-exposed mice have an increased abundance of Gram-negative bacteria and therefore, of LPS (*Escherichia coli*, *Atopobium*, *Collinsella*, *Eggerthella* and *Coriobacterium)*[68]. High-dose probiotics administration in these animals is able not only to reverse dysbiosis but can reduce the number and size of cancer nodules as well.

There are limited studies comparing the gut microbiota of HBV-related HCC and non-HBV non-HCV-related HCC. A small Asian study enrolled 90 patients, divided in three groups: HBV-related HCC (B-HCC), non-HBV non-HCV-related HCC (NBNC-HCC) and healthy controls. The gut microbiota of B-HCC patients is more heterogeneous with higher bacterial alpha diversity indices, whereas, those of healthy controls and NBNC-HCC patients exhibits similar features. However, butyrate-producing bacteria (genus *Ruminococcus*, *Feacalibacterium*, *Clostridium*) present heterogeneity in B-HCC and NBNC-HCC in the study[69]. In addition, a set of *Bifidobacterium* species is found to mark predominant dysbiosis in HBV cirrhosis patients[70]. More studies are needed to clarify the possible oncogenic role of the gut microbiota related to HBV infection in the pathogenesis of HCC.

HCC surveillance in patients with chronic hepatitis B

Eastern and western hepatological societies have the difficult task of identifying patient populations at high risk for HCC occurrence, in whom clinical and radiological surveillance is mandatory (risk above threshold, usually cumulative incidence > 1.5% yearly) and other populations where there is no certain benefit in carrying out the surveillance programs (risk unknown or below threshold)[71]. Based on these considerations, surveillance must include patients affected by cirrhosis of all causes and a subset of non-cirrhotic HBV carriers (Table 4). HCC screening and surveillance is recommended by the American Association for the Study of Liver Diseases (AASLD) guidelines in patients with cirrhosis of any cause and non-cirrhotic HBV carriers at higher risk (*i.e.,* Asian men older than 40-years-old, Asian women older than 50-years-old, patients with a family history of HCC and African or North American Blacks of any age)[72,73]. The European Association for the Study of the Liver (EASL) guidelines also include non-cirrhotic patients with high or medium risk calculated with the PAGE-B score[74,75]. The Japan Society of Hepatology (JSH) differentiates ''extremely-high-risk patients'' (hepatitis B cirrhosis) in whom surveillance is recommended every 3-4 mo and ''high-risk patients'', in whom surveillance is recommended every 6 mo and ''risk factors other than hepatitis virus infection or liver cirrhosis'' in whom the benefits of surveillance are uncertain[76,77].

Risk scores

As individual HCC risk factors cannot adequately classify patients with chronic hepatitis B according to their HCC risk, several risk scores have been developed for those undergoing viral treatment with nucleotide analogues: CU-HCC, CAG-HCC, REACH-B, PAGE-B, modified PAGE-B (mPAGE-B)[78].

CU-HCC, GAG-HCC and REACH-B have been validated in a cohort of Asian patients with chronic hepatitis B, 22% of whom with cirrhosis, treated with entecavir (ETV): The 5-year HCC cumulative incidence rates were 12.9% in cirrhotic patients and 2.1% in non-cirrhotic ones while the accuracy of CU-HCC, GAG-HCC and REACH-B scores for HCC prediction at baseline was 0.8, 0.76 and 0.71, respectively[79]. Other studies confirmed an analogue predicting value of the REACH-B score in patients treated with tenofovir[80-82].

However, CU-HCC, GAG-HCC and REACH-B predictability is proven to be poor in Caucasian subjects with chronic hepatitis B. A large study including patients treated with ETV or tenofovir showed an accuracy of 0.66, 0.74 and 0.54, respectively[83]. Subsequently, Papatheodoridis *et al*[84] validated the PAGE-B score on 1815 Caucasians treated with ETV or tenofovir for at least 12 mo. The PAGE-B score had the advantage of including simple variables (platelets, age and gender) and was able to stratify the risk of HCC development within 5 years in: Low (0%), for PAGE-B score < 10; medium (4%), for PAGE-B score 10-17; or high (about 16%), for PAGE-B score > 17. Kim *et al*[85] developed the mPAGE-B score, adding serum albumin to the PAGE-B parameters, and validating the score on Asian populations. The mPAGE-B differentiated the 5-years HCC risk in low (< 8) or high (> 13). Therefore, the PAGE B score seems to perform with an adequate accuracy both in Caucasian and Asian chronic hepatitis B patients under the current oral antiviral drugs.

Novel biomarkers

Recently, the usefulness of two novel biomarkers, hepatitis B core-related antigen (HBcrAg) and

Table 5 Molecular pathways of hepatocellular carcinoma carcinogenesis in hepatitis D virus infected patients

Cell cycle deregulation *via* signal pathways
L-HDAg - Smad 3 activation - TGFβ upregulation - cells growth and dedifferentiation
L-HDAg - antagonizes c-Jun inhibitory effect over TGFβ - TGFβ upregulation - cells growth and epithelial-mesenchymal transition
L-HDAg - TNF-α stimulation - NF-κB activation - inflammation and proliferation
L-HDAg - activates STAT3 downstream protein - JAK/STAT pathway activation - cell growth
L-HDAg - stimulates c-Fos activation - cells growth and dedifferentiation
L-HDAg - downregulates GSTP1 - tumor oncosuppressor inhibition
Oxidative stress
L-HDAg - NF-κB and STAT3 activation - ROS production - DNA damage
L-HDAg - activates promoters of GRP78 and GRP94 - ROS production - DNA damage
L-HDAg - activates TGFβ1 - Nox4 activity - ROS production - DNA damage
S-HDAg and L-HDAg - increase in TRAF2 - inflammation and ROS production
S-HDAg and L-HDAg - bind to SRE - targeting proinflammatory genes - inflammation and ROS production
Epigenetic mechanisms
S-HDAg and L-HDAg - increased activity of histone acetyltransferases and CBP - histone H3 acetylation of clusterin promoter - increased clusterin expression - prolonged cell survival
S-HDAg - stimulates Histone H1e acetylation - clusterin promoter activation - prolonged cell survival
HDV - DNMT1 and 3b increased activity - tumor suppressor inhibition
S-HDAg and L-HDAg - hypermethylation of E2F1 promoter - cell cycle dysregulation

HDAg: Hepatitis D virus antigen; Smad3: Small mother against decapentaplegic 3; TGF: Transforming growth factor; TNF: Tumor necrosis factor; NF-kB: Nuclear factor-kappa B; GSTP: Glutathione S-transferase Pi; ROS: Reactive oxygen species; GRP: Gastrin releasing peptide; HDV: Hepatitis D virus; STAT3: Signal transducer and activator of transcription 3; SRE: Stress response element; Nox4: NADPH oxidase; TRAF: Tumor necrosis factor-receptor associated factor; CBP: CREB-binding protein; DNMT1: DNA methyltransferases 1; JAK: Janus kinase.

Wisteria floribunda agglutinin-positive Mac-2 binding protein (M2BPGi), has been evaluated for the prediction of HCC occurrence. HBcrAg is a novel biomarker of HCC occurrence and consists of three products of the precore/core gene: HBeAg, hepatitis B core antigen and p22cr, a 22kDa protein present in DNA-negative Dane-like particles. It is used in Japan to support HCC screening in patients with chronic hepatitis B. Serum HBcr levels correlate with HBV replication, serum HBV DNA, intrahepatic cccDNA levels and transcriptional activity. In a large cohort study, HBcrAg is proven to be superior to HBV DNA in predicting HCC development in treatment-naïve patients with chronic hepatitis B. Tseng *et al*[51] showed that HBcrAg level is an independent risk factor of HCC in individuals with chronic hepatitis B and intermediate viral load. Another cohort study suggests a correlation between M2BPGi, a serum glycoprotein-based biomarker (glycobiomarker), fibrosis (FIB) stage and HCC. In patients with cirrhosis M2BPGi serum levels > 1.8 cut-off index are associated with a higher risk of HCC development ($P < 0.001$). Although the area under the receiver operating characteristic curves for M2BPGi and AFP are similar in cirrhotic patients of all etiologies (0.77 *vs* 0.72; $P = 0.15$), M2BPGi outperforms AFP in chronic hepatitis B patients (0.84 *vs* 0.75; $P = 0.02$)[86]. Furthermore, M2BPGi serum level before receiving NA and 48 wk after the beginning of treatment is predictive of HCC occurrence.

The impact of therapies for chronic hepatitis B infection on HCC occurrence

Nowadays, only a few classes of drugs have been licensed and therefore approved for hepatitis B treatment: Nucleos(t)ide reverse transcriptase inhibitors (NRTIs) and IFN-α.

Lamivudine

Lamivudine (LAM) has been the first nucleoside analogue used for the treatment of chronic HBV infection. In an Asian study, the cumulative incidence of HCC is 3.9% in the LAM arm *vs* 7.4% in the placebo arm ($P = 0.047$), yet the clinical benefits on disease progression and HCC occurrence are lost when patients developed resistance (11% *vs* 5% placebo)[87]. A meta-analysis of 5 studies including 1267 patients treated with LAM compared with 1022 untreated patients demonstrates that HCC incidence is reduced by 78% (2.5% *vs* 11.7%, RR = 0.22; $P < 0.001$)[87,88]. Therefore, LAM treatment seems to reduce but not to eliminate the risk of HCC.

ETV and tenofovir

Second-generation NRTIs, ETV and tenofovir [tenofovir disoproxil fumarate (TDF) or tenofovir alafenamide), have a potent suppressive effect on the DNA synthesis mechanism during HBV replication, although they have poor effect on the intracellular concentration and activity of cccDNA, which persist for years in the infected liver due to the long half-life and the resistant molecular structure. In an Asian study, ETV treated patients have a 63% reduction in the incidence of HCC at 5 years compared to those not treated (3.7% *vs* 13.7%; $P < 0.001$)[89]. A Greek study followed 321 patients with chronic hepatitis B under ETV for 30 mo comparing them with 818 patients on LAM treatment; the cumulative HCC incidence in the ETV group is 4.8% *vs* 5.6% ($P = 0.096$)[49]. In another European multicenter cohort study after a median follow-up of 39 mo, HCC developed in 71 (4.3%) out of 1666 patients with chronic hepatitis B treated with ETV or TDF; the cumulative probability of HCC results 1.3% at the first year, 3.4% at the third year and 8.7% at the fifth year after the initiation of treatment [90]. ETV and tenofovir seem to improve liver FIB to prevent cirrhosis complications and to reduce, though not eliminate, the risk of HCC.

IFN-α

Patients with a clinical response to conventional IFN-α therapy schemes show a lower incidence of cirrhosis decompensation and a decrease in HCC occurrence with a better overall survival compared with non-responders. A recent meta-analysis of 14 trials suggests that pegylated-IFN facilitates HBsAg clearance or seroconversion in chronic hepatitis B patients[15,91]. In another study evaluating long-term outcomes of IFN-α therapy in HBeAg seropositive patients by comparing 233 patients undergoing IFN-based treatment with 233 matched controls, the cumulative HCC incidence at the end of 15 years of follow-up is 2.7% *vs* 12.5% ($P = 0.01$)[92]. Finally, a meta-analysis on 2742 subjects pooled from 12 studies also shows that IFN-α treatment reduces the risk of HCC occurrence by 34% (RR = 0.66, 95%CI: 0.48-0.89)[93].

HBV vaccines

HBV vaccination prevents children from becoming HBV carriers and reduces the incidence of HCC in vaccinated populations. In Taiwan, after a vaccination campaign, the average incidence of HCC in children (6 years to 14 years) fell from 0.70 per 100000 children in 1981-1986 to 0.57 in 1986-1990 and further to 0.36 in 1990-1994 ($P < 0.01$). Moreover, after the universal HBV immunization program in the 1990s, HCC incidence reduced from 0.293-0.117 per 100000 person-years[94]. Similar findings result from South Eastern Asian and Alaskan studies[95-97]. More than 70%-80% of HCC in all developing countries are linked to chronic hepatitis B infection so widespread vaccination is the most important step to prevent more than 500000 HCC cases per year worldwide[98].

HDV INFECTION AND HCC DEVELOPMENT

Epidemiology

Recent studies estimate that between 20 and 72 million people are infected with HDV[99]. Indeed, the precise global prevalence of HDV infection has remained unestablished due to the non-standardized screening programs in different nations and the inaccessibility to testing in most highly endemic areas [100,101]. In Western Europe, the prevalence of the infection has decreased in the last 20 years as a consequence of ameliorated socioeconomic conditions and national vaccination campaigns against HBV [102,103].

Chronic hepatitis D is considered the most severe form of chronic viral hepatitis leading to a rapid progression towards liver cirrhosis and a higher mortality rate compared to other types of viral hepatitis. More than 10% of chronically HDV infected patients develop liver cirrhosis within 5 years from infection and in 30 years, more than 80% of patients suffer from cirrhosis decompensation[104].

Molecular pathways and HCC development in chronic hepatitis D infection

Recent cohort studies have found a risk as much as nine times higher in HDV-infected patients compared to HBV monoinfected ones despite the common belief that HDV doesn't represent a certain major risk factor for HCC development[105,106]. Furthermore, persistent HDV replication has been proven to be a risk factor for liver disease progression to liver cirrhosis and HCC[107]. A study by the European Concerted Action on Viral Hepatitis demonstrates an increase of HCC occurrence by a factor of 3.2 in anti-HDV positive cirrhotic patients compared to negative ones[105]. Other recent studies show an increased risk of HCC for HDV/HBV coinfected patients than in HBV monoinfected ones (adjusted HR = 9.30)[108]. One large study estimates a risk of HCC occurrence significantly higher among patients with chronic HDV infection (RR = 3.9) than among those with HBV monoinfection[109]. On the contrary, an English retrospective study reports that despite the increasing prevalence of HDV infected patients in South London, liver cancer occurrence is only slightly increased between HBV monoinfected and HBV/HDV coinfected patients (OR = 1.34)[110].

In conclusion, recent findings identify HDV infection as a risk factor for HCC even if a direct oncogenic mechanism is unlikely. So, it is uncertain whether HDV adds oncogenic effects beyond those carried by chronic inflammation, FIB and cirrhosis. The genomic signature of HDV-related HCC has been poorly understood but several studies have pointed out some potential oncogenic mechanisms involving: Interference of HDV antigen (HDAg) in the cell cycle through STAT3 and cyclophilin, alteration of protein synthesis, oxidative stress as a result of severe inflammation, aberrant silencing of tumor suppressor genes by DNA methyltransferases and a possible epigenetic control on HBV transcription[5]. These mechanisms are summarized in Table 5 and Figure 1.

VIRAL FACTORS

Role of HDV replication levels

Even if HDV replicative activity has been related to a poor prognosis, it is still uncertain whether levels of HDV DNA increase the risk of HCC development. Some studies find no correlation between viral load and HCC occurrence in HDV infected patients while some others show an increased risk of cirrhosis complications in patients with a higher HDV viraemia[104]. Further investigations are needed to point out the role of HDV replication as a risk factor in liver oncogenesis.

Role of HDAg

HDAg expression alone does not appear to have oncogenic potential. Moreover, since high levels of antigen and viral RNA can lead to a cell cycle arrest in G1 phase, this mechanism can promote DNA damage and oncogenes mutation. L-HDAg plays a key role in HDV-related oncogenesis. It can stimulate inflammatory and cell growth pathways by enhancing TNF-α production and NF-kB upregulation triggering STAT3 downstream proteins in the JAK/STAT molecular signaling and recruiting small mothers against decapentaplegic (Smad) 3 protein, involved in TGF-β activation[104]. In a similar way, L-HDAg downregulates glutathione S-transferase pi 1 (GSTP1), a tumor suppressor, and antagonizes c-Jun, by neutralizing its inhibitory effect on TGF-β cascade[111]. HBx and L-HDAg can act synergistically on NF-kB and JAK/STAT regulation increasing each other's effect.

Oxidative stress

The severe inflammation occurring in HDV infection can by itself produce free radicals through NF-kB and STAT3 pathways. In addition, L-HDAg-induced TGF-β1 can activate NADPH oxidase (Nox) 4, resulting in a further ROS levels increase[111]. Either L-HDAg and S-HDAg bind to ER stress response element and stimulate an increase in TNF receptor-associated factor 2 targeting proinflammatory genes in the generation of oxygen-derived reactive products[112]. Furthermore, HDAg can stimulate the promoters of immunoglobulin protein gastrin releasing peptide (GRP)78 and GRP94 targeting inflammatory genes and upregulating ROS production[111]. Even if the damage carried to the host genome by HDV through oxidative stress is indirect, it represents one of the most important oncogenic effects of the virus. Novel therapies such as bulevirtide can stop this process by inhibiting viral replication and consequently virus-related inflammation and oxidative stress.

Epigenetic regulation and DNA methylation/acetylation

Both HBV and HDV-related HCC enhance oncogenes and inhibit tumor suppressor genes by epigenetic regulation mostly through DNMT1 and DNMT3b proteins involved in the maintenance of methylation patterns in the human genome. The molecular mechanism of DNMT1 deregulation in HDV infected patients has not been established yet, even if some studies identify STAT3 regulation over DNMTs protein as the culprit of DNA methylation impairment in HDV-related HCC[111].

Moreover, S and L-HDAg can increase E2F transcription factor 1 promoter leading to cell cycle deregulation (G2/M switch) and Nox4 activation[111]. HDAgs impair the DNA acetylation as well, mainly by the recruitment of histone acetyltransferases and P300/CBP[104]. Histone acetyltransferases increase clusterin expression and prolongs cellular survival through its antiapoptotic effect[43].

Potential role on HBV replication

An epigenetic control of HDV over HBV transcription and regulation has been postulated. There are some evidences that long-lasting active proliferation of both viruses can lead to more severe disease until HCC development[5,113].

ENVIRONMENTAL FACTORS

Potential role of inflammation

The histological examination of liver tissue of chronically HDV-infected patients shows an increase in

HDAg specific T CD4+ lymphocytes that rises gradually along the course of the infection. Recent findings suggest that hepatitis D is an immune-mediated disease and chronic immune activation may promote hepatocarcinogenesis[5].

PATHWAYS NEEDING FURTHER INVESTIGATION

Potential role of small and long non-coding RNAs

There is increasing interest in the study of non-coding RNAs including small non-coding RNA and long non-coding RNAs (lncRNAs). According to a recent study Y3 lncRNA results significantly downregulated in HDV-related HCC suggesting a possible role in the pathogenesis of HDV-related HCC[114].

Impact of therapies for chronic hepatitis D infection on HCC occurrence

Recent long-term studies point out that pegylated (PEG)-IFN treatment is independently associated with a better clinical outcome and a longer survival. A retrospective study shows a reduced rate of liver decompensation in PEG-IFNα treated patients without any difference in terms of HCC development. In addition, complete loss of HDV RNA reached with IFN-α therapy does not seem to reduce the HCC occurrence rate[5,115]. Whether PEG-IFN treatment can reduce the risk of HCC development in HDV infected patients is unknown and more studies are needed to clarify this point. Given the recent approval of bulevirtide, data on its effect on HCC occurrence is still lacking.

HCV INFECTION AND HCC DEVELOPMENT

Epidemiology

Global prevalence of HCV, based on detectability of anti-HCV antibodies, has been estimated to be 1.6% which corresponds to almost 115 million individuals[116]. The prevalence of viremic individuals is estimated at 1% or 71 million[117]. HCV seroprevalence varies across geographical regions and is highest in Central Asia, East Asia, North-Africa and the Middle East where more than 3.5% of the total population is affected[118]. Russia, Egypt, Nigeria, India, Pakistan and China account for more than 50% of the total viremic HCV infection[116,118] whereas Western countries contribute only a small percentage (seroprevalence < 1%)[119]. The number of HCV-related deaths due to liver cirrhosis decompensation or HCC has been increased from almost 900000 deaths in the 1990s to almost 1500000 deaths in the 2010s as the result of the high prevalence and the lack of therapies[120].

Molecular pathways and HCC development in chronic hepatitis C

HCV infection has been identified as one of the major risk factors for HCC development worldwide. Prospective studies show a 15-30-fold increased risk of HCC occurrence among chronically HCV infected patients compared with HCV negative ones. HCV genetic material doesn't integrate into the host genome; therefore, HCV needs continuous replication to maintain chronic infection. Despite this, HCV exerts indirect and direct effects on hepatocarcinogenesis. On one hand, the indirect effect is related to FIB and cirrhosis. The probability of HCC development rises with the stage of FIB and most of HCV-related HCCs occur in patients with advanced FIB or cirrhosis (annual rate up to 8%, average 1%-4%)[121]. On the other hand, viral factors such as HCV core protein, non-structural proteins, structural proteins and HCV genotypes and subtypes have a direct effect on the risk of HCC development through the modulation of hepatocytes gene expression. The multifaceted HCV infection effects on cells molecular pathways and microenvironment are summarized in Table 6 and Figure 2.

VIRAL FACTORS

Role of HCV core protein

HCV core protein presents a broad intracellular distribution in host cells suggesting a role in the modulation of multiple metabolic and replicative processes. Host proto-oncogenes and tumor-suppressors are direct targets of the HCV core protein which interact with tumor-suppressor proteins such as p53, p73 and RB, downregulating their functions. Interaction between p73 and the HCV core protein leads to inhibition of cell growth arrest mechanisms[122].

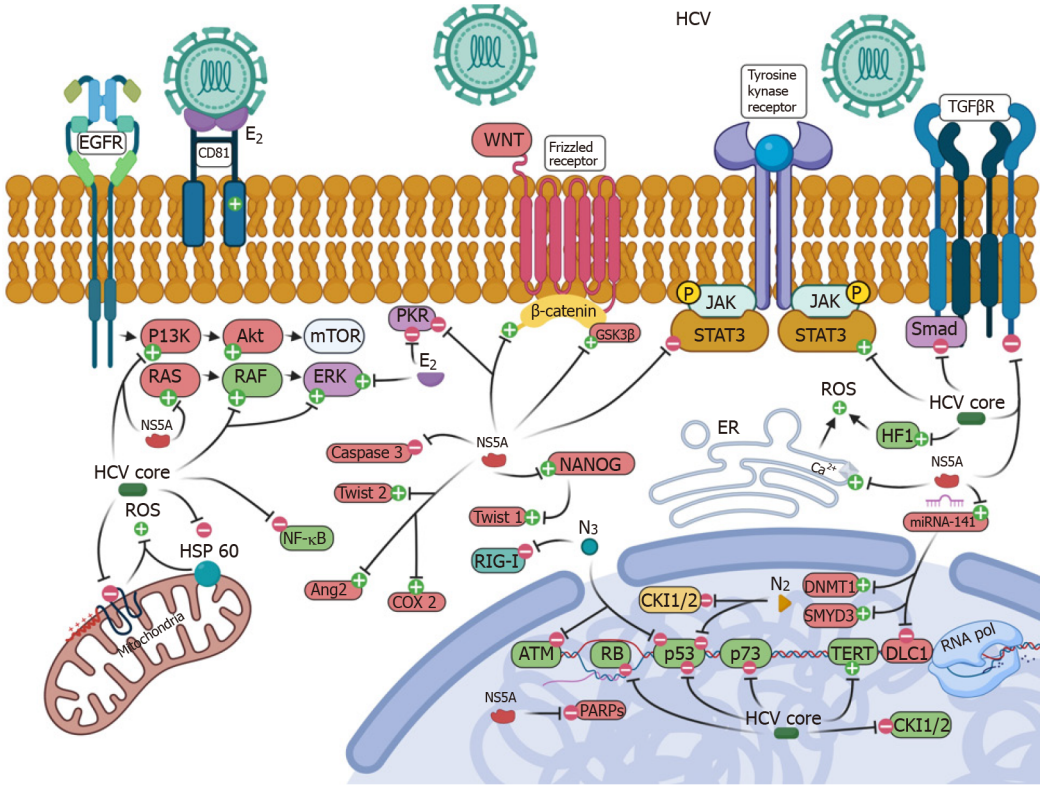
Moreover, increased TERT gene activity, typical of cells undergoing malignant transformation, is observed in primary human hepatocytes transfected with HCV core protein. TERT expression seems to be one of the earliest neoplastic events in HCC conferring an immortalized phenotype to transformed hepatocytes[123]. The HCV core protein inhibits the expression of the cyclin-dependent kinase inhibitor p21/WAF that has a role in the regulation of the cell cycle and in the induction of apoptosis. In a similar way, HCV core protein activates the rapidly accelerated fibrosarcoma 1/mitogen-activated protein

Table 6 Molecular pathways of hepatocellular carcinoma carcinogenesis in hepatitis C virus infected patients

HCV core protein-related pathways
Signaling pathways
HCV core protein - binds p53, p73 and RB - tumor suppressors inactivation
HCV core protein - increased TERT gene activity – oncogenesis
HCV core protein - induces expression of cyclin E/CDK2 - G1/S transition
HCV core protein - inhibits CKI1 - cell cycle deregulation
HCV core protein - induces RAF/MAPK pathway – oncogenesis
HCV core protein - inhibits E-cadherin expression and SFRP1 *via* histone modification - activation of WNT/β-catenin signaling - epithelial mesenchymal transition
HCV core protein - interacts with TBR1 - inhibit TGFβ signaling and prevent translocation of Smad - cell spreading, cell growth regulation
Oxidative stress and mitochondrial impairment
HCV core protein - impairs lipid β-oxidation - reduces mitochondrial electron transport chain - ROS production
HCV core protein - impairs mitophagy - mitochondrial damage - ROS production
HCV core protein -interacts with HSP60 - ROS production and inhibition of TNFα induced apoptosis
Angiogenesis
HCV core protein - stimulate an increasing in HIF1α and AP-1 - upregulation of VEGF expression - angiogenesis
HCV core protein - activates PI3K/Akt and JAK/STAT - AR activation - angiogenesis
HCV core protein - activates COX2, MMP-2 and MMP-9 – angiogenesis
Inflammation
HCV core protein - suppresses of NF-kB pathways - impaired immune response
HCV core protein - upregulates cytokines and deregulates HSCs activity - impaired immune response
E2 protein-related pathways
E2 protein - interacts with CD81 - impaired host immune system
E2 protein - activates MAPK/ERK pathway - promoting cell proliferation
E2 protein - inhibits PKR - inhibition of protein synthesis
NS2 protein-related pathways
NS2 - activates cyclinD/CDK4 - induces expression of cyclin E/CDK2 - G1/S transition
NS2 - binds p53 - tumor suppressors inactivation
NS3-related pathways
NS3 - inhibits p53 - tumor suppressor inactivation
NS3 - inhibits ATM - tumor suppressor inactivation
NS3 - suppresses of NF-kB pathways - impaired immune response
NS3 - blocks TLR3 and RIG-I - impaired immune response
NS5A-related pathways: Signaling pathways
NS5A - inhibits p53 - tumor suppression inactivation
NS5A - interacts with TGFBR1 - inhibit TGFβ signaling and prevent translocation of Smad 3/4 - cell spreading, cell growth regulation
NS5A - increases phosphorylation of GSK3β - activates β-catenin - upregulates c-Myc - cell growth
NS5A - activates Akt pathway – oncogenesis
NS5A - interacts with PI3K p85 subunit - upregulates cell survival cascade
NS5A - activates Twist 2 - epithelial mesenchymal transition
NS5A - activates RAS - enhance tumor cell invasiveness
NS5A - inhibits JAK/STAT pathway - blockage of IFN signaling

NS5A - inhibits PKR - inhibition of protein synthesis
NS5A - activates TLR4 - amplified NANOG - Twist 1 induction - oncogenesis and epithelial mesenchymal transition
NS5A-related pathways: Apoptosis
NS5A - inhibits TNFα mediated apoptosis - cell immortalization
NS5A - inactivates caspase 3 - inhibition of apoptosis
NS5A - inhibits proteolytic cleavage of death substrates (PARPs pathway) - impaired DNA repair and apoptosis
NS5A-related pathways: Oxidative stress
NS5A - induces of WNT/β-catenin signaling - upregulation of c-Myc - ROS production
NS5A - increases calcium release from ER - mitochondrial calcium uptake - ROS production
Epigenetic modifications
HCV - alters histone mark H3K27ac - TNFα and IL2 pathways - cell growth deregulation and epithelial mesenchymal transition
HCV - upregulates DNMT1 and SMYD3 - increased methylation of CDKN2A, GSTP1, APC, SOCS1, RASSF1A - tumor suppressors inhibition
HCV - increases miR-141 - inhibition of DLC1 - tumor suppressor inhibition
Inflammatory pathways
HCV - activates CCL20-CCR6 - endothelial cell invasion and angiogenesis
Switch from Th1 to Th2 - increasing in IL4-5-8-10 - loss of death control on cancer cells
Switch from Th1 to Th2 - decreasing in IL1-2-12-15 - loss of death control on cancer cells
Gut microbiota-related pathways
HCV-related dysbiosis - circulating LPS - TLR4 activation - cytokines production - JAK/STAT3 activation - cell proliferation

HCV: Hepatitis C virus; RB: Retinoblastoma; TERT: Telomerase reverse transcriptase; MAPK: Mitogen-activated protein kinase; SFRP: Secreted frizzled-related protein; WNT: Wingless-related integration site; TBR1: T-Box brain transcription factor 1; TGF: Transforming growth factor; Smad: Small mother against decapentaplegic; ROS: Reactive oxygen species; HSP60: Heat shock protein 60; TNF: Tumor necrosis factor; HIF: Hypoxia-inducible factor; AP-1: Activator protein 1; VEGF: Vascular-endothelial growth factor; PI3K: Phosphatidylinositol 3-kinase; MMP: Matrix metalloproteinase; NF-kB: Nuclear factor-kappa B; HSC: Hematopoietic stem cells; ATM: Ataxia telangiectasia mutated; TLR: Toll-like Receptor; RIG: Retinoic acid-inducible gene; TGFBR: Transforming growth factor beta receptor; GSK: Glycogen synthase kinase; RAS: Rat sarcoma virus gene; PKR: Protein kinase R; PARP: PolyADP-Ribose polymerase; IL: Interleukin; GSTP: Glutathione S-transferase Pi; DNMT1: DNA methyltransferase 1; SMYD: SET and MYND domain-containing proteins; APC: Adenomatous polyposis coli; SOCS1: Suppressor of cytokine signaling 1; RASSF1A: RAS Association Domain Family Protein 1A; DLC1: Deleted in liver cancer 1; LPS: Lipopolysaccharides; JAK: Janus kinase; STAT3: Signal transducer and activator of transcription 3; CCL: C-C motif chemokine ligand; PARPs: Poly(ADP-ribose) polymerases; CDK4: Cyclin-dependent kinase 4; COX2: Cyclooxygenase 2; RAF: Rapidly accelerated fibrosarcoma; ANG2: Angiopoietin 2; CCR: Chemokine receptor type.



kinase (MAPK) proto-oncogene pathway and nonspecific hepatitis-induced cell proliferation[124].

Furthermore, overexpression of the HCV core protein seems to be important for the regulation of epithelial mesenchymal transition (EMT) driving the activation of HSCs. The induction of EMT is mediated by the inhibition of E-cadherin expression and the induction of secreted frizzled-related protein 1 *via* DNA methylation and histone modifications. This pathway leads to activation of WNT/β-catenin signaling[123]. Finally, the HCV core protein can suppress NF-κB, impairing downstream immune response.

Indirect HCV core protein mediated damage is carried by oxidative stress through an impairment of lipid β-oxidation and alteration of intracellular lipid metabolism which is associated with a reduction of mitochondrial electron transport chain's function. This process induces further ROS production and regulates apoptosis through inhibition of the HSP60 leading to a TNF-α-mediated apoptosis. Recently, the HCV core protein has also been proven to impair mitophagy contributing to mitochondrial damage; the resulting oxidative stress has been identified as a key trigger of the hepatocarcinogenetic process [122]. Dysregulation in angiogenetic processes and upregulation of inflammatory pathways represent other targets of indirect damage mediated by the HCV core protein.

Role of other viral proteins

HCV-encoded proteins have been directly involved in the oncogenic process through interaction with several signaling pathways mainly in experimental animal models. The HCV E2 glycoprotein interacts with CD81, a cell surface marker of NK cells. This process leads to the alteration of cytokines production and dysregulation of cytotoxic granules release which impairs the host immune system[14]. In addition, E2 protein leads to MAPK/extracellular signal-regulated kinases pathway activation promoting cell proliferation and maintaining cell survival[125]. The NS2 protein can activate cyclin D/cyclin-dependent kinase 4 (CDK4) inducing cyclin E expression and stimulating cell cycle progression from G1

Figure 2 Molecular pathways in hepatitis C virus carcinogenesis. Created with BioRender.com. HCV: Hepatitis C virus; EGFR: Epidermal growth factor receptor; WNT: Wingless-related integration site; TGF: Transforming growth factor; PI3K: Phosphatidylinositol 3-kinase; Akt: AKT serine/threonine kinase; RAS: Rat sarcoma virus gene; RAF: Rapidly accelerated fibrosarcoma; mTOR: Mechanistic target of rapamycin kinase; JAK: Janus kinase; STAT3: Signal transducer and activator of transcription 3; Smad3: Mothers against decapentaplegic homolog 3; NS5A: Non-structural protein 5A; NF-kB: Nuclear factor-kappa B; ROS: Reactive oxygen species; RIG1: Retinoic acid-inducible gene 1; ERK: Extracellular signal-regulated kinases; NANOG: Nanog homeobox; ATM: Ataxia telangiectasia mutated; RB: Retinoblastoma; ER: Endoplasmic reticulum; DNMT1: DNA methyltransferase 1; TERT: Telomerase reverse transcriptase; DLC: Deleted in liver cancer; CK1/2: Casein kinase 1/2; GSK: Glycogen synthase kinase.

phase to S phase. NS2 protein is involved in HCC carcinogenesis through tumor suppressor inactivation of p53 and consequent transcriptional activation[126]. The NS3 protein is involved in tumor cell transformation, by loss of contact inhibition and growth anchorage, evasion of innate immunity, interaction with mitochondrial signaling protein, tumor suppressors inactivation (p53 and ataxia telangiectasia mutated kinase or ATM) and alteration of immunoregulatory pathways such as TLR3, retinoic acid-inducible gene I (RIG-I) and NF-κB pathways[127].

Similarly, the NS5A protein plays a role in cell cycle dysregulation through signaling pathways, immune escape, impairment of cell apoptosis and ROS production. NS5A is involved in proliferative pathways by the inactivation of p53, blockade of IFN signaling through JAK-STAT cascade and inhibition of host protein synthesis through protein kinase R (PKR)[126]. In addition, NS5A protein, like HCV core protein, can inhibit TGF-β signaling through interaction with T-box brain transcription factor 1 or direct binding to TGF-β receptor 1 and through prevention of translocation of Smad proteins[128]. On the other hand, NS5A interacts with the PI3K p85 regulatory subunit that regulates apoptotic activity of PI3K and upregulates cell survival cascade, activating Akt and Twist family BHLH transcription factor 2 pathways favoring EMT, and interacts with RAS oncogene to enhance tumor cell invasiveness[129]. NS5A stimulates TLR4 activation and its signaling through homeobox protein NANOG and consequent Twist 1 activation leading to hepatocytes dedifferentiation[126].

NS5A affects apoptosis trough downregulatory effect on TNFα-mediated apoptosis. It deactivates caspase-3 and inhibits proteolytic cleavage of death substrates known as polyADP-ribose polymerases, impairing PD cascade[126]. Moreover, HCV seems to enhance ROS formation and aberrant cell-cycle arrest due to DNA damage through dysregulation of ER-mediated calcium uptake and induction of glycogen synthase kinase 3β phosphorylation with consequent beta-catenin-dependent upregulation of c-Myc *via* NS5A[122]. Non-structural viral proteins, together with HCV core protein, play a key role in HCV mediated oncogenesis. Their multifaceted interaction with basic hepatocytes signaling pathways favors deep dysregulation of cells homeostasis and accumulation of DNA damage until malignant transformation.

Viral effect on angiogenesis

A higher vascular density has been reported in nodules of HCV-related HCC in relation to HCC nodules in patients affected by other liver diseases. Studies show upregulation of VEGF expression in patients with HCV-related HCC compared to the control group. HCV core protein can increase cellular VEGF expression through HIF-1α transcription factors and AP-1. Similarly, core protein can induce overexpression and stabilization of HIF-1α and ANG2 which upregulate VEGF expression[130]. Moreover, HCV core protein binds androgen receptor (AR), impairing transcriptional activity by activating several signaling pathways such as PI3K/Akt and JAK/STAT3. Since AR targets the VEGF gene in the liver tissue, HCV core protein upregulates VEGF expression through enhanced activity of the AR pathway[123].

Other mechanisms of HCV core-protein promoted angiogenesis and rely on upregulation of COX-2 and metalloproteinases 2 and 9 (MMP-2 and MMP-9)[126]. CCL20/C-C chemokine receptor type (CCR) 6 axis is directly involved in stimulating angiogenesis in the microenvironment of HCV-related HCC. *In vitro* experiments pointed out CCL20 as a direct promotor of angiogenesis inducing endothelial cells invasion and sprouting and migration of CCR6-positive leukocytes. A study demonstrates that HCV-induced CCL20 protein expression and secretion in hepatoma cells can be diminished and even abolished by means of antiviral treatment proving CCL20 expression to be dependent on HCV replication[131].

Role of epigenetic modifications

Epigenetic modifications in patients' liver tissue can derive both from infected hepatocytes and from virus-induced inflammatory or fibrotic responses in the cells' microenvironment. HCV-induced histone modifications and fibrogenesis are interdependent during the course of liver disease; epigenetic changes orchestrate fibrogenesis through the activation of HSCs. Specific epigenetic modifications have been identified in patients' liver tissue and humanized mouse's liver tissue where no necrotic nor inflammatory response are present, therefore, it is probable that part of the changes observed can be a direct consequence of HCV-hepatocyte interaction.

HCV upregulates methyltransferase DNMT1 that hypomethylates tumor suppressor genes such as Cyclin Dependent Kinase Inhibitor 2A, GSTP1, RUNX family transcription factor 3, suppressor of cytokine signaling 1 and RASSF1A[126]. In a similar way, an upregulation of "suppressor of variegation, enhancer of Zeste, trithorax" and myeloid nervy deaf 1 domain-containing protein 3, also named SMYD3, leads to a specific hypermethylation of histone marks H3K4 and H4K5 in tumor suppressor genes, such as RASSF1A[126].

A recent study shows that chronic HCV infection induces changes in histone mark H3K27ac which are associated with HCC risk and seem to persist after HCV cure[132]. H3K27ac is involved in pathways related to TNF-α, inflammatory response, IL-2 and activator of transcription 5 signaling. Furthermore, lower levels of H3K27ac can alter pathways associated with metabolism and coagulative cascade, such as oxidative phosphorylation, impaired fatty acid regulation or adipogenesis. Several alterations in these pathways (*e.g.*, epigenetic alteration in TNF-α signaling, G2M-checkpoint, epithelial-mesenchymal transition, PI3K, Akt and mTOR) persist even after direct-acting antiviral agents (DAAs) therapy[132].

Recently, several studies outlined the role of miRNAs-mediated epigenetic alterations in HCV-related carcinogenetic processes. One study examines the expression profiles of miRNA in more than 50 HCV-related HCCs by quantitative real-time polymerase chain reaction. Five miRNAs are examined: MiR-122, miR-100, and miR-10a seem to be upregulated, while miR-198 and miR-145 are downregulated up to 5-fold in tumors than in normal liver tissue[133]. MiR-122 is highly expressed in the liver of HCV-infected individuals due to its essential role in the stability and replication of HCV RNA[134]. Another study develops an *in vitro* model of HCV infection in primary human hepatocytes to evaluate the role of miRNAs; miR-141, which targets the tumor-suppressor gene Deleted in Liver Cancer (DLC)-1, is upregulated in HCV genotypes 1a-, 1b-, and 2a-infected cells. The rise in miR-141 levels in HCV-infected cells correlates with an inhibitory effect on DLC-1 protein and a subsequent increase in HCC development risk[122].

Role of HCV genotypes

HCV genotype 1b is associated with at least a doubled risk of HCC compared to other HCV genotypes [135,136]. HCV genotype 3 is considered a major risk factor for hepatic carcinogenesis. A multicenter Asian cohort study shows a 4.3-fold in the risk of HCC development in patients with chronic HCV genotype 3 infection compared to other genotypes[137]. Another Asian study shows a 5-year occurrence rate of HCC of 34% in genotype 3 and of 17% in non-genotype 3 groups, respectively (P = 0.002); in a multivariate analysis, HCV genotype 3 infection is independently associated with a rise of HCC occurrence rates (HR = 3.54), even after adjustment for confounding factors[138]. A further study finds an approximately doubled risk of all-cause mortality and HCC in patients with HCV genotype 3 infection, related to individuals infected with other genotypes[139]. However, the exact role of HCV genotypes in hepatocarcinogenesis processes and in the worsening of liver disease still needs to be established.

ENVIRONMENTAL FACTORS

Role of chronic inflammation and FIB

Most of HCV-related HCCs occur in cirrhotic livers following decades of chronic inflammation underscoring the key role of the virus-induced inflammatory response in the hepatic carcinogenetic processes. Generally, the inflammatory response is beneficial to the host, but in HCV patients innate and adaptive immunity result ineffective. This cycle can be primed by HCV proteins but host immune response tends to self-maintenance.

HCV interferes with various defense mechanisms; TLR3 and RIG-I gene downstream pathogen-recognition signaling pathways are blocked by the HCV protease NS3/4A; HCV proteins NS5A and core proteins can block IFN signaling interfering with JAK–STAT pathway; HCV proteins E2 and NS5A inhibit PKR, an antiviral effector that impairs protein synthesis of infected cells; HCV core protein stimulates the release of cytokines that can lead to a direct decrease in plasmacytoid dendritic cells levels among HCV-infected patients[140,141].

The persistence of chronic inflammatory response leads to the release of free radicals such as ROS and nitric oxide (NO)[142]. NO contributes to viral persistence leading to antiapoptotic effects in hepatocytes and may induce viral mutations and promote suppression of Th1 cells[143]. Also, it directly influences liver cell survival by preventing apoptosis through the activation of the NF-κB pathway. ROS induce modifications in structure and function of cancer-related proteins and genes including those fundamental for cell-cycle control, apoptosis, and DNA repair[144]. There is evidence that HCV-mediated inflammation is responsible for the promotion of hepatic carcinogenesis through oxidative DNA damage[145].

In patients affected by HCC, Th1 dominance is progressively lost due to an increase of Th2 cells[146]. Some studies typify the microenvironment of HCC metastatic phenotype as composed by a Th2-like cytokine profile, consisting in higher levels of IL-4, IL-8, IL-10 and IL-5, and lower levels of Th1-like cytokines as IL-1α, IL-1β, IL-2, IL-12p35, IL-12p40, IL-15, TNF-α and IFN-γ[147]. Moreover, the peripheral blood and the tumor tissue of HCC patients show an increased number of Tregs (with a positive direct correlation with HCV RNA levels). IL-10 seems to be highly expressed in HCC patients and its presence correlates with disease progression[148].

In conclusion, inadequate immune response is a necessary factor for hepatic cells transformation but not a sufficient one. It builds a favorable microenvironment in which all factors (etiology, genetic, epigenetic, humoral and cellular inflammation, chronic liver injury) contribute to the development of FIB and liver cells proliferation. These oncogenic factors promote DNA abnormalities that ultimately transform the hepatocytes into malignant cells.

Role of the gut microbiota

HCV-related cirrhosis is characterized by a disruption of the gut microbiota composition leading to an increased intestinal permeability and bacterial translocation. Compared to healthy individuals, bacterial alpha diversity seems to be lower in patients affected by chronic HCV infection with a reduction in bacteria of the order *Clostridiales* and an expansion in *Streptococcus species*. Gut dysbiosis begins to occur in the very early stages of the infection with the transient increase in *Bacteroidaceae* and *Enterobacteriaceae*. A decrease in the abundance of *Bifidobacteriaceae* and *Lactobacillaceae* with an increase of *Bacteroidaceae* and *Enterobacteriaceae* has been reported in the gut microbiota of patients with HCV-related HCC[149, 150]. Predicted metagenomics of microbial communities show an upregulation of urease gene, mainly encoded by *Streptococcus viridans* during chronic hepatic disease course, consistent with a significantly higher faecal pH than in healthy individuals[151]. A small study shows an increase in *Streptococcus salivarius* (*S. salivarius*) in oral and gut microbiota of patients with HCV-related HCC suggesting a possible role in oncogenesis. It has been noticed that *S. salivarius* impairs and deregulates the innate immune response of epithelial cells with a possible contribution in HCC progression[152].

DAAs treatment has proven to modulate the composition of the gut microbiota contributing to a decrease in inflammatory markers and liver stiffness but without effect on the gut barrier and its permeability. The eradication of the infection cannot resolve the intestinal dysfunction caused by liver cirrhosis but can improve the pre-existing dysbiosis[153]. Therefore, alterations of the gut microbiota may be focused as a predisposing factor for liver disease progression but further studies are necessary to establish its possible pathogenetic role in HCC development.

Role of host genetic factors

The genetic background of the host has a growing role in hepatic carcinogenesis. A systematic review found 16 genes associated with HCV-related HCC[154]. The polymorphisms identified in patients with HCV-related HCC involve genes encoding for: TGF-β1, TNF-α, mitochondrial aldehyde dehydrogenase enzyme 2, catalase, EGF, glutathione S-transferase mu 1 protein, glutathione S-transferase theta 1, HLA-Bw4, HLA-B1814 and HLA-DR11, HSPA1B, leptin receptor, IL-1b, a regulator of the p53 tumor suppressor named mouse double minute 2 homolog, UDP glucuronosyltransferase 1 family-polypeptide A7, manganese-dependent superoxide dismutase mitochondrial protein, IFN lambda 3 and lambda 4 cytokine, patatin-like phospholipase domain–containing protein 3 (PNPLA3) and MHC class I

polypeptide-related sequence A (MICA/HCP5)[154-156]. Nowadays, the genetic risk score, designed using the combination of four high risk variants in the PNPLA3, TM6SF2, MBOAT7, and Glucokinase Regulator GCKR genes, estimates the inherited predisposition to accumulate liver fat (Genetic Risk Score) and is reported as an independent risk factor for *de novo* occurrence of HCC after DAAs treatment [157].

HCC surveillance in patients with chronic hepatitis C

As already discussed, HCC surveillance in HCV-infected patients must include patients affected by cirrhosis of all causes and patients with chronic HCV infection with advanced liver FIB (Table 7). The AASLD and EASL practice guidelines recommend HCC screening and surveillance in patients with cirrhosis or with stage 3 FIB[73,75,158]. JSH still differentiates ''super-high-risk patients'' (hepatitis C cirrhosis) in whom surveillance is recommended every 3-4 mo and ''high-risk patients'', in whom surveillance is recommended every 6 mo[124].

The impact of chronic hepatitis C treatment on HCC occurrence

The utmost importance of viral clearance in the reduction of HCC occurrence among chronically HCV-infected patients has been largely established. Since the first studies on IFN-based therapy, HCC incidence shows a significant difference between patients with sustained virological response (SVR) and non-SVR patients (5.1% and 21.8%)[159]. A large meta-analysis including 31528 HCV-infected patients shows that SVR is a key factor in reducing the incidence of HCC (1.5% in SVR patients *vs* 6.2% in non-SVR patients at 3-8 years of follow up)[139,160].

PEG-IFNα

IFN-α was approved to treat HCV infection in the 1980s but its efficacy was limited (SVR rates 54%-56%). A meta-analysis of 8 long-term studies on 2649 patients with chronic hepatitis C demonstrates that HCC occurrence is significantly reduced in patients with SVR after IFN-based therapy compared to non-responder (4.2% *vs* 17.8%, HR = 0.23)[161]. The majority of the studies report that older ages, male gender, advanced liver FIB, fatty liver disease and a high post-treatment serum AFP level are the main risk factors for HCC development even after SVR[162].

DAAs

The perspective of HCV therapy has changed over the years after the introduction of DAAs therapy, which has increased the SVR rate up to 90%, with excellent tolerance compared to IFN-based regimens. Even if the therapies demonstrated high efficacy, two retrospective studies, published in 2016 and conducted respectively in Spain and Italy, supposed the existence of a higher risk of HCC occurrence and recurrence following DAAs treatment course, raising the debate about the safety profile of DAAs and, in particular, the relation between SVR with and HCC occurrence and recurrence[163]. The Spanish study registered a high recurrence rate of HCC (27.6%) among 58 patients with previous history of HCC who received DAAs[164]. In the Italian study, HCC was detected in 7.6% of patients following DAAs treatment, 28.81% of patients with and 3.16% of patients without previous HCC[165]. Furthermore, an unpredictable increase in the amount of advanced stage HCC was noticed by the same authors.

Later debates arose owing some possible biases in these studies (the small size of the cohorts, lack of untreated controls and short follow-up periods). Subsequently, further data from large real-world retrospective cohort studies with extended follow-up periods after DAAs treatment have been released. On the heels of the studies listed so far, in 2017 another meta-analysis conducted by Waziry *et al*[166] reported lack of a statistically significant increase in HCC recurrence or occurrences in either patients having undergone DAAs or IFN treatment after achieving SVR. Subsequently in 2017, a systematic review from Ioannou *et al*[167] including 62354 patients treated with DAAs, IFN or a combination of both showed no significant difference in HCC occurrence or recurrence between the three treatment regimens. In fact, SVR was associated with a 71% decrease in HCC occurrence risk with no particular differences between DAAs and IFNs. Nahon *et al*[168] enrolled 1270 HCV-infected patients with compensated cirrhosis in France, demonstrating that there wasn't any statistically significant increase in the risk of HCC occurrence following DAAs treatment (HR = 0.89), after adjustment for age, diabetes and reduced liver function. In 2018, another American study from Singer *et al*[169] showed that DAAs therapy was associated with a lower risk of HCC as compared to untreated patients (HR = 0.84) and to IFN based treatment (HR = 0.69). During the same year, an Italian study found that SVR after DAAs treatment led to a lower incidence rate of HCC in patients with HCV-related cirrhosis over a follow up of 14 mo[170]. At the end of 2018, another Italian review from Guarino *et al*[171] outlined that the alarmist data on HCC recurrence after DAAs treatment and more aggressive pattern of disease have not been confirmed by subsequent studies.

Recently, a French prospective cohort study on 9895 HCV-infected patients with a long term follow-up (mean 33.4 mo) reported that after adjusting for several variables (including non-modifiable risk factor as age, sex, geographical origin, HCV genotype and modifiable ones as FIB score, alcohol consumption, diabetes, arterial hypertension, and model for end-stage liver disease score in patients with cirrhosis), DAAs exposure decreased all-cause mortality (adjusted HR = 0.48) and the risk of HCC

Table 7 Hepatocellular carcinoma surveillance in hepatitis C virus infected patients

HCC surveillance in HCV infected patients		
Western medical societies		
EASL, 2018	High-risk patients: HCV-related cirrhosis. Chronic hepatitis C and stage	Screening with US examination with or without AFP every 6 mo for high-risk patients (incidence > 1.5%/yr)
AASLD, 2018	High-risk patients: HCV-related cirrhosis. Chronic hepatitis C and stage 3 fibrosis	Screening with US examination with or without AFP every 6 mo for high-risk group (incidence > 1.5%/yr)
Eastern medical societies		
JSH, 2017-2021	Extremely-high-risk patients: All patients with HCV-related cirrhosis. High-risk patients: Patients with chronic hepatitis C	Screening with US and tumor marker measurements (AFP, PIVKA-II and AFP-L3) every 3-4 mo in the super-high-risk population. A 6-12 mo dynamic CT scan, dynamic MRI should be performed or Sonazoid CEUS. Screening every 6 mo in high-risk populations
APASL, 2017	High-risk patients: All patients with HCV-related cirrhosis. SVR patients with chronic hepatitis C with advanced liver fibrosis, independently of the histologic response to therapy. SVR patients with chronic hepatitis C with any histologic stage of HCV with comorbidities, such as alcohol abuse and DM	Surveillance by US and AFP should be performed every 6 mo and preferably every 3-4 mo in cirrhotic patients and those at high risk of HCC
KLCSG, 2014-2018	High-risk patients: All patients with HCV-related cirrhosis. Patients with chronic hepatitis C and advanced fibrosis	Screening with US examination with or without AFP every 6 mo. If liver US cannot be performed properly, liver dynamic CT or dynamic contrast-enhanced MRI can be performed as an alternative

HCC: Hepatocellular carcinoma; HCV: Hepatitis C virus; US: Ultrasound; AFP: Alpha-fetoprotein; SVR: Sustained virological response; PIVKA-II: Protein induced vitamin K absence or antagonist-II; CEUS: Contrast enhanced ultrasound; CT: Computed tomography; MRI: Magnetic resonance imaging; EASL: European Association for the Study of the Liver; AASLD: American Association for the Study of Liver Diseases; JSH: Japan Society of Hepatology; APASL: The Asian Pacific Association for the Study of the Liver; KLCSG: Korean Liver Cancer Study Group.

development (adjusted HR = 0.66)[172]. Another large American retrospective cohort study concluded that DAAs treatment and SVR resulted in a significant benefit in overall mortality[173].

Watanabe *et al*[174] recognized FIB-4 index ≥ 4.0 and albumin ≤ 3.8 g/dL before DAAs therapy and a FIB-4 index ≥ 4.0 and AFP ≥ 6.0 after the end of DAAs therapy as independent predictors for HCC occurrence. Another study confirmed a linkage between the risk of HCC and persistently high FIB-4/[aminotransferase/platelet ratio index (APRI)], either with or without cirrhosis. HCC development risk shows a significative reduction in cirrhotic patients who showed a decrease of FIB-4/APRI scores after DAAs therapy[175].

In 2020, an Egyptian study designed with three large independent cohorts, enrolled 4400 patients with chronic hepatitis C and advanced FIB, and identified predictors of HCC development after DAAs treatment developing and validating a simple risk score (GES risk score). GES identifies three groups of patients with a different risk of HCC occurrence along the follow-up by means of simple and readily available predictors: Age, male gender, low albumin, high AFP levels and presence of cirrhosis at baseline. The cumulative incidence of HCC for GES low-risk group at 2 years was 1.2% in the derivation cohort and 0.22% in validation cohorts, while GES high-risk group showed a 6 to 30 folds higher risk, with a cumulative incidence of 7.1% and 6.1% in the derivation and validation cohorts, respectively. The study enrolled mostly genotype 4-infected patients thus further studies are needed to assess the utility of this score in clinical practice[176].

These data underline that the rise in HCC incidence suggested by the first studies in patients with HCV-related cirrhosis treated with DAAs who achieve SVR compared to those treated with IFN-based therapy may be due to confounders as patients features (age, diabetes, reduced liver function) and/or lower screening frequency. Therefore, DAAs treatment should not be withheld for the potential risk of HCC occurrence or recurrence. According to long-term post-SVR observational studies, HCC development risk remains high in patients with cirrhosis who eliminate HCV, although it is significantly reduced compared to untreated patients or patients not achieving SVR (10-year cumulative incidence rate 21.8% *vs* 5.1%)[139].

CLINICAL PRESENTATION OF HBV AND HCV-RELATED HCC: A COMPARISON

Several studies assessed the difference in clinical manifestation in HCC patients between different etiologies. Different HCC surveillance strategies need to be set according to the viral etiologies in relation to HCC age of presentation and clinical features. Two Italian studies noticed that HBV-infected patients are younger at HCC diagnosis, with a higher staging, increased probability of vascular invasion

and a worse prognosis[177]. An Asian study showed a peak incidence of HBV-related HCC in the 50-59 years old group whereas the peak annual incidence in HCV patients is over 70 years. In an HBV high endemic area, the outcome analysis of the study showed a reduced survival in HBV-related HCC compared to HCV-related HCC (1.34 years *vs* 2.17 years, adjusted for confounders). There was also a slight increase in frequency of large tumors (> 5 cm) and portal vein invasion at diagnosis in HBV-related HCC group, while multiple tumors occurred more frequently in HCV patients[178]. A cross sectional observational study from Pakistan, an HCV high endemic country, confirmed that HBV-related HCC patients were younger at presentation, but HCV-related HCC was larger, with higher AFP serum levels and more frequent vascular invasion at diagnosis[179]. Similar results were obtained in a large cohort including Asian and European patients[180-183]. These differences can be explained by the high prevalence of perinatal infections in high endemic areas and to the specific oncogenic potential of HBV. However, there was no difference in post-operative or post-treatment outcomes in the studies listed above between HBV and HCV-related HCC groups.

CONCLUSION

Chronic HBV- and HCV-related hepatitis are still pandemic, with an increased spread in low and middle-income continents, such as Asia and Africa. HBV- and HCV-infected patients have a higher oncogenic risk compared to other liver disease aetiology, mostly because of the interactions between viral proteome and transcriptome and host cells molecular pathways involving inflammation and cells replication. New data about gut-liver axis and systemic inflammation are pointing out their key role as a cofactor in hepatocarcinogenesis. Therefore, viral hepatitis B and C still represent a major public health problem worldwide although health organizations have made substantial efforts to contain their spread in recent years through the global HBV vaccination campaign and the widespread accessibility of DAAs for HCV. The broad availability of generic antivirals would allow low- and middle-income countries to strengthen their contribution to the HCV eradication program. In the meantime, one of the most important challenges is to adapt the timing of HCC surveillance in these patients with the aim of ensuring early diagnosis and rapid management to improve prognosis. In the era of coronavirus disease 2019, well-organized and accessible HCC surveillance becomes even more important due to the limited healthcare resources allocated to secondary prevention and the reluctance of patients to access healthcare facilities. In the future, new biomarkers and risk stratification systems may help clinicians to identify patients for closer follow-up leading to a more personalized approach to HCC surveillance.

Abstract

Biologics and immunomodulators (IMM) are generally considered the most effective therapies for the treatment of ulcerative colitis and Crohn's disease. However, despite the efficacy of these therapies, many patients either have a primary lack of response or a secondary loss of response to these medications. Therapeutic drug monitoring (TDM) is a systematic approach to managing such patients. In this review, we summarize the latest data on TDM, including reactive and proactive TDM, in patients with inflammatory bowel disease on biologics and/or IMM.

Key Words: Inflammatory bowel disease; Therapeutic drug monitoring; Crohn's disease; Ulcerative colitis

Core Tip: Inflammatory bowel disease (IBD), such as ulcerative colitis and Crohn's disease, are best treated with immunomodulators (IMM) or biologics. The rate of response clinically and endoscopically varies between the medications and within patient populations. Therapeutic drug monitoring (TDM) is a useful technique to assess drug and metabolite levels as well as anti-drug levels in patients on biologics or IMM in order to improve clinical outcome and prevent a multitude of complications. Here we discuss the role of TDM in patients with IBD with a focus on reactive *vs* proactive TDM.

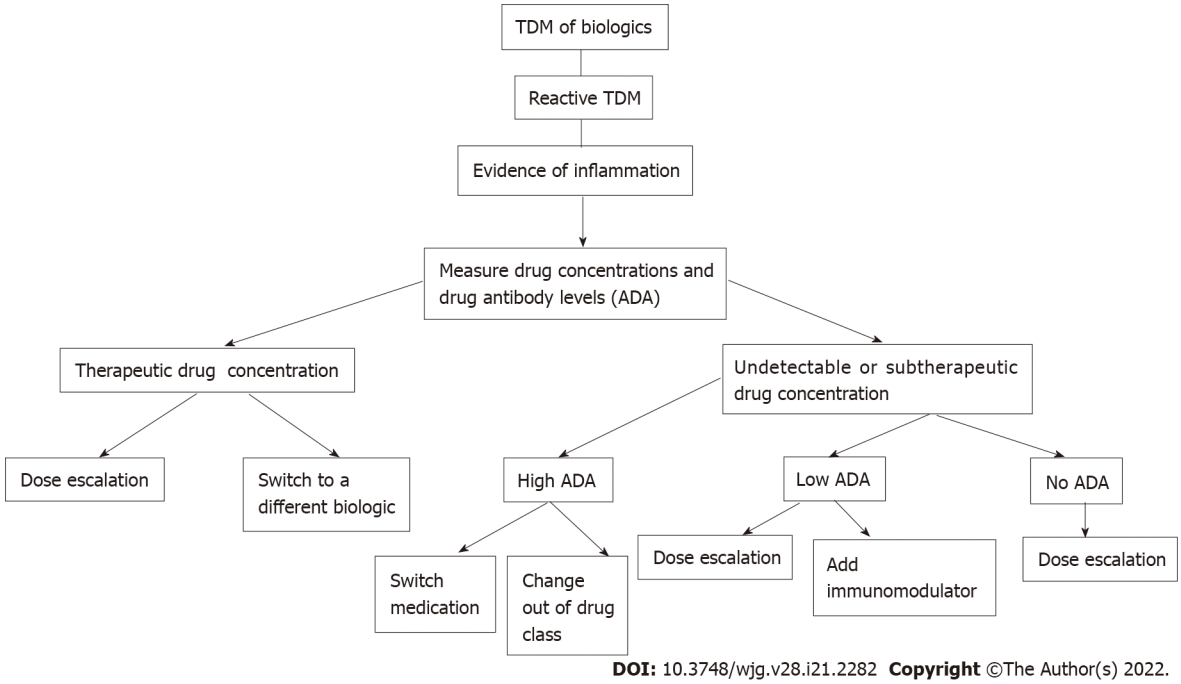
INTRODUCTION

Since the approval of the first biologic for inflammatory bowel disease (IBD) in the 1990s, treatment for IBD has evolved tremendously. In addition to tumor necrosis factor (TNF) inhibitors, thiopurines, natalizumab, vedolizumab, ustekinumab, and tofacitinib have all been approved for the treatment of IBD. Previously, patients were treated based on symptoms, but we have now discovered that utilizing more objective parameters such as clinical and endoscopic remission reduces complications and leads to better outcomes[1].

Despite having effective treatments for ulcerative colitis (UC) and Crohn's disease (CD), one-third of patients (primary non-responders) will not respond to induction therapy after a biologic. Risk factors for primary non-response include long duration of disease, smoking, extensive small bowel disease, a normal C-reactive protein (CRP) at the start of therapy, and previous exposure to a biologic agent[2].

Secondary loss of response occurs when a patient initially had response to therapy but lost that benefit over time. This can occur in up to 50% of patients and can lead to the need for either dose intensification, or the use of an alternate agent. The formation of anti-drug antibodies (ADA) and inadequate drug exposure are the main factors contributing to secondary loss of response in patients on biologic therapies[1].



Therapeutic drug monitoring (TDM) is a way to optimize the dose of biologics and immunomodulators (IMM) to optimize treatment outcomes. The levels or metabolites, as well as the development of antibodies, are used to help guide drug dosing in order to enhance drug efficacy and reduce disease complications[3]. Current AGA guidelines published in 2017 recommend reactive TDM for patients with active IBD. Reactive TDM occurs when dosing of a therapy is changed following either primary non-response or secondary loss of response. Proactive TDM involves routine monitoring of drug levels and antibodies at set intervals with dose adjustments based on drug levels. Many studies have shown that there is a correlation between positive clinical outcomes and therapeutic ranges of serum drug concentrations for each agent available to treat IBD[4]. This review aims to discuss TDM for biologics and thiopurines in treatment of active IBD.

TNF INHIBITORS

TNF inhibitors available for treating active IBD include infliximab, adalimumab, certolizumab, and golimumab. Studies have confirmed that there is a correlation between clinical response and drug concentrations of anti-TNF agents measured *via* serologic work-up.

Infliximab is a chimeric monoclonal anti-TNF agent approved for patients with active UC or CD. Studies have shown that higher infliximab concentrations lead to improved outcomes in patients with IBD. TAXIT, a prospective trial on patients with CD on infliximab, demonstrated a significant improvement in remission and lower rates of ADA with dose escalation[5]. The TAILORIX trial was a second prospective trial for patients with CD on infliximab that tried to assess whether increasing the dose of infliximab based upon a combination of symptoms, biomarkers, and serum drug concentrations leads to improved outcomes compared to dose intensification based purely upon symptoms. This trial did not reach its primary endpoint of sustained corticosteroid-free clinical remission from weeks 22 through 54[6]. However, a post-hoc analysis of the TAILORIX trial demonstrated that infliximab drug concentrations were higher in patients that achieved endoscopic remission by week 12 compared to patients who did not achieve remission, which supports TDM is beneficial for patients on infliximab[7]. Furthermore, the TAILORIX utilized an infliximab drug concentration of 3 μg/mL as a target, which is widely considered low based upon the results of several recent studies[8-11]. The low target infliximab level could have limited the efficacy analysis of TDM in the trial. Patients with UC on infliximab maintenance therapy were examined in a retrospective study that utilized TDM and endoscopic evaluation. This study was able to demonstrate that patients with endoscopic and histologic remission had significantly higher serum drug levels[12]. A cost-analysis performed on TDM for infliximab suggested that proactive TDM led to fewer flares than the reactive method, and that more patients remained on therapy with proactive TDM. Fewer flares paired with a reduction in the cost of infliximab over time suggests that proactive TDM may be more suitable for patients with IBD on biologic agents [13].

Adalimumab is a human monoclonal immunoglobulin G (IgG0 anti-TNF agent used for the treatment of active CD and UC. Numerous studies have demonstrated improved outcomes in patients with higher drug concentrations of adalimumab. Park *et al*[14] observed that higher serum drug levels of adalimumab were associated with more quiescent disease and normal CRP. The patients in this study also had higher rates of endoscopic and radiologic remission with higher serum concentrations of adalimumab. The POETIC study was a prospective study on patients with CD on adalimumab designed to evaluate the evolution of ADA over time, and its correlation with clinical outcomes. Many patients developed ADA as early as week 2, and the early development of antibodies correlated with primary non-response[15].

Figure 1 In-depth algorithm for reactive therapeutic drug monitoring. TDM: Therapeutic drug monitoring; ADA: Anti-drug antibodies.

Golimumab is a human IgG1 kappa monoclonal anti-TNF therapy for patients with UC, which was approved based on the results from the PURSUIT trial. In the PURSUIT trial, serum golimumab concentrations and ADA were measured during induction as well as through maintenance therapy. An exposure-response relationship was noted; patients receiving the lowest dose of the drug had a higher incidence of ADA, as well as a higher fecal calprotectin and serum CRP[16]. Another study was able to demonstrate a positive correlation between golimumab concentrations and clinical and endoscopic outcomes[17].

Certolizumab pegol is a PEGylated Fab' fragment of a humanized monoclonal antibody that binds to TNF. It is unique in that it lacks the Fc component that other TNF inhibitors have, making it incapable of fixing complement or binding Fc receptors[18]. Current studies show that higher certolizumab plasma concentrations lead to increased remission as well as decreased levels of CRP[19]. Patients with higher concentrations of certolizumab as early as week 2 had clinical remission by week 6 of induction, as well as continued positive outcomes during maintenance therapy[20].

VEDOLIZUMAB

Vedolizumab is a monoclonal antibody that binds $\alpha_4\beta_7$ integrin for the treatment of moderate-to-severe UC and CD. A post hoc analyses of the GEMINI data confirmed the relationship between higher vedolizumab exposure and clinical remission in patents with IBD. Both patients with UC and CD showed higher rates of remission at week 6 with higher drug concentrations, which correlated with clinical response and mucosal healing, thus confirming an exposure-efficacy relationship[21-23]. The LOVE-CD trial was a prospective trial in patients with active CD receiving vedolizumab that showed higher serum levels of vedolizumab correlated with higher rates of endoscopic and histologic remission at weeks 26 and 52[24]. One single-center, cross-sectional, retrospective study showed higher serum levels of vedolizumab correlated with lower CRP levels. However, this study failed to demonstrate a correlation between vedolizumab concentrations and mucosal healing[25]. Notably, the rate of ADA to vedolizumab seems to be relatively low[25,26].

USTEKINUMAB

Ustekinumab is a human monoclonal antibody that binds to the p40 subunit of interleukin (IL)-12 and IL-23, thus preventing the interaction with the cell surface IL-12RB1 receptor. This prevents IL-12 and IL-23 mediated cell signaling[27]. The efficacy of ustekinumab for the treatment of moderate to severe CD was demonstrated in the UNITI-1 and UNITI-2 studies[28]. An analysis of data from phase 3 studies of patients with active CD on ustekinumab demonstrated a dose response. Drug serum concentrations

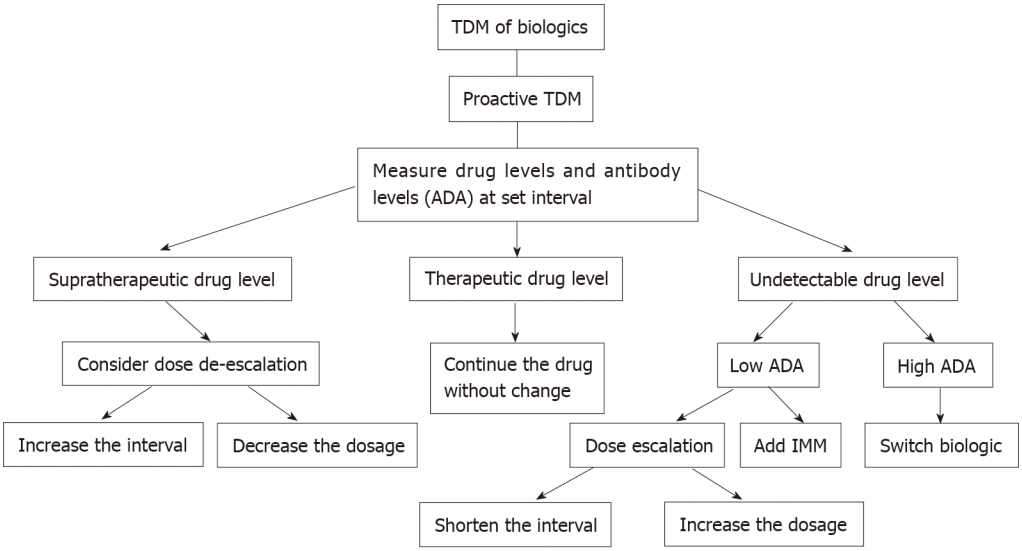
were positively associated with clinical remission and endoscopic improvement at week 44; there was also an inverse association with the CRP level. IMM were not found to have a significant effect on the serum concentration of ustekinumab[29,30]. The available data also suggest an extremely low rate of antibody formation in ustekinumab[28,29].

THIOPURINES

IMM, including azathioprine (AZA) and 6-mercaptopurine (6-MP) have been used for the treatment of IBD for many years. AZA is converted to 6-MP using a non-enzymatic pathway. 6-MP is broken down in three different ways: Into 6-thiouric acid by xanthine oxidase, activated to 6-methyl-mercaptopurine (6-MMP) by thiopurine methyltransferase (TPMT), or to 6-thioguanine dehydrogenase (6-TGN) by three different enzymes. TPMT has variants that can lead to a reduction in activity, therefore patients should have their TPMT phenotype checked prior to use. Once a thiopurine has been added to a regimen, thiopurine metabolites should be assessed, as patients have better outcomes with higher 6-TGN levels and lower 6-MMP levels[31]. Thiopurines play a role in reducing the risk of antibody formation, particularly to TNF inhibitors A study on patients with multiple different autoimmune diseases showed a reduction in ADA with the use of supplemental immunosuppressants[32].

The SONIC study is a landmark prospective trial that showed a combination therapy of AZA and infliximab for CD was more effective than infliximab monotherapy in induction and maintenance of steroid-free clinical remission at 26 and 52 wk. Combination therapy also led to lower rates of antibodies to infliximab and higher serum drug concentrations[33].

THE TRANSIENT NATURE OF SOME ADA



Although the formation of ADA can correlate to poor clinical outcomes, ADA levels may sometimes be transient[34,35]. Low levels of ADA may be overcome with higher serum drug concentrations and the addition of immunomodulators. However, if patients have sustained elevated levels of ADA, permanent loss of response is more likely to occur[36]. A small retrospective analysis of 5 patients investigated the addition of immunomodulators (thiopurines and methotrexate) to patients after the development of ADA to infliximab. All five patients had restoration of clinical response, and ADA levels gradually diminished over time[37]. It will be important for the future of IBD therapy to understand the role ADA formation plays in loss of response in patients on biologics, and the benefit of immunomodulators to recapturing response.

REACTIVE TDM

Reactive TDM is the current standard of care when treating IBD patients who have a loss of response to biologic therapy[4]. This approach can identify the subset of patients that would benefit from dose escalation of their current agent *vs* transitioning to a different therapy. Once a patient has a flare of their symptoms, drug concentrations and ADA levels are measured, and further management is based upon these results (Figure 1). A retrospective study of patients with suspected loss of response was performed that determined that the measurement of trough levels of anti-TNF agents or ADAs during a suspected loss of response led to improved interventions. Patients with high ADA levels benefited more from switching agents than from dose escalation, whereas patients with no or low ADA levels did benefit from dose intensification. This study also demonstrated that patients with adequate levels of infliximab or adalimumab with inadequate response would benefit from an agent that is out of the anti-TNF class [38]. A retrospective analysis of patients receiving infliximab who underwent dose escalation was examined, and clinical decisions with or without the use of TDM were compared. Patients for whom decisions were based upon TDM had improved endoscopic outcomes, higher rates of clinical remission, fewer hospitalizations, and less steroid use[39]. Reactive TDM has the benefit of cost savings, as less drug can be utilized, as well as the ability to try to optimize drug levels and increase the chance of recapturing response in order to prevent treatment failure[7].

PROACTIVE TDM

Proactive TDM differs from reactive TDM in that it aims to optimize drug concentrations by measuring serum drug concentrations and ADA levels at set intervals in order to prevent loss of response (Figure 2). Since the best therapeutic effect is obtained with the first biologic agent received, proponents of this approach consider it imperative to optimize the dose of the agent early in the treatment course

[40].

Fernandes *et al*[41] demonstrated in a prospective study on patients on infliximab therapy with CD and UC that proactive TDM had better outcomes than management without the use of TDM. Patients on infliximab underwent trough and ADA level measurements before the fourth infusion and at every 2 infusions, and dose-adjustment was made in order to keep a goal trough level between 3 and 7 μg/mL for CD and 5 and 10 μg/mL for UC. Compared to a retrospective cohort treated with infliximab without the use of TDM, the TDM group showed improved mucosal healing, fewer surgeries and hospitalizations, and less treatment discontinuation. A randomized, controlled trial of children with CD, the PAILOT trial, investigated proactive TDM *vs* reactive TDM. The primary endpoint was corticosteroid-free remission on adalimumab therapy. The results showed significantly higher rates of steroid-free remission in patients receiving proactive TDM than reactive TDM, as 31 children (82%) in the proactive group reached the primary endpoint, meanwhile 19 children (48%) reached the endpoint using reactive TDM[42]. Papamichael *et al*[43] performed a multicenter, retrospective study on patients receiving infliximab therapy for IBD. Proactive TDM had better clinical outcomes when compared to reactive TDM, including fewer surgeries, hospitalizations, lower ADA levels, longer time to treatment failure[44-46]. Much of the current data for TDM seems to demonstrate that proactive TDM leads to better clinical outcomes compared to reactive TDM. However, a universal analysis on cost-effectiveness is much more difficult given varying degrees of coverage on biologics and TDM assays[47,48].

IMMUNOASSAY METHODS FOR THE DETECTION OF ANTIBODIES

Although it is well known that patients with inflammatory bowel disease are at risk of developing antibodies to biologics, more attention should be paid toward the optimal methodology used to detect these antibodies. The various immunoassay methods for detection of drug antibodies are suspected to yield varying results when assessing immunogenicity of biologics due to the presence of drug and the potential underestimation of ADA[49]. Drug interference limits the detection of ADA due to the formation of ADA-drug complexes in the assay. Drug tolerant assays were developed that can detect free ADA and ADA bound in a complex. This assay can dissociate the ADA from the drug to estimate the quantity of ADA more accurately in a sample. Drug-sensitive antibody detection methods such as the antibody binding test (ABT) and bridging enzyme-linked immunosorbent assay (ELISA) preceded the drug-tolerant assays[50].

A study by Ruwaard *et al*[49] compared the efficacy of three different immunoassays to detect ADA, including ABT, ELISA, and drug-tolerant assays in 86 patients on adalimumab. There was a significant difference in the ability to detect ADA between the assays, with drug-tolerant assays detecting ADA in 69% of patients, compared to 30% in the ABT, and 2% using the ELISA. This suggests that drug-tolerant assays should be the standard when detecting ADA in patients on adalimumab. A study by Wang *et al* [50] compared ELISA to a drug tolerant assay, the homogenous mobility shift assay (HMSA), in patients treated with infliximab. This study illustrated that the HMSA was significantly more sensitive in detecting ADA, especially in the presence of high serum drug concentrations. HMSA can overcome artifacts encountered using drug-sensitive assays, as it can dissociate the ADA from the drug. These

studies suggest that future studies should consider using drug-tolerant assays as their method of detecting ADA to standardize the methodology and prevent inconsistent results between different studies.

It is still well-known that ADA formation leads to lower drug concentrations and worse outcomes in patients with IBD on biologics. The data suggest that drug-tolerant assays are ideal for detection of ADA in patients on adalimumab and infliximab. Standardization in detection of ADA would improve the variability amongst studies, thus improving clinicians' ability to use and perform TDM. Unfortunately, the available data focus on TNF inhibitors, and the applicability to non-TNF inhibitor biologics is limited. Further studies with inclusion of all biologics could help lead to implementation of international standards and improve our understanding on the impact of ADA on clinical outcomes[51].

CONCLUSION

TDM plays an important role in treatment outcomes for patients with IBD on biologic agents. TDM is useful for predicting loss of response and preventing treatment failure. Higher serum drug concentrations lead to improved outcomes, with fewer hospitalizations, surgeries, and treatment failures. Lower serum drug concentrations and the development of ADA lead to worse outcomes and loss of response. The addition of immunomodulators has not been standardized, but studies have shown that the addition of an immunomodulator to TNF inhibitors can lead to a reduction in the development of ADA as well as higher serum drug concentrations, thus eliminating the potential for failure of an agent.

Despite a multitude of studies, there are still limitations regarding the use of TDM in IBD patients. There is likely a fair amount of inter-individual variation regarding the appropriate serum concentration of various biologics, and the optimal target levels have therefore not been fully elucidated. Similarly, further research needs to be done regarding the significance of different levels of ADA. Different serum concentration and ADA assays can also complicate our interpretation of these values. Finally, analyses regarding cost-effectiveness of reactive *vs* proactive TDM in the setting of a variety of different health care settings are difficult to conduct.

Abstract

Clinical manifestations and progression of primary sclerosing cholangitis (PSC) are heterogeneous, and its pathogenesis is poorly understood. The importance of gut-liver interactions in the pathogenesis has been clinically confirmed and highlighted in different theories. Recent advances regarding biomarkers of biliary-gut crosstalk may help to identify clinically relevant PSC subgroups assisting everyday clinical work-up (*e.g.*, diagnosis, disease stratification, or surveillance) and the exploration of potential therapeutic targets. Alkaline phosphatase produced by the biliary epithelium is consistently associated with prognosis. However, its level shows natural fluctuation limiting its use in individual patients. Inflammatory, cell activation, and tissue remodeling markers have been reported to predict clinical outcome. Elevated immunoglobulin (Ig) G4 level is associated with a shorter transplantation-free survival. IgG type atypical perinuclear anti-neutrophil cytoplasmic antibodies (P-ANCAs) are non-specific markers of various autoimmune liver diseases and may reflect an abnormal B-cell response to gut microbial antigens. IgG type atypical P-ANCA identifies PSC

patients with particular clinical and genetic (for human leukocyte antigens) characteristics. The presence of IgA type anti-F-actin antibody (AAA) may predict a progressive disease course, and it is associated with enhanced mucosal immune response to various microbial antigens and enterocyte damage. IgA type anti-glycoprotein 2 (GP2) antibodies identify patients with a severe disease phenotype and poor survival due to enhanced fibrogenesis or development of cholangiocarcinoma. Elevated soluble vascular adhesion protein-1 (sVAP-1) level is associated with adverse disease outcomes in PSC. High sVAP-1 levels correlate with mucosal addressin cell adhesion molecule-1 (MAdCAM-1) expression in the liver that contributes to gut activated T-cell homing to the hepatobiliary tract. In the present paper, we review the evidence on these possible serological markers that could potentially help address the unmet clinical needs in PSC.

Core Tip: Recent advances in biomarker research may help clinicians identify relevant subgroups of primary sclerosing cholangitis (PSC) and assist everyday clinical work-up. However, a diagnostic biomarker is still an unmet need. On the other hand, several biomarkers have been reported to predict outcome in PSC; however, most of them have not been validated by subsequent studies. The IgA type anti-glycoprotein 2 antibody is the first one to be supported by a satisfactory number of clinical studies and could be incorporated into clinical practice. These discoveries also reveal different aspects of PSC providing with potential therapeutic targets.

INTRODUCTION

Primary sclerosing cholangitis (PSC) is a chronic and progressive inflammatory disease of the bile ducts, leading to the formation of intermitting bile duct strictures and dilatations, with periductal fibrosis that in most cases progresses to cirrhosis and decompensated disease stage. Moreover, PSC is associated with the development of cholangiocarcinoma (CCA) and colorectal cancer[1]. The etiology of PSC is poorly understood. However, the gut-liver interaction seems to be a driving factor in its development. It has been hypothesized that the interaction of the gut microbiome and certain genetically determined factors [such as certain human leukocyte antigens (HLA)] leads to the development of disrupted immunological pathways, as a result of an autoimmune reaction to yet unknown antigen(s). Most abnormalities discovered by genetic studies support a disruption of T cell functions. Gut-derived antigens significantly induce antigen presentation by major histocompatibility complexes (MHCs) on the surface of antigen-presenting cells to T cells, which, following clonal expansion, can be delivered to both the intestinal tract and the liver[2]. Abnormal T cell activation results in increased release of various cytokines [such as transforming growth factor-β (TGF-β)] involved in the development of fibrosis. Activation of B cells is indicated by the frequent appearance of bacterial translocation (BT) related serological antibodies [*e.g.*, anti-neutrophil cytoplasmic antibodies (ANCAs)].

The diagnosis of PSC is difficult, and no biomarker specific to the disease has been identified so far. In the presence of chronic cholestasis, the diagnosis is based on magnetic resonance cholangiography (MRCP) or, much less frequently today, endoscopic retrograde cholangiopancreatography (ERCP) with confirmation of biliary lesions and strictures. Careful exclusion of known causes of secondary sclerosing cholangitis (SSC) is also necessary. Immunoglobulin (Ig) G elevation and the presence of atypical perinuclear ANCA (P-ANCA) in serum are common but are not disease-specific serological alterations [3]. Routine liver biopsy is no longer routinely performed in the diagnosis of PSC and is only necessary in suspected cases of small duct PSC, when the cholangiogram is normal, or to confirm overlap syndrome with autoimmune hepatitis.

The disease course of PSC is variable. There are a few promising biomarkers to predict disease activity and progression, yet almost none has been validated in subsequent studies. A recently discovered serological biomarker [IgA type antibodies against pancreatic glycoprotein 2 (anti-GP2 IgA)] [4,5] is the first that has predictive value in PSC confirmed in multiple studies[6,7]. However, it has not

been integrated into clinical practice. Consequently, the question of accurate risk assessment, disease stratification, and follow-up strategy for patients with PSC is still unresolved[8].

Studying biomarkers characterizing the dialogue between the biliary tract and the intestine in PSC may not only identify clinically relevant subgroups for disease stratification, but can also unravel new pathogenesis-relevant correlations. This could in turn lead to the discovery of new therapeutic targets.

While biomarkers from other body fluids (*e.g.*, bile) can reveal important aspects of the pathogenesis, blood is more readily available for clinicians and can be obtained in a highly controlled fashion (in contrast to, *e.g.*, stool). This makes serological biomarkers the most appropriate for everyday clinical use, therefore these are the markers that we focus on in this review.

ROUTINE LABORATORY TESTS AND COMPOSITE SCORES

Alkaline phosphatase

Various clinical studies have consistently reported a correlation between alkaline phosphatase (ALP) levels and disease progression, but its individual application is difficult. In PSC, the fluctuation pattern of ALP is different from that observed in primary biliary cholangitis, and the degree of elevation is influenced by the development of various biliary complications (cholangitis, gallstones, or the appearance of a dominant stricture). Thus, it is not surprising that the ALP thresholds or values of change associated with disease outcomes in certain studies were not confirmed by other studies[9]. However, certain studies highlighted the importance of ALP fluctuation in CCA development free survival. The risk of developing CCA was significantly higher in patients with constantly high ALP levels without reduction[10-13]. Thus, further studies are needed to determine the significance of ALP level variation also in transplant free survival (due to progression of fibrosis) and treatment response.

Mayo risk score

In the absence of individual predictive markers, researchers tried to develop predictive models incorporating multiple markers. These scoring systems, however, also contain clinical parameters besides serological markers. The first and still the most widely used clinical prognostic model is the Mayo risk score (MRS), which, as modified in 2000, no longer includes invasive or subjective parameters [14]. Abnormal value of the factors included in the MRS [serum bilirubin, albumin, and aspartate aminotransferase (AST) levels, and esophageal variceal bleeding], with the exception of age, represents advanced liver disease. Thus, the discriminatory potential of this scoring system is inadequate in the early stages of PSC. In addition, the predictable time period for disease progression is only around 4 years. The model was also not able to predict the adverse disease outcome associated to high-dose ursodeoxycholic acid treatment (28-30 mg/kg/d) either[15].

Amsterdam-Oxford model

The Amsterdam-Oxford model (AOM) is another prognostic scoring system for PSC[16], which includes seven objective parameters (PSC subtype, age at diagnosis, platelet count, serum albumin, ALP, AST, and bilirubin levels). This scoring system was developed to overcome the limitations of MRS in the prediction of transplant-free survival. It can be used to estimate a longer-term prognosis of PSC (15 years) and can be recalculated at a later timepoint. However, the discriminative power of the model was only moderate (C-statistic: 0.68). In contrast, it has the advantage of being much more widely applicable (the reliability of the model was consistent in the two populations and at different timepoints) as it was developed using population-based data rather than data from transplant centers.

UK-PSC scores

The UK-PSC scores were also developed to predict transplant-free survival[17]. Two models were created for 2-year and for 10-year prediction, derived from a cohort of 1001 PSC patients and validated in two independent cohorts adding up to 451 patients. The incorporated variables were serum bilirubin, ALP, albumin, platelets, presence of extrahepatic biliary disease, and variceal hemorrhage. "Both short- and long-term UK-PSC risk scores had better performance than MRS and AST-to-platelet ratio index when predicting outcomes [C-statistics for 2-year survival (short-term) were 0.81 *vs* 0.75 and 0.81 *vs* 0.63, respectively; for 10-year survival (long-term) were 0.80 *vs* 0.79 and 0.80 *vs* 0.59, respectively]."

PSC risk estimate tool

PSC risk estimate tool (PREsTo) was developed to predict the advent of hepatic decompensation (ascites, variceal hemorrhage, or encephalopathy). The model was derived from data of a multicenter North American cohort and validated in an international multicenter cohort including 509 and 278 subjects, respectively. Individuals with advanced PSC or CCA at baseline were excluded. PREsTo incorporates nine variables: Bilirubin, albumin, serum ALP times the upper limit of normal, platelets, AST, hemoglobin, sodium, patient age, and number of years since the diagnosis of PSC. In predicting hepatic decompensation, PREsTo performed better than model of end stage of liver disease (MELD)

score and MRS (C-statistics: 0.90 *vs* 0.72 and 0.90 *vs* 0.85, respectively)[18]. The equation is not provided, and only an online calculator is available.

Enhanced liver fibrosis test

The enhanced liver fibrosis (ELF) test (Siemens ADVIA Centaur) is based on purely serological measurements summarizing three direct components of fibrogenesis (hyaluronic acid, tissue inhibitor of metalloproteinase 1, and type III procollagen amino-terminal propeptide). It has been reported to be a strong predictor of prognosis (mortality and liver transplantation) in PSC independently of MRS. Validation of this result was successful in multiple studies (C-statistic: 0.79-0.81)[19,20]. In a recent study, the ELF score slightly increased in PSC patients over a 5-year follow-up period and showed low intrapersonal variability supporting the consistency of this score[21].

IMMUNOGLOBULINS

IgG4

About 10% of patients have elevated serum IgG4 levels without IgG4-associated disease. Recently, IgG4 determination is recommended at least once in all patients with PSC[22]. Elevated serum IgG4 levels (> 140 mg/dL) in PSC patients were associated with higher values of liver function tests, higher MRS, and shorter time to liver transplantation, which clearly indicates a more severe disease course in this subgroup of patients[23]. It is unknown whether the addition of a systemic glucocorticoid to treatment in the high IgG4 subtype of PSC may be beneficial in curbing disease progression[24].

ANCAs

Various other serum autoantibodies have been described in PSC patients; however, they are considered unspecific, since they may be present also in other diseases. The most frequently observed antibodies in PSC are ANCAs, but antinuclear antibodies and anti-smooth muscle antibodies were also reported to be frequently associated with PSC[25].

The occurrence of IgG isotype atypical P-ANCAs in PSC are common (up to 80% of cases). The putative role of intestinal bacteria in ANCA formation (homology between human beta-tubulin isotype 5 and bacterial FtsZ protein, molecular mimicry) has been described[26]. Early, small scale, case-control clinical studies[27] found no correlation between ANCA formation and clinical or genetic features of PSC. Hov *et al*[28], however, in a large comprehensive case-control study, demonstrated that risk genes with a strong association to PSC formation (HLA-B*08 and DRB1*03) were also associated with ANCA formation. Interestingly, association between the presence of PSC related HLA alleles (B*08, C*07, and DRB1*03) and increased risk of acute rejection syndrome in liver transplant recipients has also been reported (while DRB1*04 was found to be a protecting factor)[29].

The antibody against serine proteinase-3 (PR3) is a type of cytoplasmic ANCA (C-ANCAs). PR3-ANCA is typically observed in small vessel vasculitis[30] but recently has been reported in ulcerative colitis (UC)[31], which prompted researchers to investigate this antibody in PSC as well. Interestingly, in the setting of PSC, PR3-ANCA seems to be associated with worse liver biochemistry rather than with a co-diagnosis of UC[32]. In a recent study by Wunsch *et al*[7], besides worse liver function tests and MELD score, PR3-ANCA has been shown to be associated with CCA development [hazard ratio (HR) = 9.8, 95% confidence interval (CI) = 1.3-74.5; P = 0.03] and risk of shorter transplant free survival (HR = 1.8; 95%CI = 1.3-2.8; P = 0.01). However, the predictive capacity of PR3-ANCA was not confirmed in the validation cohort where the frequency of PR3-ANCA was found to be surprisingly low (5% in contrast to 54% in the discovery cohort) and CCA development was also less prevalent[7].

IgA type autoantibodies

IgA is the most important immunoglobulin isotype involved in mucosal immunity[33]. Since the gut-liver interaction plays a central role in the pathogenesis of PSC, the formation of IgA type autoreactive antibodies is a characteristic feature of the disease. Under physiological conditions, monomeric IgA in serum inhibits immunological processes (so-called immunosuppressive effect). However, in pathological conditions, immune complexes formed by aggregation of monomeric IgA molecules can activate immunological processes by binding to myeloid cells[34]. IgA, produced by plasma cells lining the gut and biliary epithelium, is a highly abundant immunoglobulin in bile and plays a central role in the defense against intestinal pathogens. Biliary epithelial cells (that are the cellular targets of injury in PSC) and intestinal epithelial cells transport the IgA molecules into the biliary and intestinal lumens, respectively (→secretory IgA)[35-37]. However, in the past, most studies on serological antibodies in autoimmune liver diseases, like in the case of ANCA, have focused mainly on IgG isotype antibodies, and the IgA isotype is only recently gaining attention[38].

The work of Berglin *et al*[39] is an example, which highlighted the described importance of IgA isotype antibody related pathogenetic pathways in PSC. They demonstrated that in the presence of IgA isotype autoantibodies against biliary epithelial cells, disease progression was faster than in their

absence. No similar correlation was observed for IgG isotype antibodies.

In 2015, our group reported the association between PSC and the presence of anti- GP2 IgA antibodies in inflammatory bowel disease (IBD) patients[40]. Subsequently, anti-GP2 IgA positivity was demonstrated to be able to predict a progressive disease course in PSC by our and another group[4,5]. These results were confirmed later by further studies[6,7]. In total, 1111 PSC patients have been evaluated for the presence of anti-GP2 IgA and the prevalence was found between 30.8% and 52.2%[8]. Anti-GP2 IgA was consistently reported to be associated with a more severe PSC phenotype with a 2- to 5-fold higher risk to develop end stage liver disease with a need for liver transplantation (Figure 1). Consequently, anti-GP2 IgA may soon be integrated into clinical practice for risk assessment in PSC. Moreover, anti-GP2 IgA can also identify a subset of PSC patients with existing biliary tract cancer or with an increased risk of developing it during the disease course. This association between anti-GP2 IgA and CCA was reported by Jendrek *et al*[4] and confirmed by Wunsch *et al*[7] both evaluating two cohorts each, providing strong evidence that incorporation of anti-GP2 IgA into CCA surveillance protocols could be beneficial (Figure 1).

IgA autoantibody against F-actin has been also reported to be associated with enhanced mucosal immune response to various microbial antigens and enterocyte damage in PSC, and to identify PSC patients with progressive disease (HR = 4.54; 95%CI = 1.14-18.18; P = 0.032)[41]. Cytoskeletal F-actin initiates an extracellular damage-associated molecular pattern signaling pathway through DNGR-1/CLEC9A and Syk-SFK that results in antigen cross-presentation to $CD8^+$ T cells[42-45]. $CD8^+$ T cells, after activation in the gut, can be recruited to the liver and induce immune-mediated cholangitis in mice [46].

OTHER SEROLOGICAL BIOMARKERS

Interleukin-8

As a result of increased lipopolysaccharide (LPS) exposure, biliary epithelial cells produce interleukin-8 (IL-8), which has a proliferation-promoting effect and enhances fibrogenesis related gene expression. In the study by Vesterhus *et al*[47], using modern antibody array technology, elevated serum IL-8 showed the strongest association with poor transplant-free survival among pro-inflammatory markers. However, the predictive value of MRS and ELF test for clinical outcomes was found to be higher than that of IL-8.

Macrophage activation markers

Bossen *et al*[48] found that macrophage activation markers, soluble CD163 (sCD163) and mannose receptor (sMR), were increased according to disease severity in two independent PSC cohorts of 138 and 159 patients. In both cohorts, sCD163 and sMR levels rose in parallel with increasing liver enzymes, MRS, and ELF test. Patients with high baseline levels of sCD163 (> 3.86 mg/L) had decreased transplant-free survival during the 8-year follow-up in both cohorts (35.2% *vs* 83.0% in the combined cohort). sMR showed similar association only in one of the cohorts with more severe disease features. In Cox regression, sCD163 also performed better in the more severe cohort (HR = 3.15 and 2.89) but it lost significance in the multivariate model against ELF test and AOM score.

BT markers

In a study investigating serum markers of BT, serum levels of zonulin, intestinal fatty acid binding protein, soluble CD14 (sCD14), LPS, and LPS-binding protein (LBP) were measured in 166 PSC patients and 100 healthy controls[49]. LBP and sCD14 levels were higher, whilst zonulin levels were lower in PSC patients compared to controls. This latter difference disappeared with the exclusion of PSC patients with elevated prothrombin time (indicating advanced liver disease). In patients with CCA, sCD14 levels were higher compared to patients without it. High sCD14 and LBP values (> 1638 ng/mL and > 13942 ng/mL, respectively) were associated with reduced transplantation-free survival independently of MRS (HR = 2.26; 95%CI = 1.15-4.43; P = 0.018 and HR = 2.00; 95%CI = 1.17-3.43; P = 0.011, respectively). Further studies are needed to validate these findings.

Extracellular remodeling markers

In a cohort of 138 large-duct PSC patients (74% with IBD) using 52 UC patients as controls, Nielsen *et al* [50] investigated the predictive potential of four extracellular remodeling markers related to collagen formation (PRO-C3 and PRO-C5) and collagen degradation (C3M and C4M). All markers were elevated in PSC compared to UC patients, with PRO-C3 showing the most robust difference. High serum levels of three markers (with the exception of C3M) were associated with a shorter transplant-free survival during a 4-year follow-up period. In the univariate Cox regression model (using tertiles of the markers), PRO-C3 had the highest HR (HR = 3.02; 95%CI = 1.96-4.67, P < 0.001) but it failed to predict survival in the multivariate model including ELF test, while PRO-C5 remained an independent predictor (multivariate HR = 1.92; 95%CI = 1.28-2.88; P = 0.002). The combination of PRO-C3 and PRO-C5 resulted in a significantly improved odds ratio (OR = 47.3; P < 0.001) compared to the individual markers and

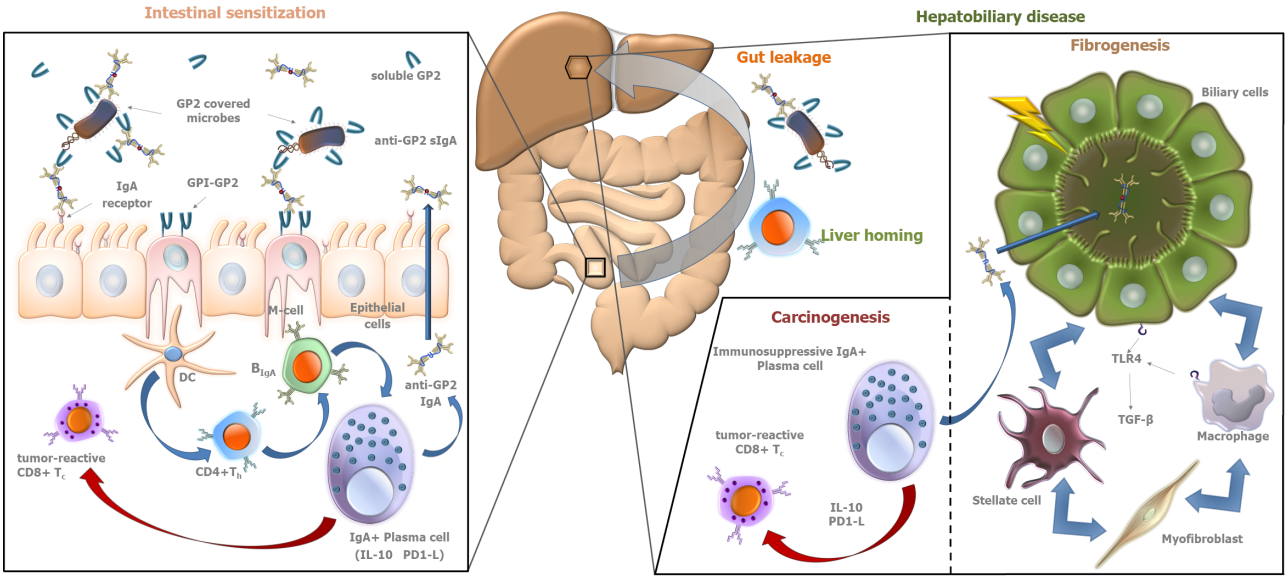

Figure 1 Autoimmunity-driven putative role of pancreatic glycoprotein 2 in fibro- and tumorigenesis in primary sclerosing cholangitis. Along with digestive enzymes, glycoprotein 2 (GP2) is secreted from pancreatic acinar cells into the intestinal lumen. In addition, GP2 is also expressed on the luminal surface of microfold cells [M-cells in Peyer's patches anchored by glycosylphosphatidylinositol (GPI)]. Both forms of the molecule interact with FimH+ bacteria and opsonize them. The anchored form may be involved in the transcytosis of bound ligands (FimH+ microbes) through M cells, which pass them to antigen-presenting cells like dendritic cells (DC) located in the mucosa-associated immune system. Microbe-bound GP2 epitopes are presented to CD4-positive T helper cells ($CD4^+ T_h$) along with bacterial antigens that lead to loss of tolerance to GP2. After clonal expansion, these sensitized cells can "home" to both the gut and the liver where they trigger (blue arrows) the differentiation of IgA^+ B cells into IgA^+ plasma cells. The produced anti-GP2 IgA is actively transported by epithelial cells to the intestinal and biliary lumens as secretory IgA (sIgA), where it binds to GP2. Epithelial cells express IgA receptors on their luminal surface that are involved in active retrograde transport of sIgA molecules (typically coupled by antigens). This process may contribute to bacterial overload of the gut mucosa, elevating the levels of bacterial components in the circulation. In the hepato-biliary tract, bacterial components trigger the Toll-like receptor 4 (TLR4)-transforming growth factor-β (TGF-β) pathway, facilitating fibrosis and cirrhosis. Meanwhile, as a response to the continuous inflammation, a line of IgA^+ plasma cells develops an immunosuppressor phenotype expressing interleukin-10 (IL-10) and programmed cell-death 1 Ligand (PD1-L). These molecules inhibit (red arrow) tumor-suppressing cytotoxic $CD8^+$ T cells ($CD8^+$ Tc), contributing to tumor development in the hepatobiliary and intestinal tract. Citation: Tornai D, Papp M. Editorial: serologic antibodies in primary sclerosing cholangitis a tell-tale sign of compromised gut-liver immunity? *Aliment Pharmacol Ther* 2021; 53: 350-351[8]. Copyright ©The Authors 2021. Published by John Wiley and Sons. (Supplementary material).

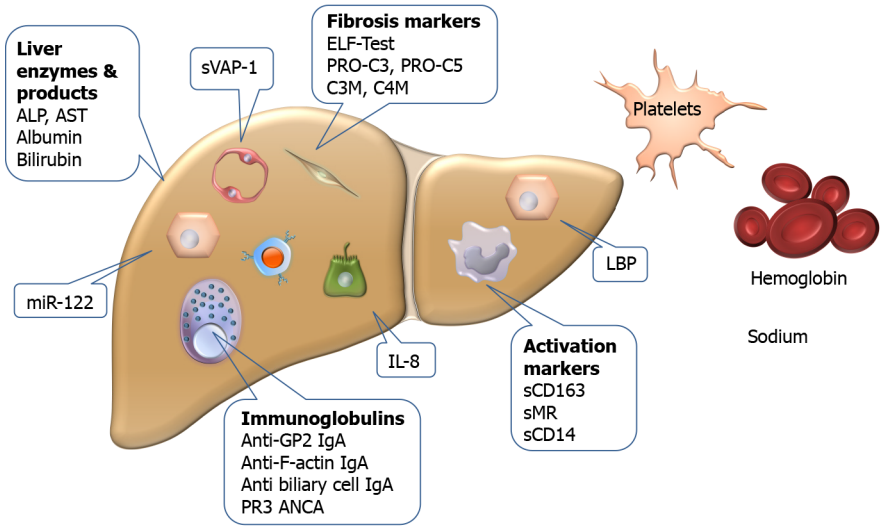
ELF test. However, in this latter test, the authors compared the outcomes associated with the first (lowest) tertile of the markers to those associated with the third (highest) tertile. Further studies are needed to confirm the importance of these findings as well.



MicroRNA-122

MicroRNA-122 (miR-122) is the most abundant microRNA in the liver, orchestrating molecular pathways in hepatocytes and regulating liver functions including lipid and cholesterol homeostasis. MiR-122 deficiency leads to inflammation, cholestasis, and ultimately fibrosis of the liver[51]. Friedrich *et al*[52] investigated the predictive potential of miR-122 in 114 PSC patients with a prospective follow-up of 10 years. They divided the population to patients with low and high miR-122 levels based on the median value of the marker (CT-value of 28.5). Low miR-122 levels were associated with a higher risk of death or need for liver transplantation (HR = 1.27; 95%CI = 1.04-1.39; P = 0.009) even in the multivariate Cox regression model including MRS, presence of dominant stricture, and IBD (HR = 1.19; 95%CI = 1.00-1.43; P = 0.045).

Soluble vascular adhesion protein 1

Expression of vascular adhesion protein 1 (VAP-1) and amine oxidase enzyme activity in the liver endothelium are increased in PSC. The former results in an elevation of its soluble form (sVAP-1) in patients' sera. Elevated levels of sVAP-1 (> 529 ng/mL) in PSC are associated with an adverse disease outcome, independent of the presence of cirrhosis (HR = 3.85; 95%CI = 1.57 to 9.34; P = 0.003)[53].

Increased VAP-1 activity results in the expression of mucosal addressin cell adhesion molecule (MAdCAM-1) in liver tissue, which is otherwise expressed only in the intestinal endothelium. MAdCAM-1 binds to α4β7 integrin receptors on effector T lymphocytes, which is required for lymphocyte homing. Thus, abnormally expressed MAdCAM-1 in the liver results in the entry of gut activated effector T lymphocytes into liver tissue[53]. The increased expression and intrahepatic activity of VAP-1 may be attributed to the altered intestinal flora and the increased amine influx into the portal tract due to the inflamed, permeable bowel. The pathological amine substrate of VAP-1 is cysteamine [53], which causes colitis and colorectal carcinoma in mice. The *Escherichia* genus, which is able to

produce cysteamine *in vitro*, is upregulated in the mucosa-associated microbiota population in PSC. However, the intestinal epithelium itself is capable of cysteamine production *via* the ectoenzyme vanin-1. The observation that cysteamine enhances colonic inflammation and carcinogenesis is consistent with the increased colon carcinoma formation observed in PSC. The aldehyde derivative formed during the metabolism of cysteamine causes abnormal collagen cross-binding, which could theoretically contribute to increased fibrogenesis. Increased VAP-1 activity in liver and colonic tissue is most likely an attempt to counteract the increased amine load resulting from colitis.

The newly discovered VAP-1 pathway is one explanation of how colitis and increased amine production lead to damage of liver tissue. VAP-1 may be a potential therapeutic target in the future due to its effect in promoting α4β7/MAdCAM-1 interaction. A VAP-1 antagonist may also be able to regulate the migration of effector T lymphocytes from the inflamed intestine to the liver and thereby inhibit fibrogenesis[53].

The biomarkers used individually or as parts of score systems are summarized in Figure 2.

SEROLOGICAL BIOMARKERS FOR DETECTING CHOLANGIOCARCINOMA IN PSC

Carbohydrate antigen 19-9 (CA19-9) is the most commonly used serological marker for screening CCA, but its application is limited in PSC by the lack of comprehensive studies comparing PSC patients with and without CCA. Most studies were too small and ultimately provided inconsistent cut-off values[54]. A recent development in this field is the discovery of the role of fucosyltransferase (FUT) 2 and 3 in influencing the serum levels of CA19-9 in patients with PSC. These enzymes catalyze the final steps of CA19-9 biosynthesis. The study identified FUT genotypes with low, intermediate, and high CA19-9 synthesis capacity displaying distinct CA19-9 serum levels[55]. According to these data, CA19-9 is not an appropriate marker for CCA screening in patients with a low CA19-9 biosynthesis genotype since they do not synthetize CA19-9. This group can be identified by a Lewis-negative blood group which is also determined by these enzymes. In contrast, the high CA19-9 biosynthesis genotype might be a reason for false positive results[55]. In addition, bacterial cholangitis can be another explanation for increased CA19-9 level in PSC patients without CCA[56].

Finally, a study demonstrated a significant influence of FUT2 genotype also on CEA serum levels. The most prominent effect was observed in the subgroup incapable of CA19-9 biosynthesis[57]. Studies with other serological biomarkers, like angiopoetin-2[58] or cytokeratin fraction 21-1[59], have not reached satisfactory results in terms of identifying individuals with CCA among PSC patients.

CONCLUSION

Several promising discoveries have been made on biomarkers for PSC. The first validated prognostic biomarker (anti-GP2 IgA) is finally ready to be incorporated into clinical practice, and the investigations

highlighted important pathophysiological mechanisms for future research that might open new avenues for medical therapy. However, we still lack specific serological markers that could support the diagnosis of PSC. Additionally, a serological marker with satisfactory discriminative power to aid the recognition of CCA in PSC patients is another unmet need.

Abstract

BACKGROUND

In the contemporary era of cancer immunotherapy, an abundance of clinical and translational studies have reported radiotherapy (RT) and immunotherapies as a viable option for immunomodulation of many cancer subtypes, with many related clinical trials ongoing. In locally advanced disease, chemotherapy or chemoradiotherapy followed by surgical excision of the tumour remain the principal treatment strategy in oesophageal adenocarcinoma (OAC), however, the use of the host immune system to improve anti-tumour immunity is rapidly garnering increased support in the curative setting.

AIM

To immunophenotype OAC patients' immune checkpoint (IC) expression with and without radiation and evaluate the effects of checkpoint blockade on cell viability.

METHODS

In the contemporary era of cancer immunotherapy, an abundance of studies have demonstrated that combination RT and IC inhibitors (ICIs) are effective in the immunomodulation of many cancer subtypes, with many related clinical trials ongoing. Although surgical excision and elimination of tumour cells by chemotherapy or chemoradiotherapy remains the gold standard approach in OAC, the propagation of anti-tumour immune responses is rapidly garnering increased support in the curative setting. The aim of this body of work was to immunophenotype OAC patients' IC expression with and without radiation and

to establish the impact of checkpoint blockade on cell viability. This study was a hybrid combination of *in vitro* and *ex vivo* models. Quantification of serum immune proteins was performed by enzyme-linked immunosorbent assay. Flow cytometry staining was performed to evaluate IC expression for *in vitro* OAC cell lines and *ex vivo* OAC biopsies. Cell viability in the presence of radiation with and without IC blockade was assessed by a cell counting kit-8 assay.

RESULTS

We identified that conventional dosing and hypofractionated approaches resulted in increased IC expression (PD-1, PD-L1, TIM3, TIGIT) *in vitro* and *ex vivo* in OAC. There were two distinct subcohorts with one demonstrating significant upregulation of ICs and the contrary in the other cohort. Increasing IC expression post RT was associated with a more aggressive tumour phenotype and adverse features of tumour biology. The use of anti-PD-1 and anti-PD-L1 immunotherapies in combination with radiation resulted in a significant and synergistic reduction in viability of both radiosensitive and radioresistant OAC cells *in vitro.* Interleukin-21 (IL-21) and IL-31 significantly increased, with a concomitant reduction in IL-23 as a consequence of 4 Gray radiation. Similarly, radiation induced an anti-angiogenic tumour milieu with reduced expression of vascular endothelial growth factor-A, basic fibroblast growth factor, Flt-1 and placental growth factor.

CONCLUSION

The findings of the current study demonstrate synergistic potential for the use of ICIs and ionising radiation to potentiate established anti-tumour responses in the neoadjuvant setting and is of particular interest in those with advanced disease, adverse features of tumour biology and poor treatment responses to conventional therapies.

INTRODUCTION

Oesophageal adenocarcinoma (OAC) is rapidly increasing in incidence in the western world, and five year survival rates rarely exceed 40%[1]. Multimodal therapy alongside surgical resection has become standard of care for locally advanced cancer of the oesophagus or the oesophagogastric junction[2]. One option is the CROSS regimen, which includes preoperative administration of carboplatin and paclitaxel with concomitant radiotherapy (RT)[3]. In Europe, radiation is delivered in 23 fractions of 1.8 Gray (Gy), giving a total dose of 41.4 Gy but this varies worldwide, with North American centres delivering up to 50.0-51.4 Gy[4], while Asian regimens can feature cumulative doses of 60 Gy[5].

Hypofractionated RT is where radiation is delivered in fewer fractions of 2.4 Gy to 5.0 Gy, but often the same cumulative dose[6]. This has the potential to reduce costs, increase patient comfort, and could be more effective compared to conventional treatment[7]. Randomised trials in breast and prostate cancer have found that both high- (≥ 5 Gy per fraction) and moderately (2.4-3.4 Gy per fraction) hypofractionated RT is non-inferior to traditional regimens[7-10]. As RT is a mainstay of treatment, and oesophageal malignancies are associated with considerable morbidity, there is interest in evaluating whether this paradigm can be applied in the upper gastrointestinal context.

Disappointingly, a pathologic complete response to treatment is observed in less than 30% of patients with oesophageal cancer undergoing chemoradiotherapy[11], and it is this small subgroup that benefits most in terms of survival[12]. More effective strategies are therefore required. One emerging approach is combining chemoradiotherapy with immune checkpoint blockade (ICB). The most widely used ICB

involves blocking the interaction of PD-1 expressed on T cells and it's ligand, PD-L1 expressed on tumour cells[13], and seeks to re-invigorate anti-tumour cytotoxic T cells[14]. Phase III trials of single agent ICB have delivered mixed results in chemorefractory advanced oesophagogastric cancer[15], but some recent encouraging results have been reported in earlier stage disease[16,17].

Radiation can sensitise tumours to immunotherapy through three main mechanisms[18]. First, radiation can increase neoantigen expression and induce immunogenic cell death, whereby release of damage associated molecular patterns (DAMPs) results in more efficient tumour antigen presentation and immune stimulation[19]. Second, radiation induced DNA damage can activate the GMP-AMP stimulator of interferon genes (cGAS-STING) cytosolic DNA sensor, resulting in type I interferon production[20,21]. Finally, RT can result in remodeling of the tumour microenvironment (TME), promoting infiltration of immune cells[22]. The latter effect is particularly affected by radiation dosage and some limited preclinical evidence suggests that hypofractionated RT can have more immunostimulatory effects than conventional fractionation[18]. However, the majority of studies in the literature to date have focused on more inherently immunogenic tumour models like melanoma or non-small cell lung cancer, or common malignancies like breast or colon cancer. There are a number of clinical studies evaluating hypofractionation in the context of squamous cell cancer of the oesophagus, however, data is lacking for OAC. In addition, there are no translational studies characterising immune response in OAC in the context of immunotherapy and thus was the premise for this study.

This study assessed the effects of hypofractionated RT on IC expression in oesophageal cancer cells *in vitro* and *ex vivo* and correlated this with clinical outcomes. We also assessed the synergistic effects of ICB and radiation on OAC cell lines. Through this, we aimed to enhance our understanding of the interplay between immunotherapy, radiation and the TME in oesophageal cancer, with the goal of identifying the most effective radiation dosing strategy to combine with immunotherapy.

MATERIALS AND METHODS

Ethics statement

We secured ethical approval for this study from the Tallaght/St James's Hospital Ethics Committee. All patients provided formal written consent for all sample and variable data collection. During the course of all steps of sample and data collection good clinical practice was maintained and ethical standards upheld. We also pseudonymised patient data to protect privacy.

Specimen collection

We secured tissue from those patients who consented to participate from 2018-2021. Tumour biopsies were obtained from patients with OAC prior to treatment at the National Centre for Oesophageal and Gastric Cancer at St James's Hospital, Dublin. A total of 17 biopsies were used for analysis with all patient samples being treatment naïve prior to having neoadjuvant therapies to ensure clinical relevance of the study population. A total of 12 men and 5 women with a mean age of 64.23 years (SD11.5) in the study. All patients had locally advanced disease and were $T3N_{any.}$

Generation of tumour conditioned media

Tumour treatment naïve tissue samples were added to L-15 (Leibovitz) Lonza™ BioWhittaker™ X-vivo media for in a 12 well plate and subsequently cultured for a period of 24 h at 37 °C, 5% CO_2. After the 24 h period expired, the tissue conditioned media was collected for storage at -80 °C.

Quantification of serum immune proteins

Tumour conditioned media (TCM) was collected based on a standard operating procedure designed as per MSD United States instructions (Meso Scale Diagnostics, United States). To assess markers of angiogenesis, vascular injury, pro-inflammatory, cytokines, chemokine as well as soluble checkpoints from TCM, a 54-plex enzyme-linked immunosorbent assay (ELISA) kit was used (Meso Scale Diagnostics, United States). The ELISA was utilized to determine the level of secretions of the following markers: C-reactive protein (CRP), Eotaxin, Eotaxin-3, FGF (basic), Flt-1, GM-CSF, ICAM-1, IFN-γ, interleukin-10 (IL-10), IL-12/IL-23p40, IL-12p70, IL-13, IL-15, IL-16, IL-17A, IL-17A/F, IL-7, IL-8, MCP-1, MCP-4, MDC, MIP-1α, MIP-1β, MIP-3α, PlGF, SAA, TARC, Tie-2, TNF-α, TNF-β, TSLP, VCAM-1, vascular endothelial growth factor (VEGF)-A, VEGF-C and VEGF-D and ICs TIM-3, TIGIT, PD-1, PD-L1, CD276 and CD80 from TCM. These assays were processed according to a standard operating procedure following consultation of the manufacturer's guidelines. The derived data with respect to all markers were normalised to protein content as determined using a Pierce bicinchoninic acid assay.

Neoplastic tissue sample digestion

In preparation for flow cytometry, the tissue samples were digested to enable phenotyping of the cancer cells. The tissue was resected using a surgical blade and added to collagenase solution (2 mg/mL of collagenase type IV (Sigma) in Hanks Balanced Salt Solution (GE healthcare) supplemented with 4%

(v/v) foetal bovine serum) at 37 °C and 1500 rpm on an orbital shaker. The cancer cells were stained with flow cytometry antibodies for subsequent analysis.

Cell culture of OAC cell lines

Human OAC cell lines OE33 were purchased from The European Collection of Authenticated Cell Cultures (ECACC), established from a poorly differentiated stage IIA adenocarcinoma of the lower oesophagus of a 73-year old female patient. An in-house isogenic radioresistant model was generated [23].

Cell viability cholecystokinin octapeptide assay

A cell counting kit-8 (CCK-8) viability assay was used to determine the impact of ionising radiation on the viability of OE33P and passage matched OE33R cells. The impact of anti-PD-1, and anti PD-L1 therapies in isolation, and dual ICB with and without radiation, at both hypofractionation and bolus dosing of clinically relevant doses on the viability of OE33P and R cells was also assessed using a CCK-8 assay. OAC cells (5×10^3) were adhered in a 96 well plate at 37 °C, 5% CO2 overnight. Cells were treated with bolus dosing or three consecutive fractionated doses of radiation with an interval of 24 h using the X-Strahl RS225 irradiator. In addition to this, the cancer cells were treated with and without radiation in the absence or presence of pembrolizumab (10 μg/mL), atezolizumab (10 μg/mL), nivolumab (10 μg/mL) or combination atezolizumab (10 μg/mL) and nivolumab (10 μg/mL), or dual atezolizumab (10 μg/mL) and pembrolizumab (10 μg/mL). All of the data were analysed from three independent experiments (Supplementary material).

Flow cytometry staining for in vitro OAC cell lines and ex vivo OAC biopsies

OE33 cells were trypsinised and stained with zombie aqua viability (Biolegend, United States) dye. Antibodies used for OAC cell lines included: PD-L1-FITC, PD-L2-PE, TIGIT-PE/Cy7, PD-1-APC/Cy7 (Biolegend, United States), OE33P and OE33R cells were fixed with 1% paraformaldehyde solution and acquired using BD FACs CANTO II (BD Biosciences) using Diva software and analysed using FlowJo v10 software (TreeStar Inc.). Tumour tissue biopsies were stained with zombie aqua viability dye (Biolegend, United States) as per manufacturer's recommendations.

Statistical analysis

GraphPad Prism 9 was utilized to analyze the results. In order to determine statistical differences between treatments in cell lines, a paired parametric statistical *t*-test was utilized. In order to determine the differences between the OE33P and OE33R cell lines an unpaired parametric *t*-test was performed. To evaluate any differences between paired treatments of patient samples, Wilcoxon signed rank test was performed. Statistical significance was pre-determined as $P \leq 0.05$.

RESULTS

IC expression by an isogenic model of radioresistance following bolus and hypofractionated RT dosing

In order to ascertain if different expression levels of IC proteins were detectable on a radiosensitive (OE33P) and a radioresistant (OE33R) OAC cell line at baseline and following variable fractions of radiation, cells were stained with antibodies for a range of IC proteins and assessed by flow cytometry 24 h after the last dose. The administration of fractionated dosing resulted in significantly higher expression of PD-1, PD-L1, PD-L2 and TIGIT ($P < 0.05$) in both parental and resistant cell lines when compared to bolus dosing (Figure 1). There was a significantly higher expression of checkpoints and their ligands in the parental cell line compared to the passage matched radioresistant cell line. There was also a significantly higher expression of PD-1 and its ligands PD-L1 and PD-L2 with bolus dosing 10 Gy and 20 Gy in OE33P cell lines compared to the radioresistant passage matched cell line ($P < 0.05$). Globally there was a higher expression of PD-1, PD-L1 and PD-L2 on the parental cell line with fractionated dosing regimens of 3X1 Gy, 3X2 Gy and 3X8 Gy compared to the radioresistant cell line ($P < 0.05$). In the case of TIGIT, there was a significantly higher upregulation in the OE33P cell line compared to the radioresistant cell line following fractionated dosing of 3X4 Gy and 3X8 Gy ($P < 0.05$) (Figure 1).

Cell viability in the context of radiation and IC blockade

IC blockade alone reduced the viability of both OE33P and OE33R cell lines, for both anti-PD-1 and anti-PD-L1 therapies. Multimodal use of both anti-PD-1 and anti-PD-L1 therapies with ionising radiation resulted in a synergistic reduction in viability in both cell lines (Figure 2).

In the OE33P cell line, 2 Gy radiation alone reduced viability to 78.49% (± 2.05, $P < 0.01$) and 4 Gy to 35.48% (± 2.08, $P < 0.01$) compared with unirradiated cells and there was a significant reduction in viability when comparing 2 Gy to 4 Gy ($P < 0.05$). In the OE33R cell line, 4 Gy reduced viability to

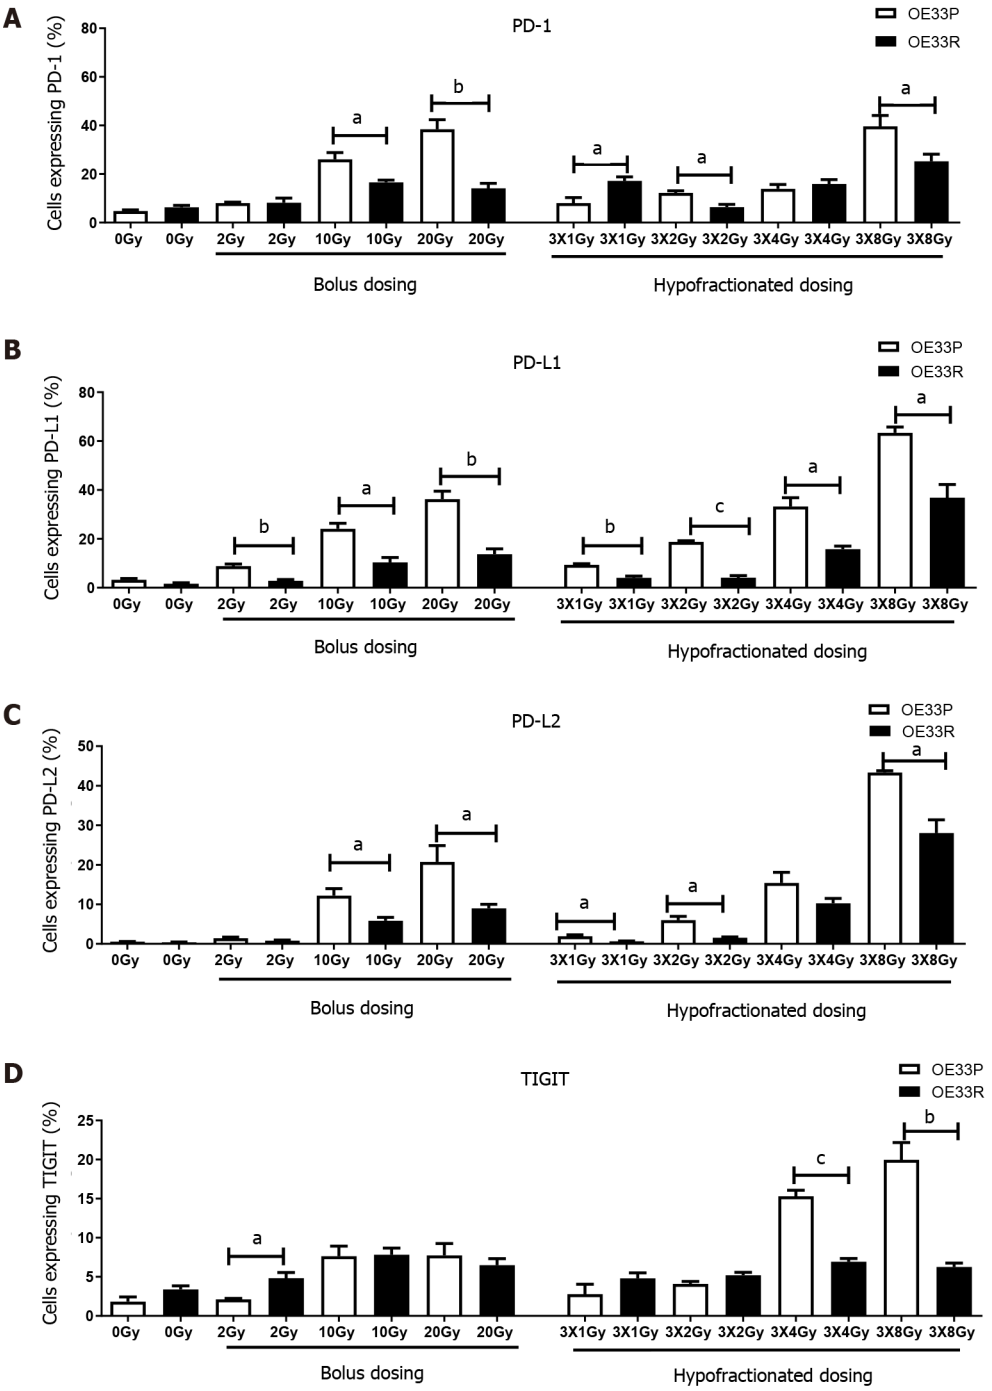

Figure 1 OE33P and R cell lines were screened for the surface expression of immune checkpoints by flow cytometry. Inhibitory immune checkpoints are expressed at a higher level on parental cell lines than the passage matched radioresistant cell line (n = 3). A: PD-1; B: PD-L1; C: PD-L2; D: TIGIT. Graph shows % expression (± SE). [a]P < 0.05; [b]P < 0.01; [c]P < 0.001 by unpaired parametric t-test.

63.33% (± 2.67, P < 0.05). Both 2 Gy and 4 Gy radiation resulted in a significantly greater reduction in viability in the OE33P cell line compared to the OE33R (P < 0.05) (Figure 2).

Compared with untreated cells, when the OE33P cells were treated with Atezolizumab alone, viability was reduced to 91.3% (± 0.30, P < 0.01) and with the addition of 2 Gy radiation viability reduced to 66.57% (± 2.40, P < 0.01) and to 48.92% (± 5.76, P < 0.01) with 4 Gy radiation. Compared with untreated OE33R cells, viability of OE33R cells treated with Atezolizumab alone was reduced to 88% (± 2.65,P < 0.05), with the addition of 2 Gy radiation viability was reduced to 75.67% (± 2.33, P < 0.01) and 38% (± 3.06, P < 0.01) with 4 Gy radiation (Figure 2B).

In the OE33P cells, Pembrolizumab treatment alone non-significantly reduced viability to 91.54% (± 2.67) compared with the untreated cells, however with the addition of 2 Gy radiation viability reduced to 65.36% (± 2.81, P < 0.01) and 48.18% (± 3.20, P < 0.01) with 4 Gy radiation when compared to untreated OE33P cells. When the OE33R cells were treated with Pembrolizumab, viability was non-significantly reduced to 92% (± 2.52), but the addition of 2 Gy radiation reduced viability to 75.33% (±

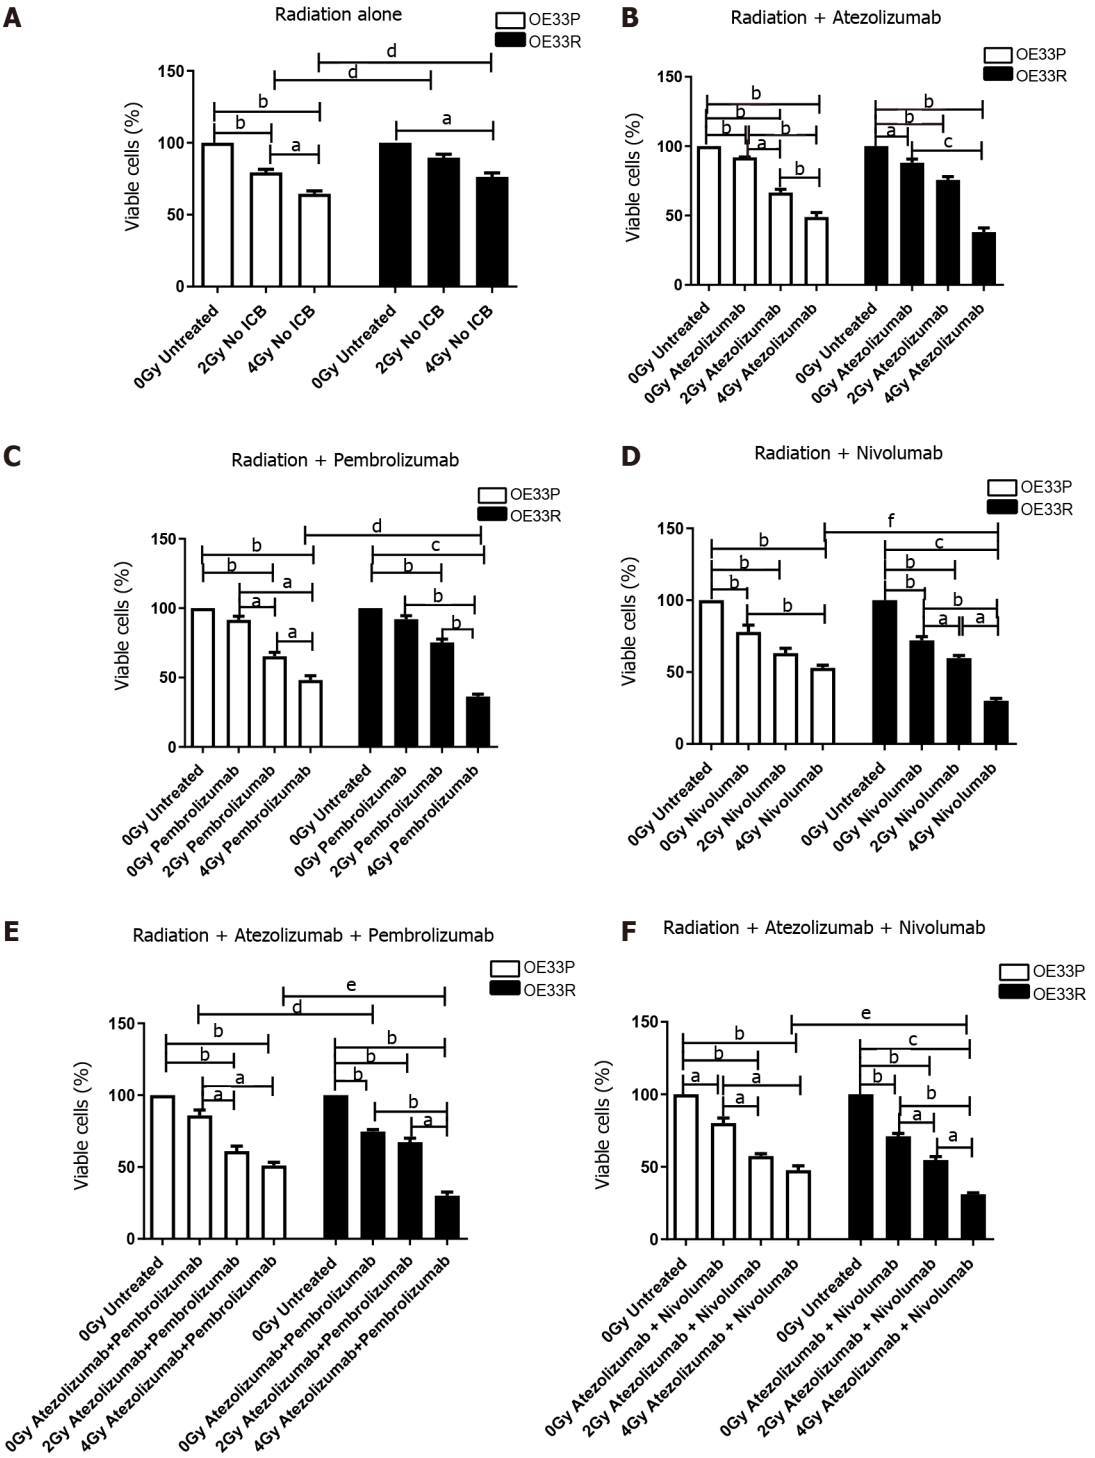

Figure 2 Viability (± SE) of OE33P and OE33R cells were assessed using a cell counting kit-8 assay with or without radiation (*n* = 3). Ionising radiation with immune checkpoint blockade results in a greater reduction in cell viability when compared to either modality alone. Graph shows % expression (± SE). A: Treatment with radiation dosing only; B: Treatment with radiation and single agent immunotherapy Atezolizumab; C: Treatment with radiation and single agent immunotherapy Pembrolizumab; D: Treatment with radiation and single agent immunotherapy Nivolumab; E: Treatment with radiation and dual immunotherapy agents Atezolizumab & Pembrolizumab; F: Treatment with radiation and dual immunotherapy agents Atezolizumab & Nivolumab. $^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$ paired *t*-test; $^{d}P < 0.05$, $^{e}P < 0.01$, $^{f}P < 0.001$ unpaired *t*-test.

2.33, $P < 0.01$) and 36.33% (± 1.67, $P < 0.001$) with 4 Gy radiation. Four Gy radiation with Pembrolizumab resulted in a significantly greater reduction in viability in the radioresistant OE33R cell line compared to the radiosensitive OE33P cell line ($P < 0.05$) (Figure 2C).

In the OE33P cells Nivolumab reduced viability to 77.94% (± 4.79, $P < 0.05$) and with the addition of 2 Gy radiation viability reduced to 63.21% (± 3.41, $P < 0.01$) and 52.98% (± 1.82, $P < 0.01$) with 4 Gy radiation compared with untreated OE33P cells. When the OE33R cells were treated with Nivolumab, viability was reduced to 72% (± 2.62, $P < 0.01$) and with the addition of 2 Gy radiation viability reduced to 59.67% (± 1.86, $P < 0.01$) and 30% (± 1.73, $P < 0.001$) with 4 Gy radiation compared with untreated

OE33R cells. Treatment with 4 Gy radiation and Nivolumab resulted in a significantly greater reduction in viability in the OE33R cell line compared to the radiosensitive cell line ($P < 0.001$) (Figure 2D).

In the OE33P cells, combination Atezolizumab and Pembrolizumab non-significantly reduced viability to 85.94% (± 3.79) but the addition of 2 Gy radiation significantly reduced viability to 61.10% (± 3.44, $P < 0.01$) and 51.07% (± 2.27, $P < 0.01$) with 4 Gy radiation compared with untreated OE33P cells. When the OE33R cells were treated with combination Atezolizumab and Pembrolizumab, viability was significantly reduced to 74.67% (± 1.33, $P < 0.01$), and with the addition of 2 Gy radiation viability was reduced to 67.33% (± 2.73, $P < 0.01$) and 30% (± 2.52, $P < 0.01$) with 4 Gy radiation. Four Gy radiation with combination Atezolizumab and Pembrolizumab resulted in a significantly greater reduction in viability in the OE33R cell line compared to the radiosensitive cell line ($P < 0.01$) (Figure 2E).

In the OE33P cells combination Atezolizumab and Nivolumab reduced viability to 80.18% (± 3.48, $P < 0.05$) and with the addition of 2 Gy radiation reduced viability further to 57.48% (± 1.64, $P < 0.01$) and 47.63% (± 3.11, $P < 0.01$) with 4 Gy radiation, compared with untreated OE33P cells. When the OE33R cells were treated with combination Atezolizumab and Nivolumab, viability was reduced to 71% (± 2.08, $P < 0.01$) and with the addition of 2 Gy radiation viability reduced to 54.67% (± 2.40, $P < 0.01$) and 31% (± 1.03, $P < 0.001$) with 4 Gy radiation compared with untreated OE33R cells. Treatment with 4 Gy radiation and combination Atezolizumab and Nivolumab resulted in a significantly greater reduction in viability in the OE33R cell line compared to the OE33P cell line ($P < 0.01$) (Figure 2F).

Profiling IC expression in fresh patient tissue samples

The *in vitro* data revealed an increase in IC expression on OAC cells post irradiation. To determine if this held true in *ex vivo* OAC tumour tissue, we profiled IC expression post irradiation with 2 Gy and 4 Gy. Subcohorts of patients demonstrated an upregulation and others a downregulation in checkpoint expression upon exposure to conventional radiation doses and hypofractionation for $CD3^+$, $CD3^+CD4^+$, $CD3^+CD8^+$ tumour-infiltrating T cells. There was a significant increase in the frequency of $CD3^+PD\text{-}1^+$ and $CD3^+CD8^+PD\text{-}1^+$ T cells in tumour tissue when irradiated with 2 Gy (26.76 ± 8.80 *vs* 16.62 ± 5.40 at 0 Gy, and 14.8 ± 4.1 *vs* 7.70 ± 2.01 at 0 Gy, respectively, $P < 0.05$). There was a significant increase in the frequency of $CD3^+CD4^+$ $PD\text{-}L1^+$ cells with 4 Gy radiation (19.4 ± 2.9 *vs* 6.27 ± 1.02 at 0 Gy, $P < 0.05$). There was an significant increase in $CD3^+TIGIT^+$ and $CD3^+CD4^+TIGIT^+$ expression with both 2 Gy (55.6 ± 8.6 *vs* 40.12 ± 5.40, and 61.29 ± 8.20 *vs* 52.17 ± 7.70, respectively, $P < 0.05$) and 4 Gy radiation dosing regimens (48.06 ± 3.10 *vs* 40.12 ± 5.40, and 65.16 ± 6.90 *vs* 52.17 ± 7.90, respectively, $P < 0.05$) when compared with unirradiated cells, and an increase in $CD3^+CD8^+$ $TIGIT^+$ expression following 4 Gy irradiation (49.55 ± 4.90 *vs* 31.07 ± 7.70, $P < 0.05$). Of interest, this population was significantly associated with advanced disease at initial presentation, poorer treatment responses, and adverse features of tumour biology, notably, lymphovascular invasion and perineural invasion.

In the cohort of patients which displayed a reduction in IC protein expression following radiation, there was a significant decrease in expression of PD-1 by $CD3^+$, $CD3^+CD4^+$ and $CD3^+CD8^+$ cells in tumour tissue when irradiated with 2 Gy *vs* 0 Gy (18.44 ± 5.90 *vs* 26.48 ± 7.50, $P < 0.05$; 10.33 ± 3.40 *vs* 14.46 ± 3.90, $P < 0.01$; 12.96 ± 5.10 *vs* 17.77 ± 8.20, $P < 0.05$; respectively) and PD-1 expression by $CD3^+$ and $CD3^+CD4^+$ when irradiated with 4 Gy *vs* 0 Gy (21.06 ± 6.90 *vs* 26.48 ± 7.50, and 10.04 ± 4.20 *vs* 14.46 ± 3.90, respectively, $P < 0.05$). There was also a significant decrease $CD3^+$, $CD3^+CD4^+$ and $CD3^+CD8^+$ cells expressing PD-L1 (15.6 ± 4.2 *vs* 20.6 ± 5.5, $P < 0.01$; 18.73 ± 11.50 *vs* 25.1 ± 13.1, $P < 0.05$; and 4.13 ± 0.90 *vs* 11.17 ± 2.80, $P < 0.05$; respectively) , TIGIT (48.61 ± 5.60 *vs* 60.13 ± 6.20, 59.88 ± 4.50 *vs* 69.57 ± 4.10, and 21.67 ± 6.40 *vs* 30.76 ± 4.50, respectively, $P < 0.05$) and TIM-3 (3.24 ± 0.90 *vs* 6.86 ± 2.50, 4.07 ± 1.30 *vs* 10.91 ± 3.30, and 3.37 ± 119.00 *vs* 9.13 ± 3.10, respectively, $P < 0.01$) with 2 Gy radiation. Similar findings were identified with 4 Gy irradiation compared to basal expression by $CD3^+CD8^+$ for PD-L1 (3.51 ± 0.60 *vs* 11.17 ± 2.80, $P < 0.05$) and TIM-3 (2.93 ± 0.70 *vs* 9.13 ± 3.10, $P < 0.05$) (Figure 3).

Clinical correlations

In order to understand potential clinical implications of these cohorts with increased and decreased IC expression post radiation, clinicopathological correlations were made based on patient tumour stage, adverse features of tumour biology, radiation and IC positivity (Table 1). There was a positive correlation basally with $PD\text{-}1^+CD3^+$ cells and lymphovascular invasion ($P = 0.04$). In terms of tumour staging, clinically there was a positive association of increasing tumour stage and $PD\text{-}L1^+CD3^+$ ($P = 0.02$) basally, $PD\text{-}L1^+CD3^+$, $TIM\text{-}3^+CD3^+$ and $TIM\text{-}3^+CD4^+$ at 2 Gy, and $TIM3^+CD8^+$ at 4 Gy ($P < 0.05$). There was a negative association between $PD\text{-}1^+CD8^+$ at 2 Gy ($P = 0.01$). In terms of clinical nodal status, there was a positive association with nodal positivity and $PD\text{-}L1^+CD4^+$ basally ($P < 0.001$) and $PD\text{-}1^+CD4^+$, $TIM\text{-}3^+CD4^+$, $TIM\text{-}3^+CD8^+$ at 4 Gy ($P < 0.05$). Pathologically, advancing tumour stage was negatively associated with $TIGIT^+CD3^+$ at 2 and 4 Gy ($P < 0.01$). Pathological nodal positivity was associated with $PD\text{-}L1^+CD4^+$ basally at 0 Gy, and $TIGIT^+CD3^+$ at 4 Gy ($P < 0.05$). It was negatively associated with $PD\text{-}L1^+CD8^+$ cells and $TIGIT^+CD3^+$ cells at 2 Gy ($P < 0.05$).

Release of angiogenic markers, cytokines, co-stimulatory molecules and soluble checkpoints post irradiation

Given the complex interplay in the tumour microenvironment between immunosuppressive factors and

Table 1 Clinicopathological characteristics of the study population illustrating the correlation for the percentage of $CD3^+$, $CD3^+CD4^+$ and $CD3^+CD8^+$ cells expressing immune checkpoints present in oesophageal adenocarcinoma tumour tissue

Positive values indicate positive correlation, negative values indicate negative correlation. Spearman correlation. Only significant data shown. Spearman *r* = 0.40-0.59 moderate, 0.60-0.79 strong and 0.80-1.00 very strong. IC: Immune checkpoint.

anti-tumour immunity, we investigated the expression of cytokines, ICs, co-stimulatory molecules, markers of angiogenesis and vascular injury with and without radiation. The administration of 4 Gy radiation was effective in significantly reducing angiogenic markers over that of untreated 0 Gy tissue; basic fibroblast growth factor (bFGF, 57.7 ± 24.5 *vs* 197.5 ± 76.2, $P < 0.05$), Flt-1 (113.5 ± 47.7 *vs* 364.7 ± 145.8, $P < 0.05$), placental growth factor (PIGF, 18.7 ± 12.1 *vs* 32.8 ± 17.8, $P < 0.05$). Whereas, a significant reduction was observed in VEGF-A following 4 Gy radiation over that of 2 Gy (522.8 ± 144.2 *vs* 583.7 ± 86.2, $P < 0.05$) (Figure 4).

There was a significant increase in the level of IL-21 (1.98 ± 0.30 *vs* 1.3 ± 0.3, $P < 0.01$) and IL-31 (0.24 ± 0.04 *vs* 0.18 ± 0.02, $P < 0.01$) with the administration of 4 Gy radiation compared to 0 Gy with a significant decrease in IL-23 (3.53 ± 1.40 *vs* 5.24 ± 1.90, $P < 0.05$) following 4 Gy radiation compared with 2 Gy. CRP, a marker of vascular injury increased significantly with 2 Gy radiation dosing compared to untreated 0 Gy tissue (7568 ± 5750 *vs* 5425 ± 2925, $P < 0.05$) but was reduced with 4 Gy compared to non-irradiated tissue (Figure 5).

In terms of IC receptor and ligand expression, there was a significant reduction in levels of soluble PD-1 (6.44 ± 2.40 *vs* 15.72 ± 6.20, $P < 0.05$), PD-L1 (3.76 ± 0.70 *vs* 8.12 ± 1.70, $P < 0.05$), TIM-3 (24.11 ± 6.20 *vs* 76.02 ± 23.50, $P < 0.05$), TIGIT (4.26 ± 1.50 *vs* 39.0 ± 3.6, $P < 0.05$) and CD276 (58.81 ± 12.80 *vs* 164.30 ± 61.02, $P < 0.05$) in the TCM following 4 Gy radiation compared with 0 Gy. In addition, 4 Gy radiation also induced a significant decrease in the release of the soluble co-stimulatory molecules CD28 (82.18 ± 27.70 *vs* 163.2 ± 56.3, $P < 0.05$), glucocorticoid-induced TNF receptor (GITR, 5.27 ± 4.10 *vs* 5.7 ± 3.8, $P < 0.05$) and OX-40 (6.7 ± 2.1 *vs* 11.9 ± 2.9, $P < 0.05$) compared to untreated tissue 0 Gy (Figure 6).

DISCUSSION

The visceral appeal of modulating the host immune system is one of simplicity in an effort to harness a profound anti-tumour response and is a principle that has existed since the development of the field of cellular immunology as an entity. Quintessentially, skewing the hosts innate immune system to boost anti-tumour immunity consists of two processes compliant to exploitation: These being the stimulant as well as the reaction. The most logical way to perturb the tumour and its microenvironment is through promoting tumouricidal effects, through systemic chemotherapy or the radiation therapy delivered.

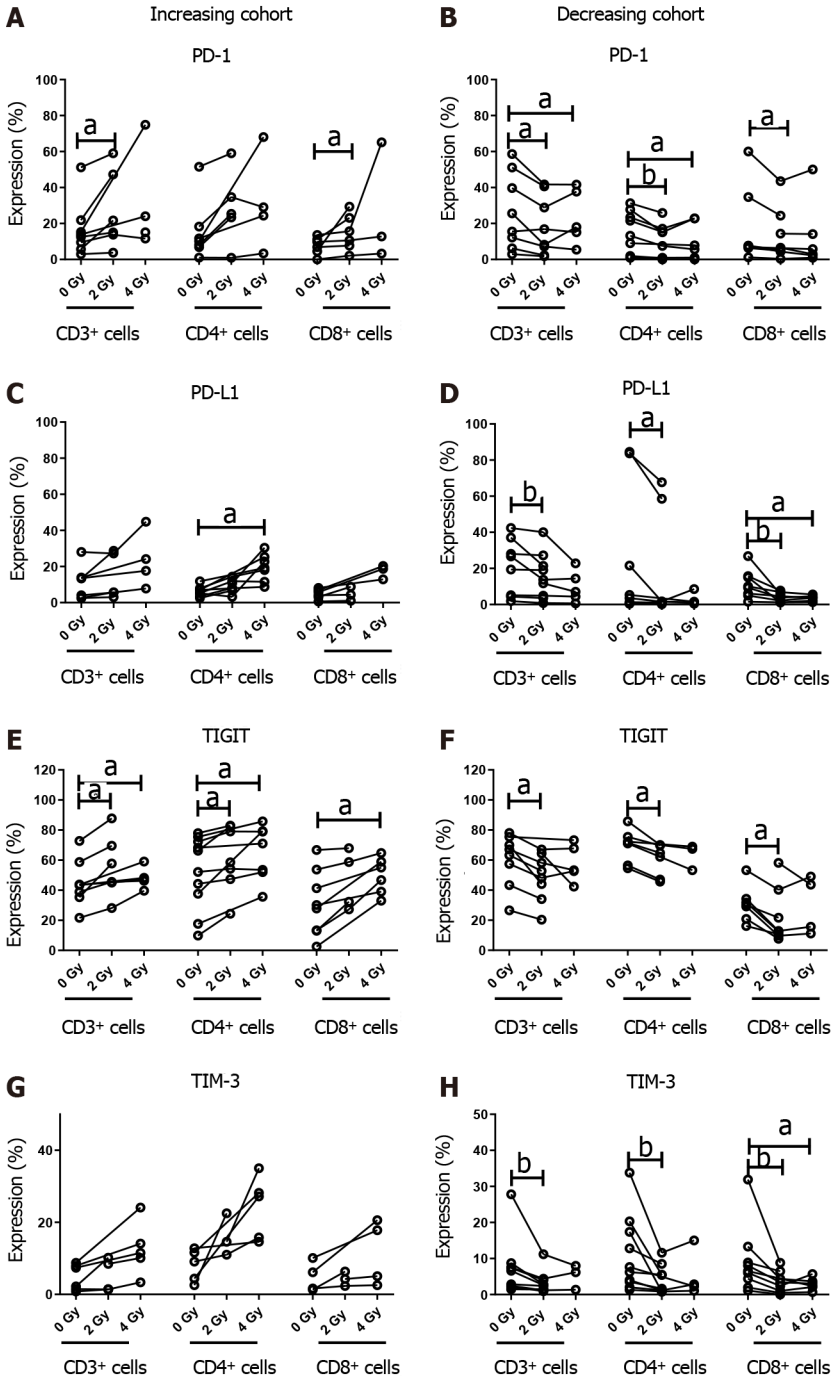

Figure 3 Oesophageal adenocarcinoma patients were screened for the surface expression of immune checkpoints *ex vivo* by flow cytometric analysis. Subcohorts where ionising radiation induced upregulation and downregulation of immune checkpoints (ICs). Inhibitory ICs are expressed at a higher level with conventional and hypofractionated dosing regimens in one cohort (n = 8). Inhibitory ICs are expressed at a lower level with conventional and hypofractionated dosing regimens in a separate cohort (n = 9). A and B: Increasing and decreasing cohort of PD-1; C and D: Increasing and decreasing cohort of PD-L1; E and F: Increasing and decreasing cohort of TIGIT; G and H: Increasing and decreasing cohort of TIM-3. [a]$P < 0.05$; [b]$P < 0.01$ by Wilcoxon signed rank test.

Increasing and propagating the anti-tumour responses thereby facilitating immune activation with optimal kinetics may achieve a synergistic anti-tumour response, producing a more profoundly durable effect on the immune system than chemo (radio) therapy alone. In this context, the landmark Checkmate-577 trial has demonstrated significantly improved disease free survival in the adjuvant setting of resectable gastroesophageal cancer[16]. The findings of increased IC expression *in vitro* and *ex vivo* through the use of radiation in the current body of work provides promising translational therapeutic rationale for their use in the multimodal paradigm. RT propagates the priming and effector phases of the anti-tumour immune response rendering it an appropriate combination with IC inhibitors (ICIs)[24]. However, inherently radioresistant tumours may pose a particular therapeutic dilemma, as they may not have a similar synergism with ICB as radiosensitive tumours. Ionising radiation is currently under investigation in metastatic oesophageal cancer with pembrolizumab (NCT02642809)

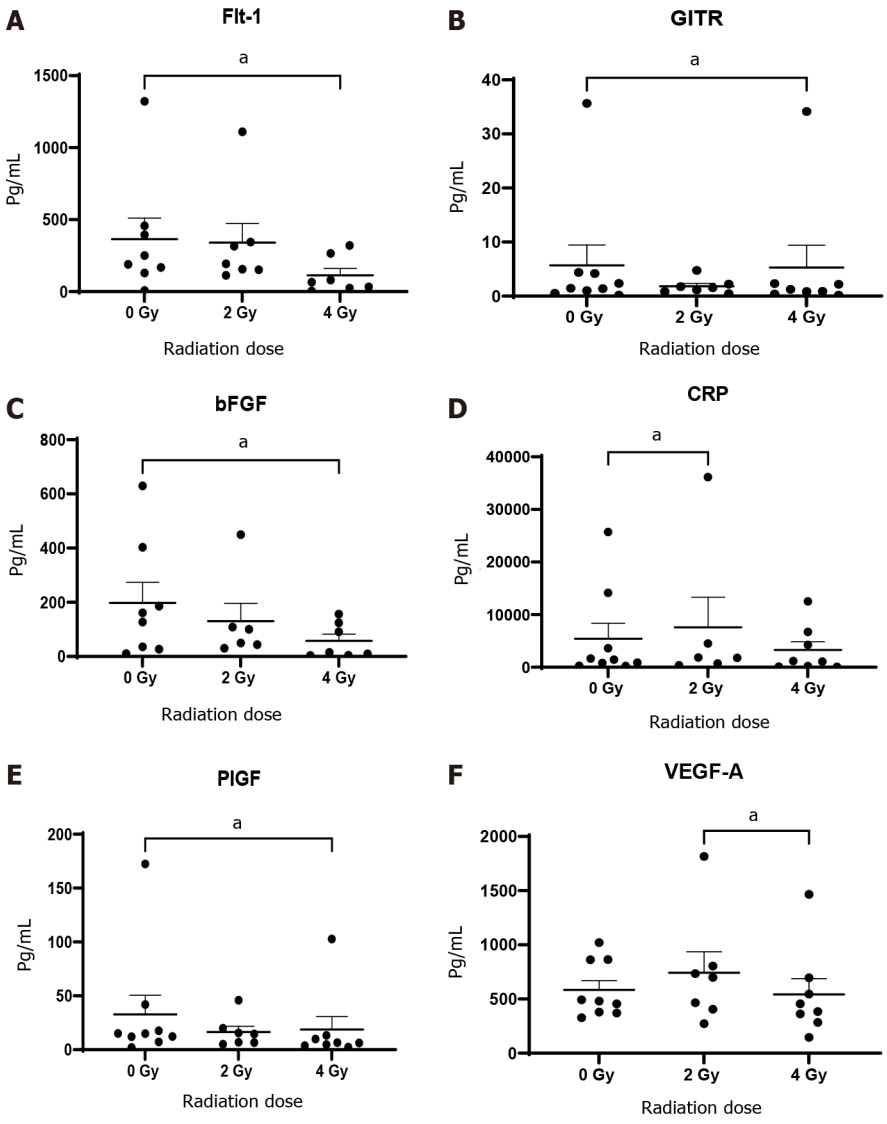

Figure 4 Conditioned media generated using oesophageal adenocarcinoma patient tumour was screened for markers by multiplex immunosorbent assay kit. Angiogenic markers Flt-1, basic fibroblast growth factor (bFGF), placental growth factor (PlGF) and vascular endothelial growth factor (VEGF)-A and vascular injury marker C-reactive protein (CRP) decrease significantly with 4 Gy radiation (n = 9). A: Flt-1; B: GITH; C: bFGF; D: CRP; E: PlGF; F: VEGF-A. $^{a}P < 0.05$ by Wilcoxon signed rank test.

and is currently under investigation in the curative setting with neoadjuvant trimodal therapy of Pembrolizumab and chemoradiotherapy in oesophageal squamous cell carcinoma (NCT03792347), with a similar trial investigating durvalumab and chemoradiotherapy in squamous cell carcinoma (SCC) and OAC (NCT02735239). The SKY-SKRAPER-07 trial is currently evaluating anti-PD-L1 Atezolizumab with anti-TIGIT therapy following chemoradiotherapy in advanced oesophageal cancer (NCT04543617). Of note, in a study by Zhao *et al*[25], they reported that with PD-1 positivity correlated with TIM-3 expression, and CD8^{+} tumour infiltrating lymphocyte density as a risk factor for recurrence free and overall survival (OS) in oesophageal SCC. The increasing expression in OAC cells and a cohort of patients following RT in this study represents promising therapeutic targets in OAC.

The clinically important observation in this study that half of the patients assessed displayed a reduction in IC expression post RT is an interesting caveat, one which suggests very different susceptibility to ICB in combination with RT and therefore, the stratification of patients into potential responders and non-responders should be addressed. In the same vein, the activation of cGAS-STING signaling, which has been recognized to potentiate systemic anti-tumour immunity and subsequent tumour rejection by dual RT and checkpoint blockade administration is promising even in those with checkpoint downregulation. A study by Vanpouille-Box *et al*[26], highlighting the importance of the cGAS-STING pathway in response to combination RT and immunotherapy, reported the knockdown of cGAS in murine cancer cells abrogated the priming of CD8^{+} T cells in tumour-draining lymph nodes and spleen, and prevented the infiltration of abscopal tumours by CD8^{+} T cells. Importantly, the synergistic and significant reduction in viability of radioresistant OAC cancer cells which we observed in this study following the dual administration of ICIs and ionising radiation is very promising.

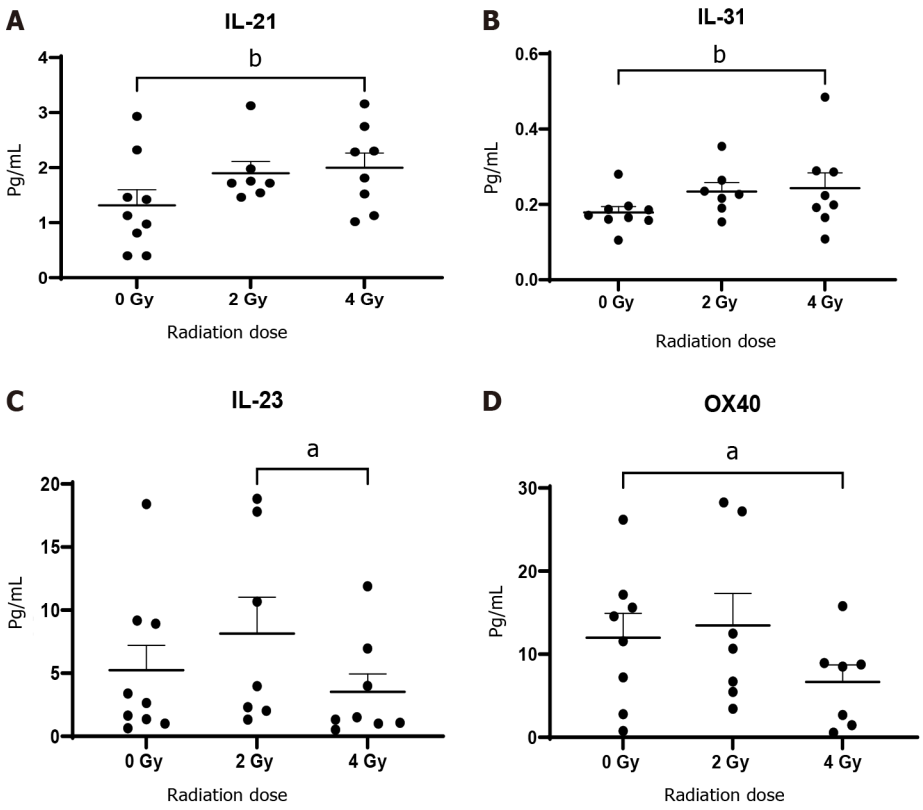

Figure 5 Oesophageal adenocarcinoma patients tumour conditioned media were screened by multiplex immunosorbent assay kit (*n* = 9). The cytokines interleukin (IL)-21 and IL-31 increase with ionising radiation while IL-23 and OX-40 decrease. A: IL-21; B: IL-31; C: IL-23; D: OX-40. [a]*P* < 0.05; [b]*P* < 0.01. Wilcoxon signed rank test to compare expression between basal levels and dosing regimens.

With respect to the use of hypofractionation in the curative setting for oesophageal cancer, there is an increasing volume of evidence demonstrating the safety and efficacy of this approach[27]. There are studies demonstrating a survival benefit of this approach particularly in the context of metastatic nodal disease. In one such study, hypofractionated radiotherapy (HFR) administered with taxane based chemotherapy in the management of post-surgery tracheoesophageal groove lymph node (TGLN) metastasis demonstrated improved OS in the HFR group compared with that of the conventional dosing treatment arm [24.1 mo (95%CI, 16.2-32.1 mo) *vs* 11.9 mo (95%CI, 9.2-14.4 mo), P = 0.024)[28]. Importantly, the study did not find a significant difference in pulmonary complications such as radiation pneumonitis (grades 3-4, 16.0% *vs* 7.1%; P = 0.314)[28].

Radiation induced lymphopenia is a frequent complication of multimodal cancer therapy and poorer outcomes are directly linked to the severity of lymphopenia[29]. Furthermore, it has been demonstrated that circulating lymphocyte count during neoadjuvant chemoradiation (CRT) in oesophageal cancer patients can predict pathological complete response (pCR) rates and low absolute circulating lymphocytes are associated with poorer outcomes[30]. The widespread adoption of immunotherapy has garnered new support and focus on the preservation of a pool of lymphocytes that are functional in enhancing immune function in the circulation and a study in pancreatic adenocarcinoma demonstrated hypofractionated CRT of 10 Gy in 3 doses over one week resulted in a decrease in the loss of T cells systemically compared to 28 daily doses of 1.8 Gy equating to 50.4 Gy[31,32].

The literature to date is concentrated primarily on evaluation of adverse events and of RT or immunotherapy in isolation. With improvements in targeted radiation delivery modalities, and technological advances, hypofractionated RT is now utilised without evidence of increased toxicities in a number of malignancies[33,34]. The Hypofractionated RT used in this instance was safe, well tolerated and provided robust survival results in those who could not receive chemoradiotherapy[35]. Furthermore, there is data in lung that conventional radiation dosing and immunotherapy is safe and feasible with no increases in adverse events[36-38].

The ATTRACTION 3 trial demonstrated a 50% reduction in serious adverse events in those treated with nivolumab *vs* conventional chemotherapy in Esophageal Squamous cell carcinoma[39]. In a study evaluating and immunotherapy in renal cell cancer, melanoma and lung, fatigue and pneumonitis were the most common adverse event. They found that toxicity did not correlate with hypofractionation or tumour type. Hypofractionated RT of pulmonary lesions was found to induce a complete response more consistently than in other sites. This study found that combining body Hypofractionated RT with immunotherapy is safe and viable, however, level I evidence is needed[40].

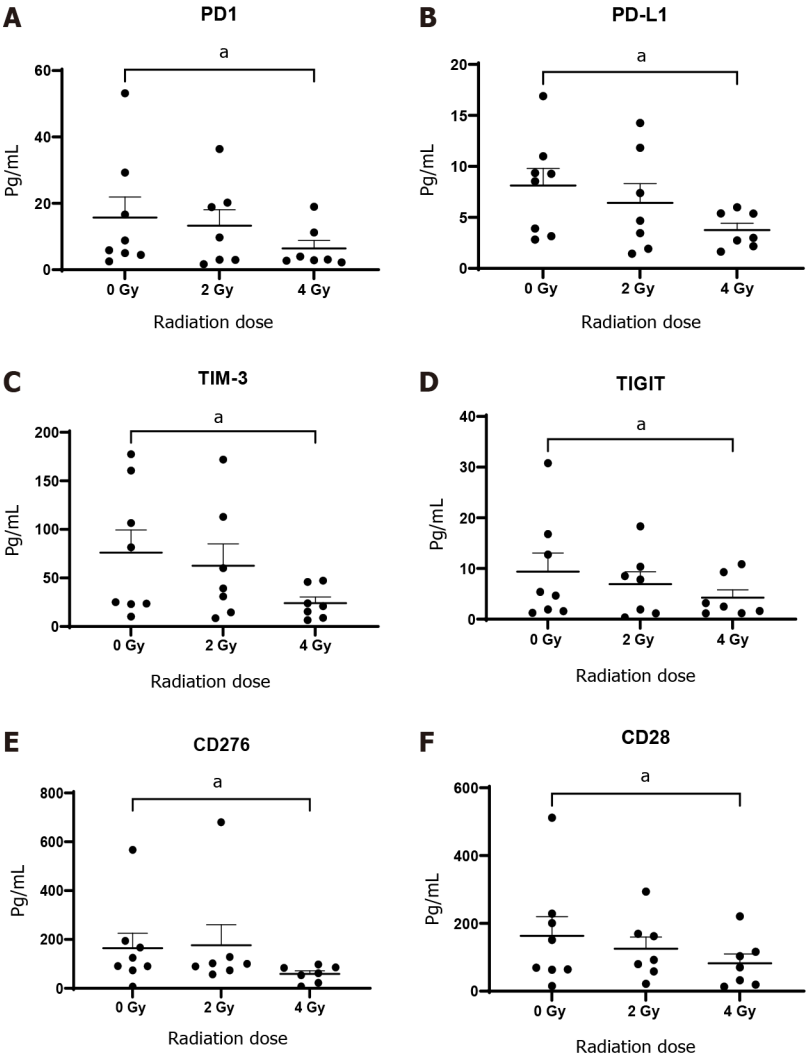

Figure 6 Oesophageal adenocarcinoma patient's tumour conditioned media were screened by multiplex immunosorbent assay kit. The inhibitory checkpoints PD-1 and its ligand PD-L1, TIGT, TIM3, immunosuppressive molecule and checkpoint CD276 (B7-H3) and costimulatory molecule CD28 significantly decrease with fractionated radiotherapy (n = 8). A: PD-1; B: PD-L1; C: TIM-3; D: TIGIT; E: CD276; F: CD28. $^{a}P < 0.05$ by Wilcoxon signed rank test.

VEGF is a mitogen essential for angiogenesis and Ramucirumab is approved for use in advanced gastroesophageal cancer patients. The use of anti-VEGF agents have shown promise in promoting improved survival when used in combination with chemoradiotherapy in colon cancer, however treatment resistance is a common problem[41]. This can be due compensatory mechanisms resulting in resistance, namely hypoxia- induced increases of other angiogenic promoters such as PIGF[42]. VEGF, bFGF and PIGF are crucial angiogenic promoters linked with tumourigenesis and Flt-1, is involved in tumour growth and metastatic dissemination, most likely *via* stimulation of macrophage-lineage cells [43]. PIGF/Flt-1 signaling can contribute to colorectal cancer progression through increasing the phosphorylation of p38 mitogen-activated protein kinase (MAPK), thereby upregulating MMP9 expression; resulting in increasing cellular migration/invasion. Therefore inhibition of PIGF/Flt-1 signalling will have therapeutic potential in lower gastrointestinal cancers[44]. In the current study radiation therapy was demonstrated to reduce the expression of these promoters of angiogenesis, which is crucial in the mitigating the risk of metastatic disease for upper gastrointestinal cancers.

The subset of cytokines expressed post radiation and immunotherapy treatment play a key role in determining the subsequent immune response elicited. In this study the OAC tumour tissue released significantly more anti-tumour IL-21 and IL-31 in response to radiation. IL-21 is produced by numerous T helper cells, such as Th1 and Th17 cells, activated Natural Killer T cells[45]. It promotes B cell differentiation into plasma cells, regulates immunoglobulin production, reshaping the tumour microenvironment and influencing the proliferation and/or effector function of both $CD4^+$ and $CD8^+$ T cells, while limiting the differentiation of Tregs[46]. IL-21 has distinct anti-tumour properties as a consequence of its ability to increase the availability of $CD8^+$ T cells through the induction of an early differentiation phenotype and Natural Killer cells[33]. IL-31 has immunoregulatory properties, with a study demonstrating that mice infused with IL-31 had tumour growth disruption and a decreased metastatic burden, supporting the use of IL-31 to offset the risk for metastatic disease development[47]. Similarly,

in a breast cancer murine model, the tumouricidal effects of T cells are increased, and myeloid derived suppressor cells and tumour-associated macrophages are reduced in tumours with high expression of IL-31, with an immunophenotype supporting antitumour immunity[48]. While both IL-21 and IL-31 were significantly increased in the TCM, the expression of IL-23, which has been documented to promote tumour metastases was decreased. IL-23 has metastases promoting properties *via* suppressing the anti-tumour properties of T cells and the anti-metastatic function of NK cells[49]. In addition to this, IL-23 was found to be overexpressed in many human cancers including colorectal and gastric cancer, and was found to be a negative prognostic indicator[50]. Of note CRP, an acute phase protein and marker of vascular injury was found to increase with 2 Gy radiation in our study. There have been epidemiologic studies to suggest that elevated CRP levels in circulation are linked with poorer outcomes in those with solid cancers, whereas elevated levels in apparently healthy subjects, is a potential independent risk factor for future risk of developing cancer of any type including lung, colorectal and gastric cancers due to chronic low inflammatory states, which is of particular relevance in OAC[51]. Therefore, the exact role of CRP in response to RT and immunotherapy requires further study.

Co-stimulatory and IC molecules can have both immunostimulatory and immunosuppressive effects. In this study a range of soluble ICIs and ligands were significantly downregulated following 4 Gy radiation treatment of OAC tumour explants. The role of soluble receptors however, and its effects on immune function remain yet to be elucidated and therefore its potential use as an oncological treatment remain unclear. Through this body of work, we observed a significant down regulation of PD-1, PD-L1, TIM-3 and TIGIT and this was paralleled by a concomitant increase in OAC cell line surface expression and a cohort of OAC tumour explants, which may go some way to explain the decrease in the soluble forms of these IC proteins post irradiation. B7-H3 (also known as CD276) is an IC molecule, with many cancers exhibiting aberrant overexpression and such upregulation is associated with aggressiveness and a poor clinical prognosis[52]. Furthermore, there are studies demonstrating a vital role for B7-H3 in promoting tumourigenesis and metastatic dissemination, proliferation, invasion and migration[52-54]. CD276 promotes tumour proliferation and invasion[55]. In addition, soluble CD276 was found to stimulate the invasion and metastatic dissemination of pancreatic adenocarcinoma cells *via* the Toll like Receptor 4/nuclear factor kappa-light-chain-enhancer of activated B cells pathway (50). Overall, additional studies are required in gastroesophageal cancers to determine the true function of soluble IC proteins and how they pertain to treatment response and immune regulation.

CD28 which is a co-stimulatory molecule is essential in the augmentation of T cell activation and metabolism, driving tumour-infiltrating T cell glycolysis. It is antagonized by CTLA-4 and PD-1[56]. In the current study, soluble CD28 is reduced with radiation, which may be immunosuppressive. Soluble CD80-Fc has been found to maintain IFN-γ release by PD-1$^+$ specific activated T cells even with PD-L1$^+$ tumour cells[57]. Soluble GITR, which was reduced in this study, represents a potential immunotherapeutic target and is found to be expressed at high levels on Tregs[58,59]. A number of phase 1 trials have identified anti-GITR antibodies to have safe pharmacological profiles, with phase II trials ongoing evaluating its combination with RT and anti-PD-1 therapy (NCT04225039). New promising approaches are focusing on the activation of co-stimulatory pathways to enhance antitumour immune responses. GITR activation can result in the inhibition of T-cell (Treg) function and promote effector T-cell function [58], and may also provide theoretical basis for the clinical application of combinations with monoclonal antibody therapy such as bFGF in molecular targeted therapies[60].

Lastly, OX40 has been demonstrated to have a crucial part to play in maintaining the immune responses in the immediate term and ongoing responses through enhancing T cell expansion, differentiation, and survival[61]. OX40 activation can have a significant impact T cell receptor (TCR) signaling through the PI3-K/PKB pathway, influencing T cell division, survival and cytokine production. This can directly increase calcium influx, and lead to IL-2, IL-4, IL-5, and IFN-γ secretion[62]. OX40 triggering regressed Treg cells, thus this allows Dendritic cells to reach the lymph nodes draining the tumour and in doing so prime the tumour-specific CD8 lymphocytes response [63]. However, in the current study radiation induces a downregulation of OX40 in TCM which may indeed be an immunosuppressive consequence of radiation therapy and one which requires further investigation. Again, more robust studies will be helpful to determine the functions of soluble co-stimulatory molecules as they may have alternate functions compared with their cell membrane bound counterparts in the tumour microenvironment.

CONCLUSION

The introduction of ICIs has resulted in enhanced survival in melanoma and non-small cell lung cancer treatment and has evolved to involve the spectrum of solid gastrointestinal malignancies with positive results of the landmark Checkmate 577 trial in the adjuvant setting most notable to date. However, there remains many issues to be interrogated including an appropriate RT regimen in conjunction with immunotherapies. There is considerable translational, preclinical and clinical data in favour of fractionated RT, and timing of RT delivery and target delineation, there remains disparity and no universal approach applicable to the clinical setting. In the current study, IC blockade in combination

with radiation synergistically reduces viability in radioresistant cells and Nivolumab appears most efficacious. There remains a need to delineate the effects of RT on host anti-tumour immunity. Additionally, lymphopenia induced by RT delivery may negate the effects of immunotherapy on offsetting T cell exhaustion, thus protocols that can minimize lymphopenia need careful design for maximal therapeutic potential. Finally, more concentrated and robust studies to determine and validate potential biomarkers to predict those who will be suitable for these treatment modalities are urgently required with profiling next-generation sequencing of tumour mutation burden based profiling, immune signatures, gene profiling signatures and the repertoire of T-cell receptors potential avenues to elucidate this.

ARTICLE HIGHLIGHTS

Research background

Oesophageal cancer is represents a difficult treatment dilemma with poor 5 year overall survival due to presentation at advanced stages due to its indolent nature as well as poor treatment responses to conventional therapies.

Research motivation

The advent of immunotherapy represents a shift in the multimodal treatment paradigm for esophageal cancer and has had mixed results in many solid tumours to date. The Checkmate 577 trial is a landmark study and is sure to revolutionize immune checkpoint blockade as the treatment modality of choice in the adjuvant setting.

Research objectives

To determine the impact of radiotherapy (RT) on immune checkpoint expression, and to determine the prevailing immune milieu in terms of markers of angiogenesis, cytokines and metastatic markers.

Research methods

This hybrid *in vitro* and *ex vivo* study is a mixture of flow cytometry, enzyme-linked immunosorbent assay kit work and cell viability by a cell counting kit-8 assay.

Research results

Radiation results in a decrease in angiogenic and metastatic markers with an increase in anti-tumour cytokines. There were two distinct subpopulations, with one cohort of patients demonstrating increased checkpoint expression as a consequence of radiation and a separate cohort demonstrating the opposite effects. The cohort with increased checkpoint expression had poorer treatment responses and were associated with adverse tumour biology.

Research conclusions

Oesophageal cancer represents an immune active tumour and is a viable target in both the neoadjuvant and adjuvant setting and should be combined with RT to exert maximum synergistic effects.

Research perspectives

This seminal study is the first of its kind and is a truly clinical and translational evaluation of the immune landscape of esophageal cancer.

Abstract

BACKGROUND

Obstructive sleep apnea (OSA)-hypopnea syndrome (OSAHS) has been recognized as a comorbidity of type 2 diabetes mellitus (T2DM); more than half of T2DM patients suffer from OSAHS. Intermittent hypoxia (IH) plays an important role in metabolic diseases, such as obesity and OSAHS, through various mechanisms, including altering the gut microecological composition and function. Therefore, it is important to study the role of gut microbiota in T2DM patients with OSAHS, which has a high incidence and is prone to several complications.

AIM

To assess whether IH is involved in altering the fecal microbiome in T2DM patients with OSAHS.

METHODS

Seventy-eight participants were enrolled from Henan Province People's Hospital and divided into healthy control (HC, n = 26), T2DM (n = 25), and T2DM + OSA (n = 27) groups based on their conditions. The fecal bacterial DNA of the research participants was extracted and subjected to 16S ribosomal RNA sequencing. The clinical indices, such as insulin resistance index, homocysteine (HCY) concentration, and the concentrations of inflammatory factors in the peripheral blood, were assessed and recorded.

RESULTS

Group T2DM + OSA had the highest apnea-hypopnea index (AHI) (2.3 *vs* 3.7 *vs* 13.7), oxygen desaturation index (0.65 *vs* 2.2 *vs* 9.1), HCY concentration (9.6

μmol/L *vs* 10.3 μmol/L *vs* 13.81 μmol/L) and C-reactive protein (CRP) concentrations (0.3 mg/L *vs* 1.43 mg/L *vs* 2.11 mg/L), and lowest mean oxygen saturation (97.05% *vs* 96.6% *vs* 94.7%) among the three groups. Twelve and fifteen key differences in amplicon sequence variants were identified when comparing group T2DM + OSA with groups T2DM and HC, respectively. We found progressively decreased levels of *Faecalibacterium*, *Eubacterium,* and *Lachnospiraceae,* and an increase in the level of *Actinomyces,* which strongly correlated with the HCY, CRP, fasting plasma glucose, and hemoglobin A1c concentrations, AHI, mean oxygen saturation, and insulin resistance index in group T2DM + OSA ($P < 0.05$).

CONCLUSION

For T2DM patients with OSAHS, IH may be involved in selective alterations of the gut microbiota, which may affect the pathophysiological development of T2DM and DM-related complications.

Key Words: Gut microbiota; Obstructive sleep apnea-hypopnea syndrome; Type 2 diabetes mellitus; Intermittent hypoxia; Obstructive sleep apnea

Core Tip: Clinically, type 2 diabetes mellitus (T2DM) patients have a significantly higher prevalence of obstructive sleep apnea-hypopnea syndrome (OSAHS) than non-T2DM patients and are more prone to diabetes-related complications and metabolic syndrome, including obesity and hypertension. In recent years, the imbalance of gut microbiota has been found to be associated with various metabolic disorders. This study revealed that intermittent hypoxia was associated with changes in the gut microbiota in patients with T2DM complicated by OSAHS. These changes may be involved in the progression of metabolic disorders through increased proinflammatory factors and impaired intestinal barrier function.

INTRODUCTION

Obstructive sleep apnea (OSA)-hypopnea syndrome (OSAHS) is characterized by recurrent partial or complete pharyngeal obstruction during sleep[1], resulting in intermittent hypoxia (IH); cyclical adverse changes in heart rate, blood pressure (BP), and sympathetic activity; and disruption of sleep architecture [2]. Epidemiological studies have shown that OSAHS is a globally prevalent chronic sleep disorder, especially in adults with type 2 diabetes mellitus (T2DM), with rates varying from 23% to 87%[3,4]. Moderate to severe OSAHS has been found to be associated with an increase in the incidence of T2DM, and the incidence of OSAHS in patients with T2DM was > 50% higher than that in those without diabetes, independent of traditional risk factors, such as obesity and other confounders. IH, a hallmark of OSAHS, plays an important role not only in the pathogenesis of OSAHS but also in reducing glycemic control and insulin resistance in patients with T2DM and diabetes-related complications[5-7], probably by activating several systematic inflammatory mediators and enhancing the oxidative stress cascade and hypothalamic-pituitary-adrenal function, among others[8].

Commensal bacteria, termed microbiota, cover every surface of our body exposed to the external environment, with 70% of these residing in the gastrointestinal tract[9]. The microbiome is a vast and complex polymicrobial ecosystem that coexists with the human organism and has been identified as playing important roles in the development of host immunological phenotypes. Gut microbiota dysbiosis has been linked to a series of metabolic disorders, such as diabetes and hypertension[10]. In a study of IH mimicking OSAHS, in an *Ldlr*$^{-/-}$ mice fed a high-fat diet, the imbalance of gut microbiota was found to be associated with adverse cardiovascular events and metabolic disorders[11,12]. Similarly, sleep fragmentation induced by OSAHS alters feeding behavior and promotes obesity and metabolic abnormalities, while the host gut microbiome changes, leading to increased intestinal permeability and chronic inflammation of adipose tissues[11,12]. For T2DM patients with OSAHS, only a few studies have focused on the relationship between severe metabolic disorders caused by IH and gut microbial dysbiosis, independent of conventional risk factors, such as obesity and hypertension. Hence, our study aimed to investigate the gut microbiota changes in T2DM patients with OSAHS.

Clinical indices, such as inflammatory factors and homocysteine (HCY), were compared for the groups as well.

MATERIALS AND METHODS

Participants

In total, 78 participants, including 25 hospitalized patients with T2DM (Group T2DM), 27 hospitalized patients with T2DM complicated by OSAHS (Group T2DM + OSA), and 26 healthy controls (HC) who were examined with a type IV portable monitor (PM, Sleep Fairy-A7, China) overnight (from 10 p.m. to 7 a.m.), were recruited from July 2019 to July 2020. Most of the sleep recording took place in a quiet and comfortable hospital ward at Henan Provincial People's Hospital; the remainder was performed by participants sleeping at home after being systematically trained in using the PM. The patient-reported periods before sleep onset and after awakening in the morning were excluded before manual scoring [13]. We collected fasting blood and fecal samples the next morning. General questionnaires were used to collect information on demographic characteristics and health status.

OSAHS assessment

Pulse oximetry was used to assess oxyhemoglobin saturation, and respiratory effort was measured with a pneumatic sensor attached to an effort belt. Nasal airflow was recorded using a nasal cannula connected to a pressure transducer. The final data were automatically generated by the software system. The scoring rules were based on the 2007 American Academy of Sleep Medicine manual. The apnea-hypopnea index (AHI) was calculated as the total number of episodes of apnea (continuous cessation of airflow for at least 10 s) and hypopnea (reduction in airflow for ≥ 10 s with oxygen desaturation of ≥ 4%) divided by the total duration of sleep events, and OSAHS was defined as an AHI of 5 events/h.

Inclusion and exclusion criteria

The inclusion criteria were as follows: (1) Age of 18-70 years; (2) Treatment-naïve type 2 diabetes based on the 1999 World Health Organization Criteria[14]; (3) 6.5% ≤ glycated hemoglobin A1c (HbA1c) ≤ 11%; (4) No antibiotic use within the 12 wk before enrollment and no probiotics and/or prebiotics; and (5) No glucose-lowering drugs other than insulin during the 12 wk before enrollment in patients with diabetes.

The exclusion criteria were as follows: (1) Body mass index (BMI) of > 28 kg/m^2; (2) Diagnoses of chronic respiratory disease, central system sleep apnea syndrome, severe heart failure, BP of ≥ 140/90 mmHg, and severe organic diseases such as cancer, myocardial infarction, and stroke; (3) Diagnoses of other types of diabetes, for example, type 1 diabetes; (4) Diagnoses of inflammatory bowel disease, coagulation disorders, connective tissue diseases, or gastrointestinal surgery, except for appendicitis and hernia surgery; (5) Participation in other programs during the previous 3 mo; (6) Alcoholism (drinking more than five times in 1 wk: > 100 g of spirits, 250 g of rice wine, or 5 bottles of beer); (7) Pregnancy; and (8) Taking drugs that may affect respiratory function, for example, anxiolytics, hypnotics, or mood stabilizers.

Sample collection

Biological samples and anthropometric data were obtained without medical treatment. Blood samples were collected after overnight fasting and centrifuged using centrifuge (Multifuge X3R, Thermo Fisher Scientific, United States) at 3000 rpm for 20 min after standing at 24 °C for 30 min to obtain serum. Fresh fecal samples, morning urine, and serum samples were immediately frozen on dry ice after collection and stored at -80 °C until further analysis.

Clinical indices

Fasting plasma glucose (FPG) concentrations were measured with the Automatic Biochemical Analyzer (TBA-120 FR, Toshiba, Japan). Fasting insulin concentrations were measured using immunochemiluminometric assays (ADVIA Centaur, Siemens A.G., German). Plasma HbAlc concentrations were measured by high-performance liquid chromatography (Bio-Rad D-10, Bio-Rad Laboratories Co., Ltd., Germany). Routine blood tests were performed using the Swelab Alfa Cell analyzer (Boule Diagnostics AB, Sweden). The Homeostatic Model Assessment for Insulin Resistance (HOMA-IR) was calculated using the following formula: FPG*FIN/22.5, where FIN is fasting insulin.

Inflammatory factors and HCY

C-reactive protein (CRP) and HCY concentrations were measured with the Automatic Biochemical Analyzer. The determination of the plasma concentrations of the lipopolysaccharide-binding protein (LBP), interleukin (IL)-6, IL-17, and transforming growth factor (TGF)-β1 was performed using human ELISA kits according to the manufacturer's instructions. The ELISA kits for the assessment of the concentrations of human LBP, tumor necrosis factor (TNF)-α, IL-17, and TGF-β1 were all from Cusabio

Biotech, Wuhan, China. The kits for high sensitivity IL-6 were purchased from Multi-Science, Hangzhou, China.

16S rRNA gene amplification sequencing

The DNA of the participants was extracted using the E.Z.N.A.® Stool DNA Kit (Omega Bio-tek, Inc., Norcross, GA, Unite States). The isolated DNA was used as the template for polymerase chain reaction (PCR) amplification of the V3-V4 region of 16S rRNA genes. The forward primer (341F) was 5'-CCTACGGGNGGCWGCAG-3', and the reverse primer (805R) was 5'-GACTACHVGGGTATC-TAATCC-3.' PCR was performed with an EasyCycler 96 PCR system (Analytik Jena Corp., AG), and the products from different samples were indexed and mixed at equal ratios for sequencing by Shanghai Mobio Biomedical Technology Co. Ltd. using the Miseq platform (Illumina Inc., San Diego, CA, Unite States) according to the manufacturer's instructions.

Sequencing data analysis

Amplicon sequence variants (ASVs) were identified with the DADA2 algorithm. The representative sequences for each ASV were annotated using the SILVA reference database (SSU138). The alpha diversity metrics (Shannon–Wiener diversity index and Simpson diversity index) were assessed by using Mothur v1.42.1. The non-parametric Mann–Whitney U test was used to test for significant differences between the two groups. The comparison of multiple groups was performed using a nonparametric Kruskal–Wallis test. Principal coordinates analysis (PCoA) based on Bray–Curtis and unweighted UniFrac distance was conducted using the R program (version 3.6.0, http://www.R-project.org/) to display microbiome space between samples. The key ASVs associated with T2DM and OSA were identified by random forest models, and those significantly associated with BMI selected by MaAsLin2 (https://github.com/biobakery/Maaslin2) were removed. A heatmap plot was drawn to indicate the distributions of the rest of the key ASVs. The linear discriminant analysis effect size (LEfSe) method (lefse 1.1, https://github.com/SegataLab/Lefse) was used to detect taxa with differential abundance. PICRUSt2 v2.4.1 (https://github.com/picrust/picrust2/wiki) was used to predict functional abundance based on 16S rRNA gene sequences.

Statistical analyses

Continuous variables are expressed as means ± SD or medians with interquartile ranges for normal distribution data or non-normal distribution data, respectively. Categorical variables are expressed as percentages. All the statistical analyses, including one-way analysis of variance, Kruskal–Wallis test, Mann-Whitney U test, and least significant difference *t*-test, were performed using SPSS version 26.0, with a two-sided P value of < 0.05 denoting statistical significance. Significant differences were adjusted by Bonferroni correction. The correlation coefficients for the concentrations of the gut microbiota, inflammatory factors, and HCY were evaluated using Spearman correlation.

RESULTS

Clinical parameters and inflammatory levels among three groups

Applying the strict inclusion and exclusion criteria described above, a total of 78 fecal samples were collected for analysis after PM assessment. We characterized the clinical indices and gut microbiomes of patients in groups HC, T2DM, and T2DM + OSA (Figure 1). There were no significant differences in sex and age among the three groups ($P > 0.05$). Compared with group T2DM, there were no significant differences in the insulin resistance index (HOMA-IR), BMI, waist-to-hip ratio, neck circumference, FPG, HbA1c, systolic BP, and diastolic BP in group T2DM + OSA; however, they were significantly increased compared with those in group HC ($P < 0.05$).

The HCY level was the highest in group T2DM + OSA compared with the other two groups. Our PM data revealed that the AHI and oxygen desaturation index (ODI) increased significantly, accompanied by a decrease in the mean oxygen saturation (SpO_2); group T2DM + OSA had lower SpO_2 than group HC. Further details on the clinical parameters of the participants with diverse severities are shown in Table 1.

The concentration of CRP increased gradually from the HC group to the T2DM group and even more in the T2DM + OSA group. In addition, the levels of TNF-α, IL-17, IL-6, and LBP increased and the levels of TGF-β1 decreased in group T2DM + OSA compared with those in group HC, while the level of TNF-α increased compared with that in group T2DM ($P < 0.05$) (Figure 2 and Supplementary Table 1).

IH is related to differences in the gut microbiota of T2DM + OSA patients

The resulting rarefaction curves showed that the microbial richness of the sampled guts was near saturation at the applied sequencing depth (Supplementary Figure 1), which was sufficient to identify most of the bacterial community members for each microbiome. The alpha diversity of the gut microbiota expressed by the Shannon estimator, ACE estimator, and Simpson index (Figure 3A-C and

[a]*P* < 0.05 *vs* HC.
[b]*P* < 0.01 *vs* HC.
[c]*P* < 0.01 *vs* T2DM.
P value: Comparison of three groups. Data are presented as the mean ± SD or median with interquartile range. The *P* value was based on Kruskal–Wallis test or one-way ANOVA. Mann–Whitney U test or least significant difference *t*-test was used to compare two groups. Significant differences were adjusted by Bonferroni correction. WHR: Waist-hip ratio; NC: Neck circumstance; FPG: Fasting plasma glucose; HOMA-IR: Insulin resistance index; HbA1c: Hemoglobin A1c; SBP: Systolic pressure; DBP: Diastolic pressure; HCY: Homocysteine; AHI: Apnea–hypopnea indices; ODI: Oxygen desaturation index; HC: Healthy control; T2DM: Type 2 diabetes mellitus; OSA: Obstructive sleep apnea.

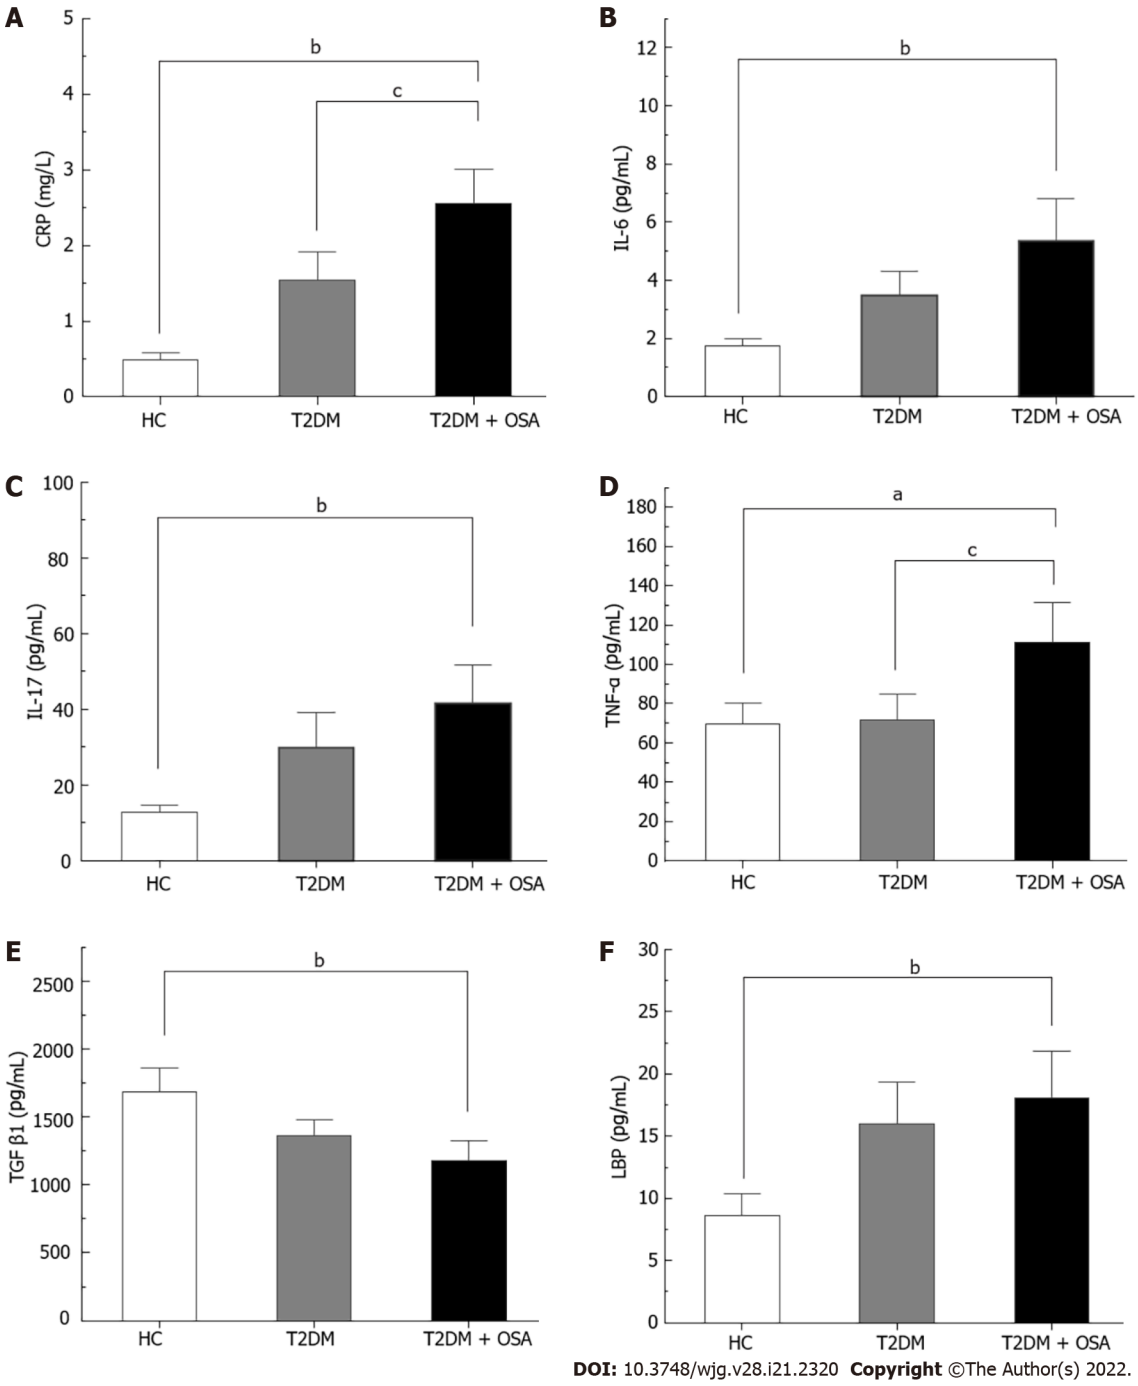
Supplementary Table 2) showed that there were no significant differences in groups HC, T2DM, and T2DM + OSA ($P > 0.05$). The overall structures of the gut microbiota in the three groups showed a minimal difference as revealed by the PCoA plot (Figure 3D); however, the difference was not significant (Adonis, $P > 0.05$).

We further analyzed the taxonomic composition and alterations of the gut microbiome. The composition and abundance of the bacterial community in each sample at the phylum and genus levels are shown in Supplementary Figure 2. At the phylum level, *Firmicutes* and *Proteobacteria* were the dominant bacteria in groups HC, T2DM, and T2DM + OSA (Figure 4A). At the genus level, we found no significant differences in the relative abundance of *Escherichia−Shigella,* which had the highest abundance among the three groups ($P > 0.05$) (Figure 4B). The relative abundance of the following genera significantly differed among groups: *Faecalibacterium* ($P = 0.0434$), *Streptococcus* ($P = 0.0393$), *Haemophilus* ($P = 0.0286$), *Phascolarctobacterium* ($P = 0.0242$), and *Oscillibacter* ($P = 0.0274$) (Figure 4C). Among the above genera, the levels of *Phascolarctobacterium* decreased and the levels of *Oscillibacter* increased in group T2DM + OSA compared with group T2DM, and the levels of *Faecalibacterium* significantly decreased in group T2DM + OSA compared with group HC. A gradually decreasing trend of *Faecalibacterium* abundance from group HC to groups T2DM and T2DM + OSA was observed (Figure 4C). Through LEfSe, we also found a significant decrease in the level of *Faecalibacterium* in group T2DM + OSA (Figure 4D).

We found 12 ASVs associated with gut microbial dysbiosis in group T2DM + OSA compared with group T2DM, including ASV632 (*Streptococcus*), ASV450 (*Clostridiaceae_Clostridium_sensu_stricto*), ASV352 (*Faecalibacterium*), ASV511 (*Roseburia*), ASV307 (*[Eubacterium]_hallii_group*), ASV1000 (*[Eubacterium]_eligens_group*), ASV995 (*Blautia*), ASV584 (*Eggerthella*), ASV535 (*Erysipelotrichaceae*_UCG-003), ASV87 (*Phascolarctobacterium*), ASV1112 (*Prevotella*), and ASV548 (*Oscillibacter*). On comparing groups HC and T2DM + OSA, 15 ASVs were different: ASV450 (*Clostridiaceae_Clostridium_sensu_stricto*), ASV511 (*Roseburia*), ASV1000 (*[Eubacterium]_eligens_group*), ASV266 (*Lachnospiraceae_unclassified*), ASV763 (*Lachnospiraceae_unclassified*), ASV367 (*Faecalibacterium*), ASV779 (*Actinomyces*), ASV986 (*Haemophilus*), ASV352 (*Faecalibacterium*), ASV436 (*Faecalibacterium*), ASV265 (*Streptococcus*), ASV535 (*Erysipelotrichaceae_UCG-003*), ASV68 (*Blautia*), ASV347 (*Saccharimonadales*), and ASV1022 (*Acinetobacter*) (Figure 5A). Therein, the relative abundance of ASV1022 (*Acinetobacter*), ASV367 (*Faecalibacterium*),

DOI: 10.3748/wjg.v28.i21.2320 **Copyright** ©The Author(s) 2022.

Figure 1 Flowchart of the study.



ASV436 (*Faecalibacterium*), ASV763 (*Lachnospiraceae_unclassified*), and ASV266 (*Lachnospiraceae_unclassified*) were progressively decreased, and the abundance of ASV779 (*Actinomyces*) increased from group HC to group T2DM and to group T2DM + OSA (Figure 5B).

IH-related gut microbiota dysbiosis was associated with abnormal metabolic and inflammatory indicators of T2DM + OSA patients

We further studied the correlations among metabolic indicators, inflammatory factors, and the above six key ASVs with ascending or decreasing trends. Spearman correlation analysis revealed that the decreased abundance of ASVs showed a significant negative correlation with indicators related to IH or respiratory disorders, such as the ODI and AHI; glucose metabolism indicators, such as HbA1c, FPG, and HOMA-IR; cardiovascular disease-related metabolic indicators, such as HCY; and inflammatory factors, such as CRP, TNF-α, and LBP. The ASV436 (*Faecalibacterium*) was negatively correlated with the AHI, ODI, FPG, HbA1c, CRP concentrations, and HOMA-IR, while the ASV763 (*Lachnospiraceae_unclassified*) was negatively correlated with the AHI and FPG, HbA1c, CRP, and LBP concentrations ($P < 0.05$). Furthermore, the ASV436 (*Faecalibacterium*), ASV1000 (*[Eubacterium]_eligens_group*), and ASV367 (*Faecalibacterium*) were positively correlated with the mean SpO_2, another IH-related indicator. Among the three groups, the gradually increasing abundance of ASV779 (*Actinomyces*) showed an opposite relationship; it was significantly positively correlated with the AHI, ODI, and TNF-α concentration and negatively correlated with the mean SpO_2 ($P < 0.05$) (Figure 6 and Supplementary Table 3).

DISCUSSION

T2DM has been linked to gut dysbiosis and chronic inflammation in several clinical and animal experiments[15-17], which may be a consequence of the loss of or deficiency in a beneficial function, such as short-chain fatty acid (SCFA)-producing bacteria production from carbohydrate fermentation, in the gut ecosystem[16]. Diseases previously partially attributed to lifestyle, such as obesity and OSAHS, are now considered microbiota-related as well[12,18]. Although much epidemiological and clinical evidence has suggested that OSAHS is an independent risk factor for the development of T2DM[19], the underlying pathogenesis of altered glucose metabolism in T2DM patients with OSAHS remains to be elucidated. Meanwhile, a longitudinal cohort study over a period of 6 years found that the insulin resistance index (HOMA-IR) was a predictor of incident "witnessed apnea", independent of obesity [20]. This showed that dysglycemia and insulin resistance may lead to the development of OSAHS. Together with the findings of the above-mentioned studies, this strongly suggests that the relationship

between T2DM and OSAHS may be bidirectional[2]. Therefore, it is necessary to investigate whether the imbalance of the intestinal microbiota plays a key role in the pathophysiology underlying metabolic dysfunction of patients with T2DM complicated by OSAHS.

In our study, the sequencing analysis of the 16S rRNA gene-tags applied to fecal samples from T2DM patients complicated by OSAHS showed differences in the relative abundances of the predominant taxa of the genera levels. We found that the concentrations of various IH-related gut bacteria, including SCFA-producing bacteria such as *Faecalibacterium* and *Lachnospiraceae,* were significantly correlated with the concentrations of FPG HbA1c and HOMA-IR, as well as the concentration of HCY, a risk predictor of hypertension and arteriosclerosis[21,22]. IH can result in hypoxia/re-oxygenation cycling events within the gut microbiome and, as a result, the biological diversity of gut microorganisms may be

modified[16]. Although the intestinal epithelium is significantly resistant to hypoxia, regulating the absorption and barrier function of the intestinal epithelium is sensitive to the oxygen level in the intestine[23]. Hypoxia/re-oxygenation can directly impair cellular function *via* an increase in permeability and bacterial translocation and a decrease in tight junction integrity[16]. In addition, studies have shown that after prolonged normoxic recovery after IH exposure, the gut microbiota and circulating endotoxemia remain negatively affected[8]. Our results do not show significant differences in α-diversity and β−diversity. However, the gradual decrease in the relative abundance of SCFA-producing bacteria (such as the ASVs of *Faecalibacterium*, *Eubacterium*, and *Lachnospiraceae*) associated with abnormal indicators of oxygen metabolism, as well as elevated levels of inflammatory indicators (including CRP, IL-17, and TNF-α), which are critically involved in the development of insulin resistance and pathogenesis of T2DM, was observed in T2DM + OSA patients[24]. Emerging evidence shows that SCFAs can modulate glycemic control, exhibit anti-inflammatory and antitumorigenic activity, and decrease oxidative stress[25-28]. Short chain fatty acids contribute to mucin synthesis, decrease bacterial translocation, maintain gut integrity, and mitigate inflammation in the intestine[29, 30]. Thus, we speculated that SCFAs may be regarded as potential targets for recognizing metabolic comorbidities in patients with T2DM complicated by OSAHS.

There are several potential mechanisms by which IH mediates its effect on metabolic dysfunction. It induces macrophages to polarize toward the pro-inflammatory subtype of M1, leading to the production of more pro-inflammatory mediators in visceral adipose tissue, such as TNF-α, IL-6, and IL-8, resulting in subsequent impairment of insulin signaling pathways and insulin resistance[7]. Here, we found that the concentration of *Lachnospiraceae* was negatively correlated with that of LBP, which is one of the reference indicators of intestinal barrier disruption, suggesting that the induction of inflammatory

processes may be due to the leakage of microbial metabolites into the circulation induced by IH. We found certain changes in the gut microbiota among the three groups over time; however, there were no significant differences between patients with T2DM with and without OSAHS. Nonetheless, the concentrations of inflammatory indicators, such as CRP, TNF-α, and IL-17, were significantly increased in T2DM patients with OSAHS, which indicates that the changes in gut microbiota may have been delayed relative to the chronic inflammatory changes in T2DM patients with OSAHS. On the other hand, some patients with relatively mild disease were included to prevent confounding by factors, including hyperglycemia and obesity, which affect the composition of intestinal microbiota[31]; as a result, the intestinal flora appeared not to have changed remarkably.

Various respiratory diseases have been associated with dysbiosis not only in the airway microbiota but also in the intestinal microbiota[32,33]. This evidence reinforced the existence of a gut-lung axis and the close relationship between intestinal and respiratory compartments; changes at one of the two sites could impact the other[34]. As a minor constituent of the airway microbiota, *Actinomyces* is related to anaerobic enzymes through GLUT1-dependent glucose elevation and MCT4-dependent lactate transport[35,36]. In our study, we observed that the increase in the relative abundance of *Actinomyces*

Figure 5 Amplicon sequence variants contributing to the changes in the gut microbiota in groups healthy control, type 2 diabetes mellitus, and type 2 diabetes mellitus plus obstructive sleep apnea. A: The heatmap shows the relative abundance of the 46 amplicon sequence variants (ASVs) significantly different in the three groups. The fold ratio (log2-transformed) indicated the relative abundance of the 46 ASVs between the two different groups [*P*1: Type 2 diabetes mellitus (T2DM) + obstructive sleep apnea (OSA) *vs* T2DM; *P*2: T2DM + OSA *vs* healthy control (HC); *P*3: HC *vs* T2DM]. $^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$. Significant difference shown by the Mann–Whitney U test; B: With the increase in disease components, six key ASVs showed increasing or decreasing trends. $^{a}P < 0.05$, $^{b}P < 0.01$.

was positively correlated with OSAHS severity indices and the concentration of TNF-α. We did not test for lung microbes; however, we speculate that they may be related to the gut-lung axis. Further experimental approaches to exploring causal links may be needed.

There are some limitations to our study. First, the sample size was relatively small. Second, the causal relationship between T2DM complicated by OSAHS and the gut microbiota was unclear. Large-scale clinical trials and gnotobiotic mice model validation may be required in the future.

Figure 6 Heatmap of correlation among key amplicon sequence variants of gut microbiota and metabolic and inflammatory indicators. The color of the cells represents the Spearman's correlation coefficient between each amplicon sequence variant and clinical parameter. [a]*P* < 0.05; [b]*P* < 0.01.

CONCLUSION

T2DM patients with OSAHS may have a higher prevalence of gut microbial dysbiosis. IH may be involved in selective alterations of gut microbiota, which may be related to increased gut permeability and concurrent systemic inflammatory changes in patients with T2DM complicated by OSAHS. These findings provide foundations for further studies on the mechanisms and interventional approaches aimed at restoration of the gut microbiota to prevent or to palliate the adverse effects of T2DM patients with OSAHS.

ARTICLE HIGHLIGHTS

Research background

Obstructive sleep apnea (OSA)-hypopnea syndrome (OSAHS), as a chronic and treatable sleep disorder, has a high prevalence in type 2 diabetes mellitus (T2DM) patients. As a landmark feature of OSAHS, intermittent hypoxia (IH) plays an important role in the occurrence and development of related complications in T2DM patients. However, the pathological mechanisms are varied and unknown. Therefore, it is important to study the role of gut microbiota, a meaningful new target, in T2DM patients with OSAHS.

Research motivation

In recent years, it has been found that gut microbiota imbalance is related to metabolic diseases. However, most studies have not discussed the relationship between gut microbiota changes and T2DM patients with OSAHS.

Research objectives

In this study we focused on IH that might be involved in altering the gut dysbiosis in T2DM patients with OSAHS. Meanwhile, we further assessed the changes of clinical indicators and inflammatory factors related to dysbiosis, aiming to provide new targets and perspectives for the pathogenesis and prevention strategies of T2DM patients complicated with OSAHS.

Research methods

A case-control study was conducted to select subjects who were divided into T2DM + OSA group, T2DM group, and healthy control group. They were examined with a type IV portable monitor

overnight. The clinical indexes, respiratory parameters, inflammatory indexes, and gut microbial community of the three groups were measured.

Research results

Among the three groups, T2DM + OSA group showed the most severe changes in sleep apnea parameters and increased systemic inflammatory factors. We found the decreased levels of short-chain fatty acid-related *Faecalibacterium, Eubacterium,* and *Lachnospiraceae* and the increased levels of *Actinomyces* at the amplicon sequence variant level. The changes in these gut microbiotas were closely related to clinical indicators as well.

Research conclusions

IH may be involved in the selective changes of intestinal microbiota, which may be related to the increased intestinal permeability and systemic inflammation response in T2DM patients with OSAHS.

Research perspectives

This study shows that IH may change the state of gut microbiota and systemic inflammation, which participate in the occurrence and development of T2MD complicated with OSAHS. In the future, large-scale clinical randomized controlled prospective trials and animal trials may be needed to further explore the corresponding causality.

ACKNOWLEDGEMENTS

We would like to thank the participants involved in this study.

Abstract

BACKGROUND

Single-nucleotide polymorphisms (SNPs) of the serotonin type 3 receptor subunit (*HTR3*) genes have been associated with psychosomatic symptoms, but it is not clear whether these associations exist in irritable bowel syndrome (IBS).

AIM

To assess the association of *HTR3* polymorphisms with depressive, anxiety, and somatization symptoms in individuals with IBS.

METHODS

In this retrospective study, 623 participants with IBS were recruited from five specialty centers in Germany, Sweden, the United States, the United Kingdom, and Ireland. Depressive, anxiety, and

somatization symptoms and sociodemographic characteristics were collected. Four functional SNPs — *HTR3A* c.-42C>T, *HTR3B* c.386A>C, *HTR3C* c.489C>A, and *HTR3E* c.*76G>A — were genotyped and analyzed using the dominant and recessive models. We also performed separate analyses for sex and IBS subtypes. SNP scores were calculated as the number of minor alleles of the SNPs above. The impact of *HTR3C* c.489C>A was tested by radioligand-binding and calcium influx assays.

RESULTS

Depressive and anxiety symptoms significantly worsened with increasing numbers of minor *HTR3C* c.489C>A alleles in the dominant model ($F_{depressive}$ = 7.475, $P_{depressive}$ = 0.006; $F_{anxiety}$ = 6.535, $P_{anxiety}$ = 0.011). A higher SNP score (range 0-6) was linked to a worsened depressive symptoms score (F = 7.710, *P-linear trend* = 0.006) in IBS. The potential relevance of the *HTR3C* SNP was corroborated, showing changes in the expression level of 5-HT$_3$AC variant receptors.

CONCLUSION

We have provided the first evidence that *HTR3C* c.489C>A is involved in depressive and anxiety symptoms in individuals with IBS. The SNP score indicated that an increasing number of minor alleles is linked to the worsening of depressive symptoms in IBS.

Key Words: Irritable bowel syndrome; 5-HT$_3$ receptor subunit gene polymorphisms; Single-nucleotide polymorphism score; Depression; Anxiety; Somatization

Core Tip: Bringing together high quality data as well as methodological expertise, our results show that: In the dominant model, *HTR3C* c.489C>A was correlated with depressive and anxiety symptoms in irritable bowel syndrome (IBS); a higher number of minor alleles, which was computed by combining the individual SNP status of *HTR3A* c.-42C>T, *HTR3B* c.386A>C, *HTR3C* c.489C>A, and *HTR3E* c.*76G>A, was linked to more severe depressive symptoms in IBS; and the potential relevance of the *HTR3C* SNP was corroborated in functional assays showing changes in the expression level of 5-HT$_3$AC variant receptors. These results will contribute towards standardization and harmonization of genetic research strategies in IBS.

INTRODUCTION

Irritable bowel syndrome (IBS) is a chronic functional gastrointestinal (GI) disorder characterized by abdominal pain and altered bowel habits[1-4]. The pathophysiology of IBS has not entirely been resolved, but is understood to be biopsychosocial and affected by an impaired function of the central and enteric nervous systems and their crosstalk *via* the brain-gut axis[5,6]. IBS patients often present with increased comorbid depressive and anxiety symptoms[7-11], highlighting the complex relationship between visceral sensitivity and subjective psychological perceptions[12,13]. Nevertheless, about 50% of IBS patients report GI symptoms but show no comorbid affective symptoms[14].

There is evidence that disturbances of the serotonergic system are important in GI disorders such as IBS and in mental disorders, both of which interact *via* the brain-gut axis[15,16]. The serotonin type 3 receptors (5-HT$_3$R) modulate key functions in the GI tract[17,18]. In line with such functions, 5-HT$_3$R antagonists are beneficial in the treatment of diarrhea-predominant IBS (IBS-D)[19-22]. 5-HT$_3$Rs are also involved in emotional processing, mood regulation, and visceral perception and have been associated with depressive and anxiety symptoms that represent comorbid phenotypes in IBS[23]. Single-nucleotide polymorphisms (SNPs) in the 5-HT$_3$R subunit genes (*HTR3*), namely *HTR3A* c.-42C>T (rs1062613), *HTR3B* c.386A>C (rs1176744), *HTR3C* c.489C>A (rs6766410), and *HTR3E* c.*76G>A

(rs56109847), are associated with IBS according to studies investigating the effects of sex or IBS subtypes [12,24-30]. However, whether *HTR3* polymorphisms are associated with IBS and comorbid depressive and anxiety symptoms has not been determined because existing studies have missing phenotypic data on comorbidities and small sample sizes. These studies had case-control designs and investigated associations between these polymorphisms in individuals with IBS phenotypes or mental behavioral conditions and controls rather than combining genetic data with specific psychosocial characteristics of IBS patients.

This multicenter observational study focused on a large IBS patient cohort comprising 768 participants from centers in Germany, Sweden, the United States, the United Kingdom, and Ireland with the aim of meeting three objectives: (1) To explore the associations between functional *HTR3* polymorphisms and psychosomatic burden (*i.e.*, depressive, anxiety, and somatization symptoms) within an IBS population; (2) To investigate the impact of the *HTR3* SNP score (computed as the number of minor alleles) on psychosomatic burden, based on our hypothesis that the observed number of minor alleles was associated with specific mental characteristics in IBS patients; and (3) To perform a functional analysis of variant 5-HT$_3$AC receptors.

MATERIALS AND METHODS

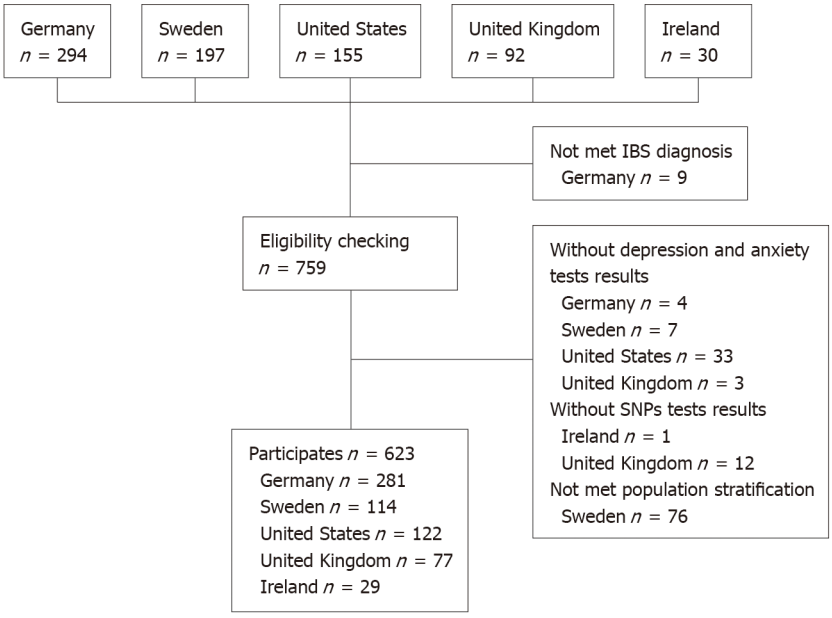
Subjects

The study population was pooled from five different tertiary care expert centers. German participants were recruited from the Specialty Clinic for Functional GI Disorders at the Department of General Internal Medicine and Psychosomatics of Heidelberg University Hospital[31] and from our clinical partners in the IBS-Net in Hamburg, Krefeld, Berlin, Vilsbiburg, and Munich (www.ibs.uni-hd.de). Swedish participants were recruited at the specialized unit for patients with functional GI disorders at Sahlgrenska University Hospital in Gothenburg. United States participants were recruited at Washington University, Barnes-Jewish Hospital in St. Louis, Missouri. United Kingdom participants were recruited at the Nottingham Digestive Diseases Center and participants from Ireland from a specialty clinic at Cork University Hospital. Participant recruitment is shown in Figure 1.

Written informed consent was obtained from all participants and the experiments were in accordance with the principles of the WMA Declaration of Helsinki and the Department of Health and Human Services Belmont Report. All studies were approved by the following local Ethics Committees: Heidelberg, Germany: Ethical Committee, Medical Faculty of the Heidelberg University Hospital (S067/2010); Cork, Ireland: Clinical Research Ethics Committee (APC024); Gothenburg, Sweden: Regional Ethical Review Board in Gothenburg (S489-02 and 731-09); Nottingham, United Kingdom: registered at clinical trial clinicaltrials.gov (identifier NCT00745004) and approved by Nottingham Research Ethics Committee 2 (REC reference number 08/H0408/134)[21]; and St-Louis, United States: Washington University St. Louis, Human Research Protection Office (IRB ID #: 201103220).

Inclusion/exclusion criteria

Only patients diagnosed with IBS according to the ROME III criteria were included in the analysis. All participants were of Caucasian ancestry and had comparable population stratification. Patients under 18 years of age or without SNP test results were excluded.



Genotyping

Genomic DNA was isolated from IBS patient blood samples using ethylenediaminetetraacetic acid according to standard protocols[32]. Four polymorphic *HTR3* loci, namely *HTR3A* c.-42C>T (rs1062613), *HTR3B* c.386A>C (rs1176744), *HTR3C* c.489C>A (rs6766410), and *HTR3E* c.*76G>A (rs56109847) were selected as target SNPs for this study. The corresponding primers were designed and synthesized using AssayDesigner 3.1 software. Genotyping was performed at the Department of Human Molecular Genetics at Heidelberg University Hospital using the KASPar® SNP Genotyping System (KBiosciences, Ltd, Hoddesdon, United Kingdom). To analyze *HTR3* SNPs, the fluorescence plate reader of the 7500 Fast Real-Time PCR System (Applied Biosystems, Foster City, California, United States) was used as recommended. About 10% of the samples were repeat tested to ensure genotyping accuracy.

Data collection

In addition to sociodemographic characteristics and IBS diagnosis, we also collected data on depressive, anxiety, and somatization symptoms[33] and genetic markers of the serotonergic system.

IBS diagnosis: The diagnostic classification of IBS was based on the Scoring Algorithm for Rome III Diagnostic Questionnaire for Adult Functional GI Disorders (SA for Rome III-DQ)[34,35] in all five centers. Percentages of the different IBS subtypes, *i.e.*, constipation-predominant IBS, IBS-D, IBS with mixed bowel habits, and unclassified IBS, were also calculated.

DOI: 10.3748/wjg.v28.i21.2334 **Copyright** ©The Author(s) 2022.

Figure 1 Recruitment strategy. IBS: Irritable bowel syndrome.

Depressive symptoms: The nine-item depression module from the Patient Health Questionnaire (PHQ-9)[36,37] was used to measure depressive symptoms in the German cohort. The Hospital Anxiety and Depression Scale depression subscale[38] was used to identify depressive symptoms in participants from Sweden, the United Kingdom, and Ireland and the Beck Depression Inventory[39] was used to measure the severity of depressive symptoms in United States participants.

Anxiety symptoms: In the German cohort, symptoms of generalized anxiety were assessed using the brief measurement for generalized anxiety disorder (GAD-7)[40]. In the cohorts from Sweden, the United Kingdom, and Ireland, the HADS anxiety subscale was used to identify anxiety symptoms. The Beck Anxiety Inventory[41] was used to assess anxiety in the United States cohort.

Somatization symptoms: In the cohorts from Germany, Sweden, and the United States, the 15-item somatization module from the PHQ-15[42] was used to identify somatization symptoms.

Genetic markers of the serotonergic system: The four functional SNPs *HTR3A* c.-42C>T (rs1062613), *HTR3B* c.386A>C (rs1176744), *HTR3C* c.489C>A (rs6766410), and *HTR3E* c.*76G>A (rs56109847) were selected for validation based on previous reports as outlined above[25].

Ligand binding and calcium influx assays

These procedures are described in the Supplementary material.

Statistical analysis

All statistical procedures were carried out using IBM SPSS Statistics 22.0 for Windows. Variables with a skewed distribution were log-transformed prior to further analysis. If different measurements had been collected in the five centers, *z* values were calculated to enable pooling. The Hardy-Weinberg equilibrium (HWE) of genotype frequency distribution was tested using SHEsis[43]. Genome-wide SNP data were generated by the Bellygenes team of D'Amato M using the Illumina Global Screening array and platform[44,45]. We used the multidimensional scaling approach to correct for population stratification in PLINK[46]. Following the guidance provided at https://github.com/MareesAT/GWA_tutorial/, our data were anchored by data of the 1000 Genomes project (http://www.1000genomes.org/). The 10 main components were used as covariates in the association tests to correct for population stratification[46] and exclude outliers. Polymorphisms were analyzed separately using the dominant and the recessive models. Also, stratified analyses based on sex and IBS subtypes were carried out. ANOVA was used to analyze group differences and to check for linear trends in depressive, anxiety, and somatization symptoms. For the independent variable, a SNP score was computed based on the number of minor alleles (*i.e.*, continuous from 0 to 8 for the four SNPs). Based on the first human *HTR3* locus-specific variant database (www.htr3.uni-hd.de)[25], scoring criteria were as follows: major allele homozygous variant gene = 0; heterozygous variant gene = 1; and minor allele homozygous variant gene = 2 (for details see Table 1). Statistical comparisons were made between the two groups using the χ^2 test or Fisher's exact test for frequencies and *t* tests or Mann-Whitney *U* tests for metric

Table 1 Strategy for computing the single-nucleotide polymorphism score

	Major allele homozygous genotype	Heterozygous variant genotype	Minor allele homozygous genotype
HTR3A c.-42C>T (rs1062613)	CC	CT	TT
HTR3B c.386A>C (rs1176744)	AA	AC	CC
HTR3C c.489C>A (rs6766410)	CC	CA	AA
HTR3E c.*76G>A (rs56109847)	GG	GA	AA

variables. Normal distribution and variance homogeneity were checked as conditions. Statistical tests were two-sided based on an alpha error of 0.05%. All analyses were explorative and not confirmatory. False discovery rates (FDRs) were calculated based on overall *P* values using the Benjamini-Hochberg method[47]. Significant values that were no longer significant after FDR multiple testing correction were named "nominally significant".

RESULTS

Sociodemographic and symptomatic characteristics

In total, 623 participants from five independent expert centers were included in this study (45.1% from Germany, 18.3% from Sweden, 19.6% from the United States, 12.4% from the United Kingdom, and 4.7% from Ireland). We excluded 76 Swedish participants who did not meet the population stratification criteria (Supplementary Figure 1). Participants from the United Kingdom and Ireland were excluded from the main analysis because the sample size was small. Table 2 presents the sociodemographic characteristics, IBS subtypes, and psychosomatic symptoms of the included participants. Participants had a mean ± SD age of 41.7 ± 16.1 years and 69.5% were female. Overall, IBS patients showed minimal to mild levels of depressive and anxiety symptoms, moderate levels of IBS symptoms, and moderate levels of somatization symptoms.

HTR3 SNP genotypes and allele frequencies

Genotype and allele frequencies of the functional *HTR3A* c.-42C>T, *HTR3B* c.386A>, *HTR3C* c.489C>A, and *HTR3E* c.*76G>A polymorphisms were calculated. No significant differences in genotype frequency were observed between sexes or IBS subtypes. For *HTR3A* c.-42C>T, the frequency of the minor *T* allele was 21.5%; for *HTR3B* c.386A>C, the frequency of the minor *C* allele was 29.6%; for *HTR3C* c.489C>A, the frequency of the minor *A* allele was 41.6%; and for *HTR3E* c.*76G>A, the frequency of minor *A* allele was 6.1%. The genotypic distribution of the four polymorphic loci of rs1062613, rs1176744, rs6766410, and rs56109847 were in accordance with HWE (all $P > 0.05$). The results are shown in Supplementary Tables 1-3.

HTR3 SNP analysis using the dominant and the recessive model

HTR3 SNPs were separately analyzed using the dominant model and the recessive model stratified for sex and IBS subtypes. Depressive and anxiety symptoms worsened significantly with increasing numbers of minor alleles of *HTR3C* c.489C>A in the dominant model ($F_{depressive} = 7.475$, $P_{depressive} = 0.006$; $F_{anxiety} = 6.535$, $P_{anxiety} = 0.011$). This seemed to be driven by female sex ($F_{depressive} = 7.040$, $P_{depressive} = 0.008$; $F_{anxiety} = 7.550$, $P_{anxiety} = 0.006$) and IBS-D ($F_{depressive} = 5.670$, $P_{depressive} = 0.018$; $F_{anxiety} = 13.444$, $P_{anxiety} < 0.001$). The same trend was also found for *HTR3A* c.-42C>T in male participants with depressive symptoms in the dominant model ($F_{depressive} = 4.149$, $P_{depressive} = 0.043$). For the recessive model, depressive and somatization symptoms worsened with increasing numbers of minor alleles of *HTR3C c.489C>A* ($F_{depressive} = 6.190$, $P_{depressive} = 0.014$) and *HTR3B c.386A>C* ($F_{depressive} = 6.482$, $P_{depressive} = 0.011$), respectively in IBS-D participants. *F* values from the ANOVA are shown in Table 3. As mentioned above, the analyses of participants from the United Kingdom and Ireland are presented separately in the Supplementary Table 4.

Effect of SNP score on psychosomatic symptoms

SNP scores ranged from 0 to 6; 37.1% had one or zero minor alleles of the analyzed *HTR3* SNPs and 30.8% had three or more minor alleles of the analyzed *HTR3* SNPs. No significant differences in SNP scores were observed between sexes ($F = 3.550$, $P = 0.060$) or IBS subtypes ($F = 1.485$, $P = 0.227$). ANOVAs were conducted and linear trends were checked to analyze the effect of SNP scores on depressive, anxiety, and somatization symptoms. Overall, an increasing number of minor alleles was linked to worsening depressive symptoms ($F = 7.710$, *P-linear trend* = 0.006). However, material trends did not reveal a link between more minor alleles and worsening anxiety or somatization symptoms. By stratifying analyses for sex, an increasing number of minor alleles was linked to worsened depressive

symptoms in female participants (F = 5.770, *P-linear trend* = 0.017). There was no significant association between SNP score and depressive, anxiety, or somatization symptoms when looking at IBS subtypes separately (Table 4). As mentioned above, the analyses of participants from the United Kingdom and Ireland are presented separately in the Supplementary Table 5.

Functional analysis of variant 5-HT$_3$AC receptors

The *HTR3C* SNP encodes the amino acid exchange p.Asn163Lys (p.N163K), and recombinantly expressed 5-HT$_3$AC receptors harboring variant 5-HT$_3$C subunits that mimic the homozygous minor allele and the heterozygous state presented with increased cell surface expression and enhanced 5-HT maximum response. Radioligand-binding assays revealed higher B_{max} values of 117.1% ± 4.38% and 111.9% ± 1.79%. Calcium influx assays showed increased 5-HT-induced maximum effects of 137.2% ± 9.0% and 151.9% ± 17.3% for the minor allele 5-HT$_3$AC 163K or combined 5-HT$_3$AC 163N/5-HT$_3$AC 163K receptors compared with the major allele representing 5-HT$_3$AC 163N receptors, respectively. The affinity of the specific 5-HT$_3$ receptor antagonist [^{3}H]GR65630, as reflected by the Kd values, and the potency of 5-HT, as reflected by the EC_{50} values, did not differ between the receptor variants (Figure 2).

DISCUSSION

Main findings

The 5-HT$_3$ receptors modulate essential functions in the GI tract such as GI motility as well as mood and emotions[19], and *HTR3* SNPs have been associated with depression, anxiety, and IBS[25]. In this study, we showed that: (1) In the dominant model, *HTR3C c.489C>A* was correlated with depressive and anxiety symptoms in IBS; (2) A higher number of minor alleles (*i.e.*, a higher SNP score, which was computed by combining the individual SNP status of *HTR3A c.-42C>T, HTR3B c.386A>C, HTR3C*

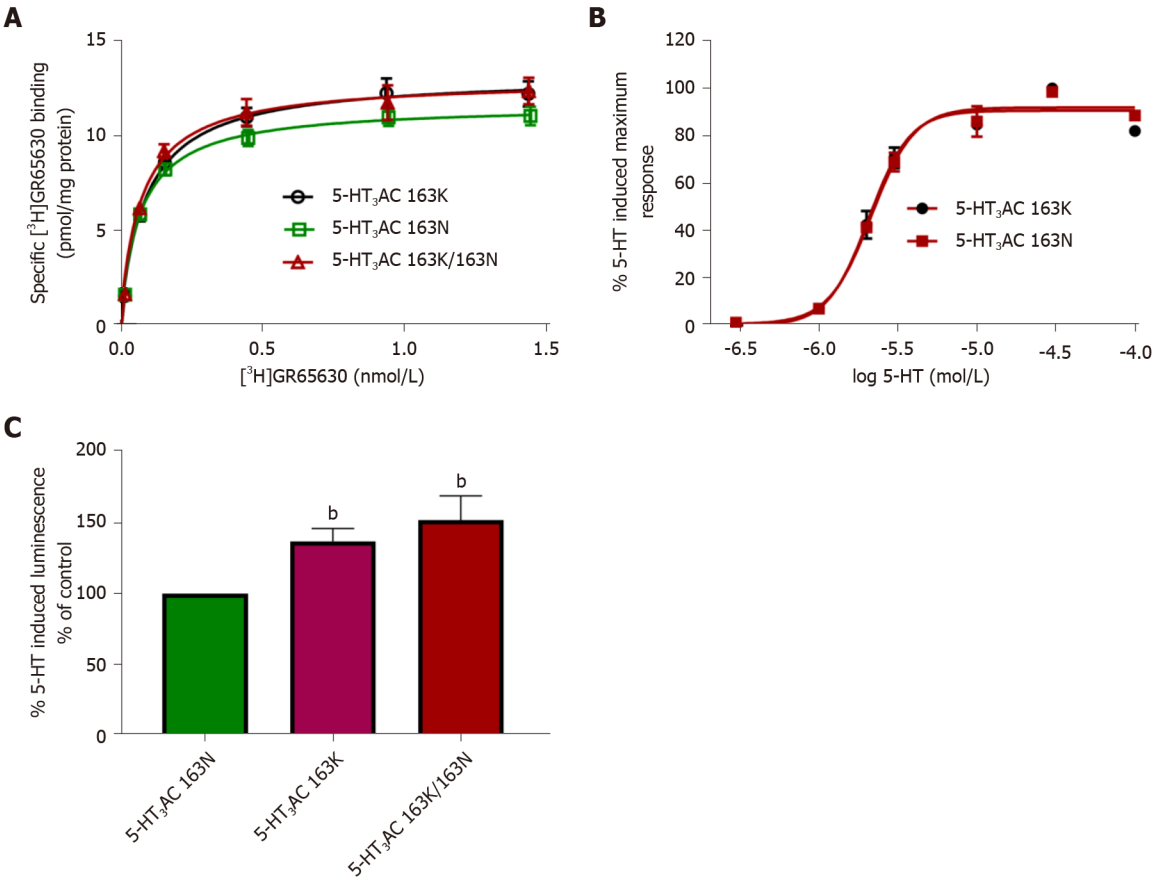
Values in bold were "nominally significant" (*i.e.*, lacking significance after false discovery rate multiple testing correction). IBS: Irritable bowel syndrome; IBS-C: Constipation-predominant IBS; IBS-D: Diarrhea-predominant IBS; IBS-M: IBS with mixed bowel habits.

c.489C>A, and *HTR3E c.*76G>A*) was linked to more severe depressive symptoms in IBS; and (3) The potential relevance of the *HTR3C* SNP was corroborated in functional assays showing changes in the expression level of 5-HT_3AC variant receptors. These findings are discussed in more detail below.

Sample characteristics

Participants with IBS were more frequently female than male, in line with previous findings[48,49] that IBS is more prevalent in young and middle-aged females. Most participants with IBS were only mildly affected by depression and anxiety symptoms. Of note, German participants only visited the Specialty Clinic for Functional GI Disorders at Heidelberg University Hospital after a long history of dealing with IBS[31]; therefore, these participants reported more severe depressive symptoms. However, causal relationships between IBS symptoms, depression, and anxiety are still controversial.



The investigated SNPs rs1062613, rs1176744, rs6766410, and rs56109847 were in accordance with HWE. There was no population stratification, and the sample was representative and excluded genotyping errors. Although participants were recruited from various centers in different countries, there were no obvious selective differences.

Connections between HTR3 SNPs and mental symptoms

***HTR3A* c.-42C>T (rs1062613):** Depressive symptoms were "nominally significantly" more severe with increasing numbers of minor *HTR3A* c.-42C>T alleles in male participants according to the dominant model. This SNP has been associated with bipolar affective disorder[50], IBS symptom severity, amygdaloid activity[29,51], early life trauma[52], altered emotional networks in the human brain, and the onset of depression[53]. However, these studies only included single sex participants and did not include subgroup analyses.

***HTR3B* c.386A>C (rs1176744):** Somatization symptoms worsened significantly with increasing numbers of minor *HTR3B c.386A>C* alleles in the dominant model. The *HTR3B* variant p.Tyr129Ser (rs1176744) has been associated with bipolar affective disorder in males and with major depression in females as well as with pain catastrophizing, a coping style characterized by excessively negative thoughts and emotions related to pain[30,54-56]. This discrepancy may be due to an enhancement or weakening of this association by polymorphic interactions in the serotonin pathways[56].

***HTR3C* c.489C>A (rs6766410):** Depressive and anxiety symptoms worsened significantly with increasing numbers of minor *HTR3C* c.489C>A alleles in the dominant model. This effect seemed to be driven by female sex and IBS-D. *HTR3C* c.489C>A was previously associated with IBS-D in female patients[57], but the proportion of male patients was small in this study, which may limit the applicability of these findings. In the recessive model, depressive and anxiety symptoms "nominally

DOI: 10.3748/wjg.v28.i21.2334 **Copyright** ©The Author(s) 2022.

Figure 2 Comparative analysis of 5-HT$_3$AC 163N (major allele homozygous), 5-HT$_3$AC 163K (minor allele homozygous), and 5-HT$_3$AC 163K/163N (heterozygous) receptors. A: Radioligand-binding studies Saturation experiments were performed in membranes of HEK293 cells transiently expressing different 5-HT$_3$ subunit combinations in triplicate with six increasing concentrations of [3H]GR65630 (0.02-1.5 nmol/L); Kd values were 0.07 ± 0.01 for 5-HT$_3$AC 163N; 0.08 ± 0.01 for 5-HT$_3$AC 163K, and 0.07 ± 0.01 for 5-HT$_3$AC 163K/163N. *n* = 6 experiments; B: Concentration response curves were assessed in a calcium influx assay (aequorin assay) in HEK293 cells transiently transfected with different 5-HT$_3$ subunit combinations in quadruplicate with seven increasing concentrations of 5-HT. pEC50 values were as follows: 68 ± 0.03 for 5-HT$_3$AC 163N 5 and 5.66 ± 0.02 for 5-HT$_3$AC 163K; C: Respective maximal calcium influx values (E_{max}) evoked by 5-HT (10 μmol/L). Data are expressed as percentages of the E_{max} of the heteromeric 5-HT$_3$AC 163N receptor (% of control), *n* = 8 experiments. Bars represent mean ± SE. $^bP < 0.01$ from ANOVA followed by Dunnett's post-test or unpaired Student's test for comparison of only two groups.

significantly" worsened with increasing numbers of minor alleles of *HTR3C* c.489C>A in Irish participants. However, these results should be interpreted with caution because the Irish sample size was low. As far as we are aware, *HTR3C* c.489C>A has not been analyzed in individuals with affective disorders before.

***HTR3E* c.*76G>A (rs56109847):** *HTR3E* is restrictedly and robustly expressed in the GI tract[58,59], suggesting that it plays a special role in 5-HT$_3$ receptor function in the gut. In this study, we did not find a relationship between functional polymorphisms of *HTR3E* and depressive and anxiety symptoms in IBS patients. This may be attributed to a floor effect because depressive and anxiety symptoms were minimal to mild in our sample[60].

The SNP score and its impact on depressive symptoms

A single gene variant is not sufficient to explain all symptoms shaping the clinical phenotype of a complex disorder like IBS[61]. By computing SNP scores based on the number of minor alleles of rs1062613, rs1176744, rs6766410, and rs56109847, our study revealed that an increasing number of minor alleles is linked to increasing severity of depressive symptoms. However, there was no obvious association between an increasing number of minor alleles and the severity of anxiety or somatization symptoms. Stratification for sex revealed a correlation between increasing numbers of minor alleles and worsening depressive symptoms in female participants.

Functional properties of variant 5-HT$_3$AC receptors

HTR3 genes encode different 5-HT$_3$ subunits to make up heteromeric receptors. The 5-HT$_3$A subunits play a major role in these receptors because they can form functional receptors on their own. The other

subunits can only form functional receptors with 5-HT$_3$A and seem to modulate the function and properties of the receptors[62]. How these native receptors might contribute to the pathogenesis of IBS, particularly regarding co-expression patterns of *HTR3*, has not been established yet. The *HTR3A* and *HTR3E* variants reside within untranslated regions and the respective SNPs correlate with increased expression levels, whereas the *HTR3B* variant changes the channel properties[25]. To gain insight into the pathophysiological relevance of the associated *HTR3C* variant c.489C>A (rs6766410), we characterized the pharmacological and functional properties of those 5-HT$_3$AC receptors that altered the 5-HT-mediated maximum response and expression of variant 5-HT$_3$AC receptors. However, how structural modifications in these receptors affect their function *in vivo* and how they modulate the serotonergic system to influence mood, emotional processing, and the manifestation of IBS and comorbid conditions remains to be determined.

Limitations and strengths

Our study has some limitations. First, different instruments were used by different centers to assess phenotypic features. To correct for this, scale scores were converted into *z* standard scores. However, given that the participants reported no severe psychosomatic symptoms, the discovery chances might be limited. Second, there is no sufficient evidence to show the relationship between risk alleles and respective major/minor alleles as patients and healthy controls were not compared in this study. Similarly, the relative strength of the cumulative effect represented by the SNP score was also affected to a certain extent. Third, our participants were all Caucasian, so the results may not apply to other ethnic groups.

Despite these limitations, our study has some strengths. First, this was a multicenter study so had a large sample size. Large, well-characterized samples like ours are necessary to identify molecular causes of IBS and comorbid conditions[12]. Second, this study investigated the association between polymorphisms in *HTR3* genes and comorbid psychosomatic symptoms for the first time. We conducted population stratification tests to ensure that the included populations were comparable. We also performed stratified analyses of sex and IBS subtypes and a more stringent multiple testing correction by FDR. Third, SNP scores have higher power and are better suited to testing multiple instead of single variants. This is useful because the pathogenesis of IBS is complex with multiple factors contributing to the manifestation of various subtypes. Also, individual genes may only play a minor role[12].

Clinical implications and further research

IBS is a complex condition. The continuous improvement of the allelic variation database for *HTR3*[25] and deep phenotyping combined with gene information (also in other datasets) may help to identify disease subgroups accurately and consistently, thereby facilitating future treatment[33,63]. This will be an important step towards standardization and unification of IBS genetic research strategies.

CONCLUSION

Our results provide the first evidence that the accumulation of *HTR3* SNPs (reflected by the SNP score computed by *HTR3A* c.-42C>T, *HTR3B* c.386A>C, *HTR3C* c.489C>A, and *HTR3E* c.*76G>A) may play a role in the pathophysiology of depressive and anxiety symptoms in IBS. This study has revealed that depressive and anxiety symptoms significantly worsened from the major to the minor allele of *HTR3C* c.489C>A in the dominant model and an increasing number of minor alleles are linked to more severe depressive symptoms in IBS.

ARTICLE HIGHLIGHTS

Research background

Over the past decades, genetic evidence on the key players within the serotonergic system including the serotonin type 3 (5-HT$_3$) receptor subunit genes (*HTR3*) accumulated showing association with irritable bowel syndrome (IBS) as well as mental illnesses. However, it has never been explored whether associations of the single-nucleotide polymorphisms (SNPs) of *HTR3* genes to depressive and anxiety symptoms can be replicated within IBS.

Research motivation

In order to address this knowledge gap, This multicenter observational study focused on a large IBS patient cohort comprising 768 participants from centers in Germany, Sweden, the United States, the United Kingdom, and Ireland.

Research objectives

The objectives are: (1) To explore the associations between functional *HTR3* polymorphisms and psychosomatic burden within an IBS population; (2) To investigate the impact of the *HTR3* SNP score on psychosomatic burden, based on our hypothesis that the observed number of minor alleles was associated with specific mental characteristics in IBS patients; and (3) To perform a functional analysis of variant 5-HT$_3$AC receptors.

Research methods

In this retrospective study, 623 participants with IBS were recruited from five specialty centers in Germany, Sweden, the United States, the United Kingdom, and Ireland. Depressive, anxiety, and somatization symptoms and sociodemographic characteristics were collected. Four functional SNPs — *HTR3A* c.-42C>T, *HTR3B* c.386A>C, *HTR3C* c.489C>A, and *HTR3E* c.*76G>A — were genotyped and analyzed using the dominant and recessive models. We also performed separate analyses for sex and IBS subtypes. SNP scores were calculated as the number of minor alleles of the SNPs above. The impact of *HTR3C* c.489C>A was tested by radioligand-binding and calcium influx assays.

Research results

Bringing together high quality data as well as methodological expertise, our results show that: (1) In the dominant model, *HTR3C c.489C>A* was correlated with depressive and anxiety symptoms in IBS; (2) A higher number of minor alleles (*i.e.*, the higher the SNP score, which was computed by combining the individual SNP status of *HTR3A c.-42C>T, HTR3B c.386A>C, HTR3C c.489C>A*, and *HTR3E c.*76G>A*) was linked to more severe depressive symptoms in IBS; and (3) The potential relevance of the *HTR3C* SNP was corroborated in functional assays showing changes in the expression level of 5-HT$_3$AC variant receptors.

Research conclusions

Our results provide the first evidence that the accumulation of *HTR3* SNPs (reflected by the SNP score computed by *HTR3A* c.-42C>T, *HTR3B* c.386A>C, *HTR3C* c.489C>A, and *HTR3E* c.*76G>A) may play a role in the pathophysiology of depressive and anxiety symptoms in IBS.

Research perspectives

We are confident that these results are of interest to your readership, as they contribute substantially to update current knowledge regarding the role of accumulation of *HTR3* SNPs in depressive and anxiety symptoms in IBS patients. In turn, our data will contribute towards standardization and harmonization of genetic research strategies in IBS.

ACKNOWLEDGEMENTS

We would like to thank all patients for their participation in this study and the supporting staff at each site. We acknowledge the kind support of Bartram CR and Hinderhofer K. We would also thank Startt B for proofreading and Bacon C for editing the manuscript. This manuscript results in part from collaboration and network activities promoted under the frame of the international network GENIEUR (Genes in Irritable Bowel Syndrome Research Network Europe), which has been funded by the COST program (BM1106, www.GENIEUR.eu) and is currently supported by the European Society of Neurogastroenterology and Motility (ESNM, www.ESNM.eu).

Abstract

BACKGROUND

Contrast-enhanced ultrasound (CEUS) can be used to diagnose focal liver lesions (FLLs) in children. The America College of Radiology developed the CEUS liver imaging reporting and data system (LI-RADS) for standardizing CEUS diagnosis of FLLs in adult patients. Until now, no similar consensus or guidelines have existed for pediatric patients to improve imaging interpretation as adults.

AIM

To evaluate the performance of CEUS LI-RADS combined with alpha-fetoprotein (AFP) in differentiating benign and malignant FLLs in pediatric patients.

METHODS

Between January 2011 and January 2021, patients ≤ 18 years old who underwent CEUS for FLLs were retrospectively evaluated. The following criteria for diagnosing malignancy were proposed: Criterion I considered LR-4, LR-5, or LR-M lesions as malignancies; criterion II regarded LR-4, LR-5 or LR-M lesions with simultaneously elevated AFP (≥ 20 ng/mL) as malignancies; criterion III took LR-4 Lesions with elevated AFP or LR-5 or LR-M lesions as malignancies. The sensitivity, specificity, accuracy and area under the receiver operating characteristic curve (AUC) were calculated to determine the diagnostic value of the aforementioned criteria.

RESULTS

The study included 63 nodules in 60 patients (mean age, 11.0 ± 5.2 years; 26 male). There were no statistically significant differences between the specificity, accuracy, or AUC of criterion II and criterion III (95.1% *vs* 80.5%, 84.1% *vs* 87.3%, and 0.794 *vs* 0.902; all $P > 0.017$). Notably, criterion III showed a higher diagnostic

sensitivity than criterion II (100% *vs* 63.6%; $P < 0.017$). However, both the specificity and accuracy of criterion I was inferior to those of criterion II and criterion III (all $P < 0.017$). For pediatric patients more than 5 years old, the performance of the three criteria was overall similar when patients were subcategorized by age when compared to all patients in aggregate.

CONCLUSION
CEUS LI-RADS combined with AFP may be a powerful diagnostic tool in pediatric patients. LR-4 with elevated AFP, LR-5 or LR-M lesions is highly suggestive of malignant tumors.

Key Words: Pediatric; Contrast-enhanced ultrasound; Liver imaging reporting and data system; Diagnosis; Focal liver lesions; Alpha-fetoprotein

Core Tip: Contrast-enhanced ultrasound liver imaging reporting and data system (CEUS LI-RADS) is used for the diagnosis of focal liver lesions (FLLs) in adult patients at high risk of hepatocellular carcinoma. CEUS has recently been approved to be used in characterization of FLLs in children. Our study investigated the diagnostic value of CEUS LI-RADS in association with serum alpha-fetoprotein (AFP) in differentiating malignant from benign FLLs in pediatric patients. Our study demonstrated that CEUS LI-RADS combined with AFP may be a powerful diagnostic tool for pediatric patients. LR-4 with elevated AFP, LR-5 or LR-M lesions are highly indicative of malignant tumors.

INTRODUCTION

Pediatric patients have different treatment strategies regarding benign and malignant focal liver lesions (FLLs)[1]. Hepatoblastoma (HB) constitutes the most common malignant tumor, accounting for 67% of all pediatric malignant FLLs, followed by hepatocellular carcinoma (HCC), at 28%[2-4]. Thanks to the development of surgical techniques and chemotherapy, the overall 5-year survival rates of HB exceed 80% with timely treatment, and those of nonmetastatic HCC patients who can be treated surgically are 70%-80%[5]. In comparison, the survival rate of children with inoperable hepatic malignancies was less than 20%[6].

Although computed tomography (CT) and magnetic resonance imaging (MRI) are usually recommended for the differential diagnosis of pediatric FLLs[7], both have some limitations. CT increases children's radiation exposure, while MRI requires a long imaging time and high cost[8-10]. Furthermore, children are exposed to the risk of contrast-induced nephrotoxicity and potential use of sedation[11]. Serum alpha-fetoprotein (AFP) is the most widely used tumor biomarker for the screening of HCC and HB in high-risk pediatric populations[12]. However, AFP levels remained in the normal range in 30%-40% of HCC patients and 10% of HB patients. Moreover, the positive predictive value of AFP is poor, making the value of AFP alone as a diagnostic tool very limited[13,14]. Therefore, developing a potent diagnostic method for differentiating benign from malignant FLLs in children is urgently needed.

The American College of Radiology developed the Liver Imaging Reporting and Data System (LI-RADS) to standardize the diagnosis of HCC and assist in the diagnosis of other hepatic malignant tumors[7]. In addition, CEUS can overcome the shortcomings of the aforementioned imaging modalities [15]. Moreover, CEUS has been approved for use in the diagnosis of FLL in the pediatric population [16]. Therefore, this study aimed to evaluate the diagnostic performance of the combination of CEUS LI-RADS and AFP in differentiating benign and malignant FLLs in a pediatric population.

MATERIALS AND METHODS

This retrospective study was approved by the institutional review board of our hospital, and informed consent was waived.

Patient selection

From January 2011 to January 2021, hepatic CEUS examinations performed in a tertiary academic medical center were retrospectively collected.

The inclusion criteria were: (1) Age ≤ 18 years at the time of examination; (2) visible liver nodules at baseline US; and (3) sufficient images of the arterial phase, portal phase, and parenchymal phase.

The exclusion criteria were: (1) Lesions previously treated; (2) known or strongly suspected active extrahepatic primary malignancy; (3) poor image quality; and (4) no accepted reference standard (see more detail in a later section).

Ultrasound examination

Conventional and contrast-enhanced US examinations were performed using a Philips IU22 system (Philips Medical Solutions; Mountain View, CA, United States) with a C5-1 convex or an L9-3 Linear probe. After routine ultrasound examinations, all pediatric patients underwent CEUS examinations using the pulse inversion harmonic imaging technique with a mechanical index less than 0.1. A bolus injection of 1.2 mL of ultrasound contrast agent (SonoVue; Bracco, Milan, Italy) was administered through a vascular catheter needle placed in the anterior cubital vein. The imaging timer was started immediately upon completion of the contrast agent injection. A 5 mL flush of 0.9% sodium chloride solution followed the ultrasound contrast agent injection. The target area was continuously scanned in the first 60 s, followed by intermittent scans and records until the examiner confidently observed washout or faded liver parenchymal enhancement, typically 5 min or longer. CEUS imaging was digitally stored for further evaluation.

Reference standards

Pathological diagnosis from surgical resection or percutaneous biopsy was taken as the reference standard. In addition, lesions without pathological diagnosis were considered benign if their size increased less than 50% at the 12-mo imaging follow-up. Meanwhile, serum AFP ≥ 20 ng/mL was regarded as elevated[13].

Diagnostic criteria for differentiating benign and malignant fills

In a previous study, lesions with categories of LR-1, LR-2 or LR-3 were considered benign, while LR-4, LR-5 or LR-M was defined as malignancy[16]. Moreover, the meta–analysis conducted by Christian *et al* [17], including 17 studies (2760 patients, 3556 lesions), showed that 80% of LR-4, 97% of LR-5, and 93% of LR-M lesions were malignant. Therefore, we proposed the following criteria for the diagnosis of malignancy in the pediatric population: Criterion I considered LR-4, LR-5, or LR-M lesions as malignancies; criterion II regarded LR-4, LR-5 or LR-M lesions with simultaneously elevated AFP (≥ 20 ng/mL) as malignancies; and criterion III took LR-4 lesions with elevated AFP or LR-5 or LR-M lesions as malignancies.

Imaging analysis

Two certified radiologists (Qiu TT and LI JW, with more than 3 years and 5 years of experience in hepatic CEUS, respectively) who were blinded to the reference standard and other clinical data reviewed the CEUS examinations of all cases independently and assigned a category according to the CEUS LI-RADS (2017 version). When there was an inconformity, arbitration from a blinded expert radiologist (Lu Q, with 17 years of experience) was performed. Briefly, the main diagnostic criteria of CEUS LI-RADS are nodule size, enhancement degree and pattern in the arterial phase, timing and degree of washout. Moreover, the ancillary features for category adjustment are nodule-in-nodule architecture and mosaic architecture.

Statistical analysis

Qualitative data are presented as the numbers and percentages. Quantitative data are presented as a combination of the mean values and standard deviations. The comparison of numeric variables was performed using t tests. Differences in categorical variables were analyzed using χ^2 tests or Fisher's exact tests. The unit of analysis is each FLL rather than each patient. The accuracy, sensitivity, specificity, area under the curve (AUC) and 95% confidence intervals (CI) were calculated to evaluate the diagnostic power of CEUS LI-RADS in association with AFP in distinguishing benign and malignant FLLs. The performance of the diagnostic criteria was further assessed by the fourfold table and compared by using the McNemar test. A P value less than 0.05 was considered statistically significant. The P values were corrected for multiple comparisons through the Bonferroni method (Bonferroni-adjusted P values < 0.017). Given that HCC more commonly occurs in children over 5 years old among pediatric patients[18], subgroup analysis was also conducted. Based on the value of κ, the strength of agreement is defined as follows: κ < 0.20 suggests poor agreement, 0.21-0.40 suggests fair agreement, 0.41-0.60 suggests moderate agreement, 0.61-0.80 suggests good agreement, and 0.80-1.00 suggests almost perfect agreement. Statistical analyses were performed using statistical software (MedCalc10.4.7.0; MedCalc Software, Ostend, Belgium).

RESULTS

Patients and liver nodule characteristics

According to the inclusion and exclusion criteria, 63 lesions from 60 patients were enrolled in this study (Figure 1), among which 3 patients had 2 FLLs. The main clinical characteristics of the patients, including age, sex, serum AFP, tumor size, and high-risk factors for HCC, are shown in Table 1. The average size of the 63 lesions was 68 ± 39 mm, ranging from 11 to 163 mm. Males accounted for 43.3% of the included patients, and AFP levels exceeding 20 ng/mL were present in 14 patients. The AFP level of malignant lesions (Figure 2) was higher than that of benign lesions [63.6% (14/22) *vs* 4.9% (2/41), $P < 0.0001$]. In our study, 14 patients had high-risk factors for HCC, including 8 chronic hepatitis B and 6 cirrhosis.

Histopathological results and follow-up results of the lesions are summarized in Table 2. Histopathological results of 52 (82.5%) lesions were obtained by surgical resections or US-guided core needle biopsies. The 11 (17.5%) lesions were regarded as benign through the one-year follow-up.

The distribution of FLLs in CEUS LI-RADS categories and lesions with elevated AFP levels are displayed in Table 3. In this study, 2 benign lesions were classified as LR-M, including one granulomatous inflammation and one abscess. Furthermore, 4 benign lesions in LR-5 included one adenomatoid hyperplasia, one abscess, and 2 focal nodular hyperplasia (FNH). Among the lesions defined as LR-4, there were only two lesions with elevated AFP. Postoperative pathology confirmed them as a regenerative nodule and an infantile hemangioendothelioma (Figure 3). The CEUS characteristics of various FLLs are presented in Table 4.

Interobserver agreement in CEUS LI-RADS classification

The rating of liver nodules according to CEUS LI-RADS of the two readers indicated good agreement, with a κ value of 0.76 (95%CI: 0.62-0.90).

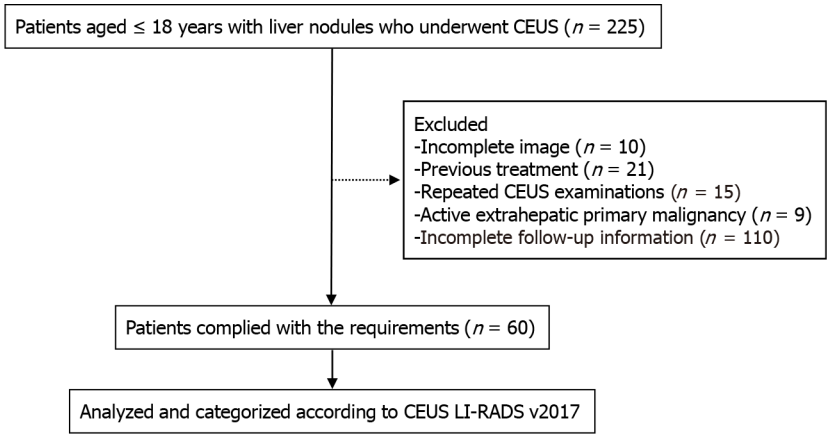
The diagnostic performance of CEUS LI-RADS combined with AFP

Table 5 summarizes the diagnostic performances of different diagnostic criteria in differentiating benign and malignant FLLs in children. Table 6 shows a comparison of different criteria on indicators of diagnostic performance. Notably, there was no statistically significant difference between the specificity, accuracy, or AUC of criterion II and criterion III (95.1% *vs* 80.5%, 84.1% *vs* 87.3%, and 0.794 *vs* 0.902; all $P > 0.017$). Notably, criterion III showed a higher diagnostic sensitivity than criterion II (100% *vs* 63.6%; $P < 0.017$). However, both the specificity and accuracy of criterion I was inferior to those of criterion II and criterion III (all P values < 0.017).

Diagnostic performance of CEUS LI-RADS combined with AFP in pediatric patients > 5 years of age

In total, 53 FLLs were included in this subgroup analysis. The diagnostic performance of CEUS LI-RADS in association with AFP for predicting overall hepatic malignancy and HCC among patients older than 5 years is shown in Supplementary Table 1. Moreover, a comparison of indicators for diagnostic power among the three criteria is shown in Supplementary Table 2. The performance of the three criteria was similar overall when patients were subcategorized by age when compared to all patients in aggregate. In short, there was no statistically significant difference between the specificity, accuracy, or AUC of criterion II and criterion III (97.2% *vs* 86.1%, 83.3% *vs* 87.0%, and 0.780 *vs* 0.931; all $P > 0.017$). Notably, criterion III showed a higher diagnostic sensitivity than criterion II (100% *vs*58.8%; $P < 0.017$). However, both the specificity and accuracy of criterion I was inferior to those of criterion II and criterion III (all $P < 0.017$). Interestingly, if LR-5 lesions with elevated AFP were regarded as HCC in this subgroup, the sensitivity, specificity, accuracy, and AUC of diagnosing HCC were 80.0% (95%CI: 44.4%-97.5%), 95.4% (95%CI: 84.2%-99.4%), 94.4% (95%CI: 84.6%-98.8%) and 0.877 (95%CI: 0.757-0.951), respectively.

DISCUSSION



Proper differentiation between benign and malignant FLLs is essential in the treatment of pediatric liver disease. We found that CEUS LI-RADS in association with AFP presented an effective way to differentiate benign tumors from malignancies in pediatric patients. The sensitivity and specificity of criterion III (LR-4 with elevated AFP or LR-5 or LR-M lesions) reached 100.0% and 80.5%, respectively.

The specificity (29.3%) of diagnostic criterion I (LR-4, LR-5, or LR-M lesions) was significantly reduced compared to criteria II and III. This may be because there were a considerable number of benign lesions in LR-4. Notably, differentiation between benign and malignant FLLs in pediatric patients by CEUS LI-RADS alone had an accuracy of 54.0% and specificity of 29.3%, suggesting that CEUS LI-RADS alone is not suitable for this scenario. CEUS LI-RADS was mainly used as a diagnostic tool for HCC in adults at high risk. This study explored the possibility of expanding the application of this diagnostic algorithm in pediatric patients. However, only a few pediatric patients have high-risk

Table 1 The clinical characteristics of enrolled 60 patients

Characteristics	All Patients (*n* = 60)	Patients with malignant lesions (*n* = 20)	Patients with benign lesions (*n* = 40)	*P* value[2]
Age, yr; mean ± SD, (range)	11.0 ± 5.2 (0-18)	9.7 ± 5.4 (0-18)	11.7 ± 5.1 (0-18)	0.98

factors for HCC, and the disease spectrum of FLLs between adults and children is different. HB and HCC account for a majority of pediatric hepatic malignancies, while hemangioma and FNH account for a majority of pediatric hepatic benign lesions. Because a significant difference in AFP was found between benign and malignant FLLs[19], CEUS LI-RADS combined with serum AFP is proposed for better characterization of FLLs in pediatric patients.

Compared with criterion III, the sensitivity (63.6%) of criterion II decreased significantly. A possible explanation was that 2 HCC patients and 6 patients with other hepatic malignancies presented normal serum AFP values (< 20 ng/mL), resulting in false negatives of the aforementioned lesions according to criterion II.

In this study, 13 FNHs were assigned to LR-4, and 2 FNHs were assigned to LR-5. A retrospective study by Kong *et al*[20] found that 42.9% of FNHs displayed global homogeneous hyperenhancement, and 42.9% of FNHs showed centrifugal enhancement in the arterial phase. Centrifugal arterial enhancement was often present in FNH < 3 cm. This is probably because the blood supply of larger lesions is more abundant[21]. Moreover, atypical FNHs could demonstrate washout in the portal and late phases[22]. Due to the above reasons, FNHs could be classified as LR-4 or LR-5 Lesions. However, AFP in patients with FNH is generally within the normal range[23]. Therefore, the combination of CEUS LI-RADS and AFP may potentially avoid diagnosing FNH as a malignancy.

FLLs: Focal liver lesions; CEUS LI-RADS: Focal liver lesions in contrast-enhanced ultrasound liver imaging reporting and data system; AFP: Alpha-fetoprotein.

We also performed subgroup analysis by the age of 5 to explore whether those patients could use CEUS LI-RADS combined with AFP to identify malignant FLLs or even HCC. For differentiating malignant from benign FLLs, the results of subgroup analysis were similar to the overall analysis. LR-5 in adult patients had a high diagnostic specificity for HCC. In this study, LR-5 Lesions with elevated AFP for diagnosing HCC presented high specificity (95.4%) in pediatric patients over 5 years old.

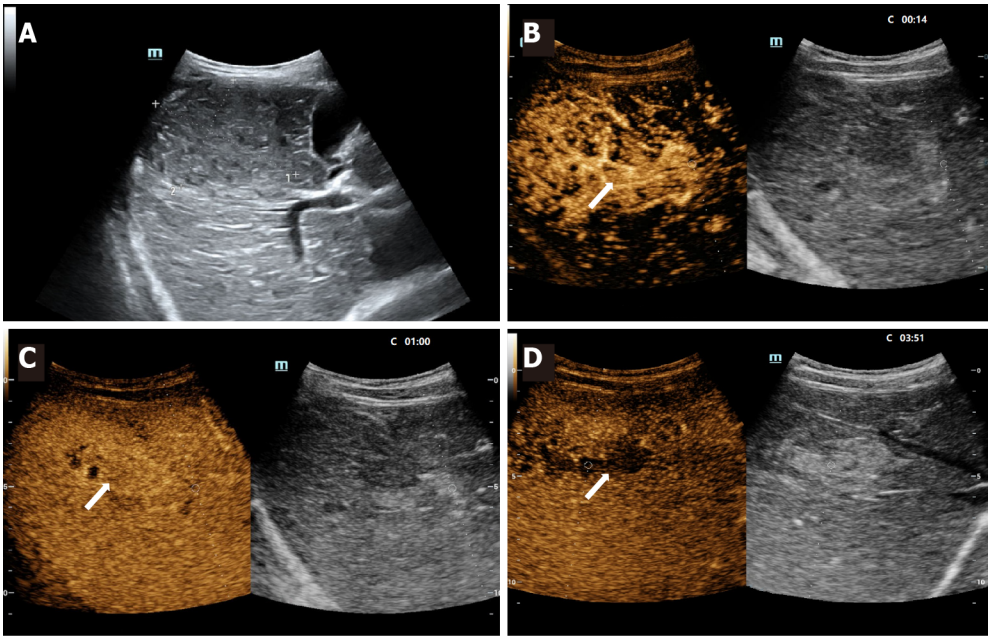
Table 5 Performance of various diagnostic criteria for differentiating benign and malignant focal liver lesions

Diagnostic criteria	Sensitivity (%)	Specificity (%)	Accuracy (%)	AUC
Criterion I	100.0 (84.6-100.0)	29.3 (16.1-45.5)	54.0 (40.9-66.6)	0.646 (0.516-0.763)
Criterion II	63.6 (40.7-82.8)	95.1 (83.5-99.4)	84.1 (72.7-92.1)	0.794 (0.673-0.885)
Criterion III	100.0 (84.6-100.0)	80.5 (65.1-91.2)	87.3 (76.5-94.4)	0.902 (0.801-0.963)

Criterion I considered LR-4, LR-5, or LR-M lesions as malignancies; criterion II regarded LR-4, LR-5 or LR-M lesions with simultaneously elevated alpha-fetoprotein (AFP, ≥ 20 ng/mL) as malignancies; criterion III took LR-4 lesions with elevated AFP or LR-5 or LR-M lesions as malignancies. AUC: Area under the curve.



Consequently, we speculate that CEUS LI-RADS combined with AFP has the potential to diagnose HCC in children older than 5 years. Nevertheless, the number (*n* = 10) of pediatric HCC patients included in this study was too small. Further study with a larger sample is needed to validate this hypothesis.

In this study, a 19-hour-old newborn patient with infantile hemangioendothelioma presented a significant increase in AFP levels (AFP > 1210 ng/mL). Regarding the features of CEUS, the patient showed inhomogeneous hyperenhancement in the arterial phase and isoenhancement in the portal and delayed phases, and there were areas of nonenhancement within the lesion. The aforementioned feature indicated that the lesion was likely a benign lesion. However, because the lesion was diagnosed as malignant by contrast-enhanced CT, the patient underwent surgical resection of the hepatic mass. Postoperative pathology confirmed that the lesion was an infantile hemangioendothelioma. Within 60 ± 24 h after birth, the serum AFP of newborns can range from 9700 to 11190 ng/mL and drop rapidly to a level close to the normal level of adults within one year[24]. Therefore, we should be meticulous with elevated AFP in differentiating FLLs of newborns. In addition, infantile hemangioendothelioma is a common benign tumor in newborns, most of which do not require surgical treatment[25]. Therefore, the diagnosis of benign and malignant FLLs in newborns should be made with caution, and the diagnostic

Table 6 Comparison of different criteria on indicators of diagnostic performance

P value	Sensitivity	Specificity	Accuracy	AUC
Criterion I *vs* criterion II	< 0.017	< 0.0001	< 0.017	> 0.017
Criterion I *vs* criterion III	-	< 0.0001	< 0.0001	< 0.0001
Criterion II *vs* criterion III	< 0.017	> 0.017	> 0.05	> 0.05

Criterion I considered LR-4, LR-5, or LR-M lesions as malignancies; criterion II regarded LR-4, LR-5 or LR-M lesions with simultaneously elevated alpha-fetoprotein (AFP, ≥ 20 ng/mL) as malignancies; criterion III took LR-4 lesions with elevated AFP or LR-5 or LR-M lesions as malignancies. AUC: Area under the curve.

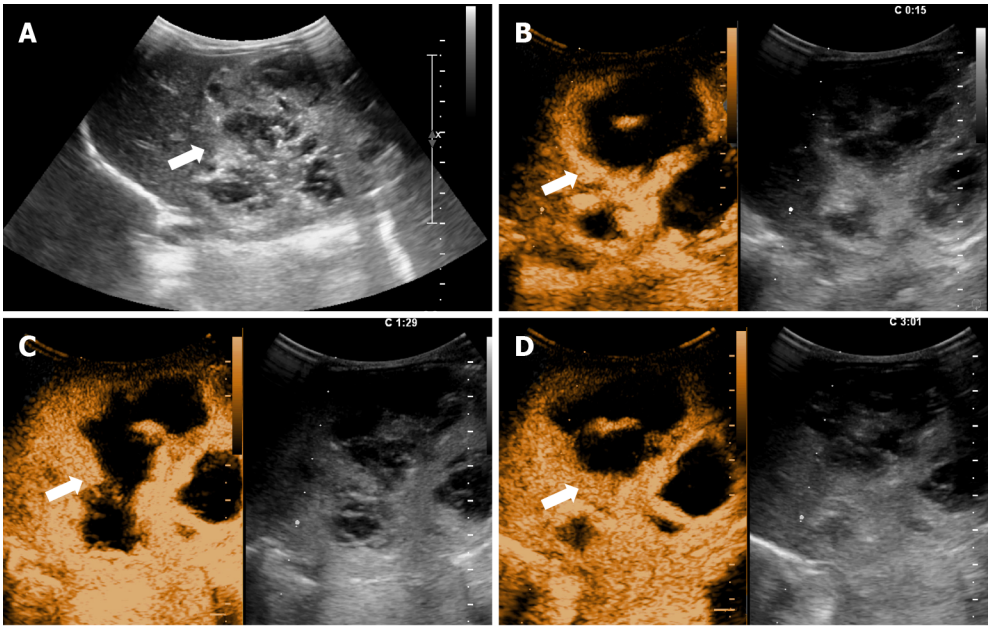

Figure 2 LR-5 nodule in a 10-year-old boy. A: A hypoechoic nodule (arrow) measuring 7.3 cm in the right lobe of the liver was shown at conventional gray-scale US; B: The lesion was inhomogeneously hyperenhanced (arrow) in the arterial phase (14 s) at contrast-enhanced US; C: The lesion was seen iso-enhanced in the portal phase (60 s); D: Mild washout in the late phase (231 s) was shown. There were small areas of nonenhancement within the lesion during the whole process. The patient had a chronic hepatitis B viral infection. The serum AFP level was greater than 1210 ng/mL. This lesion was assigned to LR-5 and was confirmed as hepatocellular carcinoma by histopathologic analysis.

method needs to be further explored.

This study had several limitations. First, this was a retrospective study with a relatively small sample size, which may inevitably lead to selection bias. Second, CEUS LI-RADS was mainly used for patients at risk of HCC, while only 14 patients in this study met the prerequisites for risk factors. Moreover, the risk factors for HCC in children do not exactly correspond to those in adults. Lastly, there were a considerable number of benign lesions confirmed by histopathology results, which might have led to the selection of benign lesions with atypical imaging findings. Thus, the specificity of the diagnostic criteria may have been underestimated.

CONCLUSION

We propose a novel method that might be a powerful diagnostic tool to differentiate malignant from benign FLLs in pediatric patients. LR-4 with elevated AFP, LR-5 or LR-M lesions could effectively differentiate benign and malignant tumors in pediatric patients.

Figure 3 LR-4 nodule in a 19-hour-old newborn. A: An inhomogeneous hyperechoic nodule measuring 7.2-cm (arrow) in the left lobe of the liver was shown at conventional gray-scale US; B: The lesion was inhomogeneously hyperenhanced (arrow) with large area of unenhancement in the arterial phase (15 s) at contrast-enhanced US; C: The enhanced area of the lesion was seen slightly hyperenhanced (arrow) in the portal phase (89 s); D: The enhanced area of the lesion was seen iso-enhanced (arrow) in the late phase (181 s). There were patchy areas of nonenhancement within the lesion during the whole process. The serum AFP level was greater than 1210 ng/mL. Infantile hemangioendothelioma was confirmed at histopathologic analysis.

ARTICLE HIGHLIGHTS

Research background

Contrast-enhanced ultrasound (CEUS) has recently been approved to be used in characterization of focal liver lesions (FLLs) in children. The America College of Radiology developed the CEUS liver imaging reporting and data system (LI-RADS) for standardizing CEUS diagnosis of FLLs in adult patients. However, it is not suitable for pediatric patients.

Research motivation

To explore a method for differentiating benign and malignant FLLs in pediatric patients.

Research objectives

To evaluate the performance of CEUS LI-RADS combined with alpha-fetoprotein (AFP) in differentiating benign and malignant FLLs in pediatric patients.

Research methods

The following criteria for diagnosing malignancy were proposed: Criterion I considered LR-4, LR-5, or LR-M lesions as malignancies; criterion II regarded LR-4, LR-5 or LR-M lesions with simultaneously elevated AFP (≥ 20 ng/mL) as malignancies; criterion III took LR-4 Lesions with elevated AFP or LR-5 or LR-M lesions as malignancies. The sensitivity, specificity, accuracy and area under the receiver operating characteristic curve (AUC) were calculated to determine the diagnostic value of the aforementioned criteria.

Research results

There were no statistically significant differences between the specificity, accuracy, or AUC of criterion II and criterion III. Notably, criterion III showed a higher diagnostic sensitivity than criterion II. However, both the specificity and accuracy of criterion I was inferior to those of criterion II and criterion III. For pediatric patients more than 5 years old, the performance of the three criteria was overall similar when patients were subcategorized by age when compared to all patients in aggregate.

Research conclusions

We propose a novel method that might be a powerful diagnostic tool to differentiate malignant from benign FLLs in pediatric patients. LR-4 with elevated AFP, LR-5 or LR-M lesions could effectively differentiate benign and malignant tumors in pediatric patients.

Research perspectives

CEUS LI-RADS combined with AFP might be a powerful diagnostic tool to differentiate malignant from benign FLLs in pediatric patients.

Abstract

BACKGROUND

Primary liver cancer (PLC) is a major contributor to cancer-related deaths. Data on global and country-specific levels and trends of PLC are essential for understanding the effects of this disease and helping policymakers to allocate resources.

AIM

To investigate the association between the burden of PLC and socioeconomic development status.

METHODS

Cancer mortality and incidence rates were obtained from the Global Burden of Disease (GBD) 2019, and the data were stratified by country and territory, sex, and the Socio-demographic Index (SDI) level. The association between the attributable etiology of PLC and socioeconomic development status, represented using the SDI, was described. The attributable etiology of PLC included hepatitis B, hepatitis C, alcohol use, and nonalcoholic steatohepatitis. The association between the attributable etiology of PLC and SDI was further stratified by sex and geographical location. A confidence analysis was also performed based on bootstrap draw.

RESULTS

The age-standardized incidence rate of PLC was 6.5 [95% confidence intervals (CI): 5.9-7.2] per 100000 person-years, which decreased by -27.5% (-37.0 to -16.6) from 1990 to 2019. Several countries located in East Asia, South Asia, West Africa, and North Africa shouldered the heaviest burden of PLC in 2019. In terms of incidence rates, the first leading underlying cause of PLC identified was hepatitis B, followed by hepatitis C, alcohol use, and nonalcoholic steatohepatitis. Regarding stratification using the SDI, the incidence rate of PLC was the highest for high and middle SDI locations. Further, the leading attributable etiologies of PLC were hepatitis B for the middle and high middle SDI locations while hepatitis C and nonalcoholic steatohepatitis for the high SDI locations.

CONCLUSION

The pronounced association between socioeconomic development status and PLC burden indicates socioeconomic development status affects attributable etiologies for PLC. GBD 2019 data are valuable for policymakers implementing PLC cost-effective interventions.

Key Words: Epidemiology; Public health; Socioeconomics; Primary liver cancer; Hepatitis; Alcohol

Core Tip: Primary liver cancer (PLC) is a common cancer with high morbidity and mortality rates. PLC usually occurs as a preventable disease. An association was identified between socioeconomic development status and PLC burden. The leading attributable etiologies of PLC were hepatitis B for the middle and high middle Socio-demographic Index (SDI) locations, and hepatitis C and nonalcoholic steatohepatitis for the high SDI locations. Our findings are valuable to implement tailored prevention strategies for PLC.

INTRODUCTION

Primary liver cancer (PLC) was the third leading cause of cancer deaths in 2020 following lung and colorectal cancer[1]. In terms of cancer-related mortality, PLC was the third leading cause in China[2] and the fifth leading cause in the United States[3]. The burden of PLC varies significantly in terms of sex and geographic region due to different risk-factor exposure. The major risk factors include chronic viral infections [hepatitis B virus (HBV), hepatitis C virus (HCV)], alcohol use, and nonalcoholic steatohepatitis (NASH), and they have been widely studied in recent years[4]. PLC is caused by chronic hepatitis B (CHB) (60%) in Africa and East Asia, whereas chronic hepatitis C (CHC) appears to be the major risk factor in the Western world[5]. Thus, it is expected that the appropriate handling of risk factors can significantly contribute to the overall reduction of PLC-related deaths in the near future.

The Global Burden of Disease (GBD) database has been constructed to improve health systems and eliminate disparities; this database comprises a comprehensive catalog of censuses, vital statistics, surveys, and other health-related data. Policymakers can benefit from the GBD database as it enables them to understand the true nature of the health challenges of a country and the shifting challenges over time. In recent years, the prevention of PLC has been eclipsed by substantial improvements in PLC treatment. Given the marked lag between risk factor exposure and the development of PLC, even the well-proven prevention approaches would take decades to reduce of the PLC burden. Although several prior studies have focused on the global prevalence of PLC[4,6], few studies focus on the tailored prevention of PLC. In this study, we focused on identifying the effect of socioeconomic development status on the attributable etiologies of PLC from a global perspective. We hope our findings will be helpful contributions for developing specialized prevention strategies for PLC. Considering the heavy burden of PLC, characterizing this association will help health workers to design tailored prevention strategies and policymakers to allocate research and clinical resources for implementing cost-effective interventions for PLC.

MATERIALS AND METHODS

Data sources

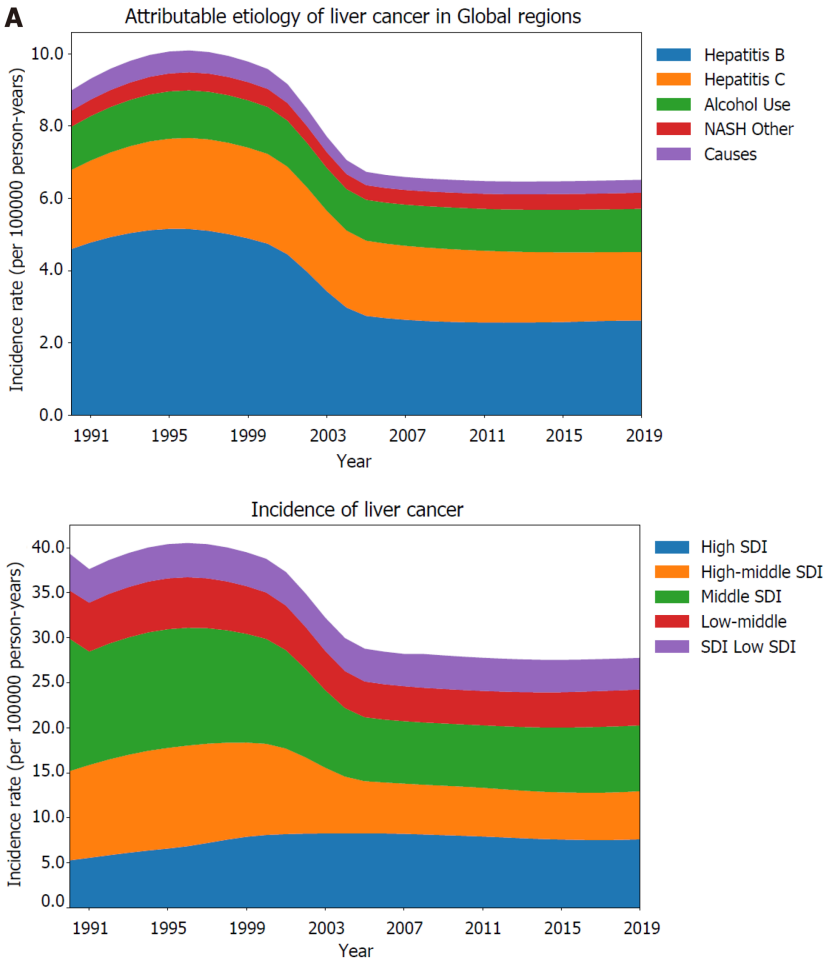
For this study, the incidence and death rates of PLC were acquired from the GBD 2019 (http://ghdx.healthdata.org/gbd-2019) that covered 204 countries and territories[7]. The incidence and death rates were age-standardized according to the GBD 2019 world population recorded per 100000 person-years. The International Classification of Diseases, Tenth Revision (ICD-10) was adopted. The ICD-10 codes for PLC are C22-C22.4, C22.7-C22.8, and Z85.05 (Supplementary material, page 17). Mortality and non-fatal estimates have been described in detail in previous studies[8,9]. Additional information is provided in the Supplementary material.

Confidence analysis

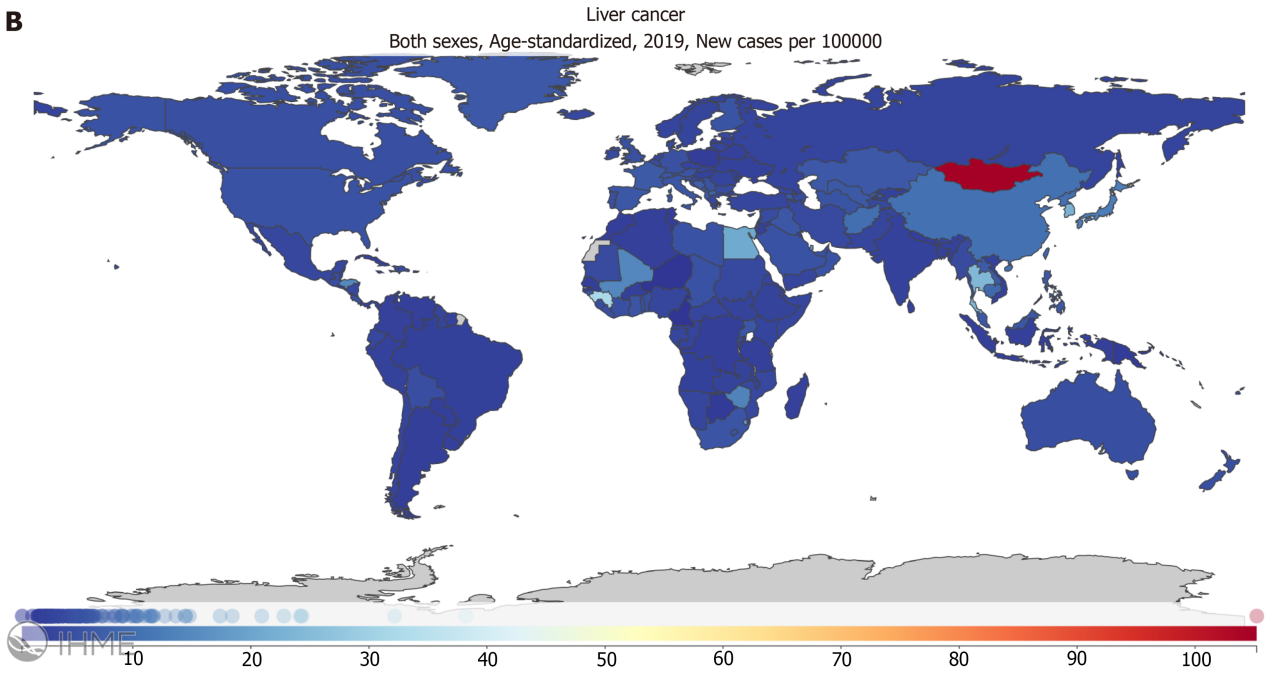
We assumed that the incidence or death rates in each year followed a log-normal distribution and that the rates in different years were independent of each other. Based on these assumptions, in each bootstrap draw, we measured the increase rates and 95%CIs based on the 25th and 975th ranked values across all 1000 draws. The 2.5% and 97.5% quantiles from the 1000 draws of the posterior distribution were used to generate 95%CIs.

Socio-demographic Index

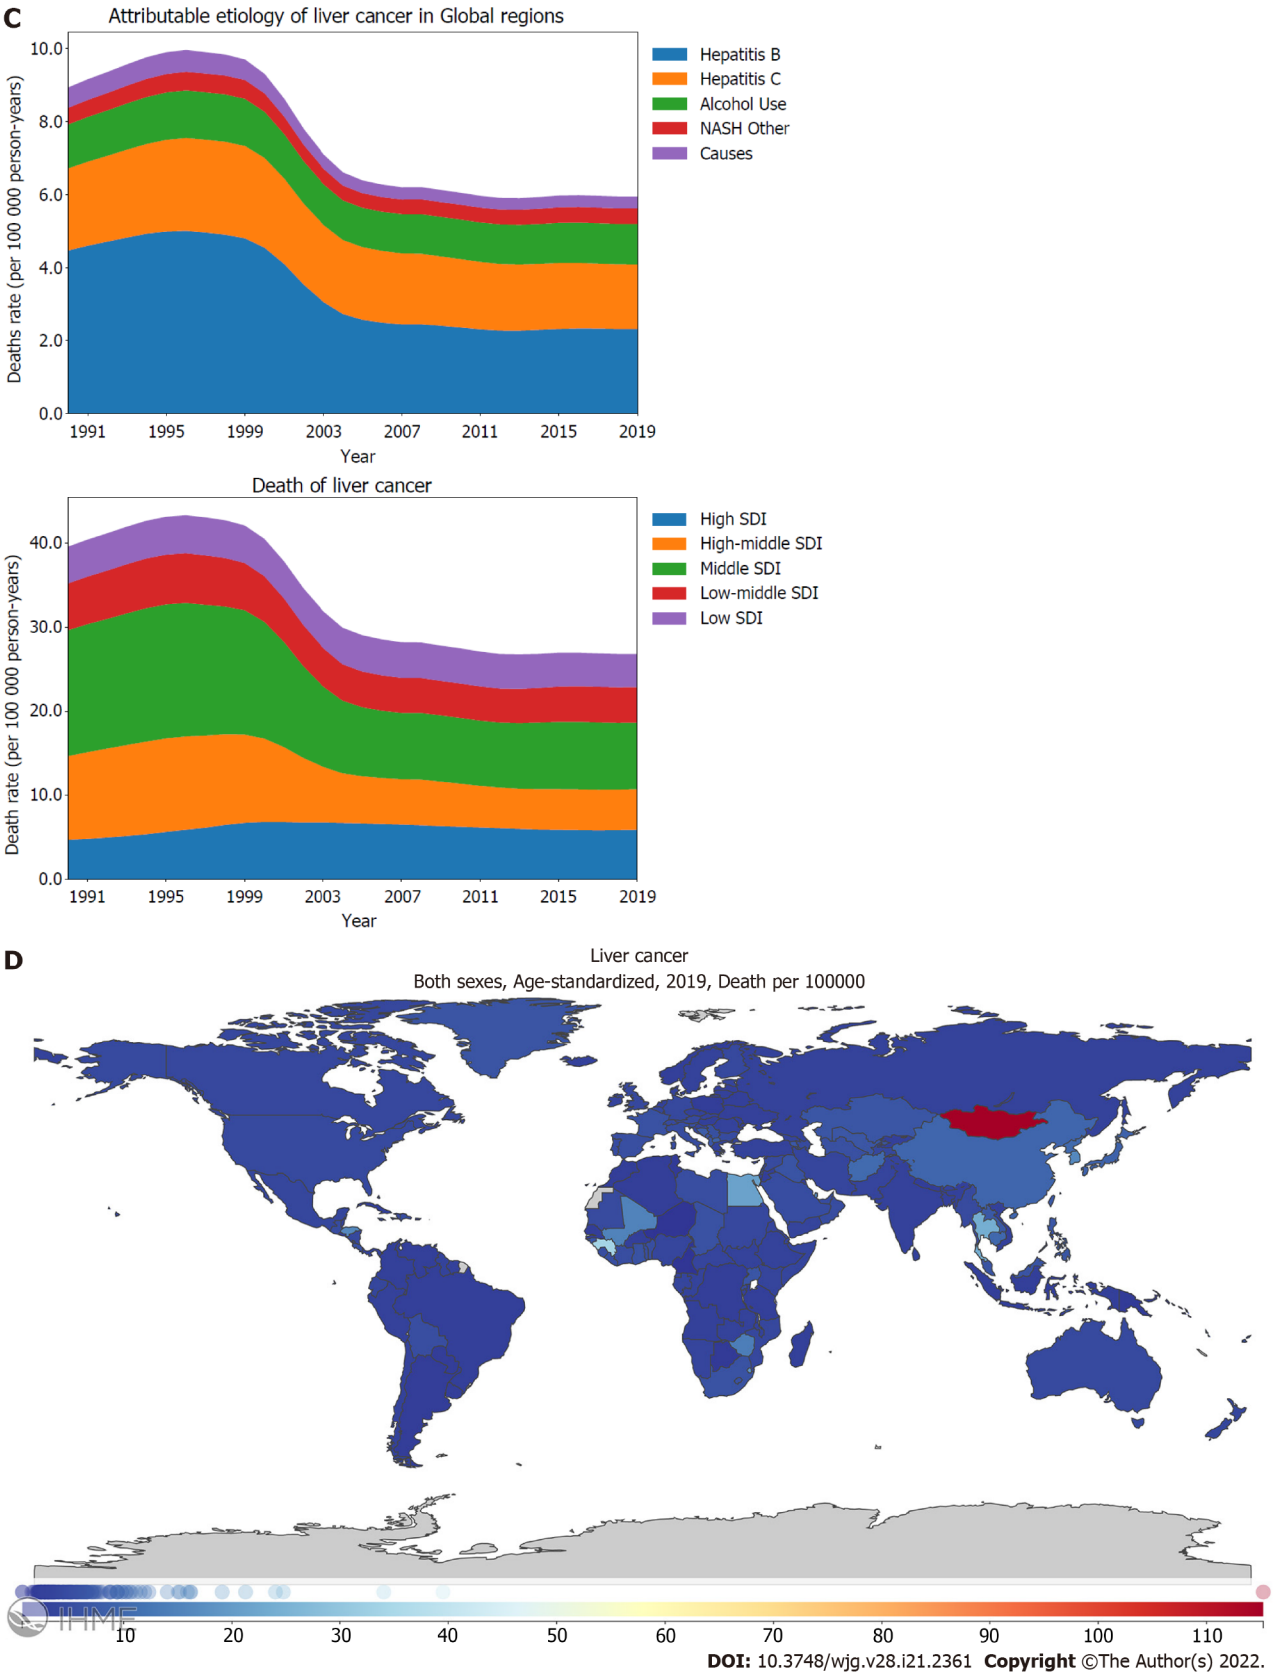
The Socio-demographic Index (SDI) incorporates the mean education level for individuals aged 15 years and older, the total fertility rate in women under the age of 25 years, and lag-distributed income per person. The method of generating the SDI is described in the report by the GBD 2016 Mortality Collaborators[10]. Further, the SDI was used to evaluate the effect of the development levels of a country or region on the burden of PLC based on data obtained from the GBD 2019 (Supplementary material, pages 1-15). The values of the SDI range from 0 to 1, which correspond to the development level of a country or region from the worst to the best. The SDI was categorized based on the references bound as low SDI, low middle SDI, middle SDI, high middle SDI, and high SDI, as shown in the Supplementary material, page 16.



Ethic statement



The study was reviewed and approved by the Ethics Committee of First Affiliated Hospital of Fujian Medical University (MTCA, ECFAH of FMU[2015]084-1).



RESULTS

Burden of liver cancer

Liver cancer is one the most common cancers. In 2019, the global age-standardized incidence rate of PLC was 6.5 (95%CI: 5.9-7.2) per 100000 person-years (Supplementary material, page 25). Fortunately, the incidence rate of PLC has declined significantly by -27.5% (-37.0 to -16.6) from 1990 to 2019 (Figure 1A; Supplementary material, page 18). The main contributor for this drop was the decreasing burden of PLC caused by hepatitis B and the declining burden of PLC in the middle SDI locations. Between 1990 and 2019, the global incidence rate of PLC peaked in 1995-1996, and then, it decreased gradually. However, the incidence rate of PLC has not declined further since 2010 (Figure 1A; Supplementary material, pages 23-25). Before 2004, the incidence rate of PLC for middle SDI locations surpassed that for high SDI locations whereas high SDI locations exceeded middle SDI locations in terms of the burden of PLC after 2004 (Figure 1A; Supplementary Figure 1B; Supplementary material, pages 29-32). In terms of the incidence rates, the leading underlying cause of PLC was HBV, followed by HCV, alcohol use, and NASH (Figure 1A). Hepatitis B manifested the most drastic decline between 1990 and 2019 as the underlying causes of PLC [57.0% (45.3-71.4)] (Figure 1A; Supplementary material, pages 19-20). Stratified using the SDI, the age-standardized incidence rate of PLC was found to be the highest for high and middle SDI locations compared to those for high middle, low middle, and low SDI locations (Figure 1A; Supplementary Figure 1B; Supplementary material, pages 29-32). Further, a declining pattern was observed for the age-standardized incidence rate of PLC in the high middle [53.8% (45.1-64.5)] and middle SDI locations [49.7% (41.1-59.9)] compared with the increasing trend in the high SDI locations [144.5% (130.3-159.6)] (Figure 1A; Supplementary Figure 1B; Supplementary material, page 18). Between 1990 and 2019, PLC caused by hepatitis B and hepatitis C showed a decreasing trend in the death rate (Figure 1C; Supplementary material, pages 21-22). Stratified using the SDI, the high middle, middle, and low middle SDI locations showed decreasing trends in the age-standardized death rate of PLC. In contrast, the high SDI location showed an increasing trend in the age-standardized death rate of PLC (Figure 1C; Supplementary material, page 18). Several countries located in East Asia, South Asia, West Africa, and North Africa shouldered the heaviest burden of the PLC incidence and death rates. For the age-standardized incidence rate of PLC, Mongolia demonstrated the highest burden [105.2 (82.6-131.5)] per 100000 person-years), followed by Gambia and Guinea (Figure 1B; Supplementary material,

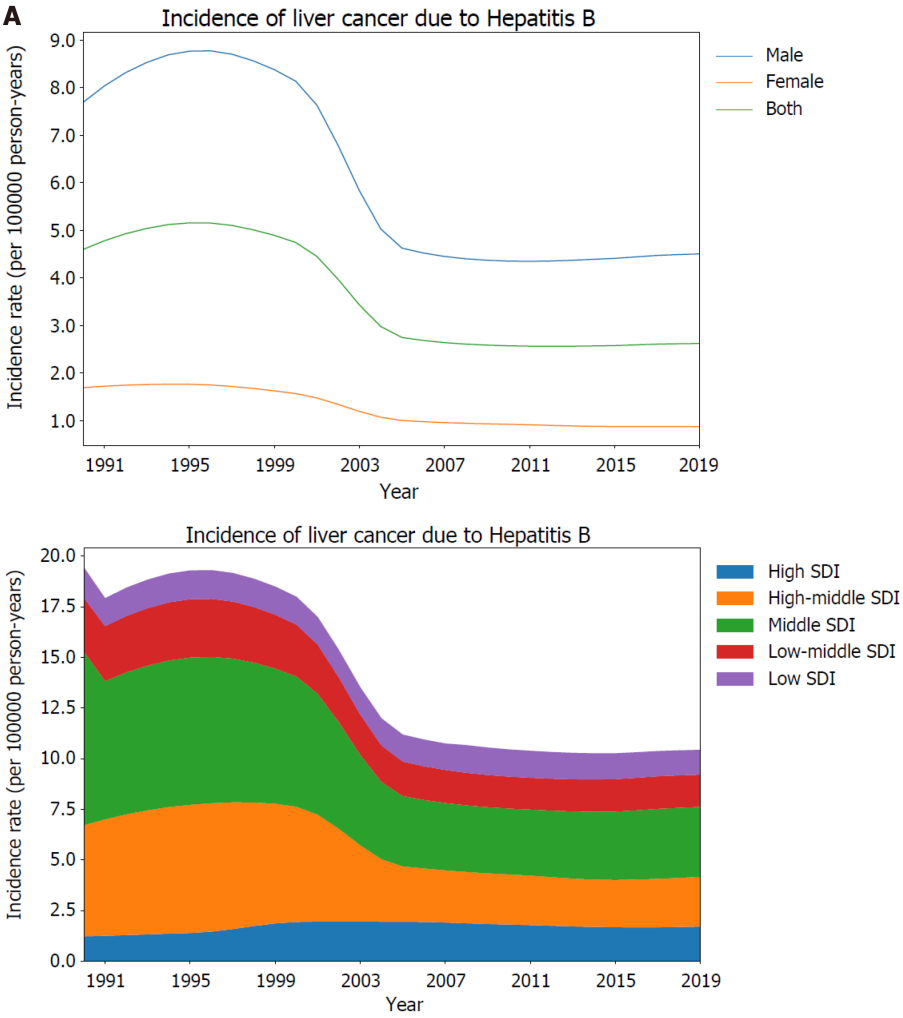
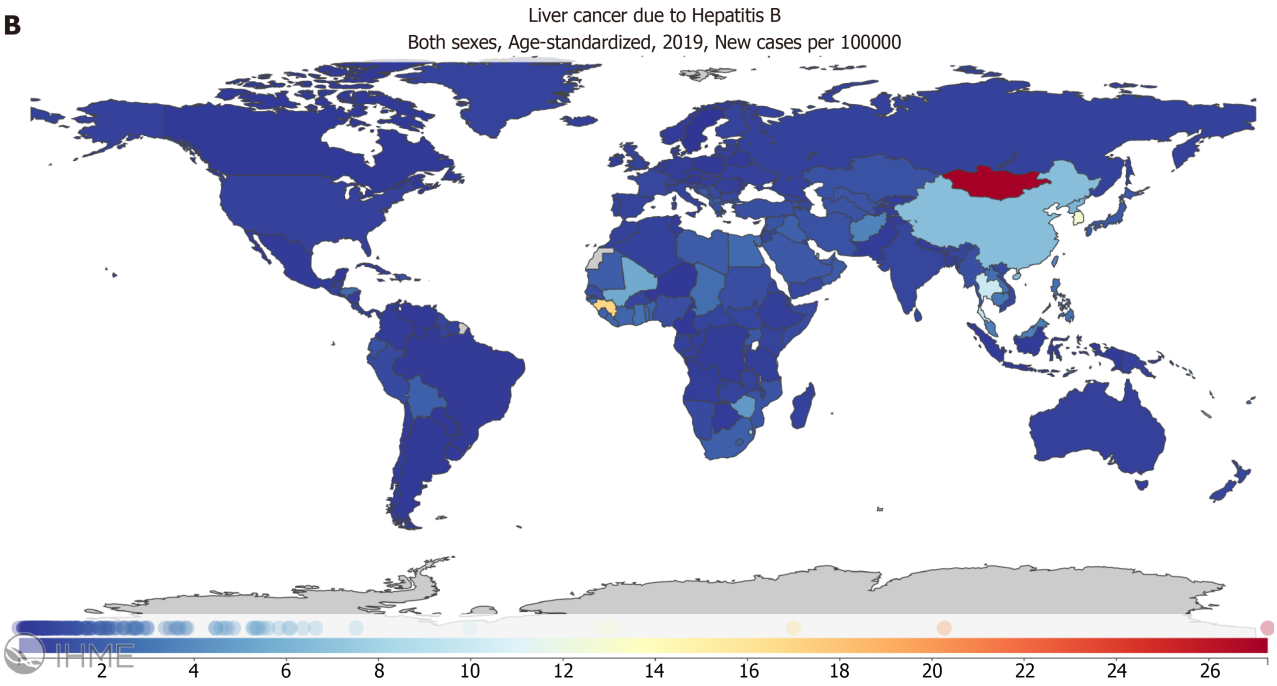
pages 33-35). Countries that possessed the highest burden PLC incidence rate also had the highest burden PLC death rate (Figure 1D; Supplementary material, pages 46-48).

Burden of liver cancer caused by hepatitis B



The global age-standardized incidence rate of PLC caused by hepatitis B reached its peak in 1995-1996, and then decreased gradually. However, the burden of the incidence rate has remained stable and has not declined further since 2005. By stratification using sex, the age-standardized incidence rate of PLC caused by hepatitis B was found to be four times higher in males than that in females (Figure 2A; Supplementary material, pages 49-50). Moreover, the age-standardized incidence rate of PLC caused by hepatitis B was found to be higher for middle and high middle SDI locations than for high, low middle, and low SDI locations (Figure 2A; Supplementary Figure 2A; Supplementary material, pages 51-57). Between 1990 and 2019, the decreasing trend in the age-standardized incidence rate of PLC caused by hepatitis B differed significantly based on SDI regions, with the highest declines in the middle [40.3% (31.1-51.8)] and high middle SDI locations [44.8% (34.2-58.8)]. In contrast, high SDI locations showed an increasing trend [139.3% (112.1-173.3)] (Figure 2A; Supplementary Figure 2A; Supplementary material, pages 19-20). In 2019, the incidence rate of PLC caused by hepatitis B differed dramatically between countries or regions. In particular, the highest age-standardized incidence rate was recorded in Mongolia with 27.3 (18.0-39.1) per 100000 person-years, followed by Gambia and Guinea (Figure 2B; Supplementary material, pages 58-61). Similar to the age-standardized incidence rate of PLC caused by hepatitis B, the burden of the PLC death rate caused by hepatitis B was higher for males than that for females (Figure 2C; Supplementary material, pages 62-63). Between 1990 and 2019, the age-standardized death rate of PLC caused by hepatitis B decreased significantly in the high middle [39.0% (30.2-50.6)] and middle SDI locations [44.7% (34.7-57.4)]. However, the high SDI locations showed an increasing trend [113.4% (90.6-141.6)] (Figure 2C; Supplementary Figure 2B; Supplementary material, pages 21-22). In 2019, Mongolia had the highest age-standardized death rate with 28.2 (18.9-40.8) per 100000 person-years, followed by Gambia and Guinea (Figure 2D; Supplementary material, pages 67-70).



Burden of liver cancer caused by hepatitis C

Hepatitis C is the second leading cause of PLC. By stratification using sex, the age-standardized incidence rate and mortality rate of PLC caused by hepatitis C in males was found to be higher than those in females (Figure 3A and C; Supplementary material, pages 71-72 and 80-81). Further, the age-standardized incidence rate of PLC caused by hepatitis C was higher for high and middle SDI locations than for high middle, low middle, and low SDI locations (Figure 3A; Supplementary Figure 3A; Supplementary material, pages 73-75). From 1990 through 2019, the age-standardized incidence rate of PLC caused by hepatitis C differed significantly between the SDI regions, with the middle [59.5% (46.5-76.3)] and high middle SDI locations [63.3% (51.3-78.0)] exhibiting declining trends whereas the high SDI location [133.4% (112.5-158.2)] showed increasing trends (Figure 3A; Supplementary Figure 3A; Supplementary material, pages 19-20). In 2019, the incidence rate of PLC caused by hepatitis C manifested a substantial variance between countries or regions. The highest age-standardized incidence rate was recorded in Mongolia with 35.0 (24.7-46.8) per 100000 person-years, followed by Egypt and Japan (Figure 3B; Supplementary material, pages 76-79). Between 1990 and 2019, the age-standardized death rate of PLC caused by hepatitis C decreased significantly in high middle [57.9% (47.5-71.1)] and middle SDI locations [58.7% (46.2-74.4)]. However, the high SDI locations showed an increasing trend [119.5% (101.8-139.8)] (Figure 3C; Supplementary Figure 3B; Supplementary material, pages 21-22). In 2019, Mongolia had the highest age-standardized death rate with 40.3 (28.6-53.3) per 100000 person-years, followed by Egypt (Figure 3D; Supplementary material, pages 85-88).

Burden of liver cancer caused by alcohol use

For PLC caused by alcohol use, the age-standardized incidence rate in males was four times higher than that in females (Figure 4A; Supplementary material, pages 89-90). Similar to PLC caused by hepatitis C, the age-standardized incidence rate of PLC caused by alcohol use was found to be higher for high SDI locations than other SDI locations when stratified using the SDI (Figure 4A; Supplementary Figure 4A; Supplementary material, pages 91-93). From 1990 through 2019, there was a notable difference in the trends for age-standardized incidence rates of PLC caused by alcohol use between SDI regions; high middle SDI locations [72.7% (54.3-96.4)] showed a significant decline. In contrast, high SDI locations showed a significant increase [163.5% (126.4-209.8)] (Figure 4A; Supplementary Figure 4A; Supplementary material, pages 19-20). In 2019, the highest incidence rate of PLC caused by alcohol use was recorded in Mongolia with 31.8 (21.3-44.7) per 100000 person-years, followed by Gambia and Thailand (Figure 4B; Supplementary material, pages 94-97). Males showed a higher burden of death rate of PLC caused by alcohol use than females, which corresponds with the higher incidence rate of PLC caused by alcohol use in males (Figure 4C; Supplementary material, pages 98-99). Between 1990 and 2019, the age-standardized death rate of PLC caused by alcohol use decreased significantly in high middle SDI locations [67.6% (50.9-88.9)]. However, high SDI locations showed an increasing trend [141.2% (111.0-179.2)] (Figure 4C; Supplementary Figure 4B; Supplementary material, pages 21-22). In 2019, Mongolia had the highest age-standardized death rate with 34.2 (23.1-47.8) per 100000 person-years, followed by

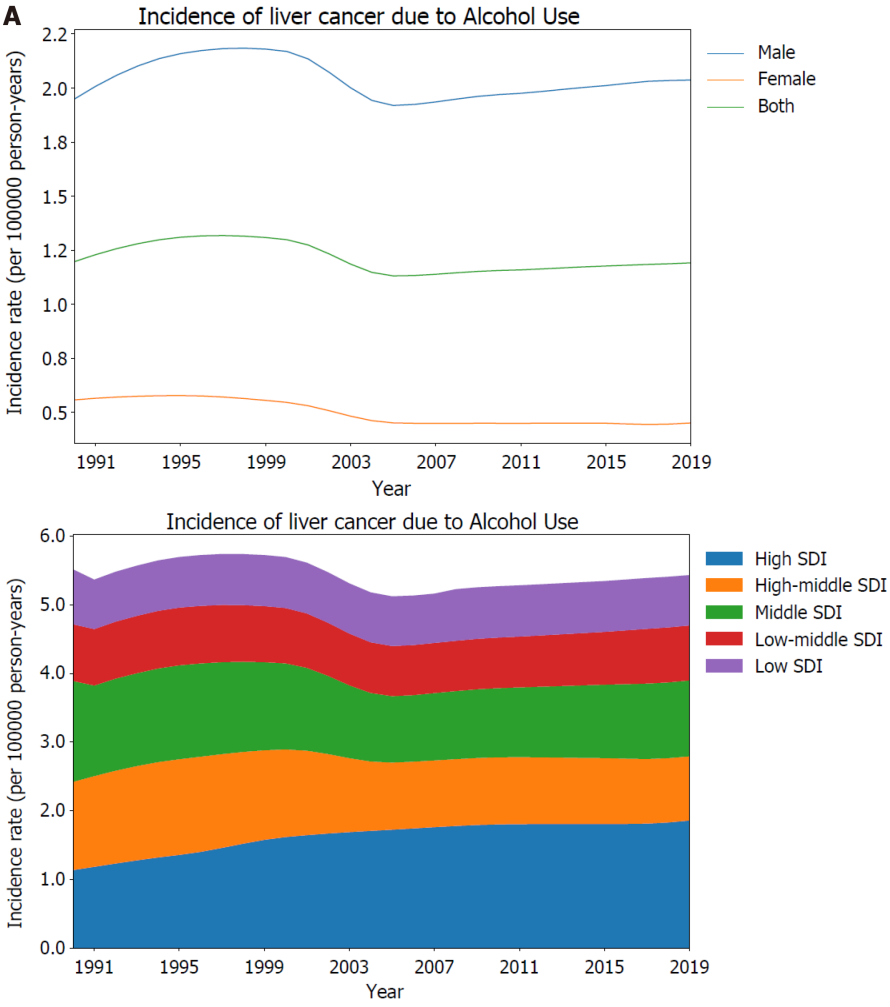
Gambia and Thailand (Figure 4D; Supplementary material, pages 103-106).

Burden of liver cancer caused by NASH

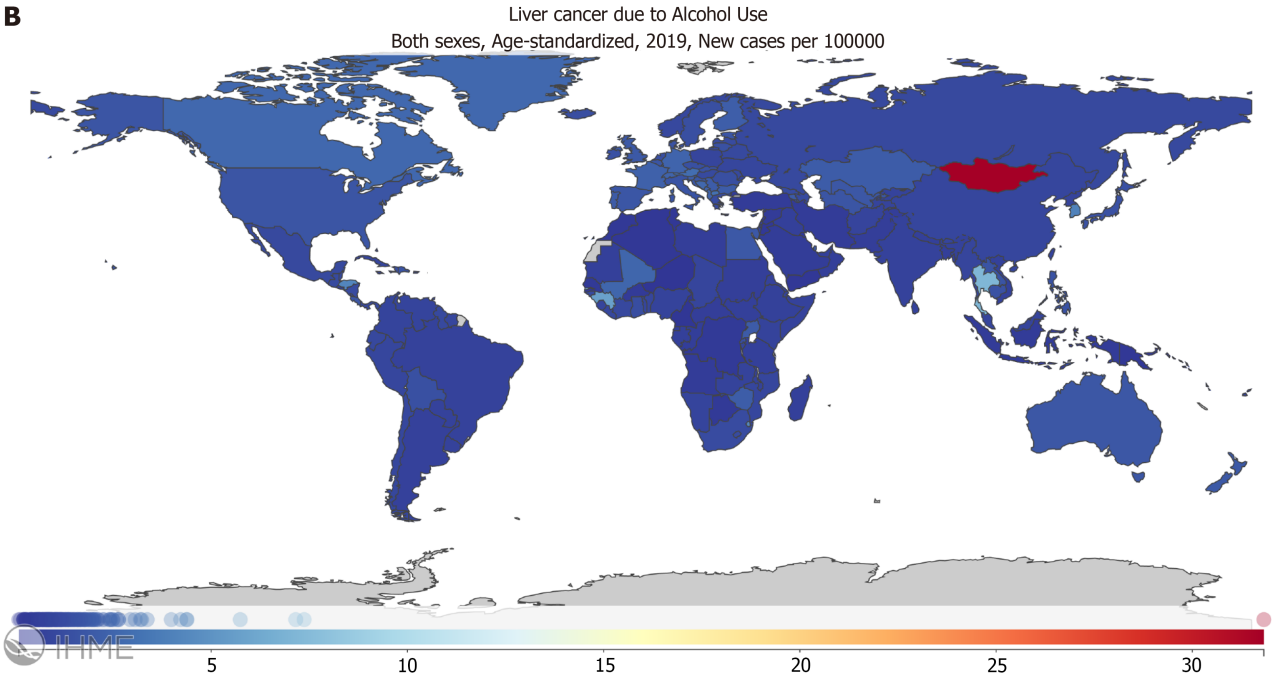
By stratification using sex, the age-standardized incidence and mortality rates of PLC attributed to NASH in males was found to be higher than in females (Figure 5A and C; Supplementary material, pages 107-108 and 116-117). Similar to the geographical variance observed in PLC caused by alcohol use, the highest age-standardized incidence and death rates of PLC attributed to NASH were reported in the high and middle SDI locations (Figure 5A and C). Between 1990 and 2019, a remarkable difference was observed in the trends of age-standardized incidence rates of PLC attributed to NASH between SDI regions, with the high middle SDI locations [72.9% (55.1-96.0)] showing a declining trend and the high SDI locations showing an increasing trend [182.9% (135.4-248.6)] (Figure 5A; Supplementary Figure 5A; Supplementary material, pages 19-20). The changing pattern for the age-standardized death rate across SDI locations was comparable to that observed in the incidence rate of the same period. In 2019, Mongolia [7.6 (4.9-11.4)] depicted the highest age-standardized incidence rate, followed by Gambia and Qatar (Figure 5B; Supplementary material, pages 112-115). Similar to the order of age-standardized incidence rate, Mongolia [8.7 (5.6-12.9)], Gambia, and Guinea had the highest age-standardized death rate (Figure 5D; Supplementary material, pages 121-124).

Burden of liver cancer attributed to other causes

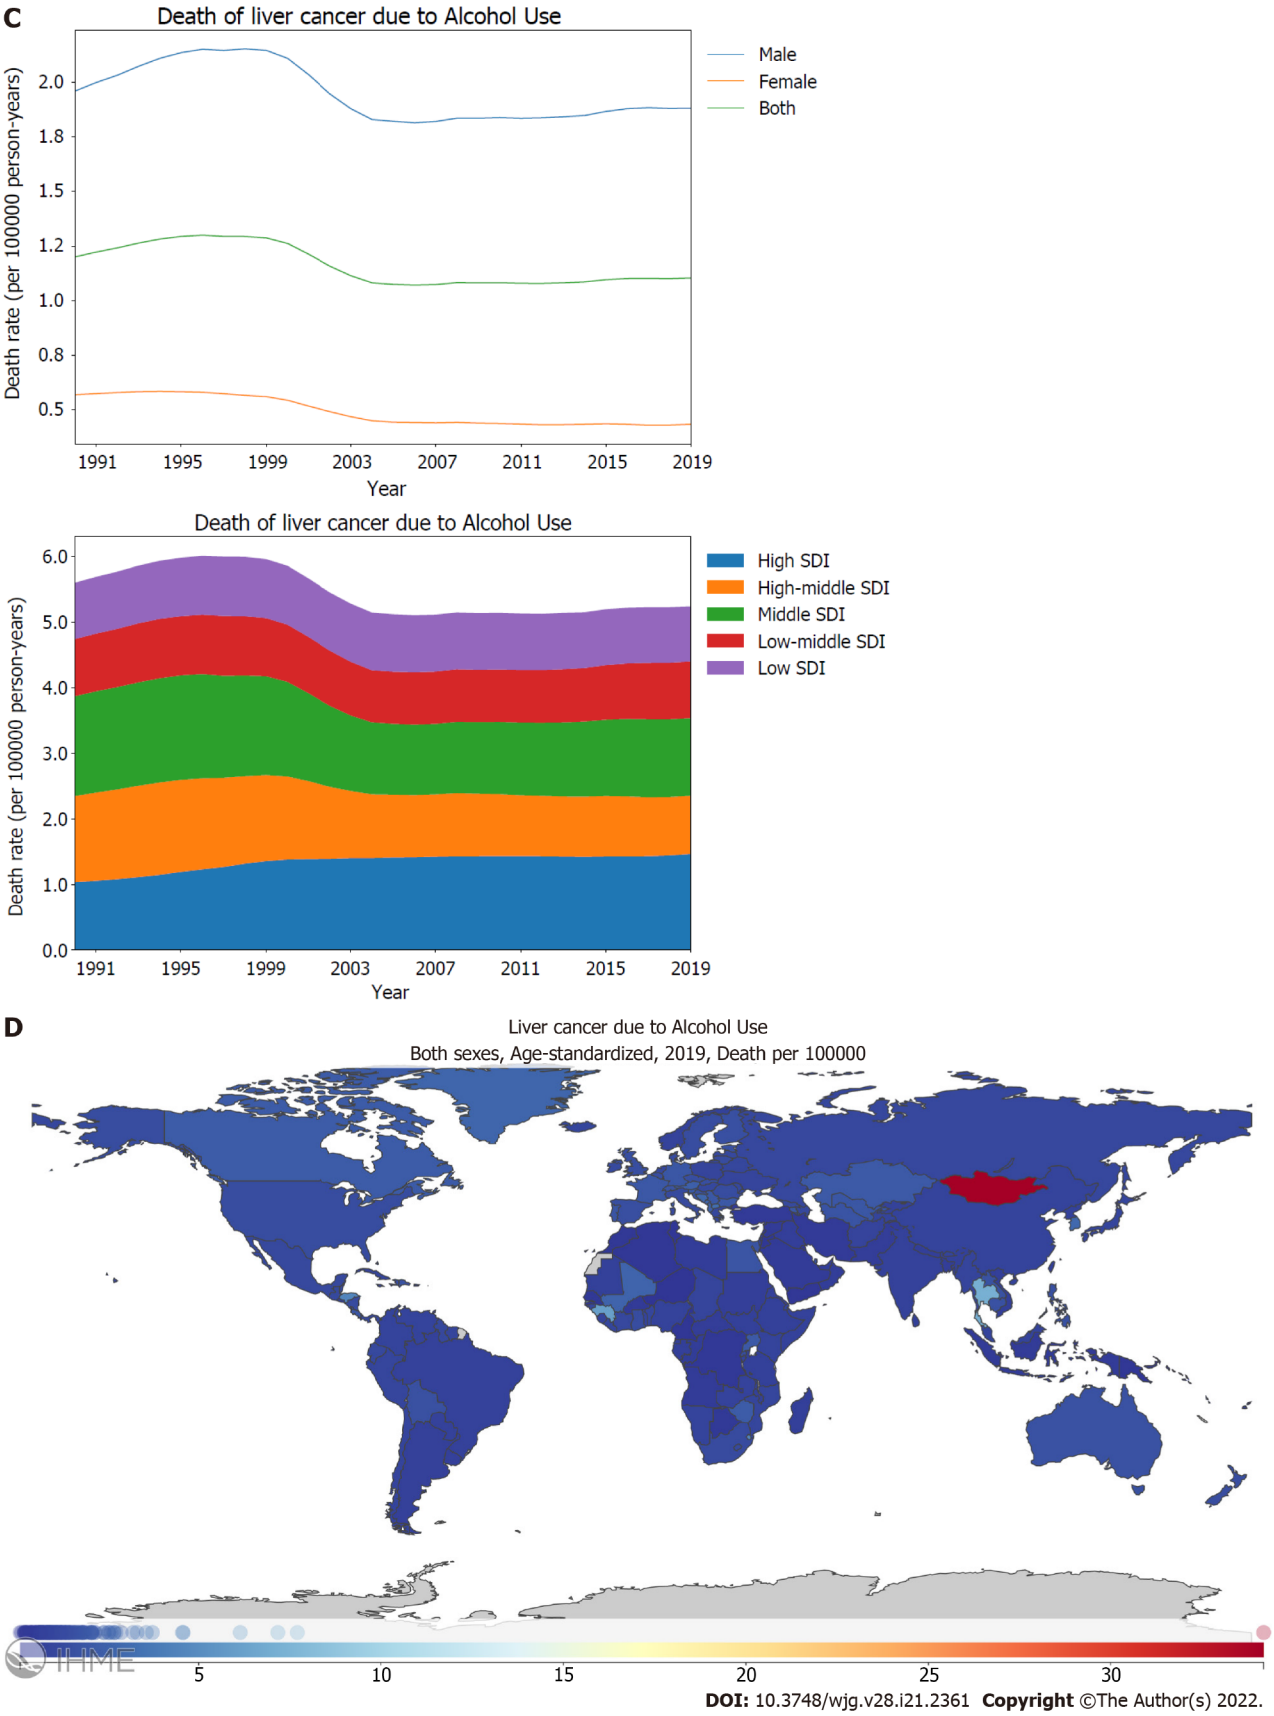
In terms of sex variance, the age-standardized incidence and mortality rates of PLC attributed to other causes were found to be higher in males (Figure 6A and C). When stratified using the SDI, higher incidence and mortality rates of PLC attributed to other causes were observed for high and middle SDI locations than for low middle and low SDI locations (Figure 6A and C). Between 1990 and 2019, there were remarkable geographical differences in the changing trend of age-standardized incidence rates of PLC attributed to other causes across the SDI regions; the high middle, middle, and low middle SDI locations showed a declining trend, whereas the high SDI locations showed an increasing trend [144.8% (112.8-186.3)] (Figure 6A; Supplementary Figure 6A; Supplementary material, pages 19-20). The geographical differences observed in the age-standardized death rate of PLC attributed to other causes across the SDI regions were comparable to the incidence rate (Figure 6C; Supplementary Figure 6B; Supplementary material, pages 21-22). The highest incidence and death rates of PLC attributed to other causes were observed for Mongolia, Gambia, and Guinea (Figure 6B and D; Supplementary material, pages 130-133 and 139-142).



DISCUSSION



Main findings



Based on the data from the GBD 2019, we explored the global burden of PLC and focused on the relationship between socioeconomics and the attributable etiologies of PLC. Our main findings are listed below: (1) Global incidence and mortality rates of PLC declined between 1990 and 2019. The decreasing burden of PLC caused by hepatitis B and the declining PLC burden in middle SDI locations was considered the main driver for this favorable trend; (2) PLC had higher prevalence in males; (3) The highest attributable etiology of PLC was hepatitis B, followed by hepatitis C, and alcohol use; (4) The leading attributable etiology of PLC in the middle SDI locations was hepatitis B; and hepatitis C and alcohol use in the high SDI locations; (5) Before 2004, the middle SDI locations surpassed high SDI locations in terms of PLC burden. However, the high SDI locations exceeded the middle SDI locations in terms of PLC burden after 2004; (6) Between 1990 and 2019, the incidence rate of PLC decreased for the high middle SDI locations; it increased for the high SDI locations, according to the stratified causes of PLC including hepatitis B, hepatitis C, alcohol use, and NASH; and (7) In 2019, several countries located in East Asia, South Asia, West Africa, and North Africa shouldered the heaviest burden for incidence and death rates of PLC.

Liver cancer

The risk factors for liver cancer include HBV, HCV, alcohol consumption, metabolic syndrome, diabetes [11]. Although there are substantial variations between countries in the underlying etiologies; globally, HBV accounts for 33%; alcohol, 30%; HCV, 21%, and other causes, 16% of liver cancer deaths[4]. Similar to these findings, we found that the leading attributable etiology of PLC was hepatitis B, followed by hepatitis C, alcohol use, NASH, and other causes, based on the GBD 2019. CHB and CHC cause sustained or repeated inflammatory damage, followed by liver fibrosis and cirrhosis. After liver cirrhosis is established, the risk of hepatocellular carcinoma (HCC) increases substantially. Further, liver cirrhosis caused by NASH substantially increases the risk for HCC[12]. A superimposed condition can enhance the possibility of PLC. For example, alcohol use can contribute to the occurrence of PLC in the setting of CHC.

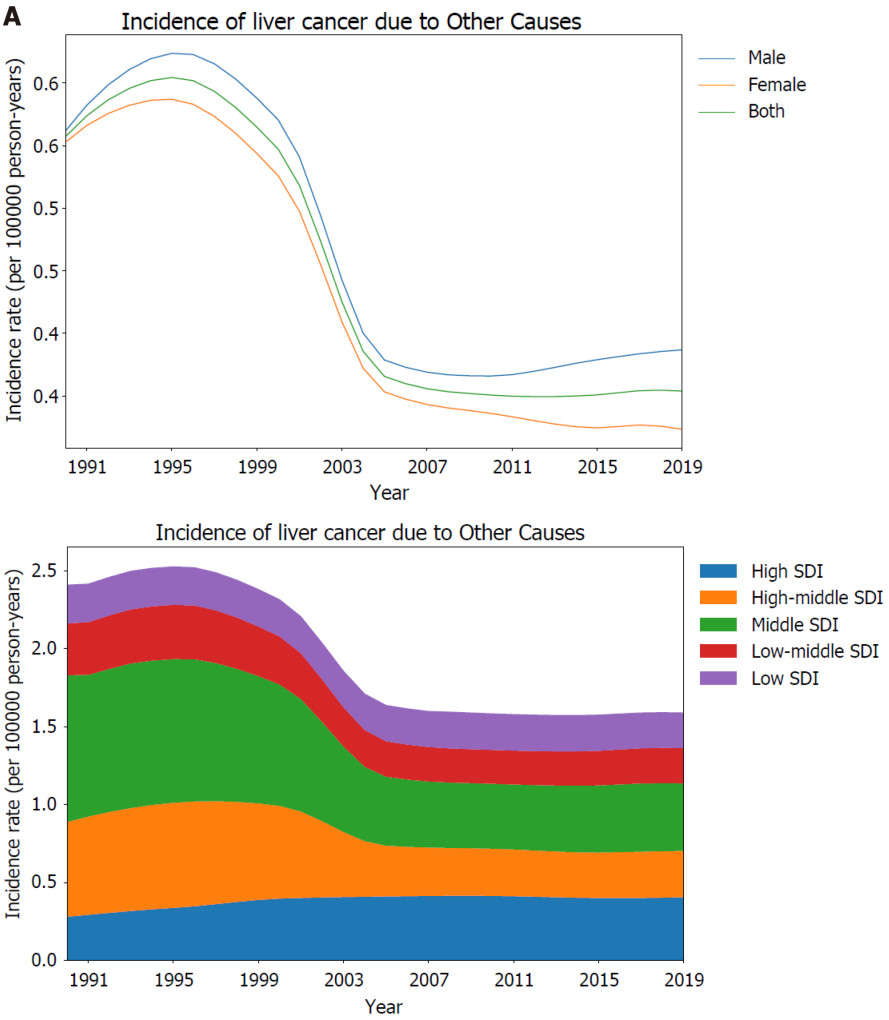
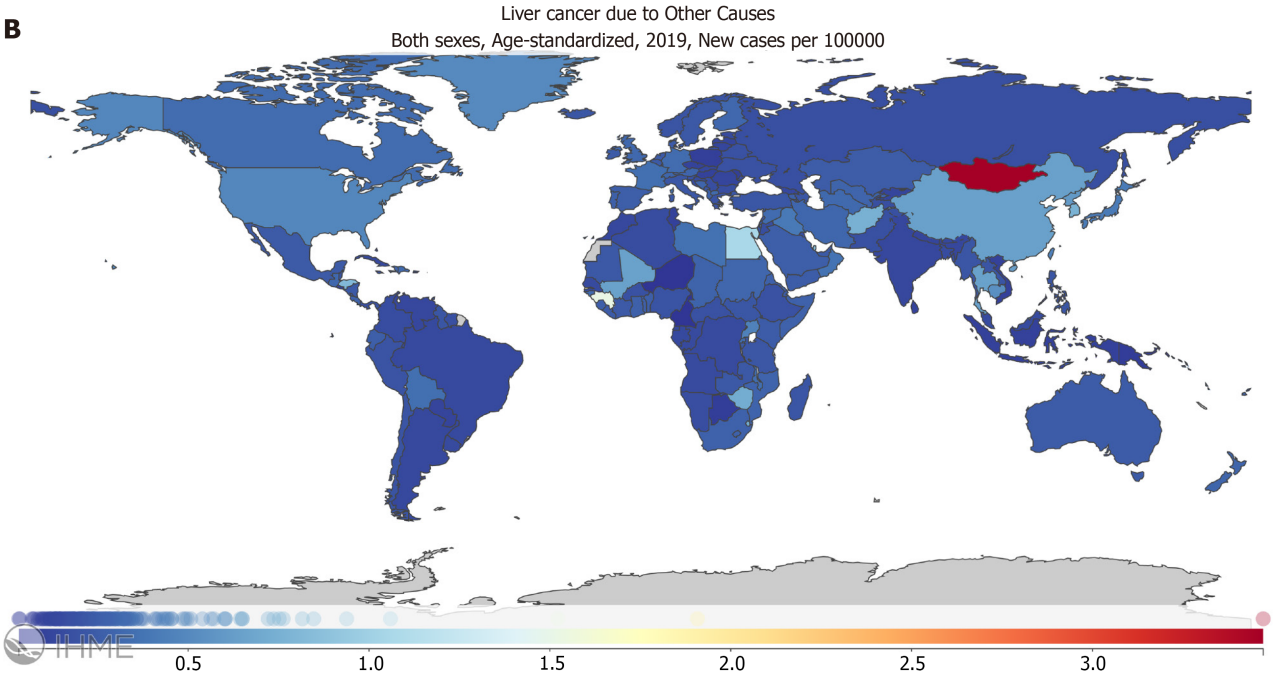
We observed an impressive association between socioeconomic status and the attributable etiologies of PLC. For high middle and middle SDI regions, hepatitis B was the main etiology of PLC whereas hepatitis C was the main etiology of PLC for high SDI regions; this was in accordance with another similar study[6]. In addition to the heavier burden of PLC caused by hepatitis C, the high SDI locations had a higher prevalence of PLC attributed to alcohol use. Given that the prevalence of drinking is greatest for high SDI locations and the least in low middle SDI locations[13], this finding was expected. Although viral hepatitis including CHB and CHC remains the most common cause of liver deaths, nonalcoholic fatty liver disease (NAFLD) is a rapidly growing contributor to liver mortality and morbidity. A similar phenomenon has been observed in China. In 2016, NAFLD cases requiring inpatient care in China outnumbered their counterparts for chronic viral hepatitis[14]. In the United States, the attributable population factors for HCC were greatest for metabolic disorders[15]. Interestingly, the global age-standardized incidence rate of PLC due to hepatitis B reached its peak in 1995-1996, then decreased gradually, as was shown in the GBD 2019. Wide HBV vaccine coverage may have been the potential cause of this beneficial phenomenon. A genetically engineered hepatitis B vaccine was available in 1986. In China, vaccination against HBV began in 1985 using a plasma-derived hepatitis B vaccine. In 1992, a genetically engineered hepatitis B vaccine was licensed in China and managed nationally. The integration of the HBV vaccination into the Expanded Program on Immunization in China has reduced chronic HBV infection by 90% among children < 15 years of age [16]. One of our studies found that the global incidence of acute hepatitis B has decreased gradually since 1990[17]. Usually, a declining trend for HBV incidence precedes a decreasing trend of PLC incidence due to hepatitis B by 10 to 20 years. Similarly, wide HBV vaccine coverage may have contributed to the declining PLC burden in high middle SDI locations since hepatitis B was the most important attributable etiology of PLC in these regions.



According to the GBD 2019 data, PLC is more prevalent in males. In fact, this is in line with several other observations[4,11]. MyD88-dependent IL-6 production, Foxa1, and Foxa2 play a role in the gender disparity in PLC[18,19]. Furthermore, according to the GBD 2019, there were 534000 (487000-589000) incident cases, and 485000 (444000-526000) deaths attributed to liver cancer globally in 2019; these were significantly lower than those reported in the GBD 2017 and GLOBOCAN 2020[1,6]. In the GBD 2019, the mapping of ICD-10 C22.9 was changed to a garbage code because this would have included both primary and secondary or metastatic cancers (see also https://www.thelancet.com/pb-assets/Lancet/gbd/summaries/diseases/Liver-cancer.pdf). In clinical practice, liver metastasis originating from colorectal cancer or stomach cancer is rather common. Therefore, fewer deaths were mapped for liver cancer in the GBD 2019 than in the GBD 2017. That is, the data of PLC from the databases of the GBD 2016 and GBD 2017 may have unintentionally included cases of metastatic liver cancer.



Prospects

In recent years, incidence and mortality rates of PLC have declined in middle SDI locations, such as China and other Eastern and Southeastern Asian countries[20-22]. In line with these findings, the PLC burden has been declining in the high middle and middle SDI locations from 1990 to 2019 according to the GBD 2019; this decline has benefited from the decreasing trend of viral hepatitis, such as CHB. However, the incidence and mortality rates of PLC increased in high SDI locations during the same period, which is in line with several other studies[4,23,24]. After 2004, the PLC burden in high SDI locations surpassed that in middle SDI locations. Several factors contributed to this reversal. First, hepatitis B was the leading attributable etiology of PLC in middle SDI locations. However, vaccination coverage for hepatitis B contributed to the declining trend of PLC in the middle SDI locations. Second, the increasing trend of PLC burden in high SDI locations was attributed to the increasing prevalence of alcohol use and metabolic risk factors for HCC, including metabolic syndrome, obesity, type II diabetes, and NASH[11,13]. As shown in Figures 4A, 4C, 5A and 5C, the gradually increasing burdens of alcohol use and NASH aggravated the burden of PLC in high SDI locations. The epidemiology of HCC has been shifting away from a disease predominated by viral hepatitis to NASH. A similar phenomenon was observed in the United States[25]. Thus, maintaining adequate surveillance of alcohol abuse and NASH is vital to develop strategies against the burden of PLC caused by these conditions.

Prevention

Although PLC causes a heavy burden of cancer incidence and mortality, it (to be precise, HCC) can be prevented by avoiding the risk factors. Compared with the cohort without vaccination, universal HBV vaccination reduced the relative prevalence of HBsAg to 0.24 (0.16-0.35)[26]. Similarly, escalating vaccination policy in China has significantly reduced the prevalence of HBsAg in the recent three decades[16]. Given the heavy burden of PLC caused by hepatitis B in middle and high middle SDI locations, universal HBV vaccination in these areas is considered a practical and principal strategy to minimize the liver cancer burden. Data have indicated that universal HBV vaccination has contributed to a dramatic decline in the PLC burden in several countries and regions[27,28]. For CHB or HBV-related liver cirrhosis, effective antiviral treatment should be provided based on the relative guidelines [29]. Treatment with > 5 years of oral antiviral therapy effectively decreases the HCC incidence regardless of whether patients have baseline cirrhosis[30]. The early diagnosis of CHB and CHC before liver cirrhosis is important considering that liver cirrhosis substantially contributes to the risk of PLC. In

areas where conditions permit, performing non-invasive examinations, such as liver stiffness measure, for individuals with high risk may be potentially beneficial. Unfortunately, there is no effective vaccine for HCV available now; however, DAA have made the eradication of HCV a reality. The achievement of an HCV cure before HCC diagnosis is associated with improved survival[31].

Globally, alcohol use was the seventh leading risk factor for deaths in 2016[13]. As shown in the GBD 2019, alcohol use is a major cause of PLC, especially in high SDI locations. This highlights the need for developing strategies to decrease alcohol use. NAFLD is the third-most common cause of cancer-related deaths worldwide and the seventh most common cause in the United States[32]. Considering the increasing trend of PLC due to NASH, especially in high SDI and middle SDI locations, the control or even reversal of NASH is of critical importance, and this can be attained with lifestyle changes comprising diet, exercise, and weight loss.

Limitations

There are several limitations to this study: (1) There is a possibility of the underestimation of the PLC burden in low middle and low SDI locations because of inadequate cancer screening. However, underestimation of the PLC burden is an inevitable problem, especially in low middle and low SDI locations owing to inadequate cancer screening and lack of registration. Similar limitations have been reported in cervical cancer screenings in low- and middle-income countries[33]. Additionally, in one of our previous studies, the underestimation of acute hepatitis in low-income countries was evident[17]; (2) Insufficient disclosure of geographical variances in large countries such as China and the United States. The GBD reports cancer burden by country or region; however, a large country has significant geographical variances in cancer burden for the urban or rural regions; (3) The lack of finer data for complex cancer, as PLC can be further divided into HCC and cholangiocarcinoma. These subgroups of cancer tend to have different etiologies and exhibit different features in terms of incidence and mortality rates; and (4) The inclusion of undefined etiologies in "other causes" can be leading causes in certain locations.

Despite these limitations, the GBD 2019 data are valuable for policymakers to implement cost-effective interventions, address modifiable risk factors, and prevent PLC efficiently.

CONCLUSION

The pronounced association between socioeconomic development status and PLC burden indicates socioeconomic development status affects attributable etiologies for PLC. GBD 2019 data are valuable for policymakers implementing PLC cost-effective interventions.

ARTICLE HIGHLIGHTS

Research background

Primary liver cancer (PLC) is a common cancer with high morbidity and mortality rates. PLC usually occurs as a preventable disease. Data on global and country-specific levels and trends of PLC are essential for understanding the effects of this disease and helping policymakers to allocate resources.

Research motivation

The association between socioeconomic development status and attributable etiologies for PLC is still unclear.

Research objectives

To investigate the association between the burden of PLC and socioeconomic development status.

Research methods

Cancer mortality and incidence rates of PLC were obtained from the Global Burden of Disease (GBD) 2019, and the data were stratified by the Socio-demographic Index (SDI) level. The association between the attributable etiology of PLC and SDI was described.

Research results

Several countries located in East Asia, South Asia, West Africa, and North Africa shouldered the heaviest burden of PLC in 2019. In terms of incidence rates, the first leading underlying cause of PLC identified was hepatitis B. The incidence rate of PLC was the highest for high and middle SDI locations. The leading attributable etiologies of PLC were hepatitis B for the middle and high middle SDI locations and hepatitis C and nonalcoholic steatohepatitis for the high SDI locations.

Research conclusions

Socioeconomic development status significantly affects attributable etiologies for PLC.

Research perspectives

Our findings are valuable to implement tailored prevention strategies for PLC.

Abstract

BACKGROUND

Given the low survival rate in pancreatic cancer, new therapeutic techniques have been explored, especially for unresectable or borderline resectable disease. Endoscopic ultrasound (EUS) provides real-time imaging and minimally invasive access for local and targeted injection of anti-tumor agents directly into the pancreatic tumor. Limited studies have been reported using this technique for the treatment of pancreatic ductal adenocarcinoma (PDAC).

AIM

To evaluate the progress made with EUS-guided injectable therapies in the treatment of PDAC.

METHODS

All original articles published in English until July 15, 2021, were retrieved *via* a library-assisted literature search from Ovid Evidence-Based Medicine Reviews and Scopus databases. Reference lists were reviewed to identify additional relevant articles. Prospective clinical studies evaluating the use of EUS-guided injectable therapies in PDAC were included. Studies primarily directed at non-EUS injectable therapies and other malignancies were excluded. Retrieved manuscripts were reviewed descriptively with on critical appraisal of published studies based on their methods and outcome measures such as safety, feasibility, and effectiveness in terms of tumor response and survival. Heterogeneity in data outcomes and therapeutic techniques limited the ability to perform comparative statistical analysis.

RESULTS

A total of thirteen articles (503 patients) were found eligible for inclusion. The EUS-injectable therapies used were heterogeneous among the studies consisting of immunotherapy (n = 5) in 59 patients, chemotherapy (n = 1) in 36 patients, and viral and other biological therapies (n = 7) in 408 patients. Eleven of the studies reviewed were single armed while two were double armed with one randomized

trial and one non-randomized comparative study. Overall, the included studies demonstrated EUS-guided injectable therapies to be safe and feasible with different agents as monotherapy or in conjunction with other modalities. Promising results were also observed regarding their efficacy and survival parameters in patients with PDAC.

CONCLUSION
EUS-guided injectable therapies, including immunotherapy, chemotherapy, and viral or other biological therapies have shown minimal adverse events and potential efficacy in the treatment of PDAC. Comparative studies, including controlled trials, are required to confirm these results in order to offer novel EUS-based treatment options for patients with PDAC.

Key Words: Pancreatic ductal adenocarcinoma; Endoscopic ultrasound-guided fine-needle injection; Local injectable therapy; Immunotherapy; Chemotherapy; Oncolytic viral therapy

Core Tip: Pancreatic ductal adenocarcinoma (PDAC) is a highly lethal malignancy. Resistance to systemic therapies may be attributable to the dense stromal matrix in the pancreatic tumor mass. Endoscopic ultrasound-guided fine-needle injection (EUS-FNI) is a novel technique to deliver various anti-tumor agents locally in real-time and may overcome this limitation. This review examines the EUS-FNI therapies used to treat PDAC.

INTRODUCTION

Pancreatic cancer is associated with a 5-year survival rate of approximately 10% at diagnosis and is the seventh leading cause of cancer-related deaths worldwide[1]. Pancreatic ductal adenocarcinoma (PDAC) accounts for more than 90% of cases of pancreatic cancer. The very low survival rate is partly due to the lack of early diagnosis and limited response to systemic therapies[2]. Only 15%-20% of patients present with surgically resectable disease and less than 10% undergo complete resection, which is the only curative intervention[3,4]. The majority of patients who present with unresectable locally advanced pancreatic cancer (LAPC) or metastatic disease are managed with systemic chemotherapy and/or radiotherapy with a very limited prognosis. The introduction of newer chemotherapy combinations and regimens have shown some promising results but still the overall survival (OS) remains dismal[5,6]. One of the many reasons for failure of systemic chemotherapy has been hypothesized as poor delivery of these agents due to abundant stromal matrix and deficient vasculature[7]. This justifies the rationale to explore the use of direct intratumoral injection for targeted delivery of an anti-tumor agent into the tumor mass while minimizing systemic complications. Percutaneous injection of direct intratumoral agents under ultrasound or computed tomography (CT) guidance has been demonstrated to be safe and feasible in phase I trials but this is technically cumbersome and difficult for administering multiple doses[8,9]. Endoscopic ultrasound (EUS) provides the opportunity for real-time visualization of the pancreatic mass and allows minimally invasive access for injectable therapies. This systematic review focuses on the methodology and outcomes of previously published clinical studies on EUS-guided fine needle injection (EUS-FNI) of anti-tumor agents in patients with PDAC.

MATERIALS AND METHODS

Literature search

An expert librarian conducted searches of the Ovid Evidence-Based Medicine Reviews (Embase, MEDLINE, Cochrane Central Register of Controlled Trials, Cochrane Database of Systematic Reviews) and Scopus databases to identify studies published between database inception until July 15, 2021, using the search strategy in Supplementary Table 1. The search was limited to full reports and articles published in English. The titles and abstracts were screened by two independent reviewers (JK and VC) and were assessed for eligibility based on the evaluation of the full manuscript. Disagreements between

the two reviewers were resolved by discussion. Additional studies were identified from searching through references and were screened similarly.

Inclusion criteria

The review is restricted to published prospective studies reporting the effects of injectable interventions primarily using the EUS-FNI technique in patients with PDAC, irrespective of the stage. Therapeutic interventions may include any form of immunotherapy, chemotherapy, or biological agents. Studies that utilized co-interventions and other modes of therapy delivery along with EUS-FNI were included. Studies were eligible if they assessed at least one of the outcomes of interest: Safety, feasibility, and efficacy in terms of tumor response and/or survival.

Exclusion criteria

Benchtop and animal models were excluded as were studies using non-EUS directed therapies. Studies investigating other pancreatic tumors and multiple gastrointestinal cancers where data for the PDAC group was not separately reported were also excluded. Studies were not considered eligible for inclusion if they did not focus on the treatment of PDAC and rather explored the effects of the interventions on palliation and symptom control.

Data extraction

Data was extracted on studies' characteristics of interest- participants, study design, interventions (*e.g.*, therapeutic agent, dosage, and EUS-FNI technique), prior therapies and co-interventions, outcome measures, and results. Relevant data from the included articles were recorded in itemized tables using Microsoft Excel for Microsoft 365 (MSO 16.0.13801.21002) 64 bit.

Outcomes

Outcome parameters of toxicity and clinical efficacy (tumor response and/or survival parameters) were reported as defined by the individual studies. Grade 3-4 AEs included those with severe or life-threatening toxicity.

Statistical analysis

Heterogeneity in data outcomes and therapeutic techniques limited the ability to perform comparative statistical analysis.

Quality assessment

The risk of bias in the included studies was assessed by two independent reviewers (JK, VJ) using the NIH Study Quality Assessment tools for controlled intervention studies and the before-after (pre-post) studies with no control group[10]. These guidelines help to rate the studies as good, fair, or poor based on a set of quality criteria questions. The tools were adapted keeping in mind the nature of the study being reviewed by identifying and reporting some questions as non-applicable as deemed by the reviewers. The results were compared, and any differences were resolved by discussion.

RESULTS

The literature search yielded 101 publications. Title and abstract screening further yielded 30 potentially eligible publications. A full review of manuscripts identified 9 eligible reports along with 4 eligible reports found after backward reference searching leading to a total of 13 full-text articles with 503 patients that were included in the systematic review. The baseline characteristics of these studies are included in Table 1. All were single arm studies except 2, one of which was a randomized controlled trial (RCT) while the other was a non-randomized study. The EUS-injectable therapy administered was heterogeneous among the studies and consisted of immunotherapy (n = 5) in 59 patients, chemotherapy (n = 1) in 36 patients, and viral and other biological therapies (n = 7) in 408 patients.

The quality assessment process identified 11 studies as good and 2 as fair, the details of which are attached in Supplementary Tables 2 and 3.

EUS-guided fine needle injection

Linear array echoendoscopes have facilitated the simultaneous visualization of a target lesion and advancement of a needle from the distal tip of the echoendoscope under precise control to aspirate, inject, or gain access to the organ[11]. This has expanded the role of EUS into the realm of therapeutic interventions with a wide range of applications. EUS-FNI has demonstrated safety and feasibility in applications such as celiac plexus block/neurolysis for the management of pancreas-related pain or pancreatic cyst ablation[12,13]. More recently, its use has been explored for the injection of anti-tumor agents in patients with pancreatic cancer as an attractive method of delivery of such agents considering its minimal invasiveness and low rate of adverse events (AEs)[14].

Table 1 Characteristics of published clinical studies using endoscopic ultrasound-guided fine-needle injection for pancreatic ductal adenocarcinoma

Ref.	Disease	Country	No. of subjects, No. of groups	Study type	EUS-FNI injectable agent	Type of therapy	Aes	Tumor response	Median survival
Chang *et al* [17], 2000	Unresectable PDAC	United States	8, single arm	Phase I	Allogeneic mixed lymphocyte culture	Immunotherapy	DLT-0	Partial remission 25%, minor response 12.5%	13.2 mo (OS)
Irisawa *et al* [21], 2007	Unresectable PDAC refractory to gemcitabine	Japan	7, single arm	Pilot clinical study	Dcs	Immunotherapy	Aes-0	Mixed response 28.6%, stable disease 28.6%	9.9 mo (OS)
Hirooka *et al* [22], 2009	LAPC	Japan	5, single arm	Phase I	OK-432-pulsed dcs	Immunotherapy	Grade 3 or 4 aes-0	Effective response 60% (partial remission 20%, stable disease 40%)	15.9 mo (OS)
Endo *et al*[24], 2012	Resectable PDAC	Japan	24, two arms	Phase I	Idcs and OK-432	Immunotherapy	Grade 3 aes-1	NA	No difference
Hirooka *et al* [25], 2017	LAPC	Japan	15, single arm	Phase I/II	Zoledronate-pulsed dcs	Immunotherapy	DLT-0 (grade 3 aes-4)	Stable disease 46.7%	11.5 mo (OS)
Levy *et al*[27], 2017	Unresectable PDAC	United States	36, single arm	Prospective non-randomized	Gemcitabine	Chemotherapy	Aes-0	Partial response 25%, stable disease 57%	10.4 mo (OS)
Hecht *et al*[31], 2003	Unresectable PDAC without liver metastasis	United States	21, single arm	Phase I/II	ONYX-015	Viral therapy	Aes-8 (four related to the virus and four to the injection technique)	Partial response 10%, stable disease 38%	7.5 mo (OS)
Hecht *et al*[9], 2012	LAPC	United States	50, single arm	Phase I/II	Tnferade Biologic	Viral therapy	DLT-3	Complete response 2%, partial response 6%, minor response 8%, stable disease 24%	297 d (OS)
Herman *et al* [33], 2013	LAPC	United States	304, two arms	Randomized phase III	Tnferade Biologic	Viral therapy	No difference in grade 3 to 4 aes	No difference	10.0 mo (OS) for both arms
Hirooka *et al* [35], 2018	LAPC	Japan	12, single arm	Phase I	HF-10	Viral therapy	DLT-0, Serious aes-2, Grade 3 aes-5	Effective response 78%	5.5 mo (OS)
Lee *et al*[36], 2020	LAPC	South Korea	9, single arm	Phase I	Ad5-DS	Viral therapy	DLT-0	Overall response 11%, disease control rate 100%	11.4 mo (PFS)
Nishimura *et al* [40], 2018	Unresectable PDAC	Japan	6, single arm	Prospective non-randomized	STNM01	RNA oligonuc-leotide	Aes-0	NA	5.8 mo (OS)
Hanna *et al* [42], 2012	Unresectable PDAC	United States, Israel	6, single arm	Phase I/IIA	BC-819	DNA plasmid	DLT-1	Overall response 33.3% and 66.7% in the two dose cohorts respectively	100% and 66.7% (six-month survival) in the two dose cohorts

AEs: Adverse events; NA: Not available; PDAC: Pancreatic ductal adenocarcinoma; LAPC: Locally advanced pancreatic cancer; iDC: Immature dendritic cell; DLT: Dose-limiting toxicity; OS: Overall survival; PFS: Progression-free survival.

Immunotherapy

Cancer immunotherapy aims to harness the inherent ability of the host immune system to mount an effective anti-tumor response against cancer cells through multiple strategies. Therapeutic cancer vaccines stimulate the activation of cytotoxic T lymphocytes (CTLs) against unique immunogenic tumor antigens by enhancing the delivery of these antigens[15].Targeting immune checkpoint inhibitor molecules aids in disrupting the immune suppressive mechanisms developed by cancer cells to evade immunosurveillance while the adoptive transfer of engineered lymphocytes expressing tumor epitopes or chimeric receptors aims to mediate anti-tumor response[16]. After mixed results with studies employing systemic immunotherapy in PDAC, direct administration with EUS-FNI has been used.

Allogeneic mixed lymphocyte culture: The first reported clinical study that used the novel delivery technique of EUS-FNI as local injectable therapy for PDAC was reported in 2000[17]. It was also the first attempt at administering biological response modifier or cellular-based immune therapy for the treatment of PDAC. The authors used allogeneic mixed lymphocyte culture prepared by coincubation of peripheral blood mononuclear cells from the patient and an allogeneic blood donor to generate a mixed lymphocyte reaction (MLR). It was based on the hypothesis that the MLR results in a high concentration of cytokines within the tumor which upregulates host anti-tumor effector mechanisms to aid in tumor regression. Patients with unresectable PDAC underwent a single session EUS-FNI procedure using 3, 6, and 9 billion cells in a dose-escalation manner. The median OS was documented to be 13.2 mo although there were only 2 partial responses and 1 minor response on either CT or EUS. Dose-limiting toxicity (DLT) was not reached and there were no procedure-related AEs were reported. Low-grade fever was the most common AE but was not associated with leukocytosis and was treated with acetaminophen. There were three grade 3 gastrointestinal toxicities and three grade 3 elevations in bilirubin which were transient and resolved after replacing the preexisting biliary stents in the patients. The encouraging results led to a multicenter RCT comparing EUS-guided injection of the allogeneic mixed lymphocyte culture to conventional IV gemcitabine therapy, but it was not completed as interim results suggested better survival and tumor response in the gemcitabine arm.

Dendritic cells as cancer vaccine: Dendritic cells (DCs) act as potent antigen-presenting cells (APCs) to generate anti-cancer immunity through stimulation of host primary T cell response. Immature or unloaded DCs (iDCs) acquire specific tumor-derived antigens, process them in situ, and migrate to lymphoid organs for presentation to CTLs[18]. Although vaccine strategies for delivering immunogenic tumor antigens themselves as synthetic peptides have been developed for different tumors, these require identification of specific antigens and evidence of their immunogenicity in the tumor microenvironment (TME). Despite autologous tumor cell lysates being used to provide specific tumor antigens in the clinical studies involving cancers with poorly defined antigens, there is evidence to support APCs as potent vaccines to more effectively cross-prime the CTLs with apoptotic tumor cells and apoptotic bodies[19,20]. Considering the difficulty in attaining sufficient quantities of tumor cells for *ex vivo* loading of DCs, it is reasonable to inject iDCs that can get exposed to tumor antigens *in vivo* after administration of apoptosis-inducing therapy like radiotherapy or chemotherapy.

The first report of the use of iDC injection for pancreatic cancer was a pilot clinical study in patients with unsuccessfully treated (gemcitabine resistant) unresectable PDAC[21]. Seven patients underwent cycles of EUS-FNI of unpulsed iDCs in the dose of 10 million cells or more at 2 to 3 sites within the pancreatic mass. iDCs were injected on days 1, 8, and 15 with cycles repeated every 28 d. Five patients received prior radiation therapy to induce apoptosis and facilitate tumor antigen cross-presentation. No procedural AEs were noted, and all DC injections were tolerated without clinical toxicity. Two patients demonstrated a mixed response and two others had stable disease for more than 6 mo. Median patient survival was 9.9 mo despite resistance to gemcitabine.

Hirooka *et al*[22] explored DC-based vaccination as first-line therapy for unresectable LAPC and combined it with gemcitabine based on its known apoptosis-inducing effects. It was postulated to release tumor antigens slowly over time for processing and presentation by DCs. The study used DCs pulsed with OK-432, penicillin killed and lyophilized preparation of a low-virulence strain of Streptococcus pyogenes, which acts as an immunopotentiating agent reported to stimulate DC maturation and T cell activation[23,24]. Conventional lymphokine-activated killer cells stimulated with anti-CD3 monoclonal antibody (CD3-LAKs) were also administrated systemically to induce additional anti-cancer activity. The results showed the combined therapy to be safe and synergistically effective with a median survival of 15.9 mo. Effective radiological tumor response was evidenced in three patients with 1 partial response and 2 long stable diseases for more than 6 mo. Interestingly, the patient with partial remission and the longest survival of 25.4 mo also exhibited significant immunological response with respect to the number of interferon gamma producing cells in peripheral blood lymphocytes (PBLs) and tumor-antigen specific CTL activity.

Based on this study, the authors reported a recent clinical study assessing the safety and efficacy of comprehensive immunotherapy combined with IV gemcitabine as first-line therapy for patients with LAPC[25]. Twelve cycles of EUS-FNI were performed using zoledronate-pulsed DCs rather than the previously used OK-432 pulsed DCs along with systemic administration of adoptive activated T lymphocytes (αβT) and gemcitabine every 14 d. DLT was reported. Grade 3 toxicity was recorded in

four patients, including the two patients that were attributed to gemcitabine. Seven of the 15 patients showed a stable disease tumor response with most showing long-term clinical responses. Patients receiving this therapy were noted to have a higher quality of life assessments as well as the immunological response which was evaluated by the ratio of the number of $CD8^+$ T cells to that of regulatory T cells ($CD8^+$/Treg ratio) was found to be significantly higher in patients with stable disease. The median OS and progression-free-survival (PFS) of 15 patients were 12.0 mo and 5.5 mo, respectively. Patients with pre-treatment neutrophil/lymphocyte ratio (NLR) lower than 5.0 demonstrated significantly longer survival. In an analysis limited to patients with an NLR lower than 5.0, the patients whose $CD8^+$/Treg ratio increased more than twofold survived longer. This suggests that using precise biomarkers such as NLR and $CD8^+$/Treg ratio can make comprehensive immunotherapy more beneficial for subgroups of patients with PDAC.

Another study compared 9 patients who received EUS-FNI of iDCs and OK-432 prior to the pancreatectomy surgery to 15 patients who did not receive this therapy[24]. The intervention group patients also received intra-operative radiotherapy to the retroperitoneal space. There were no severe toxicities following the pre-operative iDC injection except for one transient grade 3 fever. The incidence of postoperative complications was similar in both DC and non-DC groups. Although there was no statistically significant difference in OS times of both groups, the authors reported that 2 patients from the DC group, one of which was stage IV with distant lymph node metastasis, survived more than 5 years without requiring adjuvant therapy. Immunohistochemical examination of the surgically dissected lymph nodes revealed significantly higher $CD83^+$ cells in the regional lymph nodes and higher accumulated $Foxp3^+$ cells in both regional and distant lymph nodes in the DC group. This study not only demonstrated the safety and feasibility of preoperative EUS-FNI but also illustrated the potential of inducing an effective immune response against PDAC.

Chemotherapy

Although systemic chemotherapy forms the basis of standard of care (SOC) treatment for unresectable PDAC primarily LAPC, only one clinical study has so far reported the use of a chemotherapeutic agent being injected locally *via* the EUS-FNI technique.

Gemcitabine

Gemcitabine has been standard therapy for surgically unresectable PDAC since 1997 with an established record of use, safety, and relative benefit when administered intravenously[26]. Given its safety profile, it was selected to be administered in a prospective study conducted at our institution[27]. Patients with locally advanced (n = 20) and metastatic (n = 13) PDAC in whom surgical resection was not performed were included to undergo a single session of EUS-FNI using gemcitabine in the concentration of 38 mg/mL injected *via* a 22-gauge needle. The needle tip was placed 0.5-1.0 cm from the distal tumor edge with injection as the needle retracted proximally to inject approximately 50% of the dose uniformly along the perimeter of the tumor at sites of local infiltration (*e.g.*, blood vessels) and 50% within the remainder of the tumor. Multiple needle passes were performed (median 3, range 1-4) until the injectate was not limited within the tumor but instead began to infiltrate along needle tract or peritumoral sites, leading to varied injection volumes. The median volume of injectate per patient was 2.5 mL (range, 0.7-7.0 mL) corresponding to an intratumoral gemcitabine dose of 95 mg (range, 27-266 mg). Patients underwent subsequent conventional multimodality therapy: Chemoradiotherapy (n = 22), chemotherapy alone (n = 10), no therapy (n = 1), or indeterminate therapy (n = 3). There were no AEs attributable to the EUS-FNI procedure. OS at 6 mo, 12 mo, and 5 years were 78%, 44%, and 3%, respectively. The median OS was 10.4 mo [95% confidence interval (CI): 2.7-68.0]. From the 20 patients with stage III unresectable disease, 4 (20.0%) were downstaged and underwent an R0 resection. Patients who had a more complete therapy based on a visual score showed the greatest increase in median survival (P < 0.0001) with a consistent trend of increasing survival as completeness increased. Although completeness of therapy corresponded to prolonged survival, the significance of this finding is potentially limited by the subjective nature of its assessment.

Oncolytic viral therapy

Oncolytic viruses (OVs) are increasingly being explored as a therapeutic option because of their ability to be engineered for tumor selectivity and express genes of interest within the tumor cells to cause cytotoxic effects and cell death[28,29]. Unlike gene therapy, OVs are replication-competent and propagate within tumor cells, generating infectious progeny that further spreads to surrounding cells after tumor cell lysis. Therefore, in theory, OVs have the potential for efficient oncolysis in solid tumor masses[30].

Onyx-015: ONYX-015 is the first replication selective virus used in clinical trials. It is a chimeric human group C adenovirus with a deletion in the E1B-55kD gene inhibiting p53 function which is already lost in most cancer cells making them susceptible to this agent[31]. In a clinical study of 21 patients with unresectable PDAC, eight sessions of EUS-FNI with ONYX-015 were administered over 8 wk along with systemic gemcitabine therapy. The viral agent was administered in the dosage of 2×10^{10} particles/session (n = 3) and 2×10^{11} particles/session (n = 3) in phase I, and 2×10^{11} particles/session (n = 15) in

phase II of the same study which was the MTD (maximum tolerated dose). EUS-FNI was performed using a transgastric or transduodenal approach with a 22-gauge needle in a fanning pattern during the withdrawal of the needle. Two cases of duodenal perforation that were observed were attributed to the stiff tip of the echoendoscope and thus the protocol was modified only allowing for transgastric FNI. Subsequently, no luminal perforations were noted. Additionally, two cases of sepsis were noted, which may have been related to the injection technique. Thus, the protocol was again modified such that the needles were not fully retracted into the lumen during repositioning and repassage of the needle. Furthermore, the study authors instituted prophylactic administration of oral ciprofloxacin. ONYX-015 itself was well tolerated. Asymptomatic grade 3 and 4 increases in amylase and lipase were detected in 10% of patients, but no clinical pancreatitis was observed. After the combination therapy, objective partial regression of > 50% was seen in 2 out of 21 patients (10%) treated. Two patients demonstrated minor radiographic response to treatment, 6 had stable disease, and the remaining 11 had progressive disease or had to go off study because of treatment toxicity. This study established that EUS guided transgastric injection of ONYX-015 adenovirus into PDAC was both feasible and safe and that such an approach may be extended to other novel biological agents.

TNFerade: TNFerade™ Biologic (also called "AdGVEGR.TNF.11D" or "TNFerade"), is a replication-deficient adenoviral vector for selective delivery of tumor necrosis factor-α (TNF-α) into tumor cells. It consists of Egr-1 promoter gene located upstream to the cDNA which is radiation inducible, hence providing spatial and temporal control of the cytotoxicity by TNF-α[9]. TNF- α may also act as a radiosensitizer and enhance the effect of subsequent radiation therapy[32]. In a multicenter study investigating the safety and feasibility of intratumoral gene therapy with TNFerade Biologic along with standard chemoradiotherapy as first-line treatment for LAPC, subjects were administered either EUS-FNI or percutaneous injection under ultrasound or CT guidance[9]. Twenty-seven patients underwent EUS-FNI and 23 received a percutaneous injection of TNFerade once a week for 5 wk in a dose-escalation manner. A total volume of 2 mL was administered per session of EUS-FNI and injected as four 0.5 mL injections into different areas of the tumor. The maximum tolerated dose was calculated as 4×10^{11} PU after the appearance of DLT of pancreatitis and cholangitis in 3 patients at the highest dose. Overall grade 3 and 4 toxicities included GI bleeding, deep vein thrombosis (DVT), pulmonary emboli, pancreatitis, and cholangitis which had an unclear attributability to the treatment which was therefore concluded to be well tolerated. There occurred 1 complete response (2%), 3 partial responses (6%), 4 minor response (8%) and 12 had stable disease (24%). Seven patients subsequently had an operative resection, 6 of which had clear margins, and 3 had a survival of more than 24 mo. Furthermore, the overall outcome was not influenced by the mode of delivery of TNFerade Biologic (either by EUS or percutaneous injection).

Based on these results, a multicenter RCT was conducted in patients with LAPC who were assigned to receive either TNFerade along with SOC chemoradiotherapy or SOC alone[33]. TNFerade intratumoral injection was delivered in the dose of 4×10^{11} PU using a CT or ultrasound-guided percutaneous transabdominal approach (PTA) or EUS-guided transgastric or transduodenal approach before the first fraction of radiotherapy each week for 5 wk. The mode of delivery was based on the discretion of the individual study sites. SOC consisted of continuous infusion 5-fluorouracil and radiotherapy, followed by gemcitabine or gemcitabine plus erlotinib maintenance therapy. The trial was discontinued based on futility after planned interim analysis. Median OS of TNFerade plus SOC *vs* SOC alone (10.0 mo *vs* 10.0 mo; HR: 0.90; 95%CI: 0.66-1.22; $P = 0.26$) and median PFS (6.8 mo *vs* 7.0 mo, respectively; HR: 0.96; 95%CI: 0.69-1.32; $P = 0.51$) were similar in both groups. Multivariate analyses showed that the EUS-FNI approach rather than the percutaneous transabdominal approach was a risk factor for lower PFS (HR: 2.08; 95%CI: 1.06-4.06; $P = 0.032$). Higher rates of definite or probable grade 1 and 2 fever and chills were observed in TNFerade plus SOC *vs* SOC arm alone. Significantly more grade 2 to 4 toxicities were present in the TNFerade plus SOC arm, but this was not dose-limiting suggesting that conditional expression of TNF-α through Egr-1 promoter limits systemic toxicity. TNFerade administration in this study did not prove effective in prolonging survival in patients with LAPC.

HF-10: HF-10 is a spontaneously mutated oncolytic herpes simplex virus-1 reported to have high tumor selectivity and reduced neuro invasiveness[34]. A phase 1 trial published in 2018 evaluated the safety and anti-tumor effectiveness of a triple combination therapy consisting of EUS-guided intratumoral injection of HF-10 along with systemic gemcitabine and erlotinib therapy for unresectable LAPC[35]. Patients underwent twice-weekly HF10 injections to a total of four injections unless DLT appeared. Three cohorts were designed in a dose escalation of 1×10^6, 3×10^6, and 1×10^7 pfu/d. Five patients developed grade III myelosuppression due to chemotherapy and two had serious AEs (perforation of duodenum and grade IV hepatic dysfunction) which were concluded to be unrelated to HF-10. Out of the nine subjects who completed the treatment, the tumor response was three partial responses and four stable diseases. Although the median PFS was relatively short as 6.3 mo, the median OS was 15.5 mo and two patients achieved long-term survival over 3 years. Infiltration of $CD4^+$or $CD8^+$cells was well documented in surgical specimens of two patients who ultimately downstaged and underwent surgery, highlighting the idea that oncolytic viruses might not only aid in tumor destruction but may also trigger host anti-tumor response.

Ad5-DS: Ad5-DS is a second-generation, replication-competent oncolytic adenovirus containing double suicide genes that convert prodrugs, 5-fluorocytosine, and valganciclovir, to active cytotoxic metabolites. In a recent Phase I study, nine patients with newly diagnosed LAPC received EUS-guided injection of Ad5-DS with concomitant oral 5- fluorocytosine and valganciclovir along with standard-dose intravenous gemcitabine[36]. The dose cohorts were 1×10^{11}, 3×10^{11}, and 1×10^{12} viral particles (viral particles)/mL. The therapy was reported to be well tolerated no DLT occurred. Tumor response from nine patients who underwent this therapy showed that one patient had a partial response while the other eight had stable disease at 12 wk. The overall response rate was 11%, and the disease control rate was 100%. Disease progression was noted in two patients at 6.5 mo (median PFS of 11.4 mo). Adenoviral DNA was detected in the peripheral blood of 4 patients at 8 wk. Although the trends in tumor size and carbohydrate antigen 19-9 levels seemed more favorable in patients who received higher doses of Ad5-DS, no dose-response relationship was established statistically[37].

Other gene transfer therapies

STNM01: Carbohydrate sulfotransferase 15 (CHST15) is a specific enzyme that has been shown to initiate pancreatic cell mobilization and invasion through its product chondroitin sulphate-E which cleaves CD44 and releases the sCD44 variant into the extracellular space. STNM01 is a synthetic double-stranded RNA oligonucleotide that selectively represses CHST15 expression[38,39]. Six patients with unresectable pancreatic cancer were administered STNM01 *via* a single EUS-FNI procedure with 16 mL (250 nM) injectate using a conventional 22-gauge needle in an open-labeled trial[40]. The agent was injected into 16 different sites within the tumor (1 mL each). Additional STNM01 injections were delivered after 4 wk of observation for AEs and were continued until disease progression occurred. All patients tolerated the procedure well and no AEs were observed. Median tumor size changed from 31 mm to 29 mm along with a significant decrease in median serum soluble CD44 variant, 6 which may reflect CHST15 inhibition and decreased cleavage of CD44, although this finding is limited by the lack of a reference range for sCD44v6 in healthy individuals. Histological evidence of high baseline expression of CHST15 positive cancer cells was noted which showed a large reduction in 2 patients after 4 wk of treatment. Interestingly, these patients also demonstrated tumor necrosis and longest OS (15.5 mo and 18 mo, respectively) indicating that STNM01 acts on CHST15 positive cells to reverse invasion and induce local tumor necrosis although this needs further confirmatory data in future studies.

BC-819: BC-819 is a double-stranded DNA plasmid that carries the cytotoxic gene for diphtheria toxin. Its expression is controlled by the presence of the H19 promoter sequence, which is overexpressed in some tumors like PDAC, leading to selective tumor cell destruction[41]. In a clinical study involving nine patients with unresectable locally advanced PDAC (positive for H19 expression), 2 wk of twice-weekly intratumoral injection of BC-819 under either CT (n = 3) or EUS (n = 6) guidance was administered[42]. The mode of delivery was determined by the principal investigator depending on tumor size, location, and ease of injection. Injection volumes of 1 mL (4 mg of BC-819) and 2 mL (8 mg of BC-819) were delivered in a dose-escalation manner in the two cohorts using a 21- to a 22-gauge needle in a clockwise alternating injection site scheme for maximum distribution. The treatment was safe and well-tolerated. Asymptomatic elevation of lipase in one patient was considered as DLT but MTD was not reached. Partial response was observed in 3 of the 6 patients treated with the higher dose (8 mg) at three-month follow-up. Resectability assessment showed that two individuals who received chemotherapy or chemoradiation therapy after experimental treatment were down staged to resectable PDAC at three months with one patient subsequently undergoing surgery with negative margins. This indicates that BC-819 may provide additional therapeutic benefits for advanced PDAC along with systemic chemotherapy.

DISCUSSION

Pancreatic cancer remains a highly lethal malignancy. One of the challenges hypothesized with systemic administration of therapeutic agents is their lack of penetration into the pancreatic tumor bed owing to surrounding desmoplasia. Direct injection therapies are an attractive option as they can lead to greater intratumoral concentration of the drug or biologic agent while minimizing systemic side effects. EUS-FNI has emerged as an attractive delivery option as this modality can visualize the tumor and surrounding structures in real-time. This allows for precise intratumoral delivery of biological agents while minimizing the risk for AEs such as avoiding vascular or surrounding structures. Multiple candidate agents for local therapy have been identified.

Successful local delivery of chemotherapeutics is a logical option given their proven safety profile with systemic therapy. Some of these agents have been delivered into normal pancreatic tissue in animal studies using EUS-FNI with no significant AEs[43,44] Results of the clinical study using EUS-guided gemcitabine injections are encouraging although additional data is required to confirm these findings with regulated delivery of standard multimodality therapy and controlled trials assessing the effect of multiple sessions and escalating doses towards significant clinical advantage. In theory, immuno-

therapy is an attractive option, but various challenges with PDAC include the immune-suppressive TME including stromal cellular and molecular components, and other multiple immunological barriers making PDAC a "cold" tumor. Direct delivery of these iDCs into the tumor mass makes tumor antigen loading theoretically more effective for inciting T-cell response mechanisms and has provided a renaissance in the exploration of immunotherapy for PDAC. Although the mentioned limited clinical reports have established safety, feasibility, and some immunological response in their studies, there appears to be a need for increased understanding of the complex immunotherapeutic pathways in PDAC for determining the most efficacious DC activating agent and most suited combination therapy for improving outcomes. Further studies are required to confirm survival benefits, explore synergism with immune checkpoint inhibitors, and select the most appropriate patient population to benefit from these immunotherapies based on precise biomarkers like neutrophil to lymphocyte ratio (NLR) and $CD8^+$/Treg ratio[25] Novel molecular markers may also help in identifying patients with predominantly locoregional complications from PDAC that would benefit from localized therapies.

Oncolytic viral therapy is among the most promising agents for local delivery in pancreatic tumors. Although different strains of adenovirus, herpes virus, measles virus, and other viruses have shown positive results in cancer cell lines and preclinical models, limited clinical studies have performed intratumoral injection of these agents using EUS-FNI[45,46]. As PDAC mass consists of islands of neoplastic cells interspersed with dense stroma which can hinder the spread of injectable agents, OVs can overcome this problem to some extent through their replicative potential and hence increased dissemination within the tumor. Other future areas of research can include viruses targeted towards extracellular matrix disruption and combination with anti-stromal agents to allow better penetration of viral therapy.

EUS-FNI technique can further enhance tumor penetration regardless of tumor cell distribution and composition of the surrounding stroma. Injection into multiple sites in the pancreatic mass using EUS-FNI may assist with even distribution of the agent throughout the tumor. Furthermore, EUS can be used to assess response, and allow for subsequent FNI therapy. EUS, however, is associated with the need for sedation, which may add additional cost and risks associated with sedation. Further studies are needed to compare and firmly establish the most effective EUS-FNI delivery technique including the use of multiple injection sites within the tumor, multiple passes, or use of newer designed needle devices for enhanced dispersion of the agents within the desmoplastic pancreatic stroma[47].

EUS-FNI is an emerging modality for enhanced local intratumoral drug delivery[48]. Current data demonstrate that EUS-guided injectable therapies are safe for the treatment of PDAC. Larger studies, including RCTs should consider using EUS-FNI and these data are needed to establish efficacy and survival data, identify the most suitable anti-tumor agents, including combination therapy, and determine the best patient populations that may benefit from local drug delivery. Regenerative therapies, including the use of immunotherapy, DCs, and oncolytic viruses offer new hope in the management of PDAC. These advances towards novel EUS-FNI therapies should more actively involve endoscopists as part of the multidisciplinary treatment team as we hope to improve survival of our patients with PDAC.

CONCLUSION

EUS-guided injectable therapies, including immunotherapy, chemotherapy, and viral or other biological therapies have shown minimal AEs and potential efficacy in the treatment of PDAC. Comparative studies, including controlled trials, are required to confirm improved survival and establish the most effective therapeutic options. Further research is needed to offer novel EUS-based therapies as a promising treatment for patients with PDAC in the future.

ARTICLE HIGHLIGHTS

Research background

Many new treatment options for pancreatic cancer are being explored owing to its poor prognosis. Advent of therapeutic Endoscopic ultrasound (EUS) guided therapies in recent years paved the way to explore the local delivery of injectable agents. In the last 22 years, very few studies have explored the use of EUS-guided fine-needle injection (EUS-FNI) to treat pancreatic ductal adenocarcinoma (PDAC). These are mostly phase I/II clinical studies using different agents and varied methodologies with mixed results.

Research motivation

EUS-FNI has the theoretical advantage of targeted delivery of anti-tumor agents under real-time visualization and minimal invasiveness. It can also overcome the limitations of systemic therapy mainly the low penetration of these agents into the desmoplastic tumor mass of PDAC. Limited literature and

heterogeneity in methodologies and outcomes necessitated a systematic review of the present literature to understand and guide future research in this promising field.

Research objectives

To evaluate the current status of research in the novel area of EUS-guided injectable treatment for PDAC. This has helped to understand the progress made so far and draw meaningful conclusions based on the limitations and gaps found in the literature. This has also enabled the development of focused future directives for research on this topic which can potentially advance the treatment of PDAC.

Research methods

A systematic and comprehensive review of clinical studies which used EUS-guided injectable therapy for the treatment of PDAC was done. Expert librarian assisted in the electronic search of various databases. Screening of papers for eligibility was done by two study members independently. Data were collected in a standardized manner with regard to the methodologies and outcomes of these studies. A critical appraisal of the present literature on this topic was performed.

Research results

Our study demonstrates that immunotherapy, chemotherapy, oncolytic viral, and other biological therapies have been used *via* EUS-guided injection technique in different ways to study the safety and efficacy of such treatment in PDAC patients. The review of the present literature indicates that these therapies are well tolerated and feasible overall. Mixed results are demonstrated in terms of clinical efficacy.

Research conclusions

This study concludes that EUS-FNI based treatment may be administered to patients with advanced PDAC without significant toxicity. Clinical efficacy with respect to the standard of care (SOC) is not yet established. Further research should be undertaken to find out the most effective therapeutic agent, dose, and techniques that may be employed to the appropriate population of PDAC patients who would benefit the most from these.

Research perspectives

The direction of future research should be to design controlled studies and phase III trials using the data from present literature to establish efficacy in terms of tumor response and survival with respect to the SOC. Anti-tumor agents may be administered at higher doses and multiple EUS-FNI sessions to maintain the appropriate concentration in the tumor bed. Studies using appropriate combination therapies (using chemotherapy and/or radiotherapy) and different EUS-FNI techniques, for example, multiple needle passes should be encouraged as they may help in overcoming hostile tumor microenvironment of pancreatic cancer.

Abstract

We described the case of a peripancreatic paraganglioma (PGL) misdiagnosed as pancreatic lesion. Surgical exploration revealed an unremarkable pancreas and a large well-defined cystic mass originating at the mesocolon root. Radical enucleation of the mass was performed, preserving the pancreatic tail. Histologically, a diagnosis of PGL was rendered. Interestingly, two previously unreported mutations, one affecting the *KDR* gene in exon 7 and another on the *JAK3* gene in exon 4 were detected. Both mutations are known to be pathogenetic. Imaging and cytologic findings were blindly reviewed by an expert panel of clinicians, radiologists, and pathologists to identify possible causes of the misdiagnosis. The major issue was lack of evidence of a cleavage plane from the pancreas at imaging, which prompted radiologists to establish an intraparenchymal origin. The blinded revision shifted the diagnosis towards an extrapancreatic lesion, as the pancreatic parenchyma showed no structural alterations and no dislocation of the Wirsung duct. *Ex post*, the identified biases were the emergency setting of the radiologic examination and the very thin mesocolon sheet, which hindered clear definition of the lesion borders. Original endoscopic ultrasonography diagnosis was confirmed, emphasizing the intrinsic limit of this

technique in detecting large masses. Finally, pathologic review favored a diagnosis of PGL due to the morphological features and immonohistochemical profile. Eighteen months after tumor excision, the patient is asymptomatic with no disease relapse evident by either radiology or laboratory tests. Our report strongly highlights the difficulties in rendering an accurate pre-operative diagnosis of PGL.

Key Words: Peripancreatic paraganglioma; Pancreatic neuroendocrine tumor; Solid pseudopapillary neoplasm; S100; Succinate dehydrogenase subunit B gene and expression; Fine needle biopsy

Core Tip: Our report strongly supports that paraganglioma should be included in the differential diagnosis of peripancreatic/pancreatic masses, highlighting the difficulties in establishing the accurate preoperative diagnosis, even after a second-round evaluation. In fact, due to the deep localization and the lack of specific clinical manifestations and imaging data, early diagnosis often relies solely on a level of suspicion, thus making it more probable to have a missed diagnosis or misdiagnosis. Moreover, the limited time spent with a patient in an emergency setting might impair the accuracy of the diagnosis, lowering quality and outcomes of healthcare delivery. A multidisciplinary team approach, involving skilled radiologists, endoscopists, pathologists, and surgeons, is of foremost importance for proper diagnosis and management, preventing undue surgical resections.

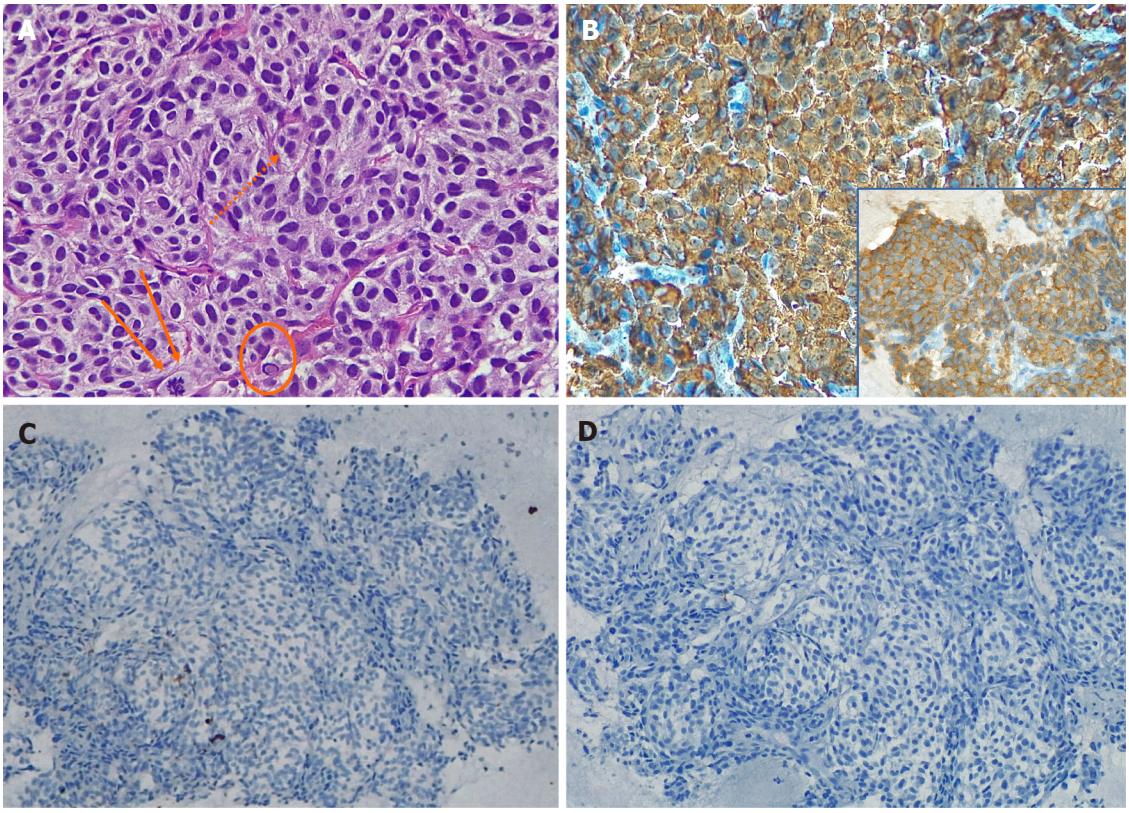
TO THE EDITOR



We read with interest the paper authored by Lanke *et al*[1] on a peripancreatic paraganglioma (PPGL) successfully diagnosed pre-operatively by endoscopic ultrasonography (EUS)-fine needle aspiration. After a careful review of the literature, the report highlights the enduring difficulties in achieving an accurate diagnosis of this rare entity prior to surgery. Among the 47 pancreatic/peripancreatic PGL reported so far, only 8 (17%) were correctly identified pre-operatively; the majority (n = 29, 62%) were misdiagnosed as pancreatic neuroendocine tumors or pancreatic neoplasms/cysts. In almost all cases (80%), the treatment of choice was surgery, demonstrating the uncertainty of classification for such lesion and its unpredictable behavior[1].

In November 2020, a 23-year-old woman complaining of left hypocondrial pain, diarrhea, and sweating lasting for 4 d, was referred to the Emergency Unit of Ospedale Unico della Versilia. The physical examination was unremarkable, but the abdominal US showed a large cystic, liquid-filled mass close to the pancreatic tail. Whole-body computed tomography (CT) scan confirmed the presence of a 95-mm cystic lesion with thickened, contrast-enhanced walls and a marked inhomogeneous boundary with the pancreatic tail. The mass seemed to be adherent to the left renal artery, left kidney hilum, and homolateral ureter (Figures 1A and 1B). Imaging work-up was completed with abdominal nuclear magnetic resonance (NMR) revealing T1 signal hyperintensity (Figure 1C) and positron emission tomography disclosing abnormal hyperactivity of the mass (standard uptake value 4.7%) (Figure 1D). The suspicion of a solid-pseudopapillary neoplasm (SPN) *vs* a cystic pancreatic tumor was posed. Blood tests, including vasoactive intestinal peptide, C-peptide, pancreatic polypeptide, serotonin, carcinoembryonic antigen (CEA), Ca-125, and Ca-19.9, were within normal range; whereas chromogranin A (CgA) serum levels exceeded 1800 ng/mL (reference range: 0-108 ng/mL). EUS-fine needle biopsy (FNB) was scheduled. EUS examination showed a 10-cm lesion of the pancreatic tail. The lesion was hypoechoic with well-defined borders and a cystic component (Figures 1E and 1F). Two FNB passes were made using a 20 Gauge needle with Rapid On-Site Evaluation to ensure adequate sampling[2]. Intracystic fluid was aspirated and analyzed with the following results: Glucose, 45 mg/dL; pancreatic amylase, 5 U/L; CEA, 1.0 ng/mL; Ca-19.9, 9 U/mL. Cell block examination disclosed nests of small to medium-sized epithelioid cells exhibiting moderate amount of amphophilic granular cytoplasm and oval to round nuclei with smooth contours and dense chromatin (Figure 2A). Occasionally, small nucleoli (Figure 2A dots), sparse mitotic figures (Figure 2A arrows), and intra-cytoplasmic hyaline globules (Figure 2A encircled) were noted, as well as vague rosette-like formations and branching hyalinized

Figure 2 Fine needle biopsy findings. A: Proliferation of small to medium-sized cells arranged in a nest pattern was evident, the cells occasionally showed small nucleoli (dots), mitotic figures (arrows), and intra-cytoplasmic hyaline globules (encircled), hematoxylin and eosin original magnification (O.M) × 40; B: Chromogranin A (CgA) positivity of neoplastic cells; inset: Synaptophysin positivity of neoplastic cells, CgA stain, O.M. × 20; B inset, synaptophysin stain, O.M. × 20; C: AE1/AE3 cytokeratins expression in scattered cells, cytokeratin AE1/AE3 stain, O.M. × 20; D: S100 negativity, S100 stain, O.M. × 20).

fibrovascular cores lined by neoplastic cells. Tumor cells diffusely expressed CgA (Figure 2B), synaptophysin (Figure 2B, inset), and GATA-3. Scattered cells were dot-like positive for AE1/AE3 cytokeratins (Figure 2C). Epithelial membrane antigen (EMA), PAX-8, and S100 protein (Figure 2D) were negative. A provisional diagnosis of neoplasm with neuroendocrine differentiation (either PGL or PanNET) *vs* SNP was made.

DOI: 10.3748/wjg.v28.i21.2396 **Copyright** ©The Author(s) 2022.

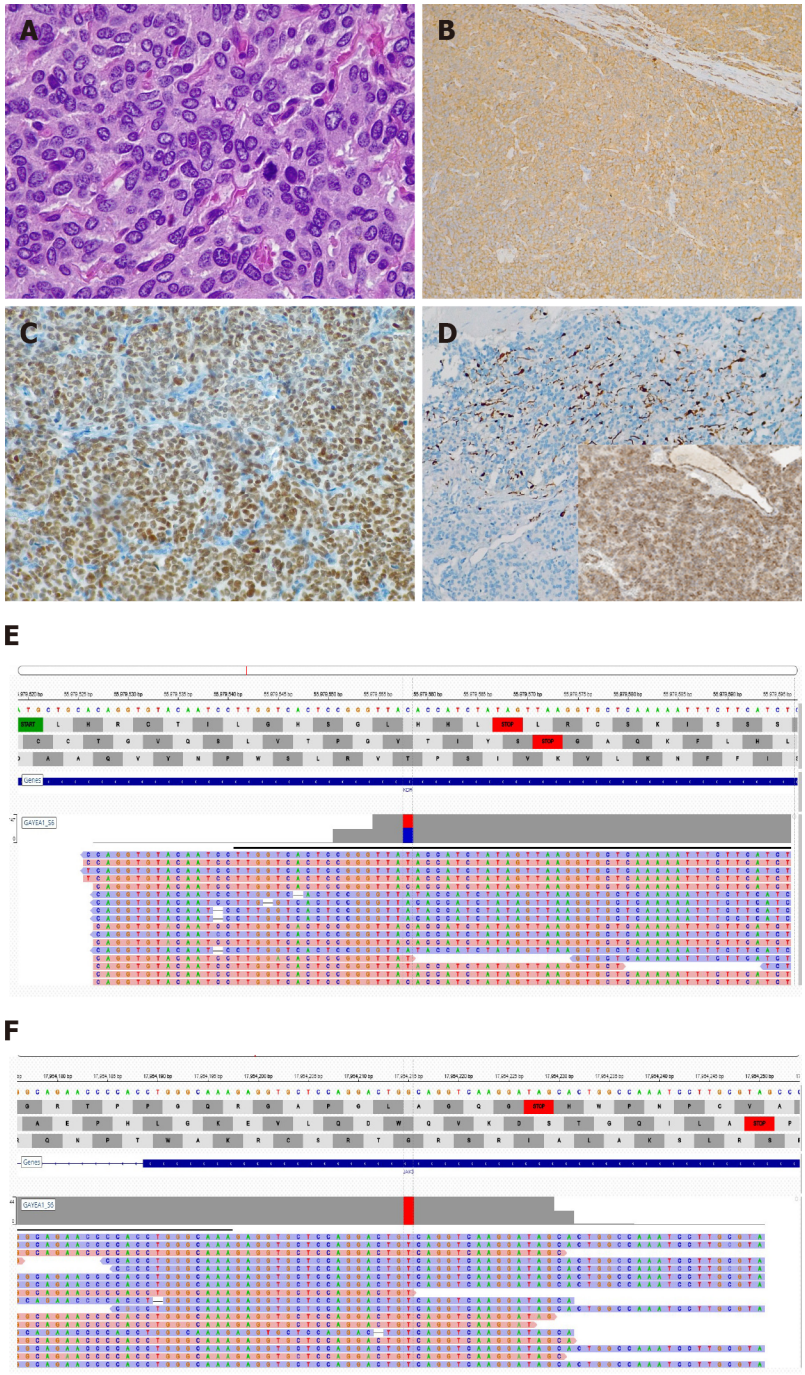

Figure 3 Macroscopic findings. A and B: At surgical exploration a large well-defined cystic mass located underneath the mesocolon plane was found; C: Radical enucleation of the lesion; D: Grossly, the cystic lesion showed a thick fibrous wall with a solid component and a yellowish, lobulated appearance on cut surface.

Surgical exploration revealed an unremarkable pancreas and a large well-defined cystic mass underneath the mesocolon plane, originating at the mesocolon root (Figures 3A and 3B). The lesion extended to the inferior margin of the pancreas and was strictly adherent but did not involve the organ parenchyma. As the capsule could be easily detached from the mesocolon sheets and vessels, radical enucleation was performed, preserving the pancreatic tail (Figure 3C).

The surgical specimen consisted of a 12-cm hemorrhagic cystic lesion, surrounded by a thick fibrous wall, with a solid component showing a yellowish, lobulated appearance on cut surface (Figure 3D). Microscopically, the tumor was composed of polygonal cells with abundant finely granular eosinophilic to amphophilic cytoplasm, mostly arranged in nests and anastomosing cords (Figure 4A). Areas with a diffuse growth pattern were also noted. Nuclei were regular, round to oval, with granular fine chromatin, small nucleoli, and occasional pseudoinclusions. The stroma was richly vascular. In the more cellular areas, pleomorphic cells with prominent nucleoli and occasional mitotic figures (2/high power field) were observed. There was evidence of focal capsular disruption. Cells were confirmed to be positive for CgA (Figure 4B), synaptophysin, GATA-3 (Figure 4C), and substantially negative for AE1/AE3 cytokeratins, EMA, and PAX-8. S100 and GFAP stained scanty cells encircling cell nests (Figure 4D). A final pathologic diagnosis of PGL, Grading System for Adrenal Phaeochromocytoma and Paraganglioma score 6 (intermediate risk), was rendered[3,4].

Given the young age of the patient and the rarity of the tumor, succinate dehydrogenase subunit B (SDHB) protein expression was evaluated, and next generation sequencing (NGS) analysis, using the commercial kit "Miriapod NGS-IL" (Diatech) on MiSeq Illumina Platform, was carried out to identify mutations affecting genes associated with syndromic and/or familial conditions (*i.e.*, *SDHB*, *VHL*, *NF1*, *RET*). *SDHB* expression was preserved (Figure 4D, inset) and none of the above-mentioned genes were found to be mutated, thus ruling out a hereditary condition[5]. Interestingly, we detected two previously unreported mutations, one affecting the *KDR* gene in exon 7 (c.889G>A missense variant)[6], and another on the *JAK3* gene (c.394C>A missense variant) in exon 4[7,8] (Figures 4E and 4F). Both mutations are known to be pathogenetic in olfactory neuroblastoma[6], some forms of leukemia, and solid tumors, such as neuroendocrine tumors[7,8].

Imaging and cytologic findings were blindly reviewed by an expert panel of clinicians, radiologists, and pathologists to identify possible causes of misdiagnosis. The major issue was lack of evidence of a cleavage plane from the pancreas at US, CT, and NMR, which prompted radiologists to establish an intra-parenchymal origin. The blinded revision shifted the diagnosis towards an extra-pancreatic lesion

DOI: 10.3748/wjg.v28.i21.2396 **Copyright** ©The Author(s) 2022.

Figure 4 Histologic and molecular findings. A: The lesion was composed of nests and cords of polygonal cells with abundant granular cytoplasm, and occasional mitotic figures in the more cellular areas, hematoxylin and eosin original magnification (O.M) × 60; B: Chromogranin A (CgA) positivity in neoplastic cells; inset: Synaptophysin positivity in neoplastic cells, CgA stain, O.M × 10; C: GATA-3 positivity in neoplastic cells, GATA-3 stain, O.M. × 10; D: S100-positive cells were scattered; inset: Succinate dehydrogenase subunit B (SDHB) expression was preserved, S100 stain, O.M. × 10; inset, SDHB stain, O.M. × 10; E: *KDR* mutation; F: *JAK3* mutation.

as the pancreatic parenchyma showed no structural alterations and no dislocation of the Wirsung duct. *Ex post*, the identified biases were the emergency regimen of radiologic examination, which impaired a precise assessment, and the very thin mesocolon sheet, probably on account of the patient's leanness, which hindered clear definition of the lesion borders, also masked by the extensive hemorrhagic component. Original EUS diagnosis was confirmed, emphasizing the intrinsic limit of the bi-dimensional image of trans-abdominal US in detecting a large mass in the same examination field. Finally, pathologic review of the FNB findings favored a diagnosis of PGL due to substantial negativity for cytokeratins and PAX-8, usually positive in PanNet[9,10], and absence of folded nuclei with longitudinal grooves, cholesterol crystals, and foamy macrophages, usually found in SPN[9]. Furthermore, diffuse cytoplasmic CgA reactivity is typically not seen in SPN[9]. The detection of S100-positive

sustentacular cells and zellballen pattern, considering the hallmarks of PGL, has limited value in the diagnosis of PGL, since they may not be present in small samples or in sympathetic PGLs, as in our case [2,11]. Eighteen months after tumor excision, the patient is asymptomatic with no disease relapse evident with CT or NMR imaging; CgA levels are within the reference range.

In conclusion, our report strongly supports the suggestion by Lanke *et al*[1] that PGL should be included in the differential diagnosis of peripancreatic/pancreatic masses, and highlights the difficulties in establishing an accurate preoperative diagnosis even after a second round evaluation. Indeed, due to the deep localization and lack of specific clinical manifestations and imaging data, early diagnosis of PGL often relies solely on the level of suspicion, thus easily resulting in misdiagnosis or missed diagnosis[12,13]. A multidisciplinary team approach, involving skilled radiologists, endoscopists, pathologists, and surgeons, is of foremost importance for proper PGL diagnosis and management in order to prevent undue surgical resections[14]. In the present case, the first radiologic mistake affected all the diagnostic work-up, even after second round evaluation, and only the long-lasting experience of the surgeon avoided over-treatment (*i.e.*, distal splenopancreasectomy, as reported in most of the cases described so far)[1]. Since there are no definite criteria for malignancy, a close follow-up after surgery is mandatory[14,15]. Pathologists play a key role in providing clues that may disclose genetic profile and predict malignant potential of the tumor[1,3,4,14,15].

ABOUT COVER

Editorial Board of *World Journal of Gastroenterology*, Conrado M Fernandez-Rodriguez, MD, PhD, Associate Professor, Unit of Gastroenterology, Hospital Universitario Fundacion Alcorcon, Av. Budapest-1, Alcorcón, Madrid 28922, Spain. cfernandez@fhalcorcon.es

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, and Scopus. The 2021 edition of Journal Citation Report® cites the 2020 impact factor (IF) for *WJG* as 5.742; Journal Citation Indicator: 0.79; IF without journal self cites: 5.590; 5-year IF: 5.044; Ranking: 28 among 92 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2020 is 6.9 and Scopus CiteScore rank 2020: Gastroenterology is 19/136.

Abstract

Patients with Crohn's disease (CD) are at a considerable risk for intestinal surgery. Approximately 25% of patients with CD will undergo an intestinal resection within 10 years of diagnosis. Postoperative complications after CD surgery have been reported in 20%-47% of the patients. Both general and CD-related risk factors are associated with postoperative complications, and comprise non-modifiable (*e.g.*, age) and potentially modifiable risk factors (*e.g.*, malnutrition). Prehabilitation focuses on the preoperative period with strategies designed to optimize

modifiable risk factors concerning the physical and mental condition of the individual patient. The aim of prehabilitation is to enhance postoperative recovery and return to or even improve preoperative functional capacity. Preoperative improvement of nutritional status, physical fitness, cessation of smoking, psychological support, and critical revision of preoperative use of CD medication are important strategies. Studies of the effect on postoperative outcome in CD patients are scarce, and guidelines lack recommendations on tailored management. In this opinion review, we review the current evidence on the impact of screening and management of nutritional status, physical fitness, CD medication and laboratory values on the postoperative course following an intestinal resection in CD patients. In addition, we aim to provide guidance for individualized multimodal prehabilitation in clinical practice concerning these modifiable factors.

Key Words: Crohn's disease; Prehabilitation strategies; Nutrition; Physical fitness; Medication; Laboratory values

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Nutritional status, medication, and laboratory values are modifiable factors that influence the postoperative course of patients with Crohn's disease. In addition, physical fitness is impaired in the perioperative course and therefore preoperative screening is warranted. Individualized multimodal prehabilitation programs aim to improve these modifiable risk factors before surgery, including smoking cessation and psychological screening and support, and should be integrated in the preoperative preparation period in order to reduce both postoperative complications and undesirable outcomes.

INTRODUCTION

Crohn's disease (CD) is a chronic inflammatory bowel disease (IBD) characterized by segmental, transmural inflammation, which most commonly affects the ileum and/or colon[1]. Although the risk of intestinal resection and re-resection has declined considerably over the past decades, approximately 25% of patients will undergo an intestinal resection within 10 years of CD diagnosis[2,3].

An intestinal resection is potentially perceived as a major life event and has a significant psychological impact on CD patients, which can result in anxiety and depressive symptoms in the pre- and postoperative setting[4]. Despite the immediate relief of symptoms and a potential increase of quality of life after CD surgery[5], important concerns are the risk of potential (severe) complications and recurrence of CD[6]. Reports on the frequency of postoperative complications, following intestinal resection in CD patients, range from 20%-47%[7-12]. Several general and CD-specific risk factors for postoperative complications have been identified. Both non-modifiable risk factors (*i.e.*, comorbidity, older age) and modifiable risk factors (*i.e.*, malnutrition, preoperative medication use, abnormal preoperative laboratory values and smoking) have been associated with postoperative complications[8-10,12,13]. In addition, preoperative physical fitness, specifically aerobic fitness, seems impaired in patients with CD[14], which may increase the risk for adverse postoperative outcomes as has been observed in colorectal cancer (CRC) surgery[15,16].

Prehabilitation focuses on the preoperative period by suggesting strategies designed to optimize modifiable risk factors concerning the physical and mental condition of the individual patient. As such, prehabilitation aims to improve the postoperative course and promotes an earlier postoperative recovery and return to functional capacity[6]. A four-pillar multimodal prehabilitation program tailored to the individual patient involves improving: (1) Physical; (2) Nutritional; (3) Psychological status; and (4) Cessation of smoking, resulted in a significant earlier recovery to the baseline functional capacity in patients with CRC[17]. In addition, preoperative physical exercise training to improve aerobic fitness significantly reduced postoperative complications in high-risk patients, both in general[18] and those with CRC[19], undergoing abdominal surgery as compared to usual care. These programs may also benefit patients in other settings of abdominal surgery, including CD[20]. However, literature on prehabilitation in CD patients scheduled for intestinal resection is scarce and guidelines lack recommendations on tailored management[21,22].

Table 1 Recommendations on screening for prehabilitation prior to intestinal surgery in Crohn's disease

Screening	
Nutritional status	Screening in all patients: Body mass index, evaluation of unintentional weight loss and assessment of dietary intake with nutritional or immunological screening tools (*e.g.*, GLIM and OPNI). Preferably assess the muscle mass (*e.g.*, with handgrip strength or consider available imaging techniques) to complement the measures of nutritional status
Physical fitness	Screening in all patients to estimate aerobic fitness with validated self-reporting questionnaire (*e.g.*, Duke activity status index, veterans-specific activity questionnaire). Consider referral of patients at risk for impaired physical fitness for comprehensive objective assessment by an exercise specialist
CD medication	Critically revise all current CD medication on a case-by-case basis
Laboratory assessment	Preoperative assessment of full blood count, CRP, and serum albumin. Assessment of vitamins and other trace elements may only be indicative in patients with biochemical remission
Smoking psychological status	Screen all patients on active smoking Discussion of expectations and potential fears for the perioperative course by treating physicians IBD team members

CD: Crohn's disease; CRP: C-reactive protein; GLIM: Global Leadership Initiative on Malnutrition; IBD: Inflammatory bowel disease; OPNI: Onodera's prognostic nutritional index.

Table 2 Recommendations for prehabilitation interventions prior to intestinal surgery in Crohn's disease

Intervention	
Nutritional	Nutritional support may be considered in case of impaired nutritional status and/or inadequate intake with regard to proteins and calories. Minimum duration of nutritional support is 1-2 wk and may be extended to 6-8 wk to fully benefit from the dietary intervention. EEN may be considered as nutritional support for immunomodulatory effect and reduction of postoperative complications. TPN seems a valid option only when enteral nutrition is contraindicated, not effective or tolerated
Physical fitness	Physical exercise aerobic activity and muscular resistance training may be considered to improve physical fitness in the preoperative course. High-intensity physical exercise should be avoided due to risk of exacerbation of inflammation and symptoms
CD medication	Wean off corticosteroids to a minimal dose (preferably < 20 mg) 6 wk prior to surgery. Consider cessation of anti-TNF-α agents (especially in case of therapy-refractory disease). If considered, a time-interval of 4 wk (ADA) or 6-8 wk (IFX) seems appropriate
Laboratory assessment	Preoperative intravenous iron therapy is recommended in case of iron deficiency anemia in the preoperative course. In case of hypoalbuminemia and an impaired nutritional status, nutritional support is advised (see nutritional and physical status)
Smoking	Preoperative cessation is recommended (*e.g.*, within smoking cessation program)
Psychological status	Provide individualized psychosocial support or refer to psychologist

CD: Crohn's disease; ADA: Adalimumab; EEN: Exclusive enteral nutrition; IFX: Infliximab; TNF-α: Tumor necrosis factor-alpha; TPN: Total parenteral nutrition.

In this opinion review, the available literature on the effect of potentially modifiable preoperative factors on the postoperative course following an intestinal resection in CD is critically appraised, with a focus on nutritional status, physical fitness, CD medication, and laboratory values. In addition, we aim to provide guidance for screening and specific interventions on these items during the preoperative course of patients with CD (Tables 1 and 2). Although psychological screening and support, as well as smoking cessation are considered essential during preoperative optimization in CD, these topics will not be addressed in this review. For these topics, management in accordance with general guidelines and integration into a multimodal prehabilitation program is recommended.

METHODS

A literature search of the EMBASE, Medline, Web of Science, Google Scholar and Cochrane Library databases was conducted, in collaboration with the Medical School Library of the Erasmus University Rotterdam. High-quality articles were cited in Reference Citation Analysis (*RCA*) (https://www.referencecitationanalysis.com). The following keywords, synonyms and their Medical Subject Headings terms were used for this search: 'Crohn's disease', 'intestinal surgery', and 'risk factors' (Supplementary material).

Studies published in the English language up to July 2021 were considered according to their topical relevance for the impact of screening and management of nutritional status, physical fitness, CD medication and laboratory values in the preoperative period related to the postoperative course

following an intestinal resection in CD patients. In the case that no relevant studies were present virtually for any of these topical contents, the literature was re-assessed in other settings of abdominal surgery (*e.g.*, patients with CRC). Only randomized controlled trials, meta-analyses, systematic reviews, observational studies (case-control study and patient series without control) were selected. Study selection was independently performed by both two reviewers (Bak MTJ and Ruiterkamp MFE) based on title and abstract. The snowball method was then applied to all of the final selected studies.

HOW TO SCREEN AND OPTIMIZE THE NUTRITIONAL STATUS AND PHYSICAL FITNESS OF PATIENTS WITH CD PRIOR TO INTESTINAL RESECTION?

Preoperative screening of nutritional status

Malnutrition is an important risk factor for a dismal postoperative course after intestinal resection in CD [23]. Malnutrition encompasses undernutrition and overnutrition. CD patients are prone to undernutrition due to inadequate nutritional intake attributable to several causes (*e.g.*, anorexia, strictures), malabsorption (*e.g.*, active inflammation or after prior resection) and chronic inflammation. However, obesity in the CD population has increased over the years[24]. Recognition of nutritional status as the key issue in preoperative optimization for patients with CD is gaining ground, since a significant benefit from dietary intervention may not only be expected after optimization of the nutritional status but also from its potential immunomodulatory effect on CD.

A first screening for malnutrition is readily available to all caregivers treating patients with CD and is recommended in all preoperative CD patients according to current guidelines[21-23]. Since a survey among 146 gastroenterologists in 2016 revealed that one-third of respondents did not routinely screen for malnutrition, exploration of the reasons for non-adherence is required[25]. The initial nutritional assessment during preoperative screening requires a combination of: (1) Body mass index (BMI); (2) Evaluation of unintentional weight loss; and (3) Assessment of dietary intake. Assessment of muscle mass preferably complements these measures. Laboratory assessment of albumin and micronutrients is not a reliable marker of malnutrition, and will be addressed in a later paragraph[23].

BMI is a commonly used indicator for body fat and thus a proxy of nutritional status. Preoperative BMI value and the rate of postoperative complications are only moderately correlated, according to abundant reports[26-30]. Nevertheless, clearly underweight patients, defined with varying cut-off values in the literature (from BMI < 16.2 kg/m^2 to BMI < 18.5 kg/m^2), are at an increased risk of a dismal postoperative course after intestinal resection, including creation of an ileostomy[9], readmission[31], intra-abdominal septic complications (IASCs)[32], and overall postoperative complications[33,34]. Similarly, clearly overweight patients suffering from obesity, defined as a BMI cut-off > 30 kg/m^2, also face an elevated risk of complications[9,28,34-36]. In addition, another study reported an increasing BMI by 1 unit (U) associated with an increased risk [odds ratio (OR) = 1.04; 95% confidence interval (CI): 1.0-1.1; P = 0.008] of postoperative complications[35].

Unintentional preoperative weight loss may occur in all CD patients independent of their baseline weight. Various studies assessing the effect of preoperative weight loss have confirmed the association with postoperative complications in CD patients. Unintentional weight loss of > 10%, as compared to baseline over the last 6 mo prior to surgery, is a commonly described cut-off[9,10,36-38]. This cut-off of significant weight loss has been observed in 23%-54% of CD patients scheduled for intestinal resection [23]. Various studies have reported a clear negative association between recent unintentional weight loss and postoperative complications in CD patients[9,10,36-38].

In addition, other measures of body composition may warrant evaluation during the preoperative assessment. The most important is sarcopenia, which is defined as low lean muscle mass in combination with either low muscle strength or low physical performance[39]. Sarcopenia can be present in both under- and overweight individuals[40]. Moreover, sarcopenia is common in CD patients, with a reported overall incidence of 52%, as determined by radiologic assessment of body mass composition (*e.g.*, skeletal mass index, total psoas index and/or Hounsfield U average calculations at the level of the third lumbar vertebral body)[40,41]. A recent meta-analysis identified sarcopenia as an independent predictor for both postoperative complications and/or undesirable outcomes (*i.e.*, poor quality of life, inadequate response to therapy) in the IBD population[42]. Especially in patients younger than 40 years, sarcopenia was a strong and independent risk factor for postoperative complications, and patients with a low or normal BMI were affected more often[43]. Handgrip strength is an accessible and reliable diagnostic method for sarcopenia applied in routine practice. When sarcopenia in CD patients is detected in the preoperative setting, a combined intervention to optimize the closely related nutritional status and improved physical fitness may enhance postoperative prognosis[44]. However, data on these specific interventions are lacking.

To date, several nutritional screening tools are available to assess the nutritional status in the IBD population. These tools combine such clinical features as BMI, weight loss, and symptoms (for instance diarrhea). Amongst these tools are the following: Nutrition Risk Screening (NRS-2002)[45]; Malnutrition Universal Screening Tool (MUST)[46]; Global Leadership Initiative on Malnutrition (GLIM) criteria[47]; and more IBD-specific tools, such as the Malnutrition Inflammatory Risk Tool (MIRT)[48] and Saskat-

chewan IBD Nutrition Risk Tool[49]. The GLIM has a higher rate of malnutrition detection in preoperative IBD patients as compared to several other screening tools (namely NRS-2002, MUST, MIRT, and Saskatchewan IBD Nutrition Risk Tool)[50]. Moreover, chronic inflammation is used as an indicator in this nutritional screening tool[47]. The Onodera's prognostic nutritional index (OPNI) is a simple and useful index to merely reflect the preoperative immunological status using serum albumin level and total lymphocyte counts. OPNI predicts the risk of postoperative complications in various types of cancer[51]. Limited data of the prognostic value of the OPNI in CD suggests that OPNI < 40 is a predictor of infectious complications or postoperative abdominal bleeding[52-54]. Overall, more data on the association between malnutrition detected by these screening tools and the postoperative course are required to support their routine use.

Future nutritional screening methods

An altered body composition is a known risk factor for postoperative complications[23]. Current available imaging techniques provide the opportunity to screen the body composition and develop new nutritional predictors for postoperative outcome. Although cross-sectional imaging with the sole purpose of evaluating body composition is not indicated, and available scans may be used for objective evaluation. Visceral fat promotes both local and systemic inflammation, resulting in a chronic inflammatory status[55,56]. Increased[57] and decreased[58] subcutaneous fat as well as increased visceral fat [59] are associated with increased risk of early postoperative complications in CD patients. Moreover, an expanded visceral/subcutaneous fat ratio (VSR) was identified as a better predictor of the postoperative outcome compared to BMI[58]. However, another study reported no association between VSR and postoperative complications[60]. In addition, there seems to be different cut-off points of total subcutaneous fat for CD patients, compared to other patients[57]. Therefore, these promising markers warrant further investigation.

Preoperative screening of physical fitness

To date, there is no routine screening for physical fitness in patients with CD in the preoperative course. In general, the physical fitness of CD patients is impaired[14,61]. Two cross-sectional studies concluded that physical fitness, specifically aerobic fitness, is impaired in the perioperative course of patients with CD as compared to the general population or other subgroups undergoing abdominal surgery[14,62]. This impairment is attributed to a lack of physical activity due to illness behavior and/or impaired nutritional status affecting muscle function[14,61,63,64]. More objective insights into the level of physical fitness in patients with CD are required, as well as into the association between physical fitness and patient-, disease-, and treatment-related outcomes. The specific subgroups of patients with impaired aerobic fitness may benefit most from a targeted and personalized physical exercise intervention. A validated self-reporting questionnaire (*e.g.*, Duke activity status index, veterans-specific activity questionnaire) may serve as a simple screening tool to identify patients with impaired aerobic fitness[65,66]. These patients may receive a comprehensive objective assessment by an exercise specialist (*e.g.*, physical therapist, clinical exercise physiologist) to evaluate the specific exercise intolerance and propose a personalized prescription for physical exercise training.

A cardiopulmonary exercise test is considered the gold standard for assessing aerobic fitness and also provides valuable information to determine physical exercise training safety (*e.g.*, contraindications) by assessing the body's integrated physiological response to progressive exercise[67]. Moreover, cardiopulmonary exercise test results can be used to optimize and personalize training intensity. When performance of a cardiopulmonary exercise test is not possible, a more practical performance-based field test to evaluate a patient's aerobic fitness can be used. The steep-ramp test is a short time maximal exercise test on a cycle ergometer, of which its primary outcome parameter (the achieved peak work rate) is highly correlated with aerobic fitness indicators obtained at the cardiopulmonary exercise test [68].

Low- to moderate-intensity physical exercise training interventions are feasible and safe in IBD patients in the non-perioperative setting, and have been associated with improved physical fitness as well as with a significant reduction of (severe) fatigue and stress, and a significant improvement of quality of life[69-71]. To date, no preoperative physical exercise training studies have been conducted in patients with CD. As aerobic and resistance training have been found to be effective for the reduction of postoperative complications and accelerates recovery of functional capacity in unfit patients undergoing abdominal surgery[18,19], patients with CD may benefit from these interventions as well in the preoperative course[72]. It seems that high-intensity physical exercise training should be avoided, as it may lead to an acute exacerbation of inflammation and CD symptoms[73]. Overall, future research for the effect of physical interventions on the preoperative course of CD patients is warranted.

Preoperative optimization of nutritional status

To reverse the negative impact of malnutrition on the postoperative course in CD patients, preoperative optimization of the nutritional status is indicated. The European Society of Clinical Nutrition and Metabolism (ESPEN) states that the preoperative optimization of the nutritional status by enteral nutrition (EN) for 7-10 d, in the case of mildly malnourished patients, or 7-14 d in the case of a severe nutritional risk, is appropriate[74]. Nutritional support is administered enterally, and only parenteral in

case EN has failed or is contraindicated (*e.g.*, due to an intestinal obstruction)[74].

A Cochrane review on preoperative nutritional support in patients scheduled for gastrointestinal surgery reported a significant reduction of anastomotic leakage and need for a temporary diverting stoma [overall risk ratio (RR) = 0.67; 95%CI: 0.53-0.85][75]. In line with these findings, a meta-analysis showed that preoperative nutritional therapy significantly reduces postoperative complications in patients with CD (OR = 0.26; 95%CI: 0.07-0.99)[76]. In particular, EN was superior to usual care (defined as no nutritional support) (OR = 0.09; 95%CI: 0.06-0.013)[76,77]. A trend towards superiority of total parenteral nutrition (TPN) as compared to standard care was observed, but statistical significance was not reached[76].

Exclusive EN (EEN) consists of complete liquid diet of various compositions and has been widely used as induction therapy in pediatric CD patients with a duration of 6 wk to 8 wk[78,79]. EEN is effective as preoperative therapy by inducing both clinical and histological remission in adult CD patients[80,81]. The anti-inflammatory effect of EEN can be attributed to the reduction of mucosal cytokines and composite alterations of the gut microbiome[81,82]. Cohort studies, which investigated the effect of EEN in the preoperative setting in the CD population, demonstrated a significant reduction in overall postoperative complications[83-85], IASCs[86,87], and postoperative abscesses and anastomotic leakage[80,86,88]. Moreover, EEN has proven to be beneficial in the reduction of C-reactive protein (CRP)[80,83-85] and the increase of albumin, OPNI, and hemoglobin level[83,84].

In case EN fails or is contraindicated, PN is suggested. PN can be divided into partial PN (PPN) and TPN. PN is administered into the venous system *via* a catheter into the superior vena cava or a peripherally-inserted central catheter. Patients treated with TPN only receive a completely intravenous (IV) nutritional liquid diet, while patients with PPN may receive nutrients from other sources alongside PN. The literature on the effect of PN on postoperative complications following intestinal resection in CD is scarce. Available studies reported a significant decrease in overall postoperative complications [89], non-infectious complications[90], anastomotic leakage[88], and the length of the resection specimen [91]. Benefits of TPN were observed in patients who were treated with TPN for ≥ 60 d[90] or for the duration of 18-90 d[89]. However, the benefit of PN as nutritional support needs to be weighed against the possible risk of catheter-related infections[92].

Reviewers' opinion

In summary, since extremes in BMI (< 18.5 kg/m^2 or > 30 kg/m^2) and recent unintentional weight loss (> 10% within 6 mo prior to surgery) have been associated with a dismal postoperative course in CD patients, we recommend the assessment of both in the preoperative setting. The detection of significant unintentional weight loss is a red flag and postponement of the intestinal resection until after restoration of the catabolic status should be considered. Moreover, assessment of handgrip strength may be used to detect sarcopenia. We consider GLIM as an appropriate screening tool for malnutrition in CD patients as chronic inflammation is included as one of the indicators. Moreover, the GLIM had a higher detection rate of malnutrition as compared to other screening tools in preoperative IBD patients. In addition, the OPNI can be used as an immunological screening tool. However, the prognostic value of these tools on the postoperative course requires further research. In our opinion, nutritional support during preoperative optimization may be considered for all patients with either an impaired nutritional status and/or inadequate intake with regard to proteins and calories. After a diagnosis of malnutrition, an individualized window to surgery needs to be decided to optimize nutritional status. As physical fitness is impaired in CD and therefore may influence the postoperative course, preoperative screening is warranted with use of self-reporting questionnaires. In addition, patients at risk may benefit from an objective assessment to evaluate specific exercise intolerance and a personalized prescription for physical exercise training. When pre- and postoperative physical fitness is impaired in patients with CD, aerobic and resistance training are recommended. The optimization period as suggested by the ESPEN (7-14 d) may be considered a minimum and, after careful evaluation per individual case, be extended up to 6-8 wk in most cases to fully benefit from the dietary intervention. EEN seems a promising preoperative nutritional intervention to improve prognosis due to its immunomodulatory effect, especially in patients with penetrating CD complications. Nutritional support is administered enterally (oral or *via* a nasogastric tube) (*i.e.*, EN), and only in exceptional situations parenterally (when enteral nutritional support fails). TPN seems a valid option only when EN is contraindicated, not effective, more tolerable.

WHAT IS THE OPTIMAL TIMING TO DISCONTINUE CD MEDICATION PREOPERATIVELY?

CD-related medication has an immunomodulatory effect and may increase the risk of infections. This may also result in postoperative surgical site infections (SSIs) and/or IASCs. The European Crohn & Colitis Organization (ECCO) guideline recommends to wean off corticosteroids 6 wk before surgery [21], while the guideline of the British Society for Gastroenterology (BSG) recommends to stop corticosteroids or minimize the dose, without specifying a window to surgery[22]. Moreover, the BSG recommends cessation of infliximab and adalimumab 6-8 wk and 4 wk prior to surgery, respectively

[22], whereas the ECCO guideline states that cessation of anti-tumor necrosis factor-alpha (TNF)-α therapy prior to surgery is not mandatory[21].

A recent Cochrane review studied the potential impact of perioperative IBD medication on the risk of postoperative (infectious) complications within 30 d in IBD patients[93]. The pooled data of this meta-analysis reported a significant association of corticosteroids with the risk of overall infectious postoperative complications (OR = 1.70; 95%CI: 1.38-2.09) and intra-abdominal infections (OR = 5.95; 95%CI: 1.04-34.1) in CD patients[93]. Furthermore, a significant increased risk of overall infectious complications (OR = 1.60; 95%CI: 1.20-2.13) was observed in patients treated with an anti-TNF-α agent [93]. No significant association was reported for patients who received the last dose of anti-TNF-α more than 8 wk before surgery[93]. However, these results should be interpreted with caution since the evidence for all outcomes was of low or very low quality, mostly due to the observational design, heterogeneity, and risk of bias of the included studies[93].

Pooled data of that meta-analysis demonstrated no significantly increased risk of overall postoperative infectious complications in CD patients treated with immunomodulatory, anti-interleukin and anti-integrin therapy[93]. Nevertheless, two retrospective studies have found a significant association of thiopurines, in combination with anti-TNF-α or corticosteroids, with IASC and overall infectious complications in the postoperative course[94,95]. The relation between vedolizumab, an anti-integrin agent, and postoperative complications has been studied in nine observational cohort studies including a total number of 799 patients and predominantly evaluating patients who underwent abdominal surgery with overall postoperative (infectious) complications as the primary endpoint[29,96-102]. Two studies found a significant increased risk of SSIs in patients treated with vedolizumab in the preoperative course[29,96]. Another study reported a significant decreased risk of postoperative ileus in CD patients with detectable vedolizumab levels as compared to non-detectable vedolizumab levels[99]. Four observational studies found the outcomes of preoperative ustekinumab use on postoperative complications and infectious complications, and found no significantly increased risk[96-98,103].

Reviewers' opinion

In accordance to the current literature and guidelines, we would recommend to wean off corticosteroids to a minimal dose, preferably < 20 mg, 6 wk prior to surgery. Moreover, cessation of anti-TNF-α agents may be considered, especially in non-responders and/or therapy refractory CD. When cessation is considered, a time interval of 4-8 wk (depending on type of anti-TNF-α agent) prior to surgery seems appropriate. Although the evidence on an association with increased risk of infections is unclear for other CD-medication, critical revision of the benefit of continuation until the date of surgery is indicated in all patients on an individual basis. In addition, since the biologic effect may last longer and vary per agent from 1 mo (prednisolone < 10 mg) to 3 mo (immunomodulators, anti-TNF-α) or longer (vedolizumab and ustekinumab), data on the effect of intervention are required to prove the beneficial effect of timely cessation[104].

WHICH LABORATORY VALUES ARE ASSOCIATED WITH THE POSTOPERATIVE COURSE AND NEED TO BE ASSESSED PRIOR TO INTESTINAL RESECTION IN PATIENTS WITH CD?

Specific recommendations concerning the preoperative assessment of laboratory values in CD patients are lacking in the BSG and ECCO guidelines[21,22]. Nevertheless, abnormal laboratory values in the preoperative setting have been associated with a dismal postoperative course in CD. Hypoalbuminemia (defined as serum albumin < 30 g/L) is one of the criteria for the diagnosis of (severe) malnutrition in general[74]. However, albumin is an acute-phase reactant protein and serum levels may decrease due to active inflammation[23]. Probably due to the chronic inflammatory state, serum albumin levels are lower in CD patients, as compared to the general population, and are reversely correlated to the disease activity[105]. Therefore, serum albumin is not a reliable marker for malnutrition in CD. Nevertheless, low serum albumin (ranging from < 29 g/L to 35 g/L) is associated with an increased risk of postoperative complications in CD patients[10,102,106-108]. These complications comprised overall early post-operative complications (< 30 d)[60,102,109-111], IASCs[10,106,112,113], SSIs[107,114], anastomotic leakage[88], and infectious complications[33,108,115].

Assessment of a full blood count, including hemoglobin and leucocyte and platelet counts, is advised in patients undergoing elective abdominal surgery[116]. The most important test seems to be that for hemoglobin, as anemia is present in up to 78% of patients requiring a surgical intervention[117]. Both a preoperative anemia (defined as < 10 g/dL)[9,37,106,108,118] and a lowered hemoglobin level (defined as lower than the reference value)[27,38,102,119] are associated with postoperative complications in CD patients. Iron deficiency anemia is the most common cause of anemia in the preoperative setting of CD. Preoperative IV iron therapy is highly effective to rapidly increase hemoglobin levels, and should be considered the first choice. Blood transfusion is a common practice to treat anemia when treatment for the underlying cause has been unsuccessful. Both intra- and perioperative blood transfusions have been

associated with infectious- and/or non-infectious postoperative complications in CD patients, whereas a preoperative blood transfusion was not associated with postoperative complications[120-123].

Elevated levels of the inflammatory markers (*i.e.*, leucocyte count) are risk factors for postoperative complications[30,120,121,124]. Furthermore, a preoperative elevated CRP level has been associated significantly with overall postoperative complications[52,125-127], infectious complications[33,57,125-127], and SSIs[57]. It is known that the malabsorption of vitamins and other trace elements is prevalent in CD patients. Plasma concentrations are influenced by active disease or result from earlier intestinal resections. These micronutrient deficiencies comprise several vitamins (most often B6, B12, D, and K), iron, folic acid, selenium, and zinc. Micronutrient deficiencies are associated with a complicated course of disease[128]. For reliable assessment of body micronutrient status, the patient needs to be in biochemical remission. However, in cases of high suspicion due to deficiency-related complaints or malnutrition, assessment of these values is indicated[23,128].

Reviewers' opinion

Although preoperative anemia, hypoalbuminemia, elevated CRP and elevated leucocyte count are associated with postoperative complications, CD-specific recommendations concerning the preoperative assessment of laboratory values and subsequent management cannot be derived from the current literature. Laboratory findings for vitamins and other trace elements are often disturbed in CD and may not reflect the actual nutritional status. These assessments only reflect the patient's nutritional status when a patient is in remission. We recommend to assess full blood count, CRP and serum albumin preoperatively as predictive markers of a complicated postoperative course and to preoperatively correct iron deficiency anemia, in accordance with the ECCO guideline[21].

CONCLUSION

Nutritional status, medication and laboratory values are modifiable factors that influence the postoperative course of patients with CD. In addition, physical fitness is impaired in CD patients and may impact postoperative outcomes. As a lower preoperative physical fitness is associated with a higher risk for postoperative complications in other populations undergoing intestinal resection, further research into interventions in CD patients is warranted. Individualized multimodal prehabilitation programs aim to improve these modifiable risk factors before surgery, including smoking cessation and psychological screening and support, and should be integrated in the preoperative preparation period in order to reduce both postoperative complications and undesirable outcomes.

Abstract

Chronic hepatitis C virus (HCV) infection is the principal etiology of cirrhosis and, ultimately, hepatocellular carcinoma (HCC). At present, approximately 71 million people are chronically infected with HCV, and 10%–20% of these are expected to develop severe liver complications throughout their lifetime. Scientific evidence has clearly shown the causal association between miRNAs, HCV infection and HCC. Although it is not completely clear whether miRNA dysregulation in HCC is the cause or the consequence of its development, variations in miRNA patterns have been described in different liver diseases, including HCC. Many studies have analyzed the importance of circulating miRNAs and their effect on cell proliferation and apoptosis. In this Review, we aim to summarize current knowledge on the association between miRNA, HCV and HCC from a diagnostic point of view, and also the potential implications for therapeutic approaches.

Key Words: Hepatocellular carcinoma; miRNA; Liver; Hepatitis C virus; miRNAs; Direct-acting antivirals; Extracellular vesicles; Transplantation

Core tip: Hepatocellular carcinoma (HCC) is one of the most life-threatening cancers worldwide. Among other factors, HCC is frequently caused by chronic hepatitis C virus infection. Currently, the mechanisms responsible for its neoplastic transformation are not completely understood. Regardless of the recent discovery and therapeutic use of latest-generation direct-acting antivirals, HCC remains an unresolved problem, even after viral eradication. In this scenario, miRNAs can become both a diagnostic tool and, hopefully, a novel therapeutic approach.

INTRODUCTION

Chronic hepatitis C virus (HCV) infection is a well-known risk factor for hepatocellular carcinoma (HCC)[1,2]. The virus belongs to the Flaviviridae family, and is the only member of the hepacivirus genus[3-6], and is presently classified in seven main genotypes, although 11 genotypes and at least 67 confirmed subtypes are known[7-10].

HCV is a single-stranded positive-sense RNA virus consisting of an icosahedral symmetrical nucleocapsid, surrounded by a double-layer lipid envelope in which the envelope glycoproteins E1 and E2 are inserted[6]. Its genome of 9.6 kb harbors an open reading frame encoding a polyprotein precursor of about 3000 amino acids, which is processed through proteolytic cleavage by viral and host proteases into smaller molecules, including structural (core, E1 and E2), p7, and nonstructural proteins (NS2, NS3, NS4A, NS4B, NS5A and NS5B)[11].

The total global prevalence of chronic HCV infection is estimated at 71 million people by the World Health Organization (WHO)[12], and varies according to health conditions, sociodemographic characteristics, and the presence of risk factors for transmission that can alter the efficiency of the transmission routes[9,13]. HCV is transmitted primarily parenterally, through large or repeated direct percutaneous exposures to infected blood[9,13-15]. Major high-risk populations include people who inject drugs (PWIDs), men who have sex with men, and prisoners[16].

The outcome of HCV infection depends strictly on the strength and breadth of the host response during the acute phase. Around 30% of HCV-infected people spontaneously clear the virus within 6 mo of infection, although the remaining 60%–80% of people, despite developing an efficient antiviral immune response, are unable to clear the virus, resulting in persistent infection[17,18]. Activation of the immune response against HCV contributes importantly to the establishment of long-lasting inflammation and consequent liver damage. The deregulation of cytotoxic cells and the continued activation of an apoptosis pathway results in scarring and progression to cirrhosis that, in 25% of HCV infected patients, can result in HCC over a period of 20–30 years post-infection[2,19,20].

Until the last decade, interferon (IFN) and ribavirin (RBV) were the only available therapies against chronic HCV infection, although they were accompanied by significant side effects. Moreover, IFN-based therapies had only limited efficacy, as the response was genotype dependent[21-24]. The recent introduction of direct-acting antivirals (DAAs) has resulted in remarkable therapeutic improvements. These are currently the standard therapeutic choice, and a sustained virology response (SVR) > 90% is attained after 12 wk of treatment. However, some patients show relapse of HCV infection, even after DAA treatment, and achieving SVR does not completely rule out the risk of developing HCC[25]. Also, following DAA treatment and subsequent viral clearance, HCV reinfections remain a problem among individuals with high-risk behaviors, *e.g.*, PWIDs[26,27].

Moreover, access to DAA therapy is not simple for all patients, and only the 62% of HCV-diagnosed patients have been treated with DAAs (WHO) (https://www.who.int/news-room/fact-sheets/detail/hepatitis-c).

Although the pathogenesis of HCV infection has not been fully elucidated, interactions between structural and nonstructural viral proteins and host cell components, such as miRNAs, have been reported by many groups. It has been shown that host miRNAs are involved in many steps of the biological cycle of HCV, such as infection and replication. Likewise, HCV infection regulates the expression of many cellular miRNAs involved, for example in liver fibrosis, hepatocarcinogenesis and HCC progression[28-31]. Due to such mutual interactions, miRNAs can be used for risk assessment and prognosis of HCV-related HCC, and could be considered for diagnostic approaches and new therapeutic strategies.

HCC

HCC is the main type of liver cancer, and the most life-threatening cancer worldwide. HCC onset consists of several processes involving multiple risk factors, but most often it presents in people with chronic liver diseases and cirrhosis[32].

The most common etiological factors that lead to liver cirrhosis, therefore predisposing to HCC transformation, are chronic infection with hepatitis B virus (HBV), HCV, or hepatitis D virus, alcoholic liver disease, and nonalcoholic steatohepatitis/nonalcoholic fatty liver disease (NAFLD). The less common causes are hereditary hemochromatosis, 1 antitrypsin deficiency, autoimmune hepatitis, porphyria, disorders of steroid hormones, Wilson's disease, and dietary aflatoxins[33-36].

Approximately 50% of all liver cancers are related to chronic viral hepatitis, which can develop into cirrhosis and HCC[37]. In particular, HCV causes chronic infections in 70%–80% of cases, while HBV leads to chronicity in only 10% of infected people[38]. Among HCV chronically infected patients, about 20% develop liver cirrhosis within 20–30 years and, once cirrhosis is established, the rate of HCC development increases by 1%–4% per year. Moreover, chronic HCV infection is associated with a 20–30-fold increased risk of developing into HCC compared to healthy individuals[39]. HCV-related HCC is mediated both by virus-related factors and host-induced immunological responses. In addition, HCV damage is a gradual and continual process, characterized by recurrent infection that induces the immune system to attack liver cells, provoking repeated damage to the genomic material that can lead to mistakes during proofreading repair[38]. Recent studies suggest that HCV core protein can promote initial development of HCC, acting on cell signaling pathways. Indeed, HCV core protein may directly inhibit the tumor suppressor genes and the cell cycle checkpoints, inducing the activation of signaling pathways that upregulate growth and cell division[40]. The specific tumor suppressor genes inhibited by HCV core protein include retinoblastoma protein and p53 tumor suppressor, which, if synergistically lost, lead to a higher degree of carcinogenesis[41]. Repeated cell cycles are associated with the accumulation of mutations that may transform hepatocytes into cancer cells. Among the genes most mutated are telomerase reverse transcriptase, tumor protein 53, and β-catenin. These mutations not only threaten telomere maintenance, but also lead to increased oxidative stress on hepatocytes, inducing chronic inflammation secondary to HCV, thus promoting HCC progression[42].

Over the last few years, in an attempt to identify new therapies and more accurate biomarkers for early diagnosis and treatment of HCC, the pivotal role played by miRNAs in the development and progression of cancer has emerged[43].

Recently, progress has been made in the study of miRNAs in HCC, with the discovery that some of them are upregulated or downregulated in HCC. Aberrant expression of miRNAs has been linked to HCC proliferation, apoptosis and invasion, but also metastasis formation, epithelial–mesenchymal transition, angiogenesis, drug resistance, and autophagy. In addition, some miRNAs can also be potential diagnostic and prediction markers for HCC[44].

HCV THERAPY

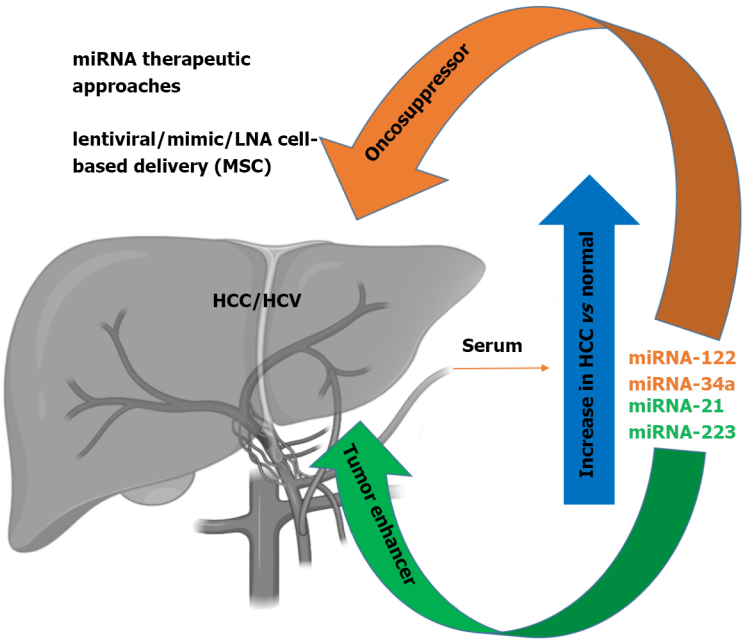
The principal goal of anti-HCV therapy is to eradicate HCV infection, thus resolving the liver disease. In the past, the standard of care for eradication of chronic HCV treatment was IFN-based therapy; most commonly in combination with RBV. However, this combination therapy had an outcome that depended on the viral genotype, was poorly tolerated, and also associated with severe side effects such as depression, flu-like symptoms, fatigue, diarrhea, and hematological toxicity[45]. These unwanted adverse effects were the main reason for patients abandoning therapy. With the introduction of the first NS5B polymerase inhibitor, sofosbuvir, in 2014, IFN-free treatment became available[46]. Hence, DAAs were introduced in clinical practice to treat HCV^+ patients, obtaining SVR rates above 90%[47,48], where SVR corresponds to a cure of the HCV infection, as late relapse occurs in less than 0.2% of cases beyond 6 mo of follow-up[49]. While patients with cirrhosis are often not treatable with IFN-based treatment, DAAs, including NS5B and NS5A inhibitors, are effective for patients with any stage of liver fibrosis, including those with advanced liver disease and decompensated cirrhosis, which predispose to developing HCC at a higher degree. This has allowed a significant increase in the number of treatable patients, with excellent safety profiles[50].

Clinically, SVR leads to stabilization and improvement of the liver function, and is thus associated with a lower risk of hepatic dysfunction, a reduced need for liver transplantation, and lower overall mortality. It has been demonstrated that DAA therapy attains much higher SVR rates than IFN-based treatment by reducing the inflammatory cargo in the liver, fibrosis, and neoplastic formation[51].

With more successful SVR obtained using DAAs in the clinic, there were higher expectations in terms of a significant reduction in the incidence of HCC. However, such expectations were not always met. In fact, despite the documented positive impact on HCV infection clearance, the effect of DAA treatment on the development and/or recurrence of HCC in patients treated for liver cirrhosis remains hard to define[52].

In a meta-analysis, Frazzoni *et al*[53] compared different trials based either on the use of DAAs or IFN [53]. The aim of this study was to define the long-term incidence and occurrence of HCC after the achievement of SVR using either IFN-free or IFN-based therapies. This investigation showed the higher safety profile of DAA therapy, accompanied by a lower risk of HCC recurrence[53]. A controversial subject is the effect of DAA-based SVR on the recurrence of HCC following curative treatment of early HCC. It has also been found that about 30% of patients with a history of curative treatment for HCC undergoing DAA therapy for HCV infection develop HCC recurrence, raising many surgical and clinical questions[54].

Some studies initially suggested that DAA treatment might increase the recurrence rate for HCC, with consequent doubts on the use of this therapy for patients with previous HCC[55]. However, these studies were not confirmed by further trials, and new guidelines were provided recommending the use of DAAs for patients with a history of HCC[56]. At present, patients with HCV-related cirrhosis who have undergone resection or ablation for HCC should not be dissuaded from receiving DAA therapy to prevent the progression of the liver disease.



The putative correlation between DAA treatment and *de novo* HCC occurrence is still a matter of debate. Some studies have shown how HCV^+ patients diagnosed as negative for HCC develop aggressive and fatal forms of liver cancer after DAA treatment[57-61]. These studies highlighted the importance of the surveillance of patients before and during DAA treatment, pointing to a possible correlation between the stage of fibrosis and the pre-existence of decompensated cirrhosis, with increased susceptibility to the development of *de novo* HCC[58,61,62].To conclude, patients failing to respond to antiviral treatment are at high risk and often need to be monitored during therapy[63]. In light of these observations, it appears clear how the use of biomarkers such as HCV/HCC/liver-related miRNA are important for early HCC diagnosis before and during DAA treatment.

HCV INFECTION AND miRNAs

As discussed above, miRNAs are active players in tumor initiation and progression for their involvement in the regulation of expression for proteins implicated in the pathophysiological mechanisms of cancer development, including cell growth, apoptosis, and metastasis[64-66]. In the liver, it has been shown that liver-enriched transcription factors such as HNF1A, HNF3A and HNF3B regulate miR-122 expression, which can function as a tumor suppressor factor by inhibiting angiogenesis, HCC growth/invasion, and high levels of HCC apoptosis and cell cycle arrest[67,68]. This miRNA represents 70% of the total miRNAs in hepatocytes[69,70], and has been therefore nicknamed hepatic miRNA. It has been found that HCV RNA possesses two tandem miR-122 complementary sites at the 5′ end of the viral genome[71], responsible for viral RNA accumulation[72]. The miR-122 binding with the HCV RNA has been described at multiple levels: miR-122 affects folding of the viral internal ribosomal entry site (IRES)[73], required for viral translation, and modulates viral replication and polyprotein translation [74]. In addition, it has been found that the stability of HCV RNA is mediated by RNA-induced silencing-like complex (RISC-like), suggesting the coordination of Ago2 and miR-122 in stabilizing and protecting the viral genome from 5′ exonuclease activity[75]. Furthermore, HCV RNA acts as a sponge for miR-122, leading to de-repression of host mRNAs normally targeted by miR-122, thus providing a fertile environment for the long-term oncogenic potential of HCV[76]. The serum levels of miR-122 are clearly higher in HCV-infected patients with HCC[77-79]. During the course of HCV infection, miR-122 is coupled with miR-34a[80] (Figure 1). While several studies have reported a downregulation of miR-34a in neoplastic transformation in various tissues[81], miR-34a was found increased in HCC[82]. Moreover, we recently reported an increase of miR-34a in HCC cells after HCV infection, the effect of which can be modulated by p53 induction[31]. It has recently been proposed that flaviviruses can upregulate expression of miRNAs that inhibit viral replication in target cells[31], demonstrating that miR34 overexpression induces the IFN-mediated response in dengue virus, West Nile virus and Japanese encephalitis virus infection[83]. In HCC cells, miR-34a induces cell cycle arrest and apoptosis. Concomitantly, other groups have also demonstrated that miR-34 inhibits fibrosis in stellate cells by regulating the TGF-β1/Smad3 pathway[84].

Expression of miR-21 increases in patients with HCV-related HCC[85], while miR-223 expression is increased in patients with advanced fibrosis compared to moderate/minimal fibrosis[86]. In contrast, during HCV-related chronic hepatitis, miR-21 and miR-223 display a pro-fibrotic/tumorigenic effect[85] (Figure 1).

Depending on the role played in viral infection, some miRNAs have been classified as pro- or antiviral. For example, miR-135a has been described as proviral miRNA because of its ability to enhance HCV RNA replication in hepatocytes. In addition, miR-135a inhibits the expression of host restriction factors, such as CXCL2, MyD88 and IRPK2, which are involved in antiviral immunity[87]. Likewise, miR-146a-5p enhances HCV infection by playing an immunoregulatory role through the downregulation of the inflammatory signaling, and by turning off the immune response in hepatocytes. Moreover, miR-146a-5p promotes the late steps of the HCV replication cycle, likely by modulating HCV assembly [88]. Another example is represented by miR-21-5p, which triggers HCC growth and metastasis by

Figure 1 Schematic representation of some major miRNAs upregulated in serum after hepatocellular carcinoma occurrence. Noteworthy, some of them (mir-122 and mi-R34a) display a tumor suppressor effect and represent not only a diagnostic target, but have been proposed in novel therapeutic approaches (Figure was created using BioRender.com). HCC: Hepatocellular carcinoma; HCV: Hepatitis C virus; LNA: Locked nucleic acid; MSC: Mesenchymal stem cell.

modulating a PTEN-dependent pathway[89].

Conversely, let-7 family miRNAs have demonstrated strong anti-HCV activity, thus being classified as antiviral miRNA[90]. It has been found that let-7b potentially reduces HCV replication through the targeting of IGF2BP1 required for HCV replication[90], and increases the cell apoptosis rate[91]. Similar to other antiviral miRNAs, mir-199a* is a HCV RNA binder in IRES, targeting the HCV 5′-UTR[64,92].

HCV-RELATED HCC miRNA-BASED APPROACHES

The mechanisms that drive liver injury during HCV infection have not been fully elucidated. Several studies have attempted to understand the interactions between viral proteins and the cellular host machinery[93]. An important effort has been made to address and understand the complex interconnections between HCV infection and miRNAs, aimed at finding new therapeutic and diagnostic tools.

It has recently been shown that the expression of specific patterns of miRNAs in HCC patients may be used for diagnostic purposes, with a sufficient level of reliability, thus highlighting a potential role of miRNAs as biomarkers[94]. Specific circulating miRNA profiles are associated with several diseases, including HCV infection. These miRNAs have been proposed as biomarkers of HCV-related HCC pathophysiology and prognosis. Many studies have focused on setting miRNA panels to be tested in HCV-related HCC patients, and used to discriminate healthy individuals from ill patients; above all, during the early phases of disease. For example, Ali *et al*[95] described and validated a panel of nine liver-associated miRNAs (miR-21, miR-30c, miR-93, miR-122, miR-125b, miR-126, miR-130a, miR-193b and miR-222)[95], while Zekri *et al*[96] identified miR-122, miR-885-5p and miR-29b as associated with fluctuations in the levels of the diagnostic liver-specific biomarker -fetoprotein (AFP)[96]. Wahb *et al*[97] suggested the use of circulating miR-9-3p and endocan as novel biomarkers for risk assessment in the early diagnosis of HCV-related HCC[97]. It has been shown that circulating extracellular vesicles (EVs) containing specific patterns of noncoding RNAs are highly related to disease progression of HCV-associated HCC[98]. Recent reports have highlighted the importance of serum miR-34a and miR-122 as biomarkers of HCV-related HCC[80]. We recently showed that HCV infection induces an increase in miR-34a expression in the HCC cell line HuH7.5, and acts as a tumor suppressor[31]. We also found that HCV infection induces the release of EVs containing miR-34a, and these EVs can exert a growth inhibition effect and induce apoptosis[31]. We were able to demonstrate that miR-34 action is not limited only to the infected cells, as EV release has a paracrine effect on neighboring hepatocytes, thus underscoring the potential use of this miRNA for therapeutic purposes[31] (Figure 1). A newly generated polymer-based nanosystem redox-sensitive, oligopeptide-guided, self-assembling, and efficiency-enhanced (ROSE) loaded with miR-34a inhibits HCC proliferation *in vitro* and *in vivo*,

reducing the epithelial mesenchymal transition[99].

Conversely, it has been demonstrated that miR-21 can act as an oncogene by stimulating HCC growth, invasion, and migration[89,100]. Indeed, it has been shown that the inhibition of miR-21 suppresses HCC growth both *in vitro* and *in vivo*[100].

It is worth mentioning that miR-122 is known to potentiate HCV replication by inhibiting the degradation of the viral genome[70]. Several clinical trials are testing the ability of reducing HCV replication using locked nucleic acid inhibition of miR-122[101-103], perhaps evidence for the efficacy of this treatment, which is devoid of adverse effects[64]. For example, miR-122 antagonists can be used as a therapeutic approach in synergistic association with DAA therapy to obtain an enhancement of the clinical outcome. These results point out the potential therapeutic interest of miR-122, in particular, for patients who do not respond to antiviral agents[104]. Recently, the use of EVs to treat HCC has become an interesting topic, but one that requires further studies. Lou *et al*[105] revealed that the injection of EVs derived from miR-122-modified mesenchymal stem cells (MSCs) can significantly improve chemotherapeutic sensitivity of HCC, and increase the efficacy of sorafenib treatment[105] (Figure 1). Wei *et al*[106] found that there are different miRNA expression patterns between HCC cells and their EVs, suggesting a self-modulating mechanism whereby HCC-cell-derived EVs were able to shuttle miRNAs to recipient cells, promote cell growth, and migration and invasion of HCC cells[106]. EVs contain both oncogenic and tumor suppressor miRNAs, and their deregulated expression in HCC tissues can promote HCC development. Therefore, EV-mediated miRNA transfer might represent a crucial mechanism, exploitable on the one hand as a diagnostic tool by identifying circulating EV-derived miRNA, and, on the other, EV-derived miRNAs could be a useful target to inhibit HCC growth. In agreement, Zhang *et al*[107] generated virus-like vectors containing both miRNA-21-sponge and pre-miRNA-122, and demonstrated that virus-like particles were able to correct HCC miRNA dysregulation, and to decrease proliferation, migration, and invasion of HCC[107].

Currently, 20 clinical trials (Table 1) are investigating both tissue-specific and circulating miRNAs as a diagnostic/prognostic tool for HCC or for monitoring HCC during a specific treatment (clinicaltrial.gov). Future clinical trials will be needed to provide appropriate analysis of the performance of miRNAs as biomarkers, and to discover new miRNA-related HCC targets for implementation of new treatments.

PERSPECTIVES FOR TUMOUR DETECTION AND INTERVENTION

As described above, there is a strong correlation between miRNA expression and HCC. However, some of the regulated miRNAs are not only related to HCV infection, but also with other pathological liver conditions. In particular, alterations in some miRNAs have been also found in NAFLD[108-110]. Among the identified miRNAs, a significant upregulation of miR-122 in the serum of NAFLD patients was noted. This variation is comparable to the upregulation of the same miRNA observed in the serum of HCC/HCV patients. Another group reported a significant increase of miR-34a expression in the serum of NAFLD patients[110], in agreement with our observations in HCV HCC cells infections[31]. These results indicate that these miRNAs could be considered potential markers of pathological liver conditions induced by inflammation or transformation (Figure 1). The most direct implication of this finding is the possibility of having new, noninvasive, and reliable biomarkers for early HCC detection that could be applied in the near future. In particular, a specific circulating miRNA expression, in association with conventional tumor markers such as AFP, protein induced by vitamin K absence/antagonist II (PIVKA-II), and classical clinical parameters has been observed[111,112]. The definition of an miRNA expression signature (88 miRNAs) provides a substantial increase of accuracy in the detection of HCC (up to 99.5%), associated with a strong sensitivity (100%), while AFP evaluation as a tumor biomarker has an accuracy and a sensitivity of 76.5% and 63.8%, respectively[111]. The strength of these results refers mostly to the detection of small HCC tumors (< 3 cm). This analysis also revealed that an miRNA expression signature shows specific variations for HCC compared to other pathological liver conditions, where cirrhotic patients or chronic hepatitis B infection can be distinguished by a characteristic alteration of expression pattern[110]. These results strengthen the possibility of using miRNAs as a new approach for early tumor detection and subsequent early intervention, particularly considering that, after HCV DAA treatment, there is still the need to monitor HCC occurrence after viral eradication, as also suggested elsewhere[31,113,114].

CONCLUSION

The introduction of DAA therapy signals a milestone in the history of HCV treatment, with achievement of SVR at high rates. However, whether the development of HCC is related to pre-existing HCV infections after DAA treatment is disputed. Not all HCV patients are eligible for DAA treatment, and HCV reinfection in high-risk populations frequently occurs. In light of this, understanding the molecular mechanisms of HCV viral infection that lead to development of liver cancer in the host is

Table 1 List of registered trials that use miRNAs as diagnostic and/or prognostic tool for hepatocellular carcinoma

Study title	Phase	Status	NCT number
MicroRNAs as diagnostic biomarkers in hepatocellular carcinoma among Somali patients	NA	Unknown	NCT03227510
Prospective cohort study of changes in circulatory microRNA of resected hepatocellular carcinoma	NA	Recruiting	NCT05148572
Clinical significance of hepatic and circulating microRNAs miR-221 and miR-222 in hepatocellular carcinoma	NA	Unknown	NCT02928627
Study of microRNAs as a diagnostic tool for HCV-related hepatocellular carcinoma	NA	Unknown	NCT03429530
Impact of IL-28B rs12979860 and rs4803217 gene polymorphisms associated with miRNAs deregulation on HCV-related hepatocellular carcinoma	NA	Unknown	NCT02507882
MiRNA as a diagnostic and prognostic biomarker of hepatocellular carcinoma	NA	Not yet recruiting	NCT02448056
Early Detection of Hepatocellular Carcinoma in a High-risk Prospective Cohort (ELEGANCE)	NA	Recruiting	NCT04965259
Blood sample collection for experimental blood test to track liver cancer	NA	Recruiting	NCT04720430
Different genetic features associated with hepatic carcinogenesis	NA	Unknown	NCT01247506
Genetic profiling of liver cancer in patients undergoing liver transplantation	NA	Active, not recruiting	NCT02412579
A study of individualized radiotherapy based on a prediction model of lymph node metastasis in hepatocellular carcinoma	NA	Unknown	NCT03416803
Fingerprint characterization of sorafenib treated HCC	NA	Unknown	NCT03958669
Risk of HCC in cirrhotic patients post DAAs treatment	NA	Unknown	NCT03414554
Risk of hepatocellular carcinoma in patient with liver cirrhosis	NA	Unknown	NCT03083002
Axitinib for the treatment of advanced hepatocellular carcinoma	2	Completed	NCT01210495
The phase III study of icaritin versus sorafenib in PD-L1 positive advanced hepatocellular carcinoma subjects	3	Recruiting	NCT03236649
The phase III study of icaritin versus HUACHANSU PIAN in hepatocellular carcinoma subjects	3	Recruiting	NCT03236636
A study of rSIFN-co in subjects with advanced solid tumors	1	Completed	NCT02387307
Stereotactic body radiation therapy and transarterial chemoembolization in treating patients with liver cancer that cannot be removed by surgery	1	Completed	NCT02507765
Nal-IRI with 5-fluorouracil (5-FU) and leucovorin or gemcitabine plus cisplatin in advanced biliary-tract cancer	2	Active, not recruiting	NCT03044587

NA: Not applicable.

fundamental.

It has been reported that cellular miRNAs may contribute to HCV pathogenesis, either by direct or indirect interactions with the viral genome or proteins. Several miRNAs and their targets have been shown to be associated with HCV and HCC progression, and might represent a diagnostic biomarker for the early prognosis of HCC. Early HCC prognosis acquires relevance during DAA treatment to minimize the risks of HCC development in HCV^+ patients. Likewise, many miRNAs could be used also for therapeutic purposes. However, further studies are needed to elucidate the molecular interplay between miRNA and HCC, and the development of novel therapeutic strategies for the treatment of HCC is a major critical goal to be achieved.

Abstract

Many metabolic factors are associated with chronic hepatitis C virus (HCV) infection and can influence the course of the illness and impact the progression of liver and non-liver-related diseases through complex interactions. Several of these factors impact the course of chronic HCV (CHC) and result in the conceptual translation of CHC from a localized to systemic disease. Besides the traditional liver manifestations associated with CHC infection, such as cirrhosis and hepatocellular carcinoma, various extrahepatic disorders are associated with HCV infection, including atherosclerosis, glucose and lipid metabolic disturbances, alterations in the iron metabolic pathways, and lymphoproliferative diseases. The coexistence of metabolic disorders and CHC is known to influence the chronicity and virulence of HCV and accelerates the progression to liver fibrosis and hepatocellular carcinoma. Insulin resistance is one of the key factors that have a tremendous metabolic impact on CHC. Therefore, there is a great need to properly evaluate patients with CHC infection and correct the modifiable metabolic risk factors. Furthermore, patients with HCV who achieved a sustained virological response showed an overall improvement in glucose metabolism, but the exact evidence still requires further studies with long-term follow-up. This review delineates the most recent evidence on the main metabolic factors associated with CHC and the possible influence of chronic HCV infection on metabolic features.

Key Words: Hepatitis C virus; Metabolic factors; Steatosis; Insulin resistance

Core Tip: Hepatitis C virus (HCV) infection has several metabolic aspects that are largely well understood; as such, HCV is nowadays considered a systemic disease rather than a local disease with different metabolic consequences. Moreover, these metabolic factors may affect the natural history of chronic liver disease and of diseases not related to the liver, which constitute a significant burden on the overall health of the human body, with an increased economic burden to patients, healthcare systems, and society if not adequately addressed and appropriately managed. More studies are needed to evaluate metabolic aspects associated with HCV infection and delineate their effects and the long-term outcome of antiviral therapies.

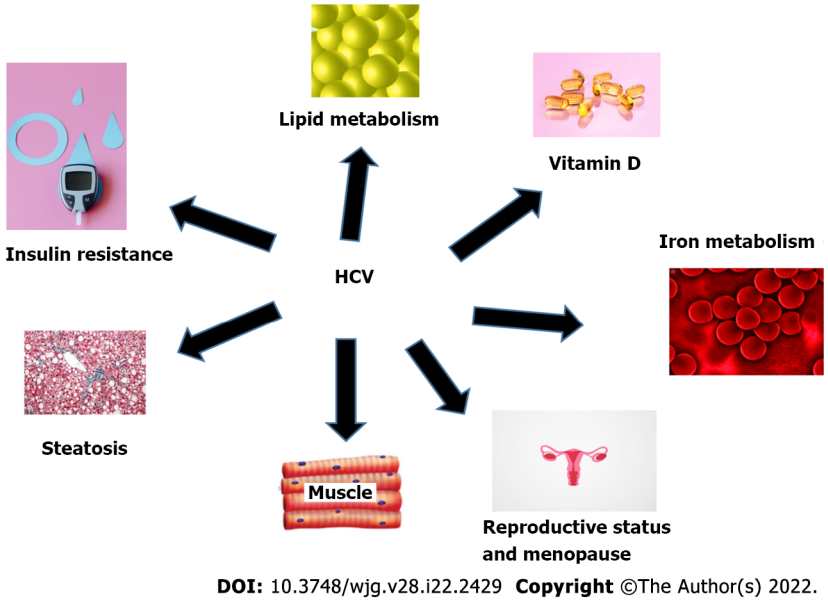
INTRODUCTION

Hepatitis C virus (HCV) infection is considered one of the most notable causes of chronic liver disease worldwide[1]. Not only does HCV infection confer the risk of developing chronic hepatitis, cirrhosis, and hepatocellular carcinoma (HCC), it also has many extrahepatic manifestations, such as disorders of glucose and lipid metabolism, polyarthritis resembling rheumatoid arthritis, vascular atheromatous disease, mixed cryoglobulinemia, lymphoproliferative diseases, renal disorders, insulin resistance (IR), type 2 diabetes (T2DM), sicca syndrome, and autoimmune disorders[2-4]. Different metabolic aspects of HCV are demonstrated in Figure 1. There are several studies on the effect of metabolic factors on the natural history of patients with chronic HCV (CHC)[5]. The deleterious effects of metabolic complications resulting from HCV infection are mainly related to glucose and lipid metabolism impairments[6].



Given that it is a systemic disease, CHC infection could influence the metabolic homeostasis of the host through several complex interactions, even in light of pre-existent metabolic status and genetic background[5]. Several factors can accelerate the disease course from CHC infection to cirrhosis and may impact the likelihood of achieving a sustained virological response (SVR) after receiving antiviral therapy. Among the reported factors are metabolic factors that may change the course of illness in CHC patients and impact the results of antiviral treatments[7], despite the apparent improvement in HCV management results after the introduction of direct-acting antivirals compared with the previous standard of care interferon-based therapy[8,9]. Interestingly, this is not a "one-way street," as CHC infection can have metabolic effects due to its influence on glucose and lipid metabolism, which impacts the host's metabolic homeostasis and may result in its extrahepatic sequelae[10]. The extrahepatic burden of HCV infection exceeds its effect on the liver as it is a significant burden on the overall health of the human body, causing increased economic burden to patients and healthcare systems[11,12].

We have discussed the most recent evidence on the main metabolic factors related to CHC, along with the proposed pathophysiological machineries essential to the correlation between HCV infection and metabolic disorders and the possible influence of CHC infection on metabolic features.

IR

IR is considered a keystone of metabolic syndrome (MS) with increasing incidence worldwide, representing a major cause of morbidity and mortality[13]. As reported in the literature, HCV infection is associated with IR in up to 80% of cases; consequently, the risk of developing T2DM is found to be twice as high as in subjects without HCV[14,15]. There is a high chance of coexistence between MS and CHC owing to many related host factors, such as the presence of visceral obesity; moreover, HCV infection itself is reported to affect glucosidic homeostasis, leading to hepatic and extrahepatic IR[1]. Moreover, CHC is found to increase the risk of developing metabolic diseases with these complications[16]. IR in patients with CHC significantly impacts the severity and progression of chronic liver disease *via* direct and indirect effects by inducing steatosis[17]. Meanwhile, steatosis activates stellate cells *via* collagenous deposition and the generation of lipid peroxides[18], which, in turn, promotes fibrogenesis *via* the direct activation of hepatic stellate cells, tumor necrosis factor-α and connective growth factor production, and ductular reactions induction[19]. In this context, a high prevalence of cirrhosis and non-SVR was observed among patients with diabetes and CHC with an observed lower rate of SVR in patients with IR, not only in interferon-based treatment[7].

Moreover, there is a reported association between IR and the presence of esophageal varices in patients with HCV-related compensated cirrhosis[20]. The potential of insulin to control dynamic components of portal hypertension, such as endothelial nitric oxide and endothelin production, might explain this[21,22]. Not only are IR and DM are more prevalent in the course of HCV infection, but they

Figure 1 Metabolic aspects of hepatitis C virus. HCV: Hepatitis C virus.

also occur post-liver transplantation in patients with CHC infection[23-25]. It's not surprising, then, that T2D is linked to a three-fold increased risk of HCC, with a higher risk seen in patients who have both HCV and T2D; this could be due to the possible molecular mechanisms and intermediaries involved in hepatic carcinogenesis, such as IR and hyperinsulinemia, oxidative stress, and reported cytokine imbalances between proinflammatory and anti-inflammatory cytokines[26]. Several studies have reported the impact of IR and steatosis and both rapid virological response and SVR in patients with CHC treated with antiviral therapy; the plausible explanations that IR and steatosis may affect the response to antiviral therapy and the reasons for the disparities in results might be due to pre-existing variances in metabolic dysfunctions and genetic diversities among the tested groups[27]. other studies reported the efficiency of proper glucose control in HCV infected patients that improve early after antiviral treatment, with benefits that are not restricted to the diabetic patient only furthermore, achievement of SVR by direct-acting antivirals (DAAs) to eliminate HCV improves their glycemic control with a possible reduction on the faster progression of hepatic fibrosis[28,29].

Also, treatment of HCV with DAAs found to improve steatosis, hepatic inflammation, and the nutritional status in most of the studied patients[30-32].

This explains how profound and widespread effects of the impairment of insulin pathways exerted by HCV infection and vice versa.

Consequently, further evidence from long-term follow-up studies is still required to determine if successful eradication of HCV can help to ameliorate IR and improve glycemic control and clinical outcomes in patients with established DM2[33,34].

STEATOSIS

In individuals with CHC, hepatic steatosis is a frequent histological finding, with a frequency of up to 80%, which is higher than that in noninfected individuals; thus, it is considered as a distinct entity in the setting of HCV viral infection with specific clinical and prognostic implications[35,36]. Not only viral factors are responsible for steatosis in patients with CHC, but there are also different common risk factors for steatosis, such as obesity, T2D, alcohol, and dyslipidemia, which are common in the examined cohorts[5]. Specific genotypes of HCV, especially the HCV genotype 3, are more correlated with hepatic steatosis; moreover, HCV has the ability to promote the intracytoplasmic deposition of fat in the liver by enhancing hepatic fatty acid production and decreasing lipid release and breakdown processes, both directly and indirectly[37]. Interestingly, steatosis has also been related to HCV viral load and was found to decrease after SVR was achieved[35]. Many studies reported that steatosis could be a predictor of liver fibrosis in patients with CHC; additionally, in untreated CHC patients, worsening of steatosis may be an independent factor related with the advancement of liver fibrosis. This could be explained by "viral" and "metabolic" steatosis, in which elevated insulin levels and inflammatory mediators on liver stellate cells promote the advancement of fibrosis and liver disease[10,38]. Steatosis may improve and even vanish following effective antiviral treatment with interferon and ribavirin, according to some reports; however, evidence for a similar effect of direct-acting antivirals is currently limited[39,40].

In contrast, cross-sectional and longitudinal studies have shown that despite achieving SVR during CHC treatment, some patients have been found with clinically significant steatosis and fibrosis[41,42]. In this clinical setting, many studies reported the association between steatosis in fatty liver and HCC development in patients with CHC[43].

VISCERAL OBESITY

In the context of steatosis and IR, visceral obesity has been associated with liver fat accumulation in healthy subjects[44,45] and is also related to viral load. Several studies have discussed the association between HCV RNA status and obesity[46].

Plausible explanations include the feasibility of adipose tissue to promote fatty substrates and a proinflammatory status that accelerate HCV replication; moreover, the ability of HCV to interfere with adipocyte function through indirect methods, and increase the inflammatory status or *via* a direct mechanism that helps to increase the colonizing adipocytes and immune cells infiltrating adipose tissue [47]. Further studies are needed to delineate the potential role of obesity in affecting SVR rates after treatment with antiviral agents.

LIPID METABOLISM

HCV infection is involved in disrupted lipoprotein homeostasis *via* impairment of the very low-density lipoprotein levels (LDLs)-releasing pathway, which is one of the main causes of hepatic fat deposition [48]. Several studies have discussed the relationship between lipoproteins and HCV cell cycle[49] and found that patients with CHC have lower serum LDL[50], which are inversely associated with the severity of liver fibrosis[51]; however, this is still a controversial issue. As reported by Nevola *et al*[15], the average LDL levels increased significantly after viral eradication, although there were no effects on triglycerides and high-density lipoprotein[15]. However, it is still debatable whether infections with HCV are linked to an increased risk of cardiovascular events such as carotid atherosclerosis, myocardial infarction, and heart attacks[52]. Notably, studies reported that patients with CHC had more atherosclerosis, as measured by carotid artery plaques and/or intima-media thickness (IMT), than healthy controls; likewise, the frequency of asymptomatic carotid atherosclerosis was higher in patients with CHC than in matched controls[7].

HCV infection could be an independent risk factor for increased carotid IMT[53] and cerebrovascular deaths[54], as reported in many types of study; this may be explained by the proinflammatory mechanisms that underlie liver fibrogenesis and could be systemically activated, leading to the promotion of atherosclerosis[7]. In contrast, several published studies have failed to show the association between atherosclerosis and HCV infection, even with an increased prevalence of IR in patients with HCV infection[55]. Therefore, further studies are needed to validate those data.

THE ROLE OF VITAMIN D

Of 25-Hydroxyvitamin D deficiency has been discovered in patients with CHC, even in those with minimal liver damage[56]; however, some studies reported no association between vitamin D status and fibrosis stage[57]. The role of vitamin D status in treatment regimens for HCV infection is still not well understood, although it is interesting that vitamin D3 supplement augments the response to antiviral therapy in infections with HCV genotypes 1-4, as reported in some randomized clinical trials[58-60].

IRON METABOLISM

It is debatable whether iron promotes or suppresses HCV viral replication, but it is considered a central component for HCV virus replication and translation[10]. In patients with CHC, elevated serum ferritin and the associated increased iron load in liver were more evident and were considered a significant predictor for hepatic fibrosis progression[61,62]. Hepcidin is a peptide hormone with an essential role in regulating iron levels under homeostatic states. Accordingly, iron metabolism alterations in CHC are related to the decreased hepcidin concentrations, although the exact underlying mechanisms remain unclear[10,63].

Still, there is an urgent need for a better understanding of how HCV impacts iron metabolism and if it could be implemented to control disease advancement[10].

SKELETAL MUSCLE

It is well known that sarcopenia, increased intramyocellular lipid accumulation, myosteatosis, and reduced muscle mass are all connected with CHC infection, especially in the advanced stages[64,65]. A high incidence rate of sarcopenia was reported, up to 70%, in patients with cirrhosis. Because of anabolic resistance, current nutritional supplementation methods have not been successful in reversing sarcopenia[66,67]. The association between CHC infection of the liver and muscle loss is well documented[68,69]. High body mass index, IR, diabetes, hepatic steatosis, increased inflammation, increased oxidative stress, lipotoxicity, and multiple factors involved in muscle depletion all are considered as independent risk factors that predispose patients with CHC to skeletal muscle disorders [70-73].

REPRODUCTIVE STATUS AND MENOPAUSE

Several studies performed on pregnant women with HCV infection reported reduced necro-inflammatory activity, and the rate of fibrosis advancement in CHC is nearly twice as fast in males compared to females[74,75]. Another report stated that long-term hormonal replacement therapy could prevent accelerated liver fibrosis in menopausal women with CHC[76]. Noteworthy improvement in sexual dysfunction was reported in males and females after HCV treatment with direct-acting antivirals[77].

CONCLUSION

The eradication of HCV remains an essential target for preventing the progression of liver disease and improving or preventing HCV-related metabolic extrahepatic manifestations that have an essential role in morbidity and mortality, affecting the patient's health-related quality of life.

Abstract

BACKGROUND

Gastric carcinoma (GC) is a common gastrointestinal malignancy worldwide. Based on the cancer-related mortality, the current prevention and treatment strategies for GC still show poor clinical results. Therefore, it is important to find effective drug treatment targets.

AIM

To explore the mechanism by which 18β-glycyrrhetinic acid (18β-GRA) regulates mitochondrial ribosomal protein L35 (MRPL35) related signal proteins to inhibit the proliferation of GC cells.

METHODS

Cell counting kit-8 assay was used to detect the effects of 18β-GRA on the survival rate of human normal gastric mucosal cell line GES-1 and the proliferation of GC cell lines MGC80-3 and BGC-823. The apoptosis and cell cycle were assessed by flow cytometry. Cell invasion and migration were evaluated by Transwell assay, and cell scratch test was used to detect cell migration. Furthermore, a tumor

model was established by hypodermic injection of 2.5 × 10^6 BGC-823 cells at the selected positions of BALB/c nude mice to determine the effect of 18β-GRA on GC cell proliferation, and quantitative reverse transcription-polymerase chain reaction (qRT-PCR) was used to detect *MRPL35* expression in the engrafted tumors in mice. We used the term tandem mass tag (TMT) labeling combined with liquid chromatography–tandem mass spectrometry to screen for differentially expressed proteins (DEPs) extracted from GC cells and control cells after 18β-GRA intervention. A detailed bioinformatics analysis of these DEPs was performed, including Gene Ontology annotation and enrichment analysis, Kyoto Encyclopedia of Genes and Genomes pathway enrichment analysis, and so on. Moreover, STRING database (https://string-db.org/) was used to predict protein-protein interaction (PPI) relationships and Western blot was used to detect the expression of proteins of interest in GC cells.

RESULTS

The results indicated that 18β-GRA could inhibit the proliferation of GC cells in a dose- and time-dependent manner. It could induce GC cell apoptosis and arrest the cell cycle at G0/G1 phase. The proportion of cells arrested at S phase decreased with the increase of 18-GRA dose, and the migration and invasiveness of GC cells were inhibited. The results of animal experiments showed that 18β-GRA could inhibit tumor formation in BALB/c nude mice, and qRT-PCR results showed that *MRPL35* expression level was significantly reduced in the engrafted tumors in mice. Using TMT technology, 609 DEPs, among which 335 were up-regulated and 274 were down-regulated, were identified in 18β-GRA intervention compared with control. We found that the intervention of 18β-GRA in GC cells involved many important biological processes and signaling pathways, such as cellular processes, biological regulation, and TP53 signaling pathway. Notably, after the drug intervention, MRPL35 expression was significantly down-regulated (P = 0.000247), TP53 expression was up-regulated (P = 0.02676), and BCL2L1 was down-regulated (P = 0.01699). Combined with the Retrieval of Interacting Genes/Proteins database, we analyzed the relationship between MRPL35, TP53, and BCL2L1 signaling proteins, and we found that COPS5, BAX, and BAD proteins can form a PPI network with MRPL35, TP53, and BCL2L1. Western blot analysis confirmed the intervention effect of 18β-GRA on GC cells, MRPL35, TP53, and BCL2L1 showed dose-dependent up/down-regulation, and the expression of COPS5, BAX, and BAD also increased/decreased with the change of 18β-GRA concentration.

CONCLUSION

18β-GRA can inhibit the proliferation of GC cells by regulating MRPL35, COPS5, TP53, BCL2L1, BAX, and BAD.

Key Words: Gastric carcinoma; 18β-glycyrrhetinic acid; Mitochondrial ribosomal protein L35; Proliferation; Invasion; Apoptosis

Core Tip: 18β-glycyrrhetinic acid (18β-GRA) is a pentacyclic triterpene derivative extracted from the natural medicine licorice. Our results showed that 18β-GRA could inhibit gastric carcinoma (GC) cell proliferation, migration, invasion, and tumor formation, induce GC cell apoptosis, and arrest the cell cycle. Tandem mass tag analysis revealed that the expression of mitochondrial ribosomal protein L35 (MRPL35) was significantly decreased after 18β-GRA intervention in GC cells, which was confirmed by Western blot results. These data indicate that 18β-GRA inhibits the proliferation/migration and promotes apoptosis of GC cells by down-regulating MRPL35 expression, suggesting that MRPL35 is a therapeutic target for GC.

INTRODUCTION

Gastric carcinoma (GC) is among the most common cancers as well as one of the most common causes of cancer-related mortality worldwide. Based on the Global Cancer Observatory (GLOBOCAN) database, GC ranks fifth in the incidence and fourth in the mortality among various types of cancers worldwide, after lung cancer, colorectal cancer, and liver cancer, and there would be more than one million new cases per year since 2020 by the World Health Organization predicting[1]. The current treatment of GC is mainly based on surgery, chemotherapy, and radiotherapy[2]. Most patients with early and advanced GC can be treated by surgery, but the treatment effect is very poor for patients with advanced GC and metastasis[3]. Although chemotherapy and radiotherapy are effective, they have severe side effects, such as hair loss and gastrointestinal reactions, leading to low compliance. Therefore, it is critical to find an effective therapeutic target for GC.

18β-glycyrrhetinic acid (18β-GRA) is a pentacyclic triterpene derivative extracted from the natural medicine licorice (Figure 1). It has significant anti-inflammatory[4], anti-oxidant, anti-bacterial, and anti-proliferative effects[5]. Recent studies have shown that 18β-GRA has reliable anticancer effects on human malignant tumors, such as lung cancer[6], breast cancer[7], colon cancer, and GC. Huang *et al*[6] found that 18β-GRA inhibited the extracellular signal-regulated kinase (ERK)/cyclic adenosine monophosphate response element binding protein (CREB) pathway by inhibiting thromboxane synthase (TxAS), thereby reducing the cell proliferation of non-small cell lung cancer (NSCLC) cells[6]. 18β-GRA showed potent inhibitory effects on human breast carcinoma MCF-7 cell proliferation in a concentration- and time-dependent manner, without affecting immortalized normal mammary epithelial cell line. 18β-GRA induced apoptosis in MCF-7 cells *via* caspase activation and modulation of the protein kinase B (Akt)/phosphorylated forkhead box O3 (FOXO3a) pathway[7]. *In vivo* and *in vitro*, 18β-GRA inhibited the proliferation, invasion, and migration of colorectal cancer cells, and had no obvious inhibitory effect on normal cells. It prolonged the survival of tumor-bearing mice by promoting apoptosis of colorectal cancer cells. Moreover, 18β-GRA inhibited the initiation and progression of gastric tumors by ameliorating the inflammatory microenvironment through down-regulation of cyclooxygenase-2 (COX-2) expression and by inhibiting Wnt-1 expression through the up-regulation of tumor suppressor miR-149-3p[8]. 18β-GRA inhibited the migration and invasion of SGC-7901 cells *via* the reactive oxygen species (ROS)/protein kinase C-α/ERK signaling pathway, and suppressed MMP-2 and 9 activities in SGC-7901 cells in a dose-dependent manner[9]. Toll-like receptor 2 (TLR2) mRNA and protein expression levels were elevated in the GC cell lines and human GC tissues. Overexpression of TLR2 was correlated with high histological grade. However, the expression of TLR2 was found to be down-regulated by 18β-GRA through a dynamic process of DNA methylation regulation. GRA pretreatment inhibited TLR2-activated GC cell proliferation, energy metabolism, and carcinogenesis [10]. In general, 18β-GRA showed an excellent inhibitory effect on GC, and its pharmacological mechanism is still worth exploring.

The human mitochondrial ribosomal protein (*MRP*) gene family consists of 30 members encoding small mitochondrial ribosomal subunits and 50 members encoding large subunits. All MRPs encoded by nuclear genes are important for the mitochondrial function and protein synthesis, which are involved in ribosomal protein transcription and translation, and mitochondrial oxidative phosphorylation. MRPs can regulate cellular functions outside mitochondria, such as cell proliferation, apoptosis, protein biosynthesis, and signal transduction. In NSCLC, overexpression of MRPL15 was associated with a poor prognosis[11]. MRPL15 plays a role in ovarian cancer through cell cycle, DNA repair, and the mTOR1 signaling pathway, suggesting that MRPL15 may be a prognostic indicator and therapeutic target for ovarian cancer[12]. Hao *et al*[13] found that MRPL42 expression was tested to be up-regulated in glioma tissues compared with normal tissues. The proliferation of glioma cells was largely blunted by silencing MRPL42. The results suggested that MRPL42 silencing resulted in increased distribution of cell cycle at G and G/M phases, while the S-phase cells decreased. Taken together, *MRPL42* is a novel oncogene in glioma[13]. In conclusion, these findings suggest that MRPs should play a crucial role in regulating the development of various malignant tumors.

Mitochondrial ribosomal protein L35 (MRPL35) is a 25 ku protein encoded by the *MRPL35* gene located on chromosome 2p11.2, which is a mitotic component of the central protuberance of the mitochondria. It is a member of the large subunit family of MRPs[14] and plays an important role in the assembly of cytochrome C oxidase complex (COX) as the specific component of mitochondrial ribosomes[15]. The expression of MRPL35 rises in the tissues of colorectal carcinoma (CRC), compared with the matched cancer-adjacent tissues. *In vitro*, down-regulation of MRPL35 resulted in increased production of ROS along with DNA damage, reduction of cell proliferation, G/M arrest, apoptosis, and autophagy induction[16]. Silencing MRPL35 suppresses the proliferation of esophageal cancer TE-1 cells, down-regulates MMP-2, and promotes cell apoptosis, after transfection of human esophageal cancer cells with lentivirus[17]. Our previous study found that the expression of MRPL35 was significantly up-regulated in GC, and the survival analysis showed that the up-regulated MRPL35 was associated with a poor survival rate in GC. Knockdown of MRPL35 was showed to inhibit proliferation of GC cells by regulating BCL-XL, PICK1, and AGR2 which are apoptosis-related proteins[18].

Figure 1 Structure of 18β-glycyrrhetinic acid. The molecular formula for 18β-glycyrrhetinic acid is C30H46O4, and the molecular weight is 470.68.

In order to more significantly explore the mechanism of 18β-GRA, we detected the expression abundance of MRPL35 in AGS, SGC-7901, MGC80-3, and BGC-823 cell lines by quantitative reverse transcription-polymerase chain reaction (qRT-PCR), and the results showed that MRPL35 expression levels in MGC80-3 and BGC-823 cell lines were similar, so we did experiment on these two cell lines (Supplementary Figure 1).

In this study, we focused on examining the effects of 18β-GRA intervention on GC cell function *in vitro* and tumor formation in nude mice *in vivo*. Tandem mass tag (TMT) analysis and STRING database prediction were used to investigate the molecular mechanism, and Western blot was used to verify the expression changes of related proteins. An important conclusion is that 18β-GRA inhibits GC cell proliferation/migration and promotes apoptosis by interfering with the expression of MRPL35-related signaling proteins, which may contribute to the development of effective therapies. These results suggest that MRPL35 may be a potential therapeutic target for the inhibition of GC by 18β-GRA.

MATERIALS AND METHODS

Cell culture and animals

Human gastric mucosal epithelial cells GES-1 (Cat. No. BNCC353464, BNCC, China) were cultured in DMEM (Cat. No. C11995500BT, Gibco, United States) containing 100 mL/L fetal bovine serum (FBS; Cat. No. SH30256.01, Gibco) and penicillin and streptomycin (Cat. No. p1400-100, Gibco). GC cell lines BGC-823 (Cat. No. GCC-ST0008CS, GeneChem, China) and MGC80-3 (Cat. No. GCC-ST0004CS, GeneChem) were cultured in RPMI-1640 (Cat. No. C11875500BT, Gibco) containing 100 mL/L FBS and penicillin and streptomycin. The culture flasks were placed in an incubator at a constant temperature of 37 ℃, with 50 mL/L CO_2 and saturated humidity. BALB/c nude mice (male, weighing 18-22 g) of specific pathogen-free (SPF) grade were purchased from the Animal Experiment Center of Ningxia Medical University. All animals were fed standard laboratory feed and water in 12 h light/dark cycle environment. The animal protocols (IACUC-NYLAC-2019-083) were approved by the Institutional Animal Care and Use Committee of Ningxia Medical University.

Cell proliferation assessed by cell counting kit-8 assay

Normal gastric mucosal epithelial GSE-1 cells were cultured in an incubator at 37 ℃ and 50 mL/L CO_2, collected, and inoculated in a 96-well plate at a density of 4 × 10^4 cells/mL. On the next day, the cells were treated with different concentrations of 18β-GRA (purity > 97%; Cat. No. G10105-10G, Sigma, United States) for 24 h, 48 h, and 72 h. Thereafter, 10 μL of cell counting kit-8 (CCK-8) (Cat. No. KGA317, KeyGEN, China) was added to each well and incubated for 2 h. Optical density (OD) was detected at 450 nm. All experiments were repeated three times.

MGC80-3 and BGC-823 cells were cultured in an incubator at 37 ℃ and 50 mL/L CO_2. Cells in the logarithmic growth phase were inoculated in 96-well plates at an adjusted concentration of 4 × 10^4 cells/mL. After 24 h, cells were treated with different concentrations of 18β-GRA for 24 h, 48 h, and 72 h. Thereafter, 10 μL of CCK-8 was added to each well and incubated for 2 h. OD was detected at 450 nm. All experiments were independently repeated at least three times.

Cell cycle and apoptosis detection via flow cytometry analysis

MGC80-3 and BGC-823 cells were inoculated in 6-well plates. The cells were treated with 18-GRA for 48

h on the second day. Then the cells were collected and centrifuged at 3000 r/min for 5 min. Annexin V-FITC apoptosis detection kit (Cat. No. KGA107, KeyGEN) was used for staining and apoptosis was detected by flow cytometry after 15 min at room temperature in dark. Cells from each group were collected, washed with pre-cooled PBS, and fixed overnight in 750 mL/L ethanol. The cells were stained with cell cycle kit and incubated at room temperature for 30-60 min in the dark. The cell cycle was detected by flow cytometry. All experiments were repeated three times.

Transwell assay

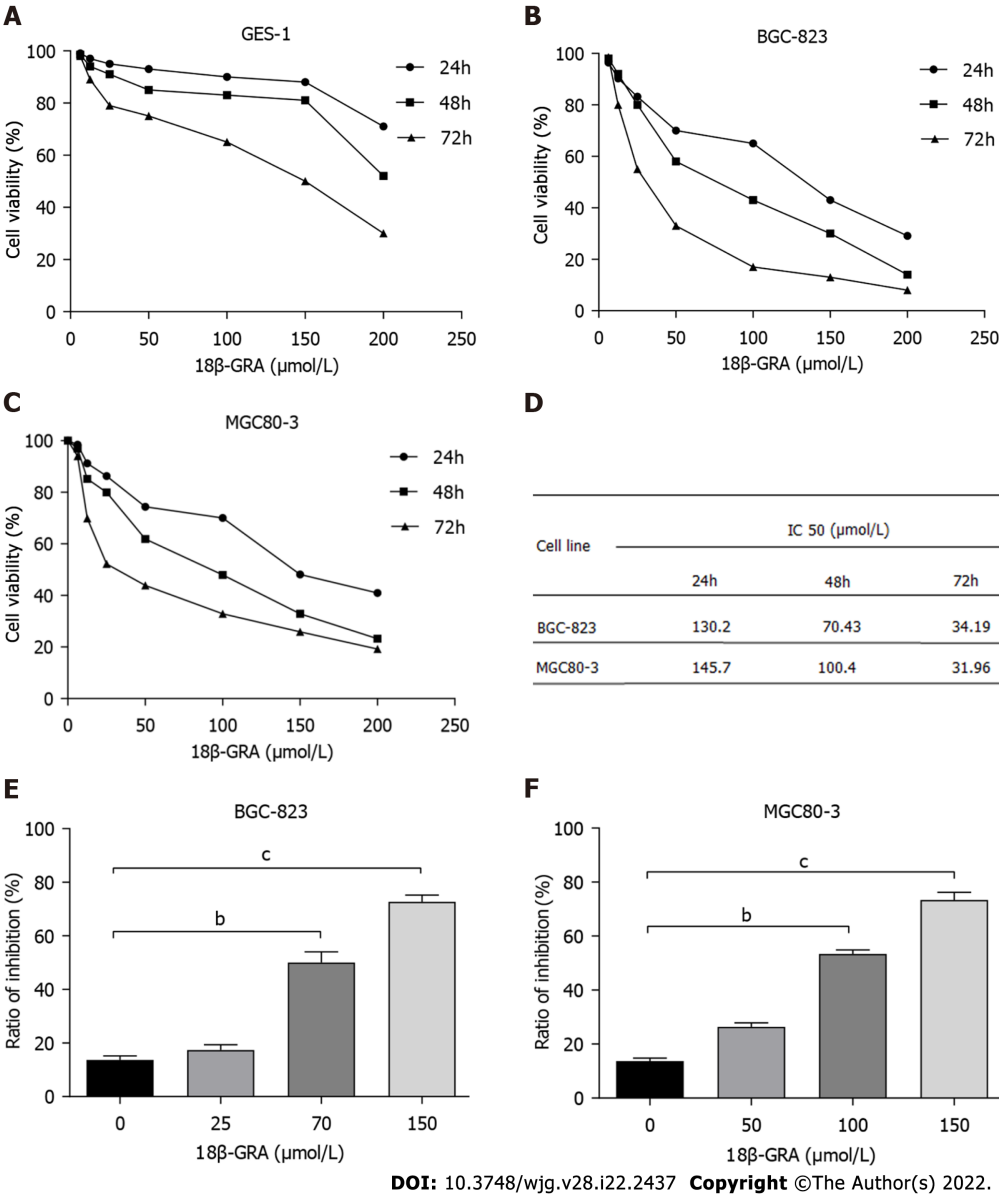
First, 8 μmol/L pore size Transwell (Cat. No. Costar.3422, Corning, United States) with and without Matrigel were placed into a 24-well plate. MGC80-3 and BGC-823 cells were inoculated into the upper chambers at 2 × 10^5 cells/mL. After adding 750 μL complete medium in the lower chambers and culturing at 37 ℃ for 24 h, the medium was replaced with medium containing different concentrations of 18β-GRA and cultured for 48 h. The cells were gently wiped off with cotton swabs and fixed with 4% paraformaldehyde for 5 min, stained with crystal violet for 5 min, and washed with PBS. Thereafter, the cells were observed with an inverted microscope and photographed to count and compare the differences in the cell invasion between groups. The number of migrated cells was counted, and the average value was used for statistical analysis. All experiments were repeated three times.

Wound scratch assay

GC cells MGC80-3 and BGC-823 were inoculated on 6-well plates. After the cells were attached, a scratch was made with a 200 μL pipette tip. The cells were washed with PBS. Then medium containing 18-GRA was added, and the cells were cultured in a 50 mL/L CO_2 incubator at 37 ℃ for 0 h and 48 h, and photographed with a microscope to calculate the cell migration rate of each group. All experiments were repeated three times.

Tumor formation experiment in BALB/c nude mice

Four-week-old male BALB/c nude mice (18-22 g) of SPF grade were purchased from the Animal Experiment Center of Ningxia Medical University. All animals were housed in polypropylene cages at a temperature of 22 ± 1 ℃ and 50 ± 5% humidity, in a 12:12 h light/dark cycle, and provided free access to standard laboratory chow and water. There were six BALB/c nude mice in each group. A microsyringe was used to extract 200 μL of BGC-823 cell suspension in logarithmic growth phase at a concentration of 2.5 × 10^6 cells/mL, which was subcutaneously injected into the right back of each nude mouse. The 18β-GRA group was intragastrically administered with 18β-GRA at 50 mg/kg[10,19] every other day, and the control group was similarly administered with equal volume of normal saline. Intragastric gavage administration was carried out in conscious animals. The tumor volume was measured daily using the formula $V = \frac{w^2 \times L}{2}$ (V, volume; W, width; L, length). All animals were euthanized by exposure to 1000 mL/L CO_2 for 5 min for tissue collection. The animal protocols were approved by the Institutional Animal Care and Use Committee of Ningxia Medical University.



qRT-PCR

Total RNA of the transplanted tumor tissue from mice was extracted using Trizol reagent (Cat. No. DP424, Tiagen Biochemical Technology, China), and PrimeScript RT reagent Kit with gDNA Eraser was used to synthesize first-strand cDNA from total RNA. qRT-PCR was used to detect by using BlazeTaq SYBR Green qPCR Mix 2.0 (Cat. No. QP031-S, GeneCopoeia, United States) according to the manufacturer's instructions. The primers used are as follows: *MRPL35*: Forward, 5′-TTGGCATCTTCAACCTACCGC-3′ and reverse, 5′-GGAGGAAACAACTGGTGTCTGA-3′; *GAPDH*: Forward, 5′-TGACTTCAACAGCGACACCCA-3′ and reverse, 5′-CACCCTGTTGCTGTAGCCAAA-3′. All experiments were repeated three times.

Protein extraction, trypsin digestion, and TMT proteomic labeling

SDT buffer was added into the control and 18β-GRA-treated GC cells. After being boiled for 15 min, the protein content was quantified with the BCA Protein Assay Kit (Cat. No. P0012, Beyotime, China), 20 μg proteins were taken, and 6 × loading buffer (Cat. No. P0015F, Beyotime) was added. After being boiled for 5 min, the proteins were separated by 12.5% sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and protein bands were visualized by Coomassie Blue R-250 staining.

The method of filter-aided sample preparation digestion was performed by adding dithiothreitol (DTT; Cat. No. 43819-5G, Sigma) to a 200 μg protein solution to a final concentration of 100 mmol/L, boiling reduced protein lysate for 5 min, and alkylation with 100 μL iodoacetamide buffer (IAA) for 15 min at room temperature protected from light. Then, 100 μL of 0.1 M tetraethyl ammonium bromide (TEAB; Cat. No. SE252676/90114, Thermo Fisher, United States) solution was added, and the mixture was centrifuged for 15 min. After 40 μL of trypsin buffer (4 μg trypsin in 40 μL of 0.1 M TEAB solution) was added, the filtrate was collected overnight at 37 ℃ to obtain peptide segments. One hundred microliters of peptide mixture was then labeled using TMT 6plex Isobaric Mass Tag Labeling kit

(Thermo Fisher, United States) according to the manufacturer's instructions.

HPLC fractionation, liquid chromatography–tandem mass spectrometry analysis, and data analysis

The labeled peptides of the two groups were fractionated with Agilent 1260 Infinity HPLC system. The peptide mixture was diluted with buffer A (10 mmol/L HCOONH4, 5%/85% ACN, pH 10.0). Liquid chromatography–tandem mass spectrometry (LC-MS/MS) analysis was performed on a Q Exactive Plus mass spectrometer (Thermo Fisher, United States), and peptides were detected on MS at a resolution of 70000 with a scan range of 350-1800 m/z and with automatic gain control of 5e4. All the original data files obtained were processed with Proteome Discoverer 2.2 (Thermo Fisher, United States) software. Proteins that met the expression fold change > 1.2 and *P* value (Student's *t* test) < 0.05 were considered to be differentially expressed proteins (DEPs).

Bioinformatics analysis

Blast2GO and InterProScan software are used to analyze the cellular processes of DEPs, the biological processes involved, and the corresponding molecular functions. The Fisher's exact test was employed to test Gene Ontology (GO) annotation/Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway/InterPro domain enrichment analysis. Fisher's exact test was used to test enrichment pathways; InterPro was used to determine enrichment domains. We used WoLFPSOR to locate and

predict DEPs. Matplotlib was used to classify samples and protein expression levels at the same time to form hierarchical cluster heat maps. A protein-protein interaction (PPI) network incorporating identified target proteins was prepared with the STRING database, using a score > 0.4 as the significance threshold for identified interactions.

Western blot analysis

The cells were collected after drug intervention. Whole cell lysates were obtained by gentle lysis (Cat. No. KGP250, KeyGEN). Protein quantitation was performed by the BCA method (Cat. No. KGPBCA, KeyGEN). The protein was separated by SDS-PAGE, and the protein was transferred to PVDF membranes by wet-transfer method. Thereafter, the membrane was incubated with 50 mL/L skim milk powder at room temperature for 1 h. Later on, the membranes were incubated with the primary antibodies, including anti-MRPL35 (Cat. No. YT5669, Immunoway; 1:2000), anti-TP53 (Cat. No. YM3052, Immunoway; 1:2000), anti-BCL2L1 (Cat. No. YT0477, Immunoway; 1:2000), anti-BAX (Cat. No. YM3619, Immunoway; 1:500), anti-COPS5 (Cat. No. ab124720, Abcam; 1:2000), anti-BAD (Cat. No. 9292, Cell Signaling Technology; 1:1000), and anti-β-tubulin (Cat. No. YM3030, Immunoway; 1:10000). Then, the membranes were washed with TBST and incubated with anti-mouse/rabbit IgG antibody (Cat. No. S001 S004, TDYBio; 1:10000) at 37 ℃ for 1 h. After washing, the proteins were detected with an ECL detection system. ImageJ software was used to measure the band intensity.

Statistical analysis

The statistical methods of this study were reviewed by Li-Qun Wang from Department of Epidemiology, Department of Medical Statistics, Institute of Public Health and Management, Ningxia Medical University. All analyses were performed using GraphPad Prism 7.0. All the data are expressed as the mean ± SE. Statistical significance was analyzed using one-way ANOVA. $P < 0.05$ was considered statistically significant.

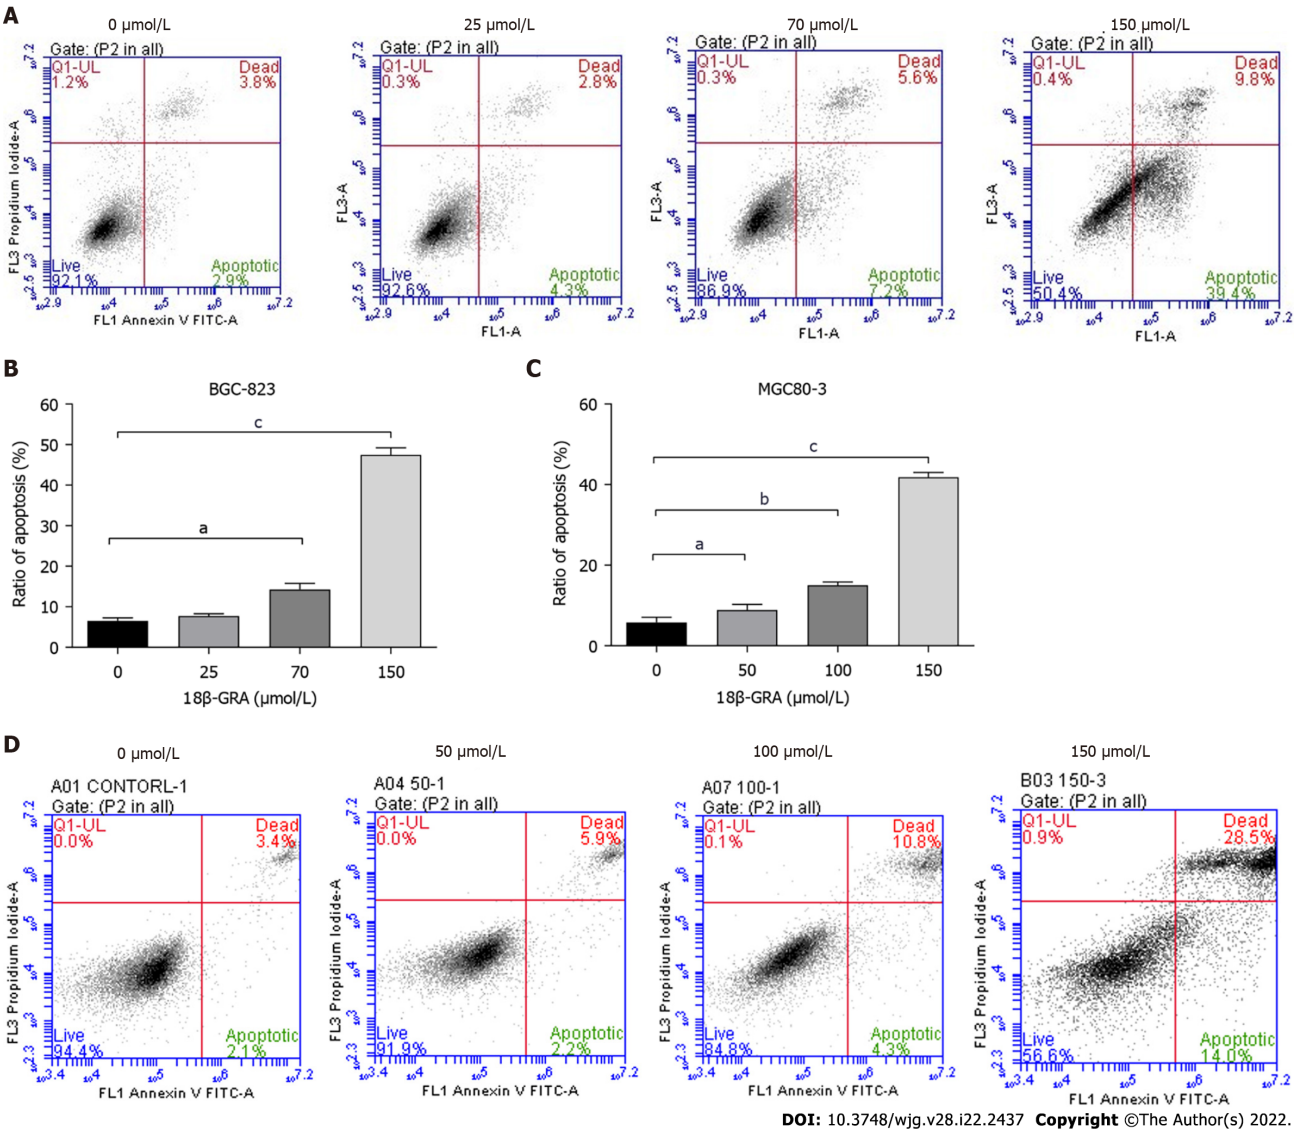
RESULTS

18β-GRA inhibits GC cell proliferation

CCK-8 assay was used to evaluate the effect of 18-GRA on the survival rate of normal gastric mucosal GES-1 cells. The results showed that 12.5-150 μmol/L of 18β-GRA had little effect on the survival rate of GES-1 cells at 24 h and 48 h. However, when the concentration of 18β-GRA was greater than 150 μmol/L, the survival rate of GES-1 cells was significantly decreased (Figure 2A).

CCK-8 results showed that 6.25-200 μmol/L of 18β-GRA inhibited the proliferation of BGC-823 and MGC80-3 cells in a time- and dose-dependent manner (Figure 2B and C). After the intervention of 18-GRA in BGC-823 and MGC80-3 cells for 24 h, 48 h, and 72 h, the 50% inhibitory concentration (IC50) of cells was calculated and is shown in Figure 2D. Based on the above results, 25 μmol/L (low), 70 μmol/L (medium), and 150 μmol/L (high) were determined for BGC-823 cells, and 50 μmol/L (low), 100 μmol/L (medium), and 150 μmol/L (high) were determined for MGC80-3 cells. Compared with the 0 μmol/L (control), the different concentrations of 18-GRA inhibited the proliferation of BGC-823 and MGC80-3 cells ($P < 0.01$) (Figure 2E and F).

18β-GRA arrests GC cell cycle



In order to study the effect of 18β-GRA on GC cell cycle, BGC-823 and MGC80-3 cells were treated with different concentrations of 18β-GRA, and the cell cycle of BGC-823 was arrested at G0/G1 phase; the proportions of cells at G0/G1 phase were 81.84% (150 μmol/L), 71.34% (70 μmol/L), and 61.66% (25 μmol/L) (Figure 3A and B). The cell cycle of MGC80-3 cells was arrested at G0/G1 phase; the proportions of cells at G0/G1 phase were 78.01% (150 μmol/L) and 73.37% (100 μmol/L) and higher than 60.57% (control). And with the increase of 18-GRA concentration, the proportion of cells in S-phase decreased (Figure 3C and D).

18β-GRA promotes GC cell apoptosis

Flow cytometry was used to detect the effects of different concentrations of 18β-GRA on GC cell apoptosis. After intervention with different concentrations of 18β-GRA in BGC-823 and MGC80-3 cells for 48 h, the apoptosis rates of BGC-823 cells were 14.27% (70 μmol/L) and 47.47% (150 μmol/L), which were higher than 6.53% (control) (Figure 4A and B). The apoptosis rates of MGC80-3 cells were 8.87% (50 μmol/L), 15.03% (100 μmol/L), and 41.8% (150 μmol/L), which were all higher than 5.8% (control) (Figure 4C and D).

18β-GRA inhibits GC cell invasion ability

BGC-823 and MGC80-3 cells were treated with different concentrations of 18β-GRA for 48 h, and the cell invasion ability was detected. The results of Transwell assay are shown in Figure 5. Compared with control, the different concentrations of 18β-GRA inhibited the invasion of BGC-823 and MGC80-3 cells (

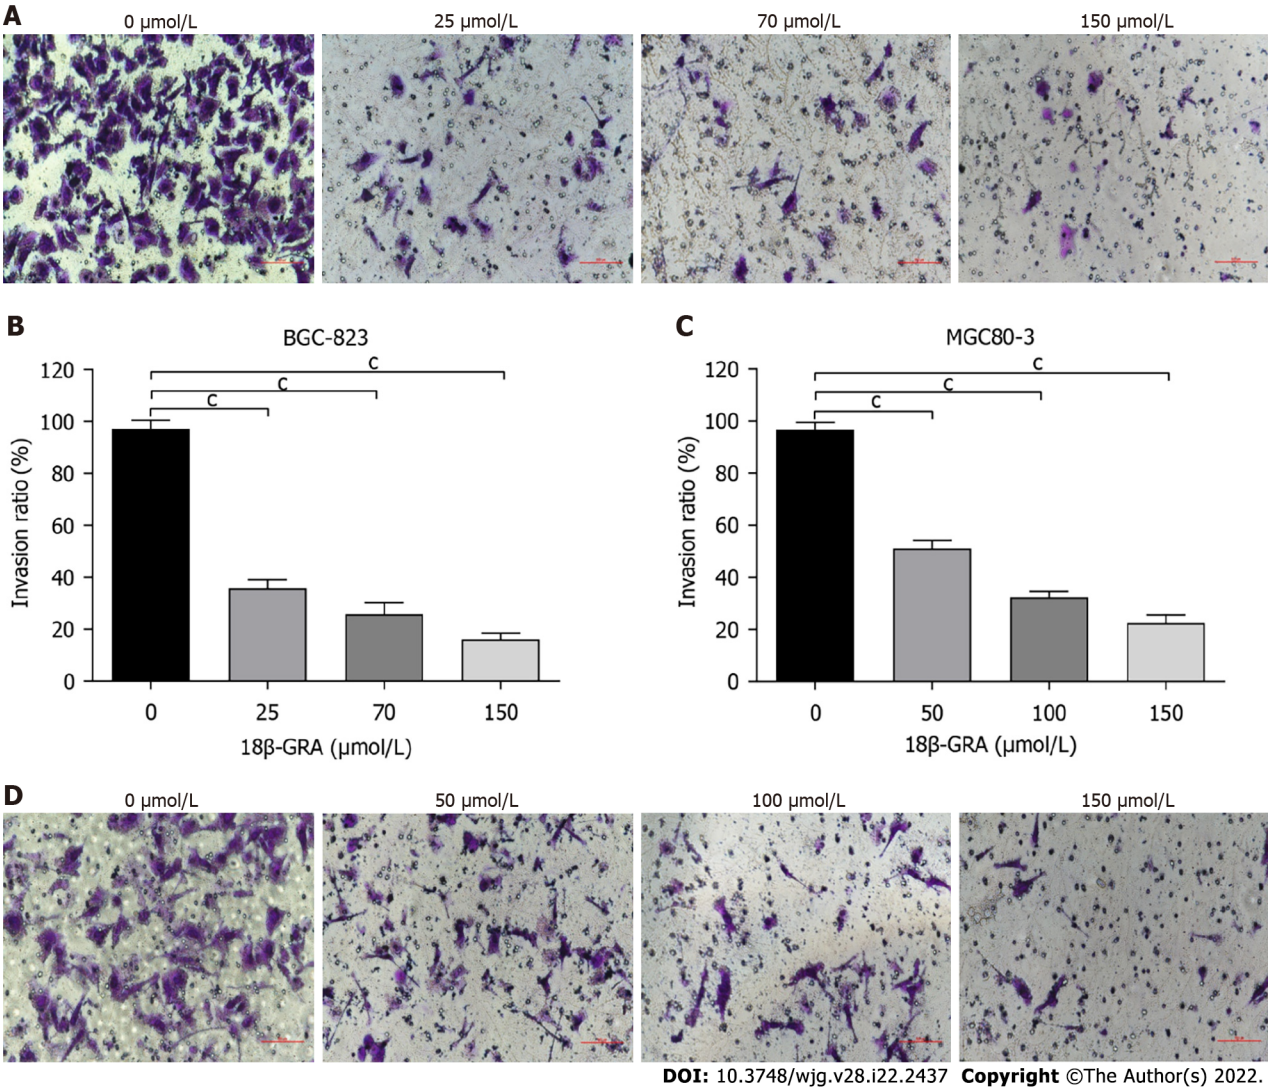
P < 0.05).

18β-GRA inhibits the migration ability of GC cells



The effect of 18β-GRA on GC cell migration was evaluated in Transwell chambers without matrigel. The migration of BGC-823 and MGC80-3 cells was inhibited after 48 h of treatment with different concentrations of 18-GRA (Figure 6).

We also evaluated the effect of 18β-GRA on GC cell migration by wound scratch assays. The migration of MGC80-3 and BGC-823 cells was inhibited by different concentrations of 18β-GRA for 48 h (Figure 7). With the increase of 18β-GRA concentration, the inhibitory effect was gradually enhanced (*P* < 0.05).

18β-GRA inhibits tumor formation in nude mice

The results of tumor formation experiments in nude mice showed that after 2 wk of continuous intragastric administration, the tumor volume in the 18β-GRA group was significantly smaller than that in the control (Figure 8A and B). The tumor volume was recorded within 2 wk, and the tumor growth curve was drawn (Figure 8C). The tumor growth rate of the 18β-GRA group was lower than that of the control (*P* < 0.01).

qRT-PCR was used to detect the expression level of *MRPL35* in the transplanted tumor tissues of mice. The results showed that the expression level of *MRPL35* in the transplanted tumor tissues of mice in the 18β-GRA group was significantly lower than that in the control (*P* < 0.001) (Figure 8D).

During the experiment, we also monitored the influence on body weight, food, and water intake in mice, and found that there was little toxic effect of 18β-GRA on them (Supplementary Figures 2-4).

18β-GRA inhibits GC cell proliferation by regulating MRPL35-related apoptosis signaling pathways

Proteomic analysis based on TMT labeling-based was performed on control and GC cells treated with 18 β-GRA. A total of 6275 proteins were identified by proteomic analysis, and 609 DEPs were screened using the expression difference ratio > 1.2 and $P < 0.05$ as the standard, among which 335 were up-regulated and 274 were down-regulated. To better visualize the DEPs, we drew the volcano plot. The red dots indicate significantly up-regulated proteins and blue dots indicate significantly down-regulated proteins (Figure 9A). Notably, after 18β-GRA intervention, MRPL35 expression was significantly down-regulated ($P = 0.000247$), TP53 expression was up-regulated ($P = 0.02676$), and BCL2L1 was down-regulated ($P = 0.01699$). The GO annotation and enrichment analysis was used to analyze the DEPs and to determine their biological processes (BP), molecular functions (MF), and cellular components (CC) (Figure 9B and C). In the BP analysis, DEPs were mainly involved in cellular processes, biological regulation, and molecular metabolism. It is mainly enriched in complement activation, alternative pathway and classical pathway, and mitochondrial translational termination. With respect to MF, the DEPs are involved in the binding, catalytic activity, molecular function regular, and so on. It is mainly enriched in the binding of collagen and fibronectin, and serine-type endopeptidase inhibitor activity. In the CC analysis, we found that the DEPs were highly localized in the cell, organelle, and protein-containing complex part. Those DEPs are mainly enriched in extracellular space, collagen-containing extracellular matrix, membrane attack complex, and mitochondrial large ribosomal subunit. The DEPs were classified by KEGG pathway enrichment analysis (Figure 9D). KEGG pathway enrichment analyses revealed these DEPs to be enriched in

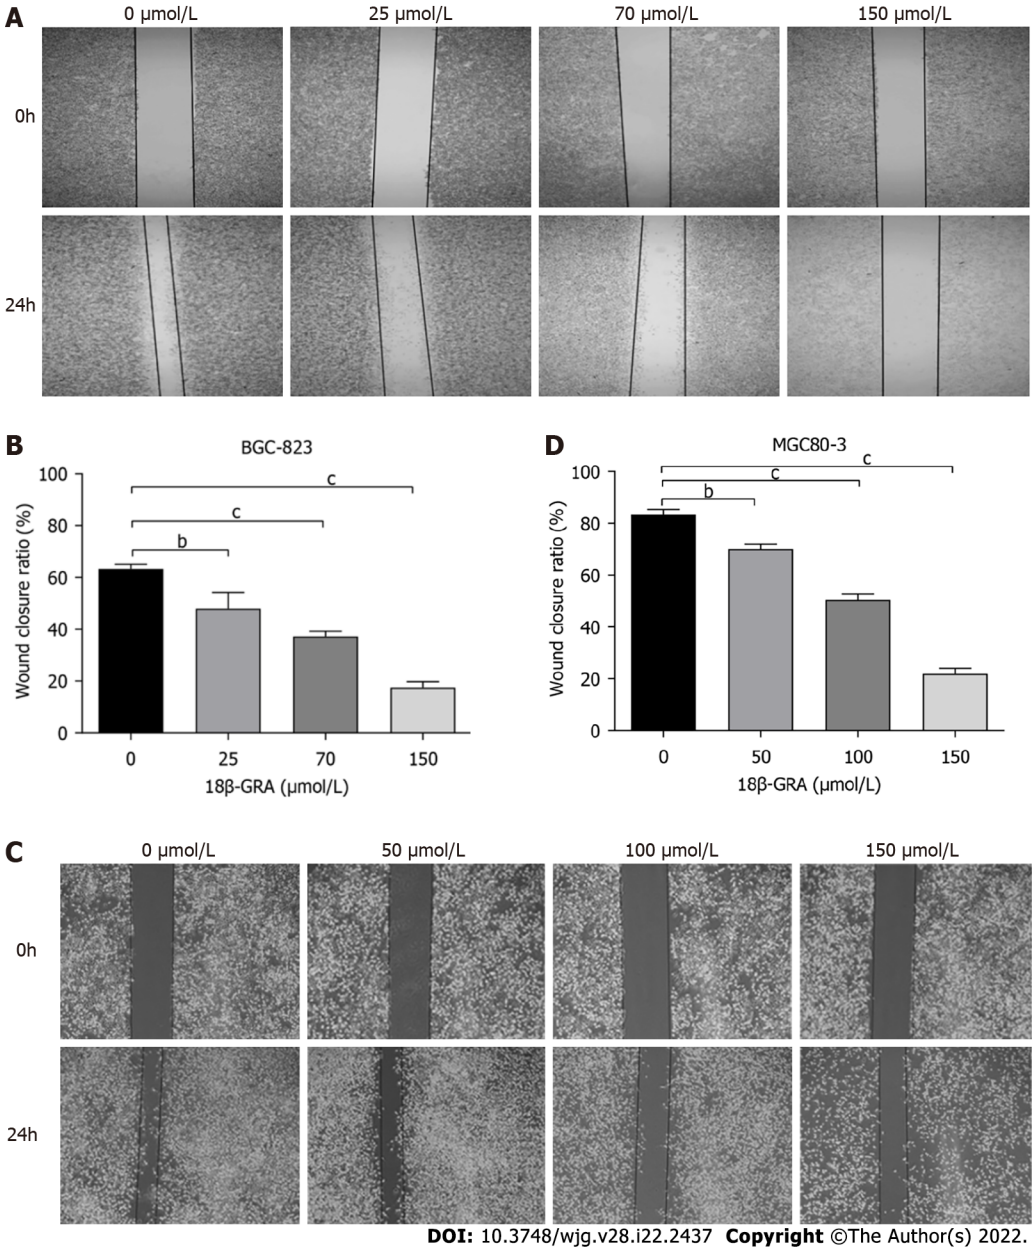
Figure 6 Effects of different concentrations of 18β-glycyrrhetinic acid on migration of human gastric carcinoma cells. A and B: Migration ability of BGC-823 cells determined by Transwell assay without Matrigel matrix gel and statistical graph; C and D: Migration ability of MGC80-3 cells and statistical graph. All analyses were repeated three times. The data is represented as the mean ± SD. $^{a}P < 0.05$; $^{b}P < 0.01$; $^{c}P < 0.001$. 18β-GRA: 18β-glycyrrhetinic acid.



complement and coagulation cascades, ECM-receptor interaction, and cell adhesion molecules. It is worth noting that these DEPs are also involved in the TP53 signaling pathway.

Wolfpsort was used to predict the subcellular localization of these DEPs, which were primarily localized to the nucleus (28.1%), cytosol (23.2%), extracellular space (18.4%), mitochondria (13.6%), and so on (Figure 10A). Further protein domain enrichment analysis showed that DEPs were significantly enriched in the immunoglobulin-like fold domain, thrombospondin type-1 (TSP1) repeat and superfamily, and fibronectin type III and superfamily protein domain (Figure 10B). Cluster analysis was performed on DEPs and drawn as a heat map (Figure 10C). Each row in the figure represents a DEP, red represents up-regulated DEP expression and green for down-regulated DEP expression; the darker the color is, the more significant the difference is.

Finally, in order to further explore the function of MRPL35, TP53, and BCL2L1, the STRING database was used to construct a PPI network, and the results are shown in Figure 10D. And we found that COPS5 is the protein connecting MRPL35 and TP53. In addition, we also found that TP53 and BCL2L1 are closely related to the pro-apoptotic proteins BAX and BAD.

Effect of 18β-GRA on the expression of MRPL35-related apoptosis proteins

Western blot was used to detect the effect of 18β-GRA on the expression of MRPL35 related proteins in gastric cancer cells. The results showed that with the increase of 18β-GRA concentration, the expression levels of MRPL35 and BCL2L1 proteins were gradually down-regulated, while the expression of TP53 protein was up-regulated. The expression of COPS5, the protein linking MRPL35 and TP53, was down-regulated, and the expression levels of pro-apoptotic proteins BAX and BAD were up-regulated. These results confirm the results of our proteomics and bioinformatics analysis above (Figure 11).

Figure 7 Effects of different concentrations of 18β-glycyrrhetinic acid on migration of human gastric carcinoma cells. A and B: Effect of 18β-glycyrrhetinic acid (18β-GRA) on migration of BGC-823 cells evaluated by Wound-scratch assay and statistical graph; C and D: Effect of 18β-GRA on the migration of MGC80-3 cells and statistical graph. All analyses were repeated three times. The data is represented as the mean ± SD. $^{a}P < 0.05$; $^{b}P < 0.01$; $^{c}P < 0.001$. 18β-GRA: 18β-glycyrrhetinic acid.

DISCUSSION

In this study, the functional changes of GC cells after 18β-GRA intervention were tested by *in vitro* experiments, and the results showed that 18β-GRA had little effect on the survival rate of normal gastric epithelial GES-1 cells, and significantly inhibited the proliferation of BGC-823 and MGC80-3 cells. Next, we detected the cell cycle and found that 18β-GRA could arrest the GC cell cycle at G0/G1 phase. After drug intervention in GC cells, the cells can either exit the cell cycle reversibly, by initiating quiescence, or irreversibly, by senescence or apoptosis. The decision to exit the cell cycle solely depends on the DNA damage checkpoint[20]. In response to irreparable DNA damage, DNA damage checkpoints can initiate quiescence, senescence, or programmed cell death, primarily through TP53-dependent pathways[21, 22]. Moreover, TP53 mutations are the most common mutations in cancer. However, even if cancer-related mutations prevent cell cycle exit, continuous proliferation of cells can still be prevented by blocking the entry of G1 cell cycle prior to replication, which relies on the activation of E2F-dependent transcription[23,24]. We investigated the effect of 18β-GRA on the apoptosis of two types of GC cells, and confirmed the results of cell cycle arrest. It was found that the cells chose to undergo apoptosis and exit the cell cycle, and TP53 played a crucial role in this process.

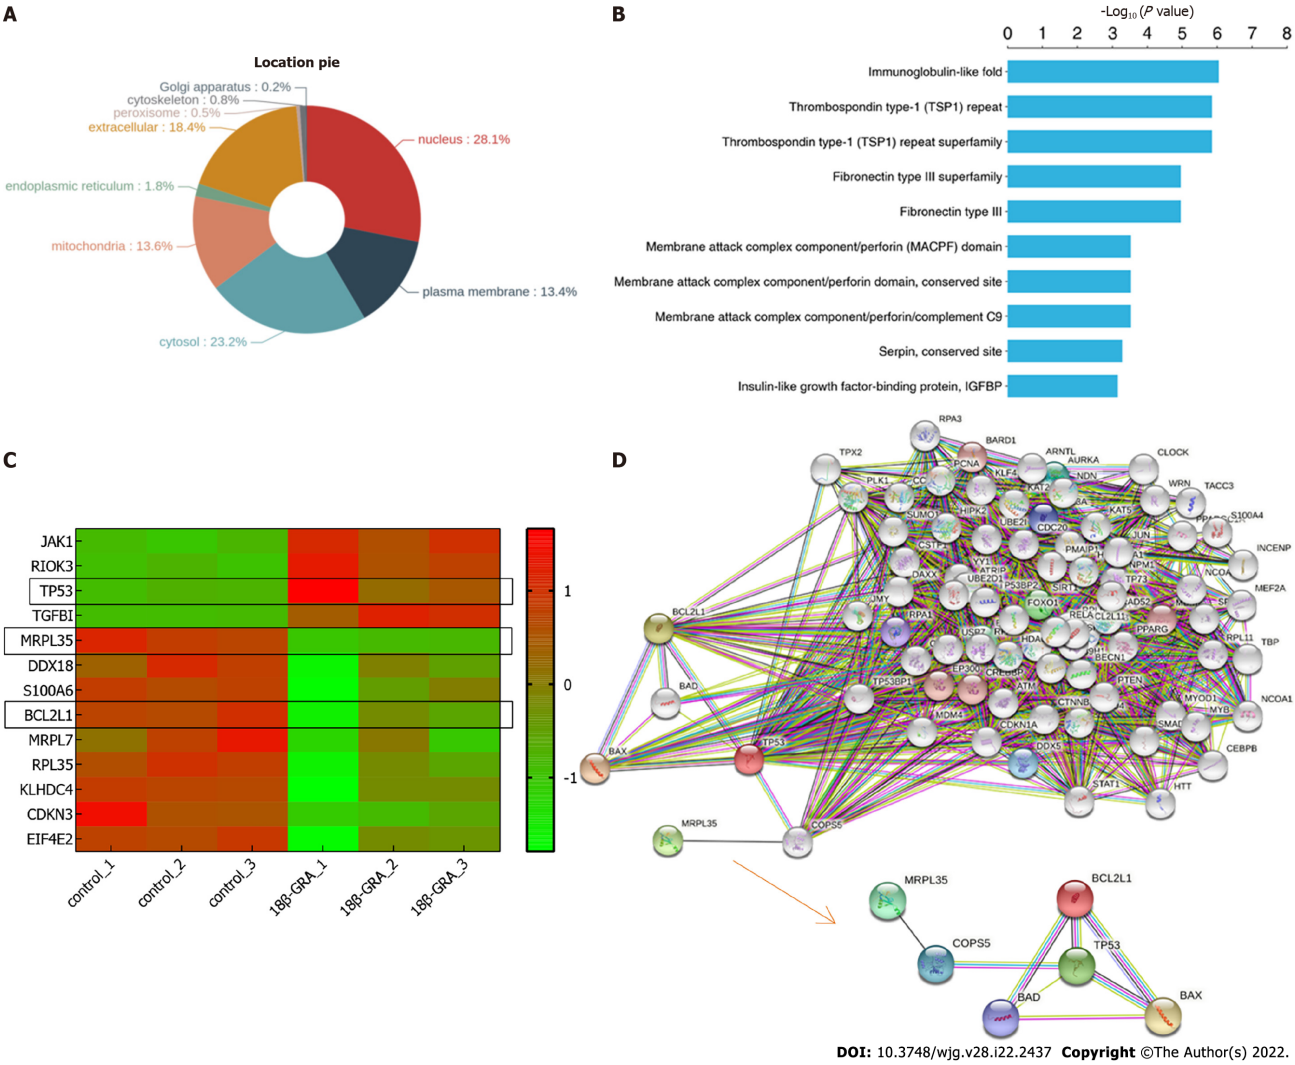
The cell invasion and migration experiments showed that cell invasion and migration were significantly suppressed after 18β-GRA intervention in GC cells. Epithelial-to-mesenchymal transition (EMT) plays an important role in the occurrence of metastasis and invasion of malignant tumors[25]. The loss of epithelial characteristics and the acquisition of mesenchymal features reduce cell adhesion and increase cell mobility. In addition, our previous experiments also showed that LINC00514 was up-regulated in GC specimens compared with non-tumor specimens, and overexpression of LINC00514 induced GC cell growth and EMT progression[26]. We used immunodeficient nude mice for tumor-forming experiments *in vivo*. It was found that subcutaneous tumor volume was significantly inhibited in nude mice after 2 wk of intragastric administration of 18β-GRA compared with the control group, and the expression level of *MRPL35* in the transplanted tumor tissues of the 18β-GRA group was significantly decreased, which also confirmed the results of cell function *in vivo*.



Based on the above results, we further investigated the mechanism of 18β-GRA in inhibiting GC cell proliferation, and promoting cell apoptosis. TMT analysis showed that there were 609 DEPs in GC cells treated with 18β-GRA, among which the expression of MRPL35, TP53, and BCL2L1 was significantly altered. GO analysis found that all these DEPs were mainly involved in cellular processes, biological regulation, and molecular metabolism, and were enriched in membrane attack complexes and mitochondrial large ribosomal subunits. In addition, subcellular localization analysis of DEPs showed that these DEPs were mainly distributed in the nucleus, cytoplasm, extracellular space, and mitochondria. Our previous study showed that the high expression of MRPL35, a member of the large subunit family of MRPs, was correlated with the poor survival rate in GC, and knocking down MRPL35 could inhibit GC cell proliferation. Interestingly, KEGG results showed that these DEPs were enriched in the TP53 signaling pathway, which was ranked tenth in the analysis. TP53 is an important protein involved in the process of cell apoptosis. As a transcription factor, TP53 is mutated in most human cancers[27]. To inhibit cancer, TP53 protein regulates the transcription of many different genes, including *BAX*, *NOXA1*, and *GADD45A*, in response to multiple stress signals, such as DNA repair, cell cycle arrest, senescence, and apoptosis, while tumor mutations can make them resistant to apoptosis

induced by the TP53 pathway. Combined with the expression changes of BCL2L1, we speculated that 18 β-GRA might play a role in inhibiting the proliferation of GC by regulating TP53 apoptosis-related signaling pathways through MRPL35. Enrichment analysis of DEP domains showed that they were significantly enriched in immunoglobulin-like folding domain, TSP1 repeats and superfamily, and

fibronectin type III and superfamily protein domain. Hence, we speculate that 18β-GRA might regulate the expression of MRPL35, induce the changes of apoptosis-related proteins TP53 and BCL2L1, and play a role in inhibiting the proliferation of GC cells.

Finally, we analyzed the input STRING database of these three signaling proteins, and found that COPS5 is the protein connecting MRPL35 and TP53. Therefore, we believe that MRPL35 is likely to play a pro-apoptotic role by regulating COPS5. In addition, we also found that TP53 and BCL2L1 are closely related to BAX and BAD. As a major regulator of mitochondrial involvement in the intrinsic apoptosis pathway, BAX controls a cell's commitment to the pathway by changing the physiology of resident mitochondria. BAX undergoes a series of ordered events that lead to the formation of pores in the outer membrane of mitochondria, facilitating the release of signaling molecules such as cytochrome C[28]. This event is commonly considered as the "point of no return" in cell death[29]. BAD, a ligand of the pro-survival protein 14-3-3, is an on-off protein in the mitochondria-induced apoptotic pathway[30]. When separated from 14-3-3, BAD may interact with BCL-2/BCL2L1 and release BAX, revealing its apoptotic activity. Binding of BAD to BCL2/BCL2L1 has also been reported to release the activator BH3-only molecules, such as Bim, Bid, and Puma, to directly activate BAX[31,32].

Based on the above mentioned proteomics and STRING analyses, we concluded that 18β-GRA is likely to inhibit the proliferation of GC cells by regulating the expression of MRPL35, thereby affecting the expression of TP53, BCL2L1, COPS5, BAX, and BAD proteins. Consistent with the above hypothesis, the expression of MRPL35, COPS5, apoptosis-related protein TP53, pro-apoptotic proteins BAX and BAD, and anti-apoptotic protein BCL2L1 was down-regulated after 18β-GRA intervention. The anti-tumor activity of GRA and its derivatives are associated with the mitochondrial apoptotic pathway of mitochondrial membrane potential depolarization, which leads to the activation of caspase-9 and caspase-3, and the production of ROS. Cancer cells can avoid apoptosis by destroying the balance

between pro-apoptosis and pro-survival, so that the apoptotic signal of mitochondria is insensitive to cell death. Studies have shown that 18β-GRA may potentiate the heat shock protein 90 inhibition-induced apoptosis in ovarian carcinoma cell lines *via* the activation of the apoptosis-related proteins and the mitochondria-mediated cell death pathway, leading to activation of caspases[33].

MRPs play a critical role in protein synthesis and mitochondrial function, and also participate in the regulation of cell apoptosis, protein biosynthesis, and signal transduction. MRPL35 and its partner MRP7 play a key role in coordinating the synthesis of the COX1 subunit with its assembly into the COX enzyme[15]. The expression of MRPL35 was found to be higher in CRC tissues than in matched cancer-adjacent tissues. *In vitro*, down-regulation of MRPL35 led to increased production of ROS along with DNA damage, decrease in mitochondrial membrane potential, and autophagy induction, thereby inhibiting the progression of CRC[16]. Oncomine showed that the expression of MRPL35 in GC tissues was significantly higher than that in adjacent tissues. Our previous results also showed that the expression of MRPL35 was significantly up-regulated in GC, which was associated with a poor survival rate of GC patients. Moreover, the knockdown of MRPL35 could inhibit the proliferation and colony formation of GC cells and induce apoptosis[18].

This study demonstrated that 18-GRA inhibited the proliferation and promoted apoptosis of GC cells by down-regulating the expression of MRPL35, which regulated TP53 and BCL2L1 proteins, both *in vivo* and *in vitro*. Our proposed research in the future will be divided into three stages: In the first stage, the signaling pathways of MRPL35, TP53, and BCL2L1 proteins will be explored, possibly through methylation, ubiquitination, acetylation, and phosphorylation. The second stage will be to evaluate the interaction mechanism between MRPL35 and COPS5 proteins. Two modes of action will be considered: Direct action and through tool protein action. Co-immunoprecipitation (Co-IP) or yeast two-hybrid system may be used. In the third stage, MRPL35 and COPS5 protein interaction sites will be explored. After silencing the MRPL35 and COPS5 domains, GST pull-down and Co-IP will be used to verify whether the two proteins interact. The present study aimed to provide a scientific basis for the treatment of GC and identify an effective drug target for the early prevention of GC.

CONCLUSION

18β-GRA can down-regulate the expression of MRPL35 protein, suppress the expression of anti-apoptotic protein BCL2L1, and promote the pro-apoptotic proteins TP53, BAX, and BAD through COPS5, thus inhibiting the proliferation of gastric cancer cells.

ARTICLE HIGHLIGHTS

Research background

Gastric cancer (GC) is a common malignant tumor of the digestive tract in the world, with more than 1 million new cases to be expected each year since 2020. Mitochondrial ribosomal protein L35 (MRPL35) is a member of the large subunit family of mitochondrial ribosomal proteins, which plays an important role in the development of cancer.

Research motivation

At present, the treatment of gastric cancer is based mainly on surgery, chemotherapy, and radiotherapy, and the first-line treatment drugs are mainly harmful due to side effects.

Research objectives

The purpose of this study was to investigate the correlation between MRPL35 apoptosis related signaling pathway and GC.

Research methods

Cell functional indexes were determined by cell counting kit-8, flow cytometry, Transwell assay, and cell scratch assay. The effect of 18β-glycyrrhetinic acid (18β-GRA) on proliferation of gastric cancer cells was observed by BALB/C tumor-forming experiments in nude mice. Tandem mass tag labeling combined with liquid chromatography–tandem mass spectrometry were used to screen for differentially expressed proteins extracted from GC cells and control cells after 18β-GRA intervention. Moreover, STRING database was used to predict protein-protein interaction (PPI) relationships and Western blot was used to detect the expression of proteins of interest in GC cells.

Research results

18β-GRA can inhibit the proliferation of gastric cancer cells, induce apoptosis, arrest the cell cycle at G0/G1 phase, and inhibit the migration and invasion of gastric cancer cells. 18β-GRA can inhibit tumor

formation in BALB/c nude mice. Compared with the control group, MRPL35 and BCL2L1 expression was significantly down-regulated and TP53 expression was up-regulated after 18β-GRA intervention. STRING analysis showed that COPS5, BAX, and BAD proteins could form PPI network with MRPL35, TP53, and BCL2L1 proteins. After 18β-GRA intervention, MRPL35, TP53, and BCL2L1 were up-regulated/down-regulated in a dose-dependent manner, as were COPS5, BAX, and BAD.

Research conclusions

18β-GRA can inhibit the proliferation of GC cells by regulating MRPL35, COPS5, TP53, BCL2L1, BAX, and BAD.

Research perspectives

MRPL35 can be used for targeted therapy of GC, and can also be used as a new biomarker for GC.

Abstract

BACKGROUND

A convolutional neural network (CNN) is a deep learning algorithm based on the principle of human brain visual cortex processing and image recognition.

AIM

To automatically identify the invasion depth and origin of esophageal lesions based on a CNN.

METHODS

A total of 1670 white-light images were used to train and validate the CNN system. The method proposed in this paper included the following two parts: (1) Location module, an object detection network, locating the classified main image feature regions of the image for subsequent classification tasks; and (2) Classification module, a traditional classification CNN, classifying the images cut out by the object detection network.

RESULTS

The CNN system proposed in this study achieved an overall accuracy of 82.49%, sensitivity of 80.23%, and specificity of 90.56%. In this study, after follow-up

pathology, 726 patients were compared for endoscopic pathology. The misdiagnosis rate of endoscopic diagnosis in the lesion invasion range was approximately 9.5%; 41 patients showed no lesion invasion to the muscularis propria, but 36 of them pathologically showed invasion to the superficial muscularis propria. The patients with invasion of the tunica adventitia were all treated by surgery with an accuracy rate of 100%. For the examination of submucosal lesions, the accuracy of endoscopic ultrasonography (EUS) was approximately 99.3%. Results of this study showed that EUS had a high accuracy rate for the origin of submucosal lesions, whereas the misdiagnosis rate was slightly high in the evaluation of the invasion scope of lesions. Misdiagnosis could be due to different operating and diagnostic levels of endoscopists, unclear ultrasound probes, and unclear lesions.

CONCLUSION

This study is the first to recognize esophageal EUS images through deep learning, which can automatically identify the invasion depth and lesion origin of submucosal tumors and classify such tumors, thereby achieving good accuracy. In future studies, this method can provide guidance and help to clinical endoscopists.

Key Words: Endoscopic ultrasonography; Convolutional neural network; Esophageal lesion; Automatically; Classify; Identify

Core Tip: Convolutional neural networks with self-learning abilities are an effective method in medical image classification, segmentation, and detection. Endoscopic ultrasonography plays an important role in the diagnosis and treatment of esophageal lesions. However, its operation and lesion identification are more difficult than ordinary endoscopy. Automatic identification technology is of great significance to its development.

INTRODUCTION

Endoscopic ultrasonography (EUS) is a mature and widely used invasive examination technology. It is a combination of ultrasound and endoscopy, and the micro high-frequency ultrasound probe is placed on the top of the endoscope to directly observe gastrointestinal mucosal lesions when the endoscope enters the body. It can be used for preoperative staging of digestive tract tumors[1], estimating the invasion depth and range[2], assessing the nature of submucosal lesions of the digestive tract wall[3-4], and diagnosing bilio-pancreatic system tumors[5-6]. The esophagus is the narrowest part of the digestive tract, and its diameter is not uniform. EUS can be used for high-precision evaluation of the esophagus. At present, common lesions of the esophagus include submucosal tumors (including leiomyoma, stromal tumor, and lipoma), precancerous lesions, and esophageal cancer.

China has a high incidence of esophageal cancer, and the current 5-year survival rate of esophageal cancer is 15%-25%[7-10]. A 13.5-year follow-up study has shown that 74% of patients with high-grade intraepithelial neoplasia (HGIN) have developed esophageal cancer[11]. Surgical and endoscopic resection (ER) has been approved as the standard treatment for esophageal HGIN, and endoscopic therapy has become a widely used method because of its safety, efficiency, and low risk of complications[12-13]. Compared with surgical treatment, endoscopic therapy can reduce complications and preserve esophageal function[9]. EUS plays an important role in the evaluation of esophageal lesions and in the determination of the need for surgery.

With the popularization of endoscopic ultrasonography in clinic, several endoscopic physicians are needed. However, endoscopic ultrasonography is different from other ultrasound techniques in that ultrasonic examination is performed on the basis of digestive endoscopy; therefore, the examiners should be professional endoscopic physicians with ultrasonic training. In addition, with the increase of chronic diseases, ageing populations, and dwindling resources, we need to shift to models that can intelligently extract, analyze, interpret, and understand increasingly complex data. The rapidly evolving

field of machine learning is a key to this paradigm shift. Artificial intelligence (AI) is a mathematical predictive technology that automatically learns and recognizes data patterns. Deep learning is an AI algorithm and an advanced machine learning method using neural networks[14]. This method aims to build a neural network that mimics brain's mechanisms for interpreting data, such as images, sounds, and text. Deep learning combines low-level features to form abstract high-level representation attribute categories or features and discover distributed feature representation of data. It is often used in AI algorithms, and it has been applied to medical diagnosis[15-18]. At present, relevant studies on deep learning in ultrasound have been found, including the classification of thyroid nodules[19-20], the diagnosis of liver diseases[21], the identification of benign and malignant breast masses[22], the imaging interpretation of carotid artery intima media thickness (FEATURED by its length)[23], and the prediction of the pancreatic ductal papillary mucinous tumor[5]. However, the research on the identification and classification of esophageal lesions by endoscopic ultrasonography has not yet been found.

This study aimed to construct a framework of deep learning network and study the application of deep learning in esophageal EUS in identifying the origin of submucosal lesions and defining the scope of esophageal lesions.

MATERIALS AND METHODS

The method proposed in this paper included the following two parts: (1) Location module, an object detection network, locating the main image feature regions of the image for subsequent classification tasks; and (2) Classification module, a traditional classification convolution neural network, classifying the images cut out by the object detection network. In the evaluation phase, all the metrics were calculated based on the ten-fold cross-validation results. The dataset was divided into the training (80%), testing (10%) and validating (10%) datasets, respectively. The detailed data statistics distribution from the esophageal lesion database is shown in Tables 1 and 2.

Location module

For gastric ultrasound images, identifying the classification of the whole image was not necessary because the introduction of background information can cause irrelevant features and affect the determination of the model. Therefore, the core area of the image was located, which can classify the image [24]. In this study, RetinaNet object detection network was used. RetinaNet network is a one-stage object detection method. It uses the focal loss cost function in the classification branch, which addresses the imbalance between positive and negative samples in one-stage object detection method.

Resnet50 network was used in the feature extraction part of RetinaNet network, and the FPN structure was added, that is, a top-down structure and lateral connection were adopted to detect the object of different scales. Finally, the features obtained were used to predict the classification branch and regression branch. The classification branch was retained; thus, the multitask training can improve the accuracy of the model, and it can be used to compare the experiment with the classification network (Figure 1).

For object detection anchor setting, this study adopted the default anchor setting methods, with anchor sizes of 32, 64, 128, 256, and 512 and aspect ratios of 1:2, 2:1, and 1:1.

Classification module

The object detection module cut out the core image block of the image and resize it to 224 × 224. Image augmentation artificially created training images through different ways of processing or combination of multiple processing, such as random rotation, shifts, shear, and flips, to address over-fitting and improve the generalization of the network (Table 3).

The classification convolution neural network used the VGGNet network. Compared with the previous network, the VGGNet network used small convolution and deeper network layers, which achieved better classification accuracy (ACC). The classification network was pre-trained on the ImageNet dataset. The last three fully connected layers of network were removed, and then two fully connected layers were added. The number of neurons was 256 and 5 (5 is the classification number of the dataset used in this paper; Figure 2).

Experiment

During the experiment, GPU configuration was a NVIDIA Geforce GTX1070ti. All the codes were written in Python 3.6, and keras was used as the deep learning library.

In the object detection experiment, smooth L1 cost function was used for regression, and focal loss cost function was used for classification. Adam was used as the optimizer, and the learning rate, momentum, and weight decay were set to 1e-5, 0.9, and 0.0005, respectively. The short side of the input image was rescaled to 800, and the long side was rescaled in equal proportion, with the maximum of 1333.

Table 1 Statistics distribution from esophageal lesion database

	Lesions invading the submucosa and muscularis mucosae	Lesions invading the muscularis propria	Lesions invading the serosal layer

Validation	59	47	9
Test	59	47	9
Total	591	470	92

Table 2 Statistics distribution from esophageal submucosal lesion database

	Lesions from the muscularis propria	Lesions from the muscularis mucosae
Train	119	294
Validation	15	37
Test	15	37
Total	149	368

Table 3 Data augmentation parameter

Transformation type	Description
Rotation	Degree range for random rotations: -90°- 90°
Shift	Shift fraction of total height and total width: 0.1
Zoom	Range for random zoom: 0.9-1.1
Flip	Randomly flip image horizontally and vertically.
Shear	Shear intensity: 0.2 (shear angle in counter-clockwise direction in degrees)

In the classification experiment, the cross-entropy loss function was used. The optimizer used SGD and set the initial learning rate to 1e-3. When the loss did not decrease, the learning rate was multiplied by a factor of 0.5 until it reached 1e-6. The batch size was set to 16.

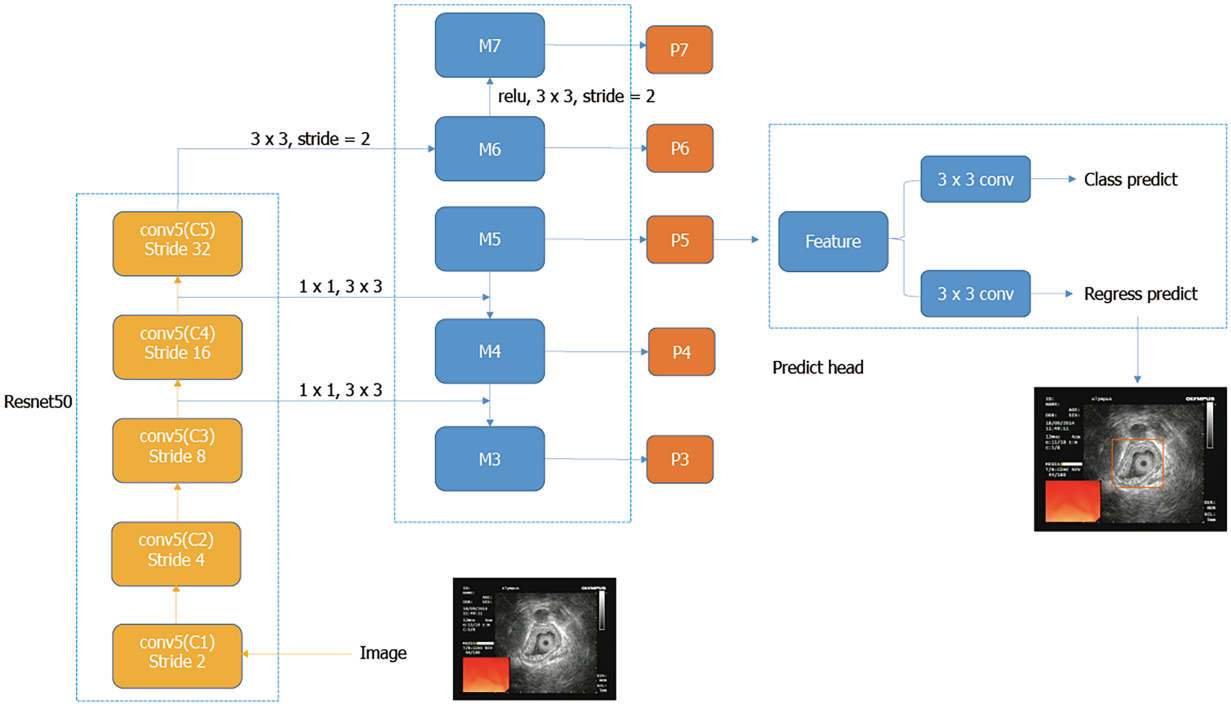
The quantitative and qualitative results of the proposed method were provided. A confusion matrix is a table that is often used to describe the performance of a classification model. Each row of the confusion matrix represents the instances of an actual class, and each column represents the instances of a predicted class. The diagonal values represent the number of correct classifications for each class, and the others represent the confusion number between every two classes. As shown in Figure 3, the ACC of using the classification network is improved compared with the classification branch of the object detection network, which is directly used for classification prediction. The classification ACC in the muscularis propria and muscularis mucosae increased significantly.

The classification performance was measured using sensitivity (SENS), specificity (SPEC), and ACC to clarify the evaluation metrics. Sensitivity measures how much a classifier can recognize positive examples. Specificity measures how much a classifier can recognize negative examples. ACC is the ratio of correct decisions made by a classifier. The sensitivity, specificity, and ACC were defined by equations (1)-(3):

$$SENS = TP / (TP + FN) \quad (1)$$

$$SPEC = TN / (FP + TN) \quad (2)$$

$$ACC = (TP + TN) / (TP + TN + FP + FN) \quad (3)$$



Where TP is the amount of positive elements predicted as positive; TN is the amount of negative elements predicted as negative; FP is the amount of negative elements predicted as positive; FN is the amount of positive elements predicted as negative.

As shown in Table 4, the classification network outperforms the classification branch of the object detection network in SENS, SPEC, and ACC. Class activation maps (CAM) can be used to obtain the discriminative image regions using a convolutional neural network and identify a specific class in the image. Therefore, a CAM can identify the regions in the image that were relevant to this class. The results of CAM are shown in Figure 4.

Table 4 Comparative sensitivity, specificity, and accuracy results of classification branch of object detection network and classification network alone

Figure 1 Structure of object detection network.

RESULTS

A total of 1115 patients were included in this analysis, including 694 males and 421 females. The age ranged from 24 to 88 years, with the majority of patients aged over 45 years. In this study, patients who underwent surgery or endoscopic treatment were followed for pathology, and 726 of them were compared for ultrasound diagnosis and endoscopic pathology. In the diagnosis of endoscopic ultrasonography, lesions invading the muscularis propria were not detected in 41 patients, and the misdiagnosis rate was approximately 9.5%. In addition, 36 patients showed pathologic invasion of the superficial muscularis propria. All patients with serosal invasion were treated by surgery, and the ACC rate was 100%. For the detection of submucosal lesions by EUS, the ACC was approximately 99.3% (Table 5).

Table 6 shows the ACC, SENS, and SPEC of each category in this study. The ACC of invasion of the serosa was 98.9%, and that of invasion of the muscularis propria and muscularis mucosa and submucosa was 73.4% and 77.11%, respectively. In submucosal lesions, the correct identification rate was 78.64% and 84.4%, respectively. The images of lesions originating from the muscularis mucosa were easily confused with the images of lesions invading the muscularis mucosa and submucosa.

DISCUSSION

Traditionally, the treatment for benign and malignant esophageal lesions is mostly surgery or chemoradiotherapy, but the surgical trauma and sequelae are relatively large. With the development of gastrointestinal endoscopy in recent years, some lesions can be treated by endoscopy, such as ER, particularly submucosal dissection, which has become the standard treatment for esophageal mucosal cancer [25-27]. In Japan, ER of esophageal cancer refers to the tumor located in the mucosal epithelium (T1A-EP

is equal to Tis *in situ* in the TNM stage[28]) or the proper mucosa (T1A-LPM) because the incidence of lymph node metastasis is low (≤ 5%)[29]. The recommended diagnostic methods are endoscopic ultrasonography[30], extended endoscopy, and narrow-band imaging (ME-NBI)[31].

Endoscopic ultrasonography plays an important role in the diagnosis and treatment of benign and malignant esophageal lesions. Xu *et al*[3] compared postoperative histological diagnosis with preoperative EUS diagnosis in patients with esophageal leiomyoma, and the diagnostic ACC of EUS was 88.6%. No treatment-related complications occurred in patients undergoing ER, and no recurrence was found in follow-up examination. In addition, Rana *et al*[32] found that small-probe EUS could predict the response to endoscopic dilation by describing the involvement degree of esophageal benign

Figure 4 Class activation map results.

stenosis and measuring the thickness of the wall. Therefore, EUS plays an important role in the diagnosis of digestive tract diseases. In this study, after follow-up pathology, 726 of the patients were compared with endoscopic pathology. The misdiagnosis rate of endoscopic diagnosis in the lesion invasion range was approximately 9.5%; 41 patients did not show lesion invasion to the muscularis propria, but 36 of them pathologically showed invasion to the superficial muscularis propria. The patients with invasion of the tunica adventitia were all treated by surgery with an ACC rate of 100%. For the examination of submucosal lesions, the ACC of EUS was approximately 99.3%. The results of this study showed that endoscopic ultrasonography had a high ACC rate for the origin of submucosal lesions, and the misdiagnosis rate was slightly higher in the evaluation of the invasion scope of lesions. Misdiagnosis might be due to the different operating and diagnostic levels of endoscopists, unclear ultrasound probes, and unclear lesions. However, when we underestimated the depth of infiltration, the disadvantage became smaller because ER combined with additional chemoradiotherapy and surgical treatment could achieve good therapeutic effects[33-34]. However, the use of EUS is difficult for non-specialist endoscopist. Therefore, a more advanced measurement method is necessary to help non-

specialists achieve diagnostic quality comparable to that of specialists without special techniques.

Deep learning is a new technique to evaluate image information objectively. In recent years, with the application of deep learning in various medical fields, remarkable progress has been made. AI is also becoming popular in ultrasonic examination. Kuwahara *et al*[5] predicted benign and malignant IPMNs by studying endoscopic ultrasonography of intraductal papillary mucinous tumors of the pancreas (IPMNs). The results showed that the SENS, SPEC, and ACC of AI for diagnosing malignant probability were 95.7%, 92.6%, and 94.0%, respectively, which were higher than those of human diagnosis. Although few studies have been conducted on AI in endoscopic ultrasonography, the diagnosis based on deep learning has shown its advantages. In this study, we found that deep learning algorithm could be used to clear the invasion scope and origin of lesions in endoscopic ultrasound images. In addition, VGGNet was used to perform classification tasks, and multiple superimposed filters were used to increase the nonlinearity of the whole function and reduce the number of parameters. The overall ACC, SENS, and SPEC were 82.49%, 80.23%, and 90.56%, respectively. However, in this study, the images of lesions invading the mucosal musculus and submucosa were easily confused with the images of lesions from the mucosal musculus, which may be caused by the lack of evident stratification due to tube wall compression or by the excessive noise in the ultrasound images caused by small lesions. No study has been conducted on the application of deep learning-based endoscopic ultrasonography in the esophagus or gastrointestinal tract, and the network framework applicable to endoscopic ultrasonography needs further screening and testing.

This study has some limitations. First, different probes or operators in endoscopic ultrasound images lead to uneven image quality levels, which may explain the low ACC in this study. Second, in this study, although the endoscopic ultrasonography probe could see seven layers of tube wall, 1-3 layers were classified into one category because the resolution of 1-3 layers was not clear in most images. Finally, the number of endoscopic ultrasound images was small, and all images were obtained from one center. Therefore, in the following study, we will obtain multi-center samples to increase the sample size and improve the image quality.

CONCLUSION

This study is the first to recognize esophageal endoscopic ultrasonography images through deep learning, which can automatically identify the lesion invasion depth and lesion source of submucosal tumors and classify such tumors, thereby achieving good ACC. In future studies, this method can provide guidance and help to clinical endoscopists.

ARTICLE HIGHLIGHTS

Research background

The esophagus is the narrowest part of the digestive tract and its diameter is not uniform. Endoscopic ultrasonography (EUS) can be used for high-precision evaluation of the esophagus. With the popularization of endoscopic ultrasonography in clinic, more and more endoscopic physicians are needed. The rapidly evolving field of machine learning is key to this paradigm shift.

Research motivation

Endoscopic ultrasonography is different from other ultrasound modalities in that ultrasonic examination is performed on the basis of digestive endoscopy, so the examiners should be professional endoscopic physicians with ultrasonic training. And as we face the interplay of increasing chronic diseases, ageing populations, and dwindling resources, we need to shift to models that can intelligently extract, analyze, interpret, and understand increasingly complex data. However, the research on the identification and classification of esophageal lesions by endoscopic ultrasonography has not yet been found.

Research objectives

The purpose of this study was to construct a framework of deep learning network to study the application of deep learning in esophageal EUS in identifying the origin of submucosal lesions and defining the scope of esophageal lesions.

Research methods

A total of 1670 white-light images were used to train and validate the convolutional neural network (CNN) system. In the study, VGGNet was used to perform classification tasks, and multiple superimposed filters were used to increase the nonlinearity of the whole function and reduce the number of parameters.

Research results

A total of 1115 patients were included in this analysis, including 694 males and 421 females. The overall accuracy, sensitivity, and specificity were 82.49%, 80.23%, and 90.56% respectively. The images of lesions originating from the muscularis mucosa were easily confused with the images of lesions invading the muscularis mucosa and submucosa.

Research conclusions

This study constructed a CNN system which can automatically identify the lesion invasion depth and the lesion source of submucosal tumors, and classify them, achieving good accuracy.

Research perspectives

In the future of medicine, artificial intelligence will reduce the workload of medical staff and make targeted tests more accurate, and in future studies, it can provide guidance and help to clinical endoscopists.

Abstract

BACKGROUND

Pancreatic ductal adenocarcinoma (PDAC) is one of the most lethal malignancies with high mortality and short survival time. Computed tomography (CT) plays an important role in the diagnosis, staging and treatment of pancreatic tumour. Pancreatic cancer generally shows a low enhancement pattern compared with normal pancreatic tissue.

AIM

To analyse whether preoperative enhanced CT could be used to predict postoperative overall survival in patients with PDAC.

METHODS

Sixty-seven patients with PDAC undergoing pancreatic resection were enrolled retrospectively. All patients underwent preoperative unenhanced and enhanced CT examination, the CT values of which were measured. The ratio of the preoperative CT value increase from the nonenhancement phase to the portal venous phase between pancreatic tumour and normal pancreatic tissue was calculated. The cut-off value of ratios was obtained by the receiver operating characteristic (ROC) curve of the tumour relative enhancement ratio (TRER), according to which patients were divided into low- and high-enhancement groups. Univariate and multivariate analyses were performed using Cox regression based on TRER grouping. Finally, the correlation between TRER and clinicopathological characteristics was analysed.

RESULTS

The area under the curve of the ROC curve was 0.768 ($P < 0.05$), and the cut-off value of the ROC curve was calculated as 0.7. TRER ≤ 0.7 was defined as the low-

enhancement group, and TRER > 0.7 was defined as the high-enhancement group. According to the TRER grouping, the Kaplan-Meier survival curve analysis results showed that the median survival (10.0 mo) with TRER ≤ 0.7 was significantly shorter than that (22.0 mo) with TRER > 0.7 (P < 0.05). In the univariate and multivariate analyses, the prognosis of patients with TRER ≤ 0.7 was significantly worse than that of patients with TRER > 0.7 (P < 0.05). Our results demonstrated that patients in the low TRER group were more likely to have higher American Joint Committee on Cancer stage, tumour stage and lymph node stage (all P < 0.05), and TRER was significantly negatively correlated with tumour size (P < 0.05).

CONCLUSION

TRER ≤ 0.7 in patients with PDAC may represent a tumour with higher clinical stage and result in a shorter overall survival.

Key Words: Pancreatic cancer; Computed tomography; Diagnostic imaging; Kaplan-Meier curve; Prognosis; Survival analysis

Core Tip: Computed tomography (CT) plays an important role in the diagnosis, staging and treatment of pancreatic tumours. Pancreatic cancer generally shows a low enhancement pattern compared with normal pancreatic tissue. In our analysis, the prognosis of patients with the tumour relative enhancement ratio (TRER) less than or equal to 0.7 was significantly worse than that of patients with TRER greater than 0.7. TRER was significantly correlated with American Joint Committee on Cancer stage, tumour stage, and lymph node stage. Preoperative enhanced CT provides a simple and effective prediction of postoperative overall survival in pancreatic ductal adenocarcinoma.

INTRODUCTION

Pancreatic adenocarcinoma is a highly malignant tumour with an estimated 56770 new cases and 45750 deaths in the United States in 2019, according to the American Cancer Society[1]. Very few patients with pancreatic adenocarcinoma have the opportunity for surgical treatment due to the low early diagnosis rate[2]. Surgery is the only potential curative treatment for resectable pancreatic cancer, and adjuvant chemotherapy, mainly gemcitabine-based regimen, is often used to improve outcome[3,4]. In recent years, neoadjuvant chemoradiotherapy has shown efficacy in improving the prognosis of patients with pancreatic cancer[5]. However, the overall prognosis is still unsatisfactory, with a 5-year survival rate as low as 8%[6]. Considering the extremely poor prognosis of pancreatic cancer, it is important to identify indicators of poor prognosis preoperatively or postoperatively. Currently, multiple diagnostic techniques are used to evaluate the aggressiveness or malignancy of pancreatic cancer to formulate the best treatment plan.

A previous study on endoscopic ultrasonography showed that the strain rate of the tumour was positively correlated with the stromal ratio of pancreatic cancer. The stroma of the tumour contributes to tumour growth and progression and plays an important role in chemotherapy resistance. Patients with a high strain rate had a poor prognosis postsurgery, but the survival of locally advanced pancreatic cancer patients receiving nab-paclitaxel and gemcitabine regimen chemotherapy had been improved[7]. Another study showed that tumour size, tumour-lymph node-metastasis (TNM) stage and distant metastasis were significantly correlated with overall survival (OS) in pancreatic cancer[8]. Computed tomography (CT) imaging has been widely used in the diagnosis, staging and treatment planning of pancreatic cancer[9]. Pancreatic cancer tumours generally show a low enhancement pattern compared with normal pancreatic tissue[10]. CT texture analysis is also used to evaluate the prognosis of pancreatic cancer[11,12]. Low vascular distribution and high metabolism in pancreatic cancer are important factors in evaluating invasiveness[13].

The purpose of this study was to evaluate the prognostic value of preoperative enhanced CT as a quantitative imaging biomarker in patients with pancreatic cancer based on the imaging characteristics

of poor blood supply and CT examination.

MATERIALS AND METHODS

Patient population

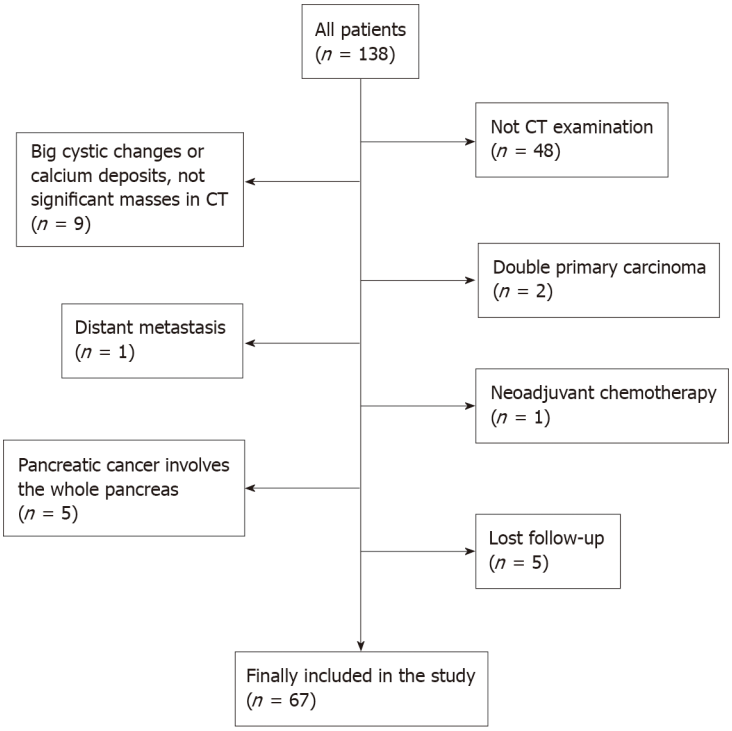
The Ethics Committee of Fujian Medical University Union Hospital, Fuzhou, China, approved this retrospective study and waived the requirement for informed consent (No. 2020KY0141).

From March 2011 to May 2018, a total of 138 consecutive patients diagnosed with pancreatic adenocarcinoma who underwent surgical resection in our department were reviewed. The last follow-up time was February 2020. The inclusion criteria were as follows: (1) Age over 18 years; (2) no neoadjuvant chemoradiotherapy and no previous history of gastrointestinal and pancreatic surgery; (3) nonenhanced and enhanced CT performed within 30 days before surgery; and (4) pancreatic adenocarcinoma confirmed by postoperative pathology. The exclusion criteria were as follows: (1) Stage IV pancreatic cancer; (2) severe complications or multiple primary cancers; (3) obvious pancreatic parenchymal atrophy, large cystic changes of the tumour and calcareous deposition; and (4) loss to follow-up. Patient sex, age, preoperative CT images, preoperative serum carbohydrate antigen 19-9 (CA19-9), tumour site, tumour size, American Joint Committee on Cancer (AJCC) (2017) TNM staging, lymph node metastasis, postoperative pathology and differentiation grade, postoperative OS and other data were collected for analysis.

CT image acquisition

CT examination was performed on a 16-row CT scanner (Bright Speed Elite, GE Health care, United States) or a 64-row CT scanner (Discovery CT750 HD, GE Health care, United States). The CT scanning parameters for all phases were as follows: Gantry rotation speed, 0.5 s; tube voltage, 120 kVp; effective amperage, 210 mAs-260 mAs; matrix, 512 × 512; field of view, 350 mm-512 mm; and slice thickness, 5-10 mm. After a nonenhanced scan, 1.5 mL/kg of nonionic contrast agent (ioversol injection, 320 mg of iodine per millilitre, Jiangsu Hengrui Medicine Co., LTD, Jiangsu Province, China) was injected with an automatic syringe at 3.0 mL/s. Using the bolus-tracking technique, a pancreatic parenchymal (PP) phase scan was performed 7 s after the enhanced value of the descending aorta at the aortic hiatus reached 150 HU, and a portal venous (PV) phase scan was performed 25 s after the PP phase scan. CT imaging data were uploaded to the Picture Archiving and Communication System (PACS) (Guangzhou YLZ Ruitu Information Technology Co., LTD, Guangzhou, Guangdong Province, China). In the process of collecting and reviewing the CT imaging results of the patient's imaging data, we tried our best to make the quality of each patient's tumour image meet our requirements.

The CT images and tumour relative enhanceement ratio (TRER) were analysed by two experienced radiologists using PACS. The region of the overall tumour (ROT) was delineated along the tumour edge at the largest and most visible level. Four regions of interest (ROIs) with diameters of 0.2-0.3 cm were randomly selected from the normal pancreatic tissue that were more than 1.0 cm away from ROT while avoiding obvious blood vessels, pancreatic ducts, pancreatic fissures and sites susceptible to intestinal gas interference. The average CT values of these 4 ROIs were used as CT values of pancreatic tissue outside the tumour (PTOT).



Tumour enhancement amplitude (TEA) = ROT value of the PV phase – ROT value of the nonenhancement phase.

Pancreas enhancement amplitude outside tumour (PEA) = PTOT value of the PV phase – PTOT value of the nonenhancement phase.

TRER = TEA/PEA.

Statistical analysis

SPSS 25.0 for Windows software from IBM was used to establish a database for statistical analysis. Among the patients' baseline data, those with a normal distribution of measurement data were represented by the mean ± SD, and an independent sample *t* test was used for comparisons between groups. The data with a nonnormal distribution were represented by the median and interquartile spacing, and comparisons between groups were tested by the nonparametric Mann-Whitney *U* test. Enumeration data were expressed in terms of frequency, and comparisons between groups were performed by the chi-squared test or Fisher's exact test. In the analysis of the relationship between TRER and OS, a receiver operating characteristic (ROC) curve was drawn. When the ROC curve was obtained, the "Coordinates of the Curve" and the corresponding "Sensitivity" and "1-Specificity" could be obtained, and their corresponding Youden indices could be calculated. The TRER corresponding to the maximum value of all Youden indices was the cut-off value of the ROC curve. The patients were divided into two groups according to the cut-off value. The corresponding survival curve was estimated by the Kaplan-Meier method (log-rank test). Cox regression was performed for the univariate (enter model) and multivariate analyses (forward LR model). In the case of correlation analysis between TRER and clinicopathological characteristics, when the clinicopathological features were grouped as unordered categorical variables, the chi-squared test was used for analysis and the Cramer's V

DOI: 10.3748/wjg.v28.i22.2468 **Copyright** ©The Author(s) 2022.

Figure 1 The study flowchart for patient selection. CT: Computed tomography.

correlation coefficient was calculated; When the clinicopathological features were grouped as ordinal categorical variables, Spearman rank correlation was used for analysis and the Spearman's correlation coefficient was calculated. The results were considered statistically significant below the bilateral 5% significance level.

RESULTS

Patient characteristics

Of 138 patients, a total of 71 were excluded from the study (a flowchart of patient selection is shown in Figure 1). Ultimately, 67 patients were enrolled in the study. The clinical characteristics of the 67 patients in our study are summarized in Table 1. The mean age of 67 patients was 60.2 ± 10.0 (range, 35-80) years old, with 42 males (62.7%). The tumour was located in the head or uncinate of the pancreas in 44 patients (65.7%) and other sites in 23 patients (34.3%). The median postoperative OS of all patients was 12.3 mo (range, 1.7-42.8 mo).

CT value, TRER and CT enhancement situation

The CT values of the nonenhancement and PV phases in tumour and extratumoural regions are shown in Table 2. The median TRER was 0.57 (interquartile range, 0.41-0.78).

In the analysis of CT images, we also found that the CT values of ROT and PTOT gradually increased from the nonenhancement phase to the PV phase, but not all CT values of the PV phase were higher than those of the PP phase (Table 3).

Survival analysis

The ROC curve was drawn according to TRER, as shown in Figure 2A. The area under the curve of the ROC curve was 0.768 (P = 0.007). The cut-off value of the ROC curve was calculated to be 0.7, and the patients were classified according to the cut-off value. TRER ≤ 0.7 was defined as the low-enhancement group, TRER > 0.7 was defined as the high-enhancement group, and the Kaplan-Meier survival curve analysis results showed that the median survival (10.0 mo) with TRER ≤ 0.7 was significantly worse than that (22.0 mo) with TRER > 0.7 (P < 0.05) (Figure 2B). Typical CT images of the low- and high-enhancement groups are shown in Figures 3 and 4, respectively.

There was no significant difference in age, sex, tumour location, CA19-9, tumour differentiation, vascular invasion, surgical margin or adjuvant chemotherapy distribution between the low-and high-enhancement groups except the AJCC stage (P = 0.015) (Table 4).

Table 1 Patient characteristics, *n* (%)

Patient characteristics	*n* = 67
Age (yr)	
≤ 60	31 (46.3)
> 60	36 (53.7)
Sex	
Male	42 (62.7)
Female	25 (37.3)
Tumour location	
Head/uncinate	44 (65.7)

CA19-9: Carbohydrate antigen 19-9; AJCC: American Joint Committee on Cancer.

Univariate and multivariate analyses

Univariate and multivariate analyses of Cox regression were performed for clinical data and TRER (Tables 5 and 6). In the univariate analysis, AJCC stage (P = 0.005), preoperative CA19-9 (P = 0.033), postoperative adjuvant chemotherapy (P = 0.000) and TRER (P = 0.001) were significantly correlated with postoperative OS, while other factors had no significant influence on postoperative OS. In the multivariate analysis, preoperative CA19-9 (P = 0.015), tumour differentiation (P = 0.001), surgical margin (P = 0.008), postoperative adjuvant chemotherapy (P = 0.000) and TRER (P = 0.009) were significantly correlated with postoperative OS.

Correlation between TRER and clinicopathological characteristics

A correlation analysis was conducted between TRER and clinicopathological characteristics (Table 7). The results showed that TRER was not significantly correlated with tumour location, preoperative serum CA19-9, lymph node metastasis, vascular invasion, or tumour differentiation (all P > 0.05). However, TRER was significantly correlated with AJCC stage (P = 0.003, Spearman correlation coefficient = -0.353), T stage (P = 0.005, Cramer's V correlation coefficient = 0.343), and N stage (P = 0.046, Spearman correlation coefficient = -0.245). The analysis of the relationship between TRER and

Figure 2 The receiver operating characteristic curve and Kaplan-Meier survival curve analysis. A: The receiver operating characteristic curve of tumour relative enhancement ratio (TRER) for patients with pancreatic ductal adenocarcinoma. The area under the curve was 0.768 (P = 0.007). The cut-off value was 0.7; B: Kaplan-Meier survival curve of postoperative overall survival for low-TRER patients and high-TRER patients. TRER: Tumour relative enhancement ratio.

tumour size showed that TRER was negatively correlated with tumour size (P = 0.001) (Figure 5).

DISCUSSION

Pancreatic cancer is a tumour with a very poor prognosis. CT plays important roles in the diagnosis of pancreatic cancer and the evaluation of the relationship between tumours and peripheral blood vessels. Our study found the clinical value of enhanced CT as a quantitative image in predicting the prognosis of pancreatic cancer.

For patients with pancreatic cancer, TNM staging, tumour size, lymph node positive rate, log odds of positive lymph nodes, R0 resection and other factors are related to patient recurrence-free survival and OS[14-16]. Our analysis results showed that patients in the low TRER group were more likely to have higher TNM stage, T stage and N stage, and TRER was significantly negatively correlated with tumour size, demonstrating that TRER could be used to predict the postoperative OS of pancreatic cancer. However, in our study, the tumour stage (AJCC) was significant in the univariate analysis but not in the multivariate analysis. This difference might be due to the relatively small sample size. Many imaging techniques combining qualitative and quantitative information with pathological findings of the tumour have been used to analyse the aggressiveness of the tumour to determine the prognosis of the patient from preoperative imaging information. Dynamic contrast-enhanced CT (DCE-CT) also shows potential value in predicting tumour response to treatment and outcome[17,18].

Currently, the qualitative analysis of CT images has gained increasing attention for the prognostic analysis of pancreatic cancer. Pancreatic adenocarcinoma, unlike other solid tumours, is known as a cold tumour with insufficient blood supply. The pathological type of 90% pancreatic cancer is invasive ductal adenocarcinoma, which is one of the most stromal malignant tumours[19,20]. The pancreas is a retroperitoneal organ, very close to the common hepatic artery, celiac artery, portal vein, superior

mesenteric vessels, and splenic vessels. As pancreatic cancer progresses, it has early infiltration or perivascular desmoplastic reactions, which can influence its direct blood supply. The correlation analysis in our study showed that the vascular invasion rate in the low TRER group was higher (31.8%) than that in the high TRER group (8.7%), but $P = 0.071$, which might be due to the relatively small sample size.

In our study, we did not find any relationship between TRER and pathological differentiation of pancreatic cancer. However, a previous study on DCE-CT showed that pancreatic tumour CT enhancement was negatively correlated with pathological grade and the degree of malignancy[21,22]. In pancreatic cancer, fibroblast hyperplasia and vascular reduction are caused by a high fibrinolysis response, which results in a low-enhancement CT pattern compared with PTOT[23]. Some studies have shown that there is no significant difference in the perfusion values of the pancreatic head, body and tail

Figure 3 A 61-year-old woman with a mass in the head of the pancreas. A-C: The nonenhancement phase (A), pancreatic parenchymal (PP) phase (B) and portal venous (PV) phase (C) of region of the overall tumour, respectively; D-F: The nonenhancement phase (D), PP phase (E) and PV phase (F) of pancreatic tissue outside the tumour, respectively. Tumour relative enhancement ratio ≤ 0.7, and the postoperative overall survival was 5.5 mo.

in normal pancreatic tissues, while the perfusion values and blood flow in the tumour centre of pancreatic cancer patients are lower than those of PTOT[24,25]. Some researchers have reported that necrosis within pancreatic adenocarcinoma influences tumour enhancement on CT[26,27]. Tumour necrosis is the final result of hypoxia, which can accelerate the progression of malignant tumours[28,29]. It is well known that larger tumours are more prone to necrosis. The indirect relationship between large tumours and weakened CT enhancement was confirmed in our research. The TRER also indirectly reflects the necrosis of the tumour. A previous study showed that patients with low CT values in pancreatic tumours at the parenchymal stage, portal venous stage, and delayed stage had shorter postoperative survival times in the univariate analysis, whereas the CT values at the pancreatic tumour parenchymal stage were positively correlated with prognosis in the multivariate analysis[30]. When Cassinotto *et al*[31] measured the average attenuation value of the overall tumour and the lowest attenuation value in the tumour centre at the PV phase, they found that lower attenuation values at the PV phase reflected higher degree of malignancy, more likely lymph node invasion, and shorter disease-free survival. The lowest attenuation in the tumour centre also reflected the degree of necrosis within the tumour tissue. However, if only the changes in pancreatic tumours after CT enhancement were analysed, it would be easy to ignore the changes in PTOT. Due to the lack of control, the difference in enhancement amplitude between ROT and PTOT could not be analysed, which would lead to the inability to analyse whether the change was caused by the tumour itself or by the blood supply of the pancreatic organs as a whole. Visually isoattenuating pancreatic cancer is defined as when the attenuation of the tumour, compared with the pancreatic parenchyma, is not visually observed to increase or decrease at both arterial and portal venous phases. In this type of tumour, the number of cancer cells is lower, the degree of tumour necrosis is lower, the prognosis is better, and an increase in serum CA19-9 is rare[27]. In our study, although the scanning period selected was the nonenhancement and PV phases, which were different from the study of visually isoattenuating pancreatic cancer, they essentially reflected the increase in tumour CT value after enhanced CT examination, and the results

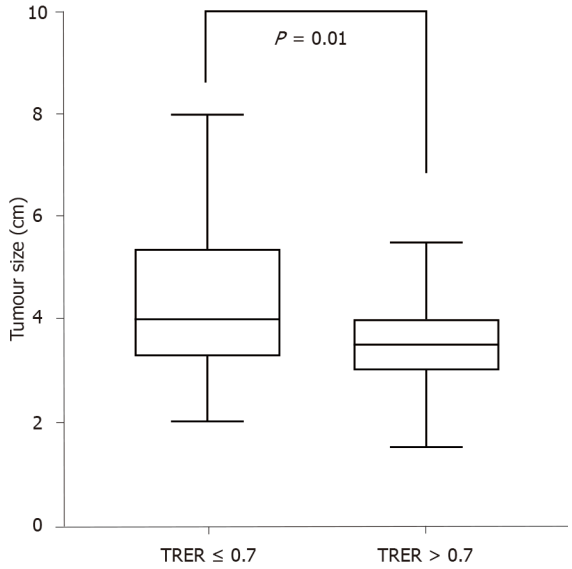
[1]Spearman rank correlation was used, and Spearman correlation coefficient was calculated. The other variables were tested by chi-square test, and Cramer's V correlation coefficient was calculated.

CA19-9: Carbohydrate antigen 19-9; AJCC: American Joint Committee on Cancer; TRER: Tumour relative enhancement ratio.



were similar; that is, patients with lower tumour CT enhancement amplitude had shorter OS. At the same time, we found no correlation between TRER and the increase in CA19-9. In Zhu *et al*'s study, the relative enhancement change (REC) was defined as the proportion of enhancement change between the tumour and pancreatic parenchyma during the PP and PV phases, showing that the postoperative OS of patients with REC < 0.9 was worse than those with REC ≥ 0.9[32]. Pancreatic cancer tissues are rich in fibrous tissue and show a pattern of delayed enhancement. However, our data showed that not all CT values of the PV phase were higher than those of the PP phase, regardless of ROT or PTOT. The CT value of the PV phase minus that of the PP phase may be negative. Therefore, when we designed the study, CT values of the PV and nonenhancement phases were selected for comparison. The final results showed that patients with a smaller TRER had worse a prognosis.

Although TRER is associated with AJCC stage, T stage, and N stage, it is not a substitute for lymph node status, tumour size, or stage. Pancreatic cancer is a kind of cold tumour with abundant stroma, and the stroma contributes to tumour growth and progression and plays an important role in the chemoresistance. This pathological feature of pancreatic cancer is similar to the pathological differentiation of tumours. It represents the characteristics of the pathology and growth of pancreatic cancer itself and will not disappear because the tumour is removed. The low-enhancement mode of CT in pancreatic

Figure 5 Correlation analysis between tumour size and tumour relative enhancement ratio. TRER: Tumour relative enhancement ratio.

cancer is partly due to the high stromal ratio of pancreatic cancer. Based on this, TRER is used as a quantitative reflection of the low-enhancement mode of CT in pancreatic cancer and the richness of pancreatic cancer stroma, which is used to predict postoperative OS. Moreover, because the postoperative prognosis of patients with low TRER is poor, such patients can consider whether to receive neoadjuvant chemotherapy.

Because tumour heterogeneity is affected by tumour blood supply, the ratio of tumour cells to stromal cells and tumour necrosis will lead to different CT values in different parts of the tumour. Although whole-volume quantitative analysis of tumour CTs is currently available, it has not been analysed in our study for the following reasons: (1) At the largest and most visible level of the tumour in CT images, the change of the tumour relative to surrounding tissue is relatively obvious, and it is easy to identify the boundary of the tumour. Moreover, it is simple to obtain the average CT value of ROT; and (2) compared with the largest level of the tumour, the CT value of the whole volume may be more easily affected by the obvious blood vessels and dilated pancreatic duct in the tumour.

There are several limitations in our study: (1) This was a retrospective study with a relatively small sample size at a single institution; (2) patients with metastasis were not studied; and (3) patients

received a variety of postoperative treatments, making it difficult to further accurately classify and perform a survival analysis, which might lead to a degree of bias.

CONCLUSION

In conclusion, TRER is a quantitative index of CT enhancement. This study showed that when the TRER of pancreatic adenocarcinoma patients was not more than 0.7, the prognosis was significantly worse, demonstrating the prognostic value of preoperative enhanced CT as a quantitative imaging biomarker in patients with pancreatic cancer.

ARTICLE HIGHLIGHTS

Research background

Computed tomography (CT) is widely used in the diagnosis, staging and treatment of pancreatic tumours. Because being rich in stroma, pancreatic cancer generally shows a low enhancement pattern compared with normal pancreatic tissue.

Research motivation

We want to use preoperative enhanced CT as a quantitative imaging biomarker to accurately predict the prognosis of patients with pancreatic cancer.

Research objectives

To analyse prognostic value of preoperative enhanced CT in pancreatic cancer.

Research methods

Sixty-seven patients with pancreatic ductal adenocarcinoma undergoing pancreatic resection were enrolled retrospectively. All patients underwent preoperative unenhanced and enhanced CT examination, the CT values of which were measured. The ratio of the preoperative CT value increase from the nonenhancement phase to the portal venous phase between pancreatic tumour and normal pancreatic tissue was calculated. The cut-off value of ratios was obtained by the receiver operating characteristic curve of the tumour relative enhancement ratio (TRER), according to which patients were divided into low- and high-enhancement groups. Cox regression was performed for the univariate (enter model) and multivariate analyses (forward LR model). Finally, Spearman rank correlation or chi-square test was used to analyse the correlation between TRER and clinicopathological characteristics.

Research results

TRER is a quantitative index of enhancement CT. This study showed that the prognosis of patients with the TRER ≤ 0.7 was significantly worse. TRER is a simple and effective parameter. Our results demonstrated that patients in the low TRER group were more likely to have higher American Joint Committee on Cancer stage, tumour stage, lymph node stage, and TRER was significantly negatively correlated with tumour size.

Research conclusions

TRER is a quantitative indicator of enhanced CT and can be used to predict postoperative overall survival in pancreatic cancer.

Research perspectives

In the future, we will further study the value of preoperative enhanced CT in predicting the efficacy of chemotherapy.

Abstract

BACKGROUND

The appearance of the intestinal mucosa during endoscopy varies among patients with primary intestinal lymphangiectasia (PIL).

AIM

To classify the endoscopic features of the intestinal mucosa in PIL under endoscopy, combine the patients' imaging and pathological characteristics of the patients, and explain their causes.

METHODS

We retrospectively analyzed the endoscopic images of 123 patients with PIL who were treated at the hospital between January 1, 2007 and December 31, 2018. We compared and analyzed all endoscopic images, classified them into four types according to the endoscopic features of the intestinal mucosa, and analyzed the post-lymphographic computed tomography (PLCT) and pathological characteristics of each type.

RESULTS

According to the endoscopic features of PIL in 123 patients observed during endoscopy, they were classified into four types: nodular-type, granular-type, vesicular-type, and edematous-type. PLCT showed diffuse thickening of the small intestinal wall, and no contrast agent was seen in the small intestinal wall and mesentery in the patients with nodular and granular types. Contrast agent was scattered in the small intestinal wall and mesentery in the patients with vesicular and edematous types. Analysis of the small intestinal mucosal pathology revealed that nodular-type and granular-type lymphangiectasia involved the small intestine mucosa in four layers, whereas ectasia of the vesicular- and edematous-type lymphatic vessels largely involved the lamina propria mucosae, submucosae, and muscular layers.

CONCLUSION

Endoscopic classification, combined with the patients' clinical manifestations and pathological examination results, is significant and very useful to clinicians when scoping patients with suspected PIL.

Key Words: Primary intestinal lymphangiectasia; Endoscopic features; Post-lymphangiographic computed tomography; Pathology

Core Tip: Primary intestinal lymphangiectasia (PIL) is a rare disorder that typically presents as protein-losing enteropathy, diarrhea, and limb edema. Here we analyzed the endoscopic presentation, post-lymphographic computed tomography findings, and pathological features of 123 patients with PIL. We classified PIL into four categories - nodular, granular, vesicle, and edema types, proposed the theory of nodular and vesicle types domestically through observation, and made breakthroughs in overcoming the issue of inaccurate diagnosis based on a few independent early-stage case reports.

INTRODUCTION

Primary intestinal lymphangiectasia (PIL), also known as Waldmann disease, is a type of abnormal intestinal lymphatic drainage that may be caused by congenital dysplasia of the lymphatic system[1]. Infants, children, and adolescents account for a large proportion of PIL patients, with occasional reports of cases in middle-aged and elderly patients[2]. PIL can cause leakage of lymphatic fluid into the gastrointestinal tract, eventually leading to protein-losing enteropathy (PLE). The main symptoms include diarrhea with limb edema, hypoalbuminemia, lymphopenia, and hypogammaglobulinemia[3, 4]. Prasad *et al*[5] concluded that the interval between symptom onset and a definitive diagnosis of PIL was as long as 54.8 mo due to the lack of knowledge of PIL by most clinicians, and their diagnosis relied on specialized examinations, such as endoscopy and histological diagnosis. At present, the diagnostic basis of such diseases includes visible typical endoscopic features, such as swelling and whitening of the intestinal villi, visible lymphangiectasis seen in the mucosa and submucosa through histopathological intestinal mucosal biopsy, and the characteristics of immunohistochemistry D2-40+[6].

As a rare disease, PIL is rarely reported domestically or internationally, and most reports have involved individual cases. Endoscopic images of individual cases revealed that patients had different mucosal manifestations, such as pinpoint white dots, diffuse villi thickening and whitening, and white spots[7-9]. A retrospective analysis of endoscopic images of patients diagnosed with PIL during a 12-year period at our research center summarized and classified them into four distinct endoscopic features and further explored the differences in radiologic and pathologic features of the different endoscopic features.

MATERIALS AND METHODS

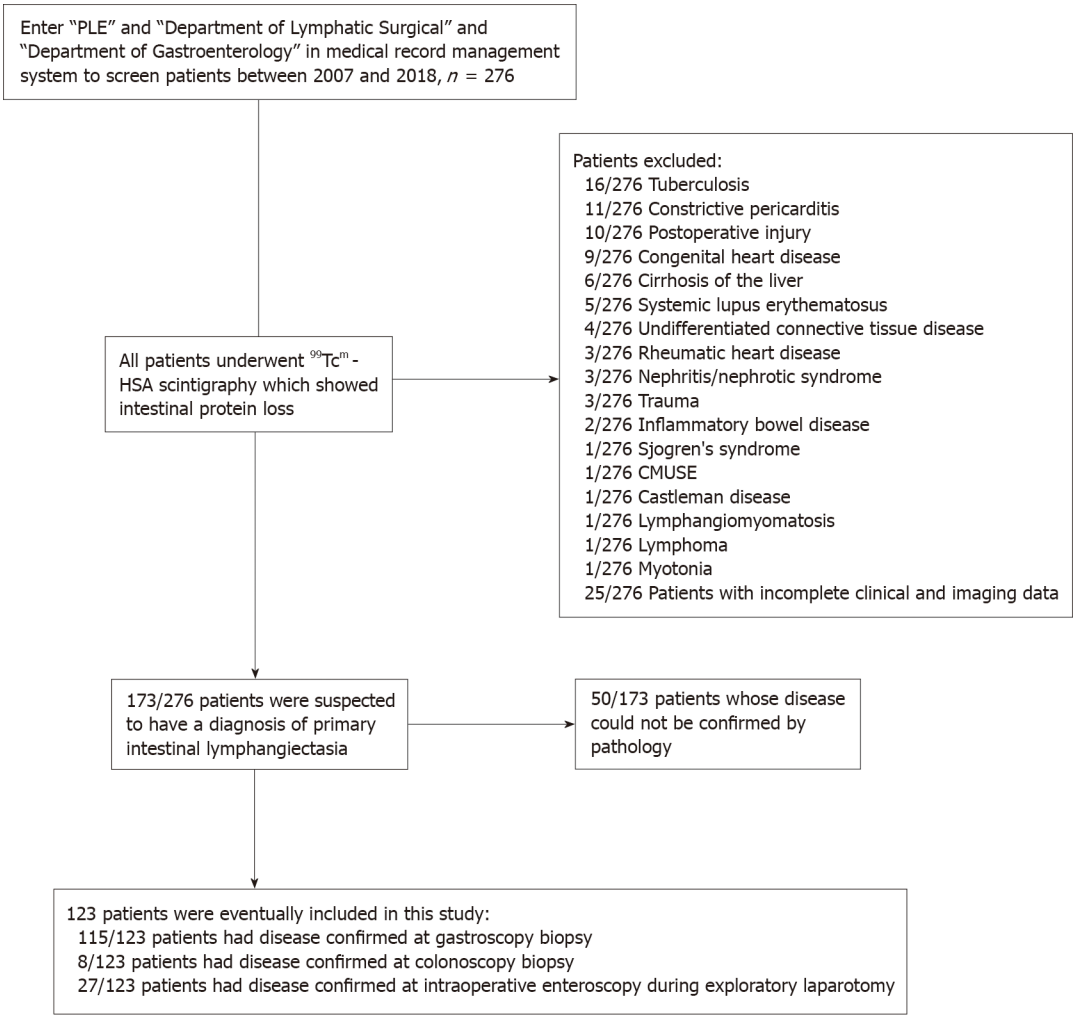
Patient characteristics

We retrospectively analyzed 685 cases of PLE at Beijing Shijitan Hospital, Capital Medical University between January 1, 2007, and December 31, 2018. After strict screening, 123 patients were included in this study. The direct indicators of diagnosis were manifestations of intestinal lymphangiectasia obtained through endoscopy, visible lymphangiectasis found in the mucosa and submucosa through histopathological intestinal mucosal biopsy or surgical specimen pathology, and a positive D2-40 on immunohistochemistry. In contrast, indirect indicators were typical clinical manifestations (*e.g.*, diarrhea, edema, and abdominal pain), hypoproteinemia (albumin concentration < 30 g/L) with positive imaging of technetium-99m human serum albumin, and secondary factors[4,10]. We summarized the patients' clinical data, including age, sex, family history, clinical symptoms, laboratory inspection results, endoscopic images, imaging examination results, and pathological examination results. The imaging data were obtained from the host computer imaging system of Beijing Shijitan Hospital. This study was reviewed and approved by the Ethics Committee of Beijing Shijitan Hospital, Capital Medical University, and all patients signed a consent form.

Endoscopic imaging

All patients included in the study underwent electronic gastroscopy (GIF-H260; Olympus, Tokyo, Japan); of them, those with no significant abnormal manifestations were examined using electronic colonoscopy (CF-H260AI; Olympus, Tokyo, Japan). In addition, patients who underwent surgery underwent colonoscopy during the operation. All patients underwent endoscopic biopsy, the specimens from which were preserved after surgery. We obtained the first endoscopic images of the patients at admission for observation and invited three experienced endoscopists (deputy chief doctors or chief doctors with at least 10 years of experience in gastroscopy and enteroscopy) to interpret the endoscopic images. In cases of disagreement regarding the classification, it was determined by the endoscopists through discussion.

Computed tomography imaging and analysis



All the patients underwent direct lymphangiography. The contrast agent injection spot was located between the 1st and 2nd toes on certain sides. The lymphatic vessel was penetrated and the contrast agent iodinated oil (10 mL/ampule; Guerbet, France) was injected at a flow rate of 4-6 mL/h. Digital subtraction angiography images were dynamically collected at different intervals to observe the development of the lymphatic system. Two hours after surgery, computed tomography (CT) examination of the chest, abdomen, and pelvis was performed using the following scanning parameters: tube voltage, 80-120 kVp; tube current, 100-120 mAs; thickness of recombination layer, 2.0 mm; and interval, 1.8 mm. Post-lymphographic CT (PLCT) images were analyzed using the following evaluation items: (1) Intestinal wall thickening, when small intestinal wall thickness was ≥ 3 mm[10]; (2) edema manifestations: hydrops in the abdominal cavity, retina, and mesentery; and (3) lymphangiectasis of the small intestinal wall and mesentery, with manifestations of irregular distribution of contrast agent in multiple dots, lines, and clusters in the small intestinal wall and/or mesentery. All CT images were evaluated by two radiologists with > 10 years of experience in abdominal imaging diagnosis. In case of any differences in the evaluation results, consensus was reached through discussion and the results were recorded.

Histopathological examination

We collected the pathological data of 123 specimens from patients with PIL, of which 27 specimens were obtained through surgical resection. Hematoxylin and eosin (H&E) and immunohistochemical staining (D2-40 and CD34) were conducted on the specimens postoperatively. Visible dilated lymphatic vessels were distributed in the lamina propria of the intestinal mucosa, submucosa, muscular layer, and the serosal layer. All pathological sections were evaluated by two physicians with 5 and 10 years of experience in pathological diagnosis.

Statistical analysis

The statistical analysis was performed using the SPSS software for Windows (version 20.0; IBM Statistics, Armonk, NY, United States). Data are presented as medians with ranges and proportions. To determine the differences between the four groups, the chi-square test (with Fisher's exact test whenever applicable) was used to compare categorical variables, while the *t*-test was used to compare continuous variables. Statistical significance was set at $P < 0.05$.

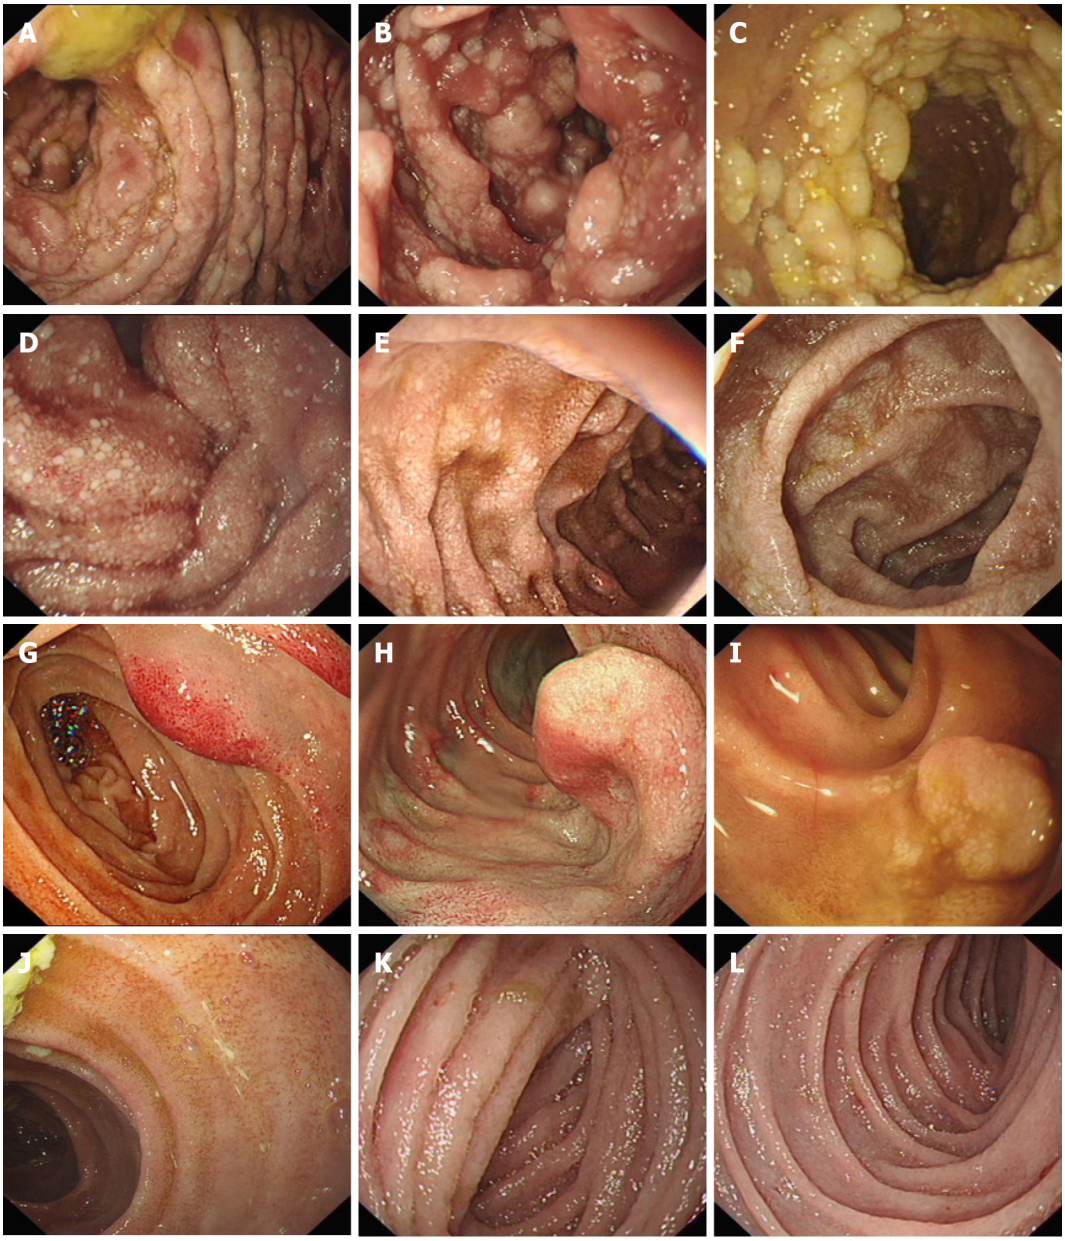
Figure 1 Patient inclusion flowchart showing the number of patients, radionuclide imaging, digestive endoscopy evaluation, and pathologic analysis. CMUSE: Cryptogenic multifocal ulcerous stenosing enteritis; PLE: Protein-losing enteropathy.



RESULTS

Endoscopic classification of PIL

Figure 1 shows a flowchart of the patient selection process. A total of 123 patients were included in this study. Gastroscopy and biopsy results were used for 115 of 123 patients with PIL, while colonoscopy and biopsy results were used for the other 8 patients with PIL. Additionally, small intestinal endoscopy was used for 27 of 123 patients with PIL, and further confirmation was made when the pathological specimens were obtained postoperatively (Figure 1). Through unanimous judgment, PIL was classified into four types according to the different morphologies of the intestinal mucosa under endoscopy: (1) Nodular type [n = 17 (13.8%); Figure 2A-C], which had a snowflake or cream yellow nodular-shaped protrusion at the surface of the mucosa, and for patients with serious symptoms, the white flakes were ring-coelom shaped, the mucosa was swollen and hypertrophic, and intestinal stenosis was present; (2) granular type [n = 74 (60.2%); Figure 2D-F], which showed white granules with disseminated changes at the surface of the mucosa, swollen villi, and lesions that were distributed regionally or in a whole section; (3) vesicular type [n = 5 (4.1%); Figure 2G-I], which showed a vesicle-shaped structure protruding from the mucosa, that part of the surface of the mucosa was hyperemic, and the lesion was isolated; and (4) edematous type [n = 27 (21.9%); Figure 2J-L], in which the villi of the small intestine were swollen and blisters were small and round, villus color was normal, and no change in the characteristic white villus was noted (Figure 2).

Clinical characteristics

Among 123 patients, 61 (49.6%) were men and 62 (50.4%) were women. The average age at onset was 17.0 ± 17.4 years (range, 0-68 years), while that at diagnosis was 22.8 ± 19.2 years. Based on the clinical manifestations, 58.5% (72/123) of the patients, including four with celiac stools, had five or more episodes of diarrhea per day. Additionally, 78.0% (96/123) of the patients had edema of the lower limbs,

Figure 2 Endoscopic images of patients with primary intestinal lymphangiectasia. The images show white mucosal plaques and spots in the small intestine, divided into four types. A-C: Nodular type; D-F: Granular type; G-I: Vesicular type; J-L: Edematous type.

eyelids, and face, 17.7% (17/96) had anasarca, 17.7% (17/96) had unilateral limb edema, and the rest had bilateral edema. Furthermore, 1.6% (2/123) of patients had concurrent cryptococcal or streptococcal infections. Other symptoms included abdominal distention [28 patients (22.8%)], abdominal pain [10 patients (8.1%)], nausea and vomiting [8 patients (6.5%)], and alimentary tract hemorrhage [4 patients (3.3%)]. There were no obvious differences in clinical symptoms among the four patient types. However, the laboratory results of the four types of PIL patients showed a significant decline in peripheral blood lymphocyte counts and IgG concentrations (Table 1).

CT characteristics

We summarized and analyzed the corresponding PLCT images of the four types of patients with PIL observed during endoscopy. The specific characteristics were as follows: (1) Nodular type: the images showed signs of intestinal wall thickening, increased mesenteric density, and no contrast distribution in the mesentery or intestinal wall (Figure 3A-C); (2) granular type: the images showed annular thickening of the small intestinal wall, increased mesenteric density, and no contrast distribution in the mesentery and intestinal wall (Figure 3D-F); (3) vesicular type: the images revealed an increased mesenteric density and distribution of contrast agents in the intestinal wall, mesentery, peripancreatic area, gallbladder fossa, hepatic hilum, and retroperitoneum (Figure 3G-I); and (4) edematous type: the images showed distribution of contrast agents in the intestinal wall, mesentery, peripancreatic area, hepatic hilum, and

retroperitoneum (Figure 3J-L).

Pathologic basis

Pathological data of 123 specimens from PIL patients were collected, and lymphatic dilation was observed in different layers of the intestinal mucosa. The specific characteristics were as follows: (1) Nodular type: Enteroscopic findings showed a white-flake nodular-type protrusion (Figure 4A). H&E staining revealed that the lamina propria and submucosa lymphatic vessels were clearly dilated. The pink liquid in the dilated lumen was lymphatic fluid, which was consistent with the manifestation observed on endoscopy (Figure 4B). Additionally, lymphangiectasia was observed in the muscular and serosal layers, and immunohistochemical staining with D2-40 (+) more clearly showed the lymphatic vessels (Figure 4C and D); (2) granular type: Enteroscopic findings showed scattered white granules (Figure 4E), and the pathological features showed that the lymphatic vessels in the mucosal lamina propria and submucosa were significantly dilated (Figure 4F). Scattered lymphangiectasia was also seen in the muscular layer and serosal layers, and the distribution of tiny blood vessels was observed around the lymphatic vessels (Figure 4G and H); (3) vesicular type: Enteroscopic findings revealed raised submucosal lesions (Figure 4I). Pathological features showed thick lymphatic vessels in the raised lesions and no obvious lymphatic dilatation in the mucosa (Figure 4J and K). A distribution of tiny blood vessels was observed around the lymphatic vessels (Figure 4L); and (4) edematous type: Enteroscopic findings revealed swollen villi and small round blisters (Figure 4M). Pathological features showed lymphatic dilatation in the submucosa and no obvious lymphatic dilatation in the lamina propria (Figure 4N and O). Tiny blood vessels were observed around the lymphatic vessels (Figure 4P).

Figure 3 Post-lymphographic computed tomography images corresponding to the four types of primary intestinal lymphangiectasia under endoscopy. A-C: Nodular type: The post-lymphographic computed tomography (PLCT) corresponding to nodular type indicates the intestinal wall thickening of the small intestine (white arrows), increased mesenteric density, and no contrast agent distribution in the mesentery and intestinal wall; D-F: Granular type: The PLCT corresponding to granular type indicates that the intestinal wall annular thickening of the small intestine, increased mesenteric density (white arrows), and no contrast agent distribution in the mesentery and intestinal wall; G-I: Vesicular type: The PLCT corresponding to vesicular type indicates the distribution of contrast agents in the intestinal wall, mesentery, peripancreas, hilar area of the liver, and retroperitoneum (white arrows), suggesting lymphatic dilation and abnormal distribution in the above areas; J-L: Edematous type: The PLCT corresponding to edematous type indicates the distribution of contrast agents in the intestinal wall, mesentery, peripancreas, gallbladder fossa, hilar area of the liver, and retroperitoneum (white arrows).

DISCUSSION

To date, there have been few studies on PIL in the English literature, most of which were reports of single cases and reviews of small cases. At present, the diagnosis of PIL is based on small intestinal endoscopy or capsule endoscopy to identify the typical characteristics of the intestinal mucosa and is confirmed through histopathological examination of the biopsy specimen of the intestinal mucosa; intestinal lymphangiectasia due to secondary causes is excluded[9,11]. The classification of intestinal lymphangiectasis using endoscopy is limited. Ohmiya *et al*[12] divided 14 patients with intestinal lymphangiectasis into white and non-white villi. However, these few cases included patients with secondary lymphangiectasias. We evaluated the endoscopic characteristics of 123 patients with PIL and found significant differences in the intestinal mucosal findings under endoscopy in different patients. Based on their endoscopic appearance, they were divided into four types: nodular, granular, vesicular,

Figure 4 Endoscopic images and corresponding histological findings of primary intestinal lymphangiectasia. A, E, I, and M: Four types of endoscopic images in patients with primary intestinal lymphangiectasia; B, F, J, and N: Hematoxylin and eosin stain showing the full mucosa of the small intestine; C, G, K, and O: Immunohistochemical stain shows that D2-40 positive cells are located in the cytoplasm and envelope of lymphatic epithelial cells and are brownish yellow (magnification: × 10), indicating dilated lymphatics; D, H, L, and P: CD34 stain showing normal vascular endothelial cells (magnification: × 10).

and edematous. The corresponding imaging and histopathological findings of each type were comprehensively analyzed. In this study, the endoscopic mucosal signs of patients with PIL were mainly white granule-like changes, a finding that was consistent with the endoscopic images reported in most studies. The nodular and vesicular types proposed in this study have not been reported previously.

PIL often develops in childhood or youth, and most cases are diagnosed before the age of 3 years. In recent years, an increasing number of cases have been reported in adults[2,13-17]. In this study, we found that the age at onset differed among the four types of endoscopy. Among them, the age at onset in patients with nodular-type PIL was the youngest (3.7 ± 6.9 years), and the earlier the age at onset, the more severe the intestinal mucosal findings. We also found clinical differences in peripheral blood lymphocyte counts and IgG levels among the four types in the laboratory examinations. Among the four types, the values of these two indicators were the lowest in patients with vesicular-type PIL, while the corresponding hemoglobin values were the lowest. By analyzing the clinical features of five patients with vesicular-type PIL, we found that four were diagnosed with gastrointestinal bleeding. The simultaneous loss of lymphatic fluid and blood from the intestinal tract can lead to a decrease in hemoglobin, lymphocyte, and immunoglobulin levels.

Figure 5 Four patterns of mucosal findings under endoscopy. Type I: Nodular type; Type II: Granular type; Type III: Vesicular type; Type IV: Edematous type.

In recent years, PLCT has been of great value in the diagnosis of PIL. Our previous studies suggested that the specific signs of PIL include diffuse nodular thickening and edema of the intestinal wall as well as the presence of a "halo sign" on the intestinal wall[14]. The abnormal distribution of contrast agents in the small intestine and mesentery of the affected segment suggests the local presence of abnormally dilated lymphatic vessels and abnormal lymphatic circulation. In this study, the PLCT signs in nodular- and granular-type patients showed intestinal wall thickening and increased mesenteric density, consistent with the mucosal findings on endoscopy. In contrast, no significant intestinal wall thickening was found in vesicular- and edematous-type patients. By observing the contrast agent distribution, we found that the PLCT images of vesicular- and edematous-type patients showed contrast agent distribution in the intestinal wall, mesentery, peripancreatic, gallbladder fossa, hepatic hilum, and retroperitoneum, indicating lymphatic dilation and an abnormal distribution in these areas. However, there was no contrast agent distribution in the small intestine or mesentery in the PLCT images of nodular- and granular-type patients, which was inconsistent with the segmental and/or diffuse lymphatic dilation of the intestinal mucosa shown by the endoscopy results. Combined with the pathological results, we speculated that the lymphatic fluid in the intestinal mucosa and submucosal lymphatic vessels of nodular- and granular-type patients are subject to retention, which increases the pressure in the lymphatic vessels. In addition, there were many submucosal muscle fiber tissues that were not conducive to the counterflow of the contrast agent into the small intestine. In the nodular type, among the five children with contrast agent negativity, the lymphatic contrast agent was sparsely distributed throughout the body, which may be related to lymphatic dysplasia.

Previous reports[10,12,15] and histopathology of PIL biopsies showed that the mucosal and submucosal lymphatic vessels were significantly dilated and the lymphatic vessels were filled with protein-rich fluid and scattered lymphocytes. There are no reports on whether lymphatic dilation exists in the muscular and serosal layers. Macdonald *et al*[16] reported a strong correlation between small intestinal vascular hypoplasia and lymphatic dilation, but there was a lack of pathological examination supporting their argument. In this study, pathological examination of nodular- and granular-type PIL showed that the villi were enlarged and clubbed or cystic, with some tips ruptured. The lamina propria, submucosa, muscular layer, and serosa of the diffuse or localized mucosa showed significant dilation of the lymphatic vessels, with the most obvious lymphatic vessel dilation in the lamina propria of the intestinal mucosa, consistent with the endoscopy findings. Among them, nodular pathology has shown a large amount of muscle fiber tissue in the submucosa, which may be related to the long course of disease and chronic inflammation. Pathological examination of vesicular-type patients showed a large number of thin-walled and irregularly dilated lymphatic vessels in the submucosa; lymphatic fluid, lymphocytes, and red blood cells in the lumen; and the accumulation of lymphocytes in the stroma, which can form lymphoid follicles. This was consistent with the prominent polyp-like morphology observed on endoscopy, and a large number of small blood vessels were observed around the lymphatic vessels, further verifying that the third type of lymphatic dilation reported by Macdonald *et al*[16] was consistent with the vesicular type in our study. Therefore, our study findings complement the histopathological findings. Pathological examination of edematous-type patients showed that the lymphatic vessels in the submucosa were significantly dilated, and the lymphatic vessels in the lamina propria were not significantly dilated, which was consistent with the endoscopy findings. The histopathological results showed that the distribution of lymphatic dilation in the intestinal mucosa and the degree of lumen dilation differed; therefore, the signs of intestinal mucosa on endoscopy varied in patients with PIL.

This study analyzed the endoscopic images of 123 patients with PIL and found that the intestinal mucosa had different endoscopic features such as diffuse white nodules, white granules, polypoid protrusion, and mucosal edema, the basis of the division into four types of endoscopic features (Figure 5). However, the four distinctive phenotypic appearances may simply be endoscopic variations

at different stages of the same disease, similar to the different endoscopic findings of eosinophilic esophagitis. The classification of PIL also requires support in animal models and molecular or genotypic bases to confirm the presence of distinct phenotypes. This study is preliminary because of its small sample size and retrospective design, and requires further validation in a multicenter prospective study.

CONCLUSION

In conclusion, PIL is a rare disorder that typically presents as PLE, diarrhea, and limb edema. Unspecific symptoms and a wide range of clinical manifestations can significantly hamper the establishment of a definitive diagnosis. PIL demonstrates four characteristics of digestive endoscopy. The identification of intestinal mucosal chorionic abnormalities in this rare disorder might be helpful for ensuring an early diagnosis and optimal treatment.

ARTICLE HIGHLIGHTS

Research background

Primary intestinal lymphangiectasia (PIL) is a rare disorder that typically presents as PLE, diarrhea, and limb edema.

Research motivation

Unspecific symptoms and a wide range of clinical manifestations can significantly hamper the establishment of a definitive diagnosis.

Research objectives

This study aimed to classify the endoscopic features of the intestinal mucosa in PIL under endoscopy, combine post-lymphographic computed tomography findings and the patients' pathological characteristics of the patients, and explain their causes.

Research methods

This retrospective analysis of endoscopic images of patients diagnosed with PIL during a 12-year period at our research center summarized and classified types into four distinct endoscopic features and further explored the differences in radiologic and pathologic features of the different endoscopic features.

Research results

The endoscopic symptoms of 123 patients with PIL can be divided into four types: Nodular (13.8%), granular (60.2%), vesicular (4.1%), and edematous (21.9%).

Research conclusions

We proposed the theory of nodular and vesicle types domestically through observation, and made breakthroughs in overcoming the issue of inaccurate diagnosis based on a few independent early-stage case reports.

Research perspectives

According to the different partings under endoscopy, the clinical symptoms, therapeutic efficacy, and prognosis of patients with PIL were observed.

Abstract

BACKGROUND

Hepatic steatosis is a major cause of chronic liver disease. Two-dimensional (2D) ultrasound is the most widely used non-invasive tool for screening and monitoring, but associated diagnoses are highly subjective.

AIM

To develop a scalable deep learning (DL) algorithm for quantitative scoring of liver steatosis from 2D ultrasound images.

METHODS

Using multi-view ultrasound data from 3310 patients, 19513 studies, and 228075 images from a retrospective cohort of patients received elastography, we trained a DL algorithm to diagnose steatosis stages (healthy, mild, moderate, or severe) from clinical ultrasound diagnoses. Performance was validated on two multi-scanner unblinded and blinded (initially to DL developer) histology-proven cohorts (147 and 112 patients) with histopathology fatty cell percentage diagnoses and a subset with FibroScan diagnoses. We also quantified reliability across scanners and viewpoints. Results were evaluated using Bland-Altman and receiver operating characteristic (ROC) analysis.

RESULTS

The DL algorithm demonstrated repeatable measurements with a moderate number of images (three for each viewpoint) and high agreement across three premium ultrasound scanners. High diagnostic performance was observed across all viewpoints: Areas under the curve of the ROC to classify mild, moderate, and severe steatosis grades were 0.85, 0.91, and 0.93, respectively. The DL algorithm outperformed or performed at least comparably to FibroScan control attenuation parameter (CAP) with statistically significant improvements for all levels on the unblinded histology-proven cohort and for "= severe" steatosis on the blinded histology-proven cohort.

CONCLUSION

The DL algorithm provides a reliable quantitative steatosis assessment across view and scanners on two multi-scanner cohorts. Diagnostic performance was high with comparable or better performance than the CAP.

Core Tip: Ultrasound is widely used to evaluate liver steatosis, but it is subjective. We developed a deep learning algorithm for quantitative steatosis scoring from ultrasound. The algorithm was trained on > 200000 images and composed of different scanners and viewpoints from both hepatic lobes. High diagnostic performance was measured across all viewpoints in separate histology proven groups, which was comparable to or better than the control attenuation parameter. We demonstrated high agreement across scanners and viewpoints. Thus, our deep learning algorithm provides a quantitative assessment with high performance and reliability.

INTRODUCTION

Liver steatosis, or fatty liver disease, is a major cause of chronic liver disease worldwide. It is estimated that nonalcoholic fatty liver disease (NAFLD) affects 20%-30% of the global population[1-3] and is associated with increased risks of cardiovascular disease, type 2 diabetes, and metabolic risk factors[4]. Unfortunately, it is an undertreated and underdiagnosed disease[5]. For those patients with more aggressive nonalcoholic steatohepatitis, the risks of liver cirrhosis, liver failure, and hepatocellular carcinoma are higher[6-8]. Liver steatosis is also associated with chronic viral hepatitis. For instance, hepatitis C can impair glucose metabolism, resulting in the accumulation of fat droplets in the liver and increasing hepatocarcinogenesis[9]. There have been reports on the interaction between liver steatosis and hepatitis B. Previous reports have also suggested that liver steatosis is associated with delayed hepatitis B surface antigen seroclearance[10]. Therefore, assessing liver steatosis is also important for chronic viral hepatitis.

Liver needle biopsy is the gold standard diagnosis at present. However, even with machine learning-based interpretation[11,12], the invasiveness of the biopsy severely limits its clinical applicability as a screening and assessment tool, and at the same time it is prone to sampling error. Thus, with the growing prevalence of NAFLD and nonalcoholic steatohepatitis, accurate, reliable, and accessible non-invasive screening tools are increasingly important to quantify liver steatosis and provide follow-up monitoring[4].

Such tools include magnetic resonance imaging with derived proton density fat fraction (MRI-PDFF), quantitative ultrasound (US), and two-dimensional (2D) US diagnoses[13]. MRI-PDFF is the best non-invasive test and can be used as a gold standard in clinical trials, but it is costly for routine clinical care [5,14]. As for quantitative US, its most popular variant is FibroScan with its control attenuation parameter (CAP) scores[15]. CAP is more available than MRI-PDFF but still requires dedicated equipment. Finally, 2D US exams have been widely used for the diagnosis of liver disease for 5 decades [13], which is partly driven by the prevalence of US equipment and its low cost. In clinical practice, 2D US is also the first-line screening modality for the detection of liver cancer[16]. Therefore, steatosis can

also be assessed from studies with a primary aim of liver tumor screening. Given these considerations, it is not surprising that 2D US is the most common tool for assessing liver steatosis[4].

A recent NAFLD epidemiology meta-analysis revealed that 90.6% of 392 studies in China used 2D US as the diagnostic modality of choice[3]. Unfortunately, US steatosis scores are considered a subjective diagnosis. A meta-analysis in 2011 reported that the kappa statistics for inter- and intra-observer reliability showed poor numbers[4]. A 2014 analysis[17], focusing on US steatosis assessment derived from routine clinical care, concluded that intra- and inter-observer agreement of binary assessment was only 51%-68% and 39%-40%, respectively, and it also noted that there was a lack of reported reliability measurements of categorical assessments. Both studies attributed the low reliability to different image acquisition practices across institutions and the subjective and variable nature of US image interpretation. More recently, Hong *et al*[18] investigated the reliability of categorical US assessments of different features and reported only moderate inter-rater agreements (intra-class correlation coefficients of 0.54) for the overall steatosis impression.

A promising alternative is to apply machine learning algorithms, *e.g.*, deep learning (DL), on 2D US liver scans. The goal is to provide a quantitative measure of liver steatosis directly from 2D US images for clinical decision support. Efforts toward this end have been reported. However, limitations in the analysis, *i.e.*, small training set sizes[19,20], only binary assessments[20-24], and single-scanner data[23-27], restrict the conclusions that can be drawn. Moreover, the reliability of these assessments, either across scanners or across different US views of the liver, have not been assessed. Relatedly, the specific number of images needed for a reliable diagnosis, and of which liver viewpoints, has also not been well articulated or characterized. This is crucial for an at-large adoption of any imaging-based diagnostic tool.

To address these limitations, we developed a scalable DL algorithm to quantitatively assess liver steatosis from 2D US using a retrospectively mined big data cohort. Cross-scanner and cross-view reliability was measured in addition to diagnostic performance against gold standard histopathological diagnoses on two clinical cohorts. Direct comparisons against CAP were also performed. The DL algorithm might serve as an effective tool for liver steatosis screening and monitoring.

MATERIALS AND METHODS

Patient cohorts and image collection

Multiple patient cohorts were collected for our study, as shown in Table 1 and Figure 1. The clinicopathological makeup of each dataset can be found in Supplementary Table 1. All US images underwent the same automatic cropping and resampling preprocessing, which is described in the Supplementary material. This study was approved by the Institutional Review Board of the Chang Gung Medical Foundation (CGMH IRB No. 201801283B0).

Big data groups (big data learning group and big data validation group)

We retrospectively collected a big data dataset from the picture archiving and communication system of CGMH, a major hospital in Taiwan (over 4 million outpatient visits/year). All patients who received elastography (a quantitative US technology), specifically acoustic radiation force impulse imaging and FibroScan, between January 3, 2011 and September 28, 2018 represented the index patients. From the index patients, we extracted all 2D US studies that were acquired within the same 2011-2018 period, resulting in multiple studies per patient. Seventy percent of the patients and their corresponding US studies were randomly selected as training data (big data learning group, BD-L), totaling 2899 patients and 200654 images. We used another 10% of the patients for validating and tuning our DL algorithm (big data validation group, BD-V), totaling 411 patients and 27421 images. The remaining 20% of the patients were not used as part of this study. In addition, any patients also found in the other datasets were also moved to this excluded cohort. The collected images were generated from 13 known scanners, which are listed in Supplementary Table 2. Each US study was accompanied by a 2D US diagnosis of steatosis severity from visual assessment using established guidelines[13,28], generated through the course of routine clinical care. These labels are used to train the DL algorithm. We enrolled the maximum number of patients that fit our inclusion criteria to provide as much data as possible for the DL algorithm.

Unblinded test group (histopathology unblinded test group)

We used a collection and selection protocol reported in prior work[29-32]. Specifically, since 2011 it has been CGMH policy to obtain elastography measurements for all patients undergoing a liver biopsy, *i.e.*, acoustic radiation force impulse and FibroScan once the latter became available. The histopathology unblinded test group (HP-U) dataset (n = 147) consists of patients with FibroScan diagnoses between the dates November 27, 2014 to September 26, 2019. Identical to a prior study[29], we included patients with chronic hepatitis B virus (HBV), chronic hepatitis C virus (HCV), and non-hepatitis B/C virus (NBNC) liver diseases. We excluded those with decompensated liver disease, toxic hepatitis, alcoholism, or autoimmune liver diseases. After exclusion of these etiologies, the majority of the NBNC group were

[1]Labels blind to deep learning researchers during course of algorithmic development.

DL: Deep learning; US: Ultrasound; BD-L: Big data learning group; BD-V: Big data validation group; HP-U: Histopathology unblinded test group; TM: Trimachine group; HP-T: Histopathology blinded test group; CAP: Control attenuation parameter; 2D: Two-dimensional; Dx: Diagnosis.

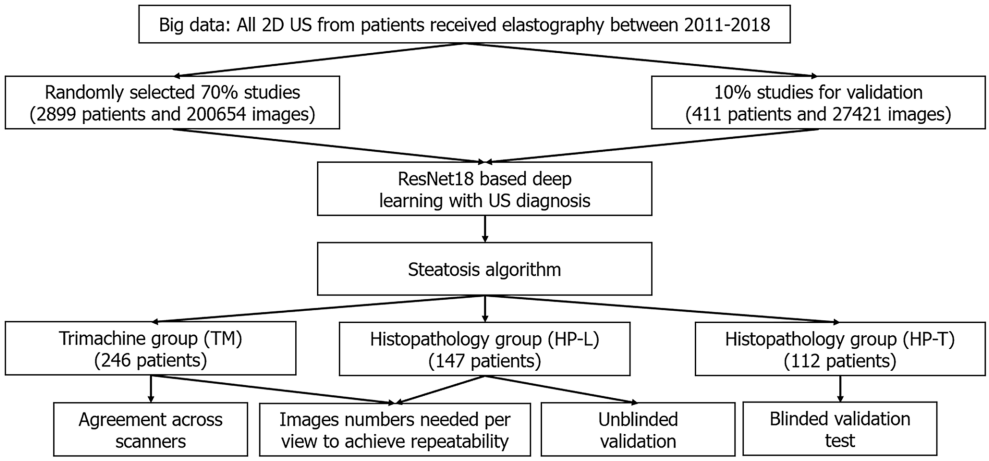

Figure 1 Flowchart. 2D-US: Two-dimensional ultrasound.

NAFLD patients (90.3% in HP-U group, Supplementary Table 1B). Histopathological analysis was performed by the same clinician (S.F.H.), and any retrospectively collected histopathological analysis not originally performed by S.F.H. was redone. Liver biopsies were collected mainly at the CGMH outpatient center and were performed to evaluate fibrosis, steatosis, or an unknown etiology[29-32]. Percutaneous liver biopsy was performed under US guidance with an 18-gauge core needle and an automatic pistol device (Magnum; Bard Peripheral Vascular, Inc, Tempe, AZ, United States). Under this standard procedure a liver specimen greater than 1.2 cm was obtained. However, a portion of the histology data was obtained from tumor resection. Following Kleiner *et al*[33], the histology diagnoses were graded into normal (5%), mild (5% and 33%), moderate (33% and 66%) and severe (66%) based on the liver fat cell fraction.

Because we were interested in US analysis, additional selection criteria were also applied. A patient must have a 2D US study that was: (1) Acquired within 3 mo of the biopsy; and (2) acquired with one of the Siemens Acuson S2000, Philips IU22, or Toshiba Aplio 300 scanners. We also excluded patients with tumors > 3 cm and with multiple cysts. Finally, US studies must have ≥ 10 images of the viewpoints depicted in Figure 1. If more than one US study qualified, we randomly selected one. All labels in HP-U were unblinded to the DL researchers of this work, but the data was treated as a test set, meaning it was only analyzed after development was complete.

Tri-machine group

We prospectively collected this cohort (n = 246) from patients that had both an US and a FibroScan study ordered and if D.I.T., Y.C.C., T.H.H., or C.J.C. conducted the image study. With the agreement of these patients, they were scanned by Siemens Acuson S2000, Philips IU22, and Toshiba Aplio 300 scanners on the same day. Studies were collected over a period from August 30, 2018 to August 27, 2019, and we only included patients diagnosed with the HBV, HCV, and NBNC criteria used in HP-U. The tri-machine (TM) cohort allowed for an assessment of agreement across scanners.

Blind testing group (histopathology blinded test group)

Finally, we included histopathology blinded test group (HP-T, n = 112), a clinical testing dataset whose labels were blind to the DL researchers involved in this project during development of the algorithm. HP-T was collected from patients that had received a liver biopsy between April 18, 2011 to May 5, 2015 and September 1, 2018 to January 29, 2021. Associated FibroScan diagnoses were only available for the later subset of patients. Also, unlike HP-U, US studies were not restricted to only the Siemens, Philips, and Toshiba scanners of TM and HP-U. In particular, 18 studies were acquired with the Aloka SSD 5500 or ATL: HDI 5000 scanners, which are not currently considered premium scanners.

Image selection

We were interested in investigating performance and reliability across viewpoints. Thus, we only included US images from the viewpoints shown in Figure 2, which can be categorized into four view groups: Left liver lobe (LLL), right liver lobe (RLL), liver/kidney contrast (LKC), and subcostal (SC). For HP-U, HP-T, and BWC, we only included studies that had ≥ 10 images of any of the studied viewpoints. BD-L and BD-V were automatically filtered with an algorithm explained in the Supplementary material.

Training steatosis assessment DL algorithm

Figure 3 illustrates the algorithmic workflow of our DL algorithm. Using the images from BD-L, we trained a multi-class deep ResNet18[34] DL classifier using the 2D US diagnoses, which were ordinal labels ranging from 0 to 3 corresponding to None; Mild; Moderate; and Severe steatosis[35]. We treated each image independently in training and followed the well-known binary decomposition approach to ordinal classification of Frank and Hall[36]. After training, a simple transformation produced a continuous score[37] for each image that ranged from 0 to 1, with higher scores corresponding to more severe steatosis. As Figure 3 indicates, during inference, we took the mean of the image-wise scores within and across each view group. The view group scores were further averaged to produce an "All View Groups" score. If one or several view groups were missing, the "All View Groups" score was calculated with what view groups were available. More details on the training strategy can be found in the Supplementary material, and a listing of hyper-parameters is given in Supplementary Table 5.

Statistical analysis

A listing of all experiments can be found in Supplementary Table 3. We evaluated the reliability and diagnostic performance of the DL algorithm. We judged P values < 0.05 as significant and corrected for multiple comparisons using the Holm-Bonferroni procedure[38].

Reliability studies

Experiment 1: We used TM and HP-U to assess how many images were needed per view group to achieve repeatability. Note, for the TM dataset we randomly selected only one US study for each patient to avoid sampling the same patient more than once. As advocated by Bland and Altman[39,40], we graphed the within-subject standard deviations across different view-group steatosis scores and measured the repeatability coefficient (RC)[40]. The difference between two repeated measurements should be within the RC value for 95% of the US studies. However, because the within-subject standard deviation was not uniform across our data (typically greater variability in repeated measurements at moderate steatosis levels), we regressed a non-uniform RC and used the worst-case RC value as a summary statistic, with 95% confidence intervals computed using percentile bootstrap (1000 bootstrap samples)[41]. More details on this calculation can be found in the Supplementary material.

Experiment 2: We also evaluated agreement across scanners using TM. We conducted a Bland-Altman analysis[39] on the difference values across view-group scores and calculated the limits of agreement (LOAs[40]), which are the limits by which 95% of the disagreements fall under[40]. Like Experiment 1, variability tended to be higher at moderate levels of severity. Therefore, we regressed non-uniform LOAs and used the maximum upper LOAs and minimum lower LOAs as summary statistics. More details can be found in the Supplementary material. We also calculated the percentage agreement, using the cutoff levels determined in Experiment 3 below.

Diagnostic testing

Experiment 3a: We validated the DL model diagnostic performance using the images and histopathological labels of HP-U. Although the HP-U labels were not blinded to the DL researchers during algorithmic development, it was treated like a test set, *i.e.* evaluation was only performed once model development was complete. Histopathological diagnoses were separated into four ordinal labels[27]. For three separations of fatty percentages, *i.e.*, grade ≥ 5%, grade ≥ 33%, and grade ≥ 66%, we used receiver operating characteristic (ROC) curve analysis and measured the area under the curve of the ROC (AUCROC). Trend tests between the DL assessment and histopathological grades were conducted using the non-parametric Jonckheere-Terpstra test[42]. The 95% confidence intervals of all AUCROCs were calculated based on DeLong's non-parametric test[43]. When needed, we determined cutoff values using the values that maximized the Youden index[44].

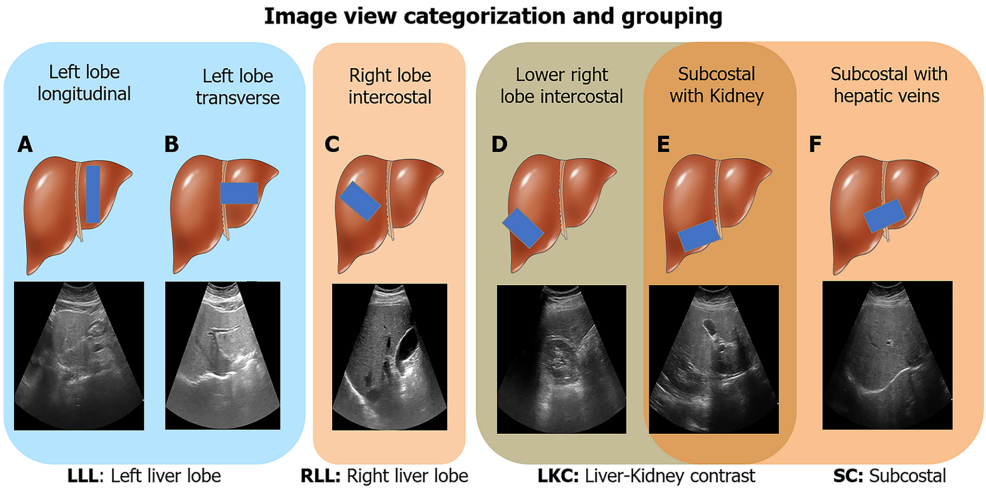

Figure 2 Image view categorization and grouping. Six ultrasound image viewpoints were used in this study. A: Left lobe longitudinal; B: Left lobe transverse; C: Right lobe intercostal; D: Lower right lobe intercostal (depicting liver/kidney contrast); E: Subcostal depicting liver/kidney contrast; F: Subcostal with hepatic veins. These views were further categorized into four groups: Left liver lobe (A and B), right liver lobe (C), liver/kidney contrast (D and E), and subcostal (E and F). LLL: Left liver lobe; RLL: Right liver lobe; LKC: Liver/kidney contrast; SC: Subcostal. Liver cartoons adapted from the DataBase Center for Life Science (https://commons.wikimedia.org/wiki/File:201405_liver.png), licensed under the Creative Commons Attribution 4.0 International[51] (Copyright permission see Supplementary material).

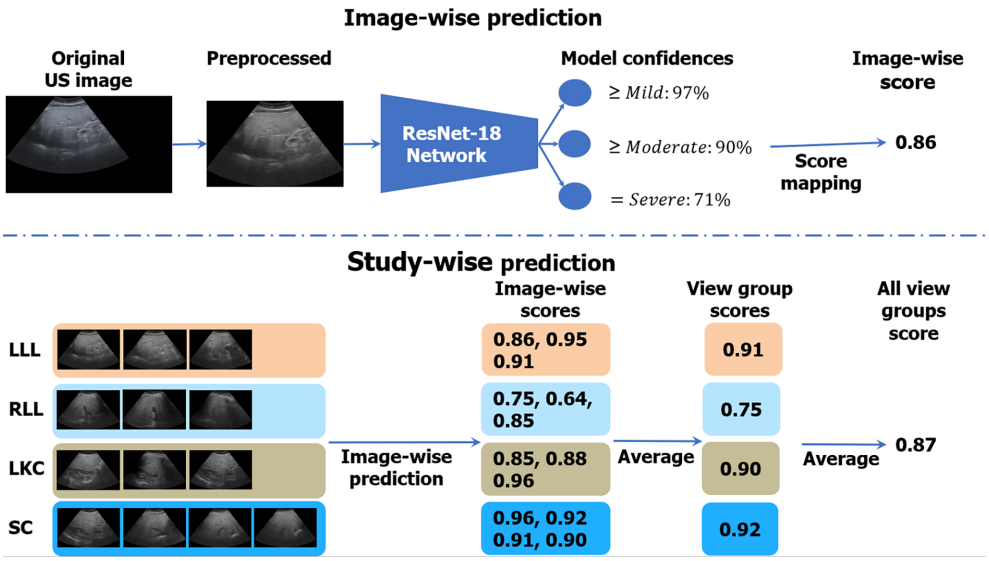

Figure 3 Algorithmic workflow. Images were first comprehensively preprocessed to remove regions outside the ultrasound beam. A deep learning neural network, called ResNet-18, was trained on individual ultrasound images in the big data learning group. The model predicted confidences in three binary cutoffs: "≥ mild", "≥ moderate", or "= severe" steatosis. The confidences were mapped to a continuous image-wise score in the range of [0, 1]. View-group scores were produced by averaging each image within the group. An "All View Groups" score was produced by averaging all available view group scores. In the figure's example, the gold standard histopathology diagnosis was a fatty cell percentage of 90%. LLL: Left liver lobe; RLL: Right liver lobe; LKC: Liver/kidney contrast; SC: Subcostal.

Experiment 3b: We compared the performance of FibroScan with that of the DL assessment, and statistical significance of any differences in AUCROCs were assessed using the StAR[45] implementation of DeLong's non-parametric test[43].

Experiment 4a: Finally, we tested our DL assessment on HP-T, whose histopathological labels were blind to the DL researchers during model development.

Experiment 4b: For patients with FibroScan diagnoses, we also compared its performance with that of the DL assessment. Experiments 4a and b used the same statistical analyses as Experiments 3a and b.

RESULTS

Repeatable measurements with a moderate number of images

We first determined how many images were needed for each view group to reach a repeatable measurement (Experiment 1 in Supplementary Table 3) using TM (one random study per patient) (n = 246) and HP-U (n = 147). The results when using three images per view group can be found in Table 2, and the complete set of results from one-to-four images can be found in Supplementary Table 6. As can be seen, depending on the view group, the max RC value was equal to or less than 30% of the DL assessment scale, which ranged from 0 to 1. In the worst case, 95% of the differences between repeated measurements should be within this max RC value. As the repeatability graph of Figure 4A demonstrates, this max RC value occurred at moderate levels of steatosis severity, which have a wide tolerance (*e.g.*, moderate fatty cell content is commonly determined as being anything between 33% and 66%). The RC values for mild and severe were much lower, suggesting that a 30% RC value was highly conservative for these ranges of severity. The repeatability graphs for all other view groups can be found in Supplementary Figure 1. Together, these data demonstrate the DL assessment can attain repeatable measurements with a moderate number of images for each view group. For the remainder of evaluations, we will only include assessments that have a minimum of three images for each view group.

Agreement across scanners was high

We used the TM dataset (n = 246) to measure agreement across measurements taken on the same day but with three different scanners (Experiment 2 in Supplementary Table 3). As the Bland-Altman plots for "All View Groups" of Figure 4B-D demonstrate, the LOAs are worse at moderate levels of severity, but they are much tighter at milder and more severe levels. This mirrors the repeatability results. Table 2 presents the Bland-Altman summary statistics for all view groups, demonstrating that the cross-scanner agreement is roughly equivalent for all view groups. For brevity we combined the results across all scanner pairs together. As can be seen, the agreement across scanners is high. The bias for "All View Groups" was close to zero, and the worst case LOAs were around 35% for every view group. The LOAs for "All View Groups" fell to 25%, suggesting that examining all view groups together can increase reliability. The percentage agreement numbers are all 92% or higher, further underscoring the high agreement across the tested scanners.

High diagnostic performance on clinical test sets

With the reliability studies completed, we validated the DL score against a histopathological gold standard for diagnosing mild-to-severe (≥ 5%), moderate-to-severe (≥ 33%), and severe (≥ 66%) fatty percentages. The results on HP-U and HP-T, Experiments 3 and 4 in Supplementary Table 3, respectively, are presented in Table 3. Focusing primarily on the HP-T results, the "Complete 4 view group study" of Table 3 only selects studies that had three or more images for every view group. This allowed an "apples-to-apples" comparison across view groups. As can be seen, the performance was comparable across view groups, suggesting that each view group provided similar diagnostic value, with all providing AUCROCs ≥ 0.84. The "Individual view group study," on the other hand, presented results when examining each view group individually, meaning only the view group in question required three or more images. This allowed for a larger sample size. In this setting "All View Groups" denoted the mean score across all view groups with three or more images, which can comprise different view groups from study to study. The ROC curves for "All View Groups" for the individual view group study can be found in Figure 5A. As can be seen in Table 3, the results for the individual view groups were broadly like those of the complete view groups study with AUCROCs ≥ 0.81. Comparing the results of HP-U to HP-T, the AUCROCs were generally similar, reinforcing the above results. However, the HP-U results were generally better, especially for diagnosing mild-to-severe steatosis. This is due to HP-T including non-premium Aloka and ATL HDI scanners in its cohort, which make it harder to accurately assess steatosis. Indeed, as Figure 5B indicates, when only selecting for the Siemens, Philips, and Toshiba premium scanners the AUCROC scores for HP-T were much improved, indicating that scanner choice does make an impact. Finally, the "FibroScan comparison study" compared the performance of FibroScan directly with the DL assessment. As can be seen, the DL assessment AUCROC values were better than FibroScan, and statistical significance was reached for all levels on the HP-U dataset and for "= severe" on the HP-T dataset (Figure 5).

DISCUSSION

Incorporating different 2D US scanner models and brands, different liver viewpoints, and prospectively and retrospectively collected images, we demonstrated that a DL-based assessment can provide quantitative and reliable hepatic steatosis scores.

Table 2 Reliability studies in different views

	Repeatability study		Cross-scanner agreement study				
View	***n***	**Max RC**	***n***	**Bias**	**Min lower LOA**	**Max upper LOA**	**Agreement**

SC	297	0.26 (0.24, 0.29)	182	0.00 (-0.01, 0.01)	-0.36 (-0.31, -0.42)	0.36 (0.31, 0.42)	94%
All view groups	-	-	237	0.00 (-0.01, 0.01)	-0.25 (-0.21, -0.28)	0.24 (0.21, 0.28)	94%

On the left, the max repeatability coefficient was tabulated when using three images for each view group (Histopathology unblinded test group and Trimachine group datasets). On the right, the bias, worst-case limits of agreement, and agreement (%) were tabulated across different view groups for the Trimachine dataset. The results for all scanner pairs were combined. Parentheses enclose bootstrapped 95% confidence intervals. RC: Repeatability coefficient; LOA: Limits of agreement; LLL: Left liver lobe; RLL: Right liver lobe; LKC: Liver/kidney contrast; SC: Subcostal.

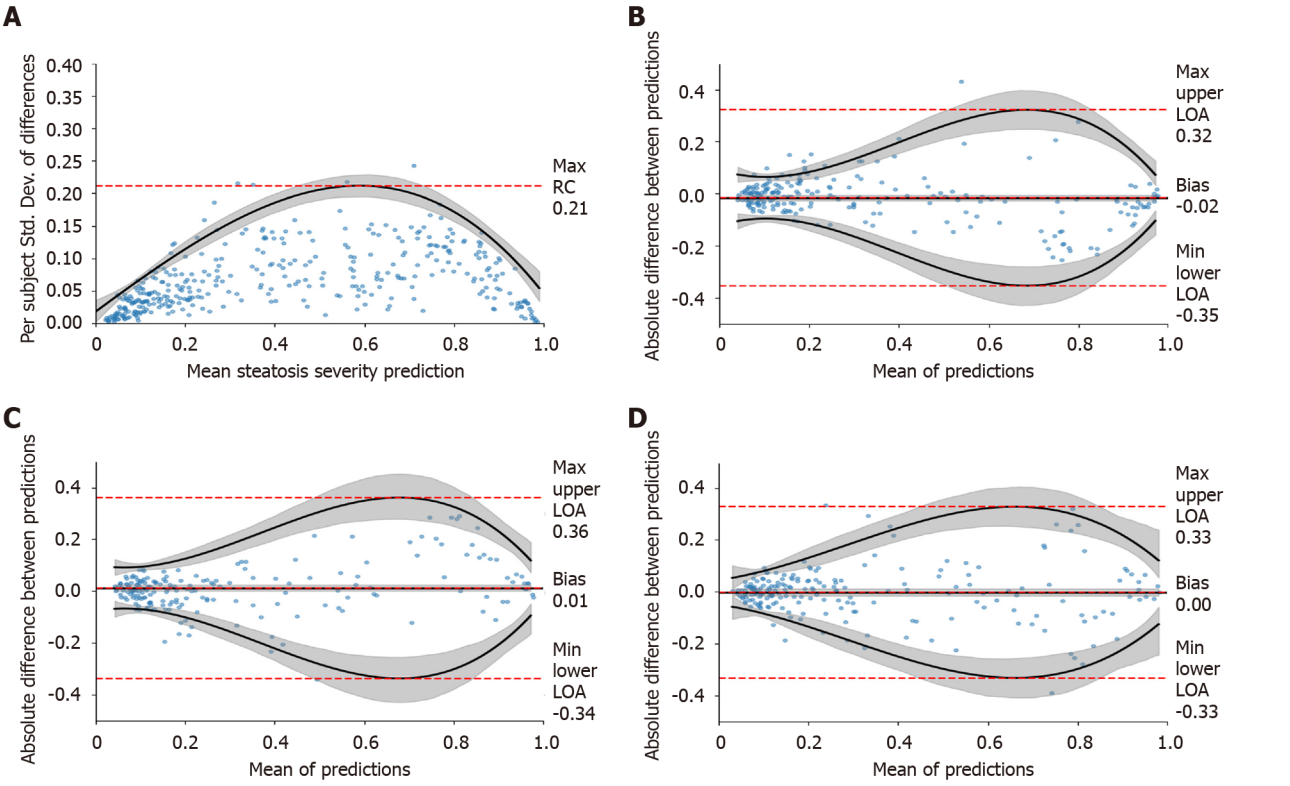

Figure 4 Repeatability study. A: A repeatability coefficient plot for right liver lobe when using three images; B-D: Cross-scanner Bland-Altman plots for Siemens-Toshiba (B), Toshiba-Philips (C), and Philips-Siemens (D), respectively. Cross-scanner plots were depicted for "All View Groups" when using ≥ three images per view group. Grey-shaded areas indicate 95% confidence intervals. RC: Repeatability coefficient; LOA: Limit of agreement.

Unlike attenuation imaging (ATI)[46], FibroScan, or some other reported DL solutions[22,25,26], our algorithm accepts images taken from both hepatic lobes rather than a selected area of interest in a specific location. We categorized 2D US images into six major viewpoints (Figure 2), which we further grouped into four view groups. We found that for each view group three images were enough to reach acceptable max RC values of 21%-30% (Table 2, Figure 4A), where the best and worst max RC values corresponded to the RLL and LKC view group, respectively. The relatively poorer repeatability of the LKC view group was likely due to the heterogenous makeup of viewpoints, as it comprises both subcostal and right lobe intercostal images. To put these repeatability ranges in context, the RC for gold standard histopathology fatty percentage assessment has been reported to be 38%[47] with poor intraclass correlation agreements of 0.57[48]. Considering our DL model's worst max RC value was 30% and that RC values tended to be much better than 30% at milder or more severe levels of steatosis (Figure 4 and Supplementary Figure 1), these repeatability measures compare well. It is also encouraging that the DL algorithm was more repeatable at milder and severe steatosis levels since such patients should indeed be less ambiguous to categorize.

[1]Filtered with a minimum of 3 images for each view group.
[2]Selecting only studies with associated FibroScan control attenuation parameter (CAP) scores.
[3]Area under the curve of the receiver operating characteristic significantly better than FibroScan CAP scores.
"Complete 4 view groups study" only selects studies where every view group is qualifying (three or more images), whereas "Individual view group study" examines the performance of each qualifying view group individually. Numbers in parentheses are 95% confidence intervals. All trends between the deep learning/CAP score and the histopathology grades were significant ($P < 0.001$). "Acc" is the classification accuracy when the threshold values calculated by optimizing the Youden index[44] are applied. LLL: Left liver lobe; RLL: Right liver lobe; LKC: Liver/kidney contrast; SC: Subcostal; HP-U: Histopathology unblinded test group; HP-T: Histopathology blinded test group; AUC: Area under the curve.

We also demonstrated good cross-scanner agreement. Bland-Altman analysis suggested bias across scanners was near zero with acceptable LOAs (35%-37%) for individual view groups, with the LOAs falling to 25% when using "All View Groups." When using categorical labels, these numbers correspond to agreements of 90% to 96%. An encouraging sign for generalizability is that cross scanner agreement is high for the Siemens: S2000 scanner, despite it being poorly represented in BD-L.

In terms of diagnostic performance, we validated on two different histology-proven cohorts (HP-U and HP-T). The "Complete view group study" of Table 3 indicated that diagnostic performance remained stable across view groups, with comparable and high AUCROC values (≥ 0.84). These results were reinforced by the "Individual view group study," which allowed each view group to be investigated individually, with a corresponding larger sample size. Again, the DL model posted good AUCROC values (≥ 0.81) across view groups and histopathology grades. As highlighted in the results, the AUCROCs in HP-T tended to be lower than in HP-U, which was most pronounced for diagnosing > 5% fatty percentage. This is explained by the 18 earlier studies acquired by low resolution scanners in HP-T (Supplementary Table 2), which produced relatively lower quality images than the more recent premium scanners. Indeed, as Figure 4B shows, excluding the older scanners raised the HP-T AUCROC scores considerably so that they matched the HP-U group (from 0.85 to 0.90 AUCROC for ≥ 5% fatty

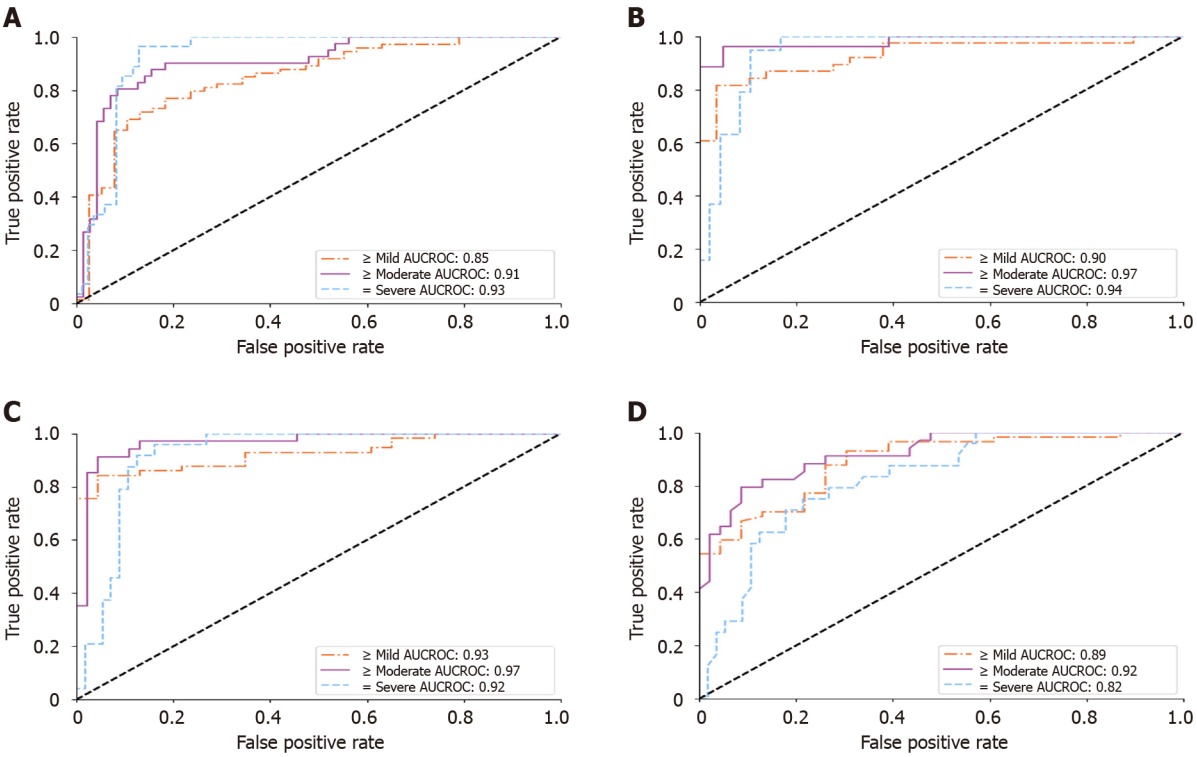

Figure 5 Receiver operating characteristic analysis on histopathology blinded test group. A and B: Receiver operating characteristic curves of the deep learning model for diagnosing hepatic steatosis grades on histopathology blinded test group (HP-T) when using all scanners and only the Siemens/Toshiba/Philips premium scanners, respectively; C and D: Only select for histopathology blinded test group studies with FibroScan diagnoses, corresponding to the performance of the deep learning algorithm and FibroScan, respectively. All receiver operating characteristic curves were measured against a histopathological gold standard. AUCROC: Area under the curve of the receiver operating characteristic.

percentage). Consequently, even though performance seemed to be stable across the tested premium scanners, the DL algorithm can be sensitive to scanner quality, which is a matter requiring further investigation.

The clinical diagnosis of our big data was generally based on the principle of Hemaguchi score, US-FLI score, and hepatorenal steatosis score[13]. Our DL algorithm demonstrated good quantitative performance despite being trained on subjective 2D US categorical labels with inter-observer variations. We speculate this is due to the exceptionally large training BD-L dataset, which included diagnoses from 63 clinicians. This allowed the DL model to "learn" and distill from a variety of clinical assessments. In addition, the DL model's continuous output allowed for a calibration against accepted gold standards. Although the distribution of etiologies between the big data training cohort and histology-proven validation cohorts were unavoidably different, validation performance remained high. Thus, these distributional differences did not seem to impede performance on a representative sample from a clinical population.

Importantly, we compared the DL algorithm's performance head-to-head with CAP of FibroScan. The DL algorithm's "All View Groups" score reported higher AUCROCs (0.92-0.97 *vs* 0.80-0.92) and accuracies (77%-91% *vs* 62%-68%) than CAP (Table 3). Statistically significant improvements were achieved for all levels on the HP-U cohort, and only for "= severe" on the HP-T cohort. This is encouraging because, unlike CAP, our DL algorithm can be applied to many different liver viewpoints and does not require additional equipment outside of an US scanner. Our DL algorithm enjoys similar advantages in flexibility over other quantitative US techniques[25,49], which examines the attenuation, brightness, or echogenicity change within a small region of interest (ROI). Such restrictions may result in missing other useful information for steatosis diagnosis (for example, liver/kidney contrast and the loss of vessel walls). Quantitative US can also not be applied to patients where the specific ROI is unable to be imaged and is often limited to a specific scanner, *e.g.*, ATI only works with Canon scanners.

The DL algorithm can be trained with large-scale retrospective datasets, which need neither costly machines nor annotation of regions of interest. Furthermore, in the inference stage, our algorithm does not require images from all hepatic views, *e.g.*, the absence of the right hepatic lobe images is acceptable, as the performance of our algorithm with left hepatic lobe images is just as good. When using "All View Groups," diagnostic AUCROCs did not improve. However, the improved cross-scanner agreement (Table 2) suggests using "All View Groups" may provide more reliability. Our algorithm could be used on different brands of scanners in different hospitals. However, each scanner or hospital may determine their cutoff values for different grades of steatosis based on their preferred gold standard (liver

histology or MRI-PDFF). Its potential applications include improved steatosis screening and longitudinal tracking in clinical settings. Our trained algorithm may be shared with researchers for non-commercial use upon reasonable requests to the clinical principal investigator (D.I.T.) and subject to IRB approval. We expect it to have good generalizability given the diversity of the BD-L dataset. Because our algorithm is trained only on retrospective US-labeled data, which are readily available in most Picture Archiving and Communication Systems, we also believe the methodology we presented here to be highly generalizable and accessible to institutions wishing to train their own algorithms.

The use of machine learning technologies for non-invasive liver steatosis assessment has received attention for a number of years[19-27]. This work represents a significant step forward. Like this work, many prior solutions were built upon recent DL techniques[22,24-27], which Supplementary Table 7 summarizes. Apart from Gummadi *et al*[22], all other works only test on a single scanner. Moreover, our evaluation includes more than one etiology: HBV, HCV, and NBNC liver diseases. In terms of training, we use so-called "big-data," which included 13 known different US scanner models and over 228000 images and 19000 US studies. This dwarfs the training set size of other works and should contribute to better model generalizability. Another important point is that most prior studies used one specific viewpoint[19,20,24] or manually defined area of interest[22,25,26], which can restrict their applicability. Like Byra *et al*[27], we investigated performance across different views. In addition, we investigated different viewpoints in both hepatic lobes. This advantage is most evident for patients with one resected hepatic lobe or a lobe whose space is occupied by a lesion. Furthermore, this study measured agreement across three different scanners and repeatability across different view groups and across different numbers of images per view group, which are analyses not found in other studies. Finally, we are the first to directly compare against a leading non-invasive alternative: CAP of FibroScan.

Our study has several limitations. First, we primarily used histology as the gold standard for assessing liver steatosis, which can suffer from sampling errors, processing variabilities, and intra- and inter-observer variability[48,50]. A histopathological gold standard also introduced patient selection bias. For example, CGMH histology is not required to initiate therapy in patients with HCV, whereas it is often required for patients with HBV or nonalcoholic steatohepatitis. In addition, we selected US studies completed within 3 mo of a liver histology study. If there were vigorous lifestyle changes within 3 mo, we may have a risk of deviation between fatty scores of US image and liver histology. Thus, investigating and validating against other non-invasive scores, both imaging and non-imaging based, remains an important task. Second, for assessing diagnostic performance we used retrospective data. To impose a degree of standardization, we required there to be at least 3 images in a view group and ≥ 10 images in the whole US study. Nonetheless, more controlled experimental settings may allow for more precise comparisons and follow-up prospective studies should implement an acquisition protocol to assess diagnostic performance in varied settings. In particular, the relatively poorer repeatability of the LKC view group should be investigated, and, if necessary, adjustments to the protocol should be made. Third, patients in HP-U and HP-T may also have co-occurring liver fibrosis, which likely has complex interactions with hepatic steatosis. The effect of this interaction on interpretations needs further study. Fourth, the scanner quality and model does seem to impact the DL model. Future work should better measure this impact, focusing on premium scanners not seen in the training data, which would better characterize generalizability. Fifth, the combined case numbers in HP-U and HP-T were more than 200, but the number with "complete view groups" was relatively small. Relatedly, the data collected in this study were all acquired from the CGMH institution, so any conclusions must be interpreted cautiously. Measuring performance across multiple centers, ideally using a prospective data collection protocol with larger evaluation cohorts, remains an important aspect of future work.

CONCLUSION

The DL algorithm provided a reliable quantitative steatosis assessment across view and scanners on two multi-scanner cohorts. Diagnostic performance was high with comparable or better performance than CAP. This algorithm could be applied to prospectively as well as retrospectively collected 2D US images.

ARTICLE HIGHLIGHTS

Research background

Two-dimensional (2D) ultrasound has been used for screening of liver steatosis for more than 5 decades. It is a cheap and non-invasive study.

Research motivation

Two-dimensional ultrasound is a subjective diagnosis that is not suitable for quantitative study.

Research objectives
To produce an objective steatosis diagnostic algorithm by deep learning from big data of 2D ultrasound images.

Research methods
Using multi-view ultrasound big data from a retrospective cohort of patients, we trained a deep learning algorithm to diagnose steatosis stages from clinical ultrasound diagnoses. Performance was validated on two multi-scanner unblinded and blinded histology-proven cohorts with histopathology diagnoses and a subset with FibroScan diagnoses. We also quantified reliability across scanners and viewpoints. Results were evaluated using Bland-Altman and receiver operating characteristic analysis.

Research results
The deep learning algorithm demonstrated repeatable measurements with a moderate number of images and high agreement across three premium ultrasound scanners. High diagnostic performance was observed across all viewpoints. Areas under the curve of the receiver operating characteristic to classify mild, moderate, and severe steatosis grades were 0.85, 0.91, and 0.93, respectively. This algorithm outperformed or performed at least comparably to FibroScan control attenuation parameter on the unblinded or blinded histology-proven cohort.

Research conclusions
This algorithm could give an objective diagnosis of steatosis from prospectively or retrospectively collected 2D ultrasound images.

Research perspectives
The cutoff values for different grades of steatosis would need future studies in different scanners and fibrosis status.

Abstract

BACKGROUND

Probiotics are a promising solution for managing irritable bowel syndrome (IBS). *Saccharomyces cerevisiae* (*S. cerevisiae*) I-3856 has already demonstrated beneficial effects in IBS subjects, particularly in IBS with predominant constipation (IBS-C).

AIM

To confirm the efficacy of *S. cerevisiae* I-3856 in the management of gastrointestinal symptoms in IBS-C.

METHODS

A randomized, double-blind, placebo-controlled clinical study was performed in a total of 456 subjects. After a run-in period, subjects were randomly assigned to the group receiving *S. cerevisiae* I-3856 (8×10^9 CFU daily) or the placebo for 8 wk, and they performed daily self-evaluations of gastrointestinal symptoms. The primary objective was to assess the effect of the probiotic on abdominal pain. The secondary objectives were the evaluation of other gastrointestinal symptoms, bowel movement frequency and consistency, and quality of life (QOL).

RESULTS

A significantly higher proportion of abdominal pain responders was reported in the Probiotic group (45.1% *vs* 33.9%, P = 0.017). A nonsignificant difference in the area under the curve for abdominal pain over the second month of supplementation was observed in subjects receiving probiotic *vs* placebo [P = 0.073, 95%CI: -0.59 (-1.23; 0.05)]. No statistically significant differences were reported in the evolution of bowel movement frequency and stool consistency between the groups. After 8 wk of supplementation, the overall QOL score was significantly higher in the Probiotic group than in the Placebo group [P = 0.047, 95%CI: 3.86 (0.52; 7.20)]. Furthermore, exploratory analyses showed statistically significant and clinically relevant improvements in QOL scores in abdominal pain responders *vs* nonresponders.

CONCLUSION

The results of this clinical study confirmed the abdominal pain alleviation properties of *S. cerevisiae* I-3856 in IBS-C. Abdominal pain relief was associated with improved QOL. ClinicalTrials.gov identifier: NCT03150212.

INTRODUCTION

Irritable bowel syndrome (IBS) is a disorder of gut-brain interaction[1] that affects approximately one in ten people globally[2]. This chronic condition is characterized by recurrent abdominal pain related with altered bowel habits. In addition to the patient's suffering, it represents a significant burden from both economic and social perspectives. It has indeed been associated with important psychosocial consequences as well as considerable costs to health care systems and society[3,4]. Limitations and impairment of social and emotional daily functioning of IBS patients is demonstrated by the consistently reported profound reductions in quality of life (QOL) compared with the general population[5,6]. QOL impairments in IBS are of similar magnitude to those in more severe diseases, such as inflammatory bowel diseases or depression[5,7,8]. The high prevalence of IBS, as well as its significant morbidity, result in substantial health care utilization and loss of work productivity that represent considerable direct and indirect costs to society[4,9,10].

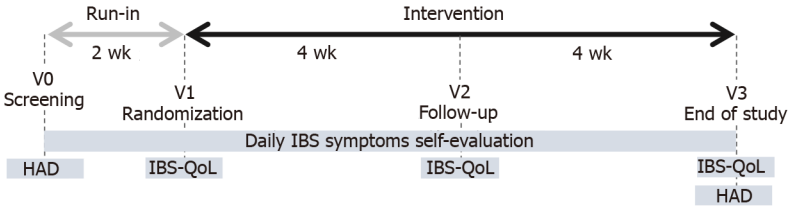
IBS is a complex and heterogenous condition. Although abdominal pain is the cardinal feature, IBS patients can be classified into different subtypes depending on their predominant stool pattern: IBS with predominant constipation (IBS-C), IBS with predominant diarrhoea (IBS-D), IBS with mixed bowel habits (IBS-M) and IBS unclassified. The pathogenesis of IBS has been described as multifactorial and involves a combination of factors related to motility, visceral hypersensitivity, mucosal immune dysregulation, alterations of gut microbiota, and central and enteric nervous system dysregulation[1]. However, interventions remain symptom-driven, and available pharmacological treatment options are of limited efficacy[11]. Complementary and alternative solutions to achieving satisfactory control of gastrointestinal symptoms and improve QOL in IBS patients are therefore of great interest. The gut microbiota has been proposed as central in IBS pathophysiology and has therefore drawn considerable

interest[12,13]. Among microbiota-directed interventions, probiotics have been recognized as a potential solution for acting on the multifactorial causes and clinical symptoms of IBS[14,15]. A meta-analysis of fifty-three randomized controlled trials (RCTs) involving a total of 5545 patients was recently performed. It demonstrated overall beneficial effects of probiotics on global IBS symptoms and abdominal pain with favourable safety profiles, although conclusions were drawn for probiotics in general[16]. Due to the important heterogeneity of both the tested strains and study designs, identifying which probiotics are relevant for IBS management remains a challenge[17]. However, a recently conducted meta-analysis provided further evidence to determine which probiotic strains are effective in IBS symptom management. Among the probiotics analysed, *Saccharomyces cerevisiae* (*S. cerevisiae*) CNCM I-3856 emerged as a recognized solution[18].

S. cerevisiae CNCM I-3856 provides statistically significant and clinically relevant benefits for individuals with IBS, as demonstrated in three RCTs[19-21] performed in a total of 679 subjects and an individual patient data (IPD) meta-analysis[22]. This meta-analysis confirmed previous observations linking *S. cerevisiae* CNCM I-3856 supplementation to improvement in gastrointestinal symptoms in all IBS subpopulations. Nevertheless, the strongest effects were reported in IBS with predominant constipation. Considering these results, we designed a clinical study to confirm the efficacy of *S. cerevisiae* CNCM I-3856 on gastrointestinal symptom management in an IBS population with predominant constipation.

MATERIALS AND METHODS

A large-scale, multicentric, placebo-controlled, randomized, double-blind, clinical study was conducted between March 2017 and May 2019. The study was approved by the Ethics Committee Ouest VI of Brest (France) and performed according to International Conference on Harmonization Good Clinical Practice and the ethical principles of the Declaration of Helsinki. Signed written informed consent for the study was obtained from all subjects before protocol-specific procedures were carried out.



The clinical trial was registered in a clinical trials registration system at ClinicalTrials.gov with the identifier NCT03150212.

Study population

Subjects with IBS were recruited by ten French general practitioners across France and in four clinical investigation centres, including Biofortis Mérieux Nutrisciences as the principal investigational centre. Females and males aged 18-75 years were eligible to participate if they met the Rome IV criteria[23] for IBS-C with a baseline score for abdominal pain ≥ 2 and < 6 assessed on a 7-point Likert scale scored from 0 (null) to 7 (severe pain) and had an IBS history between 1 and 10 years. All volunteers agreed to maintain their lifestyle behaviours during their participation in the study. Participants were excluded if they had chronic gastrointestinal conditions other than IBS, including inflammatory bowel diseases, lactose intolerance, and celiac disease. Individuals with a metabolic disorder affecting intestinal transit function or nutrient absorption, such as diabetes or unbalanced thyroid dysfunction, were excluded. Volunteers undergoing symptomatic drug treatments acting on intestinal sensitivity or motility, such as opioids and narcotic analgesics, were not eligible. Antibiotic or antifungal therapies in progress or prescribed 4 or 2 wk before randomization, respectively, were also considered an exclusion criterion. The use of probiotics, prebiotics, symbiotics or any dietary supplement that, according to the investigator, could affect study outcomes in the four weeks preceding randomization was prohibited. However, laxatives, antibloating agents, antispasmodics, anxiolytics, antidepressants, analgesics and nonsteroidal anti-inflammatory drugs were authorized if consumed for longer than three months and maintained at a stable dosage for the entire study duration.

Study design

This study consisted of a 2-wk run-in period followed by an 8-wk treatment period. Subjects visited the clinical investigation centre or general practitioner four times: V0 (screening visit), V1 (randomization visit, 2 wk after V0), V2 (follow-up visit, 4 wk after V1) and V3 (end-of-study visit, 8 wk after V1) (Figure 1). Screening visits (V0) were planned to assess whether inclusion and exclusion criteria were met and to explain study instructions. Additionally, recommendations were given to volunteers to avoid changes in lifestyle behaviours (including dietary and physical activity habits), and volunteers were asked to perform a daily evaluation of the intensity of IBS symptoms and bowel movements. At the randomization visit (V1), investigators confirmed the eligibility (including the Rome IV diagnostic criteria for IBS-C) of the volunteers by integrating the daily evaluation of abdominal pain and bowel movement consistency. Eligible subjects were randomized to receive daily *S. cerevisiae* CNCM I-3856 (Probiotic group) or placebo (Placebo group) for 8 wk. The product allocation list was prepared using SAS® software (version 9.3, SAS Institute Inc., Cary, NJ, United States) before the study started and stored confidentially by a person not related to the clinical phase or data management. The product allocation list was generated using a dynamic randomization algorithm designed to minimize imbalance between the two supplemented groups within each investigational site. Blinding of allocation was

Figure 1 Study design.

maintained until the completed study database was locked.

Data collected

During the baseline and intervention periods, volunteers were asked to perform a daily evaluation of the intensity of IBS symptoms (abdominal pain, bloating, and flatulence/borborygmi) on a 7-point Likert scale rated from 0 (null) to 7 (severe). Bowel movement consistency assessed on the Bristol stool scale (BSS) was recorded daily. Volunteers completed an IBS-specific quality of life questionnaire (IBS-QOL) at randomization (V1), follow-up (V2) and the end of the intervention (V3). The IBS-QOL is a 34-item instrument that yields an overall QOL score as well as scores for eight domains (dysphoria, interference with activity, body image, health worry, food avoidance, social reaction, sexual, relationships). Final scores were normalized to a 100-point scale, with 0 indicating the worst QOL and 100 indicating the best QOL. Anxiety and depression symptoms were also assessed using the hospital anxiety and depression questionnaire at screening (V0) and end-of-study visits (V3).

Study products and compliance evaluation

The study evaluated the probiotic yeast *S. cerevisiae* CNCM I-3856. This strain is a proprietary, well-characterized strain of Lesaffre registered in the French National Collection of Cultures of Microorganisms. The *S. cerevisiae* species was characterized using phenotypic (API® ID32C, Biomerieux SAS) and genotypic referenced methods (genetic amplification and sequencing of 26S DNA)[24,25]. Moreover, strain I-3856 can be identified *via* a polymerase chain reaction interdelta typing technique[26] and complete genome sequencing. The dose tested was of 8×10^9 CFU provided daily in two capsules of 500 mg each. The probiotic dietary supplement was provided by Gnosis by Lesaffre (a business unit of Lesaffre Group, France) and comprised *S. cerevisiae* CNCM I-3856 entirely and exclusively. The comparative product was a placebo comprising inactive ingredients, *i.e.*, maize starch and magnesium stearate. All capsules were made from hydroxypropyl methylcellulose of the same size, weight, colour and taste regardless of the group and prepared according to good manufacturing practices. Every subject consumed two capsules of 500 mg per day in the morning, just before breakfast with a glass of water. Compliance was determined through the assessment of returned packaging and interviews of the subjects at each visit.

Study endpoints

The primary endpoint was the area under the curve, *i.e.*, the sum of weekly means of daily scores of abdominal pain calculated with the trapezoidal method (interpolation of scores between weeks) from week 5 to week 8 [area under the curve (AUC) (W5-W8)], and it was determined based on previously reported data on the strain[22]. Prespecified secondary endpoints were the total AUC (W0-W8) of IBS symptoms (abdominal pain, bloating, and flatulence/borborygmi) and AUC (W5-W8) of bloating and flatulence/borborygmi scores. Mean weekly scores of gastrointestinal symptoms (abdominal pain, bloating and flatulence/borborygmi) were analysed at each week of the intervention. The evolution of abdominal pain was also assessed through the analysis of the percentage of responders. Abdominal pain response was set according to recommended guidelines[27,28]. Responders were defined as subjects who experienced a reduction of at least 30% of the mean daily abdominal pain score reported at baseline (week 0) from week 5 to week 8. The global QOL score and the eight derived subscores corresponding to the different domains of QOL were assessed at V1 and V2 and at the end of the intervention. Mean stool consistency (BSS scores) and the mean daily number of bowel movements were assessed at each week of the intervention.

Safety endpoints

The safety of the intervention was assessed considering the occurrence of adverse events and the follow-up of vital signs.

Statistical analyses

Sample size: Based on previous studies performed on IBS-C subjects, considering a 5% type-one error

rate and 80% power, 205 subjects per arm would allow the detection of a 1 arbitrary unit (a.u.) difference between groups in AUC (W5-W8) of abdominal pain scores (12% difference) assuming a standard deviation of 3.6 a.u./d.wk. Enrolling a total of 456 subjects would allow for a 10% drop-out.

Efficacy analyses: Efficacy analyses were performed for the intention-to-treat (ITT) population (including all randomized subjects in the study) and for the per-protocol population (ITT population who completed the study and presented no major protocol deviations). The primary endpoint, *i.e.*, the AUC (W5-W8) for abdominal pain, and the other AUCs of IBS symptoms were analysed using an analysis of covariance (ANCOVA) model. Repeated measurements such as the mean daily number of bowel movements, the mean stool consistency and IBS-QOL questionnaire were analysed using ANOVA models. The percentage of abdominal pain responders was analysed by a Chi^2 test. IBS-QOL scores were additionally examined in exploratory analyses that focused on abdominal pain responders. These analyses were conducted through ANCOVA models for repeated measurements with the baseline (V1) as the cofactor. For all statistical tests, the 5% level of significance was used to justify a claim of a statistically significant effect and standardized mean difference (SMD) was calculated. Hochberg adjustments were used to correct for multiple testing.

Safety analyses: The safety population included all subjects who had consumed at least one dose of the products. For each term of severity and causality, the proportion of subjects showing at least an adverse event was compared between groups using a Chi^2 or Fisher's exact test. The number of events was compared between groups using a Poisson regression model.

Software: Statistical analyses were performed using SAS® software version 9.4 (SAS Institute Inc., Cary, NC, United States). Exploratory analyses were performed using R software version 4.0.3.

RESULTS

Study flowchart and baseline characteristics of the population

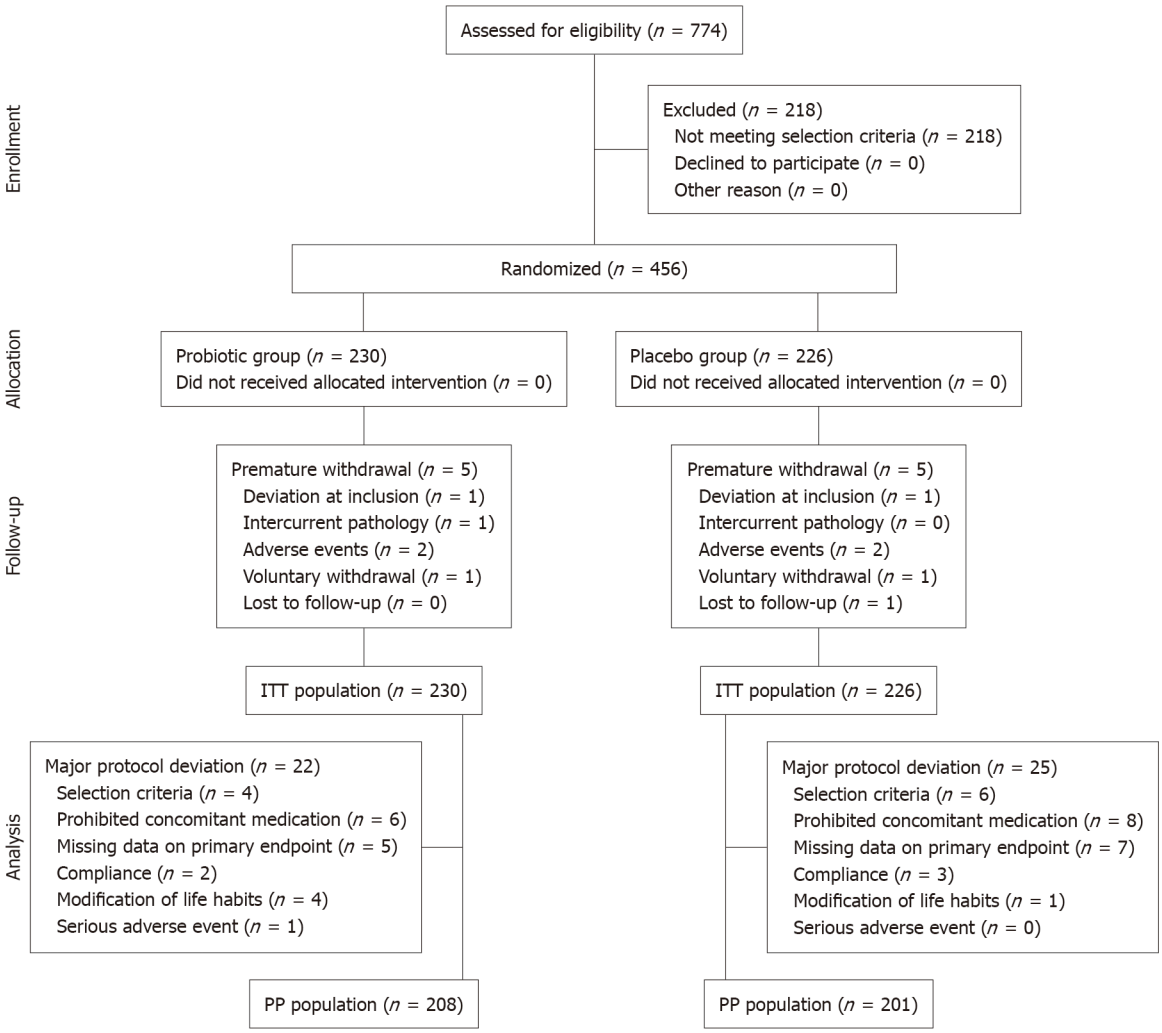
A total of 456 IBS subjects (392 females, 64 males) with predominant constipation matching the Rome IV criteria were included in this study and randomly assigned to the Probiotic group (n = 230) or the Placebo group (n = 226). The flowchart of subjects throughout the study is presented in Figure 2. The baseline characteristics of the subjects are presented in Table 1. The quantitative variables are described through the mean ± SD, and qualitative variables are described through the number of subjects and percentages (%).

Abdominal pain-AUC

The abdominal pain scores were similar at baseline in the Probiotic (3.97 ± 1.04 a.u.) and the Placebo (3.98 ± 1.07 a.u.) groups. Significant reductions in abdominal pain scores throughout the 8 wk of supplementation were observed in the Placebo group and in the Probiotic group, with reductions of 24.1% and 28.7%, respectively, from baseline at the end of the intervention (P < 0.001 in both groups). The abdominal pain over the 8-wk intervention period decreased similarly to previously reported results. A nonsignificant difference was observed in the AUC for abdominal pain over the second month of supplementation in subjects receiving probiotic *vs* placebo [-6.3%, P = 0.073, 95%CI: -0.59 (-1.23; 0.05)], between-group difference from ANCOVA model) (Figure 3). Similarly, no difference was reported in the AUC over the 8 wk of intervention.

Abdominal pain-percentage of responders

A significant difference between groups was found in the percentage of responders. The percentage of responders was significantly higher in the group receiving *S. cerevisiae* CNCM I-3856 (45.1%, 101 subjects among 224 subjects with available data) than in the Placebo group (33.9%, 74 subjects among 218 subjects with available data), resulting in an increase of 33% in the proportion of responders in the treated group *vs* placebo (Figure 3, Supplementary Figure 1) (P = 0.017, Chi^2 test).



QOL (IBS-QOL)

A higher overall IBS-QOL score, indicative of better QOL, was reported at the end of the intervention in the Probiotic group (79.51 ± 2.34 a.u.) compared with the Placebo group (75.65 ± 2.39 a.u.) in the PP population [P = 0.047, 95%CI: 3.86 (0.52; 7.20), SMD = 0.18]. Improved QOL in the Probiotic group translated into a mean increase in the overall IBS-QOL score of 11.9% from baseline. The analysis of the eight domains of the IBS-QOL questionnaire showed statistically significant differences in favour of the Probiotic group for 3 domains, *i.e.*, interference with activity [P = 0.05, 95%CI: 4.30 (0.54; 8.05), SMD = 0.18)], body image [P = 0.040, 95%CI: 3.96 (0.17; 7.75), SMD = 0.17)], and food avoidance [P = 0.030, 95%CI: 5.69 (1.10; 10.28), SMD = 0.22)] (Figure 4, Supplementary Figure 2, Supplementary Table 1). Exploratory analyses of IBS-QOL scores were conducted to evaluate the evolution of the QOL among the responders during the time of supplementation with *S. cerevisiae* CNCM I-3856. The QOL was

significantly more improved in the abdominal pain responder group than in the nonresponder group; these differences in improvement following eight weeks of intervention with *S. cerevisiae* CNCM I-3856 were observed for the overall score and for the eight subscores of the IBS-QOL questionnaire. The improvements with the largest difference between responders and nonresponders were for the body image score [between-group difference from ANOVA model: $P < 0.001$, 95%CI: 11.94 (8.53; 15.35), SMD = 0.56], health worry score [$P < 0.001$, 95%CI: 10.91 (7.16; 14.66), SMD = 0.43], food avoidance score [$P < 0.001$, 95%CI: 9.90 (5.14; 14.66), SMD = 0.38] and dysphoria score [$P < 0.001$, 95%CI: 8.86 (5.79; 11.92), SMD = 0.42] (Figure 5, Supplementary Figure 3, Supplementary Table 2).

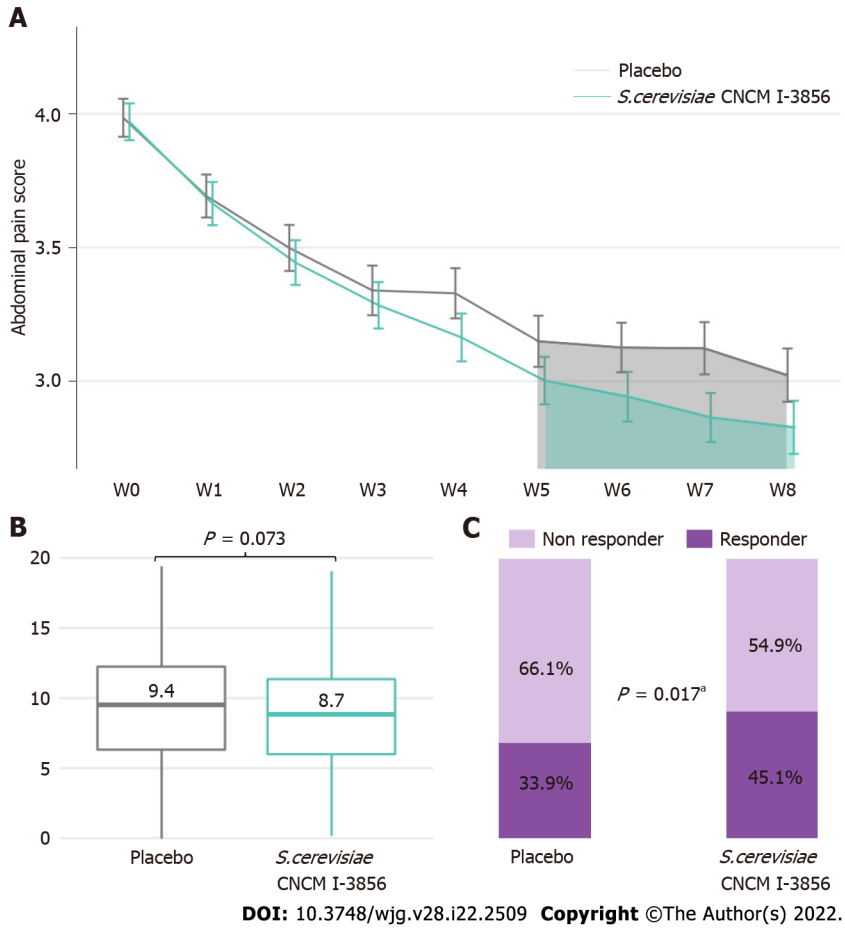

Figure 3 Abdominal pain. A: Abdominal pain score evolution; B: Area under the curve (W5-W8) of abdominal pain; C: Percentage of abdominal pain responders in the ITT population. Significant result ($^aP < 0.05$, Chi^2 test). Similar profiles were obtained for the PP population (Supplementary Figure 1).

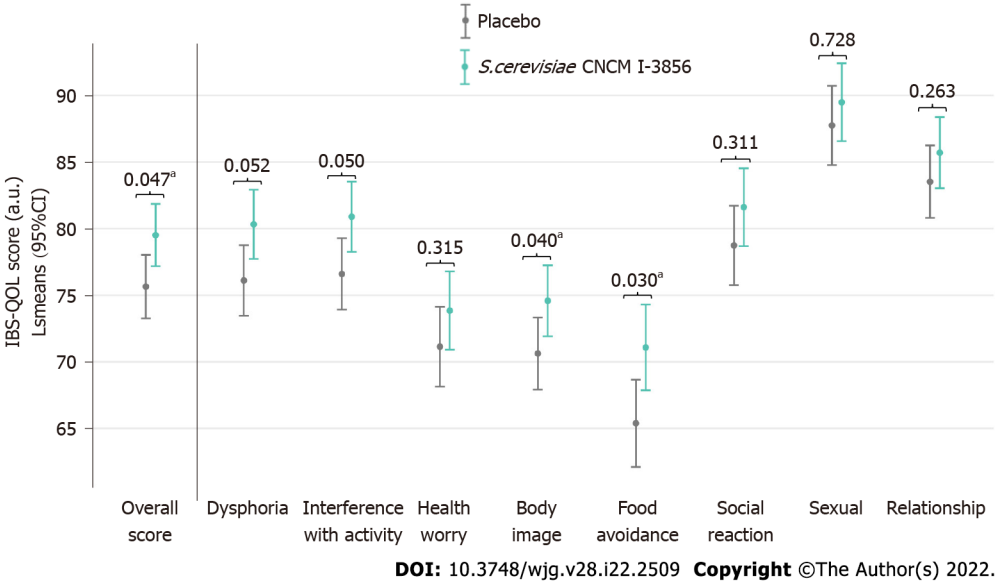

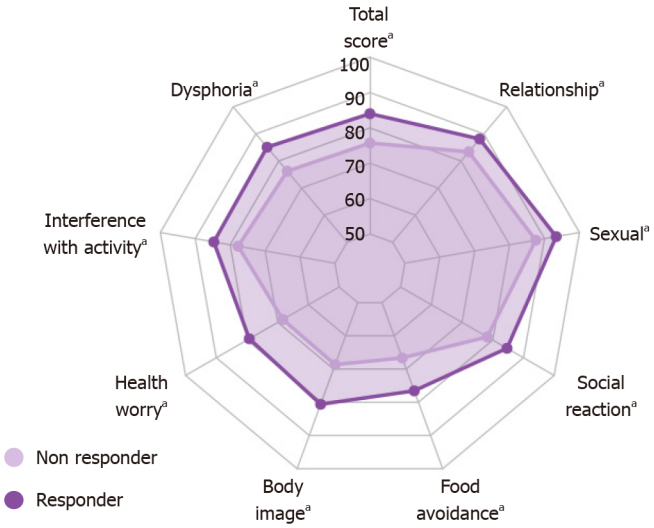

Figure 4 Irritable bowel syndrome-specific quality of life questionnaire scores at the end of the intervention (V3) in the PP population. Significant result ($^aP < 0.05$, ANOVA model).

Other gastrointestinal symptoms, bowel movement frequency and consistency

At baseline, the bloating scores were similar in both groups (3.99 ± 1.52 a.u. in the Probiotic group *vs* 4.04 ± 1.83 a.u. in the Placebo group). Kinetic profiles of the bloating score over the 8-wk supplementation period showed a statistically significant decrease in both groups corresponding to a bloating

Figure 5 Irritable bowel syndrome-specific quality of life questionnaire scores at the end of the intervention (V3) adjusted to baseline (V1) in ITT abdominal pain responders supplemented with *Saccharomyces cerevisiae* CNCM I-3856. PP population radar plot: Supplementary Figure 3. Significant result ([a]$P < 0.05$, ANCOVA for repeated measures). Between-group differences are shown in Supplementary Table 2.

score reduction of 28.4% (95%CI: 23.9-33.0) and 24.5% (95%CI: 19.7-29.5) in the Probiotic and Placebo groups, respectively (between W0 and W8, $P < 0.001$ in both groups, within-group differences from the ANCOVA model). A similar decrease in the flatulence/borborygmi score was observed in both the Placebo and Probiotic groups. The bowel movement frequency and BSS scores increased in Probiotic and Placebo groups between W0 and W8 ($P < 0.01$ from W1 to W8), but no statistically significant differences were found between the groups.

Safety

The number of adverse events per subject showed no statistically significant difference between the groups [$P = 0.50$, 95%CI: 1.10 (0.83; 1.46)], between-group difference from Poisson regression model). Similarly, there was no statistically significant difference between groups regarding the proportion of subjects with at least one adverse event (assessed for each term of severity and for adverse events whose causality with the study product or with the research was considered "not excluded") (Table 2). Descriptive statistics of the adverse events by body system are presented in Supplementary Table 3. Three serious adverse events occurred during the study (1 in the Probiotic group and 2 in the Placebo group). The relationship with the study product was considered "not excluded" for one serious adverse event in the placebo group (bowel obstruction).

DISCUSSION

The beneficial properties of *S. cerevisiae* CNCM I-3856 for gastrointestinal symptom management in the IBS population have been reported in three RCTs conducted in a total of 679 participants[19-21]. An individual patient data meta-analysis reported the strongest effects of the strain in IBS with predominant constipation[22]. To validate these observations, the effect of *S. cerevisiae* CNCM I-3856 was specifically investigated in this population in the present clinical study.

Effect of S. cerevisiae CNCM I-3856 on abdominal pain

The evolution of abdominal pain reported in IBS-C with moderate symptom severity in this study was consistent with previous findings. Lower abdominal pain intensity over the second month of supplementation was observed in the Probiotic group than in the Placebo group, although the difference was not significant. Abdominal pain alleviation during supplementation with *S. cerevisiae* CNCM I-3856 was confirmed by the higher proportion of abdominal pain responders in the Probiotic group than in the Placebo group. The definition of abdominal pain responder used in this study is aligned with current recommendations and corresponds to a reduction of abdominal pain intensity from baseline of at least 30%[27,28]. The higher rate of responders observed in this study during daily supplementation with *S. cerevisiae* CNCM I-3856 compared with placebo is consistent with previously reported results[19,22]. Pineton de Chambrun *et al*[19] reported a significantly higher percentage of responders in the probiotic group than in the placebo group (63% *vs* 47%, $P = 0.04$). The IPD meta-analysis conducted on *S. cerevisiae* CNCM I-3856 further confirmed this finding. Participants in the probiotic group had 1.51 higher odds of

Table 2 Descriptive statistics of the proportion of subjects with adverse events

	Placebo group (*n* = 226)	Probiotic group (*n* = 230)
Causality with the study product not excluded	13 (5.8)	15 (6.5)
Causality with the research not excluded	1 (0.4)	2 (0.9)
Serious	2 (0.9)	1 (0.4)
Severe	12 (5.3)	17 (7.4)
Moderate	55 (24.3)	74 (32.2)
Mild	39 (17.3)	46 (20.0)

Values are presented as the number of subjects with at least one adverse event, *n* (%).

being a responder than participants in the placebo group (P = 0.02)[22]. The abdominal pain responder definition used in previous studies was slightly different. Responders were defined as subjects experiencing a decrease in abdominal pain intensity greater than or equal to 1 a.u. of abdominal pain score, assessed on a 7-point Likert scale, for at least 50% of the second month of supplementation. Based on the mean level of abdominal pain intensity reported at baseline in this study, a decrease of 1 a.u. would correspond to a mean 25% decrease in abdominal pain intensity. The stricter definition of the responders used in our study likely contributes to the lower percentage of abdominal pain responders reported here. However, when using a more demanding definition, the present study confirmed the beneficial effect of *S. cerevisiae* CNCM I-3856 on abdominal pain. This result is of great clinical interest as it meets the clinically relevance threshold previously proposed[29]. Therefore, the relevance of *S. cerevisiae* CNCM I-3856 in addressing abdominal pain in IBS-C is confirmed. Effective solutions to managing abdominal pain may be even more critical in this subpopulation, as recent findings have shown that individuals with IBS-C experience more bothersome, frequent and diffuse abdominal pain [30].

Effect of S. cerevisiae CNCM I-3856 on QOL

Importantly, this clinical study also showed improvements in QOL in the probiotic group. Indeed, significant differences were found at the end of the intervention period in the overall IBS-QOL score as well as in several domains. Notwithstanding, the magnitudes of these differences were relatively low. The consequences of IBS on daily function in addition to physical symptoms were further investigated in abdominal pain responders to provide a more accurate understanding of the overall impact of diet supplementation with *S. cerevisiae* CNCM I-3856.

Specific tools have been developed to capture emotional, social and physical functions. The IBS-QOL is currently the most validated self-reported QOL measure[31-33]. Here, we showed that the abdominal pain alleviation reported in responders was accompanied by significant and clinically relevant improvements in IBS-QOL. A strong association between abdominal pain and QOL has been previously described, and a causality relation has been suggested[34]. Moreover, it has also been shown that IBS patients attributed their impairment in daily functioning directly to IBS symptoms[35].

QOL improvements appeared to be mainly driven by specific domains of QOL: dysphoria, food avoidance, health worry and body image. Improvement in the food avoidance subscale of the IBS-QOL is of interest, as perceived restrictions in lifestyle related to gastrointestinal symptoms are commonly reported in the literature and encountered in clinical practice[33,35]. A considerable proportion of IBS patients report an association between food and gastrointestinal symptoms[36]. Food-related gastrointestinal symptoms have been associated with more severe IBS symptoms and lower QOL[37]. Individuals with IBS have been reported to experience emotional dysphoria, which can also be described as feeling helpless, out of control and depressed. It may therefore not be surprising that individuals experiencing significant abdominal pain alleviation also reported improvement in the dysphoria subscale of the IBS-QOL. In addition, significant improvement was seen in the body image subscale of the IBS-QOL. This result also appears consistent with the literature, as individuals with IBS-C have been described as more likely to internalize their distress and to feel self-conscious about their body image[38].

Effect of S. cerevisiae CNCM I-3856 on gastrointestinal symptoms

In contrast with previous findings, no significant between-group differences were observed in the AUC for gastrointestinal symptoms. Although the clinical studies conducted on *S. cerevisiae* CNCM I-3856 in IBS present consistent designs, a significant change here is the use of Rome IV criteria to select the participants. A worldwide comparison of IBS prevalence by Rome IV and Rome III diagnostic criteria demonstrated that individuals diagnosed by Rome IV criteria exhibit higher IBS severity. Consistently, a higher level of abdominal pain was reported at baseline in this study than in previous clinical trials

conducted on *S. cerevisiae* CNCM I-3856. Among factors associated with response to placebo in IBS-C, higher baseline symptom severity was reported as an important predictor of placebo response[40]. Differences in the studied population could therefore have contributed to the lower between-group size effect reported in this study.

Previous studies have reported statistically significant effects of this probiotic on bowel transit in IBS-C, IBS-D and IBS-M, assessed by daily reporting of bowel movement frequency and consistency[22,21]. In contrast, we did not find between-group differences in bowel movement frequency or consistency in this study. Spiller *et al*[20] highlighted the possible role of accelerated bowel transit as central in the relief of abdominal pain and bloating in IBS-C. Instead, the absence of a significant effect on bowel transit in this study as well as the reported improvements in abdominal pain in all IBS subtypes suggest that other mechanisms of action may be involved and participate in the clinical benefits.

Regarding putative mechanisms of action of S. cerevisiae CNCM I-3856

Several putative mechanisms of action of *S. cerevisiae* CNCM I-3856 can be hypothesized. First, the anti-inflammatory effects of *S. cerevisiae* CNCM I-3856 have been reported in several preclinical models[41-45]. The immune-modulating properties of the strain may be relevant in IBS, as chronic low-grade intestinal mucosal inflammation has been implicated in IBS pathophysiology. Second, interactions with the gut microbiota might influence the multiple factors involved in IBS pathophysiology[12,46]. The results from trials conducted in a Simulator of the Human Intestinal Microbial Ecosystem (SHIME®) suggest that *S. cerevisiae* CNCM I-3856 can modulate gut microbiota activity towards an increase in short-chain fatty acids (SCFAs)[47]. This result may be of particular importance, as a recently published longitudinal multiomics study showed significantly lower levels of SCFAs in the stool samples of IBS-C patients than in those of healthy controls[48]. In addition, several lines of evidence suggest that increased levels of SCFAs, such as butyrate, may be beneficial in IBS management[49-51]. Nevertheless, these possible mechanisms of action remain speculative and would need to be addressed separately. Differences in microbiota composition and function between abdominal pain responders and nonresponders may provide a mechanistic basis for the beneficial effects of *S. cerevisiae* CNCM I-3856 in IBS management and warrant further exploration.

CONCLUSION

In conclusion, the results of this large-scale clinical study are consistent with previous findings and confirm the safety and efficacy of *S. cerevisiae* CNCM I-3856 for abdominal pain management in IBS-C. In addition, abdominal pain alleviation was associated with significant improvements in IBS-related QOL. Dietary supplementation with *S. cerevisiae* CNCM I-3856 therefore appears to be an interesting complementary or alternative solution for IBS management with positive implications for the day-to-day life of individuals with IBS-C.

ARTICLE HIGHLIGHTS

Research background

The gut microbiota has been proposed as central in irritable bowel syndrome (IBS) pathophysiology, and microbiota-directed intervention has therefore drawn considerable interest. Among them, *Saccharomyces cerevisiae* (*S. cerevisiae*) CNCM I-3856 is a probiotic yeast that has emerged as a recognized solution for managing IBS.

Research motivation

S. cerevisiae I-3856 has demonstrated beneficial effects in IBS subjects, particularly in IBS with predominant constipation.

Research objectives

To confirm the efficacy of *S. cerevisiae* CNCM I-3856 on gastrointestinal symptom management in an IBS population with predominant constipation.

Research methods

A total of 456 subjects were enrolled in a randomized, double-blind, placebo-controlled trial. After a run-in period to confirm IBS diagnosis, subjects were randomly assigned to the group receiving the probiotic or the placebo for 8 wk and performed daily self-evaluations of gastrointestinal symptoms. The primary objective was to assess the effect of the probiotic on abdominal pain. The secondary objectives were the evaluation of other gastrointestinal symptoms, bowel movement frequency and consistency, and quality of life (QOL).

Research results

Abdominal pain alleviation during supplementation with *S. cerevisiae* CNCM I-3856 was confirmed by the higher proportion of abdominal pain responders in the probiotic group than in the placebo group. Importantly, this clinical study also showed improvements in QOL in the probiotic group.

Research conclusions

The results of this large-scale clinical study are consistent with previous findings and confirm the safety and efficacy of *S. cerevisiae* CNCM I-3856 for abdominal pain management in IBS population. In addition, abdominal pain alleviation was associated with significant improvements in IBS-related QOL.

Research perspectives

Dietary supplementation with *S. cerevisiae* CNCM I-3856 appears to be an interesting complementary or alternative solution for IBS management with positive implications for the day-to-day life of individuals with IBS with predominant constipation. Differences in microbiota composition and function between abdominal pain responders and nonresponders may provide a mechanistic basis for the beneficial effects of *S. cerevisiae* CNCM I-3856 in IBS management and warrant further exploration.

ACKNOWLEDGEMENTS

The authors want to acknowledge Biofortis Merieux Nutrisciences and all the investigators for conducting the study.

FOOTNOTES

Author contributions: Decherf A designed the study; Desreumaux P and Bourreille A contributed to the design of the study; Clément-Ziza M, Grisoni ML and Machuron F supervised the statistical analysis operations; Mourey F drafted the publication manuscript; Legrain-Raspaud S gave final approval of the version to be published; All authors participated in interpretation of the results, critically reviewed the manuscript and approved the final manuscript for submission.

Institutional review board statement: The study was reviewed and approved by the Ethics Committee Ouest VI of Brest, France.

Clinical trial registration statement: This study is registered at ClinicalTrials.gov. The registration identification number is NCT03150212.

Informed consent statement: All study participants provided informed written consent prior to study enrollment.

Conflict-of-interest statement: Mourey F, Decherf A, Jeanne JF, Clément-Ziza M, Machuron F and Legrain-Raspaud S are employees of Lesaffre. Grisoni ML was an employee of Lesaffre during her main contribution to the study. Bourreille A and Desreumaux P received financial support for research from Lesaffre.

Data sharing statement: No additional data are available.

CONSORT 2010 statement: The authors have read the CONSORT 2010 statement, and the manuscript was prepared and revised according to the CONSORT 2010 statement.

Open-Access: This article is an open-access article that was selected by an in-house editor and fully peer-reviewed by external reviewers. Abstract

Pancreatic carcinoma (PC) has one of the highest rates of cancer-related death worldwide. Except for surgery, adjuvant chemotherapy, chemoradiotherapy, and immunotherapy have shown various efficacies depending on the stage of the patient. We read the review "Current and emerging therapeutic strategies in pancreatic cancer: Challenges and opportunities" and offer some opinions that may improve its precision and completeness. This review presents a map of appropriate therapies for PC at different stages. Based on the clinical trial outcomes mentioned in the review, we evaluated the potential therapeutic options for PC and helped explain the contradictory efficacy between different programmed cell death protein 1/programmed cell death ligand 1 clinical trials, which may have resulted from the unique features of PC. Although R0 resection and adjuvant chemotherapy are still the gold standards for PC, new modalities, with or without clinical validation, are needed to establish more specific and precise treatments for PC.

Key Words: Pancreatic carcinoma; Immunotherapy; Chemotherapy; Radiochemotherapy; Future therapies

Core Tip: For the treatment of pancreatic carcinoma (PC), although surgery with adjuvant chemotherapy or chemoradiotherapy remains the gold standard for most patients, attention needs to be given to immunotherapy and other research hotspots. In addition to programmed cell death protein 1/programmed cell death ligand 1, we suggest that immunotherapies such as agonistic CD40, adoptive T cell therapy, myeloid-targeted therapies, stroma-targeted therapies, multiple immunomodulatory agents, and other treatments such as small-molecule inhibitors, antibodies, or viruses targeting tumors, as well as gene editing techniques, may help improve the prognosis of patients with PC in the future.

TO THE EDITOR

We read with interest the review "Current and emerging therapeutic strategies in pancreatic cancer: Challenges and opportunities" by Manrai *et al*[1], who summarized the current and emerging therapeutic strategies in pancreatic cancer (PC). We agree with the main thrust of this review and want to share some ideas after a careful review and further analysis of this article.

First, we consider this topic to be of practical significance. PC is a rare cancer (3.2% in the United States in 2020[2]), but with increasing incidence and mortality (5-year overall survival: 9% in the United States[2]), it remains a burden worldwide without promising effective therapies. In this review, the authors systematically summarized the mainstream clinical trial outcomes and focused on the challenges and available treatment modalities for PC at different stages, especially the standard management of resectable, borderline resectable, locally advanced, and advanced metastatic PC. The standard management for resectable or borderline resectable PC is surgery followed by adjuvant chemotherapy. The efficacy of adjuvant or neoadjuvant chemotherapy and chemoradiotherapy has been assessed in several clinical trials. The standard treatment for locally advanced and advanced metastatic PC is gemcitabine-based chemotherapy. In addition, newer potential modalities such as immunotherapy, targeted therapy, macrophage-targeted therapy, and cancer vaccines were also mentioned, providing researchers with guidelines for present clinical applications and future research work.

Second, the efficacy of the targeted agent erlotinib in combination with gemcitabine may depend on the different stages of PC, as confirmed by various clinical trials. In contrast to the efficacy shown in patients with metastatic PC, we found that two large clinical trials that focused on different stages of PC showed little benefit. The phase III LAP07 trial in 2016 investigated the clinical value of erlotinib combined with gemcitabine in patients with locally advanced PC. Unfortunately, the median overall survival of patients who received gemcitabine alone was 13.6 mo [95% confidence interval (CI): 12.3–15.3 mo] compared with 11.9 mo (95%CI: 10.4–13.5 mo) for patients receiving gemcitabine plus erlotinib[3]. The multicenter randomized phase III CONKO-005 Trial in 2017[4] assessed this combination therapy in patients with resectable PC after R0 resection and showed median disease-free survival of 11.4 mo *vs* 11.4 mo (gemcitabine alone) and median overall survival of 24.5 mo *vs* 26.5 mo. To date, such targeted agents combined with conventional chemotherapy may not show much of an advantage. We expect to see more advances in the future.

Thirdly, in the section "Immunotherapy for pancreatic cancer," the authors stated that popular programmed cell death protein 1/programmed cell death ligand 1 (PD-1/PD-L1) suppressor pembrolizumab had limited performance in the phase II KEYNOTE-158 study, due to the rare metastatic microsatellite instability in PC. This type of poor reactivity has been explained by several unique factors in PC: The well-recognized suppressive elements in the tumor microenvironment; the functional and structural barrier imposed by stromal components; T-cell exhaustion; possible choice of the wrong immune targets; and microbial factors, including gut dysbiosis and the unexpected presence of tumor microbes[5]. We agree with this, but we want to add that the clinical feasibility of PD-1 inhibitors deserves to be recognized. Recently, several clinical trials have examined the efficacy of conventional chemotherapy in combination with PD-1 inhibitors and other antagonists that mobilize T-cell activation and have shown mild but promising success. The phase IIa COMBAT trial in 2020 utilized the CXC chemokine receptor 4 antagonist BL-8040 (motixafortide), which promoted T-cell tumor infiltration, combined with pembrolizumab and chemotherapy in metastatic pancreatic adenocarcinoma, showing that BL-8040 may increase the benefit of chemotherapy. It reveals an overall response rate of 32%, disease control rate of 77%, and median duration of response of 7.8 mo[6]. Another phase I ARC-8 trial in 2021 also preliminarily validated the feasibility of combining chemotherapy with the PD-1 inhibitor zimberelimab and AB680, which is an inhibitor of CD73, to reduce adenosine generation and thus proliferating T cells. Eleven of the 13 patients who received treatment for at least 16 wk experienced

tumor shrinkage or stabilization[7,8]. Although the outcomes were not significant, they were encouraging, and future larger controlled studies are needed, and we are hopeful of good results. We believe that the abovementioned factors will be discussed in the future.

Importantly, except for the newer modalities mentioned in the review, we found that more therapies should be included. According to previous studies, other opportunities for PC immunotherapy, such as agonistic CD40, adoptive T cell therapy, myeloid-targeted therapies, stroma-targeted therapies, and multiple immunomodulatory agents are worthy of attention, and their efficacy in various PC stages has been proven by numerous clinical trials[9].

In conclusion, this review provides a valuable clinical reference for the management of PC, helping young clinicians to learn of appropriate clinical strategies for PC. It sheds light on different strategies for dealing with PC at different stages. In addition, it summarizes both the gold standard treatments and new therapeutic strategies such as immunotherapy and targeted therapy, which can guide clinicians and researchers to find a more promising combined treatment for PC. Recently, in different types of cancer, small molecule inhibitors, antibodies, or viruses targeting tumors, as well as gene editing techniques like CRISPR-Cas9 have shown antitumor potential, based on abundant research. We should always keep in mind that although early diagnosis and R0 resection are the first and best choice for PC patients, adequate basic research is still needed aimed at new targets or mechanisms that may provide patients with more specific and precise medical care to improve their prognosis.

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, and Scopus. The 2021 edition of Journal Citation Report® cites the 2020 impact factor (IF) for *WJG* as 5.742; Journal Citation Indicator: 0.79; IF without journal self cites: 5.590; 5-year IF: 5.044; Ranking: 28 among 92 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2020 is 6.9 and Scopus CiteScore rank 2020: Gastroenterology is 19/136.

Abstract

Systemic rheumatic diseases (SRDs) are chronic, inflammatory, autoimmune disorders with the presence of autoantibodies that may affect any organ or system. Liver dysfunction in SRDs can be associated with prescribed drugs, viral hepatitis, alternative hepatic comorbidities and coexisting autoimmune liver diseases (AILDs), requiring an exclusion of secondary conditions before considering liver involvement. The patterns of overlap diseases depend predominantly on genetic determinants with common susceptible loci widely distributing in both disorders. In AILDs, it is important to identify the overlapping SRDs at an early stage since such a coexistence may influence the disease course and prognosis. Commonly co-occurring SRDs in AILDs are Sjögren syndrome (SS), rheumatoid arthritis (RA) or systemic lupus erythematosus (SLE) in autoimmune hepatitis (AIH), and SS, RA or systemic sclerosis in primary biliary cholangitis. Owing to different disease complications and therapies, it is imperative to differentiate between SLE liver involvement and SLE-AIH overlap disease. Therapeutic options can be personalized to control coexisting conditions of liver autoimmunity and rheumatic manifestations in AILD-SRD overlap diseases. The collaboration between hepatologists and rheumatologists can lead to significant advances in managing such a complex scenario. In this review, we provide a comprehensive overview on coexisting AILDs in different SRDs and the therapeutic approach in managing these overlap diseases.

Key Words: Autoimmune liver disease; Systemic rheumatic disease; Overlap disease; Liver function test; Drug-induced liver injury; Viral hepatitis

INTRODUCTION

Systemic rheumatic diseases (SRDs) are chronic, inflammatory, autoimmune disorders with the presence of autoantibodies that may affect any organ or system; they include systemic lupus erythematosus (SLE), Sjögren syndrome (SS), systemic sclerosis (SSc), rheumatoid arthritis (RA), idiopathic inflammatory myopathies (IIM), mixed connective tissue disease (MCTD), systemic vasculitis (SV), *etc.* [1]. Although SRDs can have liver involvement, most patients only have abnormal liver enzymes without significant changes in histopathology[2,3]. Hepatic dysfunction can be a secondary phenomenon, associated with prescribed drugs, viral hepatitis (VH), alternative liver comorbidities, and coexisting autoimmune liver diseases (AILDs).

The major cause of abnormal liver function test (LFT) in patients with SRDs is associated with medications, *i.e.* drug-induced liver injury (DILI)[3]. Given that a variety of medications are used in the management of SRDs, it is frequently encountered in clinical practice. High occurrences of DILI in SRDs are due to the chronic or high-dose prescription of medications, the existence of susceptible factors that makes patients prone to hepatotoxicity, and/or the use of herbal or ayurvedic compounds[2,3]. Elevated liver enzymes with predominant cholestatic or hepatocellular damage pattern can be observed in SRDs treated with non-steroidal anti-inflammatory drugs (NSAIDs), synthetic disease modifying anti-rheumatic drugs (SDMARDs), corticosteroids (CS), immunosuppressants, biologic agents or oral small molecules[2]. Most medications only cause a mild elevation in liver enzymes, which reverses with drug cessation. On rare occasions, severely irreversible hepatic damage may occur and progress into chronic liver disease or fulminant hepatic failure. Despite the relative safety with a low-dose prescription, methotrexate, a SDMARD frequently used in SRD-related arthritis, has been reported to cause acute liver dysfunction with confounding factors like concomitant NSAIDs use, and progressive liver fibrosis and cirrhosis can occur when used chronically[4]. It usually occurs after a prolong use for no less than 2 years and with a total accumulated dose of 1.5 g[5]. Notably, there is a risk of hepatitis B virus (HBV) reactivation depending on the dose and duration of CS use and the status of hepatitis B surface antigen and hepatitis B core antibody in SRDs[6]. Furthermore, acute or progressing liver dysfunction can be related to coexisting VH, requiring screen tests for HBV and hepatitis C virus (HCV) infection to provide early antiviral treatment and avoid reactivating or worsening VH after immunosuppressive therapy[3]. Table 1 summaries the hepatic abnormalities associated with the common medications used in SRDs[2,7,8]. Although immune checkpoint inhibitors have altered the therapeutic paradigm in oncological patients, there is undesirable off-target autoimmune reaction causing adverse effects like musculoskeletal manifestations and immune hepatitis, a pan-lobular active hepatitis resembling AIH[9].

Although the liver is the largest lymphoid organ involved in the immune response against invading pathogens and in the maintenance of tolerance to self-molecules, it can also be a target of autoimmune diseases[10]. AILDs are attributed to a complex interplay of socioeconomic, environmental and genetic factors, all of which may participate in their pathogenesis[11]. Most common AILDs are autoimmune hepatitis (AIH), primary biliary cholangitis (PBC) and primary sclerosing cholangitis (PSC), which may occur individually or in combination[12]. These disorders are characterized by hepatic lymphocyte infiltration, elevated liver enzymes, generation of autoantibodies, and associated HLA loci. Coexisting extra-hepatic autoimmune diseases such as SRDs, have been well described in the literature[13]. AIH often goes into disease remission with first-line therapy, including CS alone or plus AZA[14]. PBC has a normal life expectancy if treated early with ursodeoxycholic acid (UDCA) in responsive patients, while no effective therapy has been found to alter the natural course of PSC, except liver transplantation (LT) [15,16]. Some patients with AILDs may eventually progress into end-stage liver disease requiring LT, and with an increased risk of recurrent activities and acute or chronic rejection[17,18]. Currently, AILD research has focused on obtaining a better understanding of the pathogenetic process for identification

Table 1 Hepatic abnormalities associated with common medications used in systemic rheumatic diseases

Medications	Hepatic abnormalities	[2]Likelihood score category in DILI
NSAIDs	LEE, cholestasis, acute liver failure, VBDS	A for diclofenac, ibuprofen, sulindac
Glucocorticoids	LEE, NAFLD, acute liver failure, HBV reactivation	A in high dosages

Ustekinumab	Suspected liver injury, possible HBV reactivation	E′

[1]TNF blockers including adalimumab, certolizumab, etanercept, golimumab and infliximab.
[2]Categorization of Likelihood Score in drug-induced liver injury. A: Definite; B: Highly likely; C: Probable, D: Possible, E: Unlikely; E′: Suspected.
NSAIDs: Non-steroidal anti-inflammatory drugs; HBV: Hepatitis virus B; DILI: Drug-induced liver injury; DRESS: Drug rash with eosinophilia and systemic symptoms; LEE: Liver enzyme elevation; NAFLD: Nonalcoholic fatty liver disease; NRH: Nodular regenerative hyperplasia; SDMARDs: Synthetic disease-modifying antirheumatic drugs; SRDs: Systemic rheumatic disease; VBDS: Vanishing bile duct syndrome; VOD: Veno-occlusive disease.

of new therapeutic targets to reduce morbidity and improve survival[15]. Table 2 demonstrates the demographic, clinical, laboratory, pathological, therapeutic and prognostic characteristics of three common AILDs[11-20].

In AILDs, it is imperative to identify the co-occurring SRDs at an early stage by using autoantibody screening, since such a coexistence may influence their natural course and disease prognosis[21]. The patterns of overlap diseases depend predominantly on genetic determinants, with common susceptible loci widely distributing in both disorders[20]. The similar epidemiological links between AILDs and SRDs are further reflected in their shared pathogenesis, best exemplified by the concept of autoimmune epithelitis, *i.e.*, concomitant PBC and SS[22,23]. Furthermore, AILDs and SRDs have common serologic profiles with the presence of particular autoantibodies and hyper-gammaglobulinemia[21,24]. Progressive liver damage can be identified in overlap diseases despite rare complications with liver cirrhosis and hepatic failure[3]. Table 3 shows the reported prevalence of coexisting AILDs in different SRDs.

The therapeutic strategies in AILDs and SRDs are also overlapping, with CS as first-line treatment in most cases, followed by administration of immunosuppressants, and potential application of targeted therapy[21]. Nevertheless, therapeutic options can be personalized to control coexisting conditions of liver autoimmunity and rheumatic manifestations[24]. A collaboration between hepatologists and

Table 2 Demographic, clinical, laboratory, pathological, therapeutic and prognostic profiles in three common autoimmune liver diseases

Category	AIH	PBC	PSC
Demographic

rheumatologists in clinical practice can lead to significant advances in managing such a complex scenario. Herein, we provide a comprehensive overview on coexisting AILDs in different SRDs and the therapeutic approach in managing these overlap diseases.

SLE

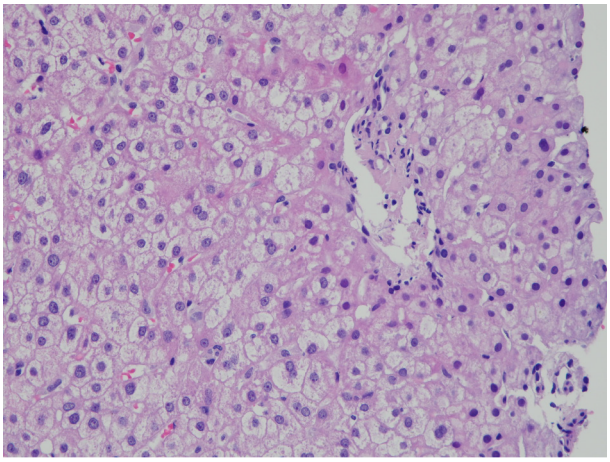
SLE is a less common SRD, occurring mostly in women of childbearing age and having heterogenous clinical manifestations affecting any organ or system as well as presenting antinuclear antibody (ANA) and a variety of autoantibodies[25]. The liver is generally not a target organ in SLE and hepatic

Table 3 Reported prevalence of concomitant autoimmune liver diseases in different systemic rheumatic diseases

Category	AIH	PBC	PSC	AIH/PBC OS
SLE	1.6%-15%	2.2%-7.5%	CR	CR
SS	0.4%-4.4%	3.4%-8.9%	CR	CR
SSc	CR	0.8%-3.3%	CR	CR
RA	1.3%	3.8%-6.3%	CR	CR
IIM	CR	0.7%	CR	CR
MCTD	1.6%	CR	NA	NA

AIH: Autoimmune hepatitis; APS: Antiphospholipid syndrome; CR: Case report; IIM: Idiopathic inflammatory myopathies; NA: Not available; OS: Overlap syndrome; PBC: Primary biliary cholangitis; PSC: Primary sclerosing cholangitis; RA: Rheumatoid arthritis; SLE: Systemic lupus erythematosus; SS: Sjögren syndrome; SSc: Systemic sclerosis.

involvement is not included in the classification or diagnostic criteria. Abnormal LFT is common in SLE, usually with subtle changes, in up to 60% of cases during the disease course, while elevated liver enzymes occur during disease flares in less than 20% of patients[3,26,27]. Hepatic dysfunction in SLE can be classified into primary form due to disease itself or secondary form including DILI, VH, vascular disorders, alternative liver comorbidities and coexisting AILDs[28]. Before considering the liver involvement in SLE, it is necessary to exclude other secondary conditions.



Lupus hepatitis (LH) is reactive liver damage caused by immune-complex deposition, in contrast to lupoid hepatitis, a term used in the 1950s to define what was later known as AIH[29,30]. This manifestation is usually synchronous with disease activity and affects less than 10% of patients[31-33]. It is characterized by asymptomatic transaminasemia with the presence of anti-ribosomal P antibody (commonly known as ARPA) and non-specific histopathological changes. Although CS may help to improve impaired LFT, there is a risk of flare up upon cessation of its use[34]. Figure 1 shows the liver biopsy finding from a patient with LH demonstrating non-specific histopathological changes.

The main cause of liver dysfunction in SLE was salicylate toxicity in the 1950s[35]. Later on, owing to a rare prescription, another common finding of liver biopsy was steatohepatitis, an alternative liver comorbidity. Nowadays, the known risk factors for development of non-alcoholic fatty liver disease (NAFLD) include obesity, physical inactivity and sedentary lifestyle[36], which are also shared by SLE. Furthermore, patients with SLE have been shown to have higher incidences of metabolic syndrome and insulin resistance[37], especially with the use of CS[38]. Increased frequencies of NAFLD have been found in liver biopsy specimens from patients with SLE[39].

The presence of antiphospholipid antibody (aPL) in SLE underlies an increased probability of thrombophilia, leading to antiphospholipid syndrome (APS) with vascular thrombosis[40]. APS can affect the hepatic circulation, causing hepatic arterial thrombosis, portal vein thrombosis and Budd-Chiari syndrome (BCS) as well as the rarely-observed liver infarction and hepatic veno-occlusive disease [40-42]. Notably, BCS resulting from the obstruction of hepatic venous outflow[43] can be an initial manifestation of patients with SLE-associated APS[44]. In particular, aPL has been reported to be involved in the pathogenesis of hepatic nodular regenerative hyperplasia (referred to herein as NRH), small-nodule transformation of hyperplastic hepatocytes with a later development of non-cirrhotic portal hypertension[3,45]. Although higher frequencies of aPL could be detected in AILDs, there was no definite clinical or histological correlation with their presence in such patients[3,46].

Autoimmune gastrointestinal diseases have been linked to SLE with shared pathogenic mechanisms responsible for the development of both disorders[47]. Although AIH and PBC are rare AILDs, the coexistence with either of these diseases is not uncommon among SLE patients with liver enzyme abnormalities, suggesting a causal relationship between their overlap[28,48,49]. Since SLE-PSC overlap disease rarely occurs (but has been described in case reports[28,48]), it remains to be ascertained whether they are casual associations. A review on individual AILD coexisting with SLE is depicted as follows.

AIH is a rare AILD characterized by interface hepatitis as the most specific histological change, and the presence of autoantibodies including anti-liver kidney microsomal-1 (LKM-1)/liver cytosol-1 (LC-1) in type II, a rare subgroup affecting female pediatric patients, and ANA/anti-smooth muscle antibody (ASMA) in type I[50]. Clinical manifestations vary from asymptomatic to nonspecific symptoms of varying severity, including fatigue, malaise, nausea, anorexia and abdominal pain. The criteria established by the International Autoimmune Hepatitis Group (commonly known as the IAHG) are usually used for the diagnosis of AIH[51]. Due to different disease complications and therapeutic regimens between AIH and LH, it is imperative to differentiate between two disease entities[28,34]. AIH may lead to end stage liver disease, and its immunosuppressive therapy needs to be continued for at least 2 years of hepatic biochemical remission before attempting withdrawal[50]. Liver biopsy is highly

Figure 1 Liver biopsied tissues from a patient with systemic lupus erythematosus liver involvement (lupus hepatitis). The portal area with minimal non-specific lymphocytic infiltration is shown. Hematoxylin and eosin staining, 400 × magnification.

recommended for their distinguishment[28,34]. LH usually demonstrates lobular infiltrates or occasionally mild periportal infiltrates, whereas AIH is characterized by portal mononuclear infiltrates invading nearby lobules to induce interface hepatitis and form hepatocyte rosettes, followed by confluent lytic necrosis and finally cirrhosis[30].

SLE-AIH overlap disease is defined by fulfilling American College of Rheumatology (commonly known as the ACR) criteria for the classification of SLE in patients who also meet IAIHG criteria for the diagnosis of AIH[34,51,52]. The prevalence of AIH in SLE ranges from 1.6% to 15%, lower in general cohorts and higher in patients with abnormal LFT[39,53-58]. Immunosuppressive treatment for AIH is also effective for SLE, and has been demonstrated to successfully apply to their overlap cases[28]. Most cases with coexisting SLE and AIH responded well to CS or plus immunosuppressants[48]. The long-term outcome for SLE-AIH overlap disease has been observed to be better than AIH alone[34]. Nevertheless, there are sporadic cases of acute liver failure or end-stage liver disease requiring LT[59, 60].

PBC is the most common AILD affecting women predominantly. It is characterized by destructive lymphocytic cholangitis involving small bile ducts, and leading to progressive ductopenia, hepatic cholestasis and biliary fibrosis[61]. Clinical manifestations vary from asymptomatic to non-specific symptoms with jaundice and pruritus. According to the guidance from American Association for the Study of Liver Diseases (commonly known as the AASLD), the diagnosis of PBC is established when two of three items are met, including biochemical cholestasis based on alkaline phosphatase (ALP) elevation, presence of antimitochondrial autoantibody (AMA), and histological evidences of nonsuppurative destructive cholangitis and interlobular bile ducts destruction[62]. The nomenclature of PBC has already shifted from cirrhosis to cholangitis, reflecting the dramatically improved prognosis upon first-line UDCA therapy without the development of cirrhosis[63,64].

SLE-PBC overlap is defined by fulfilling the diagnostic criteria for both diseases[34,52,62]. SLE usually affects younger females of childbearing age, whereas PBC is more common in middle-aged women. By genome-wide studies, both diseases have been reported to share the IRF5-TNPO3 gene-spanning haplotype loci[65]. The prevalence of PBC in SLE patients with liver dysfunction ranges from 2.2% to 7.5%, usually lower than that of AIH[39,53-55,57]. In a review of SLE overlapping with PBC, 69% were diagnosed first by PBC, 24% had coexisting SS, and 2 deaths were due to PBC-related hepatic failure[66]. For patients with concomitant SLE and PBC, regardless of the SLE treatment, UDCA is effective first-line therapy for PBC[49].

The diagnosis of PBC-AIH overlap is established with coexisting features of both diseases[67]. Two commonly used criteria for the diagnosis of PBC-AIH overlap syndrome are the IAIHG and Paris criteria[51,68]. Patients with overlapping PBC and AIH have been described to exhibit significantly higher rates of LC, portal hypertension and mortality as compared with those with AIH or PBC alone [69]. PBC with features of AIH should be considered for immunosuppressive therapy[49], while PBC-AIH overlap disease can benefit from combination treatment with UDCA and CS or plus AZA[69]. There is a rare association between SLE and PBC-AIH overlap disease[70]. In a large case series with 71 overlap patients, EHAIDs were identified in 31 (44%), while only 2 (3%) had concurrent SLE[71].

In contrast to western countries, AIH had been considered a rare etiology in the Asia-Pacific region, where VH is a major diagnosis in patients with chronic liver diseases[72]. A very low prevalence of AIH was found in Taiwan in earlier years, raising concerns about under-recognition in an area with a high prevalence of HBV infection and associated liver cirrhosis and hepatocellular carcinoma complications [73], where clinicians would have been more familiar with VH and might have tended to overlook AIH

[74]. Recent findings, however, have shown increasing annual incidences of AIH, indicating improved recognition of AIH in this region[72].

The clinical, laboratory, therapeutic and outcome profiles in 3 patients with SLE-AIH overlap disease diagnosed by ourselves are shown in Table 4. All met IAIHG diagnostic criteria for AIH[51], and case 2 also fulfilled AASLD diagnostic criteria for PBC[62]. Despite CS plus AZA therapy, case 1 progressed into advanced LC, and received LDLT with stabilized LFTs and low SLE activity. Case 2 had the initial diagnosis of AIH with transaminasemia, followed by the development of hepatic cholestasis and sicca symptoms, and finally full-blown manifestations of SLE. Under the diagnosis of coexistent AIH, PBC, SLE and SS, in addition to CS/AZA and UDCA, the patient received B-cell depleting therapy with anti-CD20 monoclonal antibody, with low-dose CS for maintenance, resulting in normalized LFT and low SLE activity. Figure 2 demonstrates histopathological findings in liver biopsy specimens from cases 1 and 2.

PSC is a rare cholestatic AILD characterized by persistent, progressive inflammation, fibrosis and stricture of the intrahepatic and extrahepatic bile ducts, leading to cirrhosis[75]. About half of the patients are asymptomatic. The diagnosis is made by cholestasis with ALP elevation and imaging of bile duct strictures, excluding secondary causes. Liver biopsy is indicated only when suspecting overlapping with other AILDs or small-duct PSC, a variant with normal cholangiogram. UDCA is the subject of debate with conflicting data to support its use in PSC[49], and end-stage liver disease requiring LT may develop in affected patients.

Although the association of SLE with PSC is considered to be extremely unusual[34,48], there are several published cases with SLE-PSC overlap disease[76-80]. Furthermore, a 1.7% occurrence of SLE was observed in a Swedish PSC cohort[81]. Whether such a coexistence indicates that both diseases might share common pathogenic pathways remains to be elucidated.

SS

SS is a common SRD affecting the exocrine glands with typical symptoms of dryness of eyes and mouth, histological evidence of focal lymphocytic sialadenitis and the presence of anti-Ro and -La antibodies [82]. The treatment of SS-related dry eyes and mouth is symptomatic with the use of artificial tear and saliva preparation. LFT abnormalities can be identified in nearly half of patients, either persistent or intermittent, and usually mild with cholestatic or hepatocellular pattern[3]. Liver involvement is considered as the most common extra-glandular feature, correlating with the disease activities of SS involving other organs[83]. In a large-scale investigation of 475 cases, after excluding DILI and alternative hepatic comorbidities, the main causes of liver dysfunction were VH in 50% and AILDs in around 20% of patients[84]. Several studies have confirmed a higher prevalence of AILDs among SS, mainly PBC (3.4% to 8.9%), followed by AIH (0.4% to 4.4%)[84-87].

The most frequently associated SRDs in PBC is SS with a prevalence ranging from 3.5% to 38%[88-94]. PBC can be considered a SS of the liver, whereas SS has been equally regarded as a PBC of the exocrine glands[21]. In addition to frequent clinical coexistence and comparable epidemiological features, SS and PBC have similar pathogenic mechanisms and genetic susceptibility backgrounds[95]. Pyruvate dehydrogenase complex E2 subunit, a PBC autoantigen, is also present on the surface of salivary epithelial cells in SS, while HLA-DR2 and -DR3 have been reported as the common susceptibility genes in both disorders[20].

Despite a higher frequency of ASMA than AMA in SS[96], the prevalence of coexisting AIH is lower than PBC[84,85,97]. Owing to a much higher prevalence of SS than SLE in the general population, the occurrence of concomitant SLE and SS in patients with AIH are 0.7% to 2.8% and 0.8% to 7.2%, respectively, lower in SLE than in SS[98-102].

There are published cases and case series describing SS-PSC overlap disease as well as a higher prevalence in small-scale PSC studies[84,103,104], implicating a causative association rather than sporadic occurrence. Notably, almost all reported patients with overlapping SS and PSC have chronic pancreatitis, demonstrating a triad syndrome complex[103]. A possibility of co-occurring IgG4-related disease (IgG4-RD) should be considered in SS-PSC overlap disease with the presentation of autoimmune pancreatitis (AIP)[104].

SSC

SSc is an uncommon SRD characterized by vasculopathy and fibrosis of the skin and internal organs, with the presence of anti-topoisomerase I and anti-centromere antibodies (ACA) in diffuse and limited cutaneous subsets, respectively[105]. It has a higher mortality rate than other SRDs. The gastrointestinal tract is affected in up to 90% of patients[106], and hepatic fibrosis has been identified at autopsy[107]. Since liver involvement is rarely observed in SSc[3], abnormal LFT should exclude other possibilities first before considering disease *per se*. There are diverse autoimmune diseases like AILDs co-occurring within SSc patients and their family members[108], suggesting common pathophysiological

mechanisms between these disorders.

Increased prevalence of PBC has been observed in SSc, varying from 0.8% to 3.3%[108-112], and there is a 2.3% to 12.4% occurrence of SSc in PBC[90-94,111]. SSc-PBC overlap disease has the presence of both ACA and AMA[113], and tends to occur in older females with the limited cutaneous subset[114]. This overlap disorder has a slower disease progression in comparison with PBC alone; however, survival is similar due to an increase in SSc-related non-liver death. The use of UDCA has been observed to reduce skin lesions in addition to improved hepatic cholestasis in overlap patients[115].

A 0.8% prevalence of SSc has been reported from a AIH cohort[98], and patients with SSc-AIH overlap disease can be found in the literature[116,117]. In a review with 11 cases[117], all had positive ACA and a later presentation of AIH, 9 with limited cutaneous subtype and 3 with AIH-PBC overlap. Despite a risk of scleroderma renal crisis under the higher dosages of CS use, there were normalized or improved LFT without the occurrence of scleroderma renal crisis in overlap patients receiving such a

Hematoxylin and eosin staining, 400 × magnification.

treatment[116].

Overlap condition with large- or small-duct PSC has been observed in patients with SSc[118,119], suggesting that the extensive disturbance of connective tissues in SSc can lead to abnormal collagen deposition in the bile duct epithelium of PSC[120].

RA

RA is a common SRD primarily affecting the joints and causing cartilage and bone damage, with extra-articular presentations and the presence of rheumatoid factor (commonly referred to as RF) and anti-cyclic citrullinated peptide (commonly referred to as CCP) autoantibodies[121]. Among patients with chronic inflammatory joint diseases, liver involvement has been recognized in RA, despite not showing a significant extra-articular manifestation[122]. Elevated liver enzymes have been identified in up to 50% of patients with RA[2]. DILI is not uncommonly observed in RA, especially under the treatment of NSAIDs and SDMARDs including leflunomide, methotrexate, penicillamine and sulfasalazine, all with potential hepatotoxicity[2,7,123]. Patients are at the hazard of developing NAFLD with the risk factors of chronic inflammation and CS use[2]. Prior to the widespread use of methotrexate in RA, the hepatic histopathological findings at autopsy were most commonly mild portal tract inflammation, rarely diffuse fibrosis of advanced grades[124]. Two rare extra-articular manifestations, rheumatoid vasculitis and Felty syndrome, have been reported to cause necrotizing hepatic arteritis with liver rupture and NRH with portal hypertension, respectively[125,126].

There were no differences in the prevalence of HBV and HCV infection in RA as compared with the general population[127]. Nevertheless, immunosuppressive therapy for RA may significantly worsen underlying VH, and further affect the clinical course and disease prognosis, requiring the survey of viral markers and their antibodies before its initiation[123]. Since the use of tumor necrosis factor (TNF) blockades in RA can cause inactive HBV reactivation[7,128], HBsAg-positive individuals should receive anti-viral prophylactic treatment[129]. Although the TNF pathway is involved in perpetuation of hepatic inflammation and fibrosis progression in HCV infection[130], further studies are needed to verify the safety of anti-TNF therapy in HCV-infected patients[131]. Notably, the use of TNF antagonists has been reported to be associated with the development of AIH in RA[7,132].

The most common coexisting AILDs in RA is PBC with a prevalence of 3.8% to 6.3%[53,97,123], while the occurrence of RA in PBC has been reported to be 1.8% to 13%[90-94]. Around 50% of patients with PBC were shown to be positive for RF[133]. Since RA is usually diagnosed before PBC in patients with the overlap disease, AMA should be screened in RA with elevated cholestatic liver enzymes[134]. Genetic studies have shown that RA has HLA-DQB1, STAT4, IRF5, MMEL1 and CTLA4 genes in common with PBC, predisposing to develop PBC in RA with the overlapping genetic trait[135]. Potentially hepatotoxic drugs used in RA can be avoided in patients with RA-PBC overlap disease[123].

AIH is rarely observed in RA with a 1.3% prevalence reported from patients with liver dysfunction [97]. Furthermore, in patients with AIH, there is a 1.6% to 5.4% prevalence of RA[98,100-102]. AIH can be diagnosed during the RA progression as acute or chronic hepatitis, but rarely fulminant hepatic failure[123]. In addition, in patients with AIH-PBC overlap disease, RA is accounting for an occurrence of 4.2%[71].

High circulating levels of TNF were found in AIH, while a TNF antagonist etanercept has been demonstrated to improve the AIH histological lesions in RA[136]. Nevertheless, anti-TNF therapy can induce the production of autoantibodies, including ANA and ASMA, leading to the development of distinct autoimmune diseases[137]. Notably, anti-TNF-inhibitor-associated AIH (also known as ATIAIH), a serious idiosyncratic DILI, has been well documented in a large-scale analysis of 389 cases [138]. ATIAIH has a female predominance, a period of 3-14 mo between starting therapy and AIH occurrence, and improvement upon medication stoppage and CS use. Infliximab is the most frequently administrated medication, and RA is the most commonly reported indication.

There was a 1.2% and a 3.4% prevalence of RA in two large-scale PSC cohorts[81,139]. In patients with RA-PSC overlap disease, the presence of HLA-DR4 has been reported to have unusual progression to cirrhosis, 14-48 mo after the diagnosis of PSC[140], implicating a clinical marker at a high risk of cirrhosis development.

Psoriatic arthritis (PsA) is a less common SRD with psoriasis (PsO) and inflammatory arthritis, associating with extra-articular manifestations which have an impact on their therapeutic regimens [141]. Similar to RA, liver enzyme abnormalities in PsA and PsO can be caused by comorbid NAFLD and used medications including NSAIDs and conventional or biologic/targeted SDMARDs. Despite an increased association of AIH in PsA and PsO[142], these patients might be under anti-TNF therapy, and both diseases are commonly observed complications in ATIAIH[138].

IIM

IIM including polymyositis (PM) and dermatomyositis (DM), an uncommon group of SRDs with the presence of myositis-specific/associated antibodies, have weakness due to skeletal muscle inflammation and extra-muscular involvement[143]. Since transaminases are also muscle-derived enzymes with increased levels during IIM disease activity, an increase of aspartate aminotransferase and alanine aminotransferase more than creatine kinase or an alteration of cholestatic enzymes should consider a possibility of hepatic dysfunction[3]. During the first 3 years to 5 years after the onset of DM, the risk of cancer is increased, rarely hepatocellular carcinoma. Since DM can be associated with malignancy as a paraneoplastic syndrome[144], sporadic cases had HBV-associated hepatocellular carcinoma with a concurrent or later diagnosis of DM[145,146].

Although IIM usually occur alone, these SRDs may associate with other extra-muscular autoimmune diseases including AILDs, more frequently in patients with PM than DM[147]. Positive AMA could be identified in 2.5% of patients with IIM[148], and there were sibling cases of familial clustering with PBC-PM overlap disease[149]. PBC can be identified in IIM with a prevalence of 0.7%[148], while the occurrence of PM in PBC ranges from 0.6% to 3.1%[90,92,93]. There are sporadic cases with PM coexisting with AIH, AIH-PBC overlap disease or PSC[150-152].

MCTD

In addition to the presence of anti-U1 small nuclear ribonucleoprotein (known as snRNP) antibody in high titers, MCTD has distinct features including Raynaud's phenomenon and puffy hands as well as mixed findings from PM, SLE and SSc[153]. It is a rare SRD with a strong HLA linkage, distinctly differing from ethnically matched healthy controls and other SRDs. Hepatic dysfunction occurs in MCTD usually caused by DILI and pulmonary hypertension-related liver congestion[97,153]. Coexistent AILDs are rarely observed in patients with MCTD[153]. In addition to published case reports, a 1.6% prevalence of AIH was found in MCTD[154], while a 0.6% prevalence of MCTD could be identified in PBC[90]. There was no observed association with MCTD in two PSC case series[81,141].

SV

SV is a rare SRD characterized by inflammation of vascular walls, resulting in a broad spectrum of clinical manifestations dependent on the site, type, and size of involved vessels[155]. Although the diagnosis relies on clinical presentations confirmed by histopathological findings, large/medium and small vessel involvement can be supported by angiographical examinations and laboratory tests (*e.g.*, ANCA), respectively[155,156]. Owing to hepatic vascular involvement[2,53], polyarteritis nodosa (referred to herein as PAN), a medium-vessel SV associated with HBV infection[157], may have elevated liver enzymes. A 2.2% prevalence of SV has been reported from a large-scale PBC series with 361 cases [94], while a 1.6% occurrence of SV was identified in a 122-patient AIH series[98]. There were sporadic cases of AIH coexisting with PAN[158].

Testing for ANCA can support the diagnosis of ANCA-associated vasculitis including eosinophilic granulomatosis with polyangiitis (also referred to as EGPA), granulomatosis with polyangiitis and microscopic polyangiitis (also referred to as MPA) in spite of seropositivity in only one-third of EGPA cases[159]. Notably, ANCA has a diagnostic relevance beyond SV, justifying its occurrence in suspected type I AIH which is lacking conventional autoantibodies[160]. AILDs usually develop atypical perinuclear-ANCA not targeting the classical myeloperoxidase with the positive frequencies highest in patients with PSC[21,156]. There is no clinical nor prognostic value of ANCA testing in patients with AILDs. This atypical autoantibody, referred to as peripheral anti-nuclear neutrophil antibody, can react with beta-tubulin isotype 5 and shares structural homology with the intestinal bacterial protein FtsZ [161]. Nevertheless, it is not specific for AILDs, and it is also present in VH and alcoholic liver disease [162]. Interestingly, ANCA was detected in the bile of PSC patients and correlated with the severity of bile duct stricture[163]. Sixteen cases of ANCA-associated vasculitis-AILD overlap disease have been reported, with twelve involving women, PBC in eleven, and MPA in eight[164-166].

OTHER SRDS

Adult-onset Still's disease (AOSD) is a rare SRD usually affecting young adults, with spiking fever, polyarthritis, evanescent rash and marked hyperferritinemia as well as uncommon life-threatening macrophage activation syndrome[167]. In medical practice, hyperferritinemia is a non-specific finding related to iron overload in only 10% of cases such as hereditary hemochromatosis, while underlying causes attributing to a reactive increase in the rest 90% patients such as AOSD[168]. Hepatic dysfunction is commonly observed in AOSD, mostly due to the disease itself and without any specific histological finding[97,167]. Coexisting AILDs have rarely been observed, and there are sporadic cases of AIH-AOSD overlap disease[169].

Behçet's disease (BD) is a SRD with a variable worldwide prevalence, characterized by vasculitis affecting the small/Large venous and arterial vessels, and presenting with orogenital ulcers, ocular lesions and systemic involvement[170]. The liver is rarely involved, and the commonest hepatic complication is BCS with thrombosis of the inferior vena cava and hepatic vein[171]. Elevated ALP levels of liver origin has been reported in 10% of patients, with a correlation to disease activity[172]. Case reports of Behçet's disease concomitant with AIH or PBC can be found in the literature[173,174].

IgG4-RD is a rare SRD, characterized by elevated serum IgG4 concentrations and fibroinflammation in the affected tissues, with dense lymphoplasmacytic infiltrates rich in IgG4-positive plasma cells and storiform fibrosis[175]. Cases of type I AIP and IgG4-related sclerosing cholangitis (commonly referred to as IgG4-SC), two common forms of IgG4-RD usually occurring in combination, have painless jaundice and cholestatic LFT abnormalities due to liver involvement[176,177]. Although CS has favorable therapeutic efficacy[49], AIP and IgG4-SC are associated with significant morbidity and mortality due to extra-pancreatic organ failure and malignancy[176]. AIP has been reported to be associated with PBC and PSC[178,179]. Infiltrating IgG4-positive plasma cells can be observed in the AIH liver, suggesting involvement of IgG4 in its pathogenesis[180]. Nevertheless, the disease concept of IgG4-AIH remains to be established[181].

Sarcoidosis is an uncommon SRD, characterized by the formation of noncaseating granulomas in various organs, predominantly the lungs, lymphatic system, skin, and eyes, or a different combination of these sites[182]. Abnormal LFT has been observed in one-fourth of patients with chronic sarcoidosis; among which, 15% are suspected of having liver involvement with cholestatic pattern of injury[183]. Although hepatic sarcoidosis is mainly asymptomatic, it can progress to LC, while such cases are rare [184]. AILDs coexisting with sarcoidosis have been reported, having a prevalence of 0.6% in AIH and 0.8% in PSC[81,99]. Several case reports have described the association of sarcoidosis with PBC[88]. A 2.7% prevalence of sarcoidosis was found in a PBC cohort from Greece[185], whereas an epidemiological study with 1510 patients from the United Kingdom failed to show an association between the two disorders[186].

Relapsing polychondritis is a rare SRD, characterized by cartilaginous inflammation throughout the body, especially involving the hyaline cartilage of the ears, nose and joints, and the respiratory tract [187]. Liver involvement with cholestatic hepatic dysfunction has been observed scarcely in such

patients[188]. The association of relapsing polychondritis with AILDs has been reported with PBC or PSC overlap diseases[189,190].

CONCLUSION

SRDs are chronic, inflammatory, autoimmune disorders with the presence of autoantibodies that may affect any organ or system. Liver dysfunction in SRDs can be associated with prescribed drugs, VH, alternative hepatic comorbidities and coexisting AILDs, requiring an exclusion of secondary conditions before considering liver involvement. The patterns of overlap diseases depend predominantly on genetic determinants with common susceptible loci widely distributed in both disorders. In AILDs, it is important to identify the overlapping SRDs at an early stage, since such a coexistence may influence the disease course and prognosis. Commonly co-occurring SRDs in AILDs are SS, RA or SLE in AIH, and SS, RA or SSc in PBC. Owing to different disease complications and therapies, it is imperative to differentiate between SLE liver involvement and SLE-AIH overlap disease. Therapeutic options can be personalized to control coexisting conditions of liver autoimmunity and rheumatic manifestations in AILD-SRD overlap diseases. The collaboration between hepatologists and rheumatologists in clinical practice can lead to significant advances in managing such a complex scenario.

ACKNOWLEDGEMENTS

The authors are indebted to Dr. IC Wu (Division of Gastroenterology and Hepatology) for his valuable comments and to other doctors at the National Cheng Kung University Hospital involved in the diagnosis and management of reported patients.

Abstract

With the development of microbiology and metabolomics, the relationship between the intestinal microbiome and intestinal diseases has been revealed. Fecal microbiota transplantation (FMT), as a new treatment method, can affect the course of many chronic diseases such as metabolic syndrome, malignant tumor, autoimmune disease and nervous system disease. Although the mechanism of action of FMT is now well understood, there is some controversy in metabolic diseases, so its clinical application may be limited. Microflora transplantation is recommended by clinical medical guidelines and consensus for the treatment of recurrent or refractory *Clostridium difficile* infection, and has been gradually promoted for the treatment of other intestinal and extraintestinal diseases. However, the initial results are varied, suggesting that the heterogeneity of the donor stools may affect the efficacy of FMT. The success of FMT depends on the microbial diversity and composition of donor feces. Therefore, clinical trials may fail due to the selection of ineffective donors, and not to faulty indication selection for FMT. A new understanding is that FMT not only improves insulin sensitivity, but may also alter the natural course of type 1 diabetes by modulating autoimmunity. In this review, we focus on the main mechanisms and deficiencies of FMT, and explore the optimal design of FMT research, especially in the field of cardiometabolic diseases.

Key Words: Fecal microbiota transplantation; Metabolic diseases; Inflammatory bowel disease; Type 1 diabetes; Metabolic syndrome

INTRODUCTION

Most of the research on microorganisms is confined to infectious diseases and the role of microorganisms in human health is largely ignored. The average weight of these microorganisms is about 1.5 kg, equivalent to the weight of the liver. There are 10^{12}–10^{14} microorganisms, which is 10 times the number of the human body's own cells, and they are mainly parasitic in the intestinal tract[1]. These symbiotic microorganisms include bacteria, viruses, archaea, fungi and, in some cases, protists, collectively known as the microbiome. The most important advantage of fecal microbiota transplantation (FMT) is the determination of cause and effect of disease through microbiology[2] .

During the long process of human evolution, the intestinal flora has coevolved with its host, along with social development, changes in diet, lifestyle and environment. Intestinal symbiotic bacteria can regulate a variety of metabolic activities that cannot be carried out by the human body itself[3]. They can obtain energy by decomposing polysaccharides, proteins and fats in food that cannot be fully digested by the host, and produce a series of metabolites that affect the health of the host. In this process, the intestinal microecosystem is closely related to the host metabolic capacity[4].

As early as 3000 years ago, cow dung was used in India to treat gastrointestinal diseases. As early as the Eastern Jin Dynasty (317–420 AD), a treatment similar to fecal bacterial transplantation, called "Huanglong Soup", was described in Ge Hong's "Urgent Prescription for Elbow Reserve", which was used to treat food poisoning and diarrhea. In traditional Chinese medicine, it is recorded that huanglian and rhubarb, among others, have the curative effect of "quenching thirst" (ancient term for diabetes). Berberine, a monomer component from huanglian, has been recognized internationally for its effect on improving glucose and lipid metabolism earlier. During World War II, German soldiers in North Africa treated diarrhea with camel excrement[5]. At present, FMT is mainly used for the treatment of recurrent *Clostridium difficile* infection (CDI) in clinical practice, and many clinical trials have confirmed that FMT is a feasible treatment[6].

At present, with the development of fast and accurate high-throughput sequencing technology and the improvement of bioinformatics technology methods, intestinal flora is closely related to metabolic syndrome (MS), type 1 diabetes (T1D) and type 2 diabetes (T2D), various cancers, and autoimmune diseases. Currently, it is believed that the FMT donor should be carefully selected and examined for infectious diseases[7]. However, due to the large difference in metabolism and diet of FMT donors, the effect of transplantation can be different. In this review, the mechanisms and deficiencies of FMT are discussed, and the optimal design of FMT is explored to maximize scientific research and clinical application methods.

COMPOSITION AND METHOD OF FMT

The main components of FMT are the gut flora of humans and other species. Humans have evolved to come into contact with a variety of bacteria, including those produced by food fermentation. The oral cavity is an important location of intestinal microbiota, which has an important effect on human health. Studies have shown that children who grow up on farms have a lower risk of asthma; a phenomenon that may be linked to changes in their gut microbiota[8]. In addition, babies born by cesarean section are at increased risk of developing autoimmune diseases, mainly because the initial microbes passed from the vagina to the baby at birth are replaced by skin microbes from the mother and surgical team members, which alter the baby's gut microbes[9]. An infant's gut microbiome can be reshaped in breast milk by adding small amounts of bacteria from the mother's feces, creating a pattern that more closely resembles that of babies born vaginally[10].

FMT has been processed into an odorless and tasteless preparation. In clinical practice, there are three methods of bacterial flora transplantation for patients willing to accept FMT: Upper, middle and lower digestive tract. The methods of transplanting upper digestive tract microflora mainly include oral

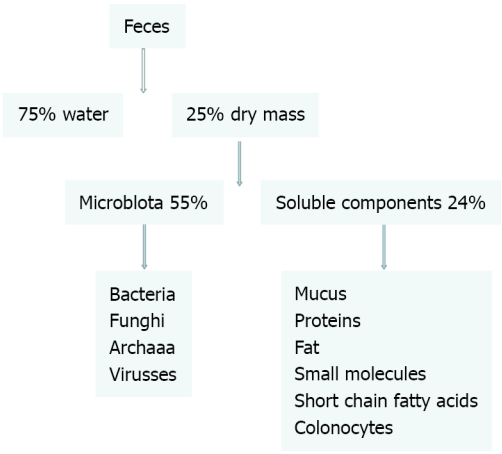
microflora liquid and oral microflora capsule. The middle digestive tract approach includes a nasointestinal tube, endoscopic biopsy hole, percutaneous endoscopic gastrostomy and jejunal catheterization, endoscopic catheterization such as Transendoscopic enteral tubing (TET)[11]. The lower gastrointestinal pathway includes colonoscopy, colostomy, enema, and colonic pathway TET. Colonic pathway TET is not only used for microflora transplantation, but also for whole colon administration such as mesalazine, hormones and traditional Chinese medicine. As a new endoscopic technique, TET is an important supplement for interventional treatment of inflammatory bowel disease[12].

FMT focuses on flora transplantation, but other components, such as phages, should not be ignored, which may be the reason for FMT's effectiveness in the treatment of recurrent CDI. Therefore, phage research is important, and animal studies have shown that fecal virus transplantation also plays an important role. Analysis of the feces of adults on a classic British diet found that 25% of the 100 g/d excreted was made up of bacteria and 75% of fiber, protein, fat, bile acids and short-chain fatty acids (SCFAs). In most FMT, however, feces are simply mixed with salt water and filtered to remove insoluble substances[13]. Thus, the potential effects of FMT may be partly due to the combined effects of these compounds (Figure 1).

AUTOLOGOUS FMT

Most studies have focused on fecal transplants from healthy donors (known as FMT allografts). However, autologous fecal transplants have significant advantages[14], such as reducing the risk of infection and increasing the efficiency of transplantation, especially in the treatment of recurrent CDI by freezing their own feces. Autologous fecal transplants are effective in many diseases, but not in disorders caused by intestinal flora disorders, such as inflammatory bowel disease[15]. Studies have shown that disorder of intestinal flora can aggravate the disease, and intestinal inflammation can also affect the composition of intestinal flora[16]. Therefore, it is speculated that fecal biobanks may contain probiotics, which have changed the composition of intestinal flora before the relapse of the disease. This requires further confirmation of the value of probiotics in intestinal flora, but there is insufficient evidence to confirm the value of probiotics collected in clinical remission. Therefore, autologous FMT can improve clinical symptoms by regulating intestinal flora to promote metabolism[17].

In conclusion, regulating the balance of intestinal flora is the primary goal of therapy. Autologous FMT through a duodenal tube or oral capsules can reshape the composition of small intestinal flora, which play an important role in the regulation of autoimmune diseases[18], mainly because the immune system response to antigenic stimuli occurs in the small intestine. It has also been suggested that autologous FMT *via* the duodenal tube may be valuable in a new method of preserving β-cell function for T1D diagnosis that is more effective than healthy donor FMT[19].



FMT AND METABOLIC DISEASES

MS

To date, the only reported study of FMT in the treatment of human MS was conducted by Witkowski *et al*[20]. This study examined the effects of FMT on glucose and lipid metabolism in men with MS in a double-blind randomized controlled trial in nine patients receiving fecal bacteria transplants from lean healthy donors (allograft group) and nine other patients[21]. They received their own fecal bacteria as a control (autologous transplantation group)[22]. After 6 wk of FMT treatment, insulin sensitivity and fecal microbial diversity were significantly increased in the allograft group, while no significant changes were observed in the autograft group. It should be noted that there were individual differences in the efficacy of FMT[23], and Gagliardi *et al*[24] suggested that the differences might have been more due to different donors than recipients, since the two subjects receiving fecal bacteria from the same donor showed similar benefits[24]. In a randomized, double-blind, controlled trial of fecal bacteria transplantation in patients with MS it was found that insulin sensitivity and butyric acid-producing intestinal flora significantly improved in patients receiving fecal donation[25]. FMT strengthened the intestinal barrier function and effectively reduced endotoxemia in a nutritionally obese rat model. It is also concluded that FMT can regulate the lipid content of obese rats and reduce hepatic steatosis[26]. There are currently four clinical trials of FMT for MS registered with clinicaltrials.gov. We believe that the results of these clinical trials can provide us with a better understanding of the role of intestinal flora in human metabolic disorders[27].

T1D

There is a close relationship between intestinal flora and diabetes mellitus. Some studies have found that the decrease of butyrate- and lactate-producing bacteria is related to the autoimmunity of β cells [28]. In addition, it has been found that the intestinal flora of children with β-cell-related autoimmune diseases lacks *Bifidobacterium*, and the bacteria producing butyrate and lactate are reduced while

DOI: 10.3748/wjg.v28.i23.2546 **Copyright** ©The Author(s) 2022.

Figure 1 Components that are transferred during fecal transplantation.

Bacteroidetes are increased[24]. Another study in Spain found similar changes in the gut flora of children with T1D, suggesting that structural changes in the gut flora may be associated with T1D[29]. A meta-genomic analysis of the intestinal flora in an included study found that, compared with the control group, patients with T1D had fewer butyrate-producing bacteria and mucin-degrading *Prevotella* and *Akkermansia*, and had more lactate-producing bacteria, and bacteria-producing SCFA other than butyrate, such as *Bacteroides* and *Riyanella*[30].All of these suggest that gut bacteria may participate in the disorder of immune function in patients with T1D[31].

Dietary fiber can be metabolized and fermented by intestinal bacteria into SCFAs, including acetic acid, propionic acid and butyric acid, which may also be involved in the pathogenesis of metabolic diseases[32]. The types and quantities of SCFAs are thought to vary with the composition of intestinal microbes. In addition to serving as an energy source for intestinal epithelial cells and liver (SCFAs are absorbed by the intestine and transported mainly through the portal vein), SCFAs are thought to have immunomodulatory effects by reducing intestinal permeability[33]. Lipopolysaccharides from intestinal translocation to the portal vein are thought to be involved in obesity-related mild inflammatory responses and insulin resistance in mice[34].

SCFAs produce a small number of microorganisms in T1D, and the incidence of T1D is significantly reduced in nonobese diabetic mice treated with *Akkermansia* or with a prebiotic diet supplemented with SCFAs[35]. It has been suggested that the restoration of intestinal flora balance through healthy donor FMT may further weaken autoimmune function and β-cell dysfunction[36]. A recent study showed that both healthy autologous and allogeneic FMT attenuates the decline of β-cell function, while donor FMT decreases at a slower rate[37]. Surprisingly, the decay rate of autologous FMT b cells was only 12 mo after three consecutive FMT treatments. Due to the significant changes in microbes from the mouth to the anus during autologous FMT[38], the immune system of the small intestine can be reshaped. Due to the lack of effective immunomodulators to treat T1D, a large number of clinical studies are needed to confirm this[39].

T2D

The association between intestinal flora and T2D was first reported by Chinese researchers led by The Shenzhen Huada Institute for Life Sciences and published in Nature in 2012[40]. This study found that the relative abundance of clostridium butyricum and its butyric acid-producing function in Chinese patients with T2D were significantly lower than those in the normal population, and lipopolysaccharide produced by conditional pathogenic Enterobacteriaceae species, hydrogen sulfide proinflammatory function and branched chain amino acid transport function levels were significantly higher than the general population[41]. These changes may be associated with impaired intestinal mucosal barrier function and increased levels of intestinal inflammation in T2D patients[42].

A randomized controlled study showed that autologous FMT can maintain normal metabolism after diet-induced weight loss[43]. It has been observed that obese donor FMT can cause rapid weight gain, so there is a link between the intestinal microbiome, obesity and insulin resistance[44]. On the contrary, non-obese donor FMT can improve insulin resistance in obese patients with MS. Another study found that donor FMT had no effect on glucose metabolism and their diets were metabolically tested. Recent studies have shown that the use of single-dose capsule FMT improves lipid metabolism and insulin resistance, mainly through continuous supplementation of low-fermenter fiber[45]. Therefore, dietary composition may affect insulin resistance of FMT, or metabolites of donor FMT may affect the enteric–brain axis[46].

NONALCOHOLIC FAATTY LIVER DISEASE

The relationship between intestinal microflora and nonalcoholic faatty liver disease (NAFLD) is increasingly close, research suggests. Intestinal flora can affect the occurrence and development of NAFLD by changing the composition of intestinal flora, increasing serum endotoxin level and intestinal permeability, producing endogenous alcohol and changing choline metabolism[47]. Animal studies have shown that FMT can improve steatohepatitis in mice induced by high-fat diet, reduce the production of lipids and proinflammatory factors in the liver, regulate the balance of intestinal flora in mice, and increase the abundance of beneficial flora[48]. After FMT treatment, the cecal butyrate concentration and intestinal tight junction protein ZO-1 increased, and the toxin release decreased, thus reducing the inflammatory response[49].

Increased intestinal permeability and metabolic endotoxin caused by changes in intestinal flora composition are involved in the progression of NAFLD in mice, and the severity of NAFLD in mice is increased when special flora are transferred to methionine- and choline-deficient diet, indicating that intestinal flora is involved in the progression of NAFLD[50]. The results of human studies also support the idea that changes in gut flora can contribute to fatty liver disease. Compared with normal subjects, NAFLD patients showed increased intestinal permeability, endotoxemia, increased numbers of g-Proteobacteria, and decreased numbers of Bacteroidetes[51].

Fatty liver often occurs in obese patients. Long-term vegans have a lower risk of NAFLD, which may be related to changes in gut flora. It is suggested that FMT treatment of long-term vegan feces can improve liver inflammation score[52]. Despite the small sample size, this study still found that the inflammatory necrotic tissue score and inflammatory gene expression were reduced after transplantation of vegan fecal flora, which may be an important indicator for predicting the progression of NAFLD to cirrhosis[53]. At the same time, an FMT study in NAFLD patients showed that healthy donor FMT reduced intestinal permeability, which is an important feature that distinguishes NAFLD from other diseases[48]. This study found that magnetic resonance imaging could not make a definitive diagnosis of hepatic adipose degeneration, which must be assessed using gold standard liver histological examination[54].

PITFALLS

Mode of delivery

Since innate and adaptive immune cell reactions occur in the small intestine, immune diseases are usually treated by oral capsules or fresh feces administered through the duodenum under strict anaerobic conditions, in order to ensure that active aerobic and anaerobic bacteria can be transplanted to the maximum extent and thus reshape the intestinal microecological balance[55]. Remodeling of the small intestinal flora is not appropriate for nonimmune diseases or diseases with distal intestinal malformations, but colonic delivery (enema or colonoscopy) may be an option[56].

Whether FMT plays an important role in other diseases besides recurrent CDI needs confirmation. Donor FMT freeze-drying capsules or frozen-solution capsules have been widely used and have gained more support due to their noninvasive administration[57], and it is also convenient for the donor and recipient to make multiple trips to the hospital for transplantation on the same day[58]. Current treatments for CDI include enemas, frozen capsules or freeze-drying formulations. However, it may not be suitable for mild intestinal microecological disorders that do not comply with GMP regulations as compared to fresh feces[59].

PREPARATION OF FMT FECAL BACTERIA LIQUID

Due to the lack of sufficient sample size and establishment of control groups in most clinical studies [55], the conclusions are not reliable, and there is controversy about the preparation of FMT fecal bacteria solution. (1) Selection of stool dilution materials[60]. It is reported that ordinary water (98.5%) has a higher disease remission rate than normal saline (86%) as a stool dilution material, but the recurrence rate of CDI with the former increased > 2 times. Other thinners, such as milk or salt water from plantain, achieved a 94% remission rate; (2) The amount of fecal bacteria liquid transplanted. When the volume of fecal bacteria liquid transplanted is > 500 mL, the remission rate of CDI is 97%, but < 200 mL, the remission rate is only 80%. However, it is difficult to compare the above conclusions because the dilution ratio of feces may vary. Currently, according to the Amsterdam protocol, 200–300 g of donor stool is dissolved in 500 mL normal saline for use (donor stool is preferably fresh within 6 h); and (3) Feasibility of frozen feces. A case report of standardized frozen stool samples used for fecal bacteria transplantation for the treatment of CDI showed that there was no statistical difference in the efficacy of standardized frozen stool compared with fresh stool. Therefore, establishment of stool donation banks and use of standardized frozen stool made fecal bacteria transplantation more feasible

in clinical practice[61]. A recent study on the treatment of CDI by oral frozen fecal bacteria capsules showed that no serious adverse reactions occurred in recurrent CDI treated by fecal bacteria transplantation *via* oral frozen fecal bacteria capsules[62]. The diarrhea relief rate of single administration was 70% (14/20), while four of six patients who did not respond to treatment achieved remission after second administration, resulting in a total remission rate of 90%. This study initially demonstrated the feasibility and safety of fecal bacteria transplantation *via* frozen fecal bacteria capsules[63].

THE PROCESSING OF FMT

Protective measures are usually taken to avoid anaerobic bacteria being killed by coming in contact with oxygen[64], but it cannot be completely avoided. Under strict anaerobic conditions, the composition of diluted or filtered microorganisms does not differ significantly before and after the entire procedure, but the activity of the preparation may have been affected[65]. Similarly, prolonged freezing at -80 °C preserved fecal components to a large extent, but whether it had an effect on fecal activity was unclear [66]. However, recent studies have shown that autologous FMT stored in glycerin at -80 °C can completely restore the intestinal lumen and mucosal microbial balance. Whether FMT regulates mild microbial disorders in these studies remains to be confirmed[67].

DIVERSITY OF THE GUT MICROBIOME

The diversity of intestinal flora increases with growth and development, and finally forms a complex and relatively stable microbial community at the age of 2–3 years, mainly including bacteria, fungi, viruses and protozoa[68]. There are > 1000 species of bacteria, most of which are obligate anaerobes, including Firmicutes, Bacteroides, Proteobacteria and Actinomycetes, among which Firmicutes and Bacteroides are dominant, accounting for > 90% of all intestinal bacteria[69].

Gut microbiome composition is temporal and spatially specific. Neonatal bacteria from the birth canal colonize the intestine within a few hours after birth. The intestinal microbial composition of early vaginally delivered babies is similar to that of the mother's vagina, while that of cesarean delivery babies is different[70]. A baby's gut microbiota can reach the level of a healthy adult at about age 1 year. Most of the microorganisms in the human intestine colonize the colon[71], and the number is 10^{12} cfu/mL. The microbial content of the jejunum, ileum and duodenum decreases successively, and there are 10^{7}, 10^{4} and 10^{3} cfu/mL, respectively. There are also differences in the types of microorganisms rich in each part. In addition, the composition of intestinal mucosa and fecal-associated microorganisms varies[72].

Individuals in the same area may have different gut microbiota. The composition and diversity of intestinal microbiota may influence the therapeutic effect of donor FMT[73], or even insulin resistance. In the past few decades, with the westernization of China's diet, intestinal microbial diversity has decreased. Preselection of donor FMT may be a feasible way to improve clinical outcomes based on the presence of a specific biological chain. Therefore, an important method to study FMT is to carefully study the baseline data of patients and the microbial composition after FMT[74]. By comparing the baseline data of the donor and the recipient and the microbial composition during a certain period of time, the number of microbes transplanted from the donor to the recipient can be calculated[75]. The most common method is fecal metagenomic sequencing, which identifies microbial species based on specific mononucleotide degeneration[76]. Sequencing techniques combined with bioinformatics analysis reveal the duration of similarity between donor and recipient strains, and how many of the transplanted microbes are likely to restore the original microbial composition[77].

DONOR-ACCEPTOR COMBINATION

FMT is thought to restore disturbed gut flora to a healthy state either by implanting a donor strain or by other donor-dependent traits, such as the amount of nonbacterial components[78]. However, not all donor gut microbiota are uniform, and comparison of gut microbiota from different donors suggests that microbial diversity and metabolites may be predictors of the success of FMT[79]. In some studies, donor microbiome and metabolomic characteristics may be associated with FMT treatment response. Therefore, the selection of appropriate donor feces is a key factor in the success of FMT[80]. However, few studies of FMT have considered the influence of the variation characteristics of the intestinal microbiome and metabolome of the donor on clinical efficacy[81].

Current studies have confirmed that after FMT treatment, the intestinal flora diversity of the recipient is significantly increased and tends to be the flora characteristics of the donor[82]. Cases that respond to FMT treatment typically show higher microbial diversity. It has been confirmed that intestinal bacterial abundance in donors that respond to FMT is significantly higher than that in donors that do not respond

[83].

To date, donor selection methods in FMT studies have included the use of a single donor or the random selection of multiple donors from a group of screened eligible donors[84]. In 2019, Zheng *et al* [85] first proposed the concept of super donors and believed that the success of FMT depends on the donor[85]. However, the definition of super donor has not been established, and the clinical efficacy of donors before FMT treatment cannot be predictedv[86]. However, the failure of randomly selected single donors may be due to the selection of ineffective donors rather than the incorrect indication selection of FMT[87]. Therefore, an alternative approach is to expose each patient to multiple donors (multidonor transplants) to reduce the risk of receiving FMT from an invalid donor[88]. However, FMT is still in the clinical research stage. Single donors can provide clearer evidence for clinical studies, while multiple donors lead to false negatives or false positives in clinical studies, thus hindering the development of the FMT field and the development of new microbiome therapies[89].

Studies have shown a surprising match between donor and recipient transplants and FMT[90]. The ability to secrete blood group antigens is associated with a reduction in gut microbial diversity, which in turn determines the likelihood of successful transplantation from nonsecreting blood group donors to secreting blood group receptors, which may also apply to human leukocyte antigens (HLAs)[91]. HLA haploidy is an important risk factor for autoimmune diseases such as T1D, and infants with HLA haploidy associated with an increased risk of T1D do form a unique microbiome[92]. What remains to be proven, however, is whether FMT can correct the high-risk microbiome associated with specific HLA haplotypes later in life[93]. In addition, it needs to be considered that intestinal immunoglobulin-secretion-binding bacteria and their components may contribute to the therapeutic effect of donor FMT [94].

CONCOMITANT MEDICATION

To facilitate colonization (also known as transplantation), the recipient's gut is usually cleaned, most commonly by enemas, laxatives, or broad-spectrum antibiotics[95]. In patients with ulcerative colitis, antibiotic administration after FMT increases the risk of transplant failure, although there is evidence that antibiotic pretreatment improves the efficacy of FMT[96]. Previous studies have shown that antibiotics, metformin, berberine and other drugs can change the intestinal flora, thus affecting the state of the body[97]. A study of Finnish children aged 2–7 years found that macrolide use was associated with subsequent long-term changes in intestinal microbiota composition and metabolism: A decrease in Actinobacteria and an increase in Bacteroidetes and Proteobacteria, decreased biliary saline hydrolyase and increased resistance to macrolides[98]. It is associated with an increased risk of asthma and weight gain. The effect of penicillin on intestinal flora was weaker than that of macrolides[99]. In addition to antibiotics, many Chinese herbal extracts can alter the intestinal flora[100]. A study in Taiwan Chang Gyeong Hospital found that ganoderma lucidum extract can reduce the body weight of high-fat-diet mice, reduce inflammatory response and insulin resistance, reduce intestinal flora Firmicutes/Bacteroidetes ratio and endotoxin levels, maintain the integrity of the intestinal barrier and reduce endotoxemia. It has been found that both berberine and metformin can reverse the changes in intestinal flora in mice induced by high-fat diet and significantly reduce the diversity of intestinal flora. Proton pump inhibitors (PPIs) are among the top 10 drugs widely used worldwide, and studies have found that PPI use is associated with intestinal infections, particularly CDI[101]. PPI users had significantly increased intestinal flora of *Enterococcus*, *Streptococcus*, *Staphylococcus* and opportunistic *Escherichia coli*[102]. In addition, cardiovascular drugs such as statins, antihypertensive drugs, antiplatelet aggregation drugs, as well as opioids and antidepressants can affect the composition of gut microbes[103]. As confounding factors such as gender and age have a great influence on these results, confounding factors should be minimized, and random number tables should be used to conduct random-grouping studies, because the reactions caused by these drugs may be caused by microbial disorders[104].

CONCOMITANT LIFESTYLE AND DIET

When a donor transplants microbes to a recipient, the difference in microbial composition between the two may be partly due to lifestyle differences between the donor and recipient[105]. If the recipient's lifestyle does not change to that of the donor after FMT, then the effect on the recipient's microbial makeup may disappear over time. People living in different continents and regions have their own unique dietary habits[106]. The diet of Europeans is rich in cheese, butter and other high-fat and high-calorie foods, while the diet of Africans is low in calories and high in dietary fiber[107]. High-throughput sequencing comparing the intestinal microbiota of European children with that of rural children from Burkina Faso, a landlocked country in Western Africa, revealed significant differences between the two[108]. *Prevotella* and Xylos bacteria, which are associated with cellulose and xylan hydrolysis, were completely absent in the intestinal flora of European children on a high-calorie and

high-fat diet, while the intestinal flora of African children on a low-calorie and high-fiber diet was rich in Bacteroidetes, especially *Prevotella* and Xylos bacteria, while Firmicutes were relatively rare[109]. In addition, African children were found to have significantly more SCFAs in their intestines than European children had, and the abundance of Enterobacteriaceae (mainly *Shigella* and *E. coli*) was found to be lower than that of European children[110]. These results suggest that the intestinal flora of African children has adapted to a diet rich in polysaccharides to ensure adequate energy intake from a fiber-rich diet and to reduce the incidence of intestinal inflammatory and infectious diseases[111]. The lack of dietary fiber in the diet of European children may be responsible for the loss of prevosiella and Xylos bacteria associated with cellulose and xylan hydrolysis[112]. Another study found that increased dietary fiber intake increased the diversity of the gut flora, as well as *Prevotella* abundance[113].

Numerous studies have shown that changes in diet determine microbial composition[114]. When autologous FMT is administered during a particular diet, the beneficial effects of the diet persist even if the diet is no longer continued[115]. Conversely, changes in an individual's microbial composition also affect diet. A large number of studies have shown that dietary response to FMT may be related to changes in microbial composition[116]. Thus, FMT transplantation using a standardized diet during clinical interventions may be more effective because an important source of microbiome variation has been eliminated, but it has been overlooked in many studies[117].

POTENTIAL MECHANISM OF ACTION

Although the causal relationship between intestinal microbiota and disease is still unclear, it is sufficient to inspire researchers to implement strategies for disease management by regulating intestinal microbiota[118]. Dietary management, antibiotics, probiotics and other interventions can directly or indirectly enable the reconstruction of intestinal flora[119]. FMT is based on microbiota treatment, in which the isolated functional bacteria are transplanted into the patient to reconstruct intestinal flora and achieve a steady state of the gut microbes so as to attain the purpose of disease treatment[120]. The specific mechanism of FMT has not been clarified yet, and its complex mechanism cannot be replaced and explained by a single strain or single signal[121]. In 2007, the "Human Microbiome Project", also known as the "Human second Genome Project", became the cornerstone of human exploration and understanding of intestinal microbes[122]. With the in-depth study of intestinal flora, the causal relationship between intestinal microbes and diseases will become more clear, and the specific action mechanism of FMT will become more clear.

FMT has made great progress in the treatment of recurrent CDI. However, due to infection and repeated use of antibiotics, the diversity of intestinal flora is low and the interactions between microorganisms are affected. Studies have shown that FMT with a healthy diversity of microbiome may increase microbial diversity levels to normal levels and enhance microbial interactions[123]. Recent studies have shown that microorganisms produced by biliary saltase may help improve the efficacy of FMT in the treatment of recurrent CDI, as the enzyme degrades taurocholic acid and effectively inhibits *C. difficile*[124]. Other studies have shown that FMT treatment can cause some subsequent problems, such as the use of antibiotics to cause bacterial dysregulation, leading to non-*C. difficile*-dependent colitis recurrence, and thus requiring new FMT corrective treatment[125].

Studies have shown that the most important source of fecal genes is prokaryotic viruses (phages)[126]. Phages are probably also the most overlooked in terms of FMT. Because diarrhea is partially relieved in patients with a small amount of microbial FMT during recurrent CDI, this suggests that phages may play an important role in maintaining host health by regulating gut microbiome composition and its phenotype[127]. Phages play an important role in gene expression of host bacteria and even determine their survival. Thus, FMT may function through donor phage regulation of the recipient flora. Currently, phage transplantation is done through aseptic filtration, which has the advantage of reducing bacterial infection. In addition, a large number of clinical studies are needed to show that phage transplantation has greater application value and potential in some diseases.

The mechanism of action of FMT therapy may be realized through multiple pathways, which may vary according to the FMT condition. However, one of the important mechanisms may be altered microbial metabolite production. This may occur during transplantation or subsequently by newly colonized microorganisms. The effect of the production of large quantities of small molecules by microorganisms on the host needs to be further clarified[128]. The most significant is SCFA butyrate, produced mainly by fibrinolytic enzyme strains, which reduces intestinal permeability and provides nutrients to intestinal cells, producing epigenetic effects[129]. In addition, fibrinolytic enzyme strains has anti-inflammatory properties and can reduce the incidence of T1D in NOD mice[130]. Therefore, FMT may modulate immune activity through autoantigens. In addition, studies have shown reduced production of butyrate strains in T1D[131]. However, when T1D patients were given high concentrations of butyrate, no significant changes were detected in immune cells, and when T1D patients were given FMT, butyrate as an active regulator of protective b cells and immune cells was not detected by metabolomics[132]. As a result, the research impact of using noninvasive biomarkers for microbial metabolism has been largely underestimated[133]. This phenomenon may partly explain some of the

differences between rodent and human studies. In addition, it should be made clear that interventional studies cannot completely exclude the potential mechanism of action of butyrate in T1D[134]. Therefore, it is a long and tortuous road to find meaningful microorganisms from clinical observational studies to improve clinical outcomes.

APPLICAATION PROSPECT OF FMT IN CLINICAL RESEARCH

FMT is a new theory and technology that has prospects in the treatment of intestinal microbiome disorders. However, the mechanism of action, ethical issues and effects of FMT are still controversial. The methodology of donor screening, the preparation and state of fecal bacteria solutions, and the approaches to transplantation are not uniform, and there are different reports on the safety and efficacy of FMT treatment[135]. In the future, more and higher-quality randomized controlled clinical trials should be carried out to address the above problems, so as to provide more adequate evidence-based medical evidence[136]. It is certain that with the deepening of scientific research, the mechanism of FMT will be gradually clarified; the intestinal microbial spectrum, microbial metabolites and their association with diseases will be more clear; and the FMT methodology will be more standardized[137]. Despite its limitations, FMT is currently one of the most important tools for studying the role of microorganisms in the pathogenesis of a range of chronic diseases. To improve the effectiveness of studies, further standardization of FMT should be carried out, such as dosage, transplantation method, and whether to use alternate pretreatment of fresh or frozen preparations[138]. In addition, accurate assessments and calculations are required to avoid type I errors in order to accurately assess efficacy. Of course, many meetings and forums are needed to reach consensus.

CONCLUSION

Donor FMT can restore intestinal microbial function and improve clinical outcomes. Therefore, the question in the future is whether the addition of specific strains of FMT to microbial-targeted therapies can help improve diet and drug therapy to improve human health. Therefore, in order to improve the clinical treatment of recurrent CDI, there is a need for more standardized FMT techniques. Rapid advances in untargeted molecules and bioinformatics have made it possible to analyze in detail the potential mechanisms of action of FMT. These results can identify important microorganisms and their metabolites, which may be used as probiotics, probiotics and epigenetic bacteria to enhance the therapeutic effect of FMT, or even replace FMT, for treatment of metabolic diseases.

Abstract

Barcelona clinic liver cancer (BCLC) intermediate stage hepatocellular carcinoma is a heterogenous disease. Transarterial chemoembolization is offered as the first line therapy in this disease stage. Recent advances in systemic therapy have markedly improved outcomes even in advanced stage disease. The use of systemic therapy in BCLC intermediate stage disease may now be of therapeutic benefit in selected patients. We will focus on "the up to seven" criteria and its utility in selecting systemic therapy.

Key Words: Chemoembolization; Hepatocellular carcinoma; Immunotherapy; Drug combinations; Review; Medical oncology

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Barcelona clinic liver cancer intermediate stage disease that exceeds "the up to seven" criteria, especially with lesions larger than 5 cm, is less likely to respond to transarterial chemoembolization (TACE) alone and is therefore a disease that may respond better to systemic therapy. The use of "the up to seven" criteria can be a helpful guidepost for when to consider systemic therapy alone or in addition to TACE. With the recent breakthroughs in immunotherapy for advanced hepatocellular carcinoma which clearly demonstrated overall survival advantage over single agent tyrosine kinase inhibitors sorafenib, it is promising that the use of immunotherapy would likely lead to better outcome when used in intermediate disease.

INTRODUCTION

Hepatocellular carcinoma (HCC) accounts for 80% of primary liver cancers worldwide[1]. It is one of the cancers with the highest mortality rate, with a 5-year survival rate of only 20%[2]. Treatment of HCC depends on the staging according to the Barcelona clinic liver cancer (BCLC) staging system which is determined by tumor characteristics, liver function (assessed by Child-Pugh score) and patient performance status[3]. Using these criteria, patients may be categorized as early, intermediate or advanced stage disease.

"THE UP TO SEVEN" CRITERIA

Candidates for liver transplantation are most often assessed using the Milan Criteria which was published in 1996. It set strict guidelines to identify individuals who are most likely to benefit from transplantation in an effort to minimize cancer recurrence and maximize overall survival (OS)[4].

Recently the authors of the Milan Criteria have purposed an expansion of the guidelines termed "the up to seven" criteria. In a study of 1556 patients who underwent liver transplantation for HCC, the authors developed software that searched for combinations of tumor characteristics exceeding the Milan criteria, but resulted in an estimated 5-year OS of at least 70%. These found characteristics were termed "the up to seven" criteria. Seven being the sum of the size in centimeters and the number of tumors. Examples, as illustrated in the study, one tumor up to 6 cm in size 6 + 1 = 7, to multiple tumors with seven as the sum of the size plus number (*i.e.*, two tumors up to 5 cm in total size , three tumors up to 4 cm in total size, *etc.*)[5].

A recent retrospective study comparing OS among liver transplant patients based on their selection by the Milan or "the up to seven" criteria found no differences between the two groups[6].

TRANSARTERIAL CHEMOEMBOLIZATION THERAPY IN INTERMEDIATE STAGE DISEASE

Patients with intermediate stage disease, classified by multi-nodular disease, Child-Pugh A-B, with an ECOG performance status of 0, with no extra hepatic spread are candidates for transarterial chemoembolization (TACE).

TACE therapy preferentially targets HCC due to the tumor's disproportionally higher arterial vascular supply compared to normal liver parenchyma[3]. The success of TACE was demonstrated with two randomized control trials (RCTs) and a meta-analysis[7-9].

TACE therapy can be given in different forms including by conventional TACE (cTACE), by drug-eluting beads-TACE (DEB-TACE) and by bland embolization (TAE) which does not use chemotherapy [10].

In cTACE, a cytotoxic drug that has been emulsified in Lipidol is intra-arterially injected followed by the embolic agent. The efficacy of cTACE was recently reaffirmed with an estimated average median OS of 30 mo[3,11-13].

In DEB-TACE, the embolic agent is loaded with cytotoxic medications[14].

In TAE, embolization is performed without a cytotoxic drug[15].

The differences in outcomes between these techniques have been compared. In a phase III trial the Precision Italia Study Group compared DEB-TACE with cTACE and found no difference in response rates, median time to progression, or survival[16]. This finding was also supported by a meta-analysis of 4 RCTs and 8 observational studies which concluded there was a non-superiority of DEB-TACE *vs* cTACE[10]. Similarly a meta-analysis comparing TAE *vs* cTACE found no difference in OS, or objective response to therapy[15].

However despite similar outcomes TAE therapy has its critics who note TAE therapy results in less tumor necrosis compared to other forms of TACE therapy which may prevent its complete adoption[17,18].

Another criticism of TACE therapy in general is that as a therapy it is non-standardized[19]. This is especially true of TACE therapy with cytotoxic agents as there are several chemotherapeutic drugs which may be used[20]. Additionally the extent to which stasis of flow is achieve in the target vessel is also physician operator dependent[21]. This lack of standardization and dependency on the skill of the interventionist makes a more uniform approach *via* systemic therapy desirable.

THE POTENTIAL OF SYSTEMIC THERAPY IN INTERMEDIATE STAGE DISEASE

Predictive factors of whether to initiate TACE include: Tumor size, vascularity, arterial anatomy, infiltrative *vs* nodular growth, presence of splenomegaly, Alfa-fetoprotein changes, albumin and bilirubin levels[22]. Furthermore the decision to repeat TACE should depend on the response based on modified RECIST criteria to prior TACE therapy[23,24]. Of note as radiographic assessment is dependent on the reading physician it is important that this be carried out by a radiologist experienced in HCC[25]. Patients who have an initial complete response to TACE may undergo a second procedure if warranted as long as they are still candidates for therapy. For patients with a partial response or even stable disease repeat treatment at regular intervals may be offered but that decision should be weighed against liver toxicity from treatment[22,26]. Patients with no objective response to two TACE treatments are unlikely to benefit from further TACE and would likely benefit from alternative therapy[26,27]. Even if clinicians are hesitant to choose systemic therapies as initial treatments in intermediate stage HCC, survival maybe improved by switching to these therapies in TACE refractory disease[28,29]. The 2018 OPTIMIS trial followed 1650 patients with unresectable HCC who were to undergo TACE therapy. 31% of these patients became TACE ineligible during the study but only 9% received sorafenib when deemed ineligible for TACE with the remainder having systemic therapy delayed or not receiving it at all[30]. It is therefore critical to determine which patients would be unlikely to benefit from TACE early as to not delay appropriate care (Table 1).

Although current guidelines recommend TACE as first line treatment in intermediate stage HCC, this disease is characterized by high heterogeneity and its real world management may be as equally diverse [27,31].

HCC exceeding "the up to seven" criteria is less likely to respond to TACE due to higher tumor burden[32,33]. In fact, patients beyond "the up to seven" criteria who undergo TACE had higher rates of liver function deterioration post procedure[34]. This is particularly concerning considering poor liver function may preclude patient's from promising systemic therapies[35,36].

In a retrospective propensity matched study by Kudo *et al*[37], patients with BCLC intermediate stage HCC beyond "the up to seven" criteria were treated with lenvatinib systemic therapy or TACE. Whereas TACE treatment led to a decline in liver function, lenvatinib treatment did not result in such a decline. OS was significantly longer in the lenvatinib group 37.9 mo *vs* 21.3 mo; hazard ratio: 0.48, $P < 0.01$. In the study protocol, after progression on lenvatinib, second line treatment including TACE, hepatic arterial infusion chemotherapy, sorafenib, regorafenib, or investigational therapies were allowed. Of note, about 70% of the patients who received lenvatinib underwent subsequent TACE. Patients who received TACE as initial treatment where allowed to undergo repeat TACE. After becoming TACE refractory, second line treatments were identical to the ones in the levantinib group [37].

Recently results from the phase III IMbrave-150 trail have changed management of locally advanced or metastatic/unresectable HCC who are either not TACE candidates or became refractory to TACE. In this trial, the immunotherapy and vascular endothelial growth factor inhibitor combination atezolizumab + bevacizumab was compared against sorafenib, the old standard of care. Median OS was 19.2 mo with the combination therapy *vs* 13.4 mo with sorafenib [HR, 0.66 (95%CI: 0.52-0.85); $P = 0.0009$][38,39]. This combination was the first to show clinical benefit over sorafenib since 2007 and is now first line therapy in the treatment of advanced stage liver cancer[40]. Immunotherapy doublet combination treatments have also shown promise. In the Checkmate-40 trial, nivolumab plus ipilimumab in the second line setting (after sorafenib) showed median OS of 22.8 mo with an overall response rate (ORR) of 32%[41]. A similar combination in a phase II study using the anti-programmed death-ligand 1 antibody durvalumab plus tremelimumab (CTLA-4 antibody) for patients who progressed on, were intolerant to, or refused sorafenib showed a median OS of 18.7 mo and an ORR of 22.7%. A trial of this combination in the first line is being tested in the phase III HIMALAYA study[42]. A press releases from the trial stated that the combination significantly improved OS compared to sorafenib with an HR of

Table 1 Considerations in initiating systemic therapy over transarterial chemoembolization[26,44,53-55]

No.	Considerations
1	Tumor exceeds "the up to seven" criteria
2	Tumor(s) larger than 5cm
3	Contiguous multinodular tumors
4	Poorly differentiated or undifferentiated HCC
5	No objective response to 2 consecvutive TACE treatments

HCC: Hepatocellular carcinoma; TACE: Transarterial chemoembolization.

Table 2 Combination therapy trials

Trial therapies	Study name	Phase	Patient number or estimation	ORR	Median PFS	Median OS
Lenvatinib + TACE *vs* Lenvatinib[47]	LAUNCH	Phase 3	338	54.1% *vs* 25%	10.6 mo *vs* 6.4 mo	17.8 mo *vs* 11.5 mo
(cTACE or DEB-TACE) + durvalumab followed by durvalumab + placebo *vs* (DEB-TACE or cTACE) + durvalumab followed by durvalumab + bevacizumab *vs* (DEB-TACE or cTACE)[48]	EMERLD	Phase 3	600	In progress	In progress	In progress
Lenvatinib + Pembrolizumab + TACE *vs* Placebo + TACE[49]	LEAP-012	Phase 3	950	In progress	In progress	In progress
Nivolumab + Ipilimumab + TACE *vs* Nivolumab + Placebo + TACE *vs* Placebo + Placebo + TACE[50]	Checkmate-74W	Phase 3	765	In progress	In progress	In progress
Brivanib + TACE *vs* Placebo + TACE[51]	BRISK-TA	Phase 3	502	48% *vs* 42%	8.4 mo *vs* 4.9 mo[1]	26.4 mo *vs* 26.1 mo
Oranitib + TACE *vs* Placebo + TACE[52]	ORIENTAL	Phase 3	889	Not reported	2.9 mo *vs* 2.5 mo[1]	31.1 mo *vs* 32.3 mo
Tremelimumab + TACE[53]		Phase 2	11	18%	7.4 mo[1]	13.6 mo

[1]Reported as time to radiographic progression.
ORR: Overall response rate; PFS: Progression free survival; OS: Overall survival; TACE: Transarterial chemoembolization.

0.78[43,44].

In select BCLC intermediate stage disease systemic therapy should be considered in the frontline setting, especially for patients who have been refractory to TACE or in whom TACE is unlikely to be effective. Patient's unlikely to respond well to TACE include patients who exceed "the up to seven" criteria, as well as those who have tumors without a clear boundary, multifocal tumors, or poorly differentiated HCC[33,34,36,45,46].

As a heterogenous disease BCLC intermediate stage HCC maybe best treated with combination therapy. In fact, the success of combination therapy in advanced disease is now being tested in BCLC intermediate stage disease. Current investigations that combine TACE with systemic therapy include the phase III LAUNCH study in which patients with BCLC stage C disease was treated with lenvatinib + TACE *vs* lenvatinib alone. The combination group saw an improved OS from 11.5 to 17.8 mo. Additional the combination had higher ORR, 54.1% *vs* 25%, and higher disease control rate (DCR), 94.1% *vs* 73.2%, as well as a longer progression free survival, 10.6 mo *vs* 6.4 mo[47]. Other upcoming TACE and systemic therapy combination treatments include the studies EMERLD-1, LEAP-012, and Checkmate-74W. EMERLD-1 will assess efficacy and safety for durvalumab monotherapy with DEB-TACE or cTACE followed by durvalumab with or without bevacizumab therapy in patients with HCC not amenable to curative therapy. LEAP-012 will test lenvatinib plus pembrolizumab *vs* placebo in combination with TACE in patients with intermediate HCC. Checkmate-74W will analyze the combination of dual immune checkpoint blockade and TACE *vs* mono-therapy immune checkpoint blockade and TACE for patients with HCC exceeding the up to seven criteria[48-50].

Although these ongoing trials are exciting, it is worth noting that several studies which combined TACE and systemic therapy have failed to show desired efficacy. These include BRISK-TA and ORIENTAL which both compared targeted therapy and TACE to TACE alone. In both trials there was no improvement in OS compared to TACE alone[51,52]. Finally in a 2017 study by Duffy *et al*[53] the

addition of anti CTLA-4 immunotherapy in 11 patients previously treated with TACE showed a OS of 13.6 mo which is comparable to systemic therapy alone[53] (Table 2).

CONCLUSION

BCLC intermediate stage disease that exceeds "the up to seven" criteria, especially with lesions larger than 5 cm, is less likely to respond to TACE alone and is therefore a disease that may respond better to systemic therapy[32,33,37,54]. The use of "the up to seven" criteria can be a helpful guidepost for when to consider systemic therapy alone or in addition to TACE. With the recent breakthroughs in immunotherapy for advanced HCC which clearly demonstrated OS advantage over single agent tyrosine kinase inhibitors sorafenib, it is promising that the use of immunotherapy would likely lead to better outcome when used in intermediate disease. However, this conjecture requires validation from prospective phase III studies.

Improvements in the treatment of liver cancer have the ability to change the lives of the nearly 800000 patients diagnosed with liver cancer annually. The use of TACE therapy rightfully remains a cornerstone of treatment. However for patients who are unlikely to benefit from TACE therapy alone such as patients exceeding "the up to seven" criteria, alternative treatments including systemic therapies warrant consideration especially with recent advancements in the field.

Abstract

BACKGROUND

Endoplasmic reticulum (ER) stress-related hepatocyte apoptosis is responsible for multiple hepatic diseases. Previous studies have revealed that endoplasmic reticulophagy (ER-phagy) promotes the selective clearance of damaged ER fragments during ER stress, playing a crucial role in maintaining ER homeostasis and inhibiting apoptosis. Family with sequence similarity 134 member B (FAM134B) is a receptor involved in ER-phagy that can form a complex with calnexin (CNX) and microtubule-associated protein 1 light chain 3 (LC3). The complex can mediate the selective isolation of ER fragments to attenuate hepatocyte apoptosis. However, the precise regulatory mechanisms remain unclear.

AIM

To elucidate the effect of FAM134B-mediated ER-phagy on ER stress-induced apoptosis in buffalo rat liver 3A (BRL-3A) rat hepatocytes and the potential regulatory mechanisms.

METHODS

ER stress-related hepatocyte apoptosis was induced using dithiothreitol (DTT). Proteins related to ER stress and autophagy were measured with western blotting. Protein complex interactions with FAM134B were isolated by co-immunoprecipitation. ER-phagy was evaluated in immunofluorescence experiments. Cell cycle distribution and apoptosis were measured by flow cytometry. Mitochondrial Ca^{2+} levels were evaluated by the co-localization of intracellular Ca^{2+}-tracker and Mito-

tracker. The small interfering RNA against *FAM134B* was used to knockdown *FAM134B* in BRL-3A cells.

RESULTS

ER stress-related and autophagy-related proteins in BRL-3A cells were elevated by both short and long-term DTT treatment. Furthermore, co-immunoprecipitation confirmed an interaction between FAM134B, CNX, FAM134B, and LC3 in BRL-3A cells. Immunofluorescence assays revealed that autolysosomes significantly decreased following short-term DTT treatment, but increased after long-term treatment. Mitochondrial Ca^{2+} levels and apoptotic rates were dramatically elevated, and more cells were arrested in the G1 stage after short-term DTT treatment; however, these decreased 48 h later. Moreover, FAM134B downregulation accelerated mitochondrial apoptotic pathway activation and aggravated hepatocyte apoptosis under ER stress.

CONCLUSION

FAM134B-mediated ER-phagy attenuates hepatocyte apoptosis by suppressing the mitochondrial apoptotic pathway. Our findings provide new evidence highlighting the importance of FAM134B-mediated ER-phagy in attenuating hepatocyte apoptosis.

Key Words: Hepatocytes; Reticulophagy; Family with sequence similarity 134 member B; Apoptosis; Endoplasmic reticulum stress; Endoplasmic reticulum homeostasis

Core Tip: We show that family with sequence similarity 134 member B (FAM134B)-mediated reticulophagy maintains the endoplasmic reticulum (ER) homeostasis in ER-stressed hepatocytes *via* the clearance of damaged ER fragments. Thereby FAM134B-mediated reticulophagy ameliorates dithiothreitol-induced hepatocyte apoptosis. Our findings provide emerging evidence of the prominence of ER-phagy in ER stress-related hepatocyte apoptosis. FAM134B may represent a potential therapeutic target for liver disease treatment.

INTRODUCTION

Endoplasmic reticulum (ER) stress-related hepatocyte apoptosis participates in multiple hepatic diseases, including viral hepatitis[1], hepatic fibrosis[2], fatty liver[3,4] and cirrhosis[5]. Therefore, the alleviation of ER stress-mediated hepatocyte apoptosis is crucial in the treatment of hepatic diseases. Recent findings have indicated that endoplasmic reticulophagy (ER-phagy) promotes degradation of damaged ER fragments during ER stress. Although ER-phagy has a vital role in maintaining ER homeostasis and inhibiting cell apoptosis[6-8], the exact regulatory mechanisms behind this are largely unknown.

Glucose-regulated protein 78 (GRP78) is a prominent ER molecular chaperone, while calnexin (CNX) is a membrane-bound lectin protein in the ER that can increase the protein folding capacity[9,10]. Even though the excessive build-up of misfolded or unfolded proteins can be alleviated *via* ER stress, previous studies reported that a selective autophagic mechanism, defined as ER-phagy, can also be activated by ER stress to restore ER homeostasis[11,12]. Family with sequence similarity 134 member B (FAM134B), an ER-resident protein, may interact with CNX in the cytosol or the ER membrane[13]. Since FAM134B is not predicted to have an ER lumenal domain, there is an indirect interaction between FAM134B and lumenal proteins through the lumen-resident segment, which has a chaperone activity attributed to CNX. CNX forms transient but relatively stable complexes with unfolded ER proteins until they either become folded or are degraded. Moreover, it has been reported that as with other cargo receptor molecules, FAM134B can interact directly with microtubule-associated protein 1 light chain 3 (LC3) when its LIR motif is exposed. The CNX-FAM134B-LC3 complex can mediate the selective isolation of ER fragments containing misfolded proteins, which are subsequently transported to lysosomes for degradation[14-16]. Thus, FAM134B-mediated ER-phagy may play an essential role in

maintaining ER homeostasis and promoting cell survival. However, it is unclear whether FAM134B-mediated ER-phagy is involved in the regulation of hepatocyte apoptosis induced by ER stress. In this study, dithiothreitol (DTT) was used to induce ER stress in buffalo rat liver 3A (BRL-3A) hepatocytes, and the expression of ER stress-related and autophagy-related proteins was assessed. In addition, small interfering RNA (siRNA) was used to knockdown the expression of *FAM134B* in hepatocytes and an apoptosis analysis followed. Our study reveals an emerging role of FAM134B-mediated ER-phagy in ER stress-mediated hepatocyte apoptosis, which may provide a novel target for the treatment of hepatic diseases.

MATERIALS AND METHODS

Antibodies and reagents

Dulbecco's modified Eagle medium (DMEM) and fetal bovine serum (FBS) were purchased from Gibco (Grand Island, NY, United States). Trypsin-EDTA solution, trypsin solution without EDTA, and penicillin-streptomycin were purchased from Biological Industries (BioInd, Israel). Bicinchoninic acid (BCA) protein assay kit, DTT, RIPA lysis buffer, and protease inhibitor were obtained from Solarbio (Beijing, China). Annexin V-FITC/PI Apoptosis Detection Kit and Cell Cycle Detection Kit were purchased from KeyGEN BioTECH (Nanjing, China). PVDF membranes were obtained from Merck Millipore. Rabbit polyclonal antibody against FAM134B was purchased from Proteintech (Wuhan, China). Rabbit polyclonal antibodies against ATG12, cytochrome c (cyt c), and cleaved caspase-3 were obtained from Cell Signaling Technology (Danvers, MA, United States). Rabbit polyclonal antibodies against β-actin, LC3, CNX, CHOP and GRP78, and the Ca^{2+} indicator (Rhod-2 AM) were purchased from Abcam (Cambridge, United Kingdom). Dynabeads protein G immunoprecipitation kit and lipofectamine 3000 reagent were purchased from Thermo Fisher Scientific, Inc. HRP-labeled Goat Anti-Rabbit IgG (H + L), Mito-Tracker Green, Lyso-Tracker Green, ER-Tracker Red, and immunofluorescence-related reagents were purchased from Beyotime Institute of Biotechnology (Nanjing, China).

Cell culture and experiment protocol

BRL-3A cells, bought from Cell Bank of the Chinese Academy of Sciences (Shanghai, China), were cultivated and maintained in DMEM culture media supplemented with 1% penicillin-streptomycin and 10% FBS. BRL-3A cells were seeded at 37 °C and 5% CO_2 in a constant temperature and humid atmosphere, pre-cultured every 3 d, and further passaged until the density reached approximately 80%. To induce the ER stress, BRL-3A cells were treated with DTT (2.0 mmol/L based on previous studies[17]) for 0, 3, 6, 12, 24, or 48 h.

Apoptosis assessment

Cells were cultured to 80% confluency and treated with 2.0 mmol/L DTT for the specified point-in-time intervals. To determine the efficacy of the different DTT treatments, a cell apoptosis analysis was evaluated with flow cytometry. Each group of cells was trypsinized without EDTA and rinsed thrice with PBS. After centrifugation at 2000 rpm for 5 min, cells were loaded with 500 μL binding buffer and labeled with 5 μL of Annexin V-FITC/PI, according to the manufacturer's instructions. Labeled cells were detected and analyzed with flow cytometry and NovoExpress® software 1.4.1. The experiments were performed in triplicate.

Cell cycle analysis

To determine the effect of DTT's 0, 3, 6, 12, 24, and 48 h incubation on the cell cycle progression of BRL-3A, the harvested cells were trypsinized without EDTA and rinsed three times with cold PBS, followed by fixation with 70% ethanol in cold storage. After 24 h incubation at 4 °C, 500 μL PI/RNase was added to each group and maintained at 37 °C for 60 min in a dark place. Stained cells were processed using flow cytometry and further measured *via* the NovoExpress® software 1.4.1. The experiments were performed in triplicate.

Western blot analysis

BRL-3A cells were grown on 10 cm diameter dishes and treated with 2.0 mmol/L DTT for different times. Cells were rinsed three times with pre-cooled PBS after experimentation and collected with cell scrapers in 100 μL RIPA buffer containing 1 mmol/L PMSF. After centrifugation at 12000 rpm for 25 min at 4 °C, the concentrations of total cellular protein extracts were determined using the BCA kit (Solarbio Science, Beijing, China), and known concentrations of BSA were used as standard. The total cellular protein extracts were denatured by boiling at 100 °C using dry bath incubator (Hangzhou Miu Instruments Co., Ltd, Zhejiang, China). Protein samples (30–40 mg) were loaded onto SDS-PAGE and transferred onto PVDF membranes for immunostaining. After blocking with 5% defatted milk for 90 min, membranes were stained overnight with primary antibodies, including β-actin (1:1000), GRP78 (1:1000), CNX (1:3000), ATG12 (1:1000), LC3 (1:1000), FAM134B (1:1000), CHOP (1:1000), cleaved

caspase-3 (1:1000), cyt c (1:1000) in cold storage, followed by incubation with secondary antibodies (1:4000). The density of protein bands on membranes was exposed and quantified *via* fluorography using Image J software. The images shown are representative of experiments carried out at least three times.

Co-immunoprecipitation analysis

BRL-3A cells, treated with DTT (2.0 mmol/L for 0 h and 24 h), were lysed in RIPA lysis buffer and the lysates were centrifuged at 12000 rpm for 15 min at 4 °C. The supernatant was resuspended in ice-cold PBS to a total volume of 500 μL, and 5 μL of the designated antibody was added overnight at 4 °C. The next day, the Ab-Ag complexes were bound to Dynabeads magnetic beads on a rotary shaker for 10 min. The magnetic bead-Ab-Ag complex was washed and eluted by adding a washing buffer and elution buffer, respectively, according to the manufacturer's protocol. Immunocomplexes were heated for 5 min at 100 °C and prepared for analysis by western blot. The images shown are representative of experiments carried out at least three times.

Calcium imaging and mitochondrial labeling

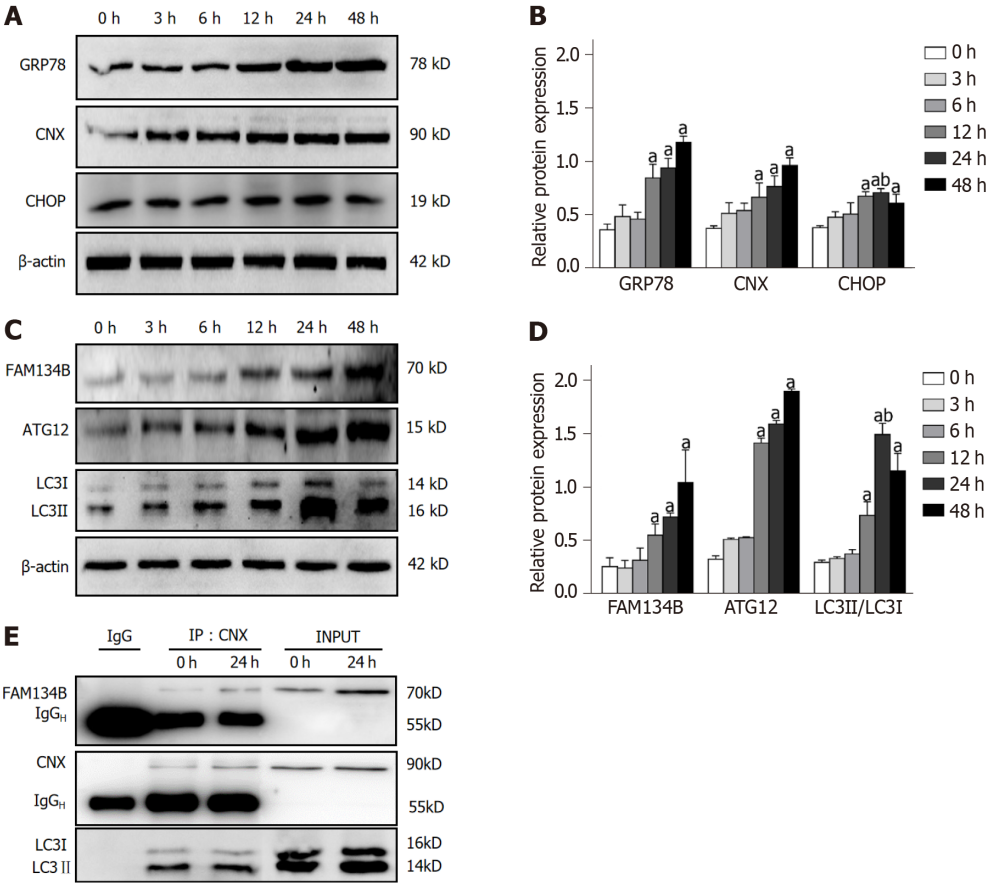
To observe the effects of DTT treatment at 2.0 mmol/L for specified time points, mitochondrial Ca^{2+} levels were determined using Rhod-2 AM, a specific detection dye for calcium. The treated cells were rinsed with HBSS three times and stained with a mixture of 5 μM Rhod-2 AM and 20 nM Mito-Tracker Green at 37 °C for 30 min in the dark. Finally, live cells were extensively rinsed thrice by adding HBSS without calcium, and images were visualized with Zeiss LSM Image Browser using a Zeiss LSM 900 confocal microscope. The images shown are representative of experiments carried out at least three times.

Live imaging of ER and lysosome

To observe the intracellular localization of the ER and lysosomes, after treatment with 2.0 mmol/L DTT for 0, 3, 6, 12, 24, and 48 h, ER and lysosomes were stained with ER-tracker and Lyso-tracker. Prior to staining, trackers were diluted appropriately in DMEM, on the basis of the manufacturer's instructions. Following dilution, cells were simultaneously incubated with the two trackers listed above, maintained for 30 min at 37 °C, and finally rinsed thrice with HBSS. Stained cells were visualized under the Zeiss LSM 900 confocal microscope. Images shown are representative of experiments carried out at least three times.

SiRNA transfections

Specific siRNA against buffalo rat *FAM134B* was designed and synthesized by OriGene. Product number and targeting sequence: SR510501A-rGrGrArArGrUrGrGrUrUrUrArUrCrArArArUr-UrCrUrGrATA; SR510501B-rArArArUrUrUrGrArCrUrUrArCrArGrUrGrGrArArArCrCAA; SR510501C-rArArGrUrGrGrUrUrUrArUrCrArArArUrUrCrUrGrArUrAGA. Cells were cultured in six-well dishes until the density of cell fusion reached 60%. Briefly, 75 pmol of *FAM134B* siRNA were added to Lipofectamine 3000 Transfection Reagent and gently mixed for 15 min, then administered to BRL-3A cells, which were resuspended in DMEM. After transfection for 6 h, cells were washed, and then supplemented with fresh medium. Finally, cells were treated with DTT (2.0 mmol/L) for a further 24 h and subjected to western blot assay and apoptosis assessment.



Statistical analysis

GraphPad Prism 7 software was used to perform all the statistical analyses and prepare experimental graphs. Data are expressed as the mean ± SD. Shapiro-Wilk normality test was used to test the normal distribution of the data and all the data were fit to a normal followed by Tukey's post hoc test was performed, and a significant difference was considered as $P < 0.05$.

RESULTS

DTT-mediated ER stress upregulates ER-phagy-related FAM134B in BRL-3A cells

To assess whether the drug treatments could alter the protein expression of CNX and GRP78, BRL-3A cells were subjected to short-term (3, 6, 12, 24 h) or long-term (48 h) treatment with DTT, and the protein extracts from BRL-3A cells were analyzed by western blot. We found that treatment of BRL-3A cells with 2.0 mmol/L DTT resulted in a prominent increase in CNX and GRP78 levels, both in a time-dependent manner (Figure 1A and B). Moreover, CHOP is a specific and stress-responsive transcription factor during ER stress and its protein expression was significantly increased in the 12, 24, and 48 h groups (Figure 1A and B). However, the expression of CHOP in BRL-3A cells treated with DTT for 48 h was lower than that after DTT treatment for 24 h. These alterations in CNX, GRP78, and CHOP confirm that ER stress in BRL-3A was activated.

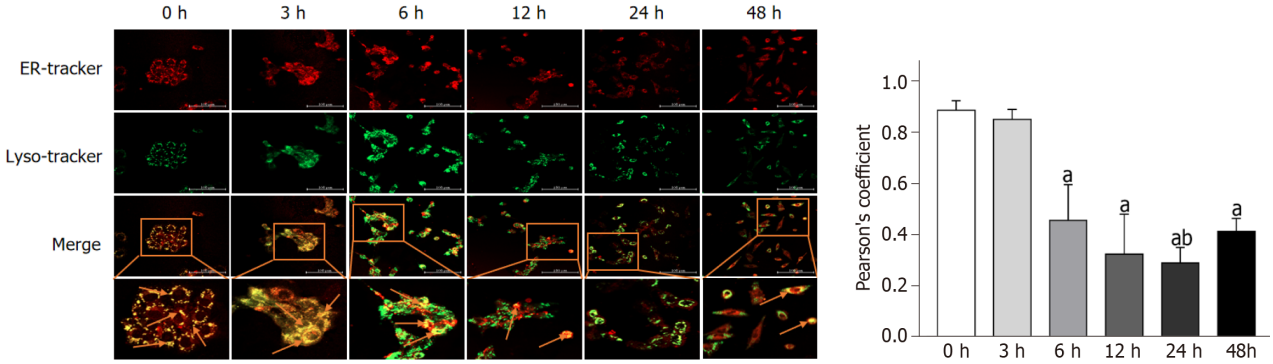
Figure 1 Impact of the endoplasmic reticulum stressor, dithiothreitol, on endoplasmic reticulophagy mediated by family with sequence similarity 134 member B in buffalo rat liver 3A cells. A and B: Buffalo rat liver 3A (BRL-3A) cells were treated with 2.0 mmol/L dithiothreitol (DTT) for the time intervals (0, 3, 6, 12, 24, 48 h); Western blot showed the effect of endoplasmic reticulum (ER) stressor, DTT, on expression of the ER stress-related proteins glucose-regulated protein 78 (GRP78), calnexin (CNX), and C/EBP homologous protein (CHOP); β-actin was used as a control for normalization; C and D: Analysis of autophagy related gene 12 (ATG12), family with sequence similarity 134 member B (FAM134B), and microtubule-associated protein 1 light chain 3 (LC3) protein expression by western blot. Protein levels were normalized to β-actin; E: BRL-3A cells were treated with 2.0 mmol/L DTT for 0 and 24 h; co-immunoprecipitation analysis detected the presence of CNX-FAM134B-LC3 complex in BRL-3A cells. Values are represented as mean ± SD (n = 3), $^aP < 0.05$ *vs* 0 h group; $^bP < 0.05$ *vs* 48 h group.

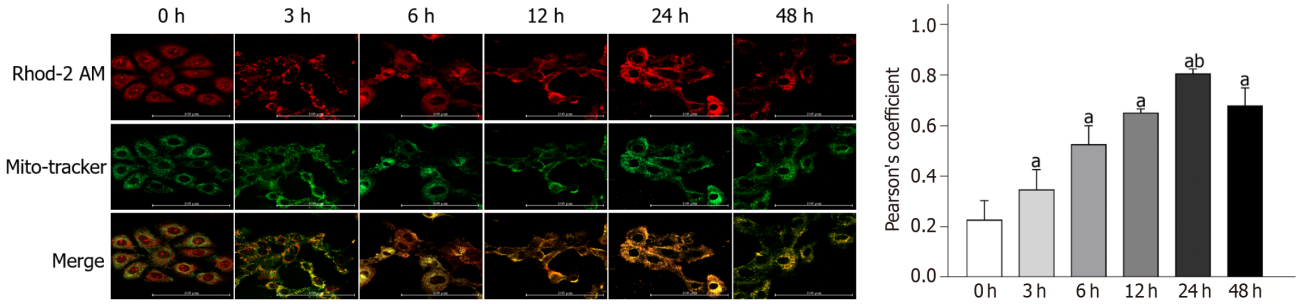
To determine the effects of ER stress on FAM134B-mediated ER-phagy, alterations in FAM134B, ATG12, and LC3 expression were detected by western blot. As expected, DTT treatment for 3, 6, 12, 24, and 48 h increased the conversion ratio of LC3-I to LC3-II and the FAM134B and ATG12 expression levels compared to those in the 0 h group (Figure 1C and D). Thus, our results revealed that the expression of FAM134B is induced in response to ER stress.



Furthermore, we used an anti-CNX antibody to immunoprecipitate the CNX-FAM134B-LC3 complex, confirming the hypothesis that FAM134B forms a complex with CNX and LC3, exerting a positive influence on ER-phagy (Figure 1E).

Long-term DTT treatment relieved the gradually blocked ER autolysosome delivery in BRL-3A cells

Typically, ER is delivered to lysosomes and finally degraded. To analyze whether ER autolysosomes are formed, we examined the subcellular location of the ER and lysosomes using cell organelle markers. As shown in Figure 2, the treatment groups of 3, 6, 12, 24, and 48 h DTT incubation significantly alleviated the co-localization of the ER with lysosomes, compared to that in the 0 h group. Notably, the colocalization of ER and lysosomes in BRL-3A cells treated with DTT for 48 h was increased compared to those treated for 24 h (Figure 2).



Short-term DTT treatment induces mitochondrial calcium uptake while prolonged DTT treatment reduces it

Calcium in the ER can be released and transferred to the mitochondria owing to an imbalance of ER homeostasis. To explore the altered localization of calcium, collected cells were co-loaded with Rhod-2 AM and Mito-Tracker Green. In response to DTT treatment for 3, 6, 12, 24, and 48 h, the co-localized fluorescence increased considerably (Figure 3). However, the distribution of the co-localized signal was

Figure 3 Impact of dithiothreitol treatment on mitochondrial calcium uptake in buffalo rat liver 3A cells. Buffalo rat liver 3A cells were treated for 0, 3, 6, 24, and 48 h with 2.0 mM dithiothreitol, followed by co-incubating with Mitochondria-Tracker Green and Rhod-2 AM, and visualized by confocal microscopy (400 ×). Scale bars indicate 100 μm. Values are represented as mean ± SD (n = 3), $^{a}P < 0.05$ *vs* 0 h group; $^{b}P < 0.05$ *vs* 48 h group.

weaker in the 48 h group, compared to that in the 24 h group (Figure 3). These results strongly suggest that mitochondrial calcium accumulation is related to DTT treatment.

DTT treatment induces cell cycle arrest and apoptosis in BRL-3A cells, which is relieved at 48 h

To further validate that DTT treatment leads to apoptosis in BRL-3A cells, we quantitatively measured the number of apoptotic cells using the Annexin V-FITC/PI double staining assay. As shown in Figure 4A and B, the ratio of apoptotic cells treated with DTT for 0, 3, 6, 12, and 24 h exhibited a time-dependent increase. Interestingly, the apoptotic percentage in the 48 h group was significantly lower than that in the 24 h group (Figure 4A and B). Subsequently, we sought to use flow cytometry to determine the impact of DTT treatment on the cell cycle progression, and the data suggests that the proportion of BRL-3A cells in G1 phase after DTT treatment was noticeably higher than that of the 0 h group (Figure 4C and D and Table 1). Moreover, the number of cells in G1 phase in the 48 h group was smaller than that of the 24 h group.

BRL-3A cells undergo apoptosis upon FAM134B knockdown

We further verified whether *FAM134B* knockdown could alter DTT-induced apoptosis. We first investigated the transfection efficiency of siRNA with three different siRNAs targeting *FAM134B* (siRNA 1, 2, and 3) and found that the *FAM134B* siRNA2 was the most effective (Figure 5A and B). Next, we investigated FAM134B protein levels by performing a western blot on already transfected samples, which were treated with DTT for 24 h. As shown in Figure 5C and D, FAM134B and β-actin expression levels were determined, and it was found that FAM134B protein levels were down-regulated compared with the control and control siRNA groups.

It has been reported that cyt c and cleaved caspase-3 are apoptosis-related proteins and important hallmarks of apoptosis activation involved in mitochondrial dysfunction. Consequently, siRNA-mediated silencing of *FAM134B* caused a high level of cleaved caspase-3 and cyt c in BRL-3A cells treated with DTT for 24 h (Figure 5E and F). We examined the rates of apoptotic cells using Annexin-V-FITC/PI staining assays, which revealed that the apoptotic rates also increased in the *FAM134B* siRNA

Table 1 The cell cycle distribution of buffalo rat liver 3A cells treated with dithiothreitol for different times was detected by flow cytometry

Group	G_0/G_1	S	G_2/M
0 h	17.08 ± 0.13	58.48 ± 3.82	23.05 ± 4.46
3 h	24.28 ± 2.03[a]	42.12 ± 3.98[a]	33.6 ± 4.72[a]
6 h	33.91 ± 1.39[a]	25.11 ± 0.11[a]	41.71 ± 2.45[a]
12 h	41.57 ± 1.08[a]	24.81 ± 5.45[a]	33.62 ± 4.73[a]
24 h	51.83 ± 1.14[a,b]	38.1 ± 3.00[a]	10.08 ± 3.28[a,b]
48 h	38.72 ± 1.18[a]	37.12 ± 8.06[a]	24.16 ± 8.38

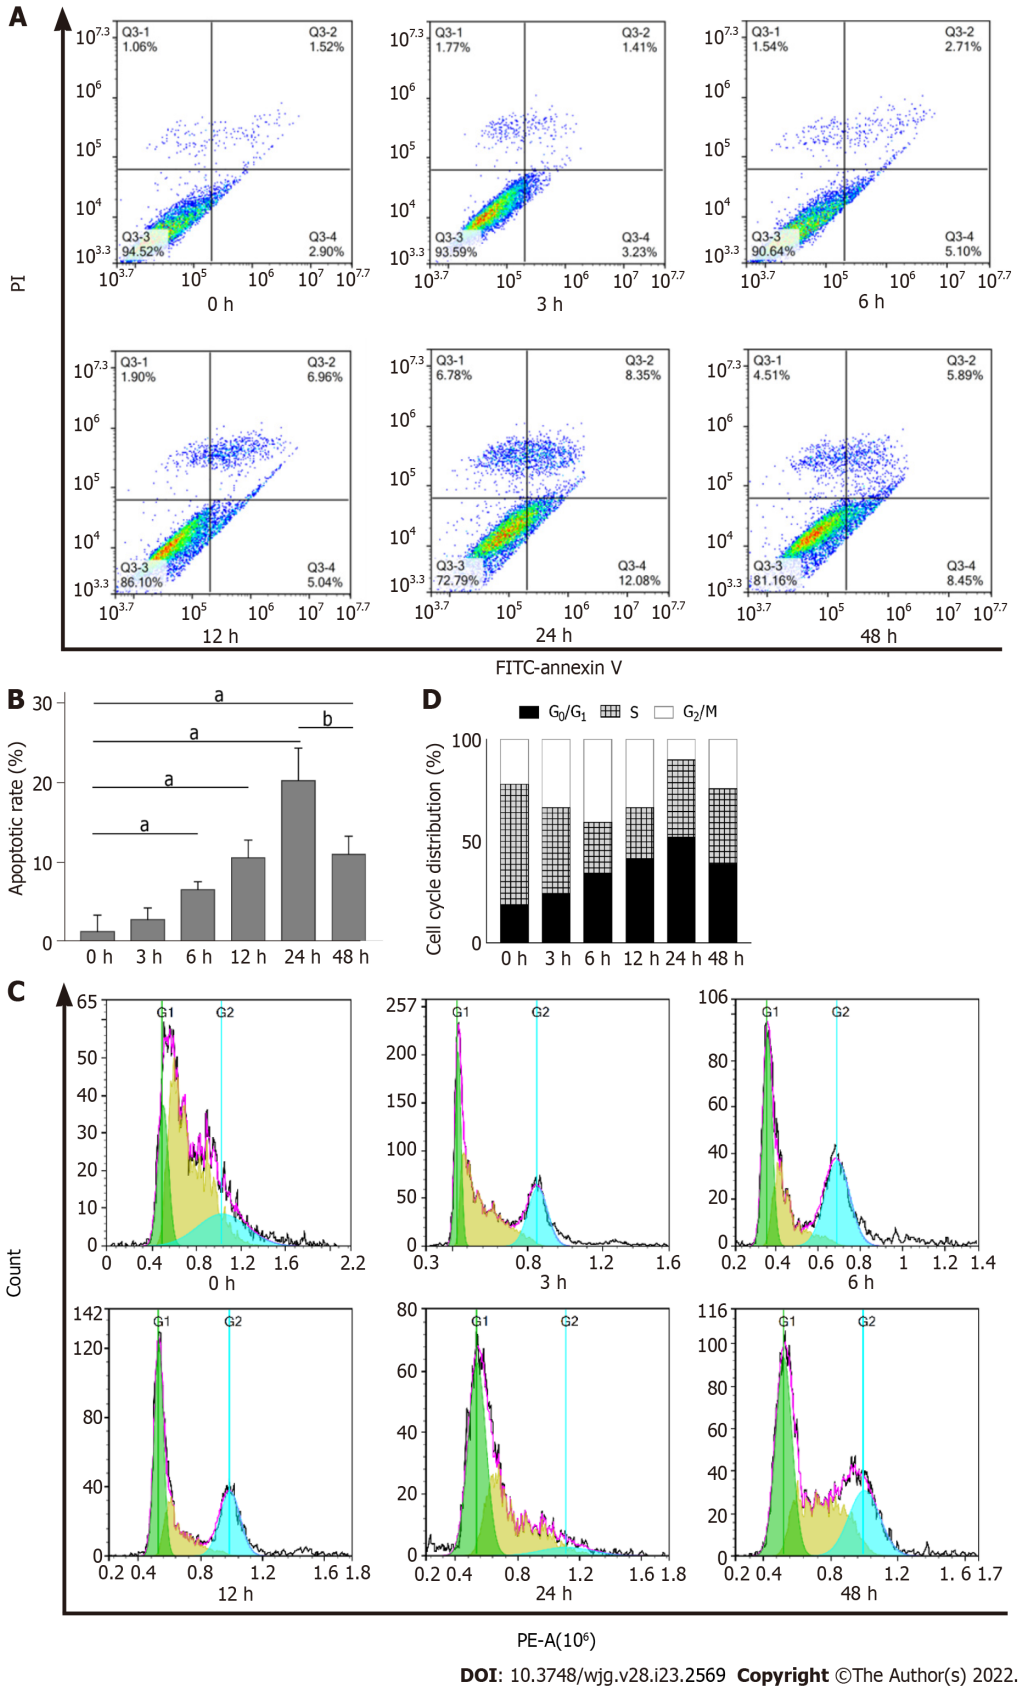
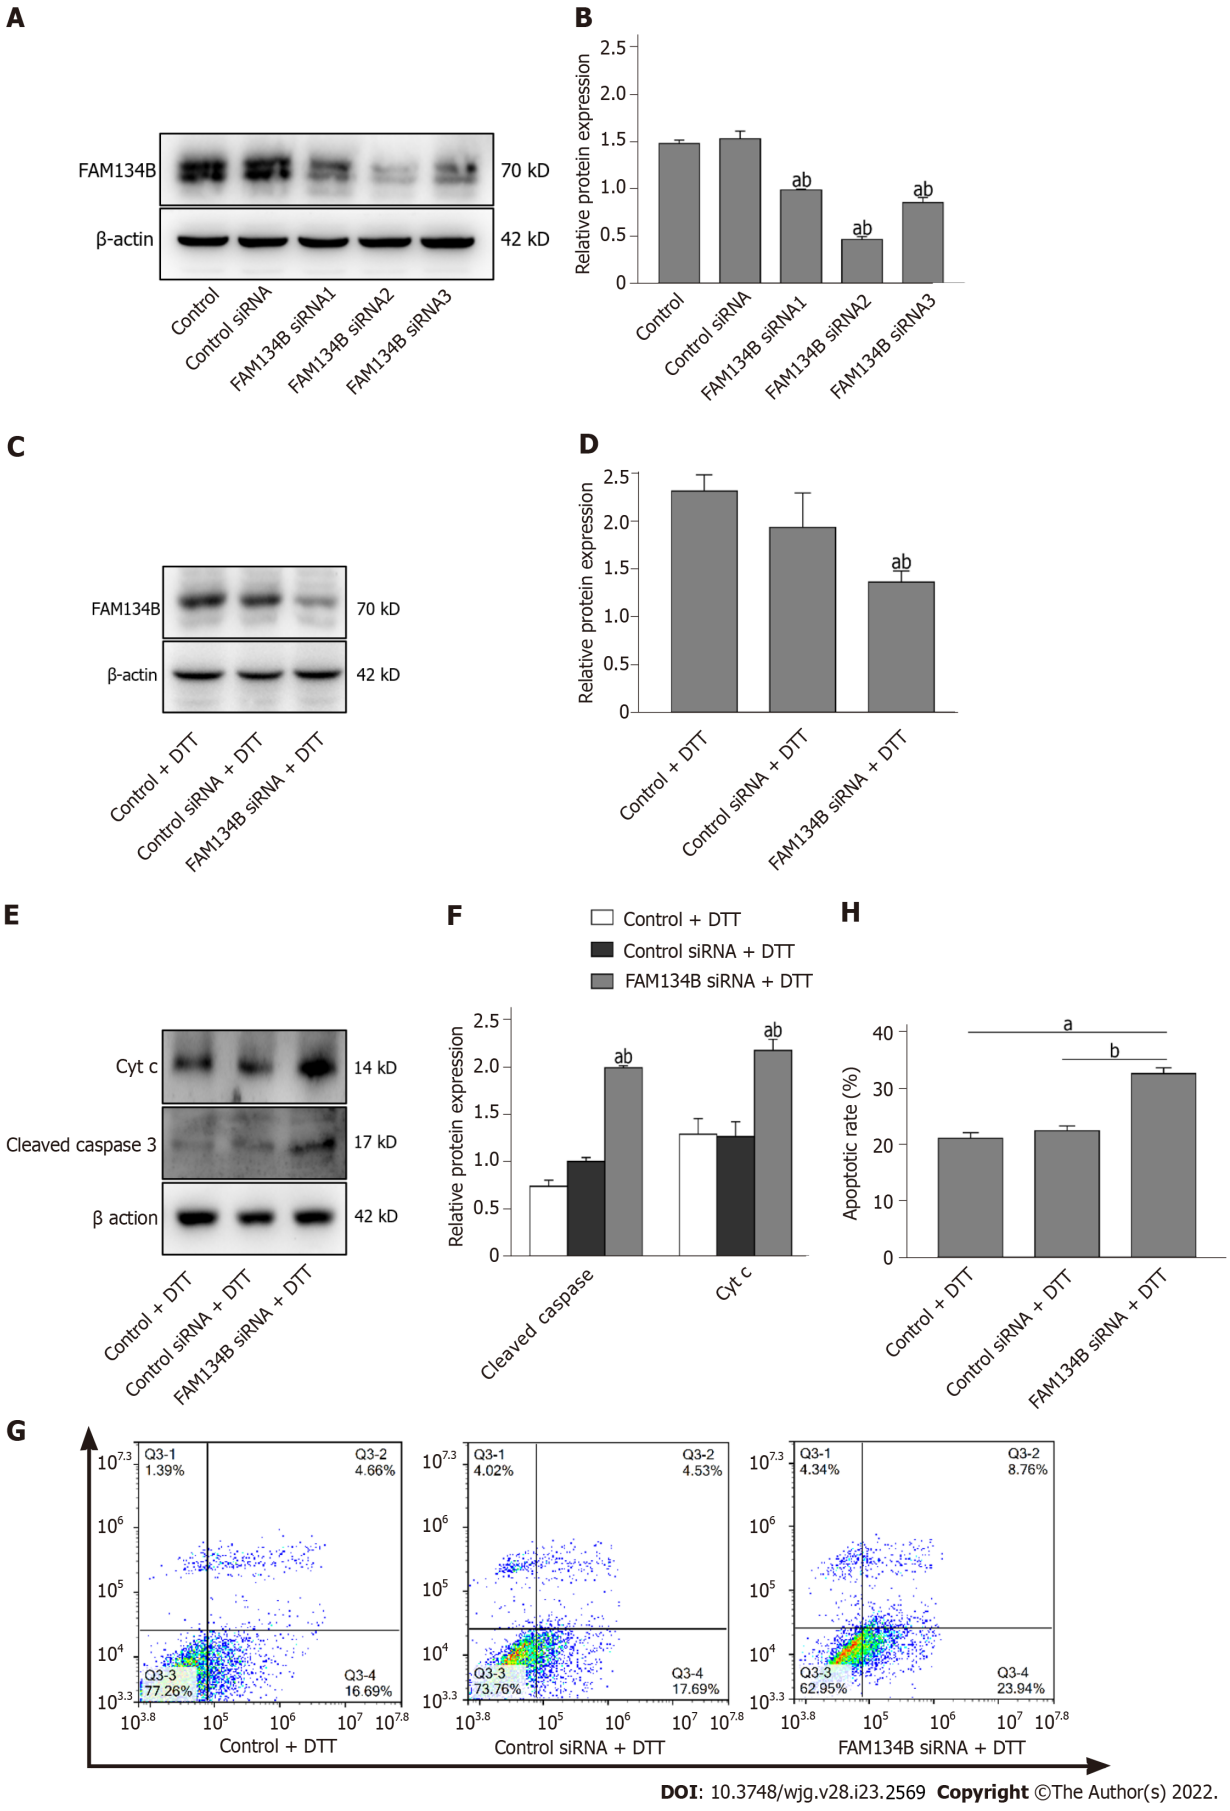
[b]$P < 0.05$ *vs* 48 h group.



group, compared with those in the control and control siRNA groups (Figure 5G and H). These results suggest that ER-phagy mediated by FAM134B is likely to serve a cytoprotective function in response to DTT treatment in BRL-3A cells.

DISCUSSION

Hepatic injury caused by multiple harmful factors is closely associated with ER stress-induced hepatocyte apoptosis[18-20]. The ER is responsible for proper protein folding, intracellular calcium storage, and lipid biosynthesis[21,22]. Various stressors, including unfolded protein aggregation in the ER, intracellular Ca^{2+} disturbance, and pharmacological inducers, such as DTT, can disrupt ER homeostasis and lead to ER stress in hepatocytes. If the ER stress cannot be alleviated, aberrant ER stress can trigger cell apoptosis[23]. In the present study, we found that the protein levels of GRP78 and CNX, which are ER stress biomarkers, were upregulated in BRL-3A cells during ER stress. GRP78 and CNX are ER chaperone proteins and accelerate the proper folding of the accumulated unfolded proteins in the ER, which engages effector mechanisms to rebalance ER homeostasis[24,25]. A series of studies have revealed that ER-phagy is an ER selective autophagy mechanism that can promote the clearance of damaged ER lumens containing the unfolded proteins, and helps restore ER homeostasis[26-28]. ER-phagy is a critical quality control mechanism for the ER in multiple cell types. Defects in ER-phagy pathways are associated with multiple human pathologies, including infectious and neurodegenerative diseases, aging and cancer. However, whether ER-phagy is involved in the regulation of ER homeostasis in hepatocytes under ER stress remains elusive. In this study, we assessed the levels of reticulophagy-related proteins in BRL-3A cells treated with DTT. We found that the levels of FAM134B and ATG12 were markedly elevated, and the ratio of LC3II/LC3I also increased. These data indicate that DTT-induced ER stress increases the level of reticulophagy-associated proteins.



Recent findings have indicated that receptor proteins of ER-phagy play crucial roles in driving the sequestration of isolated ER fragments into autophagosomes[29]. FAM134B, an ER-anchored protein, was recently proposed as a major mammalian receptor for reticulophagy[30,31]. FAM134B contains an LC3-interacting region that can interact with LC3 protein to form autophagosomal membranes, leading to efficient ER sequestration into an autophagosomal lumen[32-34]. In a previous report, the authors found that CNX serves as a co-receptor that recognizes misfolded proteins within the ER lumen and interacts with FAM134B[35,36]. In turn, the CNX-FAM134B complex binds with LC3, the autophagosome membrane-related protein, which delivers ER lumens containing misfolded proteins to the lysosome for degradation. To investigate how FAM134B modulates ER-phagy in BRL-3A cells, immunoprecipitation was performed to detect the interaction between CNX, FAM134B, and LC3. The results confirmed that CNX interacted with FAM134B, and FAM134B interacted with LC3 after DTT treatment. Thus, the formation of the CNX-FAM134B-LC3 complex allows for the selective delivery of ER lumens containing misfolded proteins to the lysosome for eventual degradation. Complete ER-phagy indicates that autophagosomes fuse to form autolysosomes[37,38], hence, we detected the number of autolysosomes in BRL-3A cells treated with DTT. We found that the formation of autolysosomes decreased in the early stages of ER stress, whereas autolysosomes were elevated in later stages. As it has been reported that CHOP can suppress autolysosome formation[39], we speculated that decreased autolysosomes in the early stages of ER stress were associated with increased CHOP expression.

The ER is the main pool for Ca^{2+} storage, and ER dysfunction leads to Ca^{2+} efflux from the ER[40,41]. In the early stages of ER stress, the suppression of the autophagosomes' fusion with lysosomes may lead to calcium release and subsequent Ca^{2+} overload in mitochondria[42-44]. As expected, we found that

Figure 5 Impact of dithiothreitol treatment on apoptosis of buffalo rat liver 3A cells lacking *FAM134B*. A and B: Buffalo rat liver 3A (BRL-3A) cells were transfected with *FAM134B* small interfering RNAs (siRNAs) 1, 2, and 3; immunoblot was used to detect the transfection efficiency of siRNA. Protein levels were

normalized to β-actin; C and D: BRL-3A cells were transfected with *FAM134B* siRNA, followed by treatment with 2.0 mmol/L dithiothreitol (DTT) for 24 h. Immunoblot was used to detect the expression of *FAM134B* in BRL-3A cells. Protein levels were normalized to β-actin; E and F: BRL-3A cells were transfected with *FAM134B* siRNA, followed by treatment with 2.0 mmol/L DTT for 24 h. Immunoblot showed the expression of cleaved caspase-3 and cyt c. Protein levels were normalized to β-actin; G and H: BRL-3A cells were transfected with *FAM134B* siRNA, followed by treatment with 2.0 mmol/L DTT for 24 h. Representative results showed the apoptotic rate in BRL-3A cells. Untransfected cells served as controls. Cells transfected with control siRNA served as transfection controls. The lower right quadrant represents the early apoptotic cells and the upper right quadrant represents the late apoptotic cells. Values are mean ± SD (n = 3), $^{a}P < 0.05$ *vs* control group; $^{b}P < 0.05$ *vs* transfection control siRNA group.

DTT treatment dramatically elevated the levels of mitochondrial Ca^{2+}, the apoptotic rate, and G1 arrest in BRL-3A cells. Nevertheless, these trends were relieved after treatment with DTT for 48 h. Our results reveal that hepatocytes initiate adaptive mechanisms in response to DTT-induced ER stress; consequently, apoptosis in BRL-3A cells treated with DTT for 48 h was lower than that in cells treated with DTT for 24 h.

To clarify whether FAM134B is involved in the regulation of cellular homeostasis during ER stress, we used a small interference RNA technique to knockdown *FAM134B* expression in hepatocytes. We found that *FAM134B* silencing not only significantly attenuated the DTT-upregulated FAM134B expression, but also accelerated the activation of the mitochondrial apoptotic pathway and aggravated DTT-triggered hepatocyte apoptosis.

CONCLUSION

In conclusion, DTT treatment significantly upregulated the protein levels of GRP78, CNX, FAM134B, and ATG12, and also increased the ratio of LC3II/LC3I in BRL-3A cells. Moreover, FAM134B-mediated reticulophagy ameliorates DTT-induced hepatocyte apoptosis *via* selective clearance of damaged ER lumens. Accordingly, knockdown of FAM134B enhanced ER stress-mediated apoptosis in BRL-3A cells. Our data show that FAM134B-mediated reticulophagy plays a key role in rebalancing ER homeostasis in hepatocytes undergoing ER stress. Therefore, FAM134B-mediated reticulophagy may be a novel therapeutic target, and our findings may provide emerging evidence to demonstrate the prominence of ER-phagy in ER stress-related hepatocyte apoptosis. Alleviation of ER stress-mediated hepatocyte apoptosis *via* restoring ER homeostasis is critical in the treatment of liver diseases.

ARTICLE HIGHLIGHTS

Research background

Hepatocyte apoptosis induced by endoplasmic reticulum (ER) stress has a strong association with the development of fibrosis, cirrhosis, and hepatocellular carcinoma. Previous studies have revealed that endoplasmic reticulophagy (ER-phagy) promotes the selective clearance of damaged ER fragments during ER stress, playing a crucial role in maintaining ER homeostasis and inhibiting apoptosis. However, the precise regulatory mechanisms remain unclear.

Research motivation

Defects in ER-phagy pathways are associated with multiple human pathologies, including infectious and neurodegenerative diseases, aging and cancer. However, whether ER-phagy is involved in the regulation of ER homeostasis in hepatocytes under ER stress remains elusive.

Research objectives

To elucidate the effect of family with sequence similarity 134 member B (FAM134B)-mediated ER-phagy on normal buffalo rat hepatocytes apoptosis induced by dithiothreitol (DTT) and explore the potential regulatory mechanism.

Research methods

A model of ER stress was established by DTT. The levels of proteins related to ER stress and ER-phagy were determined by western blot. An interaction between FAM134B, calnexin (CNX), and microtubule-associated protein 1 light chain 3 (LC3) was investigated by co-immunoprecipitation. ER-Tracker Red probe and Lyso-Tracker Green probe were used to detect the colocalization of ER with lysosome in cells. Mito-Tracker Green and Rhod-2 AM probes were used to detect the level of mitochondrial Ca^{2+} under the confocal microscopy. Flow cytometry was conducted to analyze the effect of DTT treatment on cell cycle distribution and apoptosis. The small interfering RNA against *FAM134B* was used to knockdown *FAM134B* in buffalo rat liver 3A (BRL-3A) cells.

Research results

DTT treatment upregulated glucose-regulated protein 78 (GRP78), CNX, FAM134B, and autophagy related gene 12 (ATG12) protein levels and increased the ratio of LC3II/LC3I in BRL-3A cells. FAM134B-mediated reticulophagy maintains ER homeostasis in ER-stressed hepatocytes *via* the clearance of damaged ER fragments. FAM134B-mediated reticulophagy ameliorates DTT-induced hepatocyte apoptosis. Knockdown of *FAM134B* enhanced ER stress-mediated apoptosis in BRL-3A cells.

Research conclusions

FAM134B-mediated ER-phagy attenuates hepatocyte apoptosis by suppressing the mitochondrial apoptotic pathway.

Research perspectives

FAM134B-mediated reticulophagy may be a novel therapeutic target, and our findings provide emerging evidence demonstrating the prominence of ER-phagy in ER stress-related hepatocyte apoptosis. Alleviation of the ER stress-mediated hepatocyte apoptosis *via* restoring ER homeostasis is critical in the treatment of liver diseases.

Abstract

BACKGROUND

Infliximab trough level (ITL) severely affects therapeutic outcomes of Crohn's disease (CD) patients under infliximab (IFX). Recently, frontier research has focused on identifying ITL based on different therapeutic targets. Although previous studies have elaborated clinical value of ITL monitoring on short-term outcomes in CD patients during therapy, studies contraposing the predictive value of ITL on long-term endoscopic outcomes in CD patients are still scarce domestically and overseas.

AIM

To explore the predictive value of ITL in combination with inflammatory biomarkers on long-term endoscopic outcomes in CD with clinical remission during IFX maintenance therapy.

METHODS

CD patients with endoscopic remission under long-term IFX maintenance therapy in the First Affiliated Hospital of Zhejiang Chinese Medicine University from January 2012 to December 2020 were collected. ITL and inflammatory biomarkers were continuously monitored during the therapy. The Step I study was conducted from weeks 14 to 54 of IFX treatment. The Step II study was conducted from weeks 54 to 108 of IFX treatment. Endoscopic outcomes were defined as endoscopic activity (Crohn's disease endoscopic index of severity score > 2 points or Rutgeerts score > i1) and endoscopic remission (Crohn's disease endoscopic index of severity score ≤ 2 points or Rutgeerts ≤ i1). Endoscopic relapse free survival was defined as endoscopic remission at the beginning of the study stage and maintaining endoscopic remission during the study stage.

RESULTS

At week 14, low ITL [odds ratio (OR) = 0.666, 95% confidence interval (CI): 0.514-0.862, $P < 0.01$] and high fecal calprotectin (FCP) level (OR = 1.002, 95%CI: 1.001-1.004, $P < 0.01$) increased the risk of endoscopic activity at week 54. At week 54, low ITL (OR = 0.466, 95%CI: 0.247-0.877, $P < 0.01$) and high C-reactive protein (CRP) level (OR = 1.590, 95%CI: 1.007-2.510, $P < 0.01$) increased the risk of endoscopic activity at week 108. At week 14, ITL ≤ 5.60 μg/mL [area under the curve (AUC) = 0.83, 95%CI: 0.73-0.90, $P < 0.001$] and FCP > 238 μg/g (AUC = 0.82, 95%CI: 0.72-0.89, $P < 0.001$) moderately predicted endoscopic activity at week 54. ITL ≤ 5.60 μg/mL in combination with FCP > 238 μg/g indicated 82.0% possibility of endoscopic activity. At week 54, ITL ≤ 2.10 μg/mL (AUC = 0.85, 95%CI: 0.72-0.93, $P < 0.001$) and CRP > 3.00 mg/L (AUC = 0.73, 95%CI: 0.60-0.84, $P = 0.012$) moderately predicted moderate endoscopic activity at week 108. ITL ≤ 2.10 μg/mL in combination with CRP > 3.00 mg/L indicated 100.0% possibility of endoscopic activity. From weeks 14 to 54 of IFX treatment, patients with ITL > 5.60 μg/mL had higher rate of endoscopic relapse free survival than those with ITL ≤ 5.60 μg/mL (95.83% *vs* 46.67%). From weeks 54 to 108 of IFX treatment, patients with ITL > 2.10 μg/mL had higher rate of endoscopic survival free relapsed rate than those with ITL ≤ 2.10 μg/mL (92.68% *vs* 30.77%).

CONCLUSION

Combination of ITL, CRP, and FCP contribute to long-term endoscopic prognosis monitoring. During IFX maintenance treatment, low ITL, high CRP level, and high FCP level were independent risk factors of CD patients with clinical remission in adverse endoscopy outcomes within 1-year follow-up.

Key Words: Infliximab trough level; C-reactive protein; Fecal calprotectin; Crohn's disease; Clinical remission; Long-term endoscopic outcomes

Core Tip: Previous investigations, contraposing Crohn's disease patients under infliximab (IFX) maintenance therapy, have indicated that higher IFX trough levels (ITLs) were associated with sustained drug response and clinical remission in inflammatory bowel disease patients, while lower ITLs were linked to secondary unresponsiveness of IFX. Currently, endoscopic remission or mucosal healing has been considered the main goal of biological therapy. Our study manifested that Crohn's disease patients with higher levels of IFX blood concentration and lower levels of inflammatory biomarkers tended to have a better long-term endoscopic prognosis. Combining ITL, fecal calprotectin and C-reactive protein monitoring was helpful for the timely adjustment of IFX treatment strategy.

INTRODUCTION

Crohn's disease (CD) is a persistently progressive disease with nonspecific inflammation characterized by disease scope involving the whole digestive tract and disease depth involving the whole intestinal wall. The accumulation damage of intestinal walls contributes to the occurrence of stenosis, fistula and even abscess, reducing the life quality. Therefore, recent clinical studies have consistently concluded

that therapeutic strategies and targets play key roles in controlling CD progression. Setting different therapeutic targets will have different disease outcomes. Clinical response, focusing only on the improvement of clinical symptoms, can improve the quality of daily life but not affect long-term treatment outcomes. CD patients who do not achieve deep remission may be aggravated persistently, while achieving deep remission could reduce long-term hospitalization and surgery rates. Deep remission is mainly defined in previous studies as endoscopic remission or mucosal healing. Biologics, as an important step in the therapeutic strategy of CD, can effectively control the disease progression if conducted early and completely.

In consideration of the wide use of infliximab (IFX), precisely predicting the long-term endoscopic outcomes is stressed by more and more inflammatory bowel disease (IBD) physicians. Although the IFX trough level (ITL) has been proven to be closely related to the outcome of CD, ITL alone may be biased in predicting the outcome of CD. Monitoring inflammation biomarkers is one of the important links of IFX therapy, including C-reaction protein (CRP), fecal calprotectin (FCP), *etc*. High inflammatory load affects the pharmacokinetics of IFX, inducing secondary nonresponse by decreasing blood drug concentration. Currently, it is believed that inflammatory biomarkers are good predictors of disease activity, but there is still a lack of reliable evidence for predicting disease remission. Therefore, this study intends to evaluate long-term endoscopic outcomes of CD patients receiving IFX treatment by combining the blood drug concentration and inflammatory biomarkers.

MATERIALS AND METHODS

Study subjects design

A single-center retrospective research was implemented at the First Affiliated Hospital of Zhejiang Chinese Medical University. CD patients under IFX therapy from January 2012 to December 2020 were collected. One hundred and eighty-one CD patients underwent IFX treatment. One hundred and fifty-one CD patients underwent endoscopy as well as serum concentration monitoring at week 14 after the third dose of IFX induction therapy. Inclusion criteria: (1) Endoscopic remission at week 14 [Crohn's disease endoscopic index of severity (CDEIS) score ≤ 2 points or Rutgeerts ≤ i1]; (2) Clinical remission after IFX induction therapy without corticosteroids more than 6 mo; and (3) Therapeutic strategy during maintenance stage was designed as IFX 5 mg/kg every 8 wk combined with azathioprine (AZA) 50 mg every day. Therapeutic strategic was modulated if CD patients were confronted with clinical relapse or secondary loss of response (LOR), and data analysis focused on the treatment course when patients received IFX 5 mg/kg and AZA therapy regularly. Secondary LOR was defined as a recurrence of the disease during IFX maintenance therapy. Two criteria were met to determine LOR: The recurrence of symptoms of IBD in clinical remission after induction therapy and symptoms caused by the inflammatory activity of IBD itself. Clinical relapse means Crohn's disease activity index > 150 points. Blood drug concentration monitoring and clinical, laboratory, endoscopic and imaging evaluation were implemented every 2 mo since the third dose of IFX induction therapy in all patients. The study was divided into two stages, step I study period defined as IFX maintenance therapy during week 14 to week 54 and step II study period defined as IFX maintenance therapy during week 54 to week 108.

Data collection

General data included age, sex, course, disease location, disease behavior, medication history and history of intestinal surgery. Laboratory indicators include white blood cell count, blood platelet count, CRP, erythrocyte sedimentation rate, serum albumin, FCP, ITL and anti-IFX antibody. Evaluation indicators of disease severity included Crohn's disease activity index score on clinical severity, CDEIS score on endoscopic severity in CD patients without intestinal surgery and Rutgeerts score on endoscopic severity in CD patients with intestinal surgery.

Outcome definition

Endoscopic outcomes at week 54 and week 108 after IFX initial therapy were evaluated by specialist physicians on IBD under electronic colonoscopy. Endoscopic remission was defined as CDEIS score ≤ 2 or Rutgeerts score ≤ i1, and endoscopic activity was defined as CDEIS score > 2 or Rutgeerts score > i1. Survival outcomes during IFX maintenance therapy were concentrated on endoscopic relapse-free survival, defined as sustained endoscopic remission during step I study period or step II study period.

Statistical analysis

Descriptive statistical analysis was used to describe characteristics of CD patients. Number of cases (percentage) was used to describe categorial variable. mean ± SD was used to describe continuous variable. Nonparametric Mann-Whitney test was used to compare two groups in enumeration data or measurement data without normal distribution. Two-sample t test was used to compare two groups in measurement data with normal distribution. One-way analysis of variance was used to compare multi-group if data satisfied homogeneity of variance. Nonparametric Kruskal-Wallis test was used to

compare multi-group if data not satisfied homogeneity of variance. SPSS 23.0 (Armonk, NY, United States) was used to analyze differences between groups. A P value < 0.05 was considered significant.

Receiver-operating characteristic (ROC) analysis was used to identify the best cut off level of ITL on predicting endoscopic remission as well as sensitivity, specificity, positive predictive value, negative predictive value, area under the curve and Youden Index. Univariate logistic regression analysis was used to identify the association between endoscopic activity and predictors. Log-rank test was used to identify the association between endoscopic relapse and predictors. GraphPad Prism9.0 (San Diego, CA, United States) was used to draw histograms and survival analysis curves and implement log-rank test. MedCalc19.0 was used to draw ROC curve and analyze the predictive value of indicators on endoscopic outcomes. A P value < 0.05 was considered significant.

RESULTS

Characteristics of study subjects

In total, the study cohort collected 112 CD patients achieving clinical remission after IFX induction therapy. In step I study, 19 CD patients were excluded due to data absence (n = 1, 5.26%) and endoscopic activity at week 14 (n = 18, 94.74%), while 93 CD patients with endoscopic remission at week 14 were included. In step II study, 58 CD patients were excluded due to course of therapy shorter than 2 years (n = 10, 17.24%), secondary non-response of IFX (n = 12, 20.69%), suspension of IFX therapy within 2 years for disease remission (n = 10, 17.24%) and endoscopic activity at week 54 (n = 26, 44.83%), while 54 CD patients with endoscopic remission at week 54 were included. These 12 patients did not satisfy indications of operation and received hormonotherapy as the primary choice to alleviate disease, for our center lacked other biological agents at that time. All CD patients under IFX maintenance therapy were combined with AZA (Figure 1). The dose of IFX was 5 mg/kg every 8 wk, and the dose of AZA was 50 mg every day. Characteristics of CD patients included in study are shown in Table 1.

Correlation between ITL, inflammatory biomarkers and endoscopic outcomes

In step I study, 67/93 CD patients (72.04%) sustained endoscopic remission at week 54 among. Multivariable regression analysis revealed that only ITL (OR = 0.666, 95%CI: 0.514-0.862, P = 0.002) and FCP (OR = 1.002, 95%CI: 1.001-1.004, P = 0.002) were independent risk of endoscopic activity at week 54 (Table 2). Based on incremental gain analysis, an ITL range of 5.0-7.4 μg/mL was correlated with sustained endoscopic remission rate of more than 85% (Figure 2).

In step II study, 42/54 CD patients (77.78%) sustained endoscopic remission at week 108. Multivariable regression analysis revealed that only ITL (OR = 0.466, 95%CI: 0.247-0.877, P = 0.018) and CRP (OR = 1.590, 95%CI: 1.007-2.510, P = 0.047) were independent risks of endoscopic activity at week 108 (Table 2). Based on incremental gain analysis, an ITL range of 2.0-3.9 μg/mL was correlated with sustained endoscopic remission rate of more than 85% (Figure 2).

Predictive value of ITL and inflammatory biomarkers on endoscopic outcomes

In step I study, the ROC analysis demonstrated that the best cut off level of ITL and FCP at week 14 on predicting endoscopic relapse at week 54 was 5.60 μg/ml (AUC = 0.83, 95%CI: 0.73-0.90, P < 0.001) and 238 μg/g (AUC = 0.82, 95%CI: 0.72-0.89, P < 0.001) (Table 3 and Figure 3). CD patients with ITL ≤ 5.60 μg/ml and FCP > 238 μg/g at week 14 had 82% probability of endoscopic relapse at week 54. However, CD patients with ITL > 5.60 μg/ml and FCP ≤ 238 μg/g at week 14 had 98% probability of sustained endoscopic remission at week 54.

In step II study, the ROC analysis demonstrated that the best cut off level of ITL and CRP at week 54 on predicting endoscopic relapse at week 108 was 2.10 μg/mL (AUC = 0.85, 95%CI: 0.72-0.93, P < 0.001) and 3.00 mg/L (AUC = 0.73, 95%CI: 0.60-0.84, P = 0.012) (Table 3 and Figure 3). CD patients with ITL ≤ 2.10 μg/mL and CRP > 3.00 mg/L at week 54 had 100% probability of endoscopic relapse at week 108. However, CD patients with ITL > 2.10 μg/mL and CRP ≤ 3.00 mg/L at week 54 had 97% probability of sustained endoscopic remission at week 108.

Correlation between ITL, inflammatory biomarkers and endoscopic relapse-free survival

In step I study, 26/93 (27.96%) CD patients had experienced endoscopic relapse from week 14 to week 54 of IFX maintenance therapy. The estimated endoscopic relapse-free rate was 46/48 (95.83%) in CD patients with ITL > 5.6 μg/ml and 21/45 (46.67%) in CD patients with ITL ≤ 5.6 μg/ml. The median time to endoscopic relapse of CD patients with ITL ≤ 5.6 μg/ml was 32.00 wk shorter than those with ITL > 5.6 μg/ml [hazard ratio (HR) = 16.19, 95%CI: 7.44-35.22, P < 0.0001] (Figure 4A). The estimated endoscopic relapse-free rate was 6/25 (24.00%) in CD patients with FCP > 238 μg/g and 61/68 (89.71%) in CD patients with FCP ≤ 238 μg/g. The median time to endoscopic relapse of CD patients with FCP > 238 μg/g was 21.00 wk shorter than those with FCP ≤ 238 μg/g (HR = 11.25, 95%CI: 4.26-29.73, P < 0.0001) (Figure 4B).

In step II study, 12/54 (22.22%) CD patients had experienced endoscopic relapse from week 54 to week 108 of IFX maintenance therapy. The estimated endoscopic relapse-free rate was 38/41 (92.68%) in CD patients with ITL > 2.1 μg/mL and 4/13 (30.77%) in CD patients with ITL ≤ 2.1 μg/mL. The median time to endoscopic relapse of CD patients with ITL ≤ 2.1 μg/mL was 40.00 w, shorter than those with ITL > 2.1 μg/mL (HR = 13.14, 95%CI: 3.07-56.27, $P < 0.0001$) (Figure 4D). The estimated endoscopic relapse-free rate was 4/8 (50.00%) in CD patients with CRP > 3.00 mg/L and 40/46 (86.96%) in CD patients with CRP ≤ 3.00 mg/L. The median time to endoscopic relapse of CD patients with CRP > 3.00 mg/L was 50.00 wk shorter than those with CRP ≤ 3.00 mg/L (HR = 7.85, 95%CI: 1.31-46.85, $P < 0.0001$) (Figure 4C).

DISCUSSION

Several studies have confirmed that different ITLs brought about different outcomes of CD under IFX therapy (Table 4). Tang *et al*[1] discovered that CD patients achieving mucosal healing at week 14 of IFX

therapy with ITL > 2.5 μg/mL at week 14 had 71% chance of mucosal healing at week 54, while patients with ITL < 2.5 μg/mL had only 33% chance. ITL ≥ 3 μg/mL at the beginning of IFX maintenance therapy was confirmed as a predictor of sustained response to IFX in CD patients[2]. Recently a prospective study in Japan verified that CD patients with ITL ≥ 3 μg/mL at week 14 after IFX initial therapy had much better long-term clinical outcomes than patients with ITL < 3 μg/mL, of which survival analysis indicated 100% probability of clinical remission at week 108 in the former and 33.3% probability in the latter[3]. A meta-analysis determined that ITL > 2.0 μg/mL of IBD patients under IFX maintenance therapy contributes to better prognosis such as clinical remission or mucosal healing[4]. Similarly, this study found that CD patients with ITL > 5.6 μg/mL at week 14 had a large chance of

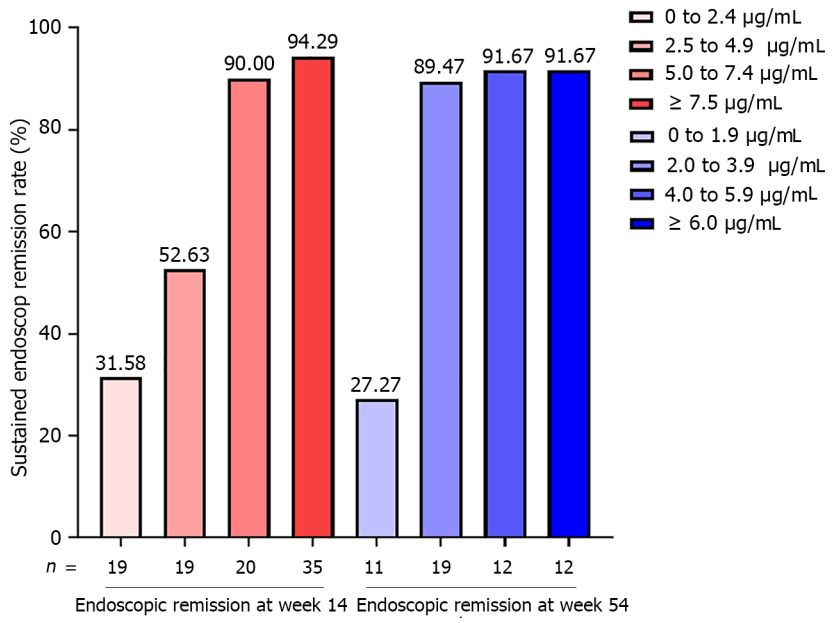

Figure 2 Incremental gain analysis of sustained endoscopic remission rate in relation to infliximab trough level at week 14 and week 54.

achieving sustained endoscopic remission during IFX maintenance therapy as well as CD patients with ITL > 2.1 μg/mL at week 54. Borren *et al*[5] implemented a multi-center retrospective study and concluded that low ITL in IBD patients during IFX maintenance therapy could not be a good predictor of clinical relapse in the next 2 years, suggesting that proactive therapeutic drug monitoring was not suitable in this group. However, this study discovered that CD patients with ITL ≤ 5.6 μg/mL at week 14 or ITL ≤ 2.1 μg/mL at week 54 were more likely to experience endoscopic relapse during the 1-year follow-up period.

According to previous studies, the challenge for IBD physicians is to frame the more suitable blood trough level of IFX to achieve better disease prognosis in clinical therapy. The elements associated with the blood trough level of IFX can be classified into three areas. Above all, the better the therapeutic goal desired by IBD physicians or patients, the higher the blood trough level of IFX is required. An observational study contraposing to CD patients with a history of intestinal surgery by Imaeda *et al*[6] verified that mucosal healing required higher ITLs as more than 4.0 μg/mL compared to those to achieve normalization of routine clinical markers. Papamichael *et al*[7] considered that ITL surpassing 9.7 μg/mL indicated 80% probability of endoscopic remission in CD patients under IFX maintenance therapy, while ITL surpassing 2.2 μg/mL was associated only with biochemical remission. Recently, a prospective study verified that ITL > 8.0 μg/mL was highly correlated with histological emission and sustained histological remission in IBD patients[8]. Perianal fistula, the most universal complications of CD patients, is another therapeutic goal. A retrospective cross-sectional study by Plevris *et al*[9] manifested that perianal fistula healing or closure is associated with higher ITLs as more than 7.1 μg/mL.

Secondly, each clinical study had different stages of IFX drug monitoring, especially during maintenance therapy. ITL continues to decrease as time passed during IFX maintenance therapy[10]. A cross-sectional study of IBD patients under IFX therapy with a fixed dose more than 6 mo found that IBD patients with ITL ≥ 3.4 μg/mL had a 73% chance of endoscopic mucosal healing[11]. Kang *et al*[12] showed that ITL ≥ 5 μg/mL during IFX maintenance therapy could identify mucosal healing in pediatric CD patients with 80% specificity. Feng *et al*[13] innovatively integrated ITL levels in different time stages to identify endoscopic mucosal healing in CD patients, indicating that patients with ITL > 4.85 μg/mL at week 14 and ITL > 2.85 μg/mL at week 30 had an 80% chance of achieving endoscopic mucosal healing. Based on incremental gain analysis in our study, sustained endoscopic remission rate at week 54 reached only 54.63% at an ITL range of 2.5 to 4.9 μg/mL at week 14 while corresponding numbers at week 108 was 89.47% at an ITL range of 2.0 to 3.9 μg/mL at week 54. Therefore, the study held the view that CD patients with endoscopic remission need higher ITL at the beginning of IFX maintenance therapy (≥ 5.6 μg/mL at week 14) than after IFX maintenance therapy over a half year (≥ 2.1 μg/mL at week 54). In addition, CD patients achieving endoscopic remission after IFX induction therapy and sustained endoscopic remission more than a half year may not need high ITL to maintain endoscopic remission.

The third element is therapeutic optimization of IFX in IBD. Adverse IFX response as high ATI level or low ITL may occur in a few CD patients during IFX maintenance therapy. Several clinical studies held the view that severe inflammatory activity of CD patients could change pharmacokinetics of anti-

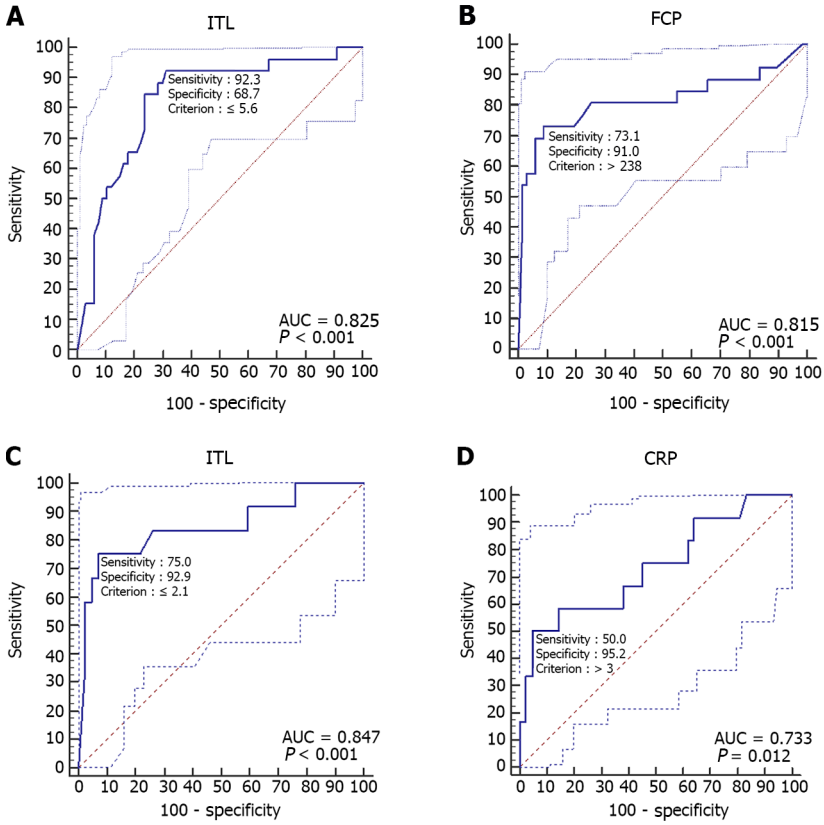

Figure 3 Receiver operator characteristic curve of infliximab trough level and inflammatory biomarkers in predicting endoscopic outcomes. A: Receiver operator characteristic (ROC) curve of infliximab trough level at week 14 in predicting endoscopic remission of Crohn's disease (CD) at week 54; B: ROC curve of fecal calprotectin at week 14 in predicting endoscopic remission of CD at week 54; C: ROC curve of infliximab trough level at week 54 in predicting endoscopic remission of CD at week 108; D: ROC of C-reactive protein at week 54 in predicting endoscopic remission of CD at week 108. tumor necrosis factor α biology[14-16]. Therapeutic optimization as increasing fixed dose from 5 mg/kg to 10 mg/kg or shortening injection interval form every 8 wk to 4-6 wk contributes to increase ITL and decrease ATI level. A study from Greece demonstrated that, for the initial measurement after therapeutic adjustment, ITL increased from 1.47 μg/mL to 8.50 μg/mL in patients with therapeutic optimization while ITL decreased from 5.65 μg/mL to 3.8μg/ml in patients without therapeutic optimization[10]. A multi-center randomized clinical trial conducted by Dreesen *et al*[17] showed that CD patients under IFX maintenance therapy as 5 mg/kg had high probability of no mucosal ulcer under endoscopy at week 54 with ITL more than 7.3mg/L, and CD patients under intensified dose IFX therapy as 10 mg/kg had 94% probability of no mucosal ulcer under endoscopy with ITL rising to more than 10.6 mg/L. Therefore, intensified therapy may contribute to mucosal healing in CD patients with ulceration if IFX injection dose is less than 10 mg/kg and ITL is less than 10.6 μg/mL. However, a few CD patients will accept combination therapy of IFX and immunosuppressant to boost the efficacy, especially AZA and mercaptopurine. AZA is a precursor of mercaptopurine, and two components ultimately produce thioguanine to exert clinical effect during metabolism. A study verified that thioguanine concentration more than 125 pmol/8 × 10^8 red blood cells could enhance ITL to 8.3 μg/mL or more and decrease positive rate of ATI[18,19]. Hence, this study mainly included CD patients with sustained clinical remission more than 6 mo under fixed therapeutic strategy of IFX 5 mg/kg every 8 wk combined with AZA 50 mg every day. Retrospective records of CD patients included would suspend if therapy strategy changed, such as intensive therapy of IFX, conversion therapy of other biologics and combination therapy of surgery or other medications. The study design eliminated the influence of therapeutic adjustment on ITL.

The greatest strength of inflammatory biomarkers compared with blood trough level is that they are unaffected by time during different monitoring stages of biological therapy in IBD patients. This study showed that ITL > 5.6 μg/mL combined with FCP ≤ 238 μg/g at week 14 moderately predicted sustained endoscopic remission during the 1-year follow-up period on CD patients with positive predictive value more than 95% as well as ITL > 2.1 μg/mL combined with CRP ≤ 3.00 mg/L at week 54, superior to use ITL as the only predictor. FCP and CRP are considered as the most universal and typical biomarkers of inflammatory evaluation in IBD, also verified to be the independent risk factors of adverse endoscopic outcomes. The study confirmed that combining blood trough level with inflam-

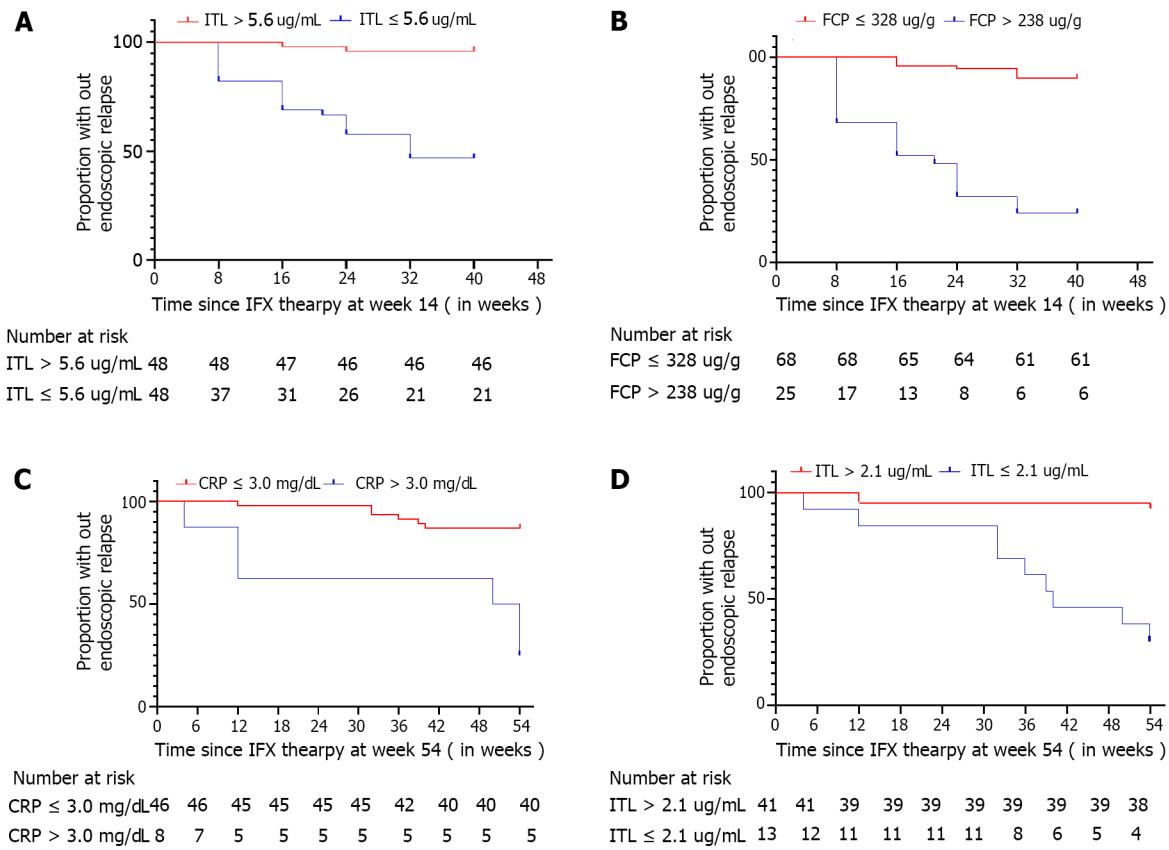

Figure 4 Proportion without endoscopic relapse. A. Time since infliximab (IFX) therapy at week 14 [IFX trough level (ITL) > 5.6 μg/mL *vs* ITL ≤ 5.6 μg/mL]; B: Time to IFX therapy at week 14 (fecal calprotectin ≤ 238 μg/g *vs* fecal calprotectin > 238 μg/g]; C: Time to IFX therapy at week 54 (C-reactive protein ≤ 3.0mg/L *vs* C-reactive protein > 3.0 mg/L); D: Time to IFX therapy at week 54 (ITL > 2.1 μg/mL *vs* ITL ≤ 2.1 μg/mL). ITL: Infliximab trough level; CRP: C-reactive protein; FCP: Fecal calprotectin; IFX: Infliximab.

matory biomarkers contributed to improving the accuracy of the prediction on endoscopic outcomes. A post hoc analysis from the CALM study manifested that CD patients with FCP < 250 μg/g mostly achieved CDEIS < 4 without deep ulceration, regardless of whether CRP < 5 mg/L. However, among patients with CRP < 5 mg/L but FCP ≥ 250 μg/g, only 16.7% achieved CDEIS < 4 without deep ulceration[20]. The result indicated that the correlation between FCP normalization and endoscopic mucosal healing in CD patients was stronger than that of CRP normalization. A previous study verified that FCP is suitable for distinguishing mild endoscopic activity from endoscopic remission, while it is difficult to distinguish partial endoscopic remission from complete endoscopic remission[21]. Similar to blood trough level, the optimal cut off value of FCP for distinguishing endoscopic activity from endoscopic remission ranges from 71 μg/g to 250 μg/g with moderate diagnostic performance[22-27]. The study identified that FCP > 276 μg/g predicted endoscopic activity at week 54 of CD patients with clinical remission at week 14 moderately with 84.6% sensitivity and 92.1% specificity. Unlike FCP, the sensitivity of CRP to mild intestinal inflammation was low and the level of CRP increased much more dramatically in CD patients with moderate to severe inflammation. Therefore, the previous study preferred to utilize CRP to distinguish moderate to severe endoscopic activity from mild to moderate endoscopic activity rather than distinguish mild endoscopic activity from endoscopic remission. A Spanish study showed that FCP > 155 μg/g in combination with CRP > 6.7 mg/L could identify endoscopic activity with 82% specificity[27].

However, the study has shortcomings in some areas. Firstly, the retrospective single-center study with small sample, inferior to prospective multi-center with greater sample, comprised some confounding factors. More real-world studies and randomized controlled trials on guidance significance of ITL to therapeutic outcomes in IBD need to be conducted. Secondly, the study primarily concentrated on mucosal inflammation located in large intestine, ignoring small intestine due to the high cost and the incomplete scoring system of small intestinal evaluation accompanied by the poor compliance of patients and the laborious operation of endoscopists. Correlation between ITL and various small intestinal examinations including endoscopy or imageology may be the focus of the future study. Last but not least, definition of deep remission on CD has been tightened. Considering transmural inflammation of CD, endoscopy is confined to mucosal inflammation and macroscopical evaluation while imageology can accurately evaluate complete volume of intestinal wall and histopathological examination, which contributes to microscopical examination. Notwithstanding endoscopic remission

considered as the main targets and histological remission considered as a novel target, the new concept of 'disease clearance', which includes clinical, endoscopic and microscopic remission, has drawn more and more attention from IBD physicians and may bring about a new upsurge of studies on IFX monitoring and new therapeutic targets[28].

CONCLUSION

In conclusion, during IFX maintenance treatment, low ITL, high CRP level and high FCP level were independent risk factors of long-term adverse endoscopy outcomes in CD patients with clinical remission. Combination of ITL, CRP and FCP contribute to long-term endoscopic prognosis monitoring. The best cut off values of ITL for predicting endoscopic activity within 1-year follow up were 5.60 μg/mL at week 14 and 2.10 μg/mL at week 54. In addition, ITL ≤ 5.60 μg/mL in combination with FCP > 238 μg/g at week 14 as well as ITL ≤ 2.10 μg/mL in combination with CRP > 3.00 mg/L at week 54 increased the precision of prediction on endoscopic outcomes at week 54 and week 108, respectively. Therapeutic optimization is still recommended in CD patients achieving endoscopic remission, provided that low ITLs or high levels of inflammatory biomarkers, such as CRP or FCP, arise to prevent endoscopic recurrence as soon as possible.

ARTICLE HIGHLIGHTS

Research background

Existing studies have confirmed that infliximab (IFX) blood concentration is closely related to remission and recurrence of Crohn's disease (CD) patients under IFX therapy. In addition, monitoring inflammatory biomarkers regularly is another important tool for prognosis assessment of CD patients. Current studies have confirmed that C-reactive protein (CRP) and fecal calprotectin (FCP) are good predictors of disease activity, but there is still a lack of reliable evidence for predicting disease remission. Therefore, in the early stage of IFX treatment, combination of IFX blood concentration and inflammatory biomarkers may contribute to predict the change of CD outcomes.

Research motivation

The best therapeutic goal of CD was initially defined as clinical remission, and then the definition was converted to endoscopic remission with precise therapy. Nowadays, some clinicians even pursue whole-wall healing with individualized therapy. However, long-term clinical prognosis rather than long-term endoscopic prognosis is still a research priority of clinical studies contrapose to CD patients under IFX therapy. Therefore, prediction on long-term endoscopic prognosis of CD patients under IFX therapy has been based solely on models because of a lack of available data.

Research objectives

To explore the predictive value of blood drug concentration on long-term endoscopic outcomes of IFX therapy for CD and establish a comprehensive outcome prediction model combining IFX blood drug concentration, CRP and FCP, so as to provide a basis for clinical decision making.

Research methods

A single-center retrospective research has been implemented in the First Affiliated Hospital of Zhejiang Chinese Medical University. CD patients under IFX therapy from January 2012 to December 2020 were collected. One hundred and eighty-one CD patients underwent IFX treatment. One hundred and fifty-three CD patients underwent endoscopy as well as serum concentration monitoring at week 14 after the third dose of IFX induction therapy. Inclusion criteria: (1) Endoscopic remission at week 14 [Crohn's disease endoscopic index of severity (CDEIS) score ≤ 2 points or Rutgeerts ≤ i1]; (2) Clinical remission after IFX induction therapy without corticosteroids more than 6 mo; and (3) Therapeutic strategy during maintenance stage was designed as IFX 5 mg/kg every 8 wk combined with azathioprine 50 mg every day. The study was divided into two stages, the Step I study was conducted from week 14 to 54 of IFX treatment, and the Step II study was conducted from week 54 to 108 of IFX treatment. Endoscopic outcomes were defined as endoscopic activity (CDEIS score > 2 points or Rutgeerts score > i1) and endoscopic remission (CDEIS score ≤ 2 points or Rutgeerts ≤ i1). Endoscopic relapse free survival was defined as endoscopic remission at the beginning of the study stage and maintaining endoscopic remission during the study stage.

Research results

In step I study, 67/93 CD patients (72.04%) sustained endoscopic remission at week 54. Multivariable regression analysis demonstrated that only ITL [odds ratio (OR) = 0.666, 95% confidence interval (CI):

0.514-0.862, P = 0.002] and FCP (OR = 1.002, 95%CI: 1.001-1.004, P = 0.002) were independent risk of endoscopic activity at week 54. The receiver-operating characteristic analysis demonstrated that the best cut off level of ITL and FCP at week 14 on predicting endoscopic relapse at week 54 was 5.60 μg/mL [area under the curve (AUC) = 0.83, 95%CI: 0.73-0.90, P < 0.001] and 238 μg/g (AUC = 0.82, 95%CI: 0.72-0.89, P < 0.001). The median time to endoscopic relapse of CD patients with ITL ≤ 5.6 μg/ml was 32.00 wk shorter than those with ITL > 5.6 μg/mL [hazard ratio (HR) = 16.19, 95%CI: 7.44-35.22, P < 0.0001]. The median time to endoscopic relapse of CD patients with FCP > 238 μg/g was 21.00 wk shorter than those with FCP ≤ 238 μg/g (HR = 11.25, 95%CI: 4.26-29.73, P < 0.0001). (II) In step II study, 42/54 CD patients (77.78%) sustained endoscopic remission at week 108. Multivariable regression analysis found that only ITL (OR = 0.466, 95%CI: 0.247-0.877, P = 0.018) and CRP (OR = 1.590, 95%CI: 1.007-2.510, P = 0.047) were independent risks of endoscopic activity at week 108. The receiver-operating characteristic analysis demonstrated that the best cut off level of ITL and CRP at week 54 on predicting endoscopic relapse at week 108 was 2.10 μg/ml (AUC = 0.85, 95%CI: 0.72-0.93, P < 0.001) and 3.00 mg/L (AUC = 0.73, 95%CI: 0.60-0.84, P = 0.012). The median time to endoscopic relapse of CD patients with ITL ≤ 2.1 μg/mL was 40.00 w shorter than those with ITL > 2.1 μg/mL (HR = 13.14, 95%CI: 3.07-56.27, P < 0.0001). The median time to endoscopic relapse of CD patients with CRP > 3.00 mg/L was 50.00 wk shorter than those with CRP ≤ 3.00 mg/L (HR = 7.85, 95%CI: 1.31-46.85, P< 0.0001).

Research conclusions

The best cut off values of ITL for predicting endoscopic activity within 1-year follow up was 5.60 μg/mL at week 14 and 2.10 μg/mL at week 54. In addition, ITL ≤ 5.60 μg/mL in combination with FCP > 238 μg/g at week 14 as well as ITL ≤ 2.10 μg/mL in combination with CRP > 3.00 mg/L at week 54 increased the precision of prediction on endoscopic outcomes at week 54 and week 108, respectively.

Research perspectives

In view of the fact that conduction of intensive monitoring for biological management plays a vital role in precise treatment for CD patients, much larger and more stringent prospective studies are warranted to provide the best predictive models as acknowledged globally in allusion to long-term endoscopic outcomes of CD patients under IFX therapy.

ACKNOWLEDGEMENTS

The authors would like to thank Dr. Bin Lv, Full Professor and Chief Physician at the First Affiliated Hospital of Zhejiang Chinese Medical University, Department of Gastroenterology, for his help in revising this paper, and Shan Liu, at the First Affiliated Hospital of Zhejiang Chinese Medical University, Clinical Evaluation Center, for help with statistical analysis.

Abstract

BACKGROUND

Tumor necrosis factor-alpha inhibitors, including infliximab and adalimumab, are

effective medical treatments for perianal fistulising Crohn's disease (CD), but not all patients achieve fistula healing.

AIM

To determine the correlation between perianal fistula healing and closure with infliximab and adalimumab trough levels.

METHODS

In this multicentre retrospective study conducted across four tertiary inflammatory bowel disease centres in Australia, we identified CD patients with perianal fistulae on maintenance infliximab or adalimumab who had a trough level within twelve weeks of clinical assessment. Data collected included demographics, serum infliximab and adalimumab trough levels (mg/L) within 12 wk before or after their most recent clinical assessment and concomitant medical or surgical therapy. The primary outcome was fistula healing, defined as cessation in fistula drainage. The secondary outcome was fistula closure, defined as healing and closure of all external fistula openings. Differences between patients who did or did not achieve fistula healing were compared using the chi-square test, *t* test or Mann-Whitney *U* test.

RESULTS

One hundred and fourteen patients (66 infliximab, 48 adalimumab) were included. Forty-eight (72.7%) patients on maintenance infliximab achieved fistula healing and 18 (27.3%) achieved fistula closure. Thirty-seven (77%) patients on maintenance adalimumab achieved fistula healing and 17 (35.4%) achieved fistula closure. Patients who achieved fistula healing had significantly higher infliximab and adalimumab trough levels than patients who did not [infliximab: 6.4 (3.8-9.5) *vs* 3.0 (0.3-6.2) mg/L, $P = 0.003$; adalimumab: 9.2 (6.5-12.0) *vs* 5.4 (2.5-8.3) mg/L, $P = 0.004$]. For patients on infliximab, fistula healing was associated with lower rates of detectable anti-infliximab antibodies and younger age. For patients on adalimumab, fistula healing was associated with higher rates of combination therapy with an immunomodulator. Serum trough levels for patients with and without fistula closure were not significantly different for infliximab [6.9 (4.3-10.2) *vs* 5.5 (2.5-8.3) mg/L, $P = 0.105$] or adalimumab [10.0 (6.6-12.0) *vs* 7.8 (4.2-10.0) mg/L, $P = 0.083$].

CONCLUSION

Higher maintenance infliximab and adalimumab trough levels are associated with perianal fistula healing in CD.

Core Tip: This multicentre retrospective study demonstrated a significant association between both infliximab and adalimumab trough levels with fistula healing, with higher levels associated with increased healing rates. Higher tertiles of both infliximab and adalimumab levels were associated with a higher proportion of patients achieving fistula healing. Fistula healing, defined as cessation of fistula drainage, is a clinically relevant endpoint that impacts on patient quality of life. Our results support dose-escalation of both infliximab and adalimumab in non-responders, targeting higher levels to achieve fistula healing prior to changing biologic therapy. Importantly, this study is the largest study to date assessing the relationship between adalimumab trough levels and clinical fistula healing.

INTRODUCTION

Perianal fistulising disease is a common manifestation occurring in up to 30% of patients with Crohn's disease (CD). The development of abnormal tracts between the bowel and perineum can cause perianal drainage, pain, bleeding, abscess formation, sepsis and faecal incontinence[1,2]. Perianal CD is

Figure 1 Correlation between serum trough level of infliximab, adalimumab and fistula healing. A: Infliximab; B: Adalimumab.

associated with significant morbidity and decreased quality of life, negatively impacting physical, emotional, sexual and social wellbeing[1-3] and is an independent predictor for decreased productivity in patients with CD[4,5]. Given that the incidence of perianal fistulising CD is highest in the third and fourth decades of life, this places significant burden on patients, society, the economy and the health care system[6].

Treatment for perianal fistulising CD requires a multidisciplinary approach involving medical management with immunosuppressants and antibiotics, as well as surgical management with sepsis control, seton insertion and sometimes diversion or resection. Anti-tumor necrosis factor (anti-TNF) alpha agents, including infliximab[7,8] and adalimumab[9,10], are the most effective medical therapies available for inducing and maintaining remission of fistulas. Unfortunately, up to 60% of patients treated with maintenance infliximab lose response within one year[7,8]. Accumulating evidence suggests that this loss of response is partly due to subtherapeutic anti-TNF trough levels. Retrospective studies and post-hoc analyses of prospective data have identified that higher infliximab trough levels are associated with fistula healing and closure compared to what is observed for mucosal healing in luminal disease, with emerging data suggesting similar results for adalimumab[11-14]. Quantitative assays for therapeutic drug monitoring (TDM) permit individualisation of infliximab and adalimumab dosing[15,16], however there are very few studies on perianal fistulising CD and the optimal target levels for perianal fistulising CD remain unclear. Our study aims to assess the association between serum trough infliximab and adalimumab levels and perianal fistula healing and closure and identify optimal target levels.

MATERIALS AND METHODS

Study design and patient population

This was a multicentre retrospective cross-sectional study of patients with perianal fistulising CD at four tertiary inflammatory bowel disease centres across Australia between January 2014 and June 2020. All patients qualified for infliximab or adalimumab under the Australian Pharmaceutical Benefits Scheme criteria[17] which constitutes the following: (1) A confirmed diagnosis of CD using clinical, radiological, histological and/or endoscopic criteria; and (2) At least one active externally draining complex perianal fistula. We included patients on maintenance infliximab or adalimumab with a documented perianal examination who had a serum infliximab or adalimumab trough level collected within 12 wk before or after their most recent clinical assessment. Infliximab and adalimumab trough levels as well as antibodies to infliximab and adalimumab were measured using a drug sensitive enzyme-linked immunosorbent assay (Grifols Promonitor for adalimumab; LISA-Tracker and Grifols Promonitor for infliximab). Infliximab and adalimumab trough levels were measured both in a proactive manner and reactive manner in patients failing treatment across the study sites. Patients who had been changed from infliximab to adalimumab or vice versa and had relevant data were included in both the infliximab and adalimumab groups.

All patients had received standard infliximab or adalimumab induction dosing (infliximab 5 mg/kg intravenously at weeks 0, 2, and 6; adalimumab subcutaneously 160 mg at week 0, 80 mg at week 2) followed by maintenance therapy. The current dose of anti-TNF therapy was recorded and patients with or without dose-escalated maintenance therapy were included. Patients who had a diversion ostomy, rectovaginal fistula or no documented perianal examination were excluded.

Demographic data

Data was retrospectively collected from a clinical database that was updated prospectively during routine clinical practice. Patient demographics collected included age, gender, weight, body mass index, smoking status and CD phenotype classified according to the Montreal Classification[18]. The location of CD was identified as ileal, ileocolonic, colonic, upper gastrointestinal involvement or no luminal disease. The presence or absence of fistulising and stricturing disease was noted, in particular the presence of anal strictures. Biochemical markers of disease activity including C-reactive protein (CRP) and albumin were also recorded.

Current management

Prior history of surgical management of perianal disease or fistula was recorded and categorised as examination under anaesthesia and curettage, examination under anaesthesia and seton insertion or fistulotomy. The duration from the last surgical procedure to the follow up visit was recorded. Concomitant medical therapy at the time of follow up was assessed, including corticosteroid use, 5-aminosalicylates and immunomodulators. The doses of infliximab and adalimumab were recorded and stratified according to dose and interval between doses. For patients on dose-escalated anti-TNF therapy, the duration between last dose escalation and follow up was recorded.

Primary and secondary outcomes

The primary outcome was fistula healing, which was defined as cessation of fistula drainage, with or without a seton *in situ*[7]. The secondary outcome was fistula closure, which was defined as healing and closure of all external fistula openings[7].

Statistical analysis

Statistical review of this study was performed by a biostatistician from the Ingham Institute for Applied Medical Research. Descriptive statistics were used to assess the baseline characteristics of both the infliximab and adalimumab cohorts. Categorical variables were expressed as percentages and compared using the chi-square test. Continuous variables were expressed using mean ± SD for normally distributed variables and median and interquartile range (IQR) for non-normally distributed variables. The means were compared using the *t* test for normally distributed variables and the mean ranks compared using the Mann-Whitney *U* test for non-normally distributed variables. A receiver operating characteristic (ROC) curve analysis was used to assess the sensitivity and specificity of infliximab and adalimumab levels at different cut-off points for predicting fistula healing. All reported *P* values were 2-sided, with $P < 0.05$ considered statistically significant. Multivariate analysis using logistic regression with forwards selection was used to analyse variables that predicted fistula healing. Variables which were statistically significant in the univariate analysis were included in the multivariate analysis model. Ethics approval was obtained from the South Western Sydney Local Health District (Human Research Ethics Committee LNR/18/LPOOL/404; Local Project Number: HE18/261).

RESULTS

Out of 454 patients screened, 114 patients (66 infliximab, 48 adalimumab) on maintenance infliximab or adalimumab for perianal CD had a trough level collected within 12 wk of clinical assessment. Five patients had been changed from infliximab to adalimumab or vice versa and were included in both the infliximab and adalimumab groups. Seventy-five (66%) patients were on combination therapy (43 azathioprine, 16 6-mercaptopurine, 16 methotrexate). Nineteen patients (28.8%) on maintenance infliximab were on dose escalated infliximab therapy (5, 7.5, 10, 15 or 20 mg/kg every 6 or 8 wk). For these patients, the median duration between last infliximab dose adjustment and follow up was 60.0 wk (IQR = 44.5-81.0). Eleven (22.9%) patients on maintenance adalimumab were on dose escalated adalimumab therapy (40 mg weekly). For these patients, the median duration between last adalimumab dose adjustment and follow up was 39.0 wk (IQR = 24.0-86.0). Fifty-nine (89.3%) patients on infliximab had prior surgical management of their fistula, with a median duration of 93.0 wk (IQR = 45.5-284.5) between their last surgical procedure and their most recent follow up visit. Thirty-seven (77.1%) patients on adalimumab had prior surgical management of their fistula, with a median duration of 83.0 wk (IQR = 28.75-223.0) between their last surgical procedure and their most recent follow up visit. Patient demographics and disease characteristics of the population are summarised in Table 1.

Association between fistula healing and closure with infliximab trough levels

Forty-eight (72.7%) patients on maintenance infliximab achieved fistula healing. Table 2 summarises the differences between patients on infliximab with and without fistula healing. Patients who achieved fistula healing had higher infliximab trough levels [6.4 (3.8-9.5) *vs* 3.0 (0.3-6.2) mg/L, $P = 0.003$], lower rates of detectable anti-infliximab antibodies (4.3% *vs* 33.3%, $P = 0.004$) and a younger age (33.0 *vs* 43.5 years old; $P = 0.003$) compared to patients who did not achieve fistula healing. The presence of

detectable anti-infliximab antibodies was associated with lower infliximab trough levels (P = 0.02). The CRP and albumin levels were not significantly different between patients with and without fistula healing. The rates of combination therapy with an immunomodulator were not significantly different between patients who achieved fistula healing and those who did not (P = 0.522).

ROC curve analysis identified a positive correlation between infliximab trough levels and healing [area under the curve (AUC) = 0.74, 95% confidence interval (CI): 0.60-0.88, P = 0.003; Figure 1A] with an infliximab trough level of 6.10 mg/L that maximised the sensitivity and specificity of predicting fistula healing [sensitivity 58%, specificity 78%, odds ratio (OR) = 4.9, P = 0.013]. Upon tertile analysis, higher tertiles of infliximab levels were associated with a higher proportion of patients achieving fistula healing with 54.5% healing rate for tertile 1 compared to 90.1% for tertile 3 (Figure 2A; P = 0.026). Out of the patients who achieved fistula healing on infliximab, 90% and 95% of the patients who achieved fistula healing were healed with an infliximab trough level of 12.7 and 14.4 mg/L respectively. Given

Figure 2 Tertile analysis of infliximab and adalimumab trough levels for patients with fistula healing and fistula closure. A: Infliximab; B: Adalimumab.

that a drug-sensitive infliximab assay was used where anti-infliximab antibody titres were only performed if infliximab concentrations were < 2.0 mg/L, anti-infliximab antibodies were not included in the multivariate analysis. On multivariate logistic regression analysis, age was associated with healing ($P = 0.026$) but adequate infliximab levels ≥ 6.10 mg/L were not ($P = 0.097$). Within our cohort, 18 (27.3%) of patients on infliximab achieved fistula closure. The infliximab trough level for patients with and without fistula closure was not significantly different [6.9 (4.3-10.2) *vs* 5.5 (2.5-8.3) mg/L, $P = 0.105$].

Association between fistula healing and closure with adalimumab trough levels

Thirty-seven (77%) patients on maintenance adalimumab achieved fistula healing. Table 3 summarises the differences in patients on adalimumab with and without fistula healing. Patients who achieved fistula healing had higher adalimumab trough levels compared to those who did not [9.2 (6.5-12.0) *vs* 5.4 (2.5-8.3) mg/L, $P = 0.004$]. Patients who achieved fistula healing had higher rates of combination therapy with an immunomodulator than those who did not ($P = 0.048$). The CRP and albumin levels were not significantly different in patients with and without fistula healing. ROC curve analysis identified a positive correlation between adalimumab trough levels and healing (AUC = 0.79, 95%CI: 0.66-0.93, $P = 0.004$) with an adalimumab trough level of 7.05 mg/L that maximised the sensitivity and specificity of infliximab levels in predicting fistula healing (sensitivity 70%; specificity 73%; OR = 6.3; $P = 0.016$; Figure 1B). Upon tertile analysis, higher tertiles of adalimumab levels were associated with a higher proportion of patients achieving fistula healing, with 62.5% healing rate for tertile 1 compared to 100% for tertile 3 (Figure 2B; $P = 0.034$). Out of the patients who achieved fistula healing on adalimumab, 90% and 95% of the patients who achieved fistula healing were healed with an adalimumab trough level of 12.0 and 18.0 mg/L respectively. On multivariate logistic regression analysis, adequate adalimumab trough levels ≥ 7.05 mg/L ($P = 0.008$) and concurrent immunomodulator therapy ($P = 0.026$) both remained associated with healing. Within our cohort, 17 (35.4%) of patients on adalimumab achieved fistula closure. The adalimumab trough level for patients with and without fistula closure was not significantly different [10.0 (6.6-12.0) *vs* 7.8 (4.2-10.0) mg/L, $P = 0.083$].

DISCUSSION

Fistulising perianal CD is a highly morbid condition for which treatment outcomes remain suboptimal in many patients. While there is limited data on the role of newer biologic agents such as ustekinumab in perianal CD[19], anti-TNF agents remain the treatment of choice. Our study showed a significant association between both infliximab and adalimumab trough levels and fistula healing, with higher levels associated with increased healing rates. We demonstrated that higher tertiles of both infliximab and adalimumab levels were associated with a higher proportion of patients achieving fistula healing. Notably, when plotting the cumulative percentage of healed patients against infliximab level, we found that 50% of the patients who achieve healing will heal with a level of 6.4 mg/L, 90% of the patients who achieve healing will heal with a level of 12.7 mg/L and 95% of the patients who achieve healing will heal with a level of 14.4 mg/L. Similarly, for patients on adalimumab, 50% of the patients who achieve healing will heal with a level of 9.2 mg/L, and 90% and 95% of patients who achieved fistula healing were healed with levels of 12.0 and 18.0 mg/L respectively. Our results support dose-escalation of both infliximab and adalimumab in non-responders, targeting higher levels to achieve fistula healing prior to

changing biologic therapy. Importantly, this study is the largest study to date assessing the relationship between adalimumab trough levels and clinical fistula healing. This data adds to the growing body of evidence that fistula healing improves with higher anti-TNF trough levels, and that higher levels may be required for perianal fistula healing than for mucosal healing in luminal CD[12-14,20].

This study did not show an association between infliximab and adalimumab trough levels and fistula closure. Not all previous studies have assessed fistula closure, but some have found that patients with fistula closure had significantly higher maintenance infliximab and adalimumab trough levels[13,14]. Our results may have been limited by inadequate power due to relatively small numbers of patients who achieved fistula closure in our cohort. We had a high fistula healing rate in this study, with 72.7% and 77% of patients on maintenance infliximab and adalimumab achieving fistula healing respectively. This finding was possibly due to high rates of combination therapy with an immunomodulator (69.7% and 60.4% in the infliximab and adalimumab groups respectively).

Randomised controlled trials have shown that infliximab is effective at both inducing and maintaining fistula healing[7,8]. Our study found that fistula healing was associated with higher infliximab trough levels. This finding is supported by a post-hoc analysis of ACCENT II which found that higher infliximab trough levels during induction were associated with a complete absence of draining fistulas at week 14[12], as well as similar findings in other studies assessing induction and maintenance infliximab therapy[11,13]. In the future, there may be a role for the infliximab biosimilar CT-P13 in order to achieve these high infliximab levels required for perianal fistula healing; with recent randomised controlled trials demonstrating higher trough levels from subcutaneous administration of CT-P13 compared to intravenous administration[21]. Interestingly, our study found that fistula healing was associated with younger age in both univariate and multivariate analyses. Whilst patient factors including albumin and body weight have previously been shown to affect infliximab trough levels[22], the influence of age is unclear. This finding may be due to the relatively younger age at diagnosis of CD for patients with fistula healing or longer duration of infliximab therapy. Five patients in this study had been changed from infliximab to adalimumab or vice versa and were included in both groups, however the anti-TNF level and anti-TNF antibody levels at the time of changing treatment were not collected. Reassuringly, previous studies have demonstrated that the presence of infliximab antibodies does not decrease future response rates to adalimumab and vice versa[23].

Adalimumab has also been shown to be effective in both inducing[9] and maintaining fistula healing [24]. Our study found that fistula healing was associated with higher adalimumab trough levels. Whilst there is limited data on the association between adalimumab trough levels and fistula healing, our findings are consistent with two smaller retrospective studies that showed that patients with fistula healing had higher adalimumab trough levels compared to those without fistula healing[14,20]. On multivariate logistic regression analysis, adalimumab trough levels ≥ 7.05 mg/L and concurrent immunomodulator therapy both remained significantly associated with healing. This reflects how concomitant immunosuppressive therapy can be used to decrease the immunogenic response and therefore improve fistula healing rates[25].

This study has several limitations. Assessment of fistula healing was based on clinical assessment, which may not be as accurate as an objective assessment such as with magnetic resonance imaging of the pelvis. A recent study has demonstrated that higher anti-TNF trough levels are associated with improved rates of radiological healing in perianal fistulising CD[26]. However, the absence of drainage remains a clinically relevant endpoint that impacts on patient quality of life. In order to provide an objective marker of response, biochemical markers of disease activity including CRP and albumin were analysed and found not to correlate with fistula healing. Data was retrospectively collected, so in order to address this we only included patients with documented perianal exams and definitions for fistula healing and closure that were in line with previous randomised controlled trials[8]. We found that fistula healing is associated with higher infliximab and adalimumab trough levels, however further randomised controlled trials are required to assess whether dose escalation to higher levels improves healing and the optimal method for dose escalation. Whilst reactive TDM with dose escalation at the time of loss of response is effective, it remains unknown whether proactive TDM with subsequent dose modification improves outcomes. Notably, all previous studies on proactive TDM have focused on luminal disease with no prospective studies evaluating proactive TDM in perianal fistulising CD.

CONCLUSION

Our study showed that higher infliximab and adalimumab trough levels are associated with perianal CD fistula healing, with higher rates of healing in higher tertiles of infliximab and adalimumab levels. However, no association with fistula closure was observed. Further prospective studies are required to confirm target infliximab and adalimumab trough levels and determine the optimal dose escalation method to achieve these target levels.

ARTICLE HIGHLIGHTS

Research background

Anti-tumor necrosis factor (anti-TNF)-alpha agents, including infliximab and adalimumab, are effective medical treatments for perianal fistulising Crohn's disease (CD), but not all patients achieve fistula healing with up to 60% of patients treated with maintenance infliximab lose response within one year.

Research motivation

Accumulating evidence suggests that this loss of response is partly due to sub-therapeutic anti-TNF trough levels. Retrospective studies and post-hoc analyses of prospective data have identified that higher infliximab trough levels are associated with fistula healing and closure compared to what is observed for mucosal healing in luminal disease, with emerging data suggesting similar results for

adalimumab. Quantitative assays for therapeutic drug monitoring permits individualisation of infliximab and adalimumab dosing, however there are very few studies on perianal fistulising CD and the optimal target levels for perianal fistulising CD remains unclear.

Research objectives
This study aims to assess the association between serum trough infliximab and adalimumab levels and perianal fistula healing and closure and identify optimal target levels.

Research methods
In this multi-centre retrospective study conducted across four tertiary inflammatory bowel disease centres in Australia, we identified CD patients with perianal fistulae on maintenance infliximab or adalimumab who had a trough level within twelve weeks of clinical assessment. The primary outcome was fistula healing, defined as cessation in fistula drainage. The secondary outcome was fistula closure, defined as healing and closure of all external fistula openings. Differences between patients who did or did not achieve fistula healing were compared using the Chi-square test, *t*-test or Mann-Whitney *U* test.

Research results
Out of a total of 114 patients (66 infliximab, 48 adalimumab), 48 (72.7%) patients and 37 (77%) patients on maintenance infliximab and adalimumab respectively achieved fistula healing. Patients who achieved fistula healing had significantly higher infliximab and adalimumab trough levels compared to patients who did not [infliximab: 6.4 (3.8-9.5) *vs* 3.0 (0.3-6.2) mg/L, $P = 0.003$; adalimumab: 9.2 (6.5-12.0) *vs* 5.4 (2.5-8.3) mg/L, $P = 0.004$]. Serum trough levels for patients with and without fistula closure were not significantly different for infliximab [6.9 (4.3-10.2) *vs* 5.5 (2.5-8.3) mg/L, $P = 0.105$] or adalimumab [10.0 (6.6-12.0) *vs* 7.8 (4.2-10.0) mg/L, $P = 0.083$].

Research conclusions
Higher maintenance infliximab and adalimumab trough levels are associated with perianal fistula healing in CD.

Research perspectives
Our study showed that higher infliximab and adalimumab trough levels are associated with perianal CD fistula healing, with higher rates of healing in higher tertiles of infliximab and adalimumab levels, but no association with fistula closure was observed. Further prospective studies are required to confirm target infliximab and adalimumab trough levels and determine the optimal dose escalation method to achieve these target levels.

Abstract

BACKGROUND

Whole-tumor apparent diffusion coefficient (ADC) histogram analysis is relevant to predicting the neoadjuvant chemoradiation therapy (nCRT) response in patients with locally advanced rectal cancer (LARC).

AIM

To evaluate the performance of ADC histogram-derived parameters for predicting the outcomes of patients with LARC.

METHODS

This is a single-center, retrospective study, which included 48 patients with LARC. All patients underwent a pre-treatment magnetic resonance imaging (MRI) scan for primary tumor staging and a second restaging MRI for response evaluation. The sample was distributed as follows: 18 responder patients (R) and 30 non-responders (non-R). Eight parameters derived from the whole-lesion histogram analysis (ADCmean, skewness, kurtosis, and ADC10th, 25th, 50th, 75th, 90th percentiles), as well as the ADCmean from the hot spot region of interest (ROI), were calculated for each patient before and after treatment. Then all data were compared between R and non-R using the Mann-Whitney U test. Two measures of diagnostic accuracy were applied: the receiver operating characteristic curve and the diagnostic odds ratio (DOR). We also reported intra- and interobserver variability by calculating the intraclass correlation coefficient (ICC).

RESULTS

Post-nCRT kurtosis, as well as post-nCRT skewness, were significantly lower in R

than in non-R (both $P < 0.001$, respectively). We also found that, after treatment, R had a larger loss of both kurtosis and skewness than non-R (Δ%kurtosis and Δskewness, $P < 0.001$). Other parameters that demonstrated changes between groups were post-nCRT ADC10th, Δ%ADC10th, Δ%ADCmean, and ROI Δ%ADCmean. However, the best diagnostic performance was achieved by Δ%kurtosis at a threshold of 11.85% (Area under the receiver operating characteristic curve [AUC] = 0.991, DOR = 376), followed by post-nCRT kurtosis = 0.78 × 10^{-3} mm^2/s (AUC = 0.985, DOR = 375.3), Δskewness = 0.16 (AUC = 0.885, DOR = 192.2) and post-nCRT skewness = 1.59 × 10^{-3} mm^2/s (AUC = 0.815, DOR = 168.6). Finally, intraclass correlation coefficient analysis showed excellent intraobserver and interobserver agreement, ensuring the implementation of histogram analysis into routine clinical practice.

CONCLUSION

Whole-tumor ADC histogram parameters, particularly kurtosis and skewness, are relevant biomarkers for predicting the nCRT response in LARC. Both parameters appear to be more reliable than ADCmean from one-slice ROI.

Core Tip: Whole-tumor apparent diffusion coefficient (ADC) histogram analysis is an emergent imaging analysis in which every voxel is used to obtain a histogram; it thus provides statistical information about tumors. Our study revealed that ADC histogram profiling is a valuable approach that can help differentiate treatment response in locally advanced rectal cancer. When determining tailored treatments that are associated with minimal morbidities, such as the watch and wait method, an accurate treatment response prediction is critical. Given the limitations of this study, more research is needed to establish the clinical utility of our findings.

INTRODUCTION

Neoadjuvant chemoradiation therapy (nCRT) is the gold standard treatment for patients with locally advanced rectal cancer (LARC), followed by surgical resection and adjuvant chemotherapy[1,2]. After nCRT, the ability to achieve tumor reduction or even a pathological complete response (pCR) is observed in approximately 75% of treated patients, whereas the remainder exhibited no treatment response[3,4]. The ability to predict the response to nCRT is important for patients with potentially curable LARC who wish to explore personalized treatment to expand their therapeutic outcomes[5].

Functional magnetic resonance imaging (MRI) techniques, such as diffusion-weighted imaging (DWI), can provide additional physiological information about a tumor's cellular environment, offering great potential to evaluate the therapeutic response to nCRT[5]. This is because the apparent diffusion coefficient (ADC), a quantitative parameter used to assess water diffusion through tissue in DWI, shows an inverse relationship with tissue cellularity[6]. Viable tumor cells restrict the mobility of water, whereas necrotic tumor cells allow the increased diffusion of water molecules[7].

The possibility that ADC may be associated with the nCRT response has been amply investigated in LARC[8-12]; however, significant correlations have not been found in any studies to date[10]. Inconsistencies in previous findings may be due to a lack of standardized imaging and acquisition techniques[5,11], but they may also be due to the fact that the ADC measurements were performed using a manually drawn region of interest (ROI) from a single slice of the ADC map, which holds limited ability to reflect the actual whole-tumor characteristics[13-15].

In the case of whole-lesion histogram analysis of the ADC, a volumetric ROI is positioned on the entire lesion over contiguous slices and a histogram of ADC values reflecting voxel frequency is constructed, leading to the improved evaluation of heterogeneity[16]. Based on this method, first-order heterogeneity parameters can be obtained, which assess the spectrum of ADC values gained from all

voxels within a volume of interest[17]. A growing number of studies have used ADC histogram parameters, as these analyses provide additional information that can aid in the discrimination between benign and malignant regions, or they can help to better characterize the response to treatment in different tumors, such as ovarian, prostate, and breast cancer[18-21]. The application of whole-volume ADC histogram analysis in rectal tumors is increasing in frequency as well, and the role of this parameter in predicting nCRT is promising but limited[22-25].

The purpose of this study was to investigate the imaging response to nCRT using DWI in patients with LARC. We hypothesized that the ADC histogram-derived parameter might better predict treatment responses to nCRT compared with ADC from the hotspot ROI, as histogram parameters can display the heterogeneous features of tumors.

MATERIALS AND METHODS

Patients

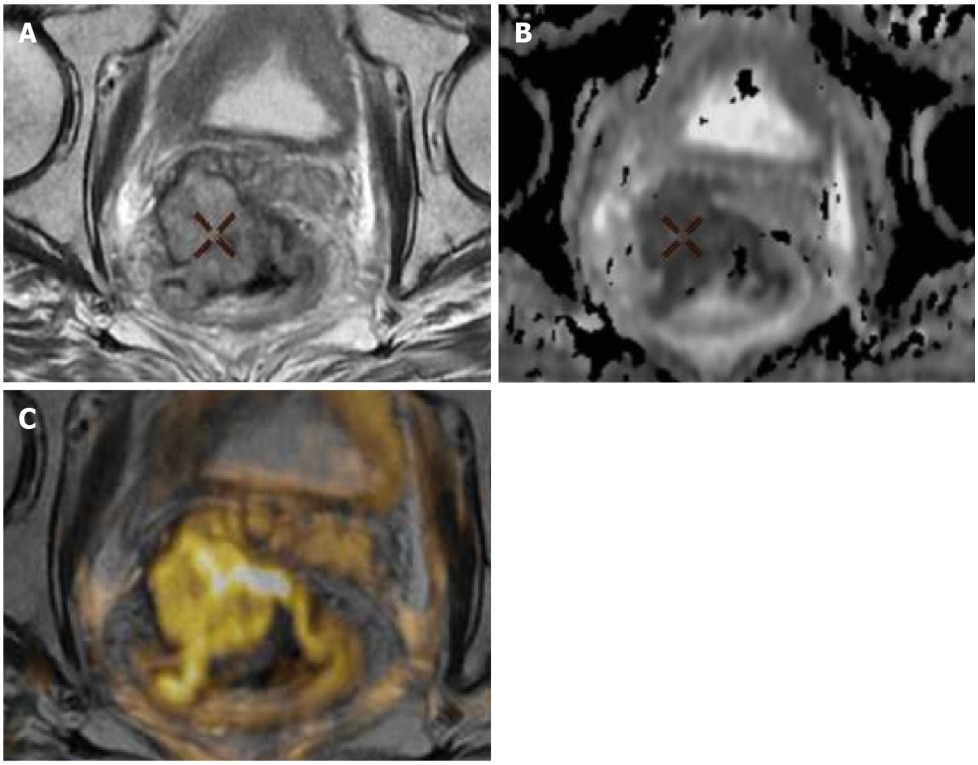
The institutional review board approved this retrospective study, and the requirement to obtain informed consent was waived given the study's retrospective nature. The study population was selected from LARC patients at our institution between February 2015 and October 2020. According to Enkhbaatar *et al*[23], we defined the inclusion criteria as follows: (1) Proven histopathology of rectal adenocarcinoma; (2) greater than stage T2 on pre-nCRT MR imaging; with or without regional lymph node metastases and no distant metastases; (3) pre- and post-nCRT rectal MRI imaging with diffusion-weighted (DW) imaging; (4) long-course nCRT; and (5) surgical resection. Mucinous tumors were excluded from this study.

Forty-eight patients were enrolled in the study (34 men and 14 women; age range: 28–84 years). All patients were further divided into two subgroups based on the pathological response of the primary tumor: responders (R) and non-responders (non-R). Only patients with grade 0 according to the TRG-Ryan system were regarded as patients with a complete pathological response (R), while patients with TRG 1-3 were non-R.

MRI protocol

All images were obtained on a 3T MRI system (Discovery MR 750w GEM®; General Electric Healthcare, Milwaukee, WI, United States) using a phased-array body coil. Intravenous antispasmodic agents were not administered, and patients received no bowel preparation before the MRI examination. Our study groups comprised patients who underwent pre-treatment MRI for primary tumor staging, and a second restaging MRI for response evaluation 6 wk after the completion of nCRT. The scanning protocol is listed in Table 1[23]. In brief, we obtained standard T2-weighted (T2W) spin-echo sequences in axial, coronal, and sagittal directions. To improve tumor tissue visualization (including the delineation of the muscular layer), these planes were planned perpendicular to the main axis of the tumor. Moreover, a T1W spin-echo sequence in an axial direction, as well as an axial non-enhanced DWI with b = 1200 s/mm^2, were acquired. ADC maps were automatically generated using the in-line software provided by the vendor during image acquisition. Additionally, axial, sagittal, and coronal fat-suppressed contrast T1W sequences were acquired and used to suppress the signal from adipose tissue. A gadolinium-based contrast agent (Gd-DTPA, Magnevist; Bayer Schering, Berlin, Germany) was used to enhance the quality of MRI. Representative images of our MRI protocol are provided in Figure 1.

Image analysis



Two radiologists (JARP and MEJ, with 10 years and 5 years of experience in gastrointestinal imaging, respectively) reviewed the imaging studies and performed all tumor measurements on the pre- and post-nCRT images. At the initial review, each radiologist was blinded to the other radiologist's opinion. Also, they were blinded to the pathology results to assess interobserver and intraobserver variability. After that, the two radiologists would hold a discussion to arrive at a final decision by consensus. If a disagreement occurred, another radiologist with 25 years of experience (YVN) aided in making the final decision.

DWI analysis was performed with a workstation using the GE Advantage Workstation 4.6 software featuring the READYVIWER application (2006–2010; General Electric, Boston, MA, United States). On the pre-nCRT b1200 diffusion images, the tumor was defined as a focal mass with high signal intensity in comparison with the signal of the normal adjacent rectal wall. More precisely, the delineated ROIs covered the edge of each lesion, and the ROIs were drawn along the inner margin of the rectal walls to avoid intraluminal gas, water, and other contents. Further, necrotic areas, cysts, and vessels related to each lesion at the corresponding slice were also avoided, as identified on T2WI images. In addition, the highest and lowest slices of the DWI images were excluded given their partial volume effects[24]. After nCRT, the tumor was defined by focal areas of residual high signal, as identified on the b1200 images within the location of the primary tumor bed and/or corresponding with the residual tumor on T2WI MRI images as a reference standard. To compare and identify the tumor location, the pre-treatment images were at the readers' disposal when analyzing the post-treatment images.

Table 1 Magnetic resonance imaging sequences and data acquisition parameters

Parameter	Magnetic resonance imaging sequences

Figure 1 Representative images of magnetic resonance imaging protocol. A-C: Axial T2 (A), apparent diffusion coefficient (ADC) map and T2 fusion ADC map color (B) and images of bulky tumor (C), showing tumor extending more than 5 mm into the mesorectal fat and invading the mesorectal fascia.

It should be noted that, in the first instance, one large ROI was placed to cover most of the largest axial tumor cross-section, which facilitated the calculation of the ADCmean values (ROI ADCmean). Thereafter, a volume of interest (VOI) was manually created on the ADC maps, where ROIs were drawn on all tumor slices (whole-lesion measurement). Within this VOI, the following parameters were calculated: (1) ADCmean, the average ADC value of all voxels within the VOI; (2) ADCn% (10^{th}, 25^{th}, 50^{th}, 75^{th}, and 90^{th} percentiles), the point at which the n% of the voxel values that formed the histogram were found to be at the left; (3) skewness, which measures the asymmetry of the distribution of values about the mean value; and (4) kurtosis, which is a measure of the 'peakedness' of the distribution of values in the ROI image. The corresponding frequency table for each lesion was exported, and the histogram parameters were computed by SPSS v. 26.0 (IBM Corporation, Armonk, NY, United States). Figure 2 is a schematic illustration of a representative ROI.

Figure 2 Images of rectal tumor before and after neoadjuvant chemoradiation therapy. A, C: T2-weighted magnetic resonance images obtained in 67-year-old man with a rectal tumor (histopathologic response Ryan 1) to evaluate tumor volume; B, D: Diffusion-weighted images (DWI) that were obtained from the same case. As we can see in the present case, regions of interest were drawn manually slice by slice on DWI images along the edge of the lesion to cover as much tumor area as possible without excluding cystic or necrotic areas. nCRT: Neoadjuvant chemoradiation therapy.

Histopathologic review

Specimens were evaluated according to an established protocol that was previously described by our research team[26]. In brief, fresh surgical specimens were evaluated to determine the quality of the mesorectal excision before being fixed in 4% formaldehyde for 48 h prior to sectioning. After fixation, the specimens were serially sectioned (in slices of 1 cm), and the mesorectal boundary was linked. When the residual tumor was visible, a minimum submission of four blocks was recommended. All mesorectal lymph nodes were histologically examined, as was the involvement of the circumferential resection margin. When no residual tumor cells were identified, each block was cut into 3 level sections, and immuhistochemistry for keratin was done. All hematoxylin and eosin slides were reviewed by an experienced pathologist (EHB, with 15 years of experience examining rectal cancer).

The pathologic response of the primary tumor was estimated using the modified Ryan's classification as follow[26,27]: TRG0, complete response with no viable cancer cells; TRG1 moderate response with single cancer cells or small groups of cancer cells; TRG2, minimal response with residual cancer outgrown by fibrosis, and TRG3, poor response with minimal or no tumor killing and extensive residual cancer.

Statistical analyses

The following formula was used to calculate changes in all metrics included in the current study: *PerC* = (Parameter post-treatment - Parameter pre-treatment) / Parameter pre−treatment × 100.

It must be noted that when pre- and post-nCRT kurtosis values were obtained, a result of +3.00 indicated the absence of kurtosis. To simplify the interpretation, we adjusted this result to 0 (*i.e.* kurtosis of –3 = 0). Thus, any reading other than 0 was referred to as an excess of kurtosis. On the other side, to negate division by 0 when calculating the percentage change in kurtosis, we added 3, *i.e.* [(Kurtosis post-treatment + 3) – (Kurtosis pre-treatment + 3) / (Kurtosis pre-treatment + 3)] × 100.

In the case of skewness, and to avoid dividing by 0, only change (not the percentage change) was used (*i.e.* skewness post treatment – skewness pre-treatment)[28]. As skewness did not have a lower bound such as kurtosis, the +/– sign was considered to calculate changes in this parameter. To compare variables among R and non-R, a Mann–Whitney *U* test (MWU) was applied, as the Kolmogorov-Smirnov test confirmed the non-normal distribution of any parameter included here. Accordingly, the data were presented as medians and interquartile ranges (IQR)[29]. When the differences in a variable were significant ($P < 0.05$) in the MWU test, the cut-off value, sensitivity, specificity, positive predictive

value, negative predictive value, area under the receiver operating characteristic (ROC) curve (AUC), and accuracy, were analyzed. The optimal cut-off values of ADCmean from the hot spot ROI and parameters derived from the histogram analysis of DWI were determined *via* the Youden index, while differences in the AUC were analyzed according to the method described by DeLong *et al*[30]. Furthermore, the diagnostic odd ratio (DOR) was designed to provide an additional measure of the performance of our potentially useful biomarkers to predict treatment response in LARC.

Finally, the intraobserver variability and interobserver variability were assessed using the intraclass correlation coefficient (ICC). For the agreement analysis, the outcomes were interpreted as follows, in accordance with Cicchetti (1994): 0.2 or less, poor agreement; 0.21–0.40, fair agreement; 0.41–0.60, moderate agreement; 0.61–0.74, good agreement; and 0.75–1.00, excellent agreement[31]. Statistical analyses were performed using SPSS v. 26. $P < 0.05$ was considered statistically significant.

RESULTS

Among the 58 patients that were originally included in this study, 10 had severe imaging artifacts. Thus, our final sample included 48 patients whose clinical and pathological characteristics are described in Table 2.

The median values and IQRs for the ROI ADCmean values and parameters derived from the histogram analysis of DWI are described in Table 3. Accordingly, post-nCRT kurtosis, as well as post-nCRT skewness, were significantly lower in R than in non-R (both $P < 0.001$, respectively). Furthermore, our results showed significant differences in the relative changes of kurtosis (Δ%kurtosis) between R and non-R ($P < 0.001$), with the largest loss of kurtosis in R. Additionally, median Δskewness displayed lower values in R than in non-R ($P < 0.001$).

We also found that patients with a favorable response (R) had higher post-nCRT ADC10th values than did non-R ($P = 0.036$). Correspondingly, the median values of Δ%ADC10th, Δ%ADCmean, and ROI Δ%ADCmean were also higher in R than in non-R, ($P = 0.020$, $P = 0.032$ and $P = 0.020$, respectively).

Receiver operating characteristics of those parameters that exhibited significant differences in the MWU test are reported in Table 4. The highest AUC values for predicting the treatment response in LARC were demonstrated by Δ%kurtosis, post-nCRT kurtosis, Δskewness and post-nCRT skewness (AUCs = 0.991, 0.985, 0.885, and 0.815, respectively). Meanwhile, the lowest diagnostic accuracy was observed in post-nCRT ADC10th (AUC = 0.681), Δ%ADCmean (AUC = 0.686), Δ%ADC10th (AUC = 0.589) and ROI Δ%ADCmean (AUC = 0.583).

The ROC curves for Δ%kurtosis, post-nCRT kurtosis, Δskewness, and post-nCRT skewness are displayed in Figure 3, while the comparison of AUC values between all of our potentially useful biomarkers for predicting the treatment response in LARC are presented in Supplementary Table 1.

It is important to mention that according to the DeLong analysis, no significant differences were found in the diagnostic accuracy of Δ%kurtosis and post-nCRT kurtosis. As well, no differences were demonstrated between Δskewness and post-nCRT skewness. However, the latter two parameters had lower accuracy than kurtosis-derivate metrics.

Finally, to verify the diagnostic accuracy of all metrics reported in Table 4, we calculated DORs. The DOR of a test is the ratio of the odds of positivity if a patient has a disease relative to the odds of positivity when a patient does not have a disease. The value of DOR ranges from 0 to infinity, with higher values indicating better discriminatory test performance[32,33]. As demonstrated in Table 5, Δ%kurtosis and post-nCRT kurtosis had the highest power of discrimination for treatment response by using DORs (approximately 376), followed by Δskewness (192.2) and post-nCRT skewness (168.6). Meanwhile, the lowest power of discrimination was observed in post-CRT ADC10th (5.48), Δ%ADCmean (4.26), Δ%ADC10th (3.65), and ROI Δ%ADCmean (3.47).

Regarding interobserver and intraobserver variability, the parameters derived from the histogram analysis of DWI, as well as the ADC values from the hotspot ROI, had an excellent agreement. The ICC measuring intraobserver variability ranges from 0.777-0.931 (Table 6), while the ICC measuring intraobserver variability ranges from 0.889-0.993 (Table 7).

DISCUSSION

Heterogeneity of malignant lesions is a feature that can be determined by characterizing changes in the histogram analysis of ADC values, which is recognized as a promising tool in cancer research when discerning between benign and malignant tumors or to better characterize the response to anti-cancer treatments[34-38].

This study focused on the ADCmean from the hot-spot ROI and a series of parameters corresponding to certain points on the ADC histogram using DWI, which have been proposed to predict treatment response in patients with rectal cancer[39,40]. As our results demonstrated, the parameters that changed significantly in response to nCRT were Δ%kurtosis, post-nCRT kurtosis, Δskewness, post-nCRT skewness, post-nCRT ADC10th, Δ%ADCmean, Δ%ADC10th, and ROI Δ%ADCmean. However, the

highest diagnostic accuracy was obtained for Δ%kurtosis, post-nCRT kurtosis, post-nCRT skewness, and Δskewness, suggesting that these metrics might be useful when selecting responders (TRG 0) for an organ preservation approach with either 'watch-and-wait' or local excision[39,40].

The results derivate from parameters with the highest diagnostic accuracy in predicting treatment response to nCRT in the current work are reviewed below.

First, we demonstrated that both post-nCRT kurtosis and post-nCRT skewness were significantly lower in R than in non-R. The overall trends from the histogram studies have shown that, following treatment, the histogram analysis of *DWI* and diffusion kurtosis imaging (DKI) shifted to the right upon decreased kurtosis and skewness in rectal cancer[39-43]. For example, in 2017, Hu *et al*[39] reported that the post-treatment mean kurtosis derived from DKI showed reduced values in R when compared with non-R patients, whereas Enkhbaatar *et al*[23] (2019) documented that the histogram of R presented negative changes in skewness following a loss of this parameter after therapy.

Table 4 Diagnostic performance of the best magnetic resonance imaging histogram derived parameters to detect responder patients

	Cutoff	Sensitivity	Specificity	PPV	NPV	Accuracy	AUC (95%CI)
Δ%kurtosis	11.85%	94.4%	96.7%	94.4%	96.7%	96.0%	0.991 (0.925-1.000)

Post-nCRT skewness	168.6	54.0-251.7
Post-nCRT ADC10th	5.48	1.0-19.6
Δ%ADCmean	4.26	1.0-14.4
Δ%ADC10th	3.65	1.0-12.5
ROI Δ%ADCmean	3.47	1.0-11.2

ADC: Apparent diffusion coefficient; nCRT: Neoadjuvant chemoradiation therapy; ROI: Region of interest.

In the same way, kurtosis from R had greater reductions than from non-R, which indicates Gaussian or flatter distributions in patients with a complete response to the therapy. In biological tissues, it is believed that the non-Gaussian behavior (more precisely, a platykurtic curve) of water might occur because of a heterogeneous environment characterized by multiple compartments, organelles, and semipermeable membranes[44]. Thus, when an important reduction in kurtosis is noticed, a higher displacement of water molecules in DWI is assumed.

Furthermore, as mentioned above, negative changes of skewness after nCRT were seen in R, while non-R exhibited positive changes in this parameter. Negatively skewed curves show the majority of scores above the mean, and positively skewed curves are just the opposite[44]. In physiology, the association between changes in skewness and responses to antineoplastic therapy have not been fleshed out, but a curve negatively skewed suggests a loss of cellular structure[23]. Therefore, favorable treatment response is suspected.

Our MWU analysis also found differences between R and non-R across other parameters, such as ADC10th, Δ%ADCth, Δ%ADCmean and ROIΔ%ADCmean, as stated in our results section. However, both the ROC curve analysis and the DOR calculation indicated that only Δ%kurtosis, post-nCRT kurtosis, Δskewness, and post-nCRT skewness appear to predict a favorable response to the therapy, whereas the other metrics did not possess that predictive property.

Briefly, the Youden index calculation indicated that post-nCRT kurtosis, post-nCRT skewness, and Δskewness values below 0.78×10^{-3} mm^2/s, 1.59×10^{-3} mm^2/s, and 0.16, respectively, might be significant indicators of the occurrence of pCR. Meanwhile, Δ% changes above 11.85% also indicated a positive treatment effect with high accuracy. It is important to remember that, according to the DeLong analysis, the kurtosis-related parameters exhibit a better diagnostic performance than do skewness-related parameters.

ADC: Apparent diffusion coefficient; ROI: Region of interest.

Aligned with this finding, numerous authors have documented that kurtosis is more directly correlated to the underlying structural, physiological, molecular, and metabolic changes that occur during tumor progression than skewness[45]. This may be the reason why the kurtosis of ADC values has been used to indicate deviations from Gaussianity, even in the most challenging mathematical designs that predict the response to chemotherapy, such as radiomics analysis[46-48].

The results obtained from the ROC curved are partially supported by the estimated DORs, which were approximately 376 for both Δ%kurtosis and post-nCRT kurtosis. This means that for the cut-off points of Δ%kurtosis and post-nCRT kurtosis calculated here, the odds for positivity among subjects with a non-pCR was 376 times higher than the odds for positivity among subjects with a pCR. In the same way, Δskewness and post-nCRT skewness demonstrated respectable diagnostic performances with DOR values of 192.17 and 168.56, respectively. Although these values appear to be lower than DORs of Δ%kurtosis and post-nCRT kurtosis, the confidence intervals for these metrics clearly overlap, so we cannot conclude that the kurtosis-related parameters were statistically better than the skewness-related parameters using DOR.

Finally, this study confirm that ADC histogram analysis is a reproducible technique. Similarly, van Heeswijk *et al*[49] demonstrated that histogram-derived parameters had good interobserver agreement, with ICC values ranging from 0.80-0.98. This result supports the method's validity and suggests that it can be used in clinical practice. Furthermore, we utilized non-precise tumor delineation, which was quicker and produced comparable findings to those obtained by an expert radiologist's measurement, suggesting that this technique could be performed semiautomatically with an excellent interobserver agreement. This finding is very important when considering the implementation of histogram analysis

in routine clinical practice.

Our study had important limitations. First, this was a retrospective, single-center evaluation. We believe that the present study might serve as a foundation for larger prospective studies in the future. Second, we included only a small number of patients (n = 48), while no validation group was included (both restricting the conception of a predictive model by using a multivariate logistic regression analysis). Third, the patient numbers among the different histopathologic TRGs were not well balanced. Only 18 patients (38%) achieved a histopathologic complete response, which may have introduced an element of statistical bias. However, these patients achieved a strict pCR, underlying the high degree of accuracy of our metrics. Fourth, the parameters obtained from the hotspot ROI were not conclusive enough to predict treatment response in the present study. This result is still in significant disagreement with our prior work where we demonstrated a high diagnostic accuracy of the Δ%ADCmean when distinguishing a pCR in rectal cancer by choosing a cutoff value of 55%[26]. Differences in research methods might explain this discrepancy, but we sustain that it is more reliable to use volumetric ROIs than one slice ROIs.

In summary, although further studies are needed to address the limitations of the current work, we demonstrated the benefits of considering measures other than the ROI ADCmean to evaluate the response to therapy in patients with LARC. Moreover, kurtosis and skewness have been selected by many radiomics studies of rectal cancer, emphasizing the importance of first-order statistics features for the assessment of therapy response[47,50]. Our results support the importance of these parameters, but they also helped us to standardize both the extraction and analysis of the data collected, which is a crucial step when developing and validating our own multiparametric model to predict treatment outcomes.

CONCLUSION

Based on the DWI technique, some whole-lesion histogram parameters could provide valuable information when diagnosing rectal cancer. In particular, kurtosis and skewness might be a useful indicator in the preoperative evaluation of a pCR in rectal cancer. Understanding skewness and kurtosis of the ADC parameters is the simplest way to recognize the deviation of Gaussianity, which indicates tumor heterogeneity. Moreover, we demonstrated high interobserver reliability for measurements of all of the histogram-derived parameters analyzed in the current work, addressing the challenges associated with replication that are well-known among more complex predictive models. Further long-term studies are needed to determine the ultimate clinical utility of our results.

ARTICLE HIGHLIGHTS

Research background

Studies have shown that successful treatment of many tumors can be detected using diffusion-weighted magnetic resonance imaging (MRI) as an increase in the apparent diffusion coefficient (ADC). However, findings from rectal cancer have been limited. Therefore, the criteria used for tumor staging and surveillance are largely based on anatomic criteria at this time. Broadly, whole lesion histogram analysis of ADC aims to fill this gap, extracting and analyzing the higher quantitative data with the aim of more accurate, tumor-specific evaluation and characterization.

Research motivation

ADC histogram parameters reflect the distribution and variation of all voxels within the entire lesion, which reduce the subjectivity of region of interest (ROI) placement and improves repeatability in the quantitative ADC analysis. Previous studies have applied volumetric ADC histogram analysis to predict treatment response of squamous carcinoma, breast cancers, and ovarian cancers. No ADC histogram study thus far has focused on locally advanced rectal cancer (LARC).

Research objectives

We aim to evaluate the effectiveness of whole lesion histogram analysis of ADC in the prediction to neoadjuvant chemoradiation therapy (nCRT) response in patients with LARC.

Research methods

This was a retrospective study. We collected data of 48 consecutive patients with histologically confirmed LARC. All patients underwent a pre-treatment MRI for primary tumor staging and a second restaging MRI for response evaluation. The sample was distributed as follows: responders (R), n = 18; and non-responders (non-R), n = 30. Eight parameters derived from the histogram analysis of ADC, as well as the ADCmean from the hot spot ROI, were obtained and compared between R and non-R. The diagnostic accuracy in the prediction of treatment response of all variables included in the present study was calculated as well.

Research results

Post-nCRT kurtosis, Δ%kurtosis, post-nCRT skewness an Δskewness exhibited the highest diagnostic performance in predicting a good response to nCRT.

Research conclusions

The results of our study support that histogram-parameters derived from ADC values can be used to stratify good responders into studies exploring individualized, less extensive treatment regimens, such as the omission of radiotherapy and less extensive surgery, or even deferral of surgery.

Research perspectives

We need to expand the sample size to confirm further the diagnostic accuracy of kurtosis and skewness. In addition, the long-term outcome of this analysis should be a radiomic model for predict treatment response in rectal cancer.

Abstract

BACKGROUND

Liposarcoma is one of the most common adult mesenchymal tumors but is uncommon in the gastrointestinal tract and extremely rare in the stomach. Furthermore, the histological subtypes of liposarcoma usually reported in the stomach are well-differentiated or myxoid, and few reports have been issued on small-sized gastric liposarcomas resected endoscopically and followed up. Herein, we report a case of primary gastric dedifferentiated liposarcoma (DL) that was resected endoscopically.

CASE SUMMARY

A 67-year-old female Korean patient was referred to our institution for further evaluation of a gastric submucosal tumor (SMT) located in the lesser curvature of the gastric body by esophagogastroduodenoscopy. Endoscopic ultrasound revealed a well-circumscribed, slightly heterogeneous, isoechoic, 17 mm × 10 mm sized mass originating from the third sonographic layer. Computed tomography showed no evidence of significant lymph node enlargement or distant metastasis. Endoscopic resection was undertaken using the snare resection technique after mucosal precutting to provide a definitive histopathologic diagnosis, which proved to be consistent with DL, based on its morphology and the immunoexpressions of MDM2 and CDK4. The patient was planned for surgery because the deep resection margin was positive for malignancy. After declining any invasive procedure or adjuvant treatment, the patient was placed under close follow-up, and at one year after endoscopic resection, remained disease free.

CONCLUSION

This is the first reported case of a small primary gastric DL resected endoscopically and followed up. This report demonstrates that when diagnosis of a SMT is uncertain, the use of invasive techniques, including endoscopic resection, should be considered.

Key Words: Gastric liposarcoma; Dedifferentiated liposarcoma; Submucosal tumor; Endoscopic resection; Case report

Core Tip: Liposarcoma is uncommon in the gastrointestinal tract and rarely encountered in the stomach. Furthermore, the dedifferentiated histologic subtype has not been previously reported in the stomach in the English literature. We experienced a case of a small (1.7 cm) primary gastric dedifferentiated liposarcoma, which was resected endoscopically. This report cautions that if a diagnosis of submucosal tumor is uncertain, the use of aggressive techniques, including endoscopic resection, should be considered.

INTRODUCTION

Liposarcoma is one of the most common adult soft tissue sarcomas and has a peak incidence between the ages 50 and 65 and a prevalence of 15%-20% among all sarcoma patients[1]. There are four histological subtypes of liposarcomas[2]. Atypical lipomatous tumor/well-differentiated liposarcoma (WDL) is the most common subtype followed by dedifferentiated liposarcoma (DL), which frequently occurs in retroperitoneum[3,4]. The myxoid and pleomorphic types usually present in the extremities [5]. Thus, liposarcoma usually arises in deep soft tissues of the proximal extremities, retroperitoneum, or trunk[6], and is encountered in the gastrointestinal tract in only 2% of cases[7].

The majority of liposarcomas of the alimentary tract arise in the esophagus[8], and liposarcomas originating at more distal sites, such as stomach, small intestine, and large intestine, are rare[9]. Less than 40 cases of primary liposarcoma of the stomach have been described in the medical literature, and the most reported histological subtypes of gastric liposarcoma are WDL and myxoid liposarcoma[10]. In fact, no report on DL of the stomach has been published in the English literature, though one case report on DL of the gastroesophageal junction was issued in 2018[11]. Here, we describe the first case of a small primary gastric DL resected endoscopically and provide a review of the literature.

CASE PRESENTATION

Chief complaints

A 67-year-old female Korean patient was referred to our institution for further evaluation and treatment of a gastric submucosal tumor (SMT) incidentally discovered by esophagogastroduodenoscopy (EGD) during a routine medical check-up.

History of present illness

The patient had experienced no abdominal pain or discomfort.

History of past illness

She had a history of breast conserving surgery due to breast cancer 6 years previously.

Personal and family history

The patient had diabetes and was being treated with oral hypoglycemic agents. She was a non-smoker and non-alcohol drinker and had no significant family history.

Physical examination

Physical examination was unremarkable, and her abdomen was soft, nontender, and nondistended with no palpable mass.

Laboratory examinations

Laboratory tests, which included common serum tumor markers such as carcinoembryonic antigen (CEA) and carbohydrate antigen 19-9 (CA 19-9), were normal.

Imaging examinations

EGD revealed a SMT-like protruding lesion of approximately 15 mm diameter located in the posterior wall of the lesser curvature of the distal part of the gastric body (Figure 1A). The lesion was covered with normally appearing mucosa except for focal mucosal erythema and depression over the lesion. Gastric endoscopic ultrasonography (EUS) examination demonstrated a well-demarcated mass, which measured 17 mm × 10 mm, located in the third layer of the gastric wall. The echo pattern of the mass was slightly heterogeneous and isoechoic (Figure 1B), but its EUS appearance was insufficient for diagnosis. The differential diagnosis included lipoma, neuroendocrine tumor, and ectopic pancreas. Initial biopsy specimens obtained at the site of the focal mucosal erythema and depression were negative for a neoplasm. Computed tomography (CT) of the abdomen showed a well-enhanced, intraluminal protruding polypoid lesion arising from the gastric body but no evidence of lymph node enlargement or distant metastasis (Figure 2).

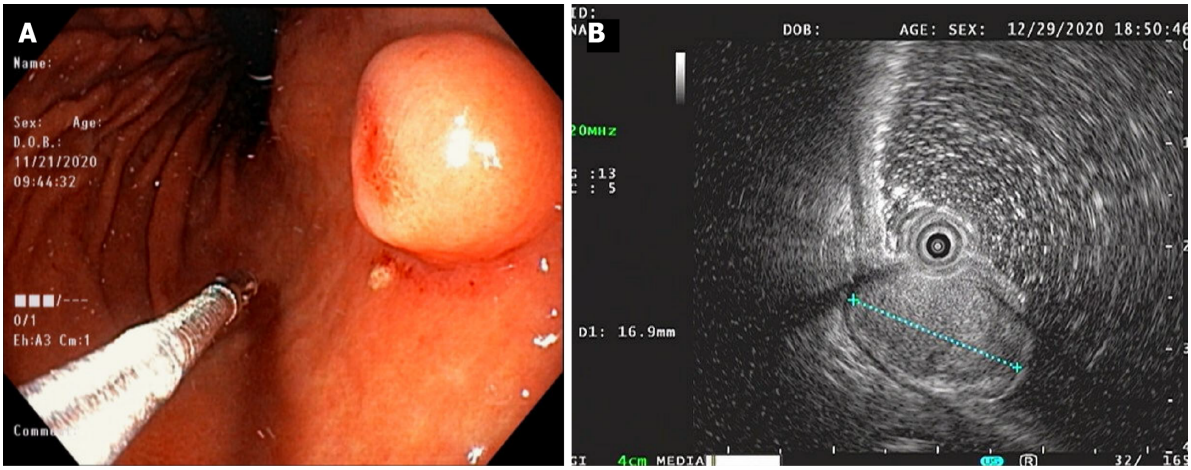
FINAL DIAGNOSIS

After initial work-up, endoscopic resection was conducted using the snare resection technique after mucosal precutting for a definitive histopathologic result (Figure 3). At gross examination, the tumor was whitish yellow, well-shaped, and solid. Histopathologic examination showed the tumor was located submucosally and primarily composed of spindle-shaped atypical cells with pleomorphic and hyperchromatic nuclei and indistinct pale cytoplasm (Figure 4A-D). Deep resection margins were positive for tumor. Immunohistochemical staining performed for the differential diagnosis of gastrointestinal stromal tumor, schwannoma, leiomyosarcoma, malignant melanoma, and any poorly or undifferentiated sarcoma, revealed tumor cells were negative for CD117, DOG1, CD34, SMA, S-100, Desmin, HMB45, and SOX10, but positive for MDM2 and CDK4 nuclear staining (Figure 4E and F). Based on these findings, the histopathological diagnosis was consistent with DL.

TREATMENT

The patient was planned for surgery because the deep resection margin was positive for DL, but declined any invasive procedure or adjuvant treatment.

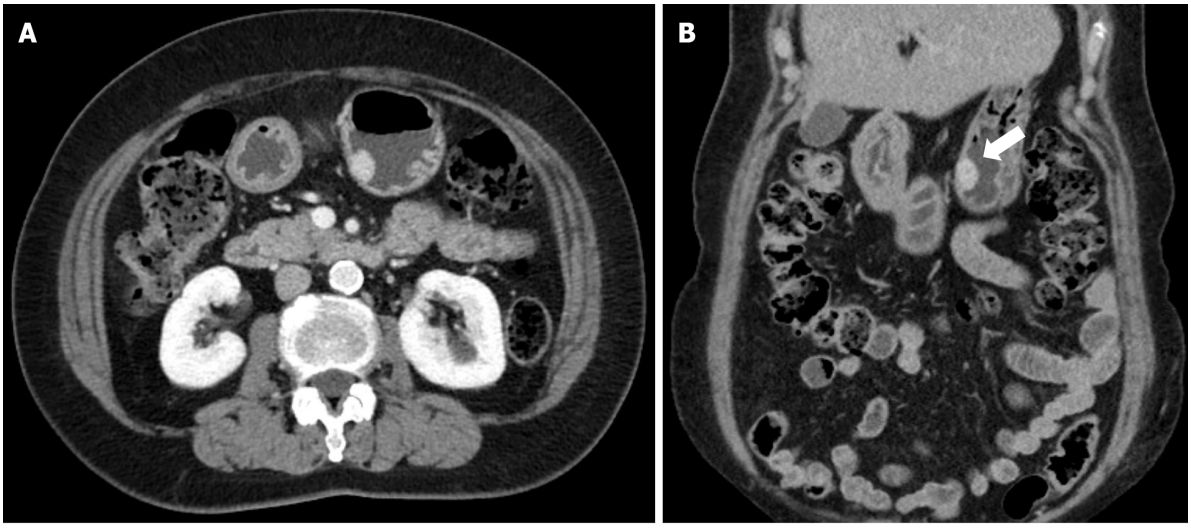
OUTCOME AND FOLLOW-UP



She remains under close follow-up, which includes biannual CT scanning and EGD, and at one year after endoscopic resection remained disease free.

DISCUSSION

Although they are the most common mesenchymal neoplasms, liposarcomas are rarely found in the gastrointestinal tract. Since the disease was first described by Abrams *et al*[12] in 1941, fewer than 40 cases of gastric liposarcoma have been reported in the literature worldwide[10]. The etiology of gastric liposarcoma remains uncertain, though some patients have a family history of soft tissue neoplasms, which suggests the involvement of genetic factors[13]. Gastric liposarcomas originate due to the proliferation of undifferentiated mesenchymal cells within submucosa and the tunica muscularis layer of stomach, and an exophytic growth is typical[10,14]. Most gastric liposarcomas are located in the antrum or lesser curvature.



As is the case for other soft tissue sarcomas, there are no characteristic clinical findings[15], and patients may remain asymptomatic for years. Symptoms depend primarily on tumor location and size and the presence or absence of ulceration. The most common symptoms are a palpable mass, mechanical obstruction, and gastrointestinal bleeding. In general, nonspecific symptoms are the main cause of delayed diagnoses, and thus, most liposarcomas are large at diagnosis. However, our patient underwent regular biennial EGD under a national cancer screening program, and the small SMT was detected early. Furthermore, endoscopic resection performed for a definite diagnosis resulted in the diagnosis of a small, asymptomatic gastric liposarcoma.

The characteristic histological features of liposarcoma are the presence of immature fat cells and lipoblasts[14]. Liposarcomas are classified histologically as WDL, DL, myxoid/round cell liposarcoma, or pleomorphic liposarcoma[2], and considerations of histological subtype are important during the disease course. While DL, round-cell, and pleomorphic liposarcomas are high-grade aggressive tumors with the ability to metastasize, WDL and myxoid liposarcomas are low-grade tumors that progress

more slowly[3,5]. Most of the gastric liposarcomas reported have been of the well-differentiated or myxoid histologic subtypes[10], and DL arising in the stomach has not been previously reported in the English literature; although a case of DL of heart and stomach was reported in 2017[16]. Notably, in this report, histopathological examination failed to determine that the primary lesion was located in the stomach. In addition, one case of primary DL of the gastroesophageal junction has been reported[11]. Thus, to the best of our knowledge, this is the first reported case of primary gastric DL.

DL is defined as a combination of WDL and high-grade sarcoma that displays evidence of non-lipogenic differentiation like undifferentiated high-grade pleomorphic sarcoma, fibrosarcoma, or myxofibrosarcoma[17,18]. DL can occur *de novo* (90% of cases) or as recurrence from a preexisting WDL (10% of cases)[19]. If DL develops from the transformation of a preexisting WDL into non-lipogenic sarcoma, dedifferentiation develops in 20% of the first and 44% of the second local recurrences and has been shown to be associated with poor progression and metastasis[5]. The histologic diagnosis of DL is generally based on the identification of WDL areas, which were scarce in our patient. In these cases, the differential diagnosis of any poorly-differentiated or undifferentiated sarcoma is important, and MDM2 and CDK4 immunohistochemical staining or FISH testing for amplification of the MDM2 and CDK4 genes is diagnostically helpful[20]. In our patient, DL was confirmed by CDK4 and MDM2 immunostaining.

Figure 3 Process of the endoscopic resection. A: Marking outside the lesion; B: Injection of saline–epinephrine for submucosal lifting; C: Circumferential mucosal incision and partial submucosal dissection; D and E: Resection using a snare; F: Resected tumor.

DL often exhibits abdominal cavity involvement usually of retroperitoneum, and an intraperitoneal origin is extremely rare[3,21,22]. When DL occurs inside the abdominal cavity it presents as a space-occupying mass lesion. The pathognomonic findings of DL in CT and magnetic resonance images are a heterogeneous, non-lipogenic, encapsulated mass[23], which are sufficient for diagnosis and obviate the need for needle biopsy. In our patient, because DL arising from the gastric wall presented as a small gastric SMT, CT was not diagnostically useful. Although EUS is considered the most useful modality in terms of defining the presumptive nature of SMT, our case demonstrates the difficulty of differentiating benign and malignant SMT by EUS alone, particularly when a lesion is small. Lesion echogenicity is also worth mentioning. Unlike the hyperechogenic EUS feature of other pathologic types[10,24,25], our case showed isoechoic EUS features, which appeared to be related to a sparsity of immature lipocytes or lipoblasts as the WDL area was extremely limited in our patient. DL seems to have a better prognosis than other high-grade sarcomas, especially in terms of its metastatic potential. Yet, careful long-term follow-up is essential because approximately 40% of DLs recur locally, 17% metastasize, and 28% of patients eventually die of the disease[1]. Surgery remains the treatment of choice for DL, and it is crucial that the tumor be completely removed[4], though the efficacies of targeted chemotherapy and radiotherapy are being investigated[26].

CONCLUSION

Liposarcoma is uncommon in the gastrointestinal tract and rare in the stomach, and primary DL in the stomach is extremely rare but should be considered in the differential diagnosis of any poorly-differentiated or undifferentiated sarcoma. The reasons why this case report is valuable are: (1) It presents the first reported case of a small primary gastric DL, resected endoscopically, and followed up; and (2) it cautions that if a diagnosis of SMT is uncertain after initial examination by EGD, EUS, and/or CT, the use of aggressive techniques, including endoscopic resection, should be considered.

Abstract

We have recently read with interest the mini-review article "Therapeutic endoscopy for the treatment of post-bariatric surgery complications". The abovementioned article is a brief overview of the different endoscopic modalities employed in the management of bariatric surgery complications and represents an important decision support tool for clinicians to improve their current practice. Although we appreciate the endeavor of Larsen and Kozarek, based on our in-depth analysis, we came across several minor issues in this article; thus, we present our comments in this letter. In case the authors contemplate these comments in their relevant research, we believe that their contribution would be considerable for future studies.

Key Words: Endoscopic treatment; Bariatric surgery; Complications; Obesity; Sleeve gastrectomy; Roux-en-Y gastric bypass

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Over the last decade, the incidence of bariatric surgery has substantially increased. Despite advances in surgical techniques, postoperative complications emerge and require a multidisciplinary approach. Currently, there is no standardized guideline-based algorithm for managing bariatric complications (BC); however, minimally invasive treatments are generally preferred over reoperations. Endoscopic procedures provide minimally invasive options to manage BC. However, their exact role has not been completely delineated. The article by Larsen and Kozarek successfully addressed this issue; however, we identified several limitations that require further consideration. Therefore, we would like to share our views on this interesting review.

TO THE EDITOR

We read with great interest the mini-review article "Therapeutic endoscopy for the treatment of post-bariatric surgery complications"[1]. In this article, Larsen and Kozarek[1] provided a concise overview of the role of endoscopy in the management of adverse events complicating the three most common types of the currently performed bariatric surgeries including Roux-en-Y gastric bypass, laparoscopic adjustable gastric band, and sleeve gastrectomy. From the extensive list of bariatric complications (BC), the authors confined their analysis only to those that are amenable to endoscopic treatment such as postoperative anastomotic strictures, leaks, fistulae, choledocholithiasis, weight regain, and band erosion. The salient highlights of this review were that the authors, by summarizing the relevant literature and incorporating their own clinical experience, were able to not only delineate the role of therapeutic endoscopy in the BC management but to also provide clinicians with practical tips that are expected to improve their daily practice. However, the most striking point of this article was that the authors holistically approached every referred complication from epidemiology to endoscopic treatment, highlighting areas that need to be further investigated. Therefore, we believe that this article has strong reference and practical value for future studies. Nonetheless, through our in-depth reading, we came across several limitations and anticipate a discussion with the authors.

First, by carefully analyzing the author's list of BC, we noticed that the endoscopic management of post-operative gastrointestinal bleeding (GIB) was not discussed in this review. The reason behind this exclusion was not mentioned by the authors. However, we regard this omission as a limitation of this article because the endoscopic management of GIB is challenging in bariatric patients. This occurs because the altered postoperative anatomy and the time interval of the bleeding episode from the operation impose restrictions not only on the type of the endoscopic equipment that would be used to approach the site of bleeding but also on the modality that would be used to achieve hemostasis. For example, standard endoscopes may not be able to reach sites of bleeding at the biliopancreatic limb or beyond the gastro-jejunal anastomosis in patients who underwent gastric bypass, whereas thermal ablation methods may cause unfavorable outcomes such as perforation in patients with freshly stapled anastomosis[2,3]. Considering these challenges, we believe that the endoscopic management of GIB has particular importance for the clinicians involved in the management of bariatric patients, and we suggest it to be supplemented in this mini-review.

Another limitation of this article is that the authors did not make clear to the reader the way they selected the studies included in this review. Although they successfully summarized the major findings of several reference studies, by performing our own literature search, we identified several omissions. For example, in the management of bariatric leakage and fistulae, the authors did not discuss the results of the most recent meta-analysis written by Rogalski *et al*[4] on the effectiveness of self-expandable stents, clipping, and tissue sealants. As a result, the authors did not make any reference to the use of fibrin glue as an alternative modality for fistulae closure in their review[4]. Likewise, by not including in their summary of evidence two reference studies on the effectiveness and safety of bougie dilations in the management of anastomotic stenosis, the authors did not discuss all available modalities that could be used as alternative options to balloon dilations[5,6]. We believe that the abovementioned information is important for the reader to acquire a complete overview of the pleiotropic role that endoscopy can play in the management of BC and, thus, needs to be supplemented.

The final limitation of this article refers to the different endoscopic techniques that can be used by clinicians to achieve biliopancreatic access in bariatric patients who underwent gastric bypass. Based on the included studies and their own experience, the authors referred to three techniques for performing endoscopic retrograde cholangiopancreatography (ERCP) in bariatric patients, including the overtube-assisted enteroscopy technique, the lap-assisted transgastric, and the endoscopic ultrasound-directed transgastric technique, with the first technique being their first-line option for most indications. However, considering that not all centers managing bariatric patients can perform these techniques, we performed our own literature search and came across an additional option. Specifically, we found that in bariatric patients who underwent gastric bypass, the biliopancreatic access to the excluded gastrointestinal part can be also achieved through the gastrocutaneous tract created after the removal of a gastrostomy tube without the need for reoperation or special equipment. This technique is known as gastrostomy-assisted ERCP, and it is performed in 3 steps. The first step includes the endoscopic insertion of the gastrostomy tube, which stays in situ for 5–14 d until the maturation of the tract. Then, the tube is removed, and the tract is dilated with a balloon to an extent that will allow the passage of the duodenoscope. After completion of the dilation of the tract, ERCP can be repeatedly performed[7]. Given the wide availability of gastrostomy tubes, we believe that the abovementioned technique has

particular value for the clinicians involved in the management of bariatric patients and should be supplemented in this review.

In summary, despite the abovementioned limitations, we believe that this article can be a valuable reference study, guiding clinicians in their daily practice. Thus, we offer our evidence-based considerations in this review to expand the value of the research basis that this article sets, leading to more comprehensive future studies.

Abstract

Inflammatory bowel diseases (IBDs) are chronic inflammatory disorders of the intestinal tract that have emerged as a growing problem in industrialized countries. Knowledge of IBD pathogenesis is still incomplete, and the most widely-accepted interpretation considers genetic factors, environmental stimuli, uncontrolled immune responses and altered intestinal microbiota composition as determinants of IBD, leading to dysfunction of the intestinal epithelial functions. *In vitro* models commonly used to study the intestinal barrier do not fully reflect the proper intestinal architecture. An important innovation is represented by organoids, 3D *in vitro* cell structures derived from stem cells that can self-organize into functional organ-specific structures. Organoids may be generated from induced pluripotent stem cells or adult intestinal stem cells of IBD patients and therefore retain their genetic and transcriptomic profile. These models are powerful pharmacological tools to better understand IBD pathogenesis, to study the mechanisms of action on the epithelial barrier of drugs already used in the treatment of IBD, and to evaluate novel target-directed molecules which could improve therapeutic strategies. The aim of this review is to illustrate the potential use of organoids for therapy personalization by focusing on the most significant advances in IBD research achieved through the use of adult stem cells-derived intestinal organoids.

Key Words: Inflammatory bowel disease; Organoids; Intestinal epithelium; 3D cell cultures; Personalized medicine

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Intestinal organoids have helped to unveil knowledge about inflammatory bowel diseases pathogenesis, focusing on the genetic and epigenetic factors involved in the onset of these diseases, the altered intestinal epithelial cell (IEC) functions, and the interplay between IECs and other surrounding cells, including immune cells and the intestinal bacteria. Intestinal organoids are currently being evaluated in pre-clinical studies as pharmacological tools to better understand the specific mechanisms of action of already used drugs on the IECs and to identify novel pharmacological targets and approaches.

INTRODUCTION

Inflammatory bowel diseases (IBDs) are chronic inflammatory disorders of the gastrointestinal tract that have emerged as a growing problem in industrialized countries[1]. IBDs include Crohn's disease (CD) and ulcerative colitis (UC)[2], which can be distinguished by differences in genetic predisposition, clinical aspects, and risk factors[3], and by the location and nature of inflammation[4]. UC is restricted to the mucosal surface of the large intestine: It starts in the rectum and extends through the entire colon in a continuous manner[3]. The severity of symptoms depends on the intestinal areas involved in inflammation[4]: It usually occurs with bloody diarrhea with pus and mucus (often nocturnal and postprandial), fever, weight loss, abdominal pain, and signs of systemic inflammation[5]. CD is characterized by the involvement of both the small and large intestine; it most commonly affects the ileocecal region, the terminal ileum, the perianal area, and the colon, with segmental and transmural inflammation, fissuring ulcerations, non-caseating granulomas, strictures, abscesses, and fistulas[4,6,7]. The clinical presentation of CD depends on the location, extent, and severity of inflammation: Patients usually show postprandial abdominal pain, especially around the periumbilical area, bloody diarrhea, nausea, emesis, dysphagia, early satiety, and weight loss[7].

Although no curative treatment is available for these diseases, current therapeutic options aim at achieving an improvement in symptoms and can be divided in two different groups: The remission induction drugs, which are used to achieve clinical remission, and the maintenance drugs which sustain the clinical remission and prevent disease relapse[8]. Aminosalicylates are administered as first-line agents to treat mild to moderately active UC. They exert their anti-inflammatory activity by binding to the peroxisome proliferator-activated receptor[9]. Glucocorticoids are used for inducing remission; when bound to their receptor, they modulate the expression of inflammatory mediators and control inflammatory states[9,10]. The thiopurines azathioprine and mercaptopurine are efficacious for maintaining remission. Thiopurines are inactive prodrugs but their metabolites (thioguanine nucleotides) are responsible for causing immunosuppression, either by inhibiting the *de novo* purine synthesis or by incorporating into the DNA or RNA[9]. Infliximab and adalimumab, which bind the pro-inflammatory cytokine tumor necrosis factor (TNF), have been introduced both for inducing remission and for maintenance therapy[11]. Furthermore, other monoclonal antibodies such as vedolizumab, a selective α4β7 integrin inhibitor, and ustekinumab, an interleukin (IL)-12/23 p40 inhibitor, have been used as alternatives for patients who have failed or are intolerant to anti-TNF therapy[12]. Eventually, thalidomide, by selectively inhibiting TNF-α expression and suppressing TNF-α -induced nuclear factor-kappa B (NF-κB) activation, can be employed when patients do not respond to the standard therapies[9,13]. Despite the multiple therapeutic options, high interindividual variability in response to these drugs is evident, and genetic and epigenetic factors could play a key role in these differences[14,15].

IBDs are multi-etiological diseases: It is currently believed that uncontrolled immune response against intestinal microbiota, combined with environmental factors in genetically predisposed individuals, leads to bowel inflammation, perturbing the mucosal barrier and increasing intestinal epithelial cell (IEC) dysfunction[16,17]. However, even today, it is not completely understood which of these factors are the initiators of inflammation and which are contributors[18]. An altered intestinal architecture and abnormalities in the intestinal wall function have been associated with the onset of the disease[19].

The current models employed to study the intestinal barrier *in vitro* show many weaknesses: Stabilized cell lines, such as the human epithelial colorectal adenocarcinoma cells Caco2 or HT-29, do not reproduce the heterogeneous intestinal cell types[20-22] and do not represent IBD pathophysiology

[23]. Animal models are highly costly, require probands to be raised for weeks[5], and may not reflect human pathobiology, which may contribute to drug failure in clinical therapy[21,24]. Consequently, new models are necessary to better define the pathogenesis underlying IBDs and to find new clinical approaches in its treatment[25].

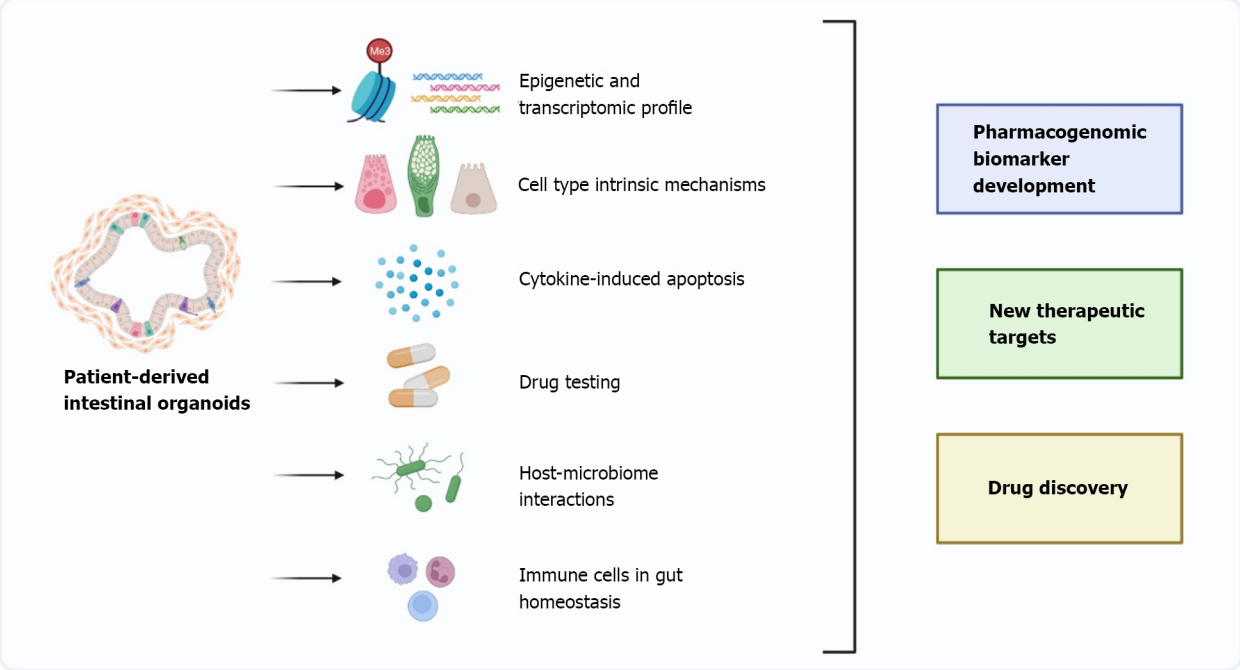
A major advancement in clinical research of human IECs is represented by the development of 3D organoid cultures, which re-create intestinal epithelial tissue *in vitro*[25] starting from adult stem cells (ASCs) or pluripotent stem cells (PSCs), such as embryonic stem cells or induced PSCs (iPSCs)[22]. These cells, grown under appropriate conditions and stimuli, self-organize and show the specific tissue structures, properties and functionality of the gastrointestinal tissue, forming a spheroid-like structure [26].

INTESTINAL ORGANOIDS

ASCs are located at the base of the intestinal crypts, which can be isolated from intestinal biopsies[27]. Intestinal crypts are embedded in a 3D membrane-like gel, such as matrigel, which mimics the extracellular matrix, and supplemented with an appropriate culture medium that is crucial for the development and expansion of ASCs, from which intestinal organoids can be obtained[5,28,29]. The organoids obtained *in vitro* with this method present only IECs (Paneth cells, goblet cells, enterocytes and enteroendocrine cells) derived from the crypt-based stem cells and are oriented with their apical side toward the lumen and their basolateral domain in contact with matrigel[25,28]. On the other hand, Spence *et al*[30], have demonstrated that it is possible to successfully generate intestinal organoids starting from iPSCs with a process that mimics organogenesis, and that this type of organoids may present not only epithelial cells but also mesenchymal cells, including myofibroblasts, and smooth muscle cells, thus providing a more accurate model[30,31]. This method is advantageous when it is necessary to generate organoids starting from tissues not easily accessible, reprogramming peripheral blood mononuclear cells or fibroblasts to a pluripotent state, thus obtaining iPSCs that can be differentiated to the tissue of interest by using dedicated protocols[29]. The reprogramming phase is complex and can be achieved using different methods. These methods are chosen according to efficiency, footprint (integration of viral vector sequences into reprogrammed cell genome), and type of somatic cells to be reprogrammed[32]. Subsequently, in order to obtain the different types of cells constituting the organ of interest, a microenvironment that mimics embryogenesis is required[33]. However, iPSC-derived intestinal organoids, unlike ASC-derived intestinal organoids, can acquire genetic and epigenetic variations. For example, mutations can occur during the reprogramming process or arise during the prolonged culture which can be conserved if they facilitate cell propagation[30,34,35].

After expansion, intestinal organoids can be employed in any experimental approach developed for cell lines, such as DNA-, RNA-, protein-based techniques, live imaging, drug screening and "omics" approaches (including single-cell RNA sequencing, MethylC sequencing, and mass spectrometry)[22]. For example, Yin *et al*[36] have combined genome-wide analysis of open chromatin by Omni Assay for Transposase-Accessible Chromatin-seq with the transcriptome data from RNA-seq. By correlating gene expression with open chromatin peaks, intestine-specific processes were identified. These results confirm the relevance of intestinal organoids to better define the genetic characteristics and, at the same time, to investigate crucial physiological and biochemical processes in the gut epithelium[36].

Organoid cultures are also a powerful model for genetic manipulation tools, such as transposon mutagenesis, siRNAs, and CRISPR-Cas (*e.g.*, knock-down, knock-out, knock-in, or overexpression)[29]. In particular CRISPR-Cas, along with transcription activator-like effector nuclease, and zinc finger nucleases technologies[37] allows the low frequency IBD-associated mutations to be gradually introduced into organoids derived from healthy patients, providing a better understanding of their effect on the epithelial cell functions[22,29]. In this way, intestinal organoids can be useful to explain in a more specific manner the effect of known genetic variants identified by genome-wide association studies[38] and can become crucial tools for IBD research, especially for the very early-onset IBD (VEO-IBD).



In addition, ASC-derived organoids can undergo extensive expansion in culture and maintain genome stability, which makes them suitable for biobanking[39].

In this review, we focus on the most significant advances in IBD research obtained using ASC-derived intestinal organoids (Figure 1).

Organoid models to study the genetic and epigenetic contribution on IBD epithelium

Several forms of IBD are polygenic and multiple susceptibility loci have been correlated to IBD onset [38]. Intestinal organoids retain the genetic and epigenetic signatures of the original tissue and can hence be employed for studying genetic and epigenetic-phenotypic profiles[22]. Moreover, the study of specific variants affecting the different cell types constituting the epithelium of IBD patients could identify sub-phenotypes of the disease that could help to understand their behavior and outcome[40].

Organoids also maintain the region-specific (duodenum/ileum/jejunum) gene expression of the gastrointestinal tract from which they derive[41]. Moreover, biopsies from IBD patients and derived

Figure 1 Intestinal organoid in inflammatory bowel disease research: The future of precision medicine. Patient-derived intestinal organoids are three-dimensional *in vitro* cell structures derived from stem cells that differentiate and self-organize into functional intestinal epithelium-specific cell types. For this reason, this model is suitable for different research approaches useful to inflammatory bowel disease (IBD) modelling and to study current and new therapeutic options. By retaining the disease-specific phenotypic defects, intestinal organoids can be employed to study epigenetic and transcriptomic profiles. In addition, the ability of intestinal organoids to differentiate into all the different cell types present in the intestinal epithelium makes this model useful to discover new cell-specific disease mechanisms. Furthermore, organoids can be used to study cytokine-induced apoptosis and to test currently used drugs to better understand their mechanisms. Co-culturing intestinal organoids with either microbiota components or immune cells helps to investigate IBD pathogenesis. Thanks to all these research approaches new pharmacogenomic biomarkers, new therapeutic targets and new drugs could be discovered, enabling the development of precision medicine for IBD patients. The image was created with https://biorender.com/.

intestinal organoids show similar expression levels of several IBD-marker genes. Dotti *et al*[42] have identified a set of genes, including *LYZ*, *CLDN18,* and *HYAL1,* upregulated both in the mucosa of patients with active UC and in the derived organoids[42]. Accordingly, the expression levels of genes encoding junctional proteins, such as *ZO-1*, also known as *tight junction protein 1*, *OCLN* and *CTNNB*, were similar in intestinal crypts from CD-patients and derived organoids.

VEO-IBDs are a subset of pediatric patients with IBD diagnosed before the age of 6 years, and up to 15% of these patients may have a rare monogenic disorder. Several defects in genes responsible for the proper intestinal epithelial barrier functions have been discovered, including *NOX1*[43] and *TTC7A*[44]. To study the impact of these mutations on IECs, Schwerd *et al*[44] generated human colonic organoids of patients affected by IBD carrying a *NOX1* p.N122H mutation[44]. These organoids show significantly less production of constitutive superoxide than organoids derived from healthy patients. This defect could favor the crypt colonization by luminal microorganisms since superoxide has an anti-adhesive or anti-invasive effect on bacteria. On the other hand, biallelic missense mutations in the *TTC7A* gene have been found in VEO-IBD patients, resulting in the activation of RhoA-dependent proteins which regulate cytoskeletal architecture by altering cell polarization and proliferation, as demonstrated in organoid cultures[45].

Among the genetic variants associated with the risk of developing IBD, polymorphisms in *NOD-2*, involved in the microbial pathogens recognition[46], and *ATG16L1*[47] genes play an important role. However, their biological functions in the intestinal epithelium of IBD patients remain unclear[47,48].

Organoids generated from *NOD2* knockout (KO) mice show increased intracellular *Escherichia coli* (*E. coli*) following metabolic stress[48], while the number of Paneth cells, known to have antimicrobial activity in the intestinal epithelium, is not affected. *Atg16L1*-deficient intestinal organoids derived from mice present a higher activation of STING-dependent type I interferon (IFN) signaling after IL-22 stimulation, leading to transient endoplasmic reticulum (ER) stress[49]. No data on patient-derived organoids with variants already associated with the increased susceptibility to IBD have been published yet.

Kelsen *et al*[50] reported transcriptomic differences from RNA sequencing between organoids derived from pediatric IBD (VEO and older onset) and non-IBD patients[50]. One of the most upregulated genes in organoids generated from pediatric IBD patients is *LYZ*, encoding for the antimicrobial protein

lysozyme, confirming previous results by Dotti *et al*[42] conducted on adult IBD patient-derived organoids[42]. In addition, an upregulation of the antigen presentation genes *HLA-DRB1* and *HLA-DRA*, necessary for T-cell activation, was demonstrated[50]. Similar results have been obtained by McDonald and Jewell[51] in mucosal epithelial cells by histological and immunohistochemical analysis on colonic biopsy specimens[51]. It is therefore possible that, since these genes are upregulated, the continuous and pathological activation of T cells may lead to the development of IBD[50]. Moreover, the same authors have found that the most downregulated gene in IBD-derived organoids was *CD177*[50], a glycosylphosphatidylinositol-anchored glycoprotein expressed in neutrophils and colon crypt cells.

Looking at the role of epigenetic modifications in IBD, a recent study showed changes in DNA methylation profiles in purified IECs from IBD, compared to non-IBD pediatric patients, that were strictly correlated to IBD pathogenesis[40]. To assess whether these alterations are also preserved in 3D models, intestinal organoids have been developed from children newly diagnosed with IBD and from healthy controls. Differences in DNA methylation and transcription profiles have been found between pediatric patient-derived organoids and controls. This suggests that IBD-associated intestinal epithelial-specific epigenetic alterations can be preserved in organoid cultures. Moreover, it has been observed that these epigenetic alterations are stable over time and therefore can contribute to chronic relapsing inflammation due to impaired IEC function[40].

These data suggest that intestinal organoids can be a promising tool to assess the molecular and functional effects on the intestinal epithelium of genetic and epigenetic variations related to IBD.

Intestinal organoids to study the epithelial barrier

The intestinal epithelium, consisting of different cell types (enterocytes, enteroendocrine cells, goblet cells, and Paneth cells), plays a fundamental role in maintaining intestinal homeostasis, acting as a physical and chemical barrier against pathogens through the production of mucus and antimicrobial peptides. A defect of these activities is evident in IBD patients, but it is still not clear whether these are primary defects or secondary effects of the inflammatory state[52].

In particular, reduced levels of trefoil factor 3 in goblet cells of IBD patients have been observed, which results in a decreased viscosity of the intestinal mucus layer and, as a consequence, the invasion of several IBD-inducing microorganisms. In IBD patients, decreased goblet cells number, diminished mucin 2 (MUC2) production, reduced mucus sulfation, and decreased mucus barrier have been detected [53-55]. Moreover, a decreased expression of constitutive defensins by Paneth cells in IBD patients has also been observed: A low expression of the constitutive human ß-defensin 1 has been demonstrated in patients with UC, while a low expression of human ß-defensin 2 and human ß-defensin 3 was demonstrated in those affected by CD, allowing bacteria to enter the intestinal mucosa[56].

Intestinal organoids can be manipulated to induce differentiation to definite lineages, allowing the study of cell-type-specific functions/dysfunctions in the context of the intestinal epithelium as described in the study conducted by Treveil *et al*[57]. Intestinal organoids can be specifically differentiated towards goblet cell or Paneth cell lineages by specific small molecules, with improved representation of these cell types within the entire organoid cell population[57]. In particular, organoids enriched in Paneth cells can be obtained with the addition of DAPT, a small molecule inhibitor of Notch signaling, whereas the differentiation towards the goblet cell lineage can be induced through the addition of DAPT and IWP-2, which inhibits Wnt signaling[58]. To characterize the effect of cell type enrichment and to predict key molecular regulators involved in Paneth cell and goblet cell specific functions, authors have used mRNA, miRNA, and lncRNA profiles[57]. Thanks to this approach, they predicted key factors involved in differentiation or maintenance of Paneth cells and goblet cells, such as Cebpa, Jun, Nr1d1, and Rxra specific to Paneth cells, Gfi1b and Myc specific for goblet cells, and Ets1, Nr3c1 and Vdr shared between them. Interestingly, several predicted regulators are associated with inflammation and IBD, indicating that their dysregulation can contribute to IBD pathogenesis[57].

Organoids derived from a mouse model of colitis were established to investigate the relationship between the differentiation state and cytokine secretion in the intestinal epithelium[59]. Undifferentiated mouse-derived intestinal organoids showed expression levels of pro-inflammatory cytokines and other inflammatory mediators higher than those differentiated into secretory or absorptive lineages. This suggests that the differentiation state of the intestinal epithelium, regardless of bacteria and immune cells, promotes the release of immunomodulatory factors and has a crucial role in maintaining intestinal homeostasis[59].

In IBD, cytokines play an important role in the pathological process. In particular, TNF-α, which is produced by immune and non-immune cells, through the activation of different pathways including NF-kB, can stimulate the production of other pro-inflammatory cytokines by macrophages and induce the death of Paneth cells, epithelial cells, and T cells[60]. TNF-α has an accepted role in the continuous immune stimulation in intestinal organoids by triggering several signaling cascades which lead to cell activation, survival, and gene expression[61]. It has also been confirmed that high expression of the TNF-α induced protein 3 gene, which encodes A20, a ubiquitin-editing enzyme and negative feedback regulator of NF-kB, promotes TNF-α dependent IEC death[62]. Intestinal organoids from A20 transgenic mice, in which A20 expression is driven by the Villin promoter, were more susceptible to TNF-dependent death. Moreover, after TNF-α addition, A20 transgenic organoids showed a strong caspase 3 and 8 expression whereas control organoids were unaffected, indicating that immune cells or gut

microbiota are not necessary for TNF-induced apoptosis of A20-expressing cells[62]. The authors demonstrated that this effect depended on receptor-interacting protein kinase 1 with its proapoptotic activity, and A20 was found to associate with the death-inducing signaling ripoptosome complex, potentiating its ability to activate caspase-8[62].

Grabinger *et al*[63] have found that both TNF-α receptors, TNFR1 and TNFR2, are involved in cell death in intestinal organoid models, although TNFR1 is the predominant mediator[63]. Indeed, the authors showed an almost complete abrogation of TNF-induced cell death in TNFR1-deficient organoids while organoids from TNFR2-deficient mice showed reduced cell death following exposure to TNF[63].

Ferrer-Picón *et al*[64] have observed that TNF-α reduces the response to butyrate of the intestinal epithelium by decreasing its uptake, oxidation, and consumption[64]. The authors have used differentiated epithelial organoids from IBD patients, which mimic the phenotype of cells residing on the luminal side of the crypt and that are directly exposed to bacteria and their metabolites, and non-IBD controls treated with butyrate and TNF-α. The expression of the butyrate transporters monocarboxylate transporter 1 (encoded by *SLC16A1*), *ABCG2,* and the butyrate receptor *GPR43* was evaluated. After TNF-α treatment, they have found a downregulation of *SLC16A1* and *ABCG2* genes, as well as an increase of *GPR43* gene expression in both IBD and non-IBD derived organoids, indicating that the response to butyrate is not intrinsically altered in IBD patients and that inflammation affected butyrate uptake and oxidation[64].

TNF-α also contributes to barrier deterioration by activating the myosin light chain kinase, which alters tight-junctions (TJ), and, therefore, intestinal permeability[63]. TJ dislocation seems to be a crucial event in IBD pathogenesis as confirmed by Hall *et al*[65]. These authors have demonstrated that the downregulation of the creatine transporter (*SLC6A8*, also known as CRT), observed in IBD patients, is associated with alterations in TJ architecture[65]. In detail, CRT-KO intestinal organoids show a leaky TJ profile, a stressed metabolic phenotype, and a diminished epithelial barrier formation. This might be caused by a decreased creatine uptake, which is required by actin and myosin to regulate TJ structure and intestinal barrier integrity[65].

The role of inflammation in the intestinal epithelial barrier function has also been investigated by the FITC-dextran 4kDa (FD4) uptake assay, using murine intestinal organoids exposed *in vitro* to dextran sodium sulfate (DSS)[66]. DSS is a sulfated polysaccharide with variable molecular weights which causes UC-like pathologies due to its toxicity to colonic epithelial cells, which results in compromised mucosal barrier function. DSS caused a decline in the absorption ability of the inflamed-organoid intestinal barrier, confirmed by FD4 altered intestinal concentration and reduced translocation to the lumen. DSS also caused increased production of TNF-α, IL-6, and other important factors involved in the epithelial barrier disruption, including matrix metallopeptidases MMP10, MMP3, the chemokine ligand CXCL1, and the proteasome-dependent protein degradation ubiquitin D (UBD)[66].

Alteration in the autophagy process within different cellular compartments could potentially lead to an inflammatory response in the gut, increasing intestinal barrier dysfunction and IBD development [67]. Autophagy is a housekeeping process that maintains cellular homeostasis, allowing the degradation and recycling of cellular components[68,69]. Autophagy is also dysregulated in intestinal organoids from patients with IBDs and in mouse intestinal organoids lacking *ATG16L1*, which show decreased Paneth cell levels and increased ER stress-induced cell death, exacerbated when cultured with TNF-α[49,68]. Additionally, recent studies have suggested a novel process by which altered autophagy is associated with IBDs: As already observed in other autophagy-deficient cellular models, such as ATG5-/- and ATG16-/- mouse embryonic fibroblast cells, Atg7−/− autophagy-deficient mouse intestinal organoids show increased levels of argonaute 2, a crucial effector of miRNAs whose upregulation in patients with IBD results in the altered expression of genes implicated in IBD pathogenesis.

Different studies have also demonstrated a crucial relationship between unresolved ER stress, failing autophagy, and pro-inflammatory mediators in IECs during active IBD. For example, IL-22 potentiates the ER stress response caused by other cytokines *via* the activation of STAT3 and induces IEC apoptosis in synergy with IL-17A[49]. Moreover, IL-22 treatment reduces the LGR5+ intestinal stem cell (ISC) levels and amplifies the number of transit-amplifying (TA) cells, an undifferentiated population in transition between stem cells and differentiated cells, by inhibiting Wnt and Notch signaling pathways [70]. All these findings show that IL-22 decreases organoid survival by limiting ISC expansion and promoting TA progenitor proliferation[71].

Intestinal organoids to study the relationship between IECs and the surrounding cells, including immune cells and microbiota

IECs are involved in complex crosstalk with other cell types, including immune and mesenchymal cells. Intestinal organoids have been used for in-depth *ex vivo* analyses of interactions between the epithelium and lamina propria cells[29] and between the epithelium and the underlying immune cells[22].

Co-culturing intestinal organoids with other specific cell types may help to investigate IBD pathogenesis. For example, Ihara *et al*[72] have established a mouse organoid–mononuclear phagocyte (MP) co-culture to study how MPs, such as dendritic cells and macrophages, accumulate in the inflamed intestine causing an imbalance between intestinal immune responses and microbiota and mediating

several interactions with other intestinal cell types[72]. The authors have revealed that excessive E-cadherin, a cell adhesion molecule crucial in the formation of adherens junctions (AJs), expressed by MPs, mediates their adhesive interactions with the epithelium, activating Notch signaling and perturbing physiological IEC differentiation and epithelial homeostasis, with the promotion of goblet cell depletion, mucus layer disruption, dysbiosis, and gut inflammation[72].

Intestinal organoids are also useful to study the interactions between IECs and luminal bacteria, involved in intestinal inflammation: Abnormal growth of a specific microorganism leads to unbalance of the gut microbiota, which may initiate intestinal inflammatory diseases, including IBD[73]. Dysregulated immune responses towards the gut microbiota induce a tissue-damaging chronic inflammatory state, leading to barrier dysfunction, infections, and intestinal inflammation[74]. Therefore, the microbiota-epithelial interaction has been investigated to understand IBD pathogenesis. Intestinal organoid models have emerged as a helpful tool to study this crucial interaction *in vitro,* showing that differences in IEC behavior can contribute to the altered composition of the gut microbiome, barrier permeability, and microbiome interaction in IBD patients[75]. This has been confirmed by Leber *et al* [74], who have used mouse intestinal organoids to study the nucleotide-binding oligomerization domain, leucine-rich repeat containing X1 (NLRX1) as a regulator of gut homeostasis, involved in the control of the immune response, microbiota composition, and metabolism[74]. Intestinal organoids derived from NLRX1-deficient mice show an altered glutamine metabolism because of increased glutamate dehydrogenase activity compared to intestinal organoids obtained from WT mice. With this abnormal host glutamine metabolism, intestinal bacteria may be less exposed to amino acids, and this may lead to increased proliferation of microorganisms capable of amino acid production[75].

In addition, it has recently been found that organoids derived from mice with highly simplified microbiota are different from those derived from mice harboring complex-conventional microbiota[76]. For example, organoids derived from mice harboring limited bacterial species have an accelerated proliferation rate, are less subjected to cell death, and respond differently to pro-inflammatory stimuli, in particular TNF-α stimulation. The effects of different concentrations of TNF-α on these two organoids have been studied: ISC growth from mice with limited bacterial species was inhibited only by the lower concentration of TNF-α tested compared to that of mice with complex bacterial species, in which growth was inhibited by all concentrations tested. Moreover, with increased concentration of the cytokine, the inhibition decreases, and, conversely, growth of organoids from mice with limited bacterial species is promoted. These results suggest that the microenvironment, such as microbial composition, of the intestinal segment from which the organoids are originated could affect ISC replication and, as a consequence, organoid growth, and could also affect the response to different concentrations of cytokines, such as TNF-α[76].

Intestinal organoids can be employed to evaluate the contribution of luminal pathogens to IBD pathogenesis. For example, the cytotoxic effect of *Clostridioides difficile* toxins on the small intestinal epithelium was studied using a jejunal-derived intestinal organoid culture developed by Engevik *et al* [77]. These organoids show high expression of the toxin A and the binary toxin *C. difficile* transferase receptors, and as a result, are more sensitive to toxin A than to toxin B, the other toxin produced by *C. difficile*, developing mucosal damage and an altered permeability[77].

In consideration of the aforementioned data, organoid models must be implemented with the intestinal microbiota to determine the specific effect of bacteria on the epithelial barrier[22]. However, organoid cultures form a spheroid with an enclosed lumen and, therefore, pathogens introduction is difficult[78]. For this reason, different techniques have been generated to better introduce microorganisms into the intestinal organoids. For example, Saxena *et al*[79] have mechanically disrupted the organoids to promote bacterial exposure; however, polarization was lost and, consequently, both the apical and basolateral domains were in contact with bacteria[79]. Leslie *et al*[80] have developed microinjection techniques to introduce bacteria into organoids but these procedures are difficult to perform and to replicate[80]. According to several studies, the culture of intestinal organoids in monolayer could overcome these limits since it preserves the major properties and factors of intestinal epithelium *in vivo*; hence, 3D organoids have been mechanically disrupted and seeded on transwell membrane gels to form a selective and permeable layer, separating the apical and basal domain which are both directly accessible[29]. This important innovation shows the ability to manipulate the model system, introducing bacteria and viruses in the culture medium on the luminal side, and represents a powerful alternative to other 2D models of primary epithelial cells by mimicking *in vivo* physiology and providing a lumen (apical side) and a lamina propria (basal domain)[29,75]. It has been demonstrated that the monolayer system successfully reflects the properties of intestinal epithelium *in vivo*, including epithelial barrier formation, polarization, and gene expression profiles[75]. The monolayer also reflects the aberrant permeability caused by pro-inflammatory cytokines, such as TNF-α and IFN-γ, which cause a mislocalization of both TJs and AJs and reduce their mRNA levels[81]. Another successful use of the organoid-derived monolayer has been demonstrated by Sayed *et al*[82]: These authors demonstrated that detection of high concentrations of the engulfment and cell motility protein 1 in the epithelium could be a diagnostic marker of dysbiosis and gut inflammation since it is a crucial intestinal bacterial sensor[82]. In addition, a co-culture of human intestinal organoid-derived monolayer and macrophages shows how epithelial and innate immune cells respond to pathogens[83]. In this model, macrophages have the capability to sense and interact with *E. coli,* when added to the apical side of IECs, by

improving their adherence properties and by promoting the generation of cell membrane projections to capture the pathogen. This system has provided an important tool to evaluate the host defense towards organisms[83].

INTESTINAL ORGANOIDS TO STUDY CURRENT THERAPIES

Intestinal organoid cultures have recently been employed to study the molecular mechanisms of action of already approved drugs (Table 1).

In IBDs, mucosal healing has emerged as a key prognostic parameter and represents the therapeutic goal in the treatment of these diseases[84]. Indeed, healing means suppression of inflammation, improvement of intestinal barrier by a dynamic interaction of cell regeneration, differentiation, and migration[19] and, consequently, sustained clinical remission, reduced rate of surgery, and lower incidence of potential long term complications such as colorectal cancer[85,86]. However, although a number of therapies have become available in recent years, IBD heterogeneity makes it difficult to obtain complete mucosal healing in order to avoid relapse, and it is not yet clear which is the optimal therapy for a specific patient. A better comprehension of the mechanisms involved in mucosal healing may contribute to ameliorating the therapeutic and clinical approaches currently used. For example, IL-10 KO mouse intestinal organoids, which spontaneously develop enterocolitis, and WT mouse intestinal organoids have been established to understand the different molecular interactions between azathioprine, 5-aminosalicylic acid, and the intestinal epithelium and the mechanistic aspects of mucosal healing[19]. In detail, the researchers have treated with TNF-α the WT and IL-10 KO organoids with and without 5-aminosalicylic acid and azathioprine and have investigated the expression levels of E-cadherin and desmoglein-2, which are closely related to the regulation of the intestinal barrier. TNF-α-treated WT organoids showed internalization and abnormal disruption of E-cadherin, while treatment with 5-aminosalicylic acid and azathioprine restored E-cadherin levels on cell membranes. On the other side, untreated IL-10 KO organoids resulted in defective E-cadherin membrane expression and increased cytoplasmatic expression, which was not further altered by TNF-α treatment. However, it was observed in both models that the effects on E-cadherin were greater with 5-aminosalicylic acid than with azathioprine treatment. Western-blot analysis confirmed that the two drugs impact only the re-distribution of proteins on the intestinal surface. Desmoglein-2 levels were reduced by TNF-α administration in WT models and restored only by 5-aminosalicylic acid whereas, in IL-10 KO organoids, desmoglein-2 expression was increased in all treatment groups by the activation of p38 mitogen-activated protein kinase pathway, a crucial factor in the maintenance of epithelial barrier[19].

Intestinal organoids have also been employed to study the effects of the thiopurine thioguanine on the replication of rotavirus, a *Reoviridae* family virus that might play a role in the pathogenesis of IBD [87]. Although thioguanine is rarely used to treat IBD due to its adverse effects, it has been proposed in the treatment or prevention of rotavirus infection *via* Rac1 inactivation. Rac1 is a member of the Rho family of small GTPases, ubiquitously expressed, which mediates several cellular signaling pathways including actin reorganization, gene transcription, apoptosis, and redox signaling. Rac1 shows two conformational states, the inactive GDP-bound structure and the active GTP-bound form which exerts the biological functions. Several viruses use Rac1 in the active conformational form to infect cells, a process impaired by a loss-of-function of Rac1 by gene knockout or knockdown. It has been demonstrated that virus replication is interrupted after thioguanine treatment at a dose of 100 ng/mL in patient-derived rotavirus isolated from human intestinal organoids. This could be due to thioguanine metabolites, deoxy-6-thioguanosine phosphate and 6-thioguanosine phosphate, that can bind to Rac1, forming a complex and inhibiting the Rac1 activity[87].

Anti-TNF agents, in particular infliximab, have been established as the reference therapy to treat refractory IBD. However, whether anti-TNF agents have any direct effect on IECs remains unknown [53]. Recently it was demonstrated that treatment of organoids from UC patients with infliximab concurrently with TNF-α did not cause a clear effect on their viability or morphology but resulted in a significant reduction of UBD mRNA expression. UBD is a ubiquitin-like modifier involved in protein degradation that is upregulated in inflamed intestinal tissue. UBD mRNA expression pattern also correlated with protein levels, as confirmed by immunoblotting of organoid lysates[88].

Glucocorticoids have beneficial effects in restoring the epithelial barrier disrupted by cytokines. Xu *et al*[89] studied the epithelial barrier function of ASCs derived intestinal organoids of CD patients and the role of glucocorticoid treatment[89]. Using confocal microscopy, they evaluated the permeation of the FD4 marker, which is used to measure macromolecular paracellular permeability from the basal to the luminal side of organoids treated with a cytokine mixture. After an increase in intraluminal FD4 concentration compared to the untreated, the authors exposed the organoids to the glucocorticoid prednisolone, which significantly reduced intraluminal FD4 permeation. In addition, prednisolone restored CLDN2 expression that was upregulated by the cytokine mixture[89]. This is crucial because CLDN2 is one of the most represented TJ components, forming cation-selective pores that make the intestinal barrier more permeable to ions and molecules and its expression is increased in CD patients biopsies[90,91]. The authors also found that the administration of mifepristone, a glucocorticoid receptor

Table 1 Molecular target identified by treatment of intestinal organoids with current therapies for inflammatory bowel disease

Molecular target	Treatment effect	Drug	Species	Ref.
E-cadherin	Re-distribution of protein on intestinal surface restored correct permeability	5-aminosalycilic acid, azathioprine	Mouse (IL-10$^{-/-}$)	[19]
Desmoglein-2	Restored physiological desmoglein-2 expression levels	5-aminosalycilic acid	Mouse (IL-10$^{-/-}$)	[19]
UBD	Restored physiological UBD expression levels	Infliximab	Human (UC patients)	[88]
CLDN-2	Restored physiological CLDN-2 expression levels	Prednisolone, tofacitinib	Human (CD and CRC patients)	[89, 92]
ZO-1	Re-distribution of protein on intestinal surface restored correct permeability	Tofacitinib	Human (CRC patients)	[92]

CD: Crohn's disease; CLDN-2: Claudin-2; CRC: Colorectal cancer; IL-10: Interleukin-10; UBD: Ubiquitin D; UC: Ulcerative colitis; ZO-1: Zonula occludens.

antagonist, reduced the beneficial effect of prednisolone, confirming that the effect is glucocorticoid receptor dependent[89].

A recent study published by Sayoc-Becerra and collaborators employed human colonic organoids to understand how tofacitinib treatment restores TJ architecture and epithelial barrier functions, achieving healing[92]. In addition to CLDNs, OCLN and tricellulin are induced by different pro-inflammatory mediators, such as IFN-γ. These proteins are highly expressed in the intestinal epithelium and control the paracellular transport of solutes, while ZO-1 regulates and assembles TJ structure. Therefore, the proper localization of these proteins is essential in the maintenance of the epithelial barrier function. Several genes are involved in regulating the epithelial barrier function, including genes that control the Janus Kinase-signal transduction and transcription pathway [Janus kinase-signal transducer and activator of transcription (JAK-STAT)]. The activation of JAK-STAT signaling induces the triggering of JAK1 and JAK2 and the phosphorylation of their downstream targets STAT1 and STAT3 which are associated with the upregulation of CLDN2, and the consequent altered permeability across the intestinal epithelium. Therefore, targeting the JAK-STAT pathway has become a new therapeutic approach in IBD, and tofacitinib has been approved as a pan-JAK inhibitor. The drug binds to the adenosine triphosphate binding site in the catalytic cleft of the kinase domain of JAK and inhibits the activation of JAK-STAT pathway. Tofacitinib has a direct effect on IECs, rescuing the permeability altered by INF-γ. After IFN-γ treatment, FD4 influx increases approximately 4-fold into the organoids, and the addition of tofacitinib restores the FD4 physiological flux. To better understand the specific mechanism of tofacitinib on IECs, ZO-1 and OCLN levels were evaluated by western blotting in intestinal organoids, but were unaltered after IFN-γ and tofacitinib treatments. These results suggest that tofacitinib is able to counter damages caused by IFN-γ on epithelial permeability by re-localization of TJ proteins rather than by increasing their expression[92].

Lloyd *et al*[93] have recently demonstrated for the first time the potential use of macrolides, in particular clarithromycin, in the treatment of IBDs[93]. Using human intestinal organoids generated from patients without evidence of IBD, these authors have demonstrated that, in addition to its antibiotic properties, clarithromycin shows anti-inflammatory effects in the intestinal epithelia, suppressing the increase in NF-kB nuclear levels induced by TNF[93].

INTESTINAL ORGANOIDS AS A RESEARCH TOOL FOR NEW POSSIBLE THERAPEUTIC APPROACHES

Recently, studies have been performed using mouse and human intestinal organoids to identify novel therapeutic targets and approaches for IBD treatment[21] (Tables 2 and 3).

The liver receptor homolog 1 (LRH-1) is a nuclear receptor that has been found in the intestinal crypts, where it promotes epithelial renewal by activating Wnt/β catenin signaling[94]. The use of human intestinal organoids has demonstrated the fundamental role of LRH-1 in intestinal epithelial homeostasis and cell survival, confirming the results derived from humanized mouse intestinal organoids in which the mouse *Lrh-1* is deleted, and the human *LRH-1* is expressed. Intestinal organoids from both CD patients and healthy controls have shown that LRH-1 overexpression abrogates TNF-α-mediated cell death and improves epithelial resistance to the effects of fluorouracil, a chemotherapeutic agent with known intestinal toxicity which has been used to mimic damaged mucosa, reducing intestinal inflammation and epithelial wounds[94]. The activation of LRH-1 is ligand-dependent and is carried out by signaling phospholipids, such as phosphatidylinositol trisphosphate, which has been demonstrated to bind with high-affinity LRH-1[95]. It has been demonstrated that modeling

Table 2 Novel potential molecular targets identified using intestinal organoids

Potential molecular targets	Effect	Species	Ref.
LRH-1	Improved resistance to pro-inflammatory mediators and induced mucosal healing	Humanized mouse (Lrh-1$^{-/-}$ LRH-1$^{+/+}$) and Human	[94]
PXR	Reduced NF-kB activity	Human (IBD patients)	[97]
IL-22-pSTAT3 SP	Restored tissue damage and intestinal homeostasis	Mouse (ATF3$^{-/-}$)	[98]
TGF-β SP	Arrested inflammatory signals	Mouse	[104]
SIRT2	Regulated Wnt/β-catenin SP	Mouse (Sirt2$^{-/-}$)	[105]

ATF3: Activating transcription factor 3; IBD: Inflammatory bowel disease; IL: Interleukin; LRH-1: Liver receptor homolog 1; NF-kB: Nuclear factor-kappa B; PXR: Pregnane X receptor; SIRT2: Human sirtuin protein 2; SP: Signaling pathway; STAT: Signal transducer and activator of transcription; TGF-β: Transforming growth factor B.

Table 3 Potential therapeutic approaches for inflammatory bowel disease treatment identified using intestinal organoids

Potential therapeutic approaches	Effect	Species	Ref.
Sex hormones	Decreased expression of ER stress markers	Human (UC female patients)	[100]
Naltrexone	Reduced ER stress levels, increased the expression of endogenous encephalins and endorphins	Human (IBD patients)	[101]
Bacillus subtilis (RZ001)	Promoted intestinal mucosa repair	Mouse	[102]
Bacterial indoleacrylic acid	Promoted anti-inflammatory cytokines secretion while inducing goblet cells differentiation	Mouse	[103]
Hyaluronan 35 kDa	Promoted epithelial wound healing	Mouse	[106]

ER: Endoplasmic reticulum; IBD: Inflammatory bowel disease; UC: Ulcerative colitis.

hydrophobic residues in the binding site of the receptor prevents ligand binding[96], resulting in a failed rescue of TNF-α-mediated cell death. This finding suggests that targeting LRH-1 could improve resistance to pro-inflammatory mediators and induce mucosal healing in IBD patients[94].

Intriguingly, pregnane X receptor (PXR), the main signal transducer in the intestinal response to xenobiotic stress, has been shown to reduce NF-kB activity, whose contribution in IBD pathogenesis is undisputed[97]. Intestinal organoids derived from patients with IBD were pretreated with TNF-α and then with the antibiotic rifampicin, a known PXR ligand. PXR inhibits the expression of several pro-inflammatory genes, especially in the IEC compartment, compared to the stromal and immunological compartments, and reduces IL-8 and IL-1β levels, which are NF-kB target genes. Therefore, the stimulation of PXR by rifampicin or other PXR ligands might be of interest as a novel therapeutic approach in IBD management, especially in patients in which hyper-activation of NF-kB pathway occurs[97].

Moreover, a novel IL-22-induced signal in IECs has been observed thanks to the use of organoids. IL-22 activates its downstream target, the activating transcription factor 3 (ATF3) which is actively involved in the IL-22-pSTAT3 signaling pathway to restore tissue damage and intestinal homeostasis [98]. Stimulation of IECs by IL-22 initiates a signal cascade leading to phosphorylation and consequent activation of STAT3 *via* the involvement of ATF3. This protein has been identified as an essential factor for IEC proliferation by directly controlling crypt regeneration and recovering and maintaining epithelial barrier functionality. To confirm these data, colon organoids from WT and ATF3$^{-/-}$ mice have been implanted into DSS-treated ATF3$^{-/-}$ mice colon through intra-rectal injection. Only mice transplanted with WT organoids showed a reduction in the inflammatory state with increased cell survival, reduced disease activity, recovered epithelial injuries, and improved colon integrity. Most importantly, inducing the IL-22 pathway can promote host defense and wound restoration and can mitigate disease progression and perpetuation[98]. However, several studies have also reported a critical role of the STAT3 signaling pathway, demonstrating that it suppresses the autophagy processes, causing bacterial invasion and intestinal inflammation[99]. Indeed, the inhibition of this pathway protects the *Salmonella*-infected-intestinal mouse-organoid model from bacterial-induced injury, reducing the pro-inflammatory cytokine levels and restoring the autophagy processes. Interestingly, persistent alteration in autophagy processes could lead to chronic intestinal inflammation, exposing the

intestinal epithelium to bacteria and pathogens[99].

In addition to IL-22, IL-28 has also emerged as a novel therapeutic approach by promoting mucosal healing and wound repair *via* the phosphorylation and activation of STAT1. This has been confirmed by using organoids derived from WT, IL28RA$^{-/-}$, and STAT1-lacking mice. IL-28 controls proliferations of intestinal crypts in WT organoids by activating IL-28RA and STAT1 signaling pathways, and induces the overexpression of several genes implicated in crucial functions, including the positive regulation of cytokine production, immune response, and wound healing. This suggests that the epithelial STAT1 phosphorylation by IL-28 balances gut homeostasis.

Of note, some pro-inflammatory cytokines have also been found to be negatively modulated by high levels of progesterone and estrogen released during pregnancy in IBD patients[100]. To clarify the effect of sex hormones, van der Giessen *et al*[100] have established intestinal organoids from UC females and mimicked the tissue inflammation with tunicamycin, which results in an increased expression of ER stress markers, including the 78 kDa glucose-regulated protein 78 (GRP78), CCAAT-enhancer-binding protein homologous protein (CHOP), and phosphorylated inositol-requiring enzyme 1 (IRE1). Specifically, GRP78 expression is decreased after progesterone addition, the stress-downstream target CHOP is reduced with estrogen alone or in combination with progesterone, and IRE1 phosphorylation is decreased upon treatment with estrogen, progesterone, or with their combination. In addition, IL-8 and IL-6, which are highly expressed in inflamed intestine, are modulated by hormones only in tunicamycin-treated organoids, thus suggesting that estrogen and progesterone decrease the stress-induced cytokine production. Moreover, sex hormones positively modulate the intestinal barrier by ameliorating TJ dynamics *via* the upregulation of CLDN1, CLDN2, and OCLN. A limitation of this study is the hormone concentration used *in vitro*, that was significantly higher than the *in vivo* hormone levels during pregnancy. However, a new possible clinical approach in IBD, applying treatment with sex hormones could be proposed[100].

ER stress has also been significantly reduced by a low dose of naltrexone, an opioid antagonist that acts on the μ-opioid receptor (MOR)[101]. This has been confirmed using intestinal organoids from patients with IBD treated with LPS, which induces the expression of GRP78, an important ER stress marker. Treatment with naltrexone reduced ER stress levels and increased the expression of encephalins and endorphins, endogenous agonists of opioid receptors. Interestingly, low doses of naltrexone induced clinical improvement in 74.5% of patients with refractory IBD and long-lasting disease remission in 25.5%. In addition, it has been reported that naltrexone is safe in pediatric IBD patients. The molecular mechanism by which naltrexone is able to reduce ER stress is not entirely clear; however, the authors hypothesize that it could be due to the antagonism on MOR[101].

Organoid cultures have also been treated with several luminal bacteria to better comprehend their positive modulation of inflammatory flares during IBD. For example, the probiotic *Bacillus subtilis* RZ001 promotes intestinal mucosa repair in organoid models by upregulating the expression of MUC2 in the mucus layer[102]. On the other hand, Wlodarska *et al*[103] have evaluated the role of bacteria that are able to use mucins as an energy source as a new possible therapeutic approach by the release of the indoleacrylic acid (IA), a beneficial bioactive tryptophan metabolite[103]. Bacterial IA treatment does not change organoid growth or size but increases the expression of genes associated with goblet cell functions, such as MUC2, which is decreased during intestinal inflammation, and the expression of target genes in the NF-E2-related factor 2-mediated antioxidant pathway, which also suppresses pro-inflammatory pathways and activates aryl hydrocarbon receptor signaling. In fact, an upregulation of the aryl hydrocarbon receptor target gene *CYP1A1* was observed. In addition, IA increases MUC2 and IL-10 levels and decreases TNF expression in LPS-treated co-cultures of bone marrow-derived macrophages and murine intestinal organoids, thus suggesting that IA can simultaneously promote anti-inflammatory cytokines secretion while inducing goblet cells differentiation[103].

Another important anti-inflammatory function has been found for transforming growth factor β (TGF-β): TGF-β signaling pathway arrests inflammatory signals in the intestinal compartment through small mother against decapentaplegic (SMAD4) activation as downstream target[104]. After the binding to its receptors, TGF-β induces the phosphorylation and activation of receptor-SMADs, which consequently bind SMAD4, translocate into the nucleus, and regulate gene transcription, thus acting as transcriptional repressors or activators of genes. The anti-inflammatory effect of TGF-β has also been demonstrated using mouse intestinal organoids: In particular, it has been observed that exposure to TNF-α induces the expression of *CCL20*, that encodes for a chemokine that is up-regulated by inflammatory signaling pathways, and that, following the addition of TGF-β, this induction is interrupted [104].

The canonical Wnt signaling pathway plays a fundamental role in maintaining intestinal epithelium homeostasis, preserving the undifferentiated ISC profile, inducing proliferation and controlling differentiation[105]. The epithelial human sirtuin protein 2 (SIRT2) is also known to be involved in cell differentiation, growth, and autophagy. To better investigate the role that these factors play in IBD, Li *et al* [105] have used WT and SIRT2 KO mouse intestinal organoids. The inhibition of SIRT2 determines the activation of the Wnt/β-catenin signaling pathway and exhibits enhanced epithelial proliferation, which coincides with what has been seen *in vivo* on the mucosa of IBD patients. Furthermore, TNF treatment of WT organoids reduces SIRT2 expression, suggesting that TNF may induce Wnt/β-catenin signaling through repression of SIRT2 expression. In this way, the critical role of Wnt pathway and the beneficial

effect of SIRT2 in the intestinal epithelium was demonstrated[105]. More studies are required to understand the effective role of Wnt signals in the intestinal epithelium.

Kim *et al*[106] have demonstrated that oral treatment with hyaluronan 35 kDa (HA35) may be an effective therapy for IBD patients, promoting epithelial wound healing *via* the activation of RhoA/Rho-associated protein kinase signaling. The use of mouse intestinal organoids has confirmed that HA35, which is specifically internalized by the layilin receptor, induces ZO-1 expression, and restores the epithelial barrier, which is disrupted during active IBD[106].

In addition to all these possible therapeutic targets, Davoudi *et al*[107] have used mouse intestinal organoids to study novel drug-delivery strategies, including nanoparticles and microparticles-based therapies, to provide drug delivery at specific areas, thus reducing the disadvantages of systemic treatments that result in non-selective distribution of drugs and side effects[107]. Authors have inserted 5-aminosalicylic acid or rhodamine B, used as a tracer dye, into polylactic-co-glycolic acid nanoparticles and have loaded them into the lumen of intestinal organoids. By confocal fluorescent microscopy, it was shown that rhodamine B was released into the lumen and digested after 3 d, demonstrating the ability of the organoid to digest nanoparticles and confirming the adsorption of nanoparticles inside the lumen with no negative consequences on organoid growth. This is a trojan horse system in which the drug is concealed from the host cells, and could represent a new therapeutic approach for delivering drugs to the specific inflamed location, reducing adverse reactions[107].

LIMITATIONS OF INTESTINAL ORGANOID TECHNOLOGY

Although the future applications and clinical contributions of intestinal organoids seem to be very encouraging, there are still several issues to overcome. One of the limitations is that several components used to culture intestinal organoids, such as the matrigel and some growth factors, are derived from cell lines. Therefore, they might contain large amounts of xenogenic factors and unknown components that could potentially cause pathogen/immunogen transmission to organoid cultures, in addition to the large variability between the different production batches used. For these reasons, growth conditions must be further optimized and standardized[21]. For example, Wnt-conditioned medium might be replaced with commercial variants[58] and matrigel might be substituted by synthetic extracellular matrices, such as collagen and hydrogel. Yin *et al*[58] have used small molecules, including valproic acid and CHIR99021, a glycogen synthase kinase 3β inhibitor, as conditioned media to maintain self-renewal of mouse $Lgr5^+$ ISCs, resulting in homogeneous cultures[58]. Moreover, the current protocols used to isolate and culture intestinal organoids must be improved because it has been shown that the intestinal crypts isolated from actively inflamed segments often do not allow for correct growth of intestinal organoids due to the loss or disruption of the epithelial layer[21]. Another limit is that intestinal organoids lack other cell and tissue types, including nervous tissue, endothelium-lined blood vessels, and immune mediators, which are crucial for drug pharmacokinetic analyses and disease modeling; in addition, they lack the physiological intestinal and blood flow, the mechanical deformations similar to those seen in the contractions of peristalsis, and the gut microbiota[21,108]. For these reasons, the intestinal organoid technology still requires standardized methods to include the intestinal microbiota and immune cells of the lamina propria, which could allow for mechanistic studies of IBDs[29]. Moreover, ASC-derived intestinal organoids miss the mesenchymal structure in contrast to those derived from iPSCs[21,22].

CONCLUSION

The intestinal epithelium plays a pivotal role in the maintenance of intestinal homeostasis by controlling the microbial composition and lamina propria factors and its study is important to increase knowledge on IBD pathogenesis. Intestinal organoids provide advantages by better reflecting the *in vivo* physiology of intestinal epithelium and are thus becoming an important tool for IBD modeling.

Intestinal organoids demonstrated that IECs play an important role in promoting the inflammatory states, by releasing several pro-inflammatory cytokines; the contribution of the interplay with surrounding cells and with bacteria-host interactions, occurring in patients with IBDs, has also been explored. Furthermore, intestinal organoids have been used to better understand the mechanisms of already-approved drugs for the management of IBD and to comprehend their effects on the intestinal epithelium. In addition, since they can be generated from a specific patient, they could be used to test different drugs to optimize and personalize treatment, reducing therapy failure and the occurrence of adverse effects.

However, it is important to underline that this recent technology still needs to be improved and currently, in the literature, the data available are few and preliminary. Therefore, more studies are required to improve this technique and to better understand how to use intestinal organoids, especially in the context of personalized therapy and drug development for IBD.

Abstract

Drug-induced autoimmune hepatitis (DIAIH) is a specific phenotype of drug-induced liver injury that may lead to the devastating outcome of acute liver failure requiring liver transplantation. Drugs implicated in DIAIH include antimicrobials such as nitrofurantoin and minocycline, non-steroidal anti-inflammatory drugs, statins as well as anti-tumor necrosis agents. The clinical features of drug-induced liver injury are indistinguishable from idiopathic autoimmune hepatitis (AIH) as both may have positive AIH-related autoantibodies, elevated immunoglobulin G, as well as similar histopathological findings. In patients who show no clinical improvement, or there is progressive liver injury despite cessation of the suspected drug, a liver biopsy should be considered, whereby the presence of advance fibrosis on histology favors the diagnosis of idiopathic AIH. Empirical treatment with corticosteroids may be required in patients with non-resolving liver injury. A typical clinical scenario supportive of DIAIH includes a history of drug exposure with spontaneous resolution of liver injury after drug withdrawal and the absence of relapse after rapid steroid taper. In this article we report two cases of DIAIH secondary to Sorafenib and Atorvastatin along with a review of currently available literature. Early identification and treatment often lead to a favorable outcome in DIAIH.

Key Words: Drug-induced liver injury; Drug-induced autoimmune hepatitis; Autoimmune hepatitis; Review

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Drug-induced autoimmune hepatitis is uncommon in clinical practice but may have devastating consequences. It is important to distinguish drug-induced autoimmune hepatitis from idiopathic autoimmune hepatitis as the former may not require prolong course of immunosuppressant. This minireview highlights the key differences between these two closely-linked entities.

INTRODUCTION

Idiosyncratic drug-induced liver injury (DILI) is rare and affects 14-19 per 100000 persons yearly[1,2]. Despite its relatively low incidence, it is a leading cause of acute liver failure in the United States[3], Europe[4,5], and Japan[6]. In patients with DILI, liver-related death and liver transplantation occur in 3.6%-10% of cases[7].

Drug-induced autoimmune hepatitis (DIAIH) is a specific phenotype of idiosyncratic DILI with features indistinguishable from idiopathic autoimmune hepatitis (AIH), as it shares serological markers and/or histological features with idiopathic AIH[8]. Various terms have been used synonymously with DIAIH, including immune-mediated DILI[9] and drug-induced AIH-like injury[10].

Due to its rare occurrence, it is difficult to estimate the frequency of DIAIH. In addition, studies use varying definitions of DIAIH and drug causality assessments, as well as having diverse patient populations with different follow-up periods (Tables 1 and 2). It is estimated that DIAIH accounts for 2%-18% of AIH cases[10-14], and 2.9%-8.8% of all DILI are due to DIAIH[15,16]. The increasing incidence of AIH has been in part attributed to prevalent use of anti-tumor necrosis factor agents[14].

DRUGS ASSOCIATED WITH DIAIH

Multiple drugs that have been associated with DIAIH are classified into those with definite association (*e.g.*, Minocycline, Nitrofurantoin, Infliximab), probable association (*e.g.*, Diclofenac, Atorvastatin, Rosuvastatin, Etanercept), and possible association, depending on the cases reported and associations as summarized in the most recent American Association Society of Liver Disease AIH Practice Guidance [10].

DIAIH is classically associated with minocycline, nitrofurantoin, methyldopa, dihydralazine, and tienilic acid[17]. DILI with autoimmune phenotype defined as DILI with presence of AIH antibodies (antibodies to nuclear antigen, smooth muscle, and soluble liver antigen) occur in 83%, 74%, 60%, and 43% of nitrofurantoin, minocycline, methyldopa, and hydralazine related DILI cases, respectively[15]. Immuno-allergic phenotype characterized by any combination of rash, fever, facial edema, lymphadenopathy, and eosinophilia is common in DILI associated with these four drugs as well, ranging from 11%-27%[15]. Another important cause of DIAIH include statins, where DIAIH or DILI with immune features occurs in about 8.5%-27.2% of all statin related DILI[18,19].

In recent years, there has been a change in the predominant culprit drugs causing DIAIH to anti-tumor necrosis factor[14], statins, and non-steroidal anti-inflammatory drugs[16,20,21] with notable contribution from complementary alternative medicines in studies from Asia[22].

PATHOGENESIS OF DIAIH

Reactive metabolites generated from hepatic metabolism of drugs bind to cellular proteins such as components of CYP450, which is then recognized as neoantigens by heightened immunological response leading to AIH[11,23,24] as a result of misdirected immune response against self[25].

In this minireview, we highlight two recent cases of DIAIH induced by Sorafenib and Atorvastatin seen at our center. We also aim to review the current literature on DIAIH and discuss distinguishing features between DIAIH and AIH.

De Boer *et al*[15], 2015, United States	a: National prospective DILI database (*n* = 1322), subgroup of DILI secondary to Nitrofurantoin, hydralazine, Minocycline and methyldopa (*n* = 88); b: 2004-2014; c: 6 mo, 12 mo or 24 mo until normalization of LFT	a: Autoimmune (AI) DILI–AI score based on seropositivity for AIH antibodies and raised IgG); b: RUCAM (definite, highly probable and probable)	47, 3.6%	Two groups: (a) 18 non-AI DILI due to 4 drugs; (b) 67 (reference cohort, DILI due to Augmentin, Isoniazid, Diclofenac)	Similar HLA-DRB1*03:01 (15%) and HLADRB1*04:01 (9%) percentage in patients with DILI compared to population controls from National Marrow Donor Program (12% and 9%, respectively)
Hisamochi *et al*[22], 2016, Japan	a: All DILI who underwent liver biopsy, *n* = 62; b: 1988-2010; c: Median 2290 d	a: Revised IAIHG criteria; b: RUCAM and JDD-W scale	23, NA	39	Culprit drugs: CAM (69.6%); NSAIDs (8.7%). IgG reduction in 87%. 50% (8/16) relapsed (4 not treated with steroids, 2 previously received steroids and 2 on tapering dose of steroid dosage). Median time to relapse 283 d (range, 47-1090 d). Rise in IgG with relapse
Licata *et al*[16], 2014, Italy	a: Single centre hospitalized patients with DILI, *n* =136 (44 with liver biopsy); b: 2000-2011; c: Mean 26 mo (12-84 mo), at least 1 yr after stopping immunosuppressants	a: Simplified AIH score ≥ 6; b: RUCAM (definite, highly probable, probable and possible)	12, 8.8%	124	Culprit drugs: NSAIDs (50%) - (Nimesulide/ketoprofen); Antimicrobials (25%) (Augmentin/Ceftriaxone); CAM (17%). 38.2% of all DILI patients had positive AIH antibodies but only 42.9% with positive antibodies have DIAIH. All DIAIH were treated with corticosteroids and all achieved remission at 15 mo. 58.3% (7/12) had addition of Azathioprine. One patient had a flare while on tapering prednisolone. In 41% (5/12), immunosuppressant was stopped after 2 yr, with no relapse

DIAIH: Drug-induced autoimmune hepatitis; DILI: Drug-induced liver injury; RUCAM: The Roussel Uclaf Causality Assessment Model; NSAIDs: Non-steroidal anti-inflammatory drugs; AIH: Autoimmune hepatitis; IAIHG: International AIH Group; IgG: Immunoglobulin G; CAM: Complementary alternative medicines.

CASE DISCUSSION

Patient A

A 61-year-old man and teetotaler presented with a 1-week history of jaundice and malaise. He was on Atorvastatin 40 mg daily for 4 years for hyperlipidemia. He had a normal liver function test (LFT) prior to admission. He was started on Sorafenib 6 wk prior to presentation with jaundice for recurrent sarcoma of the left thigh. Clinical examination was unremarkable apart from scleral icterus. The LFT showed severe hepatocellular (HC) injury [bilirubin 4.56 mg/dL, alkaline phosphatase (ALP) 190 U/L, alanine transaminase (ALT) 1004 U/L, aspartate transaminase (AST) 790 U/L, international normalized ratio (INR) of 1.53]. Viral hepatitis screen, AIH-specific antibodies, and abdominal imaging were unremarkable. Of note, serum immunoglobulin G (IgG) was elevated (18.6 g/L). The liver biopsy showed features supportive of DILI and AIH (Figure 1). The Simplified AIH score was 6. The Roussel Uclaf Causality Assessment Model (RUCAM) score was 9 for Sorafenib and 6 for Atorvastatin. Diagnosis of Sorafenib-induced AIH was made. His LFT improved spontaneously with normalization of LFT 8 wk after stopping Sorafenib (Figure 2A).

Patient B

A 65-year-old man who was on Atorvastatin 40 mg daily presented with an incidental finding of acute HC pattern of liver injury 18 mo after initiation of Atorvastatin (albumin 39 g/L, globulin 39 g/L, bilirubin 0.64 mg/dL, ALP 107 IU/L, ALT 696 U/L, AST 381 U/L). Viral hepatitis screening, AIH-specific antibodies, and abdominal imaging were unremarkable. His serum IgG was normal (14.28 g/L). Atorvastatin was stopped, and an improvement in LFT was noted within the 1 wk (albumin ALT 474 U/L, AST 195 U/L). The RUCAM score for Atorvastatin was 4. As such, he was given the diagnosis of possible Atorvastatin-induced DILI. However, despite this initial improvement in his LFT, there was subsequent deterioration 2 wk after stopping Atorvastatin (albumin 34 g/L, globulin 43 g/L, ALP 137

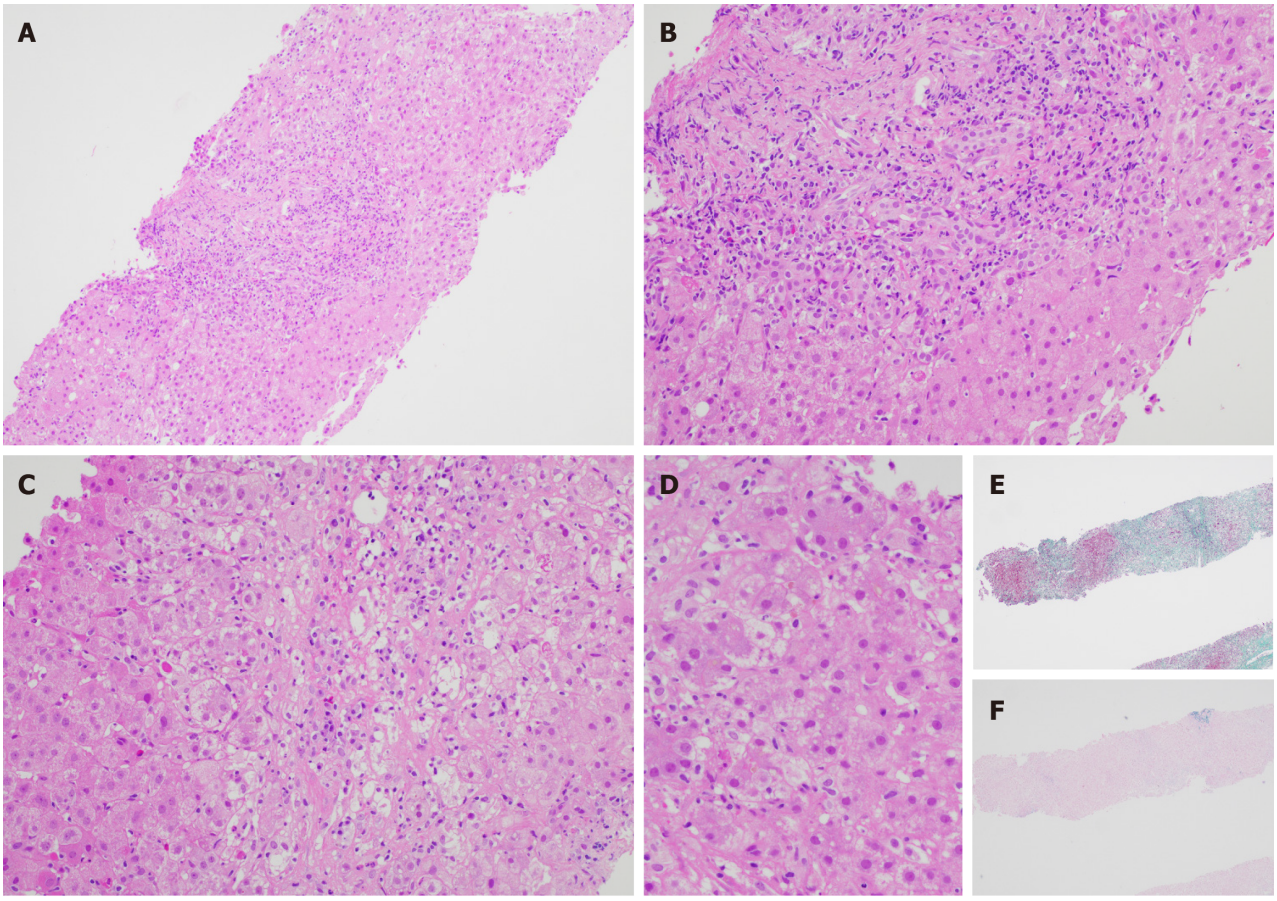
DIAIH: Drug-induced autoimmune hepatitis; DILI: Drug-induced liver injury; RUCAM: The Roussel Uclaf Causality Assessment Model; NSAIDs: Non-steroidal anti-inflammatory drugs; AIH: Autoimmune hepatitis; IAIHG: International AIH Group; CAM: Complementary alternative medicines.

U/L, ALT 1404 U/L, AST 676 U/L, INR 1.09). A liver biopsy was performed 3 wk after stopping Atorvastatin in view of worsening acute liver injury. This showed marked HC injury with histological features suggestive of AIH (Figure 3). Following the liver biopsy, there was again spontaneous improvement (ALT 699 U/L), but this did not persist. Two months after cessation of Atorvastatin, he had severe HC injury with jaundice (bilirubin 11.87 mg/dL, ALP 96 U/L, ALT 1095 U/L, AST 938 U/L, INR 1.33) and elevated IgG (28.35 g/L). Liver biopsy was repeated, and this again demonstrated features of AIH. He was then started on prednisolone with rapid improvement of LFT (Figure 2B). The final diagnosis was Atorvastatin-induced AIH.

WHEN TO SUSPECT DIAIH IN PATIENTS WHO PRESENTS WITH DILI

The cases described above highlight two possible presentations of DIAIH. The first patient (patient A) had DILI and histological features compatible with AIH on liver biopsy. Although Sorafenib has not been reported to be associated with DIAIH, the temporal sequence of this case presentation and subsequent spontaneous resolution after cessation of Sorafenib is in keeping with DIAIH.

DIAIH shares many similar characteristics with DILI without features of AIH. More than half of DIAIH present with acute liver injury associated with jaundice in 70%-75% of cases[16], which is similar to DILI. On top of that, rash may be present in 4.5% of DIAIH and 7.9% of DILI[26].



The following pointers are useful in identification of DIAIH in patients who present with DILI. The main differences between these two conditions are also summarized in Table 3: (1) DIAIH and AIH should always be considered as differentials in a patient with a hepatocellular pattern of DILI. DIAIH is rarely associated with a cholestatic/mixed picture, and it is only seen in 8% of cases[16]; (2) A detailed medication history with a focus on recent drug exposures including complementary alternative medicines is essential[10]; (3) The latency period of drug exposure in DIAIH is usually prolonged compared to other types of DILI, some with a latency period exceeding 1 year, *e.g.*, nitrofurantoin and minocycline[15]; (4) Seropositivity for AIH antibodies, *e.g.*, antinuclear antibody (ANA), anti-smooth muscle antibody, anti-liver kidney antibody, and elevated serum IgG suggest possible DIAIH. However, not all patients with DIAIH have detectable autoantibodies or elevated IgG. Similarly, a proportion of patients with DILI may have detectable AIH antibodies[15,16]; (5) In the presence of detectable AIH antibodies and elevated IgG, AIH scoring (either pre-treatment score for Revised International AIH Group criteria[27] or simplified AIH score[28]) is useful to assess for possible or

Table 3 Comparison between drug-induced autoimmune hepatitis and drug-induced liver injury

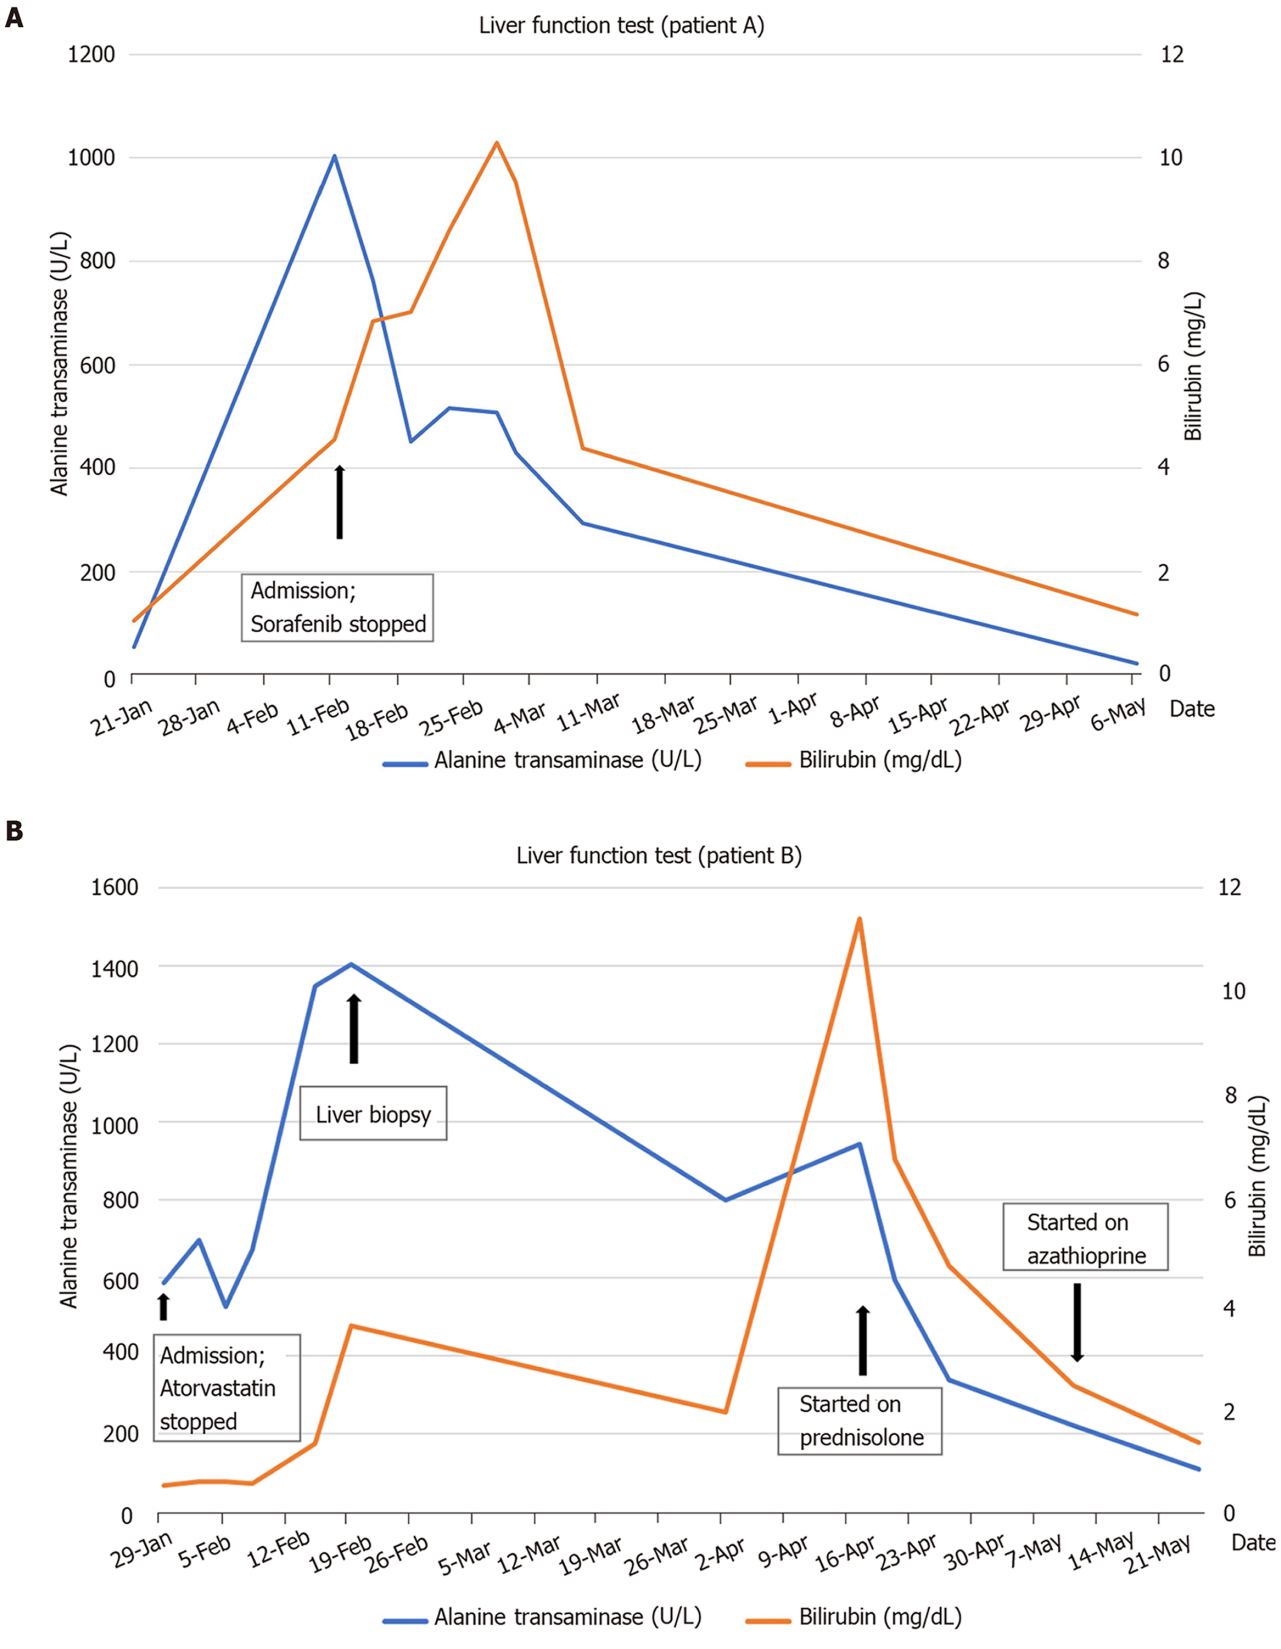
Figure 1 Liver biopsy specimen for patient A. A: Low power view [hematoxylin & eosin (H&E) 100 ×] displays conspicuous portal and lobular inflammation with lobular disarray. Mild steatosis is also noted; B: Higher magnification of the portal tract (H&E 200 ×), zone 1, shows moderate chronic inflammation, lymphoplasmacytic predominantly, and rare eosinophils, with interface damage; C: At similar magnification (H&E 200 ×), the lobule including the perivenular region, *e.g.*, zones 2 and 3, exhibits lobulitis characterized by aggregates of plasma cells, swollen hepatocytes with rosetting, Councilman bodies, and hepatocyte drop-out; D: High power view (H&E 400 ×) demonstrates rosetting of hepatocytes with droplets of orange-brown bile pigment; E and F: Histochemical stains Masson trichrome (E, 40 ×) showing collapse with mild early young fibrosis and Victoria blue (F, 40 ×) revealing paucity of elastic fibers, thus in keeping with subacute injury. Overall, the appearances are supportive of subacute drug-induced liver injury in association with autoimmune hepatitis histological pattern.

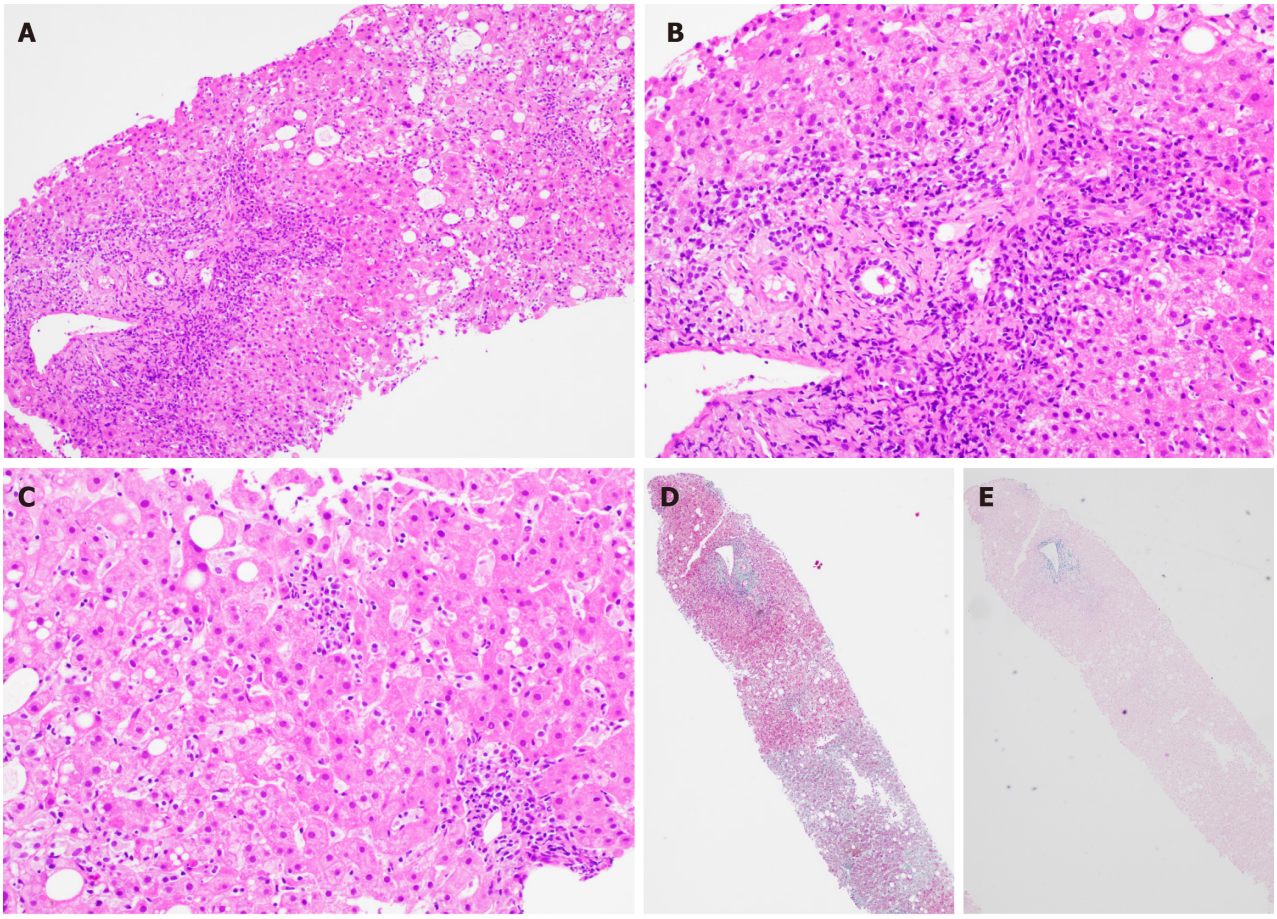


probable AIH; (6) Liver-specific causality assessment tools may be used to ascertain the strength of association between drug exposure and clinical manifestation, *e.g.*, RUCAM[29]; and (7) Liver biopsy is the cornerstone for the diagnosis of DIAIH and should be considered in the following scenarios: (a) Non resolving or worsening liver injury despite stopping possible culprit drugs; (b) Seropositivity of AIH antibodies, raised IgG, or possible AIH based on AIH scoring systems.

Known culprit drugs of DIAIH such as nitrofurantoin may be overlooked as these agents are associated with longer latency period and have a lower ALT at presentation. A higher fibrosis stage or cirrhosis may be observed as a higher proportion of these patients are unknowingly continued on Nitrofurantoin prior to the diagnosis[30]. This underscores the importance of understanding the common culprits of DIAIH, where a significant proportion of DILI presents with DIAIH[15]. LiverTox® is an up-to-date online resource that provides information on hepatotoxicity caused by medications and supplements[31].

With the increasing use of targeted tumor therapies such as kinase inhibitor and immunotherapy, there are some case reports of DIAIH associated with these medications. To our knowledge, this is the first case report of Sorafenib-induced AIH. Imatinib, another type of kinase inhibitor, has also been reported to be associated with DIAIH[14,32].

Several studies have attempted to compare the differences between DIAIH and DILI (Table 1)[15,16,22], with key features of DIAIH including significantly longer duration of drug exposure and latency; higher ALT and AST; higher proportion of patients with positive ANA and SMA, and higher level of serum IgG, as summarized in Table 3.



Liver biopsy is key in differentiating DIAIH from DILI without features of AIH[10,33]. In patients with DIAIH, the histopathological features are similar to that of idiopathic AIH with significantly higher proportion of patients showing severe portal inflammation, prominent portal-plasma cells, rosettes, and severe focal necrosis as compared to other types of DILI[16].

Figure 2 Bilirubin and alanine transaminase trend for patients A and B. A: Patient A; B: Patient B.

Though there is no significant difference in the severity and outcomes of DIAIH compared to other types of DILI, it is crucial to identify DIAIH in patients who present with DILI, as DIAIH may require treatment with immunosuppressants if liver injury does not improve with cessation of possible culprit drugs[10,31,33]. A significantly higher proportion of patients (50% to 80%) with DIAIH are treated with corticosteroids/immunosuppressants as compared to non-DIAIH DILI, and DIAIH will need longer

Figure 3 Liver biopsy findings for patient B. A: Low power view [hematoxylin & eosin (H&E) 100 ×] shows portal and lobular inflammation with lobular disarray and mild steatosis; B: Higher magnification of the portal tract (H&E 200 ×) demonstrates moderate plasma cell-rich chronic inflammation with continuous interface damage; C: Lobulitis with aggregates of plasma cells and rosetting of hepatocytes is present in the lobule (H&E 200 ×); D and E: Masson trichrome (D, 40 ×) and Victoria blue (E, 40 ×) display mild early young fibrosis and paucity of elastic fibers, respectively. The absence of old mature type fibrosis suggested not a chronic injury. The autoimmune hepatitis histological pattern observed was therefore interpreted to be drug related, atorvastatin-induced.

term follow up even when LFT normalizes as late relapses may occur in up to 50% of cases where immunosuppressants are stopped[22]. Majority of relapses occur within a year, but some may present late up to 3 years after the initial diagnosis, and risk factors for late disease recurrence are not clear.

DIFFERENTIATING DIAIH AND IDIOPATHIC AIH

The second case highlights the difficulty in differentiating DIAIH from idiopathic AIH. Both conditions have overlapping clinical presentations with HC pattern of liver injury and may have detectable ANA, SMA, and raised IgG in some cases[10,11]. A number of studies compared the difference between DIAIH and AIH (Table 2), with the key differences summarized in Table 4. Some useful features to distinguish between these two entities:

Clinical presentation

Majority (60%-83%) of DIAIH present with an acute presentation, whereas it is seen in less than 20%-35% of cases with idiopathic AIH[10,34]. Most studies of the two conditions do not demonstrate a significant difference in LFT levels[14,21,30,34], but ALT[13,30,34], AST[14,34], and bilirubin[14,34] tend to be higher in patients with DIAIH. Only one study[20] showed a significantly higher level of bilirubin, AST, and ALT in patients with DIAIH. There was no significant difference in the proportion of patients with detectable ANA (77-94%)[20,21] and elevated IgG (36%-59%)[14], although one study showed AIH had higher level of serum IgG compared to DIAIH; it was not, however, statistically significant[14]. Immuno-allergic presentation with skin rash, fever, lymphadenopathy, and eosinophilia favor DIAIH, as it may occur in up to 30% of DIAIH[10,11].

Table 4 Comparison between drug-induced autoimmune hepatitis and autoimmune hepatitis

Clinical features	DIAIH	AIH
Demographics		
Female, %	82%[32]; 91%[34]	80% (P = 0.635)[32]; 92% (P = 0.95)[34]
Clinical presentation		
Acute presentation	> 60%[14]; 55%[32]; 83%[34]	< 20%[14]; 47% (P = 0.618)[32]; 35% (P < 0.001)[34]
Hypersensitivity reaction (fever, rash, eosinophilia)	Up to 30%[14]	Unusual[14]
Cirrhosis at presentation, %	0%[34]	34.8% (P = 0.07)[34]
Temporal relationship with drugs	Positive	Negative
Concurrent AI disease	Unusual[14]	Present in 14%-44%[14]
Biochemical results		
ALT (U/L), mean ± SD	548 ± 335[20]	227 ± 121 (P = 0.021)[20]
AST (U/L), mean ± SD	460 ± 321[20]	202 ± 57 (P = 0.018)[20]
Serology		
IgG, mean ± SD (g/L)	13.4 g/L[14]; 21.4 ± 7.5 [34]	18.6 g/L (P value non-significant)[14]; 24.3 ± 11.2 (P = 0.422)[34]
Pre-treatment score		
RUCAM score, median (range)	6 (3-10)[21]	3.5 (0-7) (P < 0.01)[21]
Revised IAIHG score, median (range)	9.5 (4-14)[21]	13 (9-18)[21]
Simplified AIH score, median (range)	4 (2-6)[21]	5 (1-7) (P = 0.385)[21]
Histopathology		
F3-F4, %	33.3%[34]	54.4% (P = 0.15)[34]
Typical histology (portal inflammation, interface hepatitis, plasma cells infiltrates)	18.2%[20]	54%[20]
Treatment and response to treatment		
Time to biochemical remission, mean (mo)	2[34]	16.8 (P <0.001)[34]
Treatment with Azathioprine or Mycophenolic acid in addition to corticosteroids, %	57%[13]; 15%[14]; 28% [20]; 20%[21]	86% (P = 0.024)[13]; 83% (P < 0.001)[14]; 90% (P = 0.023)[20]; 85% (P < 0.01)[21]
Biochemical remission, %	95%[21]	77.3% (P = 0.08)[21]
Treatment discontinuation, %	69%[14]; 100%[20]; 85% [21]; 25%[34]	26% (P < 0.02)[14]; 25% (P = 0.013)[20]; 5% (P < 0.1)[21]; 3% (P < 0.001) [34]
Relapse rate, %	0%[14]; 15%[21]; 60% [32]; 0%[34]	43% (P = 0.022)[14]; 70% (P < 0.01)[21]; 83% (P = 0.538)[32]; 18% (P = 0.10) [34]
Time to relapse (wk), median (range)	131 (37-216)[34]	14 (1-155) (P = 0.033)[34]
Outcomes		
Liver transplant/death, %	0%/0%[32,34]	2.8%/7% (P = 0.748 for liver transplant; p = 0.65 for death)[32]; 5.6%/2.8% (P = 0.40 for liver transplant; P = 0.55 for death)[34]

DIAIH: Drug-induced autoimmune hepatitis; DILI: Drug-induced liver injury; ALT: Alanine transaminase; AST: Aspartate transaminase; RUCAM: The Roussel Uclaf Causality Assessment Model; SD: Standard deviation.

AIH scoring and causality assessment

In a cohort of 44 patients with DIAIH and AIH, the simplified AIH score was not useful in differentiating the two entities[21]. Of note, patients with AIH had significantly higher pre-treatment AIH score compared to patients with DIAIH. The sensitivity and the specificity for pre-treatment AIH score (using a cut off of ≥ 12 – probable AIH) was shown to be 59% and 82%, respectively. As for RUCAM, using a cut off of ≥ 6 (probable), the specificity reaches 91%, albeit with a low sensitivity at 32%. When these are used in combination, there is still a potential for misdiagnosis in up to 11% of patients.

Histopathology

Both DIAIH and AIH share similar histological findings (portal and periportal infiltrates of lymphocytes, lobular hepatitis, plasma cells, and eosinophils) with no clear differentiating features, except presence of advance fibrosis or cirrhosis favoring idiopathic AIH[11,34]. However, a significantly higher proportion of patients with AIH showed typical features of AIH (54%) as compared to DIAIH (18.2%)[20], specifically in terms of portal inflammation with interface hepatitis and plasma cell infiltrates. The same study also found that DIAIH tended to have more eosinophilic infiltrates, which was not noted in other studies[21].

Treatment and response to treatment

The cornerstone in the management of DIAIH is to stop the culprit drug. Spontaneous improvement of LFT may then occur, as was observed in patient A. The most consistent and significant differentiating feature between DIAIH and AIH in published case series thus far lies in the response to treatment (Table 4). In cases where liver injury does not resolve despite cessation of the culprit drug or where the degree of DILI is severe, corticosteroids are usually started as per the initial management of AIH. Most studies on DIAIH exclusively include patients who were treated with immunosuppressants[14,20,21,30]. Both DIAIH and AIH showed excellent response to corticosteroids, with remission rate exceeding 90% in most cases[21,30-34].

It should be borne in mind that there is discrepancy in literature regarding the mean time to achieve immunosuppression induced remission in DIAIH and AIH. While one study demonstrated similar 3 mo mean time to remission[21] in both conditions, another showed a significant difference, where DIAIH took a significantly shorter time than AIH to achieve remission[34] (2 mo *vs* 16.8 mo). This may be attributed to the heterogeneity of the study population. Resolution of DIAIH usually occurs after 1 mo (rarely up to 3 mo) of immunosuppression. Unlike in AIH, DIAIH rarely requires long term immunosuppression and has very low relapse rates after cessation of immunosuppressants over a long follow-up of up to 4 years[10,11,13-15,20,21,34] (Table 2). In cases where DIAIH relapses, the time to relapse is significantly longer compared to AIH[30], which implies that patients with DIAIH will require a longer period of follow-up after resolution of liver injury as compared to the usual DILI. Interestingly, despite similar time to remission in the two groups, Weber *et al*[21] showed that an early rapid response to corticosteroid treatment differentiates DIAIH from AIH with good sensitivity and specificity at 77%, respectively. The early rapid response was defined by 9% drop of ALT per day in the first week of corticosteroid therapy.

The use of steroids appears to be a promising means of differentiating DIAIH or AIH in the early course of disease with better sensitivity than RUCAM and AIH score[21]. This also has the potential benefit of avoiding long term immunosuppressive therapy in DIAIH. Also, in 30%-35% of DIAIH cases that were initially seropositive for ANA and SMA, the antibodies became undetectable at 6 mo following the initial DILI, which was independent of treatment with corticosteroids[15].

Major hepatology society guidelines recommend a similar approach in terms of corticosteroids initiation in non-resolving DIAIH and AIH[10,11]. However, there is no consensus regarding treatment duration and methods to confirm remission before discontinuation of immunosuppressants. Thus, the decision and timing to stop treatment should be assessed on case-by-case basis[10]. In fact, one study has shown success in tapering off immunosuppression within 3-17 mo without evidence of relapse[20].

Risk alleles and monocyte-derived hepatocyte like cells

Risk alleles for idiopathic AIH such as HLA DRB1 DRB1*03:01 or DRB1*04:01 are uncommon in DIAIH and, if this is detected, may favor a diagnosis of AIH[10]. The MetaHeps® test, which uses monocyte-derived hepatocyte-like cells, has been used to differentiate DIAIH from AIH with high sensitivity and specificity[21]. However, this test is not readily available, thereby limiting its utility in clinical practice. The lymphocyte toxicity assay described by Neuman *et al*[35] can sometimes be helpful in differentiating drug hypersensitivity syndromes from idiopathic AIH as well.

Outcomes

The long-term outcome of DIAIH is excellent with a survival rate between 90%-100% without liver transplantation[10]. This is in contrast with idiopathic AIH, where there is a high risk of relapse upon treatment withdrawal and risk of progression to cirrhosis, resulting in the need for liver transplantation [10,11,34]. It is also noteworthy that DIAIH can lead to chronic DILI with abnormal LFT lasting more than 6 mo in 17%-22% of cases[15,36].

CONCLUSION

In summary, it is important to differentiate between DIAIH and AIH in patients who present with DILI, as the management and outcome differ. Early recognition of DIAIH is key as the mainstay of management is cessation of culprit drug and in some cases, initiation of corticosteroids with the aim to

avoid long-term immunosuppression.

ACKNOWLEDGEMENTS

We acknowledge all our colleagues in the Department of Gastroenterology and Hepatology and Pathology at Changi General Hospital who help manage the 2 patients described in the manuscript. We would also like to thank the 2 patients described here who readily consented to be described in this manuscript.

Abstract

Introduction of proton pump inhibitor (PPI) therapy into clinical practice has revolutionized treatment approach to acid-related diseases. With its clinical success came a widespread use of PPI therapy. Subsequently, several studies found that PPIs were oftentimes overprescribed in primary care and emergency setting, likely attributed to seemingly low side-effect profile and physicians having low threshold to initiate therapy. However, now there is a growing concern over PPI side-effect profile among both patients and providers. We would like to bring more awareness to the currently available guidelines on PPI use, discuss clinical indications for PPIs and the evidence behind the reported side-effects. We hope that increased awareness of proper PPI use will make the initiation or continuation of therapy a well informed and an evidence-based decision between patient and physician. We also hope that discussing evidence behind the reported side-effect profile will help clarify the growing concerns over PPI therapy.

Key Words: Proton pump inhibitor; Side-effects; Gastro-esophageal reflux disease; Therapy

Core Tip: Proton pump inhibitor (PPI) therapy is a cornerstone therapy for acid-related diseases. Its clinical success can be attributed to anti-secretory properties superior to any prior agents and seemingly low side-effects profile. As more patients were started and continued PPI therapy long-term, some studies began reporting side-effects associated with this therapy. Concerns over risks associated with PPI use grew over the last couple of years among both patients and providers. We hope to bring awareness to the current guidelines and the evidence behind the reported side-effects as better understanding of this evidence can improve medical practice. Both patients and providers should have all the evidence at hand when discussing initiation or continuation of PPI therapy.

INTRODUCTION

Proton pump inhibitors (PPIs) were first introduced more than two decades ago but have quickly become a cornerstone therapy for the acid-related diseases. They were regarded for their superior antisecretory properties and seemingly low side-effect profile, which ultimately contributed to low threshold for therapy initiation[1]. They became first-line treatment for esophagitis, gastro-esophageal reflux disease (GERD), peptic ulcer disease (PUD), Zollinger-Ellison syndrome (ZES), and *Helicobacter pylori* (*H. pylori*) infection[2]. Many patients started on PPI therapy continued it long-term without a clear expectation of the therapy duration. Rising number of patients on chronic PPI therapy led to growing concerns over medication side-effect profile. Especially as some reports claimed that improper long-term PPI use has risen significantly in the last decade with some data suggesting that only half of patients on PPI therapy had an appropriate indication[3,4]. Improper PPI use is multifactorial and comes from a pattern of preventable chain of events (Figure 1). This discussion is important because PPIs affect patients' quality of life, and need to be taken judiciously and according to the evidence-based guidelines.

BACKGROUND

PPIs work by suppressing gastric acid secretion by directly inhibiting gastric acid pump (H+/K+ adenosine triphosphatase (ATPase)) of the parietal cells[5]. PPIs are prodrugs that are only activated once exposed to the acidic environment of the parietal cells[6]. Once active, their half-life ranges from 0.6-1.9 h, depending on the type of PPIs used (Table 1)[7-9]. After PPIs are no longer metabolically active, they are metabolized by the hepatic P450 enzymes, primarily by CYP2C19 with minor contribution from CYP3A4 (Table 1)[6,10]. Once metabolized, they are excreted renally, with lansoprazole and dexlasoprazole also being excreted by the gut (Table 1)[11].

Not all patients metabolize PPIs at the same rate, causing variation in bioavailability. The hepatic P450 system is partially responsible for this variation. Patients of Asian ethnicity and older patients tend to have slower P450 systems and, as a result, have increased bioavailability of PPIs[6].

Currently available PPIs include esomeprazole, lansoprazole, omeprazole, dexlansoprazole, pantoprazole, and rabeprazole[12]. None of the PPIs has shown superiority in their antisecretory properties and are used interchangeably in clinical practice[13]. While there are no studies to support superiority, omeprazole is among the 10 most prescribed medications in the United States[6]. From the variety of PPIs available, esomeprazole and lansoprazole have the highest bioavailability: 89% and 80%-90%, respectively (Table 1)[11]. The lowest bioavailability is seen with rabeprazole at 52%[11]. Majority of PPIs must be taken 30 min prior to the first meal of the day. Esomeprazole requires 60 min prior to food intake administration[14]. Pharmacokinetics of dexlansoprazole, pantoprazole, and rabeprazole are unaffected by the food ingestion and can be taken at any time (Table 1)[14].

CLINICAL INDICATIONS

PPIs are used as a first line therapy for GERD, acid-related erosive esophagitis, peptic stricture, Barrett esophagus, and high risk of ulcer bleeding while on nonsteroidal anti-inflammatory drugs (NSAID) therapy[15]. It is also considered for treatment of eosinophilic esophagitis (EoE), non-erosive reflux disease (NERD), *H. pylori* infection (in combination with antibiotics), hypersecretory syndromes (*e.g.*

Table 1 Type of proton pump inhibitor available

PPI	Omeprazole	Esomeprazole	Lansoprazole	Dexlansoprazole	Pantoprazole	Rabeprazole
Half-life (T1/2) (hrs)[7-9]	0.6-1.0[7]	1.1[8]	0.9-1.6[7]	1-2[9]	0.9-1.9[7]	1[7]

ZES), prolonged mechanical ventilation, and functional dyspepsia[16]. While PPIs are considered for gastroprotection for patients on NSAID therapy, steroids are not an indication to start PPIs when used in ambulatory setting[17,18]. Some reports did suggest that there is an increased risk of PUD in patients taking steroids, but it was only statistically significant in hospitalized patients on brief courses of steroids[18]. As a result, these patients may be considered for a brief PPI therapy while inpatient. PPIs can also be used in conjunction with pancreatic enzyme replacement for refractory steatorrhea[17,19].

CURRENT GUIDELINES ON PPI USE

The current guidelines for PPIs are created for clinicians to prescribe PPIs appropriately and effectively to the patients who would benefit from the therapy. We are going to discuss guidelines proposed by multiple societies including the American College of Gastroenterology (ACG), American Gastroenterological Association (AGA), Society of American Gastrointestinal and Endoscopic Surgeons (SAGES), the Canadian Association of Gastroenterology (CAG), and the European guidelines (Table 2). All these guidelines are of moderate to high quality of evidence and are recommended strongly unless indicated

Table 2 Guidelines on proton pump inhibitor use

ACG/ACG/CAG/SAGES/European guidelines	Recommendation
GERD[19,20,22]	Trial an 8-wk duration of once daily PPI in patients with heartburn and regurgitation without reflux symptoms
	Once daily dosing-administer PPIs 30 min to 1 h before a meal; twice daily dosing-administer PPIs 30 min to 1 h before breakfast and dinner
	For patients experiencing refractory GERD, optimize PPI therapy with patient compliance, dosage and timing to achieve symptom control before further exploration
	Prescribe continuous daily PPIs over H2RAs for erosive esophagitis maintenance healing
	Continue lifelong PPIs in patients with LA Grade C or D erosive esophagitis
	If patients with normal esophageal mucosa or LA Grade A esophagitis have normal ambulatory reflux monitoring results after 2-4 wk discontinuation of PPI therapy, it is strongly recommended to stop PPI use (low level of evidence)
Dyspepsia[23]	Patients < 60 years old, tested *H. pylori* negative or symptoms persist after eradication therapy, should start empiric PPI therapy
	Functional dyspepsia patients, tested *H. pylori* negative or symptomatic after infection treatment, should be on PPIs
H. pylori infection[24]	If active or history of PUD, and tested *H. pylori* positive, start eradication treatment (10-14 d) with PPIs and antibiotics
	Dyspepsia patients found to be *H. pylori* positive on gastric biopsy, treat with eradication therapy consisting of PPIs and antibiotics for 10-14 d
	GERD patients who are found *H. pylori* positive should be offered eradication therapy for 10-14 d course
	Use levofloxacin triple regimen consisting of PPI, amoxicillin and levofloxacin as salvage therapy if first line eradication therapy fails
Barrett's esophagus[25,26]	Recommend once daily dosing PPIs primarily indicated for symptomatic relief
	Twice daily dosing can be considered in patients with esophagitis or poor symptomatic relief
EoE [28,29]	Recommend PPI therapy for clinical and histological remission of EoE
NSAIDs[31,32]	PPIs are indicated for patients at risk of GI bleeds for gastroprotection (age > 65 years, high dose NSAID use, previous history of ulcers, concomitant therapy with corticosteroids, anticoagulants and antithrombotics)
	Prescribe continuous or intermittent high dose PPI the following 3 d after GI ulcer bleed was stopped endoscopically

ACG: American College of Gastroenterology; AGA: American Gastroenterological Association; SAGES: Society of American Gastrointestinal and Endoscopic Surgeons; CAG: Canadian Association of Gastroenterology; PPI: Proton pump inhibitor; *H. pylori*: *Helicobacter pylori*; H2RA: Histamine 2 receptor antagonist; GERD: Gastro-esophageal reflux disease; PUD: Peptic ulcer disease; LA: Los Angeles; EoE: Eosinophilic esophagitis; NSAID: Nonsteroidal anti-inflammatory drug; GI: Gastrointestinal.

otherwise.

GERD treatment guidelines

An 8-wk duration of once daily PPIs is strongly recommended in patients with GERD to assess for adequate response. However, if GERD appears to be refractory, optimal PPI therapy should be confirmed first before further investigation. While there is no standardized definition of long-term PPI use, based on the ACG 2021 GERD guidelines, 8-wk therapy is the therapy duration following which patients get stratified into those who responded to therapy and those who are refractory to therapy[20]. Optimal therapy includes ensuring the patient is compliant with PPI therapy and takes medications appropriately with correct timing and dosage. Multiple studies show that a significant number of patients who optimize therapy improve symptoms[20]. In patients with known erosive esophagitis, medical therapy with daily PPIs is recommended but is given at half of the healing dose for maintenance to prevent recurrence[21]. PPIs should be prescribed over histamine 2 receptor antagonists (H2RAs) for erosive esophagitis due to their superiority in faster healing rates and better heartburn symptom control. It was found that almost all patients with Los Angeles (LA) grade C erosive esophagitis who stopped PPI therapy relapsed within 6 mo. However, recurrence of erosive esophagitis may occur as soon as 1 wk to 2 wk after PPI discontinuation. It is therefore recommended patients who have a more severe esophagitis (LA grade C or D) should be on a lifelong PPI therapy[20]. It is

important to note that PPI therapy may be ineffective in patients with large hiatal hernias. Transabdominal or transthoracic large hiatal hernia repairs should be strongly considered in patients who experience symptoms of severe gastroesophageal reflux, gastric outlet obstruction and/or strangulation. Fundoplication as a treatment option for reflux produced mixed outcomes and therefore no strong recommendation can be made[22].

In patients with an unclear GERD diagnosis, ambulatory reflux monitoring may be helpful in guiding PPI therapy in patients with refractory reflux symptoms and without severe esophagitis[23]. This diagnostic approach helps support or negate a GERD diagnosis. Patients with incomplete symptom relief after an 8-wk course of PPI therapy can discontinue PPIs for 2-4 wk. If normal results in reflux monitoring are seen after PPI cessation in patients with normal EGD findings or LA Grade A esophagitis, then other causes of symptoms should be investigated, and PPI therapy can be stopped. Although this approach is strongly recommended, more studies are necessary for high evidence support [20].

Dyspepsia treatment guidelines

Several randomized control trials (RCTs) found a statistically significant effect in use of once daily PPI dosing for symptomatic relief of dyspepsia symptoms. It is therefore strongly recommended that patients under 60 years of age who tested *H. pylori* negative or continue to experience symptoms after *H. pylori* treatment should be prescribed empiric PPI therapy. Functional dyspepsia patients are also recommended a two-to-eight-week duration of PPI course for symptomatic improvement with some RCTs suggesting a number needed to treat of 10. However, if patients do not respond after 8 wk of therapy, PPIs should be discontinued as there was no utility found in increasing the dose. Other drug therapies can therefore be considered in symptomatic management[24].

H. pylori treatment guidelines

Patients with current or history of peptic ulcer without known *H. pylori* eradication should be tested with a urea breath test, fecal antigen test or gastric mucosal biopsy. If *H. pylori* positive, treatment options should be offered. Eradication treatments include first line bismuth quadruple therapy (PPI, bismuth, tetracycline and nitroimidazole) or clarithromycin triple therapy (PPI, clarithromycin, and amoxicillin or metronidazole) for 10-14 d. If gastric biopsies are done in patients with dyspepsia and are found to be *H. pylori* positive, multiple studies demonstrated that eradication treatment improves symptoms. If patients with GERD do not experience symptoms of dyspepsia or have a history of PUD, it is unnecessary to test for *H. pylori*. However, if found to be positive, treatment options should be offered. If first line therapy for eradication treatment fails, it is recommended to use the levofloxacin triple regimen as a salvage treatment. The regimen consists of PPI, amoxicillin, and levofloxacin. A treatment duration of 14 d can be effective but supported by low quality of evidence so further studies are warranted[25].

Barrett's esophagus treatment guidelines

Patients with Barrett's esophagus are typically prescribed PPIs due to GERD symptoms and to reduce the risk of neoplastic changes. Several studies demonstrated that maintenance PPI therapy reduced risk of neoplastic changes compared to H2RA therapy or no anti-acid reflux medications. According to the AGA and ACG guidelines, once-daily PPI therapy is recommended for patients with Barrett's esophagus[26,27]. Twice daily dosing can be considered in BE patients with inadequate symptomatic control or in patients with esophagitis[26].

EoE

Previous guidelines suggested PPI use as a trial therapy to differentiate EoE from GERD[28]. However, the PPI trial should no longer be used as GERD and EoE share many similarities and are not mutually exclusive entities[29]. The 2017 United European Gastroenterology (UEG) guidelines suggested PPIs as recommended treatment for EoE which is proven to demonstrate symptomatic improvement and histological remission. Early observational studies and case reports demonstrated this phenomenon and many RCTs followed which supported the use of PPI therapy in EoE. A recent systematic review with meta-analysis showed clinical improvement and histological remission with PPI therapy[30]. Duration and dosage for treatment is however still under investigation; twice daily administration and long-term PPI therapy is recommended but has low evidence[30].

NSAID use

PPI therapy is necessary to prevent NSAID-related ulcer complications including upper gastrointestinal (GI) bleeds. Many studies reported decreased prevalence of upper GI ulcers and bleeds while on NSAID therapy if PPIs are co-administered[31]. PPI therapy is indicated in NSAID users at risk for GI bleeds which includes those on high dose NSAIDs, age greater than 65 years, prior history of ulcers, and/or concurrent use of antiplatelets, anticoagulants or corticosteroids[31,32]. Long term daily PPI therapy is not supported by high quality evidence and is a conditional recommendation. For patients who have a bleeding GI ulcer that was managed endoscopically with hemostatic therapy, high dose PPI therapy

should be given continuously or intermittently for the following 3 d for further gastroprotection[33].

RISKS ASSOCIATED WITH PPI USE

PPIs have been associated with electrolyte disturbances, increased fracture risk, gastrointestinal and lung infections, kidney disease, dementia, cardiovascular events, and gastric mucosal changes associated with potential increased risk of neoplasia. We are going to discuss the PPI-associated side-effects and the supporting data behind them (Table 3).

Electrolyte abnormalities

PPIs are thought to cause reduction in vitamins and minerals due to reduced intestinal absorption caused by decreased gastric acid secretion. While there is data on B12 and iron malabsorption associated with PPI use, some studies argue against this association. One large case control study confirmed that PPIs were associated with increased risk of iron deficiency anemia and vitamin B12 deficiency[34,35]. In contrast, a small observational study evaluated patients with ZES on chronic PPI therapy and did not find any association with iron malabsorption[36]. Another cross-sectional study found no association between long term PPI use and vitamin B12 deficiency[35].

Hypomagnesemia is another electrolyte derangement that has been attributed to PPI therapy. The first case report that linked hypomagnesemia with PPI use was in 2006, which prompted further research on this topic[37]. A 2014 meta-analysis of 9 observational studies found an association between PPI use and hypomagnesemia, but there was notable heterogeneity among the studies reported[38]. After review of 38 cases in Adverse Event Reporting System and 23 case reports, the United States Food and Drug Administration (FDA) recommends obtaining magnesium levels prior to PPI therapy initiation[39].

Hypocalcemia/fracture risk

PPIs are associated with hypocalcemia and potentially increased risk of bone fractures. Calcium salts, such as calcium carbonate, need highly acidic environment for absorption. PPIs block acid production and, as a result, prevent absorption of calcium carbonate[40]. Calcium malabsorption increases risk of osteoporosis and subsequent bone fractures. A large case control study from the United Kingdom reported that patients on chronic PPI therapy were more likely to fracture their hip with incidence rate of 4.0/1000 person years compared to non-users of 1.8/1000 person years. It is important to note that patients in the study had multiple comorbidities that could have served as confounding factors[40]. In contrast, a large-scale case control study performed among the Danish population found no dose-dependent relationship between PPI use and the risk of bone fracture[41]. In a 2018 meta-analysis, 12 of the included studies failed to show an association between PPI use and fracture incidence or decrease in bone mineral density[42]. Another meta-analysis of 18 observational studies demonstrated a modest hip, spine, and any-site fracture risk[43].

Kidney disease

In the recent studies, PPIs were noted to have an association with acute kidney injury (AKI) and subsequent development of chronic kidney disease (CKD). One of the proposed mechanisms is that PPIs lead to a cell mediated immune response causing acute intestinal nephritis (AIN). A meta-analysis of 9 observational studies supported an association relationship between PPI use with AKI and CKD[44]. Furthermore, Lazarus *et al*[45] found that PPIs were associated with a 20%-50% higher incidence rate of CKD. It was unclear from the study, however, if comorbidities served as confounding factors. Interestingly, an observational study of a veterans database consisting of mainly elderly males reported an association between PPI use and development of CKD with duration-dependent risk of end stage renal disease (ESRD)[46]. In contrast, a recent large observational study evaluating CKD patients did not confirm an association of PPI use and ESRD[47]. Although there is no clear guideline yet available, clinicians can choose to routinely monitor creatinine levels and/or obtain urinalysis testing in high-risk patients on PPI therapy to assess for kidney disease progression[48].

Dementia

PPIs are thought to increase production of β-amyloid plaques and increase affinity of tau proteins towards brain tissue. Both processes are key in pathogenesis of Alzheimer's Disease (AD)[40]. A systematic review established a 1.4-fold increased risk of dementia with PPI use. However, one of the studies demonstrated a negative correlation[49]. Additionally, a 2019 meta-analysis of 6 cohort studies found no significant association between PPI use and AD[50].

Gastrointestinal infections

PPIs are thought to alter intestinal microbiota and, as a result, may predispose patients to gastrointestinal infections[51,52]. A systemic review and a meta-analysis of 56 studies found that PPI therapy

Table 3 Proton pump inhibitor associated side effects

PPI associated adverse risks	Proposed mechanism	Evidence type	Conditional recommendations to reduce risk
Electrolyte abnormalities: Hypomagnesemia, vitamin B12, iron	Decreased acid secretion decreases intestinal absorption of minerals/vitamins	Observational studies, conflicting evidence[33,34,36,37]	Unless other risk factors present, no recommendation to increase intake of vitamins/minerals or have routine screening of levels[19]
Fracture risk/hypocalcemia	Decreased acid secretion decreases calcium carbonate absorption	Observational studies, conflicting evidence[39,40-42]	Without other risk factors for bone disease, no recommendations to increase calcium/vitamin D intake or have routine bone mineral density exam[19]
AIN/CKD/ESRD	Initiate cell mediated immune response in kidneys	Observational studies, conflicting evidence[43-46]	Without other risk factors, there is no recommendation to routinely screen for kidney function in patients on PPIs[19]
Dementia	Increase β-amyloid plaque production and increase affinity of tau proteins	Observational studies, conflicting evidence[48,49]	No recommendations on dementia prevention in patients on PPI
Gastrointestinal infections: *C. diff*, SIBO, SBP	Alter gut microbiota due to decreased acidic environment	Observational studies, conflicting evidence[34,51-55]	For patients who develop *C.diff* infection while on PPI, can consider switching to H2 blockers [55]
Community acquired Pneumonia	Increase bacterial colonization in stomach from hypochlorhydria leading to lung micro-aspiration events Alter respiratory flora	Observational studies, RCTs, conflicting evidence[57-59]	No strong recommendation can be made
Gastrointestinal malignancies	Hypergastrinemia resultant from decreased acid production increases ECL cell hyperplasia	Observational studies, RCTs, conflicting evidence[60-62,64,65]	Given conflicting data, no recommendation on prevention can be made
Adverse Cardiovascular effects- arrythmias, decreased clopidogrel bioavailability, increased digoxin toxicity	Hypomagnesemia- torsade de pointes CYP450 inhibitor- decreases drug bioavailability Interaction with ATP-dependent P-glycoprotein impair endothelial function and platelet induction	Observational studies, RCTs, conflicting evidence[59,66]	For patients with significant esophagitis (grade C or D) or with poorly controlled GERD, PPI treatment outweighs the debatable cardiovascular risks[19]

GERD: Gastro-esophageal reflux disease; PPI: Proton pump inhibitor; AIN: Acute intestinal nephritis; CKD: Chronic kidney disease; ESRD: End stage renal disease; *C. diff*: *Clostridium difficile*; SIBO: Small intestinal bacterial overgrowth; SBP: Spontaneous bacterial peritonitis; ECL: Enterochromaffin-like; RCTs: Randomized control trials.

increases the risk of *clostridium difficile (C. difficile)* infection[53]. While a nationwide cohort study in Denmark found that the risk of community acquired *C. difficile* doubles in patients on PPI, but several other studies failed to replicate these results[52,53].

A meta-analysis of 19 observational studies reported a moderate risk of small intestinal bacterial overgrowth (SIBO) for patients on long-term PPI[52]. In contrast, a retrospective case control study found no significant association between the two[54].

Another type of gastrointestinal infection that PPIs have been associated with is spontaneous bacterial peritonitis (SBP). A meta-analysis from 8 observation studies revealed a threefold higher risk of developing SBP while on PPIs in cirrhotic patients[35]. Another meta-analysis of 16 observational studies confirmed this association but only in the case control studies of the meta-analysis[55]. In contrast, one retrospective cohort study established that PPI therapy did not increase the risk of recurrent SBP in cirrhotic patient population[56].

Pneumonia risk

PPIs are thought to increase bacterial colonization in the stomach from hypochlorhydria and lead to lung micro-aspiration events or potentially alter respiratory flora leading to pulmonary infections[57,58]. A systemic review of 33 studies and a meta-analysis of 26 studies including 4 selected RCTs found a 1.5-fold increased risk of community acquired pneumonia (CAP) for patients on PPI therapy and a 1.6-fold increased hospitalization risk[58]. In contrast, another meta-analysis of RCTs found no association between PPI use and respiratory infections[59]. PPIs have been reported as possible contributors to the ventilator associated pneumonia, but the quality of evidence is low[60].

GI malignancies

There is growing number of studies reporting association of chronic PPI therapy with gastric cancer[61-63]. The decreased acid production and subsequent hypergastrinemia may cause hyperplasia of enterochromaffin-like (ECL) cells[35,64]. A meta-analysis of 7 observational studies and 1 RCT showed an increased risk of fundic gastric polyps while on PPI therapy, but the clinical significance of this finding remains undetermined[65]. It is important to note that another meta-analysis of 6 RCTs revealed that while there was ECL cell hyperplasia noted with chronic PPI use, the hyperplasia had no stigmata of dysplasia or neoplasia[66].

Adverse cardiovascular events

While PPIs do not have a direct association with cardiovascular complications, they have cardiovascular side-effects primarily thought their effects on magnesium (hypomagnesemia), drug-drug interactions, impairment of endothelial function and induction of platelets[67]. PPIs, particularly omeprazole, were thought to decrease clopidogrel efficacy from interference of its metabolism leading to increased cardiovascular events. Therefore, the FDA recommends against omeprazole and clopidogrel co-administration[67]. The COGENT study found no difference in cardiovascular events among patients on clopidogrel and omeprazole compared to patients on clopidogrel alone. Although the study was terminated early due to loss of funding[60].

The data on PPI side effect profile remains controversial. It is important to note that the evidence provided by ACG in their 2021 guidelines presented 95% confidence intervals for reported adverse events such as cardiovascular events, kidney disease, gastrointestinal complications, dementia, bone fractures, Vitamin 12 deficiency, gastric cancer, hypomagnesemia, and all-cause mortality-all of which crossed 1, making these hazard ratio and odds ratio statistically insignificant.

DRUG-DRUG INTERACTIONS

PPIs can decrease drug solubility either due to alteration in gastric pH or inhibition of the CYP450 system leading to decreased metabolism of certain drugs. The bioavailability of ketoconazole and atazanavir, for example, may be decreased by 50% or more with PPI co-administration. The metabolism of clopidogrel, simvastatin, phenytoin and many other drugs depends on the CYP450 system and coadministration of PPIs can decrease its clearance[68]. Also, PPI interaction with the ATP-dependent P-glycoprotein can inhibit digoxin efflux and increase its toxicity[69]. Another important consideration is in patients with hepatitis C who are placed on direct-acting antivirals (DAAs). There is a significant risk of failure of hepatitis C therapy in patients on concurrent PPI therapy likely because of decreased DAA bioavailability in the setting of altered gastric acidity[70]. It is important to be mindful of PPI administration especially in cases of polypharmacy in the elderly to ensure adequate efficacy of the prescribed medications.

STRATEGIES TO MINIMIZE SIDE-EFFECT PROFILE

As perception of PPI therapy is starting to change with more studies reporting consequences of long-term PPI use, strategies to minimize harm from its use become an important discussion. It is equally as important to understand the evidence behind the reported side effects and educate patients on their risks and benefits.

Strategy 1: Evidence-based initiation of therapy

The decision of starting PPI therapy should be evidence-based. There are several guidelines on disease processes that require PPI therapy, and it is important to have a good understanding of level of evidence and recommendation behind them. The 2021 ACG guidelines on GERD management have a strong recommendation supported by moderate quality evidence to start patients with heartburn and regurgitation symptoms on empiric PPI therapy for 8 wk[20]. Sometimes, further evaluation may be needed after the first empiric trial. These guidelines also have a strong recommendation supported by moderate evidence for patients who have high suspicion of GERD, but diagnosis is not definitive, to undergo reflux monitoring with BRAVO performed off PPI therapy to either confirm or rule out GERD [20]. This study may help differentiate dyspepsia from GERD. The 2017 ACG guidelines on dyspepsia and *H. pylori* had a strong recommendation supported by high quality evidence to start empiric PPI therapy on patients who were confirmed to have *H. pylori* infection, have dyspepsia but are *H. pylori* negative, have symptoms of dyspepsia persist despite *H. pylori* eradication, have functional dyspepsia [24,25]. The 2016 ACG guidelines on Barrett's esophagus provided a strong recommendation supported by moderate evidence that once-daily PPI therapy should be implemented in patients at high risk for developing Barrett's esophagus-male gender with more than 5 years of frequent (weekly or more) heartburn or regurgitation and two or more risk factors such as age greater than 50, Caucasian race,

central obesity, current or history of smoking, confirmed family history of Barrett's esophagus or esophageal adenocarcinoma[26]. While there are no official guidelines supporting this, PPIs have been successfully implemented in EoE treatment with 69.2% of patient achieving histologic remission compared to 41.7% of patients on empiric elimination diet alone[71].

Strategy 2: Need for ongoing treatment revisited at follow up

Another important strategy is to minimize risks by evaluating whether patient needs to stay on PPI therapy. Ongoing risks and benefit discussion with the patient along with weaning trials play a key role. As of 2021, ACG has a conditional recommendation supported by low evidence to have discontinuation trials of PPI therapy for patients with reflux symptoms who responded to 8-wk empiric PPI treatment attempted or for patients who have endoscopic or histologic evidence of esophageal or gastric mucosal healing[20,72]. It is important to note that weaning trials should not be attempted in patients with significant erosive esophagitis, BE, or history of esophageal adenocarcinoma[15,26].

In 2017, American Gastroenterological Association (AGA) came up with best practice advice[15]. They supported weaning off trials for patients with uncomplicated GERD. For patients who are unable to wean off therapy, BRAVO study or high-resolution manometry (HRM) are indicated to distinguish GERD from a functional syndrome[15]. HRM can be further used as a diagnostic evaluation in patients with refractory reflux symptoms prior to anti-reflux surgery[73]. HRM helps differentiate reflux from hiatal hernia and esophageal dysmotility[73]. The AGA recommended that if patients had an episode of bleeding from NSAID therapy should be started on long-term PPI therapy, especially is they must continue NSAID therapy.

Strategy 3: Dosing adjustment tailored to patient

As discussed previously, PPI metabolism relies on hepatic P450 system. Some patients are fast metabolizers, others may be slow, so it is not always easy to predict a particular patient's ability to metabolize PPIs. We know that patients of Asian descent and older patients tend to have slower P450 system and may have a higher concentration of PPIs available from the same dose[6]. This is something that is important to consider when selecting a starting dose or trying to decrease the dose later in treatment. The 2021 ACG guidelines provided conditional recommendation supported by low quality evidence that patients who require maintenance therapy with PPIs should be given the lower dose that controls their symptoms and maintains healing of tissues[20]. This was echoed in 2017 AGA guidelines as well suggesting that the lowest effective PPI dose should be used[15]. Same degree recommendation and evidence was put forward for as needed PPI therapy for patients with NERD[20]. pH testing (such as BRAVO) along with pH impedance can help facilitate titration to the minimum possible PPI dose to achieve optimal anti-secretory effects[74]. pH testing can also help tailor PPI therapy dosage and duration in Barrett's esophagus patient population[75].

Strategy 4: Looking for alternative options

While some conditions, such as erosive esophagitis, BE, prior history of esophageal adenocarcinoma, gastric ulcers, EoE require long-term acid-suppression with PPI therapy, many other conditions may be considered for an alternative therapy with H2 blockers, life-style modifications, or both[76]. One of the most common indication for PPI therapy is GERD and dyspepsia. Both conditions can be trialed with H2 blockers in attempts to come off PPI therapy. There are novel medications being developed such as potassium-competitive acid blockers (P-CABs), which bind to potassium inions thus blocking the hydrogen-potassium ATPase enzyme[77]. Similar to PPIs, P-CABs have a dose depended effects on gastric acid production[77]. Weight loss in overweight and obese patients had moderate evidence and strong recommendations for patients struggling with GERD suggested by ACG in 2021[20]. The rest of the life-style modifications, such as avoiding meals within 2-3 h of bedtime, tobacco products, trigger foods, and elevation of the head of the bed for nocturnal symptoms-all had only conditional recommendation supported by low quality evidence[20].

Surgical options need to be discussed with patients unwilling to commit to long-term PPI. Anti-reflux Surgery (LARS) is an alternative treatment to long-term pharmacologic therapy, especially in patients with large hiatal hernias or Barrett's esophagus but was noted to have higher risks of symptom recurrence, especially in obese patients[78,79]. As a result, some studies reported that the utilization of anti-reflux surgery is greater when used in conjunction with weight loss in patients with BMI over 35 [80]. Despite initial success with LARS, studies reported that as many as 48% patients who have undergone LARS resumed PPI therapy at 5-year mark[81]. Additionally, LARS requires pre-surgery work up, which includes HRM.

PATIENT'S PERCEPTION OF PPI THERAPY

Patients understanding of therapy and how it works directly contribute to patient satisfaction and treatment success. Shared decision-making regarding duration of treatment and side-effect profile is key. Patient's participation and understanding of therapy are especially important because PPI

treatment comes with limitations of short-half life and meal dependent administration.

In the setting of new concerns regarding PPI's side-effects and growing media coverage of this topic, patients are increasingly more worried about staying on PPIs long-term. Therefore, increasing awareness among primary care providers on the proper use of PPIs is crucial. Additionally, managing patient's expectations and educating on the evidence behind the reported side effects becomes important. Prior to the therapy initiation, anticipated duration of treatment should be discussed with the patient. Risks and benefit discussion needs to take place. Whether the PPI therapy is prescribed by the primary care or gastroenterology physician, the decision to start the therapy should be evidence-based and rely on most recent guidelines supported by high quality evidence. Additionally, prescribing physicians should have an ongoing discussion with their patients and re-evaluation of their need to stay on PPI therapy. Working together with the patient, setting realistic expectations from the beginning, following evidence-based guidelines, and continuing to re-evaluate of need for therapy could increase patient satisfaction with medical care, provide reassurance, and help more people to safely benefit from PPI therapy.

CONCLUSION

Since their first introduction to the medical practice, PPIs have come a long way and we now know much more about their pharmacodynamics and side-effect profile. The side-effect data remains controversial with most recent ACG guidelines arguing against significant risks associated with this therapy. While data provided by ACG is reassuring, PPI therapy should still be utilized according to evidence-based practice. We now know more about which patients are more likely to benefit from this therapy and why some patients should only be on it short term. As our understanding of this therapy deepens, our practice should change to help more patients to safely benefit from PPIs. Following evidence-based guidelines and working together with a patient managing expectations and educating on risks may be the key to successful come back of PPI therapy.

Abstract

Celiac disease (CD) is well recognized as a systemic, chronic autoimmune disease mainly characterized by gluten-sensitive enteropathy in genetically predisposed individuals but with various extraintestinal features. One of the affected organs in CD is the pancreas, consisting of both endocrine and exocrine alterations. Over the last decades there has been increasing interest in the pancreatic changes in CD, and this has been reflected by a great number of publications looking at this extraintestinal involvement during the course of CD. While pancreatic endocrine changes in CD, focusing on type 1 diabetes mellitus, are well documented in the literature, the relationship with the exocrine pancreas has been less studied. This review summarizes currently available evidence with regard to pancreatic exocrine alterations in CD, focusing on risk of pancreatitis in CD patients, association with autoimmune pancreatitis, prevalence and outcomes of pancreatic exocrine insufficiency in newly diagnosed and gluten-free diet treated CD patients, and the link with cystic fibrosis. In addition, we discuss mechanisms behind the associated pancreatic exocrine impairment in CD and highlight the recommendations for clinical practice.

Key Words: Pancreas; Celiac disease; Autoimmune; Pancreatitis; Cystic fibrosis; Exocrine insufficiency

Core Tip: Celiac disease (CD) is currently regarded as a systemic, chronic, immune-mediated disease triggered by gluten ingestion in genetically susceptible individuals. In the last decade there has been an increasing number of publications on extraintestinal involvement during the course of CD, some of which have assessed the pancreatic changes associated with this disease. This review summarizes currently available data with respect to exocrine pancreatic changes in CD, focusing on practices for clinicians.

INTRODUCTION

Celiac disease (CD) is an immune-mediated enteropathy that occurs in genetically predisposed individuals upon ingestion of gluten. Initially considered a small bowel disease, now it is widely recognized as a systemic illness, which accounts for its many protean manifestations. The systemic character along with its various clinical presentations make CD a sometimes difficult to recognize clinical chameleon. The wide spectrum of presenting features, sometimes subclinical, hinders case-finding strategies and delays diagnosis, as CD is often not considered among the differential diagnoses [1,2]. Moreover, there is also the further drawback of poor awareness among different medical specialties[3].

Among the extraintestinal features of CD[4-6], pancreatic involvement has rarely been reported compared to other organ-specific manifestations such as cutaneous, hematologic, liver-related, rheumatologic, cardiovascular, or neurological impairments[7-13]. Moreover, while some of these systemic features have been incorporated into case-finding and screening strategies such as anemia, osteoporosis or chronic liver disease[14], pancreatic-associated involvement in CD is scarcely reported in currently available guidelines[15-17]. The association between the pancreas and CD covered in guidelines is limited to the need to consider pancreatic exocrine insufficiency (PEI) as an alternative diagnosis in non-responsive CD and the fact that upper gastrointestinal surgery including pancreas-related indications may unmask subclinical CD[15,16]. This has also been highlighted by previous reports on the impact of CD on exocrine and endocrine pancreas, which also set the need for further research focused on this association[18]. Contrasting the well-documented pancreatic endocrine changes in CD, referring to type 1 diabetes mellitus in particular, the relationship with the exocrine pancreas has been less covered in the literature.

On the other hand, the wide spectrum of pancreatic diseases does not include CD as a risk factor or associated condition, except counting CD as a potential cause of PEI[19]. Pancreatic involvement can occur in patients with CD, either caused by the small-bowel disease or co-existing with it. The main mechanisms for this association are believed to be the impaired cholecystokinin (CCK) and secretin release, but also the chronic duodenal inflammation that can lead to secondary modifications of papillary mucosal area[20].

Our aim was to summarize currently available evidence with regard to exocrine pancreatic involvement in CD, looking at CD as a risk factor or associated condition with pathologies of the exocrine pancreas, and testing indications regarding the bidirectional association of the two diseases.

SEARCH STRATEGY

For this purpose, we searched PubMed in January 2022 for all publications on the association between pancreas and CD, using the medical subject headings (MeSH) terms–"pancreas" (ID: D010179) and "celiac disease" (ID: D002446), with the following search syntax (("pancreas" [Mesh]) OR (pancreas [Title/Abstract])) AND (("celiac disease" [Mesh]) OR (celiac disease [Title/Abstract])). We performed additional searches with pancreas-related terms, "Pancreas, exocrine" (ID: D046790), "pancreatitis" (ID: D010195), "pancreatitis, chronic" (ID: D050500), "autoimmune pancreatitis" (ID: D000081012) and "celiac disease" (ID: D002446). The extended search yielded a total of 889 results, of which 145 were duplicates. Search results were imported into Reference Citation Analysis (Baishideng Publishing Group, Inc.), which was used for article processing and selection. We filtered the search for reviews, editorials, comments and opinion articles (n = 140). We excluded papers referring to the association of CD with diabetes or alterations of the endocrine pancreas (n = 66). The remaining titles and consecutive abstracts were screened for pertinence to the topic. We selected relevant articles on exocrine pancreatic involvement in CD for full-text analysis and summarized findings according to significant associations. References and citing articles of selected papers were also analyzed for potentially relevant articles that

might have been missed in the initial search. The process of article selection is detailed in Figure 1.

CD AND RISK OF PANCREATITIS

CD patients are at risk both for acute pancreatitis (AP) and chronic pancreatitis (CP)[21-23]. While some have described worse outcomes and increased medical burden among CD individuals[21], others have found lower morbidity and mortality among this patient group[24] (Table 1).

Several pathogenic mechanisms have been theorized to account for the elevated pancreatitis risk in CD–malnutrition, papillary stenosis, and immune phenomena[25] (Figure 2). Severe malnutrition affects pancreatic secretion and can cause pancreatic atrophy[26]. Also, chronic inflammation of the duodenal mucosa in CD patients can also involve the papillary area and lead to papillary stenosis and consequent pancreatic disease[20]. Finally, autoimmune pancreatitis (AIP) or other autoimmune phenomena such as islet-specific autoantibodies in CD-associated type 1 diabetes mellitus can contribute to the link between pancreatitis and CD[27,28].

With regard to CP, results are also discordant using similar diagnostic criteria; while some authors have reported CP features to be common in CD patients undergoing endoscopic ultrasound (EUS) assessment[29], others did not reveal significant structural alterations in the pancreatic parenchyma of CD individuals[30]. In their study using EUS criteria and elastography, Rana *et al*[30] concluded that PEI is functional and reversible after gluten-free diet (GFD). Supporting this finding, the pathognomonic pancreatic calcifications have been rarely reported in CD[31-35]. However, a biopsy-based study published as abstract has shown CD prevalence as high as 7.4% in established CP, recommending screening in this group[36].

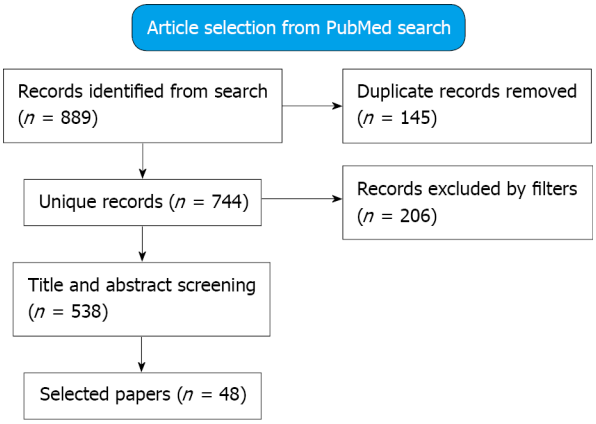
Concerning CD screening in pancreatic diseases, there have been reports of asymptomatic hyperenzymemia, macrolipasemia, or macroamylasemia[37-42] in CD patients, but prevalence studies are missing. According to these reports, decrease or even resolution of macroamylasemia/macrolipasemia or elevated pancreatic enzyme levels can be seen on GFD. Of note, the occurrence of hyperenzymemia in CD can be a confounder for the reported elevated risk of AP associated with CD, by overdiagnosing AP in this scenario.

On the other hand, idiopathic recurrent pancreatitis and sphincter of Oddi dysfunction might be considered a testing indication for CD, given the mechanism of chronic papillitis[20,43]. Non-response to treatment in CP might warrant testing for CD, as suggested in some case reports[31].

EXOCRINE PANCREATIC INSUFFICIENCY AND CD

CD is a well-recognized less common etiology of PEI[19,44,45]. This is well reported in currently available guidelines[46]. EPI has been reported with variable frequency in CD patients, depending on the test used to diagnose it. Early studies were based on direct pancreatic function testing (pancreatic enzyme or bicarbonate secretions measurements) and found that PEI is common in classical CD, but non-severe[47]. Fecal elastase (FE) is recommended for detecting PEI in newly diagnosed CD[48]. Impairment of pancreatic exocrine function can be seen both in newly diagnosed CD, in up to 80% of cases[19], and in treated CD, where it should be considered a cause of treatment failure in patients unresponsive to GFD[49,50]. In this latter group comprising GFD-treated CD patients with continuing diarrhea, EPI has been reported in 12%-18% of cases[51,52]. While CD patients improve with pancreatic enzyme replacement therapy (PERT), probably paralleling the restoring of mucosal architecture on GFD, some authors have reported that PERT could be discontinued in some patients who experience improvement in symptoms[53]. However, in CD patients with PEI, who report good adherence to GFD but experience continued malabsorption with adequate dosing PERT, additional pathogenic mechanisms such as enteric infections (*e.g.*, *Giardia*), small intestinal bacterial overgrowth, or complications such as refractory CD and enteropathy associated T-cell lymphoma should be sought[54]. Moreover, gastroparesis in the setting of type 1 diabetes mellitus associated with CD could contribute to incomplete response to PERT. PEI should be readily recognized in slowly recovering children with CD on GFD, as it might accelerate weight increase with adequate enzyme supplementation[55].

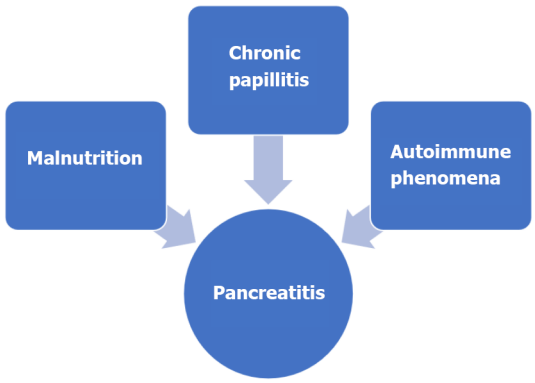
Correlation of certain genetic polymorphisms with PEI has also been studied, but without conclusive associations in a small cohort of CD patients[56].



A concern with using FE is represented by the lower diagnostic accuracy compared to direct pancreatic function testing, variability among different tests and analytical processing of samples, taking into account the potential dilution due to diarrhea[57-59].

Despite the increased risk of pancreatitis in CD discussed above, changes in pancreatic enzyme secretion in these patients seen to be mainly functional, as reported by Rana *et al*[30], who found no correlation with structural parenchymal alterations, assessed by EUS. Another study, based on magnetic resonance imaging assessment, did not reveal morphological changes in CD patients with PEI[60]. This impaired function of the exocrine pancreas is also supported by the inverse correlation between mucosal damage and pancreatic enzyme levels, with reversal of PEI on GFD[19,61]. However, protein

Table 1 Summary of studies looking at acute pancreatitis and chronic pancreatitis prevalence among individuals with celiac disease



Ref.	CD, *n*	Pancreatitis prevalence	OR of AP	Outcome
Alkhayyat *et al* [21], 2021	133400	AP 1.06%; CP 0.52%	OR for AP = 2.66; OR for CP = 2.18	Worse outcomes compared to non-CD
Osagiede *et al* [24], 2020	337201	AP 2.2%	OR = 1.92	Lower morbidity and mortality, attributed to less severe forms of AP or lower baseline comorbidities
Sadr-Azodi *et al* [22], 2012	28908	Pancreatitis 1.4%	HR for gallstone-related AP = 1.59; HR for non-gallstone-related AP = 1.86; HR for CP = 3.33	Increased risk of severe AP (gallstone-related: HR = 3.18; non-gallstone related: HR = 2.00)
Ludvigsson *et al* [23], 2007	14239	Pancreatitis any type 0.66%	HR for pancreatitis of any type = 3.3; HR for CP = 19.8	Patient population was represented by hospital inpatients, leaving out those managed as outpatients

AP: Acute pancreatitis; CD: Celiac disease; CP: Chronic pancreatitis; HR: Hazard ratio; OR: Odds ratio.

Figure 2 Mechanism behind the increased pancreatitis risk in celiac disease patients.

malnutrition, also present in CD patients, has been shown to be associated with acinar cell atrophy and fibrosis[18].

The main mechanism of PEI in CD patients is disruption of mucosal release of enteric hormones, mainly CCK and secretin, which represent a potent stimulus for pancreatic function. While exocrine pancreatic function is intrinsically normal, impaired CCK and secretin release from the atrophic mucosa leads to decreased secretion of enzymes into the duodenal lumen. The functional PEI that occurs in CD is reversible upon exogenous administration of CCK-pancreozymin[62]. Others have suggested that PEI can develop independent of this reduced entero-hormone release[63]. Another theorized mechanism is deficiency of amino acids, which leads to reduced protein synthesis for pancreatic enzymes. This mechanism is also backed up by the fact that correction of deficiencies alleviates PEI in CD patients[64].

Table 2 Mechanisms of pancreatic exocrine insufficiency in celiac disease

No.	
1	Impaired secretion of cholecystokinin and secretin from the diseased small bowel mucosa
2	Reduced amino acid uptake in the small bowel, which subsequently leads to reduction in precursors for synthesis of pancreatic enzymes
3	Morphologic alterations in pancreatic parenchyma secondary to protein malnutrition

Another hypothesis, but probably of less significance, is that of structural changes in the pancreatic parenchyma (acinar atrophy, fibrosis) seen in advanced malnutrition[65]. Mechanisms behind EPI in CD are summarized in Table 2[18,47,50,66].

CYSTIC FIBROSIS AND CD

Another underrecognized, pancreas-related association for CD is cystic fibrosis (CF), an autosomal recessive disease characterized by mutations in the CF transmembrane conductance regulator gene, which encodes a chloride and bicarbonate channel expressed in epithelial cells in multiple organs[67]. While the pancreatic dysfunction in CF is well known, altered immune regulation has been described in these patients, which predisposes them to developing autoimmune phenomena. The systematic review and meta-analysis by Imrei *et al*[68] showed pooled prevalence of 1.8%-2.3% of biopsy-proven CD among CF patients, which is more than twice that of the general population[69]. Based on this observation, the authors recommend routine screening for CD in CF patients. This recommendation is supported by another group[70], who suggested performing CD screening in CF with persistent gastrointestinal symptoms or malabsorption (including improper weight and/or height gain in pediatric patients), despite adequate enzyme replacement therapy.

AIP AND CD

AIP is a chronic fibroinflammatory disease of the pancreas, with a relapsing steroid-responsive pattern. Given the common immune dysregulation background of both AIP and CD, researchers have looked whether there is an association of the two. While some isolated reports have shown a potential link between AIP and CD[71,72], a study looking at CD frequency in a cohort of AIP patients did not show an increased CD prevalence among this group (1.4%) and concluded that serologic screening for CD is not supported[73]. However, a murine model of AIP has provided insight that gliadin sensitization and challenge can induce pancreatitis and extrapancreatic inflammation in HLA-DQ8 transgenic mice[74]. On the other hand, immunoglobulin G4-positive cells, which have been searched for in duodenal/ampullary biopsies as an alternative to pancreatic biopsy for diagnosing AIP, have also been reported in 7 of 18 CD patients in the study by Cebe *et al*[75]. Given the scarce data on AIP and CD, further research is warranted to conclude if there is a link between the two beyond the plausible biologic mechanism. A recognized association is that of type 2 AIP and ulcerative colitis, and considering the also established connection between CD and inflammatory bowel diseases[76], linking the three diseases might provide some insight on the relationship between AIP and CD.

CONCLUSION

Pancreatic involvement, both endocrine and exocrine, is frequent in CD and should be searched for in the appropriate clinical setting. Conversely, certain pancreatic-related diseases should prompt looking for CD–CF with ongoing digestive symptoms, non-responsive CP, idiopathic recurrent pancreatitis. Concomitant pancreatic disease in a CD patient may contribute to aggravated malnutrition and should be readily recognized in order to improve nutritional status and prognosis. Also, there is increasing data that impaired pancreatic function in CD can improve on a GFD.

FOOTNOTES

Author contributions: Balaban DV proposed the research idea; Balaban DV, Enache I, and Ciochina M performed the literature search and article selection, and drafted the initial version of the manuscript; Popp A and Jinga M critically reviewed the manuscript and supervised the project; All authors contributed to drawing the figures and tables, and have read and approved the final version of the manuscript.

Conflict-of-interest statement: All the authors report no relevant conflicts of interest for this article.

Abstract

BACKGROUND

Chronic inflammation due to *Helicobacter pylori* (*H. pylori*) infection promotes gastric carcinogenesis. Tumour necrosis factor-α (TNF-α), a key mediator of inflammation, induces cell survival or apoptosis by binding to two receptors (TNFR1 and TNFR2). TNFR1 can induce both survival and apoptosis, while TNFR2 results only in cell survival. The dysregulation of these processes may contribute to carcinogenesis.

AIM

To evaluate the effects of TNFR1 and TNFR2 downregulation in AGS cells treated with *H. pylori* extract on the TNF-α pathway.

METHODS

AGS cell lines containing TNFR1 and TNFR2 receptors downregulated by specific shRNAs and nonsilenced AGS cells were treated with *H. pylori* extract for 6 h. Subsequently, quantitative polymerase chain reaction with TaqMan® assays was used for the relative quantification of the mRNAs (*TNFA, TNFR1, TNFR2, TRADD, TRAF2, CFLIP, NFKB1, NFKB2, CASP8, CASP3*) and miRNAs (miR-19a, miR-34a, miR-103a, miR-130a, miR-181c) related to the TNF-α signalling pathway. Flow cytometry was employed for cell cycle analysis and apoptosis assays.

RESULTS

In nonsilenced AGS cells, *H. pylori* extract treatment increased the expression of genes involved in cell survival and inhibited both apoptosis (*NFKB1, NFKB2* and *CFLIP*) and the *TNFR1* receptor. TNFR1 downregulation significantly decreased

the expression of the *TRADD* and *CFLIP* genes, although no change was observed in the cellular process or miRNA expression. In contrast, TNFR2 downregulation decreased the expression of the *TRADD* and *TRAF2* genes, which are both important downstream mediators of the TNFR1-mediated pathway, as well as that of the *NFKB1* and *CFLIP* genes, while upregulating the expression of miR-19a and miR-34a. Consequently, a reduction in the number of cells in the G0/G1 phase and an increase in the number of cells in the S phase were observed, as well as the promotion of early apoptosis.

CONCLUSION

Our findings mainly highlight the important role of TNFR2 in the TNF-α pathway in gastric cancer, indicating that silencing it can reduce the expression of survival and anti-apoptotic genes.

Key Words: Gastric cancer; *Helicobacter pylori*; Tumour necrosis factor-α signalling pathway; *TNFR1*; *TNFR2*; miRNAs

Core Tip: This study demonstrated for the first time the effect of TNFR1 and TNFR2 downregulation on an AGS cell line treated with *Helicobacter pylori* extract. Although TNFR1 downregulation did not promote significant changes in the expression of mRNA and miRNAs of the tumour necrosis factor-α (TNF-α) signalling pathway, TNFR2 downregulation promoted important changes in the signalling mediators evaluated. We observed a reduction in the expression of cell survival and anti-apoptotic genes and an increase in the expression of miR-19a and miR-34a, which affected cell cycle kinetics and contributed to early apoptosis. Thus, our findings highlight the important role of TNFR2 in the TNF-α signalling pathway in gastric carcinogenesis.

INTRODUCTION

Gastric cancer (GC) has high rates of incidence and mortality worldwide, especially in Eastern Asia, Eastern Europe and Latin America[1]. In Brazil, it is the fourth most common cancer in men and the sixth most common in women[2]. *Helicobacter pylori* (*H. pylori*) is the main risk factor for the development of gastric neoplasms, since it is responsible for chronic inflammation in the gastric mucosa and for the GC progression cascade[3]. Consequently, it can trigger the host's immune response, which leads to changes in the expression of genes related to inflammation, cell kinetic regulation and miRNAs [4-6]. After infection by this bacterium, tumour necrosis factor-α (TNF-α) stands out among the mediators of inflammation and is considered to be a key mediator linking inflammation and cancer[7,8].

TNF-α is a pleiotropic proinflammatory cytokine that is important in the signalling and regulation of multiple cellular responses and processes, such as the production of other inflammatory cytokines, and cell communication, survival, proliferation and apoptosis[9]. These different functions are accomplished due to the ability of TNF-α to bind to TNFR1 (TNFRSF1A) or TNFR2 (TNFRSF1B) receptors, thus resulting in different cellular processes. Both receptors are transmembrane proteins, and although they are largely similar in terms of extracellular structure, their intracellular domains are different, and thus dictate the cellular fate for either survival or death. Though only TNFR1 has a death domain, the TNF-α signalling pathway triggered by this receptor is able to induce both cell survival and apoptosis, while TNFR2 results only in cell survival[10,11]. The signalling cascade after TNF-α/TNFR1 binding that results in cell survival starts with the recruitment of TRADD and is mediated by activation of nuclear factor-kappaB (NF-κB) and transcription of pro-survival and anti-apoptotic genes, such as cellular inhibitor of apoptosis proteins (cIAP), TRAF2 and cFLIP, and of inflammatory cytokines. However, this signal complex is transient; TNF-α rapidly dissociates from TNFR1 and binds to the Fas-associated death domain protein to form another signal complex, which coordinates downstream signalling of the caspase cascade and apoptosis. Conversely, as TNFR2 does not have a death domain, it induces long-lasting NF-kB activation by recruiting existing cytoplasmic TRAF-2/cIAP-1/cIAP-2 complexes that can inhibit pro-apoptotic factors and maintain cell survival and proliferation[9-12].

Regulation of signal transduction triggered by TNF-α requires a constant balance between the opposing functions of cell survival and cell death to maintain homeostasis. Thus, an imbalance in these processes due to changes in the expression of receptors, downstream genes, ligands and pro-/anti-apoptotic mediators may support the tumorigenic process[13]. A recent study by our research group showed dysregulation in the TNF-α signalling pathway in GC samples with an upregulation of cell survival-related genes and of TNFR2 expression, thus suggesting a prominent protumor role by TNA-α /TNFR2 binding in gastric neoplasm[14]. Furthermore, we showed through a miRNA:mRNA interaction network that this signalling pathway can be regulated by miRNAs. In addition, *H. pylori* infection was also associated with an increased expression of *TNF-α* mRNA and protein, and dysregulated miRNA expression in chronic gastritis patients. The expression pattern of these genes/miRNAs was normalized after treatment to eradicate bacteria, indicating that this pathogen influences the host's inflammatory response in part by its action on miRNAs[6].

In accordance with our previous results, we thought it was important to evaluate the effect of silencing TNFR1 and TNFR2 receptors in an AGS gastric cell line after treatment with an *H. pylori* extract on *TNF-α* mRNA expression and on downstream genes related to its signalling pathway (*TRADD, TRAF2, CFLIP, NFKB1, NFKB2, CASP8* and *CASP3)*. In addition, we also investigated the same miRNAs previously studied (miR-19a, miR-34a, miR-103a, miR-130a and miR-181c)[14], as well as the cell cycle and apoptosis. Overall, our results highlight the main role of the TNFR2 in TNF-α signalling in an AGS cell line, while treatment with *H. pylori* extract induces prosurvival gene expression mainly through TNFR1.

MATERIALS AND METHODS

Cell culture

AGS GC cells from the Cell Bank of Rio de Janeiro, Brazil (BCRJ code 0311) were incubated at 37 °C and 5% CO_2 in HAM-F10 medium (Cultilab, SP, Brazil) supplemented with 10% foetal bovine serum and 1× antibiotic/antimycotic (Gibco, Invitrogen Life Technologies, Carlsbad, CA, United States). The culture medium was replaced every two to three days. The HGC-27 GC cell line, provided by Dr Marcelo Lima Ribeiro (São Francisco University-USF, SP, Brazil), was also used in early experiments as an alternative line for follow-up experiments, and 293T cells of human embryonic kidney were provided by Dr Luisa Lina Villa (University of São Paulo–USP, SP, Brazil) for transfection experiments. The cells were maintained under the same conditions as the AGS cell line except for the culture medium, which was Dulbecco's modified Eagle medium (Gibco, Invitrogen Life Technologies, Carlsbad, CA, United States). Stable shRNA-expressing cell lines with reduced expression of TNFR1 (called shTNFR1) and TNFR2 (called shTNFR2) were kept in a similar culture medium to the nonsilenced AGS cells, and further supplemented with 0.5 μg/mL puromycin or 200 μg/mL G418, respectively.

Treatment with H. pylori extract

The previously described *H. pylori* Tox+ strain (cagA+/vacA s1m1) was grown in a selective medium (pylori-Gelose; BioMérieux, Marcy-l'Étoile, France) at 37 °C under microaerophilic conditions[15]. This strain is not resistant to any antibiotic used to treat *H. pylori*. *H. pylori* extract was prepared according to the protocol described by Li *et al*[16]. In brief, the *H. pylori* Tox+ strain was harvested and suspended in distilled water at a concentration of 2 × 10^8 CFU/mL. Next, the suspension was incubated at room temperature for 40 min and centrifuged at 20000 *g* for 20 min. The supernatant was filtered using a 0.2 mm filter and stored at -20 °C until use. The extract was tested several times (4, 6 and 24 h) using differing *H. pylori* extract volumes (50, 100, 150 and 200 μL) to verify the best experimental conditions. Then, 2 × 10^5 nonsilenced AGS cells and AGS cells with downregulation of TNFR1 (shTNFR1) and TNFR2 (shTNFR2) were seeded in 12-well plates. After 48 h, the medium was replaced with 500 μL of HAM-F10 containing 30% v/v *H. pylori* extract or the same proportion of water (control). Cells were incubated with *H. pylori* extract for 6 h in an incubator at 37 °C. For all experiments, three temporally independent events were performed.

Cell viability assay

MTT ([3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide]) assays (Sigma–Aldrich, St. Louis, MO, United States) were employed to evaluate the viability of silenced and nonsilenced AGS cells after different treatment conditions with *H. pylori* extract (times and *H. pylori* extract volumes). In summary, the culture medium was removed, and 300 μL of fresh medium containing 1 mg/mL MTT reagent was added to each well. After 30 min of incubation at 37 °C, the medium with MTT reagent was replaced by the same volume of dimethyl sulfoxide (DMSO) (Sigma–Aldrich, St. Louis, MO, United States). The absorbance at 540 nm was measured using a FLUOstar Omega spectrophotometer (BMG Labtech, Ortenberg, Germany).

Transfection with shRNA

MISSION® Lentiviral Transduction Particles (Cat. SHCLNV, Sigma–Aldrich, St. Louis, MO, United States) were used to integrate shRNA into the genome of AGS cells to knockdown TNFR1 and TNFR2 expression. Verified viral vectors were purchased from Sigma–Aldrich, and the standard manufacturer's protocol was followed to generate the cell line. Stably transfected clones were selected by growing the cells in the presence of puromycin or G418, which acted as selection pressure (for TNFR1: 1 μg/mL puromycin and for TNFR2: 400 μg/mL G418). Different plasmids containing shRNAs were used to generate clones, of which the one showing the best knockdown efficiency was used for all experiments. The sequence of the shRNA in the construct was CTTGAAGGAACTACTACTAAG for *TNFR1* and GCCGGCTCAGAGAATACTATG for *TNFR2*. TNFR1 and TNFR2 levels were assessed by quantitative polymerase chain reaction (PCR) and Western blotting to verify the knockdown. Similar transfections were carried out with an empty vector (Sigma–Aldrich, St. Louis, MO, United States), which served as the transfection control.

Western blot analysis

Protein extraction was performed by lysis of nonsilenced AGS cells and AGS cells containing a shRNA or an empty vector with CelLytic™ MT Cell Lysis Reagent (Sigma–Aldrich, St. Louis, MO, United States). The lysis reaction was centrifuged at 12000 *g* for 10 min after a 15 min incubation. The protein concentration was determined using a Pierce™ BCA Protein Assay kit (Thermo Scientific, Massachusetts, United States) according to the manufacturer's protocol. Thirty micrograms of protein was separated on an 8%-12% sodium dodecyl sulphate-polyacrylamide gel by electrophoresis (120 min) and then transferred to PVDF or nitrocellulose membranes (MilliPore Corporation, Burlington, Massachusetts, EUA) using an Electrotransfer TE70XP system (Hoefer) for 80 min. Membranes were blocked with 5% nonfat dry milk for 60 min and were then incubated overnight at 4 °C with the following primary antibodies: Anti-TNFR1 (dilution 1:500) (Cell Signalling, Massachusetts, United States), anti-TNFR2 (dilution 1:5000) (Abcam Cambridge, United Kingdom) and anti-GAPDH (dilution 1:30000) (Abcam, Cambridge, United Kingdom). After being washed, the membranes were incubated at room temperature under stirring with horseradish peroxidase-conjugated goat anti-rabbit (dilution 1:2000) secondary antibodies (Abcam, Cambridge, United Kingdom). Bands were revealed by enhanced chemiluminescence, visualized in a ChemiDoc™ Imaging System (BioRad, Hercules, California, United States) and quantified using Image Lab 6.0 Software (BioRad, Hercules, California, United States).

Quantification of mRNA and miRNA expression by RT–qPCR

After 6 h of incubation, the medium containing *H. pylori* extract or water was removed, and total RNA was extracted from AGS cells with a miRNeasy Micro Kit (Qiagen, Valencia, CA, United States) according to the manufacturer's protocol. Complementary DNA (cDNA) for mRNA and miRNA was synthesized using a High-Capacity cDNA Archive Kit (Applied Biosystems, Foster City, CA, United States) and a TaqMan® MicroRNA Reverse Transcription Kit (Applied Biosystems, Foster City, CA, United States), respectively. Quantitative PCR (qPCR) was performed with TaqMan® assays (Applied Biosystems, California, United States) for the genes *TNFA* (Hs01113624_g1), *TNFR1* (*TNFRSF1A*) (Hs01042313_m1), *TNFR2* (*TNFRSF1B*) (Hs00961749_m1), *TRADD* (Hs00182558_m1), *TRAF2* (Hs00184192_m1), *CFLIP* (*CFLAR*) (Hs00153439_m1), *NFKB1* (Hs 00765730_m1), *NFKB2* (Hs01028901_g1), *CASP8* (Hs01116281_m1) and *CASP3* (Hs00234387_m1) and for the target miRNAs hsa-miR-19a-3p (MIMAT0000073; ID 000395), hsa-miR-34a-3p (MIMAT0004557; ID 002316), hsa-miR-103a-3p (MIMAT0000101; ID 000439), hsa-miR-130a-3p (MIMAT0000425; ID 000454) and hsa-miR-181c-5p (MIMAT0000258; ID 000482) (Applied Biosystems, California, United States), as described in our previous study[14]. *ACTB* (Catalogue#: 4352935E) and *GAPDH* (Catalogue#: 4352934E) genes were used for normalization of mRNA quantification, while endogenous RNU6B (ID 001093) and RNU48 (ID 001006) levels were used for miRNAs. All reactions were performed in triplicate. Relative quantification (RQ) of mRNA and miRNA expression was calculated by the $2^{(-\Delta\Delta Ct)}$ method[17], and nonsilenced AGS without *H. pylori* extract treatment was used as a calibrator (AGS-C). RQ values are expressed as the mean ± SD of gene and miRNA expression for all experimental groups in relation to nonsilenced and untreated AGS, with RQ = 1.

Cell cycle analysis

The cell distribution at different phases of the cell cycle was estimated by measuring the cellular DNA content using flow cytometry. After incubation with *H. pylori* extract or water, nonsilenced AGS, shTNFR1 and shTNFR2 cell lines were harvested with trypsin and fixed in 70% ethanol at 4 °C for at least 24 h. Subsequently, the cells were washed, centrifuged and incubated with 200 μL of Guava® Cell Cycle Reagent (Merck Millipore, Burlington, Massachusetts, United States) for 30 min in the dark. Cell cycle distribution was measured by a Guava® EasyCyte Flow Cytometer and analysed with Guava® InCyte software (Merck Millipore, Burlington, Massachusetts, United States).

Apoptosis analysis

Apoptotic cell death was also measured by flow cytometry using a fluorescein isothiocyanate (FITC)

Annexin V Apoptosis Detection Kit (BD Pharmingen™; BD Biosciences, Franklin Lakes, NJ, United States) according to the modified manufacturer's protocol. After treatment, adherent cells were harvested with Accutase® (Sigma–Aldrich, St. Louis, MO, United States) since this solution avoids membrane damage[18]. After this step, the cells were washed with cold phosphate-buffered saline, centrifuged, resuspended in 1× binding buffer and stained with 5 μL of Annexin V-FITC and 5 μL of propidium iodide (PI, 50 μg/mL) for 15 min at room temperature in the dark. The labelling of cells was evaluated using a flow cytometer and was analysed with Guava® InCyte software. From the scatter diagram and quadrant plotting, the results are presented as follows: Living cells (FITC-/PI-) located in the lower left quadrant, early apoptotic cells (FITC+/PI-) in the lower right quadrant and late apoptotic cells (FITC+/PI+) in the upper right quadrant.

Statistical analysis

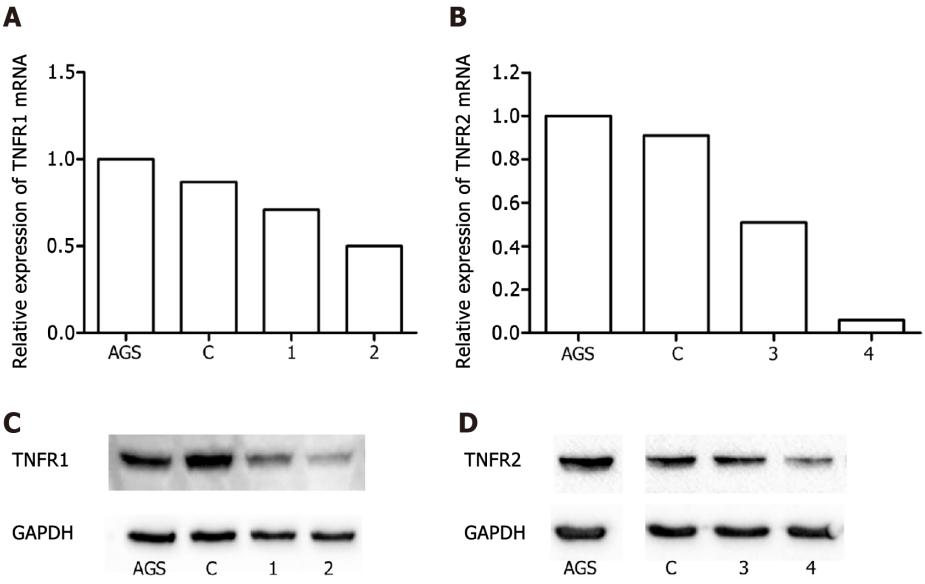
Statistical analysis of the data was performed in GraphPad Prism Software version 6.01 using two-way ANOVA with Bonferroni post hoc test. The results are expressed as the mean ± SD from three experiments conducted independently. A $P < 0.05$ was considered statistically significant.

RESULTS

The AGS cell line treated with H. pylori extract expresses TNFA, TNFR1, and TNFR2 receptors

Initially, both AGS and HGC-27 cell lines were cultured to evaluate the mRNA expression levels of *TNFA, TNFR1* and *TNFR2* receptors by qPCR. The analyses showed that both cell lines expressed *TNFA* and *TNFR1,* but *TNFR2* was expressed at lower levels in HGC-27 cells than it was in AGS cells (Supplementary Figure 1). The AGS cell line was chosen for additional experiments since it was not reasonable to use HGC-27 in the TNFR2 silencing experiments.

To standardize treatment conditions, several volumes of *H. pylori* extract (50, 100, 150 and 200 μL) were tested at different incubation times (4, 6 and 24 h) in the AGS cell line to establish the best conditions for inducing *TNFA* expression without reducing cell viability. The best results were obtained with an *H. pylori* extract concentration of 30% v/v (150 μL) at 6 h of incubation (Supplementary Figures 2 and 3). Under these conditions, there was an increase in *TNFA* expression (RQ = 3.59) without an impact on cell viability (98.9%).



The effect of TNFR1 and TNFR2 downregulation and treatment with H. pylori extract on TNF-α signalling downstream gene expression

The effect of TNFR1 and TNFR2 downregulation on GC cells was evaluated after transfection of the AGS cell line with two specific shRNAs targeting the genes, *TNFR1* (called shTNFR1) and *TNFR2* (called shTNFR2), followed by antibiotic selection. RT–qPCR and Western blotting were used to evaluate the efficiency of silencing. Stable lines with the shRNAs exhibited a 59% reduction in TNFR1 and a 63% reduction in TNFR2 protein expression (Figure 1).

Initially, we evaluated the effect of treatment with *H. pylori* extract on the expression of genes of the TNF-α signalling pathway in nonsilenced AGS cells. After *H. pylori* extract treatment (AGS-*H. pylori* extract), nonsilenced AGS cells showed significantly upregulated mRNA expression of *TNFR1* and of anti-apoptotic and cell proliferation genes, such as *CFLIP, NFKB1* and *NFKB2* (Supplementary Figure 4A), compared to the control (AGS-C). In addition, *H. pylori* extract treatment increased the mRNA expression of *NFKB1* and *NFKB2* in a TNFR1-downregulated cell line (shTNFR1-*H. pylori* extract), whereas the expression of *TNFR2* and *TRADD* was reduced (Supplementary Figure 4B). On the other hand, the expression of the evaluated genes was not significantly changed by *H. pylori* extract treatment in the shTNFR2 cell line (Supplementary Figure 4C).

With regard to the influence of *TNFR1* and *TNFR2* downregulation on the expression of TNF-α signalling genes (Figure 2), a significantly downregulated mRNA expression of *TNFR1* (RQ = 0.83 and 1.03, respectively), *TRADD* (RQ = 0.60 and 0.41, respectively) and *CFLIP* (RQ = 1.25 and 1.36, respectively) was observed in shTNFR1-*H. pylori* extract and shTNFR2-*H. pylori* extract cells compared to that in AGS-*H. pylori* extract cells (RQ = 1.73, 0.98 and 2.09, respectively) (Figure 2B, D and F). Furthermore, *TNFR2* (RQ = 0.27, $P < 0.05$), *TRAF2* (RQ = 0.68, $P < 0.05$) and *NFKB1* (RQ = 1.67, $P < 0.05$) were reduced in shTNFR2-*H. pylori* extract cells compared to AGS-*H. pylori* extract cells (RQ = 0.86, 1.29 and 2.39, respectively) (Figure 2C, E and I). When we compared the nonsilenced and silenced AGS cell lines without *H. pylori* extract treatment (control-C), *TNFR2* mRNA expression was increased in shTNFR1-C (RQ = 1.49) compared to AGS-C (RQ = 1.00) and reduced in shTNFR2-C (RQ = 0.50) compared to shTNFR1-C and AGS-C. Likewise, *TRADD* mRNA expression was downregulated in shTNFR2-C (RQ = 0.35) compared to the other control groups (AGS-C and shTNFR1-C). There was no significant change in *TNFA, CASP3, CASP8* and *NFKB2* mRNA expression.

In general, the downregulation of TNFR1 and TNFR2 significantly influenced the mRNA expression of *TRADD* ($P < 0.001$) and *TRAF2* ($P < 0.01$), whereas the expression of *TNFR1, TNFR2* and *CFLIP* was also affected by treatment with *H. pylori* extract ($P < 0.01$ for all). In contrast, only the *H. pylori* extract

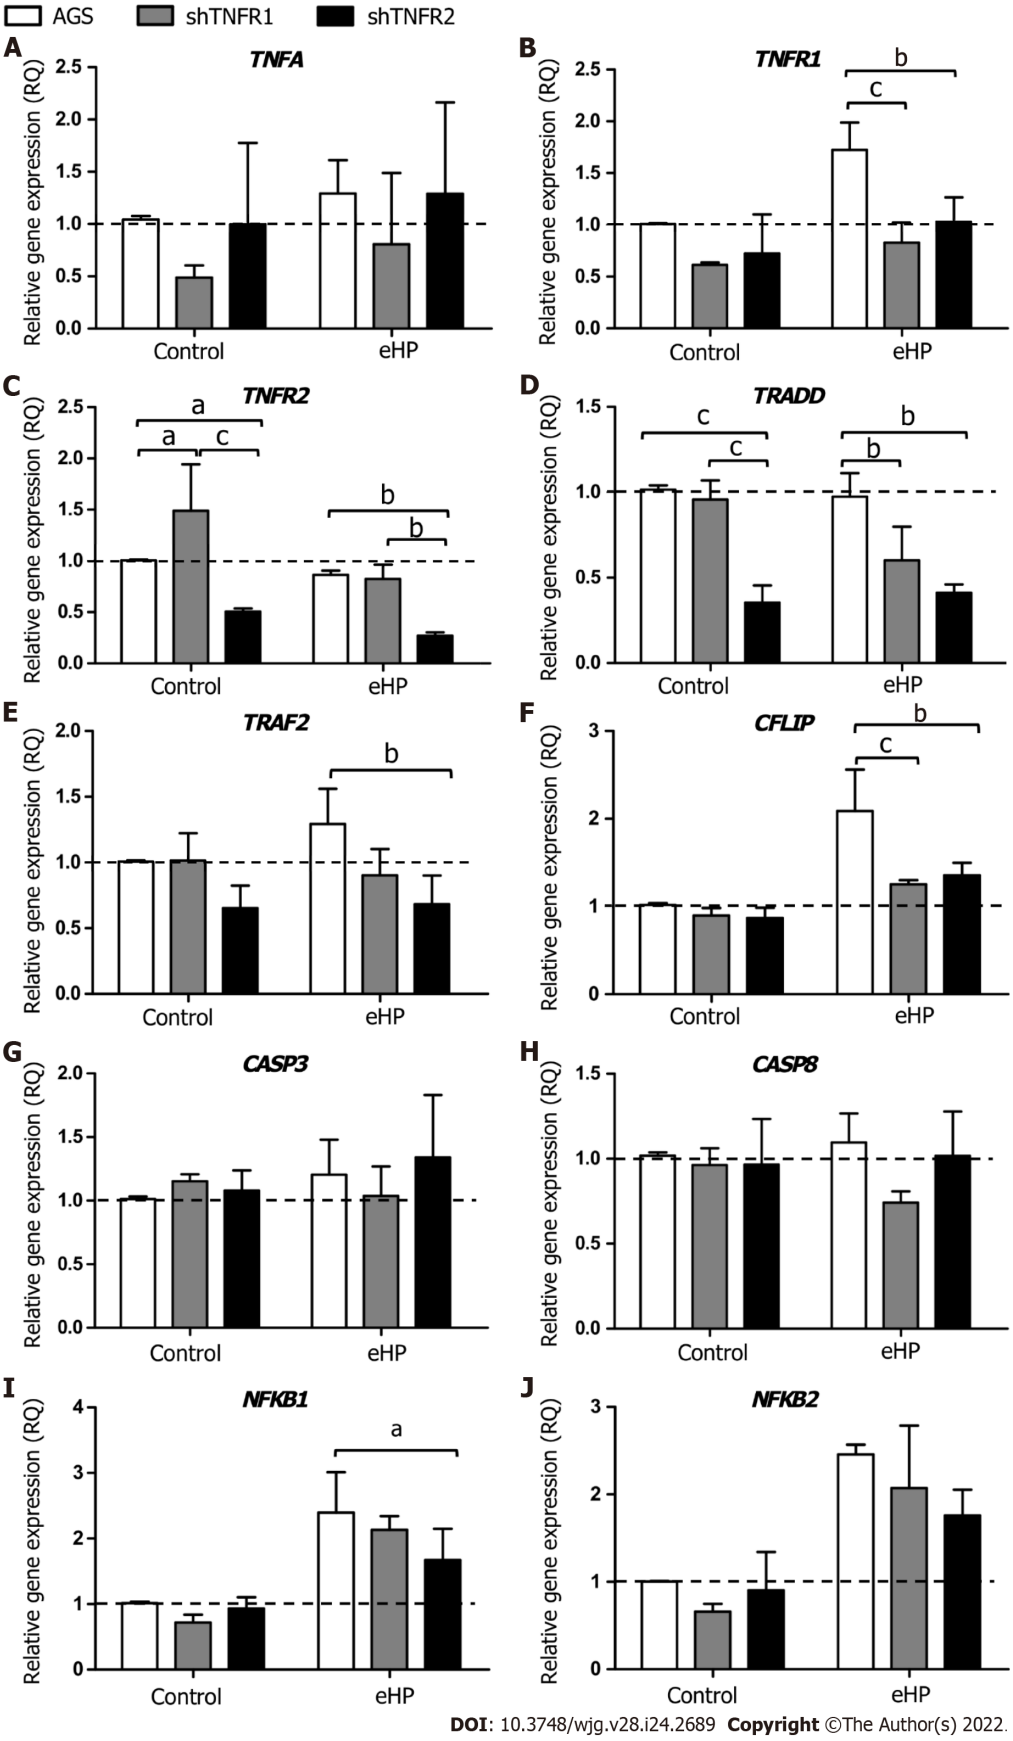
Figure 1 The efficiency of *TNFR1* and *TNFR2* expression silencing in AGS cells. A and B: Expression levels of *TNFR1* and *TNFR2* mRNA evaluated by real-time reverse transcription-quantitative polymerase chain reaction; C and D: Protein expression of *TNFR1* and *TNFR2* evaluated by Western blotting. Downregulation of *TNFR1* (A-C) and *TNFR2* (B-D) was confirmed by the reduction in the expression of receptors *TNFR1* and *TNFR2* following treatment with shRNAs 2 and 4, respectively. AGS: Nonsilenced cell line; C: Control transfected with empty vector; 1 and 2: Different shRNA clones for *TNFR1*; 3 and 4: Different shRNA clones for *TNFR2*.

treatment contributed to the differences observed in *NFKB1* and *NFKB2* mRNA expression ($P < 0.001$ for both).

TNFR2 downregulation upregulates miR-19a and miR-34a expression

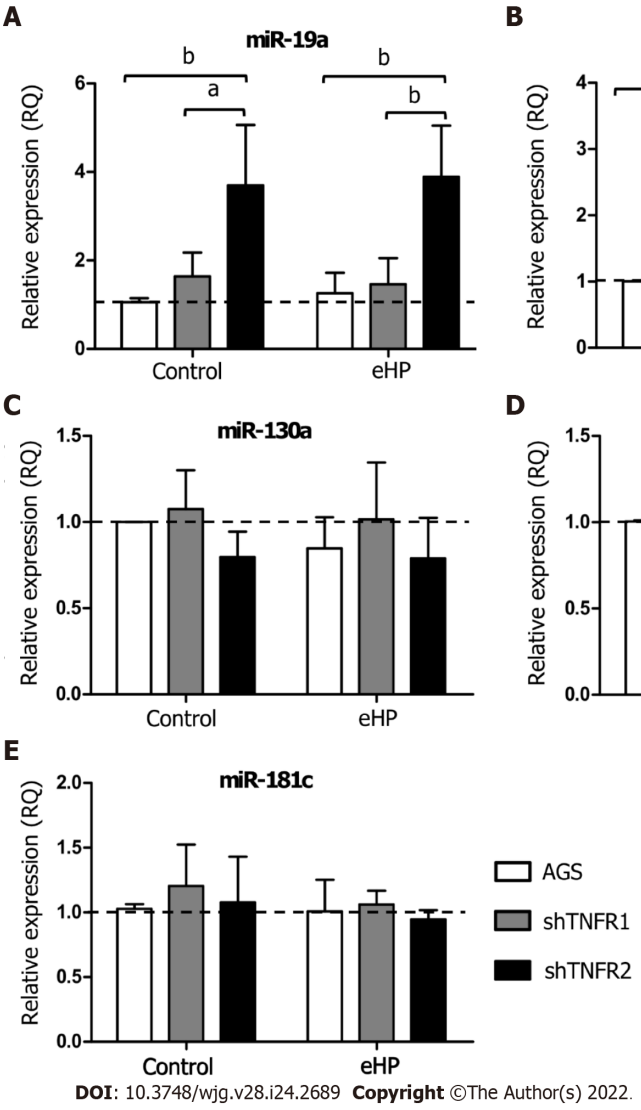


The expression of miRNAs miR-19a, miR-34a, miR-103a, miR-130a and miR-181c was evaluated in the AGS, shTNFR1 and shTNFR2 cell lines with and without *H. pylori* extract treatment (Figure 3 and Supplementary Figure 5). No significant change in the expression of these miRNAs was found in AGS and shTNFR1 cells regardless of *H. pylori* extract treatment. However, TNFR2 receptor downregulation resulted in a significant increase in the expression of miR-19a and miR-34a in shTNFR2-C cells (RQ = 3.70 and 2.64, respectively) compared with that of the AGS-C ($P < 0.01$ and $P < 0.001$, respectively) and shTNFR1-C cells ($P < 0.05$ and $P < 0.001$, respectively) cells and in shTNFR2-*H. pylori* extract cells (RQ = 3.89 and 1.69, respectively) compared to AGS-*H. pylori* extract ($P < 0.01$ and $P < 0.05$, respectively) and shTNFR1-*H. pylori* extract cells ($P < 0.01$ and $P < 0.01$, respectively) (Figure 3A and B).

TNFR2 downregulation promotes a reduction in G0/G1 phases and an increase in S phase

The effect of TNFR1 and TNFR2 downregulation after *H. pylori* extract treatment on cell cycle progression was evaluated by flow cytometry. Overall, *H. pylori* extract treatment did not affect the cellular distribution in the G0/G1, S and G2/M phases in nonsilenced AGS, shTNFR1 and shTNFR2 cells (Supplementary Figure 6). However, TNFR2 downregulation significantly reduced the number of cells in G0/G1 phase regardless of *H. pylori* extract treatment and led to an increase in the number of cells in S and G2/M phases in shTNFR2-C cells compared to that of the AGS-C cells (Figure 4).

Downregulation of TNFR2 promotes early apoptosis



In addition, we also investigated the effect of partial TNFR1 and TNFR2 inhibition and *H. pylori* extract treatment on apoptosis, which was evaluated through Annexin-V and PI double staining by flow cytometry. Treatment with *H. pylori* extract did not induce changes in the rates of early and late apoptosis in the nonsilenced AGS and both silenced AGS cell lines compared to the respective untreated cell lines (Supplementary Figure 7). However, after *H. pylori* extract treatment, the percentage of early apoptotic cells was significantly higher in shTNFR2 cells (1.27%) than in AGS (0.56%) and shTNFR1 cells (0.52%), whereas the percentage of late apoptotic cells was significantly reduced after *H. pylori* extract treatment (Figure 5). Together with the cell cycle results, these data indicate a relationship between decreased cell quantity in the G0/G1 phase and increased early apoptosis as a result of TNFR2 downregulation.

DISCUSSION

TNFR1 and TNFR2 differ in their intracellular domains and cellular expression; thus, the role of each receptor in the TNF-α-triggered signalling pathway varies according to the pathological condition, activating different cellular processes, such as cell survival and apoptosis[10]. This is the first study to investigate the effect of TNFR1 and TNFR2 downregulation on AGS cells treated with *H. pylori* extract. Our results show that *H. pylori* extract treatment of nonsilenced AGS cells upregulated the mRNA expression of proliferation (*NFKB1* and *NFKB2*) and antiapoptotic genes (*CFLIP*) by activating TNFR1. TNFR1 downregulation did not promote extensive changes in the expression of genes or miRNAs involved in the TNF-α signalling pathway or in cellular processes. In contrast, TNFR2 downregulation significantly decreased *TRADD* and *TRAF2* mRNA expression, which may impair TNFR1-mediated TNF-α signalling, and increased miRNA expression, which promoted a block in the G_1/S transition and an increase in early apoptosis.

H. pylori infection can deregulate the expression of several genes and miRNAs, as previously shown by our research group[6]. Recently, increased mRNA levels of *TNFA* and other proinflammatory mediators, such as interleukin (IL)-1β and IL-8, have been reported in an AGS cell line after infection by

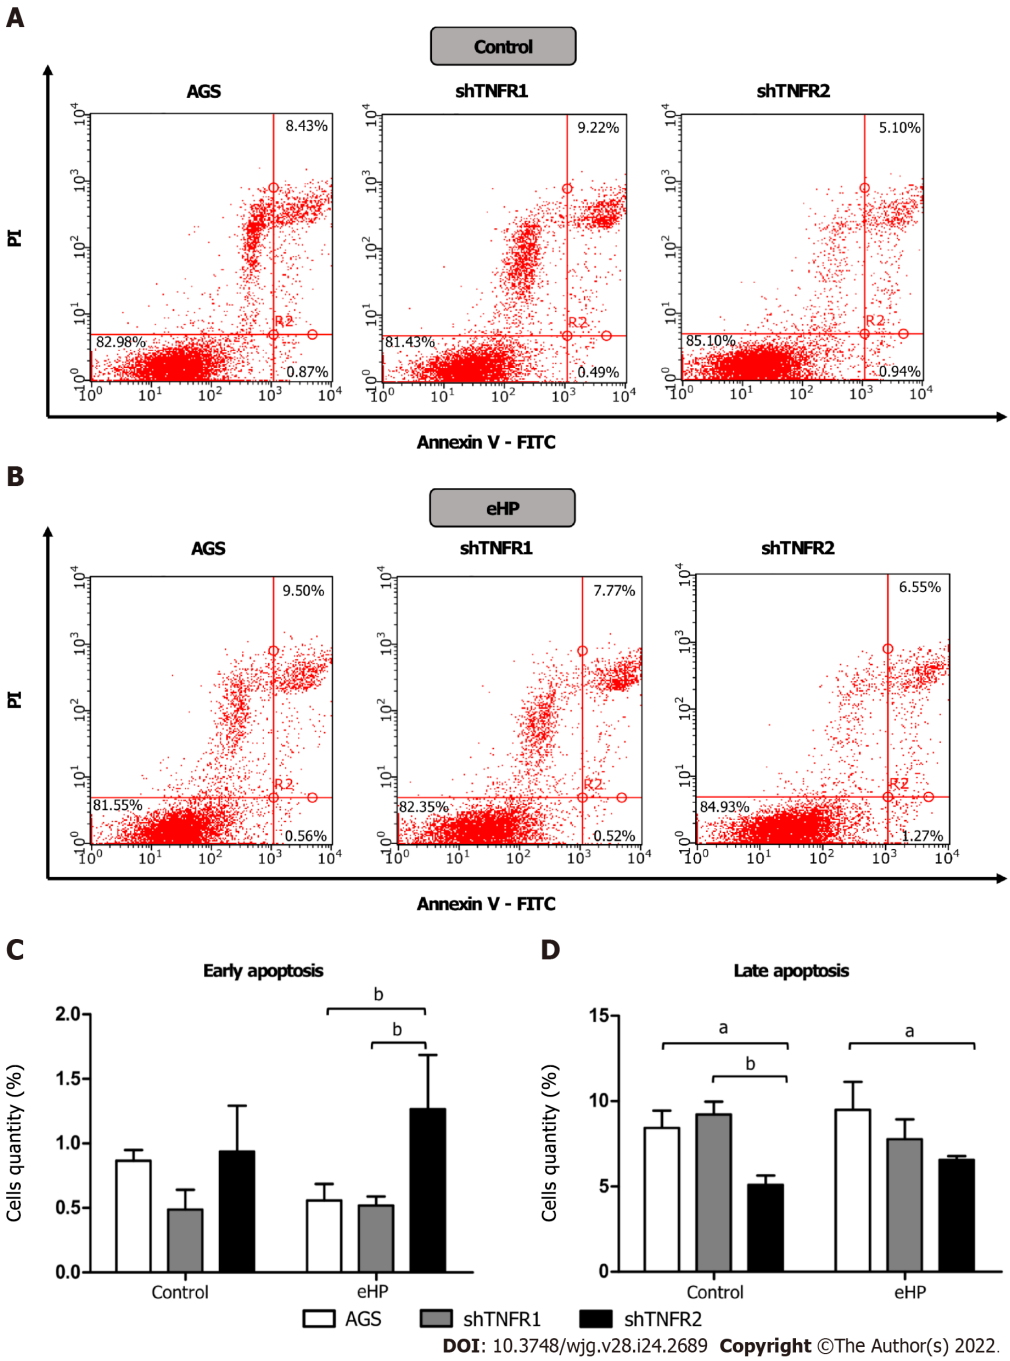

Figure 4 Cell cycle distribution analysis. Number of cells in the G0/G1, S and G2/M phases of the cell cycle in nonsilenced AGS cells, cells with TNFR1 downregulated (shTNFR1), and cells with TNFR2 downregulated (shTNFR2) without additional treatment (control) and those treated with the *Helicobacter pylori* extract. A: G0/G1; B: S; C: G2/M. Bars represent the mean ± SD from three independent trials. Statistically significant difference: $^{a}P < 0.05$; $^{b}P < 0.01$; $^{c}P < 0.001$. eHP: *Helicobacter pylori* extract.

H. pylori[19]. Our results show high *TNFR1* mRNA expression after *H. pylori* extract treatment in nonsilenced AGS cells, suggesting that *H. pylori* infection promotes activation of the TNFR1-mediated TNF-α signalling pathway in AGS cells, directing signal transduction to the cell survival pathway due to the increased expression of *NFKB1, NFKB2* and *CFLIP* (Figure 6A). In agreement with this finding, previous studies showed that *H. pylori* activates NF-κB in a manner dependent on the bacterial cell number[20] due to significant IκB-α degradation[21], resulting in the induction of anti-apoptotic gene transcription, such as *CFLIP* transcription[22]. Therefore, our results indicate that *H. pylori* extract also induces cell survival and inflammation due to TNFR1-mediated TNF-α signalling, which leads to NF-κB activation and the consequent production of antiapoptotic mediators, such as cFLIP.

TNFR1 downregulation resulted in a significant increase in *TNFR2* mRNA expression in nontreated AGS cells, while a decrease in the expression of T*RADD* and *CFLIP* mRNA was observed in cells treated with *H. pylori* extract, although no change was observed in apoptosis and cell cycle assays (Figure 6B). In oesophageal carcinoma cells treated with TNFR1-siRNA, Changhui *et al*[23] demonstrated an increase in cell proliferation and a reduction in apoptosis rate after 24 h of transfection, and the cell proliferation level was time-dependent[19]. The present study, when evaluated together with the results of *H. pylori* extract, suggests that the assays of cellular processes after 6 h of treatment may have been insufficient in shTNFR1 and nonsilenced AGS cells. Wan *et al*[24] showed that AGS cell coculture with *H. pylori* inhibited apoptosis and increased viability through upregulation of TRAF1, which was triggered by NF-κB activation. However, the peak of TRAF1 expression occurred after 12 h of infection, and its effect on cell viability started only after 24 h. Therefore, the role of TNFR1 downregulation in GC cell lines still needs to be further investigated.

Conversely, the downregulation of TNFR2 expression significantly decreased the expression of two important mediators of the TNFR1-mediated signalling pathway, TRAF2 and TRADD, in addition to *NFKB*1, *CFLIP* and *TNFR1* expression. Moreover, there was an increase in early apoptosis, with concomitant G1/S transition phase arrest (Figure 6C). These results agree with those previously reported by our group in GC patient samples, in which we found upregulation of *TNF/TNFR2* and cellular survival genes such as *TRAF2*, *CFLIP*, and *NFKB2* and downregulation of *TNFR1* and *CASP3* [14], thus emphasizing the important role of TNFR2 in gastric carcinogenesis and TNFR2 silencing as a promising strategy for anticancer therapy[25].

TRADD is an essential adaptor protein that functions in TNFR1-mediated apoptotic signalling under physiological conditions[26]. However, the dependence of this mediator seems to be cell-type specific [27], as TRADD knockout mice were resistant to TNFR1-induced toxicity in a hepatitis model[28]. However, this pathway was not completely impaired in macrophages deprived of TRADD[27].

A: Cells without additional treatment (control); B: Cells treated with the *Helicobacter pylori* extract; A and B: Representative images of the cell distribution and percentage in the different quadrants indicating viable cells (Annexin V-/PI-) in the lower left, early apoptotic cells (Annexin V+/PI-) in the lower right and late apoptotic cells (Annexin V+/PI+) in the upper right; C and D: Histogram bars represent the mean ± SD from three independent trials for early (C) and late (D) apoptosis. Statistically significant difference: $^{a}P < 0.05$; $^{b}P < 0.01$. eHP: *Helicobacter pylori* extract.

Therefore, apoptosis can occur even with reduced expression of TRADD, as observed in the present study after TNFR2 downregulation. In turn, TRADD inhibition reduces NF-κB activation[12], impairing the transcription of anti-apoptotic genes, such as *TRAF2* and *CFLIP*, as observed in this study.

As mentioned, shTNFR2 cells also exhibited reduced expression of TRAF2. This protein has an essential role in signal transduction and is triggered by both TNFR1 and TNFR2, suggesting the existence of crosstalk between them[29], which influences the signalling outcome after TNF binding [30]. TRAF2 recruits cIAP1 and cIAP2 after interaction with these receptors, thereby triggering nuclear translocation of NF-κB[30]. Therefore, TRAF2 is a negative regulator of TNF-induced apoptosis[30], and the use of this protein after TNFR2 activation results in TNFR1-induced apoptosis to the detriment of proliferation[25]. Therefore, a decrease in TRAF2 expression favours TNFR1-mediated apoptosis, contributing to the increase in the percentage of early apoptotic cells after TNFR2 downregulation.

Figure 6 Schematic comparison of the tumour necrosis factor-α signalling pathway and cell fate in nonsilenced AGS, shTNFR1 and shTNFR2 cells with downregulation after treatment with *Helicobacter pylori* extract. After the tumour necrosis factor (TNF)-α/TNFR1 interaction, TRADD, RIP1, TRAF2 and cellular inhibitor of apoptosis proteins are recruited, which results in nuclear factor-kappaB (NF-κB) activation and transcription of prosurvival and antiapoptotic genes, such as CFLIP, that inhibit the activity of the death-inducing signalling complex, which is formed after dissociation between TRADD and TNFR1. As with TNFR1, TNFR2 stimulation leads to NF-κB activation and cell survival; A: Treatment with *Helicobacter pylori* (*H. pylori*) extract resulted in increased expression of TNFR1, NFKB1, NFKB2 and CFLIP mRNAs in nonsilenced AGS cells. Therefore, the cell survival pathway is activated due to NF-kB activation (red ellipse) through the TNFR1-TNF signalling pathway with consequent production of the antiapoptotic CFLIP; B: In shTNFR1-*H. pylori* extract cells, TNFR1 downregulation resulted in decreased expression of TRADD and CFLIP mRNAs; however, it did not change cell fate; C: In shTNFR2-*H. pylori* extract cells, TNFR2 downregulation decreased the expression of TRAF2 and TRADD, decreased NFKB1, CFLIP and TNFR1 expression, and upregulated miR-19a and miR-34a. This led to an increase in apoptosis, impairing cell survival due to arrest in the G1/S transition phase.

Moreover, we found that TNFR2 downregulation also promoted a decrease in the ratio of cells in the G0/G1 phase and an increase the ratio of cells in the S and G2/M phases, suggesting that TNFR2 inhibition may delay cell cycle progression and arrest cells at the G1/S transition[31]. These changes in the cell cycle could also be related to the DNA damage response[32], leading cells to early apoptosis, as seen in our results. Recent studies have shown increased expression of genes related to the response to DNA damage and repair, such as *APE1, H2AX* and *PARP-1,* in GC samples, thus possibly influencing the survival of tumour cells[33,34]. Yang *et al*[35] demonstrated that TNFR2 enhances DNA damage repair by regulating PARP expression in breast cancer cells. Furthermore, they showed that TNFR2 silencing led to an increase in pH2AX, which is a DNA damage marker.

Based on the function of each receptor and the existence of crosstalk between them, it is possible that the simultaneous inhibition of both TNFR1 and TNFR2 may have a greater antitumor effect on GC than the downregulation of TNFR2 alone. Furthermore, TNF-α and its receptors, in addition to being expressed by tumour cells, are also expressed by cells present in the tumour microenvironment as immune cells[36]. Oshima *et al*[8] demonstrated that the stimulation of TNFR1-mediated TNF-α signalling in cells in the tumour microenvironment promoted gastric tumorigenesis through the induction of tumour-promoting factors (*Noxo1* and *Gna14*) in tumour epithelial cells, highlighting the importance of the tumour microenvironment[37] and the need for *in vivo* studies.

Furthermore, considering the important role of miRNAs in the development of cancer, as they act as regulators of signalling pathways and are consequently involved in various cellular processes, we also evaluated the expression of miRNAs miR-19a, miR-34a, miR-103a, miR-130a and miR-181c. These miRNAs were chosen from data analysis publishedin public databases[38-42] and due to their interaction with TNF-α pathway genes, as observed in our recent study[14]. Regardless of *H. pylori* extract treatment, shTNFR1 and nonsilenced AGS cells did not dysregulate miRNA expression. However, TNFR2 downregulation caused an upregulation of miR-19a and miR-34a (Figure 3A and B).

MiR-34a is dysregulated in different types of cancer and is linked to the proliferation, differentiation, migration, invasion, treatment, and prognosis of cancer[43]. Although most studies suggest a tumour-suppressor role for miR-34a[44-46], we recently observed overexpression of this miRNA in GC samples [14], thus also indicating its oncogenic action. In contrast, in both AGS and BGC-823 cell lines, an upregulation of this miRNA inhibited proliferative and migratory abilities in sevoflurane-induced GC cells, whereas *in vivo* knockdown of miR-34a stimulated tumour growth, indicating its action as a tumour suppressor in the AGS cell line[47]. In addition, stable transfection of pre-mir-34a in KatoII cells

increased the percentage of apoptotic cells and reduced the proliferation rate, suggesting that its high expression promotes apoptosis[48]. In the present study, upregulation of this miRNA in shTNFR2 cells suggests that miR-34a expression can be modulated by TNFR2-mediated TNF-α signalling and is able to exert an anti-proliferative and pro-apoptotic effect. Similarly, miR-19a was overexpressed in the shTNFR2 cell line, indicating that miR-19a and TNFR2 are related to each other in GC. miR-19a has a known oncogenic function in various kinds of cancer[49], with *TNFA, TNFR1* and *TNFR2* being its validated targets[38,39,50]. However, miR19a may play a tumour-suppressive role, as reported in prostate cancer, by suppressing invasion and migration in bone metastasis[51], and in rectal cancer cells, by inducing apoptosis[52]. For both miRNAs, functional studies are needed to assess what targets the miRNAs are related to with respect to TNF-α signalling in GC.

The other miRNAs evaluated (miR-103a, miR-130a and miR-181c) were not dysregulated in the AGS cell line. Although different studies have shown the involvement of these miRNAs in gastric neoplasms [53-55], their pro- or antitumor roles are still controversial. This is due to the influence of several factors in the regulation of gene expression, such as the stage of tumour development and the presence or absence of infectious agents[6].

CONCLUSION

In conclusion, based on our results, shRNA-mediated downregulation of TNFR2 in AGS cells was able to reduce the expression of pro-survival and anti-apoptotic genes, in addition to affecting miRNA expression, the cell cycle, and promoter apoptosis. The blocking of TNFR2 expression may cause antitumor effects, suggesting possible targets for future studies into therapeutic strategies for treating GC. Furthermore, the *H. pylori* extract increased the expression of prosurvival genes, mainly through TNFR1-mediated TNF-α signalling, thus emphasizing the role of bacterial infection in promoting GC progression.

ARTICLE HIGHLIGHTS

Research background

The tumour necrosis factor-α (TNF-α) signalling pathway triggered by TNFR1 and TNFR2 controls several biological processes, influencing cell fate. Thus, the deregulation of this pathway to cause an imbalance between the processes of cell survival and death may contribute to the tumorigenic process. This variety of functions is exercised by the ability of TNF-α to bind to TNFR1 or TNFR2, which results in different cellular processes. Both receptors are transmembrane proteins and are largely similar in extracellular structure, but their intracellular domains are different, and dictate the cellular fate for either survival or death. Since only TNFR1 has a death domain, the TNF-α signalling pathway triggered by TNFR1 is able to induce both cell survival and apoptosis, whereas TNFR2 results only in cell survival. The TNF-α signalling pathway also modulates the immune response and inflammation, so deregulation of this pathway has been implicated in inflammatory diseases and cancer. Therefore, studies are needed to better understand the relationships of this signalling network *via* TNFR1 and TNFR2 and its protumorigenic or antitumorigenic effects.

Research motivation

We proposed the present study based on our previous studies, which showed deregulation in the expression of genes and miRNAs of the TNF-α signalling pathway and its receptors TNFR1 and TNFR2 in fresh tissues of chronic gastritis and gastric cancer (GC) patients. Therefore, we decided to evaluate the effect of silencing TNFR1 and TNFR2 on GC cell lines.

Research objectives

According to the role of TNFR1 and TNFR2 in cellular responses triggered by TNF-α, and considering that studies addressing the role of these receptors in gastric neoplasm are limited and inconclusive, we proposed to couple the silencing of TNFR1 and TNFR2 receptors in an AGS gastric cell line and the treatment with *Helicobacter pylori* (*H. pylori*) extract to determine the effects on *TNF-α* mRNA expression and on downstream genes related to its signalling pathway. Moreover, we also investigated previously studied miRNAs that target genes in the TNF-α pathway to jointly determine their influence on the cell cycle and apoptosis.

Research methods

Stable AGS GC cells containing TNFR1 and TNFR2 receptors downregulated by specific shRNAs and nonsilenced cell lines were treated with 30% v/v *H. pylori* extract [*H. pylori* Tox+ strain (cagA+/vacA s1m1)] for 6 h. After silencing, TNFR1 and TNFR2 levels were assessed by quantitative polymerase

chain reaction (qPCR) and Western blotting to confirm the knockdown effect. Subsequently, mRNA and miRNAs were quantified by qPCR using TaqMan gene and miRNA expression assays. The MTT assay was employed to evaluate the viability of silenced and nonsilenced AGS cells after different treatment conditions with *H. pylori* extract, and flow cytometry was used for cell cycle analysis and apoptosis.

Research results

Our results showed that *H. pylori* extract treatment increased the expression of genes involved in cell survival (*NFKB1* and *NFKB2*) and inhibited apoptosis (*CFLIP*) and *TNFR1* in nonsilenced AGS cells. TNFR1 downregulation significantly decreased the expression of the *TRADD* and *CFLIP* genes; however, no change in the cell cycle, apoptosis or miRNA levels was observed. In turn, TNFR2 downregulation decreased the expression of the *TRADD* and *TRAF2 genes*, which are both important downstream mediators of the TNFR1-mediated pathway, as well as the *NFKB1* and *CFLIP* genes, while upregulating the expression of miR-19a and miR-34a. Consequently, there was a decrease in the ratio of cells in the G0/G1 phase and an increase in cells in the S phase, as well as the promotion of early apoptosis.

Research conclusions

Our findings highlight that treatment with *H. pylori* extract increased the expression of pro-survival genes, mainly through TNFR1-mediated TNF-α signalling, emphasizing the role of bacterial infection in promoting GC progression. In the AGS cell line, TNFR1 and TNFR2 downregulation decreased the expression of prosurvival and antiapoptotic genes and affected miRNA expression and cellular processes, such as the cell cycle and apoptosis, emphasizing that shRNA-mediated downregulation of these receptors can have an antitumor effect.

Research perspectives

According to our results, we can mainly highlight the important role of TNFR2 in the TNF-α pathway in GC, indicating that silencing TNFR2 can reduce the expression of survival and anti-apoptotic genes. Thus, blocking this receptor may result in antitumor effects, suggesting possible targets for future *in vivo* studies into therapeutic strategies for treating GC.

Abstract

BACKGROUND

Stool DNA (sDNA) methylation analysis is a promising, noninvasive approach for colorectal cancer screening; however, reliable biomarkers for detecting early-stage colon cancer (ECC) are lacking, particularly in the Chinese population.

AIM

To identify a novel stool-based assay that can improve the effectiveness of ECC screening.

METHODS

A blinded case-control study was performed using archived stool samples from 125 ECC patients, and 125 control subjects with normal colonoscopy. The cohort was randomly divided into training and test sets at a 1.5:1 ratio. Targeted bisulfite sequencing (TBSeq) was conducted on five pairs of preoperative and postoperative sDNA samples from ECC patients to identify DNA methylation biomarkers, which were validated using pyrosequencing. By logistic regression analysis, a multiplex stool-based assay was developed in the training set, and the detection performance was further assessed in the test set and combined set. The χ^2 test was used to investigate the association of detection sensitivity with clinico-

pathological features.

RESULTS

Following TBSeq, three hypermethylated cytosine-guanine sites were selected as biomarkers, including paired box 8, Ras-association domain family 1 and secreted frizzled-related protein 2, which differed between the groups and were involved in important cancer pathways. An sDNA panel containing the three biomarkers was constructed with a logistic model. Receiver operating characteristic (ROC) analysis revealed that this panel was superior to the fecal immunochemical test (FIT) or serum carcinoembryonic antigen for the detection of ECC. We further found that the combination of the sDNA panel with FIT could improve the screening effectiveness. In the combined set, the sensitivity, specificity and area under the ROC curve for this multiplex assay were 80.0%, 93.6% and 0.918, respectively, and the performance remained excellent in the subgroup analysis by tumor stage. In addition, the detection sensitivity did not differ with tumor site, tumor stage, histological differentiation, age or sex, but was significantly higher in T4 than in T1-3 stage tumors (P = 0.041).

CONCLUSION

We identified a novel multiplex stool-based assay combining sDNA methylation biomarkers and FIT, which could detect ECC with high sensitivity and specificity throughout the colon, showing a promising application perspective.

Key Words: Colon cancer; Early screening; Stool biomarker; DNA methylation; Fecal immunochemical test

Core Tip: Stool DNA (sDNA) methylation analysis has a promising application in the early diagnosis of colorectal cancer. However, reliable biomarkers for detecting early-stage colon cancer (ECC) are lacking. In this study, by targeted bisulfite sequencing, we identified a novel multiplex stool-based assay combining three sDNA methylation biomarkers and fecal immunochemical test. Further validation in larger samples by pyrosequencing showed that it enabled the diagnosis of ECC with high sensitivity and specificity throughout the colon. To our knowledge, this is the first study to focus on ECC screening in China.

INTRODUCTION

Colorectal cancer (CRC) has emerged as a major public health issue in China, with 521400 new cases and 248000 deaths occurring in 2018[1]. The incidence of colon cancer has increased significantly in the past decades, with a trend in younger patients, and most cases are in advanced stages at initial diagnosis[2]. Early screening is the key to improving survival and reducing morbidity[3]. Compared with the high positive rate of rectal palpation in rectal cancer, colonoscopy is currently the main tool and gold standard for detecting colon cancer, but is invasive, costly and poorly tolerated[4]. The fecal immunochemical test (FIT), computed tomography (CT) colonography and blood tumor markers, such as serum carcinoembryonic antigen (CEA), provide relatively noninvasive and painless methods, but their sensitivity for detecting early-stage colon cancer (ECC) is limited[5,6]. Thus, the identification of novel biomarkers that are highly specific, sensitive, and noninvasive is urgently needed for the screening of ECC.

CRC development is characterized by the progressive accumulation of genetic and epigenetic alterations that transform colonic epithelial cells into adenocarcinoma cells[7,8]. These cells are continuously shed into the colonic lumen and mixed with stool[9]. Moreover, the molecular changes caused by CRC tumorigenesis are reportedly present in the stool earlier than in the blood[10]. Hence, detecting aberrant DNA methylation in stool DNA (sDNA) has been proposed as a promising noninvasive alternative for CRC screening. To date, a number of sDNA methylation biomarkers have been reported for the detection of different stages of CRC, including secreted frizzled-related protein 2

(SFRP2), N-myc downstream-regulated gene 4 (NDRG4), ventralis intermedius, COL4A2 and GATA4 [11]. Further studies revealed that the combination of multiple biomarkers contributed to a higher diagnostic accuracy than a single biomarker[12]. For instance, a multitarget sDNA test Cologuard, combining NDRG4 and BMP3 methylation, Kirsten rat sarcoma mutations, β-actin and a hemoglobin assay, has been approved for average-risk CRC screening by the US Food and Drug Administration and is now available clinically[13]. However, the reported sensitivity and specificity of the same sDNA methylation biomarker varied greatly among studies, due to the different study populations (mainly the ethnic, geographic and dietary differences), inclusion criteria and levels of examination[14,15]. Moreover, few studies have focused on the sDNA screening test for ECC, especially in the Chinese population.

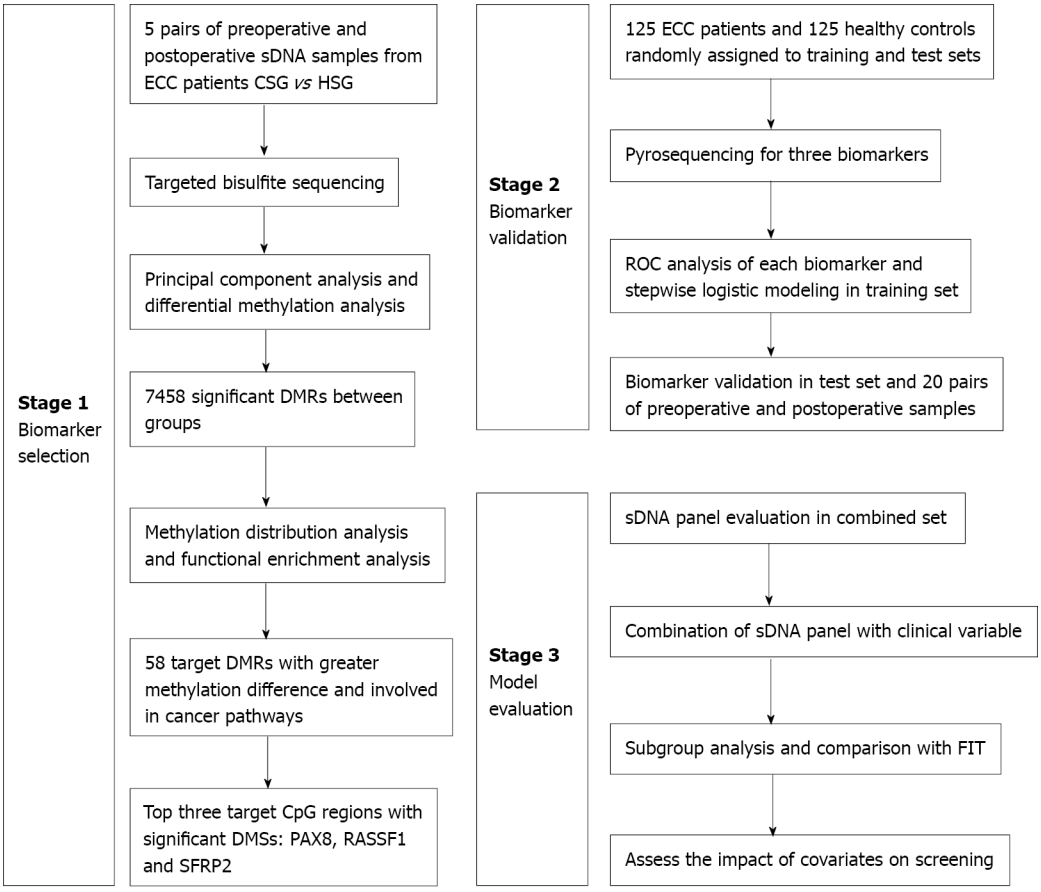
In this study, using targeted bisulfite sequencing (TBSeq), we identified a novel panel of sDNA methylation biomarkers for ECC detection, which was validated in a training and test design with pyrosequencing (PSQ). We further investigated the detection performance of the sDNA panel combining conventional screening methods, and assessed the effects of clinical covariates on test performance. To our knowledge, this is the first work to focus on ECC screening in China.

MATERIALS AND METHODS

Study design and study population

Between November 2018 and June 2020, a single-center, case-control study was performed at Yangpu Hospital Affiliated to Tongji University, using archived stool samples from 125 patients with sporadic ECC and 125 individuals with normal colonoscopy results. The diagnosis of stage I and II colon cancer was histologically confirmed after surgery. All subjects were of Han race living in Shanghai, and the inclusion of patients and controls was carried out to achieve a good match in terms of age and sex. Those who had a history of digestive cancer, inflammatory bowel disease or familial adenomatous polyposis, or an unconfirmed diagnosis were excluded. In addition, clinical information including tumor site, histological differentiation, tumor stage and preoperative serum CEA level was abstracted from medical records. These participants were randomly divided into training and test sets with a sample size ratio of 1.5:1. All subjects provided written informed consent, and this study was approved by the Ethical Committee and Institutional Review Board of our hospital (LL-2018-SCI-003). This study was registered at the Chinese Clinical Trial Registry (ChiCTR1800019552). The study design consisted of three stages: Biomarker selection, biomarker validation and model evaluation, as shown in Figure 1.

Sample collection and processing



All participants were required to undergo screening colonoscopy and provide a fresh stool sample before bowel purgation. In addition, 20 randomly selected ECC patients (6 stage I and 14 stage II cases) were asked to provide stool samples at six months after radical surgery with no tumor recurrence. One part of the stool sample was used for FIT (FASURE; NewScen Coast, China), and the result was evaluated at the manufacturer's recommended positivity cut-off of 200 ng hemoglobin/mL buffer. The other part (minimum 50 g) was immediately extracted or stored at -80 °C for further use, sDNA was extracted with a QIAamp DNA Fast Stool Mini Kit (Qiagen, Germany), and the quality and concentration were determined by spectrophotometry (NanoDrop 2000; Thermo-Fisher Scientific, United States). Among the 20 pairs of preoperative and postoperative sDNA samples, five pairs (2 stage I and 3 stage II cases) were randomly selected for biomarker identification using TBSeq and named cancer sample group (CSG) and healthy sample group (HSG), respectively.

TBSeq

We used CATCH-Seq target enrichment technology (Novogene, China) to perform bisulfite sequencing, to evaluate 23441 [cytosine-guanine (CpG) islands] (CGIs) (about 83% of the 28226 CGIs in the human genome) and the promoter regions of 19369 RefSeq genes (within 2 kb before the transcription start site) [16,17]. Briefly, according to the manufacturer's protocol, genomic DNA (1 μg) was fragmented into 200-300 bp fragments using a Covaris S220 (Covarias, United States). The DNA fragments were then sheared, end-repaired and dephosphorylated. The blunt fragments were subsequently A-tailed and ligated to sequencing adaptors that were synthesized with 5′-methylcytosine instead of 5′-cytosine and index sequences. Following the liquid hybridization capture procedure, the target enriched library was bisulfite-converted (EZ DNA Methylation Kit; Zymo Research, United States) and then amplified by polymerase chain reaction (PCR). After quantification and quality control, sequencing was performed on an Illumina Hiseq 2500 platform (Illumina, United States).

Analysis of sequencing data

Preprocessing included quality control using FastQC, adapter trimming using cutadapt, and read alignment and methylation calling using Bismark with Bowtie2 (hg19/GRCh37). The coverage depth of each base and CpG site was calculated, and the results were filtered by criteria of at least 5X coverage.

Figure 1 Flow diagram of the study design. Candidate methylation biomarkers were selected by targeted bisulfite sequencing and then validated using pyrosequencing. At last, a diagnostic model was constructed and evaluated. CSG: Cancer sample group; HSG: Healthy sample group; DMRs: Differentially methylated regions; DMSs: Differentially methylated sites; ROC: Receiver operating characteristic; sDNA: Stool DNA; FIT: Fecal immunochemical test; PAX8: Paired box 8; RASSF1: Ras-association domain family 1; SFRP2: Secreted frizzled-related protein 2; CpG: Cytosine-guanine; ECC: Early-stage colon cancer.

The CpG sites that were located on the Y chromosome and overlapped with single nucleotide polymorphisms (SNPs) registered in the SNP database (http://www.ncbi.nlm.nih.gov/projects/SNP/) were excluded from the analysis. For the methylated sites, the methylation level was calculated using the formula: ML = mC/(mC + umC), where ML represents the methylation level, and mC and umC represent the number of methylated and unmethylated C-sites, respectively. Methylation levels of the specified functional regions including CGI, CGI shore (0-2 kb from CGI), CGI shelf (2-4 kb from CGI), promoter, 5′ untranslated regions (UTR), 3′UTR and exon, were summarized to show the distribution [18]. Methylation density was defined as the percentage of methylated CpG sites among all CpG sites within the given region.

In-house scripts were used to identify a differentially methylated site (DMS) by Fisher's exact test with false discovery rate correction. Statistical significance for DMS between the two groups was determined if the adjusted P value < 0.05 and the difference in methylation level > 0.25. A differentially methylated region (DMR) was identified by swDMR software (http://122.228.158.106/swDMR/) using the sliding-window approach, in which the window was set to 1000 bp and the step length was 100 bp. The DMR should contain at least two CpG sites (all sites are hypermethylated or hypomethylated), and the distance between the adjacent CpG sites was < 100 bp. In addition, the DMRs with an adjusted P value < 0.05 and a difference in methylation level > 0.1 were considered candidate DMRs.

Biomarker selection

By comparing the methylation status between the CSG and HSG, 7458 DMRs were obtained based on the above standards. To strengthen the robustness of the candidate biomarker, the DMRs located far from CGIs and promoter regions were filtered out. Moreover, to reduce the noise due to sample heterogeneity, it was essential to select biomarkers that had greater methylation difference between groups (P > 0.35) and that were significantly enriched in well-established cancer pathways (adjusted P < 0.05). In total, 58 target DMRs were selected, and each DMR contained at least two significant DMSs. According to the guanine-cytosine percent, primer lengths, amplicon lengths, predicted melting temperatures and the number of SNPs in the primers, the score representing the difficulty levels for all the candidate

PSQ

To measure the methylation levels of the three target CpG regions in the 250 stool samples, PSQ was conducted (Oebiotech, China) without knowledge of either the clinical diagnosis or FIT result, sDNA extraction and bisulfite conversion were performed as previously described[19]. The PSQ primers were designed to amplify two to five CpG sites in target sequences using PyroMark Assay Design software (Qiagen, Germany). Primer sequences were listed in Table 1. For methylation-specific PCR (MSP), 50 ng of bisulfite modified DNA was amplified in a 25 μL reaction. The cycling conditions were recommended by the manufacturer and were as follows: A denaturing step of 15 min at 95 °C, then 45 cycles at 94 °C for 30 s, 56 °C for 30 s and 72 °C for 30 s, and a final elongation step of 10 min at 72 °C. PSQ was performed on a PSQ HS96A instrument according to the manufacturer's guidelines using PyroMark Gold Q96 Reagents (Qiagen, Germany). The methylation index of each gene in each sample was calculated as the mean percentage of mC for all examined CpGs in target regions. All experiments included a negative control without a template[19].

Diagnostic model building

Based on the PSQ results, a logistic regression model was developed to define a linear combination of variables that optimized the discrimination between ECC patients and healthy controls. The modeling strategy consisted of age, sex, FIT, preoperative CEA level and sDNA methylation biomarkers in a base model and adding quadratic and pairwise interactions of these variables using backward selection with $P < 0.05$ for retention. The formula was as follows: $Y = \beta0 + \beta1X1 + \beta2X2 + \ldots + \beta nXn$ where X represented the exploratory variable[20]. The linear discriminant score with the corresponding cut-off value was then applied to the study population. Receiver operating characteristic (ROC) analysis was applied to compare the accuracy of nested logistic models and to investigate the added value of each variable.

Table 3 Diagnostic sensitivity, specificity and area under the receiver operating characteristic curve for various indexes

Study population	Index	Sensitivity (%)	Specificity (%)	AUC (95%CI)

Statistical analysis

All statistical analyses were conducted using Prism 8 for Windows (GraphPad, United States) and R software v3.5.2 (R Foundation for Statistical Computing, Austria). c^2 test or Fisher's exact test was used to compare categorical variables, and Student's *t*-test or Mann-Whitney *U* test was used to compare continuous variables. Principal component analysis (PCA) was performed to visualize the degree of similarity between samples according to their DNA methylation state[21]. A volcano plot and a Circos plot were used to present the differences in DMR methylation levels between groups[22]. To determine the functions and enriched pathways of these DMR-related genes, Gene Ontology (GO) and Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway analyses were performed[23]. The sensitivity, specificity, and area under the ROC curve (AUC) with corresponding 95% confidence intervals (CIs) were calculated and compared. The χ^2 test was also used to assess the association of detection sensitivity with clinicopathological covariates. For all analyses, $P < 0.05$ was considered statistically significant.

RESULTS

Clinicopathological features of the study population

Overall, this study enrolled 125 ECC patients and 125 healthy controls, with a median age of 69 (range, 48-94) and 68 (range, 42-92) years, respectively; 47.2% of patients and 49.6% of controls were females. Age and sex were well-balanced between patients and controls. With the conventional 5 ng/mL cut-off, serum CEA positivity was observed in 29.6% of patients and 0% of controls, and the difference was statistically significant ($P < 0.001$). FIT also showed a significantly higher positivity rate in the patients than in the controls (62.4% *vs* 3.2%, $P < 0.001$). Of these ECCs, 64 (51.2%) tumors were located proximal to the splenic flexure and 61 (48.8%) were distal. According to the postoperative pathological examination, there were 47 (37.6%) stage I tumors and 78 (62.4%) stage II tumors; 98 (78.4%) cases were well or moderately differentiated, and 27 (21.6%) were poorly differentiated. In addition, study participants were randomly divided into training and test sets with a 1.5:1 split. The differences in all these features between the training and test sets were not significant (all $P > 0.05$), indicating similar

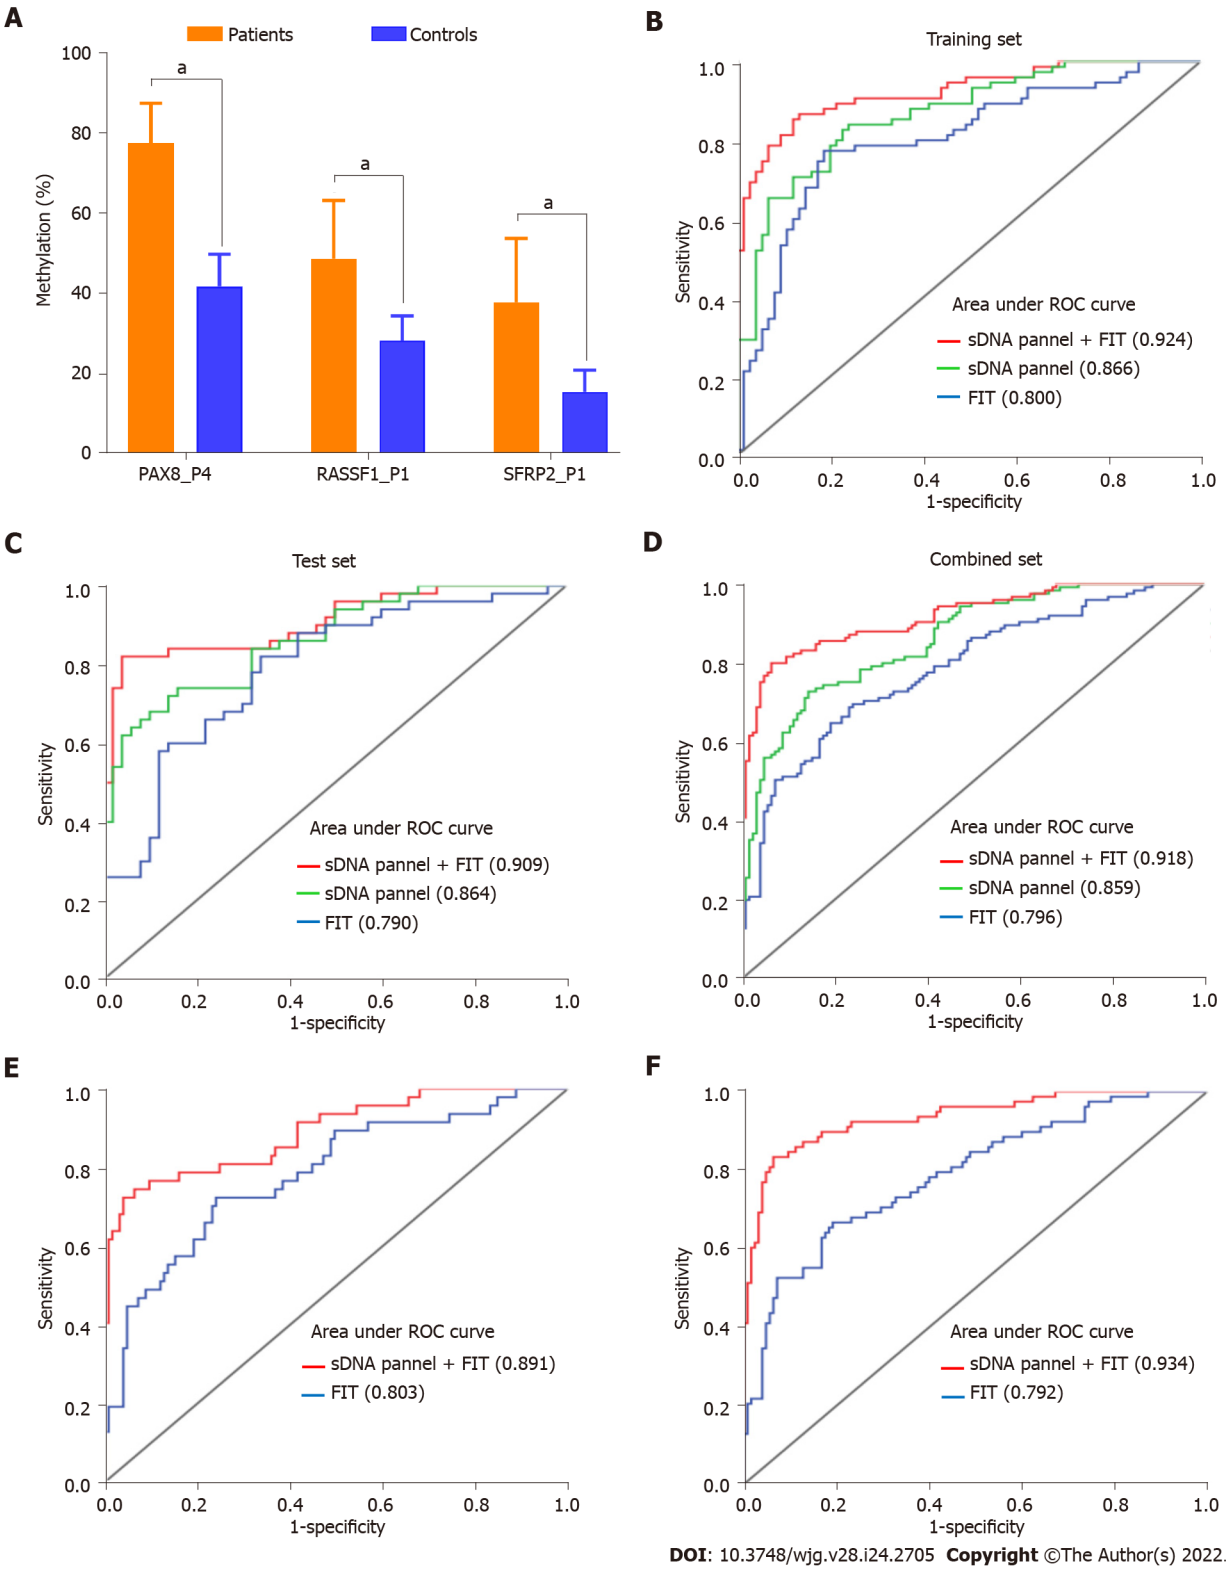
composition and the comparability (Table 2).

DNA methylation analysis by TBSeq

A total of 11.69 G and 11.08 G raw bases were generated on average for the HSG and CSG, respectively. All samples showed a bisulfite conversion rate greater than 99%. After data filtering, approximately 2.8 million CpGs on the target sequencing region were obtained for each sample, and the depth of coverage ranged between 23.66 and 32.24 (Supplementary Table 1). A PCA was performed on the methylation profiles, and demonstrated that the groups had intragroup similarity, but also intergroup dissimilarity (Figure 2A). In addition, the mean methylation densities of the HSG and CSG were 52.8% and 65.4%, respectively (Figure 2B); compared with 50.4% of CpG sites in the HSG, 58.0% of CpG sites in the CSG had a methylation level above 80% (Figure 2C).

Candidate biomarkers discovery



As shown in Figure 3A, in total, 7458 DMRs were identified in the CSG compared with the HSG (adjusted $P < 0.05$ and methylation level difference > 0.1), including 3743 hypermethylated and 3715 hypomethylated DMRs. Among them, 1883 DMRs (25.3%) were located in the CGIs, and 1978 (26.5%) were located in the regions flanking CGIs (CGI shore and shelf) (Figure 3B). Moreover, of the 3861 CGI-related DMRs, 2531 overlapped with the promoter regions of the 20579 genes with known functions (Figure 3C). To determine changes in the methylation status of gene functions, GO and KEGG pathway analyses were conducted and revealed that these 2062 DMR-related genes were significantly enriched in cell migration, focal adhesion, Wnt, Ras, Rap1 and MAPK signaling pathways, *etc* (Figures 3D and 3E, adjusted $P < 0.05$). To mine the data for potential early screening biomarkers, 58 DMR-related genes that differed most in methylation level between the groups and that were involved in the important cancer pathways were selected (Figure 3F). With the PSQ criteria, the top three target CpG regions within the promoters of paired box 8 (PAX8), Ras-association domain family 1 (RASSF1) and SFRP2 were finally identified, and contained five, two and two significant DMSs, respectively (Table 1).

Biomarkers validation by PSQ

To assess the screening effectiveness of these three biomarkers, PSQ was successfully performed in all sDNA samples. Using the 150 subjects in the training set, ROC analyses showed that the AUCs for the five DMSs of PAX8 ranged from 0.784 to 0.826, the AUCs for the two DMSs of RASSF1 were 0.782 and 0.763, and the AUCs for the two DMSs of SFRP2 were 0.697 and 0.641, respectively (Supplementary Figures 1A, 1B and 1C). In addition, serum CEA positivity was detected in 14.0% of the 150 subjects, with a sensitivity of 28.0% and an AUC of 0.640; FIT positivity was detected in 34.0% of the 150 subjects, with a sensitivity of 64.0% and an AUC of 0.800 (Table 3). By stepwise logistic modeling, an sDNA methylation panel including three DMSs was constructed as follows: Y = -10.937 + 0.097 × PAX8_P4 + 0.054 × RASSF1_P1 + 0.058 × SFRP2_P1. These three DMSs showed significantly increased methylation in patients compared with controls (all $P < 0.05$; Figure 4A) as well as in the comparison between the 20 pairs of preoperative and postoperative patient samples (all $P < 0.05$; Supplementary Figures 1D, 1E and 1F). The sensitivity and AUC for this sDNA panel were 82.7% and 0.866 (95%CI: 0.810-0.923), respectively, which were superior to any single index above (Figure 4B, Table 3). Subsequently, this panel was validated in an independent test set, and the AUC reached 0.864 (95%CI: 0.795-0.933), also offering an advantage over FIT (Figure 4C).

Evaluation of the diagnostic model

The diagnostic performance of the sDNA panel was also confirmed in the combined set, achieving an AUC of 0.859 (0.815-0.904) (Figure 4D). In addition, among the 168 subjects with negative FIT and the 213 subjects with negative serum CEA, the AUCs for this panel reached 0.807 (95%CI: 0.734-0.880) and 0.864 (95%CI: 0.816-0.913), respectively (Supplementary Figure 2). We further investigated whether the combination of the sDNA panel with clinical variables could improve the effectiveness of ECC screening. The results showed that the inclusion of FIT was accompanied by a relative increase in sensitivity and AUC, as compared with the sDNA panel, serum CEA or FIT alone (Table 3, Figure 5). In contrast, the contribution of age, sex or preoperative CEA level to aggregate panel discrimination was minimal (data not shown). For example, in the combined set, the sensitivity, specificity and AUC for the sDNA panel combining FIT were up to 80.0%, 93.6% and 0.918 (95%CI: 0.884-0.952), respectively (Figure 4D, Table 3). In the subgroup analysis by tumor stage, this multiplex assay showed excellent performance for both stage I and II ECCs, with an AUC of 0.891 (95%CI: 0.832-0.950) and 0.934 (95%CI: 0.899-0.970), respectively (Figures 4E and 4F).

Impact of covariates on screening

We also analyzed the impact of clinicopathologic covariates on assay screening. First, we found that the

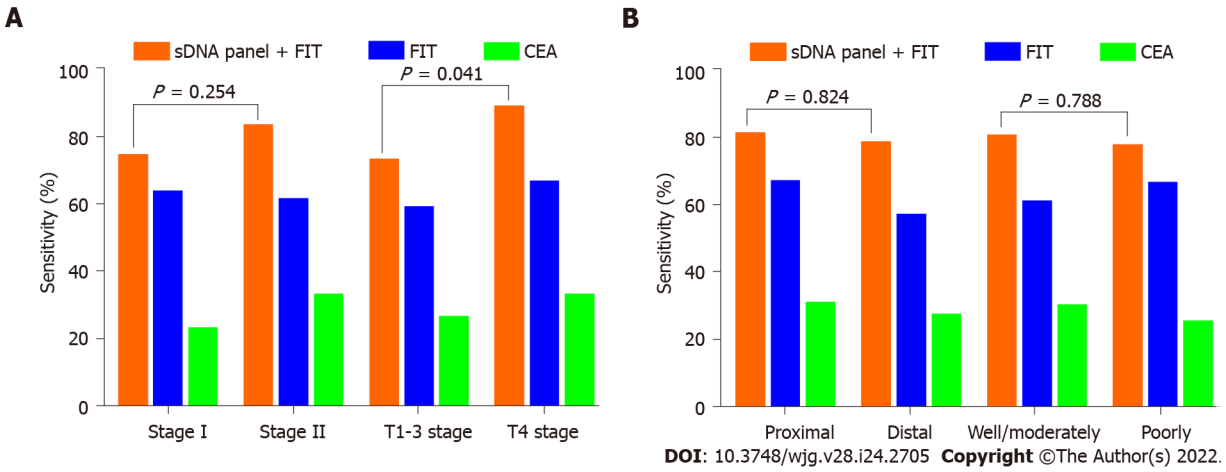

Figure 5 Impact of clinicopathologic covariates on screening. A: Sensitivities of fecal immunochemical test (FIT), serum carcinoembryonic antigen (CEA) and stool DNA (sDNA) panel + FIT for the detection of early-stage colon cancer (ECC), according to tumor-node-metastasis stage or T stage; B: Sensitivities of FIT, serum CEA and sDNA panel + FIT for the detection of ECC, according to tumor site or histological differentiation. sDNA: Stool DNA; FIT: Fecal immunochemical test; CEA: Carcinoembryonic antigen.

detection sensitivities of the sDNA panel combining FIT for stage I and II ECCs were 74.5% and 83.3%, respectively, with no statistical difference (P = 0.254; Figure 5A). However, the detection sensitivity of 88.9% for T4 stage tumors was significantly higher than the aggregate sensitivity of 73.2% for T1-3 stage tumors (P = 0.041; Figure 5A). Second, this multiplex assay detected 81.3% of proximal ECCs *vs* 78.7% of distal ECCs (P = 0.824; Figure 5B). Third, the detection rate for poorly differentiated tumors was comparable to that for well or moderately differentiated tumors (77.8% *vs* 80.6%, P = 0.788; Figure 5B). In addition, the sensitivity also did not vary significantly according to age or sex of the patients (data not shown).

DISCUSSION

CRC is the third most prevalent cancer in China, with an increasing proportion of colon cancer diagnoses over the decades[2]. Effective screening measures are highly needed to lessen this burden, especially for ECC due to its occult onset. Compared with conventional methods, the sDNA test provides a biologically rational approach based on tumor exfoliation and is noninvasive, requires no unpleasant cathartic preparation, no diet or medication restriction[24]. However, reliable biomarkers particularly for ECC detection are lacking. In the present study, we provided a novel multiplex stool-based assay that enabled the diagnosis of ECC with high sensitivity and specificity.

Aberrant DNA methylation is an early and frequent event in carcinogenesis and therefore has great potential for ECC screening[25]. To identify the candidate methylation biomarkers, we performed high throughput TBSeq with five pairs of preoperative and postoperative sDNA samples from ECC patients, where the paired design can help reduce the influence of background noise and improve the feature discriminability. Three of our candidate biomarkers were finally selected: RASSF1, SFRP2 and PAX8. The first two have been identified in various cancers including CRC[26,27], to be the commonly silenced tumor-suppressor genes by promoter hypermethylation[28]. PAX8 is a member of the paired box family of transcription factors[29], and its epigenetic silencing has also been observed in some tumor types, including colon cancer[30]. A recent study found that PAX8 hypermethylation accelerated gastrointestinal stromal tumor progression by downregulating Wnt4 expression[31]. Anglim *et al*[32] reported a panel of eight hypermethylated genes containing PAX8, which showed high sensitivity and specificity for the early detection of squamous cell lung cancer.

To date, there have been various methods for detecting abnormal DNA methylation[33,34]. MSP is a simple, rapid and inexpensive method, but is not capable of pattern recognition and identification of CpG sites outside the methylation-specific primers. Bisulfite sequencing was once considered the gold standard for DNA methylation determination. The disadvantage lies in its tedious and time-consuming procedure, and a minimum number of 10-20 clones are required to detect interindividual variabilities in DNA methylation. Methylation-sensitive high-resolution melting is a relatively new technique for methylation assessment based on post-PCR melting curve analysis. It gives a range of methylation estimates rather than a single value, being mainly suitable for large sample screening[35]. MethyLight is a sensitive, high-throughput methylation assay that was developed based on MSP, while the major disadvantage is the high cost of a TaqMan probe[36,37]. In our study, biomarker validation was performed using PSQ, which overcomes the defects of the above methods, combining the measurement

of multiple methylation biomarkers with high throughput in a single test[38]. Therefore, PSQ has been suggested as the new gold standard test for methylation detection. The results of PSQ confirmed that the three biomarkers by TBSeq were reliable and feasible.

By logistic regression analysis, a three-DMS panel was developed in this study and was proven more effective than a single biomarker for ECC screening. We further found that the combined detection of the sDNA panel and FIT was characterized by a relative increase in diagnostic performance, which was successfully validated in an independent test set, as well as in the combined dataset. Actually, many attempts at CRC early screening in the Chinese population have been made, but none have gained wide acceptance[12]. Liu *et al*[39] developed an sDNA methylation panel, including COL4A2 and TLX2, which showed a high sensitivity of 91% for advanced-stage CRC detection with 97% specificity, but the performance for early-stage CRC was significantly weakened, with a sensitivity of 52% and specificity of 86%. In the study by Zhang *et al*[40], an sDNA panel that examined SFRP2 and WIF-1 promoter methylation was identified, and the sensitivities for detecting stage I and II CRC were 55% and 80%, respectively. Recently, another novel multidimensional assay combining FIT, sDNA mutation, methylation and intestinal bacteria analysis was reported by Mo *et al*[41]. It displayed the highest sensitivity of 91.89% in stage III CRC, whereas the sensitivity for stage I-II CRC was relatively low (76.27%). Comparatively, the sensitivity, specificity and AUC of our multiplex stool-based assay for detecting ECC reached 80.0%, 93.6% and 0.918, respectively, showing a promising prospect for practical application.

The effect of covariates on test performance was also investigated. It has been suggested that the conventional screening modalities, including colonoscopy and FIT, seem less sensitive for proximal than distal colon neoplasms[42,43]. In this study, our stool multiplex assay showed comparable efficacy for the detection of both proximal and distal ECC, which was consistent with the previous finding by Imperiale *et al*[13]. Given this performance characteristic, the sDNA test has the potential to improve the screening efficiency for neoplasms throughout the colon, and would be a valuable complement to colonoscopy as an interval test. Furthermore, we found that the sensitivity of this stool multiplex assay for ECC did not vary significantly according to age, sex, histological differentiation or tumor stage, but was significantly higher at T4 stage. Further studies are needed to determine their association and causality. In addition, some studies revealed that the sDNA test sensitivity increased as the tumor size increased[13,41]. Unfortunately, this variable was not included in our study.

The major strength of our study was the training and test set design involving blinded assays in the laboratory, which provided objective data to assess the test performance. The limitations of this study should also be mentioned. First, these analyses were based on data obtained from a single institution in China, and the sample size was relatively small. Second, other factors not included in this study could not be examined for confounding effects. As a result, a large-scale, prospective multicenter study is warranted to further confirm the value of our assay.

CONCLUSION

In conclusion, we developed and validated a novel multiplex stool-based assay combining sDNA methylation biomarkers and FIT, which could detect ECC with high accuracy throughout the colon.

ARTICLE HIGHLIGHTS

Research background

Colorectal cancer (CRC) is one of the most prevalent malignancies in China with an increasing ratio of colon to rectal cancer over the decades. Early screening is the key to reducing this burden. The traditional screening methods, including colonoscopy, fecal immunochemical test (FIT) and serum carcinoembryonic antigen (CEA), have reached a bottleneck, especially for early-stage colon cancer (ECC) due to its occult onset. Thus, precision and effective non-invasive biomarkers are highly desirable.

Research motivation

Detection of aberrant methylated DNA in stool has been proven to be a promising noninvasive method for the early diagnosis of CRC. However, the reported screening efficacy of the same biomarker varied across different studies. Moreover, effective biomarkers for detecting ECC are scarce, especially in the Chinese population.

Research objectives

The objective of our study was to identify a novel assay based on stool DNA (sDNA) methylation biomarkers which could improve the effectiveness of ECC screening. We also investigated the influence of clinicopathologic covariates on test performance.

Research methods

We performed a blinded, single-center, case-control study using archived stool samples from 125 ECC patients and 125 individuals with normal colonoscopy (controls); the subjects were randomly assigned to a training or test set at a 1.5:1 ratio. Targeted bisulfite sequencing (TBSeq) was performed on five pairs of preoperative and postoperative sDNA samples from ECC patients to identify DNA methylation biomarkers. Pyrosequencing (PSQ) was used for validation of the candidate biomarkers in large samples. A stepwise logistic regression analysis was applied to the data of the training set to develop a multiplex stool-based assay. The detection performance was further evaluated in the test set and combined set. In addition, the association of detection sensitivity with clinicopathologic covariates were analyzed by χ^2 test.

Research results

Through TBSeq, the three top hypermethylated genes, paired box 8, Ras-association domain family 1 and secreted frizzled-related protein 2, that were involved in the important cancer pathways were selected as biomarkers. Based on the PSQ results, an sDNA panel containing the three biomarkers was developed by logistic regression modelling. Receiver operating characteristic (ROC) analysis showed that this panel offered an advantage over any single biomarker, FIT or serum CEA in the detection of ECC. Further analysis revealed that the inclusion of FIT could effectively improve the detection accuracy. In the combined set, the sensitivity, specificity and area under the ROC curve for the sDNA panel combining FIT reached 80.0%, 93.6% and 0.918, respectively. Moreover, this multiplex assay maintained excellent performance in the subgroup by tumor stage. Additionally, we found that the detection sensitivity of the multiplex assay was significantly higher in T4 than in T1-3 stage tumors (P = 0.041), but was not affected by tumor site, tumor stage, histological differentiation, age or sex.

Research conclusions

The present study identified a novel multiplex stool-based assay, including three sDNA methylation biomarkers and FIT, capable of detecting ECC with high sensitivity and specificity. Importantly, the detection rate by this assay was related to T stage but not tumor site, tumor stage, histological differentiation, *etc*.

Research perspectives

Our study provided a new and promising approach for improvement of ECC screening in the Chinese population. Further demonstrations on a large-scale, prospective multicenter study are needed to conclusively evaluate its value.

Abstract

BACKGROUND

Bleeding is one of the major complications after endoscopic submucosal dissection (ESD) in early gastric cancer (EGC) patients. There are limited studies on estimating the bleeding risk after ESD using an artificial intelligence system.

AIM

To derivate and verify the performance of the deep learning model and the clinical model for predicting bleeding risk after ESD in EGC patients.

METHODS

Patients with EGC who underwent ESD between January 2010 and June 2020 at the Samsung Medical Center were enrolled, and post-ESD bleeding (PEB) was investigated retrospectively. We split the entire cohort into a development set (80%) and a validation set (20%). The deep learning and clinical model were built on the development set and tested in the validation set. The performance of the deep learning model and the clinical model were compared using the area under the curve and the stratification of bleeding risk after ESD.

RESULTS

A total of 5629 patients were included, and PEB occurred in 325 patients. The area

under the curve for predicting PEB was 0.71 (95% confidence interval: 0.63-0.78) in the deep learning model and 0.70 (95% confidence interval: 0.62-0.77) in the clinical model, without significant difference (P = 0.730). The patients expected to the low- (< 5%), intermediate- (≥ 5%, < 9%), and high-risk (≥ 9%) categories were observed with actual bleeding rate of 2.2%, 3.9%, and 11.6%, respectively, in the deep learning model; 4.0%, 8.8%, and 18.2%, respectively, in the clinical model.

CONCLUSION

A deep learning model can predict and stratify the bleeding risk after ESD in patients with EGC.

Key Words: Clinical model; Deep learning model; Post-endoscopic submucosal dissection bleeding; Stratification of bleeding risk

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Bleeding is one of the major complications after endoscopic submucosal dissection (ESD) in early gastric cancer patients and requires hospital-based intervention. We established a deep learning model to stratify the bleeding risk after ESD and demonstrated its performance compared with a clinical model. The deep learning model showed acceptable area under the curve and could stratify the post-ESD bleeding risk as low-, intermediate-, and high-risk categories, which correlated with actual bleeding rate comparatively. A deep learning model would be valuable in assessing the bleeding risk after ESD in early gastric cancer patients.

INTRODUCTION

In South Korea, gastric cancer has a high incidence and is the second most common malignancy and the fourth most common cause of cancer-related mortality[1]. After the advent of screening programs for gastric cancer in South Korea and Japan, up to 50%–70% of cases with gastric cancers have been diagnosed at an early stage[2-4]. With the increasing rate of diagnosis at early stages, endoscopic submucosal dissection (ESD) is being actively applied for the minimally invasive treatment of early gastric cancer (EGC) without suspicion of regional lymph node metastasis[5,6].

In accordance with the current trend of active use of ESD, it is necessary to pay attention to the post-ESD complications. Bleeding is one of the significant complications, with an incidence of 3.6%–6.9%[7, 8]. Because bleeding after ESD requires hospitalization and hemostatic interventions, there is a need to predict patients at a high risk of bleeding after ESD. Therefore, there have been reports on risk factors related to bleeding after ESD[9-12]. Recently, a predictive risk-scoring model for bleeding after ESD was proposed in Japan; this tool is expected to raise awareness regarding the potential bleeding sources and thus, help physicians manage patients with EGC who are treated with ESD[13].

Currently, artificial intelligence systems are being applied in various fields of gastroenterology[14]. The machine learning models showed good performance in the triage of necessity for intervention in patients with upper gastrointestinal bleeding and predicting recurrent ulcer bleeding[15,16]. Deep learning is advantageous over the machine learning model among artificial intelligence systems; its performance is optimized by automatic learning while experiencing various cases. It can integrate and interpret multiple factors simultaneously without external intervention. Hence, the automatically trained deep learning model can generalize well. There has been no study on the efficacy of deep learning for predicting post-ESD bleeding (PEB), and no study has compared these systems with a clinical model.

This study aimed to develop and compare the performance of the deep learning and clinical model for predicting PEB in EGC patients. We chose deep learning among the artificial intelligence systems as a sophisticated algorithm.

MATERIALS AND METHODS

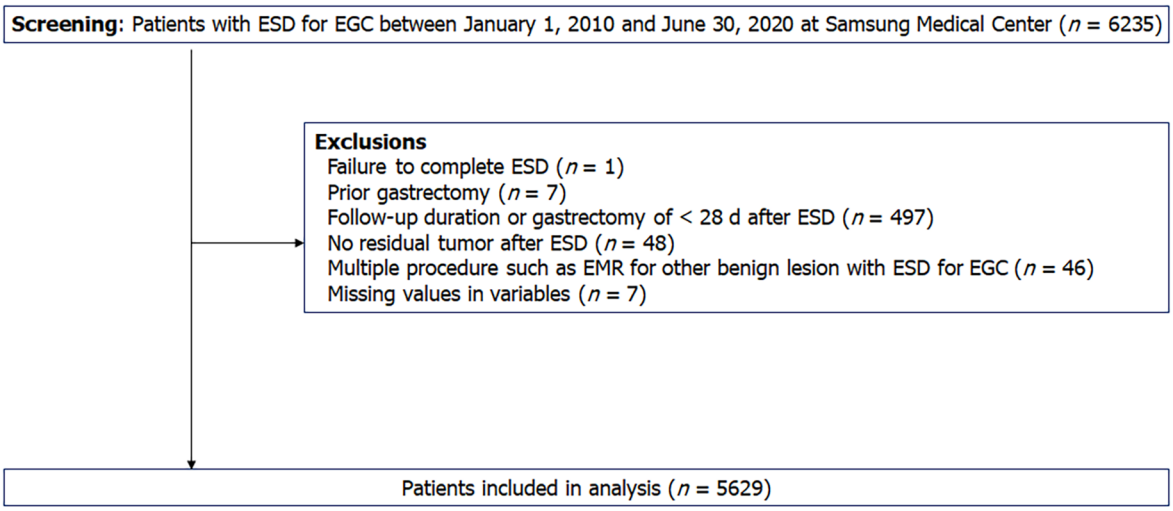
Patients

Patients who underwent ESD for EGC between January 2010 and June 2020 at the Samsung Medical Center, Seoul, South Korea, were screened retrospectively. We excluded cases with: Failure to complete ESD (n = 1); prior gastrectomy (n = 2); additional gastrectomy within 28 d after ESD (n = 497); no residual tumor in the ESD specimen (n = 48); multiple procedures, such as EMR for other benign lesions and ESD for EGC (n = 46); and missing values for important variables (n = 7) (Figure 1). A total of 5629 patients were included in the analysis, and they were randomly categorized into the development set (80%) and the validation set (20%). The Institutional Review Board of the Samsung Medical Center, Korea, approved this study, and the requirement for obtaining informed consent was waived owing to the study's retrospective nature.

Outcome, data sources, study variables, and definitions

The main outcome included the development of a deep learning model and a clinical model that predict the bleeding after ESD in patients with EGC and the comparison of performance between the deep learning model and the clinical model.

The variables used to build the deep learning and clinical models were collected from the medical records retrospectively based on the date of ESD. These variables included: Age; sex; comorbidities such as hypertension, diabetes mellitus, liver cirrhosis, and chronic kidney disease (estimated glomerular filtration rate < 60 mL/min per 1.73 m^2); patient management with antithrombotic agents (ATs) [aspirin, P2Y12 receptor agonist (P2Y12RA), warfarin, direct-acting oral anticoagulants (DOAC), and cilostazol], non-steroidal anti-inflammatory drugs (NSAIDs), interruption of ATs, replacement of antiplatelet agents (APA), and heparin bridging; tumor characteristics (single or multiple lesions, location, pathologic size, type of differentiation); piecemeal resection; and laboratory data (albumin level and international normalized ratio).



Bleeding after ESD was defined as the presence of signs of bleeding (melena, hematemesis, or a decrease in the hemoglobin level by > 2 g/dL) along with endoscopic stigmata of recent bleeding, such as Forrest class Ia, Ib, IIa, and IIb, within 28 d after ESD. Interruption of ATs was defined as the discontinuation of these medications before the procedure, according to the recommended duration. Replacement of APA was described as when the procedure was performed with aspirin or cilostazol alone in patients who were receiving multiple APAs. Heparin bridging was defined as the administration of heparin during the period between the discontinuation and resumption of anticoagulants. A hemoglobin reduction of > 2 g/dL was evaluated by calculating the differences in the hemoglobin levels between the day before and after ESD.

Development of the deep learning and clinical models

We built a deep learning model and a clinical model based on the development set, which comprised 80% of the overall cohort. Subsequently, we validated the deep learning and clinical models in the validation set, which comprised 20% of the overall cohort. The categorical variables were converted using one-hot encoding, and the continuous variables were normalized, as preprocessing. We built the deep learning model as follows: First, we augmented the development set using the borderline synthetic minority over-sampling technique to overcome the imbalance of the dataset. Synthetic data were generated from 5%–100% of the majority class. Second, we constructed the deep learning model using automated machine learning, called Keras Tuner, to tune hyperparameters automatically. The initial architecture of the model was configured similarly to a transformer based on the attention mechanism [17]. Then, we set the number of neurons as a hyperparameter variable, ranging from 12 to 24, in four dense layers. The learning rate was also set to a range from 1e-2 − to 1e-4 −. The combination of hyperparameters was determined using Bayesian optimization. Finally, we evaluated the performance in the validation set using a model tuned with the 20% of synthetic data of the majority class. The optimal units of dense layers were selected to 24. The optimal number of attention head was chosen to 16. The architecture is depicted in Supplementary Figure 1. The optimal learning rate with Adam optimizer was 1e-3.

Multivariable logistic regression analysis was performed in the development set to build the clinical model. Then, the clinical model was constructed as a formula with the sum of the beta coefficient values of significant factors with a P value of < 0.05.

The calculated value from the deep learning and clinical models was multiplied by 1000 and converted as a score. The score that indicated the risk probability was divided by the decile in the development set. We selected cutoff to discriminate the risk categories as low-, intermediate-, and high-risk at a bleeding rate of < 5% and < 9% in the development set referred to in a previous report[13]. Decile 1st to 4th was allocated to low risk, 5th to 8th to intermediate risk, and 9th to 10th to high-risk category. Figure 1 Patient flowchart. EGC: Early gastric cancer; ESD: Endoscopic submucosal dissection.

Statistical analysis

Descriptive statistics for continuous and categorical variables are presented as means (standard deviation) and frequencies (%). The deep learning model and the clinical model for prediction of bleeding after ESD were evaluated using two methods. First, sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and receiver operating characteristic area (ROC) curve along with the area under the curve (AUC) were analyzed. The performance with AUC was compared using the bootstrap test. Second, the risk stratification of PEB based on the development set was applied to the validation set and compared with the actual bleeding rate in the validation set. For example, if the score of calculated cases belongs to the high-risk category, we verified that the real bleeding rate was in the predicted range of 9% or higher. The predictors for PEB were identified with multivariable logistic regression analysis in the entire cohort and development set. Model development for deep learning was performed using Tensor Flow 2.4.0, and Python 3.8.5. statistical analyses were performed using the R software (version 3.5.1, Vienna, Austria).

RESULTS

Baseline characteristics

Of the 5629 patients, 325 experienced post-ESD bleeding (PEB). The non-PEB and PEB groups were comparable in age, liver cirrhosis status, albumin level, international normalized ratio level, a proportion of aspirin or cilostazol use, undifferentiated tumor type, and piecemeal resection. The PEB group had a higher proportion of males and comorbidities (hypertension, diabetes mellitus, and chronic kidney disease) than the non-PEB group. P2Y12RA and anticoagulants (warfarin or DOAC) and the proportion of patients receiving replacement therapy or heparin bridging were higher in the PEB group than in the non-PEB group. The PEB group had a higher proportion of multiple tumors and middle location of tumors and larger size of tumors than the non-PEB group (Table 1). There was no difference in the baseline characteristics between the development and validation sets (Supplementary Table 1).

Predictors for bleeding after ESD

In the overall cohort, the independent predictors were identified as follows: Age [odds ratio (OR) = 0.98; 95% confidence interval (CI): 0.96–0.99; *P* value < 0.001], male (OR = 1.65; 95%CI: 1.19–2.28; *P* value = 0.003), hypertension (OR = 1.56; 95%CI: 1.19–2.03; p value = 0.001), chronic kidney disease (OR = 1.78; 95%CI: 1.18–2.70; *P* value = 0.006), P2Y12RA (OR = 2.40; 95%CI: 1.22–4.74; *P* value = 0.011), DOAC (OR = 4.31; 95%CI: 1.26–14.78; *P* value = 0.020), middle location (OR = 1.72; 95%CI: 1.07–2.74; *P* value = 0.024), and size (OR = 1.03; 95%CI: 1.02–1.04; *P* value < 0.001) (Supplementary Table 2).

In the development set, age (OR = 0.98; 95%CI: 0.96–0.99; *P* value = 0.001), male (OR = 1.54; 95%CI: 1.09–2.19; *P* value = 0.015), hypertension (OR = 1.35; 95%CI: 1.00–1.82; *P* value = 0.049), chronic kidney disease (OR = 1.78; 95%CI: 1.12–2.84; *P* value = 0.015), P2Y12RA (OR = 2.26; 95%CI: 1.05–4.88; *P* value = 0.037), middle location (OR = 1.97; 95%CI: 1.14–3.41; *P* value = 0.015), and size (OR = 1.04; 95%CI: 1.03–1.05; *P* value < 0.001) were identified as independent predictors. The clinical model was a formula described bottom of Table 2.

INR[2]	1.0 ± 0.1	1.0 ± 0.1	0.106

[1]*P* value calculated using Student's *t*-test for continuous variables or Pearson's chi-square test for categorical variables for overall data.
[2]mean ± SD presented for continuous variables.
Values are expressed as *n* (%) unless otherwise specified. AT: Antithrombotic; DOAC: Direct oral anticoagulant; INR: International normalized ratio; NSAIDs: Non-steroidal anti-inflammatory drugs; PEB: Post-endoscopic submucosal dissection bleeding; P2Y12RA: P2Y12 receptor antagonist.

Performance and comparison of deep learning model and clinical model

The deep learning model was found to have a sensitivity of 64.3%, specificity of 74.0%, PPV of 11.4%, NPV of 97.5%, and AUC of 0.71 (95%CI: 0.63–0.78). The clinical model had a sensitivity of 69.6%, specificity of 71.0%, PPV of 11.1%, NPV of 97.8%, and AUC of 0.70 (95%CI: 0.62–0.77) (Table 3 and Figure 2). There were no significant differences in the AUCs between the deep learning and clinical models (Table 3).

The score multiplied by 1000 to the derived value based on the deep learning and clinical models reflects the risk probability and was divided into deciles. The maximum cutoff was 35.9 in low risk, 57.5 in intermediate risk, and over the 57.5 was assigned to a high-risk category of the deep learning model based on development set (Table 4). In the clinical model, the maximum cutoff was 12.7 in low risk, 24.6

in intermediate risk, and over 24.6 was considered a high-risk category based on development set (Table 4). In the validated set, the deep learning model showed an actual bleeding rate in low-, intermediate-, high-risk categories, respectively, of 2.2%, 3.9%, and 11.6%; the clinical model showed an actual bleeding rate of 4.0%, 8.8%, and 18.2%, respectively, in low-, intermediate-, high-risk categories (Table 4).

DISCUSSION

The deep learning and clinical models for predicting bleeding after ESD in patients with EGC showed good performance. We demonstrated that deep learning and clinical models could stratify the PEB risk, which correlated with actual bleeding rates. Hence, we suggest that the deep learning model can aid in the prediction of bleeding after ESD, in addition to the clinical model.

This study was the first to establish a deep learning model for predicting bleeding after ESD and demonstrate its performance compared to that of a clinical model. The strengths of this study were its large sample size and the relatively recent data from a single institution. In addition, we included all essential variables and sought the advantages of the deep learning model that can deal with extensive

Table 3 Utility of deep learning model and clinical model

	Deep learning model	Clinical model	*P* value
Sensitivity (%)	64.3 (45.8–84.1)	69.6 (54.2–80.8)	
Specificity (%)	74.0 (50.6–89.2)	71.0 (68.5–79.5)	
PPV (%)	11.4 (7.4–18.1)	11.1 (8.0–15.4)	
NPV (%)	97.5 (96.4–98.7)	97.8 (96.6–98.7)	
AUC (95%CI)	0.71 (0.63–0.78)	0.70 (0.62–0.77)	0.730

One thousand times for bootstrapping were conducted to measure 95% confidence intervals. *P* value for statistical significance between area under the curves was derived from Delong's test. AUC: Area under the curve; CI: Confidence interval; NPV: Negative predictive value; PPV: Positive predictive value.

[1]The score is calculated with probability multiplied by 1000 and presented as maximum cutoff in each decile.
Decile 1st to 4th: Low-risk category. Decile 5th to 8th: Intermediate-risk category. Decile 9th to 10th: High-risk category. The Cochran–Armitage test for trend was performed.

data and complex problems and improve its performance incrementally by automated learning. We included all types of ATs separately and clarified the distinction between patients without an indication for ATs, patients who received an interruption before the procedure, and patients who received replacement or heparin bridging.

Our study identified younger age, male sex, hypertension, chronic kidney disease, P2Y12RA use, DOAC use, middle tumor location, and tumor size as the predictors of PEB. Previous studies also reported that younger age was associated with PEB[18-20]. It is unclear why younger age was associated with PEB. Several reports proposed that atrophic change along with aging might relate to decreasing the vascularity on the mucosal and submucosal layers[18,20-23]. Although aging and changes in intestinal vasculature have not been clearly elucidated, a decrease in the volume of vasculature with aging was observed in animals[24]. Aspirin did not increase the PEB risk after discontinuation about 1 wk[25]. Although some reported that maintaining aspirin did not increase the PEB risk[25-28], a meta-analysis showed that aspirin was associated with increased bleeding risk, requiring clinical caution[29]. There is still controversial due to limited evidence for P2Y12R[9,13,20,30]. In comparison, an increased bleeding risk after ESD has been reported consistently in patients receiving dual antiplatelets. In addition, there

Figure 2 Area under the curve for prediction of bleeding after endoscopic submucosal dissection in deep learning model and clinical model.

were reports that warfarin or DOAC are related to bleeding risk[13]; rather, some reported heparin bridging was associated with PEB risk[9,26]. The irony is that most of the patients who experience heparin bridging take warfarin or DOAC, but the results about each factor were inconsistent in previous retrospective studies. It is assumed that the duration of discontinuation and other individual factors might influence these results. In addition, it has been suggested that large size[8,19,20], CKD with hemodialysis[13,26,31], and long procedure time[20] were associated with bleeding after ESD. The upper location showed increased PEB risk[18,32]; in contrast, some others reported lower location related to increased PEB risk[18,32]; a recent meta-analysis did not prove significance according to the location[8].

Recently, a predictive risk-scoring model for PEB in Japan showed that CKD with hemodialysis, usage of aspirin, P2Y12RA, cilostazol, warfarin, DOAC, lower third tumor location, tumor size > 30 mm, and the presence of multiple tumors were the predictors of PEB, whereas interruption was a protective factor against PEB[13]. Another recent model proposed a simple algorithm including significant factors with continuous use of ATs, size ≥ 49 mm, and age < 62 years. We also found an association between P2Y12RA or DOAC usage and PEB; however, other ATs were not associated with PEB, and interruption and heparin bridging or replacement of APA were not identified as the protective factors. In our institution, ESD is classified as a high-risk procedure based on the national practice guidelines, and experts are consulted before ESD in patients receiving ATs. The expert assesses the thromboembolic risk depending on the underlying disease and recommends the possibility of interruption, duration of interruption, and the need for heparin bridging or replacement of APA[33-36]. Recently, a guideline published in South Korea also categorized ESD as an ultra-high-risk procedure and recommended interruption of ATs with heparin bridging or replacement of APA according to the thromboembolic risk [37].

The deep learning model in our study showed an AUC of 0.71, which was comparable to the AUC of 0.72 for a risk-scoring model in Japan[13] and the AUC of 0.70 for the clinical model in our study. In the validation set, predicted low-, intermediate-, and high-risk categories showed an actual bleeding rate of 2.2%, 3.9%, and 11.6%, respectively in the deep learning; 4.0%, 8.8%, and 18.2%, respectively, in the clinical model. Our study demonstrated that the deep learning and clinical models can stratify the bleeding risk after ESD. The predicted risk categories correlated with actual bleeding rate; even considering the actual bleeding rate was slightly lower than predicted range of ≥ 5% and < 9% (intermediate risk) in the deep learning and was close to upper range in the clinical model. Our findings support the clinical potential of the deep learning model for predicting PEB risk based on its comparable performance. Because bleeding after ESD requires intervention and hospitalization, physicians are concerned about the occurrence of PEB as a major complication. Based on the risk-prediction model, physicians could carefully assess the bleeding risk and perform preventive hemostasis during the procedure. Suppose additional management like the shielding method for preventing PEB in the selected high-risk group is attempted; in that case, it is anticipated that the deep learning model could support risk stratification.

Our study has several limitations. Due to its retrospective design, information such as the timing of the resumption of ATs, endoscopist's experience, defect size, and procedure duration was missing. Furthermore, our study was designed as a single-center study; hence, hospital-based validation in other hospitals was not performed, and further proof is warranted. However, the deep learning model might

be generalizable because it automatically identifies the risk or probability of bleeding without the external intervention of known relevant factors. Both the deep learning and clinical models showed a low PPV, which may be related to the low incidence of bleeding after ESD, even though bleeding is one of the major complications. In our cohort, the number of patients who received anticoagulants (warfarin or DOAC) was small; therefore, it is possible that the statistical significance of these variables was insufficient for establishing a clinical model in the development set. In this regard, despite the fact that our study focused on the development of a deep learning model and a clinical model, as well as the utility of the deep learning model, further accumulation of data and additional analysis will be required before the commencement of the clinical application of artificial intelligence systems.

CONCLUSION

In conclusion, we introduced a deep learning model to predict the risk of bleeding after ESD in patients with EGC. The model demonstrated its performance as comparable to the clinical model. The deep learning model could help physicians raise caution to the PEB and would be a desirable tool for supporting ESD application.

ARTICLE HIGHLIGHTS

Research background

With the increasing rate of diagnosis at early stages of gastric cancer, endoscopic submucosal dissection (ESD) is being actively applied as the minimally invasive treatment. Bleeding is one of the significant complications, with an incidence of 3.6%–6.9%. Because bleeding after ESD requires hospitalization and hemostatic interventions, there is a need to predict patients at a high risk of bleeding after ESD.

Research motivation

Currently, artificial intelligence systems are being applied in various fields of gastroenterology. Deep learning among artificial intelligence systems was automatically trained so that it could be generalized well. There has been no study on the efficacy of deep learning for predicting post-ESD bleeding (PEB), and no study has compared these systems with a clinical model.

Research objectives

This study aimed to develop and compare the performance of the deep learning and clinical model for predicting PEB in early gastric cancer (EGC) patients.

Research methods

Patients who underwent ESD for EGC between January 2010 and June 2020 at the Samsung Medical Center, Seoul, South Korea, were screened retrospectively. We built a deep learning model and a clinical model based on the development set, which comprised 80% of the overall cohort. Subsequently, we validated the deep learning and clinical models in the validation set, which comprised 20% of the overall cohort. The deep learning model and the clinical model for prediction of bleeding after ESD were evaluated using two methods. First, sensitivity, specificity, positive predictive value, negative predictive value, and receiver operating characteristic area curve along with the area under the curve (AUC) were analyzed. The performance with AUC was compared using the bootstrap test. Second, the risk stratification of PEB based on the development set was applied to the validation set and compared with the actual bleeding rate. The authors selected cutoff to discriminate the risk categories as low-, intermediate-, and high-risk at a bleeding rate of < 5% and < 9% in the development set referred to in a previous report.

Research results

Of the 5629 patients, 325 experienced PEB. The AUC for predicting PEB was 0.71 (95% confidence interval: 0.63-0.78) in the deep learning model and 0.70 (95% confidence interval: 0.62-0.77) in the clinical model, without significant difference (P = 0.730). In the validated set, the deep learning model showed an actual bleeding rate of 2.2%, 3.9%, and 11.6% in low-, intermediate-, high-risk categories, respectively; the clinical model showed an actual bleeding rate of 4.0%, 8.8%, and 18.2% in low-, intermediate-, high-risk categories, respectively.

Research conclusions

In conclusion, we introduced a deep learning model to predict the risk of bleeding after ESD in patients with EGC. The model demonstrated its performance as comparable to the clinical model.

Research perspectives

Based on the risk-prediction model, physicians could carefully assess the bleeding risk and perform preventive hemostasis during the procedure. Suppose additional management like the shielding method for preventing PEB in the selected high-risk group is attempted; in that case, it is anticipated that the deep learning model could support risk stratification.

Abstract

BACKGROUND

The prognosis of hepatocellular carcinoma (HCC) remains poor and relapse occurs in more than half of patients within 2 years after hepatectomy. In terms of recent studies, microvascular invasion (MVI) is one of the potential predictors of recurrence. Accurate preoperative prediction of MVI is potentially beneficial to the optimization of treatment planning.

AIM

To develop a radiomic analysis model based on pre-operative magnetic resonance imaging (MRI) data to predict MVI in HCC.

METHODS

A total of 113 patients recruited to this study have been diagnosed as having HCC with histological confirmation, among whom 73 were found to have MVI and 40 were not. All the patients received preoperative examination by Gd-enhanced MRI and then curative hepatectomy. We manually delineated the tumor lesion on the largest cross-sectional area of the tumor and the adjacent two images on MRI, namely, the regions of interest. Quantitative analyses included most discriminant factors (MDFs) developed using linear discriminant analysis algorithm and histogram analysis with MaZda software. Independent significant variables of clinical and radiological features and MDFs for the prediction of MVI were estimated and a discriminant model was established by univariate and

multivariate logistic regression analysis. Prediction ability of the above-mentioned parameters or model was then evaluated by receiver operating characteristic (ROC) curve analysis. Five-fold cross-validation was also applied *via* R software.

RESULTS

The area under the ROC curve (AUC) of the MDF (0.77-0.85) outperformed that of histogram parameters (0.51-0.74). After multivariate analysis, MDF values of the arterial and portal venous phase, and peritumoral hypointensity in the hepatobiliary phase were identified to be independent predictors of MVI ($P < 0.05$). The AUC value of the model was 0.939 [95% confidence interval (CI): 0.893-0.984, standard error: 0.023]. The result of internal five-fold cross-validation (AUC: 0.912, 95%CI: 0.841-0.959, standard error: 0.0298) also showed favorable predictive efficacy.

CONCLUSION

Noninvasive MRI radiomic model based on MDF values and imaging biomarkers may be useful to make preoperative prediction of MVI in patients with primary HCC.

Key Words: Hepatocellular carcinoma; Microvascular invasion; Magnetic resonance imaging; Radiomic analysis; Imaging biomarkers

INTRODUCTION

As important therapies for hepatocellular carcinoma (HCC), liver resection and transplantation are widely applied in clinic and the techniques have great advances. However, the prognosis remains poor and relapse occurs in more than half patients within 2 years after hepatectomy[1]. In terms of recent studies, microvascular invasion (MVI) is one of the potential predictors of recurrence[2,3]. MVI, only seen under the microscope, is defined as the appearance of tumor cells in smaller vessels inside the liver which include small portal vein and small lymphatic vessels or hepatic artery[4,5]. And MVI can be classified as four subclasses varying from M0 to M3, and higher grade usually indicates higher invasiveness of HCC and poorer survival rate[6]. Nonetheless, MVI is diagnosed by post-surgery histological result at present, which is the gold standard. The accurate prediction of MVI before operation can help achieve the anatomic resection with expanding resection margin even for a small tumor[7]. Thus, accurate preoperative prediction of MVI is potentially beneficial to the optimization of treatment planning[3,8].

There have been some studies to preoperatively predict MVI in terms of serum markers, radiological features, or imaging techniques[9-11]. For example, albumin was independently associated with MVI [9]. Besides, non-smooth tumor margins had strong diagnostic power and were of great importance for MVI assessment[10]. Moreover, gadolinium ethoxybenzyl-diethylenetriaminepentaacetic acid (Gd-EOB-DTPA), a special hepatocellular parenchymal contrast agent for magnetic resonance imaging (MRI), was valuable for MVI prediction as well[11,12]. However, the levels of serum markers are instable and likely to be affected by other diseases, and the imaging characteristics are evaluated subjectively and lack of conformance between observers. Thus, a more reliable biomarker is needed for preoperative prediction of MVI.

Quantitative analysis may have advantages over subjective analysis in reflecting valuable microscopic image features. Radiomic analysis can quantify the spatial variations in gray-level patterns, image spectral properties, and pixel interrelationships, which therefore has attracted great interest[13-15]. Using automation algorithms based on big data and with the advantages of noninvasiveness, radiomics analysis provides a powerful tool for modern medicine, and it can broadly combine multiple biomarkers and then guide clinical decision-making for patients suspected with cancer[16]. Various machine-learning methods have been used for radiomic analysis for MVI prediction, such as support vector machine and random forest[17,18]. To the best of our knowledge, there is not yet radiomics study based on linear discriminant analysis (LDA) algorithm to predict MVI. Additionally, even without spatial information, histogram analysis alone can indicate a gray-level distribution and is used for MVI prediction[19,20].

Our aim was to identify the histogram parameters alone that are predictive for MVI, and determined the prediction capacity of LDA radiomic models based on multiple phases in pre-operative Gd-enhanced MRI alone or combined with the image features for detecting MVI.

MATERIALS AND METHODS

Patients

Patients who underwent Gd-enhanced MRI examination before surgery were consecutively recruited between June 2019 and November 2021. The inclusion criteria were: (1) Solitary HCC lesion which was resectable or multiple HCC lesions appearing within one liver lobe; (2) No macroscopic vascular invasion; (3) Received the examination of Gd-enhanced MRI of the liver [with or without hepatobiliary phase (HBP)] within 1 mo before surgery; (4) Received curative hepatectomy; and (5) Verification of MVI by pathological evidence. The exclusion criteria were as follows: (1) Other anti-tumor therapies had been performed before surgery; (2) Pathological or clinical information was incomplete; (3) Imaging was not enough for analysis as a result of motion artifact; and (4) MRI performed in a different 3.0T MR machine. A total of 113 patients (91 men and 22 women; age ranging from 29–88 years, median age 58 years old) were included. According to pathologic results, HCC patients were allocated into MVI-positive (MVI+) and MVI-negative (MVI-) groups. The inclusion and exclusion criteria are shown in the flow diagram (Figure 1). This single-center retrospective cohort study was approved by the Institutional Review Board (No. [2019]283), and the requirement for informed consent was waived.

MRI examination

A 3.0T MR machine (MAGNETOM Verio; Siemens, Healthcare, Erlangen, Germany) with a dedicated phased-array body coil was used for MRI. The standard abdominal MRI protocol included: (1) Axial T2-weighted fat-suppressed turbo-spin-echo: Repetition time (TR)/echo time (TE), 4700/79 msec, slice thickness, 5 mm, slice gap, 1 mm, FOV, 21 mm × 38 mm; (2) In-phase and out-of-phase axial T1-weighted imaging (T1WI): TR/TE, 133/2.5 msec (in-phase), 6.2 msec (out-phase), slice thickness, 5 mm, slice gap, 1 mm, FOV, 21 mm × 38 mm; (3) Diffusion-weighted imaging (b = 50, 800 sec/mm^2) performed using a free-breathing single-shot echo-planar technique, TR/TE, 9965/73 msec, slice thickness, 5 mm, slice gap, 1 mm, FOV, 21 mm × 38 mm. The MRI system automatically calculated the corresponding ADC maps; and (4) Contrast enhanced MRI: A 3D gradient echo sequence with volumetric interpolated breath-hold examination was performed before and after injection of gadobenate dimeglumine (MultiHance; Bracco) at a dose of 0.2 mL/kg and at a rate of 2 mL/sec followed by a 20 mL saline flush with the following parameters: TR/TE, 3.9/1.4 msec, slice thickness 3 mm, slice gap, 0.6 mm, FOV, 25 mm × 38 mm. Hepatic arterial phase (AP), portal venous phase (PVP), equilibrium phase (EP), and HBP images were obtained at 20–30 sec, 70–80 sec, 180 sec, and 90 min after contrast medium injection, respectively.

Radiomic analysis

MaZda software (version 4.6.0, available at http://www.eletel.p.lodz.pl/mazda/) was used for radiomic analysis[21], and Digital Imaging Transformation and Communications in Medicine (DICOM) format was needed for compatibility with MaZda software. Images (MVI+ and MVI-) were loaded into the MaZda software; then, regions of interest (ROIs) were segmented manually by one radiologist, on the largest cross-sectional area and adjacent two images of the tumor or largest lesion (in the case of multiple lesions), which also included cystic necrotic regions. To delineate the tumor, the reference was based on HBP or T2-weighted imaging (T2WI) (in the case of artifact) images which were first segmented. Subsequently, the ROI was overlaid onto other phase images as required. If the respiratory movement caused the change of tumor location, the ROI was finely adjusted.

Radiomic analysis was performed with the MaZda package after loading all segmented tumor T2WI and T1WI + Gd images; within each ROI, 101 features were generated. Six different statistical image descriptors including gradient features, histogram features, gray level co-occurrence matrix, gray level run-length matrix, wavelet transform, and autoregressive model were used to create these radiomic features[21,22]. In each ROI, gray-level was normalized to minimize the effect of brightness and contrast

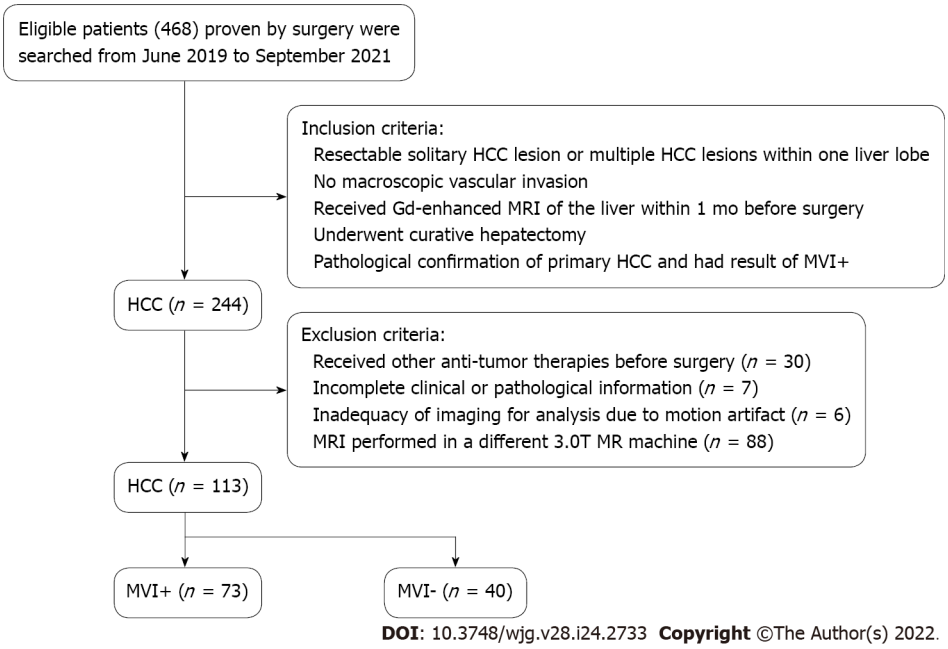

Figure 1 Flowchart of study selection process. HCC: Hepatocellular carcinoma; MVI: Microvascular invasion.

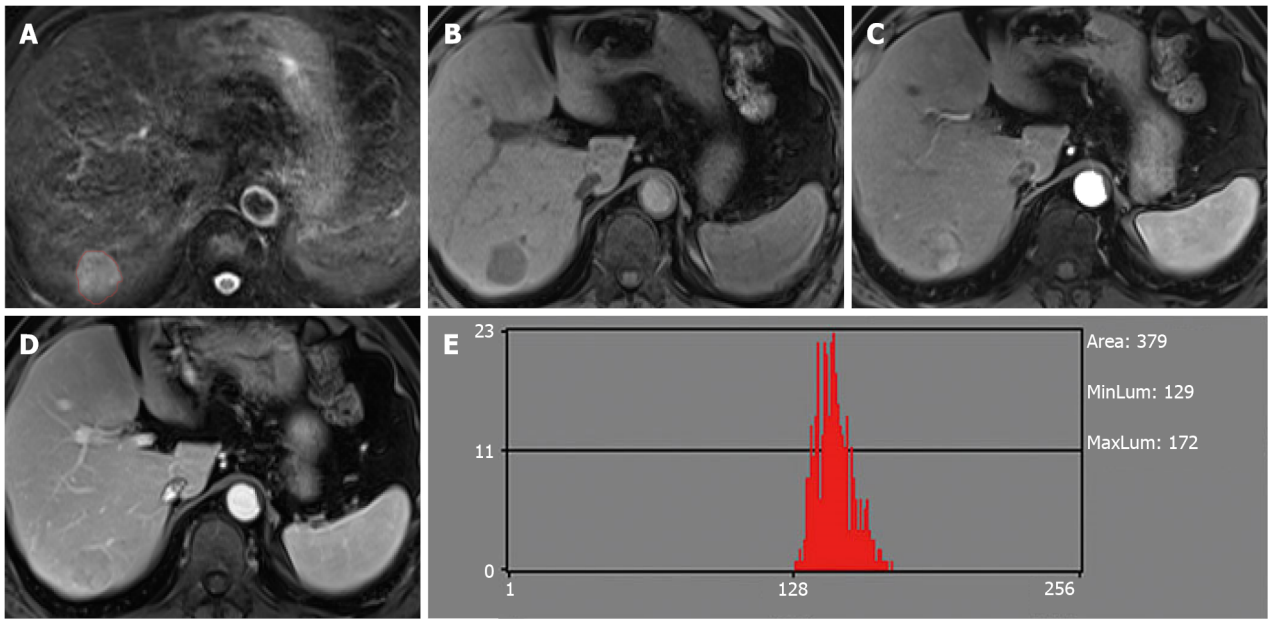
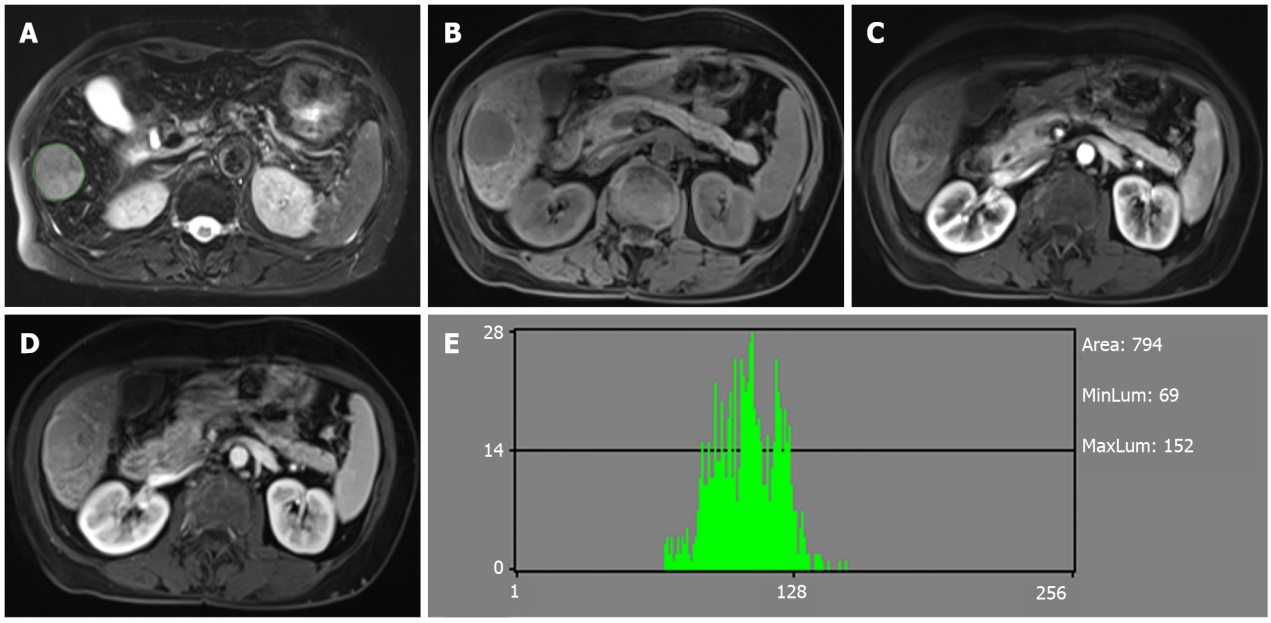


variation by image intensities in the range μ ± 3σ (μ, gray-level mean; σ, standard deviation), and the range was quantized to 6 bits/pixel[23,24].

Dimension reduction is necessary because it is impractical for clinicians to analyze all radiomic features on each patient and curse of dimensionality may happen in the case of too many features. Thus, the useful features were selected among 101 features in each sequence using algorithms, *i.e.*, mutual information (MI), Fisher coefficient (Fisher), and probability of classification error and average correlation coefficients (POE + ACC). These algorithms were used to select 30 highest discriminative power features in each sequence for further analysis. The statistical B11 radiomic analysis package (a plug-in of Mazda software) was used for analyzing these 30 features. A LDA model with the lowest misclassification rate was used to calculate the most discriminant factor (MDF)[25], which served as a comprehensive variable for discrimination and represented a linear transformation of these input 30 features that achieved the maximum separation for samples the between MVI+ and MVI- groups and the minimum separation of samples within each group. Hence, there were six MDFs, *i.e.*, MDF_{T1WI}, MDF_{T2WI}, MDF_{AP}, DMF_{PVP}, MDF_{EP}, and MDF_{HBP}.

The values of the nine histogram features (mean, variance, skewness, kurtosis, percent 1%, percent 10%, percent 50%, percent 90% and percent 99%) previously described (*i.e.*, one of six different statistical image descriptors used for radiomic analysis) were separately saved in addition for the comparison with MDF values. All characteristics of radiomic analysis were generated as presented in Figures 2 and 3.



Analysis of semantic features

In each case, an optimal window setting was adjusted to evaluate the preoperative MR images in the Picture Archiving and Communication System. The imaging features for each HCC were evaluated by two abdominal radiologists independently based on the following criteria: (1) Arterial rim enhancement, defined based on the image with irregular ring-like enhancement with relatively hypovascular central areas in the AP[26,27]; (2) Arterial peritumoral enhancement, defined based on the detectable crescent or polygonal shaped enhancement outside the tumor margin, which broadly contact with the tumor border in the AP, changing to isointense with liver parenchyma background in the delayed phase [28]; (3) Tumor margin, also defined as smooth margin, with the representative image being nodular tumors with smooth contour, or non-smooth margin presenting as non-nodular tumors with irregular margin that had surrounding budding portion in the transverse and coronal HBP images[10,28]; (4) Radiological capsule, presenting as peripheral edge of smooth hyperenhancement in the portal venous or EP[28,29]; (5) Tumor hypointensity in the HBP, shown as lower SI than that of the surrounding liver [12,30]; and (6) Peritumoral hypointensity in the HBP, defined as wedge-shaped or flame-like hypointense area of hepatic parenchyma located outside of the tumor margin in the HBP[31]. Two radiologists assessed the features of the HCC images or the largest lesion (in the case of multiple lesions). The final decision was based on their consensus.

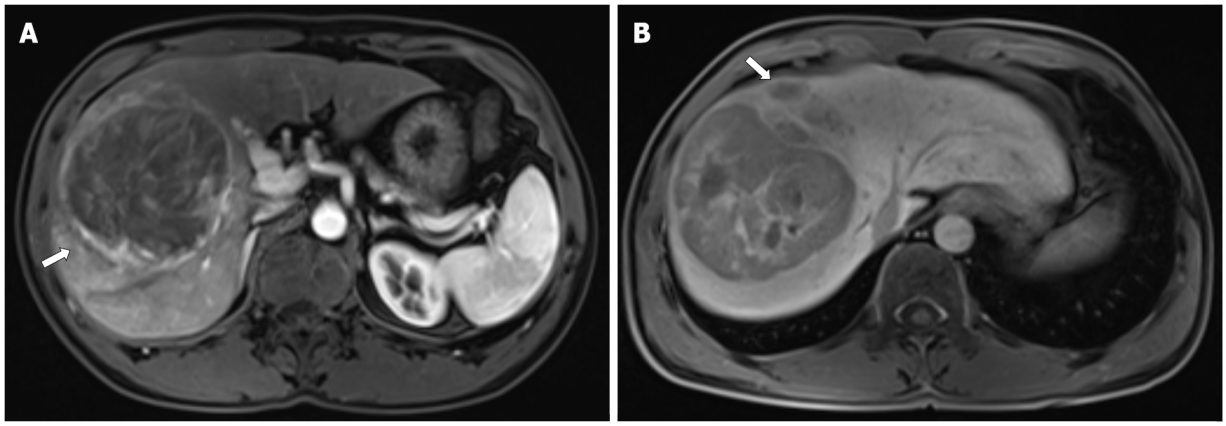
Figure 3 Hepatocellular carcinoma with microvascular invasion in a 68-year-old woman. A: The lesion also showed slightly high signal intensity on T2-weighted imaging (T2WI) and was segmented; B: T1WI showed hypointensity; C: Hyper-enhancement in the arterial phase; D: The lesion showed wash-out in the portal venous phase; E: Histogram map derived from the portal venous phase indicating that the parameter of histogram was significantly different between the two groups.



Histopathological analysis

The tumor size, number, and capsule condition were collected and analyzed. The histological type, differentiation grade, lymphocyte infiltration, satellite nodules, MVI status, and chronic liver disease were compared[32]. The definition of MVI was the presence of tumor emboli in an endothelial cells-lined vascular space. The experienced pathologists reported the histopathological results after reviewing the clinical and imaging files.

AFP: Alpha-fetoprotein; HBsAg: Hepatitis B surface antigen; MVI: Microvascular invasion.

areas under the ROC curve (AUCs) were used to assess the predictive efficacy and the optimal cutoff values from the maximum Youden's index were calculated, as well as the corresponding sensitivity and specificity for discriminating between MVI+ and MVI-. Univariate and multivariate logistic regression analyses were performed to confirm the significant variables related to MVI including clinical factors, imaging features, and MDFs in different sequences, and then build a discriminant model. Multivariate logistic regression analysis was performed using forward stepwise elimination method to identify the independent predictors. The prediction ability of significant MDF and the discriminant model was evaluated by AUC. Five-fold cross-validation was performed using the "caret" package, and nomogram was used as a graphical representation using the "rms" package (R software version 4.0.2, http://www.r-project.org). Student's *t*-test or Mann-Whitney U test was used to compare the continuous variables. Fisher's exact test or Pearson's chi-squared test was used to compare the categorical variables. $P < 0.05$ indicated statistical significance.

RESULTS

Patient characteristics

The patients were divided into two groups according to the histopathological results: MVI+ group and the MVI- group. Among 113 HCCs, 73 had MVI (4 patients had no HBP images), while 40 had no MVI (4 patients had no HBP images). The patients' clinical and radiological characteristics are listed in Tables 1 and 2, respectively. There were statistically significant differences in alpha-fetoprotein (AFP), pathologic grade, maximum tumor diameter (MTD), arterial rim enhancement, tumor margin, and peritumoral hypointensity in the HBP between the MVI+ and MVI- groups ($P < 0.050$).

Table 2 Comparison of different imaging features according to microvascular invasion

MRI feature	MVI+ (*n* = 73)	MVI- (*n* = 40)	*P* value
MTD (cm)[1]	7.23 ± 4.30	3.80 ± 2.43	< 0.001

Present	52 (75.4)	2 (5.6)	

[1]Data are the mean ± SD.

There were eight patients who had no HBP images. HBP: Hepatobiliary phase; MVI: Microvascular invasion; MTD: Maximum tumor diameter; MRI: Magnetic resonance imaging.

Radiomic analysis

For the MVI+ and MVI- patients, the values of MDFs resulting from the LDA model under B11 analysis were significantly different between the two groups ($P < 0.001$). The analysis of MDF values with ROCs generated an AUC of 0.82 [95% confidence interval (CI): 0.77-0.87] for T1WI; 0.77 (95%CI: 0.72-0.83) for T2WI; 0.84 (95%CI: 0.80-0.88) for AP; 0.85 (95%CI: 0.81-0.90) for PVP; 0.84 (95%CI: 0.79-0.88) for EP; and 0.83 (95%CI: 0.78-0.87) for HBP images. Cutoff values of -1.38×10^{-3} (T1WI), 4.73×10^{-3} (T2WI), 1.97×10^{-2} (AP), 4.17×10^{-3} (PVP), 2.25×10^{-2} (EP), and 4.30×10^{-4} (HBP) were obtained with corresponding high sensitivities and specificities (T1WI: 78% and 78%; T2WI: 59% and 80%; AP: 87% and 66%; PVP: 67% and 90%; EP: 68% and 85%; HBP: 76% and 79%, respectively). The predictive power (AUC) of MDFs derived from the radiomics analysis was better than that of all other histogram parameters (T1WI: 0.52-0.68; T2WI: 0.53-0.70; AP: 0.54-0.69; PVP: 0.50-0.74; EP: 0.51-0.74; HBP: 0.52-0.65) (Tables 3 and 4). The MRI images of four MVI+ and MVI- cases in the AP and PVP are presented, which show similar histogram features but different MDFs (Figure 4 and Supplementary Table 1).

Association of MDFs and patient characteristics with microvascular invasion

We excluded the patients who had no HBP images. MDF values were derived from the largest cross-sectional area of images for univariate analysis. Univariate analysis showed that MDF_{T1WI} greater than -1.38×10^{-3} [odds ratio (OR) = 11.2000, 95%CI: 4.346-28.861; $P < 0.001$], MDF_{T2WI} greater than 4.73×10^{-3} (OR = 6.066, 95%CI: 2.334-15.765; $P < 0.001$), MDF_{AP} greater than 1.97×10^{-2} (OR = 8.552, 95%CI: 2.967-24.650; $P < 0.001$), MDF_{PVP} less than 4.17×10^{-3} (OR = 0.050, 95%CI: 0.017-0.143; $P < 0.001$), MDF_{EP} less than 2.25×10^{-2} (OR = 0.095, 95%CI: 0.037-0.244; $P < 0.001$), and MDF_{HBP} greater than 4.30×10^{-4} (OR = 8.800, 95%CI: 3.222-24.032; $P < 0.001$) were important risk factors related to the presence of MVI. Among patient characteristics, univariate analysis showed that MTD (OR = 1.351, 95%CI: 1.146–1.593; $P < 0.001$), AFP level (OR = 3.818, 95%CI: 1.357–10.605; $P = 0.028$), arterial rim enhancement (present *vs* absent, OR = 5.683, 95%CI: 1.977–16.340; $P = 0.001$), tumor margin (non-smooth *vs* smooth, OR = 4.024, 95%CI: 1.555–10.414; $P = 0.004$), and peritumoral hypointensity in the HBP (present *vs* absent, OR = 52.000, 95%CI: 11.287–239.569; $P < 0.001$) were significant risk factors associated with the presence of MVI

AUC: Area under the receiver operating characteristic curve; MDF: Most discriminant factor; MVI: Microvascular invasion.

(Table 5).

Multivariate analysis of MDF values and patient characteristics with microvascular invasion

Multivariate analysis of the above 11 significant parameters showed that only MDF_{AP} (> 1.97 × 10^{-2} *vs* ≤ 1.97 × 10^{-2}, OR = 7.654, 95%CI: 1.860-31.501; P = 0.005), MDF_{PVP} (> 4.17 × 10^{-3} *vs* ≤ 4.17 × 10^{-3}, OR = 0.182, 95%CI: 0.047-0.705; P = 0.014), and peritumoral hypointensity in the HBP (present *vs* absent, OR = 37.098, 95%CI: 6.861-200.581; P < 0.001) were independent predictors related to the presence of MVI (Figure 5).

Table 5 Univariate analysis of risk factors for most discriminant factors and patient characteristic

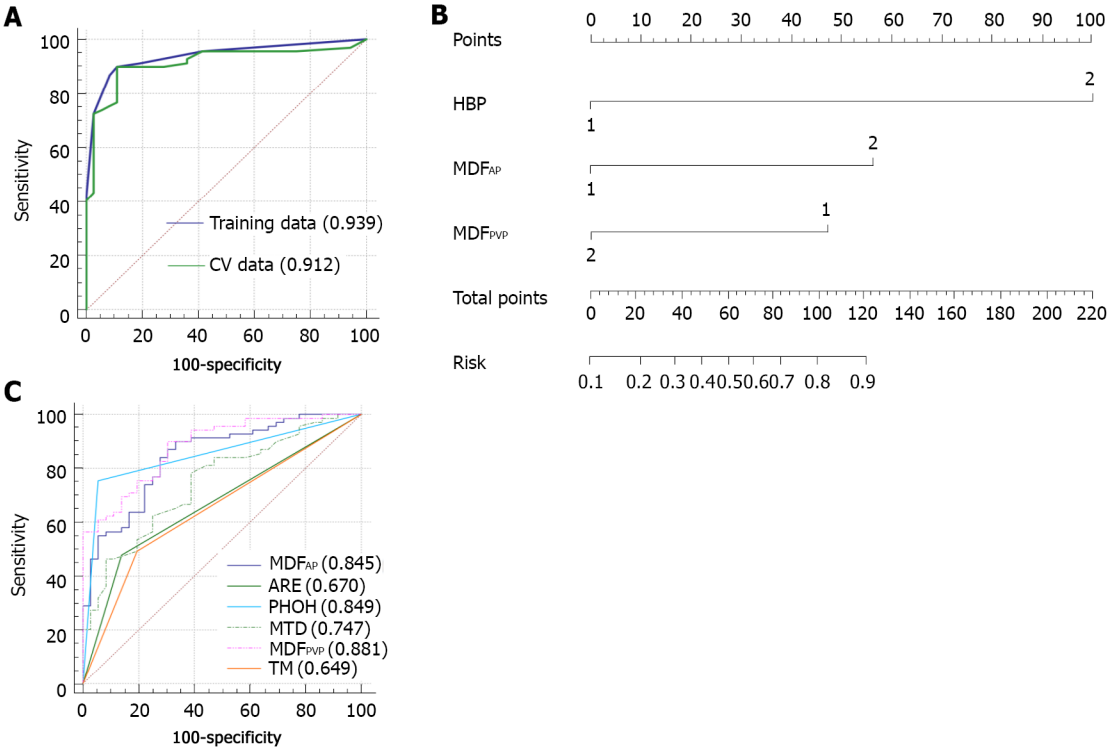
Variable	OR	95%CI	*P* value
MDF_{T1}	11.200	4.346-28.861	< 0.001[a]
MDF_{T2}	6.066	2.334-15.765	< 0.001[a]
MDF_{AP}	8.552	2.967-24.650	< 0.001[a]
MDF_{PVP}	0.050	0.017-0.143	< 0.001[a]
MDF_{EP}	0.095	0.037-0.244	< 0.001[a]
MDF_{HBP}	8.800	3.222-24.032	< 0.001[a]
MTD	1.351	1.146-1.593	< 0.001[a]
AFP	3.818	1.375-10.605	0.028[a]
Pathologic grade			0.105
Arterial rim enhancement	5.683	1.977-16.340	0.001[a]
Arterial peritumoral enhancement			0.215
Tumor margin	4.024	1.555-10.414	0.004[a]
Radiological capsule			0.275
Tumor hypointensity in HBP			0.215
Peritumoral hypointensity in HBP	52.000	11.287-239.569	< 0.001[a]

[a]*P* < 0.05, statistically significant results from logistic regression analysis. Variables with [a]*P* < 0.05 in univariate logistic regression analysis were applied to a multivariate logistic regression analysis.

MDF: Most discriminant factor; AFP: Alpha-fetoprotein; AP: Arterial phase; CI: Confidence interval; EP: Equilibrium phase; HBP: Hepatobiliary phase; MTD: Maximum tumor diameter; OR: Odds ratio; PVP: Portal venous phase.

The risk scores for individual patients based on the final discriminant model were calculated using the following formula: Logit (P) = −4.612 + 3.614 × peritumoral hypointensity on HBP (absent = 0, present = 1) + 2.035 × MDF_{AP} (≤ 1.97×10^{-2} *vs* > 1.97×10^{-2}, ≤ 1.97×10^{-2} = 0, > 1.97×10^{-2} = 1) - 1.876 × MDF_{PVP} (≤ 4.17×10^{-3} *vs* > 4.17×10^{-3}, ≤ 4.17×10^{-3} = 0, > 4.17×10^{-3} = 1). The probabilities of MVI were calculated by the formula [P = e Logit (P)/1 + e Logit (P)].

The AUC of the final model was 0.939 (95%CI: 0.893-0.984; standard error: 0.023) and the optimal cutoff value was 0.595881 ≈ 0.60 (specificity: 89%; sensitivity: 90%; Youden's index: 0.788) (Figure 6A). The result of internal five-fold cross-validation (AUC: 0.912; 95%CI: 0.841-0.959; standard error: 0.0298) also showed favorable predictive efficacy (Figure 6A). The independent predictive factors were integrated into a nomogram by the multivariate logistic regression analysis (Figure 6B).



Comparison of area under the receiver operating characteristic curve values of MDF values and imaging features

We generated the ROC curves of MDF_{AP} and $MDF_{PVP,}$ respectively, which were independent predictors. The ROC curves of imaging features which were significantly different were also generated alone. The results were compared using the Delong test. The MDF_{AP} and MDF_{PVP} had significantly higher AUCs than MTDs, arterial rim enhancement, and tumor margin ($P < 0.05$; Supplementary Table 2). However, there were no differences in AUCs among MDF_{AP}, MDF_{PVP}, and peritumoral hypointensity in the HBP ($P > 0.05$; Supplementary Table 1). Comparison of ROC curves is shown in Figure 6C.

DISCUSSION

MVI indicates the invasiveness of HCC and poor prognosis[2,3]. Therefore, the pre-operative prediction of MVI is an important factor for assessing long-term patient survival and treatment optimization. The quantification of MRI images by radiomic analysis can characterize the heterogeneity of tumor and has demonstrated previous success in reflecting histological subtype[33,34]. In the present study, through the analysis of the top 30 parameters in each sequence, an overall discriminator, MDF, was generated with the LDA model, providing better prediction ability for MVI than the histogram features.

Our study showed a high sensitivity of MDF values from radiomic analysis on preoperative Gd-enhanced MRI images and/or specificity in distinguishing between MVI+ and MVI-. The AUCs of MDF values of six sequences, all of which were more than 0.75, outperformed those of all histogram

Figure 6 Area under the receiver operating characteristic curve of the final model. A: Receiver operating characteristic (ROC) curves of the selected model and the ROC curve of the 5-fold cross-validation; B: Nomogram of the integrated model. Hepatobiliary phase (HBP) means peritumoral hypointensity in the HBP, most discriminant factor (MDF)$_{AP}$ means the MDF of the arterial phase, and MDF$_{PVP}$ means the MDF of the portal venous phase; C: Comparison of ROC curves for prediction of microvascular invasion. The area under the ROC curve (AUC) was largest for the MDF$_{PVP}$ alone (AUC = 0.881). ARE: Arterial rim enhancement; MTD: Maximum tumor diameter; PHOH: Peritumoral hypointensity in the HBP; TM: Tumor margin.

parameters and imaging features. The MDF values of AP and PVP images had significantly higher AUCs than most of imaging features. MDF values could provide additional information useful for clinical management decisions. Moreover, MaZda software can be easily used for general clinicians without additional requirement of expertise, easily serving as a potential powerful tool in preoperative prediction of MVI.

LDA has been used in radiomics studies recently[35]. Han *et al*[35] found that LDA and support vector machine achieved optimal performance when compared with multiple machine learning methods[35]. In our study, among the LDA models based on various sequences, MDF$_{AP}$ and MDF$_{PVP}$ were significant independent factors for the prediction of MVI, and showed satisfactory predictive efficacy with an AUC greater than 0.80. Histogram parameters have been used in quantitative analysis of MVI in clinical studies[19,20]. Li *et al*[19] performed histogram analysis of intravoxel incoherent motion and the best parameter provided a sensitivity of 81% and specificity of 85%[19]. It was based on whole tumor volume, but only 41 patients were enrolled. Wang *et al*[20] used computational quantitative measures based on the maximum cross-sectional area to predict MVI of small HCC, but only in HBP images[20]; the AUC, sensitivity, and specificity were 0.91, 0.87, and 0.80, respectively. In our study, the radiomic analysis-based MDF outperformed each individual histogram parameter in predicting the presence of MVI. Therefore, we considered that MDFs on the basis of LDA model that contained more comprehensive information could evaluate the Gd-enhanced MR images and determine MVI status better than histogram analysis alone.

Multivariate analysis of the 11 risk factors identified in the univariate analysis found that only peritumoral hypointensity in HCCs in the HBP, MDF$_{PVP}$, and MDF$_{AP}$ were independent predictors of MVI. Pathologically, MVI is usually found in the small portal vein and hepatic artery[4]. It may be detected in the small liver lymphatic vessels. But it is mostly found in small branches of the portal vein. This may explain why the MDF$_{PVP}$ and MDF$_{AP}$ were independent predictors of MDF values in the model that predicted MVI. The MDF$_{PVP}$ whose OR was less than 1 may be a protective factor, which means that the higher the MDF$_{PVP}$, the less possible the presence of MVI. MVI may affect the biological functions of the canalicular transporter multidrug resistance-associated protein 2 or the organic anion transporting peptides, both of which lead to the elimination of gadoxetate disodium. That may be the reason why peritumoral hypointensity appeared in HCCs in the HBP[12]. The OR of peritumoral hypointensity in the HBP was quite high, which may result from relatively small sample size.

It has been reported that MR findings including arterial peritumoral enhancement and non-smooth tumor margin were independent predictors associated with the presence of MVI or indicated the association between the hypointensity of HCCs in HBP images and a higher frequency of MVI[12,17], which is not consistent with our study. One possible reason for the inconsistence may be the differences between study populations, as all patients enrolled in that study had a single HCC with a diameter ≤ 5 cm. The inherent and technical inconsistencies between the observers in two studies may also account for the incompatible results. Arterial rim enhancement can predict biological characters of HCCs, including MVI, rapid progression, and early recurrence[26,36]. Our study showed that rim enhancement in the AP was not an independent predictor of MVI, and the reason may be that rim enhancement in AP is uncommon in HCC but more often seen in mass-forming cholangiocarcinoma or metastasis[37].

There are some limitations in this study. First, a selection bias may exist due to the retrospective study. Second, the radiomic analysis was performed only on the largest cross-sectional area and two adjacent images of the tumor. There may be information loss compared to whole tumors. In spite of this, our results showed excellent discriminative efficacy between the MVI+ and MVI- groups. Third, different MVI grading indicates a decreasing gradient of overall survival and time to early recurrence, which was not analyzed in the MVI+ group due to the small sample size. Finally, this study was performed at only one institution, causing the sample size small relative to the number of variables. Further multicenter, prospective studies are needed to validate the results of this study.

CONCLUSION

In conclusion, radiomic analysis based on preoperative Gd-enhanced MR images may be feasible for predicting MVI of HCC. Upon the application of MRI findings and radiomic variables in our model, the diagnostic prediction of MVI showed a high specificity and sensitivity, indicating that this method is a useful tool for clinicians in treatment decision-making.

ARTICLE HIGHLIGHTS

Research background

The prognosis of hepatocellular carcinoma (HCC) remains poor and relapse occurs in more than half of the patients within 2 years after hepatectomy. Microvascular invasion (MVI) is one of the potential predictors of recurrence. MVI is defined as the appearance of tumor cells in smaller vessels inside the liver which include small portal vein, and small lymphatic vessels or hepatic arteries. Accurate preoperative prediction of MVI is potentially beneficial to the optimization of treatment planning.

Research motivation

There have been some studies to preoperatively predict MVI in terms of serum markers, radiological features, or imaging techniques. However, the levels of serum markers are instable and likely to be affected by other diseases, and the imaging characteristics are evaluated subjectively and lack of conformance between observers. Thus, a more reliable biomarker is needed for preoperative prediction of MVI.

Research objectives

The aim of this study was to develop a radiomic analysis model based on pre-operative magnetic resonance imaging (MRI) data to predict MVI in HCC.

Research methods

A total of 113 patients recruited to this study have been diagnosed as having HCC with histological confirmation, among whom, 73 were found to have MVI and 40 were not. All the patients received preoperative examination by Gd-enhanced MRI and then curative hepatectomy. We manually delineated the tumor lesion on the largest cross-sectional area of the tumor and the two adjacent images on MRI. Quantitative analyses included most discriminant factors (MDFs) developed using a linear discriminant analysis algorithm and histogram analysis *via* MaZda software. Independent significant variables of clinical and radiological features and MDFs for the prediction of MVI were estimated and a discriminant model was established by univariate and multivariate logistic regression analysis. Prediction ability of the above-mentioned parameters or model was then evaluated by receiver operating characteristic (ROC) curve analysis, and five-fold cross-validation was applied *via* R software.

Research results

The area under the ROC curve of the MDF (0.77-0.85) outperformed the histogram parameters (0.51-0.74). After multivariate analysis, MDF values of the arterial and portal venous phase, and peritumoral

hypointensity in the hepatobiliary phase were identified to be independent predictors of MVI ($P < 0.05$). The area under the ROC curve (AUC) value of the model was 0.939. The result of internal five-fold cross-validation (AUC: 0.912) also showed favorable predictive efficacy.

Research conclusions

Noninvasive MRI radiomic model based on MDF values and imaging biomarkers may be useful to make preoperative prediction of MVI in patients with primary HCC.

Research perspectives

We believe that noninvasive radiomic models based on pre-operative MRI data have potential to be widely used in clinical fields.

ACKNOWLEDGEMENTS

We thank the radiographers at the First Affiliated Hospital of Fujian Medical University for scanning the patients and data collections in this study.

Abstract

BACKGROUND

Accurate diagnosis of colorectal premalignant polyps, including adenomas, is vital in clinical practice.

AIM

To investigate the diagnostic yields of novel findings of brown slits for adenomas.

METHODS
Patients who underwent colonoscopy at the Toyoshima Endoscopy Clinic were enrolled. Polyps sized ≥ 5 mm suspected of adenomas or clinically significant serrated polyps were included in the study. We defined the surface structures of colorectal polyps, which were brown curves inside and along the tubular glands identified using a combination of a new X1 system (Olympus Corporation) and a conventional magnifying colonoscope with non-staining narrow band imaging (NBI), as brown slits. The brown slits corresponded to slit-like lumens on endocytoscopy and histological crypt openings of an adenoma. We evaluated the diagnostic performance of brown slits for adenoma.

RESULTS
A total of 108 Lesions from 62 patients were eligible. The average age was 60.4 years and 41.9% were male. The mean polyp size was 7.45 ± 2.83 mm. Fifty-seven lesions were positive for brown slits. Histopathological diagnosis comprised 59 low-grade tubular adenomas, 16 sessile serrated lesions, and 33 hyperplastic polyps. Among 59 adenomas, 56 (94.9%) were positive for brown slits. Among 16 sessile serrated lesions, 0 (0%) was positive for brown slits. Among 33 hyperplastic polyps, 1 (3.0%) was positive for brown slits. The sensitivity, specificity, and accuracy of brown slits for adenoma were 94.9%, 98.0%, and 96.3%, respectively. The positive predictive value and negative predictive value of brown slits for adenoma were also excellent for 98.2%, and 94.1%, respectively.

CONCLUSION
Brown slits on conventional magnifying endoscopy with non-staining NBI using the X1 system were useful for diagnosing colorectal adenoma. The new endoscopy system could be examined using new standards.

Key Words: Adenoma; Colonoscopy; Narrow band imaging; Magnifying endoscopy; X1; Serrated polyp; Colorectal neoplasm; Endocytoscopy

INTRODUCTION

Colorectal adenoma is a premalignant neoplasm composed of a dysplastic epithelium. Removal of adenomas reduces the risk of colorectal adenocarcinoma[1,2]. Colorectal adenomas are found in ≥ 40% of proper colonoscopies, given that an accurate diagnosis of adenoma is crucial in routine endoscopic practice[3-6]. Colorectal serrated polyps are precursors with different molecular pathways and biological behaviors from adenomas[2,7,8]. Clinically significant serrated polyps (CSSPs), comprising all sessile serrated lesions (SSLs), all traditional serrated adenomas (TSAs), hyperplastic polyps ≥ 10 mm in size anywhere in the colorectum, and hyperplastic polyps ≥ 5 mm in size between the cecum and descending colon are recommended to be endoscopically removed[9-12]. The number, size, grade of dysplasia, and histological subtype of premalignant polyps, including both adenomas and serrated polyps, are the best determinants of the long-term risk of advanced neoplasia and inform surveillance decision-making[7,13-16].

Magnification, dye sprays, and modified light wavelengths, such as narrow band imaging (NBI) and blue laser imaging (BLI), are used to diagnose premalignant polyps better. The criteria for conventional magnifying endoscopy include pit pattern diagnosis using chromoendoscopy[17] and the Japan NBI expert team (JNET) classification using NBI and BLI[18-20]. The standards for ultra-high magnifying

endocytoscopy (EC) are as follows: EC classification, which evaluates the glandular structure and cellular atypia after double staining with methylene blue and crystal violet[21-24], and EC vascular classification, which evaluates the microvessels using NBI[25,26]. Slit-like lumens and microvessels with clear margins showing a network are good indicators of adenoma in EC, whereas narrow serrated lumens and obscure microvessels predict hyperplastic polyps. Sasajima *et al*[21] and Mori *et al*[23] have elucidated that long tubular pits (slit-like lumens) on EC are histologically equivalent to the crypt opening using the horizontal and vertical sections of specimens, respectively.

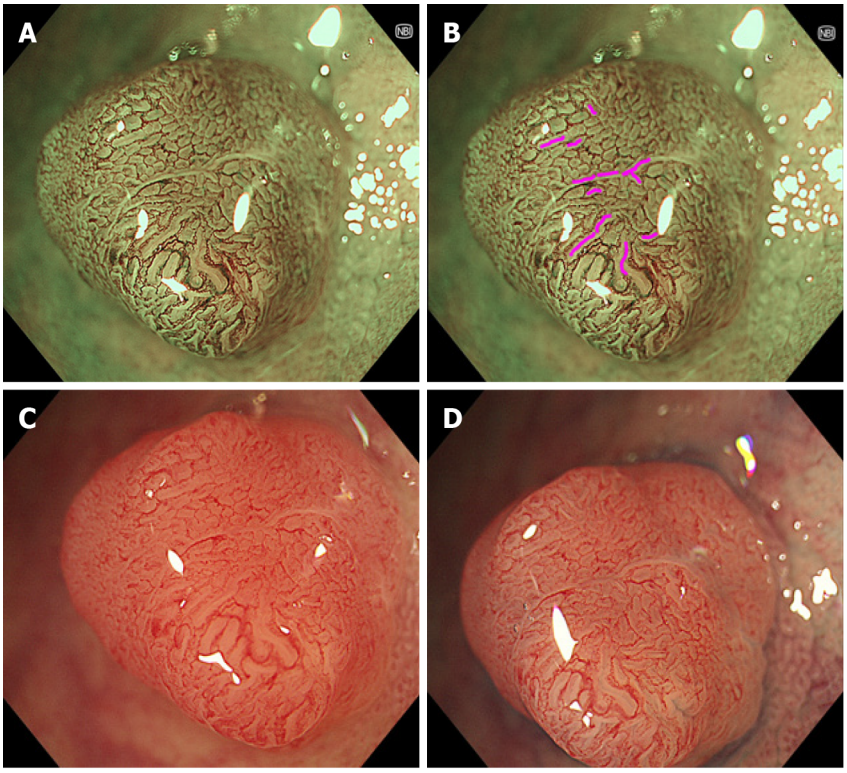
In 2020, a novel endoscopic system, which is a set of an EVIS X1 Video System Center (CV-1500) and a 4K ultra-high definition 32-inch liquid crystal display (LCD) monitor (OEV321UH), was released by Olympus Corporation, Tokyo, Japan. When using the same scope, this system has higher image quality and higher magnification than the previous generation's Olympus system, which is a set of EVIS Elite Video System Center (CV-290) and a high-definition 26-inch LCD monitor (OEV262H). For example, the magnifications of conventional magnifying endoscopes of Olympus' CF-HQ290Z and PCF-H290Z were 80 × and 110 ×, respectively, using the Elite system, while the magnifications increased to 95 × and 170 ×, respectively, using the X1 system. Given this, we hypothesized that the new X1 system allows conventional magnifying endoscopy to visualize the structures that could only be observed with EC, and to improve polyp diagnosis. Using a combination of the X1 system and the conventional magnifying endoscope with non-staining NBI, we identified the findings corresponding to the slit-like lumens, which present the crypts of adenoma. Then, we defined the findings as "brown slits" (Figure 1A and B).

To the best of our knowledge, there are no studies in which conventional magnifying endoscopy has verified the evidence accumulated by EC. Therefore, we focused on brown slits detected on conventional magnifying endoscopy using the X1 system and investigated their performance for adenoma diagnosis.

MATERIALS AND METHODS

Study design and overview

This retrospective study was conducted at the Toyoshima Endoscopy Clinic, a representative outpatient endoscopy-specialized clinic in Japan. This study was conducted in accordance with the ethical guidelines for medical studies in Japan. Written informed consent to use clinical information was obtained from the patients before colonoscopy. The study design was described in a protocol prepared by the Toyoshima Endoscopy Clinic and the Sakitani Endoscopy Clinic, and was approved by the Certified Institutional Review Board, Yoyogi Mental Clinic on July 16, 2021 (approval No. RKK227). We published this study's protocol on our institute's website (www.ichou.com) so that patients could opt out of the study if desired. All clinical investigations were performed in accordance with the ethical guidelines of the Declaration of Helsinki.



Study subjects

We enrolled patients who underwent colonoscopy at the Toyoshima Endoscopy Clinic in May and June 2021. Polyps sized ≥ 5 mm suspected of adenomas or CSSPs were included in this study[23,27,28]. The exclusion criteria were ulcerative colitis, poor bowel preparation, lesions for which endoscopic imaging could not be obtained, and lesions for which the specimen could not be collected. We also excluded histologically diagnosed adenocarcinomas, TSAs, and normal mucosa.

Brown slits for adenoma

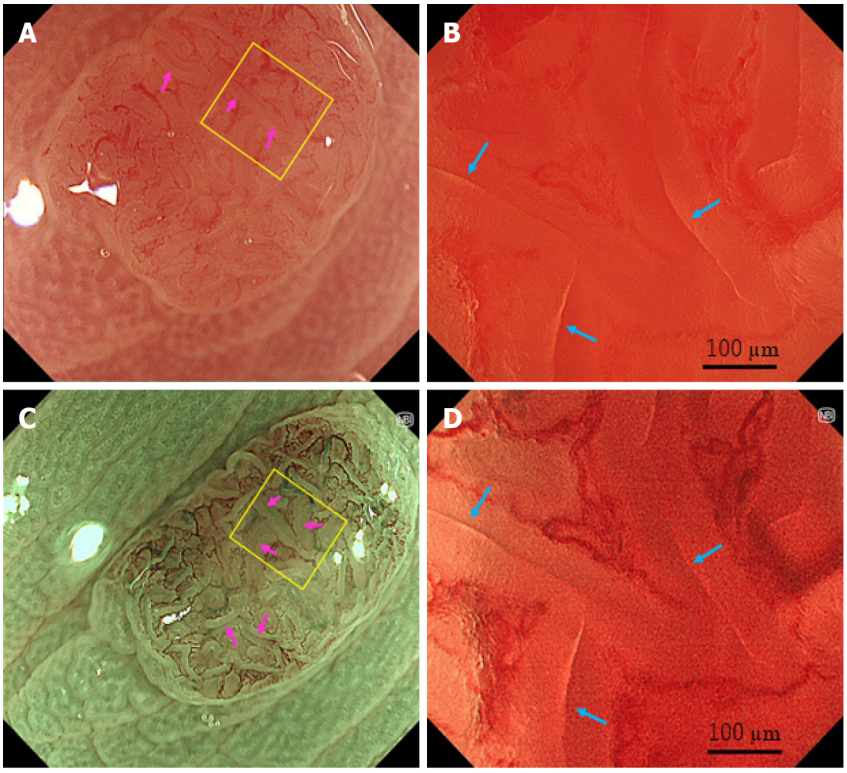
Figure 1 shows typical images of a tubular adenoma observed using a combination of the conventional magnifying endoscope (CF-HQ290Z) and the X1 system, at full zoom magnification with NBI and WLI with or without indigo carmine spraying. Brown slits inside and along the tubular glands surrounded by microvessels were identified (pink curves in Figure 1B). We defined this brown pattern as a brown slit. The brown slit was additionally defined as having a length longer than the width of the tubular gland (approximately 100 μm). The brown slits were visible as faint and pale red slits on WLI (Figure 1C). Indigo carmine accumulated in the crypt openings that corresponded to brown slits (Figure 1A, B and D).

Figure 2 shows representative images of a tubular adenoma using a combination of the endocytoscope (CF-H290EC, Olympus Corporation) and the X1 system. To obtain a fully zoomed image with 790× magnification with a focusing depth of 35 μm, the endoscopist softly contacted the lesion with the endoscope lens[26]. On ultra-high magnifying observation with NBI, slits with a mixture of brown and white colors inside and along the tubular glands were visualized (Figure 2D, blue arrows). This tubular structure corresponded to a slit-like lumen for staining EC[22-25]. The microvessels were clearly identified surrounding the tubular gland and showed a vessel network[25]. On ultra-high magnifying observation with white light imaging (WLI), although microvessels were obscure, slits with a mixture of red and white colors were seen similar to the slits on NBI observation (Figure 2B, blue arrows). We could recognize tubular glands surrounded by the microvessels and brown and pale red slits inside and

DOI: 10.3748/wjg.v28.i24.2748 **Copyright** ©The Author(s) 2022.

Figure 1 Representative images of "brown slits" in a low-grade tubular adenoma using conventional magnifying endoscopy. A set of a conventional magnifying endoscope (CF-HQ290Z), X1 system, and 4K 32-inch monitor was used. A, B: Full-zoom (95 ×) magnification, narrow band imaging. Brown slits were observed inside and along the tubular glands surrounded by the microvessels; C: Full-zoom magnifying, white-light imaging observation without indigo carmine spraying showed faint and pale red slits inside and along the tubular glands; D: Full-zoom magnifying, white light imaging with indigo carmine spraying showed indigo carmine accumulated in the site corresponding to the brown slits.

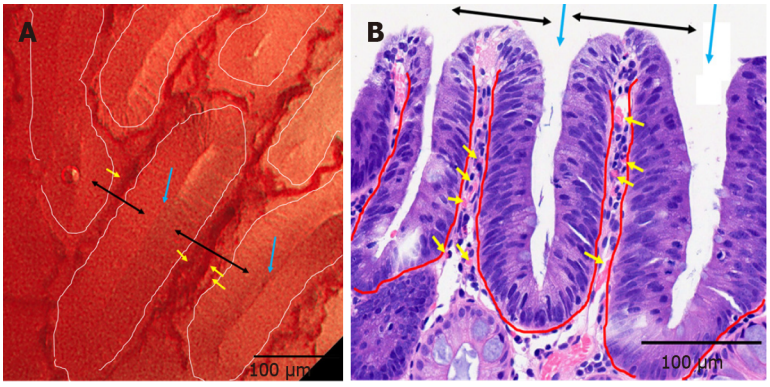
along the tubular glands with NBI and WLI, respectively, when we observed with approximately 100 × magnification, which was similar to the full zoom of conventional magnifying endoscopy (Figure 2A and C, pink arrows).



The correspondence between EC and histology is presented in Figure 3. Variably shaped tubular glands (surrounded by white and red curves in Figures 3A and B, respectively) with homogeneous widths of approximately 100 μm were observed. The crypts (blue arrows in Figure 3A and B) were detected as brown and white slits inside and along the tubular glands on EC. The microvessels (yellow arrows in Figure 3) were observed in the intervening part (black arrows in Figure 3). The size and position of the crypt, intervening part, and microvessels were consistent between EC and histology.

From the above, the brown slits on conventional magnifying endoscopy with NBI corresponded to slit-like lumens on EC and crypt openings on histology.

Colonoscopy



Brown slits were diagnosed in real-time during colonoscopy. Before the colonoscopy, the endoscopists discussed and obtained consensus for the brown slits while viewing the images on non-magnifying, conventional magnifying, and ultra-high magnifying observation. Two expert endoscopists conducted all colonoscopies. An endoscopic set of the X1 system and CF-HQ290Z or PCF-H290Z was used. Colonoscopes without a magnifying function and those with an autofocus function were excluded. The optical enhancement of the NBI was set in mode A8. When a lesion was detected, the surface was washed to remove mucus and dye, and a non-magnifying observation was conducted. Subsequently, the endoscopists focused on and diagnosed brown slits at almost full zoom. The polyp was observed without indigo carmine staining. Location, size, and morphology according to the Paris classification, the presence or absence of brown slits, and endoscopic polyp diagnosis were recorded. The colonoscopists classified each polyp as an adenoma, SSL, or hyperplastic polyp. The lesion size was calibrated by comparison with closed cups of biopsy forceps (approximately 2.5 mm).

Before examination, patients underwent bowel preparation with 2 L of polyethylene glycol solution or 1.8 L of isotonic magnesium citrate. If necessary, additional magnesium citrate or polyethylene glycol was provided. Patients were sedated using midazolam and pethidine hydrochloride. Scopolamine butylbromide or glucagon was intravenously administered to suppress bowel peristalsis. The polyps were resected using snear polypectomy with or without submucosal saline injection.

Figure 3 Correspondence between endocytoscopy and histology in a low-grade tubular adenoma. A: A set of an endocytoscope (CF-H290EC), X1 system, and 4K 32-inch monitor was used. Full-zoom magnifying, narrow band imaging observation. Variably shaped tubular glands (surrounded by white curves) with homogeneous widths of about 100 μm. The crypts (blue arrows) are detected as brown and white slits inside and along the tubular glands. The microvessels (yellow arrows) are identified in the intervening part (black arrows); B: Vertical sections stained with hematoxylin-eosin. The tubular glands (surrounded by red curves), crypts (blue arrows), intervening parts (black arrows), and microvessels (yellow arrows) are seen in endocytoscopy.

Pathology

Fixed specimens were subjected to histological examination. The reference standard was histopathology using standard hematoxylin-eosin staining. All lesions were diagnosed according to World Health Organization criteria[2] by a gastrointestinal pathologist. The pathologist classified each polyp as a tubular adenoma, villous adenoma, adenocarcinoma, SSL, TSA, microvesicular hyperplastic polyp (MVHP), goblet cell-rich hyperplastic polyp (GCHP), or normal mucosa.

Statistical analysis

The diagnostic performance of brown slits for colorectal adenoma was calculated using BellCurve for Excel (version 3.21; Social Survey Research Information Co., Ltd., Tokyo, Japan).

RESULTS

Of the 115 Lesions in 64 patients who met the criteria, 1 adenocarcinoma in situ, 1 TSA, 4 normal mucosae, and 1 lost specimen were excluded. A total of 108 Lesions in 62 patients were enrolled. Table 1 shows the characteristics of the study participants (mean age, 60.4 years; males, 41.9%). Of the lesions, the mean polyp size was 7.45 mm (range, 5–15 mm), and 57 and 51 were positive and negative for "brown slit" signs, respectively. Histopathological diagnosis of the polyps comprised 59 low-grade tubular adenomas, 16 SSLs, 27 MVHPs, and 6 GCHPs.

Table 2 presents the number of lesions in the brown slits. The diagnostic performance of brown slits for colorectal adenomas is shown in Table 3. The sensitivity, specificity, accuracy, positive predictive value, and negative predictive value were excellent for 94.9%, 98.0%, 96.3%, 98.2%, and 94.1%, respectively.

DISCUSSION

We defined the polyp's surface structure observed on conventional magnifying endoscopy with non-staining NBI using the X1 system as brown slits. The brown slits corresponded to the slit-like lumens detected on EC and to the histological crypt opening of the tubular gland of the adenoma. This study elucidated that the brown slits were highly accurate for differentiation between colorectal adenomas and serrated polyps with a sensitivity, specificity, and accuracy of 94.6%, 98.3%, and 96.5%, respectively. Kudo *et al*[22] reported that the sensitivity, specificity, and accuracy of slit-like lumens were 82.5%, 100%, and 83.9%, respectively, when comparing colorectal adenoma and hyperplastic polyps. The strength of the brown slits is not only the high diagnostic performance, but also the convenience of identification using a conventional magnifying endoscope with non-staining NBI. Kudo *et al*[25] reported that obtaining a clear ultra-high magnification view using EC was difficult and long. Thus, brown slits are simple and meaningful in daily practice.

Compared with EC, conventional magnifying endoscopy has advantages, such as not requiring contact, thereby reducing bleeding or tissue damage; easy focusing; and high familiarity. Additionally, CF-HQ290Z (4700000 yen: $ 40941) and PCF-H290Z (4500000 yen: $ 39199) are cheaper than CF-H290EC (7900000 yen: $ 68817). In the future, it would be beneficial if the accumulating evidence with the EC could be applied with conventional magnifying endoscopy.

JNET types 1 and 2A correspond to histological classifications of hyperplastic polyp/SSL and low-grade intramucosal neoplasia, respectively. JNET classification was comprehensively judged with two scales: surface pattern and vessel pattern[18,19]. Kobayashi *et al*[19] reported that the sensitivity, specificity, and accuracy of JNET 2A for low-grade intramucosal neoplasia were 91.4%, 75.1%, and 89.1%, respectively. Because the brown slit sign is based only on the surface pattern, it may be simpler and easier than the JNET classification.

The reasons why the set of X1 system allowed the visualization of the brown slits, which accurately predicted adenomas, were considered as follows: compared to the Elite system, the X1 system has a higher magnification and image quality due to 4K resolution, additional amber color LED, and a new noise reduction system. We previously reported that the new 290 series endoscopic system had advantages in polyp detection and procedure over the previous 260 series model[29]. Improvements of the endoscopic system may increase the visibility of the polyp findings.

The present study had some limitations. The slit-like lumens and a normal pit-like structure on staining EC distinguish low-grade adenoma from advanced neoplasia and allow DISCARD strategy[13,24,30]. Fused gland formations on EC staining can predict the histological grade of differentiation and risk factors for lymph node metastasis in T1 colorectal adenocarcinoma[31]. EC with NBI can examine the diameter and caliber variation of tumor microvessels that are associated with the depth of cancer invasion[32]. EC with NBI also possibly differentiates diminutive hyperplastic polyps from adenomas based on the microvessel pattern[26]. However, the present study excluded carcinomas, TSAs, and diminutive polyps. Furthermore, there were no villous adenomas. Validation of these EC-based evidence by applying conventional magnifying endoscopy in the future is desirable. Second, this was a retrospective study that was limited to single-center expert endoscopists. Prospective analysis at multiple centers, including non-experts, is needed. Third, the NBI mode and 290 series endoscopes were used in this study. Verification using other image-enhancing modalities, such as BLI[20], linked color imaging (LCI, Fujifilm Corporation)[33], texture and color enhancement imaging (TXI, Olympus Corporation), and using new colonoscopes, such as CF-EZ1500D and CF-XZ1200 (Olympus Corporation), are warranted. Fourth, the diagnostic efficacy of brown slit sign has not been proven to be

equivalent to that of the JNET classification, although the brown slit sign may be simpler and easier than the JNET classification. The comparison of the diagnostic efficacy between brown slit sign and the JNET classification is future issue.

CONCLUSION

Brown slits on conventional magnifying NBI endoscopy using the X1 system were useful for diagnosing colorectal adenoma. The new endoscopy system could be examined using new standards.

ARTICLE HIGHLIGHTS

Research background

Accurate diagnosis of colorectal premalignant polyps, including adenomas, is vital in clinical practice.

Research motivation

Using a combination of the X1 system and the conventional magnifying endoscope with non-staining narrow band imaging (NBI), we identified the findings corresponding to the slit-like lumens, which present the crypts of adenoma.

Research objectives

The authors investigated the diagnostic yields of novel findings of brown slits for adenomas.

Research methods

Patients who underwent colonoscopy at the Toyoshima Endoscopy Clinic were enrolled. Polyps sized ≥ 5 mm suspected of adenomas or clinically significant serrated polyps were included in the study. We defined the surface structures of colorectal polyps, which were brown curves inside and along the tubular glands identified using a combination of a new X1 system (Olympus Corporation) and a conventional magnifying colonoscope with non-staining NBI, as brown slits. The brown slits corresponded to slit-like lumens on endocytoscopy and histological crypt openings of an adenoma. We evaluated the diagnostic performance of brown slits for adenoma.

Research results

A total of 108 Lesions from 62 patients were eligible. The average age was 60.4 years and 41.9% were male. The mean polyp size was 7.45 mm. Fifty-seven lesions were positive for brown slits. Histopathological diagnosis comprised 59 low-grade tubular adenomas, 16 sessile serrated lesions, and 33 hyperplastic polyps. The sensitivity, specificity, and accuracy of brown slits for adenoma were 94.9%, 98.0%, and 96.3%, respectively.

Research conclusions

Brown slits on conventional magnifying endoscopy with non-staining NBI using the X1 system were useful for diagnosing colorectal adenoma.

Research perspectives

The new endoscopy system could be examined using new standards.

Abstract

BACKGROUND

Colorectal anastomotic leakage (CAL) is one of the most dreaded complications

after colorectal surgery, with an incidence that can be as high as 27%. This event is associated with increased morbidity and mortality; therefore, its early diagnosis is crucial to reduce clinical consequences and costs. Some biomarkers have been suggested as laboratory tools for the diagnosis of CAL.

AIM

To assess the usefulness of plasma C-reactive protein (CRP) and calprotectin (CLP) as early predictors of CAL.

METHODS

A prospective monocentric observational study was conducted including patients who underwent colorectal resection with anastomosis, from March 2017 to August 2019. Patients were divided into three groups: G1 – no complications; G2 – complications not related to CAL; and G3 – CAL. Five biomarkers were measured and analyzed in the first 5 postoperative days (PODs), namely white blood cell (WBC) count, eosinophil cell count (ECC), CRP, CLP, and procalcitonin (PCT). Clinical criteria, such as abdominal pain and clinical condition, were also assessed. The correlation between biomarkers and CAL was evaluated. Receiver operating characteristic (ROC) curve analysis was used to compare the accuracy of these biomarkers as predictors of CAL, and the area under the ROC curve (AUROC), specificity, sensitivity, positive predictive value, and negative predictive value (NPV) during this period were estimated.

RESULTS

In total, 25 of 396 patients developed CAL (6.3%), and the mean time for this diagnosis was 9.0 ± 6.8 d. Some operative characteristics, such as surgical approach, blood loss, intraoperative complications, and duration of the procedure, were notably related to the development of CAL. The length of hospital stay was markedly higher in the group that developed CAL compared with the group with complications other than CAL and the group with no complications (median of 21 d *vs* 13 d and 7 d respectively; $P < 0.001$). For abdominal pain, the best predictive performance was on POD4 and POD5, with the largest AUROC of 0.84 on POD4. Worsening of the clinical condition was associated with the diagnosis of CAL, presenting a higher predictive effect on POD5, with an AUROC of 0.9. WBC and ECC showed better predictive effects on POD5 (AUROC = 0.62 and 0.7, respectively). Those markers also presented a high NPV (94%-98%). PCT had the best predictive effect on POD5 (AUROC = 0.61), although it presented low accuracy. However, this biomarker revealed a high NPV on POD3, POD4, and POD5 (96%, 95%, and 96%, respectively). The mean CRP value on POD5 was significantly higher in the group that developed CAL compared with the group without complications (195.5 ± 139.9 mg/L *vs* 59.5 ± 43.4 mg/L; $P < 0.00001$). On POD5, CRP had a NPV of 98%. The mean CLP value on POD3 was significantly higher in G3 compared with G1 (5.26 ± 3.58 μg/mL *vs* 11.52 ± 6.81 μg/mL; $P < 0.00005$). On POD3, the combination of CLP and CRP values showed a high diagnostic accuracy (AUROC = 0.82), providing a 5.2 d reduction in the time to CAL diagnosis.

CONCLUSION

CRP and CLP are moderate predictors of CAL. However, the combination of these biomarkers presents an increased diagnostic accuracy, potentially decreasing the time to CAL diagnosis.

Core Tip: Colorectal anastomotic leakage (CAL) remains a serious postoperative complication. It is associated with high morbidity rates, affecting overall costs and patients' quality of life. Clinical criteria, imaging studies, and biomarkers have been considered to increase diagnostic accuracy. Plasma C-reactive protein, calprotectin, procalcitonin, white blood cell count, and eosinophil cell count have been proposed as predictors of anastomotic leakage. The combination of C-reactive protein and calprotectin after a minimal clinical suspicion of CAL has shown good diagnostic accuracy, allowing clinicians to reduce the time to CAL detection. Regression models can facilitate building a decision model, as the score proposed for the early detection of CAL.

INTRODUCTION

Colorectal anastomotic leakage (CAL) is one of the most frequent complications after colorectal surgery, representing a dreaded issue for patients and surgeons. The reported incidence ranges from 0.2% to 27.2%, depending on the study nature, level of anastomosis, or pathology[1-5]. This occurrence is associated with increased morbidity, mortality, reoperation, and health care costs[6-9]. Thus, its clinical relevance should not be underestimated. It also has a negative impact on a patient's quality of life[2,4].

Early CAL detection is key to decreasing related morbidity and mortality; therefore, a prompt and timely diagnosis is crucial[5,10,11]. Initially, it is difficult to distinguish CAL from other postoperative abdominal complications. Surgeons should be aware of subtle clinical signs, and then order additional tests including serum biomarkers, proper imaging, or even early reoperation. Unfortunately, diagnosis is often delayed, because of a misleading clinical picture, non-systematic assessment, or inconclusive investigations[11-15]. Besides clinical parameters, several biomarkers (plasma or intraperitoneal), imaging methods such as abdominal computed tomography (CT) scan or water-soluble contrast enema, and scores have been proposed to reduce the time to diagnosis and to establish an appropriate management pathway[16-19].

Plasma C-reactive protein (CRP) has been proposed as an early predictor of postoperative infectious complications[16,20-23]. This biomarker is an acute phase protein, increasing between 6 h and 48 h after surgery, and returning to baseline if inflammation ceases. After this period, a high CRP level is associated with postoperative infectious complications, especially in patients with CAL[24-26]. On the other hand, calprotectin (CLP) is a useful biomarker of inflammation and infection[18,27]. Fecal CLP has been widely used as a marker of gastrointestinal inflammation. However, some authors suggest that high levels of serum CLP could be associated with septic intra-abdominal complications, such as early-stage CAL[18,28].

The aim of this study was to evaluate the utility of plasma CRP and CLP, individually or combined, to shorten the time to CAL diagnosis.

MATERIALS AND METHODS

Study design and population

This was a prospective observational, single-center study that included adults over 18-years-old who underwent urgent or elective colorectal resection, regardless of the surgical approach (open or laparoscopic), indication (benign or malignant), and option for a protective stoma. The study was conducted in the colorectal division of a non-academic hospital accredited by Joint Commission International® and included about 500000 inhabitants. The data were collected between March 1, 2017 and August 31, 2019. The local ethics committee approved the study, and potential participants provided written informed consent before inclusion.

Definitions

CAL was defined in accordance with the following criteria[29]: (1) Clinical: Enteric discharge from abdominal drain or wound, rectovaginal fistula, or anastomotic defect found by digital examination; (2) Radiological (CT): Extravasation of endoluminally administered contrast, intra-abdominal collection around the anastomosis, presacral abscess near the anastomosis or perianastomotic air, and free intra-abdominal air; and (3) Surgical findings (reoperation): Necrosis of the anastomosis or signs of peritonitis and anastomotic defect.

Faced with clinical deterioration and/or serum biomarker increase, patients underwent further imaging with abdominopelvic CT scan (and water-soluble contrast enema if colorectal anastomosis was present). Once diagnosed, anastomotic leakage was classified into two categories: (1) Minor: Patients with CAL and Clavien-Dindo grade I or II, requiring no active intervention (radiological or surgical intervention) (Grade A of the International Study Group of Rectal Cancer definition); and (2) Major: All other patients with CAL[30,31]. Definitions of other postoperative complications, such as pneumonia, urinary tract infection, paralytic ileus, and surgical wound infection, are available in Supplementary material 1A (Definitions).

Exclusion criteria

Patients were excluded from the study if they were younger than 18-year-old, pregnant, unable to give or not providing written informed consent, R0 resection with anastomosis not having been performed, or presence of inflammatory bowel disease.

Study protocol and variables

Prospective data were collected and recorded in an electronic database according to the study protocol (Supplementary material 1B – Study protocol). Five biomarkers were measured in the first 5 postoperative days (POD), including white blood cell (WBC) count, eosinophil cell count (ECC), CRP, CLP, and procalcitonin (PCT). Clinical criteria, such as abdominal pain and clinical condition, were also assessed. Blood samples were analyzed at the Leiria Hospital Centre laboratory, according to the techniques described in Supplementary material 1C (Laboratory). The 90-d follow-up included data of all postoperative complications, the length of hospital stay, and the readmission rate. Discharge criteria are available in the Supplementary material 1B (Study protocol). All patients received prophylactic antibiotic accordingly to hospital infection control committee protocol.

Statistical analysis

Data were analyzed by using standard descriptive statistics and graphical analysis. One-way analysis of variance was performed to compare the differences in mean biomarkers' values across the three relevant groups of patients (G1 – no complications; G2 – complications not related to CAL; and G3 – CAL). Chi-squared tests were conducted to assess the association between other categorical variables and the patients. Receiver operating characteristic (ROC) curve analysis was employed to evaluate each biomarker as an appropriate classifier to detect CAL early. The area under the receiver operating characteristic curve (AUROC) was used to establish the diagnostic performance of the studied biomarker. Liu's method was used to establish the threshold value of each biomarker, and its sensitivity (SS) and specificity (SP) were defined[32]. The negative likelihood ratio (NLR) and positive likelihood ratio (PLR), and the negative predictive value (NPV) and positive predictive value (PPV) were computed by combining the observed incidence of CAL with the estimated SS and SP at the optimum cut-off value.

The added value of combining two different biomarkers, observed on POD3 or POD5, as a classifier to predict early CAL was explored. Regression models (probit, logit, and complementary log-log) were used to analyze binary dependent variables, and the observed CAL status (0/1) in a pairwise manner of all biomarkers included in our study: WBC, ECC, CRP, PCT, and CLP. Several potential classifiers of CAL were built, applying a non-linear combination of two different biomarkers. To minimize overfitting, the "leave-one-out" methodology was adopted[33]. The AUROC graph was used to select the classifier (defined by the model and the combination of two biomarkers) with the best predictive diagnostic performance. Liu's method was adopted to select the cut-off value for CAL.

The expected reduction in time to CAL diagnosis obtained by using one biomarker or a pairwise combination of biomarkers was estimated. This was the difference between the observed and the expected mean time to CAL diagnosis, if a specific classifier is used. The expected time to CAL diagnosis was computed by using the following expression: $S \times d1 + [(1 - S) \times d2]$, where S is the SS of the classifier, d1 is the POD of the classifier yielding a positive cut-off value for CAL, and d2 is the day of diagnosis if the classifier provides a false-negative result (time to CAL diagnosis estimated in the dataset). The statistical methods of this study were reviewed by Óscar Lourenço from the Faculty of Economics, CeBER, University of Coimbra, Portugal. All data management and statistical analyses were conducted with Stata Statistical software (Release 16; StataCorp, College Station, TX, United States).

RESULTS

Patients and outcomes

During the study period, we included 458 consecutive patients who underwent colorectal resection, and 62 (13.5%) were ruled out [exclusion criteria (n = 31), no consent (n = 15), no anastomosis (n = 16)] as shown in Figure 1. Patient characteristics, divided into three groups (G1, G2, and G3, as previously defined), are shown in Table 1. Age, the Charlson Comorbidity Index, and American Society of Anesthesiologists grade seem to affect CAL onset.

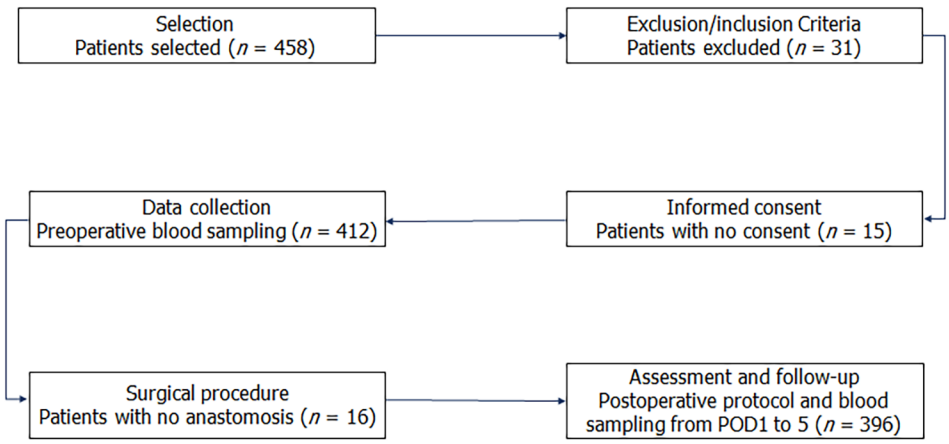

Table 2 summarizes the main operative characteristics. Eighty-two percent of patients had a laparoscopic approach, and the most common procedures performed were right colectomy (n = 196; 49.5%) and sigmoid colectomy/rectosigmoid resection (n = 74; 18.7%). The surgical approach ($P < 0.001$), the volume of blood loss ($P < 0.001$), the occurrence of intraoperative complications ($P < 0.001$), and the duration of the procedure ($P = 0.011$) were significantly related to the development of CAL.

In this study, CAL developed in 25 of 396 patients (6.3%) and was more frequent in men than women (68% *vs* 32%). Twenty-three patients with CAL (92.0%) were diagnosed during the first hospital admission. The mean ± SD and median time for CAL detection were 9.0 ± 6.8 d and 8 d (interquartile range = 7), respectively. Anastomotic leak was significantly associated with a longer hospital stay

Figure 1 Flow diagram of patients according to the study protocol. POD1: Postoperative day 1.

(median of 21 d *vs* 7 d and 13 d, in G1 and G2 patients, respectively; $P < 0.001$), the readmission rate (20% *vs* 6.4% and 5.4%), and the reoperation rate (12% *vs* 3.2% and 1.8%). Table 3 provides a summary of 90-d morbidity and mortality rates. Based on the Clavien-Dindo classification, grades III and IV complication were significantly higher in the G3 cohort (84.0% *vs* 17.0%; $P < 0.001$) (Table 4).

Table 5 outlines the intraoperative and postoperative details of patients with CAL (G3) based on the CAL classification (minor *vs* major). Seven patients (28.0%) were managed nonoperatively and two (8.0%) underwent radiologic drainage of intraabdominal collections. The remaining 16 patients (64.0%) required surgical intervention. Of the 16 reoperated patients, 10 (56%) had an anastomosis takedown with an end stoma and 6 (44%) received a defunctioning stoma. The 90-d mortality rate was 0.8%, representing 3 patients with CAL.

Group 1: No complications; Group 2: Complications not related to colorectal anastomotic leakage (CAL); Group 3: CAL. RS: Rectosigmoid; AV: Anal verge.

Clinical criteria – postoperative trend and predictive effect

Abdominal pain: Abdominal pain was markedly higher and persistent from POD3 onwards in G3 patients (Figure 2A). The AUROC for abdominal pain on POD3, POD4, and POD5 was 0.77, 0.84, and 0.83, respectively, as shown in Supplementary Table E (Supplementary material 2A) and Figure 3A. The predictive effect was higher on POD4 with an estimated AUROC of 0.84.

Clinical condition: The clinical condition was worse in G3 compared with G2 patients, and it was significantly different after POD3 (P = 0.001). The overall postoperative trend was a declining clinical condition, as shown in Figure 2B. The AUROC for the clinical condition on POD3, POD4, and POD5 was 0.62, 0.81, and 0.90, respectively, as shown in Supplementary Table E (Supplementary material 2A) and Figure 3B. The prediction effect was higher on POD5 with an estimated AUROC of 0.90.

Biomarkers – postoperative trend and predictive effect

WBC count and ECC: During the first five POD, WBC in G3 patients was higher than that in patients without CAL and was significantly different on POD2, POD4, and POD5 (P = 0.01 for each day). On the other hand, ECC was lower in G3 patients and significantly different on POD1 and POD5 (P = 0.04 and P = 0.01, respectively), as presented in Supplementary Figures 1 and 2 (Supplementary material 2B). Overall, the postoperative course showed a sustained trend for both blood cell counts, except for ECC on POD5. The AUROC for WBC and ECC from POD1 to POD5 is presented in Supplementary Figures 3 and 4, respectively (Supplementary material 2B). The predictive effects of blood cell count were better on POD5. On POD5, when ECC was greater than 250 cells/μL, the AUROC, SS, and SP were 0.70, 89.0%, and 43.0%, respectively, as shown in Table 6.

CRP, PCT, and CLP: The mean values of CRP, PCT, and CLP increased promptly after surgery in all

groups. CRP decreased in G1 patients and remained elevated in patients with a complicated postoperative course, but was significantly higher than in G3 patients. On POD5, the mean CRP level in G3 patients was significantly higher than that in G1 patients (195.5 ± 139.9 mg/L *vs* 59.5 ± 43.4 mg/L; $P < 0.00001$) (Figure 4A). Patients with major CAL had a higher mean CRP level than those with minor CAL (251.45 mg/dL *vs* 107.64 mg/dL; $P = 0.01$) (Table 5). On POD3, POD4, and POD5, the overall diagnostic accuracy of CRP to detect CAL was expressed by an AUROC of 0.76, 0.76, and 0.81, respectively (Figure 5A). On POD5, the optimum cut-off value of 96.8 mg/L was estimated, resulting in an SS and SP of 78%, an NPV of 98%, and a PPV of 19% (Table 6).

The PCT level tended to be stable from POD3 onwards. The mean values were higher in G3 patients than in patients without CAL, but without statistical significance [on POD5, 0.23 ± 0.08 ng/mL *vs* 0.22 ± 0.07 ng/mL; Supplementary Figure 5 (Supplementary material 2C)]. The AUROC on POD3, POD4, and POD5 was 0.57, 0.50, and 0.61, respectively, as shown in Supplementary Figure 6 (Supplementary material 2C). The best predictive effect was on POD5. When PCT was greater than 0.39 ng/mL, the SS and SP were 44.0% and 79.0%, respectively (Table 6).

CAL: Colorectal anastomotic leakage; POD: Postoperative day; CRP: C-reactive protein; CLP: Calprotectin; CT: Computed tomography; LOHS: Length of hospital stay; NA: Not applicable.

In the first 5 POD, the mean CLP value tended to follow the pattern of CRP, although it was not as pronounced (Figure 4B). The mean CLP value was significantly higher in G3 patients from POD2 onwards. On POD3, the mean values of G1 *vs* G3 patients were 5.26 ± 3.58 μg/mL *vs* 11.52 ± 6.81 μg/mL ($P < 0.00005$). On POD3, POD4, and POD5, the CLP AUROC was 0.78, 0.67, and 0.65, respectively, as presented in Table 6 and Figure 5B. On POD3, a cut-off value of 6.57 μg/mL yielded a sensitivity of 71.0% and a specificity of 72.0% (Table 6).

Finally, when we analyzed the best predictors (CRP and CLP) for major CAL, the AUROC of CRP was 0.74 and 0.88 for POD3 and POD5, respectively. CLP was a better predictor of CAL than CRP at POD3, with an AUROC of 0.92 (Figure 5C and D).

Combination of biomarkers: Tables 7 and 8 present the AUROC of several possible classifiers of CAL, built with the Probit model, on POD3 and POD5, respectively. The combination of CRP and CLP on POD3 showed the best performance, with an AUROC of 0.82 (Table 7). Of note, on POD5, the combination of CRP and ECC also generated good predictive performance (AUROC = 0.81). However, with the aim of early CAL diagnosis, we chose the combination of CRP and CLP on POD3. Thereafter, we determined the probability of CAL, based on the computed equation P (CAL) = F [-3.0842 + (0.094 ×

DISCUSSION

This study assessed the usefulness of biomarkers for the early detection of CAL. Clinical criteria demonstrated high diagnostic accuracy (AUROC > 0.8) on POD4 and POD5. Changes in the abdominal pain pattern and worsening of the clinical condition were associated with an increased risk of CAL diagnosis. Both clinical criteria seem to be an useful early markers for this condition, producing the best overall diagnostic accuracy of the parameters analyzed. Three large and well-conducted studies on the association between pain and postoperative complications are worth reporting. Boström *et al*[34] examined a cohort of 3084 patients and estimated that increased postoperative pain is associated with a high risk of CAL, being an independent marker and suggesting a need for further diagnostic measures. The other two studies had similar conclusions, although they were not exclusive for colorectal surgery [14,35]. A worse clinical condition and abdominal pain not localized to the wound are two of four modified Dutch leakage (DULK) score criteria, scoring 1 point each. Using a cut-off value of 1 point produced an overall SS and NPV of 97.0% and 99.5%, respectively[10]. We should bring the clinical

Figure 4 C-reactive protein (A) and calprotectin (B) levels. Values are the mean ± SE. G1: No complications; G2: Complications not related to colorectal anastomotic leakage; G3: CAL; ▲ : *P* statistically significant ($P < 0.05$).

method to the forefront, being aware of the clinical signs of CAL. They are very helpful for the early diagnosis, as "red flags" for further investigation.

In our study, particularly on POD4 and POD5, WBC and ECC showed a distinct tendency in patients with and without CAL, with a high NPV (from 94%-98%) but low accuracy (AUROC from 0.54 to 0.70). In G3 patients, WBC plateaued after the acute inflammatory response, a phenomenon that was notably different from patients without CAL. In a large retrospective study, Warschkow *et al*[16] found that the WBC level contributed little to the early detection of septic complications, with a lower diagnostic accuracy than plasma CRP. In several other studies, researchers have estimated, from POD5 to POD7, an AUROC and SS ranging from 0.63 to 0.82 and from 58% to 74%, respectively[15,16,20,24,35].

Some researchers have proposed eosinopenia as a biomarker in this scenario. They concluded that it might help to identify several sepsis-related conditions, distinguished from other causes of systemic inflammatory response syndrome. It seems to be an interesting biomarker because of its widespread availability and low cost[36]. Shaaban *et al*[37] defined an optimum cut-off value of 50 cells/μL, which produced an SS, SP, and NPV of 81%, 65% and 80%, respectively. At hospital admission, ECC < 40 cells/μL is an independent prognostic factor for mortality[38,39]. Our study is original in assessing the usefulness of ECC for the early diagnosis of CAL. The mean ECC level showed a non-significant decline after POD4 in G3 patients, and a modest diagnostic accuracy (AUROC from 0.54 to 0.70) when compared with other biomarkers. Nevertheless, ECC could still be used in CAL diagnosis as a fast, simple, convenient, and inexpensive biomarker. It should be considered in the decision-making process

and future research[40].

The usefulness of CRP as a biomarker for early detection of CAL has been investigated by several groups[19,25,39,41,42]. In this study, the plasma CRP level exhibited a propensity to normalize from POD3 onwards in patients without CAL (G1 and G2). However, it remained steadily increased in G3 patients, with a markedly high mean value from POD1 to POD5. Yeung *et al*[43] performed the most comprehensive meta-analysis available in the literature, including nearly 7000 patients pooled from 23 studies. From POD1 to POD7, patients with CAL had a significantly higher mean CRP level compared with patients without CAL ($P < 0.001$)[43]. In this study, CRP was the best predictor for CAL on POD4 and POD5, with a maximum AUROC of 0.81 (cut-off value of 96.8 mg/L and an NPV of 98%) on POD5. Similar results have been published by other authors. Ortega-Deballon *et al*[26] estimated on POD4 an AUROC of 0.72 with a cut-off of 125 mg/L, yielding an SS and NPV of 81.8% and 95.8%, respectively. Garcia-Granero *et al*[25] reported that CRP level showed a good predictive ability for major CAL on POD5, with an AUROC of 0.85 (cut-off value of 135 mg/L and an NPV of 98%). In the Italian ColoRectal Anastomotic Leakage (iCral) multicentric prospective observational study, the CRP level was a good positive and excellent negative predictor of CAL, with an AUROC of 0.81 on POD6 (cut-off value of 81.5 mg/L), and an SS and NPV of 80.9% and 97.7%, respectively[41]. In the meta-analysis by Yeung *et al*[43], AUROC analysis established a threshold CRP level for CAL of 115 mg/L on POD5, with an SS and SP of 100%. All of these authors recommended CRP levels to predict CAL, and our group advocates a similar practice and suggests the use of this biomarker to expedite further investigation and treatment [25,26,41,43].

CLP, a sign of neutrophil activation, could be a promising early marker for excessive inflammatory response in major abdominal catastrophes, such as CAL. To date, only Reisinger *et al*[18] have studied the predictive value of CLP in CAL diagnosis. In G3 patients, the mean postoperative CLP level peaked on POD3 and was notably higher, persisting thereafter. On POD3, the AUROC (0.78) and SS (71%) were slightly higher than the CRP level, although they were lower than those obtained in the pioneering study by Reisinger *et al*[18] (0.92 and 86%, respectively). One possible explanation could be our compre-

hensive definition of CAL and the larger sample size. It remains unclear to what extent CLP level is an early predictor that is better than CRP for detecting CAL. As a neutrophil activation marker, CLP could be increased early after anastomotic failure, compared with CRP, which indicates a delayed systemic inflammatory response. Our study shows that CLP is worth evaluating for early diagnosis of CAL.

We demonstrated in the first 5 POD, the mean PCT values were marginally higher in G3 patients but with lower accuracy, SS, and SP than CRP and CLP levels. However, it had a high NPV (> 95%), making it an adequate and useful marker for early and safe discharge after colorectal surgery, considering the current enhanced recovery after surgery routine. In contrast to our study, Giaccaglia *et al*[17] estimated that on POD5, PCT had better accuracy than CRP (0.86 *vs* 0.81), as well as a high NPV (98.3%). A recent meta-analysis published by Su'a *et al*[44] determined a diagnostic accuracy of 0.88 on POD5 and an optimum cut-off value on POD3 and POD5 of 0.25 and 680 ng/mL, respectively. The NPV ranged from 95% to 100%. In agreement with these authors, we believe that PCT is a useful negative predictor for CAL; as a single test, however, it is worthless for CAL diagnosis.

We verified that, with the exception of plasma CRP on POD5 (AUROC > 0.80), each biomarker individually was a modest predictor of CAL[45]. The combination of two or more biomarkers has been considered in previous studies[17,18,41]. In this study, the combination of CRP and CLP values on POD3 increased diagnostic accuracy, shortening the mean CAL diagnosis by 5 d. This reduction would likely lead to reduced morbidity and mortality. Reisinger *et al*[18] confirmed a significant improvement in diagnostic accuracy (AUROC = 0.93) with the combination of CRP and CLP plasma levels on POD3, an SS of 100%, and an SP of 89.0%, decreasing the median time to diagnosis by 3 d. Furthermore, Giaccaglia *et al*[17] found that by adding PCT to CRP on POD5, the diagnostic accuracy markedly improved (AUROC = 0.90). Similarly, the iCral study demonstrated that the combination of CRP and PCT with a clinical score (DULK score) allowed the exclusion of CAL on POD2 (NPV = 99%)[41]. We believe that a user-friendly diagnostic tool, combining CLP and CRP levels by this mathematic model, would help the surgeon to diagnose CAL early. Consequently, this biomarkers' combination may be included in a standard postoperative surveillance program, as a warning tool for CAL. In the case of a "positive test", this protocol recommends abdominal and pelvic CT scan or early reoperation in case of imaging-dubious or -negative, to reduce the time to CAL detection and enable prompt management.

Strengths and limitations of the study

One strength of this study was its prospective design and independent data collection model, which minimized observer bias. Second, it was one of the largest monocentric sample size published to date. Based on the recent meta-analyses of Waterland *et al*[46] van Helsdingen *et al*[47], only two monocentric prospective studies have enrolled more than 400 patients. Furthermore, we analyzed five biomarkers, including plasma CLP, which was first studied by Reisinger *et al*[18]. Third, we chose a comprehensive definition of CAL, recently defined by van Helsdingen *et al*[29] to include all patients with CAL, minimizing selection bias. We did not exclude minor CAL from the cohort, which also affected the predictive effect of the analyzed biomarkers. In addition, to keep the biomarkers optimum cut-off values in AUROC analysis both standardized and reproducible, we adopted Liu's method. This method defines the optimum cut-off point as the point maximizing the product of SS and SP[48]. These reasons may explain some differences in biomarkers' diagnostic accuracy in this study. Fourth, we tried to adapt the study protocol to daily practice, making its enforcement easier in the future. Hence, we included all patients undergoing colorectal resection, even those with a diverting ostomy. In addition, clinicians were not blinded to the daily biomarkers' results and might use those data according to the study protocol. Finally, we proposed a predictive tool based on the combination of two biomarkers that improved CAL diagnostic accuracy. Adoption of this tool in daily practice might shorten the time to CAL diagnosis and management. Moreover, the data from this study provide information for the development of more complex mathematical predictive models, including machine learning methods.

This study had several limitations. First, the monocentric design may limit the external validity of the results. Second, our sample had some grade of heterogeneity, because the study population included benign and malignant disorders, elective and urgent procedures, and anastomosis within different levels of the colon and rectum. Third, we designed a phase I diagnostic study and estimated cut-off values for early CAL detection. However, we should change the direction of interpretation, running from the diagnostic test result toward the CAL diagnosis. To address this issue, we are performing a new multicentric prospective phase II diagnostic study, using the predictive tool and defined biomarkers cut-off values[49]. Fourth, plasma CLP measurement is expensive and these kits are not easily accessible in daily clinical practice. Finally, our study did not address the cost-effectiveness of biomarkers' measurement. It is crucial to estimate the economic burden of CAL, including the cost related to a delayed diagnosis, the high rate of false positives, and unjustified reoperations or frequent readmissions.

CONCLUSION

In conclusion, we found that clinical criteria have added value as a warning sign of CAL. On the other

hand, CRP and CLP levels are the best early predictors of CAL. Particularly relevant is the combination of CLP and CRP early during POD3, and its potential to markedly reduce the time to diagnosis of CAL. By reducing the time to CAL diagnosis, reduced morbidity and mortality are expected. Additional studies are needed to confirm the predictive ability of this model on early CAL detection and its utility in routine clinical care.

ARTICLE HIGHLIGHTS

Research background

Colorectal anastomotic leakage (CAL) is a major complication in abdominal surgery. Prompt diagnosis can reduce morbidity and mortality associated with this condition. Serum biomarkers have been proposed as predictors of CAL.

Research motivation

Biomarkers such as C-reactive protein (CRP) and white blood cell (WBC) count are frequently requested in the postoperative period of colorectal surgery. However, the usefulness of these and other biomarkers remains unclear.

Research objectives

To assess the role of CRP, WBC, eosinophil cell count, calprotectin (CLP), and procalcitonin in the first 5 postoperative days (PODs) after colorectal surgery, and thus, discuss in what order these biomarkers can be employed in clinical practice.

Research methods

From March 2017 to August 2019, we measured and analyzed five serum biomarkers daily in 396 patients who underwent colorectal surgery. The area under the receiver operating characteristic curve, specificity, sensitivity, positive predictive value (PPV), and negative predictive value (NPV) were used to estimate the best predictive diagnostic performance.

Research results

CRP had an NPV of 98% on POD5. The combination of CLP and CRP measurement presented a high diagnostic accuracy (AUCROC = 0.82) on POD3. We identified a reduction of 5.2 d to the diagnosis of CAL.

Research conclusions

The combination of CRP and CLP demonstrated good diagnostic accuracy. These tests can likely be used to reduce time to CAL detection.

Research perspectives

Further studies should test a warning index score built from selected predictive variables as biomarkers CRP and CLP.

Abstract

We read the article titled, "Long-term follow-up of liver alveolar echinococcosis using echinococcosis multilocularis ultrasound classification," by Schuhbaur J with great interest. However, we found some worthwhile issues that we believe should be discussed with the authors, and have provided our comments in this letter. It would be valuable if the authors could provide further information about the clinical stages, follow-up time, and clinical outcomes of the patients.

Key Words: Alveolar echinococcosis; Albendazole; Surgical treatment; Ultrasound; Follow-up

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Although many experts suggest that radical surgery combined with albendazole treatment is the optimal option for alveolar echinococcosis patients, no clear consensus has been reached on whether long-term treatment using albendazole alone without any surgical intervention can cure or control the disease. Therefore, some professional issues need to be clarified by discussion with peers, in order to benefit as many patients as possible.

TO THE EDITOR

We read the article titled, "Long-term follow-up of liver alveolar echinococcosis using echinococcosis multilocularis ultrasound classification," by Schuhbaur *et al*[1] with great interest. In this significant study, the authors observed changes in sonomorphology during the follow-up of hepatic lesions using a sonomorphologic classification scheme. However, after reading the article carefully, we found some worthwhile issues that we would like to discuss with the authors.

Alveolar echinococcosis (AE) is an infectious zoonotic parasitic disease, which has been a major public health problem in its epidemic area[2]. In the large majority of cases, the liver is the first organ to be infested by the larvae. Hepatic AE often invades the surrounding vessels and adjacent organs in its advanced stages. The mortality rate within 10 years after diagnosis is more than 90% if the lesion is inadequately or not treated[3]. According to the World Health Organization Informal Working Group on Echinococcosis criteria[4], radical surgery combined with albendazole treatment is the optimal option for AE patients. In this article, the authors included 59 patients from Germany's national echinococcosis database, who were "considered" to have hepatic AE, and long-term follow-up using ultrasound was performed. However, they did not mention the clinical stages, specific follow-up time, and clinical prognosis of these patients. Hepatic AE is known as "parasitic cancer," due to its tumor-like characteristics with infiltration of vessels or biliary structures and distant metastasis. To date, no clear consensus has been reached on whether long-term treatment using albendazole alone without any surgical intervention can cure or control the disease. A 5-year analysis of two distinct cohorts in Bern, Switzerland and Besancon, France demonstrated that conservative treatment was less effective than surgical therapy[5]; however, longer follow-up results have not been available. Currently, "watch and wait" is not recommended unless complete inactivity of the AE lesion can be confirmed, in order to avoid delayed treatment resulting in adverse outcomes[6].

The authors' team proposed an ultrasonographic classification scheme for hepatic AE in 2015[7], which was used to follow 59 patients. However, we noted that the authors stated that all but 1 patient received antiparasitic drugs, but they also claimed that more than half of the patients (55.9%) were defined as "probable" hepatic AE. In such a case, the use of albendazole and other drugs with hepatotoxicity may cause unnecessary harm to patients. According to a recent study with long-term observation of 117 AE patients, about 44.4% experienced adverse reactions when taking albendazole, and severe liver toxicity occurred in 7.7% patients[8]. We believe that the authors should have provided a more detailed explanation about whether the use of albendazole is indeed necessary for these patients. The high rate of inoperable disease at diagnosis underscores the need for an early, definitive diagnosis. However, in cases that cannot be confirmed by conventional examination, supplementary tests such as serology and positron emission tomography (PET)/computed tomography (CT) may be useful.

Bresson-Hadni *et al*[9] suggested that "surgical resection, if feasible, is the gold standard for treatment." We also believe that early radical resection of the lesion should be considered in patients with hepatic AE, unless it is defined as unresectable. Based on the clinical guidelines and previous reports, the objectives for the treatment of hepatic AE should include the following: Completely removing the parasitic lesion, combined with 2 years of albendazole treatment after surgery; if this is not possible, reducing the proliferating potential of echinococcosis multilocularis by continuous administration of albendazole; and lesions that are massively calcified and/or negative by CT or PET may benefit from a "watch-and-wait" approach.

In summary, we admire the efforts of the authors in using ultrasound to assess sonomorphology changes over time in hepatic AE lesions. Nevertheless, it would be valuable if the authors could provide further information about the clinical stages, follow-up time, and clinical outcomes of the patients.

FOOTNOTES

Author contributions: Maimaitinijiati Y performed the research and wrote the letter; Meng Y and Chen X revised the letter.

Abstract

Significant developments in colorectal cancer screening are underway and include new screening guidelines that incorporate considerations for patients aged 45 years, with unique features and new techniques at the forefront of screening. One of these new techniques is artificial intelligence which can increase adenoma detection rate and reduce the prevalence of colonic neoplasia.

Key Words: Basic concepts; Assessment of artificial intelligence in endoscopy; Current applications; Ethics; Safety challenge

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Artificial intelligence (AI) is an integral part of endoscopy and health care in colorectal cancer screening because it has been shown to increase adenoma detection rates and reduce the prevalence of colonic neoplasia. It will soon provide an "optical biopsy" of polyps, assisting advanced therapeutic endoscopy-resection and 'discard– no pathology present. 'Innovations in AI have changed and improved the lives of gastroenterologists by examining quality monitoring *via* a single integrated system. The only boundaries of AI are clinical research trials and reimbursement.

TO THE EDITOR

Artificial intelligence can increase adenoma detection rate in randomized control trials

Artificial intelligence (AI) has been shown to improve the adenoma detection rate (ADR) in colorectal cancer screening. It has been evaluated in multiple randomized controlled trials, showing that the withdrawal time does not vary at any polyp size, location, or morphology[1]. It also improves detection in serrated lesions; however, its usefulness is not clear for advanced adenomas, given that data are available from only three studies. A potential weakness of these studies is that they are largely confined to China and Italy. While the ADRs in China are low, ranging from 17% to 28%, in Italy, Repici *et al*[2] reported a rate of 40% to 55%. Studies conducted in the United States will be forthcoming.

AI in gastroenterology: Potential weaknesses

In this issue of the *World Journal of Gastroenterology*, a review article by Kröner *et al*[3] is entitled "Artificial intelligence in gastroenterology: a state-of-the-art review discussing the findings and a broad spectrum of clinical applications." The authors reviewed the literature highlighting the use of AI in current and future applications, especially in the detection of lesions and identification of pre-malignant or malignant lesions. However, we would like to mention that colonic disease detection of lesions using techniques such as polyp identification and classification are limited in number; these are not available in all AI systems, and clinical trial data from the USA are particularly limited[4]. Pentax Medical, Medronic, and EndoBrain provide only colonic polyp detection, and they lack the ability to classify the features of the CAD EYE system (Fujifilm) used in Europe and Japan[4]. Although the authors outlined the study limitations because of the lack of creating "universal datasets" and the lack of validating external in clinical settings and advise on future directions for research in this field, the important boundaries of AI are around clinical research trials, assessing AI in daily clinical practice, and around reimbursement and other ethical issues and safety challenges not highlighted here[3].

We would like to mention recent studies related to these important boundaries of AI use. It is expected that AI will compensate for human errors and the limits of human capabilities in performing real-time diagnostics of colonic lesions by providing accuracy, consistency, and greater diagnostic speed. However, Byrne *et al*[5] showed that 15% of polyps can not be classified. Therefore, further clinical trials are required to assess these benefits[5]. Whether endoscopic procedures become more efficient and of a higher quality when assisted by AI is yet to be proven. However, this new technology can mimic human behavior, identify colonic lesion precursors of colorectal cancer in at-risk patients[6], and can support medical decision-making[6].

Current endoscopy practices include the real-time administration of AI with computer vision to identify and delineate colonic lesions. This was achieved using an algorithm to diagnose and classify defined lesions. By applying machine learning (ML), the algorithm was trained using a large dataset of predefined polyp-containing video frames. These images include several key characteristics such as virtual chromoendoscopy, surface pit pattern morphology, microvascular pattern, high-magnification, and endocytoscopic appearance.

However, the promising applications of AI-assisted endoscopy raise several issues. Validation and quality control, video and image limitations, and annotation burden are primary areas of concern. Additionally, the data gathered has inherent biases due to a disproportionate representation of those with certain ethnicities, geographic and cultural inequities, and small segments of the population. Even if represented proportionately, inaccuracies can result in harmful consequences. Other contributors to bias included technical differences in colonoscopy techniques, bowel preparation, and colonoscopy equipment. The algorithm is as effective as the database.

Other issues with AI/ML are ethical and can be resolved by the careful and thorough regulation of data ownership and security. Data ownership could involve the patient, doctor, and/or the healthcare system, and the involvement of the Health Insurance Portability and Accountability Act, General Data Protection Regulation, industry, and science must be addressed. Finally, the endoscopist is responsible for the patient, not the computer.

The use of AI to demonstrate and characterize colonic lesions based on real-time signalling profiles is feasible. Video camera movement and tissue pathology captures a pair of frames, identifies recognized landmarks, and matches them by computing relative frames. Tissue classification was performed for all lesion types in real-time[7]. Its accuracy is evaluated by comparing it with the dual judgments of humans; however, few health professionals and patients wish to submit tissues for histological analyses [8].

Computer-assisted endoscopy has many clinical applications, including safety alerts, no-go zones, difficult notifications, staff notifications, and auto reports. Furthermore, AI supports decision-making by endoscopists, improves advanced therapeutic endoscopy and workflow, increases safety, reduces the need for manpower, and minimizes the need for humans to perform autonomous functions. Its limitations include physician resistance, limited video availability, data ownership, regulations, liability, privacy, lack of reimbursement, and cultural perceptions.

Currently, the fees for AI services are not standardized; however, there is an implementation cost. Given that better polyp detection results in more surveillance examinations, quality-based reimbursements could result in increased compensation. On the other hand, polyp diagnosis assisted by

AI has been shown to result in cost savings for the patient, particularly when the resultant strategy is "diagnose and leave without pathology"[9]. Overall, AI did not change the withdrawal timing and reduced the time required for endoscopic procedures. However, the cost and burden of these procedures remain unproven.

Real world testing needed

Evaluation of AI in healthcare requires real-world testing, including a minimal amount of randomized control trial data and a concentration of early stage research statistics such as ex vivo data, still images, and retrospective videos. Images should be carefully selected, and study designs should meet published standards such as preservation and incorporation of valuable endoscopic innovations, resect and discard criteria, and medical device approval by the US Food and Drug Administration. Furthermore, technical performance studies such as ML accuracy, system output accuracy, and usability, in addition to workflow studies such as effectiveness, efficiency, satisfaction, ease of use, learning ability, and utilization should be conducted. Additionally, health impact studies evaluating decision impact, patient outcomes, process outcomes, cost-effectiveness, care variability, and population impact should be conducted. Therefore, examination quality metrics are necessary, such as colonoscopy quality assessment *via* AI[10].

At this time, algorithms meet the preservation and incorporation of valuable endoscopic innovation criteria; however, multi-center trials have not been started. Experience is gained primarily from single-center studies conducted by expert endoscopists. Additionally, randomized controlled trials have not been performed, and magnifying scope technology is not available in some countries such as the USA[11]. Once these requirements are met, AI can become widely used in the daily practice of endoscopy, providing examination quality, polyp detection, polyp classification, and automatic reports. There are still a lot of unanswered questions and issues to be furthered discussed. However, we believe that the AI assisted colonoscopy, all in one integrated system, quality metrics of the colonoscopy exam, detection and classification of colonic lesions will play a key role in daily endoscopy clinical settings after 4-5 years.
