ABOUT COVER

Associate Editor of *World Journal of Gastroenterology*, Marc D Basson, MD, PhD, MBA, FACS, Senior Associate Dean for Medicine and Research, School of Medicine and Health Sciences, University of North Dakota, 1301 N Columbia Road, Grand Forks, ND 58201, United States. marc.basson@und.edu

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, and Scopus. The 2021 edition of Journal Citation Report® cites the 2020 impact factor (IF) for *WJG* as 5.742; Journal Citation Indicator: 0.79; IF without journal self cites: 5.590; 5-year IF: 5.044; Ranking: 28 among 92 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2020 is 6.9 and Scopus CiteScore rank 2020: Gastroenterology is 19/136.

Abstract

The integrity of the gastrointestinal mucosa plays a crucial role in gut homeostasis, which depends upon the balance between mucosal injury by destructive factors and healing *via* protective factors. The persistence of noxious agents such as acid, pepsin, nonsteroidal anti-inflammatory drugs, or *Helicobacter pylori* breaks down the mucosal barrier and injury occurs. Depending upon the size and site of the wound, it is healed by complex and overlapping processes involving membrane resealing, cell spreading, purse-string contraction, restitution, differentiation, angiogenesis, and vasculogenesis, each modulated by extracellular regulators. Unfortunately, the gut does not always heal, leading to such pathology as peptic ulcers or inflammatory bowel disease. Currently available therapeutics such as proton pump inhibitors, histamine-2 receptor antagonists, sucralfate, 5-aminosalicylate, antibiotics, corticosteroids, and immunosuppressants all attempt to minimize or reduce injury to the gastrointestinal tract. More recent studies have focused on improving mucosal defense or directly promoting mucosal repair. Many investigations have sought to enhance mucosal defense by stimulating mucus secretion, mucosal blood flow, or tight junction function. Conversely, new attempts to directly promote mucosal repair target proteins that modulate cytoskeleton dynamics such as tubulin, talin, Ehm^2, filamin-a, gelsolin, and flightless I or that proteins regulate focal adhesions dynamics such as focal adhesion kinase. This article summarizes the pathobiology of gastrointestinal mucosal healing and reviews potential new therapeutic targets.

Key Words: Intestine; Mucosa; Repair; Restitution; Sheet migration; Stomach ulcer

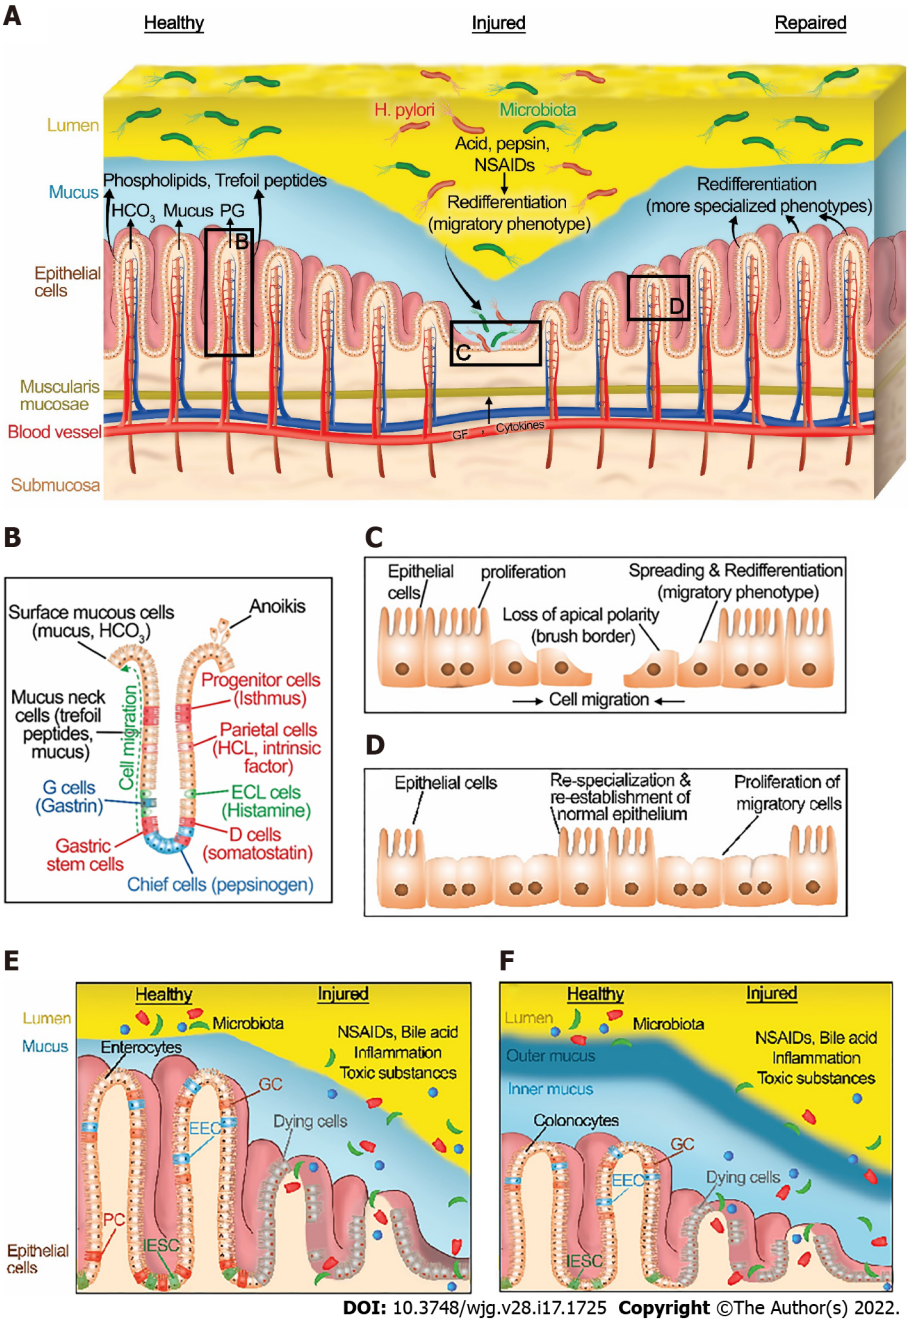
INTRODUCTION

Upon injury, gastrointestinal (GI) epithelial tissue is capable of renewing itself within hours to months by replacing damaged or dead cells, depending on the site and size of the wound. In order to appreciate potential new therapeutic targets, this review will first summarize the current understanding of the processes of mucosal healing and defense and describe their major extracellular regulators. Then, the importance of the quality of ulcer healing and novel approaches to promote such healing will be reviewed. This review focuses on mucosal injury and repair. Deeper injuries such as a deep ulcer, trauma, fistula, or surgical transection and anastomotic healing all require a complex interaction among endothelial cells, fibroblasts, and other cell types to reconstitute the submucosal and muscular layers of the bowel wall. This is beyond the scope of the current review but has been previously reviewed[1-5]. Angiogenesis is critical to these efforts, and requires a complex interaction between endothelial cells, the extracellular matrix, growth factors and cytokines, and other cell types[6,7].



PHYSIOLOGY OF MUCOSAL HEALING

The integrity of the gastrointestinal mucosa is crucial for gut homeostasis. The gut lining is continuously injured during normal gut function[8] by a variety of noxious luminal substances and abrasive interactions with luminal contents (Figure 1A). However, there is normally an equilibrium between gut injury, mucosal healing, and diverse factors that protect the mucosa[5]. This equilibrium favors healing in a healthy state. Under normal physiological conditions, GI epithelial cells migrate from the base of the crypt to the villi, where their interaction with each other and the extracellular matrix (ECM) is disrupted leading to epithelial cell shedding (anoikis)[9] (Figure 1B).

PROTECTIVE FACTORS FOR THE GASTROINTESTINAL MUCOSA

The gastrointestinal mucosa is protected at three levels: pre-epithelial, epithelial, and sub-epithelial defenses. Pre-epithelial protection, the first line of mucosal defense, is provided by the secretion of mucus, bicarbonate, phospholipids, prostaglandins, and trefoil peptides (Figure 1A and B). These factors not only neutralize the acid but also inactivate pepsin at the gastric mucosal surface. In addition, phospholipids secreted into mucus contribute to the hydrophobicity of mucus and prevent back-diffusion of hydrogen ions[10]. Prostaglandins are abundant in gastric juice. They inhibit acid secretion and stimulate mucus and bicarbonate secretion[11]. Bicarbonate-rich mucus is secreted throughout the GI tract, by mucoid cells in the stomach and goblet cells in the intestines, creating a near-neutral pH at the epithelial surfaces in the GI tract, thereby protecting the GI mucosa against autodigestion by the gastric juice and other noxious agents in the lumen[12,13].

Intestinal epithelial cells consist of four important cell types (Figure 1E and F). Enterocytes and colonocytes are most common in the surface epithelium. They are critical for the digestion and absorption of nutrients. Paneth cells are highly specialized cells located in small intestinal crypts. Paneth cells are essential for the secretion of antimicrobial peptides (AMP) such as defensins. These AMPs modulate the composition of the small intestinal microbiota. Goblet cells produce various types of mucin and are found throughout the GI tract. Similarly, enteroendocrine cells are scattered along with the epithelial cells of the GI tract. They produce and secrete more than 20 different hormones in response to nutrients in the lumen that regulate hunger, appetite, and satiety[14]. Intestinal epithelial

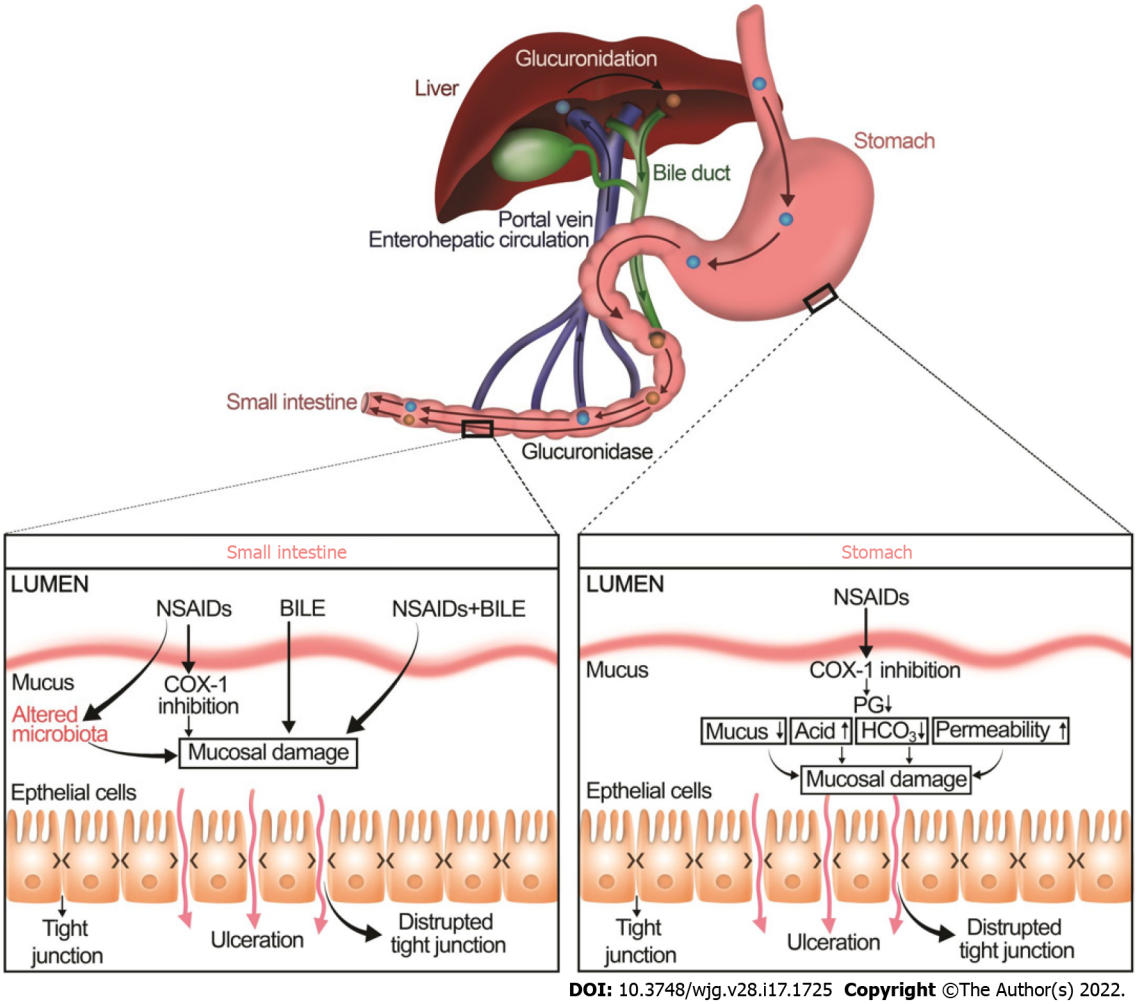
Figure 1 Normal gastrointestinal homeostasis, injury, and healing. A: Structure of gastric epithelium in healthy, injured, and repaired states. A healthy gastric barrier is essential to maintain gastric homeostasis. In a healthy state, there is an equilibrium between gastric injury and mucosal healing. An excess of destructive factors such as acid, pepsin, nonsteroidal anti-inflammatory drugs (NSAIDs), and *H. pylori* leads to gastric barrier disruption. These noxious agents then diffuse deeper into the mucosa and create wounds. Epithelial cells at the edge of the injury redifferentiate to a migratory phenotype and collectively migrate as a sheet to close the wound. After successful restitution, the migrated cells redifferentiate to more specialized phenotypes. B: A diagram depicting the structure and cell types of gastric epithelium. C: In the injured state, epithelial cells at the edge of the wound spread and redifferentiate to a migratory phenotype, losing their classical apical brush border and assuming a more squamous morphology. Then, they migrate as a sheet to cover the injured area, with cells at the front of the migrating sheet transmitting traction forces to cells farther back *via* cell-cell contacts. Epithelial cells behind these migrating cells subsequently proliferate to provide more cells to fully cover larger wounds. D: Cells that have migrated across the defect may themselves then proliferate once the barrier has been reformed. In addition, following migration and proliferation, the migrated cells redifferentiate back to more specialized phenotypes. E: Structure of small intestinal epithelium in healthy and injured states. F: Structure of large intestinal epithelium in healthy and injured states. A healthy intestinal barrier is essential to maintain intestinal homeostasis. In the healthy state, there is an equilibrium between intestinal injury and mucosal healing. An excess of destructive factors such as NSAIDs, inflammation, bile acid, and toxic luminal substances leads to intestinal barrier disruption. These noxious agents then diffuse deeper into the mucosa and create wounds. Epithelial cells at the edge of the injury follow the processes described in the figure legends for in Figure 1C and D. IESC: Intestinal epithelial stem cells; EEC: Enteroendocrine cells; GC: Goblet cells; NSAIDs: Nonsteroidal anti-inflammatory drugs; *H. pylori*: *Helicobacter pylori*; PG: Prostaglandins; ECL cells: Enterochromaffin-like cells; PC: Paneth cells; IESC: Intestinal epithelial stem cells.

stem cells (IESCs) are crucial to maintaining intestinal epithelial function and homeostasis in both the small intestine and large intestine. IESCs divide for self-renewal and generate progenitor cells that undergo differentiation into enterocytes, colonocytes, Paneth cells, goblets cells, and enteroendocrine cells[15].

Epithelial protection represents the second line of defense. GI epithelial cells are connected to each other *via* tight junctions and act as a physical barrier against acid or toxic luminal agents. In addition to stimulating mucus and bicarbonate secretion, prostaglandins reduce the permeability of the epithelium by closing the apical spaces between the epithelial cells, and thus decreasing the exposure of deeper layers along the GI tract to noxious agents by modulating these tight junctions[16]. Tight junction proteins are either transmembrane proteins such as occludin, claudins, and junction adhesion molecule proteins or cytoplasmic plaque proteins such as the zonula occludens proteins. The dysregulation of these proteins *via* toxin exposure or autoimmune diseases such as celiac disease may lead to disruption of gastrointestinal barrier function[17]. For example, ulcerative colitis may alter the intestinal barrier function *via* changing the phosphorylation of colonic claudins[18]. The architecture and function of tight junctions are slightly divergent between the different regions of the GI tract and also between different epithelial cells. For example, disruption of occludin alters intestinal barrier function whereas occludin disruption does not cause barrier dysfunction in the stomach[19]. Moreover, the expression of tight junction proteins varies even among the different epithelial cells. For instance, IESCs and Paneth cells have high occludin levels whereas claudin-1, -2, and -7 expression is elevated in Paneth cells, IESCs, and enterocytes, respectively[20].

The final mucosal defense is sub-epithelial protection through augmentation of mucosal blood flow. Vascular flow not only removes acid rather than allowing it to diffuse deeper into the mucosa but also supplies necessary nutrients and oxygen to the epithelial cells for energy-consuming processes such as ion transport and secretion. Gut epithelial cells undergo continuous dynamic self-renewal in response to the damage caused by destructive factors under normal physiological conditions[21,22].

DRIVERS OF MUCOSAL INJURY



Although the gut epithelium can maintain normal homeostasis in the presence of modest or transient exposure to injurious stimuli, high level or extensive interactions with noxious factors such as excessive secretion of gastric acid and pepsinogen, the substantial inflammation caused by inflammatory bowel disease, or toxic luminal contents including ethanol or medication such as non-steroidal anti-inflammatory drugs (NSAIDs) can unbalance the equilibrium between mucosal injury and healing (Figure 1A).

Gastric juice includes mucus, hydrochloric acid (HCl), bicarbonate, pepsin, and intrinsic factor secreted by mucoid cells, parietal (oxyntic) cells, and chief (zymogenic) cells in the stomach (Figure 1B). *Helicobacter pylori (H. pylori)* infection, a gram-negative bacterium responsible for 90% of duodenal and gastric ulcers, impairs the bicarbonate secretion and promotes gastric acidity as well[23]. Such hyperacidity may injure the mucosa, causing gastritis, duodenitis, peptic ulcer disease (PUD), or gastroesophageal reflux disease (GERD)[24].

The gastrointestinal mucosa is subjected to numerous physical forces such as strain and pressure during both normal gut function and illness. For instance, luminal chyme, peristalsis contractions, rhythmic villous motility, and some pathological conditions such as inflammatory bowel disease (IBD) may adversely impact GI mucosal healing by increasing luminal pressure[25-29]. Such pressure increases have been shown to inhibit mucosal healing, at least in mice, despite increased mucosal proliferation, and appear to act by inhibiting the cell motility required for restitution[28].

The balance between mucosal injury and healing may also be shifted by drugs such as NSAIDs, corticosteroids, bisphosphonates, potassium chloride, steroids, and fluorouracil[23,30,31]. In particular, many studies have documented that NSAIDs decrease mucus hydrophobicity as measured by contact angle goniometry whereas prostaglandins, gastroprotective compounds, increase the contact angle of gastric mucosa[32,33]. NSAIDs, the most commonly prescribed medications, increase the development of ulcers in the upper and lower GI tract by two distinct mechanisms (Figure 2)[34-37].

NSAIDs injure the upper GI mucosa mainly by cyclooxygenase (COX)-1 inhibition, resulting in a decrease in prostaglandins, mucus, and bicarbonate secretion. Moreover, NSAIDs also alter another important component of mucosal defense, the gastric microcirculatory system. Upon irritation, the gastric mucosa normally increases blood flow to remove any toxins, bacterial products, or back-diffusing acid. Impairment of this hyperemic reaction increases the vulnerability of gastric mucosa to damage[38]. Inhibition of prostaglandins, potent vasodilators, by NSAIDs leads to an increase in vascular tone and thus reduces gastric mucosal blood flow[39], consequently, increases ischemic tissue damage and exacerbating the mucosal injury[40]. NSAIDs may also induce local gastric mucosal injury independent of prostaglandin deficiency[41]. NSAIDs may lyse phospholipids from mucosal epithelial cells and may increase mucosal permeability, which then allows mucosal exposure to luminal aggressive factors such as bacteria and gastric acid[42].

DOI: 10.3748/wjg.v28.i17.1725 **Copyright** ©The Author(s) 2022.

Figure 2 Non-steroidal anti-inflammatory drugs induce mucosal injury in the upper and lower gastrointestinal tract by two distinct mechanisms. In addition to principal luminal aggressors such as acid, pepsin, *Helicobacter pylori* in the stomach and acid, bile, and pathogens in the small intestine, nonsteroidal anti-inflammatory drugs (NSAIDs) increase mucosal damage in both upper and lower GI by two different mechanisms. In the stomach, the inhibition of COX-1 by NSAIDs reduces prostaglandin secretion which in turn reduces mucus and bicarbonate secretion and increases acid secretion, resulting in increased permeability and eventually mucosal damage. In the small intestine, NSAIDs bind to bile in the enterohepatic circulation. This potentiates the mucosal damage caused by bile. NSAIDs also increase mucosal damage in the small intestine by altering the gut microbiota. The NSAID-associated increase in enteric gram-negative bacteria appears to contribute to intestinal lesions by increasing inflammation. NSAIDs: Nonsteroidal anti-inflammatory drugs.

The molecular and cellular mechanisms of NSAID-induced lower GI mucosal injury are clearly distinct from NSAID-induced upper GI injury[42,43]. As in the stomach, NSAIDs may inhibit COX-1 and contribute to mucosal damage. However, unlike gastric injury, the bile acid and intestinal microbiota play a crucial role in the pathophysiology of NSAID-induced intestinal injury[42,44]. NSAIDs and gut microbiota have complex and dynamic interactions. The gut microbiota can alter the efficacy and toxicity of NSAIDs either directly by biotransforming them into metabolites or indirectly by altering the host metabolism (*e.g.*, interfering with hepatic function)[45]. On the other hand, NSAIDs themselves can directly change the composition and function of the gut microbiota or indirectly by altering the physiological functions of the host[45]. For instance, NSAIDs alter the intestinal microbiome by increasing the total number of bacteria and the proportion of gram-negative bacteria, which seems to be linked to the activation of toll-like receptor (TLR) 4 that increases inflammation and contributes to an intestinal injury[46-48].

NSAIDs make complexes with bile acids by glucuronidation in the liver. This interaction alters the stability and structure of bile acids and potentiates bile acid toxicity in the lower GI tract[42]. These NSAID-bile acid complexes are secreted into the duodenum and subsequently reabsorbed back in the ileum *via* the enterohepatic circulation. Within the intestinal lumen, particularly, in the colon, conjugated primary bile acids are deconjugated into more toxic secondary bile acids, mainly by the gram-positive bacteria[49]. There is crosstalk between the microbiome and the bile acids because bile acids can control the composition of the intestinal microbiome, which in turn regulates the composition and size of the bile acid pool[50,51]. Alteration in the colonic microbiota may cause a shift towards to generation of more toxic secondary bile acids, which eventually increase intestinal permeability, particularly in the colon, bacterial translocation, and mucosal inflammation[52-54].

NSAID-induced ulcers are traditionally treated with proton pump inhibitors (PPIs) or histamine-2 receptor antagonists (H2-antagonists)[55,56], which permit ulcer healing by reducing gastric acid secretion without directly affecting mucosal restitution[5,57,58]. Although PPIs have historically been co-prescribed with NSAIDs to ameliorate gastroduodenal injury and are used to treat NSAID injury, such use may increase the risk of a different problem. There is no evidence that gastric acid plays a key role in the pathogenesis of NSAID-induced lower GI[42,59]. PPIs may worsen NSAID-induced enteropathy by increasing gastric pH and thus changing the enteric microbiome by increasing the number of gram-negative bacteria[35,42,60-62]. Thus, even though PPIs are still recommended to treat upper GI ulcers, their prophylactic use with NSAIDs to prevent upper GI injury is no longer recommended unless the patient has a moderate to high risk of peptic ulcer disease[62,63]. Similar concerns are likely to exist for H-2 blockers.

Inflammatory bowel disease is a broad term to describe disorders including Crohn's disease (CD) and ulcerative colitis (UC) that are characterized by excessive activation of the mucosal immune system to normal microflora. This causes chronic inflammation and damages the gut mucosa[64,65]. Since the etiology of IBD is still unclear, the primary goal of treatment is centered on the elimination of inflammation with medical therapies such as 5-aminosalicylate, antibiotics, corticosteroids, immunosuppressants, and biological therapy[66-68]. Management of IBD with targeted therapies has been discussed in detail in a recent review[68]. However, none of these therapies is perfect, and even if patients achieve symptomatic remission, maintaining that remission can be challenging[69]. Recent evidence highlights the importance of mucosal healing over and above symptomatic remission in the quality of life and long-term prognosis of IBD patients[70-72].

MUCOSAL HEALING PROCESSES

Once an injury has occurred, diverse processes such as redifferentiation to a migratory phenotype[73-75], migration, proliferation, and eventual redifferentiation back to more specialized cells after healing are all regulated by various factors including growth factors, cytokines, physical forces, and the extracellular matrix itself. These coordinate healing of the injury (Figure 1). At the subcellular level, wounding of the apical plasma membrane is common in the epithelial cells of the intact, normal functioning stomach and intestines *in vivo* after mechanical and chemical stressors[8,76,77]. Since maintenance of plasma membrane integrity is essential for cell viability, the wounded cell rapidly repairs the injury to restore internal homeostasis and prevent cell death. Plasma repair processes such as tension reduction, budding, patch, endocytosis, and exocytosis may be triggered by the toxic level of Ca^{2+} influx through the plasma membrane wound to then reseal the injured plasma membrane[78,79].

Relatively small or superficial multicellular mucosal injury undergoes complex wound healing processes that quickly reconstitute the mucosal barrier, depending on the size and depth of the injury. Small wounds, less than eight cells in size, may close by the spreading of neighboring cells and formation of new cell-cell contacts[80,81] or by purse-string wound closure, which involves the formation of a multicellular actin cable purse string around the wound, with actin cables that parallel the wound edge. This then contracts, pulling the adjacent cells together[5,82].

Mucosal injury involving more than eight cells is generally too large for purse-string wound closure. This then requires restitutive epithelial sheet migration to close the injury. Depending on the size and depth of these larger wounds, wound closure will require a longer healing time and may require one or more complex overlapping processes such as differentiation, proliferation, and angiogenesis for wound healing[5,83,84].

Restitution requires a phenotypic redifferentiation. Although some authors describe the initial steps of this process as dedifferentiation, it is the firm opinion of the senior author that this should rather be considered a redifferentiation toward a migratory phenotype. The gut epithelium normally consists of a monostratified layer of differentiated epithelial cells. At the edge of a mucosal wound, epithelial cells change their phenotype from differentiated columnar enterocytes or gastric cells to a migratory phenotype. They lose their typical morphology and (for enterocytes and parietal cells) their microvilli [85], disassemble their apical specialized membrane components[86], flatten out and extend lamellipodia toward the defect. Such migrating cells adopt a squamous morphology with altered integrin[87-89] and cytoskeletal organization[73,85] and specialized cell signaling pathways[90-93] that adapt these cells toward motility (Figure 1C)[73,85,94-96] Moreover, it is worth noting that these signaling events are not only regulated by the activation of signaling proteins but also by the distribution and the amount of the signaling proteins within the migrating cells. For instance, both the actual amount of total focal adhesion kinase (FAK) and the amount of active FAK decrease while the ratio of activated to total FAK increases both in vitro[94] and in vivo[92] as the epithelial cells shift to the migratory phenotype[73]. Similarly, both paxillin protein and tyrosine-phosphorylated paxillin decrease in migrating cells compare to static cells[94]. (Paxillin is an adapter protein critical to focal adhesion complex assembly and disassembly in response to various stimuli.)[97-100]. Total p38, ERK1, and ERK2 proteins do not show differences between migrating and static cells[94]. However, phosphorylated p38 increases, and phosphorylated ERK1 and ERK2 decreases in motile cells compared with nonmigrating

cells[94].

Furthermore, the distribution of these signaling proteins also changes in migratory phenotype. In confluent cells, FAK localizes mainly in a perinuclear pattern while FAK appears explicitly at the cell borders contacting other cells in motile cells, with FAK immunoreactivity decreasing toward the migrating lamellipodia that face the wound edge[94]. In contrast to FAK, paxillin is localized at the lamellipodial edges in migrating cells[94]. The difference is more than semantic because considering these migratory cells as a specialized phenotype opens up the possibility for therapy to modulate that phenotype and thereby promote mucosal healing.

The transverse actin cables that drive purse-string closure for smaller wounds line up parallel to the wound edge at the migrating front, connected by cell-cell contacts, and unite the migrating front, so that these redifferentiated cells collectively migrate as a sheet, a.k.a., restitution, to close the wound (Figure 1C)[101-103]. Slightly deeper wounds that injure the basement membrane expose the cells to the interstitial extracellular matrix. While the basement membrane is predominantly laminin and type IV collagen, the deeper interstitial matrix is rich in type I collagen, across which the cells may migrate more rapidly[104,105].

After the closure of the wound by successful restitution, the migrating cells must redifferentiate back to the more specialized phenotypes required for the normal biology of the mucosa (Figure 1D)[102]. Tarnawski *et al*[106] have demonstrated the critical relationship between defective redifferentiation of these migratory cells and subsequent ulcer recurrence. This will be considered in more detail below.

If the wound surface area is extensive, restitution will likely be insufficient to seal the wound. In this situation, epithelial cell proliferation increases behind the migrating cells to create a larger pool of epithelial cells that can then migrate across and cover the defect (Figure 1C)[107]. However, if the wound extends into deeper layers such as the submucosa and muscularis, these must also be reconstructed for healing by processes beyond the scope of this review. In particular, the reconstitution of nutrient vessels in the submucosa is critical for mucosal wound healing because these provide oxygen and nutrients to the mucosa and remove waste products from the wound site[108,109]. This neovascularization can occur by two distinct processes called angiogenesis and vasculogenesis[110-114]. Angiogenesis refers to the process where new blood vessels are formed from preexisting blood vessels from the wound's adjacent vasculature by sprouting and forming tube-like structures and networks. Vasculogenesis is the *de novo* formation of new blood vessels from the differentiation of bone marrow-derived progenitor stem cells.

RESTITUTION AND QUALITY OF ULCER HEALING AS THE SINE QUA NON FOR WOUND HALING

GI ulcers have traditionally been assessed in clinical settings by a superficial visual endoscopic examination that cannot assess the histological and ultrastructural characteristics of the mucosa or deeper layers. Ulcer recurrence is, unfortunately, common, with rates exceeding 60% if the underlying problem has not been successfully addressed[23]. Recurrence of GI ulcers may be related to many factors including gastric acid secretion, *H. pylori*, NSAIDs, hormonal complications, size and depth of ulcers, anti-ulcer treatment, age, gender, comorbidity, alcohol consumption, and smoking[115-118]. In 1991, Tarnawski *et al*[119] drew attention to the relationship between recurrence of ulcers and ultrastructural abnormalities of deeper layers such as poor `redifferentiation, dilation of glands, reduced mucosal height, and disorganized microvascular network after ulcer healing and proposed the concept of the quality of ulcer healing (QOUH)[119-121]. QOUH is defined as ideal ulcer healing, demonstrating flat ulcer scar, high functional restoration, and histological maturity of the regenerated tissue[115,122]. Many patients treated with PPIs for GI ulcers still suffered from a recurrence of ulcers despite continuous anti-ulcer therapy[115,122-124]. It appears that acid inhibition by PPIs or H_2-antagonists may be insufficient for successful high-quality gastroduodenal ulcer healing because low levels of prostaglandins and high levels of oxygen free radicals entail poor QOUH and thus potentiate ulcer recurrence[122,125,126].

Overall, cumulative data highlight the necessity of QOUH for successful and permanent ulcer healing and point out that contemporary treatments such as PPIs and H_2-antagonists do not always provide such high-quality healing. Therefore, to improve QOUH and decrease the rate of recurrence of GI ulcers, new antiulcer drugs need to be developed to address this. Investigation of the endogenous biologic regulation of mucosal healing, suggests new therapeutic targets, both extracellular and intracellular.

REGULATORS OF MUCOSAL HEALING AND POTENTIAL NEW THERAPEUTIC TARGETS

Supplementing available therapeutic modalities that attempt to minimize or reduce injury, investigators have more recently focused on enhancing mucosal defense or promoting mucosal repair. Both mucosal defense and mucosal healing processes such as restitution, proliferation, angiogenesis, and vasculogenesis can be influenced by acid secretagogues, growth factors, trefoil peptides, cytokines, angiogenic factors, luminal nutrients, and the gastrointestinal microbiota[5,25,127]. In addition, physical forces like strain and pressure, engendered by peristalsis, villous motility, and interaction with luminal contents can influence intestinal epithelial migration and proliferation in a complex manner influenced by the deposition of fibronectin at the site of injury[25,128,129].

Acid secretagogues

Under physiological conditions, the stomach protects itself against various forms of endogenous and exogenous injury, primarily by gastric acid. Gastroprotective mechanisms could be triggered by acid secretagogues such as gastrin, histamine, and thyrotropin-releasing hormone (TRH)[130-132]. Pentagastrin, synthetic gastrin, stimulates gastroprotection in acidified aspirin-induced gastric injury in rats, likely through the activation of histamine-2 receptors, since this is abolished by ranitidine[133]. However, exogenous gastrin protects the rat gastric mucosa against ethanol-induced lesions but not against aspirin-induced gastric damage in rats[134]. Several studies have shown that exogenous histamine-stimulated acid secretion also exerts a protective effect on the gastric mucosa against erosions induced by exogenous HCl in rabbits and frogs by stimulating a greater alkaline tide[135,136]. The central vagal activation by intracisternal injection of the thyrotropin-releasing hormone analog RX77368 enhances mucosal resistance as well by stimulating mucosal blood flow *via* prostaglandin-independent manner which eventually results in the removal of diffused acid from the subepithelial interstitial space [137]. In addition, RX77368 increases the thickness of the mucus gel *via* prostaglandin-dependent manner which slows down the acidification of surface cells[137]. The potential therapeutic adaptation of molecules like RX77368 and other acid secretagogues awaits the further exploration of the disparities between results depending on how the ulcers are induced, as well as challenges with their pharmacologic delivery.

Growth factors, trefoil peptides, and cytokines

Growth factors have diverse pathophysiologic effects, including cytoprotection against destructive agents, epithelial wound healing in response to injury[102,138-140], and angiogenesis[141-144]. Epidermal growth factor (EGF) and transforming growth factor TGF-α are structurally related but different polypeptide growth factors[145]. They both bind to the same cell-surface EGF/TGF-α -receptor and induce generally similar effects[145].

EGF may act in a cytoprotective fashion against mucosal injury by increasing secretion of mucus and bicarbonate[146-148], enhancing blood flow[149-151], or releasing other cytoprotective agents such as prostaglandins[152]. Pretreatment of the stomach[153,154], small intestine[146,155], and colon[149,150] tissues, both *in vivo* and *in vitro*, with EGF decreases mucosal damage by various noxious agents. TGF-α is similarly cytoprotective against gastric injury by ethanol, acetic acid, or aspirin[156,157]. Pretreatment of Caco-2 cells with EGF prevents deoxycholate-induced cellular damage, at least in part, by changes in intracellular calcium content[158], suggesting that EGF exerts direct cytoprotective effects on the epithelium in addition to its effects on blood flow and mucus secretion. Furthermore, because this EGF-induced cytoprotection was observed following only 30 minutes of pretreatment (insufficient for proliferation), these results also suggest that this protection is independent of the mitogenic effects of EGF [158]. Consistent with this idea, adding EGF to the basal surface of rabbit primary gastric epithelial cell monolayers cultured on collagen-coated inserts enhances cytoprotection against apical surface acid by opening the plasma membrane calcium channels and increasing intracellular calcium[159].

In addition to their cytoprotective effects, EGF and TGF-α also promote mucosal healing after injury, stimulating both cell motility and cell proliferation[104,140,154]. Indeed, part of the epithelial mucosal shift to a phenotype adapted to wound healing may be an increase in sensitivity to these growth factors. A recent study demonstrated a 75-fold increase in the number of cells expressing detectable EGF-receptors at the ulcer margin after gastric ulcer induction in rats[160]. Either parenteral or local submucosal intra-ulcer injection of EGF caused a comparable acceleration in the healing of acetic-acid-induced rat gastric ulcers, at least in part by increasing gastric blood flow, decreasing gastric acid secretion, and upregulating COX-2 expression[161]. This is in agreement with previous reports suggesting that COX-2 -influences mucosal healing by regulating both the hyperemic response and epithelial cell proliferation[162,163].

The trefoil peptides may also offer new opportunities for therapy because they are important both for mucosal defense[164-166] (by increasing the viscoelasticity of mucus[167,168]) and mucosal repair[169-171] (by influencing reepithelization[171] and inflammation[172]). The trefoil factor (TFF) family includes TFF1 (also called pS2) expressed in gastric surface mucous cells, TFF2 (also called a spasmolytic polypeptide or SP) produced by mucus-producing gastric mucous neck cells, antral gland cells, and duodenal Brunner's glands, and TFF3 (also called intestinal trefoil factor or ITF), predominantly

produced by goblet cells of the small and large intestine and found abundantly within the mucus. A trefoil domain consists of three loops created by disulfide bonds and all TFFs are comprised of two trefoil domains[173]. Trefoil peptides have been detected in different forms including monomers, dimers, and complexes with other molecules. This influences the strength of their association with mucin[173]. In particular, TFF dimers tightly interact with mucin, increasing the viscosity and elasticity of mucus in comparison to the effect of TFF monomers[167,174].

The TFFs are mostly distributed to the basolateral domain of gastric neck cells and parietal cells in the stomach, the Paneth cells in the small intestine, and the crypt cells in the colon[175]. TFF interactions and specific functions have been discussed in detail in a recent review[176]. A specific TFF receptor has not yet been described. However, some binding and functional studies propose potential TFF receptors that may influence epithelial restitution. TFFs have been reported to bind to transmembrane proteins such as the β1 integrin subunit, CRP-ductin, CXC chemokine receptor (CXCR) 4, CXCR7, proteinase-activated receptor (PAR) 2, PAR4, leucine-rich repeat and Immunoglobin-like domain-containing protein (LINGO) 2, LINGO3, and EGFR[177-181]. TFF3 enhances wound healing by activating EGFR and inducing MAPK[182] and PI3K/Akt signaling pathways *in vitro*[183] whereas TFF2 directly activates CXCR4 and enhances the phosphorylation of ERK1/2 and Akt in gastric epithelial cells[184]. Indeed, the CXCR4 antagonist AMD3100 blocks TFF2-dependent gastric epithelial repair[170]. TFFs, specifically TFF2 and TFF3, regulate epithelial motility *via* integrin-binding and activating focal adhesion kinase as well[175]. TFF2 also promotes cell migration *via* PAR4[185], while TFF3 activates PAR2[186]. Furthermore, TFF2 peptide may be required for optimum activity of EGFR and/or EGF signaling in the stomach because heparin-binding EGF and TGF-α do not induce EGFR activation in the stomachs of *Tff2* KO mice[177].

Oral administration of trefoil peptides, recombinant human SP, or rat ITF protects the gastric mucosa against ethanol or indomethacin-induced injury in a prostaglandin-independent manner[164]. Similarly, a more recent study has also shown that both parentally and topically applied trefoil peptides reduce ethanol-induced gastric damage, assessed by measurement of gastric mucosal Na^+ leakage and area of macroscopic injury in rats[187]. Complementing these results, transgenic mice that overexpress human TFF1 display increased resistance to indomethacin-induced small intestinal damage[188] whereas ITF-deficient mice are more prone to ulceration and hemorrhage after oral administration of dextran sulfate sodium (DSS)[189], suggesting that trefoil peptides play an important role in GI mucosal protection. There are likely to be several mechanisms by which the trefoil peptides promote mucosal healing. For instance, exogenous recombinant TFF2 increases epithelial wound healing by decreasing inflammation by negatively regulating IL-12 production from macrophages and dendritic cells[172] whereas exogenous TFF3 activates epithelial wound healing *via* the Na/H exchanger-2[171] and accelerates gastric repair *via* a mechanism that does not require cyclooxygenase activation[170].

TGF-β expression increases in affected mucosa from patients with IBD[190], and at the edge of human gastric and colonic ulcers[92]. Intravenous administration of recombinant bone morphogenetic protein (BMP)-7, a subfamily of TGF-β superfamily, for five days significantly accelerates the healing of trinitrobenzene sulfonic acid (TNBS)-induced colitis in rats by decreasing the expression of pro-inflammatory cytokines (IL-6, TNF-b, ICAM-1)[191]. It should be noted that all of these growth factors and cytokines mentioned in this section interact in a complex fashion, and TGF-β potentiates many of them [127,192,193]. TGF-β also stimulates the synthesis of FAK, a key intracellular signal protein for cell motility and proliferation[92].

Basic fibroblast growth factor (bFGF) and hepatocyte growth factor (HGF) stimulate the healing of acetic acid-induced gastric lesions in rats similarly when administered intraperitoneally or by local submucosal injection at the ulcer site, suggesting that these growth factors also accelerate mucosal repair[161]. The healing of gastric ulcers by bFGF and HGF may involve enhancement of gastric blood blow around the ulcer, suppression of gastric acid secretion, and upregulation of COX-2 expression [161].

When the mucus barrier fails due to overexposure to the noxious agents, acid-back diffusion occurs. In healthy mucosa, increased blood flow response rapidly increases the circulation of pH neutral or slightly alkaline blood through the mucosa to neutralize the diffused acid[103]. Moreover, new vasculature is needed to perfuse and support the newly forming tissue. Therefore, wounds deeper than the epithelial layer also require the formation of new blood vessels in granulation tissue for mucosal healing. Like restitution and proliferation, neovascularization is also modulated by growth factors. Vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), nerve growth factor (NGF), fibroblast growth factor (FGF), and angiopoietin-1(Ang1) are essential for blood vessel regeneration *via* angiogenesis and vasculogenesis following mucosal damage[141-144] and can therefore facilitate deep wound healing[112,193-195]. VEGF, the most potent angiogenic factor, is an indispensable regulator of angiogenesis, making it potentially an ideal candidate to induce angiogenesis/vasculogenesis in mucosal healing. Since VEGF is digested in the lumen by proteolytic enzymes, Jones *et al*[141] used a single injection of a nonviral naked DNA plasmid encoding VEGF and Ang1 directly into the injured area to reduce such deleterious effects. They demonstrated that local gene therapy with a combination of VEGF and Ang1 cDNAs increases gastric ulcer healing and generates more mature vessels and a more complete epithelial structure in acetic acid-induced gastric injury in rats, suggesting that a combination of growth factors may have better therapeutic potency than the use

of any individual factor[141]. Similarly, local gene therapy with serum response factor (SRF) accelerates ulcer healing as well as muscle restoration in acetic acid-induced gastric ulcers in rats[196]. A recent study indicated that angiogenesis and vasculogenesis go hand in hand while forming new vessels in granulation tissue[197]. Delivering such naked genes to a damaged site at endoscopy may be a promising tool to treat such ulcers by increasing the bioavailability of essential GFs.

Cytokines are also involved in the regulation of mucosal barrier function at multiple levels including mucosal homeostasis and inflammation[198]. Proinflammatory cytokines such as tumor necrosis factor (TNF) and IL-13 are upregulated in the inflamed mucosa of IBD patients. Anti-TNF therapy promotes mucosal healing in many patients, but not all patients respond to anti-TNF therapy. Many investigators have therefore focused on other cytokines to improve mucosal barrier function. Unfortunately, many of these attempts have ended disappointingly. For instance, experimental colitis in mice is controlled by using ROR-gamma null Th17 cells, which cannot produce IL17A/F and not induce colitis[199]. However, an anti-IL17A monoclonal antibody not only failed to improve CD in clinical trials but actually aggravated adverse symptoms[200]. IL-13 has seemed similarly promising in pre-clinical studies[201-204], but a trial of IL-13 blockade in UC failed[205]. Such failures of blockade of pro-inflammatory cytokines have recently prompted attempts to use anti-inflammatory IL-10 family cytokines to promote colonic mucosal healing. IL-10 is a major anti-inflammatory cytokine that targets hematopoietic cells in various autoimmune diseases[206]. Gene therapy with a single intravenous injection of an adenoviral vector encoding IL-10 (AdvmuIL-10) diminishes TNBS-induced colitis in mice, decreasing histological injury scores, weight loss, stool markers of inflammation (IL-1β and TNFR-II), and serum amyloid protein in comparison to empty cassette virus (Adv0) or PBS treated mice in TNBS-induced colitis model[207]. Gelatin microspheres containing IL-10 have been developed to increase local bioavailability as a sustained release preparation[208]. Gelatin-microsphere-IL-10 treatment remarkably decreases colonic inflammation in IL-10(-/-) mice compared to treatment with IL-10 alone treatment, at least in part by decreasing IL-12 mRNA expression and down-regulating CD40 expression in macrophage-1 positive cells[208]. However, recombinant IL-10 did not improve clinical symptoms in Crohn's disease[209]. Such disappointing results raise the possibility that manipulating a single cytokine may have unpredictable results because of its effects on the web of compensatory pro-inflammatory and anti-inflammatory cytokine pathways in the inflamed mucosa[198].

One cytokine that may be promising is IL-22. Even though it belongs to the IL-10 family of cytokines, IL-22 is unlike IL-10 in that it targets non-hematopoietic epithelial cells. IL-22 is produced by, apart from the adaptive T cell, innate cells including innate lymphoid cells (ILCs), specifically ILC3 cells in the GI tract. IL-22 has dual roles in inflammation. It can act as a protective (anti-inflammatory) cytokine or a pathological (pro-inflammatory) cytokine[210]. IL-22 influences various tissue epithelial functions such as inflammation[211,212], barrier integrity, regeneration, wound healing[213-215], and host defense against pathogens[216,217]. Beneficial effects of IL-22 have been demonstrated in various murine colitis models[210,218]. However, IL-22 actually appears to worsen the anti-CD40-induced colitis model, in that neutralization of IL-22 reduces the weight loss and colitis scores caused by the anti-CD40 injection and administration of IL-22 then recreates the colitis[219]. Thus, although most animal studies raise the possibility that recombinant human (rh) IL-22 might be a promising therapy for IBD, it remains unclear which effect will be seen in human disease. However, as for other cytokines, the short half-life of rhIL-22 (less than 2 h) limits its clinical applications. Several groups have sought to overcome this obstacle by engineering recombinant fusion proteins with a half-life of 1-2 wk to improve the cytokine's pharmacokinetic properties. Currently, seven IL-22 clinical trials have been investigated for different indications. UTTR1147A is a human IL-22 fusion protein that links the human IL-22 with the Fc portion of human immunoglobulin (Ig) G4, which is prepared for IBD studies[220]. Extensive *in vitro* and *in vivo* studies suggest that UTTR1147A decreases histologic colitis severity by a pathway involving STAT3 activation[220]. These pre-clinical studies demonstrate that UTTR1147A is well tolerated and is not associated with increased inflammatory cytokines in mouse, rat, and monkey studies[220]. A randomized phase-I healthy volunteer study of UTTR1147A demonstrated satisfactory safety and pharmacokinetic profile[221]. A phase-II open-label extension study to evaluate the long-term safety and tolerability of UTTR1147A in patients with moderate to severe UC and CD continues with an estimated completion date in 2025[222].

Therapeutic use of growth factors (except BMP-7) may be limited by their low protein stability[144]. In addition, despite their beneficial effects on the GI tract, long-term or systemic use of any growth factors, trefoil peptides, or cytokines that stimulate cell proliferation, either for cytoprotection or for mucosal healing, may raise concerns about inducing hyperproliferative or dysplastic lesions and potential tumorigenesis. This remains an open issue for such mitogens.

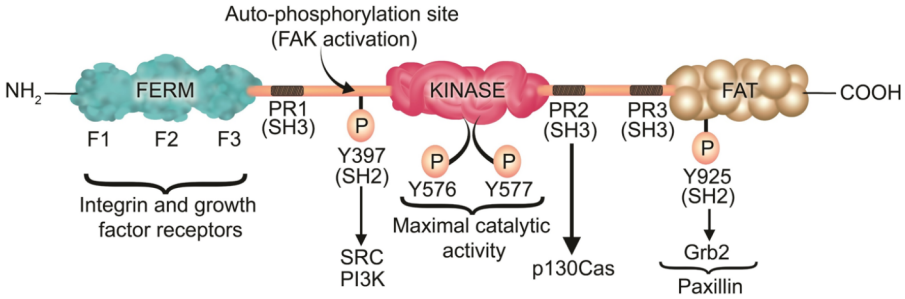
Luminal nutrients and GI microbiota

Luminal nutrients and microbiota are also crucial for the maintenance and repair of the gut mucosa. Short-chain fatty acids (SCFAs) are produced by commensal microbiota, mostly by gram-positive anaerobic bacteria, and are essential for perpetuating intestinal health[223,224]. These SCFAs, especially butyrate, are a major energy source for enterocytes and support gut homeostasis[225-227]. SCFAs may stimulate the differentiation of epithelial cells and their proliferation in vivo[228-230], whereas they promote only differentiation in cell culture models but inhibit proliferation and migration[231-235].

Long known as an energy supply for colonocytes and enterocytes, SCFAs have attracted may also enhance gut barrier function. SCFAs decrease acid-back diffusion by dilating arterial walls and increasing blood flow in gut mucosa[236,237]. In addition, several studies have documented improved intestinal barrier function after SCFA supplementation[238-240]. The SCFAs activate 5′ adenosine monophosphate (AMP) kinase and therefore promote tight junction assembly, which in turn enhances intestinal barrier function[241,242]. However, a recent clinical study found no evidence that butyrate monotherapy or a combination of three SCFAs offered any advantage over placebo in improving the disease activity index in ulcerative colitis patients receiving maintenance oral anti-inflammatory medication[243].

Amino acids such as arginine, histidine, and glutamine promote enterocyte proliferation and decrease mucosal permeability by regulating tight junction proteins[244-247]. A recent study proposed that histidine and arginine play an important role in stimulating intestinal restitution, probably stimulating FAK *via* the TGF-β/Smad2 signaling pathway[248]. Glutamine modulates the phenotype of gut epithelial cells by stimulating proliferation and decreasing differentiation *in vitro*[249]. Similarly, many studies have been shown that glutamine also promotes cell proliferation of intestinal epithelial cells in weanling mice[250] and weaning piglets[251], prevents mucosal injury, and regulates enterocyte restitution following acetic acid-induced intestinal injury in rats[252].

Biologically active phospholipids in milk, phosphatidylcholine (PC) and phosphatidic acid (PA), and their metabolites such as lysophosphatidic acid (LPA), all act to increase the barrier function of GI mucosa by increasing the hydrophobicity of the mucus[253]. This makes the tissue non-wettable[10] and provides mucosal protection against aspirin-induced gastric injury in mice[253]. Dietary essential omega-6 fatty acids can enhance the biosynthesis of prostaglandins and increase the GI mucosal barrier [254]. Milk fat globule-epidermal growth factor 8 (MFG-E8), a glycoprotein found in mammary epithelial cells but also produced by lamina propria macrophages, also plays a vital role in modulating enterocyte migration along the crypt-villus axis[255].



Extracellular matrix

Epithelial sheet migration during gut-healing requires crosstalk between focal adhesion (FA) complexes in the lamellipodium and the ECM. The extracellular matrix is an extremely dynamic meshwork comprised of proteins, glycosaminoglycans, and glycoconjugates. Its composition and organization differ between tissue types and with physiological and pathological conditions[256,257]. Besides its structural support, the ECM has a direct role in gastrointestinal wound healing by inducing extensive signaling cascades[258-260]. Plasma and tissue fibronectin accumulating in deeper wounds also help to shift the cells to a phenotype that responds to repetitive deformation by increased motility rather than by classical differentiation[129,261]. ECM remodeling is performed by matrix proteinases such as matrix metalloproteinases (MMPs), lysyl oxidases, and heparanases[262]. The gelatinases, a subgroup of MMPs, consist of two proteinases gelatinase A (MMP-2) and gelatinase B (MMP-9). In particular, MMP-9 is upregulated in the inflamed intestinal mucosa of IBD patients[263-267]. Furthermore, anti-gelatinase neutralizing antibodies have been reported effective in murine DSS-induced colitis[268]. However, a phase II, randomized, placebo-controlled study found that the MMP-9 inhibitor andecaliximab did not induce a significant symptomatic or endoscopic response in patients with active Crohn's disease[269]. This lack of efficacy in Crohn's disease prompted the termination of another clinical trial of the same agent in active ulcerative colitis[270]. Thus, while modulation of matrix metalloproteinases remains an attractive target in IBD, further exploration of the science involved and the reasons for the failure of the clinical trial are needed.

Regulation of cytoskeleton

Epithelial restitution begins at the edge of the wound with the redifferentiation of epithelial cells. Reorganization of the actin cytoskeleton is controlled by the Rho family of GTPases including RhoA, Rac1, and Cdc42 (Figure 1C)[93,271-273]. Epithelial cells then form protrusions called lamellipodia with new focal adhesions (FAs) at the leading edge of the motile cells. The migrating cell increases its contractile forces and disassembles focal adhesions at the rear edge allowing the entire cell to move forward[274-276]. Cell-cell linkages[276] transmit this force to other cells behind the migrating front and stretch the epithelial layer across the wound as a sheet. This sheet migration is characteristic of epithelial cells and differs from the individual cell motility displayed by other cell types.

The cytoskeleton, a complex and dynamic network of actin filaments, microtubules, and intermediate filaments, is also an important factor in wound healing[277]. Epithelial restitution relies on the coordination of forward protrusions and retraction forces at the rear edge, which is orchestrated by the actin and microtubule cytoskeleton[278]. In the lamellipodium, the elongating actin filaments produce the driving forces for the protrusion while microtubules form a polarized network that permits organelle and protein transport throughout the cell during cell migration[279,280]. Intermediate filaments, however, are generally considered for the maintenance of the overall cell shape[280]. Alternatively, or in combination with therapy to reduce ongoing injury by improving mucus barrier function and promoting angiogenesis, one could consider attempting to directly stimulate restitution in order to accelerate barrier reconstitution. Thus, proteins that modulate cytoskeleton dynamics might be targeted for optimal wound repair. Fidgetin-like 2 (FL2), a microtubule-severing enzyme, regulates the

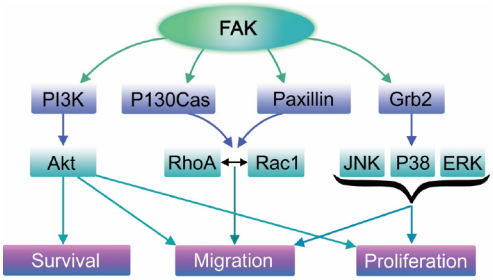
Figure 3 Focal adhesion kinase structure, phosphorylation sites, and its associated proteins. Focal adhesion kinase (FAK) contains an N-terminal band 4.1-ezrin-radixin-moesin (FERM) domain comprised of three lobes (F1, F2, and F3), a central kinase domain, a C-terminal FAT domain, and two linker domains with three PR regions that bind SH3 domain containing protein such as p130Cas. Y397 is the site of the FAK autophosphorylation, crucial for FAK activation, which interacts with proteins containing the SH2 domain such as Src and PI3K. Subsequently to the SH2 binding, Src binds to the PR1 SH3 domain (PXXP) and further phosphorylates the Y576/577 sites on FAK, which are crucial for the maximal catalytic activity of FAK. Further FAK phosphorylation at Y925 creates a binding site for Grb2. The phosphorylation of FAK-Y-925 and subsequent Grb2 binding disassociates paxillin from FAK, which results in FAK release from FAs, thus stimulating FA disassembly. The FERM domain regulates the interactions of FAK with growth factor receptors and integrins. The FAT domain recruits FAK to FAs by associating with paxillin. FERM: Band 4.1-ezrin-radixin-moesin; FAT: Focal adhesion targeting; PR: Proline-rich region; SH: Src homology; P: Phosphorylation.

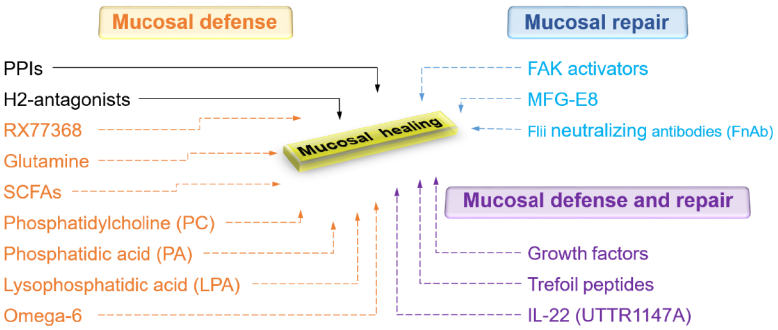
organization of the microtubule cytoskeleton for faster and successful repair of murine wounds[281]. Actin remodeling proteins such as talin[282], Ehm^2[283], filamin-a[284], gelsolin[285], and flightless I (Flii)[286] have also been identified as potential new targets for improved wound healing. Unlike other members of the gelsolin family, Flii inhibits actin polymerization and FA turnover, thus decreasing migration[286,287]. Flii neutralizing antibodies (FnAb) decreased wound area with a quicker rate of healing in porcine and murine models of wound healing, respectively[288,289].



Regulation of FAs

Cell migration, and consequently wound healing, depend critically on the dynamics of assembly and disassembly of FAs. The subunit composition of integrin receptors and the downstream signaling pathways may vary in different scenarios[290-293]. Nevertheless, integrin binding to ECM triggers focal adhesion formation by recruiting many structural and signaling proteins including FAK, a non-receptor tyrosine kinase[294-298]. FAK regulates FA dynamics both by recruiting other FA proteins such as Src to FA sites and by phosphorylating other signaling and adapter FA proteins such as paxillin and p130Cas [299-301]. FAK also influences the cytoskeletal remodeling essential for cell migration by regulating the Rho family of small GTPases such as Cdc42, Rac1, and RhoA[302-305]. Inhibition of FAK inhibits cell migration[94,298].

Although FAK appears to activate cell motility and promote restitution, and FAK is indeed activated during cell motility, levels of both activated FAK and total FAK protein (including both active and inactive FAK) actually decrease in migrating GI epithelial cells *in vitro* and at the edge of human gastric and colonic ulcers *in vivo* even though the proportion of activated FAK increases (at least *in vitro*)[92, 94]. This reflects decreased FAK synthesis in cells that have adopted the migratory phenotype[306]. This apparently paradoxical reduction in this important protein makes FAK an attractive target for possible therapeutic intervention to promote mucosal healing.



FAK is a 125 kDa protein comprised of an N-terminal FERM (band 4.1-ezrin-radixin-moesin) domain, a central kinase domain, three proline-rich regions that are binding sites for Src homology 3 (SH3) domain-containing proteins, and a C-terminal focal adhesion targeting (FAT) domain (Figure 3).

The FAT domain consists of a four-helix bundle[307] and is critical for targeting FAK to FAs *via* binding to paxillin[308]. In an inactive (autoinhibited) state there is an interaction between the FERM and kinase domains which prevents FAK autophosphorylation at Y397[309]. Upon competitive binding of candidate activating proteins such as the cytoplasmic regions of β-integrins or growth factor receptors on the F2 domain of FERM, the autoinhibited conformation of FAK is disassembled[310]. This conformational change allows Y397 phosphorylation, a key event in FAK activation[311]. In a subsequent step, Src is recruited and activated *via* SH2 binding to pY397 and SH3 binding to the PxxP sequence in the linker region, an essential step in promoting cell migration[311]. Then, Src phosphorylates the activation loop residues Y576 and Y577 of FAK and it acquires full catalytic activity after phosphorylation of the activation loop[312]. Phosphorylation of FAK at tyrosine 925 residue creates an SH2 binding site for the growth factor receptor-bound protein 2 (Grb2), adaptor protein[313]. The Grb2 binding site at FAK-Y-925 overlaps with one of the paxillin binding sites in the FAT domain of FAK[313]. The binding of Grb2 disassociates paxillin from FAK and potentiates the release of FAK from FAs[313]. On the other hand, paxillin acts as a scaffold protein for ERK signaling[305]. Subsequently, ERK may modulate FA turnover by further phosphorylating paxillin[305]. Therefore, Paxillin and Grb2 are critical FA proteins that interact with FAK and play an important role in FA turnover[97,313].

Figure 4 Focal adhesion kinase plays a crucial role in several signaling pathways that promote migration, proliferation, and survival. Upon its activation, focal adhesion kinase (FAK) directly binds PI3K, leading to the activation of Akt. Activated Akt then stimulates numerous cellular functions including cell survival, proliferation, and migration *via* various signaling cascades depending on the cell type and species. In addition, FAK may recruit Grb2 and subsequently activate the Ras/Raf/MAPK pathway, enhancing cell proliferation and motility. Finally, FAK may directly bind to paxillin and p130Cas, promoting lamellipodium formation, and thus migration *via* Rac GTPase activation.

PPIs: Proton pump inhibitors; H2-antagonists: Histamine-2 receptor antagonists; RX77368: The thyrotropin-releasing hormone analog; SCFAs: Short-chain fatty acids; FAK: Focal adhesion kinase; MFG-E8: Milk fat globule-epidermal growth factor 8; Flii: Flightless I.

FAK has both a structural role as a scaffold for protein-protein interactions and a kinase function that phosphorylates many substrates in diverse signaling events[314,315]. Its non-kinase scaffolding function allows several different proteins to bind its N-terminal FERM domain and C-terminal FAT domain, tethering them into complexes (Figure 3). For instance, FAK may regulate cell migration serving as a scaffold for Src phosphorylation of p130Cas[316] in FAs. Similarly, nuclear FAK may promote cell survival functioning as a scaffold to stabilize p53-Mdm^2 complexes, promoting p53 ubiquitination and proteasomal degradation[317]. On the other hand, in its kinase signaling capacity, FAK triggers many downstream signals including the Ras/Raf/MAPK[97,296,318-320], p130Cas-Crk[321-324], and phosphatidylinositol 3-kinase (PI3K)-Akt pathways[317], which in turn coordinate to regulate cell proliferation, migration, and survival (Figure 4)[313,325].

Recent evidence suggests that direct modulation of FAK activity is possible, practical, and effective *via* small molecule FAK activators[326]. A novel small molecule with drug-like properties, ZINC40099027 (ZN27), that mimics the FERM domain of FAK has been identified from the ZINC database and activates FAK in human intestinal epithelial cells without activating Pyk2, the closest paralogue of FAK, or Src, another canonical nonreceptor tyrosine kinase within focal adhesions[327]. Indeed, ZN27 directly activates both full-length 125 kDa and its 35 kDa kinase domain, increasing the maximal activity (V_{max}) of FAK, suggesting that ZN27 is a highly potent and selective activator acting allosterically on the 35 kDa FAK kinase domain[328]. ZN27 not only activates FAK but also stimulates intestinal epithelial migration *in vitro* and mucosal healing in mice after ischemic injury or injury by indomethacin[327]. ZN27 also activates FAK in gastric epithelial cells and promotes gastric mucosal healing in mice subjected to chronic ongoing injury by aspirin[58]. Structure-activity-relationship studies have developed a library of novel FAK activators based on ZN27, that have drug-like properties, activate FAK, and stimulate epithelial sheet migration in vitro[329]. At least one such molecule (dubbed compound 3) demonstrates reasonable drug-like properties based on *in vitro*, *in vivo*, and *in silico* results with no obvious toxicity[329]. Further development of this lead molecule may offer the potential for a new therapeutic approach to actually stimulate mucosal healing by activating FAK.

CONCLUSION

Given the enormous impact of GI mucosal healing on human health, there is certainly a need to expand therapeutic options in this regard. A new understanding of the biology of mucosal healing suggests several different possibilities (Figure 5). These include FAK activators, UTTR1147A, endoscopic gene therapy for angiogenic growth factors, mucus barrier enhancement *via* the thyrotropin-releasing hormone analog RX77368 or trefoil peptides, enhanced energy for the mucosa with butyrate, and attempts to increase the regenerative ability of the epithelium with growth factors, cytokines, or trefoil peptides. Future work will determine which of these potentially promising avenues will prove successful and will need to balance their effects against potential risks and issues, including bioavailability, mitogenicity, and tumorigenesis.

FOOTNOTES

Author contributions: Oncel S and Basson MD equally contributed to this manuscript with regards to the conception and structure of the manuscript in addition to the literature review; The final draft of the manuscript was read and approved by all the authors.

Conflict-of-interest statement: The senior author (Basson MD) is co-inventor on patents applied for by the University of North Dakota describing the use of small molecule FAK activators to promote mucosal healing. The authors have no other conflicts of interest.

Open-Access: This article is an open-access article that was selected by an in-house editor and fully peer-reviewed by external reviewers. It is distributed in accordance with the Creative Commons Attribution NonCommercial (CC BY-NC 4.0) license, which permits others to distribute, remix, adapt, build upon this work non-commercially, and license their derivative works on different terms, provided the original work is properly cited and the use is non-commercial. Abstract

Gastroenteropancreatic neuroendocrine neoplasms (GEP-NENs) are rare epithelial neoplasms derived from pluripotent endocrine cells along the gastrointestinal tract and pancreas. GEP-NENs are classified into well-differentiated neuroendocrine tumors and poorly differentiated neuroendocrine carcinomas. Despite overlapping morphological features, GEP-NENs vary in molecular biology, epigenetic, clinical behavior, treatment response, and prognosis features and remain an unmet clinical challenge. In this review, we introduce recent updates on the histopathologic classification, including the tumor grading and staging system, molecular genetics, and systemic evaluation of the diagnosis and treatment of GEP-NENs at different anatomic sites, together with some insights into the diagnosis of challenging and unusual cases. We also discuss the application of novel therapeutic approaches for GEP-NENs, including peptide receptor radionuclide therapy, targeted therapy, and immunotherapy with immune checkpoint inhibitors. These findings will help improve patient care with precise diagnosis and individualized treatment of patients with GEP-NENs.

Key Words: Gastroenteropancreatic neuroendocrine neoplasms; Neuroendocrine tumours; Neuroendocrine carcinoma; World Health Organization classification; Diagnosis; Treatment

Core Tip: Gastroenteropancreatic neuroendocrine neoplasms (GEP-NENs) are rare tumors, but their incidence rates have been steadily increasing over the past 3 decades. GEP-NENs consist of a genetically heterogeneous group of tumors ranging from slow-growing well-differentiated neuroendocrine tumor to aggressive, poorly differentiated neuroendocrine carcinoma. Surgery is the cornerstone for the clinical management of localized tumors. However, GEP-NENs have frequently been diagnosed at a later stage and, therefore, remain an unmet clinical challenge. In this review, we discuss recent updates on the histopathologic classification, molecular genetics, and systemic evaluation of diagnosis and treatment of GEP-NENs at different anatomic sites.

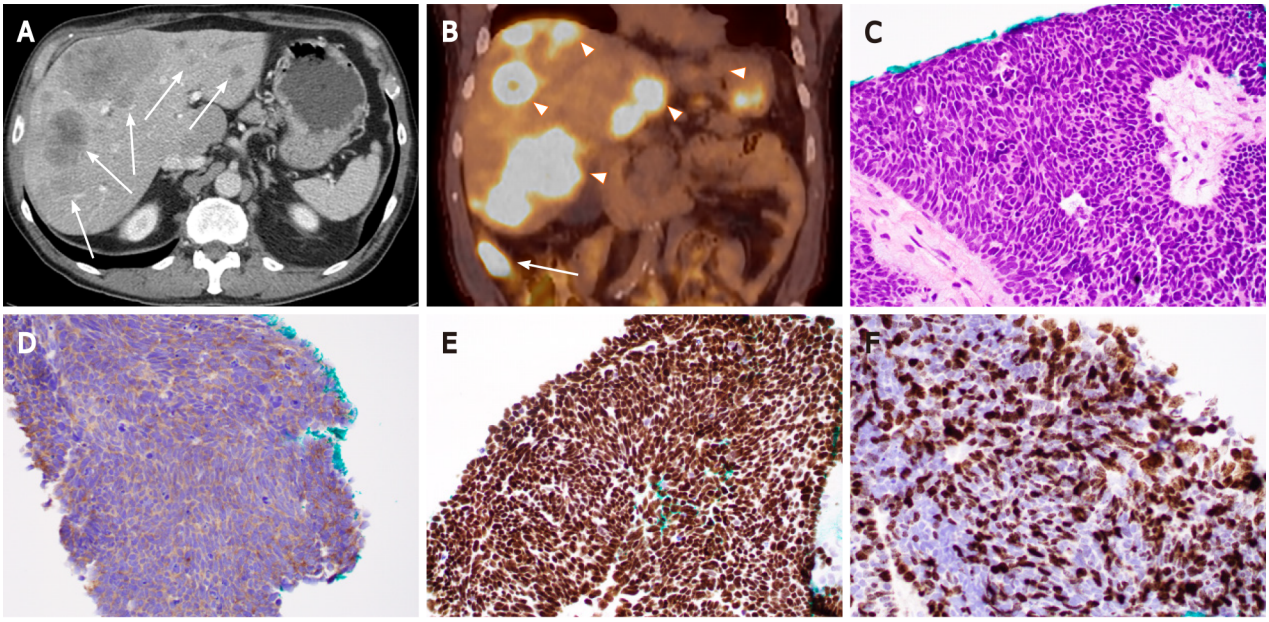
INTRODUCTION



Gastroenteropancreatic neuroendocrine neoplasms (GEP-NENs) are epithelial neoplasms with neuroendocrine differentiation that occur inside the gastrointestinal (GI) tract and the pancreas[1]. They are a group of tumors with significant heterogeneity and complex clinical behavior, ranging from slowly growing well-differentiated gastroenteropancreatic neuroendocrine tumors (GEP-NETs) to highly aggressive, poorly differentiated gastroenteropancreatic neuroendocrine carcinomas (GEP-NECs)[1-3]. The traditional term for a NET is carcinoid, which has been largely discouraged in the updated disease classification published by the World Health Organization (WHO)[1].

GEN-NENs are relatively rare (1.0%-1.5% of all GEP neoplasms, 6.98 and 0.4 new cases *per* year *per* 100000 individuals in the United States for GEP-NETs and GEP-NECs, respectively)[4-7], although their incidence has significantly increased in the past 3 decades, largely due to the improved awareness and detection rate. The majority (> 95%) of GEP-NENs are sporadic, although some (approximately 5%) could be part of syndromic presentations, including multiple endocrine neoplasm type 1 (MEN1), neurofibromatosis type 1 (NF1), and von Hippel–Lindau syndrome (VHL)[1-4].

Based on the embryological development of the GI tract, GEP-NENs can be divided into foregut (the esophagus to the proximal duodenum and pancreas), midgut (the distal duodenum to proximal two thirds of the transverse colon), and hindgut NENs (distal third of the transverse colon to the rectum)[5, 6], with the midgut (especially the small intestine) being the most common site for GEP-NENs. For example, Figure 1 shows the case of a 71-year-old Caucasian man who was initially identified to have multiple liver masses on computed tomography (CT) scans. CT-guided percutaneous liver needle core biopsy showed poorly differentiated neuroendocrine carcinoma and a small cell type, and the tumor cells were positive for neuroendocrine markers and GI tumor markers. A positron emission tomography (PET)/CT scan revealed the primary lesion in the ileum (Figure 1). In addition, compared with their foregut and hindgut counterparts, midgut NENs are more commonly associated with carcinoid syndrome[7]. In this review, we will discuss anatomic origin and pathologic feature-based classification systems for GEP-NETs as well as the diagnosis and current update of therapy. Based on our practice, we will also share some experience in the work-up of some unusual and challenging cases with diagnostic pitfalls.

HISTOPATHOLOGIC CLASSIFICATION

Tumor differentiation is closely associated with the clinical behavior of GEP-NENs and refers to how much the tumor tissue looks like the normal tissue that it was derived from. Based on tumor differentiation and histopathologic features, GEP-NENs can be classified into three major categories: Well-differentiated NETs, poorly differentiated NECs, and mixed neuroendocrine-nonneuroendocrine neoplasms (MiNENs)[8]. Well-differentiated GEP-NETs commonly present with a uniform population of tumor cells with round nuclei and finely stippled "salt-and-pepper" chromatin[9]. Their common growth patterns include nests, trabeculae, acini, and ribbons. On the other hand, poorly differentiated GEP-NECs could be further classified into small-cell NECs and large-cell NECs based on their cytological features and commonly grow in sheets or nests with frequent tumor necrosis[10]. Small-cell NECs have features that include blue cells with scant cytoplasm, finely dispersed chromatin, nuclear molding, smudging, no distinct nucleoli, high mitotic rate, and patterns of rosettes and/or peripheral palisading (Figure 1). Large-cell NECs also have a neuroendocrine architecture and features of large cells with abundant cytoplasm, round and vesicular nuclei, and prominent nucleoli. Some NECs have a concurrent adenocarcinoma component and are categorized as MiNENs[11,12].

Figure 1 Ileal small cell neuroendocrine carcinoma with liver metastases in a 71-year-old man. A: Computed tomography (CT) image (axial) showing ileal and multifocal liver lesions (arrow); B: Positron emission tomography-CT image showing ileal (arrow) and liver lesions (arrowheads) with hypermetabolic activity; C: Histopathologic features of small cell neuroendocrine carcinoma. Note the tumor cells with peripheral palisading, rosetting, scant cytoplasm, nuclear molding, finely granular chromatin, and lack of prominent nucleoli; D-F: Tumor cells with positive immunoreactivity for synaptophysin (D) and CDX2 (E) as well as a high Ki-67 proliferation index (70%) (F). (C-F: 400 ×).

Tumor grade is another important factor closely correlated with the clinical behavior of GEP-NENs. It refers to how abnormal the tumor cells look under a microscope, and in the case of GEP-NENs, the tumor grade is usually determined by the proliferation rate of the tumor cells that could be reported by the mitotic rate (number of mitoses *per* 2 mm^2) and/or the Ki-67 proliferation index (average nuclear immunolabeling based on at least 500 tumor cells) (Table 1). The current guidelines use a 3-tier tumor grading system: Low-grade (grade 1, G1) tumors with a mitotic rate up to 2 *per* 2 mm^2 or a Ki-67 proliferation index up to 3%, intermediate-grade (grade 2, G2) tumors with a mitotic rate from 2 to 20 *per* 2 mm^2 or a Ki-67 proliferation index from 3% to 20%, and high-grade (grade 3, G3) tumors with a mitotic rate greater than 20 *per* 2 mm^2 or a Ki-67 proliferation index greater than 20%[13]. A suggestion has been made to use a Ki-67 proliferation index of 5% as the cutoff level, instead of 3% according to current guidelines, for better risk stratification in patients with G1 to G2 tumors[14], although additional large-scale studies are needed to validate this proposed cutoff value. Due to the heterogeneity among tumor tissues, a routine practice is to perform measurements in the most mitotically active tumor area. In cases with discrepancies between the mitotic rate and Ki-67 proliferation index, the tumor will be placed into the highest-grade category. A higher Ki-67 proliferation index is associated with a poorer prognosis[15]. In fact, the Ki-67 proliferation index appears to be a better prognostic marker than the mitotic rate for metastatic pancreatic and midgut NENs[16]. Of note, all NECs were high-grade carcinomas with a poorly differentiated morphology and a high Ki-67 proliferation index (> 20%, more than 50% in the majority of the cases) (Figure 1) and high mitotic count (> 20 *per* 2 mm^2). Historically, all G3 GEP-NENs were conceptually equal to NECs before 2017. However, recent studies have clearly demonstrated that G3 GEP-NETs and GEP-NECs are genetically different entities[17]. In general, G3 GEP-NETs are morphologically well differentiated and clinically less aggressive than GEP-NECs and have a poorer response to platinum-based chemotherapy[18].

All GEP-NENs are characterized by the expression of neuroendocrine markers, with or without secretion of biologically active substances. Immunohistochemical staining is often necessary, not only to confirm the diagnosis and to assign the tumor grade category but also to investigate the tumor origin in cases of metastasis. GEN-NENs are derived from the neuroendocrine epithelium and therefore normally express cytokeratin (CK), with CK8 and CK18 being the most common[19]. The expression of CK could separate GEP-NENs from their great mimics pheochromocytoma/paraganglioma. General neuroendocrine markers are also frequently used in routine practice to establish the diagnosis. Well-differentiated NETs usually express somatostatin receptors. In fact, the expression of somatostatin receptor subtype 2A (SSTR2A) is the basis of functional imaging (such as gallium Ga 68 dotatate) and somatostatin analog (SSA) therapy, including octreotide acetate and peptide receptor radionuclide therapy (PRRT) (such as lutetium Lu 177 dotatate)[20]. Some commonly used neuroendocrine immunohistochemical markers include chromograin A (CgA), synaptophysin (SYN), and CD56. Recent studies have demonstrated INSM1 (insulinoma-associated protein 1) as a novel and more specific marker of

Table 1 World Health Organization classification for gastroenteropancreatic neuroendocrine neoplasms[1]

	Differentiation	Mitotic rate (%)	Ki-67 proliferation index (%)

[1]Data derived from Klimstra *et al*[1].

neuroendocrine differentiation. In the case of poorly differentiated NECs, INSM1 appears much more sensitive (95%) than CgA (83%) and SYN (82%)[21]. Immunohistochemical staining could also be helpful to identify unknown primary tumors in cases of metastasis. Up to 20% of NETs originally present as liver or bone metastasis from unknown primary tumors, and identification of the primary tumor has significant therapeutic and prognostic implications. The jejunum, ileum, and pancreas appear to be the most common primary sites for patients with NET liver metastases of occult origin[22,23]. CDX2 immunoreactivity is present in the majority of jejuno-ileal NETs, and up to 24% of metastases are primarily pancreatic NETs[24]. The novel marker SATB2 (special AT-rich sequence-binding protein 2) is frequently and strongly expressed in NETs of the lower GI tract and has shown value in assigning NEC sites of origin[25]. For metastatic GEP-NENs, additional immunohistochemical panels include PDX-1 (pancreatic and duodenal homeobox 1), PAX6 (paired Box 6), PAX8 (paired Box 8), ISL1 (islet 1), NESP55 (neuroendocrine secretory protein 55), PR (progesterone receptor), and PrAP (prostate acid phosphatase)[26,27]. We performed PAX6 and PAX8 immunohistochemical staining on 178 NETs, including 110 primary NETs (26 pancreatic, 10 gastric, 12 duodenal, 22 jejuno-ileal, 10 rectal, and 30 pulmonary) and 68 NETs metastatic to the liver (24 pancreatic, 1 duodenal, 37 jejuno-ileal, 1 rectal, and 5 pulmonary). Among primary GEP-NETs, PAX6 and PAX8 were positive in 65% (17/26) and 73% (19/26) of pancreatic, 0% (0/10) and 10% (1/10) of gastric, 92% (11/12) and 92% (11/12) of duodenal, 0% (0/22) and 0% (0/22) of jejuno-ileal, and 90% (9/10) and 80% (8/10) of rectal NETs, respectively. PAX6 and PAX8 positivity was seen in 46% (11/24) and 50% (12/24) of metastatic pancreatic NETs to the liver, respectively. None of the nonpancreatic NETs metastatic to the liver were immunoreactive for either PAX6 or PAX8[27].

MOLECULAR GENETICS

GEP-NENs consist of a biologically distinct group of tumors with great genetic heterogeneity. Largely driven by high-throughput technologies and next-generation sequencing, significant progress has been made in recent years in understanding the key molecular drivers of tumorigenesis and progression, especially pancreatic and small bowel NENs[28-30]. Approximately 10%-20% of pancreatic NETs (P-NETs) are associated with hereditary genetic syndromes, including MEN-1, NF1, VHL, and tuberous sclerosis[31]. In cases with sporadic P-NETs, three types of major molecular alterations have been detected, including somatic mutations in *MEN1* (44%), *DAXX* (death-domain associated protein)/*ATRX* (alpha thalassaemia/mental retardation syndrome X-linked mutations) (43%), and mammalian target of rapamycin (mTOR) pathway genes such as *PTEN*, *TSC2*, and *PIK3CA* (14%)[32]. Identification of mTOR pathway gene alterations has clinical relevance due to the available targeted therapy. Germline mutations in DNA repair genes, including *MUTYH*, *CHEK2*, and *BRCA2*, have been reported in sporadic P-NETs[33]. Chromosome 18 deletion is detected in 60%-90% of small intestinal NETs (SI-NETs), although its significance is still unclear at this time[34]. Chromosome 14 gain is also frequently detected in advanced and metastatic disease[35]. Approximately 8% of SI-NETs have somatic mutations in *CDKN1B*[36,37]. A recent study demonstrated that, as epigenetically dysregulated tumors, SI-NETs could be divided into three subgroups: (1) Chromosome 18 deletion with *CDKN1B* mutations and CpG island methylator phenotype (CIMP) negativity, the largest subgroup (55%) with the most favorable prognosis; (2) The absence of arm-level copy-number variation (CNV) with a high level of CIMP positivity, the subgroup (19%) with intermediate prognosis; and (3) The presence of multiple CNVs, the subgroup (26%) with a young age at onset and the worst prognosis[38]. In addition to P-NETs and SI-NETs, more studies are needed to understand the molecular genetics of GEP-NETs in other anatomic

sites.

From a molecular genetics point of view, pancreatic NECs (P-NECs) are entirely biologically different entities from P-NETs. The most common molecular alterations in P-NECs are somatic mutations in *TP53*, *RB1*, *CDKN2A*, and *KRAS*[39]. Notably, mutations in the *TP53* and *RB1* genes appear to be recurrent molecular events in GEP-NECs from different anatomic sites, including the stomach and colorectum [40]. *KRAS* mutations have also been detected in gastric and colorectal NECs, although *BRAF* mutations have only been reported in colorectal NECs[30]. Interestingly, somatic mutations in *DAXX*, *ATRX*, and *MEN1* are almost exclusively detected in well-differentiated NETs but not poorly differentiated NECs [41].

The pathological diagnosis of grade-3 well-differentiated NETs and poorly differentiated NECs could be challenging in some cases because of the high mitotic rate (> 20 *per* 2 mm^2) and high Ki-67 proliferation index (> 20%), particularly for the limited sample made from endoscopic ultrasound-guided fine-needle aspiration (EUS-FNA). The distinct molecular profile could help to separate these two entities. In practice, immunohistochemistry using antibodies against DAXX, ATXR, p53, and RB1 could be performed to surrogate for genetic status[42]. Poorly differentiated NECs frequently have absent RB1 and aberrant p53 protein expression, together with normal expression of DAXX and ATRX. On the other hand, normal RB1 and p53 protein expression is normally found in well-differentiated NETs.

CLINICAL PRESENTATION, DIAGNOSIS, AND TREATMENT

Gastric NENs

Gastric NENs (G-NENs) originate from different neuroendocrine cell types in the gastric mucosa, including enterochromaffin (EC) cells (serotonin producing), enterochromaffin-like (ECL) cells (histamine producing), D-cells (somatostatin producing), and G-cells (gastrin producing)[43]. The diagnosis of G-NENs is usually performed incidentally during upper GI endoscopy due to the lack of specific symptoms, although rare cases could be seen in systemic syndromes, especially Zollinger-Ellison syndrome. Gastric NETs (G-NETs) are commonly subclassified into three distinct types that are mostly derived from ECL cells (Table 2). NETs derived from D cells, G cells, and EC cells are extremely rare.

Type 1 G-NETs are the most common NETs (80%-90%) in the stomach and associated with advanced autoimmune metaplastic atrophic gastritis. It is more commonly seen in females that frequently have additional autoimmune disorders, such as type 1 diabetes mellites and Hashimoto's thyroiditis. The presence of autoimmune antibodies, including anti-parietal cell antibodies and anti-intrinsic factor antibodies, leads to the destruction of parietal cells and achlorhydria[44]. Laboratory testing shows elevated serum gastrin, decreased vitamin B12, and high gastric pH (> 7). Gastrin induces ECL cell hyperplasia (< 0.5 mm) and ultimately G-NETs when the lesions measure 0.5 mm or larger.

Type 1 G-NETs are usually diagnosed under upper GI endoscopy with biopsy. It usually presents with multiple small (< 1 cm) reddish polyps or nodules of the gastric body (Figure 2A) and fundus. Histologically, type 1 G-NETs show tumor cells with abundant eosinophilic cytoplasm, monotonous round nuclei, and characteristic chromatin arranged in trabecular or nested patterns (Figure 2B and C). Necrosis is not a feature for this type of tumor. The background gastric mucosa shows atrophic gastritis with frequent intestinal metaplasia (Figure 2B and C inset). In addition, the spindle cell morphology of type 1 G-NETs has been reported by us with histological features mimicking spindle cell gastrointestinal stromal tumors (GISTs) (Figure 2D)[45] and therefore represents a potential diagnostic pitfall.

Most type 1 G-NETs are small G1 tumors and are limited to the mucosa and rarely the submucosa. Imaging study is usually unnecessary. However, EUS is likely warranted if the tumor is greater than 1-2 cm due to a higher risk for lymph node metastasis (2%-9%), muscularis propria invasion, and angioinvasion[46]. The management of type 1 G-NET is generally conservative with endoscopic surveillance due to its favorable prognosis. Endoscopic resection could be performed on cases with larger lesions (> 5 mm) (Figure 3). Gastrectomy is only reserved for rare high-risk cases.

Type 2 G-NETs are rare and account for 5%-6% of G-NETs. They occur in Zollinger-Ellison syndrome in the setting of MEN-1 syndrome, and patients are younger. Type 2 G-NETs are usually caused by duodenal gastrinoma[47]. The common clinical presentation includes abdominal pain and watery diarrhea. Laboratory testing shows elevated serum gastrin and low gastric pH (< 2). Additional genetic testing is recommended to confirm MEN-1 syndrome in suspicious cases. Endoscopically, type 2 G-NENs present with multiple gastric polyps or nodules. Multiple gastric peptic ulcers are common findings. These polypoid lesions are usually larger but typically less than 2 cm. The microscopic features of type 2 G-NENs are similar to those of type 1 G-NENs, presenting as low-grade tumors (G1 tumors being the most common) in a background of ECL hyperplasia. However, background gastric mucosa in type 2 G-NETS demonstrates parietal cell hypertrophy/hyperplasia. Type 2 G-NETs are mostly limited to the mucosa and submucosa. It has a higher risk of lymph node metastases (up to 30%) and therefore a slightly worse prognosis than type 1 G-NETs.

The clinical management of type 2 G-NETs also includes endoscopic surveillance, endoscopic resection, and rarely surgery. It is of clinical importance to locate and resect the primary gastrinoma.

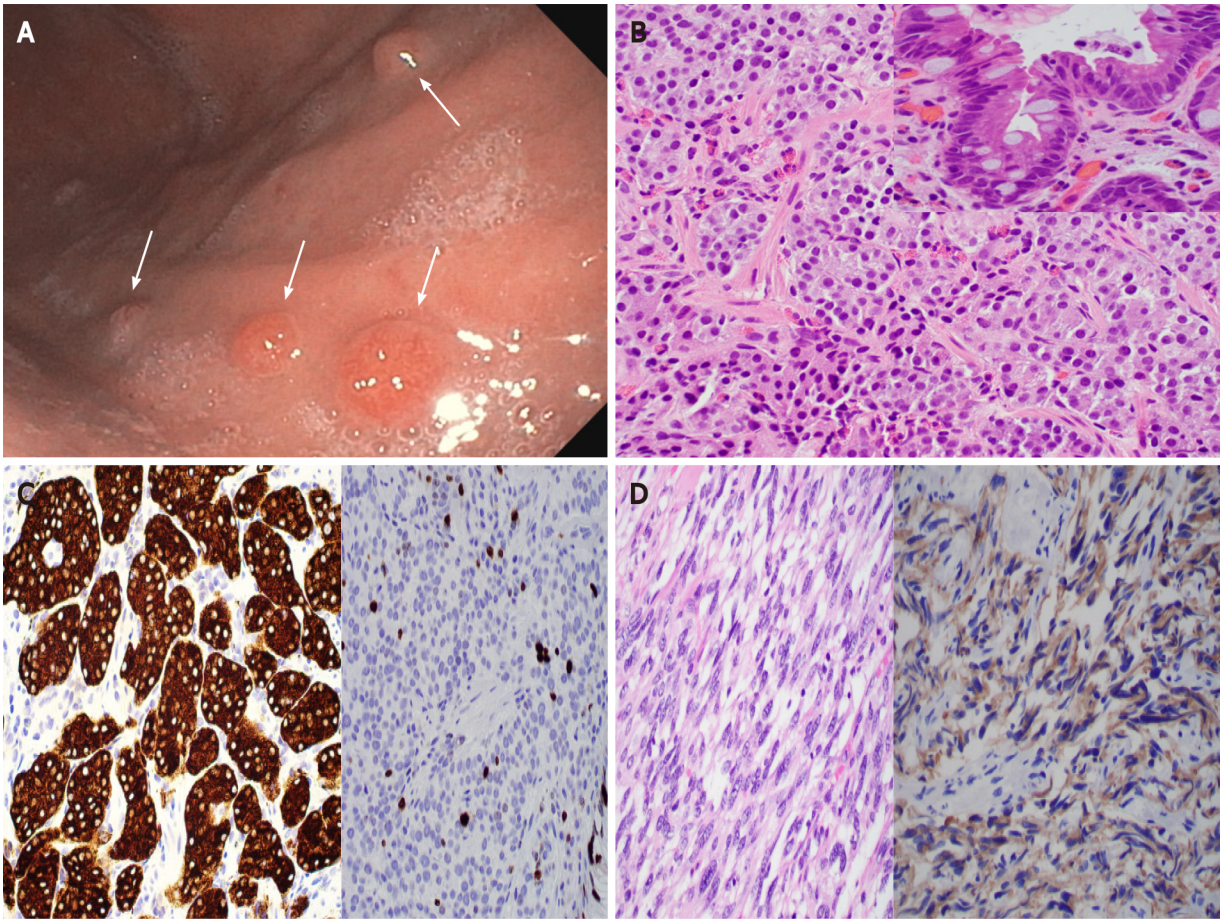
Table 2 Clinicopathologic characteristics of gastric neuroendocrine tumor

	Type 1	Type 2	Type 3
Relative frequency (%)	70-80	5-6	10-15
Gender	F > M	F = M	M > F
Cell of origin	ECL	ECL	ECL, EC, *etc.*
Associated disease	AMAG; Pernicious anemia	MEN1; ZES	None (Sporadic)
Site of tumors	Fundus and corpus	Fundus and corpus, occasionally antrum	Anywhere
Size of tumors	< 1 cm	< 2 cm	2-5 cm
Number of tumors	Multiple	Multiple	Single
Plasma gastrin level	High	High	Normal
Gastric acid output	Low or absent	High	Normal
Metastatic rate (%)	2-5	10-30	50-100
Tumor related death (%)	Approximately 0	< 10	25-30

ECL: Enterochromaffin-like cell; EC: Enterochromaffin cell; F: Female; M: Male; AMAG: Autoimmune metaplastic atrophic gastritis; MEN1: Multiple endocrine neoplasm type 1; ZES: Zollinger-Ellison syndrome.

SSAs have been proposed in the treatment of type 2 G-NETs, although large-scale cohort studies are necessary for their validation.

Type 3 G-NETs are sporadic tumors and account for 10%-15% of all G-NETs. Laboratory testing showed normal serum gastrin and gastric pH. The clinical presentations are nonspecific, including abdominal pain, melena, and weight loss. Carcinoid syndrome could be seen in patients with liver metastases. Endoscopically, the tumor is usually a single large lesion (> 2 cm) arising in the normal background mucosa. These tumors commonly have aggressive clinical behavior, characterized by higher tumor grade, higher tumor stage, and frequent lymph node and distant metastases. The diagnosis involves upper GI endoscopy and biopsy. EUS is required to measure the depth of invasion and to evaluate lymph node status. Additional imaging studies, including computed tomography (CT), magnetic resonance imaging (MRI), and somatostatin receptor scintigraphy (SRS), are recommended for perioperative tumor staging.



Compared with the favorable prognosis in types 1 and 2 G-NETs, type 3 G-NETs frequently present as high-grade and deeply invasive tumors. Lymph node metastases are found in up to 71% of type 3 G-NETs measuring 2 cm or larger[48]. Although endoscopic resection could be applied for small and superficial lesions, radical surgical resection (total or subtotal gastrectomy) with lymphadenectomy is often the treatment of choice for type 3 G-NETs.

Gastric NECs (G-NECs) are poorly differentiated carcinomas with high mitotic counts and frequent necrosis. They have been further subclassified into small cell NECs (SCNECs) and large cell NECs (LCNECs)[49]. Histologically, SCNECs are similar to their counterparts in the lung, featuring small neoplastic cells with scant cytoplasm and hyperchromatic nuclei. Prominent nucleolus is uncommon. In contrast, LCNECs have large neoplastic cells with abundant eosinophilic cytoplasm, vesicular nuclei, and prominent nucleoli. G-NECs are high-grade neoplasms by definition, with a high Ki-67 proliferation index (> 20%, often more than 60%-70%) and a high mitotic rate (> 20 *per* 2 mm^2). For G-NECs, surgical resection is often required, and postoperative chemotherapy is advised in cases with metastatic disease[50].

Small intestinal NENs

The incidence of small intestinal NENs (SI-NENs) has been increasing steadily over the past 3 decades to 1.05 new cases *per* 100000 individuals *per* year[51,52], and they are the most common GEP-NENs (29.5%) in the United States, followed by the rectum (29.2%) and pancreas (13.5%)[52]. The clinical presentations include nonspecific abdominal pain, mass effects (small bowel obstruction), and symptoms related to excess hormone secretion. Ampullary NENs could cause jaundice and acute or chronic pancreatitis. Duodenal gastrinoma is a cause of Zollinger-Ellison syndrome. Despite relatively slow growth, the small intestine is the most common primary NET site for metastatic disease along the GI tract[53].

CT scans are the most common imaging modalities for the diagnosis of SI-NENs. Other imaging studies include ultrasound, MRI, and SRS. Endoscopy with biopsy is the gold standard for the diagnosis of SI-NENs. Endoscopic examination of SI-NENs includes capsule endoscopy, colonoscopy, and double-balloon enteroscopy. Duodenal and periampullary NETs are usually single small (< 2 cm) polypoid or nodular lesions limited to the mucosa and submucosa. NETs at the jejunum and ileum are usually large

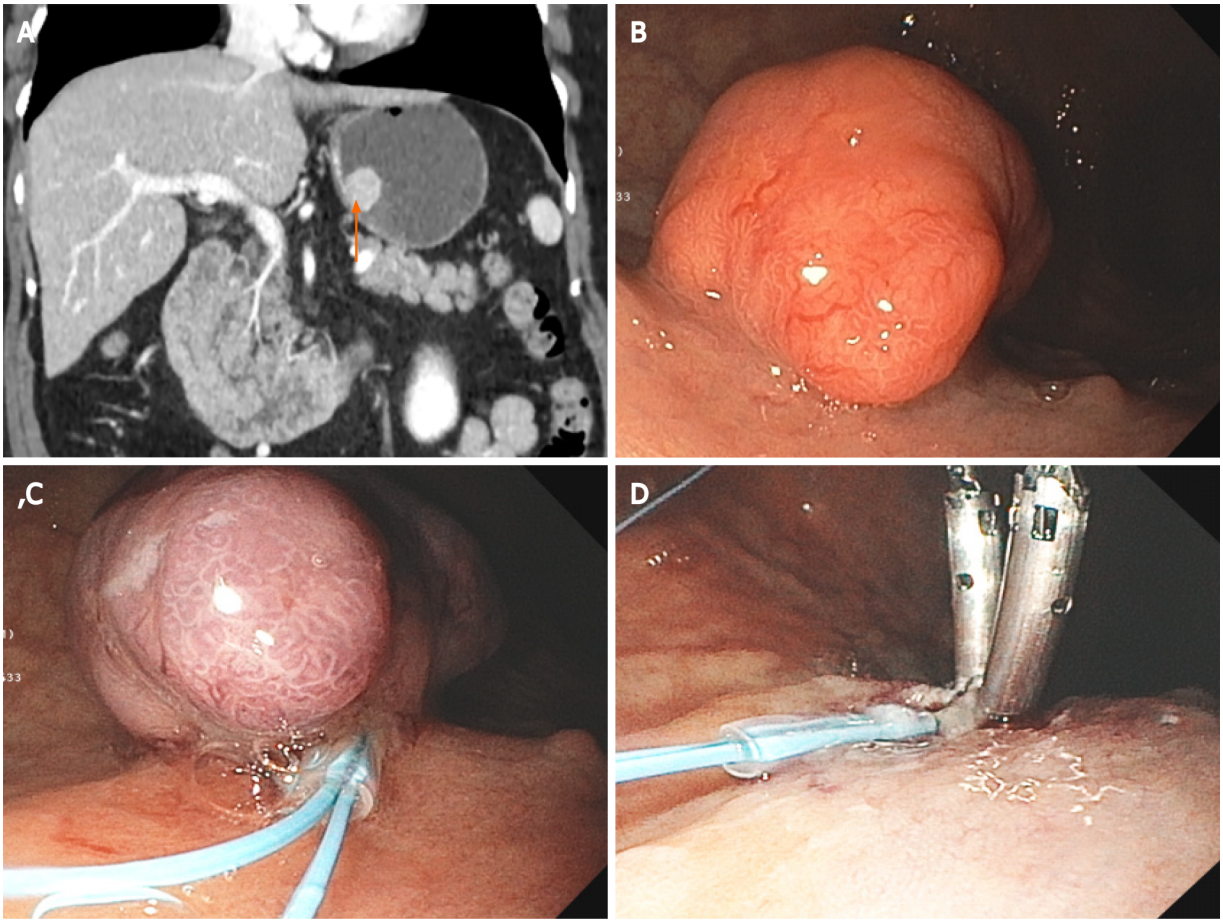
Figure 2 Type 1 gastric neuroendocrine tumor with usual and unusual histology. A: Endoscopic photo showing four nodules (arrows) in the gastric body of a 56-year-old woman with a history of autoimmune chronic atrophic gastritis (ACAG); B and C: Biopsy of the nodules showing well-differentiated neuroendocrine tumor (B, H&E stain, 400 ×) with intestinal metaplasia on the overlying mucosa (B inset), positivity for synaptophysin (C, left), and a 7% Ki67 index (C, right); D: Gastric biopsy in an 83-year-old woman with ACAG showing a neuroendocrine tumor with unusual spindle cell morphology mimicking gastrointestinal stromal tumor (GIST) (left, H&E stain), which is positive for synaptophysin (right) and negative for GIST markers.

(> 2 cm) and multifocal, with frequent deep invasion and lymph node metastases[54].



SI-NENs are morphologically similar to NENs at other sites. A few relatively specific histological features include psammoma bodies in somatostatin-producing D-cell NETs and nested growth patterns with peripheral palisading in serotonin-producing EC-cell NETs. Gangliocytic paraganglioma is a rare NET that is typically encountered in the second part of the duodenum and is characterized by the presence of three distinct components: A neuroendocrine epithelioid component, a Schwannian spindle cell component, and a ganglion cell-like component[55].

For localized SI-NETs, the standard of care is complete surgical resection of the primary tumor, regional lymph nodes, and mesenteric fibrotic tissue. A consensus has not been reached with routine administration of octreotide preoperatively or intraoperatively[56]. For metastatic disease, treatment options are surgical resection, liver-directed therapy (in cases predominantly with liver metastasis), and systemic therapy including SSA, PRRT, everolimus (mTOR inhibitor), and cytotoxic chemotherapy.

Appendiceal NENs

The appendix is a frequent primary site for GEP-NENs, with an incidence rate of approximately 0.15-0.6 new cases *per* 100000 individuals *per* year in the United States[52,57,58]. They frequently occur in children and young adults with a slight female predominance[59]. Appendiceal NENs (A-NENs) have the most favorable prognosis among all subgroups of GEP-NENs[52].

The common clinical presentations of A-NENs are similar to those of acute appendicitis. Carcinoid syndrome is extremely rare in A-NENs and is mostly associated with metastatic disease. Histopathologic evaluation is crucial to establish the diagnosis of A-NENs. The application of imaging studies, including CT and MRI, has limited value for the detection of small primary A-NENs. However, colonoscopy is recommended given that up to 18% of patients with A-NENs have concurrent GI neoplasms[60].

Figure 3 Large gastric neuroendocrine tumor. A: Computed tomography image showing a 2.3 cm mass (arrow) at the posterior wall of the body of a 74-year-old woman with a history of autoimmune chronic atrophic gastritis; B: Endoscopic image showing the large polypoid lesion in the gastric body; C and D: Endoscopic mucosal resection of the polypoid type 1 neuroendocrine tumor.

The majority (80%) of A-NENs are small and only incidentally found in appendectomy specimens [52]. Most A-NENs (60%-75%) are located at the appendiceal tip; therefore, the appendiceal tip should be examined carefully on all appendectomy specimens. The histological features of A-NENs are similar to those of NENs of other primary sites, with the exception of tubular NETs. Tubular NETs are rare benign neoplasms with a predominant tubular growth pattern, so it is important not to misdiagnose them as adenocarcinomas[61]. Of note, goblet cell adenocarcinoma (formerly goblet cell carcinoid) is no longer considered an A-NEN[62]. Currently, we believe that this is an unusual type of adenocarcinoma with neuroendocrine differentiation.

The management of A-NENs depends on the stage of the disease determined by the tumor size, location, and tumor extension. Simple appendectomy is considered adequate for tumors less than 10 mm. Right hemicolectomy is indicated for tumors larger than 20 mm. The implication of right hemicolectomy in A-NETs with a size of 10-20 mm is still controversial, likely depending on the presence of high-risk features (positive margin after appendectomy, base location, Ki-67 index of 3% or higher, > 3 mm mesoappendiceal invasion, angioinvasion, and perineural invasion)[63,64]. For patients with more advanced disease (stages III and IV), the treatment usually includes curative surgery and systemic therapy.

Colorectal NENs

The incidence rates of colonic and rectal NENs are 0.2 and 1.2 new cases *per* 100000 individuals *per* year in the United States, respectively[52]. The mean age for colonic NENs is 65 years, which is significantly older than that for rectal NENs (56 years) due to late detection. The presentation of colorectal NENs is similar to that of colorectal adenocarcinoma with nonspecific mass-related effects, abdominal pain, and bleeding. Classic carcinoid symptoms could be seen in some cases, often with liver metastases.

The majority (70%) of colonic NETs (C-NETs) are located on the right side of the colon, especially the cecum[65]. C-NETs are usually larger, with an average size of 4.9 cm[66]. Approximately 30%-40% of C-NETs have local or distant metastasis at the time of presentation. Colonoscopy with biopsy is commonly performed to establish the diagnosis. C-NETs are usually derived from EC cells or Kulchitsky cells

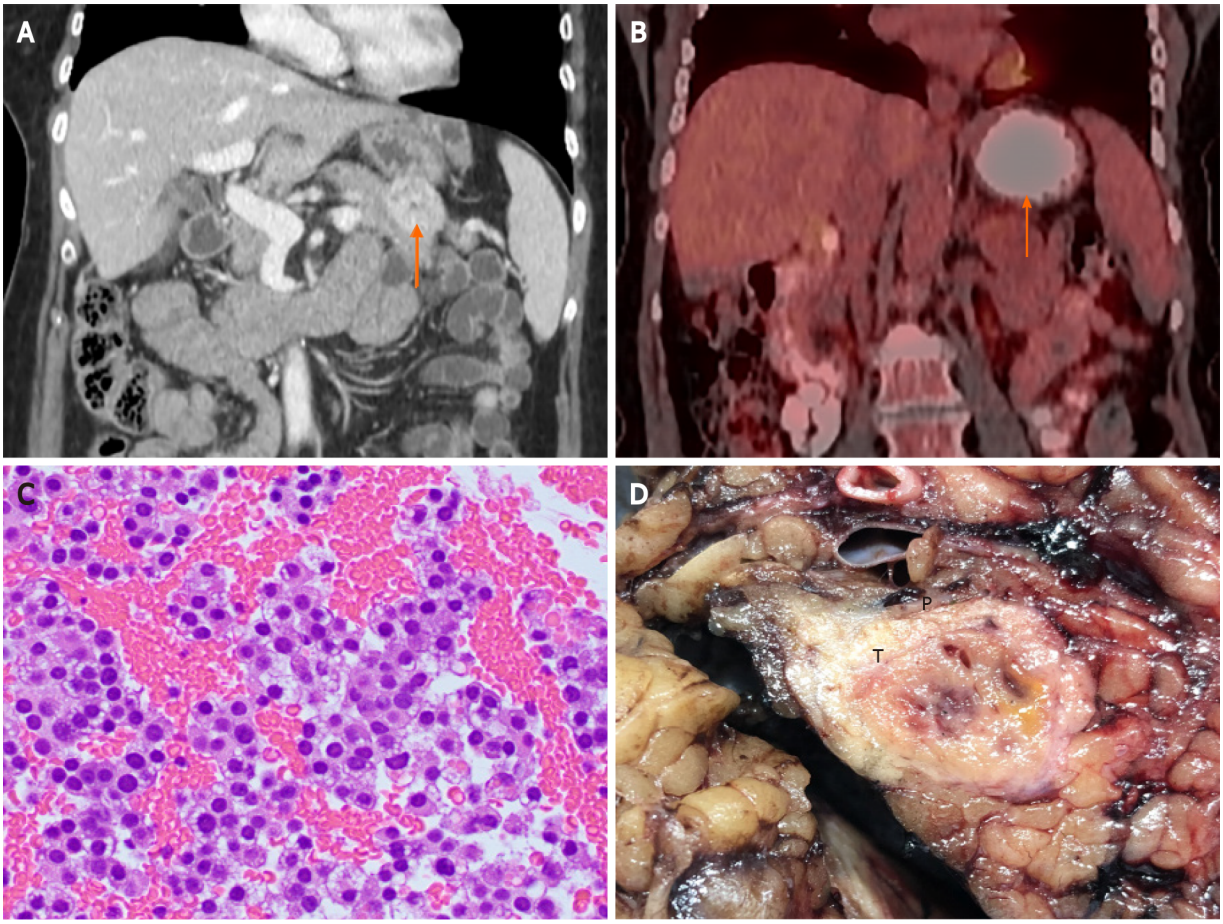
within the crypts of Lieburkuhn. Therefore, C-NETs typically show EC cell features, including insular growth patterns and CDX2 immunoreactivity. Necrosis is usually absent. The preferred treatment is colectomy with lymphadenectomy.

Rectal NETs (R-NETs) are relatively smaller (< 1 cm), smooth, round polypoid lesions and generally have a better prognosis than their counterparts in the colon. R-NETs are subgrouped into the L-cell (glucagon-like peptide and pancreatic polypeptide producing) type and non-L-cell type according to their origin[67], with the L-cell type being the dominant type. L-cell R-NETs typically present with trabecular or tubular growth patterns. Of note, non-L-cell-type rectal NETs usually present as larger masses and have an increased risk of lymphovascular invasion and worse prognosis[68].

For the purpose of tumor staging, it is recommended to use EUS and MRI of the pelvis to determine the depth of invasion and lymph node status and to use SRS-based scans to determine distant metastases. Endoscopic mucosal resection and endoscopic submucosal dissection are indicated for small (1 cm or smaller) and superficial R-NETs if there is no evidence of muscularis propria invasion or lymph node metastases[69]. For R-NETs larger than 2 cm in size, low anterior resection or abdominal resection is recommended.

Pancreatic NENs

As rare neoplasms, the incidence rate for pancreatic NENs (P-NENs) is 1.0 new cases *per* 100000 individuals *per* year in the United States[70] and accounts for 2%-4% of all pancreatic neoplasms[71]. All P-NETs are considered to have malignant potential. These tumors are derived from pancreatic islet cells and could be subclassified into functioning and nonfunctioning subgroups. Functioning P-NETs, including insulinoma, gastrinoma, VIPoma, and glucogonoma, cause clinical hormone hypersecretion syndromes. The clinical presentations of functioning P-NETs are mostly related to hormone effects, such as hyperglycemia in insulinoma and large-volume secretory diarrhea in VIPoma. In contrast, nonfunctioning P-NETs are usually incidental findings on imaging studies for other causes or mass effects at late stages. With the increased use of imaging studies, nonfunctioning P-NENs have become more common, accounting for more than 60% of all P-NENs[72].



Insulinoma and gastrinoma are the two most common functioning P-NETs. In suspected cases of insulinoma, 72-h fasting tests for blood glucose, insulin, C-peptide, and proinsulin levels should be performed together with drug tests for sulfonylurea. In suspected cases of gastrinoma, laboratory testing includes fasting gastrin level and gastric pH. Laboratory testing for serum glucagon and VIP levels would be helpful for the diagnosis of glucagonoma and VIPoma. The circulating CgA level is also a sensitive and specific diagnostic marker for P-NETs, with the exception of insulinoma[73], and it has no added value for the diagnosis of nonfunctioning P-NETs.

The most common imaging studies for P-NENs include EUS, CT, MRI, and 68Ga-dotatate PET. Radiolabeled glucagon-like peptide-1 receptor (GLP-1R) scintigraphy is another sensitive tool to detect small insulinomas[74]. Based on our experience, P-NETs could appear as thin-walled cystic lesions with no communication with the pancreatic duct (Figure 4) that clinically and radiologically may mimic mucinous cystic neoplasms. Clinicians and pathologists should be aware of this unusual presentation to avoid misdiagnosis.

Microscopically, P-NETs are well-differentiated neoplasms that do not differ from NETs from other primary sites (Figure 5). One or more neuroendocrine markers (CgA, SYN, CD56, and neuron-specific enolase) and one epithelial marker (cytokeratin AE1/AE3 and CAM5.2) are indicated for the diagnosis of P-NENs. Ki-67 immunoreactivity is warranted to assign tumor grade. Insulin immunoreactivity is necessary in the diagnosis of insulinoma in cases of multifocal tumors or insulinomatosis. In the cases of metastatic disease, some markers (Pax 6, Pax8, ISL-1, PDX-1, and CDX2) could be helpful to determine pancreatic origin[75].

Surgical resection is the preferred and only curative therapy for P-NENs. Conservative management was suggested for small (< 2 cm) low-grade nonfunctioning P-NETs due to their excellent prognosis[76, 77]. However, even for small-sized nonfunctioning P-NETs, surgical resection is indicated in cases with high-risk features (55 years or older, grade 3 tumor, and distant metastases)[78]. Local resection or enucleation could be applied in localized and easily accessible disease to maximally reserve pancreatic tissue[79], especially if the tumor is located more than 2-3 mm from the pancreatic duct. Depending on the tumor location, surgical resection procedures for P-NENs include partial pancreaticoduodenectomy and distal pancreatectomy. Regional lymphadenectomy is recommended for surgical resection of P-NENs.

P-NENs commonly present with liver metastases. Surgical resection should be considered in metastatic disease for both nonfunctioning and functioning P-NENs. The presence of liver metastases is not a counterindication to surgical management for P-NEN patients[80]. Efforts should be made if surgical removal is feasible for both primary pancreatic tumors and metastatic liver lesions. However, it is still under debate whether to resect the primary tumor in cases of unresectable metastatic liver lesions. Surgical resection of metastatic liver lesions should be avoided in cases with unresectable primary P-NENs[81].

NOVEL THERAPEUTIC APPROACHES

The treatment options for advanced and metastatic GEP-NENs have significantly expanded during the past two decades[82,83]. Some important clinical studies, including the PROMID[84] and CLARINET [85] trials, have demonstrated a significant efficacy of SSA in the control of tumor growth in patients with metastatic GEP-NETs. A recent CLARINET FORTE phase 2 clinical trial further supports the clinical benefit of the SSA lanreotide autogel (LAN), which led to significantly improved progression-free survival (PFS) and disease control rate in patients with GEN-NETs, especially in cases with a Ki67 index ≤ 10%[86]. In addition to SSA[87], novel therapeutic approaches, including PRRT, targeted therapy, and immunotherapy, have demonstrated promising clinical benefits[88-90].

PRRT is a type of systemic radiotherapy specifically targeting tumor cells expressing SSTR[91]. In the phase 3 NETTER-1 trial, for patients with metastatic well-differentiated midgut NETs, treatment with ^{177}Lu-dotatate led to a significantly improved PFS (median PFS not reached *vs* 8.4 mo in the control group with high-dose octreotide alone) and an improved radiographic response rate (18% *vs* 3% in the control group)[92]. The most common adverse effects for ^{177}Lu-dotatate are nausea and vomiting. Based on this trial, PRRT with ^{177}Lu-dotatate has been approved for patients with advanced GEP-NETs and SSTR expression on imaging.

Due to the hypervascularity in GEP-NETs, multiple clinical trials have investigated the therapeutic effects of targeted therapy against vascular endothelial growth factor (VEGF) receptors. In a phase 3 trial, patients with low- to intermediate-grade P-NETs received placebo *vs* sunitinib, a tyrosine kinase inhibitor targeting multiple receptors, including VEGF receptors-1, 2, and 3. Sunitinib led to a significantly longer median PFS [11.4 mo *vs* 5.5 mo in the control group; hazard ratio (HR) for progression or death, 0.42; $P < 0.001$][93]. Sunitinib has been approved for patients with advanced P-NETs.

mTOR is a multifunctional serine/threonine kinase related to NET growth. mTOR pathway genes, including *PTEN*, *TSC2*, and *PIK3CA*, are also frequently mutated in NETs. Multiple clinical trials have been conducted to test the treatment effect of the mTOR inhibitor everolimus in GEP-NETs. In the

RADIANT-3 trial, for patients with advanced P-NETs, everolimus treatment led to a significantly longer median PFS (11 mo *vs* 4.6 mo in the control group; HR: 0.35)[94]. In the RADIANT-4 trial, patients with advanced nonfunctioning GI and lung NETs had a longer median PFS in the everolimus arm (11 mo *vs* 3.9 mo in the control group; HR: 0.48)[95]. Everolimus is approved for patients with advanced P-NETs and nonfunctioning GI NETs.

Immune checkpoint inhibitors and antibodies targeting programmed cell death protein-1 (PD-1), programmed cell death protein ligand-1 (PD-L1), or cytotoxic T lymphocyte-associated antigen 4 (CTLA-4), have demonstrated promising therapeutic responses in various types of cancers[96]. Based on the durable antitumor efficacy and favorable safety profile in patients with advanced metastatic Merkel-cell carcinoma, a high-grade cutaneous NEC[97], immunotherapy has been proposed to be potentially effective for advanced NENs with microsatellite instability, high tumor burden, and/or mutational load [98]. Multiple clinical trials have been conducted to test the efficacy of immunotherapy in GEP-NENs. Currently, these studies only showed very limited therapeutic effects for GEP-NENs[99-101]. Interestingly, in a phase 1b trial on toripalimab (an anti-PD-1 antibody) for patients with high-grade NENs, patients with PD-L1 expression greater than 10% and/or high tumor mutational burden (TMB) had a better objective response rate (ORR) than low PD-L1 (< 10%) (50.0% *vs* 10.7%, $P = 0.019$) and low TMB patients (75.0% *vs* 16.1%, $P = 0.03$)[100]. Therefore, PD-L1 expression is a potential therapeutic and prognostic biomarker for GEP-NENs.

CONCLUSION

GEP-NENs are relatively rare tumors, although the incidence rates have been steadily increasing over the past three decades. GEP-NENs consist of a genetically heterogeneous group of tumors ranging from slow-growing, well-differentiated NETs to aggressive, poorly differentiated NECs. Great progress has

been made toward understanding their unique molecular genetics and combating advanced disease through improved diagnostic tools and effective therapeutic regimens. A multidisciplinary and personalized treatment approach would be crucial to achieve optimal clinical outcomes for patients with GEP-NENs.

Abstract

Theranostics is the highly targeted molecular imaging and therapy of tumors. Targeted peptide receptor radionuclide therapy has taken the lead in demonstrating the safety and effectiveness of this molecular approach to treating cancers. Metastatic, well-differentiated gastroenteropancreatic neuroendocrine tumors may be most effectively imaged and treated with DOTATATE ligands. We review the current practice, safety, advantages, and limitations of DOTATATE based theranostics. Finally, we briefly describe the exciting new areas of development and future directions of gastroenteropancreatic neuroendocrine tumor theranostics.

Key Words: DOTATATE; Theranostics; Gastroenteropancreatic neuroendocrine tumors; ^{68}Ga DOTATATE; ^{177}Lu DOTATATE; Review

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: ^{68}Ga and ^{64}Cu DOTATATE positron emission tomography imaging is the most sensitive and accurate method to identify well-differentiated gastroenteropancreatic neuroendocrine tumors (GEP-NETs). The paired therapeutic radiotracer, ^{177}Lu DOTATATE, delivers targeted radiation which can prolong progression free survival. This is now established as the therapeutic best standard of care for patients with progressive, metastatic, or unresectable well-differentiated somatostatin receptors positive GEP-NETs. Ongoing investigations continue to expand the potential indications for DOTATATE theranostics. Additional novel ligands are also currently being developed for targeted imaging and therapy of GEP-NETs.

INTRODUCTION

Neuroendocrine tumors (NETs) are a relatively rare and heterogeneous group of tumors arising from neuroendocrine cells throughout the body, which can cause a variety of symptoms based on the location and cell type. Midgut NETs are the most common, with the small bowel being the most frequent site of the primary lesion[1,2]. Although the incidence is relatively low, the majority are slow-growing, well-differentiated tumors which effectively contributes to a high prevalence. Improved clinical, laboratory, and imaging detection also likely contribute to an apparent increasing prevalence. NETs are often detected incidentally or after they metastasize and cause clinical symptoms either from their hormonal release and/or from mass effect.

Gastroenteropancreatic neuroendocrine tumors (GEP-NETs) comprise the majority of NETs (over 75%), with lung NETs comprising an additional approximately 15%[1]. GEP-NETs are characterized according to the WHO 2010 classification system based on the Ki-67 index, a widely used marker of cell proliferation. In this classification, GEP-NETs are scored as G1 (Ki-67 ≤ 2%), G2 (Ki-76 = 3%-20%), or G3 (Ki-67 > 20%), with G1 and G2 classified as well-differentiated tumors, and G3 tumors classified as poorly differentiated/de-differentiated carcinomas. Further stratification of G3 tumors can be assigned into well-differentiated (Ki-67 20%-50%) and poorly differentiated carcinomas (Ki-67 > 50%). This classification system, as well as the proposed subdivision of G3 tumors, has prognostic utility and helps direct appropriate diagnostic imaging and therapy.

The majority of well differentiated GEP-NETs (> 90%) express the G-coupled protein somatostatin receptors (SSTR)[3-5]. The WHO classification typically correlates with SSTR expression with well-differentiated tumors (G1 and G2) highly expressing SSTRs, and poorly differentiated tumors (G3) having lower SSTR expression. Diagnostic imaging and targeted radionuclide therapy take advantage of tumor SSTR expression by utilizing radiopharmaceuticals that bind to the same ligand. This elegant duality is emblematic of the expanding field of "theranostics", a portmanteau of therapy and diagnostics.

In this paper, we review the current approaches to the diagnosis and treatment of GEP-NETs. We focus primarily on DOTATATE (^{68}Ga DOTATATE and ^{64}Cu DOTATATE) positron emission tomography (PET)/computed tomography (CT) imaging and ^{177}Lu DOTATATE peptide receptor radionuclide therapy (PRRT), and conclude with future directions of GEP-NET theranostics.

DOTATATE PET IMAGING

Somatostatin is an endogenously produced peptide hormone that binds to various SSTRs. In humans, there are 5 subtypes[6], with GEP-NETs predominantly expressing SSTR-2 both in the primary tumor and in their metastases[7].

The currently approved nuclear medicine DOTATATE PET imaging agents used to bind SSTR-2 are composed of three functional parts: (1) The radioactive PET imaging component (^{68}Ga or ^{64}Cu); (2) The PET radiometal chelator and linker, DOTA (tetraazacyclododecanetetraacetic acid); and (3) The peptide binding part, TATE (tyrosine-3-octreotate)[8]. The earlier imaging agents used to visualize GEP-NETs was a single photon octreotide-based agent, [^{123}I-Tyr^3]octreotide[4], followed by ^{111}In pentetreotide (Octreoscan, Mallinkcrodt)[9]. ^{111}In pentetreotide remained the mainstay of GEP-NET imaging until the approval of the PET imaging agents. Both ^{68}Ga DOTATATE and the closely related ^{68}Ga DOTATOC have received approvals in Europe and the United States[10,11], as has the more recently approved ^{64}Cu

DOTATATE. Because of the extremely high binding affinity of ^{68}Ga DOTATATE to SSTR-2 (approximately 100 times greater than ^{111}In-pentetreotide)[12], the superior imaging characteristics of PET compared to SPECT, and the lower radiation delivered, DOTATATE PET imaging is now recommended in all cases over ^{111}In-pentetreotide[13], including use in both adults and children[14].

Indications

The appropriate use criteria for SSTR imaging in cases of known or suspected well-differentiated NETs with ^{68}Ga- and ^{64}Cu DOTATATE PET/CT imaging and ^{177}Lu DOTATATE peptide receptor radionuclide have been recently summarized[13]. These include the following nine indications: (1) Initial staging after the histologic diagnosis of NET; (2) Evaluation of an unknown primary; (3) Evaluation of a mass suggestive of NET not amenable to endoscopic or percutaneous biopsy; (4) Staging of NET before planned surgery; (5) Monitoring of NET seen predominantly on SSTR PET; (6) Evaluation of patients with biochemical evidence and symptoms of a NET; (7) Evaluation of patients with biochemical evidence of a NET without evidence on conventional imaging or a prior histologic diagnosis; (8) Restaging at time of clinical or laboratory progression without progression on conventional imaging; and (9) New indeterminate lesion on conventional imaging with unclear progression[13].

In addition to its primary use in GEP-NETs, ^{68}Ga DOTATATE PET has been used to image other SSTR positive tumors such as paragangliomas, pheochromocytomas, neuroblastomas, meningiomas, medullary thyroid cancers, Merkel cell carcinomas, small cell carcinomas, esthesioneuroblastomas, and tumor-induced oncogenic osteomalacia[8].

Technique

^{68}Ga DOTATATE is readily compounded from generator eluted ^{68}Ga and a sterile vial kit[15]. Before intravenous administration, there is little patient preparation except for good hydration and frequent voiding to minimize radiation dose to the kidneys. An uptake phase between radiotracer administration and PET imaging is typically approximately 60 min, similar to ^{18}F fluorodeoxyglucose (FDG) PET. This allows time for tumor uptake and for background washout clearance *via* the kidneys, which is analogous to the procedure used in FDG PET. Patients are typically imaged from the mid-thigh to the skull. In cases where tumor is known or suspected outside of this field of view, or in cases of unknown primary, longer imaging times may be needed to include the extremities. Intravenous contrast is not essential for accurate interpretation in most cases, but it can be helpful in some clinical settings. Additional procedural details are listed in the European Association of Nuclear Medicine guidelines [14].

Many patients with GEP-NETs will be on short- or long-acting somatostatin analogue (SSA) therapy which could interfere with ^{68}Ga DOTATATE PET uptake due to competitive binding. Temporary discontinuation of short-acting SSAs is recommended for 24-48 h, and long-acting SSAs should be avoided for approximately 4-6 wk[8,16]. Long-acting release (LAR) SSAs are administered on 4 wk cycles, allowing ^{68}Ga DOTATATE imaging to be scheduled for the end of the monthly cycle prior to redosing. Regardless of the specific approach, subsequent ^{68}Ga DOTATATE scans are preferably performed with the exact timing between SSA injections.

Normal biodistribution

The normal biodistribution of ^{68}Ga DOTATATE differs in several aspects compared to the most commonly used radiotracer, ^{18}F FDG. For both ^{68}Ga DOTATATE and ^{18}F FDG, the genitourinary tract is the normal route of excretion for unbound radiotracer, and thus high radiotracer activity can be seen in the kidneys, ureters, and bladder. In ^{68}Ga DOTATATE, the spleen has the highest normal activity, followed by the adrenal glands[17]. Unlike FDG, the pituitary is the only part of the central nervous system with high physiologic uptake. Salivary glands and the thyroid can have moderate uptake. Activity in the pancreas is variable and occasionally focal in the head and uncinate process[18]. Variable but typically lower-level diffuse uptake is seen in the small and large bowel[8]. Physiologic uptake in the liver can be quite variable[19], and uptake can be low in the spleen and liver if total body tumor burden is high ("sink effect")[20]. ^{68}Ga DOTATATE uptake is otherwise low throughout the muscles, adipose tissue, and bone.

Dosimetry

The recommended dose for ^{68}Ga DOTATATE is 2 MBq/kg of body weight (0.054 mCi/kg) up to 200 MBq (5.4 mCi). The organ with the highest dose delivered is the spleen due to its high uptake. The whole body radiation effective dose equivalent (EDE) from ^{68}Ga DOTATATE PET is 2-3 mSv[21,22], which is approximately only 10% of the 26 mSv received from a typical dose (222 MBq or 6 mCi) of ^{111}In pentetreotide. Despite the addition of an EDE of 1-9 mSv from the CT component, which is needed for attenuation correction and anatomic localization, the total dose of ^{68}Ga DOTATATE PET/CT (3-12 mSv) remains significantly lower than that of ^{111}In pentetreotide.

Imaging performance

Due to the very high affinity of ^{68}Ga DOTATATE for SSTR-2, target lesions typically show extremely

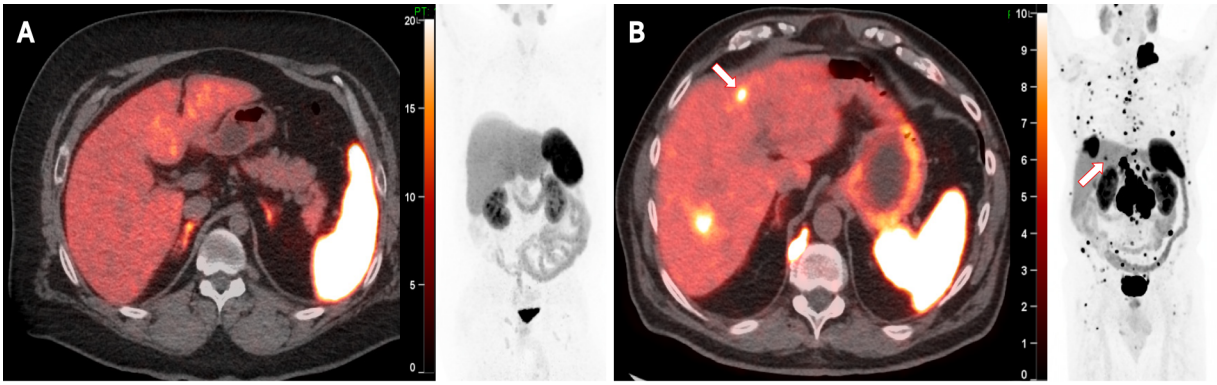
high uptake. With deficient (*i.e.*, very low) background radiotracer uptake throughout most of the body including the thorax, head and neck, bone marrow, muscle, and brain (except the pituitary), the tumor to background ratio can be exceptionally high. In a large prospective study of GEP-NETs comparing accuracy of ^{68}Ga DOTATATE, conventional imaging [CT and magnetic resonance imaging (MRI)], and ^{111}In pentetreotide, ^{68}Ga DOTATATE showed clear superiority in lesion detectability with mean tumor SUVmax values of over 65[23]. Figure 1 shows an example of normal intense uptake in the spleen and adrenals and moderate ^{68}Ga DOTATATE uptake in the liver. Small liver lesions can also be visualized despite relatively high liver background activity. Extremely high radiotracer activity can be seen in larger lesions, as shown in Figure 2.

False positives are uncommon and do not typically present a diagnostic dilemma. The most common causes of false positives are inflammation or infection due to leukocytes and macrophages expressing SSTR-2[24]. For example, inflammatory prostatitis is relatively common and can show intense focal uptake within the prostate[25]. Other potential causes of false positive can arise from osteoblastic activity[26], such as in degenerative changes, fractures, fibrous dysplasia, vertebral hemangiomas, and epiphyses in pediatric patients[27,28].

False negative results may be due to loss of receptor expression. GEP-NETs that dedifferentiate and subsequently lose SSTR-expression may show lower ^{68}Ga DOTATATE avidity. Another cause of false negatives, as seen in PET imaging, may arise from small lesions below PET resolution. In our experience, however, the highly avid ^{68}Ga DOTATATE uptake in well differentiated GEP-NETs is commonly adequate to overcome the limitations of partial volume effect. If tumor uptake is sufficiently high, it can also overcome the detrimental effects of a relatively low administered dose and other physical limitations of ^{68}Ga compared to ^{18}F[29-32]. Small lesions can be readily visualized in phantom and patient clinical studies if the background activity is low. The non-contrast portion of the CT frequently does not reveal hepatic lesions; however, hepatic GEP-NETs as small 5 mm may be visualized despite high normal background liver activity[30].

Role in evaluation and value in management

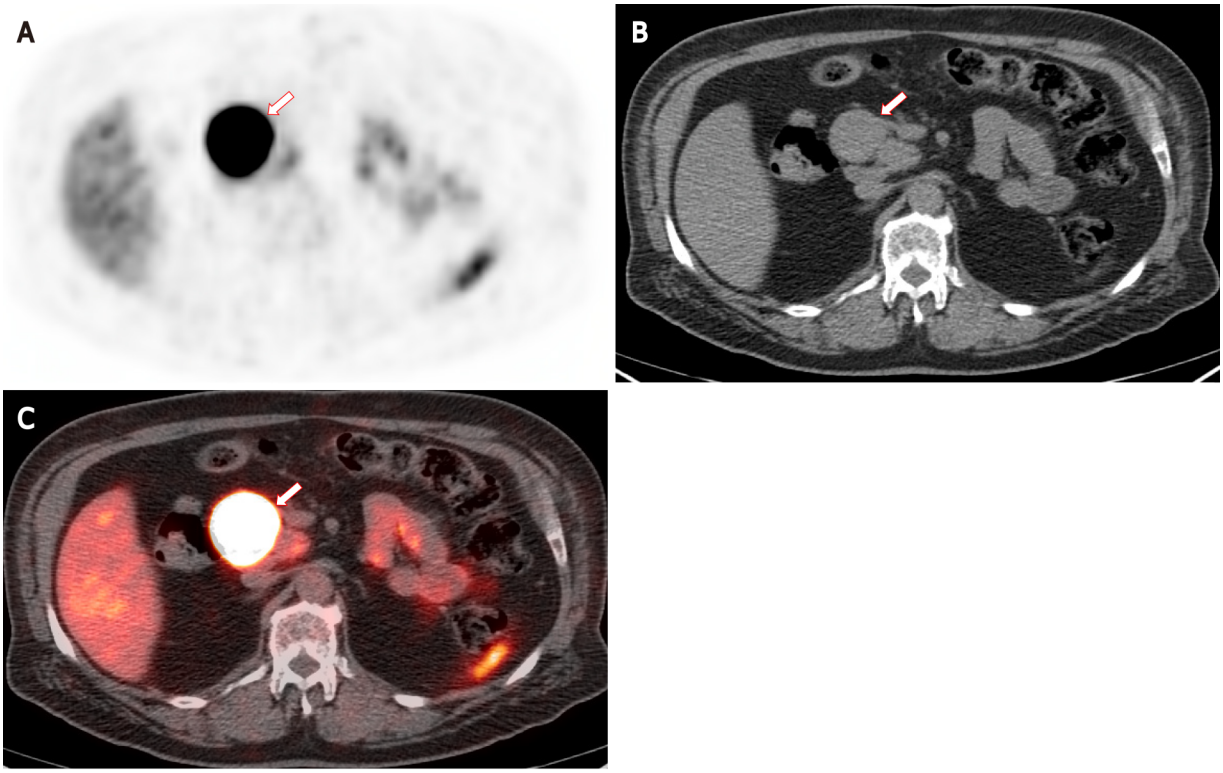
^{68}Ga DOTATATE PET is an excellent study for evaluating GEP-NETs and demonstrates very high sensitivity and specificity of 93% and 95%, respectively[33]. Its superior performance in detecting GEP-NETs compared to ^{111}In pentetreotide and CT or MRI is well established[23]. This can result in a significant change in clinical management in up to a third of patients even when compared to ^{111}In pentetreotide[34-36]. ^{68}Ga DOTATATE has also shown increasing utility in detecting lesions not seen on other modalities. It can confirm suspicion of GEP-NET found on other modalities, determine the true extent of tumor, stage disease, identify otherwise occult tumors such as thoracic ACTH-secreting carcinoids, and guide treatment options. It may be used to confirm a clinical or biochemical suspicion of GEP-NET, identify the primary lesion in known metastatic disease, determine resectability, exclude greater extent of disease prior to resection, and importantly, identify candidates for hormonal therapy or PRRT[8].



^{64}Cu DOTATATE

The primary practical advantage of ^{64}Cu DOTATATE is its longer physical half-life (^{64}Cu t½ = 12.7 h). This allows for more flexibility in production, shipment to distant locations, and flexibility in the timing of PET imaging. ^{68}Ga DOTATATE (^{68}Ga t½ = 68 minutes) is typically produced at a site close to the PET imaging center due to the short physical half-life. ^{64}Cu DOTATATE allows flexibility for delayed imaging three hours after injection with no significant difference in lesion detectability[37]. Compared to the DOTATOC ligand, the ^{64}Cu DOTATATE showed slightly higher lesion detectability than ^{68}Ga DOTATOC[38]. Other differences between ^{64}Cu compared to ^{68}Ga do not appear to have a large clinical impact on lesion detectability. ^{64}Cu compared to ^{68}Ga has a disadvantage in a lower percentage of positrons emitted *per* decay (17.5% *vs* 88.9%). However, ^{64}Cu has the physical advantage of shorter mean positron range prior to annihilation (0.7 mm *vs* 3.5 mm) which can improve spatial resolution[39]. Data are emerging to support quantitative imaging of ^{64}Cu DOTATATE which correlates with prognosis[40, 41]. Finally, pre-clinical studies of new investigational agents, such as ^{55}Co DOTATATE, show the potential for further improvements in tumor uptake and image contrast when compared to currently approved agents[42].

Role of FDG-PET



FDG is a glucose analogue that enters cells through glucose transporters, undergoes phosphorylation, and then remains trapped within the cell as FDG-6-phosphate. This imaging metric of glycolysis is frequently upregulated in many cancers and generally associated with more aggressive, rapidly growing malignancies.

Well differentiated GEP-NETs, however, are typically slower growing, have lower mitotic rates, and have lower rates of proliferation including lower Ki-67 indices. The WHO classification of GEP-NETs relies on the Ki-67 index which reflects cellular proliferation. As GEP-NETs become more dedifferentiated, they tend to lose SSTRs expression and decrease in ^{68}Ga DOTATATE avidity. These often exhibit a more aggressive and faster growing phenotype with increasing proliferation (Ki-67) and increasing

glycolytic activity. Clinically, when a known GEP-NET tumor increases in size, yet decreases in ^{68}Ga DOTATATE avidity, an FDG-PET can be useful in identifying tumor which may be exhibiting this dedifferentiating phenotype ("flip-flop" effect), and warrant consideration of a change in therapy. Patients with NETs demonstrating FDG avid disease are at a 10 fold increased risk of death[43]. Other studies have shown similar findings[44,45].

FDG PET may also be useful in identifying heterogeneity of tumors by directing biopsy of tumors suspicious for a more aggressive or higher-grade histology. When both ^{68}Ga DOTATATE PET-CT and FDG PET-CT are performed, the differential imaging features may assist in prognosis and guide therapy options. FDG PET can therefore be complementary and aid in management decisions in which tumor dedifferentiation is suspected. An example of an FDG positive hepatic metastasis is shown in Figure 3.

Figure 3 73 year old female with well-differentiated neuroendocrine tumor (Ki-67 = 6%) and liver metastases with an unknown primary. A: ^{68}Ga DOTATATE positron emission tomography (PET)/computed tomography (CT) fusion and whole-body PET projection confirms multifocal hepatic metastases SUVmax 34.4 with an area of focal decreased DOTATATE avidity (arrow); B: Fluorodeoxyglucose (FDG) PET/CT fusion and whole-body PET shows mismatched focal intense increased FDG uptake SUVmax 9.1 (arrow), suggestive of heterogeneous tumor phenotype with areas of dedifferentiation.

THERAPY

Treatment options

Partial or complete surgical resection of GEP-NET is the preferred approach when possible[46]. Hormone therapy is another mainstay of GEP-NET treatment. Short- or long-acting SSAs bind to SSRTs and inhibit or slow tumor growth while simultaneously helping with hormone secretion related symptoms. Additional treatment options may include mTOR inhibitors, VEGF inhibitors, chemotherapy, radiation, and liver metastases directed embolization therapies[47]. More recently, ^{177}Lu DOTATATE PRRT has been established as a safe and effective treatment of metastatic GEP-NETs.

PRRT

PRRT is the logical extension of SSTR imaging into the treatment realm and comprises the therapy component of theranostics. The imaging radionuclide (^{68}Ga or ^{64}Cu) is replaced with a beta emitter, ^{177}Lu, which deposits lethal radiation precisely to the SSTR-2 positive cells, providing targeted radiotherapy to tumors. The resultant ^{177}Lu DOTATATE radionuclide delivers local radiation specifically to tumor visualized on ^{68}Ga DOTATATE imaging. ^{177}Lu is primarily a beta emitter with a mean range of 2 mm in tissue, and a small fraction is gamma radiation (6.6% at 113-keV and 11% at 208-keV). This results in a relatively low exposure to individuals surrounding the patient, allowing therapies to be performed as an outpatient. The relatively long half-life of 6.7 d (160 h) delivers sustained radiotherapy for a prolonged period; however, this requires extended precautions to avoid exposure from urinary contamination. ^{177}Lu DOTATATE (Lutathera) was approved by the EMA in 2017 and by the FDA in January 2018[47].

Patient selection

^{177}Lu DOTATATE was approved specifically for treatment of SSTR-positive GEP-NETs that have progressed on SSA therapy[47]. The most appropriate patients for therapy are based upon guidelines developed by the NETTER-1 trial[48]. There are multiple considerations for patient selection for PRRT; however, patients with progressive metastatic low and intermediate grade GEP-NETs typically have highly positive SSTR scans and are most likely to benefit.

Technique

The standard protocol for ^{177}Lu DOTATATE therapy is based upon the NETTER-1 trial[48]. Patients are prescribed four doses of 7.4 GBq (200 mCi) eight weeks apart for a cumulative dose of 29.6 GBq (800 mCi). At least 30 min prior to therapy administration, an amino acid infusion is started for renal protection and lasts four hours. The two amino acids required for renal protection are arginine and lysine. Although other formulations of different amino acids exist, they do not provide any additional benefit and can cause significant nausea and vomiting.

Based on the typical dose of 7.4 GBq of ^{177}Lu DOTATATE, the exposure rate at 1 m is 2 mR/h and decreases by 50% within 24 h[47]. If the patient is able to abide by standard radiation safety precautions, this can be performed as an outpatient. Precautions include bathroom hygiene, similar to radioiodine treatments, and appropriate distancing from others, specifically children and pregnant women, for approximately 3 d after therapy. Individualized safety instructions may be prepared by a radiation safety officer or radiation physicist, depending on the institution, and reviewed with the patient during the consent process.

Efficacy

^{177}Lu DOTATATE therapy in GEP-NETs has demonstrated efficacy in many studies over several years. The most notable large prospective randomized trial is the NETTER-1 trial[48]. This prospective randomized trial in adults with biopsy-proven low- and intermediate grade (G1 or G2, *i.e.*, Ki-67 level ≤ 20%) GEP-NETs evaluated subjects treated with ^{177}Lu DOTATATE and SSA compared to a control group on high dose SSA alone. Inclusion criteria were metastatic disease or locally advanced and inoperable disease which was progressing on SSA[48].

The primary endpoint of the study was progression free survival (PFS) with secondary endpoints of objective response rate (ORR), overall survival (OS), safety, and the side-effect profile. Patients were judged to have failed treatment if there was tumor progression based on follow up imaging by CT or MRI according to RECIST 1.1 criteria[49].

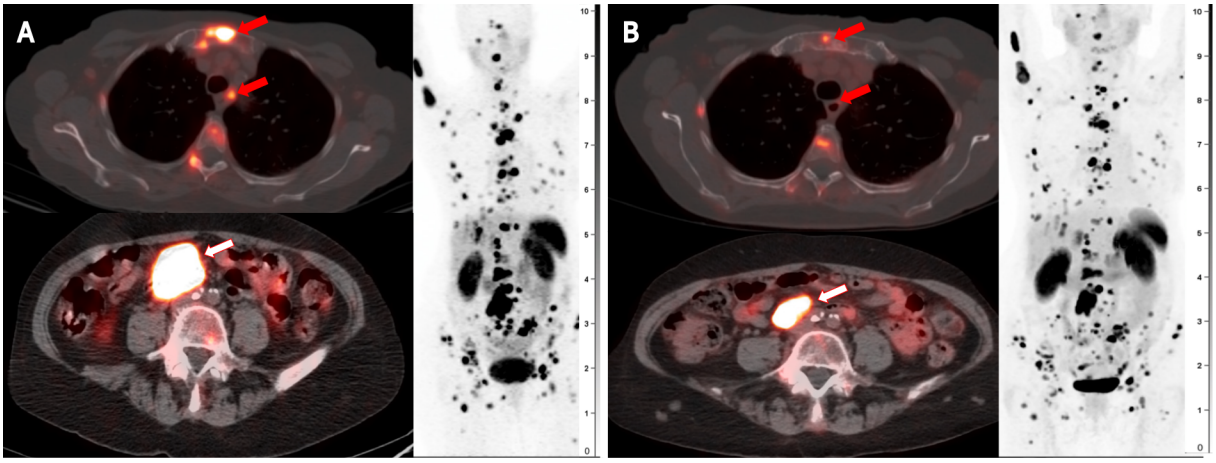
Patients in the treatment arm experienced significantly better PFS at 20 mo of 65.2% (95%CI: 50.0-76.8) compared to 10.8% (95%CI: 3.5-23.0) in the control group. In other words, in the treatment group there was a 79% lower risk of disease progression or death and a 60% lower risk of death alone. The secondary endpoint of ORR was 18% in the treatment group and 3% in the control group. As noted in the NETTER-1 study, multiple large randomized trials with other systemic therapies, such as SSAs alone or in combination with other non-radionuclides, showed response rates of only 5% or less[50-53]. Median overall survival could not be calculated yet at the conclusion of NETTER-1, but there was a trend towards longer overall survival in the treatment group. An example of a patient with partial response to ^{177}Lu DOTATATE is shown in Figure 4.

Adverse side effects and overall safety

In NETTER-1, transient WHO grade 3 and 4 hematologic toxicity (thrombocytopenia 2%; lymphopenia 9%; neutropenia 1%) and no renal toxicity were reported after 14 mo of follow up[48]. Rare but serious side effects including acute leukemia and myelodysplastic syndrome have been reported, occurring in < 1% and < 1%-2% of patients, respectively[47,48,54]. Other studies have similarly shown limited side effects with ^{177}Lu DOTATATE therapy[54,55].

Common mild side effects (Grade 1 or 2) include nausea (59%) and vomiting (47%)[48]; however, this has been primarily attributed to the specific amino acid infusion. Use of the simpler arginine and lysine infusion appears to have much lower incidence and severity of side effects. Fatigue (40%), decreased appetite (18%), headache (16%), and alopecia (11%) were significantly higher in the ^{177}Lu DOTATATE treatment group[48]. Although relatively frequent, abdominal pain (26%), and diarrhea (29%) were not statistically different compared to the control group. An uncommon side effect of treatment is hormone crisis, which in one study of 504 patients happened in only 6 (or 1.2%) and can be adequately managed in a brief hospital stay with complete recovery[54].

FUTURE DIRECTIONS



While ^{68}Ga- and ^{177}Lu DOTATATE have shown remarkable efficacy in imaging and treatment of GEP-NETs, many additional imaging and treatment options are currently under investigation. A comprehensive review is not possible in the context of the rapidly evolving landscape of theranostics. A few representative clinical trials are briefly mentioned to provide a perspective of the breadth of ongoing investigations.

Current clinical trials

Extending PRRT into higher grade GEP-NETs is an active area of investigation. The COMPOSE trial compares well-differentiated higher grade (G2 or G3, Ki-67 index between 10%-55%) GEP-NETs treated with ^{177}Lu Edotreotide (DOTATOC) compared to best standard of care chemotherapy regimens[56]. The COMPETE trial similarly evaluates advanced GEP-NETs for safety and efficacy of ^{177}Lu DOTATOC compared to Everolimus[57]. The NETTER-2 trial investigates higher proliferation index tumors (G2 or G3) as first line therapy with ^{177}Lu DOTATATE therapy and SSA compared to high dose SSR therapy alone[58].

^{177}Lu DOTATATE retreatment

While ^{177}Lu DOTATATE is now given as a four dose regimen, additional doses have been administered on an investigational basis. If a patient shows continued improvement in tumor burden and symptoms throughout the ^{177}Lu DOTATATE treatment course established by NETTER-1, (four cycles, 8 wk apart), they may benefit from continued treatment with additional doses of ^{177}Lu DOTATATE. A meta-analysis suggests that ^{177}Lu DOTATATE re-treatment in patients with advanced GEP-NETs is well tolerated with a safety profile similar to initial PRRT[59]. This provides an additional treatment strategy potentially to improve PFS, OS, and disease related survival.

A: Pre-therapy; B: Post-therapy. (A; top) Sternal osseous metastases are partially improved (red arrow; B top), and a mediastinal node is resolving (red arrow; paratracheal). (Bottom row) Dominant pelvic nodal mass (A; white arrow) has decreased (B; white arrow) in size 3.3 × 2.1 (previously 3.7 × 2.6), and uptake SUVmax 39.6 (previously 46.8).

Alternative PRRT agents

Either systemic or arterially-delivered PRRT with ^{90}Y DOTATATE or -DOTATOC is an approach that is under further investigation. ^{90}Y is beta emitter with a higher energy and longer mean free path in soft tissue than ^{177}Lu. This theoretically favors treatment of larger tumors where high intratumor pressure limits blood flow and radiotracer delivery. However, a variety of factors mediate tumor killing including bystander effect[60]. A major limiting drawback of ^{90}Y is its greater toxic effects to surrounding tissues and bone marrow[61]. Renal dose is also higher than ^{177}Lu which poses a higher risk of nephrotoxicity[62]. Arterially-administered ^{90}Y DOTATATE is more focally directed but is operator intensive and requires a prolonged procedure typically performed in the interventional radiology suite.

Novel imaging and treatment agents

Antagonists: In contrast to the established SSTR agonists (*e.g.*, DOTATATE), somatostatin antagonists are currently being investigated for imaging and therapy of GEP-NETs. Agonist-ligand complexes are internalized into the cell and entrapped, which is believed to generate higher contrast imaging and prolonged tumor targeted therapy. Antagonists were developed to evaluate the functions of receptors [63] and are typically not internalized, but this may be overcome by binding to a higher number of receptor sites than agonists[64]. The SSTR-2 antagonist JR11 has shown uptake in renal cell cancers, most breast cancers, non-Hodgkin lymphomas, and medullary thyroid cancers with binding comparable to NET targeting with SSTR-2 agonists[65]. This study also showed that peritumoral vessels, lymphocytes, nerves, mucosa, and stroma were more strongly labeled with the antagonist than with the agonist. Antagonists, therefore, may show higher binding leading to improved detection and more avid tumor binding in targeted radiotherapy. ^{68}Ga NODAGA-LM3, ^{68}Ga DOTA-LM3, and ^{68}Ga NODAGA-JR11 (OPS202) are three of the agents showing early promise[66-68] with clinical trials underway[69]. Similar to DOTATATE, therapeutic radionuclides can be attached to these antagonists for PRRT[70,71].

Alpha emitters: PRRT for GEP-NETs is currently performed primarily by beta emitters (^{177}Lu and ^{90}Y), but targeted alpha therapy (TAT) is potentially much more effective[72,73]. Alpha particles travel a much shorter distance in tissue, typically on the order of only a few cell diameters, and deliver a dramatically higher damaging radiation effect to cells compared to beta emitters. In contrast to beta emission, which results primarily in single breaks in DNA, highly energetic alpha particles result in clusters of double stranded DNA breaks which are irreparable and highly lethal[72]. Alpha particles also generate more ionization events and an immunogenic cell death which could generate an immunostimulatory environment and promote an abscopal effect[73]. The dual effect of higher tumor cell death and limited radiation to non-target tissues increases the lethality to tumor cells and decreases the off-target adverse side effects.

The primary systemic alpha emitter under investigation is ^{225}Ac which can be stably bound to DOTATATE or DOTATOC[73]. Early studies have shown promising results[74,75] with avoidance of severe renal and hematologic toxicity[76]. In the future, this could be given as an initial treatment strategy, in sequence with ^{177}Lu DOTATATE, or as a salvage therapy for patients progressing on ^{177}Lu PRRT.

Additional therapies or combination therapies

Beyond radionuclides, there are other drugs and regimens being developed for treatment of GEP-NETs. These therapies may provide additional benefits to PRRT, particularly if they can be used to sensitize tumors to PRRT or be sequenced in such a way to deliver synergistic lethality. Alternative methods of administration may also allow higher local dose PRRT *via* intra-arterial rather than systemic delivery[77, 78]. PRRT could also be used in a neoadjuvant fashion prior to surgery to make some patients operative candidates and increase the chances of curative resection[54]. The sorting out of the milieu of therapies, their timing, and indications will require ongoing research.

CONCLUSION

Currently, the most sensitive and accurate established method to image well-differentiated GEP-NETs is with DOTATATE PET imaging. Due to the favorable uptake properties and biodistribution, targeted PRRT with ^{177}Lu DOTATATE has been established as best standard of care for patients with progressive, metastatic, or unresectable well-differentiated SSTR positive GEP-NETs. ^{177}Lu DOTATATE is well tolerated with a very mild toxicity profile and rare serious adverse events. Ongoing investigations are continuing to expand in both imaging and therapy applications for DOTATATE and novel ligand theranostics for GEP-NETs.

Abstract

BACKGROUND

Colorectal cancer (CRC) is an extremely malignant tumor with a high mortality rate. Little is known about the mechanism by which forkhead Box q1 (FOXQ1) causes CRC invasion and metastasis through the epidermal growth factor receptor (EGFR) pathway.

AIM

To illuminate the mechanism by which FOXQ1 promotes the invasion and metastasis of CRC by activating the heparin binding epidermal growth factor (HB-EGF)/EGFR pathway.

METHODS

We investigated the differential expression and prognosis of FOXQ1 and HB-EGF in CRC using the Gene Expression Profiling Interactive Analysis (GEPIA) website (http://gepia.cancer-pku.cn/index.html). Quantitative real-time polymerase chain reaction (qRT-PCR) and Western blotting were used to detect the expression of FOXQ1 and HB-EGF in cell lines and tissues, and we constructed a stable low-expressing FOXQ1 cell line and verified it with the above method. The expression

changes of membrane-bound HB-EGF (proHB-EGF) and soluble HB-EGF (sHB-EGF) in the low-expressing FOXQ1 cell line were detected by flow cytometry and ELISA. Western blotting was used to detect changes in the expression levels of HB-EGF and EGFR pathway-related downstream genes when exogenous recombinant human HB-EGF was added to FOXQ1 knockdown cells. Proliferation experiments, transwell migration experiments, and scratch experiments were carried out to determine the mechanism by which FOXQ1 activates the EGFR signaling pathway through HB-EGF, and then to evaluate the clinical relevance of FOXQ1 and HB-EGF.

RESULTS

GEPIA showed that the expression of FOXQ1 in CRC tissues was relatively high and was related to a lower overall survival rate. PCR array results showed that FOXQ1 is related to the HB-EGF and EGFR pathways. Knockdown of FOXQ1 suppressed the expression of HB-EGF, and led to a decrease in EGFR and its downstream genes *AKT*, *RAF*, *KRAS* expression levels. After knockdown of FOXQ1 in CRC cell lines, cell proliferation, migration and invasion were attenuated. Adding HB-EGF restored the migration and invasion ability of CRC, but not the cell proliferation ability. Kaplan–Meier survival analysis results showed that the combination of FOXQ1 and HB-EGF may serve to predict CRC survival.

CONCLUSION

Based on these collective data, we propose that FOXQ1 promotes the invasion and metastasis of CRC *via* the HB-EGF/EGFR pathway.

Key Words: Colorectal cancer; Forkhead Box Q1; Heparin binding epidermal growth factor; Epidermal growth factor receptor pathway; Migration; Invasion

Core Tip: Invasion and metastasis play important roles in tumorigenesis, resulting in the death of most colorectal cancer (CRC) patients. Forkhead Box q1 (FOXQ1) is a well-established oncogene in multiple tumors, including CRC. Our previous study suggested that FOXQ1 positively regulates the expression of heparin-binding epidermal growth factor (HB-EGF) and triggers the activation of the epidermal growth factor receptor (EGFR) pathway in CRC. However, the role and mechanism of how FOXQ1 promotes tumorigenesis in CRC by activating the HB-EGF/EGFR pathway remain unexplored. In the present study, our findings demonstrated that the essential role of FOXQ1-induced invasion and metastasis in CRC was related to activation of the HB-EGF/EGFR pathway.

INTRODUCTION

Colorectal cancer (CRC) is the third most common cancer in the world and the fourth most common cause of cancer death in the world[1]. Among all cancerous processes involved, local invasion and metastasis are the main factors related to cancer. The metastatic dissemination of primary tumors is directly related to the survival rate of patients, accounting for approximately 90% of all colon cancer deaths[2]. The median survival of metastatic CRC is less than 2 years[3]. Therefore, clarifying the mechanism of invasion and metastasis is the key to improving the survival rate of patients with CRC.

Forkhead Box q1 (FOXQ1) is a member of the forkhead transcription factor family[4], and it promotes tumorigenesis by activating cell proliferation, invasion and apoptosis[5]. Kaneda *et al*[6] found that compared to adjacent tissues, *FOXQ1* is overexpressed in CRC. Overexpression of *FOXQ1* reduces cell proliferation but increases cell tumorigenicity and tumor growth, and it inhibits apoptosis and promotes angiogenesis, thereby promoting CRC tumorigenesis. Liu *et al*[7] also demonstrated that the expression of *FOXQ1* in either CRC tissue samples or cancer cell lines is higher than that in normal colorectal tissues and cell lines, and they reported that FOXQ1 promotes cancer metastasis by regulating PI3K/AKT signaling. Weng *et al*[8] verified that FOXQ1 can be used as an independent indicator of the prognosis of CRC patients.

The epidermal growth factor receptor (EGFR) signaling pathway plays an important role in physiological processes, such as cell growth, proliferation, and differentiation. The expression level of *EGFR* gradually increases from normal mucosa, adenomas with low-grade dysplasia, and adenomas with high-grade dysplasia to CRC, confirming that EGFR plays an important role in CRC[9]. Heparin-binding epidermal growth factor (HB-EGF) is one of the seven major ligands of EGFR. HB-EGF was originally identified as a secreted product from human macrophage U937 cells, and it induces cell proliferation and differentiation[10,11]. Soluble HB-EGF (sHB-EGF) is the main stimulator of cell proliferation. The affinity of sHB-EGF binding to target cells to promote proliferation of the target cells and activation of EGFR tyrosine kinase activity is 20-40 times higher than that of EGF. Thus, sHB-EGF is the most effective EGFR signaling pathway activator[12,13]. Membrane-bound HB-EGF (proHB-EGF) is affected by a variety of proteins, and it can be shed into active sHB-EGF to promote cell proliferation[14-16].

There is evidence that poor prognosis and low survival rates for CRC are associated with abnormally activated signaling pathways, including the EGFR signaling pathway[17]. In advanced CRC the most commonly used targeted therapies are the monoclonal antibodies cetuximab and panitumab, which block EGFR activation[18]. Activation of EGFR signaling leads to resistance to chemotherapy in CRC cells and promotes cell survival, while inhibition of EGFR signaling significantly reduces proliferation in CRC cells[19]. In nasopharyngeal carcinoma, Luo *et al*[20] reported that FOXQ1 induces vasculogenic mimicry through the EGFR signaling pathway, thereby promoting the metastasis of nasopharyngeal carcinoma cells. Our previous study suggested that FOXQ1 positively regulates the expression of HB-EGF and triggers the activation of the EGFR pathway in CRC[21]. However, the role and mechanism of how FOXQ1 promotes tumorigenesis in CRC by activating the HB-EGF/EGFR pathway remain largely unknown. Therefore, we analyzed the correlation between FOXQ1 and the HB-EGF/EGFR pathway by constructing *FOXQ1* knockdown cells and using tissue microarrays, cell function experiments, quantitative real-time polymerase chain reaction (qRT-PCR), and western blotting. Our findings elucidated the critical role of the FOXQ1 and HB-EGF/EGFR pathways in CRC, providing theoretical support for the clinical application of targeted FOXQ1 in the treatment of CRC.

MATERIALS AND METHODS

Cell cultures

The human CRC cell lines, DLD1 and SW480, as well as the human embryonic kidney 293 (HEK293) cell line were purchased and authenticated from the Cell Bank of the Chinese Academy of Science in Shanghai, China. DLD1 cells were cultured in RPMI 1640. SW480 and HEK293 cells were cultured in DMEM. All media were supplemented with 10% heat-inactivated fetal bovine serum (Life Technologies BRL), and the cells were maintained in a 5% CO_2-humidified atmosphere at 37 °C.

Plasmid construction and transfection

Three siRNAs targeting the human FOXQ1 sequence (NM_033260.3) were designed using siRNA Target Finder (InvivoGen, San Diego, CA, United States), and one scrambled siRNA was designed as a negative control, refer to our previous research[21]. The pSPAX2 packaging system from Addgene was used to construct a lentiviral PLKO.1 vector (PLKO.1-puro-shFOXQ1). After each group of recombinant plasmids was confirmed by sequencing, lentiviral vectors and packing vectors (pRSV-rev, pMDlg-pRRE and pCMV-VSV-G) were cotransfected into HEK293 cells using Lipofectamine® 2000 transfection reagent (Life Technologies). Lentivirus was collected to infect DLD1 and SW480 cells. Stable cells were generated after selection with puromycin (Solarbio, Beijing, China) (0.4 ng/μL for DLD1 cells and 0.1 ng/μL for SW480 cells) for 7-14 d after infection. The most effective knockdown cells were designated DLD1-shFOXQ1 and SW480-shFOXQ1, and the corresponding controls were named DLD1-shControl and SW480-shControl, respectively.

Flow cytometry

Cell surface HB-EGF was detected using APC-conjugated anti-human HB-EGF (eBioscience, San Diego, CA, United States). APC-conjugated mouse IgG2ak isotype was used as a control (eBioscience, San Diego, CA, United States) according to the manufacturer's directions. Briefly, CRC cells were harvested and blocked with blocking buffer (PBS containing 2% BSA) for 10 min at 4 °C and then stained with 5 μL of monoclonal HB-EGF antibody (eBioscience, San Diego, CA, United States) for 30 min at 4 °C. After two washes, cells were resuspended in 100 μL of PBS. Samples were analyzed using a MoFlo flow cytometer (Beckman Coulter) and FlowJo software (Becton, Dickinson and Company).

Western blotting

Protein extracts were isolated from 10^6 treated cells using mammalian cell lysis reagent containing protease inhibitor cocktail (Sigma–Aldrich, St. Louis, MO, United States) and phosphatase inhibitors (Roche, United States) following the manufacturer's directions. Equal amounts of protein (30 μg) were resolved on a 10% sodium dodecyl sulfate (SDS)-precast polyacrylamide gel (Bio–Rad Laboratories) and

transferred to an Immobilon-polyvinylidene difluoride membrane (Millipore, Billerica, MA, United States). The membranes were blocked and incubated with the following primary antibodies: FOXQ1 (Abcam, Cambridge, MA, United States), HB-EGF (Abcam, Cambridge, MA, United States), phosphor-PI3K (Cell Signaling Technology, Cold Spring Harbor, NY, United States), PI3K (Proteintech, Wuhan, China), Akt (Proteintech, Wuhan, China), phosphor-Akt (Proteintech, Wuhan, China), phosphor-MAPK (Cell Signaling Technology, Cold Spring Harbor, NY, United States), MAPK (Proteintech, Wuhan, China), EGFR (Proteintech, Wuhan, China), KRAS (Proteintech, Wuhan, China), RAF (Proteintech, Wuhan, China), E-cadherin, N-cadherin, vimentin and β-actin (Proteintech, Wuhan, China). Blots were then incubated with the appropriate peroxidase-conjugated secondary antibody as follows: HRP-Rb-anti-goat (Cell Signaling Technology, Cold Spring Harbor, NY, United States) or HRP-goat-anti-mouse (Proteintech, Wuhan, China), respectively. The proteins were detected using an ECL system (Millipore, Braunschweig, Germany) and visualized with a ChemiDoc XRS system (Bio–Rad, Hercules, CA, United States).

RNA isolation and qRT–PCR

Total RNA was isolated using TRIzol (Invitrogen, Carlsbad, CA, United States) according to the manufacturer's protocol. Total RNA (1 μg) was reverse transcribed into cDNA using PrimeScript RT reagent (TakaraBio, Japan), and qRT–PCR was performed using a LightCycler 480 (Roche, United States) with SYBR Premix Ex Taq (Takara, China). Each sample was analyzed in triplicate, and Glyceraldehyde-3-phosphate dehydrogenase(GAPDH) was used as the reference. Quantitative results were calculated using the $2^{-\Delta\Delta CT}$ method. Primers used for qRT–PCR were designed and synthesized by Takara (Dalian, China) (Table 1).

Epidermal growth factor/platelet-derived growth factor pathway cDNA array assay

The human epidermal growth factor (EGF)/platelet-derived growth factor (PDGF) Signaling RT² Profiler™ PCR Array (SABiosciences), which profiles the expression of 84 genes related to EGF/PDGF-mediated signal transduction, five housekeeping genes and three controls, was used to analyze the effect of FOXQ1 on EGF/PDGF signaling-related gene expression (Table 2). Total RNA was extracted with TRIzol reagent according to the manufacturer's manual. DNase treatment was performed by amplification grade I DNase I (Sigma–Aldrich, St. Louis, MO, United States) according to the manufacturer's instructions. Each total RNA preparation (5 μg) was digested with 1 μL of DNase I (1 unit/μL) and 1 μL of 10 reaction buffer in a volume of 10 μL. After incubation and addition of Stop Solution, DNase I was denatured by incubation at 70 °C for 10 min. The RNA samples were kept on ice for another 5 min and then converted into cDNA with the RT² PCR Array First Strand Kit (SuperArray) according to the manufacturer's protocol. cDNA (20 ng) was combined with RT² SYBR Green/Fluorescein PCR master mix (SuperArray), and equal amounts of this mixture (25 μL) were added to each well of the RT² Profiler PCR plate containing the predispensed gene-specific primer sets. PCR cycles were performed according to the manufacturer's instructions. The relative level of mRNA expression for each gene in each sample was first normalized to the expression of GAPDH in that sample and then normalized to the level of mRNA expression in the DLD1-shControl.

ELISA

Exogenous recombinant HB-EGF protein at a final concentration of 50 ng/mL was added to the cell culture medium when the cell density reached 80%, and the culture medium was changed after incubation for 24 h[22]. The supernatant was collected after the cells were cultured for another 24 h. The protein concentrations of soluble HB-EGF, ADAM9, ADAM10, ADAM12 and MMP-7 in the cell culture medium were determined by ELISA detection kits against human HB-EGF, ADAM9, ADAM10, ADAM12 and MMP-7, respectively (R&D Systems, Minneapolis, United States).

Cell proliferation

DLD1-shFOXQ1 and SW480-shFOXQ1 cells (2,000 cells/well in a 96-well plate) were incubated with medium containing 10% FBS at 37 °C for 24, 48, 72 and 96 h. At the end of incubation, 10 μL of Cell Counting Kit-8 (CCK-8) solution (Beyotime Biotech, Shanghai, China) was added to each well with 100 μL of medium and incubated for another 4 h at 37 °C, and the OD at 450 nm was measured by a microplate reader (BioTek, Winooski, VT, United States). The effect of siRNA FOXQ1 on CRC cell viability was assessed as the percent of cell viability compared to vehicle-treated control cells, which were arbitrarily assigned as 100% viability.

Cell migration and wound-healing assay

Cell migration was analyzed using Transwell inserts with 8.0 μm membrane pores (BD, San Jose, CA, United States) according to the manufacturer's protocol. Migration was additionally evaluated with the wound-healing assay. Briefly, DLD1-shFOXQ1/SW480-shFOXQ1 and DLD1-shControl/SW480-shControl cells were seeded in 6-well plates at a density that enabled a confluency of 80% to be attained 24 h after plating. A 10 μL filter tip was used to gently scratch the cell monolayer across the center of the well. Cells were then gently washed twice with PBS to remove the dislodged cells, and fresh medium was added. The first images of the scratch area were then acquired. Cells were cultured in serum-free medium for another 48 h, and a second set of images was then acquired to determine the extent of wound closure.

CRC tissue microarray

Tissue microarrays containing a total of 90 pairs of colorectal tumor tissues and matched adjacent normal tissues, together with pathological staging data in accordance with TNM classification of the American Joint Committee on Cancer (2010) and follow-up survival time after surgery, were obtained from Shanghai Biochip Co. Ltd., Shanghai, China (HCol-Ade180Sur-06). FOXQ1 (ab51340) and HB-EGF (ab192545) antibodies were purchased from Abcam (Cambridge, MA, United States). Tissue microarray analysis was performed using a standard immunohistochemistry (IHC) protocol. The median value of the immunoreactivity score (IRS) was selected as the cutoff for high and low protein expression levels based on a measure of heterogeneity according to the log-rank test with respect to disease-specific survival (DSS) as described previously. Cutoff values for the scoring system were assigned as follows:

Table 3 Correlation between heparin binding epidermal growth factor expression and clinicopathological characteristics of colorectal cancers in cohort of human colorectal cancer tissues

Clinicopathological variables		Cohort tumor HB-EGF expression		*P* value
		Negative (*n* = 26)	Positive (*n* = 39)	
Age (yr)		65.72 (10.37)	69.43 (7.98)	
Gender	Female	11	23	> 0.05

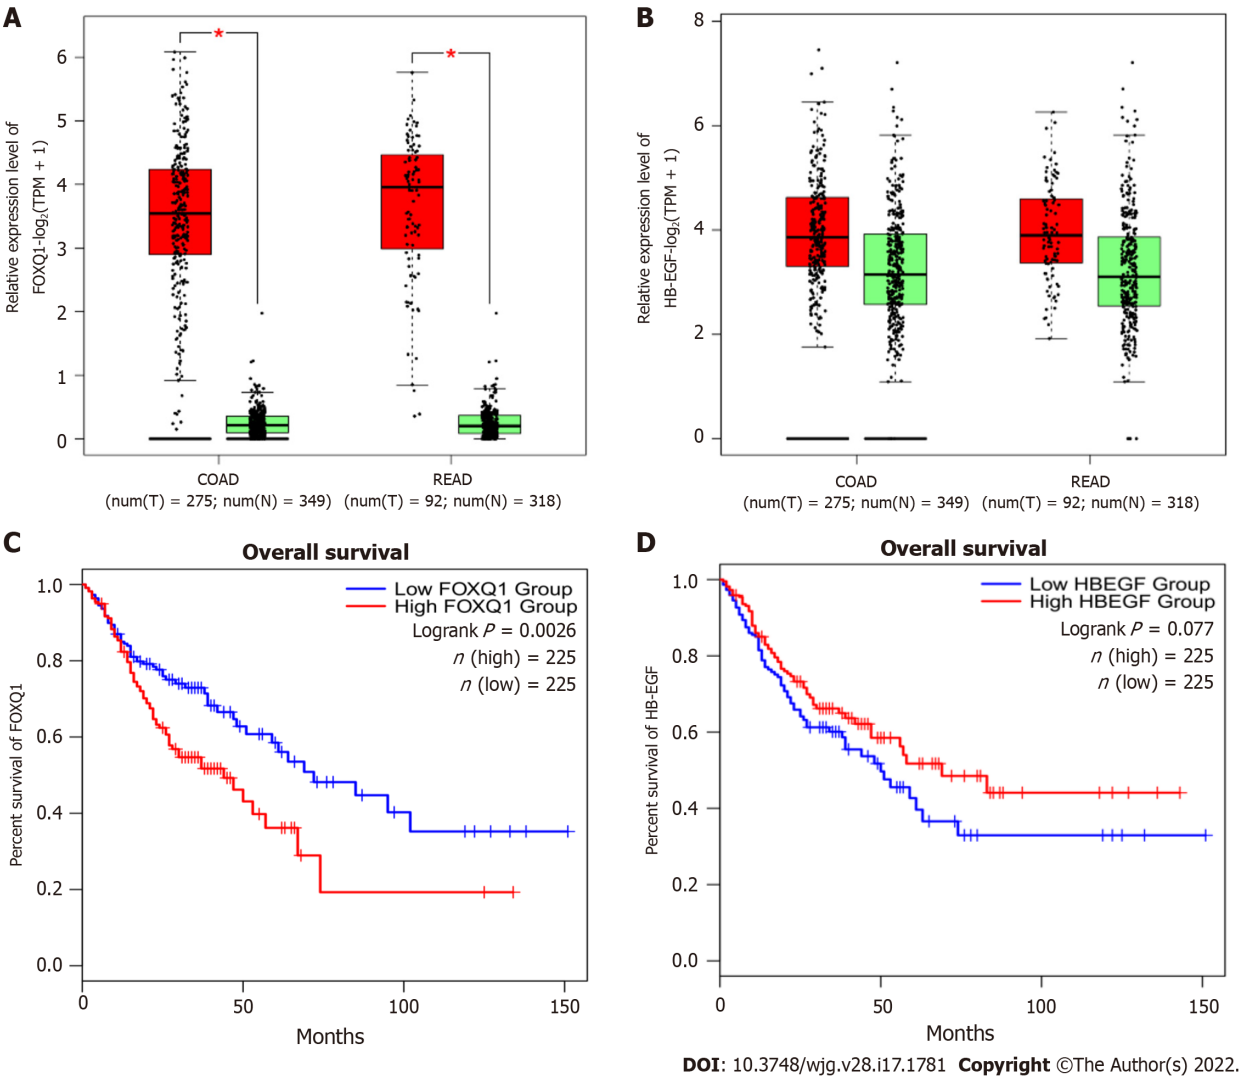
		FOXQ1, negative (*n* = 31)	FOXQ1, positive (*n* = 34)	χ^2	*P* value
HB-EGF	Negative (*n* = 26)	20	6	4.116	< 0.05
	Positive (*n* = 39)	11	28		

FOXQ1: Forkhead Box q1; HB-EGF: Heparin binding epidermal growth factor.

High expression of FOXQ1 and HB-EGF were defined as an IRS of ≥ 4 (4, 6, 8, 9 and 12); and low expression was defined as an IRS of < 4 (0, 1, 2 and 3)[23]. Immunostained sections were scanned using a microscope (Axiovert 200, Carl Zeiss, Gttingen, Germany). Data for 25 patients were excluded because the dots were off the chips during the experiment. In total, data for 65 patients with CRC were included in the final analysis (Tables 3 and 4).



Statistical analysis

Statistical analyses were performed using GraphPad Prism 8 and SPSS v.19. An unpaired two-tailed Student's *t*-test was performed for two-group comparisons, and one-way analysis of variance (ANOVA) was performed for multiple group comparisons. Survival curves were calculated using the Kaplan–Meier algorithm and log-rank test. $P < 0.05$ was considered to indicate a statistically significant difference.

RESULTS

Expression and prognosis of FOXQ1 and HB-EGF in CRC and normal colorectal tissues

To determine the expression levels of FOXQ1 and HB-EGF in CRC, we investigated the expression and prognosis of FOXQ1 and HB-EGF in CRC in the Gene Expression Profiling Interactive Analysis (GEPIA) online database (Figure 1). The results showed that FOXQ1 was upregulated in CRC compared to normal samples according to GEPIA (Figure 1A). Increased expression of FOXQ1 was also associated with worse overall survival (Figure 1C). The expression of HB-EGF in CRC was not significantly different from that in normal colorectal tissues (Figure 1B), and its expression had no significant effect

on the overall survival of patients with CRC (Figure 1D).

Construction of FOXQ1 knockdown CRC cell lines

To elucidate the functional roles of FOXQ1 in CRC, we generated CRC lines with stable FOXQ1 knockdown. Among the CRC lines we tested, DLD1 and SW480 cells had relatively high endogenous FOXQ1 expression as described previously[21]. Because the high expression of FOXQ1 in these two cells lines has also been confirmed in several other independent studies[3,4,8,9,24], we selected these two cell lines for knockdown studies. qRT–PCR assays verified significant FOXQ1 knockdown in DLD1-shFOXQ1 and SW480-shFOXQ1 cells. FOXQ1 mRNA expression in DLD1-shFOXQ1 and SW480-shFOXQ1 cells was significantly reduced compared to that in the control DLD1-shControl and SW480-shControl cells (Figure 2A). Western blot analysis also verified that the expression of FOXQ1 was significantly downregulated (Figure 2B).

Knockdown of FOXQ1 suppresses the expression of HB-EGF and blocks the EGF/PDGF signaling pathway in vitro

A panel of PCR arrays consisting of 84 representative genes related to the EGF/PDGF signaling pathways was used to detect the transcriptional signatures of DLD1-shFOXQ1 and DLD1-shControl cells. Differentially expressed genes with statistical significance were identified by volcano plot filtering. The results showed that 18 genes had expression changes with a fold-change ≥ 2.0 ($P < 0.05$)(Figure 2C). Among these 18 genes, 12 genes were associated with EGFR signaling pathways, including HB-EGF (FC = -2.19), and there were several novel genes of the three main EGF/PDGF downstream signaling

DOI: 10.3748/wjg.v28.i17.1781 **Copyright** ©The Author(s) 2022.

Figure 2 Forkhead Box q1 knockdown induces heparin binding epidermal growth factor suppression and epidermal growth factor/platelet-derived growth factor signaling pathway blockade *in vitro* according to transcriptional analysis of the generated forkhead Box q1 knockdown cell line. A: Quantitative real-time polymerase chain reaction was performed to evaluate mRNA expression in the knockdown of forkhead Box q1 in DLD1 cells (DLD1-shFOXQ1) and SW480-shFOXQ1 cells (two-tailed, unpaired Student's *t* test). Bars represent the mean ± SE of three independent experiments; B: Western blotting was performed to evaluate FOXQ1 protein expression in DLD1-shFOXQ1 and SW480-shFOXQ1 cells; C: Volcano plot illustrating differentially expressed genes using the epidermal growth factor (EGF)/platelet-derived growth factor (PDGF) array to compare DLD1-shFOXQ1 and DLD1-shControl cells. The vertical blue points in the plot represent 84 genes related to the EGF/PDGF signaling pathways. The vertical green line indicates a fold-change in gene expression of 1. The vertical pink lines indicate the threshold for fold-change (≥ 2.0 and ≤ -2.0). The horizontal blue line indicates the threshold for the *P* value of the *t* test. $^{a}P < 0.05$; $^{b}P < 0.01$; $^{c}P < 0.001$. pathways (MAPK/ERK1/2, PI3K/AKT and JAK/STAT3). These novel genes included RAS, PI3K and STAT3 as well as several intracellular transcription factors activated by these signaling pathways, such as c-JUN and c-FOS (Table 2).

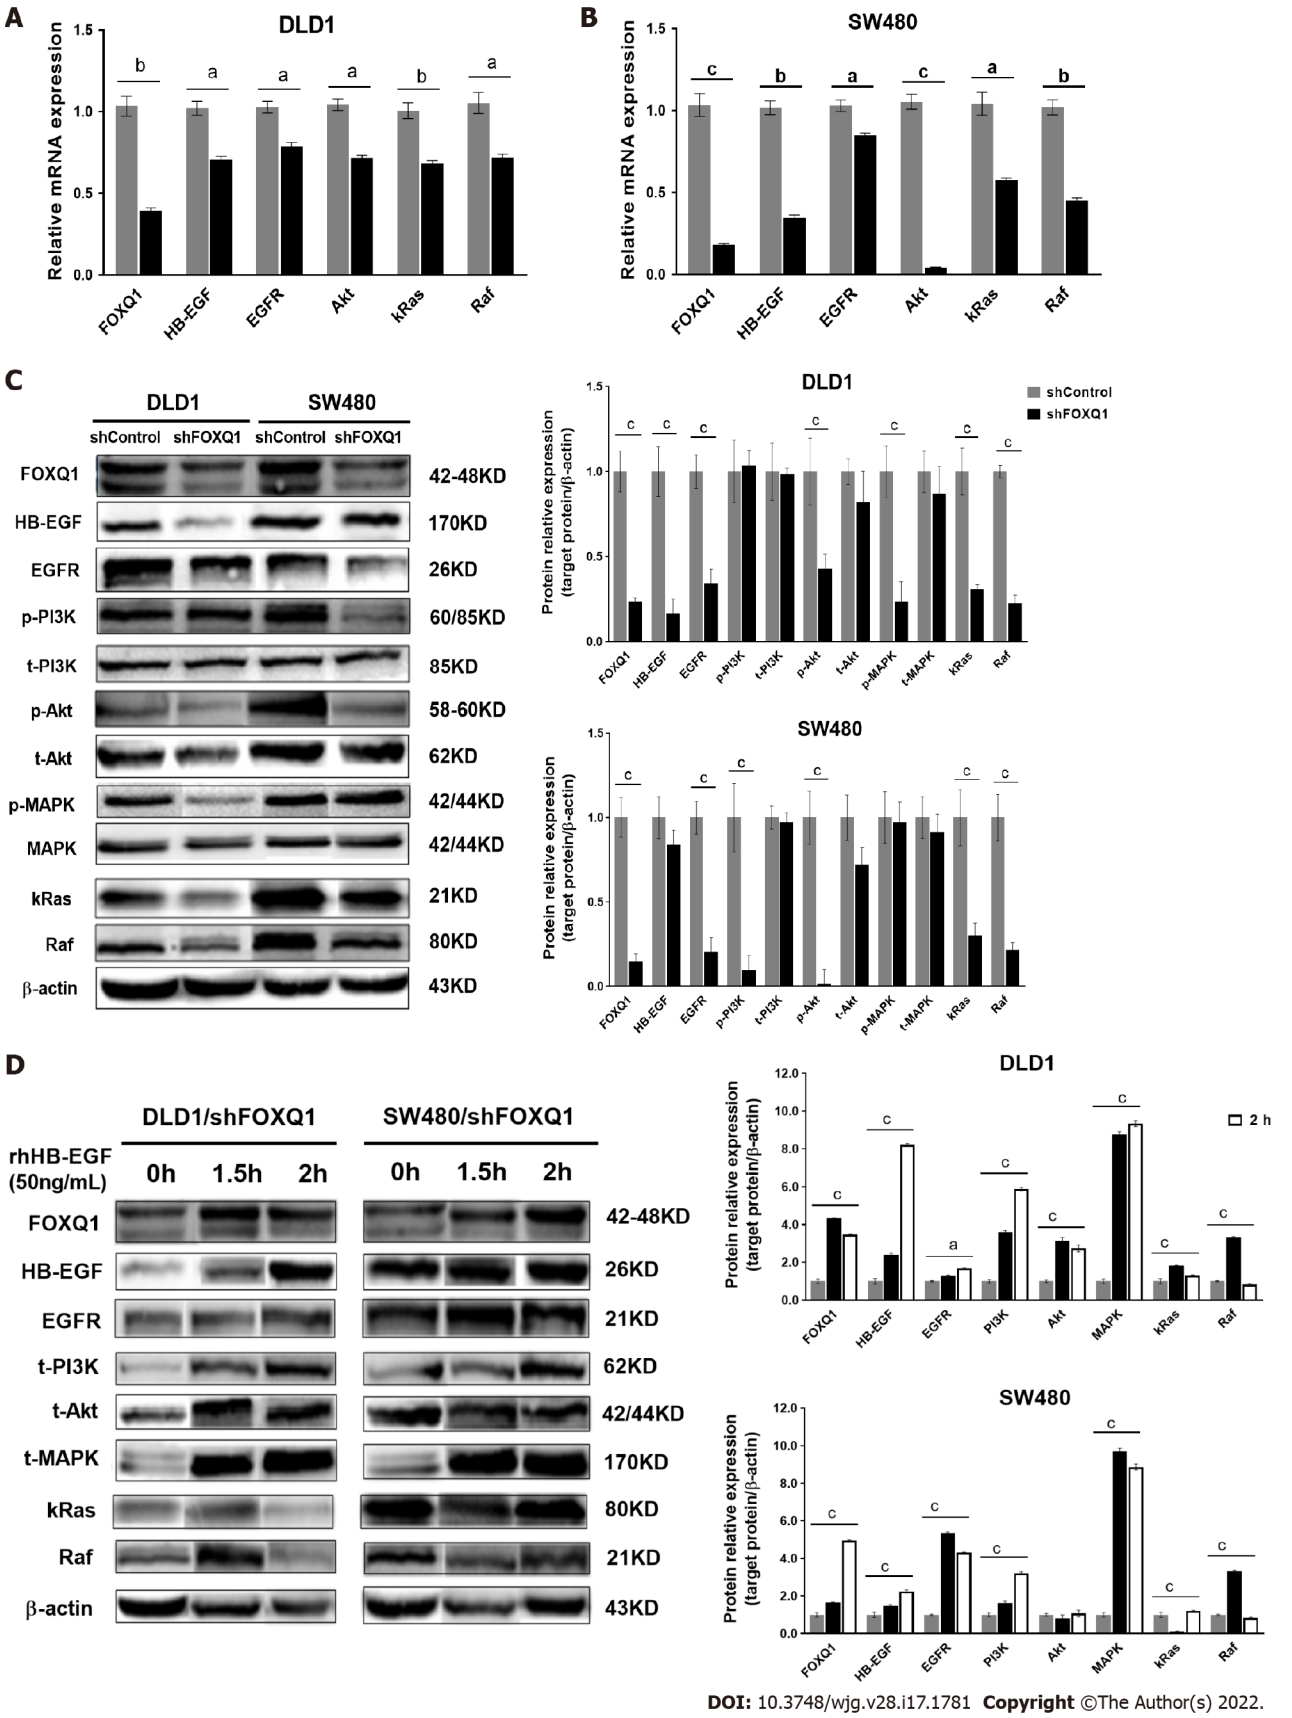
Effect of FOXQ1 expression on HB-EGF expression and extracellular release ability in CRC cells

Western blot analysis confirmed that knockdown of FOXQ1 in CRC cells resulted in a significant decrease in the expression of HB-EGF in DLD1 cells (Figure 3A), but no significant changes in HB-EGF were observed in SW480 cells (Figure 3A). Flow cytometry analysis confirmed that knockdown of FOXQ1 expression in CRC cells did not affect the expression level of proHB-EGF (Figure 3B). ELISA results indicated that knockdown of FOXQ1 significantly reduced the shedding of soluble HB-EGF (sHB-EGF) in DLD1 cells but did not affect the shedding of HB-EGF in SW480 cells (Figure 3C). Among the four proteins that affect the release of the extracellular domain of proHB-EGF, three (ADAM9, ADAM12 and ADAM7) were decreased significantly in both DLD1-shFOXQ1 and SW480-shFOXQ1 cells, while ADAM10 was not changed. The feedback regulation of ADAM9, ADAM12 and MMP7 secretion by HB-EGF from CRC cells was studied by adding exogenous recombinant human HB-EGF (rhHB-EGF). The results showed that rhHB-EGF reversed the decline in the expression of ADAM9, ADAM12 and MMP7 in DLD-shFOXQ1 cells. However, only the decreased expression of ADAM9 was reversed by rhHB-EGF in SW480-shFOXQ1 cells (Figure 3D).



FOXQ1 regulates EGFR and downstream signaling pathways by regulating HB-EGF

To verify the role of FOXQ1 in activating the HB-EGF/EGFR signaling pathway, we performed qRT–PCR analysis in DLD1-shFOXQ1 and SW480-shFOXQ1 cells. The results confirmed that FOXQ1 knockdown resulted in a significant decrease in the mRNA expression of HB-EGF, EGFR and downstream genes (AKT, RAF and KRAS) in DLD1-shFOXQ1 and SW480-shFOXQ1 cells (Figure 4A and B). In addition, the Western blot analysis showed that knockdown of FOXQ1 resulted in a significant decrease in HB-EGF and EGFR expression as well as decreased AKT and MAPK

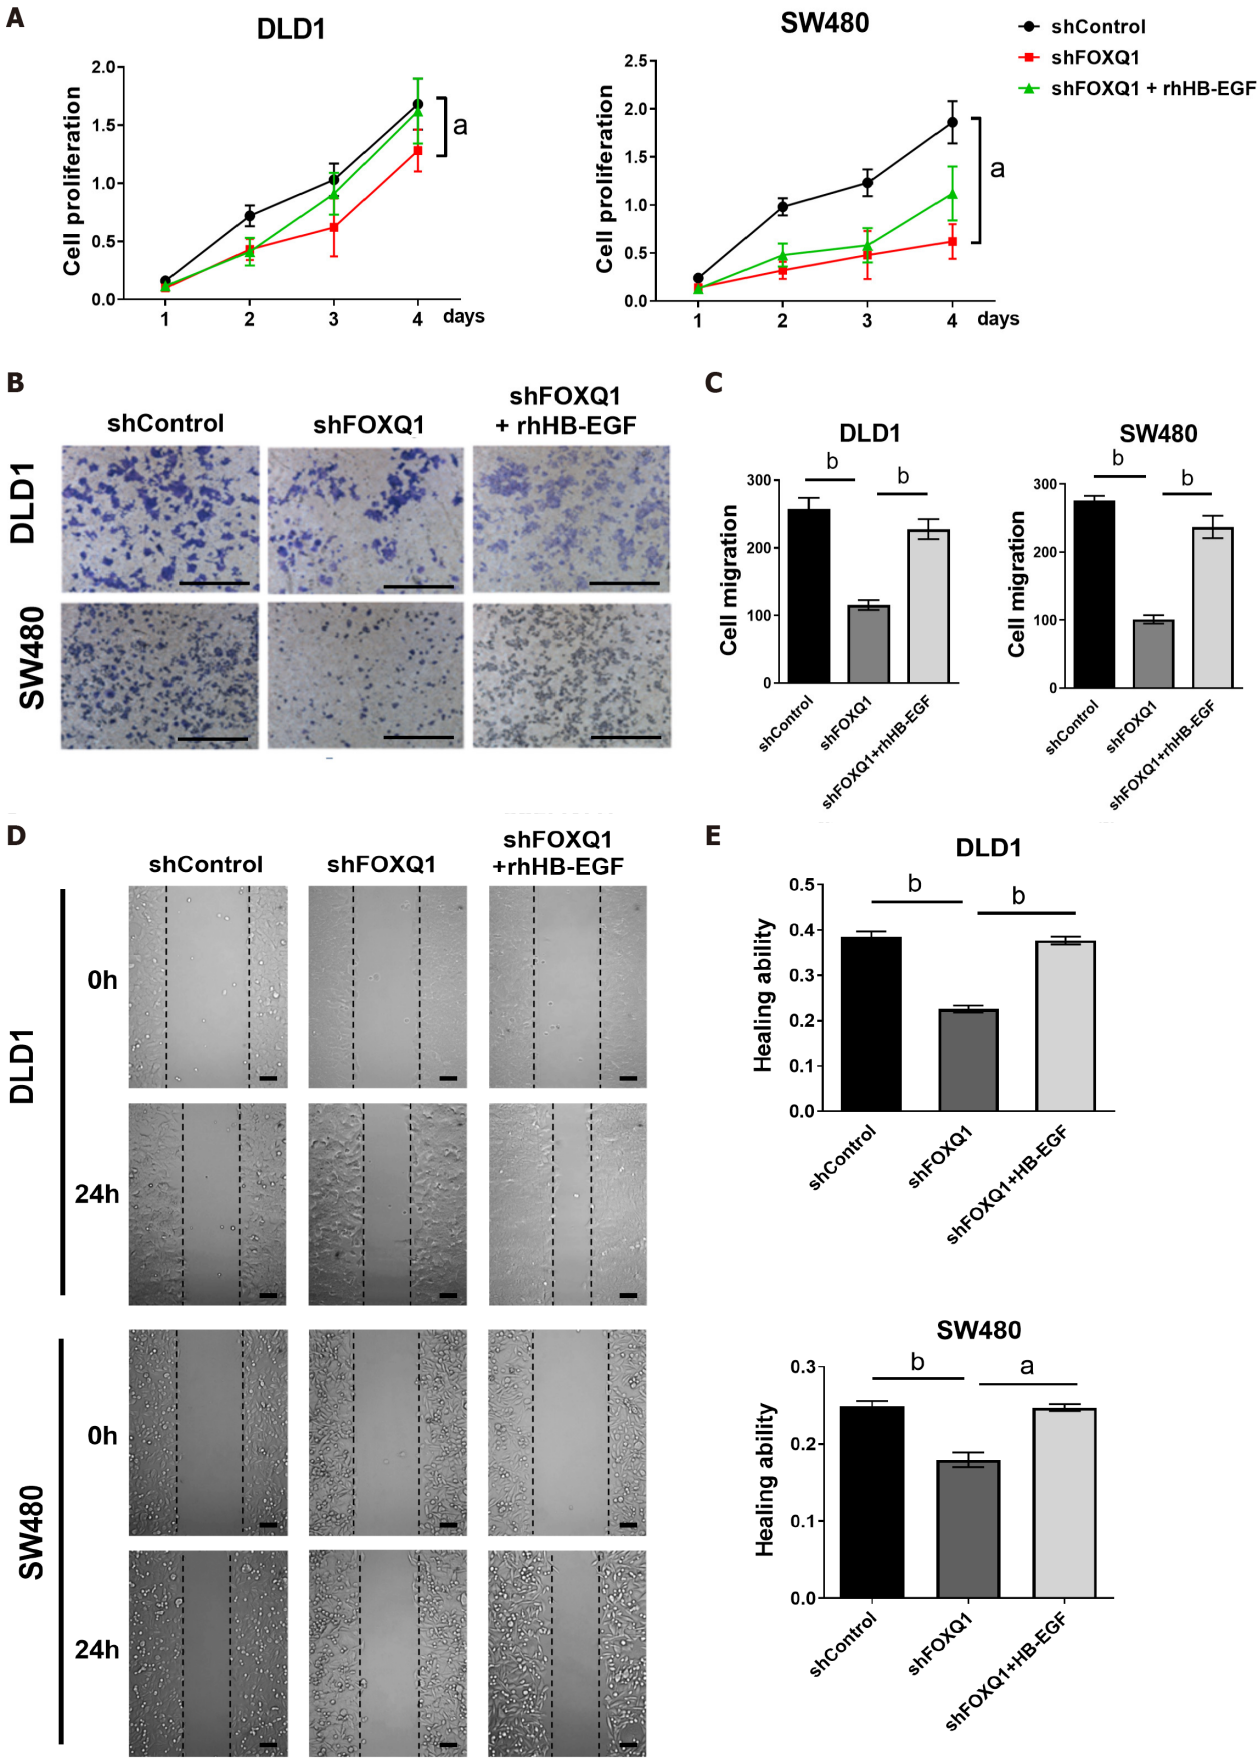
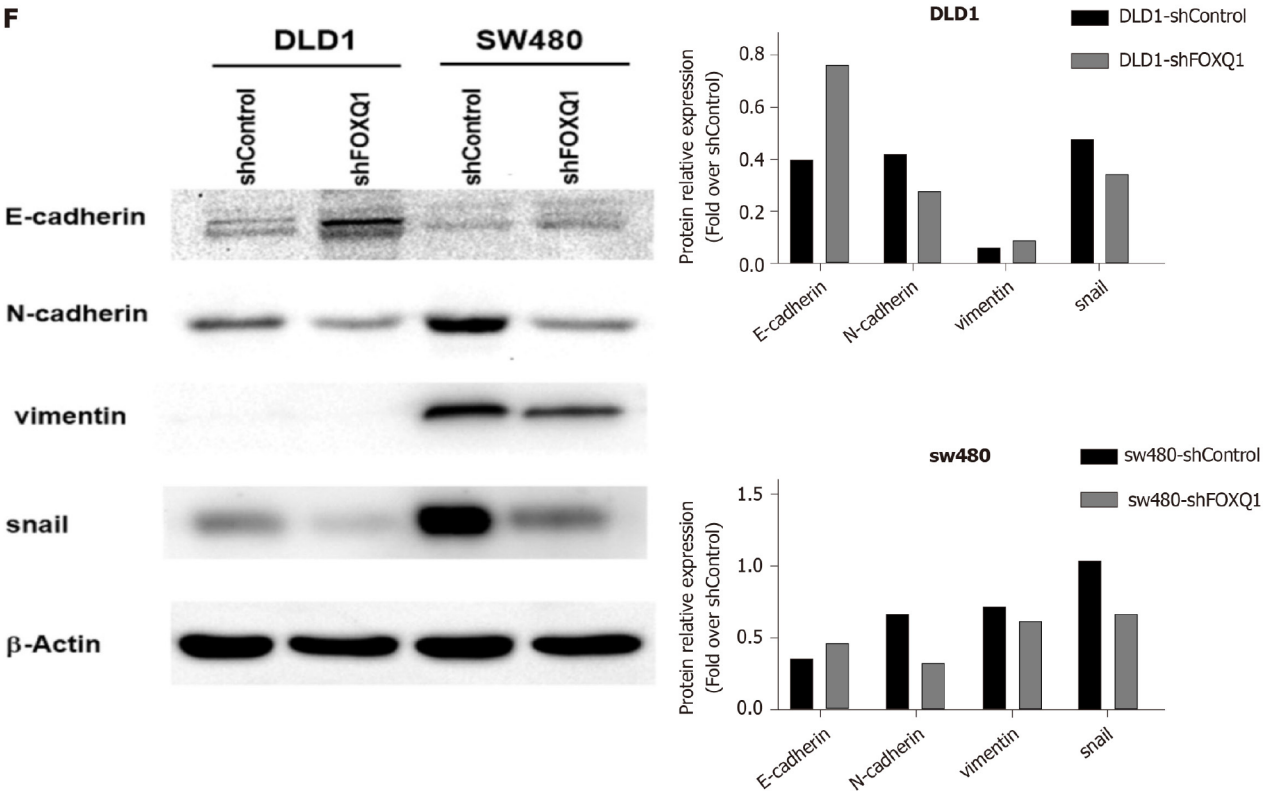
phosphorylation in DLD1-shFOXQ1 cells compared to DLD1-shControl cells. In SW480-shFOXQ1 cells, EGFR and HB-EGF expression was significantly decreased, and AKT and PI3K phosphorylation was inhibited compared to that in SW480-shControl cells (Figure 4C). Furthermore, Western blot analysis confirmed that the decreased expression of important downstream genes was rescued by rhHB-EGF protein in either DLD1-shFOXQ or SW480-shFOXQ1 cells (Figure 4D).

rhHB-EGF reverses the FOXQ1 knockdown-induced suppression of CRC cell proliferation and migration in vitro

CCK-8 results confirmed that FOXQ1 knockdown significantly inhibited the proliferation of DLD1-shFOXQ1 and SW480-shFOXQ1 cells, and the inhibitory effect was partially reversed by exogenous rhHB-EGF (Figure 5A). The results of the Transwell migration assay confirmed that FOXQ1 knockdown also reduced the migration of DLD1 and SW480 cells, and the inhibitory effect was also reversed to a large extent by rhHB-EGF (Figure 5B and C). Scratch experiment results confirmed that FOXQ1 knockdown reduced the wound-healing ability of DLD1 and SW480 cells, which was also reversed to a large extent by rhHB-EGF (Figure 5D and E). We next analyzed the protein expression during cell invasion and metastasis (Ecadherin, N-cadherin, Vimentin and Snail), Western blot analysis indicated that FOXQ1 knockdown reduced the expression in DLD1-shFOXQ1 and SW480-shFOXQ1 cells (Figure 5F).



Prognostic value of the combination of FOXQ1 and HB-EGF



To verify the clinical relevance of our findings, we evaluated the expression of FOXQ1 and HB-EGF in human CRC tissue biopsies (cohort, $n = 65$) (Tables 3 and 4). IHC analysis showed that FOXQ1 was significantly upregulated in CRC tissues compared to adjacent nontumorous tissues and that HB-EGF was moderately upregulated (Figure 6A). Although the overexpression of HB-EGF had no significant correlation with any clinicopathological characteristics of CRCs (Table 3), further analysis verified the positive correlation between FOXQ1 and HB-EGF (Table 4). In a cohort of 65 CRC patients, Kaplan–Meier survival analysis results showed that CRC patients with positive expression of FOXQ1 had shorter overall survival than those with negative expression of FOXQ1. Furthermore, Kaplan–Meier survival analysis of CRC patients with positive coexpression of FOXQ1 and HB-EGF had the shortest overall survival times compared to the corresponding single-negative or double-negative groups in the cohort of 65 CRC patients (Figure 6B).

DISCUSSION

Studies have indicated that *FOXQ1* is an oncogene in multiple tumors, including CRC[24], breast cancer [25], lung cancer[26], gastric cancer[27], liver cancer[28], pancreatic cancer[29], ovarian cancer[30], and neuroglioma[31]. In CRC, FOXQ1 promotes tumor invasion and metastasis through the Wnt signaling pathway, and it affects the prognosis of patients[24]. EGFR is overexpressed in a variety of cancers, including CRC. EGFR overexpression and activation have a positive effect on the cell growth and metastasis of a variety of solid tumors, including CRC[17]. Metastasis is a multistep process in which tumor cells spread from the primary site to distant sites and form secondary tumors[32], and is the leading cause of death in CRC patients. Many downstream targets of HB-EGF and EGFR include MAPK, p-MAPK, RAS, RAF, PI3K, p-PI3K, AKT, p-AKT, and AKT protein kinases, leading to many processes related to tumor progression, including cell growth[33], epithelial-mesenchymal transition (EMT)[34], metastasis[35], and angiogenesis[36]. FOXQ1 can regulate FAK, PI3K, AKT, and many other key proteins in the PI3K/AKT signaling pathway and promotes the phosphorylation of the above proteins to maintain the activation of PI3K/AKT signaling[37]. FOXQ1 can also combine with VEGFR2 and VE-cadherin to promote angiogenesis and endothelial cell migration and rearrangement[24].

In our previous studies, we found that the mRNA and protein expression levels of FOXQ1 gradually increase with the pathological development of colorectal adenoma to colorectal adenocarcinoma, and the increased expression of FOXQ is not only involved in the process of colorectal adenoma carcinogenesis, but is also closely related to invasion and metastasis of CRC[38]. The differential expression of genes that are involved in the process of colorectal adenoma carcinogenesis screened by the gene chip has been analyzed by signal pathway analysis, suggesting that the abnormally high expression of FOXQ1 is closely related to the activation of the EGFR signaling pathway[39]. Studies have shown that the abnormal activation of the EGFR pathway plays an important role in malignant growth, invasion,

and metastasis of colorectal tumors. When sHB-EGF binds to EGFR, the tyrosine kinase activity of EGFR is activated, mainly by activating the MAPK/ERK1/2, PI3K/AKT, and JAK/STAT3 signaling pathways, leading to the proliferation, invasion, metastasis, and apoptosis of tumor cells[40]. The results of this study also proved that knockout of *FOXQ1* caused a decrease in gene expression in these three signaling pathways.

Combined with the analysis in Figure 3B-D, these results suggested that FOXQ1 may regulate the EGFR pathway by promoting the separation of ProHB-EGF into sHB-EGF. AMAD7, AMAD9, and AMAD12 are also factors that affect the separation of ProHB-EGF[41]. In this study, decreased expression levels of AMAD7, AMAD9, and AMAD12 were also observed in DLD1-shFOXQ1 and SW480-shFOXQ1 cells, but this indirect regulation should be further verified in other CRC cell lines.

In this study, FOXQ1 was determined to be upregulated in CRC cell lines. The results showed that *FOXQ1* knockdown inhibited the proliferation, migration and repair capabilities of CRC, which was consistent with our previous results[21,42]. When rhHB-EGF protein was added, the proliferation ability of the cells was not completely restored, but the migration and repair ability of CRC cells was partially restored. These results indicated that the effect of FOXQ1 in promoting the proliferation of CRC cells is not directly mediated by HB-EGF; however, the regulation of the invasion and metastasis of CRC cells by FOXQ1 is partly mediated by HB-EGF. HB-EGF is related to the abnormal proliferation of skin and mucosal cells, and high expression of HB-EGF is closely related to the occurrence and development of a variety of tumors; the expression of the *HB-EGF* gene is significantly increased in various human cancers and cancer-derived cell lines, indicating that HB-EGF plays an important role in tumor invasion and metastasis[43-46].

Studies have shown that FOXQ1 is related to the poor prognosis of CRC[47]. In this study, we conducted pathological and survival analyses on 65 CRC patients. These findings suggested that the expression of FOXQ1 and its coregulatory protein HB-EGF may have a prognostic correlation with CRC. Thus, FOXQ1 may serve as a therapeutic target for CRC treatment by blocking the HB-EGF/EGFR pathway. Our research suggests that FOXQ1 activates the EGFR signaling pathway by regulating the expression of HB-EGF, thereby affecting the invasion and metastasis of CRC. Regarding the limitations

Figure 6 Prognostic value of the combination of forkhead Box q1 and heparin binding epidermal growth factor. A: Representative immunohistochemical images of forkhead Box q1 (FOXQ1) and heparin binding epidermal growth factor (HB-EGF) positive coexpression and negative coexpression in human colorectal cancer tissues and adjacent nontumorous tissues. Scale bars represent 200 μm; B: Kaplan-Meier survival analysis was used to evaluate the overall survival rate in the following patients: FOXQ1-positive and FOXQ1-negative patients; HB-EGF-positive and HB-EGF-negative patients; and FOXQ1-positive and FOXQ1-negative coexpressing HB-EGF-positive and HBEGF-negative patients. $^{a}P < 0.05$; $^{b}P < 0.01$; $^{c}P < 0.001$ indicate a significant difference between the indicated groups (log-rank test). FOXQ1: Forkhead Box q1; HB-EGF: Heparin binding epidermal growth factor.

of this study, it is necessary to construct a FOXQ1 high-expressing cell line and combine it with the dual luciferase reporter gene system to further verify whether FOXQ1 is directly involved in the transcriptional regulation of HB-EGF. Next, we will further explore the regulation of FOXQ1 on EGFR and its downstream signaling pathways through *in vivo* and *in vitro* studies. We will conduct a more comprehensive study on the role of HB-EGF in the invasion and metastasis of CRC to provide more possibilities for the treatment of CRC.

CONCLUSION

In conclusion, we have demonstrated that decreased FOXQ1 expression was also associated with a lower ability to invade and metastasize in CRC. FOXQ1 promotes the invasion and metastasis of CRC by activating the HB-EGF/EGFR pathway. These data indicated that FOXQ1 and HB-EGF may be potential biomarkers to improve the accuracy of CRC diagnosis and treatment.

ARTICLE HIGHLIGHTS

Research background

Invasion and metastasis play important roles in tumorigenesis, resulting in the death of most colorectal cancer (CRC) patients. Forkhead Box q1 (FOXQ1) is a well-established oncogene in multiple tumors,

including CRC. However, the role and mechanism of how FOXQ1 promotes tumorigenesis in CRC by activating the heparin-binding epidermal growth factor (HB-EGF)/epidermal growth factor receptor (EGFR) pathway remain largely unknown.

Research motivation
Our study aims to elucidate the critical role of FOXQ1 and HB-EGF/EGFR pathways in CRC, and to provide theoretical support for the clinical application of targeted FOXQ1 in the treatment of CRC.

Research objectives
To determine the role of FOXQ1-induced invasion and metastasis, which are related to activating the HB-EGF/EGFR pathway, and to explore the mechanism by which FOXQ1 promotes tumorigenesis by activating the HB-EGF/EGFR pathway in CRC.

Research methods
We analyzed the correlation between FOXQ1 and the HB-EGF/EGFR pathway by constructing *FOXQ1* knockdown cells, tissue microarray, cell function experiments, quantitative real-time polymerase chain reaction (qRT–PCR), flow cytometry, ELISA, western blot, and the Gene Expression Profiling Interactive Analysis (GEPIA) website.

Research results
GEPIA showed that the expression of FOXQ1 in CRC tissues was relatively high and was related to a lower overall survival rate. PCR array results showed that *FOXQ1* is related to the HB-EGF and EGFR pathways. Knockdown of *FOXQ1* suppressed the expression of HB-EGF and led to a decrease in EGFR and its downstream genes *AKT*, *RAF*, *KRAS* expression levels. After knockdown of *FOXQ1* in CRC cell lines, cell proliferation, migration, and invasion were attenuated. Adding HB-EGF restored the migration and invasion ability of CRC, but the cell proliferation ability was not restored. Kaplan–Meier survival analysis results showed that the combination of FOXQ1 and HB-EGF may serve to predict CRC survival.

Research conclusions
FOXQ1 promotes the invasion and metastasis of CRC by activating the HB-EGF/EGFR pathway.

Research perspectives
In this study, our results indicated that FOXQ1 and HB-EGF may be potential biomarkers to improve the accuracy of CRC diagnosis and treatment.

Abstract

BACKGROUND

The occurrence and development of acute liver failure (ALF) is closely related to a series of inflammatory reactions, such as the production of reactive oxygen species (ROS). Hypoxia inducible factor 1α (HIF-1α) is a key factor that regulates oxygen homeostasis and redox, and the stability of HIF-1α is related to the ROS level regulated by Sirtuin (Sirt) family. The activation of Sirt1 will lead to a powerful antioxidant defense system and therapeutic effects in liver disease. However, little is known about the relationship between HIF-1α and Sirt1 in the process of ALF and the molecular mechanism.

AIM

To investigate whether HIF-1α may be a target of Sirt1 deacetylation and what the effects on ALF are.

METHODS

Mice were administrated lipopolysaccharide (LPS)/D-gal and exposed to hypoxic conditions as animal model, and resveratrol was used as an activator of Sirt1. The cellular model was established with L02 cells stimulated by LPS. N-acetyl-L-cysteine was used to remove ROS, and the expression of Sirt1 was inhibited by nicotinamide. Western blotting was used to detect Sirt1 and HIF-1α activity and related protein expression. The possible signaling pathways involved were analyzed by immunofluorescent staining, co-immunoprecipitation, dihydro-ethidium staining, and Western blotting.

RESULTS

Compared with mice stimulated with LPS alone, the expression of Sirt1 decreased, the level of HIF-1α acetylation increased in hypoxic mice, and the levels of carbonic anhydrase 9 and Bcl-2-adenovirus E1B interacting protein 3 increased significantly, which was regulated by HIF-1α, indicating an increase of HIF-1α activity. Under hypoxia, the down-regulation of Sirt1 activated and

acetylated HIF-1α in L02 cells. The inhibition of Sirt1 significantly aggravated this effect and the massive production of ROS. The regulation of ROS was partly through peroxisome proliferator-activated receptor alpha or AMP-activated protein kinase. Resveratrol, a Sirt1 activator, effectively relieved ALF aggravated by hypoxia, the production of ROS, and cell apoptosis. It also induced the deacetylation of HIF-1α and inhibited the activity of HIF-1α.

CONCLUSION
Sirt1 may have a protective effect on ALF by inducing HIF-1α deacetylation to reduce ROS.

Key Words: Acute liver failure; Deacetylation; Hypoxia inducible factor 1α; Reactive oxygen species; Sirtuin1

Core Tip: Hypoxia inducible factor 1α (HIF-1α) is a transcription factor that regulates oxygen homeostasis. Under hypoxic conditions, HIF-1α translocates to the nucleus and binds to β-subunits, resulting in transcription of target genes. In acute liver failure, HIF-1α contributes to early liver cell necrosis. The activation of Sirtuin1 (Sirt1) will result in a powerful antioxidant defense system. This study examined the influence of Sirt1-mediated pathways on HIF-1α expression *in vivo* and *in vitro*, explored the relationship between Sirt1 and HIF-1α, and further explored its potential mechanism.

INTRODUCTION

Acute liver failure (ALF) refers to a large number of necrosis of liver cells or severe liver damage caused by various reasons[1]. ALF is often accompanied by coagulation dysfunction and progressive multiple organ failure due to liver metabolism disorders and decreased immune function[2]. The occurrence and development of ALF is closely related to a series of inflammatory reactions, such as the release of inflammatory cytokines and the production of reactive oxygen species (ROS)[3].

Hypoxia-inducible factor (HIF)-1 consists of an oxygen-regulated subunit HIF-1α and a constitutive expression subunit HIF-1β. The activity and stability of the alpha subunit of HIF are regulated by its post-translational modifications such as acetylation[4]. Under hypoxic conditions, HIF-1α acts as a primary transcription factor to regulate hypoxia-related anti-inflammatory responses[5]. HIF-1α is a key factor that regulates oxygen homeostasis and redox and promotes effective adaptation to hypoxia[6]. During the development of liver diseases such as liver cancer, hypoxia is a common finding. Hypoxia promotes the stabilization of HIF-1α. HIF signal in innate immune cells and liver cancer cells is beneficial to the recruitment and maintenance of primordial tumorigenic immune cells and promotes immune evasion[7].

The monitoring of HIF-1α activity by members of the Sirtuin (Sirt) family has been a topic of interest in recent years[8-10]. According to reports, HIF-1α has been confirmed to be related to Sirt1, Sirt2, and Sirt3 in the Sirt family, and the stability of HIF-1α is related to the ROS level regulated by Sirt3 and the oxygen level regulated by Sirt6[11-14]. Sirt2 causes protein hydroxylation and ubiquitination by increasing the binding of HIF-1α to propylamine hydroxylase[8]. However, the regulation mechanism of Sirt1 on HIF-1α activity has always been a controversial topic.

Sirt1 in the sirtuin family is a nicotinamide adenine dinucleotide-dependent protein lysine deacetylase with diverse physiological functions such as anti-inflammation, neuronal signaling, DNA repair, and stress response. Sirt1 has been shown to be an important target for the treatment of various diseases[15,16], and its activation will lead to a powerful antioxidant defense system and therapeutic effects in liver ischemia reperfusion[17]. Studies have shown that Sirt1 regulates HIF-1α through the formation of physical complexes between proteins, and Sirt1 may have a negative regulatory effect on HIF-1α[18]. Sirt1 has also been reported to regulate HIF-1α actively by stabilizing the protein[19]. Whether Sirt1 is used as a negative regulator or a positive regulator of HIF-1α or depends on the experimental conditions or experimental models remains to be further studied.

In this study, we examined the regulation of Sirt1 on HIF-1α activity in ALF and explored its possible molecular mechanisms.

MATERIALS AND METHODS

Mice

Male C57BL/6J wild-type mice aged 5-6 wk were purchased from Wuhan Biomedical Research Institute of Wuhan University. All mice were raised in the specific pathogen free animal facility of Renmin Hospital of Wuhan University with conditions of light-controlled, room temperature 25 °C, and humidity 55 ± 5%, and they were free to eat and drink. All animal operations were approved by the Animal Care and Use Committee of Renmin Hospital of Wuhan University, China (Approval No. WDRY2021-K016).

Animal models

The mice were randomly divided into six groups with 6 mice in each group: Saline control group; Hypoxia group; Lipopolysaccharide (LPS) group; Hypoxia + LPS group; Resveratrol group; and LPS + Hypoxia + Resveratrol group. Hypoxia group and Hypoxia + LPS group were cultured in COY Vinyl Anaerobic Chambers (COY, Grass Lake, MI, United States). To avoid pulmonary and cerebral edema caused by a rapid drop in oxygenation, the fraction of inspired oxygen (FiO_2) (1%/d) was gradually decreased from 21% normoxia (room-air oxygen) to 8% oxygen (severe hypoxia) over the course of 2 wk, followed by continual exposure to 8% oxygen for an additional 2 wk. On the 14th d after being exposed to 8% oxygen, Resveratrol (10 mg/kg; Sigma–Aldrich, St. Louis, MI, United States)[20] was given intragastrically in Resveratrol group and LPS + Hypoxia + Resveratrol group while LPS (100 μg/kg; Sigma–Aldrich) was administrated by intraperitoneal injection combined with D-Gal (400 mg/kg) in LPS group and LPS + Hypoxia + Resveratrol group[21]. Twenty-four hours after LPS administration, animals were quickly euthanized with inhaled CO_2, followed by the collection of blood samples and liver tissues[21].

Cell culture

Human embryonic liver cell line L02 was purchased from China Center for Type Culture Collection (Wuhan, China). N-acetyl-L-cysteine (NAC) (Beyotime, Shanghai, China) (5 mmol/L)[22], nicotinamide (NAM) (Beyotime) (5 mmol/L)[23], GW6471 (Sigma-Aldrich) (3 μM)[24] or Compound C (Sigma-Aldrich) (10 μM)[25], which were dissolved in dimethyl sulfoxide (Sigma-Aldrich), were used to pretreat L02 cells for 1 h, followed by LPS (5 μg/mL)[26] treatment. Hypoxic conditions (1% O_2) were obtained using humidified variable aerobic workstation InVivo2 400 (Ruskinn, Pencoed, United Kingdom)[27]. For transient transfection, cells were transfected with 2 μg plasmid of pECE-flag-Sirt1 (Addgene, Cambridge, MA, United States) and pECE empty vector (Addgene).

Biochemical analyses

Blood samples were collected after mice were anesthetized. The level of malondialdehyde (Cat. No. GM1134), superoxide dismutase (Cat. No. GM1133), and glutathione peroxidase (Cat. No. GM1135) were determined with commercial kits (Servicebio, Wuhan, China), respectively, according to the manufacturer's instructions.

Histopathological examination

The liver tissues were sliced completely and stained with hematoxylin-eosin. The pathological changes of liver tissue were observed and evaluated by light microscope (Olympus, Tokyo, Japan). The degree of liver damage in the ALF models were assessed by the liver histology score.

Immunofluorescent staining

Liver tissue sections were intact, and L02 cell suspensions were fixed on glass slides. Sections were fixed with 4% paraformaldehyde for 30 min, and 50-100 μL membrane rupture working solution and 3 % hydrogen peroxide solution were added in sequence according to the manufacturer's instructions. Primary antibody against acetyl-lysine or HIF-1α (Santa Cruz Biotechnologies, Dallas, TX, United States) diluted 1:100 with 5% bovine serum albumin was added on the slides and tissue sections, and the slides were incubated overnight at 4 °C in a wet box. Then, slides were incubated with secondary antibody (1:50 dilution, Beyotime), and they were imaged using a fluorescent microscope (Olympus).

Immunoprecipitation

Approximately 1 mg of total protein was incubated with anti-Sirt1 antibody (Servicebio) or anti-HIF-1α antibody (Servicebio) overnight at 4 °C followed by precipitation with 20 μl of protein A/G-Plus-Agarose (Servicebio) for 4 h at 4 °C. The precipitated complex was immunoblotted with anti-Sirt1, anti-HIF-1α, or anti-acetyl-lysine.

Detection of ROS production

L02 cell suspensions were fixed on glass slides. Cell culture fluid (2 mL) was added and the culture was continued for about 6 h. Dihydroethidium (1 mL) (Cat. No. GDP1018), which was dissolved in dimethyl

sulfoxide at a ratio of 1:1000, was added to each well, and the samples were incubated in the dark. An appropriate amount of DAPI solution was added to the wells and stained. Then, a drop of anti-fluorescence quenching medium was added into the hole; the slides were imaged under a fluorescent microscope.

Western blotting

Proteins were extracted from cells and tissues as directed by the radioimmunoprecipitation assay kit (Sigma-Aldrich). An appropriate amount of concentrated sodium dodecyl sulfate polyacrylamide gel electrophoresis protein loading buffer was added to the collected protein samples, and then 5-10 μL of the sample was loaded in the sodium dodecyl sulfate polyacrylamide gel electrophoresis gel sample holes. Low voltage constant pressure electrophoresis for the upper gel and high voltage constant voltage electrophoresis were applied, when bromophenol blue entered the lower gel. After electrophoresis, the proteins were transferred to polyvinylidene fluoride membranes. The following primary antibodies were used: Sirt1 (Cat. No. 9475, Cell Signaling Technology, Danvers, MA, United States), peroxisome proliferator-activated receptor alpha (PPARα, Cat. No. 23398R, Bioss, Woburn, MA, United States), HIF-1α (Cat. No. 20398R, Bioss), AMP-activated protein kinase (AMPK, Cat. No. 32047, Abcam, Cambridge, United Kingdom), p-AMPK (Cat. No. 131357, Abcam), Bnip3 (Cat. No. 109414, Abcam), and glyceraldehyde-3-phosphate dehydrogenase (Cat. No. 8245, Abcam). Image Lab statistical software (Bio-Rad, Hercules, CA, United States) was used to evaluate band intensities on Western blots.

Statistical analyses

Statistical analysis was performed using GraphPad Prism software version 8.0 (San Diego, CA, United States). The Y axis was labeled as fold of control mean. Data were expressed as the means ± standard deviations. Differences among multiple groups were evaluated using conventional Student's *t* test or analysis of variance. Statistical significance was considered at $P < 0.05$.

RESULTS

Hypoxia aggravated ALF and increased the expression and acetylation of HIF-1α

The liver structure of each group was shown by histopathological examination. Compared with the control group, large-scale hepatocyte necrosis in the LPS and Hypoxia groups and the number of infiltrating inflammatory cells were significantly increased, while the inflammatory response was significantly more severe in the LPS + Hypoxia group (Figure 1A). Next, we tested the expression of some key proteins in ALF. As shown in Figure 1B, compared with the control group, the expression of Sirt1 in the LPS group was significantly reduced, and hypoxia aggravated this effect. The expression of Bcl-2 adenovirus E1B-interacting protein 3 (Bnip3) in the LPS + hypoxia group was significantly increased, as was carbonic anhydrase 9 (CA9), both of which are regulated by HIF-1α, suggesting that hypoxia significantly increased the activity of HIF-1α in the LPS group. Of note, the expression of HIF-1α in the LPS + Hypoxia group was significantly increased in the form of acetylation. LPS significantly increased HIF-1α acetylation induced by hypoxia (Figure 1C).

Hypoxia reduced the expression of Sirt1, causing the activation and acetylation of HIF-1α

To detect changes in the expression of Sirt1 in L02 cells during hypoxia, we measured the expression levels of Sirt1, HIF-1α, and Bnip3 using Western blotting. Compared to the control group, hypoxia reduced Sirt1 expression and upregulated HIF-1α and Bnip3 expression in a time-dependent manner (Figure 2A-D). Through immunofluorescence experiments, we found that as the duration of hypoxia increased, the expression of HIF-1α increased significantly in the form of acetylation (Figure 2E). We then analyzed the interaction between Sirt1 and HIF-1α. After hypoxia induced endogenous HIF-1α, Sirt1-HIF-1α binding was observed (Figure 2F). We next examined whether Sirt1 deacetylates HIF-1α. Immunoblotting with anti-acetyl-lysine in HIF-1α immunoprecipitates was used to detect the lysine acetylation level of HIF-1α. As shown in Figure 2G, Sirt1 overexpression significantly decreased HIF-1α acetylation, suggesting that Sirt1 regulated lysyl acetylation of HIF-1α. These results suggested that hypoxia-induced enhancement of HIF-1α activity and lysine acetylation were related to the down-regulation of Sirt1.

The inhibition of Sirt1 induced activation of HIF-1α and subsequently increased the production of ROS induced by hypoxia

Next, we explored the possible molecular mechanisms of the interaction between Sirt1 and HIF-1α. As shown in the Figure 3A, LPS increased the expression of HIF-1α, and the expression of Sirt1 was further reduced after HIF-1α was increased by hypoxia in L02 cells. At the same time, the use of a specific Sirt1 inhibitor NAM to inhibit Sirt1 further aggravated this effect. Sirt1 appear to interact with HIF-1α in L02 cells. Studies have found that excessive production of ROS is considered harmful and related to hypoxia [28]. Oxidative stress has been shown to promote inflammation during ALF[29]. How oxidative stress is

involved in inflammation during ALF remains unclear. Therefore, we examined the antioxidant effect of Sirt1 during hypoxia. DHE staining showed that the level of ROS stimulated by LPS was significantly increased by hypoxia, and this effect was enhanced when NAM was used to inhibit the Sirt1 signaling

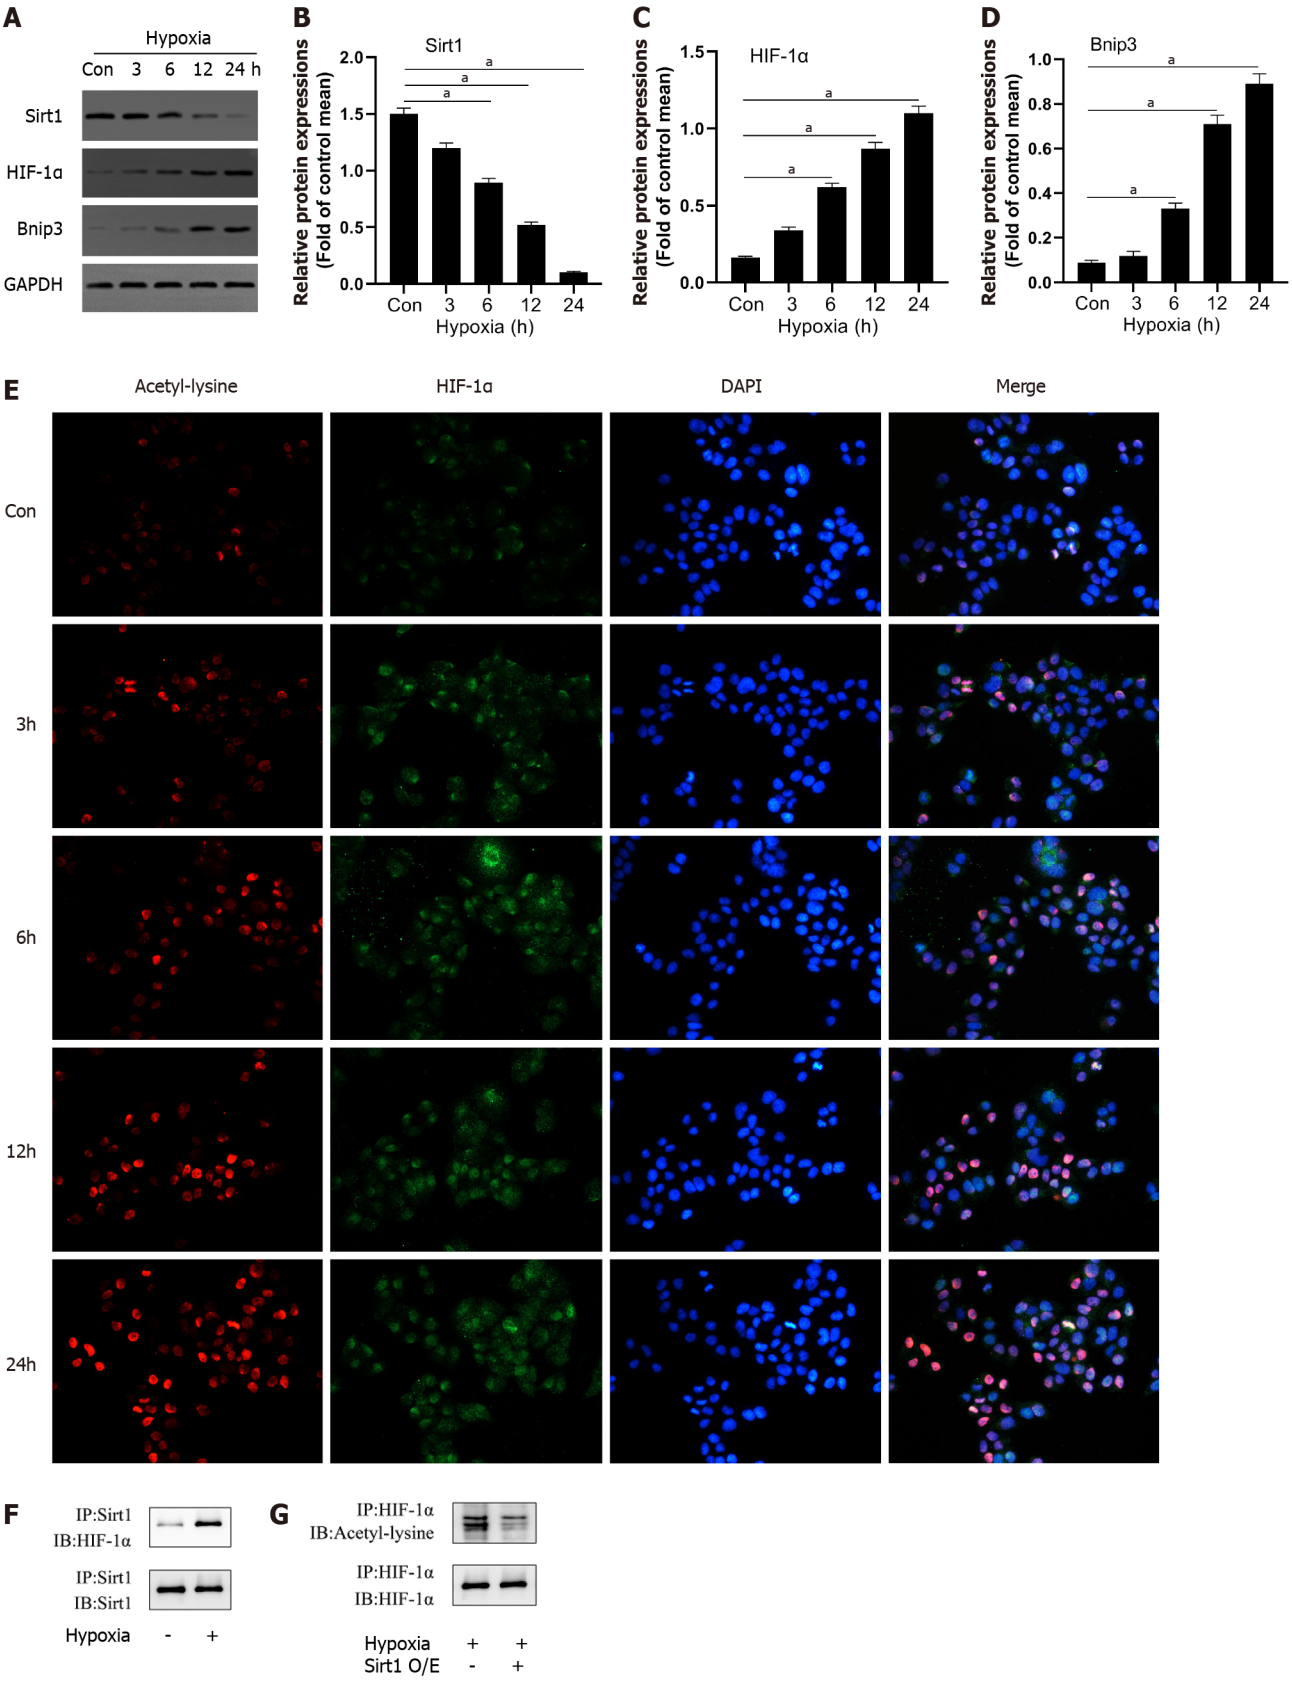

Figure 2 Hypoxia decreased Sirtuin1 expression leading to the acetylation and activation of hypoxia inducible factor-1α. Data shown are means ± standard deviations (SDs) of three separate experiments. [a]*P* < 0.05 *vs* Control group; [b]*P* < 0.05 *vs* Lipopolysaccharide (LPS)-treated group; [c]*P* < 0.05 *vs* LPS + Hypoxia-treated group; one-way analysis of variance with Bonferroni's *post hoc* test; the error bars indicate the SDs.

pathway (Figure 3B and C). Next, we found that the expression of Sirt1 was increased and HIF-1α was opposite when NAC was used, which is an effective ROS scavenger (Figure 3D). At the same time, LPS-induced levels of ROS were significantly reversed by NAC (Figure 3E and F).

The inhibition of Sirt1/PPARα signaling pathway increased hypoxia-induced ROS production in vitro

Some studies have shown that liver PPARα expression is lower in patients with hepatitis C and advanced nonalcoholic fatty liver disease, perhaps due to the inhibitory effect of multiple cytokines[30]. This also shows that increasing PPARα may help reduce liver inflammation. In our study, as shown in Figure 4A, in the L02 cells stimulated by LPS, PPARα expression was decreased and aggravated after hypoxia intervention, and its effect was further aggravated when NAM was used to inhibit the Sirt1 signaling pathway, suggesting that hypoxia-induced PPARα inhibition was closely related to Sirt1. In addition, Sirt1 expression was further reduced by the PPARα inhibitor GW6471, while HIF-1α was opposite (Figure 4B) and the levels of ROS were also improved (Figure 4C), suggesting that the inhibition of Sirt1/PPARα signaling pathway might increase hypoxia-induced ROS production in L02 cells.

The inhibition of Sirt1/AMPK signaling pathway increased hypoxia-induced ROS production in vitro

AMPK acts as a regulator of cellular energy metabolism and redox homeostasis. More and more evidence shows that AMPK plays a protective role by regulating the redox system[31]. Next, we further studied whether Sirt1 can regulate AMPK and its role in cell hypoxia in L02 cells. As shown in Figure 5A, the phosphorylation level of AMPK in L02 cells induced by LPS after hypoxia treatment was significantly reduced, while NAM pretreatment aggravated this effect, indicating AMPK could be modulated by hypoxia *via* Sirt1. In addition, AMPK inhibitor Compound C further reduced the expression of Sirt1, the expression of HIF-1α was further increased (Figure 5B), and the levels of ROS were also improved (Figure 5C). Therefore, these results suggested that Sirt1/AMPK signaling pathway might be involved in modulating ROS in LPS-stimulated L02 cells during hypoxia.

The activation of Sirt1 induced the inactivation and deacetylation of HIF-1α and subsequently rescued the progressive aggravation of ALF induced by hypoxia in vivo

Finally, to determine further whether Sirt1 attenuated the progressive aggravation of ALF induced by hypoxia through the Sirt1/AMPK or the Sirt1/PPARα pathway, LPS-stimulated mice were exposed to hypoxia with or without resveratrol treatment, which is a Sirt1 activator. Compared with the LPS group, activation of Sirt1 by resveratrol alleviated the more sever liver tissue damage in the LPS + Hypoxia group (Figure 6A and B). LPS + Hypoxia group mice showed lower activity of superoxide dismutase and glutathione peroxidase, while malondialdehyde levels were increased, indicating that hypoxia led to decreased antioxidant activity. However, resveratrol treatment could significantly improve the activity (Figure 6C). As shown in Figure 6D, resveratrol dramatically alleviated hypoxia-induced reduction levels of PPARα protein and the phosphorylation of AMPK in LPS-stimulated mice, suggesting that Sirt1 was a key regulator on the activation of PPARα and the phosphorylation of AMPK during hypoxia in ALF. Finally, we demonstrated with animals whether Sirt1 has a regulatory effect on hypoxia-induced HIF-1α lysine acetylation and HIF-1α activity. As shown in Figure 6E, with the intervention of resveratrol, the expression of HIF-1α and the level of acetylation decreased significantly. These findings indicate that the activation of Sirt1 induced HIF-1α inactivation and deacetylation, thereby alleviating the progressive aggravation of ALF induced by hypoxia.

DISCUSSION

Recently, more and more studies have confirmed the effect of Sirt1 in liver disease. Sirt1 has been confirmed to have a protective effect in a variety of disease models, including liver fibrosis[32], drug-induced liver injury[33], non-alcoholic fatty liver disease[34], and fatty liver[35]. As well known, HIF-1α is a transcription factor that can promote the adaptive response of cells to hypoxia. Some reports have mentioned the connection between Sirt1 and HIF protein, but there are still many controversies about the results. According to reports, in hypoxic Hep3B or HEK293 cells, Sirt1 targeted HIF-2α and increased the transcriptional activity of HIF-2α but not HIF-1α[36]. On the contrary, another group of studies

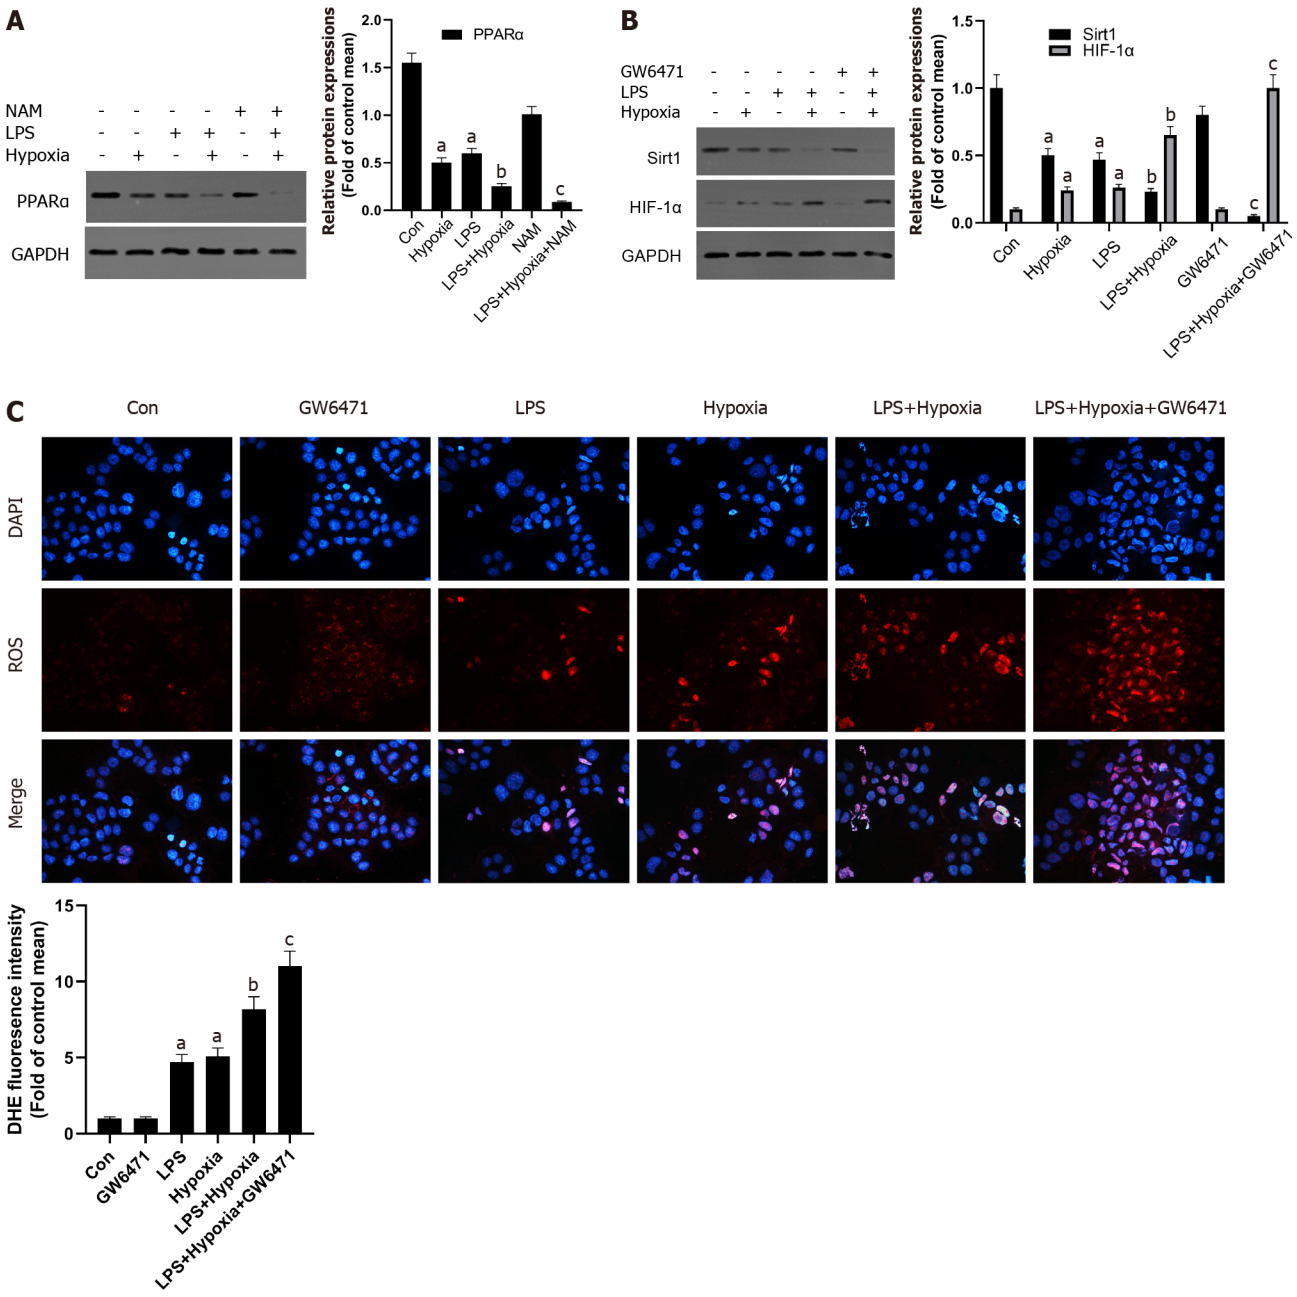

Figure 4 The inhibition of Sirtuin1/peroxisome proliferator-activated receptor alpha signaling pathway increased hypoxia-induced reactive oxygen species production. A: Western blotting was performed to measure the levels of peroxisome proliferator-activated receptor alpha (PPARα) in L02 cells; B: The levels of Sirtuin1 (Sirt1) and hypoxia inducible factor (HIF)-1α in L02 cells; C: Reactive oxygen species productions were detected by dihydroethidium (DHE) staining and evaluated by quantification of mean fluorescence intensity in DHE staining. Data shown are means ± standard deviations (SDs) of three separate experiments. $^{a}P < 0.05$ *vs* Control group; $^{b}P < 0.05$ *vs* Lipopolysaccharide (LPS)-treated group; $^{c}P < 0.05$ *vs* LPS + Hypoxia-treated group; one-way analysis of variance with Bonferroni's *post hoc* test; the error bars indicate the SDs.

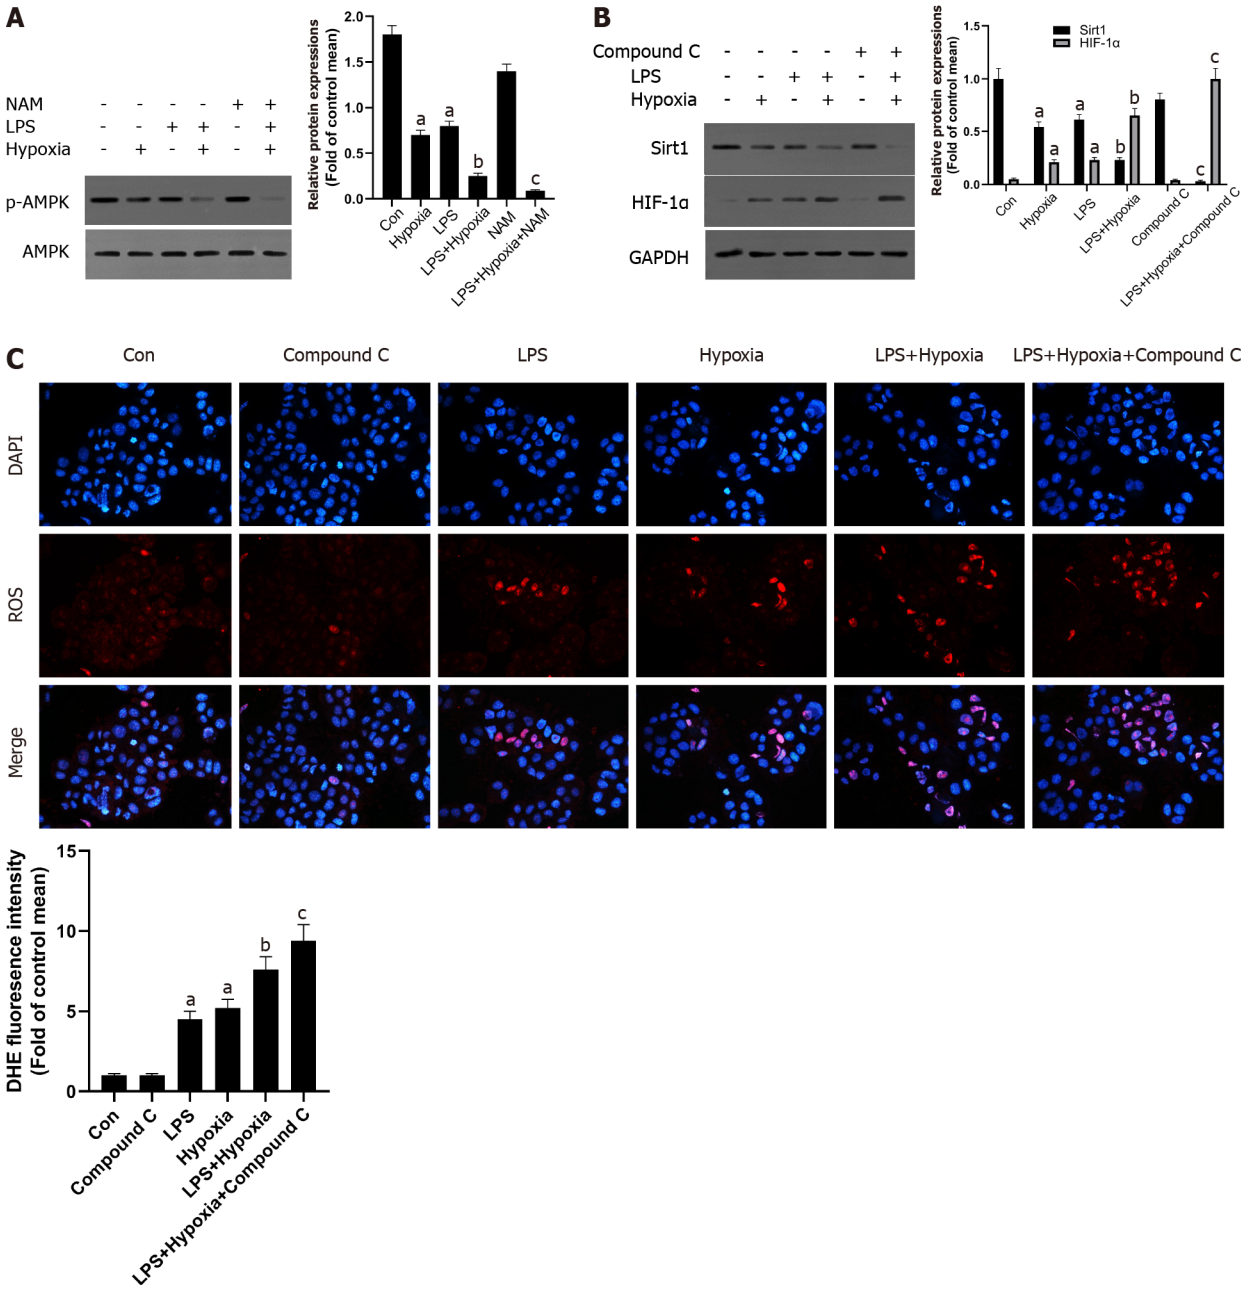
showed that Sirt1 interacted with HIF-1α, causing HIF-1α deacetylation to promote its activity in Hep3B and Huh7 cells[19]. Therefore, the regulation of Sirt1 on the activity of HIF-1α and its expression seems to be cell-type-specific, which is currently unclear. It has not been reported that the beneficial effect of Sirt1 activation is related to its HIF-1α deacetylation against ALF.

In our research, we found that the activity of HIF-1α increased after acetylation and promoted hepatocyte apoptosis in ALF models and hypoxia models *in vitro*. In addition, we demonstrated that the expression of Sirt1 in L02 cells decreased in a time-dependent manner due to hypoxia, which was closely related to the activation and acetylation of HIF-1α. During hypoxia, with the decrease of the level of nicotinamide adenine dinucleotide, the activity of Sirt1 decreased and HIF-1α transcription activity further increased[18,19]. Therefore, the insufficient expression of Sirt1 in the liver or the acetylation of HIF-1α might be the key mediators of ALF.

Next, we carefully evaluated Sirt1's regulatory effect on HIF-1α activity in ALF and explored its possible molecular mechanisms. ROS are by-products of normal metabolism in living cells, but



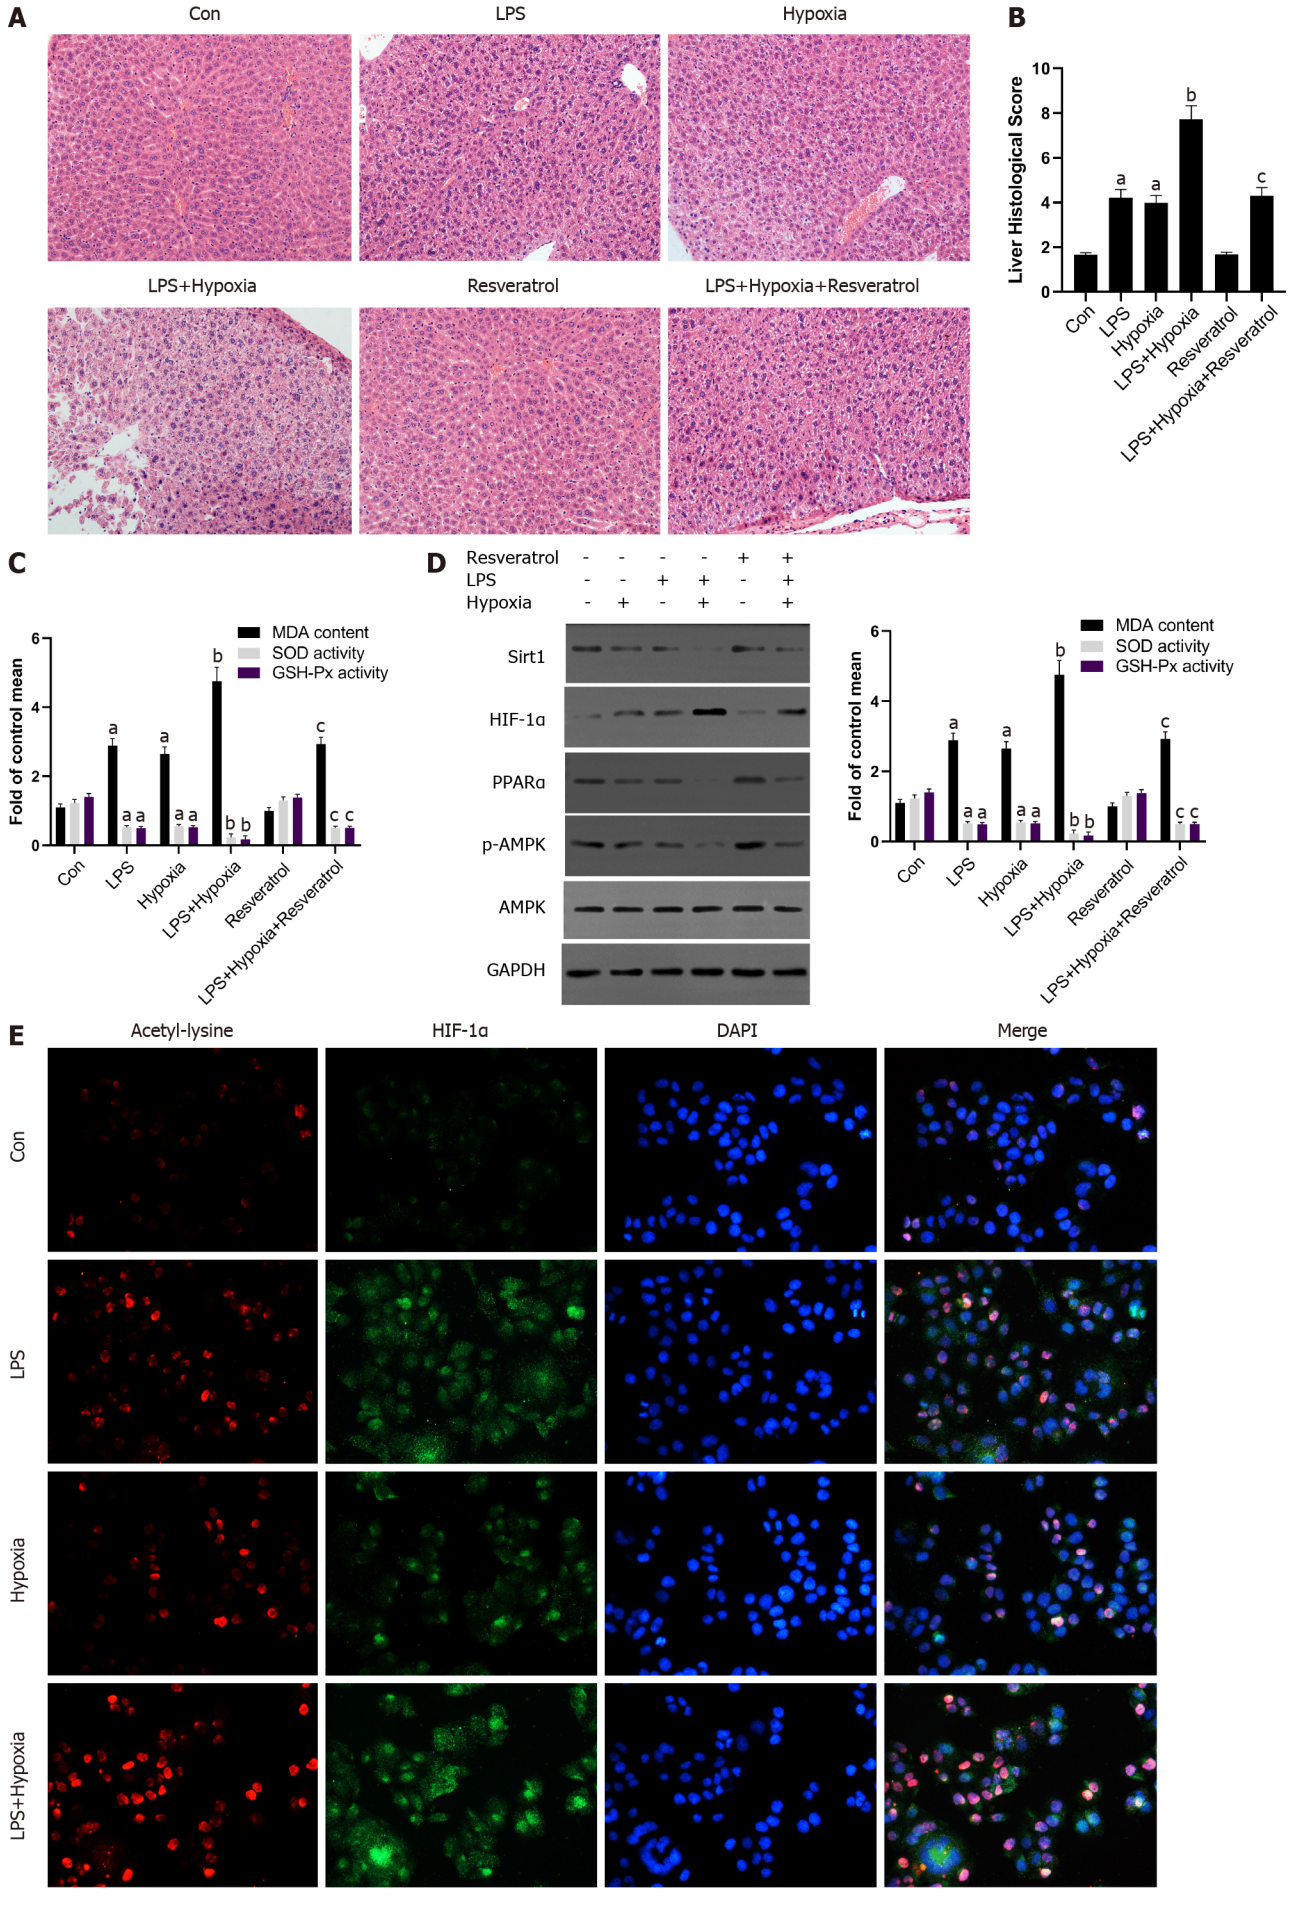


Figure 5 The inhibition of Sirtuin1/AMP-activated protein kinase signaling pathway increased hypoxia-induced reactive oxygen species production. Data shown are means ± standard deviations (SDs) of three separate experiments. $^{a}P < 0.05$ *vs* Control group; $^{b}P < 0.05$ *vs* Lipopolysaccharide (LPS)-treated group; $^{c}P < 0.05$ *vs* LPS + Hypoxia-treated group; one-way analysis of variance combined with Bonferroni's post hoc test; the error bars indicate the SDs.

excessive ROS accumulation can damage organelles, leading to increased oxidative stress[37,38]. ALF produces excessive amounts of ROS due to insufficient detoxification of toxic substances in the liver [39]. Sirt1 has been reported to play an important role in anti-inflammatory and antioxidant processes [40]. Here, we demonstrated that HIF-1α was over-activated in hypoxia due to increased level of ROS in the absence of Sirt1, and the effect was inhibited by the antioxidant NAC, indicating that ROS was involved in this activation.

In particular, PPARα is reported to be a potent inhibitor of NF-κB signaling pathway and inflammation[41]. The positive effect of Sirt1 on the inflammatory pathway may be related to PPARα[42], and the interference of PPAR transcriptional activity may disturb estrogen/androgen receptor expression and impair steroidogenesis and ROS metabolism[43]. In addition, PPARα contributes to the protection of redox homeostasis[44]. Previous studies have confirmed that Sirt1 can regulate AMPK, which is an important energy sensor[45]. AMPK acts as a regulator of cellular energy metabolism and redox homeostasis. More and more evidence shows that AMPK plays a cardiovascular protective role by

regulating the redox system[46]. In diabetes, the activation of AMPK increases the expression of mitochondrial antioxidant enzymes and leads to a decrease in the production of mitochondrial ROS in endothelial cell[47].

Our experiments revealed that the inhibition of PPARα and the phosphorylation of AMPK induced by hypoxia were closely related to Sirt1, and the inhibition of Sirt1/PPARα or Sirt1/AMPK signaling pathway might increase hypoxia-induced ROS production in L02 cells. In order to determine whether the activation of Sirt1 induced inactivation of HIF-1α, the progressive aggravation of ALF induced by hypoxia *in vivo* was rescued in mice treated with resveratrol. As expected, the activation of Sirt1 significantly alleviated the degree of liver damage in ALF and enhanced antioxidant activity. Resveratrol dramatically alleviated the hypoxia-induced reduction level of PPARα protein and the phosphorylation of AMPK in LPS-stimulated mice. In addition, the activation of Sirt1 induced the deacetylation of HIF-1α compared to LPS-stimulated mice exposed to hypoxia; the expression of HIF-1α and the level of acetylation decreased significantly.

One limitation of our study is that we did not use HIF-1α overexpressing mice *in vivo* to test whether the increase of Sirt1 activity can rescue ALF. We need to conduct further experiments to solve this problem.

CONCLUSION

In summary, we have demonstrated that Sirt1 reduced oxidative stress in ALF by regulating the activity and acetylation of HIF-1α, achieved by normalizing the Sirt1/PPARα and Sirt1/AMPK pathway. Our research showed that the deacetylation and inactivation of HIF-1α induced by the activation of Sirt1 might have therapeutic benefits in reducing liver damage during ALF.

ARTICLE HIGHLIGHTS

Research background

Acute liver failure (ALF) is a life-threatening disease that can rapidly develop into multiple organ failure. The mortality rate is high. If effective treatment measures are not taken, various complications will occur, including cerebral edema, sepsis, renal failure, gastrointestinal bleeding, and respiratory failure. Hypoxia inducible factor 1α (HIF-1α) is a transcription factor that regulates oxygen homeostasis. In ALF, HIF-1α contributes to early liver cell necrosis. Sirtuin1 (Sirt1) plays a key role in health by deacetylating target proteins in many tissues, including the liver. The activation of Sirt1 will result in a powerful antioxidant defense system. However, the role of Sirt1 in ALF and the relationship between Sirt1 and HIF-1α remain unclear and require further investigation.

Research motivation

The results of this study might provide a basis for the application of Sirt1 in the treatment of ALF and further understanding of the mechanism of Sirt1 and HIF-1α in the process of ALF.

Research objectives

This study detected the changes in the expression of Sirt1 and HIF-1α in liver tissues and hepatocytes under hypoxia during the ALF process as well as the differences in the expression levels of key enzymes. In addition, this study further explored the relationship and mechanism of Sirt1 signaling pathway and HIF-1α expression.

Research methods

Western blotting was used to detect the expression levels of Sirt1 and HIF-1α related proteins in mouse liver tissues, and immunofluorescence staining was used to observe the acetylation level of HIF-1α. Detection of HIF-1α and reactive oxygen species (ROS) levels and the correlation analysis between Sirt1 and HIF-1α were performed. Finally, Sirt1 was activated to observe the influence of the Sirt1 signaling pathway and HIF-1α on ALF, and changes in the expression levels of related markers were detected.

Research results

The expression of Sirt1 decreased and the level of HIF-1α acetylation increased in hypoxic mice, and the levels of carbonic anhydrase 9 and Bcl-2-adenovirus E1B interacting protein 3 increased significantly, which was regulated by HIF-1α, indicating an increase of HIF-1α activity. Under hypoxia, the down-regulation of Sirt1 activated and acetylated HIF-1α in L02 cells. The inhibition of Sirt1 significantly aggravated this effect and the massive production of ROS. The regulation of ROS was partly through peroxisome proliferator-activated receptor alpha or AMP-activated protein kinase (AMPK). The activation of Sirt1 effectively relieved ALF aggravated by hypoxia, the production of ROS, and cell apoptosis. It also induced the deacetylation of HIF-1α and inhibited the activity of HIF-1α.

Research conclusions

The inhibition of peroxisome proliferator-activated receptor alpha and the phosphorylation of AMPK induced by hypoxia were closely related to Sirt1, and the inhibition of Sirt1/PPARα or Sirt1/AMPK signaling pathway might increase hypoxia-induced ROS production. The activation of Sirt1 reduced oxidative stress in ALF by regulating the activity and acetylation of HIF-1α.

Research perspectives

The results of this study showed that the deacetylation and inactivation of HIF-1α induced by the activation of Sirt1 might have therapeutic benefits in reducing liver damage during ALF. This study preliminarily clarified the role of Sirt1 and HIF-1α in ALF, so as to deepen the understanding of the mechanism of ALF, and provided guidance for the selection of ALF treatment targets. The results of this study indicate that Sirt1 activator may have a certain prospective application as a therapeutic drug for ALF.

Abstract

BACKGROUND

Obesity and comorbidities onset encompass gut dysbiosis, altered intestinal permeability, and endotoxemia. Treatments that target gut dysbiosis can cope with obesity and nonalcoholic fatty liver disease (NAFLD) management. Peroxisome proliferator-activated receptor (PPAR)-alpha activation and dipeptidyl-peptidase-4 (DPP-4) inhibition alleviate NAFLD, but the mechanism may involve gut microbiota modulation and merits further investigation.

AIM

To address the effects of PPAR-alpha activation and DPP-4 inhibition (isolated or combined) upon the gut-liver axis, emphasizing inflammatory pathways in NAFLD management in high-fat-fed C57BL/6J mice.

METHODS

Male C57BL/6J mice were fed a control diet (C, 10% of energy as lipids) or a high-fat diet (HFD, 50% of energy as lipids) for 12 wk, when treatments started, forming the groups: C, HF, HFA (HFD + PPAR-alpha agonist WY14643, 2.5 mg/kg body mass), HFL (HFD + DPP-4 inhibitor linagliptin, 15 mg/kg body mass), and HFC (HFD + the combination of WY14643 and linagliptin).

RESULTS

The HFD was obesogenic compared to the C diet. All treatments elicited significant body mass loss, and the HFC group showed similar body mass to the C group. All treatments tackled oral glucose intolerance and raised plasma glucagon-like peptide-1 concentrations. These metabolic benefits restored *Bacteroidetes*/*Firmicutes* ratio, resulting in increased goblet cells *per* area of the large intestine and reduced lipopolysaccharides concentrations in treated groups. At the gene level, treated groups showed higher intestinal *Mucin 2*, *Occludin*, and *Zo-1* expression than the HFD group. The reduced endotoxemia suppressed inflammasome and macrophage gene expression in the liver of treated animals. These observations complied with the mitigation of liver steatosis and reduced hepatic triacylglycerol, reassuring the role of the proposed treatments on NAFLD mitigation.

CONCLUSION

PPAR alpha activation and DPP-4 inhibition (isolated or combined) tackled NAFLD in diet-induced obese mice by restoration of gut-liver axis. The reestablishment of the intestinal barrier and the rescued phylogenetic gut bacteria distribution mitigated liver steatosis through anti-inflammatory signals. These results can cope with NAFLD management by providing pre-clinical evidence that drugs used to treat obesity comorbidities can help to alleviate this silent and harmful liver disease.

Key Words: Nonalcoholic fatty liver disease; High-fat diet; Peroxisome proliferator-activated receptor-alpha; Dipeptidyl-peptidase-4-inhibitor; Dysbiosis; Inflammation

Core Tip: Chronic high-fat diet (HF) intake alters the phylogenetic microbiota composition, sending harmful proinflammatory signals to the liver that elicit nonalcoholic fatty liver disease in mice. Here, we treated HF diet-induced obese mice with a peroxisome proliferator-activated receptor-alpha agonist (WY14643), a dipeptidyl-peptidase-4 inhibitor (linagliptin), or their combination, focusing on gut–liver axis modulation. The treatments rescued gut dysbiosis and endotoxemia due to increased tight junction gene expression, mucin production, and numerical density of goblet cells in the intestinal crypts. Treated mice benefited from downregulated *Tlr4*, *Cd206*, and *Nlrp3*, alleviating fatty liver through anti-inflammatory signals such as increased *IL-10* and *IL-13*.

INTRODUCTION

The prevalence of obesity worldwide has tripled during recent decades, necessitating large budgets for public health systems due to associated comorbidities[1,2]. Excessive dietary saturated fat intake triggers insulin resistance, white adipocyte hypertrophy, low-grade inflammation (metainflammation), brown adipose tissue dysfunction (whitening), fatty liver, and, as more recently described, alteration in the composition of the gut microbiota (dysbiosis)[3,4].

The digestive tract is populated by several microorganisms, predominantly including bacteria from the *Firmicutes* and *Bacteroidetes* phyla, and this population is influenced by the quality of the diet[5]. Excessive saturated fat in the diet increases the proportion of gram-negative bacteria with lipopolysaccharides (LPS) in the composition of their outer wall[6]. LPS is an endotoxin that compromises the integrity of the intestinal mucosa through alterations in the structural proteins of tight junctions (TJs), resulting in increased intestinal permeability and the migration of LPS to other tissues[5,7].

The gut–liver axis comprises the anatomical communication between these two organs *via* the portal vein[8]. A recent study by our group has demonstrated phylogenetic changes in the gut microbiota of mice after seventeen weeks of high-fructose diet feeding, with a significant increase in liver steatosis and inflammation, indicating the progression of nonalcoholic fatty liver disease (NAFLD) (fatty liver disease associated with metabolic dysfunction) to more harmful forms of liver diseases[9]. Given this scenario, the identification of metabolic pathways that rescue gut dysbiosis and mitigate the liver changes arising

from a dietary excess of saturated fat is pertinent, considering the high prevalence of obesity, its deleterious health effects, and the fact that there is, thus far, no treatment directed exclusively toward NAFLD[10].

Peroxisome proliferator-activated receptors (PPARs) are transcription factors involved in several metabolic pathways. The pharmacological activation of the PPAR-alpha isoform promotes reduced body mass, increased insulin sensitivity, the formation of beige adipocytes[11], and a significant reduction in NAFLD by increasing mitochondrial beta-oxidation[9]. Recently, PPAR-alpha deletion promoted intestinal dysbiosis and inflammation in mice[12]. The dipeptidyl-peptidase-4 (DPP-4) inhibitor linagliptin extends the glucagon-like peptide-1 (GLP1) time of action through beneficial brown and white adipocyte remodeling, browning induction, and M2 macrophage polarization, in addition to enhancing liver vascularization, supressing *de novo* lipogenesis, and alleviating endoplasmic reticulum stress[13,14].

This study aimed to address the effects of PPAR-alpha activation and DPP-4 inhibition (isolated or combined) on the gut–liver axis, emphasizing inflammatory pathways in NAFLD management in high-fat-fed C57BL/6J mice.

MATERIALS AND METHODS

Animals and diet

Adult male C57BL/6J mice were group-housed (n = 5 *per* cage) and maintained under controlled temperature (21 ± 2 °C) and humidity (60 ± 10%) with free access to water and feed in a ventilated rack containing cages for the mice (NexGen mouse 500, Allentown, PA, United States). The environment comprised a 12/12 h light–dark period and air renewal cycles (15 min/h). The procedures followed the recommendations of the National Institutes of Health Guide for the Care and Use of Laboratory Animals (NIH publication No. 85-23, revised 1996) and were approved by our local Ethics Committee (Institute of Biology, CEUA number 041/2018).

Experimental protocol

Fifty adult male C57BL/6J mice (3 month old) from the Central Biotery of the Federal Minas Gerais University were used in this study. Initially, the animals were randomly assigned to two nutritionally different groups: (1) Control group (C) – animals that received a control diet (14% of energy as protein, 10% as fat, and 76% as carbohydrates; total energy 15 KJ/g, n = 10); and (2) High-fat group (HF) – animals that received a high-fat diet (14% of energy as protein, 50% as fat and 36% as carbohydrates; total energy 21 KJ/g, n = 40).

After twelve weeks, the C group and ten animals from the HF group continued the same food scheme for an additional five weeks, whereas the remaining animals from the HF group were randomly subdivided according to the treatment into the following groups: (1) HFA received the PPAR-alpha agonist (WY14643, Sigma–Aldrich, 3.5 mg/kg body mass) incorporated into the HF diet (n = 10) for five weeks; (2) HFL received the DPP-4 inhibitor (linagliptin, Boehringer Ingelheim, 15 mg/kg body mass) incorporated into the HF diet (n = 10) for five weeks; and (3) HFC received the combination of a PPAR-alpha agonist with a DPP-4 inhibitor (at the same doses used in the groups receiving monotherapy) incorporated into the HF diet (n = 10) for five weeks.

The entire experimental protocol lasted for 17 wk (12 wk of obesity induction + 5 wk of treatment). The doses of WY-14643 and linagliptin were based on previous experiments conducted by our group[4,9]. PragSoluções (Jaú, São Paulo, Brazil) produced the experimental diets according to the recommendations of the American Institute of Nutrition (AIN 93M)[15]. All groups were treated following the order in which the groups were described.

Food/energy intake and body mass

Food intake was measured daily by subtracting the remainder of the diet verified on the following day from the amount of diet offered on the previous day. Energy intake comprised the product of the food consumption and the energy contained in 1 g of each diet (in kJ). Animal body masses were assessed on a digital scale once a week (BL-3200H, precision 0.01 g).

Metabolic analysis

One week before sacrifice, the animals were subjected to the oral glucose tolerance test (OGTT). Under a 6-h fast (time 0) and after 15, 30, 60, and 120 minutes of the orogastric gavage of a glucose solution (2 g/kg body mass), blood samples were obtained from the caudal vein. A manual glucometer (Accu-Chek, Roche, São Paulo, SP, Brazil) was used to measure the blood glucose levels at different times. The area under the curve (AUC) indicated the oral glucose tolerance (GraphPad Prism, version 8.3 for Windows, GraphPad Software, La Jolla, CA, United States).

Sacrifice and ELISA

Mice were fasted for 6 h. Under intraperitoneal anesthesia with ketamine (240 mg/kg) and xylazine (30 mg/kg), blood samples obtained by cardiac puncture were separated by centrifugation (712 ×*g*) to obtain plasma samples to perform biochemical analyses. The liver, large intestine (cecum), and small intestine (jejunum and ileum) were carefully dissected, weighed, and analyzed following the protocols for different techniques.

An ELISA was performed to measure plasma GLP1 (multispecies GLP1 ELISA Kit Cat. #EZGLP1T-36K, Millipore, Missouri, United States), and LPS (multispecies LPS ELISA Kit Cat. #SEB526Ge-96T, Cloud-Clone Corp., Katy, United States). A semiautomatic spectrophotometer and a commercial kit (K117, Bioclin, Quibasa, Belo Horizonte, MG, Brazil) were used to measure hepatic triacylglycerol (TAG) as previously described[16].

Histology

Liver and cecum fragments fixed in Millonig-buffered formalin (pH 7.2-7.4) were subsequently dehydrated, diaphanized, embedded in Paraplast Plus (Sigma–Aldrich, St. Louis, MO, United States) and sectioned (5 µm thick) with a microtome. Slides stained with hematoxylin and eosin (liver) or Alcian Blue (Sigma Chemical Company-pH 2.5) plus Periodic Acid-Schiff (PAS, intestine-Sigma Chemical Company) were photographed using a Leica DMRBE microscope (Wetzlar, Germany) and an Infinity Lumenera digital camera (Ottawa, ON, Canada). The images were analyzed in a blinded manner with STEPanizer (www.stepanizer.com) as described below:

Hepatic stereology: Five animals *per* group and ten images *per* animal were analyzed. The volume density of liver steatosis [Vv (liver, st)] was estimated by the point-counting technique, following the formula: Vv (liver, st) = Pp (liver, st)/PT (Pp is the number of points that reached fat droplets, and PT is the total test points). The images were analyzed with STEPanizer using a 36-point test system[17].

Gut stereology: The number of goblet cells *per* area [Q_A(goblet)] was estimated using STEPanizer. All goblet cells within the test area were counted, except those touching the forbidden lines. The result was divided by the test area measured in mm^2.

16S rDNA polymerase chain reaction amplification

The feces found in the mouse cecum were used to extract microbial DNA using the QIAamp Fast DNA Stool Mini Kit (Qiagen, Düsseldorf, Germany) according to the manufacturer's instructions. The DNA quantity, purity, and concentration were determined using Qubit (Life Technologies, Carlsbad, California, United States) and horizontal electrophoresis (1% agarose gel). Real-time quantitative polymerase chain reaction (PCR) assays were used for the relative quantification of specific phyla of microorganisms (*Bacteroidetes, Firmicutes, Actinobacteria, Proteobacteria*) in fecal microbiota from the mouse guts by detecting 16S rRNA genes. For relative quantification, the abundances of different phyla were normalized by the $^{\Delta\Delta}$Ct method relative to the total bacterial amount in the samples[18]. The indicators used are described in Table 1.

Real-time reverse transcriptase–PCR

Total RNA was extracted from 50 mg of the liver and 70 mg of the small intestine (jejunum and ileum) using TRIzol reagent (Invitrogen, CA, United States). Afterward, the addition of 200 µL of chloroform was followed by centrifugation (1200 *g* for 10 min at 4 °C for liver samples and 12000 *g* for 15 min at 4 °C for intestine samples). The RNA extract portion was separated, and 500 µL of isopropanol was added and allowed to stand for 10 min (liver samples) or 15 min (intestine samples) to precipitate the RNA. Then, the samples were centrifuged (1200 *g* for 10 min at 4 °C for liver samples and 12000 *g* for 10 min at 4 °C for intestine samples). The isopropanol was removed, and the formed pellet was resuspended in 500 µL of 75% ethanol for liver samples or 70% ethanol (ice-cold) for intestine samples and then centrifuged (1200 *g* for 5 min at 4 °C for liver samples and 10000 *g* for 5 min at 4 °C for intestine samples).

The ethanol was removed, and the pellet was resuspended in 20 µL (liver)/50 µL (intestine) of deionized water (Milli-Q). The samples were subjected to a dry bath (50 °C for 5 min) and quantified by using Nanovue equipment (GE Life Sciences). For RNA transcription into complementary DNA (cDNA), 1.0 µg RNA was treated with DNAse I (Invitrogen, CA, United States). First-strand cDNA synthesis was performed using Oligo (dT) primers for reverse transcriptase mRNA and Superscript III (both from Invitrogen). qPCR was performed using a CFX96 recycler (Bio–Rad, Hercules, CA, United States) and SYBR Green mix (Invitrogen, Carlsbad, CA, United States). *Beta-actin* was used to correct the expression of the target genes in liver samples, and *Gapdh* was used for intestine samples. The primer sequences used are shown in Table 2 (liver) and Table 3 (intestine). All gene symbols are italicized (the first letter capitalized), and protein symbols are italicized in uppercase[19].

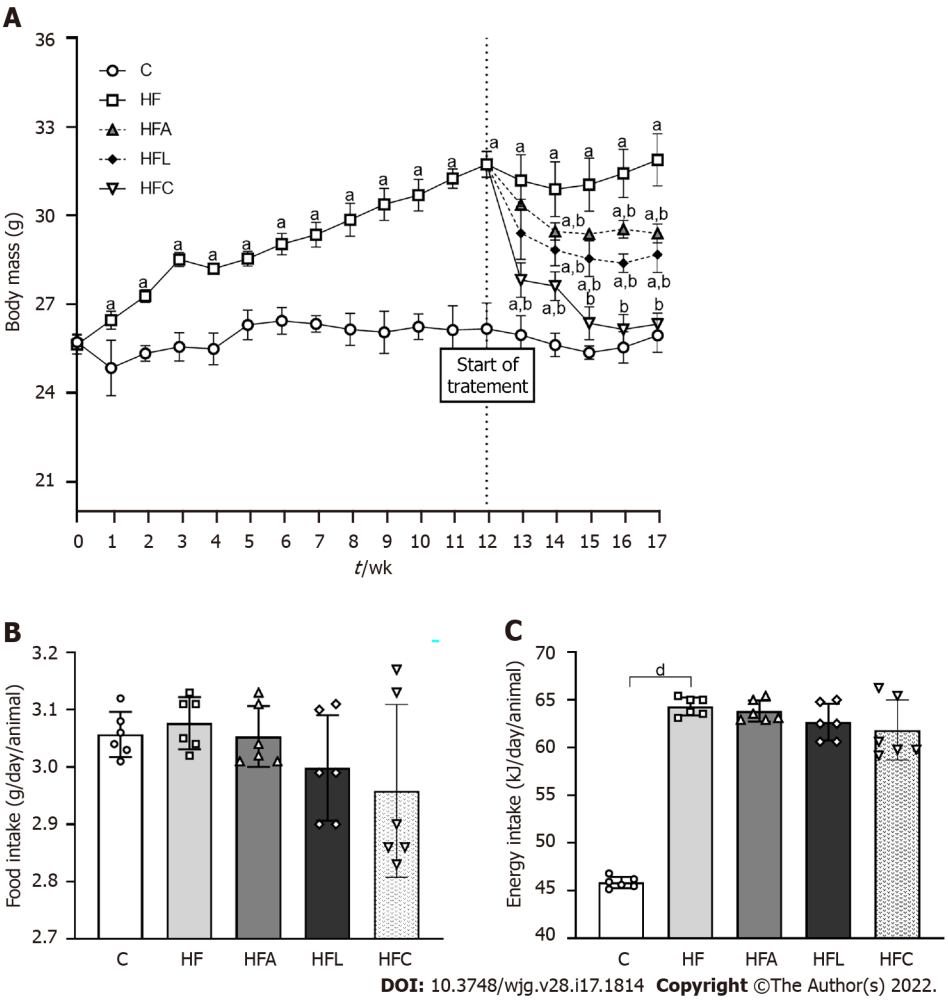
increases or decreases in five replicates, the probability of occurrence is $P = (1/2)^5 = 0.05$. Therefore, a minimum of 5 replicates was adopted for the analyses[20]. The data are shown as the mean and SD. During the first 12 wk, statistical analysis comprised Student’s t test and Welch's correction. At the treatment phase, data were analyzed using Brown–Forsythe and Welch one-way ANOVA with the Dunnett T3 post hoc test[21]. A $P < 0.05$ was considered significant (GraphPad Prism version 8.3 for Windows, GraphPad Software, La Jolla, CA, United States).



RESULTS

Treatment reduced body mass without altering energy intake

The animals in the C and HF groups had equal body mass (BM) at baseline. All animals tolerated the diets and treatments well. The protocol was maintained as previously stated. In the 13th week, the HF group was overweight compared to the C group (+30%), and this characteristic persisted until the end of the experiment. Figure 1A depicts these results. Although food intake did not differ between the groups (Figure 1B), the energy intake in the HF-fed groups was higher than that in the C group (Figure 1C).

All proposed treatments rescued glucose tolerance and increased GLP1 concentrations

Figure 2A shows the OGTT curve, in which the HF group showed a significant increase in fasting glucose (T0) compared to the C group. This difference remained until the end of the test (T120). The C group and the treated groups exhibited rescued baseline blood glucose levels at the other evaluation times (T30, T60, and T120). On the other hand, the HF group did not reach baseline glucose levels,

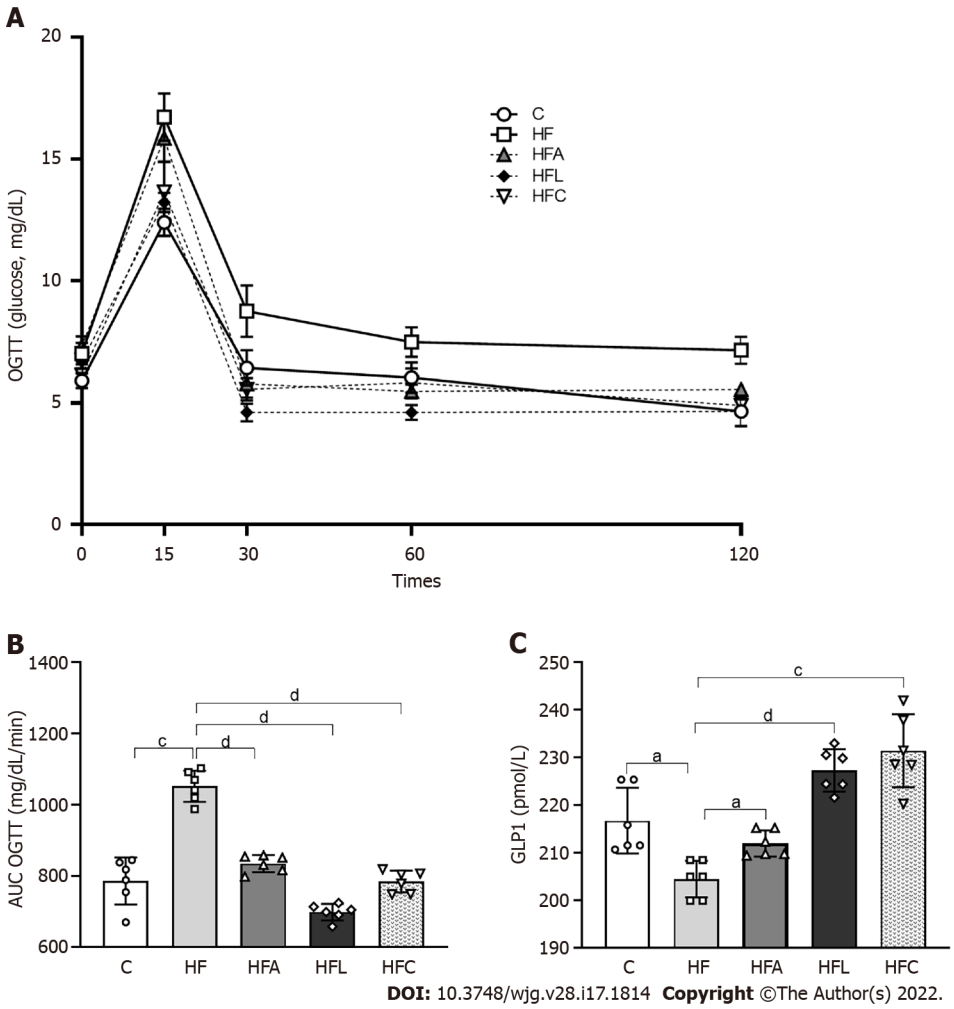
Figure 1 Body mass and food behavior. A: Body mass evolution; B: Food intake; C: Energy intake. Brown-Forsythe and Welch one-way ANOVA and Dunnett T3 *post hoc* test (mean ± SD, $n = 6$). Significant differences are indicated as follows: $^{a}P < 0.05$; $^{b}P < 0.01$; $^{d}P < 0.0001$. C: Control diet; HF: High-fat diet; HFA: High-fat diet plus PPAR-alpha agonist (WY14643); HFL: High-fat diet plus DPP-4 inhibitor (linagliptin); HFC: High-fat diet plus the combination of WY14643 with linagliptin.

indicating a delay after glucose overload and implying oral glucose intolerance, as confirmed by the higher AUC for OGTT in the HF group than in the C group (+23%, Figure 2B). In contrast, all treated groups showed lower AUCs than the HF group, indicating oral glucose intolerance alleviation.

Plasma GLP1 concentrations diminished in the HF group compared to the C group (Figure 2C). As expected, treatment with linagliptin enhanced GLP1 concentrations in the HFL group (+13%), which also occurred in the HFC group and after the single treatment with the PPAR-alpha agonist in the HFA group compared to the HF group (Figure 2C).



Treatments recovered the microbiota composition and reversed endotoxemia in HF-fed mice

The amplified 16S rRNA genes of cecal gut bacteria were measured at the end of the experiment to evaluate the microbiota composition. The HF group showed a *Firmicutes* phylum increase coupled with decreases in the *Proteobacteria* and *Bacteroidetes* phyla compared to the C group, as shown in Figure 3A. However, all treatments reversed these phylogenetic alterations in the treated groups. The treatments restored the amount of *Bacteroidetes* to resemble that in the C group and caused a significant decrease in *Proteobacteria*, which can play a decisive role in the beneficial effects observed due to the proposed treatments. Changes in the microbiota composition in the HF group triggered increased LPS concentrations (+10%, Figure 3B), while the HFL and HFC groups showed significantly reduced plasma LPS concentrations (-11% for HFL *vs* HF and -12% for HFC *vs* HF).

The hepatic mRNA expression of both *Lbp* (Figure 3C) and *Tlr4* (Figure 3D) genes increased in the HF group compared to the C group, while the treated groups showed significantly reduced expression.

DPP-4 inhibitor and PPAR-alpha agonist improved the intestinal barrier structure and protection

The HF group showed an 80% decrease in intestinal *Mucin2* gene expression compared with the C group. Conversely, the HFA, HFL, and HFC groups showed significant increases in *Mucin2* expression (+439% for HFA *vs* HF, +345% for HFL *vs* HF, and +670% for HFC *vs* HF; Figure 4A).

Figure 2 Carbohydrate metabolism. A: Oral glucose tolerance test; B: Area under the curve for oral glucose tolerance test; C: Plasma glucagon-like peptide 1 concentrations. Brown-Forsythe and Welch one-way ANOVA and Dunnett T3 *post hoc* test (mean ± SD, $n = 6$). Significant differences are indicated as follows: $^{a}P < 0.05$; $^{c}P < 0.001$; $^{d}P < 0.0001$. C: Control diet; HF: High-fat diet; HFA: High-fat diet plus PPAR-alpha agonist (WY14643); HFL: High-fat diet plus DPP-4 inhibitor (linagliptin); HFC: High-fat diet plus the combination of WY14643 with linagliptin; AUC: Area under the curve; OGTT: Oral glucose tolerance test; GLP1: Glucagon-like peptide 1.

In agreement with the previous result, the HF group also had reduced intestinal *Zo-1* (-38%, Figure 4B) and *Occludin* (-78%, Figure 4C) expression compared to the C group. On the other hand, the HFA group showed a 238% increase in *Occludin* expression, whereas the HFL and HFC groups had > 500% increases in the expression of this gene (Figure 4C). Regarding *Zo-1* gene expression, all treated groups had a significant increase (+166% for HFA *vs* HF, +397% for HFL *vs* HF, and +102% for HFC *vs* HF; Figure 4B).

The high intake of saturated fat altered the histochemical pattern of the intestinal mucosal cells, as revealed by the reaction with Alcian Blue and PAS. Figure 4D shows decreased mucus in the HF group, while the treatments elicited an increase in mucus production in the apical region of the crypts, followed by an increased presence of goblet cells (mucus-producing cells). Gut stereology confirmed these observations with the results of Q_A (goblet), which showed a reduction in the HF group compared to the C group (-44%), while the HFA (+68%), HFL (+47%), and HFC (+56%) groups showed an increase in the number of goblet cells *per* tissue area (Figure 4E).

DPP-4 inhibitor and PPAR-alpha activation mitigated liver steatosis

HF-fed mice exhibited noticeable microvesicular liver steatosis, while mice in all treated groups showed liver steatosis mitigation, with the liver parenchyma resembling that in the C group (Figure 5A).

In accordance with these histological findings, Vv (liver, st) in the HF group was higher than that in the C group (+38%, Figure 5B). All treated groups showed drastic reductions in liver steatosis (-72% for HFA *vs* HF, -50% for HFL *vs* HF, and -77% for HFC *vs* HF).

Consistent with the stereological findings, hepatic TAG levels increased in the HF group (+38%). Conversely, the treated groups showed lower hepatic TAG concentrations than that in the HF group (-11% for HFA, -16% for HFL, and -13% for HFC; Figure 5C).

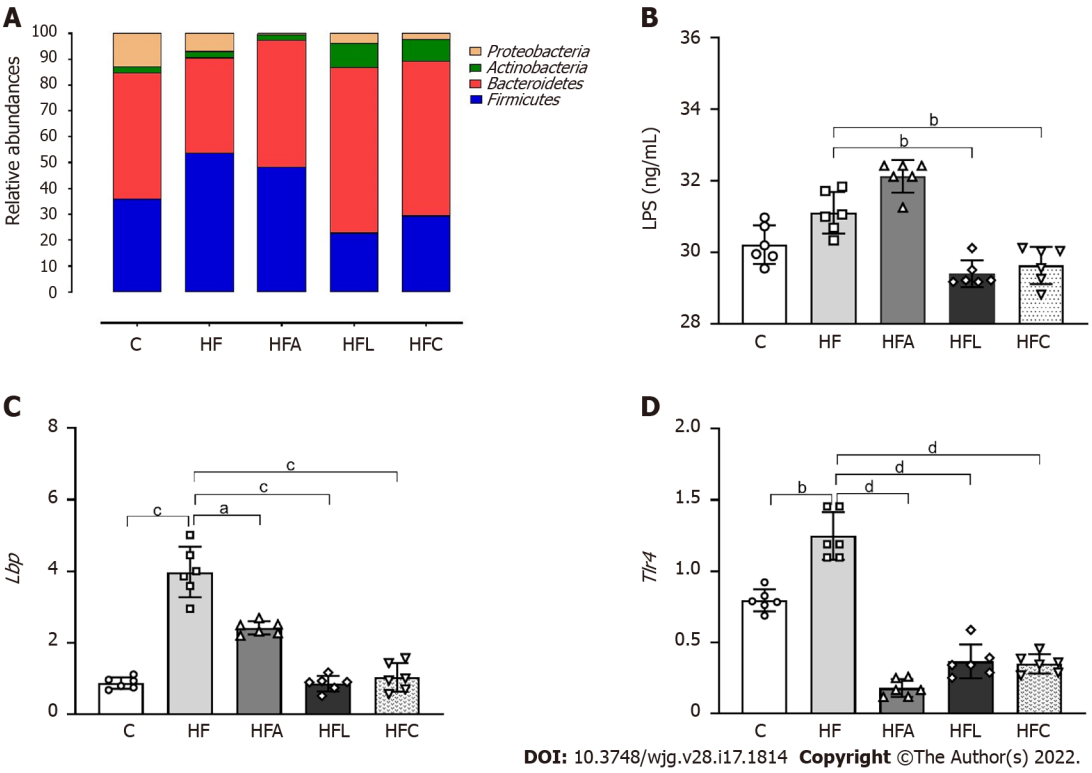

Figure 3 Gut-liver axis. A: Phylogenetic microbiota composition; B: Plasma lipopolysaccharide concentrations; C: Hepatic *Lbp* gene expression; D: Hepatic *Tlr4* gene expression. Brown-Forsythe and Welch one-way ANOVA and Dunnett T3 *post hoc* test (mean ± SD, $n = 6$). Significant differences are indicated as follows: $^{a}P < 0.05$; $^{b}P < 0.01$; $^{c}P < 0.001$; $^{d}P < 0.0001$. C: Control diet; HF: High-fat diet; HFA: High-fat diet plus PPAR-alpha agonist (WY14643); HFL: High-fat diet plus DPP-4 inhibitor (linagliptin); HFC: High-fat diet plus the combination of WY14643 with linagliptin; LPS: Lipopolysaccharide.

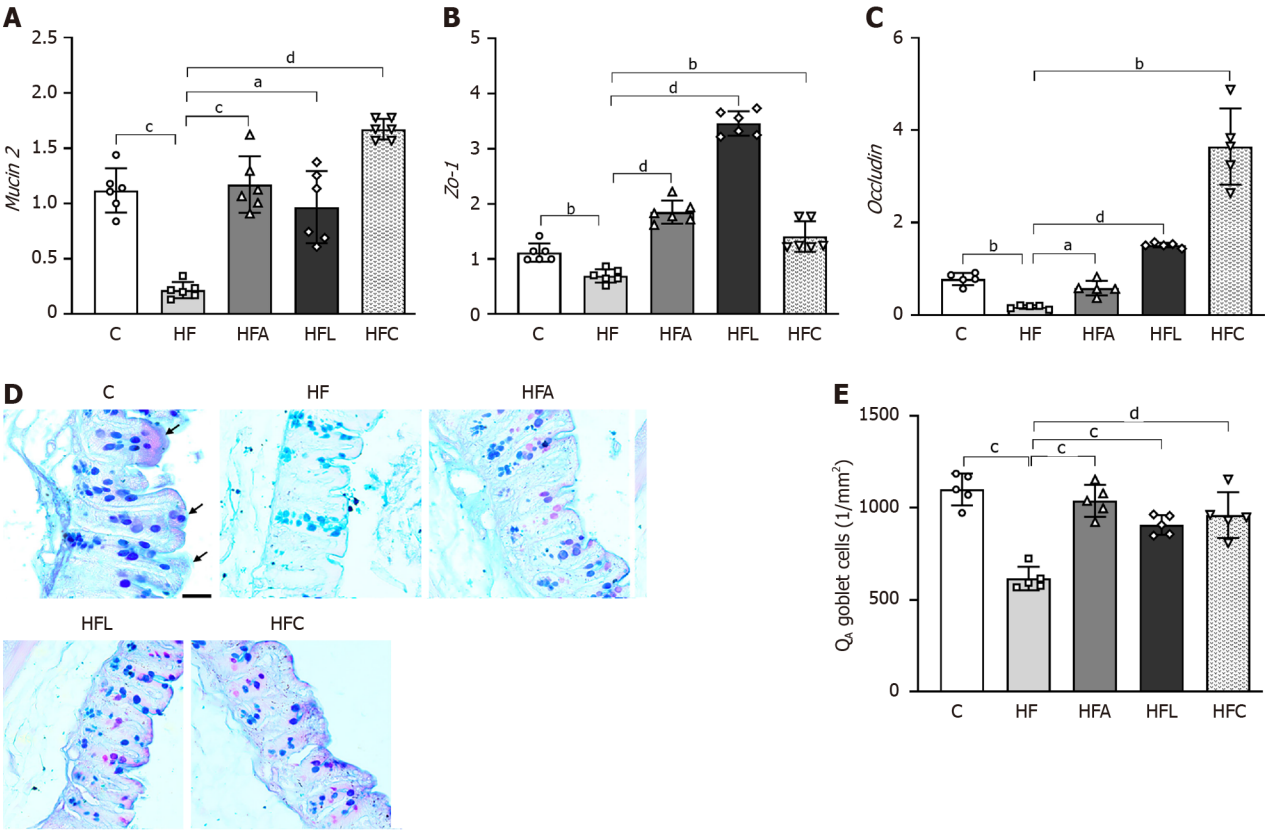
DPP-4 inhibition and PPAR-alpha activation attenuated macrophage activation and reduced liver inflammation in HF-fed mice

The HF group showed higher expression of *Cd206*, which is a specific marker of macrophages, than the C group (+103%, Figure 6A). In contrast, the treated groups showed reduced *Cd206* expression (-67% for HFA *vs* HF, -65% for HFL *vs* HF, and -74% for HFC *vs* HF).

In addition to the *Cd206* results, the HF diet significantly reduced *IL-10* expression compared to the C group (-54%), whereas the combined treatment yielded an 80% decrease in HFC *IL-10* expression compared to HF (Figure 6B). *Nlrp3* showed similar results to those of the *Cd206* gene, with higher expression in the HF group than in the C group (+128%) and reduced expression in the HFA (-72%), HFL (-88%), and HFC (-85%) groups compared to the HF group (Figure 6C).



Regarding the *IL-13* cytokine, the HF group exhibited a significant increase compared to the C group (+290%). Only the HFA and HFC treatments were able to reduce the expression of this cytokine in comparison with the HF group (-39% and -67%) (Figure 6D).

DISCUSSION

Excessive saturated fat intake causes overweightness, oral glucose intolerance, gut dysbiosis, and morphological and functional intestinal barrier alterations. Hence, HF animals had endotoxemia with proinflammatory signals directed toward the liver, causing substantial NAFLD. Single treatment with the PPAR-alpha agonist or DPP-4 inhibitor and the combined treatment yielded beneficial results, rescuing body mass, oral glucose tolerance, gut goblet cell numerical density *per* area, *TJ* gene expression, phylogenetic microbiota distribution, and LPS concentrations. Thus, treated animals showed liver steatosis and inflammation mitigation due to gut dysbiosis and endotoxemia control.

The chronic ingestion of a diet with a high content of saturated fats increases body mass and impairs glucose and lipid metabolism[22]. Accordingly, HF-fed mice were overweight and showed oral glucose intolerance, along with difficulty in rescuing glycemic levels during the OGTT compared to the C group. These metabolic alterations were paralleled by gut dysbiosis in the HF group, confirming that dietary patterns interfere with the gut–liver axis, favoring NAFLD pathogenesis and progression.

The integrity of the intestinal barrier structure and function relates to the gut microbiota composition. The gut microbiota comprises a great diversity of symbiotic bacteria, whereas the intestinal barrier relies on junctional proteins that make this epithelium less permeable to pathogens and toxins. In this way,

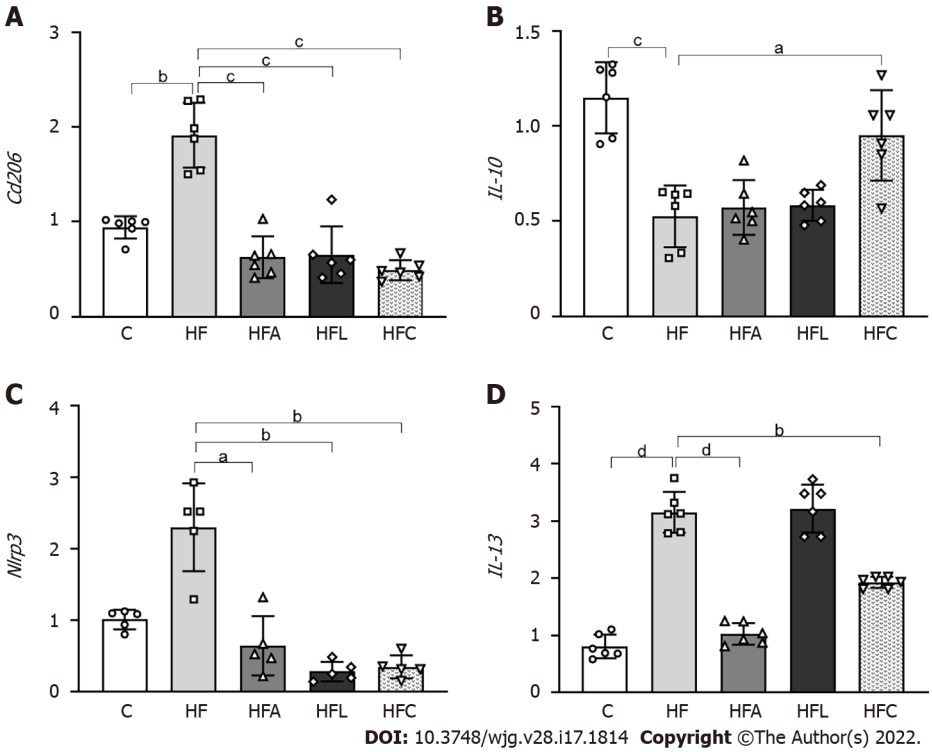
both mechanisms prevent metabolic dysregulation and contribute to maintaining gut homeostasis[23-25].

Dysbiosis caused by the chronic consumption of fats is usually characterized by an increase in *Firmicutes* relative to *Bacteroidetes*, as shown by the HF group. These two phyla constitute more than 90% of the phylogenetic category currently known and characterized in the intestine of experimental models [26]. Conversely, all treated groups showed a reduction in the quantitative percentage of *Firmicutes*, especially the groups treated with the DPP-4 inhibitor and the combined therapy.

The rescuing of gut dysbiosis in the treated groups resulted in marked improvements in TJ gene expression. An HF diet also impairs the junctional components present in the intestinal epithelium, making it more permeable and consequently more susceptible to the translocation of microorganisms and toxins into systemic circulation. The increase in intestinal permeability is known as a leaky gut[25, 27].



The leaky gut was rescued through enhanced expression of TJ genes in all treated groups. MUCIN2 knockout mice exhibit alterations in TJ structural proteins, in addition to mitochondrial damage and inflammation, which agrees with a leaky gut[28]. The treatments significantly augmented *Mucin2*, which is the major goblet cell gene responsible for mucin secretion, in addition to the gene expression of the TJs *Occludin* and *Zo-1*[29]. PPAR-alpha has recently been described as essential for lipid droplet formation and crypt expansion in the intestine during chronic HF diet intake[30]. Sitagliptin, as a DPP-4 inhibitor, exerted protective effects on the intestinal barrier (high *occludin* and *Zo-1* levels) by GLP-2 induction in experimental colitis[31]. Herein, the combination of these drugs resulted in the highest intestinal expression of *Mucin2* and *Occludin*, indicating that adequate function of goblet cells and well-preserved TJs may underlie the mechanisms involved in the beneficial results obtained in the HFC group.

HF diet intake also impairs the epithelium lining the intestinal mucosa. The goblet cells found in the intestinal villi and crypts are mucin producers that play a crucial role in protecting and lubricating the intestinal mucosa. The number of goblet cells indirectly reflects the ability to secrete mucus[25]. Herein, the HF diet caused a reduced number of goblet cells *per* area of the gut crypt, while all treatments

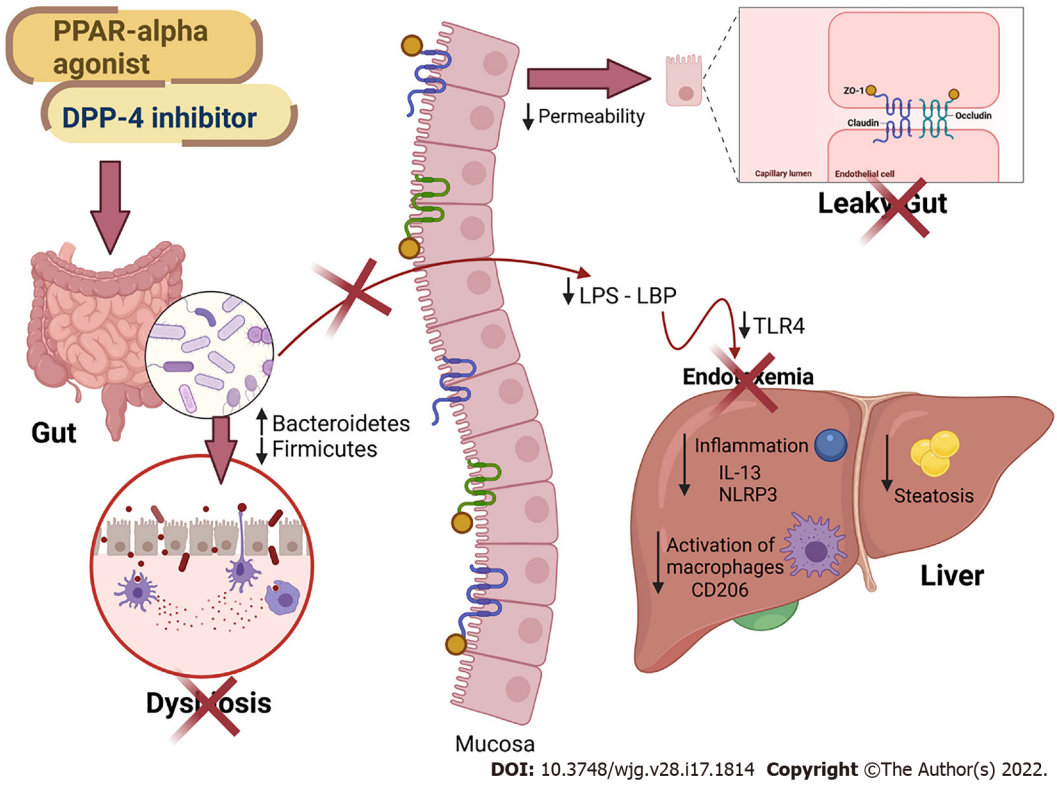
reversed this alteration with the normalization of the numerical density of goblet cells and *Mucin2* gene expression. Hence, the treatments supported intestinal barrier integrity and reduced the translocation of endotoxins, such as LPS, into systemic circulation, rescuing the mice from a condition called metabolic endotoxemia[32].

The high translocation of endotoxins derived from the gut microbiota induces Toll-like receptor (TLR) activation. LPS is the most common pathogen-associated molecular pattern (PAMP), and its binding to TLR4 is catalyzed by lipopolysaccharide-binding protein (LBP), which is mainly expressed in the liver and adipose tissue[32].

LPS stems from the destruction of the bacterial cell wall. An increase in LPS in systemic circulation triggers the release of proinflammatory cytokines and an inadequate amplification of the immune response, causing tissue damage[26]. An increase in plasma LPS levels was observed in the HF group, characterizing the involvement of the epithelium with a consequent increase in intestinal permeability, making the epithelium more permeable to the entry of microorganisms. Additionally, we showed that hepatic *Lbp* and *Tlr4* gene expression increased in the HF group, inducing the translocation of cytokines associated with inflammation and changing hepatic lipid metabolism, reconfiguring this metabolism to become a potent inducer of fatty liver, and contributing to the pathogenesis of NAFLD.

In contrast, the treatments normalized *Lbp* and *Tlr4* expression, with both emerging as targets for NAFLD treatment. The DPP-4 inhibitor alogliptin suppressed TLR4 *via* ERK activation, resulting in decreased matrix metalloproteinases and proinflammatory cytokines in U937 histiocytes[33]. Sitagliptin was previously shown to attenuate NAFLD by suppressing inflammation and insulin resistance due to TLR4/NF-kB pathway downregulation in diabetic rats[34]. PPAR-alpha activation by WY-14643 mitigated liver steatosis in high-fructose-fed mice by reducing LPS concentrations, improving the intestinal barrier ultrastructure, upregulating hepatic beta-oxidation, and suppressing lipogenesis in mice[9].



A recent study showed that systemic LBP blockade or decreased LBP levels in the liver normalized glucose homeostasis, mainly by reducing fasting glucose levels, without changing adiposity or liver steatosis[35]. In this study, the group treated with the PPAR-alpha agonist as monotherapy did not show reduced LPS concentrations. However, the treatment reduced *Lbp* expression, producing anti-inflammatory and anti-steatotic effects similar to those of the other treatments.

In this context, macrophages play roles in acute and chronic inflammatory liver diseases. Macrophages have receptors, such as CD163 and CD206, which participate in the phagocytosis of harmful substances. Due to its high affinity for macrophages, CD206 is a potential biomarker of hepatic macrophage (Kupffer cells) activation, which indicates inflammation and fibrosis in chronic liver diseases[36]. In response to LPS and other stimuli, the metabolic profile of macrophages and dendritic cells stimulates the glycolytic pathway, resulting in the metabolic accumulation of citrate and succinate, which, in turn, regulate the gene expression of cytokines such as interleukin 10 (IL-10)[37]. Recent evidence shows that IL-10 may play a dual role in some contexts by stimulating the immune response rather than suppressing it. However, the cytokine IL-10 has emerged as an anti-inflammatory mediator determining the protection of its host in response to pathogens[38].

Our results showed that *Cd206* macrophages were activated in the HF group, reinforcing the idea that the chronic consumption of this type of diet activates inflammatory pathways that contribute to the development of liver disease. In contrast, the groups treated with the PPAR-alpha activator and DPP-4 inhibitor showed reduced expression of *Cd206* macrophages, conferring a protective effect against the activation of inflammatory pathways. Recent evidence showed that highly fibrous livers had a higher density of *Cd206* macrophages[36]. *IL-10* gene expression was reduced in the HF group. However, only the combined treatment increased *IL-10* expression, implying that the isolated treatments might have acted through another anti-inflammatory pathway. IL-13 overexpression in HF diet-fed mice is a pathway related to fatty liver and insulin resistance onset. Combined treatment and PPAR-alpha activation alone markedly reduced hepatic *IL-13* expression, which combined with reduced macrophage activation and glycemic homeostasis to alleviate fatty liver[39].

Concerning inflammasomes, NLRP3 is present mainly in immune and inflammatory cells, such as macrophages, monocytes, dendritic cells, and neutrophils, after activation by inflammatory stimuli. NLRP3 is activated by numerous PAMPs, such as hyperglycemia, fatty acids, bacterial toxins, and bacterial and viral nucleic acids[40]. Studies in macrophages and animal models have shown that oxidized low-density lipoproteins and cholesterol crystals trigger NLRP3 activation. In macrophage and type 2 diabetes animal models, glucose and free fatty acids trigger inflammasome activation, damaging glucose metabolism and favoring insulin resistance[41]. Thus, NLRP3 may contribute to the appearance and progression of several diseases related to metabolic syndrome.

In this study, we showed that treatment with the PPAR-alpha agonist and DPP-4 inhibitor produced a potent anti-inflammatory effect in the liver, as they demonstrated reduced gene expression of *Nlrp3* and *Cd206*. The blockade of NLRP3 has recently improved NAFLD and mitigated liver fibrosis in two models of steatohepatitis[42], highlighting the proposed treatments as viable tools to control fatty liver. Two DPP-4 inhibitors were previously shown to suppress NLRP3 in human macrophages by downregulating the TLR4-IL-1beta pathway[43]. Sitagliptin alleviated liver injury caused by thioacetamide in mice by decreasing NLRP3 and exerting anti-apoptotic effects[44]. Regarding PPAR-alpha activation, oleoylethanolamide protected against LPS-induced liver injury in mice by suppressing NLRP3[45]. However, the present study is the first to report the effects of both drugs and their combination on the gut–liver axis in HF-fed mice. Figure 7 summarizes our main findings.

DOI: 10.3748/wjg.v28.i17.1814 **Copyright** ©The Author(s) 2022.

Figure 7 Main findings of the study. All treatments alleviated fatty liver by countering gut dysbiosis and rescuing the intestinal barrier integrity. The reduced lipopolysaccharide (LPS) influx to the liver caused reduced inflammasome and CD206 macrophage activation. Peroxisome proliferator-activated receptor-alpha activation and DPP-4 inhibition can be regarded as viable tools to treat leaky gut and prevent LPS-driven hepatic steatosis. PPAR: Peroxisome proliferator-activated receptor; DPP-4: Dipeptidyl peptidase-4; LPS: Lipopolysaccharide; LBP: Lipopolysaccharide-binding protein; TLR4: Toll-Like receptor 4; ZO-1: Zonula occludens 1; NLRP3: NLR family pyrin domain containing 3; CD206: Cluster of differentiation 206; IL: Interleukin. Created with Biorender: www.biorender.com.

Some limitations of the present study comprise the absence of female mice evaluations to determine possible sexual dimorphism, the lack of plasma glucose concentration measurements, and the inability to determine LBP concentrations, although its gene expression was evaluated. Future research should also include the evaluation of genera and families in the *Proteobacteria* phylum, as it seems to be involved in the harmful evolution of NAFLD.

CONCLUSION

In conclusion, HF-fed mice showed impairment of the intestinal barrier and alteration in the phylogenetic diversity of the gut microbiota, leading to dysbiosis, and contributing to the influx of LPS into the liver. An impaired gut–liver axis favors liver damage, making the liver more susceptible to NAFLD through proinflammatory signals (*Tlr4* and *Nlrp3* upregulation). Treatment with the PPAR-alpha agonist and the DPP-4 inhibitor modulated the gut microbiota and rescued intestinal barrier gene expression and goblet cell numerical density, reducing endotoxemia and liver steatosis through anti-inflammatory signaling. Given the beneficial effects of the treatments found, these treatments have become possible therapeutic strategies for the NAFLD spectrum of diseases.

ARTICLE HIGHLIGHTS

Research background

Gut microbiota can be modified by the dietary composition and play a role in fatty liver pathogenesis through endotoxemia. Peroxisome proliferator-activated receptor (PPAR)-alpha activation has previously rescued the gut–liver axis with anti-steatotic effects in high-fructose-fed mice, whereas a high-dose dipeptidyl peptidase-4 (DPP-4) inhibitor (linagliptin) inhibited hepatic lipogenesis in high-fat-fed mice. The combination of these drugs could restore the gut–liver axis in obese mice.

Research motivation

Nonalcoholic fatty liver disease (NAFLD) is highly prevalent among obese individuals and can evolve into harmful liver diseases. Currently, there is no treatment directly prescribed to counter NAFLD. Herein, we propose a drug combination (PPAR-alpha agonist plus DPP-4 inhibitor) that can alleviate fatty liver by modulating the gut–liver axis with anti-inflammatory properties.

Research objectives

To evaluate the effects of monotherapy with a PPAR-alpha agonist (WY14643) or a DPP-4 inhibitor (linagliptin) and their combined treatment on the gut–liver axis, highlighting the intestinal barrier, endotoxemia, and inflammatory pathways in the livers of high-fat-fed mice. These preclinical insights can help establish new strategies for the treatment of NAFLD.

Research methods

Mice were fed a control diet (C, 10% of energy as lipids) or a high-fat diet (HF, 50% of energy as lipids) for 12 wk. Then, the HF group was randomly divided into four groups: HF, HF-A (treated with the PPAR-alpha agonist), HFL (treated with the DPP-4 inhibitor), and HFC (treated with the combination of both drugs). The treatments lasted for five weeks. The gut–liver axis was assessed by histological, biochemical, stereological, and molecular techniques.

Research results

The HF diet yielded overweightness and oral glucose intolerance, altered gut microbiota composition, and decreased the numerical density of goblet cells and tight junction gene expression, with increased plasma lipopolysaccharide (LPS) concentrations and increased fatty liver. The combined treatment rescued all of these metabolic alterations by restoring the gut microbiota and intestinal barrier markers, resulting in decreased LPS concentrations and fatty liver through anti-inflammatory signals. Further studies may focus on the *Proteobacteria* phylum, whose alteration can trigger harmful signaling to the liver.

Research conclusions

The combination of PPAR-alpha activation with DPP-4 inhibition yielded marked anti-steatotic effects by modulating the gut–liver axis, with reduced endotoxemia and amelioration of the intestinal barrier histology and gene expression. In turn, the livers of obese mice treated with the drug combination benefited from downregulation of the *Tlr4* and *Nlrp3* pathways and exhibited a hepatic parenchyma similar to that in the C group. Of note, we used stereology to estimate the numerical density of goblet cells in cecum slides stained with Alcian Blue and Periodic Acid-Schiff. This technique can be used to assess the effects of different interventions on the intestinal barrier and leaky gut in further studies.

Research perspectives

This study brings novelty to the treatment of NAFLD, which is a challenge to the scientific community. Our results confirm the importance of the gut–liver axis in the pathogenesis of fatty liver and propose a combined treatment that targets the gut microbiota composition, endotoxemia, and intestinal barrier alterations to alleviate fatty liver through local anti-inflammatory effects in HF-fed mice.

Abstract

BACKGROUND

There remains a dearth of Asian epidemiological literature for paediatric inflam-

matory bowel disease (PIBD).

AIM

To describe the presenting features of PIBD from 7 Asia-Pacific pediatric gastroenterology centers *via* a central standardised electronic data platform.

METHODS

Clinical, endoscopic and radiologic data at diagnosis from the registry were extracted between 1st January 1995 to 31st December 2019. Disease phenotypic characteristics were classified as per the Paris classification system.

RESULTS

There was a distinct rise in new PIBD cases: Nearly half (48.6%) of the cohort was diagnosed in the most recent 5 years (2015-2019). The ratio of Crohn's disease (CD):Ulcerative colitis (UC):IBD-Unclassified was 55.9%:38.3%:5.8%. The mean age was 9.07 years with a high proportion of very early onset IBD (VEO-IBD) (29.3%) and EO-IBD (52.7%). An over-representation of the Indian/South Asian ethnic group was observed which accounted for 37.0% of the overall Singapore/Malaysia subcohort (6.8%-9.0% Indians in census). Indian/South Asian CD patients were also most likely to present with symptomatic perianal disease (P = 0.003). CD patients presented with significantly more constitutional symptoms (fever, anorexia, malaise/fatigue and muscle-wasting) than UC and higher inflammatory indices (higher C-reactive protein and lower albumin levels).

CONCLUSION

We observed a high incidence of VEO-IBD and an over-representation of the Indian ethnicity. South Asian CD patients were more likely to have symptomatic perianal disease.

INTRODUCTION

The epidemiology of inflammatory bowel disease (IBD) is a dynamic and rapidly evolving landscape. Recent publications over the past decade document the rise in IBD incidence in traditionally low-prevalence regions (Asia, Africa, South America) while the incidence is somewhat stabilising in high-prevalence western nations[1]. In particular, there is an increased impetus to focus on paediatric IBD (PIBD) epidemiology as the rising incidence of childhood-onset disease appears to be driving this overall trend in certain regions[2]. Very-early onset IBD (VEO-IBD), generally defined as disease onset prior to the age of 6 years, was once considered rare but now represents the fastest growing age bracket of IBD incidence in certain countries[3]. Yet in spite of these global trends, there remains a dearth of epidemiological literature for PIBD in Asia, in particular the regions of Central, South and Southeast Asia. This begets the question whether these countries are truly 'low prevalence' in the absence of national IBD registries such as those established in Japan[4] and South Korea[5]. Apart from studies

published out of these East Asian cohorts, current literature is mostly limited to single centre publications[6-8] from countries in the Asia-Pacific region. Epidemiological data from these publications would only represent 'the tip of the iceberg' of the true burden of IBD and may not necessarily encapsulate recent regional epidemiological trends in disease incidence and behaviour.

There are numerous challenges in establishing a robust disease registry within Asia, especially with chronic diseases of emerging importance such as PIBD. For one, there is significant heterogeneity in disease awareness, diagnostic evaluation processes and therapeutic strategies across the vast Asian continent. This inevitably results in variations in case definitions with consequent epidemiological data inconsistencies. The aim of the present study was to describe the presenting features of PIBD managed in 7 paediatric gastroenterology centers across six Asia-Pacific countries and regions *via* a centrally-hosted electronic data capture platform using international standardised definitions.

MATERIALS AND METHODS

Establishing a multi-centre Asian PIBD registry network

The concept and goal of establishing a standardised disease data capture platform across Asian paediatric gastroenterology centres were first discussed amongst paediatric gastroenterologists practising across 7 tertiary centres in 6 Asian countries (Malaysia, Philippines, Singapore, Sri Lanka, Taiwan R.O.C., Thailand) in 2017. A consensus was established amongst the network committee members with regards to the standardisation of disease data collected both retrospectively and prospectively. Anonymised clinical data was to be collected on patient demographics, diagnostic evaluation and disease characteristics based on clinical examination, laboratory, endoscopy and radiology investigations. The diagnosis and classification of IBD into one of three disease subtypes [Crohn's disease (CD), Ulcerative colitis (UC) and IBD-unclassified (IBD-U)] was determined by each participating centre based on the revised Porto criteria[9] as agreed within the network. The Paris Classification[10] (paediatric modification of the Montreal classification for IBD) system was then utilised to describe disease behaviour and phenotype. Electronic case report forms were thereafter loaded on a secure REDCAP data-capture platform centrally hosted by the Singapore Clinical Research Institute.

Ethics approval

Ethics approval for the storage of anonymised clinical data on a multi-centre central data registry hosted by the Singapore Clinical Research Institute was granted by the National Healthcare Group (NHG) Domain Specific Review Board (Approval letter for study code NUH/2019-00060 dated 23rd January 2020), followed by a separate ethics approval for data extraction and analysis (Approval letter for study code 2019/00751 dated 20th October 2021 to 19th October 2022).

Data extraction and analysis

For the purposes of analysis of clinical features at diagnosis, data from the registry was extracted for patients diagnosed with IBD between 1st January 1995 to 31st December 2019. The patient's inclusion criteria were: (1) Gastroenterologist-confirmed diagnosis of IBD at the participating site; (2) Age below 18 years at the point of diagnosis; and (3) Resident (citizens, permanent residents or long-term visitors) of the country of the participating site. Medical tourists (non-resident patients visiting the country solely for the purpose for medical assessment/treatment) were excluded. We stratified the cohort (1995-2019) into five equal time-intervals, each of 5-year duration, for the intent of analysing change in IBD incidence and evolution of diagnostic practices with time.

VEO-IBD was defined by an age of onset less than 6 years and EO-IBD, by an age of onset less than 10 years. Symptomatic perianal disease was defined as perianal pain or discharge due to a fistula or abscess/collection. A 'perianal manifestation' of CD, symptomatic or otherwise, was defined broadly as large inflamed perianal tags, poorly healing perianal fissures ascribed to CD or perianal fistula/abscess or collection evident clinically or *via* imaging. South Asians were defined as people of Indian, Bangladeshi, Pakistani, Sri Lankan (Sinhalese/Tamil) or Maldivian origin. Anthropometric Z-scores for children of age 0-5 years were measured based on the World Health Organization (WHO) Child Growth Standards, while those for children aged 5-19 years were measured on the WHO Reference 2007. Linear growth failure was defined as a height Z-score of -2 and lower.

Disease severity was defined based on the patients' respective Paediatric Crohn's Disease Activity Index (PCDAI) (Inactive: ≤ 10, mild: 11-30, moderate-severe: > 30)[11] and Paediatric Ulcerative Colitis Activity Index (Inactive: < 10, mild: 10-34, moderate: 35-64, severe ≥ 65)[12] scores.

The date of IBD diagnosis was taken as the date of diagnostic endoscopy. For the purposes of this publication discussing solely the presenting clinical features at diagnosis, we only included clinical data occurring within 3-mo prior or after the date of diagnosis and before any therapeutic intervention.

Statistical analysis was done through SPSS Version 27 whereby we compared presenting symptoms, biochemical indices and growth indices between the key phenotypic subgroups (CD and UC); the overall effect of ethnicity on IBD phenotype and behaviour. Continuous variables (laboratory invest-

igation values, anthropometric indices) were compared through the student's *t*-test while most of the other outcomes (clinical findings, disease phenotype and behaviour) were classified as categorical variables/dichotomous outcomes and these were compared through the chi-square test. A *P* value of less than 0.05 was deemed as a significant difference in outcomes, otherwise stated as 'NS' (non-significant). Whereby multivariate analysis was required in determining the effect of South Asian ethnicity on the incidence of perianal disease in CD adjusting for inter-ethnic variability in disease phenotype, logistic regression was used to calculate an adjusted odds ratio.

RESULTS

Three hundred and eleven children were recruited from seven participating tertiary centres across six countries within the Asia-Pacific region. There was a distinct rise in the number of new PIBD cases recorded across the network, with nearly half (48.6%, 151/311) of the entire cohort being diagnosed in the most recent 5 years (2015-2019) of recruitment (Figure 1). Table 1 illustrates the overall distribution of CD *vs* UC *vs* IBD-U, in which the CD:UC ratio was approximately 1.5:1 while the proportion of IBD-U was 5.8%. While there were more males in the overall cohort (58.2% male), we did not observe any significant gender predilection across the three disease subtypes: Male CD 58.0% *vs* male UC 57.0% *vs* male IBD-U 66.7% ($P = 0.75$).

High incidence of VEO and EO disease

The mean age of disease presentation was 9.07 years for the entire IBD cohort which is within the age definition of EO disease. UC patients presented at a significantly younger age than CD patients (7.73 years *vs* 10.18 years, $P < 0.001$), with the mean age of IBD-U patients (7.34 years) similar to that of UC. When stratifying age of onset into VEO disease and EO disease, 29.3% of the entire cohort was classified as VEO-IBD and more than half (52.7%) was early-onset. There was a significantly higher proportion of VEO-IBD and EO-IBD presenting as a UC phenotype as compared to CD (Table 1). Across a period of 20 years, the proportions of VEO-IBD and EO-IBD remained relatively stable, approximately at 30% and 50% of the cohort per time interval respectively (Figure 2).

Over-representation of the Indian/South Asian ethnicity

For a meaningful interpretation of ethnic predilection amongst Asian IBD patients, the multi-racial sub cohorts from Singapore and Malaysia were chosen as the other participating sites were relatively more homogeneous in ethnic group distribution. The three main ethnic groups in these two countries are Chinese, Indian/South Asian and Malay as listed in Table 2[13,14]. A distinct over-representation of the Indian/South Asian ethnic group was observed, with Indians/South Asians accounting for 37.0% of the overall Singapore/Malaysia IBD cohort relative to a minority representation of 6.8%-9.0% in both the countries' respective population census. There was a significantly higher proportion of UC patients relative to CD amongst the Malay ethnic group (CD:UC ratio 0.7, $P = 0.037$).

Increased constitutional symptoms, extraintestinal manifestations and higher inflammatory indices in CD

Abdominal pain ($P = 0.004$) and clinically evident abdominal tenderness ($P = 0.003$), fever ($P < 0.001$), loss of appetite ($P = 0.001$) and malaise/fatigue ($P = 0.016$) were significantly more common amongst CD patients relative to UC. While there was a non-significant higher proportion of CD patients presenting with weight loss (46.6% CD *vs* 37.0% UC), clinically evident muscle wasting was significantly more common in CD (14.4% CD *vs* 5.9% UC, $P = 0.022$).

Although CD patients had numerically lower mean weight Z-scores [(-1.4) *vs* (-1.0)] and height Z-scores [(-0.8) *vs* (-0.6)] than UC, only the mean body-mass index Z-score of CD patients was significantly lower [(-1.5) *vs* (-0.9), $P = 0.013$]. There were approximately similar rates of linear growth failure across the three disease subtypes: 18.4% CD *vs* 16.1% UC *vs* 17.6% IBD-U (Table 3). There was a non-significant higher proportion of patients with joint pains (7.5% CD *vs* 5% UC) and clinically evident arthritis (6.9% CD *vs* 2.5% UC) in CD patients. Other extraintestinal manifestations (EIMs) such as oral ulcers (20.7% CD *vs* 0.8% UC, $P < 0.001$) and erythema nodosum (4.6% CD *vs* 0.0% UC, $P = 0.018$) were more common in CD than UC. Hepatic involvement (hepatomegaly and elevated transaminases) was however more commonly observed in UC than CD, consistent with a significantly higher association of autoimmune liver disease/primary sclerosing cholangitis with UC than CD (17.6% UC *vs* 1.1% CD, $P < 0.001$).

CD patients also presented with significantly higher C-reactive protein (CRP) levels (mean 54.6 CD *vs* 20.1 UC, $P < 0.001$) and lower albumin levels relative to UC. However, there was no significant difference in mean haemoglobin and proportion of severe anaemia (defined as ≤ 7.0g/dL: 4.0% CD *vs* 5.0% UC, $P = 0.601$) at presentation between CD and UC.

Faecal calprotectin testing

16.1% of the cohort had a faecal calprotectin (50/211) assayed at baseline. There was no significant

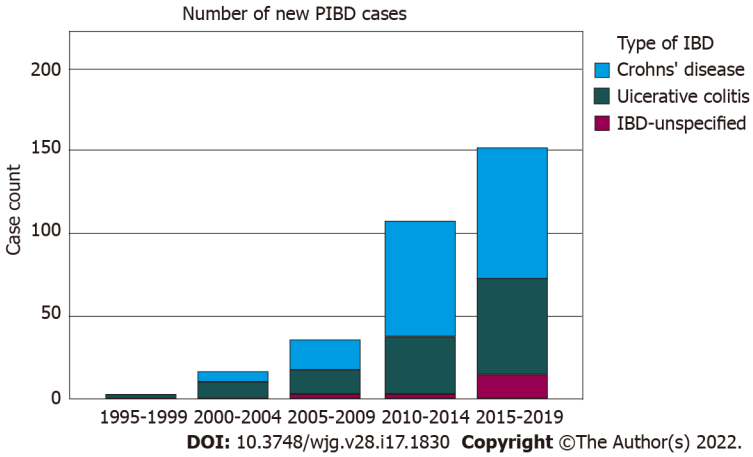
CD: Crohn's disease; IBD-U: Inflammatory bowel disease-Unclassified; UC: Ulcerative colitis.

difference between the mean values in CD and UC (Table 3). Amongst children with CD, faecal calprotectin values were lower in patients with isolated ileal disease (L1) compared to ileocolonic (L3) disease (468.7 in L1 *vs* 749.2 μg/g in L3, $P = 0.05$). No discernible difference in mean faecal calprotectin values was noted amongst children with UC; left sided disease (E1/E2: 547.0 μg/g) *vs* more extensive disease (E3/E4: 555.6 μg/g).

Small bowel imaging and endoscopy

There was a progressive decline in the use of small bowel follow through studies across the cohort. Since 2010, there has been increasing use of either MR enterography or intestinal ultrasound although approximately 60% of the cohort have not had any form of small bowel imaging (Figure 3). Complete endoscopy as per Porto guidelines (upper and lower endoscopy) was performed in 79.1% of the cohort.

Disease behaviour and phenotype of CD patients



The ileocolonic location was the most common disease location in the entire cohort of CD patients, with pure inflammatory disease being most common (90.7%) followed by luminal penetrating disease (5.3%) and stricturing disease (3.3%). Isolated L4 disease (absence of terminal ileal or colonic disease) was relatively uncommon at 4.0% of the CD cohort. Over half of the CD patients had at least moderate

South Asian CD patients were strongly associated with perianal symptoms at presentation (P = 0.003), the physical finding of asymptomatic perianal tags (15.5% South Asian *vs* 7.5%, P = 0.042), as well as any form of perianal manifestation (symptomatic and asymptomatic, detected on either clinical examination or perianal imaging; P = 0.003). Adjusting for inter-ethnic differences in CD incidence, the

South Asian ethnicity remained strongly associated with symptomatic perianal disease at presentation (B co-efficient 1.264, $P = 0.001$). Sri Lanka was the only participating South Asian site in this study, and only 1 out of 19 Sri Lankan IBD patients had presented with symptomatic perianal disease. All the South Asian CD patients in this subgroup analysis (Table 4) were either first- or second-generation immigrants within Singapore or Malaysia.

Disease behaviour and phenotype of UC patients

Overall, pan colonic involvement was the most common location in UC (72.6%) and almost half (48.8%) of UC patients had at least moderate disease severity at presentation. South Asian UC patients had slightly less cases of isolated proctitis than the non-South Asian UC sub cohort (6.9% proctitis South Asian *vs* 7.8% non-South Asian).

DISCUSSION

This first publication from the Asian PIBD registry gives valuable insights into the distinct epidemiological patterns of a rapidly emerging chronic disease in the Asia-Pacific region. Existing literature from published adult cohorts documents the distinct rapid rise in overall IBD incidence across the Asia-Pacific region[15] ascribed to increased urbanisation and industrialisation of developing areas with a consequent change in lifestyle and environmental factors. Our pooled data across major paediatric gastroenterology centres in the Asia-Pacific region verifies the rise in PIBD incidence, particularly in the last decade of data collection (2010-2019). This is also consistent with rising trends observed in other Asian paediatric cohorts in Saudi Arabia[16], Bahrain[17], Japan[18], South Korea[19] and China[20]. There still remains a knowledge gap on the epidemiological trends of PIBD in many parts of Asia, particularly Central and South Asian regions, although recently published studies out of Kazakhstan [21], India[22] and Nepal[23] reaffirm IBD as an emerging health issue.

Several other factors have been proposed as reasons for the observed rise in IBD incidence within the Asia-Pacific region, namely increased disease awareness amongst healthcare professionals, improved access to healthcare resources and better diagnostic modalities in rapidly industrialising areas. While such factors may account for part of the initial observed rise in incidence in the earlier decades, they do not sufficiently explain the sustained year-on-year rise in PIBD incidence seen in developed regions of our network[6,24] as well as other highly industrialised regions in Japan and South Korea.

The key strength of a multi-centre registry in this ethnically and culturally diverse region would be to allow epidemiological comparisons amongst multi-racial Asian populations (*e.g.*, Singapore/Malaysia) and ethnically homogeneous populations (*e.g.*, Philippines/Sri Lanka/Thailand). In Singapore and Malaysia where the Chinese and Malay populations form the majority ethnic group respectively and the Indians are an ethnic minority, we affirm earlier findings from adult Southeast Asian cohorts[25,26] that there is an ethnic predisposition to IBD incidence with an over-representation of the Indian/South Asian subgroup (37% IBD *vs* 6%-9% general population). This is similar to observations in the United Kingdom and Canada where IBD is seen with greater frequency amongst both South Asians born in the United Kingdom[27] and South Asian migrants to the United Kingdom[28], as well as the paediatric South Asian community in British Columbia, Canada[29]. Similarly, in a study of 30812 IBD subjects diagnosed in the United States, Malhotra *et al*[30] found that residents of Indian ancestry carried the highest risk for all types of IBD, compared to residents of Jewish, East Asian or Hispanic ancestries.

With combined Singaporean and Malaysian data, we were able to discern unique characteristics of each ethnic group. The CD:UC ratio varied distinctly across the three ethnic groups (Chinese 1.2; Indian/South Asian 1.0 and Malay 0.7) and this is likely attributed to inter-ethnic differences in environmental factors, such as diet, diversity in gut microbiome[31] including *Helicobacter pylori* (*H. pylori*)[32] as well as socio-economic status[33]. This inter-ethnic variation in IBD incidence has been observed between African Americans and white Americans previously[34]; white Americans were reported to have a CD:UC ratio > 1.0 with Hispanic Americans having an inverse ratio[35], paralleling what is observed between Chinese and Malays in our cohort. A similar variegation of CD:UC ratio was seen in a Latin American systematic review by Kotze *et al*[36], in which only certain states in Brazil reported a CD:UC ratio > 1 whereas most of the other Latin American countries had a CD:UC ratio < 1. The authors concluded similarly that regions within Latin America that experienced higher degrees of economic development and 'Westernisation' had a higher proportion of CD cases.

We also observed a strongly significant association between the South Asian ethnicity and symptomatic perianal disease (pain or perianal discharge) at presentation, only in the South Asian populations of Singapore and Malaysia. Interestingly, despite less South Asians having the CD phenotype than Chinese, the South Asian ethnicity was significantly associated with asymptomatic perianal tags. The latter physical finding may be a prelude to developing symptomatic perianal Crohn's later in the clinical course, as seen in this study by Singer *et al*[37] showing a higher rate of perianal fistulisation in patients initially presenting with non-penetrating perianal lesions. The observation of increased rates of symptomatic perianal disease was not appreciated in the native South Asian population of Sri Lanka within the limits of small patient numbers recruited in this sub cohort. A

previous questionnaire survey conducted in India estimated the incidence of perianal disease at presentation in Indian paediatric CD patients at 18.0%, which is not strikingly higher than paediatric cohorts in Israel (13.3%)[38] and Canada (16.0%)[39]. More recent Indian studies, which included

perianal disease developed both at diagnosis and subsequent follow-up, however, have found even lower rates than other Asian cohorts. Banerjee *et al*[40] reported 7.4% perianal involvement amongst CD patients and a multicentre paediatric study in India reported 10.9% of CD patients with perianal disease(fistula or abscess). These findings suggest South Asian CD patients in their native countries do not experience disproportionately high rates of perianal disease.

On the contrary, countries with a high South Asian immigrant population report findings congruent with our cohort's. A previous paediatric study in San Francisco likewise demonstrated similar findings in our cohort, where South Asians tended to have more perianal fistulising disease at presentation than their Caucasian counterparts[41]. A recent adult cohort study published by Jangi *et al*[42] also showed South Asian CD patients in the United States were more likely to experience symptomatic perianal disease than white patients. Current findings from our study and the above-mentioned cohorts may suggest these phenotypic trends may be unique only to South Asians who have migrated from their native countries to relatively more developed and urbanised regions. A possible explanation is that South Asians may carry an intrinsic genetic predisposition for IBD, which results in a distinct disease phenotype in the setting of specific environmental exposures after migration[43]. A review by Foster and Jacobson[44] discusses these hypothetical gene-environmental interactions in South Asian immigrants, postulating the role of dietary changes from a traditionally high carbohydrate/low saturated fat diet to one which is highly processed. Other possible factors discussed include an increased exposure to urban pollutants and a reduced exposure to potentially protective factors such as vitamin D, *H. pylori* and helminths.

Overall, we do report a moderately high rate of perianal involvement in our CD patients at presentation (13.2% with symptomatic perianal disease and up to 30.5% with some form of perianal manifestation of CD either clinically detected or *via* imaging. An earlier Singaporean paediatric cohort reported a 21.6% incidence of perianal disease amongst CD patients at diagnosis[6] with mainland Chinese and South Korean paediatric CD cohorts reporting even higher rates of perianal involvement 42.4% Shanghai[45] , 47.1% [(perianal fistulising disease) only South Korean[46]]. Some variability in the reported rates of perianal involvement across CD cohorts could be accounted by differences in disease definitions as well as the extent of perianal imaging performed, which may detect indolent perianal fistulising disease in otherwise asymptomatic patients. A large IBD cohort of 5223 white Americans, 35 United States-born Asians and 81 Asian immigrants also reported Asians having a significantly higher rate of perianal disease (at presentation and follow-up) than whites (33% *vs* 18%)[47]. Further prospective follow-up of our cohort is required to ascertain if an even greater proportion of CD patients will evolve to develop perianal disease beyond the point of diagnosis.

Interestingly, we also found a very high proportion of VEO-IBD (29.3%) in our cohort, which appears to be stably high across a 20-year period of analysis. In comparison, data from the EPIMAD registry in France (n = 1412) reported a VEO-IBD rate of 3.0% based on a similar age definition for VEO-IBD[48]. Other Asian cohorts have similarly reported comparatively high rates of VEO-IBD, albeit using varying ages for definition. A single centre study in Beijing, Mainland China (n = 184) reported 41.8% of hospitalised children with IBD were VEO[49]; a cohort in Saudi Arabia reported 15.9% of patients were younger than 4 years at time of onset[16] and a recent Indian multicentre paediatric study had reported 19.1% of patients being VEO[22]. It is not certain if this epidemiologic trend is unique to regions where IBD is of emerging importance, as a Canadian study across 5 provinces reported VEO-IBD as the subgroup with the most rapid increase in incidence relative to the other age groups[2].

Aside from the South Asian predisposition and younger age of onset, the clinical presentation and extra-intestinal manifestations of CD and UC were similar to other Asian and Western paediatric and adult cohorts[50]. Abdominal pain and constitutional symptoms (fever, loss of appetite, oral ulcers, malaise) were more common presenting features in CD than UC; bloody diarrhoea and associated liver disease/primary sclerosing cholangitis were more common in UC at presentation, the latter being a well-established association. EIMs such as arthritis and erythema nodosum were more common in CD than UC, as also seen in a Mainland Chinese cohort[20]. We also reaffirm the finding of significant heterogeneity of CRP response between CD and UC, as discussed extensively in published literature[51, 52]. Within the limits of a small sample size, we noted that faecal calprotectin values vary with disease location in CD but not in UC. Previous correlation studies have also similarly observed lower values of faecal calprotectin in CD patients with pure ileal disease[53].

While CD patients had numerically lower weight Z-scores and height Z-scores than UC patients, these comparisons were not statistically significant. This is due to a relatively high rate of linear growth failure (16.1%) reported in UC patients in our cohort, which is higher than the typical prevalence of 3%-10% previously described[54]. It is uncertain if this truly reflects a unique UC phenotype or whether some of these UC patients will be re-classified as CD with evolution of disease and/or further diagnostic modalities performed. As approximately 60% of our cohort did not undergo any form of small bowel imaging and 20% did not undergo an upper gastrointestinal endoscopy, we could expect changes in these initial diagnostic labels had more complete evaluation been performed.

There are a few limitations to our study; firstly, as most of the data was collected retrospectively, we were not able to compute patient disease activity indices in all patients because of incomplete clinical, biochemical, imaging or endoscopy records. Secondly, a lack of access and/or consistency in performing small bowel imaging and upper gastrointestinal endoscopy could have resulted in inaccurate disease

classification. However, as almost half of our cohort was diagnosed in the recent 5 years, we are confident that the disease phenotype has been more accurately assessed and documented in these later years.

Another limitation was the predominance of Southeast Asian participating centres in our network, with the lack of East and West Asian representation. However, we were able to mitigate this as there already exists a substantial amount of published literature from established Japanese, South Korean and mainland Chinese cohorts as previously cited. Hence, we were able to compare certain epidemiological features such as age of onset and the proportion of perianal disease as discussed above.

Lastly, the number of patients captured within our network may only represent 'the tip of an iceberg'. We acknowledge that access to healthcare services may be very limited in rural regions of the participating countries, and there may be an inevitable selection bias in recruiting patients living in the proximity of major Asian city centres (Singapore, Kuala Lumpur, Bangkok, Manila, Colombo, Chinese Taipei) where our participating sites are located. Hence, there could be a number of children with IBD who do not present to centres equipped with adequate disease knowledge and diagnostic capability, and thus remain undiagnosed. At the same time, there could be a number of adolescent IBD patients who are managed by adult gastroenterologists. The general lack of national chronic disease registries for PIBD in the respective countries of this network further adds to the challenges in obtaining complete epidemiologic data. These factors discussed suggest the true burden of PIBD in the Asia-Pacific region is very likely under-estimated.

CONCLUSION

Our study presents epidemiological data from the largest multi-centre Asian-Pacific paediatric cohort to date, and reaffirms the rising trend of PIBD across our registry, particularly in the past decade (2010-2019). We also report a substantially higher incidence of VEO-IBD than European cohorts and this is similarly observed in other Asian cohorts in mainland China and the Middle East. The unique multi-ethnic demographic composition of our cohort allows for distinct phenotypic differences to be seen between ethnicities, chiefly the over-representation of the Indian/South Asian ethnicity and its strong association with symptomatic perianal CD. Prospective follow-up data from this registry would also ascertain if any of these observed epidemiologic trends within this publication have implications on medium to longer term disease outcomes.

This inaugural publication from our registry likely under-estimates the true burden of IBD in Asia, and the way forward to address these identified knowledge gaps, would be to encourage more tertiary centres from diverse parts of Asia to partake in the Asian PIBD registry. This will improve the representativeness of our cohort and enhance the ability to make both intra- and inter-regional comparisons in disease behaviour and phenotypic trends.

ARTICLE HIGHLIGHTS

Research background

There remains a dearth of epidemiological literature on paediatric inflammatory bowel disease (IBD) in most parts of Asia. While there have been several published cohort studies out of East Asia, little is known on the actual disease burden beyond isolated case series and single-centre studies in the rest of the Asia-Pacific region. This would represent the first cohort study from a multi-centre Asian-Pacific PIBD registry first initiated in 2017.

Research motivation

The main issue was a lack of a standardised data platform in Asian-Pacific paediatric gastroenterology centres. A standardised data platform is vital to allow an accurate and validated way of reporting the disease behaviour and phenotype of PIBD across different healthcare systems in the heterogeneous Asia-Pacific region. This facilitates meaningful epidemiological comparisons with other established PIBD cohorts from North America and Western Europe.

Research objectives

This cohort study describes the epidemiological characteristics of all PIBD patients at the point of initial presentation, whom are managed at one of seven paediatric gastroenterology centres in the Asian-Pacific region (Singapore, Sri Lanka, Malaysia, Thailand, Philippines, Taiwan R.O.C). The objectives were to establish if there were unique disease characteristics of PIBD in the Asia-Pacific region in contrast to East Asian and Caucasian cohorts, as well as inter-ethnic disease phenotypic differences in the multi-ethnic populations of Asia-Pacific.

Research methods

Standardised disease data collection forms using existing validated disease activity indices and disease classification systems for PIBD were stored electronically on a centrally-hosted secure REDCAP platform. Participating Asian-Pacific sites were invited to enrol patients with an established diagnosis of IBD from the point of initial presentation.

Research results

Epidemiological data from our registry demonstrates a rapid rise in PIBD incidence, particularly in the last 5 years. The unique disease characteristics of our Asian-Pacific cohort include a large proportion of very-early onset (VEO)-IBD (29.3%) similar to the high proportions of VEO disease reported from mainland China, Saudi Arabia and India. There is also a relative over-representation of the Indian/South Asian ethnicity in the multi-ethnic countries of Singapore and Malaysia. Patients of Indian ethnicity with Crohn's disease (CD) were also most likely to present with symptomatic perianal disease.

Research conclusions

The rise in PIBD incidence across the Asian-Pacific region is consistent with the observed rise in incidence in many other global cohorts. The high proportion of very early onset IBD in the Asia-Pacific region may represent a shift in epidemiological trends in PIBD, as other established IBD cohorts similarly report the fastest growth in IBD incidence amongst very young children. The higher incidence of symptomatic perianal CD amongst Indian patients in Singapore/Malaysia suggests inter-ethnic genetic differences may cause variability in disease behaviour.

Research perspectives

Future research should be targeted at establishing national disease data registries to fully encapsulate the true burden of IBD in the Asia-Pacific region, and prospective follow-up data from this multi-centre registry is essential to determine if any of the observed epidemiological trends at diagnosis have implications on longer term outcomes.

Abstract

BACKGROUND

Ampullary adenoma is a rare premalignant lesion, but its incidence is increasing. Endoscopic papillectomy has become the first treatment of choice for ampullary adenomas due to its safety and effectiveness, thereby replacing surgical resection. However, recurrence rates and adverse events after endoscopic papillectomy were reported in up to 30% of cases.

AIM

To review the long-term outcomes of endoscopic papillectomy and investigate the factors that affect these outcomes.

METHODS

We retrospectively analyzed the data of patients who underwent endoscopic papillectomy for ampullary adenoma at five tertiary hospitals between 2013 and 2020. We evaluated clinical outcomes and their risk factors. The definitions of outcomes were as follow: (1) curative resection: complete endoscopic resection without recurrence; (2) endoscopic success: treatment of ampullary adenoma with endoscopy without surgical intervention; (3) early recurrence: reconfirmed adenoma at the first endoscopic surveillance; and (4) late recurrence: reconfirmed adenoma after the first endoscopic surveillance.

RESULTS

A total of 106 patients were included for analysis. Of the included patients, 81 (76.4%) underwent curative resection, 99 (93.4%) had endoscopic success, showing that most patients with non-curative resection were successfully managed with endoscopy. Sixteen patients (15.1%) had piecemeal resection, 22 patients (20.8%) had shown positive/uncertain resection margin, 11 patients (16.1%) had an early recurrence, 13 patients (10.4%) had a late recurrence, and 6 patients (5.7%) had a re-recurrence. In multivariate analysis, a positive/uncertain margin [Odds ratio (OR) = 4.023, P = 0.048] and piecemeal resection (OR = 6.610, P = 0.005) were significant risk factors for early and late recurrence, respectively. Piecemeal resection was also a significant risk factor for non-curative resection (OR = 5.424, P = 0.007). Twenty-six patients experienced adverse events (24.5%).

CONCLUSION

Endoscopic papillectomy is a safe and effective treatment for ampullary adenomas. Careful selection and follow-up of patients is mandatory, particularly in cases with positive/uncertain margin and piecemeal resection.

Key Words: Endoscopic papillectomy; Ampullary adenoma; Clinical outcome; Recurrence; Adverse event

Core Tip: This is a multi-center study evaluating the clinical outcomes of 106 patients who underwent endoscopic papillectomy for ampullary adenoma. In our results, margin-positive/uncertain pathologic reports and piecemeal resection were significant factors for the curative resection and recurrences. Unexpectedly, many recurrences were observed in margin-negative resection, but in most cases, they were successfully managed with minimally invasive endoscopic therapies. Since there is no definite factor for predicting and preventing recurrence and re-recurrence, regular follow-up with endoscopy should be performed in every patient regardless of resection margin or resection type, especially in patients with margin-positive/uncertain and piecemeal resection.

INTRODUCTION

Ampullary adenomas (AAs) are rare lesions, with a prevalence of 0.04%-0.12% in autopsy, and account for 0.2%-5% of newly diagnosed intestinal neoplasms[1-3]. As the number of endoscopic surveillance or computed tomography (CT) scans has increased, the number of AAs detected has also increased. Patients with AA are often asymptomatic, and other complaints are related to biliary or pancreatic obstruction, such as jaundice, biliary colic, or pancreatitis. Even in asymptomatic patients, an AA needs to be removed because of its malignant potential[4]. Furthermore, complete excision of AAs is necessary because of poor diagnostic accuracy with false-negative rates of up to 30% and diagnostic discrepancy of pathologic results, reported as 25%-60%, with forceps biopsy[5,6].

Endoscopic papillectomy (EP) was first introduced for the treatment of AA by Suzuki *et al*[7] in 1983, and both endoscopic and surgical approaches have been considered for the treatment of AA. EP is now considered as the first treatment of choice for benign AA due to the high recurrence, mortality, and morbidity of surgery[8-11]. Nevertheless, there remain concerns regarding EP. The reported EP adverse event rate is over 20% and while most cases are not severe, this cannot be neglected[12]. The recurrence rate after EP is high at 58.3%, and re-recurrence or persistence of AA has often been reported, requiring patients to undergo additional procedures or surgery[13,14]. Despite recent guidelines, there is no consensus on outcome parameters, and there are no established indication for EP or guidelines for EP technique, and no guidelines for the management of recurrence and re-recurrence[12,15,16].

Here, we aimed to evaluate the clinical outcomes of patients who underwent EP and investigate the factors that affect recurrence and adverse events to assist in improving the outcomes of EP and establishing the guidelines for EP.

MATERIALS AND METHODS

Study design

We retrospectively reviewed the medical charts of patients who underwent EP for AA between January 2013 and December 2019 and their follow-up data until December 2020 at five tertiary hospitals: Korea University Anam Hospital, Korea University Guro Hospital, Korea University Ansan Hospital, Hanyang University Seoul Hospital, and Hanyang University Guri Hospital. We excluded patients who underwent EP or surgical ampullectomy prior to enrollment and those who were followed up for less than a year after EP. Patients with non-adenomatous lesions were also excluded.

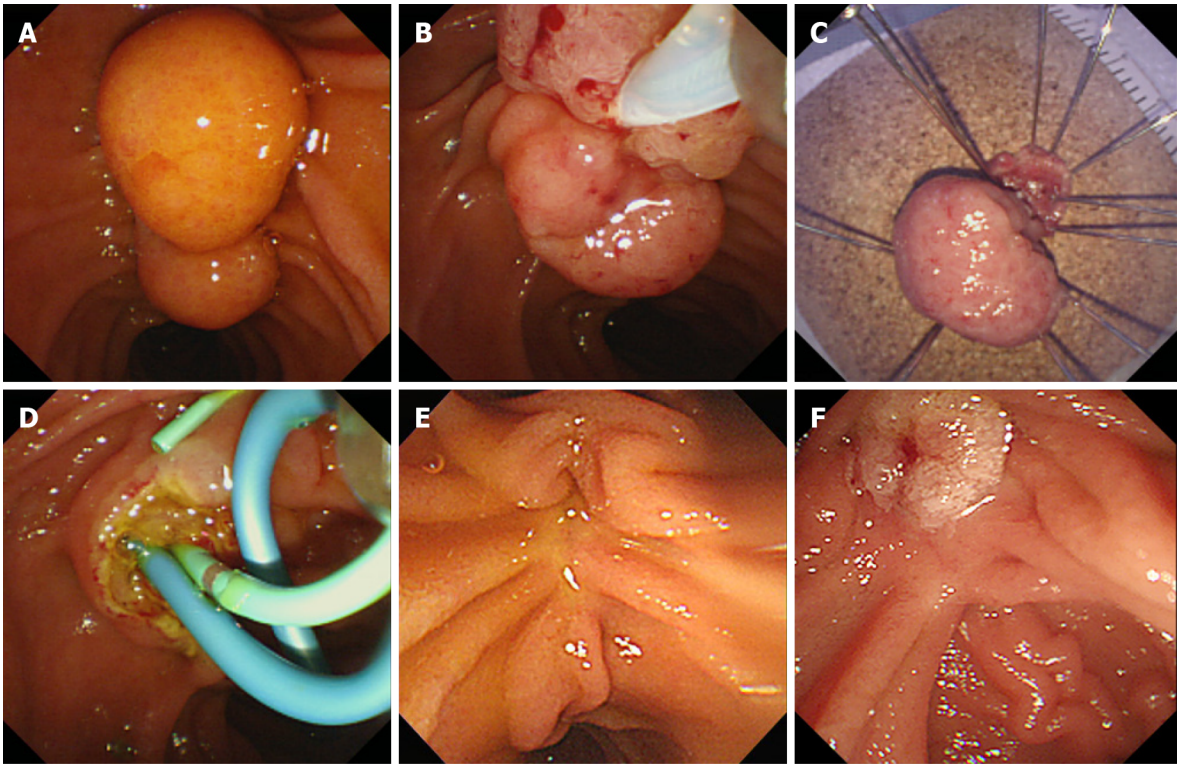
Patient baseline characteristics including age, sex, body mass index, clinical presentations, and initial pathologic reports of the lesion were recorded. Patients were screened for familial adenomatous polyposis (FAP), and mean follow-up periods were calculated. Parameters for EP techniques were recorded using written reports of EP, endoscopic images, and fluoroscopic images. These parameters included endoscopic ultrasound (EUS), cholangiogram, pancreatogram, submucosal lifting, type of resection(*en-bloc*/piecemeal), thermal ablation after resection, complete endoscopic resection, bile duct stent insertion (BDS), and pancreatic duct stent insertion (PDS).

EP procedure

EP was performed at five tertiary hospitals with over 500 endoscopic retrograde cholangiography (ERCP) annual cases by seven experts with over five years of ERCP experience. Before EP, EUS was performed at the endoscopist's discretion. After adequate sedation, the ampulla of Vater was carefully inspected for its size, extent, and signs of malignancy (Figure 1A). Following the inspection, a cholangiogram and pancreatogram were obtained in cases requiring evaluation of a possible intraductal invasion. Then, snare polypectomy was performed (Figure 1B). Mucosal lifting using saline was performed if needed. With a standard polypectomy snare, the adenoma was tightly grasped, and the electrical current was applied until complete resection of the lesion was achieved.

En-bloc resection of AA was first attempted, and a piecemeal resection was performed if *en-bloc* resection was not possible. The resected specimen was removed and sent for pathologic evaluation (Figure 1C). The specimen was reviewed by a gastrointestinal pathologist and one or more residents in each hospital.

The EP site was observed for possible remnant lesions and immediate adverse events. Where remnant tissue was suspected, removal was performed with repeated biopsy, snaring, or thermal ablation with argon plasma coagulation (APC). In the event of immediate bleeding, epinephrine was sprayed with additional APC if bleeding persisted. In the event of duodenal perforation, endoscopic hemoclips were applied for the primary closure and surgery was subsequently performed. Sphinterotomies, BDS, and PDS were performed if needed (Figure 1D). The procedure was terminated if there was no more residual tissue or in the absence of immediate adverse events. Subsequently, the patient was observed on the ward with physical examination, monitoring of vital signs, laboratory tests, and X-rays for early adverse events. The details of each endoscopic procedure were determined by the endoscopist.



All patients underwent routine follow-up after EP. Within 3 mo of the procedure, patients underwent endoscopic surveillance for assessment of remnant tissue and recurrence, and stent removal (Figure 1E). Biopsy was performed if any remnant lesion was suspected. If the biopsy result showed remnants or early recurrence, additional therapeutic plans were decided by the endoscopist with the patient (Figure 1F). If no abnormal lesion was identified, the patient underwent further surveillance at six-monthly intervals for the first two years and annually thereafter.

Outcome measures

EP results included the resection specimen size, pathologic findings, accuracy of endoscopic biopsy, resection margin, curative resection, early and late recurrence, re-recurrence, endoscopic success, mean hospital stay, and mean adenoma-free period. EP outcomes were obtained from pathologic reports and medical charts.

Curative resection was defined as complete endoscopic resection without recurrence during follow-up. Early recurrence was defined as reconfirmed adenoma following biopsy at the first surveillance endoscopy. Late recurrence was defined as reconfirmed adenoma following biopsy after the first surveillance endoscopy. Re-recurrence was defined as recurrence of adenoma at the follow-up biopsy after the treatment of early or late recurrence. Endoscopic success was defined as treatment of AA with endoscopy, including cases with residual tissue, recurrence or complications, without surgical intervention. Resection margins were categorized into 3 groups, negative, positive, and uncertain, and they were analyzed as positive/uncertain group and negative group[17,18].

Adverse events of EP were categorized into early events (pancreatitis, delayed bleeding, cholangitis, and perforation) occurring within 30 d of the procedure and late events (papillary stenosis and death) occurring after 30 d following the procedure. Endoscopic adverse events and their severity were graded according to the American Society for Gastrointestinal Endoscopy criteria[19]. We set the minimum follow-up duration to one year to avoid underestimation of recurrence and adverse events. Univariate analysis and multivariate analysis were performed to evaluate the risk factors of early and late

Figure 1 Endoscopic papillectomy of ampullary adenoma. A: Careful inspection of the ampulla was required before the procedure; B: Endoscopic papillectomy was performed using a conventional polypectomy snare; C: The resected specimen was retrieved and pinned on a cork with nails for pathological evaluation; D: The resected area was carefully inspected, and an additional procedure including common bile duct stenting (blue stent) or pancreatic duct stenting (green stent) was performed; E: Endoscopic surveillance was mandatory; F: If recurrence was suspected, additional treatment was considered.

recurrence, non-curative resection, and adverse events.

Statistical analysis

Continuous variables were expressed as mean and standard deviation, and Categorical variables were expressed as a number and percentage. Univariate logistic regression analysis was performed to analyze the risk factors for early and late recurrences, non-curative resection, and adverse events. Variables that were significant in the univariate analysis were included in the multivariate logistic regression analysis. A P value < 0.05 was considered significant. The probability of adenoma-free after EP was analyzed using the Kaplan–Meier method. The statistical analyses were performed using the SPSS version 22.0 software (IBM Corp., Armonk, N.Y., USA).

RESULTS

We retrospectively collected the medical records of 119 patients and their follow-up data (Figure 2). We excluded seven patients who failed to meet the follow-up criteria or were lost to follow-up within a year of the procedure, and six patients because of non-adenomatous lesions. After the exclusion criteria were applied, 106 patients were finally included for analysis.

Patient baseline characteristics are shown in Table 1. Seventy-three patients (68.9%) were asymptomatic, and AA was diagnosed incidentally from screening endoscopy or CT scan. The most frequent symptoms associated with AA were jaundice in 16 patients (15.1%) and abdominal discomfort in 13 patients (12.3%). All patients underwent biopsy before the EP procedure, and their pathology reports were as follows: chronic inflammation in 2 patients (1.9%), atypical proliferative epithelium in 3 patients (2.8%), adenoma with low-grade dysplasia in 91 patients (85.8%), and adenoma with high-grade dysplasia in 10 patients (9.4%).

The EP techniques used for the patients are listed in Table 2. EUS was performed in 37 patients (34.9%), and a cholangiogram and pancreatogram were obtained in 70 patients (66.0%) and 87 patients (82.1%), respectively. Four patients (3.8%) underwent submucosal lifting with normal saline. *En-bloc* resection was performed in 90 patients (84.9%), and piecemeal resection was performed in 16 patients (15.1%). After the resection, thermal ablation was performed in 24 patients (22.6%) because of remnant tissue or immediate bleeding. Complete endoscopic resection was successfully performed in 105

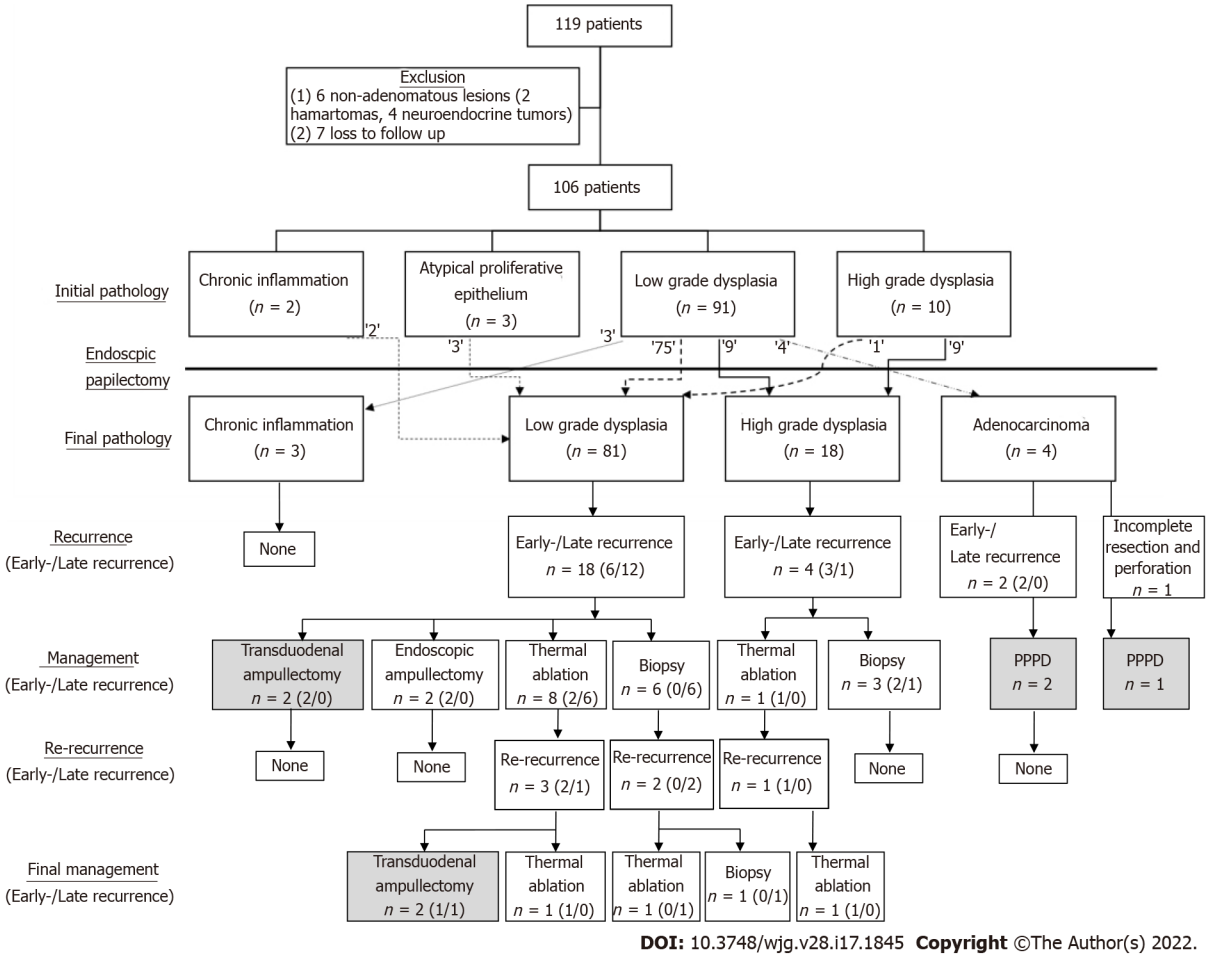
Initial pathology	
Chronic inflammation	2 (1.9)
Atypical proliferative epithelium	3 (2.8)
Low-grade dysplasia	91 (85.8)
High-grade dysplasia	10 (9.4)
Mean follow-up, mo	36.2 ± 18.3

patients (99.1%), and in one patient the lesion could not be completely removed due to underlying fibrosis and a diagnosis of adenocarcinoma was finally made. BDS and PDS were performed in 25 patients (23.6%) and 78 patients (73.6%), respectively.

Table 2 also summarizes the results of the EP. The mean size of the resected specimen was 13.6 ± 5.5 mm, and the final pathologic results were as follows: chronic inflammation in 3 cases (2.8%), low-grade dysplasia in 81 cases (76.4%), high-grade dysplasia in 18 cases (17.0%), and adenocarcinoma in 4 cases (3.8%). Figure 2 shows the diagnostic discrepancies between the initial and final pathologies. Lesions that showed chronic inflammation or atypical proliferative epithelium on initial biopsy were all low-grade dysplasia on final diagnosis. Out of 91 cases of low-grade dysplasia on the initial biopsy, the final pathologic results were chronic inflammation in three cases (2.8%), low-grade dysplasia in 75 cases (82.4%), high-grade dysplasia in 9 cases (9.9%), and adenocarcinoma in four cases (3.8%). Out of 10 cases of high-grade dysplasia on the initial biopsy, the final pathologic results were low-grade dysplasia in one case and high-grade dysplasia in nine cases. Endoscopic biopsy was accurate in 84 patients (79.2%), with underestimation in 18 patients (17.0%) and overestimation in 4 patients (3.8%).

R0 resection was achieved in 84 patients (79.2%), and curative resection was achieved in 81 patients (76.4%). Early recurrence was found in 11 patients (10.4%), late recurrence was found in 13 patients (12.3%), and all recurrences were local lesions. Re-recurrence occurred in six patients (5.7%), and patient characteristics are summarized in Supplementary Table 1. Figure 2 also shows the number of early and late recurrences from final pathologic results, how these cases were managed, how many re-recurrences occurred after the initial management, and final management of re-recurrences.



Initial management of the 11 patients with early recurrence involved endoscopic therapy in 7 cases (two EPs, two biopsies, and three thermal ablations) and surgery in four cases [two transduodenal ampullectomies (TA) and two pylorus-preserving pancreaticoduodenectomies (PPPD)]. Three patients with re-recurrence were managed with thermal ablation (two cases) and TA (one case). The 13 patients with late recurrence were initially managed endoscopically (six biopsies and seven ablations), and three patients with re-recurrence underwent thermal ablation, biopsy, and TA, respectively. Altogether, 99 patients (93.4%) were managed by endoscopy alone, and seven patients (6.6%) underwent additional surgical management: four patients due to a remnant lesion, two patients due to re-recurrence, and one patient due to incomplete resection and perforation (Figure 2). The mean adenoma-free period was 29.6

Figure 2 Flowchart of the study. After applying the exclusion criteria, 106 patients were enrolled, showing the correlation between the initial and final pathology. After the procedure, remnant and recurrent lesions were identified in follow-up surveillances. Most of these lesions were successfully managed with endoscopy. The gray-colored box indicates surgical management.

Table 3, Table 4, and Table 5 show the univariate and multivariate analysis of the risk factors for early recurrence, late recurrence and non-curative resection, respectively. Age over 65, EUS, size > 1.5 cm and positive/uncertain resection margin were statistically significant risk factors for early recurrence in univariate analysis, and positive/uncertain resection margin [Odds ratio (OR) = 4.023; 95%CI: 1.088-16.387; P = 0.048] was the significant factor for early recurrence in multivariate analysis. Presence of symptom (OR = 4.659; 95%CI: 1.292-16.797; P = 0.019) and piecemeal resection (OR = 7.114; 95%CI: 1.993-25.398; P = 0.003) were significant risk factors for late recurrence in univariate analysis, and piecemeal resection (OR = 6.610; 95%CI: 1.760-24.820; P = 0.005) was the only significant factor for late recurrence in multivariate analysis. Body mass index over 25, presence of symptom, and piecemeal resection were significant risk factors for non-curative resection, and multivariate analysis showed that piecemeal resection (OR = 5.424; 95%CI: 1.582-18.600; P = 0.007) was a significant risk factor for non-curative resection.

Altogether, adverse events occurred in 26 patients as shown in Table 6. Early adverse events were as follows: pancreatitis in 14 patients (13.2%), delayed bleeding in 11 patients (10.4%), cholangitis in six patients (5.7%), and perforation in one patient (0.9%). No late adverse events were reported. In most cases, the severity of adverse events was classified as either mild or moderate, except for one case with perforation. Table 7 shows the univariate and multivariate analysis of risk factors for adverse events, including pancreatitis and delayed bleeding. FAP, pancreatogram, thermal ablation and PDS were significant risk factors for pancreatitis in univariate analysis, and in multivariate analysis, thermal ablation (OR = 4.128; 95%CI: 1.005-17.128; P = 0.048) was a positive risk factor, while PDS (OR = 0.205; 95%CI: 0.044-0.945; P = 0.042) was a negative risk factor for pancreatitis. Cholangiogram, piecemeal resection, and BDS were significant risk factors for delayed bleeding in univariate analysis, and piecemeal resection (OR = 6.698; 95%CI: 1.1.599-28.057; P = 0.009) was the only significant risk factor in multivariate analysis. No significant risk factor for cholangitis or perforation was identified.

DISCUSSION

Of the 106 patients, curative resection was performed in 81 patients (76.4%) with 26 cases of adverse events (24.5%), 11 early recurrences (10.4%), 13 Late recurrences (12.3%), and 6 re-recurrences (5.7%). Our results were consistent with those of previous studies showing curative resection rates of 73.0%-82.7%, adverse events rates of 15.0%-43.6%, early recurrence rates of 2.7%-19.0%, and late recurrence rates of 0-23.9%[14,20-23]. There are large variations in the reported outcomes, particularly among studies involving small numbers of cases because there is no consensus on which parameter best represents the performance of EP. The parameters used in previous studies are inconsistent, and inclusion criteria for EP vary.

Factors used for the evaluation of outcomes in previous studies include visual resection margin, histologic resection margin, recurrence, adverse events, need for surgery, and combinations of these factors. We suggest that curative resection (negative visual resection margin and no recurrence), adverse events, and endoscopic success (negative visual resection margin and no need for surgery) best represent the outcomes of EP. An ideal outcome for EP is the achievement of complete removal of the AA, without adverse events, and without recurrence, which is curative resection with no adverse event. Moreover, even in the event of recurrence, most of these patients can be and are managed endoscopically, representing cases of endoscopic success. We attempted to identify the factors that could predict and improve these outcomes.

In 84 patients (79.2%) the initial and final pathologic results were consistent, which is comparable to previously reported studies[20,23]. The initial biopsy result for the four patients with adenocarcinoma was reported as low-grade dysplasia. Biopsies of AA can occasionally be insufficient because the biopsy is often performed using a forward-viewing endoscope, making a targeted biopsy difficult. Therefore, even if the initial result is benign, it is important to remove the lesion completely with an adequate margin-free area in case of malignancy.

The ampullary lesions found after EP are often described as remnant/residual or recurrence in the literature[14,20,22-24]. Currently, these two categories are clinically distinguished according to the

timing of lesion discovery: most studies define remnant/residual as the part of the previous lesion found at the first or any surveillance endoscopy performed 3-6 mo after EP, and recurrence as the lesion found after the first surveillance endoscopy or 6 mo after EP. Both are confirmed histologically. There is a clear difference between these definitions as remnant/residual refers to the remaining part of the pathologic lesion, while recurrence refers to a pathologic lesion that is newly developed after the procedure[25]. However, it is often difficult to separate these cases clinically. Diagnosis of a remnant could be delayed and the lesion may be found after the first surveillance endoscopy for a number of reasons including small size of remnant tissues and tissue burn from the procedure, and the delay in diagnosis leads to underestimation of remnant/residual lesions and overestimation of recurrence cases [18]. Considering a newly identified lesion at the first surveillance endoscopy as a remnant/residual in R0 resection may also be controversial. Therefore, instead of labeling these two groups differently, it is preferable to refer to both lesions as recurrence and distinguish these cases according to the timing of diagnosis. The recent European Society of Gastrointestinal Endoscopy guideline states that up to two thirds of recurrences are early recurrences[15].

These two groups differ in terms of the timing of the diagnosis and clinical implications, and there may also be differences in patient management. Recurrences were managed at the endoscopist's discretion using various strategies, including endoscopic and surgical management. Except for early recurrence from adenocarcinoma that was managed with PPPD, it was difficult to identify which factors were considered for a particular treatment. However, early recurrences tend to be managed more aggressively than late recurrences, although the numbers were small for comparisons to be statistically significant (3 *vs* 1 TA and 2 *vs* 0 additional EP for early *vs* late recurrences). This tendency may be explained in that in cases of early recurrence, the initial removal of the lesion has been incomplete, so more invasive treatment may be required compared to the previous treatment method. Conversely, late recurrences are newly developed lesions that are typically small or are early lesions.

It is often difficult to establish which area of the adenoma is responsible for the recurrence because recurrences are typically small, but it can be presumed that they occur from the bile duct, pancreatic orifice, base of ampulla, or resection margin. Reported risk factors for recurrence include age, sex, FAP, intraductal involvement, incomplete resection, piecemeal resection, and final pathology, although the results of these studies are rather inconsistent[13,23,25-27]. Here, a positive/uncertain resection margin in the pathologic report was a significant risk factor for early recurrence, and piecemeal resection was a significant risk factor for late recurrence. This is the first study to analyze the risk factors for both early and late recurrence, considering the different definitions and characteristics of recurrence. A positive resection margin could increase the risk of remnants at the resection margin, but this association was not found to be significant in previous studies[25]. This may be because the positive margin following an EP

procedure is occasionally unreliable, as the resected lesions are often too small to be properly manipulated, and cauterization may mask a positive margin[17]. Also, many previous studies do not clearly state how they analyzed the lesion with uncertain margin. More studies are needed to understand the clinical implications of a positive/uncertain resection margin and develop further management strategies for margin-positive/uncertain lesions. Additionally, to reduce recurrence after EP, it is important to check the peripheral and deep margin of the lesion meticulously before the EP, including intraductal involvement, and secure the resection margin properly during the EP. This is because recurrence could be caused by the poor selection of patients or inability to secure the margin

during the procedure, which is sometimes inevitable due to the characteristics of the lesion or the procedure itself. A more aggressive procedure could secure an adequate margin but may cause adverse events such as perforation, so proper selection of patients and careful approaches are mandatory. Similar considerations apply to the higher risk of late recurrence in piecemeal resection. In piecemeal resection, the resection margin may be unreliable, and a thorough evaluation and follow-up for recurrence is required. Piecemeal resection was a significant risk factor for non-curative resection, meaning *en-bloc* resection is a significant protective factor for curative resection, while a pathologic margin was not significant. A positive/uncertain margin and piecemeal resection are important factors for recurrence prediction, although their negative predictive values were 79.8% and 77.4%, respectively; thus, curative resection cannot be assumed in lesions with a negative margin or *en-bloc* resection.

Interestingly, our study was the first to compare the effects of factors including hospital setting and endoscopist experience on the outcome of EP (Supplementary Table 2), and these were not significant for remnant, recurrence, or adverse events. These findings suggest that there was no significant difference in EP results between hospitals with a certain volume of ERCP cases and endoscopists with a certain level of experience. Further studies with larger number of patients are needed to support our

Figure 3 Adenoma-free survival after endoscopic papillectomy. The vertical axis of the graph indicates the adenoma-free probability, and the horizontal axis shows time to remnant or recurrence after endoscopic papillectomy. The longest adenoma-free period before recurrence was 27 mo, and the longest adenoma-free period without recurrence was 94 mo.

suggestion.

Of the six patients with re-recurrence, two patients experienced re-recurrence even after a further session of endoscopic treatment and underwent surgery. Patients with persistent AA showed no specific features to guide the early prediction of the lesion characteristics and early transition to more invasive therapy. The finding that EUS was performed in both patients with re-recurrence suggests that EUS may not adequately predict recurrence or persistence. Moreover, it is unclear as to what extent a benign, although premalignant, AA lesion should be treated at recurrence, considering the adverse events associated with the available treatments. High-quality recommendations or guidelines are necessary.

Our results showed that most adverse events caused by EP showed mild- to moderate-grade severity. The role of thermal ablation in bleeding remains controversial and studies have shown that the risk of pancreatitis increased with the size of the lesion and when hemostasis was performed[22,23,28]. Here, thermal ablation was not significantly associated with bleeding or recurrence although it increased the risk of pancreatitis. The role of PDS is still under debate, but results of several studies, including ours, advocate the use of PDS for prophylaxis of pancreatitis[29-31]. Moreover, no pancreatic stenosis was observed, and this could be explained by our relatively high PDS rate at 73.6%. Hence, it is expected that PDS will help prevent pancreatitis and pancreatic stenosis, and we recommend routine pancreatic stenting, if possible. Also, our result showed that piecemeal resection was the only significant risk factor for delayed bleeding. Piecemeal resection was performed for lesions where *en-bloc* resection was impossible, therefore, the lesions with piecemeal resection tend to be larger[32]. A previous study did not show the correlation between piecemeal resection and bleeding, based on the small number of piecemeal resection cases, but colonic lesions with piecemeal resection show significant bleeding during endoscopic mucosal resection[32,33]. Further research is needed to support the role and adverse events of piecemeal resection in endoscopic papillectomy.

Our study has several limitations. As the indications for EP have not been established, selection bias could not be avoided. Moreover, due to the lack of guidelines on the optimal EP technique, several decisions made during the procedure were at the discretion of the endoscopist. Not all hospitals distinguished margin-positive cases as vertical or lateral involvement, therefore, we simplified the involvement of the margin as positive/uncertain or negative. Finally, the study design was retrospective, and factors regarding the procedure and follow-up could not be controlled.

CONCLUSION

EP is a feasible treatment option for AA with high technical success. However, diagnostic discrepancy, remnant lesions, recurrence, and adverse events cannot be neglected. Unlike gastric or colon adenoma resection, even in cases of complete resection, remnant lesions, recurrence, and re-recurrence were identified, emphasizing the importance of follow-up. For patients with a positive/uncertain resection margin in particular, close follow-up for early recurrence is required, and the possibility of late recurrence should be considered in patients with piecemeal resection. Especially in patients with a positive/uncertain resection margin or piecemeal resection, the possibility of recurrence should be

considered, and closer follow-up for recurrence is required.

ARTICLE HIGHLIGHTS

Research background

The incidence of ampullary adenoma (AA) is increasing, partly from increasing number of imaging studies and from true increase in incidence. Because of its malignant potential, AA has to be removed either surgically or endoscopically.

Research motivation

The role of endoscopic papillectomy (EP) in treatment of AA has been growing due to its relatively low invasiveness, but recurrences and side effects are reported in up to 30% of cases.

Research objectives

Our study aimed to evaluate the clinical outcomes of EP in patients with AA, performed at five tertiary hospitals.

Research methods

We collected the clinical data of patients with AA who underwent EP at five tertiary hospitals between 2013 and 2020 and analyzed the clinical outcomes and adverse events. Clinical outcomes were curative resection, defined as complete endoscopic resection without recurrence, endoscopic success, defined as treatment of ampullary adenoma with endoscopy alone, and recurrence, defined reconfirmed adenoma in endoscopy. Recurrence was divided into early and late, based on an interval of 6 mo.

Research results

Among 106 patients included, curative resection was achieved in 81 patients (76.4%), endoscopic success was achieved in 99 patients (93.4%), early recurrence was identified in 11 patients (16.1%), and late recurrence was identified in 13 patients, and re-recurrence was identified in 6 patients (12.3%). In multivariate analysis, the risk of early and late recurrences was significantly increased in a positive/uncertain margin and piecemeal resection, respectively. The risk of non-curative resection was significantly increased in piecemeal resection. Twenty-six patients experienced adverse events (24.5%): 14 pancreatitis, 11 delayed bleeding, 6 cholangitis, and 1 perforation.

Research conclusions

EP is a relatively safe procedure with high endoscopic success rate. Due to the diagnostic discrepancy, recurrence, re-recurrence and adverse events, careful selection and follow-up of patients are also needed.

Research perspectives

A positive/uncertain margin and piecemeal resection were significant risk factors for poor outcomes; therefore, every effort should be made to ensure adequate free margin and to perform *en-bloc* resection during EP.

Abstract

BACKGROUND

Endoscopic biliary drainage using a self-expandable metallic stent (SEMS) has been widely performed to treat distal malignant biliary obstruction (DMBO). However, the optimal position of the stent remains unclear.

AIM

To determine the ideal position for SEMS placement.

METHODS

In total, 135 DMBO patients underwent SEMS (uncovered or covered) placement over a ten-year period. A total of 127 patients with biliary obstruction between the junction of the cystic duct and Vater's papilla were enrolled. An SEMS was placed through the upper common bile duct 2 cm from the biliary hilar duct in 83 patients (Hilar group) or near the top of the biliary obstruction in 44 patients (Lower group). Technical and functional success, adverse events, and risk factors for SEMS dysfunction were evaluated.

RESULTS

The stent patency period was significantly longer in the Hilar group than in the Lower group (P value < 0.01). In multivariate analysis, the only statistically significant risk factor for SEMS dysfunction was being in the Lower group

(hazard ratio: 9.94, 95% confidence interval: 2.25–44.0, $P < 0.01$).

CONCLUSION
A longer patency period was achieved by positioning the SEMS near the biliary hilar duct.

Key Words: Endoscopic biliary drainage; Malignant biliary obstruction; Uncovered self-expandable metallic stent; Covered self-expandable metallic stent; Biliary hilar duct; Patency period

Core Tip: Endoscopic biliary drainage using a self-expandable metallic stent (SEMS) has been widely performed to treat distal malignant biliary obstruction (DMBO). However, the optimal position of the SEMS remains unclear. This study indicated that the stent patency period was significantly longer when the SEMS was placed near the biliary hilar duct. Furthermore, the placement of a longer SEMS from the biliary hilar duct was thought to overcome several factors of recurrent biliary obstruction in DMBO patients.

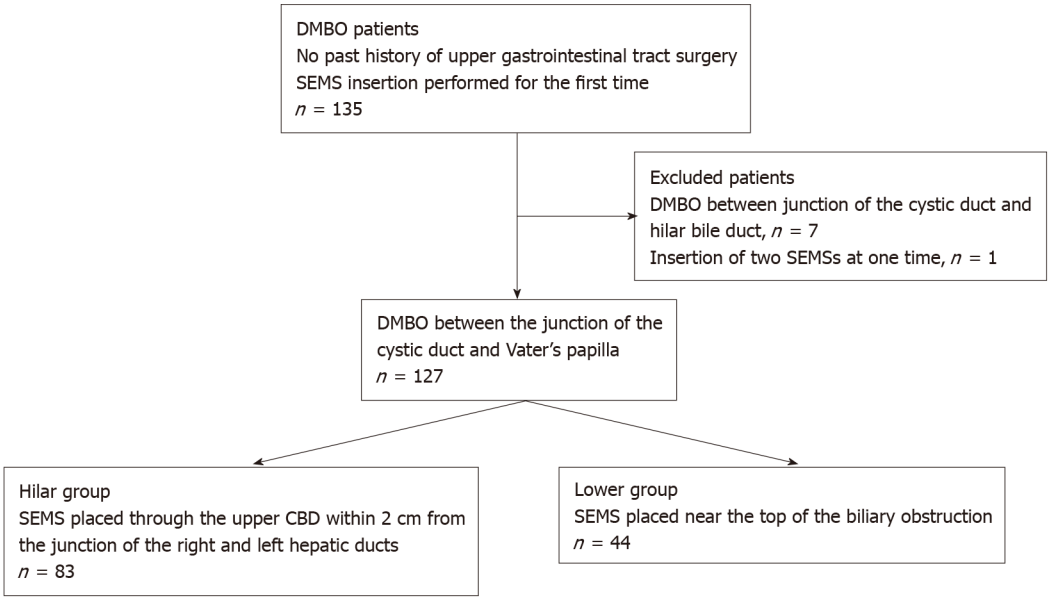
INTRODUCTION

Stricture of the common bile duct (CBD) can occur in several severe diseases (for example, bile duct cancer, pancreatic cancer, or metastasis of other cancers). Since transpapillary biliary stent insertion was first reported by Sohendra and Reynders-Frederix[1], it has become the first choice for biliary drainage in patients with malignant biliary obstruction. At present, uncovered self-expandable metallic stents (USEMSs) and covered SEMSs (CSEMSs) have been reported to be more effective at preventing recurrent biliary obstruction (RBO) than plastic stents (PSs) in distal malignant biliary obstruction (DMBO) patients[2,3].

Whether a USEMS or CSEMS should be used remains a topic of debate. Three reports have asserted that the patency period of CSEMSs is superior to that of USEMSs[4-6]. However, others have found that the patency period is similar between CSEMSs and USEMSs[7-9]. Although CSEMS insertion has some disadvantages (such as cholecystitis, pancreatitis, and migration), the stent can be removed[7,10-13].

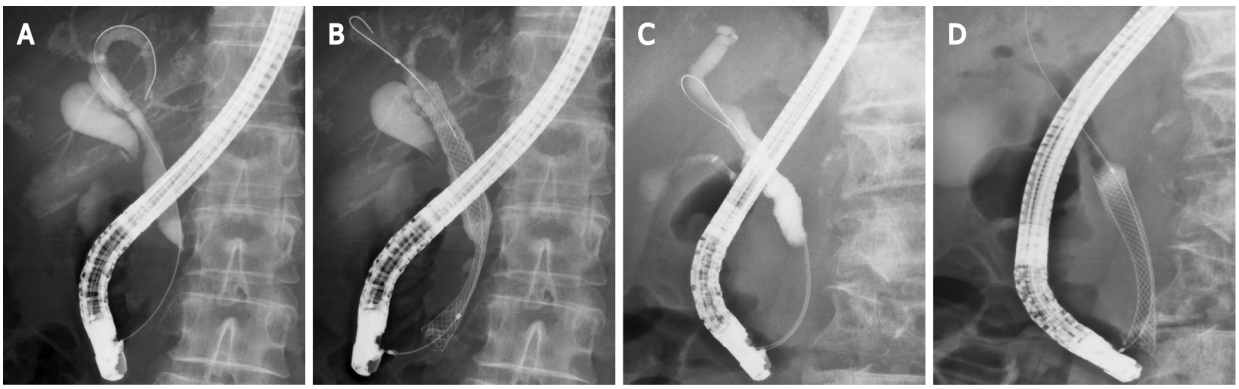
Based on the above findings, SEMS placement may help drain unresectable DMBOs. Determining which stent (USEMS or CSEMS) should be used has gained increasing attention. However, the optimal position of the inserted SEMS has rarely been discussed and remains unclear. Therefore, we aimed to determine the ideal position for SEMS placement.



MATERIALS AND METHODS

Study design and ethics approval

This was a retrospective study. The patients were not required to provide informed consent because this study used anonymized clinical data obtained after each patient had provided written consent and agreed to undergo medical procedures. Additional details of this study are published on the home page of Fukushima Medical University (approval number 2453).



Patients

A total of 135 DMBO patients underwent SEMS placement between January 2011 and February 2021 (Figure 1). These patients did not undergo previous surgery of the upper gastrointestinal tract and were undergoing SEMS placement for the first time. Seven of these patients whose biliary obstruction was located between the junction of the cystic duct and hilar bile duct were excluded from this study. In addition, one patient who underwent double SEMS placement was excluded. Finally, 127 patients whose biliary obstruction was located between the junction of the cystic duct and Vater's papilla were enrolled. The SEMS was placed through the upper CBD within 2 cm from the junction of the right and left hepatic ducts in 83 patients (Hilar group) (Figure 2A and B). In the other 44 patients (Lower group),

Figure 2 Representative cases from each group. A and B: A patient with distal malignant biliary obstruction (DMBO) in the Hilar group who underwent self-expandable metallic stent (SEMS) placement near the biliary hilar duct; C and D: A patient with DMBO in the Lower group who underwent SEMS placement near the top of the biliary obstruction.

the SEMS was placed near the top of the biliary obstruction (Figure 2C and D).

Endoscopic biliary drainage

With the patient in a prone position, a duodenoscope was inserted after the patient was sufficiently sedated with midazolam. When the duodenoscope reached Vater's papilla, biliary cannulation was initiated. After the range of the DMBO was confirmed by cholangiography, an SEMS was inserted from the upper part of the obstruction to Vater's papilla. Endoscopic sphincterotomy (EST) was performed for first-time endoscopic biliary drainage with a PS or before SEMS insertion. The position and type of SEMS (USEMS or CSEMS) were randomly determined by each endoscopist. All the procedures were performed by pancreaticobiliary specialists or trainees under the guidance of specialists.

The USEMSs used in this study were as follows: BileRush, 8 mm × 6 cm, 10 mm × 6 or 8 cm (Piolax, Kanagawa, Japan); Bonastent, 10 mm × 8 cm (Standard Sci Tech, Seoul, Korea); HANARO, 10 mm × 7 cm (Boston Scientific, Tokyo, Japan); Niti-S Large cell, 10 mm × 5, 6, 8, or 10 cm (Taewoong Medical, Gyeoenggi-do, Korea); WallFlex, 10 mm × 6, 8, or 10 cm (Boston Scientific); X Suit NIR, 10 mm × 8 cm (Olympus Medical, Tokyo, Japan); and Zilver, 10 mm × 6 cm, and Zilver 635, 10 mm × 6, 8, or 10 cm (Cook Medical Japan, Tokyo, Japan). The CSEMSs used in this study were as follows: Bonastent, 10 mm × 7 cm (Standard Sci Tech); HANARO, 10 mm × 5, 6, or 8 cm (Boston Scientific); Niti-S Comvi, partially covered, 10 mm × 6, 7, or 8 cm (Taewoong Medical); WallFlex, fully covered, 10 mm × 6 cm, and partially covered, 10 mm × 6 or 8 cm (Boston Scientific); and X Suit NIR, 10 mm × 4, 6, or 8 cm (Olympus Medical).

Outcomes of interest

The primary outcome was the stent patency period. The secondary outcomes were the technical success rate, functional success rate, adverse events (pancreatitis, post-EST bleeding), severity of adverse events, and stent dysfunction rate. These outcomes were defined according to partially revised versions of the reported criteria[14]. The stent patency period was determined as the time from first SEMS insertion to SEMS dysfunction. SEMS dysfunction was defined as the recurrence of hepatic dysfunction, jaundice, or dilated bile tract on ultrasonography or computed tomography (CT), which required secondary SEMS placement. Technical success was defined as successful placement of an SEMS that reached from the upper part of the obstruction to Vater's papilla. Functional success was defined as the return of alanine transaminase (ALT) or total bilirubin (TB) levels to normal values (ALT < 27 U/L, TB < 1.2 mg/dL) or less than half of the pretreatment values. Adverse events and the severity of adverse events were defined according to Cotton's criteria[15]. Posttreatment pancreatitis was also confirmed by contrast-enhanced CT.

In addition, the patient characteristics (age, sex, serum ALT level, serum TB level, cause of stricture, chemotherapy, duodenal stricture, CBD diameter above the stricture, CBD stricture diameter, CBD stricture length), year of procedure (2011-2015, or 2016-2021), stent diameter, type of SEMS used (USEMS or CSEMS), SEMS shortening, and observational period were compared between the Hilar group and the Lower group. The maximum serum ALT and TB values recorded in the previous week up to endoscopic SEMS insertion were used. The cause of stricture was divided into pancreaticobiliary and metastatic. Duodenal stricture was defined as a stricture that was difficult for the upper gastrointestinal scope to pass through. The diameter and length of the CBD stricture were measured by endoscopic retrograde cholangiography. The year of the procedure was compared between the groups because the techniques and devices have advanced over the approximately ten-year study duration. SEMS shortening was determined as more than 1 cm of shortening evident on X-ray or CT imaging after SEMS placement.

Statistical analyses

Student's t test or Welch's t test was used to compare continuous variables. Fisher's exact test was used to compare nominal variables. To analyze the SEMS patency period, the log-rank test was used. To analyze the factors that influenced SEMS dysfunction, a Cox proportional hazard model was used. $P < 0.05$ was considered statistically significant. All statistical analyses were performed using EZR (Saitama Medical Centre, Jichi Medical University, Saitama, Japan).

RESULTS

The patient characteristics are shown in Table 1. There was no significant difference in age, sex, serum ALT level, serum TB level, stricture cause, chemotherapy, duodenal stricture, CBD diameter above the stricture, CBD stricture diameter, or CBD stricture length between the Hilar group and the Lower group.

The outcomes of SEMS placement are shown in Table 2. There was no difference in the procedure year, technical success rate, functional success rate, adverse events, or SEMS shortening between the two groups. The rate of CSEMS use and the SEMS diameter were also not significantly different between the two groups. Regarding the type of SEMS used, the covered WallFlex (Boston Scientific) stent was used significantly more frequently in the Hilar group than in the Lower group (28/83 (33.7%) *vs* 7/44 (15.9%), *P* value = 0.038), and the X Suit NIR stent was used significantly more frequently in the Lower group than in the Hilar group (6/44 (13.6%) *vs* 0/83 (0%), *P* value < 0.01). SEMS dysfunction was observed significantly more often in the Lower group than in the Hilar group [18/44 (41%) *vs* 2/83 (2.4%), *P* value < 0.01]. The causes of SEMS dysfunction were as follows: Ingrowth (1) and overgrowth (1) in the Hilar group, and ingrowth (3), overgrowth (2), ingrowth and overgrowth (8), top edge closed by the CBD wall (4), and dislocation (1) in the Lower group. In the cases in which the top edge was closed by the CBD wall, the SEMSs used were the Zilver 635 (Cook Medical), WallFlex (Boston Scientific), Niti-S large cell (Taewoong Medical), and HANARO (Boston Scientific) stents. A representative case in which the top edge of the SEMS was closed by the CBD wall is shown in Figure 3. The observational period was longer in the Lower group than in the Hilar group (9.12 ± 12.07 mo *vs* 4.16 ± 5.76 mo, *P* value = 0.012).

The results of the stent patency comparison are shown in Figure 4 and Supplementary Figure 1. The stent patency period was significantly longer in the Hilar group than in the Lower group (Figure 4A, *P* value < 0.01). The stent patency period was not significantly different between the groups when the patients were divided according to the use of a covered WallFlex stent, use of a covered X Suit NIR stent, observational period (Figure 4B-D), age, sex, serum ALT level, serum TB level, metastatic or pancreaticobiliary status, presence or absence of chemotherapy, presence or absence of duodenal stricture, CBD diameter above the stricture, CBD stricture diameter, CBD stricture length, year of procedure, USEMS or CSEMS, presence or absence of SEMS shortening (Supplementary Figure 1).

Table 1 Patient characteristics

	Hilar group (*n* = 83)	Lower group (*n* = 44)	*P* value
Age, yr	68.4 ± 11.8	71.2 ± 11.2	0.22
Sex

CBD diameter above stricture, mm	11.5 ± 4.3	12.2 ± 4.0	0.40
CBD stricture diameter, mm	0.61 ± 0.89	0.72 ± 0.8	0.50
CBD stricture length, cm	2.64 ± 1.35	2.34 ± 1.11	0.21

Values are presented as the mean ± SD or *n* (%).
ALT: Alanine transaminase; TB: Total bilirubin; CBD: Common bile duct.

The risk factors for SEMS dysfunction are shown in Table 3. Serum ALT level and lower placement were statistically significant factors in the univariate analysis [ALT: hazard ratio (HR): 1.003, 95% confidence interval (CI): 1.001–1.01, *P* value < 0.01; Lower group: HR: 11.42, 95%CI: 2.61–49.83, *P* value < 0.01]. However, the only statistically significant risk factor in the multivariate analysis was lower placement (HR: 9.94, 95%CI: 2.25–44.0, *P* < 0.01).

DISCUSSION

In this study, we investigated the ideal position for SEMS insertion in DMBO patients. The results demonstrated that the SEMS patency period was longer when the stent was placed near the hilar duct.

This finding suggests that this position overcomes several causes of SEMS dysfunction. As shown in Table 2, the main causes of SEMS dysfunction were tumor ingrowth and/or overgrowth and a top edge closed by the CBD wall; notably, overgrowth and a top edge closed by the CBD wall were prevented by using a longer SEMS. Longer SEMSs can delay stent dysfunction due to tumor overgrowth. In the four patients in the Lower group, the top edge of the SEMS was closed by the CBD wall, which may be caused by linearization of the SEMS. The axial force on the stent is thought to be related to the linearization and closing of the top edge by the CBD wall. However, in the four patients with SEMS dysfunction caused by closure of the top edge by the CBD wall, the SEMSs were not necessarily affected

Figure 3 A patient with closure of the top edge of the self-expandable metallic stent by the common bile duct wall. A: A patient with distal malignant biliary obstruction who underwent uncovered self-expandable metallic stents (USEMS) placement near the top of the biliary obstruction; B: The top edge of the SEMS was closed by the common bile duct wall (arrows). Upper bile tract dilation was observed; C: An additional USEMS was placed near the biliary hilar duct.

by high axial force, except for the WallFlex (Boston Scientific) stent. When a short SEMS is placed near the top edge of the DMBO, the axial force might be enhanced by the biliary stricture. Using longer SEMSs overcomes this problem because the axial force decreases with increasing distance between the top edge of the SEMS and CBD stricture[16]. In fact, a biliary obstruction was relieved by placing a second SEMS near the biliary hilar duct (Figure 3C).

In past reports, time to adequate expansion, degree of CBD stricture[17], duodenal invasion[18], duodenal SEMS[19], and anticancer treatment[18,20] were reported as risk factors for RBO. The factors

related to SEMS expansion and CBD stricture were not an issue in this study because functional success was achieved in almost all the patients. Anticancer treatment has been reported to cause RBO as follows. Although anticancer treatment reduces the tumor burden, it can dislocate the CSEMS or induce neutropenia and bacterial overgrowth and, ultimately, cholangitis or sludge formation in the bile duct [20]. However, anticancer treatment was not proposed as a risk factor for RBO in a study that involved patients with a USEMS[21]. This study involved both USEMSs and CSEMSs. Therefore, anticancer treatment may not be a risk factor for SEMS dysfunction. Duodenal invasion from tumors reduces peristalsis and causes food impaction in the biliary duct, and a duodenal SEMS prevents the outflow of bile juice[19]. In this study, any RBO requiring additional SEMS placement was defined as SEMS dysfunction so that SEMS occlusion caused by tumors could be properly evaluated and cases of SEMS occlusion by food impaction could be excluded. Therefore, SEMS placement near the biliary hilar duct was revealed as a new factor related to longer SEMS patency.

There were some limitations to this study. First, this was a retrospective observational study performed at a single institution. In the future, it is hoped that a prospective multicenter study will confirm our findings. Second, the type of SEMS was not unified. The axial force or shortening length varied among the SEMSs. Measurement of the axial force was difficult in this study; instead, different kinds of SEMSs were compared. As a result, the type of SEMS did not influence SEMS dysfunction. The WallFlex stent (Boston Scientific), which has a high axial force and a high shortening rate[22], was used significantly more often in the Hilar group. However, remarkable shortening was rarely observed (the presence or absence of shortening was confirmed in 23 patients 24 h after SEMS placement and in 99 patients more than 48 h after SEMS placement). This was likely due to the placement of an SEMS with a longer than established length because the SEMS could not fully expand in the area of the stricture. As described above, the axial force decreases with increasing SEMS length. Because of these factors, the difference in the type of SEMS did not influence the outcomes. Third, SEMS obstruction of sludge or food debris was not considered SEMS dysfunction. In past reports, sludge formation has been proposed

to be a cause of SEMS dysfunction[4,5,21]. This factor is surely important for comparisons of patency periods between USEMS and CSEMS. If SEMS obstruction of sludge or food debris was considered stent dysfunction, the patency period was also significantly longer in the Hilar group than in the Lower group (Supplementary Figure 2). Therefore, the obstruction of sludge or food debris did not influence the results of this study. As described above, the SEMS obstruction of sludge or food debris was excluded from SEMS dysfunction to properly evaluate the relationship between the positions of the SEMS and tumor in this study.

CONCLUSION

The results of our study revealed that placement of an SEMS near the biliary hilar duct could delay tumor overgrowth and prevent closure of the top edge of the SEMS by the CBD wall. Thus, in DMBO patients, the SEMS should be placed near the biliary hilar duct to achieve a longer patency period.

ARTICLE HIGHLIGHTS

Research background

Endoscopic biliary drainage using a self-expanding metallic stent (SEMS) has a longer patency period than endoscopic biliary drainage using a plastic stent. Therefore, endoscopic SEMS placement is desirable for the treatment of unresectable distant malignant biliary obstruction (DMBO).

Research motivation

The type of SEMS that should be used for DMBO is a point of active discussion. However, the appropriate position for SEMS insertion is unknown.

Research objectives

To clarify the appropriate SEMS insertion point for DMBO.

Research methods

Among 135 DMBO patients who underwent SEMS placement, 127 patients with biliary obstruction between the junction of the cystic duct and Vater's papilla were enrolled. In 83 patients (Hilar group), an SEMS was placed through the upper common bile duct within 2 cm from the biliary hilar duct. In the other 44 patients (Lower group), an SEMS was placed near the top of the biliary obstruction. The patency period was compared between the Hilar group and Lower group. The risk factors for SEMS dysfunction were also investigated.

Research results

The patency period of SEMS was significantly longer in the Hilar group patients. Multivariate analysis revealed that the Lower group classification was the only significant risk factor for SEMS dysfunction.

Research conclusions

SEMS placement near the biliary hilar duct extends the patency period in DMBO patients.

Research perspectives

SEMS placement near the biliary hilar duct might prevent obstructive jaundice and cholangitis and contribute to improved prognosis in DMBO patients.

Abstract

Helicobacter pylori (*H. pylori*) has long been believed to be the major colonizer of the stomach, but recent advances in genetic sequencing have allowed for further differentiation of the gastric microbiome and revealed the true complexity of the gastric microbiome. One of the few studies specifically evaluated the microbiome in the *H. pylori* negative patient population. They concluded that various stages of gastric carcinogenesis are associated with distinct bacterial taxa that could service both a predictive and diagnostic purpose. While the study has some limitations, the conclusions they make are intriguing and should prompt a larger prospective study to be done that spans multiple geographic regions.

Key Words: Gastric cancer; Gastric carcinogenesis; Microbiome; Dysplasia; Intestinal metaplasia

Core Tip: Gastric tumorigenesis in *Helicobacter pylori* (*H. pylori*) negative patients remained a mystery for many years until genetic sequencing allowed for a closer look at the composition of the gastric microbiome. Primary colonizers of the stomach in *H. pylori* negative patients at various stages of gastric tumorigenesis and were able to conclude that there are distinct bacterial taxa associated with these stages. Their study is comprehensive but needs a larger prospective study to further support this hypothesis, particularly in other geographic areas with varying risk profiles.

TO THE EDITOR

We read with great interest the case control study by Sun *et al*[1]. These authors performed a genetic analysis of gastric mucosa from 134 *Helicobacter pylori* (*H. pylori*) negative patients, which included a variety of gastric pathology: 56 cases of superficial gastritis, 9 cases of atrophic gastritis, 27 cases of intestinal metaplasia, 29 cases of dysplasia, and 13 cases of gastric cancer[1]. Additionally, gastric juice samples from 18 cases of superficial gastritis, intestinal metaplasia, and dysplasia were included and analyzed[1]. Genetic analysis was performed using a 16S rRNA[1]. The goal of the study was to understand whether there is a distinct pattern in the microbiome of various gastric disease types.

The study demonstrated that microbiota of the gastric mucosa varies across different stages of gastric carcinogenesis[1]. Specifically, Sun *et al*[1] found that as the stages of carcinogenesis progress, there is less microbiota variability within gastric mucosa[1]. Of note, their data established that different stages of gastric carcinogenesis had distinguishable microbiota taxa for both gastric mucosa and gastric juice [1]. For example, intestinal metaplasia and dysplasia had predominantly *Ralstonia* and *Rhodococcus* while *Streptococcacaeae* and *Lactobacillaceae* were more prominent in pre-cancerous lesions and gastric cancer [1]. Sun *et al*[1] concluded that their results may facilitate prediction of intestinal metaplasia and dysplasia progression to gastric cancer.

It was long believed that due to the highly acidic environment, *H. pylori* was the predominant colonizer of the stomach. In the recent years, however, genetic sequencing allowed further differentiation of the gastric microbiota[2]. Similar to the study by Sun *et al*[1], prior studies established that microbial diversity decreased significantly with gastric carcinogenesis[3,4]. There were a few studies, however, that were arguing that the opposite is true. The studies by Castaño-Rodríguez *et al*[5] and Eun *et al*[6] suggested that gastric cancer was associated with increased diversity of microbiome[5,6]. These results were supported by the more recent studies. A recently published study by Dai *et al*[7] analyzed gastric microbiome of 37 patients with gastric cancer using the same 16s rRNA gene sequencing[7]. They concluded that pre-cancerous and cancerous gastric lesions had an increased diversity in microbiome and specifically an abundance of *Lactobacillus*, *Streptococcus*, *Bacteroides*, and *Prevotella*[7]. While their conclusions on the increased microbial diversity in gastric cancer argues against conclusions set forth by Sun *et al*[1], they do agree on the distinguishable bacterial taxa associated with gastric cancer that could be used as a predictive marker of neoplastic conversion in pre-malignant lesions. Perhaps these observational disparities could be attributed to geographic, environmental, and patient population differences or even variability of the microbiome throughout various stages of gastric cancer itself.

Sun *et al*[1] concluded that there are certain bacteria that predispose patients to development of gastric cancer. With this, we wonder, if there are bacteria that would instead be protective against gastric cancer. Goldin and Gorbach[8] were one of the first to establish an association between probiotics and cancer prevention back in 1980[8]. Since then, multiple studies have attempted to investigate probiotics as a possible adjunct to cancer therapy. Lee *et al*[9] found that *Bacillus polyfermenticus* was able to reduce gastric adenocarcinoma cell proliferation by more than 90% *in vitro*[9]. Similarly, Han *et al*[10] found that *Lactococcus lactis* was able to reduce gastric adenocarcinoma cell proliferation by more than 80% *in vitro*[10]. While both studies were done *in vitro*, they proposed interesting conclusions that should be further investigated for efficacy *in vivo*. If proved to be successful and safe *in vivo*, targeted probiotics could be a new exciting adjunctive therapy for patients with gastric cancer.

The study conducted by Sun *et al*[1] was retrospective. The patients in the study had a known diagnosis of gastric cancer. Subsequently, it is important to consider a theory that the observed bacterial taxa were a result of neoplastic changes rather than bacteria being responsible for cancer development (*i.e.* reactive changes rather than causal association). This theory can be better investigated by a prospective study in which patients at high risk for developing gastric cancer are followed over time and changes in their microbiome are documented along with histopathological or endoscopic findings.

Sun *et al*[1] rightfully excluded patients who were on active antibiotic therapy, however, it is unclear how many of them had significant antibiotic exposure prior to the study. The association between antibiotic use and cancer remains unclear, however, there is literature reporting cases of antibiotic use and subsequent development of malignancy. Petrelli *et al*[11] conducted a systematic review with meta-analysis and concluded that antibiotics were an independent risk factor for cancer development (OR: 1.18, 95%CI: 1.12-1.24, $P < 0.001$)[11]. This is the reason we believe a thorough antibiotic use history should be collected on patients in studies investigating microbiome and its effects on cancer development.

Gastric cancer is a prominent malignancy affecting many people worldwide but has a notoriously higher incidence rate in Asia[12]. As a result, many of the studies on this topic originate from Asia. Sun *et al*[1] study, for example, was limited to Peking University Hospitals patient population in China, which may have introduced a geographic confounding variable. This may make their conclusions less applicable to the patients of other geographic areas. The study recruitment period was limited to September 2019 to October 2020. Lastly, gastric juice data was only collected for superficial gastritis, intestinal metaplasia, and dysplasia patients, and not for atrophic gastritis or gastric cancer patients. Despite some of the limitations, the study by Sun *et al*[1] had a comprehensive analysis and proposed very interesting conclusions that should be further replicated in larger studies.

In summary, the authors should be commended for their work. They investigated the microbiome in a large group of patients at different stages of gastric cancer tumorigenesis in an *H. pylori* negative patient population, which is generally understudied. Sun *et al*[1] study set comprehensive exclusion criteria limiting many confounding factors. They have demonstrated a well conducted analysis that showed there are distinct bacterial taxa associated with each of the stages of gastric carcinogenesis that could be of great clinical value and help triage gastric lesions. Going forward, large prospective randomized controlled trials that encompass multiple geographic areas could help solidify the conclusions set forth by Sun *et al*[1].

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, and Scopus. The 2021 edition of Journal Citation Report® cites the 2020 impact factor (IF) for *WJG* as 5.742; Journal Citation Indicator: 0.79; IF without journal self cites: 5.590; 5-year IF: 5.044; Ranking: 28 among 92 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2020 is 6.9 and Scopus CiteScore rank 2020: Gastroenterology is 19/136.

Abstract

Gut microbiota has a significant role in gut development, maturation, and immune system differentiation. It exerts considerable effects on the child's physical and mental development. The gut microbiota composition and structure depend on many host and microbial factors. The host factors include age, genetic pool, general health, dietary factors, medication use, the intestine's pH, peristalsis, and transit time, mucus secretions, mucous immunoglobulin, and tissue oxidation-reduction potentials. The microbial factors include nutrient availability, bacterial cooperation or antagonism, and bacterial adhesion. Each part of the gut has its microbiota due to its specific characteristics. The gut microbiota interacts with different body parts, affecting the pathogenesis of many local and systemic

diseases. Dysbiosis is a common finding in many childhood disorders such as autism, failure to thrive, nutritional disorders, coeliac disease, Necrotizing Enterocolitis, helicobacter pylori infection, functional gastrointestinal disorders of childhood, inflammatory bowel diseases, and many other gastrointestinal disorders. Dysbiosis is also observed in allergic conditions like atopic dermatitis, allergic rhinitis, and asthma. Dysbiosis can also impact the development and the progression of immune disorders and cardiac disorders, including heart failure. Probiotic supplements could provide some help in managing these disorders. However, we are still in need of more studies. In this narrative review, we will shed some light on the role of microbiota in the development and management of common childhood disorders.

Key Words: Gut microbiota; Dysbiosis; Children; Gastrointestinal disorders; Immune disorders; Allergic disorders; Cardiac disorders

Core Tip: Gut microbiota has an intimate relationship with the various health conditions of the human body. It interacts with different body parts, affecting the pathogenesis of many local and systemic diseases. Gut dysbiosis is observed in many childhood disorders, inside and outside the gastrointestinal tract. Probiotic supplements could provide some help in managing these disorders. However, we are still in need of more studies. In this narrative review, we will shed some light on the role of microbiota in the development and management of common childhood disorders.

INTRODUCTION

The human has an intimate symbiotic relationship with microbes. The human body harbors about 10-100 trillion microbial cells. Most of these microbes are present mainly in the gut as it provides a warm, stable, and eutrophic environment. There is significant variability in microbial composition at different body sites, with a vast difference between health and disease. Although the term microbiota is sometimes interchangeably used with the term microbiome, microbiota refers to the organisms living in a specific environment, and microbiome refers to the microorganisms and their genome in a particular environment[1]. The microbial microbiome has a set of genes of approximately 3.3 million active genes compared to 22000 human genes. The gut microbiota is the organisms that inhabit the gut, forming about 60% of the dry faces; 99% are anaerobic bacteria. Though bacteria form the main bulk of the microbiome, viruses, archaea, and eukaryotes are present in fewer numbers, but we should not ignore their presence[2].

Microbial colonization with more than 1000 species plays an essential role in gut development and maturation. There is evidence that gut colonization started in utero, and bacteria were detected from the amniotic fluid meconium and placenta in healthy term babies[3]. After delivery, the microbiota of the vaginally delivered neonates resembles those of their mother's vagina, while those delivered by cesarean section resemble those of the mother's skin. Then the infant microbiota changes gradually with every change in the infant diet from the simple neonatal microbiota with a predominance of facultative anaerobic bacteria, such as *Enterobacteria, Enterococci*, and *Streptococci*, to the more complex adult-type by the first few years of life with greater diversity and ability to biosynthesize vitamins and digest polysaccharides[4]. However, the child's microbiota continues to develop throughout childhood and adolescence. Despite being like the adult regarding the number of the detected species, the gut microbiota of children and adolescents may differ in genera's relative abundances[5]. Their gut microbiota has more abundances of *Bifidobacterium spp.*, *Faecalibacterium spp.*, and members of the *Lachnospiraceae* than the adults' gut microbiota with more abundances of *Bacteroides spp.* The microbiome also is different in children with more genes involved in amino acid degradation, vitamin synthesis, triggering mucosal inflammation, and oxidative phosphorylation compared with that observed in the adults with more genes associated with inflammation and obesity. So, as expected, the gut microbiota and microbiome go through a continuous and persistent development throughout life[6].

FUNCTION OF GUT MICROBIOTA

Gut microbiota exerts some essential functions in the human body's immunological, metabolic, structural, and neurological landscapes. Gut microbiota also significantly influences an individual's physical and mental health[7]. Gut microbiota significantly impacts normal and physiological gut development and helps gut mucosa maturation and differentiation and its immune system. It restricts the growth of the pathogenic and the potential pathogenic microbes, competes with them, and inhibits their ability to invade and implement the ecosystem. Some microbiota strains can secrete bacteriocins antimicrobial substances to inhibit other bacterial proliferation.

Other microbiota strains can ferment and digest nondigestible carbohydrates, fibers, and endogenous intestinal mucus, producing gases and short-chain fatty acids (SCFAs) such as acetate (the most abundant), propionate, and butyrate. These SCFAs can modulate the various activities in the gastrointestinal tract, including cell proliferation and differentiation, water and electrolytes absorption, hormonal secretion, and immune system activation[8,9]. SCFAs can serve as a food substrate for colonocytes (butyrate) and regulate leukocyte function and immune system activation by producing different eicosanoids, cytokines (IL-2, IL-6, IL-10, and TNF-α), and chemokines production with inducing balance among pro-inflammatory and anti-inflammatory mechanisms. SCFAs may also affect leucocyte chemotaxis, affecting their ability to migrate to the focus of infection or inflammation to destroy the target microbes[10].

Lack of SCFA is one of the causes of leaky gut and local gut inflammation that enhance microbial invasion. Butyrate can also induce colon cancer cells apoptosis and activate intestinal gluconeogenesis to enhance energy balance. It is crucial for glucose homeostasis by regulating hepatic gluconeogenesis and stimulating satiety signaling. The metabolic effects of SCFAs are not limited to the intestine but have extra-intestinal effects. Acetate SCFAs play a crucial role in regulating cholesterol metabolism and lipogenesis[11]. Microbiota also has an essential metabolic function in the biosynthesis of vitamins (vitamin K, biotin, folic acid, vitamin B12, and pantothenic acid) and amino acids from urea or ammonia. It also plays a role in xenobiotics and drug metabolism[12].

Gut microbiota can affect the host's energy balance through different mechanisms. It extracts energy from nondigestible dietary components and impacts gut transit, energy intake, and energy expenditure [13]. It also can modify the available pool of bile acids, affecting their composition and abundance. Gut microbiota-derived enzymes can metabolize the bile acids produced by the liver, a critically crucial process to maintain a healthy gut microbiota, enhance lipid and carbohydrate metabolism, increase insulin sensitivity, and enhance innate immunity[14]. The gut microbiota connects with the brain through several various mechanisms. These mechanisms include neurotransmitters production or modulation of their catabolism, vagus nerve signaling, and the hypothalamus-pituitary axis activation [15]. Gut microbiota produces hundreds of neurochemical substances used by the brain to regulate its basic physiological processes and mental functions such as learning, memory, and mood[16].

FACTORS AFFECTING THE CHILDREN'S GUT MICROBIOTA

The type and the quantities of the gut microbiota show wide individual variability. Many host and bacterial-related factors affect bacterial colonization in the different parts of the human gut. The host factors include the host's age, genetic pool, general health, dietary factors, using medication, pH, peristalsis, and the transit time of the part of the intestine, mucus secretions containing immunoglobulin, and the tissue oxidation-reduction potentials. The microbial factors include nutrient availability, bacterial cooperation or antagonism, and bacterial adhesion[17,18]. Each part of the gut has its microbiota due to its specific characteristics. Table 1 shows the microbiota in the different parts of the gut.

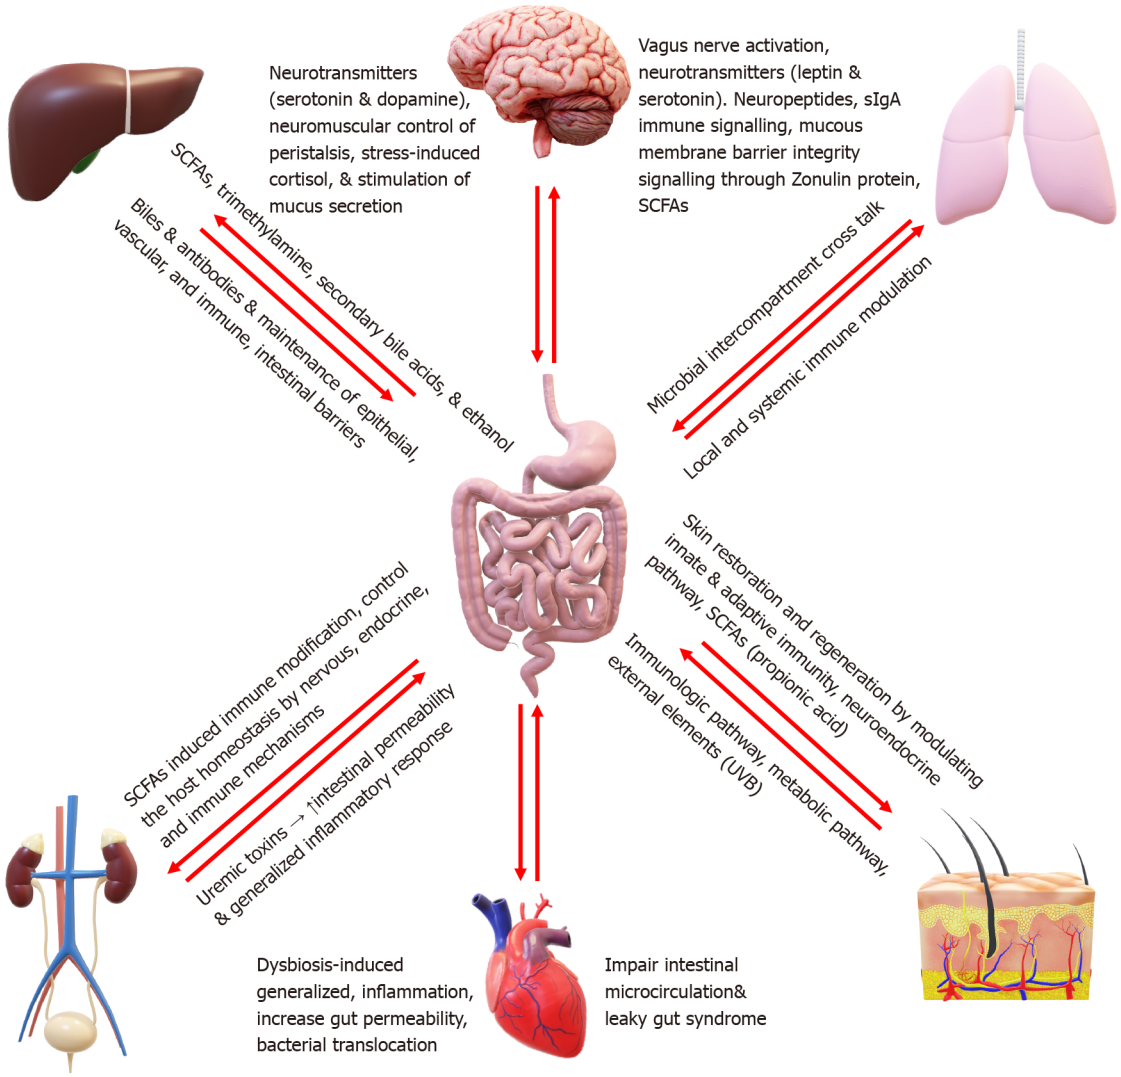
The ability of the host genetics pool to modify the gut microbiome structure is still controversial. There is a strong association between the Lactase gene and the relative abundance of *Bifidobacterium*. However, this association could be related to lactose consumption[19]. The vitamin D receptor gene is associated with some variation in gut microbiota[20]. Other studies proved the association of some host genetic variations with the abundance of certain microbiota species. However, the origin of association is still uncertain[21]. The host diet is crucial in developing gut microbiota as carbohydrate fermentation is one of its core functions. The microbiota of the small intestine adapts quickly to varying nutrient availability in the lumen and can rapidly metabolize the simple carbohydrates. On the other hand, the colon microbiota can degrade complex carbohydrates. A high-fat diet stimulates the proliferation of *Clostridium* and suppresses the proliferation of *Bifidobacterium* and *Bacteroides*[22]. Dietary modification produces rapid alteration of the colonic microbiota within two days and long-term changes[23].

The type of delivery can early-life microbiome. However, this effect may differ upon intrapartum antibiotic exposure. The gut microbiota of vaginally delivered infants shows enrichment of *Bifidobacterium spp.* and reduction of *Enterococcus* and *Klebsiella spp.* Over the first year of life, the gut microbiota in infants born with caesarean section appears less stable with a predominance of pathogenic bacteria such as *Klebsiella* and *Enterococcus* and delayed acquisition of the beneficial *Bifidobacterium*[24]. Breast or

Table 1 The microbiota in the different parts of the gut

Site	pH	Predominant microbiota	Bacterial load (CFU/gram content)	Other factors
Mouth	6.5-7	Bacteria (esp *Fusobacterium nucleatum)*, fungi, viruses and protozoa	700 species	Ideal warm environment
Stomach	Strong acidic	*Lactobacilli, streptococci, Lactobacillus, Peptostreptococcus, Helicobacter pylori*, and yeasts	Low (10^2)	Gastric acidity, Acid suppressive therapy, *H. pylori* colonization, the reflux of bile, mucus thickness and gastric peristalsis
Duodenum	4-5	*Lactobacilli* and *Streptococci*	More than (10^2-10^4)	Age, diet, antibiotic, and proton pump inhibitor use
Jejunum-ileum	6-7.4	*Firmicutes* and *Proteobacteria*	More than duodenum (10^6-10^8)	Nutrient reach environment faster transit time, bile acids, and antimicrobial peptide exposure
Colon	Left colon 6.1-7.5; Cecum 5.7; Rectum 6.7	*Bacteriodetes* (especially the genera *Bacteroides* and *Prevotella*) and *Firmicutes* (especially members of the genus *Clostridium*). Methanogenic archaea and fungi; Cecum: Aerobic bacteria; Rectum: *Bacteroides* and *Prevotella*.	10^{10}-10^{12}	High diversity and density, no digestive secretions, nutrient-poor environment, & slow transit time (30 h)

H. pylori: *Helicobacter pylori*.



bottle feeding also significantly impacts the gut microbiota. Exclusively breastfed infants have lower microbial diversity with a predominance of infant-type *Bifidobacteria* than formula-fed babies whose gut microbiota is more diverse and like older children. The predominance of infant-type *Bifidobacteria* significantly impacts the immune system's maturation and development, which may help decrease the incidence of childhood infections[25].

The gut microbiota develops throughout human life in predictable patterns, with fast change from the neonatal pattern to the age of three, reaching the adult pattern. Then the microbiota goes into a stable phase until middle age, and then it goes into accelerated changes in late adulthood. These changes could be related to aging itself, underlying diseases, and the use of medications. At the same time, changes in the microbiota pattern can predict decreased longevity[26]. The use of the proton pump inhibitors is associated with decreased bacterial richness and predominance of an unhealthy gut microbiome which predisposes to *Clostridium difficile* enteric infections[27]. Antibiotics negatively impact the gut microbiota by reducing the species diversity, altering the metabolic activity, and favoring the predominance of antibiotic-resistant microbial strains, which sequentially can cause antibiotic-associated diarrhea and recurrent *Clostridium difficile* infections[28].

Microbial cooperation is a characteristic feature of microbial communities. An example of bacterial cooperation appears clearly in *Bacteroidales*, the predominant Gram-negative bacteria in the human gut. *Bacteroides ovatus* and *Bacteroides vulgatus* showed a mutual relation where *Bacteroides ovatus* can digest the dietary complex polysaccharide inulin producing energy and food source for other *Bacteroides*, including *Bacteroides vulgatus*. In return, *Bacteroides vulgatus* benefits *Bacteroides ovatus* by detoxifying inhibitory substances and the secretion of a depleted or growth-promoting factor. This bacterial cooperation is vital to stabilize the gut ecosystem[29]. Bacterial antagonism is common in microbial communities and contributes to specific bacterial strains' different compositions and relative abundance. It also helps for the long-term stability of the microbial community. This antagonism can occur by interference competition with the secretion of specific molecules such as antibacterial peptides and proteins that inhibit other strains. These antimicrobial toxins perform a significant role in microbiota-mediated colonization resistance by inhibiting the invasive pathogens[30]. Bacterial adhesion to gut epithelial surfaces affects their retention time and, therefore, considerably impacts interactions between the microbiota and their hosts. This adhesion ability of some bacteria could help their transient colonization in the gut and help to boost their immunomodulatory effects and enhance the gut barrier and metabolic functions[31].

GUT-MICROBIOTA AXES

The intestinal microbiota is considered an organ of the human body, with its features making it crucial in various body functioning. There is a mutual bidirectional relation of the gut, microbiota, and the other body systems, forming different systemic axes, *e.g.*, Brain-gut-microbiota axis, liver- gut-microbiota axis, skin- gut-microbiota axis, kidney- gut-microbiota axis, lung- gut-microbiota axis (Figure 1).

DOI: 10.3748/wjg.v28.i18.1875 **Copyright** ©The Author(s) 2022.

Figure 1 The different gut-microbiota-axes (brain-gut-microbiota axis, liver- gut-microbiota axis, skin- gut-microbiota axis, kidney- gut-microbiota axis, lung- gut-microbiota axis).

BRAIN-GUT-MICROBIOTA AXIS

The brain and the gut interact together through the central and the enteric nervous system. The brain interacts with the gut through several mechanisms, including neurocrine and endocrine pathways, which may be involved in gut microbiota-to-brain signaling, and the brain can, in turn, alter gut microbiota composition. The brain controls the gut and gut microbiota through neurotransmitters such as serotonin and dopamine, neuromuscular control of peristalsis, stress-induced cortisol, and stimulation of mucus secretion[32]. On the other hand, the gut affects the brain through vagus nerve activation, neuropeptides, and neurotransmitters such as leptin and serotonin, immune signaling through secretory IgA, mucous membrane barrier integrity signaling through Zonulin protein, and SCFAs such as butyrate[15,33]. Alternatively, the microbiota affects the brain through different mechanisms. Some strains of Lactobacillus and Bifidobacterium can produce gamma-aminobutyric acid (GABA), which is the dominant brain inhibitory neurotransmitter. Other bacterial species such as *Enterococcus* and *Escherichia* and some candida strains can produce serotonin. Some bacillus species can produce dopamine neurotransmitters. Bacteria can also affect the brain by making SCFAs (such as butyric acid, propionic acid, and acetic acid), stimulating the sympathetic nervous system, and inducing mucosal serotonin release sequentially, impacting the memory and learning process in the brain[34].

LIVER-GUT-MICROBIOTA AXIS

The liver-gut-microbiota axis is a bidirectional relationship between the liver and the gut and its

microbiota on the other side. The gut-derived products are transported directly to the liver through the portal veins, and the liver manufactures the bile and antibodies to be transported back to the intestine. The gut microbiota is essential for preserving the immune homeostasis of the liver-gut-microbiota axis. Microbe-derived metabolites, such as SCFAs, trimethylamine, secondary bile acids, and ethanol, may play a role in non-alcoholic fatty liver disease pathogenesis. On the other hand, liver cirrhosis induces intense changes in gut microbiota and impairment of the intestinal epithelial, vascular, and immune barriers[35]. A change in gut microbiota structure can activate the mucosal immune response triggering homeostasis imbalance. This imbalance results in bacterial transport and immune cells migrating to the liver, inducing inflammation-mediated liver injury and tumor progression[36,37].

HEART-GUT-MICROBIOTA AXIS

The heart-gut axis is relatively newly described based on intestinal microbiota's ability to affect the cardiovascular status and vice versa. Gut dysbiosis is linked to the state of generalized inflammation associated with increased risk of obesity and type II diabetes mellitus, which are important cardiovascular risk factors, especially for atherosclerosis and heart failure. At the same time, the diet that can cause dysbiosis, *e.g.*, a high fatty diet, can also cause metabolic syndrome. On the other side, Most cardiovascular disease (CVD) risk factors, such as aging, dietary patterns, obesity, and a sedentary lifestyle, can induce gut dysbiosis. Dysbiosis can also increase gut permeability, leaky gut syndrome, and bacterial translocation and are considered risk factors for CVD. Meanwhile, congestive heart failure will impair intestinal microcirculation aggravating the leaky gut syndrome and causing more bacterial translocation worsening the heart failure with a vicious cycle[38-40].

KIDNEY-GUT-MICROBIOTA AXIS

The gut microbiota has critical roles in various diseases involving hypertension and chronic kidney disease. The gut microbiota connects with the nervous, endocrine, and immune systems to control the host homeostasis, involving blood pressure and renal functions. The gut–kidney axis is conducted through metabolism-dependent mechanisms and immune pathways[41]. SCFAs produced by commensal gut microbiota can affect the kidneys through a wide range of mechanisms, including immune system modification and interactions with the renal cognate receptors and transporters[42]. On the other side, kidney injury causes uremic toxins accumulation in the intestine with increased intestinal permeability and generalized inflammatory response[43]. Uraemia increases bacterial translocation and impairs immunity by decreasing T and B cell responses from vaccination and decreasing the memory of T and B cells. Increased nitrogen waste products in uremia promote the overgrowth of proteolytic bacteria[44].

LUNG-GUT-MICROBIOTA AXIS

Despite the clear anatomical distinction between the gut and the lung, recent evidence showed that the gut and lung microbiota affect each other, significantly impacting respiratory diseases[45]. The lung microbiome is much lower than the gut microbiota. Its composition depends on the oropharynx and upper respiratory tract microbial colonization through salivary micro-inhalations, the host abilities for microbial elimination, primarily through cough and mucociliary clearance, the interactions with the host immune system, and on local conditions that control the microbial proliferation, such as oxygen concentration and local pH[46]. The lung microbiota composition is also strongly correlated with the gut microbiota composition. The gut microbiota enriches the lung bacteria, impacting the gut microbiota composition. For example, inhalation of gastroesophageal content (through gastroesophageal reflux) and sputum swallowing may explain this inter-organ connection. The lung-gut-microbiota axis may also involve indirect communications through the host immune modulation either by gut microbiota's local or systemic immune impact, especially on the pulmonary immune system[47].

SKIN-GUT-MICROBIOTA AXIS

Skin and gut play crucial immune and neuro-endocrine roles and are distinctively related in function. The gut microbiota affects the skin microbiome through the skin-gut-microbiota axis. SCFAs produced from fiber fermentation by gut microbiota have a significant role in skin microbiota composition and immune defense mechanisms[44]. Propionic acid has a powerful antimicrobial effect against the community-acquired methicillin-resistant Staphylococcus aureus[49]. Gut microbiota also helps skin

restoration and regeneration by modulating innate and adaptive immunity. It enhances the skin barrier through modulation of T cell differentiation in response to different immune stimuli[50]. Several environmental factors, *e.g.*, diet and psychological stress, can impact the gut microbiome, directly or indirectly influencing skin health.

GUT MICROBIOTA IN COMMON PEDIATRIC DISORDERS

Table 2 summarizes the disease-associated dysbiosis and the proposed probiotics.

GUT MICROBIOTA AND CHILD NEURODEVELOPMENT

Gut microbiota exerts a considerable effect on the child's physical and mental development. The human brain has a rapid growth rate throughout the perinatal period, matching the remarkable maternal and infant microbiota changes[51]. The microbiota plays an essential role during brain development through its effects on gamma-aminobutyric acid and serotonin synthesis from tryptophan and altered neurotransmitters such as noradrenaline and dopamine. Serotonin is crucial to brain development. Decreased brain serotonin impair synaptogenesis and the brain wiring, causing long-term neurodevelopmental impairment[52]. About 95% of the body's serotonin is formed by the gut microbiota, affecting mood and gastrointestinal activity. However, scientists found that serotonin cannot cross the blood-brain barrier. So, it works mainly on the peripheral enteric nervous system and works as a hormone affecting different tissues, including those regulating metabolic homeostasis[53]. However, the beneficial role of probiotics in alleviating the manifestation of many psychiatric disorders such as depression and anxiety could be related to their ability to secrete serotonin, a significant player in many psychiatric disorders[54]. Meanwhile, animal studies showed that probiotic use might cause rising plasma tryptophan levels, decreased serotonin concentrations in the frontal cortex, and decreased cortical dopamine metabolites, thus improving depressive symptoms[55].

SCFAs, a product from the fermenting effects of the colonic bacteria, regulate microglial homeostasis. The effects of SCFAs are markedly observed during the early phases of brain development during the early postnatal stage, while brain plasticity is still preserved[56]. Two interesting studies showed that gut microbiota is crucial to maintain healthy microglia functions, vital to preventing neurodevelopmental and neurodegenerative disorders[57,58]. Tamana *et al*[59] showed that boys who have a higher *Bacteroidetes* ratio in the gut microbiota at one year have higher cognitive functions and advanced linguistic skills after one year of follow-up. They also observed that girls have cognitive and linguistic scores than boys at the same age. They also noted a higher *Bacteroidetes* ratio in girls than boys. They related this increase in cognitive function due to the sphingolipid production by *Bacteroidetes*, which is an essential substrate for brain structures and functions. Factors that deplete *Bacteroidetes*, *e.g.*, caesarean section or flourish *Bacteroidetes* such as normal vaginal delivery, breastfeeding, high-fiber diet, exposure to pets, and outdoor nature with green spaces can negatively or positively impact child cognitive functions[60].

Investigating the underlying mechanisms of neural development and neuropsychiatric disorders proved that the intestinal microbiota could affect brain physiology and behavior through the humoral and neural pathways of gut-brain communication, suggesting that the gut microbiota has a vital role in many neuropsychiatric disorders[61]. Autism is a multifactorial disease in which the gut microbiota plays an important role. The gut microbiota in children with autism showed plenty of *Bacteroidetes* and a lesser amount of *Firmicutes* than controls with characteristic mucosal microbiota signatures. This dysbiosis observed in children with autism correlates with cytokine quantities and tryptophan homeostasis. However, we do not know whether the observed dysbiosis is a cause or a result of the associated behavior problem observed in children with autism[62,63]. The effect of the gut microbiota is not limited to the child's gut but is also related to the maternal gut microbiota. A study by Li *et al*[64] found significant differences in the gut microbiota composition between the mothers and children with autism spectrum disorder (ASD) compared to healthy children and their mothers. They found that mothers of children with ASD had more *Alphaproteobacteria, Proteobacteria, Acinetobacter, and Moraxellaceae* than mothers of healthy children. Children with late-onset (regressive) autism have more colony numbers of fecal clostridial species and non-spore-forming anaerobes and microaerophilic bacteria, which are absent in the typically developed children, which could be related to the frequent use of antibiotics, disrupting the microbiota with more colonization by these types of autism-promoting microbiota species[65]. According to this hypothesis, the use of minimally absorbed oral vancomycin can induce temporary improvement in autistic symptoms[66]. However, a metanalysis that included 28 studies done on children with autism by Bezawada *et al*[67] showed the inconsistency of the data due to heterogeneity of the included populations and the used methods. They suggested that despite several reasons to consider the role of gut microbiota and their product in the pathogenesis of autism, we need more studies to understand better and confirm their effects. The developing hypothesis of a microbiota-gut-brain axis proposes that gut microbiota modulation may be an amenable strategy to developing a

Table 2 The diseases-associated dysbiosis and the proposed probiotics

The disease	Encountered dysbiosis	The proposed probiotics
Autism[57,58]	Mother have abundance of *Alphaproteobacteria, Proteobacteria, Acinetobacter,* & *Moraxellaceae*. Children have more clostridial species, non-spore-forming anaerobes, and microaerophilic bacteria	No suggested type yet
Malnutrition[60]	Less Bifidobacteria. More pathogenic microbes (Escherichia coli, Fusobacterium mortiferum, & Streptococcus spp.)	The lack of strong evidence for specific types of probiotics
Obesity[75-78]	Less *bifidobacteria*. More *Bacteroides* & Staphylococcus spp.	Bifidobacterium lactis and Lactobacillus GG
Infant colic[85-87]	More abundance of *Proteobacteria*. Less abundance of the genera *Lactobacillus* & *Bifidobacterium*. Reduced gut bacterial diversity	Lactobacillus reuteri DSM17938 in breastfeeding infants
Functional abdominal pain[90,91]	More *Prevotella*, *Lactobacillus*, *Veillonella*, & *Parasporo* bacterium. Less *Verrucomicrobium* & *Bifidobacterium*	Sporobacter & Subdoligranulum
Functional constipation[94,95]	More Prevotella. More butyrate-producing bacteria as Roseburia, Coprococcus, & Faecalibacterium	Still investigational
Necrotizing entero-colitis[98,99]	More Citrobacter koseri and/or Klebsiella pneumoniae. Reduced diversity. Less Lactobacillus abundance	*Bifidobacteria* and *Lactobacillus*
Helicobacter pylori infection[102,106,107]	Prevotella, Clostridium, Proteobacteria, and Firmicutes. Less Bacteroides	Saccharomyces boulardii, L. acidophilus, L. casei DN-114001, L. gasseri, and Bifidobacterium infantis 2036 and Lactobacillus reuteri Gastrus
Coeliac disease[109, 114-116]	Reduced Gram-positive/Gram-negative bacteria ratio. Less *Bifidobacterium, Clostridium histolyticum, Clostridium. lituseburense* and *Faecalibacterium prausnitzii*. More *Bacteroides-Prevotella* group. Less IgA coating the *Bacteroides-Prevotella* group	*Lactobacillus rhamnosus, Bifidobactera breve* & *Longum,* and *Lactobacilli* strains (*L. ruminis, L. Johndoni, L. amylovorus, L. salivaris*)
Inflammatory bowel diseases[122,126-128]	Less abundance of the healthy commensal (such as Clostridium IXa and IV groups, Bacteroides, Bifidobacteria). More abundance of the pathogenic bacteria as sulphate-reducing Escherichia coli	Still controversial. Saccharomyces boulardi. Escherichia coli Nissle1917, Bifidobacterium breve, Bifidobacterium bifidum, Lactobacillus acidophilus
Cystic fibrosis[135-137]	Aberrant colonization of gut and respiratory microbiota due to altered intestinal & airway microenvironment	*Lactobacillus rhamnosus GG* & *Lactobacillus reuteri*
Allergic rhinitis[140, 142-144]	Decrease gut bacterial diversity	*Lactobacillus paracasei*. *Bifidobacteria* mixture
Bronchial asthma[147]	Relative abundance of the bacterial genera *Rothia*, *Veillonella*, *Lachnospira*, & *Faecalibacterium*. Low total & gut microbial diversity	Still controversial
Atopic dermatitis[154-157]	Reduced microbial diversity. More abundance of pathogenic Staphylococcus aureus and Malassezia. Presence of Clostridioides difficile. More Bifidobacteria abundance. Lower lactobacilli abundance	Topical Roseomonas mucosa
Psoriasis[160,161,163, 164]	More bacterial diversity & heterogeneity. More *Staphylococcus aureus*. Less Staphylococcus epidermidis & Propionibacterium acnes. Reduced microbiota stability. Variable topographic dysbiosis	Sill controversial. Oral Lactobacillus, one sachet thrice daily with biotin
Systemic lupus erythematosus[166, 168]	Less microbiota abundance and diversity	Animal studies showed *Lactobacillus fermentum* CECT5716 (LC40)
Juvenile idiopathic arthritis[172,174]	Less Faecalibacterium Prausnitzii abundance. More Bifidobacterium abundance, mostly B. adolescentis	Not conclusive. Trial with Lactobacillus acidophilus, Lactobacillus casei, Lactobacillus bulgaricus, Lactobacillus rhamnosus, Bifidobacterium breve, Streptococcus thermophile & Bifidobacterium longum
Dental caries[176,178, 179]	More abundance of Prevotella melaninogenica, Leptotrichia shahii, Leptotrichia HOT 498, Veillonella dispar, and Streptococcus mutans	Insufficient evidence. Lactobacillus rhamnosus may help
Chronic congestive heart failure[180,184, 187,189]	Decreased gut microbiota diversity. More pathogenic Microbes as *Campylobacter, Yersinia enterocolitica, Salmonella, Shigella* & *candida*. Low *Coriobacteriaceae*, *Erysipelotrichaceae* and *Ruminococcaceae*	*Bifidobacteria,* yeasts, and lactic acid-producing bacteria such as *Lactobacillus rhamnosus* GR-1. *Saccharomyces boulardii*

new therapeutic approach for complex central nervous system disorders[68].

Epilepsy is a common childhood disorder. There is a close relation between epilepsy and autoimmune diseases and between gut microbiota and autoimmune disease; a suggested association arises between epilepsy and gut microbiota. An exciting study by Huang *et al*[69] presented forty children who developed benign infantile convulsions after mild gastroenteritis, linking changing the gut microbiota and the epileptogenesis. Şafak *et al*[70] tried to elaborate on the relationship between gut microbiota and epileptogenesis. They studied the intestinal microbiota composition in patients with idiopathic focal epilepsy and compared them to a healthy volunteer group. They found an increased prevalence of *Fusobacteria species* in patients with epilepsy (10.6%) but not in the healthy volunteer

group. This significant taxonomic drift and variations in the intestinal microbiota and the resulting gut dysbiosis may be associated with certain forms of epilepsy.

Meanwhile, some anticonvulsants can be metabolized by the gut microbiota, affecting their efficacy. For example, the intestinal microbiota can metabolize Zonisamide to 2-sulfamoyl-acetyl-phenol, which is pharmacologically not active[71]. In addition, the anti-epileptic effects of the ketogenic diet used in drug-resistance epilepsy (although its exact mechanism of action is unclear) could be related to the ketogenic diet-induced changes in the gut microbiome composition and function of patients with epilepsy. The gut microbes modify the seizure vulnerability through mechanisms different from just alterations of beta-hydroxybutyrate levels (a measure of ketosis). The anti-seizure protective effects of diet and microbiota are associated with elevating hippocampal GABA relative to glutamate content[72]. The probiotics supplement could provide additional benefits to the anti-epileptics, especially in drug-resistant epilepsy. Gómez-Eguílaz *et al*[73] supplied patients with drug-resistant epilepsy with a probiotic mixture for four months. The patients showed a significant reduction in seizures frequency and improved quality of their life. Consequently, reformation of the gut microbiota through fecal microbiota transplantation, probiotic supplement, and the ketogenic diet has potential favorable impacts on drug-resistant epilepsy[74].

GUT MICROBIOTA AND CHILD PHYSICAL DEVELOPMENT AND NUTRITION

The gut microbiota typically develops hand in hand with the child's growth. The prenatal microbial communities affect fetal and postnatal development. Maternal microbiota is a crucial element for intrauterine growth. An exciting study by Sato *et al*[75] showed that the maternal gut microbiota correlates with the neonatal anthropometrics measures. In male neonates, the head circumference and weight are negatively correlated with genus *Eggerthella* and *Parabacteroides*. In female neonates, a high ratio of *Streptococcus* correlates with low anthropometric measures. Neonates with very low birth weight and restricted extrauterine growth had a predominance of *Proteobacteria* of their intestinal microbiota [76]. The gut microbiota affects growth by affecting growth hormone and insulin-like growth factor 1 production and regulation through its effects on the hypothalamic-pituitary–somatotropic axis. Delayed maturation and colonization of the gut microbiota may result from underlying food insecurity, malnutrition, and infections and could negatively impact the child's nutritional status[77]. The malnutrition-associated dysbiosis of the gut microbiota starts with depletion of the *Bifidobacteria* followed by the establishment of potentially pathogenic microbes (*Escherichia coli, Fusobacterium mortiferum*, and *Streptococcus spp*.), causing diarrhea and essential nutrients malabsorption[78]. Dysbiosis may result in a generalized inflammatory state and enteropathy that may precipitate growth faltering. The effects of these microbiota changes are significant in the first 1000 d. It provides a window of opportunity for modifying the gut microbiota through different interventions such as diet, antibiotic use, supplementary probiotics, prebiotics, symbiotics, postbiotics, or fecal microbiota transplantation to restore the proper growth and development[79].

Dysbiosis may explain why malnourished children may miss up the desired weight compared to their well-fed counterparts, despite gaining some weight and growing better with nutrient-rich supplements. Subramanian *et al*[80] showed significant differences in the proportions and species of gut microbiota in children up to two years of age with and without malnutrition. Children with malnutrition showed the immaturity of their gut microbiota, resembling their healthy counterparts but at a younger age. This malnutrition-induced microbiota imbalance fails to recover even after correcting the malnutrition. Oral probiotic supplements with beneficial gut bacteria and fecal transplantation from healthy children can restore the malnutrition-induced dysbiosis, and the malnourished children thrive. Probiotic supplements can improve a child's growth by preventing infections and micronutrient deficiency. They have been shown to improve the absorption of specific nutrients (vitamin B12, calcium, and zinc) and decrease the possibility of anemia[81]. However, there is no clear evidence to use them in the treatment of malnutrition. This lack of evidence is also augmented by the difficulty of modifying the gut microbiota. It resists long-term change and is affected by other factors such as diet and sleep pattern [82].

The cause of malnutrition also impacts the composition of gut microbiota. For example, moderate-to-severe diarrhea in children reduces bacterial diversity and changes gut microbiota composition[83]. Diarrhea can also affect weight, height, and the child's mental development, especially for diarrhea occurring below the age of 2 years[84]. The diarrhea-induced changes in gut microbiota increase the risk of persistent diarrhea, which causes stunted growth and decreases the affected children's mental abilities. Interventions to restore the gut microbiota as prebiotic and probiotic supplementation could help to combat the risk of diarrhea and the resulting malnutrition[85].

Meanwhile, subclinical changes in the gut microbiota may result in stunting even in the absence of clinically evident infections such as diarrhea. For example, poor hygiene may cause persistent exposure to environmental pathogens inducing subclinical alteration in the gut microbiota structure and function and consequently cause stunting[86]. For instance, poor sanitary conditions with chronic exposure to environmental pathogens resulting in subclinical alteration in the gut microbiota structure and function

initiate a condition known as environmental enteric dysfunction. This environmental enteric dysfunction induces a cell-mediated inflammation that ends in stunting[87].

CHILDHOOD OBESITY

The link between gut microbiota and obesity was evident in the adult population but not yet well documented in childhood. Obesity correlates with altered gut microbiota distinguished by raised *Firmicutes* and reduced *Bacteroidetes* abundance. This correlation is believed to be through the powerful effects of the gut microbiota on the human metabolic and immune status. Higher levels of SCFAs, a fermentation product by the gut microbiota, were found in children with obesity which tightened the relationship between the gut microbiota and the development of obesity[88]. The maturation patterns of gut microbiota in infancy can impact the relative chance of developing overweight and obesity in later childhood. Pregnant women with a high body mass index (BMI) have a higher load of *Bacteroides* than those with normal BMI[89].

Consequently, the maternal microbiota during pregnancy and breastfeeding significantly affects the newborn microbiota. The presence of *Bacteroides spp.* or their relatives and the relative lower abundances of *Bifidobacteria* in early infancy are related to developing childhood overweight and obesity. *Staphylococcus* spices may also serve as a predictive but inconsistent tool for childhood BMI[90]. Children with an average BMI at seven years have more *Bifidobacterium spp.* in their gut during their first year of life than children with high BMI[91]. Gut microbiota could modify obesity through its role in metabolic regulation, food availability, and digestion. Gut microbiota has extra-intestinal effects involving the brain, liver, and adipose tissue, possibly linked to obesity, insulin resistance, diabetes mellitus type-II, and related cardiovascular disorders. Gut microbiota might also impact food intake and satiation through gut peptide signaling[92].

Consequently, gut microbiota can modify energy regulation and systemic inflammation, two crucial pillars for obesity development. Early modification and restoration of gut microbiota may be an encouraging tool to counteract the increasing childhood metabolic disorders, including overweight and obesity, providing the specific anti-obesity microbiota[93]. Despite the evidence of the beneficial effects of probiotics on glucose tolerance, insulin sensitivity, and inflammatory markers, there is no substantial evidence to recommend the use of probiotics in obesity[94]. Antenatal supplement with *Bifidobacterium lactis and Lactobacillus GG* decreases the risk of gestational diabetes mellitus and consequently reduces the risk of macrosomia and large baby size at birth, an effect that could last up to six months after birth [95,96].

GUT MICROBIOTA AND FUNCTIONAL GASTROINTESTINAL DISORDERS IN INFANCY AND CHILDHOOD

Gut microbiota can modulate various types of chronic pain through direct modulation of neuronal excitability dorsal root ganglia and neuroinflammation regulation in the central and peripheral nervous systems[97]. Numerous studies reported a strong association between the human gut microbiota and the development of functional gastrointestinal disorders, especially for infant colic, functional constipation, and irritable bowel disease. Randomized controlled trials showed that probiotics could be helpful in a variety of functional gastrointestinal disorders, including infant colic and irritable bowel syndrome. Probiotics may induce gut microbiota diversity with strain-specific effects on colonization resistance, the integrity of the epithelial barrier, signal transduction modulation, with a significant impact on both innate and adaptive immune responses, and notable effects on visceral hyperalgesia[98,99].

Infant colic

About 20% of infants developed infant colic, with prolonged crying without apparent cause. The exact etiology of infant colic is unknown, but many factors are proposed to have a role, such as gastrointestinal, psychosocial, and neurodevelopmental factors[100]. Several studies addressed the role of the gut microbiota in developing infant colic. Gut dysbiosis was described in infant colic in the form of more abundance of *Proteobacteria* and less abundance of the genera *Lactobacillus* and *Bifidobacterium* with reduced gut bacterial diversity[101]. A metanalysis done by Sung *et al*[102] showed that *Lactobacillus reuteri* DSM17938 was an effective treatment for infant colic in breastfed infants. Still, they cannot generalize this recommendation to formula-fed infants with colic, which needs further research. The unique effect of *Lactobacillus reuteri* DSM17938 in the breastfed infant may be related to the distinctive structure of breast milk or probably the direct effects of *Lactobacillus reuteri* or human milk oligosaccharides in breast milk[103]. How probiotics improve infant colic is not yet determined but may be mediated *via* modifying the activity of the colonic intrinsic sensory neurons with improving the gut motility. In addition, they have positive impacts on function and visceral pain[104].

Functional abdominal pain

About one-third of the school-aged children suffer from abdominal pain weekly, which causes school absenteeism and limitation of their social activities in about 20% of them. In children, functional abdominal pain is defined as when it persists for two or more months without an evident organic cause [105]. Function abdominal pain is further subclassified into four conditions: irritable bowel syndrome (IBS), functional dyspepsia, abdominal migraine, and functional abdominal pain not otherwise specified [106]. Despite the high prevalence of dysfunctional abdominal pain, the exact pathogenesis is not well-defined. However, many risk factors increase the rate of dysfunctional abdominal pain, including the winter season, sleep, school stress, and diet. Many studies relate dysbiosis of the gut microbiota to dysfunctional abdominal pain such as irritable bowel syndrome. Rigsbee *et al*[107] showed that children with irritable bowel syndrome had more abundance of *Prevotella*, *Lactobacillus*, *Veillonella*, and *Parasporo* bacterium and less quantity of *Verrucomicrobium* and *Bifidobacterium*.

On the other hand, a low fermentable substrate diet decreased the abdominal pain frequency in children with irritable bowel syndrome by increasing the abundance of bacterial taxa belonging to the genera *Sporobacter* and *Subdoligranulum* and reduced the abundance of taxa belonging to *Bacteroides* [108]. Probiotic use might change the gut microbiota composition and decrease inflammation. It could also promote the physiology of the gut and improve functional symptoms. Some probiotics may impact colonic motility by increasing stool fluidity through modifying water and electrolytes secretion and absorption, smooth muscle cell contractions modification, increasing the production of lactate and SCFAs, and reducing intraluminal pH[109].

Functional constipation

Functional constipation is a common childhood disorder characterized by reduced gut movements and/or hard stools without organic causes. Functional constipation affects about 18% of infants and 3% of children and adolescents worldwide, with considerable influence on the child's and family's quality of life[110]. The pathophysiology of functional constipation is multifactorial, with a complex interaction between gastrointestinal dysmotility, psychological factors, and gut microbiota. Disturbances in gut microbiota may promote development and affect the outcome of functional constipation in children [111]. Zhu *et al*[112] showed that obese children suffering from constipation had a low-fiber diet and lower prevalence of gut *Prevotella* with an increased ratio of butyrate-producing bacteria such as *Roseburia*, *Coprococcus,* and *Faecalibacterium* than the control, which could be related to the low fiber intake. Probiotics can enhance intestinal transit time, stool frequency, and consistency[113]. Data about the efficacy of probiotic use to treat functional constipation are conflicting. A metanalysis by Gomes *et al* [114] showed that "despite the probiotics' positive effects on certain characteristics of the intestinal habitat, there is still no evidence to recommend it in the treatment of constipation in pediatrics". So, the use of probiotics to treat functional constipation is still investigational.

GUT MICROBIOTA AND GASTROINTESTINAL DISEASES IN INFANCY AND CHILDHOOD

Necrotizing enterocolitis

Necrotizing enterocolitis (NEC) is a significant danger to neonatal life, especially preterm neonates. Prematurity is associated with many risk factors that alter the infant microbiome. These factors include mode of delivery, maternal microbiome diversity, feeding pattern, antibiotic use, environmental exposure to pathogenic and commensal bacteria in the neonatal intensive care unit[115]. Dysbiosis, alterations in the gut microbiome, and low microbial diversity of the preterm neonate significantly correlate with a higher risk and raised rate of complication of necrotizing enterocolitis and, consequently, the development of late-onset sepsis. Low microbiota diversity may provoke pathogenic bacteria overgrowth, a significant risk factor that promotes NEC development[116]. Dobbler *et al*[117] found powerful domination of *Citrobacter koseri* and/or *Klebsiella pneumoniae*, reduced diversity, less *Lactobacillus* abundance, and an altered microbial-network structure during the first days of life, correlate with NEC risk in preterm infants.

Oral administration of probiotics shows a significant reduction of NEC incidence. However, their safety still needs to be proven as preterm babies have immature immune systems with possible vulnerability even to the commensal bacteria[115]. Probiotic supplementation allows restoration of the normal commensal bacteria with the transition to the beneficial bacteria through enhancement of mucosal barrier function competitive inhibition of the pathogenic bacteria. It induces an anti-inflammatory effect on mucosal signaling[118]. Probiotics upregulate the cytoprotective genes of the gut and down-regulate the pro-inflammatory gene expression. They also enhance butyrate and other SCFAs productions to nourish colonocytes. Some probiotics decrease the pH and lower the oxygen tension in the intestinal lumen, thus inhibiting the growth of pathogenic bacteria, especially *Enterobacteriaceae*. Other probiotics can support the maturation intestinal barrier and functions and regulate cellular immunity through balancing the Th1:Th2 ratio[119].

Helicobacter pylori infection

Helicobacter pylori (*H. pylori*) is a flagellated, spiral-shaped, Gram-negative bacillus that colonizes the human gastric mucosa causing gastric mucosa inflammatory response, gastric and/or duodenal ulcers, intestinal metaplasia, or even gastric cancer[120]. *H. pylori* infection in children differs from the adults in the prevalence, rate of complications, difficulties in diagnosis, and the higher rate of antibiotic resistance. The prevalence of *H. pylori* in children is higher in developing countries (20%) than in developed countries (0.5%)[121]. *H. pylori* infection in children increases the risk of gut colonization with *Prevotella, Clostridium, Proteobacteria, and Firmicutes* compared to children without infection who have more *Bacteroides*. These changes in the gut microbiota associated with *H. pylori* infection could be related to the development of chronic gastrointestinal diseases and drug resistance[122]. Eradication of *H. pylori* has a positive and negative impact on the host. It may restore the gut microbiota with decreased abundance of *Bacteroidetes* and increase *Firmicutes*, producing plenty of SCFAs with positive and negative effects[123]. While supplements with probiotic strain can improve infection conditions, it is not enough to eradicate *H. pylori* infection[124]. Adding probiotics to the traditional triple therapy to eliminate *H. pylori* increases the chance of successful treatment and decreases the therapy-related side effects compared to treatment without probiotics[125]. The addition of *Saccharomyces boulardii* to the standard treatment of *H. pylori* increases the eradication rate and reduces the therapy-related side effects [126]. Addition of *Lactobacillus*- and *Bifidobacterium*-containing probiotics such as *L. acidophilus*, *L. casei* DN-114001, *L. gasseri*, *Bifidobacterium infantis* 2036, and *Lactobacillus reuteri Gastrus h*ad the same beneficial effects during *H. pylori* therapy[127]. Various studies reported that certain probiotic strains could demonstrate an inhibitory activity against *H. pylori* bacteria. In contrast, other strains can ease the side effects of antibiotic therapy and subsequently improve the *H. pylori* eradication rate[128].

Coeliac disease

Coeliac disease (CD) is a life-long chronic autoimmune inflammatory systemic disorder but mainly affects the small intestine due to a deviated immune response to dietary gluten proteins (glutenins and gliadins) in genetically susceptible individuals. Several risk factors increase the risk of CD, including a family history of CD or dermatitis herpetiformis, delivery with caesarean section, type-1 diabetes mellitus, chromosomal abnormalities (Down syndrome or Turner syndrome), Addison's disease, and presence of other autoimmune disorders as autoimmune thyroiditis, or microscopic colitis[129]. As mucosal immune response *via* IgA secretion is among the first defense lines accountable for neutralizing harmful antigens and pathogens, patients with CD have significantly lower levels of IgA-coated fecal bacteria than in healthy controls. De Palma *et al*[130] found a significant reduction of the Gram-positive/Gram-negative bacteria ratio in patients with CD than in healthy controls. They also found less predominance of *Bifidobacterium, Clostridium histolyticum, Clostridium lituseburense and Faecalibacterium prausnitzii*, more abundance of *Bacteroides-Prevotella* group, and reduced IgA coating the *Bacteroides-Prevotella* group. Dysbiosis and predominance of the bacteria associated with the development of CD can be a risk factor for CD, either by its direct effects on the mucosal immune responses or by increasing the inflammatory reactions to gluten[131]. Fasano *et al*[132] found increased Zonulin expression in the intestinal tissues during flaring of celiac disease. Zonulin is a human protein like a toxin derived from *Vibrio cholera* called Zonula occludens toxin. Both Zonulin and Zonula occludens toxin increase intestinal permeability by decreasing the mucosal epithelium's tight intercellular junction.

Meanwhile, dysbiosis may result in a complication of the strict gluten-free diet, which reduces the beneficial bacteria, especially *Bifidobacterium* and *Lactobacillus*, and abundance of gram-negative bacteria such as *Bacteroides* and *Escherichia coli*[133]. The gluten-free diet-induced dysbiosis results from excluding crucial dietary carbohydrate resources, the primary resources for the energy required by the beneficial bacteria[134]. Despite being the only available treatment for CD, compliance with the gluten-free diet is complex. Consequently, there is a strong need for alternative therapy. Probiotics could supplement a gluten-free diet in patients refractory to the gluten-free diet. Probiotics can help to support the gluten-free diet through different mechanisms: improving the intestinal barrier function by *Lactobacillus rhamnosus* containing probiotics[135], anti-inflammatory modulation by *Bifidobacterium breve* and *Bifidobacterium longum*[136], and gluten degradation, lysing the proline/glutamine-rich gluten peptides, and reduction of the gluten concentration and toxicity by *Lactobacilli* strains (*L. ruminis, L. Johndoni, L. amylovorus, L. salivaris*)[137]. The use of probiotics enriched with *Lactobacilli* species may relieve the effects of accidental or contaminant gluten exposure by chopping up gluten proteins into smaller portions, not triggering an immune reaction or damaging the patients[138]. However, we need more studies and effort to evaluate probiotics in CD management.

Inflammatory bowel diseases

Inflammatory bowel diseases (IBD, Crohn's disease, ulcerative colitis, and unclassified) are a group of chronic, relapsing, and remitting inflammatory diseases of the gastrointestinal tract in a genetically predisposed person due to an aberrant immune response against gut microbiota, causing intestinal damage[139]. About 25% of the patients develop the disease before the age of 20 years, 18% before the age of 10 years, and 4% before the age of 5 years, and still on the rise[140]. Crohn's disease and ulcerative colitis affect the terminal ileum and colon, where there is heavy bacterial colonization. The

presence of IgG antibodies and hyperactive presentation of T-lymphocytes in the intestinal mucosa indicates a decrease in the local tolerance mechanisms[141]. In normal situations, the commensal bacteria cannot invade the intestinal mucosal barrier. Even when succussed to pass through it, it is rapidly phagocytosed and eliminated by the mucosal macrophage. Under unusual conditions, these commensal bacteria can cross the mucosal barrier and induce the inflammatory cascade[142]. Fava *et al* [143] found that patients with IBDs have different microbiota composition than that observed in the healthy controls, with decreased abundance of the healthy commensal (such as *Clostridium* IXa and IV groups, *Bacteroides*, *Bifidobacteria*) and increased the pathogenic bacteria as sulfate-reducing *Escherichia coli* reaching up to 40% of the dominant bacteria and consequently decreasing the microbiota diversity. The observed dysbiosis coupled with defective innate immunity and reduced bacterial killing ability due to impaired phagocytosis, decreased mucosal IgA and defensins, and over destructive adaptive immunity with ineffective regulatory T cells and antigen-presenting cells initiate the process of the pathogenesis of IBDs[144].

Treatment of pediatric IBDs is one of the fundamental challenges to pediatricians with frequent treatment failure and numerous therapy-associated side effects. Gut microbiota modification is one of the promising therapies for IBDs but is still controversial. Probiotics supplementation can restore the metabolic activity of the intestinal microbiota and modify their relative components by inhibiting the pathogenic bacterial overgrowth, decomposing their antigen, secreting antimicrobial substances, and increasing mucosal IgA. Probiotics also help to improve mucosal barrier function and preserve their integrity by tightening the epithelial junction and stabilizing the intestinal permeability. They also modulate intestinal epithelial and mucosal cells' immune response and induce T-cell apoptosis. Consequently, probiotics regulate the immune response and decrease the production of pro-inflammatory factors[145,146].

However, probiotic treatment for IBDs is still controversial. Vilela *et al*[147] showed that administering *Saccharomyces boulardii* helped maintain remission, improve intestinal permeability, and bowel sealing in patients with Crohn's disease. Kato *et al*[148] and Kruis *et al*[149] showed that *Escherichia coli* Nissle1917, *Bifidobacterium breve*, *Bifidobacterium bifidum*, and *Lactobacillus acidophilus* showed a promising effect on in maintaining the remission phase in patients with ulcerative colitis as effective as the standard mesalazine therapy but with high safety and tolerability profiles. However, Bousvaros *et al* [150] showed that the addition of probiotic *Lactobacillus rhamnosus* strain GG (LGG) to the standard therapy showed no significant differences compared to placebo in prolonging remission in children with Crohn's disease. Moreover, we need more randomized controlled studies to evaluate the effectiveness of *Lactobacillus GG* and other probiotic strains in children with IBDs.

GUT MICROBIOTA AND RESPIRATORY DISORDERS IN INFANCY AND CHILDHOOD

The gastrointestinal microbiota plays a crucial role in future lung development and future health status. Perinatal antibiotic use induces highly selective alterations on the resident gut microbiota, leading to precise modifications in susceptibility to TH2- or TH1-/TH17- determined lung inflammatory disorders [151].

The coronavirus disease 2019 infections in childhood

The coronavirus disease 2019 (COVID-19) is a real worldwide threat for all individuals of different ages, including children. Despite being mainly a respiratory disease, the gastrointestinal tract is a significant target, especially children. The virus can actively infect the gastrointestinal tract cells and replicate in the epithelium of the small and large intestine, stimulating an excessive immunological reaction in the host [152]. Angiotensin-converting enzyme-2 (ACE2) receptors are highly expressed in the upper esophagus and absorptive enterocytes from the ileum till the colon. The ACE2 receptor is an essential receptor for the virus entry to the cell membrane of host cells, with the interaction between the S protein of severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2). This interaction induces a state of an inflammatory cascade that ends with dysbiosis and leaky gut syndrome. The degree of expression of ACE2 throughout the gut is an essential factor that aggravates or alleviates the resulting gut dysbiosis and gastrointestinal leakage[153]. Meanwhile, SARS-CoV-2 infection causes many plasma cells and lymphocytes infiltration. It possibly provokes interstitial edema and the deterioration of the intestinal-blood barrier, causing the spread of endotoxins, viruses, bacteria, and microbial metabolites into the systemic circulation, impairing the host's response to SARS-CoV-2 infection and causing multisystem dysfunction and even septic shock[154].

The resulting dysbiosis lasts for a long time after clearance of SARS-CoV-2 virus from the body, indicating the presence of a more long-long-term harmful effect on the gut microbiome, in the form of reduced beneficial bacteria such as *Lactobacillus*, *Bifidobacterium,* and *Faecalibacterium prausnitzii* and more abundance of *Clostridium hathewayi, Clostridium ramosum, Coprobacillus, Candida* and *Aspergillus.* The presence of comorbidities such as diabetes mellitus, hypertension, and old age, and antibiotics, antivirals, antifungal, and steroid use increase dysbiosis severity[155]. Diversity of the gut microbiota and the gut predominance of beneficial bacteria share in determining the course of COVID-19 infection.

Restoring the gut microbiota diversity could help improve the severity of the disease. Dietary supplements with specialized pre/probiotics such as fructooligosaccharide, galactooligosaccharide could improve gut dysbiosis, especially in patients presenting with gastrointestinal manifestations such as diarrhea and thus improving the overall immune response in these patients[156]. Probiotics can produce bioactive peptides capable of inhibiting the ACE receptors by blocking the active sites, preventing the entry of SARS-CoV-2 from attacking the enterocytes. We can use prebiotics, probiotics, or symbiotics to protect the high-risk groups, such as healthy contacts with a suspected case or the front-line caregivers[157]. However, microbiota modulation as a treatment method of patients with COVID-19 disease is based on indirect evidence and needs further studies.

Cystic fibrosis

Cystic fibrosis is an inherited systemic disease that produces severe injury to the lungs, digestive system, and other body organs and might lead to death. The relation between the microbiota and cystic fibrosis is bidirectional. Loss of the function of cystic fibrosis transmembrane conductance regulator results in aberrant colonization of gut and respiratory microbiota due to altered intestinal and airway microenvironment even in the absence of antibiotic use[158,159]. Homozygous cystic fibrosis is associated with more significant changes in the gut microbiome and the severity of the disease. The resulting changes in the gut microbiota associated with cystic fibrosis induce changes in the airway microbiota due to the dynamic interaction between gut and airway microbiota[160].

On the other hand, the gut microbiota could impact the disease severity and progression. Restoration of the gut microbiota in cystic fibrosis either by adding oral probiotics, prebiotics, or even postbiotics by adding certain bacterial strains, indigestible fibers, or SCFAs; namely, butyrate improves the gut and the systemic inflammation, energy intake, nutritional status, and the respiratory function of the patients [161]. Oral probiotic intake, especially with LGG and *Lactobacillus reuteri*, can reduce inflammation, improve body weight, reduce pulmonary exacerbations, and upper respiratory infections and improve the pulmonary functions in children with cystic fibrosis with mild-to-moderate lung disease. These effects are related to the probiotics' anti-inflammatory and immunomodulatory properties and their impact on the intestinal barrier[162-164]. However, a recent multicentre study by Bruzzese *et al*[165] showed that LGG supplementation had no significant effect on the respiratory and nutritional outcomes in a large group of children with cystic fibrosis. This study's failure to show a beneficial effect for LGG supplementation could be related to the lower dose of probiotics. They used 109 colony-forming units instead of 1010 in the previous two studies. Meanwhile, we remain in need of more studies to confirm these effects.

Allergic rhinitis

Allergic rhinitis in children has a significant impact on the child's health with many comorbidities, impaired quality of life, and poor educational performance. It may progress to asthma or complicate the control of existing asthma[166]. Many factors that cause decreased microbial diversity (*e.g.*, delivery by caesarean section) are associated with an increased risk of allergic rhinitis and other atopic diseases such as atopic dermatitis and asthma. Bisgaard *et al*[167] found that the bacterial diversity in the early gut microbiota at one and twelve months after birth was negatively associated with the increased risk of allergic sensitization, peripheral blood eosinophilia, and allergic rhinitis. As the gut microbiome shows significant development during the first year of life, it is highly susceptible to disruption during that time. Early antibiotic use has a significant adverse effect on the gut microbiota by modifying the relative abundance of the bacterial composition and initiating dysbiosis, with increasing the risk for childhood allergic diseases[168].

Oral Probiotic supplementation can alter the gut microbiota in children with notable positive immunomodulatory effects help prevention of allergic diseases, including allergic rhinitis. Lin *et al*[169] examined the effects of *Lactobacillus paracasei* supplementation on the treatment of perennial allergic rhinitis in children between 6-13 years. They found significant improvement in individual parameters in the rhino-conjunctivitis quality of life questionnaires, including sneezing, nasal itching, and swollen puffy eyes in the supplemented group, but without significant effects on total symptom score and the nasal total symptoms score. Miraglia Del Giudice *et al*[170] found that children supplemented with probiotic *Bifidobacteria* mixture for four weeks achieved a significant improvement of allergic rhinitis symptoms than the control without probiotic supplementation. A metanalysis by Güvenç *et al*[171] showed the evident beneficial immunologic and clinical effects of probiotics, especially for *Lactobacillus paracasei*-33 strains in managing patients with allergic rhinitis despite the high heterogeneity among the included studies. However, despite the beneficial effects of probiotics in improving allergic rhinitis symptoms and the patient quality of life, there is limited evidence for the primary preventive role of probiotics supplementations in children with a high risk of allergic rhinitis[172,173].

Bronchial asthma

Asthma is a prevalent childhood disease. More than 300 million children and adults are affected by asthma worldwide. The development of asthma is multifactorial and is affected by environmental and other exogenous factors and genetic predisposition. Shaping the lung microbiota, especially during birth

and very early life, plays a crucial role in asthma development. Arrieta *et al*[174] found a significant decrease in the relative abundance of the bacterial genera *Rothia*, *Veillonella*, *Lachnospira*, and *Faecalibacterium*, in children at risk of asthma. The noticed abundance of these bacteria decreases the fecal acetate levels and consequently induces dysregulation of enterohepatic metabolites. In the same context, Abrahamsson *et al*[175] showed that children who developed asthma at the age of 7 years had a reduced total and gut microbial diversity in the first month of life than healthy children.

On the other hand, more abundance of the good bacteria as *Bifidobacterium longum* and less quantity of *bacteroid fragilis* in the gut microbiota early in life reduces the risk of asthma[176]. The recent decrease in pediatric asthma incidence, noted in some parts of Europe and North America, could be related to judicious antibiotic use during early infancy and childhood that preserve the gut microbiota community [177]. The use of oral probiotics, prebiotics, or synbiotics (combination of pro and prebiotics) could modify the airway microbiota directly through microaspiration of the probiotic strain from the gastrointestinal tract to the airway or indirectly through their metabolic products[178]. Probiotics might generate local effects, such as reducing mucosal permeability and thus decreasing systemic antigens penetration, enhancing local IgA production, and tolerance induction. Their systemic anti-inflammatory effects are mediated through Toll-like receptors, stimulating Th1 response to allergens, enhancing tolerogenic dendritic cells, and the production of Treg[179]. Probiotic supplementation could restore the airway microbiota dysbiosis, promoting the healthy microbiota, which could modify the course of the pulmonary disorders. However, there are not enough studies concerned with the effects of probiotic supplementation on childhood asthma. A systemic review by Lin *et al*[180] failed to confirm the beneficial role of probiotic supplementation on the disease course in children with bronchial asthma.

GUT MICROBIOTA AND SKIN DISORDERS IN INFANCY AND CHILDHOOD

Atopic dermatitis

Atopic dermatitis (AD) is a common chronic, recurrent inflammatory skin disease in children, affecting about 20% worldwide and on the rise, especially in developed countries. Skin microbiota can reflect general human health. The quantitative and qualitative skin and gut microbiota composition alteration can trigger various diseases, including allergic dermatoses[181]. The skin microbiota of children with AD shows significant dysbiosis, with reduced microbial diversity and more abundance of pathogenic *Staphylococcus aureus* and *Malassezia*[182]. Melli *et al*[183] showed an association between the presence of *Clostridioides difficile*, more quantity of *Bifidobacteria*, and a lower abundance of lactobacilli in the gut microbiota of children with atopic dermatitis. Bacterial strains such as *Staphylococcus epidermidis*, *Staphylococcus cohnii*, Gram-negative *Roseomonas mucosa,* and *Cutibacterium* strains that inhibit *Staphylococcus aureus* can serve as potential probiotics in children with atopic dermatitis[184]. Myles *et al*[185] showed that the local application of *Roseomonas mucosa* to the skin of 10 adults and five children with atopic dermatitis was associated with significant improvement of atopic dermatitis severity, a decrease in topical steroid requirement, and *Staphylococcus aureus* burden with no adverse events or treatment complications. Probiotics can decrease the severity and progression of atopic dermatitis by reducing inflammation through modulating T-cell immune response and improving the Th1/Th2 ratio; inhibiting Th2 cell response, and decreasing cytokines production such as IL-4, IL-5, IL-6, IL-13, and INF, enhance phagocytosis, increase serum IgA is increased[186]. Probiotics also inhibit the differentiation of mature dendritic cells and naive T cells' transformation into Th2[158]. Probiotics also can regulate brain function involving stress response on the gut-brain axis[187].

Psoriasis

Psoriasis is a chronic, complex, immune-mediated, inflammatory disease characterized by keratinocytes hyperproliferation. Unlike atopic dermatitis, patients with psoriasis have more bacterial diversity and heterogeneity with increased *Staphylococcus aureus* and decreased *Staphylococcus epidermidis* and *Propionibacterium acnes* and reduced microbiota stability than in healthy controls. *Staphylococcus aureus* colonization of the skin triggers Th17-induced inflammation with impaired community stability and accumulation of pathogenic bacteria[188]. The bacterial dysbiosis in psoriasis shows topographic changes. An exciting study by Fahlén *et al*[189] showed a significant decrease in the ratio of *Staphylococci* and *Propionibacteria* in psoriasis limb skin and enriched *Proteobacteria* in the trunk skin in patients with psoriasis than in controls. Gut dysbiosis also plays a significant role in psoriasis. There is a decrease in gut *Bifidobacterium* and *Firmicutes* and an increase in *Bacteroidetes* in patients with psoriasis than in healthy children. This gut dysbiosis also correlates with the severity of the disease[190]. Probiotics use in the treatment of psoriasis is promising *via* immune modifying response through restoring the gut microbiome. Vijayashankar *et al*[191] described the successful use of oral *Lactobacillus* strain with biotin to treat pustular psoriasis. However, a systematic review and meta-analysis by Zeng *et al*[192] showed that prebiotics might positively impact relieving the clinical symptoms of psoriasis with a low incidence of side effects. The probiotics exert their effects through their immunomodulatory effect on the skin and repair the skin barrier by decreasing the bacterial load and restoring the skin microbiota.

GUT MICROBIOTA AND IMMUNE DISORDERS

The relation between adaptive immunity and gut microbiota is well documented. Systemic lupus erythematosus (SLE) is a chronic systemic severe autoimmune disease that affects connective tissues. Pathogenesis of SLE results from the interaction between genetic and environmental factors[193]. Gut microbiota dysbiosis with disturbed composition and activity plays a role in many autoimmune diseases, including SLE and rheumatoid arthritis. A study done by Ma *et al*[194] found that the fecal microbiota of SLE mice had lesser community abundance and diversity than healthy mice. They can also induce anti-double-stranded DNA (anti-dsDNA) antibodies production in germ-free mice, promote the inflammatory response resembling SLE inflammation, and modify the SLE susceptibility genes expression in these mice by fecal microbiota transplantation. Another interesting experimental study by Ma *et al*[195] performed fecal microbiota transplantation from healthy controls and patients with active untreated SLE to germ-free mice. The Germ-free mice developed a series of lupus-like phenotypic and laboratory features that confirm the contributing role of abnormal gut microbiota in promoting SLE development.

On the other hand, Toral *et al*[196] found that *Lactobacillus fermentum* CECT5716 (LC40) ameliorates disease activity and cardiovascular complications in female mice models by improving gut barrier integrity. At the same time, de la Visitación *et al*[197] showed that *Lactobacillus fermentum* CECT5716 (LC40) prevented renal damage in a female mouse model of SLE. Long-standing use of probiotics is supposed to counteract the imbalance in the gut microbiota that causes reduced antibody production and attenuated inflammatory response, resulting in reduced severity and improving the signs and the manifestation of SLE[198]. However, we need more human-based studies on patients with SLE, as most animal-based studies confirmed the potential beneficial role for oral probiotics intake, which can alter the gut microbiome's composition and prevent SLE progression.

Gut dysbiosis is also a potential pathogenic factor for developing juvenile idiopathic arthritis (JIA). Wu *et al*[199] were able to induce autoimmune arthritis in mice using segmented filamentous bacteria, which could elaborate the potential role of the microbiota and development of autoimmune arthritis. On the other hand, some degree of intestinal inflammation is observed in about two-thirds of children with spondyloarthritis arthritis which may indicate that gut microbiota in children with spondyloarthritis is both modified and unusually affected by the deviated immune system[200]. Meanwhile, Stoll *et al*[201] found less abundance of *Faecalibacterium Prausnitzii* and a more abundance of *Bifidobacterium*, mostly *B. adolescentis*, in children with enthesitis-related arthritis than in healthy control. However, Öman *et al* [202] found no significant variations in microbiota α-diversity or composition between children with JIA, their healthy siblings, or unrelated healthy controls. Trials to modify gut microbiota using probiotics, exclusive enteral nutrition, or other modalities have variable success. Esmaeili *et al*[203] found no significant differences in the improvement criteria of rheumatoid arthritis in patients supplemented with synbiotic (500 mg capsule containing a prebiotic (fructooligosaccharides) and probiotics including 10^9 CFU/mL of *Lactobacillus acidophilus, Lactobacillus casei, Lactobacillus bulgaricus, Lactobacillus rhamnosus, Bifidobacterium breve, Streptococcus thermophile, and Bifidobacterium longum*,) for three months and placebo groups. They suggested that lack of response is probably related to the short duration of the treatment, but we think that the dose also was suboptimal. However, we need more studies with different probiotic strains and concentrations.

GUT MICROBIOTA AND DENTAL DISORDERS

Dental caries is a common pediatric disorder, especially in children with special needs. Understanding the association between specific bacterial strains in dental biofilms and different health conditions is crucial to preventing and combating dental caries. Richard *et al*[204] found that the microbiomes of supragingival dental plaque vary considerably between tooth surfaces and in children with different caries activities. Qudeimat *et al*[205] found that children with active caries have a significantly higher abundance of *Prevotella melaninogenica, Leptotrichia shahii, Leptotrichia HOT 498, Veillonella dispar,* and *Streptococcus mutans*. In comparison, children without active caries had a significantly higher abundance of *Lautropia mirabilis, Corynebacterium durum, Corynebacterium matruchotii,* and *Neisseria elongata*. Kanasi *et al*[206] also confirmed the presence of diverse microbiota that varied in children with severe caries from caries-free children. Probiotics might be helpful to inhibit or treat dental caries, periodontitis, or gingivitis. Certain probiotic bacterial strains have variable effects on the gut microbiome. Each probiotic bacterial strain has specific abilities to inhibit the growth of particular strains, particularly cariogenic bacterial strains and yeast[207].

Probiotic dairy products have a naturally occurring buffer to acid. When combined with calcium and calcium lactate effects, it produces anti-cariogenic properties that benefit the oral cavity. In the short term, probiotic products can hamper the development of harmful strains, but the long-term effects have not been thoroughly studied. Lee *et al*[208] showed that *Lactobacillus* species strongly inhibited the growth of oral *streptococci*. They also showed that *Lactobacillus rhamnosus* might inhibit oral biofilm formation by decreasing the glucan production of *Streptococcus mutans*. Systematic review and meta-

analysis by Gruner *et al*[209] showed insufficient current evidence to recommend probiotics in managing dental caries but support using probiotics to manage gingivitis or periodontitis. Future studies are needed to confirm the role of probiotics in the management of dental caries.

GUT MICROBIOTA AND CARDIAC DISORDERS

Recent evidence revealed that modifications of the gut microbiota composition and function could accelerate the progression of CVDs. The gut microbiota has a crucial effect in inducing inflammatory and immune responses that could link the gut microflora to heart failure. The gut microbiota of patients with chronic heart failure has more pathogenic bacteria such as *Campylobacter* and *Shigella* and more candida than the healthy controls. The ratios of these pathogenic bacteria and candida positively correlated with the severity of heart failure[210]. Increased intestinal permeability is observed in a significant portion of patients with congestive or right-sided heart failure, which correlates with right atrial pressure[211]. This observation could explain the increased serum endotoxin levels in patients with chronic heart failure. Reduced cardiac output and systemic congestion observed in heart failure cause intestinal mucosal ischemia and/or edema, which increases the bacterial translocation and the circulating endotoxins that can promote the underlying inflammation observed in patients with heart failure[212]. These mucosal changes also cause enhanced bacterial growth, which is reflected by the increase in serum levels of immunoglobulin A-antilipopolysaccharide[213]. In heart failure, there is a decreased gut microbiota diversity with an increased ratio of the pathogenic bacteria such as *Shigella*, *Campylobacter*, *Yersinia enterocolitica*, *Salmonella*, and *Candida* species[214]. Luedde *et al*[215] also observed significant downregulation of key intestinal bacterial groups such as *Coriobacteriaceae*, *Erysipelotrichaceae*, and *Ruminococcaceae*.

Probiotics may have significant beneficial effects on cardiovascular health. The effects are strain-specific and target specific cardiovascular risk factors. For example, *Lactobacillus rhamosus* can significantly reduce body weight while *Lactobacillus acidophilus*, *Lactobacillus rhamnosus,* and *Bifidobacterium bifidum* can dramatically lower blood glucose levels by 38% in patients with DM type II. At the same time, *Lactobacillus acidophilus* and *Bifidobacterium lactis Bb12* significantly lower fasting blood glucose, hemoglobin A1c, and malondialdehyde and raise erythrocyte glutathione peroxidase and superoxide dismutase activities and improve total antioxidant states. Meanwhile, *Lactobacillus acidophilus, Lactobacillus reuteri,* and *Bifidobacterium longum* improve dyslipidemia, increase high-density lipoprotein (HDL) cholesterol level, and reduce low-density lipoprotein (LDL)/HDL cholesterol ratio. *Lactobacillus curvatus* and *Lactobacillus Plantarum* increase apolipoprotein AV and LDL particles size. *Streptococcus thermophiles* can significantly decrease systolic blood pressure[92,216-219].

Probiotics may have a role in managing heart failure, primarily those containing *Bifidobacteria*, yeasts, and lactic acid-producing bacteria, as they can reduce inflammation, repair, protect the intestinal mucosal barrier, and improve its function[220]. Gan *et al*[221] showed that six weeks of supplementation with *Lactobacillus rhamnosus* GR-1-containing probiotic could significantly improve left ventricular hypertrophy and increase its ejection fraction in rates with induced myocardial infarction due to coronary artery occlusion. Animal studies also showed that probiotics could decrease myocardial cell apoptosis and alleviate ventricular remodeling in rat models of spontaneous hypertension[222]. There are very few studies of the effects of probiotics in human patients with heart failure. Costanza *et al*[223] studied the impact of three months of supplementation with *S. boulardii* (1000 mg per day) on outpatients with heart failure with NYHA class II or III and left ventricular ejection fraction (LVEF) < 50%. The supplemented patients showed a significant reduction of left atrium diameter and improvement of LVEF compared to the patients supplemented with placebo. Children with heart failure may have underlying cardiac conditions that increase the risk of infective endocarditis. Probiotics in such patients are not entirely safe, and there is a risk of bacterial translocation with a possible occurrence of sepsis and infective endocarditis. Their safety in such vulnerable patients requires additional studies.

LIMITATIONS FOR PROBIOTIC USE

Despite probiotics being part of the body's good microbiota and are safe in most cases, there are some limitations to their use. The side effects of probiotics lie in four categories: excessive immune stimulation, adverse metabolic activities, generalized infections, and gene transfer[224]. They may occasionally trigger allergic reactions, especially with *Saccharomyces boulardii* in those with a history of yeast allergy, and should be used judiciously. Abdominal discomfort could happen in the first few days of therapy, occasionally with diarrhea and bloating. Probiotics are safe to be used by children, especially those containing *Bifidobacteria* or *Lactobacillus*, which can be used for up to one year without any safety issues[225]. Bacteriemia and infective endocarditis have been recorded in a few patients taking probiotics containing *Bifidobacteria* or *Lactobacillus* probiotics, especially among patients with central lines or impaired immunity, *e.g.*, who are suffering from tuberculosis or acquired immune deficiency

syndrome[226]. Probiotics containing *Lactobacilli* can cause mural and valvular infective endocarditis. Although this is extremely rare, patients with valvular heart disease may be more prone to this complication. Before dental or surgical procedures, patients with valvular or congenital heart disease with high-pressure shunt should discontinue probiotic use[227]. Some probiotics may transmit antibiotic resistance genes, such as enterococci. Other probiotic strains such as the Bacillus cereus group can produce enterotoxins and emetic toxins[228]. Another limitation is the lack of international regulatory measures that control probiotics production and prescription. Another limitation is the need to elucidate the mechanism of action of each probiotic, the ideal strain and its effect for each medical condition, and which health benefits can be gained[229]. We need to do more clinical and mechanistic studies to understand better the interaction between the microbes and host cells, including the mucus and immune defenses, and produce effective interventions.

CONCLUSION

There is an intimate relationship between the human and his body microbes. The gut is the primary residence for this microbiota, as it provides the bacteria with a convenient environment for thriving. The microbiota plays a significant role in gut development, maturation, and immune system differentiation. It exerts a considerable effect on the child's physical and mental development. Gut dysbiosis is also a potential pathogenic factor for developing various childhood disorders inside and outside the gastrointestinal tract. Probiotics may have a role in managing these disorders with variable degrees. Even though probiotics could help address these disorders, we need more studies to prove the efficacy, select the proper probiotic for each disease, the appropriate dose, and ensure its safety.

Abstract

Crohn's disease (CD) remains a chronic, incurable disorder that presents unique challenges to the surgeon. Multiple factors must be considered to allow development of an appropriate treatment plan. Medical therapy often precedes or complements the surgical management. The indications for operative management of CD include acute and chronic disease complications and failed medical therapy. Elective surgery comes into play when patients are refractory to medical treatment if they have an obstructive phenotype. Toxic colitis, acute obstruction, perforation, acute abscess, or massive hemorrhage represent indications for emergency surgery. These patients are generally in critical conditions and present with intra-abdominal sepsis and a preoperative status of immunosuppression and malnutrition that exposes them to a higher risk of complications and mortality. A multidisciplinary team including surgeons, gastroenterologists, radiologists, nutritional support services, and enterostomal therapists are required for optimal patient care and decision making. Management of each emergency should be individualized based on patient age, disease type and duration, and patient goals of care. Moreover, the recurrent nature of disease mandates that we continue searching for innovative medical therapies and operative techniques that reduce the need to repeat surgical operations. In this review, we aimed to discuss the acute complications of CD and their treatment.

Key Words: Crohn's disease; Intestinal obstruction; Free perforation; Intra-abdominal sepsis; Perineal sepsis; Acute bleeding

Core Tip: Crohn's disease remains a chronic and incurable disorder. Multiple factors must be considered to allow the development of an appropriate treatment. The indications for operative management of Crohn's disease include acute and chronic disease complications and failed medical therapy. Progression into a complicated phenotype can be characterized by the formation of stenosis or abscesses/fistulas. Elective surgery comes into play when patients are refractory to medical treatment if they have an obstructive phenotype. Indications for emergency surgery include intestinal obstruction, abdominal and perineal sepsis, toxic colitis, or massive hemorrhage.

INTRODUCTION

Crohn's disease (CD) is a chronic and unremitting inflammatory disease that can involve all the gastrointestinal tract. It was first described by Crohn *et al*[1] in a case series presented at the American Medical Association annual meeting in 1932, at which time they noted a transmural inflammatory condition of the terminal ileum[1].

The incidence of CD has increased in recent years[2,3]; Ng *et al*[4] described that the higher prevalence was in Europe (322 *per* 100000 in Germany) and North America (319 *per* 100000 in Canada). In the last 30 years, a major increase has also been described in Asia, Africa, and South America[5,6].

There is no agreement between the various authors on the gender predominance[7]. Some case studies propose a female predominance in Western population and a male predominance in Eastern countries; in others there are no differences[8]. The age of presentation shows a bimodal trend with a first peak between 15-30 years (men manifest the disease earlier than women) and a second peak between 60 years and 70 years (mostly women)[9].

CD has a multifactorial etiology[10-12]. It has been described in the literature that patients who had an appendectomy for perforating appendix have a major risk to develop CD, while appendectomy for other causes is linked to a lower risk of CD[13].

The pathogenesis is unclear[5]. An excessive immune response against intraluminal bacteria occurs in the mucosa in susceptible patients and leads to a chronic inflammation that can involve all the gastrointestinal tract[7]. It is localized in the small intestine or proximal right colon with a preference of the terminal ileum in most cases[14]. The histologic findings that characterized the disease are non-caseating granulomas and discontinuous transmural lesions with inflammation penetrating to the muscolaris propria, resulting in structuring and fistulization[15].

Due to the high variability of localization and severity of inflammation, the disease can have different clinical manifestations that range from very mild to severe. Sometimes, the disease can present as an acute and severe form since from beginning[7,14,16,17].

A cure remains elusive, and efficient management of CD is essentially multidisciplinary[18,19]. Surgery is still required even if the number of operations has decreased in recent years mainly for the introduction of biological therapy[19,20].

Uncomplicated forms identified patients with a prevalent inflammatory phenotype[7,19]. On the other hand, patients affected by a form of CD with a progressive complicated phenotype present with stenosis (structuring phenotype) or abscesses/fistulas (penetrating phenotype). Elective surgery comes into play when patients are refractory to medical treatment if they have an obstructive phenotype. According to the existing literature, the risk of surgery at 1, 5, and 10 years after diagnosis of CD is 16.3%, 33.3%, and 46.6%, respectively[21]. It is still controversial whether medical treatment reduces the need for surgery[22] or not[23,24].

The indications for operative management of CD also include acute and chronic disease complications. Since CD is characterized by periods of exacerbation and remission, it is not uncommon that an acute presentation of complications that requires urgent/emergency surgery in 6%-16% of cases[24]. Patients requiring emergency surgery are generally in critical conditions and present with intra-abdominal sepsis and a preoperative status of immunosuppression and malnutrition that exposes them to a higher risk of complications and mortality. Although most acute complications of CD are managed

nonoperatively, it is important to recognize those that require a surgical approach. In this review, we aimed to discuss the acute complications of CD and their treatment, focusing on the recent results of surgical, endoscopic, and percutaneous treatments, as individual treatments and as integrated therapy.

DIAGNOSIS

Patients with CD, who present to the emergency department with symptoms of acute complications, must be properly framed to formulate an accurate diagnosis and decide what is the best possible treatment. First, a blood chemistry panel must be obtained. It must include full blood count, electrolytes, liver enzymes, renal function, and inflammatory biomarkers, such as C-reactive protein, serum albumin, and fecal calprotectin level. It is fundamental to rule out possible blood infections by carrying out blood and stool cultures and toxin test for *Clostridium difficile*[7,19].

Typically, the laboratory panel of a patient with acute CD complications is characterized by anemia, increased leukocytosis, thrombocytosis, altered liver and kidney function, and increased inflammatory markers. Neutrophil/lymphocyte ratio, obtained by dividing the absolute number of neutrophils by the absolute number of lymphocytes, is described by many authors as a good predictor of sepsis and in the case of CD as an index of acute disease complicated by the presence of abscesses. In this context, Khoury *et al*[25] developed a clinical score to predict the presence of intra-abdominal abscess (Table 1). For patients with a low score (≤ 7) the probability of an intra-abdominal abscess is very low, and therefore an urgent computerized tomography (CT) scan can be avoided. On the other hand, a high score (> 9) would warrant urgent imaging for the elevated risk of this intra-abdominal finding. In this scenario, the disease severity indices, such as Harvey-Bradshaw Index[26] (Table 2), Crohn's disease activity index (Table 3)[27-29], and Prognostic Nutrition Index[30], are also useful. This last index, calculated using the formula Prognostic Nutrition Index = 10 × albumin (g/dL) + 0.005 × total lymphocyte count/μL measured in peripheral blood with a reference value ≤ 40, is widely used to evaluate the nutritional status of the patient and to predict the risk of postoperative complications after gastrointestinal surgery [30,31]. A preoperative low nutritional prognostic index is a useful predictor of postoperative infectious complications in patients with CD-related bowel resection[31,32].

Abdominal CT scan with intravenous contrast is the first choice of examination for the diagnosis[33]. It allows the evaluation of the presence of complications such as bleeding, perforation, obstruction due to strictures, and the presence of abscesses. The procedure is essential to decide whether to proceed with a surgical treatment or opt for initial nonoperative management[34]. A frequent use of CT scan has been reported for all patients who were admitted to the emergency department for abdominal pain[35], but CD patients are irradiated more often for diagnostic purpose, with a higher exposure to X-rays[36]. Several studies evidenced that CD patients are exposed to CT scan radiation up to 2-3 times *per* year[36-39]. It is also described that children who are exposed early to CT scan have an increased risk of brain tumor and leukemia[40,41]. Craig *et al*[41] evaluated a low dose CT protocol, reaching radiation levels as low as a plain abdominal X-ray, which provided similar diagnostic efficacy even with low-quality images. The diagnostic accuracy of magnetic resonance imaging (MRI) enterography/enteroclysis is like CT scan and prevents exposure to ionizing radiations. It has a few detriments such as limited availability, high cost, and time consumption[27].

As recommended by recent guidelines for the management of CD in the emergency setting[7], point of care ultrasonography can have a role in showing free fluid, abscess, or intestinal distension, especially when CT scan is not available. Bettenworth *et al*[42] in their review showed that sensitivity of the ultrasonography for stricture diagnosis runs from 80% to 100% with specificity rates of 63%-75%. A systematic review by Panés *et al*[43] revealed that the sensitivity and specificity for ultrasound in the detection of complication are high and comparable to MRI[43].

INITIAL OPTIMIZATION

Since urgent surgery in patients with CD is burdened by a high rate of complications due to intra-abdominal sepsis, immunosuppression, and malnutrition, it is necessary to optimize their general conditions and nutritional status, delaying surgery` if feasible.

Preoperative corticosteroid use is associated with increased risk of postoperative complications[44,45]. Reduction of corticosteroid doses may decrease postoperative complications but should be carefully monitored to avoid increasing CD burden[19]. Meta-analyses of prospective and retrospective studies reported up to a doubling of surgical site infection for patients on steroids[46,47].

The application of biologic therapy before urgent surgery is still unclear. The PUCCINI trial showed no effect of anti-tumor necrosis factor α on postoperative complications[48]. Current evidence suggests that preoperative treatment with vedolizumab or ustekinumab does not increase the risk of postoperative complications in patients with CD having abdominal surgery, and cessation of these therapies prior to surgery is not mandatory[49-51].

Table 1 Variables independently associated with abscess in the clinical score of Khoury *et al*[25]

Parameters	Coefficient estimate	*P* value	Weight appointed for the score
Ileo-colonic location	0.32 ± 0.16	0.04	× 1
Perianal disease	1.17 ± 0.32	0.0002	× 3
Absence of current corticosteroids	0.62 ± 0.21	0.003	× 2
NLR > 11.75	1.15 ± 0.17	< 0.0001	× 3
CRP > 0.5 mg/dL	1.67 ± 0.21	0.03	× 5

Modified from Khoury *et al*[25]. NLR: Neutrophil/lymphocyte ratio; CRP: C-reactive protein.

Table 2 Harvey-Bradshaw index (simple index)

Variable No.	Variable description
1	General well-being (0 = Very well; 1 = Slightly below par; 2 = Poor; 3 = Very poor; 4 = Terrible)
2	Abdominal pain (0 = None; 1 = Mild; 2 = Moderate; 3 = Severe)
3	Number of liquid stools daily
4	Abdominal mass (0 = None; 1 = Dubious; 2 = Definite; 3 = Definite and tender)
5	Complications: arthralgia, uveitis, erythema nodosum, aphthous ulcer, pyoderma gangrenosum, anal fissure, new fistula, abscess (score 1 for item)

Modified from Harvey and Bradshaw[26].

Table 3 Crohn's disease activity index

Variable No.	Variable description	Multiplier
1	Number of liquid or soft stools (each day for 7 d)	× 2
2	Abdominal pain, sum of 7 daily ratings (0 = None, 1 = Mild, 2 = Moderate, 3 = Severe)	× 5
3	General well-being, sum of 7 daily ratings (0 = Generally well, 1 = Slightly under par, 2 = Poor, 3 = Very poor, 4 = Terrible)	× 7
4	Number of listed complications (arthritis or arthralgia, iritis or uveitis, erythema nodosum or pyoderma gangrenosum or aphthous stomatitis, anal fissure or fistula or abscess, other fistula, fever over 37.8 °C	× 20
5	Use of diphenoxylate or loperamide for diarrhea (0 = No, 1 = Yes)	× 30
6	Abdominal mass (0 = No, 2 = Questionable, 5 = Definite)	× 10
7	Hematocrit (males 47-Hct %, females 42-Hct %)	× 6
8	Body weight (1-weight/standard weight) × 100 (add or subtract according to sign)	× 1

Modified from Best *et al*[29]. Hct: Hematocrit.

Malnutrition is an independent risk factor for postoperative poor outcomes[52,53]. Preoperative nutritional assessment should be performed for all patients with CD who need surgery[19]. The European Society for Clinical Nutrition and Metabolism stated that serum albumin of < 3 g/dL, body mass index < 18.5 kg/m^2, and weight loss > 10%-15% within 6 mo are the best indicators of severe malnutrition in CD patients[54]. The nutrition of choice should be the enteral nutrition that can be replaced with the parenteral one only in those patients who cannot tolerate the first or have severe contraindications such as a high flow intestinal fistula, intestinal perforation, or intestinal ischemia[55,56]. Brennan *et al*[57] observed that patients who received preoperative nutritional support had a rate of postoperative complications of 20% compared with 61.3% in the group without nutritional support. Zhu *et al*[58] suggested that enteral nutrition is feasible in CD patients with non-radiologically-drainable abdominal abscess.

INDICATIONS TO EMERGENCY SURGERY

Acute bowel obstruction, intra-abdominal sepsis, hemorrhage, acute toxic colitis, and perianal sepsis are the indications for an emergency procedure in patients with CD. The incidence of acute complications of CD are shown in Table 4.

Acute surgical emergencies in patients with CD are associated with high morbidity and mortality. Postoperative mortality rates for nonelective surgeries in CD have decreased but remain significantly higher than the mortality rate following elective surgery (3.6% *vs* 0.6%)[59,60]. Although most acute complications of CD are managed nonoperatively, it is important to recognize those that require surgical management. Another issue is the prevention of recurrence, which is still much debated.

INTESTINAL OBSTRUCTION

Acute intestinal obstruction is the most frequent complication in patients with CD, especially in patients with ileo-colic localization (35%-54%), while in jejunal (22%-36%) or colic (5%-17%) localizations the frequency is lower[19,61-63]. Gastroduodenal obstruction is rare, occurring in 0.5% to 13% of patients [62,64]. Patients with gastroduodenal strictures present with postprandial fullness, early satiety, vomiting, and upper abdominal pain[65,66]. Patients with obstruction of the small intestine present with nausea, vomiting, dehydration, crampy abdominal pain, bloating, obstipation, and constipation. Patients with colonic obstruction may present without nausea and vomiting but with bloating, distension, and abdominal pain, in addition to constipation. Initial management of bowel obstruction includes bowel rest, intravenous hydration, and nasogastric decompression in the presence of vomiting [42].

Strictures complicating CD can be classified as inflammatory or fibrostenotic[67]. Patients with inflammatory disease deserve medical therapy, such as steroids for reducing inflammation. Patients who do not improve with medical therapy and in whom an occlusion due to fibrosis can be hypothesized need receive a CT scan or an MRI. In these patients, an interventional approach, endoscopic or surgical, is usually needed[7]. Deferred surgery is the preferred option in adult patients with small bowel obstruction without bowel ischemia or peritonitis. Endoscopic balloon dilatation (EBD) is a suitable treatment option for patients with short (< 5 cm) strictures[68]. For fibrotic strictures, EBD has a technical success rate of 89% to 92%, with 70% to 81% of patients presenting free of occlusive symptoms in the short term[69]. In contrast for the long term, 73.5% of patients require repeat dilatation and 43% a surgical intervention within 2 years[70]. Fully covered self-expandable metal stents (FCSEMS) have been used for endoscopic treatment of patients for whom EBD was unsuccessful. In a multicenter, open-label, randomized trial[71], 80 patients were randomly assigned to treatment: 39 (49%) patients to the FCSEMS group and 41 (51%) patients to the EBD group. Overall, 33 (80%) of 41 patients in the EBD group and 20 (51%) of 39 patients in the FCSEMS group could avoid a new therapeutic intervention in 1 year (odds ratio: 3.9; 95% confidence interval: 1.4–10.6; $P = 0.0061$). Two of 80 patients had perforations (1 patient in the EBD group and 1 patient in the FCSEMS group)[71]. EBD is more effective than FCSEMS for CD strictures, with a good safety profile for both the treatments.

Surgery is mandatory for intestinal obstruction with potential impending perforation, with long or multiple strictures, when the strictures are not endoscopically accessible, when medical or endoscopic treatment does not result in an adequate reduction of clinical symptoms, or when there is a suspicion of an underlying malignancy[7,72,73]. If emergency surgery is indicated, a laparoscopic approach is recommended when appropriate expertise exists[74,75].

The surgical treatment of choice is a segmental resection of the involved segment with primary anastomosis. In fact, the most important principle in the surgical management of CD is to resect only the segment of bowel affected by the complication to prevent short bowel syndrome. Even if adjacent areas of bowel are clearly diseased, that should be ignored[76]. Furthermore, when two intestinal segments are involved, but with a healthy segment in between, the resection of the healthy segment depends on its length, too[77]. If it is 10 cm or longer, it probably should be saved. If it is 5 cm or shorter it should be included. In the other cases, the surgical attitude will depend on previous resection, configuration of blood supply, and mobility of the mesentery. The anastomosis could be either hand-sewn or stapled, end-to-end or side-to-side[78]. The literature does not describe a superiority of one technique over another, and the final decision can be left to the surgeon preference[78-80]. If a stapled anastomosis is performed, some authors advise performing it with an isoperistaltic configuration to allow an easier subsequent endoscopic surveillance. If the bowel wall is edematous due to chronically inflammation, a hand-sewn anastomosis would be better[80]. The general conclusion favors stapled side-to-side anastomosis. The diameter of the anastomosis plays a role as well, with the assumption that a wider anastomosis will have a lower rate of clinical and surgical complications[81,82].

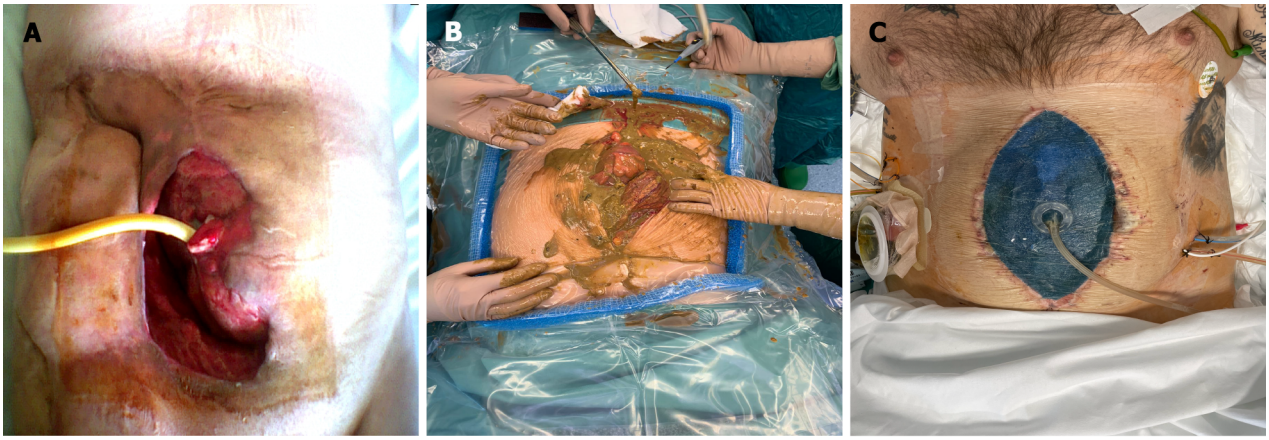
Other surgical options include stricturoplasty, intestinal bypass, and creation of ileostomy. Short fibrous strictures, multiple strictures, short bowel syndrome, rapid recurrence of obstruction due to CD, and duodenal CD are indications for stricturoplasty. Contraindications to stricturoplasty are multiple strictures in a short intestinal segment, a long stricture (> 20 cm), or stricture close to the resection site

Table 4 Incidence of acute complications in Crohn's disease

Complication	Incidence (%)	Ref.
Small bowel obstruction	35.0-59.0	[63]
Gastroduodenal obstruction	0.5-15.0	[64]
Colonic strictures	5.0-17.0	[73]
Intra-abdominal abscess	10.0-28.0	[85,156]
Free bowel perforation	1.0-6.5	[104,105]
Acute appendicitis	0.1-2.0	[113]
Bleeding	1.0-6.0	[126]
Perianal disease with left-sided colon or rectal involvement	17.0-43.0	[145]
Isolated perianal involvement	5.0	[146]

[83]. Bypass operations have largely been abandoned because of the subsistence of disease activity[83]. An ileostomy is required when it is not safe to perform an anastomosis, such as in case of severe patient instability, malnutrition, intra-abdominal sepsis, chronic immunosuppression, or when a small bowel resection is performed together with colonic or rectal resection[76,79].

INTRA-ABDOMINAL SEPSIS



Abscess

The presence of an abscess occurs in up to 20% of CD patients[84-86]. It typically results from a penetrating disease phenotype with a distal stricture[80]. An abscess is categorized as active at Harvey-Bradshaw Index[26] and severe with a Crohn's disease activity index > 450[27-29]. Abscess is defined as an inflammatory mass consequent to bowel perforation promptly covered by fibrin that adheres to the loops surface causing adhesions among them. It can be associated with other CD complications such as fistulas (40%) and stenosis (51%)[14,85]. Usually, these patients present to the emergency department with fever associated with abdominal pain, palpable masses, and rebound tenderness. In 28% of cases they can have a generalized sepsis[84]. Therefore, it is crucial that they receive a proper clinical evaluation. If an abscess is suspected, cross-sectional imaging is recommended. CT scan is the gold standard for their detection in the emergency setting, and it also identifies concomitant fistulae or bleedings. MRI has a similar accuracy with a lower ionizing radiation exposure, but it is not always accessible in the emergency department. Point of care in the United States can have a role in the initial assessment, and it is extremely useful in rural hospitals where CT is not available[7,87,88]. Moreover, if there is an indication to the positioning of a percutaneous drainage, both ultrasonography and CT can be used as guides[86,89]. In selected cases, endoscopic ultrasound can be employed for draining the cavity by a transvaginal or transrectal approach[90,91].

When the abscess diagnosis is confirmed, the best patient tailored treatment must be defined. In stable patients with abscesses smaller than 3 cm, early empiric antimicrobial therapy is recommended with a close clinical and biochemical monitoring. If the abscess is > 3 cm, percutaneous drainage with antibiotics is endorsed[7,89]. The drainage approach depends on the abscess site. It can be transgluteal for pelvic abscesses but also transabdominal. The catheter, whose size must be chosen considering the viscosity of the fluid collected, is left in place, and the daily quantity and quality of the drain must be recorded carefully[84,92].

Percutaneous drainage is a validated procedure because it may avoid an immediate operation, delaying to elective surgery[93,94]. Inflammation will have enough time to resolve, making possible limited intestinal resections and reducing the need of a diverting stoma creation. In addition, the nutritional status could be optimized and steroids interrupted before surgery, reducing the risk of anastomotic leak[53,84]. According to some studies, percutaneous drainage is a bridge to definitive surgical treatment. On the other hand, more recent studies have demonstrated that most patients do well with only percutaneous drainage and do not need any other surgical treatment with success rates that vary from 50% to 95%. The risk of recurrence, more often within 3 years, must be considered[95-97]. Immediate surgery should be considered in cases of patients with septic shock or failure of percutaneous drainage due to multiple and multilocular abscesses and those associated with a fistula (Figure 1A)[84,98].

Another key factor in the conservative treatment in CD patients with abscess is antibiotic therapy. Therefore, it is important to collect a sample of drained fluid and send it for a microbiological test. The culture can reveal the type of microorganisms in the pus, allowing the optimization of the antimicrobial

Figure 1 Intra-abdominal sepsis. A: Abscess in the right iliac fossa, spontaneously draining to the skin, associated with high-flow enteric fistula. Foley catheter placed in the fistulized small intestine; B: Fecal contamination of the peritoneal cavity in a patient with Crohn's disease with perforation of the transverse colon; C: Open abdomen after treatment of intestinal perforation in Crohn's disease. Negative pressure intraperitoneal device placement.

therapy, increasing the chances of conservative treatment success. Reuken *et al*[99] found that the culture was positive in about 88% of patients and usually polimicrobic. The most common pathogens were *Escherichia coli*, *Streptococcus spp*., *Enterococci*, *Candida*, and anaerobes. The most used empirical first-line antibiotics were broad spectrum penicillins, followed by cephalosporins and quinolones[99]. These treatments were inadequate in patients on immunosuppression or with a prolonged hospitalization and that could be linked to a higher risk of failure[80]. The appropriate duration of antibiotic therapy is unclear. Also, anti-tumor necrosis factor therapy can have a role in the treatment of an abscess, but only if associated to antimicrobial treatment that must be continued for 3 mo[100].

After antimicrobial treatment and percutaneous drainage clinical improvement is expected in 3–5 d, with a gradual decrease in the drain output. According to the American Society of Colon and Rectal surgeons, after a successful resolution of an abscess with percutaneous drainage and antibiotics, a drain study to exclude a concomitant fistula could be beneficial[80]. If a patient's condition does not improve, a re-evaluation is mandatory[84], and if the abscess has not been adequately drained, repositioning of the drain or an operation must be considered.

When a surgical exploration must be performed for conservative treatment failure or for concomitant CD complications, some issues need to be considered. First, if the patient is unstable, an open approach is recommended, considering the damage control surgery principles. There is also room for open abdomen use. An operation with a bowel resection gives better results than an operative drainage alone, which determines a higher rate of reoperation and enterocutaneous fistula formation. In case of septic shock, it may be appropriate to perform bowel resection with stapled off bowel stumps, peritoneal lavage, and open abdomen with a planned second exploration in the next 24-48 h after the patient has been stabilized in the intensive care unit. At this point, surgeons must decide whether to create a stoma or anastomize the stumps[89,101]. In the case of a stable patient and technical skills available, laparoscopy is recommended to reduce hospital stay and morbidity. Both open and laparoscopic extensive resections must be avoided because they can lead to immediate or future short bowel syndrome in these patients[80].

Even after success of conservative treatment, patients with a concomitant stenosis, an enterocutaneous fistula, or refractory active disease are likely to require surgery[102]. It is believed that a window of 6 to 8 wk after the resolution of the acute clinical scenario could permit a good improvement of the clinical and nutritional status as well as a proper imaging and endoscopic work-up. This work-up aims to avoid unexpected findings during the elective operation[93]. Moreover, as already discussed, the surgical outcomes will be better and comparable to CD patients with non-penetrating disease, as it is also confirmed by recent research[103]. In their study on 592 patients, Collard *et al*[103] compared patients who underwent an ileocolonic resection after a conservative treatment for an abscess to CD patients without a penetrating disease who had the same operation[103]. In the first group, all the patients underwent a CT scan after the percutaneous drainage to demonstrate a complete resolution of the abscess. Nevertheless, the persistence of an abscess, defined by the presence of a pus-like or purulent collection in the site of the original abscess, was found in 25% of cases. There were no differences between the two groups for rate of primary anastomosis, need of additional intestinal resection, incidence of intraoperative and postoperative complications, and length of hospital stay.

Free perforation

Free peritoneal perforation in CD is a rare condition that occurs in 1%-3% of CD patients as a first manifestation or in the course of the disease[104,105]. It is one of the main indications for emergency

surgery with a high rate of morbidity and mortality in the case of delayed surgery[104]. Greenstein *et al* [106] reported that perforation can occur in the ileum or in the colon indifferently, without a preference for location. Instead, the Connect study of Doh *et al*[105] found that ileal perforation had a higher incidence (86.2%), while colonic perforation occurred in only 7.4% of the patients. Some authors described that steroid treatment increases the risk of free perforation[107-110]. The role of anti-tumor necrosis factor agents in the etiopathogenesis of free perforation is not clear yet[111]. The mechanism leading to free perforation is still unclear, but there are two most likely hypotheses. The first and more conceivable is that the increase of intraluminal pressure proximal to a stenosis causes a bowel distension that can perforate the thin layer overlying a deep ulcer, while the second suggests that the perforation is consequent to intestinal ischemia due to inflammation of the small vessels[105].

The intestinal segment affected by the perforation should be resected by either directly performing a primary anastomosis or proceeding with an enterostomy. According to our practice, in the case of severe abdominal contamination (Figure 1B), we recommend not to close the laparotomy but to perform a second look as already described by Liu *et al*[112], using the technique of open abdomen with negative pressure wound therapy (Figure 1C). In this way, it is possible to prevent intra-abdominal sepsis and during the second look, optimize the resection. In some selected cases, a primary anastomosis could be feasible as the vacuum system allows a good intra-abdominal clearance. We also recommend this technique in the setting of damage control surgery with a hemodynamically unstable patient, when the decision to perform an enterostomy will be postponed to the second look.

Acute appendicitis

Appendiceal CD is a rare condition, whose incidence varies from 0.1% to 2.0%[113]. After the first case described in 1953[114], there was an initial interest in the topic with most of the cases described in the late 1980s and early 1990s[115,116]. In 1990, Ruiz *et al*[117] identified 85 cases of CD limited to the appendix[117]. The disease was found most frequently in the second and third decades. The authors suggest that a prolonged preoperative history of symptoms should alert the surgeon to this possibility [117]. Lindhagen *et al*[118] identified 50 cases and added 12 of their own[118]. The indication for surgery in their patients were appendicitis in 8 patients, appendiceal abscess in 2 patients, suspected pyosalpinx in 1 patient, and ovarian cyst in 1 patient. All but 2 of the 8 appendicitis patients underwent appendectomy; the others underwent a more extensive resection. There were no postoperative complications. The authors concluded that when CD is confined to the appendix the prognosis is very favorable [118].

When considering acute appendicitis in CD patients, it is essential to differentiate between patients admitted to the emergency department with a possible appendicitis who already have been diagnosed with CD and patients who underwent an appendectomy. The histopathology reveals the disease. In a recent study, a group from Seoul analyzed 2179 appendectomies. Among these only 12 (0.55%) were compatible with CD at histology[113]. The 12 patients presented to the emergency department with right lower quadrant pain, abdominal pain, and diarrhea. The duration of symptoms varied from 2 to 5 mo[113]. They did not present systemic manifestations such as uveitis, arthralgia, and arthritis. The histological examination revealed transmural inflammation, lymphoid aggregates, and epithelioid granulomas as peculiar features present in all the cases, followed by appendiceal wall thickening and mucosal ulceration. When the diagnosis is made, the patient must be referred to a tertiary center for future gastroenterology follow-up.

Sometimes the appendix inflammation is consequent/reactive to terminal ileitis in patients affected by CD. Since the acute presentation is like common appendicitis, it is crucial to focus on symptoms like recurrent abdominal pain or diarrhea, lack of fever, weight loss, microcytic anemia, hypoalbuminemia, and hypoproteinemia. In fact, these symptoms are more typical of CD rather than appendicitis. If there is a suspicion of CD, the entire small and large bowel should be carefully examined to verify the presence of the disease and its extent.

In patients with known CD, medical treatment for ileocecal CD is recommended. In fact, if in the rare cases of CD localized only in the appendix, the appendectomy can be performed safely. The clinical scenario is completely different when there is active ileocecal disease. In this situation, there are some issues that need to be considered. The main goal is to avoid an ileocecal resection, when possible, for limiting the unnecessary excision of intestinal segments. An ileocecal resection is the operation of choice in the case of cecum involvement to reduce the risk of leak from the appendix stump and formation of enterocutaneous fistula. Furthermore, if the patient has experienced severe symptoms due to ileitis, an ileocecal resection is the treatment of choice, followed by biologic therapy. Otherwise, the patient will continue suffering CD symptoms with 38% requiring a resection within 1 year. Finally, it is not necessary to remove a macroscopically normal appendix during an exploration for suspected appendicitis if there are findings that raise doubts of CD[119].

ACUTE COLITIS

Toxic colitis represents a potentially fatal condition that may in occur in patients affected by inflam-

matory bowel disease. Studies have demonstrated that as many as 50% of all toxic colitis cases may be secondary to Crohn's colitis[72,120,121]. Diagnostic criteria include: Severe diarrhea (6 or more bloody bowel movements *per* day); temperature higher than 37.8 °C; heart rate > 90 beats/min; anemia (hemoglobin < 10.5 g/dL); an elevated erythrocyte sedimentation rate (< 30 mm/h); hypoalbuminemia (< 3.0 g/L); and leukocytosis (> 10.5 × 10^9 cells/L)[122]. Toxic megacolon is defined when radiographic imaging demonstrating dilation of the transverse colon to at least 6 cm is associated to the previously mentioned criteria[7,72]. Cytomegalovirus infection has been identified in 25% to 36% of patients with steroid-refractory acute colitis. Studies have demonstrated that *Clostridium difficile* infection in the setting of severe or toxic colitis is associated with increased morbidity and mortality.

When toxic colitis is diagnosed, intensive medical therapy should be promptly administered. Intravenous methylprednisolone, 60 mg *per* day, or hydrocortisone, 300 mg, are the medications of choice[123]. Treatment with higher doses of intravenous corticosteroids have not been demonstrated to reduce colectomy rate and should not be considered. In general, a response to steroid therapy includes improvement or resolution of the systemic inflammatory response syndrome and a decrease in stool frequency. In the case of overall clinical improvements over the course of the following 3 d, maintenance therapy could be considered. If there is no response to corticosteroid therapy, rescue therapy is used. Infliximab has now emerged as the most widely used rescue therapy due to its low toxicity, ease of administration, and consequently the possibility to be used for maintenance therapy. One recent literature review demonstrated immediate response rates to infliximab as a rescue therapy agent range between 50% and 83%, with long-term response rates slightly lower at 50% to 63%[124].

Contrarily, in the case of worsening clinical condition or failure to improve, a transition to either rescue therapy or an urgent colectomy should be taken into account. If a patient presents with peritonitis or evidence of free perforation on imaging, surgical exploration is mandatory. Perforation in patients with toxic megacolon is associated with a high mortality rate (27%–57%), regardless of whether the perforation is contained or free[7]. The transverse colon is the area of greatest concern in toxic megacolon. The surgical option of choice is subtotal colectomy with end ileostomy, which allows for future reconstructive options avoiding permanent stoma by ileorectal anastomosis (Figure 2). This could be suggested for patients without rectal or perianal involvement. A total proctocolectomy should be avoided even if total proctocolectomy with permanent stoma is the safest option to avoid further operation in high-risk patients[72] because it is associated with greater postoperative morbidity and mortality due to increased operative time, risk of blood loss, pelvic sepsis, and pelvic nerve damage. The patient typically improves over the ensuing few days. An ileoproctostomy can be recommended 6 mo later in selected patients who demonstrate minimal mucosal inflammation, adequate rectal compliance, absence of significant anoperineal disease, and sufficient sphincter strength[72].

BLEEDING

Gastrointestinal bleeding is a common complication in patients affected by CD. Inflammation/ulceration of the bowel are the basis of its onset. Usually, conservative treatment and endoscopy are sufficient to resolve this condition that rarely requires an emergency surgical procedure. Severe intestinal hemorrhage, on the other hand, is a rare occurrence in CD, with reported incidence between 0% and 6%[125,126]. The underlying pathophysiology of the hemorrhage most often is a result of focal erosion into an intestinal vessel. Due to the infrequency of significant bleeding in CD, as stated before, all common causes of upper and lower gastrointestinal bleeding should be assessed. Localization of the bleeding site is essential regardless of the planned therapy.

Management of gastrointestinal bleeding related to CD begins with hemodynamic assessment. In a stable patient the localization of the lesion could be identify by endoscopy or radiology. Nasogastric tube, in case of hematemesis, should be inserted to protect the airway and decompress the stomach. Gastroscopy could be required to rule out upper gastrointestinal bleeding. If a lower gastrointestinal source is suspected, a retrospective study[127] reported that the detection rate for vascular lesions was higher for colonoscopy following contrast-enhanced CT scan than for colonoscopy alone.

The role of angiography and of angioembolization must be still clarified. Most of the data suggest that angiography/angioembolization could be feasible in stable patients, but further studies are needed to better define outcomes in the emergency setting[7]. The major advantage is that it can control severe bleeding without bowel preparation. Disadvantages include the risk of bowel ischemia and the administration of intravenous contrast. In particular the rate of bowel ischemia following embolization was 1%–4% in recent studies[128].

In the case of hemodynamic instability, resuscitation by intravenous fluid/blood product administration is fundamental aiming to normalize blood pressure and heart rate prior to endoscopic evaluation/intervention. Packed red blood cells should be transfused to maintain the hemoglobin above 7 g/dL. A threshold of 9 g/dL should be considered in patients with massive bleeding, significant comorbidities (especially cardiovascular ischemia), or possible delay in receiving therapeutic interventions[7]. The decision to perform an urgent surgical procedure depends on the bleeding source itself, the hemodynamic condition of the patient, and on the availability/feasibility of less invasive

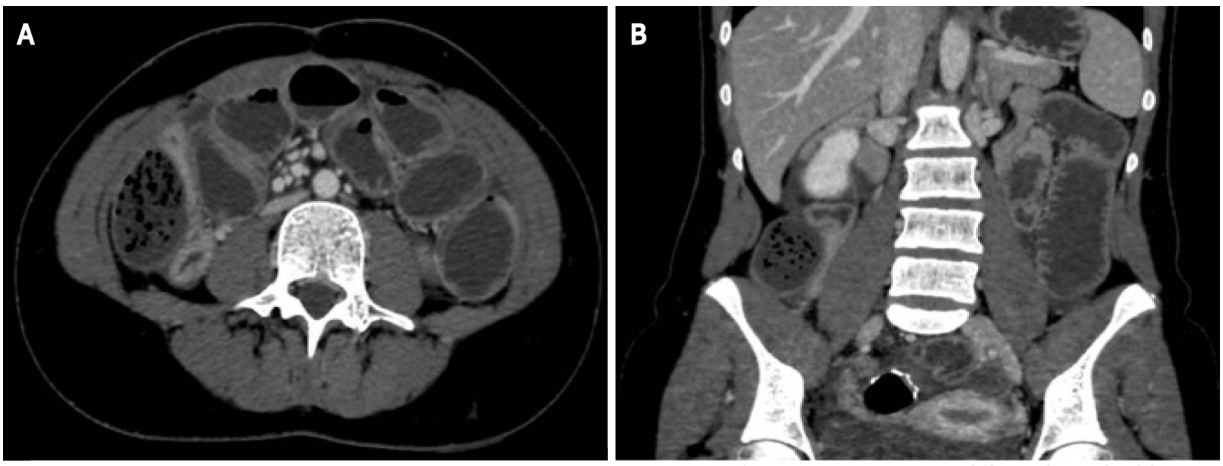
Figure 2 Surgical specimen of total intra-abdominal colectomy in patient with acute colitis.

therapeutic options (*i.e.* endoscopy or angiography). In the case of persistent hemodynamic instability, operative management is necessary. The most challenging situation is represented by patients who have a primary or recurrent hemorrhage without an identifiable source of bleeding. In these cases, the likelihood of successfully eradicating the source of hemorrhage through a "blind" intestinal resection must be weighed against the risk of recurrent bleeding and of creating short bowel syndrome in patients with extensive disease or multiple previous resections.

POSTOPERATIVE RECURRENCE

Postoperative recurrence is the appearance of new lesions after surgery for CD. After the first intestinal resection, 25%-45% of patients are likely to need further operations within 10 years[129]. One year after an initial resection, 60%-80% of patients possess endoscopic recurrence, 10%-20% experience clinical relapse, and 5% demonstrate operative recurrence[130]. Diagnosis of postoperative recurrence is primarily based on clinical symptoms and endoscopic findings. Rutgeerts *et al*[131] developed an endoscopic scoring system to assess endoscopic recurrence (Table 5).

Therefore, ileocolonoscopy is the gold standard to identify the presence and severity of CD recurrence, and it is recommended within the first year after surgery[20]. An emerging and less invasive method to identify postoperative recurrence is the small intestine contrast ultrasonography, which is comparable to ileocolonoscopy to detect lesions related to CD[132]. Fecal calprotectin is another noninvasive diagnostic and monitoring tool because a later correlation was found between endoscopic severity and calprotectin levels[133].



In the last few decades, the risk of major abdominal surgery within the first 5 years of diagnosis has declined, due to the advances in medical treatment of CD. However, there is still a great debate in the literature about risk factors for postoperative recurrence in Crohn's disease (Figure 3). According to the European Crohn's and Colitis Organization guidelines, smoking, prior intestinal surgery, penetrating disease, absence of prophylactic treatment, perianal location, presence of granulomas in the surgical specimen, and myenteric plexitis are considered predictors of early postoperative recurrence after ileocolonic resection[20]. Santiago *et al*[134] identified the presence of colic disease as an independent risk factor for postoperative recurrence and reoperation, while colectomy or proctocolectomy performed during the first surgery have a protective role against reoperation in patients with CD[134]. Liu *et al*[112] in 2020 published a series on the comparison between primary anastomosis and staged surgery in emergency treatment of complicated CD. The results of this study showed a lower surgical recurrence rate for staged surgery, probably linked to the reduction of inflammatory activity when a fecal diversion is performed[112]. A young age, less than 16 years, was identified as another risk factor for repeated abdominal surgery in CD patients by a multicenter study of the Korean Inflammatory Bowel Disease Study Group as well as the presence of stricturing disease behavior[135].

Other recent fields of investigation focus on the role of anastomotic technique in the pathogenesis of postoperative recurrence. In 2014 and 2018, two meta-analyses were performed to define the optimal surgical technique of anastomosis. The conclusions were that stapled isoperistaltic side-to-side anastomosis, because of its larger lumen, can significantly reduce the incidence of postoperative complications and recurrence[136,137]. In 2011, Kono *et al*[138] introduced a new anastomotic technique. The Kono-S is an antimesenteric functional end-to-end hand sewn anastomosis, with the two stumps sutured to create a "supporting column," which allows preservation of the diameter and prevents stenosis and distortion of the anastomosis[138]. The SuPREMe-CD Study, a randomized clinical trial

Table 5 Endoscopic scoring system for postoperative recurrence

Grade	Endoscopic findings
0	No endoscopic recurrence
1	≤ 5 aphthous lesions
2	> 5 aphthous lesions with normal mucosa between the lesions, or skip areas of larger lesions, or lesions confined to ileocolonic anastomosis
3	Diffuse aphthous ileitis with diffuse inflammation of the mucosa
4	Diffuse inflammation with larger ulcers, nodules, and/or narrowing

Modified from Rutgeerts *et al*[131].

that compared Kono-S anastomosis and stapled side-to-side anastomosis, confirmed the reduction of postoperative recurrence when the Kono-S anastomosis was performed[139].

Few studies in the literature analyzed the correlation between emergency surgery for CD and postoperative recurrence. However, emergency surgery would seem to be another independent risk factor for surgical recurrence[140]. Urgent surgery may be related to more aggressive disease, and greater variation in the anastomotic technique in urgent surgery may affect the risk of recurrence[81]. Furthermore, a recent paper highlights that an end-to-end anastomosis is associated with an increased risk of early postoperative recurrence in the subset of patients undergoing an emergency operation as well as smoking and the failure to commence early medical prophylaxis[141].

Another important topic about the risk of recurrence in CD is represented by the role of the mesentery. Patients with CD are characterized by a peculiar form of adipose tissue hypertrophy, known as "creeping fat"[142], which seems to be an independent predictor of early clinical recurrence of CD when there is an advanced mesenteric involvement in the surgical specimen[143]. An international, multicenter, randomized controlled trial by Li *et al*[144] is ongoing to compare conservative limited resection and surgery with mesenteric excision in CD, and its results may provide important insights about the most appropriate surgical technique. One of the most common components of CD that manifests itself after proctocolectomy is the recurrence of disease in the ileostomy or remaining small bowel.

PERIANAL SEPSIS

Perianal fistulas and abscesses are common in CD with an incidence up to 43% and are more frequent in patients with distant colonic or rectal disease[145,146]. They require a multidisciplinary (both medical and surgical) approach to achieve a complete fistula healing and reduce the negative effect on the patient's lifestyle[147,148].

Abscess is a consequence of cryptoglandular inflammation/infection as described by Eisenhammer [149] in 1956 and can be the first sign of CD. It may result in a fistula that is classified based on its

Table 6 Perianal Crohn's disease activity index

Categories affected by fistulas	Score
Discharge	
No discharge	0
Minimal mucous discharge	1
Moderate mucous or purulent discharge	2
Substantial discharge	3
Gross fecal soiling	4
Pain/restriction of activities	
No activity restriction	0
Mild discomfort, no restriction	1
Moderate discomfort, some limitation of activities	2
Marked discomfort, marked limitation	3
Severe pain, severe limitation	4
Restriction of sexual activity	
No restriction sexual activity	0
Slight restriction sexual activity	1
Moderate limitation sexual activity	2
Marked limitation sexual activity	3
Unable to engage in sexual activity	4
Type of perineal disease	
No perineal disease/skin tags	0
Anal fissure or mucosal tear	1
< 3 Perianal fistulae	2
≥ Perianal fistulae	3
Anal sphincter ulceration or fistulae with significant undermining of skin	4
Degree of induration	
No induration	0
Minimal induration	1
Moderate induration	2
Substantial induration	3
Gross fluctuance/abscess	4

Modified from Irvine[151].

location as described by Parks and Gordon[150], in up to 40% of cases. Both abscesses and fistulas are manifestations that can bring the patient to emergency physicians attention (Table 6)[151].

Most patients with a perianal abscess present with pain, swelling, and redness of the interested area. High abscesses also known as supraelevator abscesses do not extend to the more superficial perianal tissues and are not associated to visible and palpable inflammatory signs but more often to systemic signs like fever and malaise[7,149]. If a supraelevator source is suspected, a CT scan or MRI is useful because it gives more information about the abscess extension but also on eventual associated intrabdominal findings[7].

When approaching a patient with a perianal abscess or fistula, the initial goal must be the sepsis control. The early drainage is the only accepted treatment for this purpose, eventually associated to gram negative and anaerobic spectrum antibiotics in patients on immunosuppression and in those with septic shock[152,153]. It is recommended to leave a Petzer or a Malecot catheter in wide ischiorectal abscesses[147,153]. It is better to perform the drainage under general anesthesia, especially if the patient

is in pain, because this will allow a better exploration.

As a result of the inflammation, it could be challenging to find the underlying fistula, and unsuccessful attempts could cause tissue destruction and create an iatrogenic track. There is no evidence to support wound packing following the drainage. Nevertheless, it could have a hemostatic role in the case of bleeding. If the fistula track is evident, a loose draining seton should be inserted. There should be no attempt to lay the fistula open at the same time to preserve future anal function whose damage would negatively impact the patient's lifestyle[153].

In the emergency setting, there is no room for treatment such as fibrin glue, fistula plug, ligation of the intersphincteric fistula tract, advancement flap, and stem cells. These will be considered when the acute process is completely solved. At this point, the patient will be referred to a tertiary center, and a multidisciplinary team will decide the best treatment plan[154]. The work-up will also include a sigmoidoscopy to define if perianal sepsis was associated to an active proctitis[147].

A recent United Kingdom survey summarized the state of the art on acute management of perianal sepsis in CD; 32% of the responding surgeons (133/179) confirmed that they would drain sepsis, 31.1% would consider placement of a seton, and only 0.6% would consider excision of the fistula track. That is in accordance with the previous evidence. When further investigations are needed, MRI is the imaging procedure of choice (96.1%). Most respondents (42.2%) would start antimicrobial therapy preoperatively, and the antibiotic of choice is metronidazole (77.9%). In the case of recurrent sepsis, most respondents created a diverting stoma. In fact, as demonstrated in other studies, it may improve quality of life in patients with severe and recurrent perianal CD[155,156].

CONCLUSION

CD is a chronic and recurrent inflammatory disease that can present with acute complications. The patient's clinical status and assessment of the background disease location and severity must be considered to guide diagnosis and treatment of the acute complications. CD is unremitting and incurable. Therefore, treatment aims to induce a deep and prolonged remission, prevent and address complications of the disease, avoid extensive bowel resections, and improve quality of life. Acute surgical emergencies in patients with CD are associated with a high morbidity and mortality. Although most acute complications of CD are managed nonoperatively, it is important to recognize those that require surgical management.

Abstract

Inflammatory bowel disease (IBD) is a chronic illness characterized by relapsing inflammation of the intestines. The disorder is stratified according to the severity and is marked by its two main phenotypical representations: Ulcerative colitis and Crohn's disease. Pathogenesis of the disease is ambiguous and is expected to have interactivity between genetic disposition, environmental factors such as bacterial agents, and dysregulated immune response. Treatment for IBD aims to reduce symptom extent and severity and halt disease progression. The mainstay drugs have been 5-aminosalicylates (5-ASAs), corticosteroids, and immunosuppressive agents. Parenteral, oral and rectal routes are the conventional methods of drug delivery, and among all, oral administration is most widely adopted. However, problems of systematic drug reactions and low specificity in delivering drugs to the inflamed sites have emerged with these regular routes of delivery. Novel drug delivery systems have been introduced to overcome several therapeutic obstacles and for localized drug delivery to target tissues. Enteric-coated microneedle pills, various nano-drug delivery techniques, prodrug systems, lipid-based vesicular systems, hybrid drug delivery systems, and biologic drug delivery systems constitute some of these novel methods. Microneedles are painless, they dislodge their content at the affected site, and their release can be prolonged. Recombinant

bacteria such as genetically engineered *Lactococcus Lactis* and eukaryotic cells, including GM immune cells and red blood cells as nanoparticle carriers, can be plausible delivery methods when evaluating biologic systems. Nano-particle drug delivery systems consisting of various techniques are also employed as nanoparticles can penetrate through inflamed regions and adhere to the thick mucus of the diseased site. Prodrug systems such as 5-ASAs formulations or their derivatives are effective in reducing colonic damage. Liposomes can be modified with both hydrophilic and lipophilic particles and act as lipid-based vesicular systems, while hybrid drug delivery systems containing an internal nanoparticle section for loading drugs are potential routes too. Leukosomes are also considered as possible carrier systems, and results from mouse models have revealed that they control anti- and pro-inflammatory molecules.

Key Words: Inflammation; Inflammatory bowel diseases; Colitis; Ulcerative; Crohn's disease; Drug delivery systems; Drug carrier

Core Tip: Current literature on novel drug delivery systems is extensive. However, limited content is available that focuses on the novel drug delivery strategies, focally the enteric-coated microneedles pills and biological drug delivery systems. In our review, we discuss multiple novel approaches comprehensively, after outlining the disease course in inflammatory bowel diseases (IBD) and how the conventional routes of drug administrations are deficient in addressing some aspects of disease treatment. We specify that novel carrier systems can be considered for targeting inflamed sites in IBD and discuss the implications of choosing such routes.

INTRODUCTION

Inflammatory bowel disease (IBD) is chronic, relapsing intestinal inflammation[1]. The disorder is most common in Western industrialized countries[2] and is mainly characterized by the two idiopathic phenotypes of IBD; Ulcerative colitis (UC) and Crohn's disease (CD)[3]. The illness can be classified as mild, moderate, or severe based on clinical, para clinical parameters and symptoms such as abdominal spasms, rectal bleeding[4]. Intestinal and extraintestinal complications also manifest in the disease[2], and IBD is known to significantly affect the quality of life of the patients[4].

The main aim of IBD treatment is to ameliorate patients' quality of life[5] by diminishing the extent and symptoms of intestinal inflammation[3], revitalizing nutrition lost, assisting psychosocially, and altering disease course in those undergoing severe forms[5]. Therapy is decided after determining the type of disease and site involved[3]. Routine treatment options for mild attacks include 5-aminosalicylates (5-ASA) such as mesalazine or olsalazine, while for moderate to severe IBD, corticosteroids are prescribed. Probiotics, antibiotics, chemically modified drugs, enzymatic, prodrug therapy, enteric-coated drugs can be used in the early stages, too[5]. For severe disease stages, immunosuppressive agents like azathioprine and anti-TNF-α-antibodies are specified[2]. Surgery is performed in the refractory or fulminate disease stages[2] and is reported to be required by 30%-40% UC and all CD patients at least once in a lifetime[3].

The IBD medication administration's modes are the conventional parenteral, peroral, and rectal routes[2], while the peroral route is most preferred, indicated for targeting the colon[3]. However, there is variable intestinal absorption *via* this route, and treating intermittent inflamed areas is challenging by oral drug delivery systems[2]. Systematic drug reactions by absorption of luminal released active agents through the healthy and inflamed mucosal wall into systematic circulation, inability to deliver to an affected gastrointestinal section only[2] and the reliance of the conventional delivery systems on unstable parameters such as intestinal motility, time, pH, and microbial and enzymatic degradation for optimal drug delivery[5] have rendered these standard methods unsatisfactory.

To balance therapeutic efficacy and risk of adverse side effects[2], novel drug delivery systems have been suggested that provide a more localized delivery and circumvent unnecessary drug exposure[6]. Inspired by the German physician Paul Ehrlich who first proposed drug targeting of active agents to pathogenic or cancerous cells while preventing side effects, the new synthetic/biologic drug delivery

systems known[2] incorporate liposomes, solid lipid nanoparticles, nanostructured lipid carriers, nano emulsions, hydrogel, and eukaryotic systems *via* resealed erythrocytes, macrophages, prokaryotic cells such as bacterial capsules[5]. These innovative approaches minimize drug loss, increase drug bioavailability[5], increase the local concentration of drugs at inflamed tissue and increase patient's compliance lowering the frequency of drug intake[2]. This review presents an overview of enteric-coated microneedle pills, nano-drug delivery systems, including size-mediated targeting, surface-charged targeting, redox-mediated targeting, and ligand-mediated targeting techniques. Furthermore, prodrug delivery systems, lipid-based vesicular delivery systems, hybrid drug delivery systems, and biologic drug delivery systems are also discussed. All that is being seen as a more disease-oriented[2] approach for restoring gut homeostasis in IBD.

PATHOLOGICAL MECHANISM OF IBD

In IBD, the intestinal barrier is disrupted, characterized by a reduced number of secretory cells, which lead to a decrease in antimicrobial secretion, and a loss of epithelium. A decrease in goblet cells at the inflamed site causes a reduction in mucus. Bacteria from the lumina side and immune-related cells infiltrate the mucosa and constitute the pathophysiological state in IBD[2]. The two main phenotypes of IBD are UC and CD, respectively. Inflammation in UC is superficial, limited to the colon. The disease starts in the rectum and extends continuously through the colon. The extent of colonic involvement defines disease distribution; proctitis to left-sided colitis or extensive colitis (pancolitis)[7]. In CD, the inflammation extends to the serosa. The disease is transmural and is found anywhere along the gastrointestinal length, mostly the ileum and colon. Endoscopy reveals mucosa's "sandpaper" appearance in UC, while in CD, the mucosa is cobblestone[8]. The etiology of IBD is unknown, and the interaction of genetic disposition with environmental factors in the microbiome leads to improper immune activation resulting in clinical presentation observed in IBD[9].

Rare genetic variants have been identified in early onset and severe IBD patients indicating a relation with pathways leading to intestinal inflammation. Genome-wide association studies have also identified 201 Loci implicated in IBD[9]. NOD2 is the first gene associated with IBD[9], and is related to CD susceptibility[3]. Environmental agents can trigger IBD in genetically susceptible individuals; medications can alter the intestinal microbiome, which is linked with an increased risk of developing IBD. An increase in bacteria with inflammatory potentialities and a decrease in anti-inflammatory bacteria are reported[9]. Mucolytic bacteria are also found to be increased in the intestine[9]. A dysregulation between anti and pro-inflammatory signals, causing migration of leukocytes to the intestinal mucosa exacerbated by an enhanced T-cell immune response, is noted in UC and CD[9]. Th-2 cell response is dominant in UC and antibodies recruitment. IL-5 is also elevated in UC. However, antigens eliciting the response are not known[3]. Moreover, a Th-1 inflammatory response is signified in CD, resulting in granulomatous inflammation with increased levels of proinflammatory cytokines such as IFN-γ, IL-2, and TNF-α. Suppressor cytokines produced by T regulatory cells are reduced[3].

ENTERIC-COATED MICRONEEDLE PILLS

Microneedle pills were first considered as a fix to deliver drugs through the transdermal system in 1998 [10]. Increasing the permeability of the human skin, a painless drug delivery system was formulated. However, the lack of stratum corneum in the GI tract established a strong case for microneedles in oral delivery. Coated microneedles provide extended controlled release reducing the required dosage frequency of many medications[11]. An ingestible microneedle pill for adalimumab, a tumor necrosis factor blocker, developed by Rani Therapeutics LLC[12] demonstrated a higher serum adalimumab concentration for the first eight hours to its administration as compared to the subcutaneous route.

Microneedles are either solid or hollow with the biologics contained in the reservoir, released upon breach of the mucosal lining of the GI tract. Microneedles are prepared using biodegradable polymers and coated by a pH-resistant coating to withstand the acidic range of pH of the gut[13]. Following ingestion, microneedles travel to the required location and spill their contents upon peristalsis and or penetrate the tissue and break off in hollow and solid microneedles, respectively[13].

The retention time of the microneedles was seven days at the minimum in a study[13], with no tissue damage reported. The safety profile and the extended retention warrants its potential use as a drug delivery system in IBD. However, patient-to-patient variation in intraluminal pressure presents a significant challenge along with the impact of food in the GI tract on the efficacy of the drug delivery system[14].

NANOPARTICLE DRUG DELIVERY SYSTEM

Size-mediated targeting

Size-dependent targeting is the most common mechanism for NPs drug delivery systems targeting the inflamed colon. During inflammation, enhanced permeability and retention (EPR) is observed, which increases penetration of nano-particles in the inflamed regions[15-18]. Furthermore, increased secretion of mucus leads to a thick mucus layer which increases the probability of adhesion of nanoparticles[19, 20]. The size of mucous fiber networks varies from 10-200 nm; hence modifying the particle size to nano-formulations assists in movement inside the fiber network[21-24]. It is reported that diarrhea affects particles > 200 μm, which are subsequently washed away[25] whereas, neutrophils, macrophages, M cells, and enterocytes rapidly internalize particles < 500 nm *via* the process of transcytosis[26]. Lamprecht *et al*[27] compared fluorescent polystyrene particles of sizes 10 mm, 1 mm, and 100 nm following oral gavage among healthy and trinitrobenzene sulfonic acid (TNBS)-induced colitic rats. The 100 nm formulation displayed the greatest bio adhesion to the inflamed colon compared to healthy rats. Another study done on oxazolone-induced colitis in mice reported that budesonide-filled poly lactic-co-glycolic acid (PLGA) NPs of size 200 nm accumulated at the inflamed colon[28]. Similarly, Nagasaki's group[29,30] developed a nanoparticle sized 40 nm (RNP O), which localized in the inflamed colonic mucosa, and reduced inflammation by consuming the excessive ROS. The increased epithelial enhanced permeability and retention (epEPR) during inflammation leads to increased uptake of NPs and prolongs the retention time[31]. This consequently leads to the accumulation of drugs and increased efficacy. Another study investigated the penetration of fluorescently labeled PLGA particles, sized 250 nm and 3 nm, into rectal mucosa in healthy and IBD human subjects. They reported that significantly more 3 nm particles were found accumulated in the mucosal surface, while most of the 250 nm particles had penetrated inside and translocated to the serosal surface[32]. The probability of systemic absorption increases with smaller particles and could lead to adverse side effects. This difference in the behavior of NPs accumulation in humans and rodent colitis models requires further studies to reach a definite conclusion.

Surface-charge targeting

The surface charge of the nanoparticles can be altered to control interaction with the colonic mucosa to increase the efficacy of the drug delivery system. The colonic mucosa comprises negatively charged carbohydrates molecules, sulfates, sialic acid, and colonic mucins, which enable the positively charged NPs to adhere to the mucosal surface due to electrostatic interaction. In a study, clodronate loaded nanoparticles based on cationic polymethacrylate (Eudragit RL) and free clodronate were administered in mice induced with 2,4,6-TNBS and oxazolone colitis. A significant reduction in myeloperoxidase activity was observed in colitis-induced mice models, whereas free clodronate failed to produce ameliorating effect[33]. In an *ex vivo* study, Lautenschlager demonstrated that cationic chitosan modified PLGA nanoparticles adhered to intestinal mucosa[34]. However, the cation became immobilized after attaching to the mucosa, which led to a premature release of the drug. This was due to the strong electrostatic attraction experienced by the negatively charged mucosa[34]. In comparison, negatively charged NPs precisely attach to specific positively charged proteins and show greater penetration into the intestinal mucosa. During the inflammatory process of colonic mucosa, the epithelium is damaged, and positively charged proteins such as transferrin and eosinophil cationic proteins accumulate[35,36]. This enables nanoparticles with the negative surface charge to adhere to the positively charged mucosal surface due to electrostatic interaction. Jubeh *et al*[37] studied the varied adhesion of anionic, neutral, and cationic liposomes in healthy and inflamed colon explants from rats inflicted with DNBS colitis. They reported that anionic liposomes were 2-times more likely to adhere to the inflamed mucosa than neutral or cationic liposomes. In healthy colonic mucosa, the cationic liposomes displayed preferential binding, which was 3-fold higher than neutral or anionic liposomes[38]. Similarly, Beloqui *et al*[39] reported that negatively charged NPs, comprised of budesonide, invaded deeper into mucosa in the colitis group while staying on the mucosal surface in a healthy cohort.

Redox-mediated targeting

Endogenous ROS are produced because of the physiological metabolism of oxygen. In patients suffering from IBD, increased production of ROS is observed, which is localized to the site of inflammation and correlated with disease progression[40,41]. This increase is due to the inflammatory cells present in the intestinal mucosa[42]. Subsequently, redox-dependent nanoparticle drug delivery systems have emerged[43,44]. Zhang *et al* developed oxidation-sensitive β-cyclodextrin material (OxβCD), which was loaded with Tpl. This drug delivery system could successfully consume ROS and mitigate symptoms in 3 mouse colitis models[45,46]. Sun *et al*[47] synthesized redox-sensitive NPs composed of carboxymethyl inulin. The NPs accumulate in the inflamed regions of the intestine. Vong *et al*[30] developed NPs composed of nitroxide radicals (RNPo), which exhaust the ROS in the inflamed gut regions and thereby reduce inflammation. The group of mice treated with oral RNPo for one week showed reduced disease activity compared with the group administered mesalamine[30]. Li *et al*[48] synthesized Ac2-26-encapsulated nano therapy using OxβCD. This drug delivery system is ROS-responsive and stimulates

the release of Ac2-26 in response to increased ROS concentration in GIT.

In conclusion, since a high concentration of ROS is found in the inflamed regions of GIT[42], redox-dependent targeting *via* NPs may produce beneficial results. However, volatility in low pH, high enzyme environment, and rapid drug release hinder the use of redox-mediated drug delivery systems.

Ligand-mediated targeting

Under inflammatory processes, ligand-dependent NPs have shown to be a precise method of drug localization, minimal side effects, and increased therapeutic efficacy[49]. Overexpression of inflammatory markers on cell surface provides molecular targets for anchoring NPs[50,51]. PLA NPs, which carry CD98 Fab antibodies, and chitosan/polyethyleneimine NPs modified with CD98 antibody were developed to treat mice with colitis. During inflammation, cells in colonic mucosa overexpress CD98 glycoprotein, which becomes the target of action for the ligand-modified NPs[52,53]. Similarly, mannose receptors are overexpressed on macrophages, which are targeted by mannosylated poly (amido amine)-modified NPs[54]. Moreover, increased expression of CD44 is observed in the macrophages and inflamed epithelial cells during colitis[55-57]. Hyaluronic acid can attach to CD44; hence, HA-modified NPs have been developed and tested successfully in mice with UC[58]. Increased expression of folate receptors has also been observed during inflammation[59-61]. Naserifar *et al*[62] successfully demonstrated the efficacy of oral administration of folic acid conjugated PLGA NPs loaded with resveratrol in TNBS rats.

Besides overexpression of ligands/receptors on colonic epithelial cells, endothelial adhesion molecules (ECAMs) are also upregulated. Vascular adhesion molecules-1 are ECAMs against which polylactic acid (PLA)-PEG particles modified with monoclonal antibodies have been developed. The drug delivery system showed increased adhesion to the endothelium in dextran sodium sulfate (DSS)-induced colitis[63]. In conclusion, ligand-modified NPs promise to be a potential alternative for targeted drug delivery in cases of IBD. However, concerns regarding IV administration, antibody precipitated immune reaction, ligand instability inside GIT hamper its utilization.

PRODRUG

In prodrug systems, a pharmacologically active agent is protected in a temporarily inactive form that gains bioactivity on exposure to enzymes overexpressed in inflammatory tissues. This allows drug delivery to specific sites[64]. Several 5-ASA formulations have been used as prodrugs for selective delivery to the colon, azo conjugates being the most common and effective[65]. Many 5-ASA derivates were also shown to be transportable substrates for Intestinal H+-coupled oligopeptide transporter 1, the expression of which is increased in chronic inflammatory conditions such as IBD[66]. Furthermore, a synthetic prodrug of 4-ASA, an isomer of 5-ASA, was prepared and shown to be suitable for the treatment of colon inflammatory diseases[67]. To reduce endoplasmic reticulum (ER) stress, an aggravating factor for IBD, Kim *et al*[68] synthesized prodrugs for 4-phenyl butyric acid, which effectively reduced the colonic damage and inflammation in a rat colitis model. Moreover, Shen *et al*[69] designed a novel pH/reactive oxygen species (ROS) dual-responsive prodrug micelle GC-B-Que. In his vivo experiments, he found that the GC-B-Que micelles tended to accumulate in sites of inflammation within the intestine and showed better therapeutic efficacy than free drugs[69]. Using a prodrug approach for management of IBD allows accumulation of drugs at sites of inflammation, avoiding unwanted side effects on healthy intestinal tissue.

LIPID-BASED VESICULAR DELIVERY SYSTEM

Liposomes are lipid bilayer vesicles that consist of an aqueous core. They can carry both hydrophilic and lipophilic drugs[70]. For use as a drug delivery system for IBD, liposomes can be modified with lactoferrin which can specifically bind to low-density lipoprotein receptor-related protein that is expressed on the inflammatory macrophages. Zhao *et al*[71] designed a lactoferrin-modified liposome (LF-lipo) for delivering patchouli alcohol to colonic macrophages for anti-inflammatory activity. The results showed decreased disease activity index and body weight loss in DSS salt -induced colitis mice. In another study, an oxymatrine loaded, nitric oxide releasing liposome, tested in DSS-induced ulcerative colitis mice, was shown to significantly alleviate inflammation. Moreover, the results also revealed that liposomes could accumulate in the inflammatory colon efficiently and can be maintained for more than 36 h[72]. Furthermore, in an *in vivo* experiment, curcumin-loaded liposomes (CUR-LPs) were shown to allow sustained release of CUR in the simulated gastrointestinal tract, attenuate the clinical symptoms of ulcerative colitis and prevent DSS-induced colon tissue damage and colon shortening[73]. Liposomes have also been loaded with heparin for intrarectal delivery in the form of enema, which has demonstrated dose-dependent anti-inflammatory activity *in vivo*[74]. Krill oil incorporation into liposomes has demonstrated a high capacity to entrap the IBD drug budesonide, and

results of an *in vitro* study indicate that using KO liposomes as an IBD drug carrier may yield increased drug accumulation in the inflamed intestinal region[75]. Keratinocyte growth factor (KGF), previously shown to be an effective drug for ulcerative colitis, faces several obstacles for clinical such as poor stability, short half-life, and easy degradation; therefore, liposomes were considered as a potential delivery system. KGF was encapsulated into liposomes (KGF-Lips), and neutrophil membrane vesicles were then inlaid in KGF-Lips to construct a neutrophile-like liposome (KGF-Neu) which was shown to significantly improve the chemical stability of KGF[76]. Anemia is frequently seen in patients with IBD, which is responsible for a significant loss of quality of life. Treatment with oral liposomal iron was shown to be effective in improving mild iron deficiency anemia and quality of life, as well as in decreasing fatigue in patients with inactive or mildly active IBD[77].

HYBRID DRUG DELIVERY SYSTEMS

Although difficult to prepare, hybrid drug delivery systems hold great promise as they integrate the advantages of several different carriers into one. An external compartment is used to protect drugs from gastric degradation and denaturation at low pH, and the internal section of NPs is developed for loading drugs[78]. Kotla *et al*[79] fabricated hyaluronan (HA) functionalized polymeric nano-drug delivery system (Cur-HA NPs) using curcumin as a model fluorescent drug. HA functionalization was shown to increase cellular interaction and uptake following the use of Cur-HA NPs on colon epithelial-like (HT-29) monolayers cell cultures indicating that this system is effective for oral delivery of drugs to treat local colonic disease[79]. Furthermore, encapsulation of curcumin with bovine b-lactoglobulin has been shown to increase its aqueous solubility, and encapsulation with succinylated- b-lactoglobulin prevented its release when subjected to gastric fluids[80]. In another study, Zhang *et al*[81] developed a phospholipid vesicle co-hybridized with HA and ethanol (HA-ES) for transdermal delivery of eugenol (EUG)/cinnamaldehyde (CAH). Results of the subsequent study showed that HA-ES as carriers effectively improved the percutaneous absorption of EUG and CAH in a rat ulcerative colitis model[81]. To improve the colon targeted oral delivery of Berberine, Zhang *et al*[82] designed a micro-and nano-encapsulated hybrid delivery system, which resulted in significant alleviation of acute colitis in a DSS induced colitis mice model. To overcome limitations faced by nanoparticle systems, Naeem *et al*[83] developed a "nanoparticles-in-enteric microparticles" (NPsinMPs) system. A (PLGA) polymer-based NP system was encapsulated in pH-sensitive Eudragit FS30D microparticles. NPisMPs provided complete protection of NPs in both gastric acid and intestinal-like pH. Moreover, NPs, after releasing from NPsinMPs, accumulated in the inflamed colon of mice after oral administration and significantly alleviated murine experimental colitis when compared to the bare nanoparticle[83].

BIOLOGICAL DRUG DELIVERY SYSTEMS

Apart from maintaining intestinal homeostasis and synthesizing bile acids[84], bacteria could also be used as a potential delivery system in IBD. Recently, scientists ventured to use bioengineered bacteria as a delivery system of therapeutics in various diseases[85]. *Lactococcus Lactis (L. Lactis)* was the front runner in the race of effective biological vectors. *L. Lactis* is present in abundance in plants in an inactive state, gaining the active status in the gut of ruminants[86].

In 2006, genetically engineered *L. Lactis* was graded safe as a drug delivery system[87]. Due to the immunomodulatory functions of *L. Lactis*, its use as a vector to transport cytokines has been reported in numerous studies. One of the first applications of genetically modified (GM) *L. Lactis* in mice to produce interleukin-10 (IL-10) for IBD treatment was reported in 2000[88]. In 2003, recombinant *L. Lactis* strain labeled Thy12 successfully produced IL-10 in pigs[89].

A phase I clinical trial aimed to treat CD patients with genetically engineered *L. Lactis*. The results backed up its safety profile and solidified the effectiveness of the containment strategy[90]. In another study, orally administered *L. Lactis* was seen to ameliorate inflammation of the colon in mice by delivering anti-murine TNF nanobodies to the inflamed site[91]. Similarly, a study of mice with induced colitis showed mitigation of the disease upon application of *L. Lactis* carrying the anti-TNF scFv expression vector[92]. In a 2020 study of a DSS induced colitis mouse model, inflammation was seen to be reduced by blocking the IL-1 signaling using genetically modified Lactic acid bacteria (gmLAB)[93].

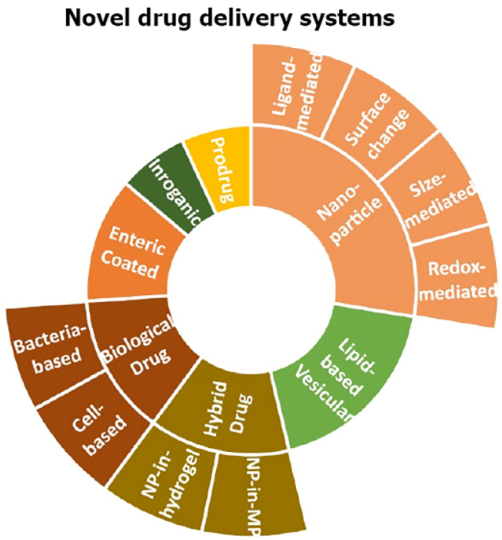
These studies show the therapeutic nature of recombinant bacteria as a vector in the treatment of IBD. *L. Lactis* is demonstrated to be safe and potent in inducing anti-inflammatory effects. However, studies should investigate further into the risk of unintended transgene escape, and focus attempts must be made to develop various other anti-inflammatory substances by *L. Lactis*[89].

Apart from bacteria, eukaryotic cells can be utilized as a delivery system of therapeutics for IBD. GM immune and red blood cells (RBCs) are used as nanoparticle (NP) carriers *via* injection from these cells. Endothelial cells in blood vessels present as a barricade in the route of NPs to their target destination. In a study of a mouse model of acute inflammation, activated neutrophils took up intravenously administered NPs and crossed the barrier into the inflamed tissues[94]. This study highlighted the

ability to "hijack" neutrophils to transport NPs to the diseased site.

Another study by Corbo *et al*[95] implemented the mechanism of α4β7 integrins, which promote entry of T cells to intestinal sites[96]. The study employed this principle to investigate the effect of specialized leukosomes (SLKs) in alleviating inflammation in mice models of IBD. SLKs were associated with modulating both pro and anti-inflammatory molecules. Immune cells are presumably blocked by SLKs, as indicated by the reduction in CD45+ cells in the colon of mice treated with SLKs. However, further studies must be initiated examining the mechanism of functioning of SLKs in-depth. Furthermore, a risk-benefit analysis must be conducted to assess its safety.

Similarly, RBCs are increasingly being popular based on their high bioavailability in blood. Due to the rapid clearance of NPs in blood, a study successfully reported a novel method of adhering them to circulating RBCs to enhance their vascular circulation[97]. A clinical trial by Castro *et al*[98] assessed the impact of autologous RBCs loaded with dexamethasone 21-Phosphate (Dex 21-P) on children with steroid-dependent Crohn's disease. During treatment, the pediatric Crohn's Disease Activity Index was sufficiently reduced, and 78% of the patients stopped taking steroids. Overall, 44% showed remission, indicating the safe and efficacious nature of RBCs laden with Dex 21-P. Another study corroborated these findings as steroids were withdrawn entirely in all the patients and were in clinical remission after three infusions[99]. Further large-scale controlled studies should examine the safety and potency of this therapy in IBD patients. In future studies focus should be on the delivery of drugs directly to the inflamed sites and on the concentration of dexamethasone to increase the bioavailability.



DISCUSSION

Various nanoparticle drug-delivery systems exist. Size-dependent is the most popular mechanism. During inflammation, increased permeability, and retention (EPR) and enhanced mucosal secretions lead to increased efficacy of size-dependent targeting. However, systemic absorption of nanoparticles could lead to adverse side effects, which require further investigation. In addition to size, the surface charge of nanoparticles can also be modified to increase effectiveness. Due to electrostatic attraction, positively charged nanoparticles can adhere to the negatively charged colonic mucosa.

Moreover, redox-dependent nanoparticles use the increased amounts of ROS produced by intestinal mucosal cells during inflammation. However, volatility in low pH and quick drug release limit their use. Lastly, ligand-dependent NPs precisely target colonic mucosa with increased efficacy. NPs attach to the inflammatory markers' ligands/receptors and ECAMs on the cell surface. A ligand-dependent deliveries system is a promising alternative; however, the concern of antibody precipitated immune reaction and instability inside GIT warrants further investigations. The existing targeted novel drug delivery systems are illustrated in Figure 1.

CONCLUSION

In our review, we divulged several drug delivery systems that have been under investigation in previous studies. These carrier systems were found to be potential options for drug delivery, with enteric-coated microneedles and recombinant bacteria termed safe upon use, while further analysis needs to be undertaken to assess the reliability of eukaryotic cells as delivery systems. Due to increased epithelial permeability and retention, Nanoparticles are well-absorbed in inflamed mucosa and have shown to be efficacious. However, accumulation of NPs might be observed that requires further study. Redox-dependent nanoparticle drug delivery systems have also emerged, such as NPs composed of nitroxide radicals (RNPo), which have successfully reduced inflammation by exhausting ROS, but their utilization might be limited due to factors such as rapid drug release. Ligand-depending NPs are efficient localized treatment, and HA-coated NPs and folic acid conjugated PLGA NPs loaded with resveratrol in TNBS have shown positive results in animal models. 5-ASA formulations, its isomers comprise some of the prodrug systems well in practice, and a novel pH/ROS dual-responsive prodrug micelle GC-B-Que has been found to display high therapeutic efficacy. Liposomes modified with lactoferrin, CUR-LPs, and heparin loaded liposomes are lipid based vesicular systems that have been anti-inflammatory. Importantly, oral liposomal iron is advantageous in alleviating anemia often observed in IBD patients. Hybrid methods of drug delivery have been proven to be effective in alleviating colitis across various studies. Leukosomes as carrier systems have also been found to be effective in mediating inflammatory response in IBD, but more clinical trials involving human subjects are warranted. Conventional drug delivery systems have certain caveats associated with their use, and novel drug delivery systems are being resorted to avoiding the adverse outcomes reported with the former routes; however, more research is needed to substantiate the efficacy of the novel carrier systems. Overall, given the challenge of delivering a drug to the inflamed site in IBD and the unique presentations of the disease in various patients, the new strategies can be instrumental in improving disorder symptoms and disease course.

Abstract

The immune system plays a vital role in maintaining the delicate balance between immune recognition and tumor development. Regardless, it is not uncommon that cancerous cells can intelligently acquire abilities to bypass the antitumor immune responses, thus allowing continuous tumor growth and development. Immune evasion has emerged as a significant factor contributing to the progression and immune resistance of pancreatic cancer. Compared with other cancers, pancreatic cancer has a tumor microenvironment that can resist most treatment modalities, including emerging immunotherapy. Sadly, the use of immunotherapy has yet to bring significant clinical breakthrough among pancreatic cancer patients, suggesting that pancreatic cancer has successfully evaded immunomodulation. In this review, we summarize the impact of genetic alteration and epigenetic modification (especially histone deacetylases, HDAC) on immune evasion in pancreatic cancer. HDAC overexpression significantly suppresses tumor suppressor genes, contributing to tumor growth and pro-

gression. We review the evidence on HDAC inhibitors in tumor eradication, improving T cells activation, restoring tumor immunogenicity, and modulating programmed death 1 interaction. We provide our perspective in targeting HDAC as a strategy to reverse immune evasion in pancreatic cancer.

Key Words: Histone acetylation; Histone deacetylases inhibitors; Immune evasion; Pancreatic cancers; Pancreatic ductal adenocarcinoma

Core Tip: There are several broad reviews covering histone deacetylases (HDAC) in cancer but none on its role in modulating immune evasion in pancreatic cancer. This is the first review to discuss the role of HDAC in the context of immune-evading pancreatic cancer. We also summarize the evidence of HDAC inhibitors in targeting immune-evading pancreatic cancer. This mini review also covers our perspective in the strategies to target overexpression of HDAC in pancreatic cancer.

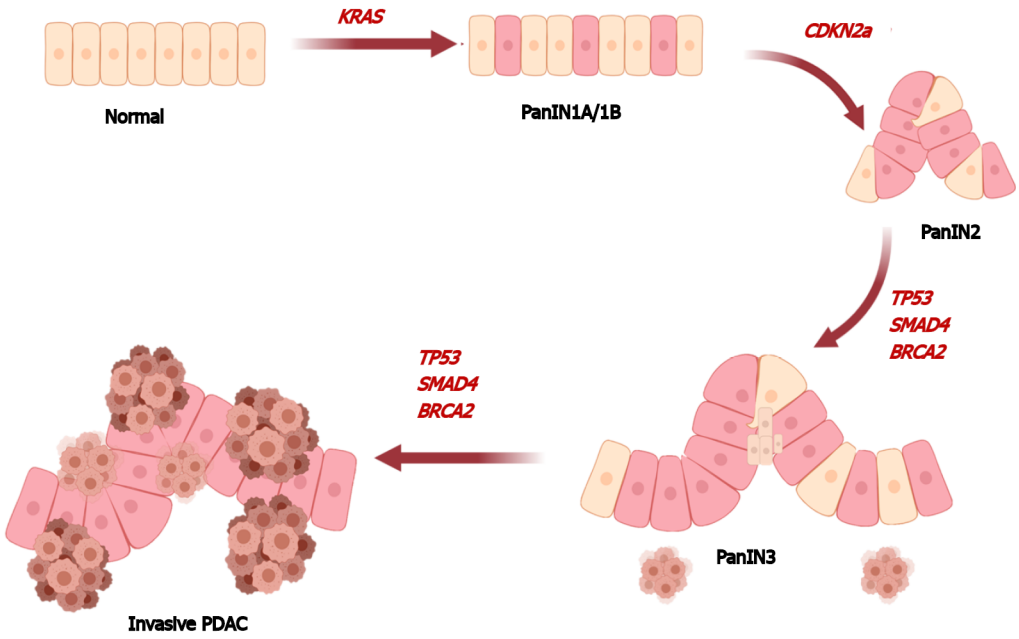
INTRODUCTION

Pancreatic cancer is the seventh most common cause of cancer-related deaths worldwide[1]. Pancreatic ductal adenocarcinoma (PDAC) is the most ubiquitous type of pancreatic cancer and remains incurable for 95% of patients. Pancreatic cancer is characterized by a devastating prognosis, with the lowest overall 5-year survival rate among all cancers[2]. The average survival time for pancreatic cancer is less than six months if left untreated[3]. Pancreatic cancer is thus estimated to be the second leading cause of death in the United States by 2030[3].



The dismal prognosis of PDAC is partly contributed by the lack of early clinical symptoms and poor sensitivity of PDAC diagnostic tests. Moreover, the treatment modalities available to date are generally ineffective for management of PDAC. Currently, the mainstay treatment for PDAC is surgery but only approximately 10% of PDAC patients qualify for surgical resection upon diagnosis[4]. Among the patients who undergo surgical resection, only < 25% could survive for more than five years. Besides, chemotherapeutic strategies have been exhausted in PDAC treatment, in which the use of chemotherapy has been limited by its well-established low efficacy, high toxicity and drastic decline in quality of life [5]. As a result, the search for an effective treatment regimen for PDAC remains a significant challenge.

Recently, immunotherapy has been hailed as a breakthrough in the realm of cancer therapy, which warrants further exploration for PDAC treatment. The use of immunotherapy in PDAC, however, is largely limited by its immune evasion barrier[6]. Thus, understanding the diverse mechanisms underlying the immune evasion in pancreatic cancer may empower the search for methods to tackle and prevent the bypass of immune surveillance[6,7].

GENETIC ALTERATION IN PDAC POTENTIATES ITS IMMUNE EVASION CAPABILITY

PDAC is an exocrine pancreatic cancer derived from pancreatic ductal cells. The progression to PDAC is characterized by its transition from normal pancreatic ductal cells to pancreatic intraepithelial neoplasia (PanIN) or its precursor lesions[8]. PanIN may be differentiated into three grades based on its histological or architectural changes[8]. PanIN1A and PanIN1B are characterized by the low-grade dysplasia while PanIN2 is characterized by the loss of polarity, nuclear crowding, enlargement of cell, and its typical papillary development. PanIN3 represents mature lesions with drastic nuclear aberrations, luminal necrosis, and show epithelial cell budding into the ductal lumen[8]. High-grade PanIN is almost uniquely found in invasive PDAC[8]. These precursor lesions develop into invasive PDAC following the accumulation of genetic mutations (Figure 1). Pertinent genetic alterations include *KRAS* oncogene mutation, the initiating genetic event in PDAC, followed by the loss of function in essential tumor suppressor genes such as *CDKN2a*, *TP53* and *SMAD4* (Figure 1).

KRAS oncogene mutation is found in nearly all PDACs[9]. High expression of the mutated *KRAS* is also associated with poor prognosis[9]. The *KRAS* GTPase switches between being bound to guanosine

DOI: 10.3748/wjg.v28.i18.1934 **Copyright** ©The Author(s) 2022.

Figure 1 Association of common genetic alterations and pancreatic ductal adenocarcinoma pathogenesis. The progression from the early to invasive stage of pancreatic ductal adenocarcinoma (PDAC) is supported by different genes alteration at different stages. *KRAS* mutation transforms the normal pancreatic ductal cells to pancreatic intraepithelial neoplasia (PanIN). The PanIN1A, PanIN1B and PanIN2 are low grade PanIN. Additional mutation such as *CDKN2A* is required to develop PanIN2. As the disease deteriorates, additional genes mutation such as *TP53*, *SMAD4* and *BRCA2* are involved to develop high grade PanIN3 and eventually invasive PDAC. PDAC: Pancreatic ductal adenocarcinoma. The figure in this review paper is created by using BioRender.com by the authors.

diphosphate, GDP (inactive state) and being bound to guanosine triphosphate, GTP (active state)[10]. In cancer development, missense mutations cause RAS to be persistently bound to GTP allowing an unlimited cellular proliferation. The alteration of *CDKN2a* results in unimpeded G1/S transformation and unrestrained cell division, facilitating tumor to evade host immunomodulation[11]. As expected, PDAC patients with *CDKN2a* inactivation are associated with poor overall survival and prognosis[11].

The metastasized tumors also exhibit several genetic alterations, namely *TP53*, *BRCA2* and *SMAD4*, indicating that these tumors have successfully evaded host immunosurveillance by leveraging on these genetic alterations[12-14]. *TP53* tumor suppressor gene on chromosome 17p is often mutated in cancer [15]. Up to 75% of PDACs present with loss or mutation of *TP53* expression[15]. The loss of *TP53* gene expression decreases cell cycle arrest and apoptosis, allowing for damaged DNA to replicate and aggregate genetic alterations. Accumulation of *TP53* mutants significantly increases the incidence of cancer metastasis[12]. Similarly, *BRCA2* is essential in restoring damages to double-stranded DNA. *BRCA2* mutations can cause alterations of *TP53* tumor suppressor genes, leading to pancreatic tumorigenesis[13]. Loss of *SMAD4* (an effector of the transforming growth factor β signaling pathway) promotes pancreatic cancer progression and increases rate of metastasis[14]. *SMAD4* inactivation in PDAC is also associated with poor prognosis and short overall survival[14].

Nevertheless, the genetic alterations in PDAC are still unable to explain the complex immune evasion in PDAC, indicating that other more pertinent underlying factors may be the driving force for immune-evading PDAC.

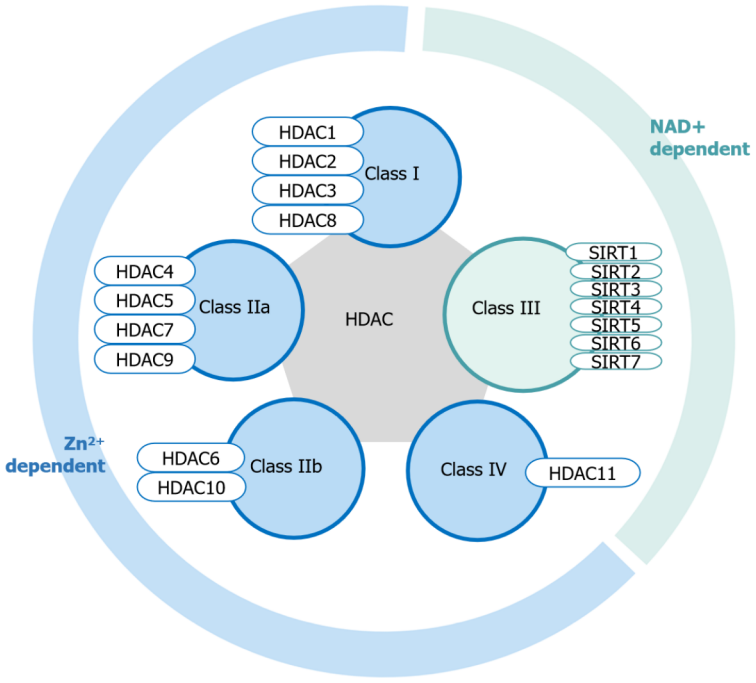
HISTONE DEACETYLASES IN CANCER

Epigenetic abnormalities are also crucial in carcinogenesis and the pathophysiology of cancer. Histone modification is one of the essential epigenetic processes involved in tumorigenesis and progression[16]. Histone acetylation is strictly controlled by a balance between histone acetyltransferase and histone deacetylases (HDAC) with opposing enzymatic activities. Histone acetylation is associated with an increased transcription level, while deacetylation is correlated with its repression. Histone deacetylation increases the ionic interactions between positively charged histones and negatively charged DNA, this limits the access to transcription machinery and represses gene transcription[17]. HDACs also remove acetyl groups and repress the transcription of essential genes such as tumor suppressor genes[18]. HDACs can also regulate the transcription of tumor suppressor gene *via* the formation of corepressor complexes or direct interaction with the transcription factors[19]. Notably, HDACs may also deacetylate

nonhistone proteins, resulting in dysregulation of cellular homeostasis including cell-cycle progression and apoptosis[18,19]. There are 18 potential HDACs grouped into four classes, based on their homology to yeast proteins. Class I (HDAC 1–3 and 8), Class II (HDAC 4–7, 9 and 10) and Class IV (HDAC 11) HDACs are zinc dependent while Class III HDACs are nicotinamide adenine dinucleotide (Figure 2). Class III HDACs are also referred to as sirtuins (SIRT 1–7) (Figure 2)[20].

The dysregulation of post-translational histone modification, especially histone acetylation, leads to gene transcription dysregulation. Overexpression of HDAC results in significant suppression of tumor suppressor genes, contributing to tumor growth and progression[17,20]. In PDAC, more than half of PDACs were stained positive for HDAC 1. The high expression of HDAC 1 has been correlated with a poorer distant metastasis-free survival[21]. Separately, another study also showed that overexpression of HDAC 1 was linked to a lower overall survival[22]. Treatment with HDAC 1 inhibitors decreased the invasion and metastasis ability of PDAC[21]. In addition, HDAC 2[23], HDAC 7 [24] and HDAC 8[24] overexpression is commonly found in PDAC.

Recently, HDAC has been highlighted for its contribution towards immune evasion. For example, HDAC 3 transcriptionally regulates programmed death ligand 1 (PD-L1) expression[25]. It is reported that higher expression of HDAC 3 is positively correlated with increased PD-L1 expression[25]. Such phenomena suppress immune cells that carry PD-L1 receptors, thus disputing immunosurveillance[25]. HDAC overexpression is also a common observation among other immune-evading solid tumors[17]. In particular, the high expression HDAC 1 is found in gastric and prostate cancers; while HDAC 2 overexpression is associated with gastric, cervical and breast cancers[17]. HDAC 1–3 are highly expressed in renal cell cancer and Hodgkin's lymphoma[17]. Overexpression of HDACs is linked to a significant decline in overall survival and prognosis[20]. It is believed that mutation or loss of HDAC expression is correlated with increased oncogene expression[17]. For instance, *Rb* tumor suppressor gene needs the concomitant action of HDAC to suppress transcription of other essential oncogenes. Loss of HDAC reduces the protective effect of *Rb* tumor suppressor gene[26]. Due to the roles and targetability of HDACs, targeting HDAC has garnered much attention as an effective anticancer therapeutic strategy.



HDAC INHIBITORS AS CANCER THERAPY

HDAC inhibitors bind directly to the active sites on HDAC enzymes, and inhibit the deacetylation effect of HDAC. Each HDAC inhibitor contains a cap, connecting unit, linker and a zinc-binding group that chelates the cation in the target HDAC[27]. HDAC inhibitors can be classified based on their specificity towards HDACs, namely the pan-HDAC inhibitors, Class I or Class II specific inhibitors. HDAC inhibitors can change the acetylation status of both nonhistone proteins and chromatin, causing a viable gene expression alteration, induction of apoptosis and cell cycle arrest[27]. HDAC inhibitors can target not only the tumor cell itself, but also the tumor microenvironment and immune milieu, making the use of HDAC inhibitor a promising strategy to eradicate immune evaded PDAC[27].

The overexpression of HDACs in cancer allows cancer cells to have increased sensitivity to HDAC inhibitors, leading to the induction of growth arrest, differentiation inhibition and eventual tumor cell death without compromising the nontumor cells[27]. Given PDAC's therapeutic resistance to conventional therapy, it is not surprising that the use of HDAC inhibitor as an alternative treatment option has been studied. Ivaltinostat (CG200745), a pan-HDAC inhibitor, demonstrates inhibitory effects on PDAC tumor growth by upregulating proapoptotic proteins BAX and p21[28]. Treatment of PDAC cells with belinostat (PXD101), a Class I and II HDAC inhibitor, also induces cell cycle arrest and tumor regression [29]. A Phase I clinical study using escalating doses of dacinostat (LAQ824), another pan-HDAC inhibitor, showed that the drug was well tolerated by PDAC patients[30]. A significant accumulation of histone acetylation was reported among the patients treated with dacinostat[30]. However, most patients in this trial discontinued dacinostat treatment due to disease progression[30], indicating an unresolved limitation of prescribing HDAC inhibitor as monotherapy for pancreatic cancer.

In combination, HDAC inhibitors show a better effect with other chemotherapeutic agents. The combination of two Class I HDAC inhibitors, romidepsin and ricolinostat (ACY-1215), showed potent synergy with gemcitabine in a panel of PDAC cell lines[31]. Combination of entinostat (Class I HDAC inhibitor), vorinostat (Class I and II HDAC inhibitor) and cyclooxygenase (COX)-2 inhibitors showed complete stalling of PDAC cell growth[32]. In addition, the use of vorinostat and trichostatin A (Class I and II HDAC inhibitor), showed induction of apoptosis in caspase-independent pathways, even for antineoplastic drug-resistant PDAC cell lines[24]. Combination of trichostatin A and proteasome inhibitor PS-341 downregulated antiapoptotic factors and synergistically induced apoptosis[33]. In a separate study, trichostatin A together with silibinin demonstrated a synergistic growth inhibitory effect on PDAC cells by inducing G2/M cell cycle arrest and apoptosis[34].

Meanwhile, the combination of ivaltinostat, gemcitabine and erlotinib significantly reduced PDAC tumor size up to 50%[28]. Ivaltinostat enhanced gemcitabine sensitivity in gemcitabine-resistant pancreatic cancer cells[28]. The use of valproic acid (Class I HDAC inhibitor) confers a synergistic effect with gemcitabine on PDAC cells, lending support to the postulation that targeting HDAC may be a promising strategy to overcome therapeutic resistance and circumvent immune evasion strategies[35].

Figure 2 Histone deacetylases classification. Histone deacetylases (HDAC) can be divided into two major classes, namely Zn-dependent and NAD dependent. Class I (HDAC 1–3 and 8), Class IIa (HDAC 4, 5, 7 and 9), Class IIb (HDAC 6 and 10) and Class IV (HDAC 11) are Zn-dependent HDAC. Class III (SIRT1 to 7) is NAD^+ dependent HDAC. HDAC: Histone deacetylases. The figure in this review paper is created by using BioRender.com by the authors.

HDAC inhibitors demonstrated anti-angiogenic effects by regulating angiogenic related transcriptional factors such as von Hippel-Lindau (VHL), hypoxia inducible factor-1a (HIF-1a) and vascular endothelial growth factor (VEGF)[36]. Rosengren RJ team found novel HDAC inhibitors, Jazz90 and Jazz167, which had a superior potency and anti-angiogenic effects than conventional HDAC inhibitor suberoylanilide hydroxamic acid (SAHA) in prostate cancer cell lines[37]. Independently, Vyas A team synthesised novel SAHA analogues with greater anti-angiogenic effects using the chick chorioallantonic membrane assay[38]. Several clinical trials are ongoing to evaluate the clinical benefits of HDAC inhibitors in targeting angiogenesis in cancer, however, to the best of our knowledge, there is no solid evidence on its benefits among pancreatic cancer patients. More studies are needed to investigate the potential of HDAC inhibitors as anti-angiogenesis agents in PDAC.

In view of their promising combinatory therapeutic efficacy, there has been growing interest in the use of HDAC inhibitors with other therapeutic agents for pancreatic cancer patients (Table 1). However, the use of HDAC inhibitors has been studied in the treatment of lymphoma and other nonpancreatic tumors[39]. For example, HDAC inhibitor has been approved by the FDA for various cancer treatments. Romidepsin[40] and vorinostat[41] have been approved for refractory cutaneous T cell lymphoma while panobinostat[42] (Class I, II and IV HDAC inhibitor) has been approved for multiple myeloma. Likewise, belinostat[42] and tucidinostat[39] (Class I, II, and III inhibitor) have been approved for the treatment of peripheral T cell lymphoma.

HDAC INHIBITORS REVERSE IMMUNE EVASION IN CANCER

HDAC inhibitors enhance immune cell activation

The PDAC tumor microenvironment is composed of regulatory T cells, tumor-associated macrophages (TAMs) and myeloid-deprived suppressive cells (MDSCs) that inhibit ability of cytotoxic T cells (CTLs) in tumor recognition and clearance[6,43]. Cells in the tumor microenvironment can also produce immunosuppressive cytokines including interleukin (IL)-1, IL-6, IL-10, and tumor necrosis factor-α (TNF-α) to cause T cell anergy or tolerance, resulting in immune evasion[44]. Other important cells in the tumor microenvironment include the fibrotic matrix, pancreatic stellate cells and cancer associated fibroblasts (CAFs); all of which can adhere to infiltrating T lymphocytes and prevent their entry into cancer cells, resulting in T cell anergy[44]. In particular, the activated CAFs create a dense stroma that dominates in PDAC, mediating tumor growth and survival by the production of extracellular matrix proteins, growth factors and cytokines[6,45]. CAFs represent the majority type of cells in PDAC stroma and have been acknowledged to be one of the key contributing factors to the immune evasion of cancer cells[45]. CAFs can limit access of infiltrating immune cells to cancer cells through the release of dense

Table 1 Investigational histone deacetylases inhibitors in pancreatic cancer patients

[1]HDAC: Histone deacetylases.
[2]FOLFOX regimen consists of folinic acid, 5-fluorouracil, and oxaliplatin.

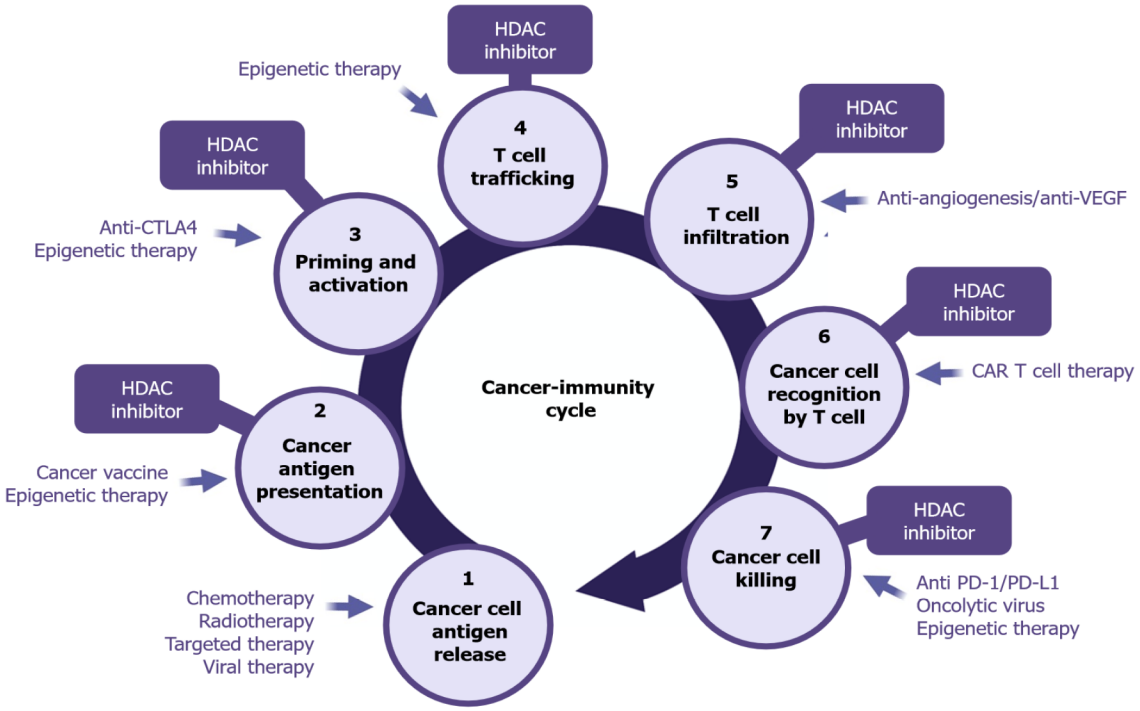
collagen networks, resulting in a physical hurdle that disrupts T cell dispersal and inhibition of T cell migration in areas of increased collagen deposition, such as that of PDAC tumors[45]. CAFs have been demonstrated to upregulate immune checkpoints on Cluster of Differentiation (CD)4$^+$ T cells and CTLs, thus resulting in reduced immune function of T cells[45]. Within the immunosuppressive tumor microenvironment, PDACs can disrupt the immunogenic effects of CTLs, by which the CTLs that presented in PDACs may be poorly cytotoxic and nonfunctional[46]. Multiplex staining has demonstrated that proximity of T cells to PDACs is correlated with patient prognosis and survival[47]. As a result, exclusion of T cells from the tumor microenvironment correlates with the tumor initiation and progression.

HDAC inhibitors can modulate immune evasion by modulating immune cell functions[48]. HDAC inhibitors can also increase the expression of major histocompatibility complex (MHC) and its costimulatory molecules leading to T-cell activation[48]. For example, AR42 (a pan-HDAC inhibitor) enhances its adaptive immunity through improving the functions and capabilities of CTLs and natural killer (NK) cells in murine melanoma[49]. Meanwhile, trichostatin A suppresses CD4 T cells from undergoing apoptosis, leading to enhanced antitumor effect[50]. Entinostat increases CTL cytotoxic function and T cell signatures in ovarian tumors[51]. Entinostat also reverses CTL–T regulatory (Treg) cell ratios in the ovarian tumor microenvironment, thus facilitating CTL accumulation at the tumor site[51]. Therefore, HDAC inhibitors have a pivotal role in sustaining T-cell-mediated antitumor immunity. Further studies are required to understand their underlying mechanisms in reversing T cell resistance.

HDAC inhibitors enhance tumor immunogenicity

The intrinsic resistance of PDAC tumors to immune eradication is mainly due to its nonimmunogenic characteristic[6,7]. Tumors can further evade CTL-induced tumor lysis *via* immunoediting, or changes in immunogenicity of cancer cells[52]. Host immune system can alter the expression profile of tumors, in turn enabling them to evade immune detection[53]. The development of PDAC has been described to reflect the three Es of cancer immunoediting, which are elimination, equilibrium and escape[6,54]. The elimination phase occurs during cancer immunosurveillance, when immune effector cells are enlisted to the cancerous tissue to eliminate PDAC cancer cells. Immune effector cells, including CTLs can eliminate most of the vulnerable tumor cells, leaving the resistant tumor clones behind. These resistant tumor clones then expand and remain undetected by the immune system. During the equilibrium phase, a unique equilibrium between antitumor and protumor immune cells is sustained until tumor escape mechanisms are established. During the escape phase, an immunosuppressive microenvironment is formed with the presence of TAMs and MDSCs, creating an effective barrier against the effector immune cells such as CTLs[6,54]. Taken together, such immunoediting has allowed PDAC to bypass immune detection, whereby PDAC continues to grow, progress and metastasize.

HDAC inhibitors may reverse immune evasion in tumors by enhancing tumorigenicity. Trichostatin A induced suppression of tumor growth by improving the immunogenicity of the metastatic tumor cells in a murine study[21,55]. Trichostatin A also increased the MHC Class I expression that translated into enhanced susceptibility to being killed by cytotoxic T cells[55]. Entinostat altered the tumor microenvironment by increasing the MHC Class II expression and its transactivator[56]. Entinostat also re-expressed the natural killer cell receptor and ligand, leading to a decrease in the immunosuppressive effects by host immune cells[57]. Another study using vorinostat and entinostat revealed that breast and prostate carcinoma cells became more sensitive to T-cell-mediated lysis after treatment with HDAC inhibitors. Treatment with vorinostat increased CTL sensitivity, leading to tumor lysis, demonstrating the enhancement of antigen-specific CTL-mediated killing by HDAC inhibitors[58]. Entinostat can sensitize immune checkpoint inhibitors by ablating MDSC-mediated immunosuppressive effects in PDAC tumor-bearing mice[59]. Such exciting findings have rendered the researchers to launch their human clinical trial to investigate the combination of entinostat with nivolumab (a checkpoint inhibitor) in unresectable PDAC patients (Clinical Trial NCT03250273)[60]. Other studies showed that epigenetic modulators[61,62] (including HDAC) could improve tumor immunogenicity and could be a promising translational intervention in cancer.



Given the high frequency of *KRAS* mutations in pancreatic cancer patients, mRNA vaccine that targets a specific mutant has gained attraction[63]. In theory, mRNA vaccine encodes KRAS mutant-specific antigens into the host's cytoplasm, leading to the eradication of tumor cells with KRAS mutation by host's immune system[63]. mRNA-5671/V941 is being investigated as monotherapy or in combination with immunotherapy for pancreatic cancer patients with *KRAS* mutation (NCT03948763). However, it remains uncertain whether cancer vaccine could be given along with HDAC inhibitors since HDAC inhibitors may also enhance tumor immunogenicity. Barouch DH group demonstrated that the combination of romidepsin, I-BET151 and cancer vaccine enhanced the CTL cell response in a mouse model, indicating the possible synergism between HDAC inhibitor and cancer vaccine[64]. Thus, further studies are warranted to explore the efficacy of cancer vaccine as a monotherapy or in combination with other therapeutic agents.

HDAC inhibitors counteract PD-L1 and PD-1 interaction

Tumor-infiltrating lymphocytes including CTLs produce a high level of programmed death (PD)-1 while PDAC cells counteract by overproducing the specific ligand of PD-1, which is PD-L1. The interaction between PD-1 and PD-L1 results in T-cell depletion[6,65]. Studies have shown that PD-1 and PD-L1 interaction impedes T-cell growth and that tumor-cell-borne PD-L1, and thus induce apoptosis of tumor-specific T-cell clones[66]. Such transformation turns CTLs into a dysfunctional state of exhaustion that characterized by the loss of CTL proliferation ability as well as the loss of CTL cytotoxic functions [67,68]. As a result, CTLs will be downregulated, and tumor cells can then escape the cytotoxic killing by CTLs.

PD-L1 is overexpressed in PDAC and the higher level of PD-L1 has been linked to a poorer prognosis for PDAC patients[52,67]. In addition, a higher HDAC 3 expression has been linked to the increased PD-L1 expression on PDAC cells[25]. HDAC 3 modulates PD-L1 expression *via* the signal transducer and activator of transcription 3 pathway[22]. HDAC 3 inhibitor (RGFP966) reduces PD-L1 mRNA and protein expression levels, thus enhancing immunosurveillance and aiding the reversal of immune evasion[25].

Another study reported that combination of CG-745 (HDAC Class I and IIb inhibitor) and anti-PD-1 antibody showed synergistic tumor eradication in two syngeneic cancer mouse models[69]. Further mechanistic studies indicated CG-745 increased T-cell activation and macrophage M1 polarization, helping the anti-PD-1 anticancer effect[69]. In addition, HDAC inhibition with entinostat improved the antitumor effect of PD-1 blockade in two syngeneic cancer mouse models[70]. The combination of entinostat and PD-1 inhibitor reduced the tumor burden and improved its survival[70]. Additional analyses indicated that entinostat upregulated PD-L1 in tumors, blocked the immunosuppressive function of MDSCs, and reduced *COX-2*, *inducible nitric oxide synthase* (*iNOS*) and *arginase-1* mRNA expression[70]. Romidepsin enhanced the PD-1 blockade in a murine tumor model, leading to tumor rejection[71]. Individual treatment with romidepsin or PD-1 blocker did not result in significant tumor suppression[71]. Further analyses indicated that romidepsin increased PD-L1 Levels in the tumor[71]. Romidepsin and PD-1 blocker synergized by unleashing the interferon-dependent response in T-cell recruitment to the upregulated PD-L1 tumor cells[71]. Unlike entinostat[70], romidepsin-treated tumor did not alter the MDSC population[71], indicating that HDAC inhibitors have varied impacts on PD-1 and PD-L1 interaction, which can be independent of MDSC modulation. Further study is warranted to explore how HDAC inhibitor affects PD-1 and PD-L1 interaction. Such findings support the notion that HDAC inhibitors can modulate PD-1 and PD-L1 interaction in tumors apart from their canonical role in inhibiting HDAC.

Figure 3 Role of histone deacetylases inhibitors in targeting cancer immune evasion. Cancer–immunity cycle is a continuously cyclical process to amplify the immune response leading to cancer eradication. The cancer–immunity cycle has seven steps: Step 1: Dying cancer cells release neoantigen (Step 2). These neoantigens are captured by antigen-presenting cells and present the antigens on the major histocompatibility complex to T cells (Step 3), allowing the T cells to be primed and activated. Once T cells are activated (Step 4), T cells are transported to the tumor site and (Step 5) infiltrate the tumor. Once inside the tumor (Step 6), T cells recognize the tumor cells, and (Step 7) kill the tumor cells. Histone deacetylases inhibitors will support Steps 2–7 of the cancer–immunity cycle. Such effects can be synergized with other therapeutic agents. CAR: Chimeric antigen receptor; CTLA4: Cytotoxic T-lymphocyte associated antigen 4; PD-1: Programmed death protein 1; PD-L1: Programmed death ligand 1; VEGF: Vascular endothelial growth factor; HDAC: Histone deacetylases. The figure in this review paper is created by using BioRender.com by the authors.

CONCLUSION

PDAC is often synonymous with a "death sentence". The high mortality and poor outcome of PDAC are mainly due to PDAC being refractory to most forms of contemporary therapeutic strategies. Given that the hallmark of PDAC is a highly dense stroma and immense microenvironment, immunotherapy stands out as a promising novel approach to PDAC treatment. Chen and Mellman proposed that cancer immunity is a series of ongoing cyclical events (Figure 3)[72]. Disruption in the major events in the cancer–immunity cycle leads to immune evasion in cancer[6].

HDAC inhibitors have grained traction in medical research as a promising approach to counteracting immune evasion strategies to strengthen Steps 2–7 of the cancer–immunity cycle (Figure 3). HDAC overexpression as a contributing factor to immune evasion and subsequent carcinogenesis have been increasingly recognized. The use of HDAC inhibitors to eliminate cancerous cells (Step 7 of the cancer–immunity cycle, Figure 3) is also gaining traction. Further research is warranted to investigate the effectiveness of HDAC inhibitors in cancer patients. HDAC inhibitor use may well be the key to a long-awaited treatment regimen for cancer patients. The direction for HDAC inhibitors in cancer treatment seems to lean towards combination therapy (Figure 3), with chemotherapy, radiotherapy or immunotherapy. HDAC inhibitors have been widely used with checkpoint inhibitor antibodies in preclinical models. Such combinations have demonstrated successful enhancement of antitumor efficacy and an increase in immune-cell activation.

Studies on HDAC inhibition to circumvent immune evasion are still limited. Current use of HDAC inhibitor to treat PDAC has had promising results, but studies are often still in the early preclinical stage, with much still unknown about the effect of HDAC inhibitors in PDAC patients. There remain much hope and scope in investigating HDAC inhibitors in clinical trials, which will help shed light on the effectiveness of HDAC inhibitors as an adjunct therapy in PDAC.

The ability of HDAC inhibitors to inhibit histone deacetylation may also have its limitations. HDAC inhibitors have poor physiochemical features and unfavorable pharmacokinetics[73]. HDAC inhibitors may also nonspecifically block angiogenesis, which may disrupt drug delivery through blood vessels to solid tumors[73]. In addition, the anti-inflammatory properties of HDAC inhibitors have been postulated to induce apoptosis among immune cells[73]. Current evidence supports the understanding

that HDAC inhibitors may counter immune-cell suppression and apoptosis by enhancing anti-PD1 blockade effects[25]. Moreover, there must be an intact immune function in the host as a prerequisite for HDAC inhibitors to modulate antitumor immune response[6]. Moreover, HDAC inhibitors have yet to utilize the current advanced drug delivery systems that offer site-specific drug delivery[74] with enhanced tumor targeting and reduced toxicity[73]. We believe that, by targeting HDAC in the immune evaded pancreatic cancer, the greatest therapeutic outcome will emerge.

Abstract

BACKGROUND

Emerging evidence links gut microbiota to various human diseases including colorectal cancer (CRC) initiation and development. However, gut microbiota profiles associated with CRC recurrence and patient prognosis are not completely understood yet, especially in a Chinese cohort.

AIM

To investigate the relationship between gut mucosal microbiota profiles and CRC recurrence and patient prognosis.

METHODS

We obtained the composition and structure of gut microbiota collected from 75 patients diagnosed with CRC and 26 healthy controls. The patients were followed up by regular examination to determine whether tumors recurred. Triplet-paired samples from on-tumor, adjacent-tumor and off-tumor sites of patients diagnosed with/without CRC recurrence were analyzed to assess spatial-specific patterns of gut mucosal microbiota by 16S ribosomal RNA sequencing. Next, we carried out

bioinformatic analyses, Kaplan-Meier survival analyses and Cox regression analyses to determine the relationship between gut mucosal microbiota profiles and CRC recurrence and patient prognosis.

RESULTS

We observed spatial-specific patterns of gut mucosal microbiota profiles linked to CRC recurrence and patient prognosis. A total of 17 bacterial genera/families were identified as potential biomarkers for CRC recurrence and patient prognosis, including *Anaerotruncus*, *Bacteroidales*, *Coriobacteriaceae*, *Dialister*, *Eubacterium*, *Fusobacterium*, *Filifactor*, *Gemella*, *Haemophilus*, *Mogibacteriazeae*, *Pyramidobacter*, *Parvimonas*, *Porphyromonadaceae*, *Slackia*, *Schwartzia*, TG5 and *Treponema*.

CONCLUSION

Our work suggests that intestinal microbiota can serve as biomarkers to predict the risk of CRC recurrence and patient death.

Key Words: Gut microbiota; Colorectal cancer; Prognosis; Colorectal cancer recurrence; Biomarker; 16S rRNA sequencing analysis

Core Tip: Emerging evidence indicates that besides genetic and epigenetic factors, the gut microbiota is capable of driving colorectal cancer (CRC) progression. Here, we analyzed the gut mucosal microbiota of 75 triplet-paired samples collected from on-tumor, adjacent-tumor and off-tumor sites of patients diagnosed with/without CRC recurrence and 26 healthy controls. After a long-term follow-up, we identified spatial-specific bacterial taxa whose abundances are associated with overall survival and disease-free survival. Our data reveal the profiles of gut mucosal microbiota that increase risk of CRC recurrence and affect patient prognosis, which may serve as potential new biomarkers for CRC diagnosis.

INTRODUCTION

Colorectal cancer (CRC) is a major cause of cancer-related deaths with the third highest mortality and the fourth highest incidence worldwide, according to GLOBOCAN 2020 (global cancer statistics)[1], which indicates a public health issue. Although many new treatment options of CRC have doubled, survival prognosis for early-stage patients with non-metastasized disease is still better than that for advanced-stage patients[2]. Currently, treatment of CRC mainly depends upon tumor-node-metastasis (TNM) stage of disease, and the patient's physical fitness and intent. However, previous studies showed that disease recurrence was observed in 40% of treated patients with stage I-II CRC (lymph node negative postoperative) and 70% of those with stage III CRC[3], which is proposed to be related to rat sarcoma viral oncogene and microsatellite status[4]. Thus, treatment strategy merely depending on CRC TNM stage may cause over-treatment or under-treatment, leading to CRC recurrence. Moreover, the molecular mechanisms behind CRC recurrence are not yet completely understood. Therefore, we still need to explore more suitable biomarkers for assessing prognosis of CRC patients in order to achieve optimal personalized treatment.

In addition to hereditary and lifestyle factors, the human gut microbiota is considered as an important risk factor for CRC initiation as well as development. With the continuous development of high-throughput sequencing, the compositional structure of the human gut microbiota is revealed to be closely involved in CRC initiation, development and treatment[5]. Moreover, pathogenic bacteria have been identified from the human gut microbiota and their procarcinogenic properties have been demonstrated to play a role in causing gut microbial dysbiosis in the complex environment of the human intestinal tract. Certain bacterial species, including *Bacteroides fragilis* (*B. fragilis*), *Clostridium septicum*, *Enterococcus faecalis*, *Escherichia coli*, *Fusobacterium* spp., *Helicobacter pylori* and *Streptococcus bovis* have been identified to play a role in driving colorectal carcinogenesis[6]. The mechanisms behind these pathogenic bacteria involve bacterial-derived genotoxicity and other virulence factors that regulate host defense systems, metabolism, oxidative stress and antioxidative defense modulation[6].

Evidence has linked gut microbiota to prognosis of CRC. A pilot study has shown that high abundance of *Fusobacterium nucleatum* (*F. nucleatum*) and *B. fragilis* were independent indicators for poor patient survival, while high abundance of *Faecalibacterium prausnitzii* predicted improved survival rate [7]. In addition, most studies supported that increased relative abundance of *B. fragilis* and *F. nucleatum* were associated with short-term survival and late stage of CRC[8]. Enterotoxigenic *B. fragilis* (ETBF) and *Fusobacterium* spp. levels were significantly higher in late stage (III/IV) CRC than those in early stage (I/II) CRC, and high abundance of *Fusobacterium* was reported to be associated with high microsatellite instability (MSI)[9,10]. Compared to *F. nucleatum*-negative cases, multivariable hazard ratio for CRC-specific mortality in *F. nucleatum*-high cases was 1.58[9]. After neoadjuvant chemoradiotherapy, *F. nucleatum* persistence was associated with high relapse rates in locally advanced CRC[11]. CRC patients with low levels of *F. nucleatum* had significantly longer overall survival (OS) and disease-free survival (DFS) than patients with moderate and high levels of *F. nucleatum* that were obvious in late-stage CRC patients[12-15]. However, extensive bacterial taxa associated with prognosis of CRC are unclear, especially in a Chinese cohort.

To investigate the profiles of gut mucosal microbiota associated with CRC recurrence and survival of CRC patients, we collected gut mucosal microbiota from CRC patients when they received radical resection or palliative surgery in Tianjin Union Medical Center, China. For each patient, triplet-paired CRC samples were collected from on-tumor, adjacent-tumor and off-tumor sites. Additional samples were collected from 26 healthy controls. We performed 16S ribosomal RNA (rRNA) gene sequencing and analyses on these gut mucosal microbiota. Next, we carried out Kaplan-Meier survival curve analyses for OS and DFS. Our data suggest that a number of bacterial genera/families, including *Anaerotruncus*, *Bacteroidales*, *Coriobacteriaceae*, *Dialister*, *Eubacterium*, *Fusobacterium*, *Filifactor*, *Gemella*, *Haemophilus*, *Mogibacteriazeae*, *Pyramidobacter*, *Parvimonas*, *Porphyromonadaceae*, *Slackia*, *Schwartzia*, TG5 and *Treponema*, are associated with survival of CRC patients and CRC recurrence. We further performed the univariate and multivariate Cox regression analyses. Our data reveal that high abundance of *Anaerotruncus*, *Bacteroidales*, *Coriobacteriaceae*, *Dialister*, *Eubacterium*, *Filifactor*, *Haemophilus*, *Mogibacteriazeae*, *Pyramidobacter*, *Slackia*, *Treponema* and TG5 are associated with worse OS or DFS.

MATERIALS AND METHODS

Patients and sample collection procedures

This study analyzed 69 pathologically confirmed CRC patients, who received radical or palliative surgeries at Tianjin Union Medical Center, Tianjin, China from December 2016 to September 2017. These patients were followed up by regular examination or telephone survey. DFS was defined as the time period from the date of surgery to the time of tumor recurrence, and OS was defined as the time period from the date of surgery to the time of death. Our study was conducted in accordance with the Declaration of Helsinki. Every patient provided written informed consent for the collection of samples and subsequent analysis when required, and the study was approved by the Ethics Committee of Tianjin Union Medical Center. The TNM staging was determined according to the American Joint Committee on Cancer staging handbook (8th edition). Whether a patient received chemotherapy or not depended on his/her TNM stage, physical state score and intention. Imaging examination was arranged for every 2-6 mo or when a patient's condition changed to determine whether the disease recurrence occurred.

DNA library preparation and 16S rRNA sequencing

ZR Fungal/Bacterial DNA kit (Zymo Research, Irvine, CA, United States) was used to isolate bacterial DNA from intestinal microbiota samples according to the manufacturer's instructions. Quant-iT PicoGreen dsDNA assay kit (Thermo Fisher, Sunnyvale, CA, United States) was used to quantify the DNA amounts. The hypervariable regions of 16S rRNA gene amplicon libraries targeting the V3-V4 regions were prepared according to the Illumina manufacturer's manual. The amplification primers were used according to the Illumina manufacturer's manual. The forward and reverse primers were used as follows: 5'-TCGTCGGCAGCGTCAGATGTGTATAAGAGACAGCCTACGGGNGGCWGCAG and 5'-GTCTCGTGGGCTCGGAGATGTGTATAAGAGACAGGACTACHVGGGTATCTAATCC. The products of polymerase chain reaction were examined using agarose gel electrophoresis (1% concentration of agarose gel; 100 V; 40 min electrophoresis time). The AMPure XP beads (Beckman Coulter, Fullerton, CA, United States) were used to purify the amplified DNA libraries, and Quant-iT PicoGreen dsDNA assay kit (Thermo Fisher, Sunnyvale, CA, United States) was used to quantify the DNA library amounts. All the DNA samples were stored at -20 °C until used.

Quality control, operational taxonomic unit picking and diversity analyses of 16S rRNA amplicons

The 16S rRNA amplicon libraries were sequenced for 2 × 300 bp on Illumina MiSeq platform. The read information was listed in Supplementary Table 1. The FastQC program was used to perform quality control and filtering of raw paired-end reads (https://www.bioinformatics.babraham.ac.uk/projects/fastqc/, accessed on 5 June 2019). Next, PandaSeq v2.10 was used to assemble paired-end reads

with default parameters[16]. The QIIME pipeline v1.9.1 (http://qiime.org/home_static/dataFiles.html, accessed on June 5, 2019) and Greengenes database v13.8 were used for de novo operational taxonomic unit (OTU) picking and taxonomic assignment[17]. Briefly, we generated the mapping file that contains all the information about the sequencing samples including sample ID, barcode sequences and sample types. The python command, pick_otus.py, was used to pick OTUs based on sequence similarity (threshold of 97%) of the assembled reads, which is commonly used to define bacterial species. The python command, pick_rep_set.py, was used to pick the representative sequences for each OTU. USEARCH 6.1 was used for chimera detection and filtering. The python command, assign_taxonomy.py, was used to assign taxonomy to OTU representative sequences. The python command, make_rarefaction_plots.py and online MicrobiomeAnalyst (https://dev.microbiomeanalyst.ca/MicrobiomeAnalyst/home.xhtml, accessed on 28 August 2021) were used to calculate alpha diversities within the samples[18,19]. The 16S rRNA paired-end reads have been submitted to the Sequence Read Archive database at the National Center for Biotechnology Information website under accession number PRJNA606879.

Bioinformatic analyses of gut mucosal microbiota for CRC patients

The beta diversity of gut mucosal microbiota among the samples collected from CRC patients with and without recurrence was calculated using principal component analysis on MicrobiomeAnalyst website [18,19]. The linear discriminant analysis (LDA) effect size was analyzed using online MicrobiomeAnalyst[18,19].

Statistical analysis

Statistical analyses were performed using SPSS Version 23. The statistical significance of multiple sample comparisons were calculated using one-way analysis of variance with Kruskal-Wallis test. The Kaplan-Meier survival curves for OS and DFS and the optimal cutoff value of RiskScore were calculated using R software package maxstat (maximally selected rank statistics with several *P* value approximations version: 0.7-25)[20]. We set the minimum number of samples in the grouping to be greater than 25% and the maximum number of samples in the grouping to be less than 75% and finally obtained the optimal cutoff value of each bacterial taxa. Based on this cutoff threshold, the patients were divided into groups with high and low abundance of the bacterial taxa. Furthermore, the survivfit function of R software was used to analyze the prognostic differences between the two groups, and the significance of prognostic differences between the two groups was evaluated by logrank test. According to the cutoff value of each bacterial taxon, we divided the patients into groups with high and low abundance of the bacterial taxa and then conducted Cox regression analyses. The Cox regression analyses based on the proportional hazards model were carried out using SPSS v. 23 program.

RESULTS

Clinicopathological features of CRC patients

We summarized the patients' clinicopathological data in Table 1. The median age of 75 patients was 63.4 years, and 60% of them were males. The pathological type of all patients was categorized as adenocarcinoma, and most of the tumor cells were poorly differentiated. Most patients were diagnosed as microsatellite stable based on immunohistochemical evaluation of components of the mismatch repair machinery, including MLH1, MSH2, MSH6 and PMS2. All patients did not receive chemotherapy or other antitumor therapy before surgery. After surgery, 44 of 75 patients received chemotherapy based on FOLFOX (CapeOX) or FOLFIRI regimen, 4 of them received radiotherapy, and 6 of them received targeted therapy. The median follow-up duration for all cases after surgery was 51.2 mo (2.90-57.03 mo). There were 6 patients who failed to be followed up. Until August 23, 2021, a total of 17 patients diagnosed with I-III stages had relapsed and 20 patients had died.

Altered alpha-diversity of gut mucosal microbiota at adjacent-tumor sites for CRC recurrence

Although tumor tissues can be removed by surgery, the microbiota residing in the tumor surrounding tissues, *e.g.*, those at the adjacent-tumor sites as well as those in the remaining intestinal tissues where tumors are removed, may retain pathogenic bacteria that have the capabilities to drive CRC, leading to CRC recurrence. Therefore, we hypothesize that gut mucosal microbiota profiles at on-tumor or adjacent-tumor sites may be linked to CRC recurrence. To examine this, we assessed microbial alpha-diversities of biopsy samples collected from on-tumor, adjacent-tumor and off-tumor sites of patients with and without CRC recurrence. The 16S rRNA gene hypervariable V3-V4 regions were sequenced and analyzed for five α-diversity indices including Chao1, Fisher, Observed OTU, Shannon and Simpson (Figure 1). Analyses of species variations based on these five metrics consistently indicated that species diversities at on-tumor or off-tumor sites of patients with and without CRC recurrence showed no significant differences (Student *t*-test, $P < 0.05$) (Figure 1). Analyses of species variations based on Chao1 (Student *t*-test, $P = 0.0092$), Fisher (Student *t*-test, $P = 0.0092$) and observed OTU (Student *t*-test, *P*

Table 1 Summary of clinicopathological factors of colorectal cancer patients

Characteristics	*n*	%	Characteristics	*n*	%

= 0.0092), but not Shannon (Student *t*-test, $P = 0.1314$) and Simpson (Student *t*-test, $P = 0.2513$), showed significant differences at adjacent-tumor sites of patients with and without CRC recurrence (Figure 1). Although Shannon and Simpson metrics did not show statistical significance, analyses of the α-diversities based on the five metrics suggested that at adjacent-tumor sites, those from patients with CRC recurrence were higher than those from patients without recurrence (Figure 1). These data suggest that there is no significant difference of composition of gut mucosal species at on-tumor and off-tumor sites between patients with and without CRC recurrence. However, compositions of internal species showed differences at adjacent-tumor sites between patients with and without CRC recurrence.

Microbiota profiles linked to CRC recurrence

To assess whether the structure diversities (beta-diversity) of gut microbiota show differences between patients with and without CRC recurrence, we performed principal component analysis for abundance of genera identified at on-tumor, adjacent tumor and off-tumor sites of CRC patients diagnosed with and without disease recurrence. The microbiota structure diversities at on-tumor, adjacent tumor and off-tumor sites of CRC patients diagnosed with and without disease recurrence showed differences (Figure 2), suggesting that the structures of gut microbiota were different at these sites in patients with and without CRC recurrence.

We next compared the differential relative abundance of bacterial taxa at the phylum level between patients with and without CRC recurrence. Among all the samples, *Firmicutes*, *Proteobacteria*, *Bacteroidetes* and *Fusobacteria* showed the top relative abundance (Figure 3). *Firmicutes*, *Bacteroidetes* and *Fusobacteria* showed higher relative abundance at on-tumor sites of patients diagnosed with CRC recurrence than those at on-tumor sites of patients diagnosed without CRC recurrence (Figure 3). At adjacent-tumor sites, the relative abundance of *Fusobacteria* in patients with CRC recurrence were dramatically higher than those in patients without CRC recurrence (Figure 3). By contrast, the relative abundance of *Fusobacteria* at off-tumor sites showed no differences between patients with and without CRC recurrence (Figure 3). The relative abundance of *Firmicutes* and *Bacteroidetes* at off-tumor sites of patients with CRC recurrence were lower than those of patients without CRC recurrence (Figure 3). Collectively, these data suggest that species from *Fusobacteria*, *Bacteroidetes* and *Firmicutes* may play roles in worsening or improving the patient prognosis.

Altered gut mucosal microbiota signatures in CRC recurrence

We next carried out the linear discriminant analysis effect size to predict site-specific biomarkers that are associated with CRC recurrence. By setting LDA score > 3.0 [false discovery rate (FDR) adjusted *P* value < 0.1], a total of 100 genera were identified to show significant differences of relative abundance between patients with and without CRC recurrence (Figure 4, Supplementary Table 2). The top 10 genera/families with the highest LDA scores were *Fusobacterium* (LDAscore = 5.56, FDR adjusted *P* = 0.0026), *Faecalibacterium* (LDAscore = 5.29, FDR adjusted *P* = 0.0176), *Peptostreptococcus* (LDAscore = 5.13, FDR adjusted *P* = 0.0026), *Streptococcus* (LDAscore = 5.08, FDR adjusted *P* = 0.0639), *Parvimonas* (LDAscore = 5.04, FDR adjusted *P* = 0.0072), *Burkholderiales* (LDAscore = 5.03, FDR adjusted *P* = 0.0018), *Pseudomonas* (LDAscore = 4.82, FDR adjusted *P* = 0.0301), *Caulobacteraceae* (LDAscore = 4.77, FDR adjusted *P* = 0.0043), *Mitsuokelia* (LDAscore = 4.77, FDR adjusted *P* = 0.0011) and *Pseudomonadales*

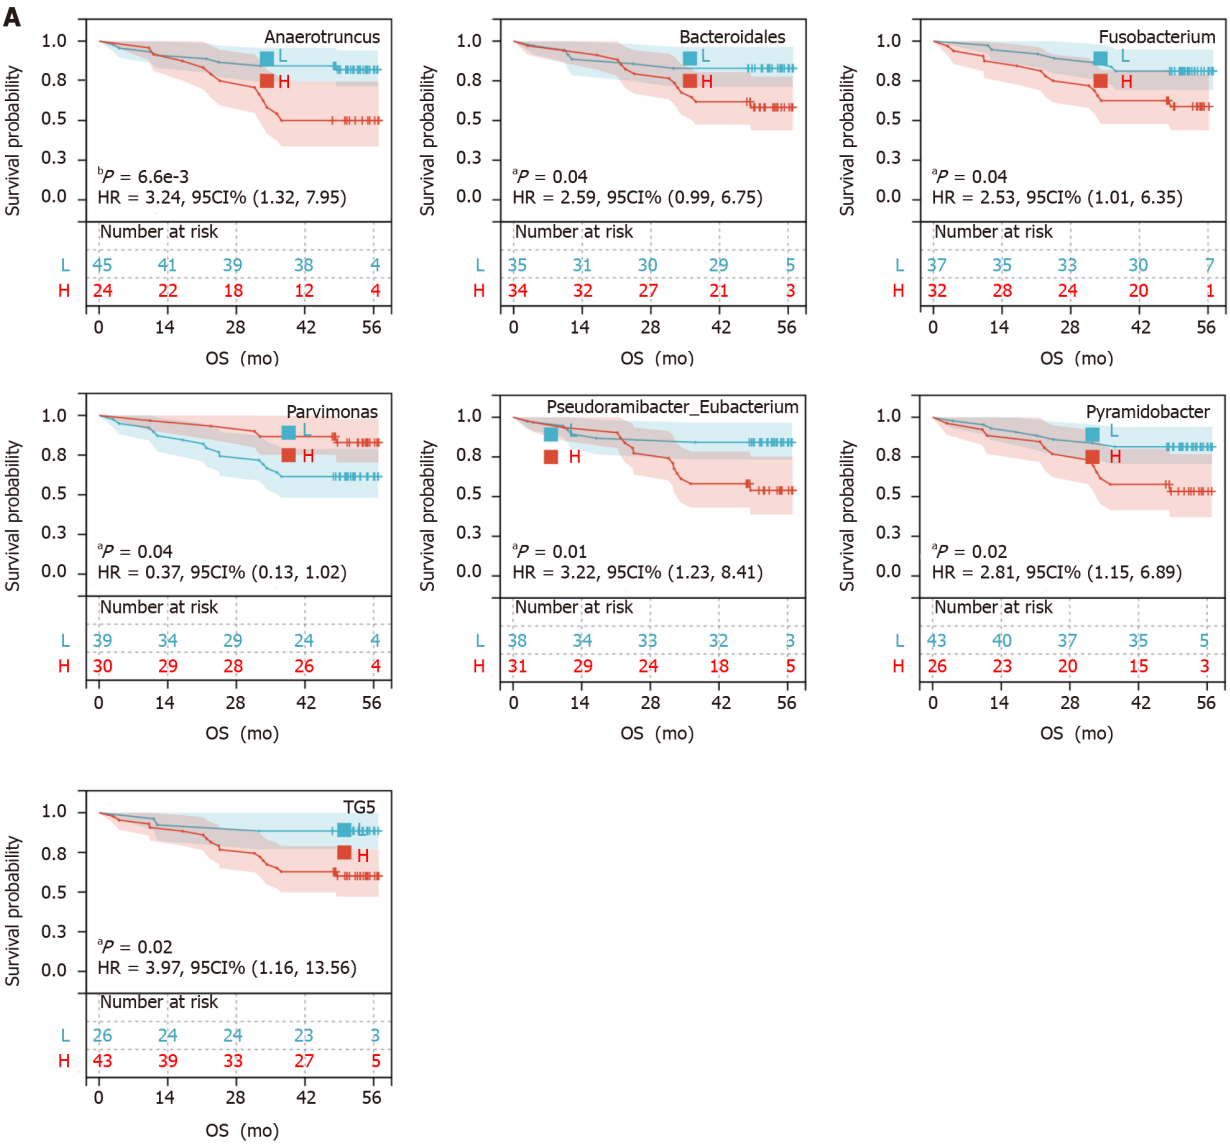
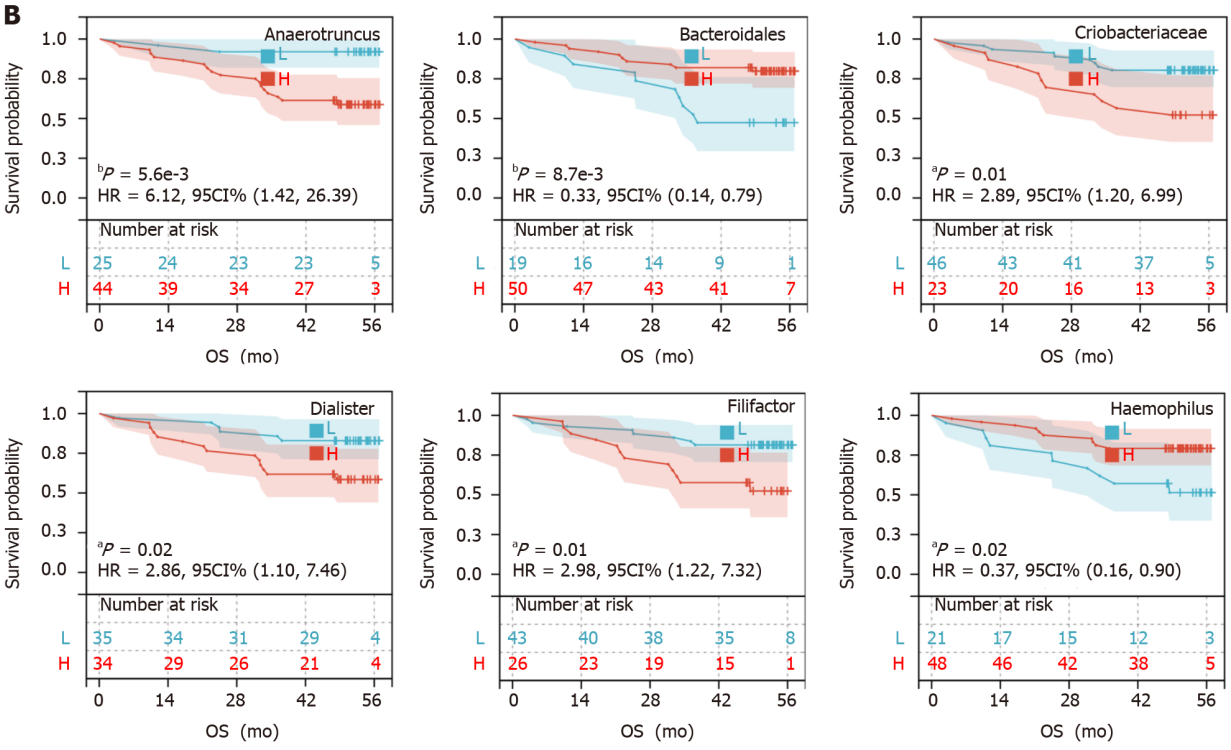
in interacting with host cells and worsening patient prognosis.

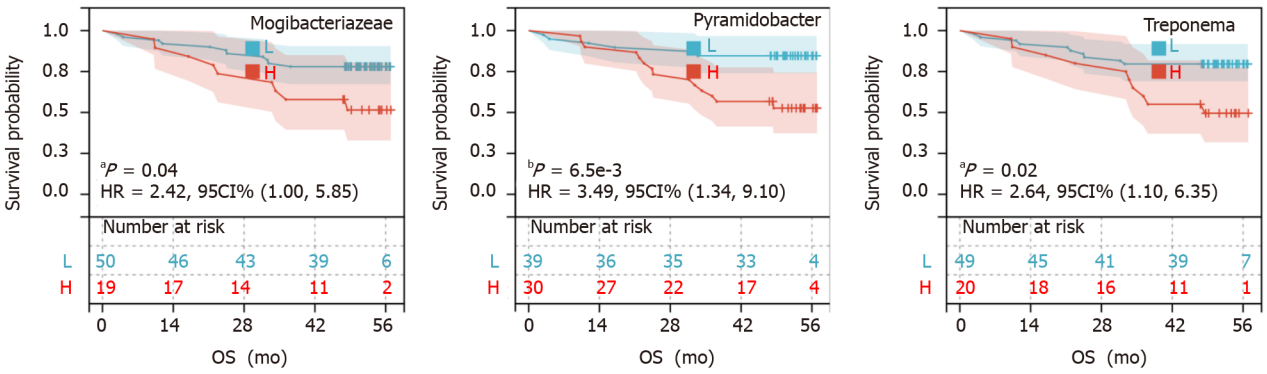
Gut mucosal microbiota profiles associated with prognosis and survival of CRC patients



Next, we selected those genera/families that were significantly associated with CRC recurrence based on LDA effect size analysis and used their abundance to evaluate their effects on prognosis and patient survival. The Kaplan-Meier survival analysis curves showed that seven bacterial genera at on-tumor sites and nine bacterial genera at adjacent-tumor sites were capable of significantly predicting the OS of patients ($P < 0.05$) (Figure 5). High abundance of *Anaerotruncus*, *Bacteroidales*, *Fusobacterium*, *Pyramidobacter*, *Pseudoramibacter_Eubacterium* and TG5 at on-tumor sites predicted shorter OS, whereas high abundance of *Parvimonas* was associated with longer OS (Figure 5A). At adjacent-tumor sites, high abundance of *Anaerotruncus*, *Coriobacteriaceae*, *Dialister*, *Filifactor*, *Mogibacteriazeae*, *Pyramidobacter* and *Treponema* predicted shorter OS, whereas high abundance of *Haemophilus* and *Bacteroidales* indicated longer OS (Figure 5B). The cutoff values were shown in Supplementary Table 3.



We next performed Kaplan-Meier survival analyses to analyze DFS between patients with high and low abundance of specific bacterial taxa. A total of eleven genera at on-tumor sites and eight genera at adjacent-tumor sites were capable of predicting DFS obviously ($P < 0.05$) (Figure 6). High abundance of *Anaerotruncus*, *Bacteroidales*, *Erysipelotrichaceae_Eubacterium*, *Filifactor*, *Mogibacteriazeae*, *Pyramidobacter*, *Pseudoramibacter_Eubacterium*, *Porphyromonadaceae*, *Slackia* and TG5 at on-tumor sites were associated with shorter DFS, whereas high abundance of *Gemella* was associated with longer DFS (Figure 6A). At the adjacent-tumor sites, high abundance of *Anaerotruncus*, *Coriobacteriaceae*, *Dialister*, *Filifactor*, *Pyramidobacter* and *Schwartzia* showed shorter DFS, while high abundance of *Haemophilus* and *Bacteroidales* were associated with longer DFS (Figure 6B).



According to the abundance cutoff value of each genus calculated by Kaplan-Meier survival analyses (Supplementary Table 3), we divided the patients into two groups with high or low abundance of each genus. Then, we investigated the survival risk associated with the abundance of each genus/family and other clinicopathological features *via* univariate and multivariate COX regression analyses. According to the univariate Cox regression analysis results, we chose bacterium or clinicopathological feature with significance ($P < 0.1$) and additional bacterium with significance in Kaplan-Meier analysis ($P < 0.05$) to further perform multivariate Cox regression analysis.

Interestingly, although gender, age, differentiation, smoking and drinking histories showed no significance ($P > 0.05$) in univariate DFS or OS Cox regression analyses (Supplementary Tables 4 and 5), the TNM stage and location of tumor in intestine showed significant influences on patient survival based on multivariate OS Cox regression analysis ($P < 0.05$) (Supplementary Figures 1 and 2). CRC III/IV stage and CRC located in the right colon revealed shorter OS than CRC I/II stage and CRC located in the left colon or rectum, respectively. Moreover, only CRC III/IV stage showed shorter DFS than CRC I/II stage (Supplementary Figure 2). In addition, MSI was associated with improved DFS rates in all patients based on multivariate Cox regression analysis (Supplementary Figure 3). Univariate Cox regression OS analysis indicated patients with high abundance of *Anaerotruncus*, *Bacteroidales*, *Pyramidobacter*, *Pseudoramibacter_Eubacterium* and TG5 at on-tumor sites were associated with shorter OS rates (Supplementary Figure 1). However, no significant differences were found between these bacteria and OS in multivariate analysis (Supplementary Figure 1). At adjacent-tumor sites, univariate analysis showed high abundance of *Anaerotruncus*, *Coriobacteriaceae*, *Dialister*, *Filifactor*, *Mogibacteriazeae*, *Pyramidobacter* and *Treponema* and low abundance of *Bacteroidales* were associated with shorter OS rates. In multivariate analysis, high abundance of *Anaerotruncus* and low abundance of *Haemophilus* were associated with shorter OS rates (Supplementary Figure 2).

High abundance of *Anaerotruncus*, *Bacteroidales*, *Erysipelotrichaceae_Eubacterium*, *Mogibacteriazeae*, *Pyramidobacter* and *Pseudoramibacter_Eubacterium* at on-tumor sites predicted shorter DFS rates in univariate analysis, whereas high abundance of *Mogibacteriazeae* and *Slackia* were associated with shorter DFS rates in multivariate analysis (Supplementary Figure 3). In univariate analysis of bacterial taxa at adjacent-tumor sites, high abundance of *Anaerotruncus, Coriobacteriaceae*, *Dialister*, *Filifactor, Pyramidobacter* and *Schwartzia* indicated shorter DFS rates (Supplementary Figure 4). Meanwhile, low abundance of *Bacteroidales* was associated with shorter DFS rates (Supplementary Figure 4). In multivariate analysis, there was no correlation between these bacteria and DFS rates (Supplementary Figure 4).

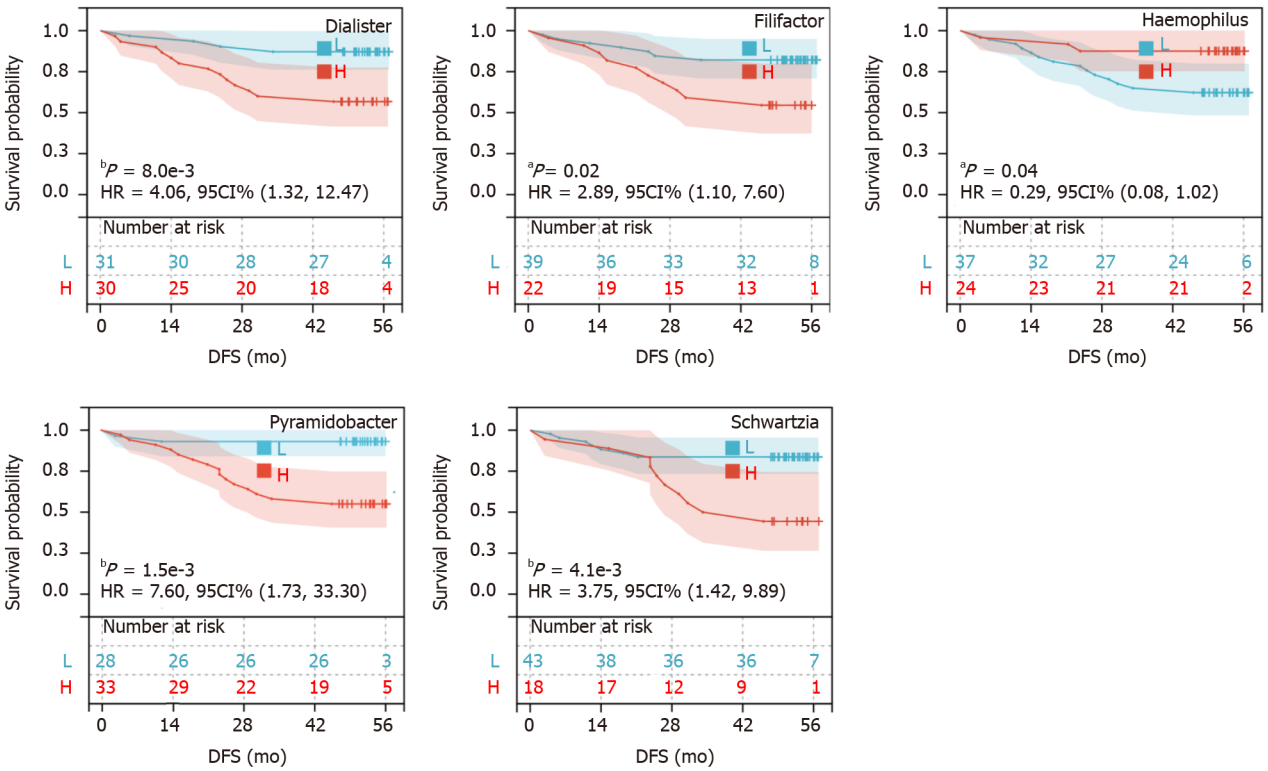
DISCUSSION



Emerging evidence indicates that the gut microbiota plays pivotal roles in CRC incidence and progression[21]. Most previous studies have focused on identifying gut microbiota profiles linked to CRC carcinogenesis and revealing the physiological roles of specific species, *e.g.*, *F. nucleatum*, *Peptostreptococcus anaerobius*, *B. fragilis* and *Eubacterium rectale*, in CRC tumorigenesis and development [22-25]. However, few reports have fully screened the gut microbiota profiles linked to prognosis and survival of CRC patients[7]. Up to date, only *F. nucleatum* and *B. fragilis* were evaluated for their impacts on patient prognosis[7,8,13,14]. Therefore, our understanding of bacterial taxa associated with clinical outcomes of CRC is incomplete. Profiling these bacterial taxa will pave a way for further understanding their functional roles in impairing clinical outcome of CRC and development of novel strategies for prevention of CRC recurrence. In this study, we explored large-scale screening of gut mucosal microbiota of triplet-paired biopsy samples collected from on-tumor, adjacent-tumor and off-tumor sites of CRC patients and identified critical bacterial taxa that were linked to prognosis and survival of CRC patients.

Our data revealed that a number of bacterial genera/families at on-tumor and adjacent-tumor sites are capable of influencing DFS and OS rates. High abundance of *Anaerotruncus* and *Pyramidobacter* indicated shorter DFS and OS rates in Kaplan-Meier survival analyses and increased the risk of CRC recurrence and patient death according to our Cox regression analyses ($P < 0.05$). High abundance of *Coriobacteriaceae*, *Dialister* and *Filifactor* at adjacent-tumor sites and high abundance of *Bacteroidales*, *Pseudoramibacter_Eubacterium* and TG5 at on-tumor sites indicated shorter DFS and OS rates and increased the risk of CRC recurrence and patient death ($P < 0.05$). Conversely, high abundance of *Parvimonas* at on-tumor sites showed longer OS rates. Meanwhile, high abundances of *Bacteroidales* and *Haemophilus* at adjacent-tumor sites indicated longer DFS and OS rates, but only *Haemophilus* decreased the risk of death in multivariate Cox regression analysis ($P < 0.05$). High abundances of *Fusobacterium* at on-tumor sites and *Treponema* at adjacent-tumor sites indicated shorter OS rates, but only *Treponema* increased the risk of death ($P < 0.05$). High abundance of *Erysipelotrichaceae_Eubacterium*, *Gemella*, *Porphyromonadaceae* and *Slackia* at on-tumor sites and *Coriobacteriaceae* at adjacent-tumor sites indicated shorter DFS rates, and *Erysipelotrichaceae_Eubacterium*, *Gemella*, *Slackia* and *Schwartzia* increased the risk of recurrence ($P < 0.05$). In multivariate regression analysis, *Haemophilus* showed a protective effect and *Anaerotruncus* showed a detrimental effect when referred to death ($P < 0.05$), and *Mogibacteriazeae* and *Slackia* showed obvious detrimental effects when referred to recurrence ($P < 0.05$).

As well-recognized oral pathogens, *F. nucleatum*, *Parvimonas micra* and *Gemella morbillorum* were significantly enriched in both right- and left-sided CRC tumors[26]. *F. nucleatum* in tumor samples was reported to be associated with worse outcomes in terms of OS, DFS or cancer-specific survival, with hazard ratios ranging from 1.58 to 19.96[27]. However, our data showed that the abundance of *F. nucleatum* only affected OS but not DFS rates. This observation is consistent with two previous studies. Wei *et al*[7] reported that high abundance of *F. nucleatum* or *B. fragilis* was associated with poor OS rates after surgery. A meta-analysis found that enrichment of *F. nucleatum* in tumor tissue was associated with worse OS among CRC patients ($n = 5$ studies, HR = 1.87; 95%CI: 1.12–3.11; $I^2 = 60.6\%$) but was not associated with DFS ($n = 3$ studies, HR = 1.48; 95%CI: 0.84–2.59; $I^2 = 88.5\%$)[28].

F. nucleatum may contribute to CRC progression in an established tumor microenvironment due to its highly adherent, invasive and proinflammatory nature that can take advantage of a compromised colonic epithelial cell layer. Moreover, *F. nucleatum* is an asaccharolytic bacterium that will not compete for glucose, a preferred substrate in tumor metabolism, and *F. nucleatum* can tolerate the hypoxic tumor environment[26,29]. In addition, *F. nucleatum* is capable of functioning as a bridge-forming bacterium to interact with other bacterial colonizers, leading to a complex biofilm formation in the human body[30,

31]. The increases in *F. nucleatum* abundance were observed in both biopsy site and saliva samples of CRC[32].

Flynn *et al*[33] proposed a polymicrobial synergy model that certain oral pathogens may cooperate to fight off the host immune system for survival and be able to establish a niche containing mixed species in the gut. The intestinal mucosa and epithelium are falling off and replaced constantly, which provide available nutrients and binding sites for adhesive bacteria. Intestinal and oral environments share similar pH, which is conducive for bacteria to form biofilm and persist in the host. Initiation or progression of tumorigenesis benefit these bacteria for proliferation because local inflammatory responses during tumorigenesis increase available nutrients in the niche[33]. Polymicrobial colonization at the tumor site by bacterial species that are phylogenetically related to those classified as oral pathogens (*e.g.*, *Fusobacterium*, *Anaerococcus* and *Parvimonas*) could promote tumorigenesis by modifying the tumor microenvironment and eliciting an elevated response of T helper 17 cells, which is linked to a poor prognosis of CRC patients[34].

The order *Bacteroidales* contains more than 35 species, including the best studied genus *Bacteroides*, which is highly abundant in gut microbiota of a healthy human[35-39]. Due to its high density, it is proposed that the species in this order may form mutualistic relationships with the host gut and play a role in stabilizing the compositional structure of the gut microbiota. However, certain species from this order are pathogenic and considered as potential driver bacteria for CRC. For example, ETBF secretes a zinc metalloprotease toxin, known as *B. fragilis* toxin, that is associated with inflammatory bowel disease and CRC[40]. ETBF can induce production of reactive oxygen species in host cells that cause oxidative DNA damage, induce inflammation and disrupt the integrity of the epithelial barrier. In addition, ETBF is able to activate the β-catenin nuclear signaling cascade and induce proliferation of host cells[41]. Although *B. fragilis* may enhance the efficiency of immune checkpoint inhibitor therapy[42], ETBF has been reported to decrease OS and DFS of CRC patients[27,42].

Unexpectedly, our data showed that *Bacteroides* at on-tumor and adjacent-tumor sites displayed distinguishable effects on OS and DFS (Figures 5 and 6). High abundance of *Bacteroides* at on-tumor sites manifested worse OS and DFS, whereas those at adjacent-tumor sites showed better OS and DFS. It was reported that high levels of defined chemokines (*e.g.*, CCL5 and CCL17) in CRC tissues may attract beneficial T cells [cytotoxic T lymphocytes, T-helper (Th) 1 cells, interleukin-17-producing Th cells and regulatory T cells] and lead to improved patient survival. Titers of *Bacteroidales* were positively correlated with expression levels of individual chemokines and the extent of T cell infiltration[43]. Loading *Bacteroidales* to tumor xenografts recruited T cells, indicating that *Bacteroidales* is capable of controlling the extent of tumor infiltration by beneficial immune cells[43]. However, CRC tissue was

infiltrated by more "not effector" T cells (Th2/Th0/regulatory T cells/Tnull) with regulatory or anergic properties, which are unable to kill CRC cells and may contribute to CRC promotion[44]. Therefore, *Bacteroidales* at off-tumor sites here may play a protective role in recruiting beneficial T cells (*e.g.*, Th1, Th17, *etc*), leading to improved prognosis of CRC patients. On the other hand, *Bacteroidales* at on-tumor sites may contribute to CRC recurrence as pathogens or thrive as passenger bacteria.

In our Kaplan-Meier survival analyses, high abundance of *Anaerotruncus* at either on-tumor sites or adjacent-tumor sites was associated with shorter OS and DFS, suggesting that the genus increases the risk of CRC recurrence and patient death. The genus *Anaerotruncus* contains only one validly published species, namely *Anaerotruncus colihominis*. *Anaerotruncus colihominis* was first identified as a Gram-positive, anaerobic bacillus that was isolated from the stool specimens of two children[45]. Moreover, this species was isolated from the blood culture of humans with nosocomial bacteremia[45]. Significant enrichment of *Anaerotruncus* was found in the endometrium of patients with endometrial cancer, suggesting that this bacterium promotes inflammation and tumorigenesis[46]. High fat diets are generally considered as a high risk factor for CRC. Abundance of *Anaerotruncus* is considered to be linked to consumption of saturated fatty acids in both men and women[47]. In mouse model experiments, high fat diets and high sucrose diets led to conditional pathogenic bacterial growth, such as *Anaerotruncus* and *Bacteroides*. These bacteria played a proinflammatory role in disrupting the integrity of epithelial barrier function[48-50].

Several genera, including *Pyramidobacter* and *Mogibacteriaceae*, are sulfidogenic and associated with CRC[51-55]. *Pyramidobacter* is mainly isolated from the human oral cavity, upper gastrointestinal tract and bile[56,57]. The genus *Pyramidobacter* contains anaerobic, Gram-negative bacilli that produce acetic, isovaleric acids and many other trace chemicals as metabolism products[51]. Abundance of *Pyramidobacter* was found to be higher in older adults and was positively correlated with proinflammatory cytokine interleukin-6 that promotes CRC development[58]. In addition, the family *Mogibacteriaceae* was reported to be associated with CRC and observed to co-occur with *F. nucleatum*[53,59]. Our previous study also reported that *Mogibacterium* from the family *Mogibacteriaceae* was associated with *Peptostreptococcus* in gut microbiota isolated from CRC patients[60].

Several genera identified in this study were reported to be associated with CRC previously. The role of *Eubacterium* in CRC initiation was underestimated for a long time. Recently, we identified *Eubacterium* as a potential driver bacteria contributing to CRC and experimentally showed that the lipopolysaccharide of *Eubacterium rectale* activates the transcription factor NF-κB, which regulates innate and adaptive immune responses in normal colon epithelial cells[22]. The genus *Dialister* was detected in the blood of patients with oral infections that cause bacteremia[61]. A meta-analysis based on 26 studies that used next-generation sequencing to analyze microbiota showed that the relative abundance of *Dialister* was significantly higher in cancer patients than those in control samples[62]. The metabolism end products of *Dialister* include acetate, lactate and propionate that may cause carcinogenesis[62]. *Treponema denticola* is an oral pathogen and associated with an increased risk of CRC[63]. The genus *Schwartzia* is linked to CRC carcinogenesis-related gene methylation[64]. The family *Coriobacteriacea*e is considered a commensal or probiotic bacteria residing in the human gut[65]. Their roles in driving CRC recurrence are unknown.

Unlike other critical genera analyzed in this study, low abundance of *Haemophilus* at adjacent-tumor sites indicated longer OS and DFS than those with high abundance in our Kaplan-Meier analyses. *Haemophilus* is a commensal microorganism, which belongs to the phylum *Proteobacteria*. It is an opportunistic pathogen that may lead to infections such as endocarditis and pneumonia. *Haemophilus* in stool samples showed significantly higher proportions in the CRC group than in the control group[66]. The proportions of *Haemophilus* decreased after tumor removal *via* surgery, indicating it is a carcinogenesis pathogen indirectly[67]. However, decreased abundance of *Haemophilus* was observed in stage I/II CRC compared to stage 0 (earliest) CRC, which may be due to overgrowth of other harmful bacteria that acted as competitors during the transition from precancerous lesions to late-stage CRC[68].

According to our COX regression analysis, location (right/left colon or rectum) is another risk factor for patient death. Compared to left colon or rectum, right colon obviously increased risk of death. Consistent with our results, a study showed that the 10-year OS of patients with CRC at the right-sided colon was shorter than that of patients with CRC at the left-sided colon[68]. There is a more abundant blood supply in the right-sided colon than other parts of colon, which benefits tumor growth and results in common clinical symptoms including anemia, emaciation, fever and dyscrasia. Tight-sided CRC exhibits more mucinous and advanced TNM stage[69]. Obviously different patterns of microbiota structures and abundances were found between left-sided and right-sided colons of CRC patients[69]. Moreover, invasive bacterial biofilms were found in 89% of right-sided CRC cases but in only 12% of left-sided CRC cases[69]. Therefore, right-sided CRC specific bacterial species with concomitant procarcinogenic epithelial responses may contribute to the development of right-sided CRC[70].

We further identified that TNM stage showed an obvious impact on survival of CRC patients. Patients with stage III/IV CRC had a higher risk of death and disease recurrence, which is consistent with previously reported results[71]. At the same time, microsatellite status was another factor that influenced patient survival in our study. MSI may decrease the risk of CRC recurrence compared to microsatellite stable patients. Moreover, it was reported that MSI shows stage-specific impacts on the prognosis of CRC patients[70]. In stages II and III CRC, high MSI tumors had superior prognosis

compared with high microsatellite stable tumors. In stage IV CRC, although 4% of tumors were identified as high MSI tumors, these tumors were recognized to be associated with inferior survival[70]. Sequencing paired colon tumor and normal-adjacent tissue and mucosa samples revealed significant enrichment of *B. fragilis* and *F. nucleatum* in deficient mismatch repair CRC but not in proficient mismatch repair CRC[72].

CONCLUSION

In this work, we identified critical bacterial taxa that are associated with prognosis and survival of CRC patients. Our work suggests that intestinal microbiota can serve as biomarkers to predict the risk of CRC recurrence and patient death. Unexpectedly, most of these identified genera have not been investigated for their physiological roles in interacting with host intestinal cells. On the other hand, some well-recognized CRC drivers, *e.g.*, *Peptostreptococcus* and *Streptococcus*, are not associated with CRC recurrence according to our observations. Thus, the mechanism behind bacteria-driving CRC recurrence may be different from those proposed for bacteria-driving CRC development. The activities of complex immune cells, *e.g.*, various types of T cells (*e.g.*, Th1, Th2 and Th17) and macrophages, in response to these bacterial activities may need to be considered. Further functional analyses of physiological roles of these bacteria in patient prognosis and CRC recurrence will shed light on developing novel strategies for CRC treatment and prevention.

ARTICLE HIGHLIGHTS

Research background

Colorectal cancer (CRC) is one of the most common malignant tumors. Gut mucosal microbiota is considered to be one of the key factors promoting CRC. There is evidence that certain gut bacteria are linked to the prognosis (recurrence, overall survival and disease-free survival) of CRC, but there is a lack of research on the relationship between large-scale intestinal microbiota profiles and CRC recurrence/patient prognosis.

Research motivation

Our study focused on the relationship between the abundance of intestinal microbiota at different positions and CRC recurrence/patient prognosis. This study provides novel potential biomarkers for patient prognosis in the future.

Research objectives

The main objective of this study was to evaluate whether the abundance of intestinal microbiota at on-tumor or adjacent-tumor sites can predict CRC recurrence and patient prognosis. Our study has preliminarily suggested that some gut bacteria may have predictive values for CRC recurrence and patient prognosis. These results can provide new biomarkers for prediction of CRC recurrence in the future.

Research methods

We collected intestinal bacteria from different locations of the intestinal mucosa of patients and healthy controls. The bacterial taxa and abundance were determined by high-throughput 16S ribosomal RNA sequencing. The relationship between gut mucosal microbiota profiles and CRC recurrence and patient prognosis was explored by bioinformatics analysis, Kaplan-Meier survival analysis and Cox regression analysis. These methods have been well established in the field.

Research results

Through analysis, gut mucosal microbiota profiles are associated with CRC recurrence and patient prognosis. Abundance of some bacterial genera/families, *e.g.*, *Anaerotruncus*, *Bacteroidales* and *Fusobacterium*, may have prognostic value for CRC recurrence and patient prognosis. The mechanism studies exploring the roles of gut mucosal microbiota in CRC recurrence and patient prognosis need to be carried out in the future.

Research conclusions

This study provides new potential biomarkers identified from gut mucosal microbiota for CRC recurrence and patient prognosis.

Research perspectives

In the future, it is necessary to explore the mechanism of how gut mucosal bacteria affect CRC recurrence and patient prognosis.

Abstract

BACKGROUND

Fibromyalgia (FM) syndrome is mainly characterized by widespread pain, sleeping disorders, fatigue, and cognitive dysfunction. In many cases, gastrointestinal distress is also reported, suggesting the potential pathogenic role of the gut microbiota (GM). The GM is deeply influenced by several environmental factors, especially the diet, and recent findings highlighted significant symptom improvement in FM patients following various nutritional interventions such as vegetarian diet, low-fermentable oligosaccharides, disaccharides,

monosaccharides, and polyols based diets, gluten-free diet, and especially an ancient grain supplementation. In particular, a recent study reported that a replacement diet with ancient Khorasan wheat led to an overall improvement in symptom severity of FM patients.

AIM

To examine the effects of ancient Khorasan wheat on the GM, inflammation, and short-chain fatty acid production in FM patients.

METHODS

After a 2-wk run-in period, 20 FM patients were enrolled in this randomized, double-blind crossover trial. In detail, they were assigned to consume either Khorasan or control wheat products for 8 wk and then, following an 8-wk washout period, crossed. Before and after treatments, GM characterization was performed by 16S rRNA sequencing while the fecal molecular inflammatory response and the short-chain fatty acids (SCFAs) were respectively determined with the Luminex MAGPIX detection system and a mass chromatography-mass spectrometry method.

RESULTS

The Khorasan wheat replacement diet, in comparison with the control wheat diet, had more positive effects on intestinal microbiota composition and on both the fecal immune and SCFAs profiles such as the significant increase of butyric acid levels (P = 0.054), candidatus *Saccharibacteria* (P = 9.95e-06) and *Actinobacteria*, and the reduction of *Enterococcaceae* (P = 4.97e-04). Moreover, the improvement of various FM symptoms along with the variation of some gut bacteria after the Khorasan wheat diet have been documented; in fact we reported positive correlations between *Actinobacteria* and both Tiredness Symptoms Scale (P < 0.001) and Functional Outcome of Sleep Questionnaire (P < 0.05) scores, between *Verrucomicrobiae* and both Widespread Pain Index (WPI) + Symptom Severity scale (SS) (P < 0.05) and WPI (P < 0.05) scores, between candidatus *Saccharibacteria* and SS score (P < 0.05), and between *Bacteroidales* and Sleep-Related and Safety Behaviour Questionnaire score (P < 0.05).

CONCLUSION

The replacement diet based on ancient Khorasan wheat results in beneficial GM compositional and functional modifications that positively correlate with an improvement of FM symptomatology.

INTRODUCTION

Fibromyalgia (FM) is a systemic syndrome of unclear etiology, characterized by widespread pain and tenderness, sleeping disorders, fatigue, and cognitive dysfunction[1]. It has been hypothesized that low-grade systemic inflammation, a preponderance of pro-oxidative state, and an insufficient antioxidant

capability – as demonstrated by the low levels of some minerals and vitamins in FM patients – could contribute to the disease development, by reducing the pain threshold and inducing fatigue and mood disorders[2]. In many cases, gastrointestinal distress is also reported, suggesting a potential involvement of the gut microbiota (GM), as demonstrated by the rather frequent dysbiosis found in FM subjects[3,4].

The GM is a complex ecosystem composed of hundreds of thousands of microorganisms involved in various useful functions that range from the host organism's defense to homeostasis maintenance and the metabolite production, such as short-chain fatty acids (SCFAs) that show anti-inflammatory properties[5]. The GM is deeply influenced by several environmental factors, especially the diet, which seems to be involved also in the FM syndrome. Recent evidence documented a significant symptom improvement in FM patients following various nutritional interventions such as vegetarian diet, low-fermentable oligosaccharides, disaccharides, monosaccharides, and polyols based diets or gluten-free diet[6].

In recent years, the potential health benefits of ancient grains have emerged and we have shown that the consumption of products made with *Triticum turgidum ssp. turanicum* (Khorasan) improves both the inflammatory profile and the gastrointestinal symptoms in different patient groups[7]. Furthermore, our recent study demonstrated that a replacement diet with ancient Khorasan grain led to an overall improvement in symptom severity and sleep pattern of FM patients[8]. However, as far as we know, no studies are available to evaluate the possible beneficial effects of ancient grain consumption on the GM of FM patients. Therefore, the aim of this present study was to examine whether a replacement diet with ancient Khorasan wheat could influence the GM composition, the fecal molecular immune profile, and SCFAs production in patients suffering of fibromyalgia syndrome.

MATERIALS AND METHODS

Study design and participants

Participants were considered eligible for inclusion in this randomized, double-blind crossover trial (Figure 1) if they were aged 18-70 years and had a documented diagnosis of FM. The exclusion criteria were as follows: celiac disease, gluten sensitivity (assessed on the basis of medical evaluation, taking into account both the negative results of blood tests for celiac disease and the absence of celiac symptoms during a diet containing gluten) or wheat allergy, any known organic disease or clinical alarm signs, pregnancy or breast-feeding, and use of probiotics or antibiotics in the past 2 mo.

The experimental wheat used in this study was organic Khorasan wheat (*Triticum turgidum subsp. Turanicum*), KAMUT brand, supplied by Kamut Enterprises of Europe. KAMUT®, a registered trademark of Kamut International, Ltd., and Kamut Enterprises of Europe, bv, guarantees that the wheat is pure ancient Khorasan wheat and is organically grown and processed. The organically cultivated modern variety named "palesio" was used as control wheat.

After a 2-wk run-in period, eligible participants were randomly assigned to consume either Khorasan or control wheat products (500 g/wk of pasta, 150 g/d of bread, 500 g/mo of crackers, and 1 kg/mo of biscuits) for 8 wk and then, following an 8-wk washout period, crossed.

During both intervention periods, all participants were encouraged to maintain their usual eating habits, but they were not allowed to eat other cereal-based products. Instead, during the washout period participants were allowed to eat all foods according to their usual eating habits. In the second intervention period, the group assigned to consume the control grain products in the first intervention period was assigned to consume the Khorasan products, and *vice versa*.

At the beginning and at the end of each intervention period, we collected stool samples, in order to perform GM characterization, SCFAs evaluation, and immunological analysis. The following validated self-administered questionnaires were used for evaluation: Widespread Pain Index (WPI), Symptom Severity scale (SS), FM severity scale (WPI + SS), FM Impact Questionnaire (FIQ), Fatigue Severity Scale (FSS), Tiredness Symptoms Scale (TSS), Sleep-Related and Safety Behaviour Questionnaire (SRSBQ), Restorative Sleep Questionnaire-Daily, and Functional Outcome of Sleep Questionnaire (FOSQ).

In general, as previously reported[8], both interventions resulted in an amelioration of all questionnaires scores; however, a statistically significant decrease in WPI + SS, FOSQ, and FIQ scores was observed only after the Khorasan diet.

The study was approved by the local Ethics Committee "Comitato Etico Regionale per la Sperimentazione Clinica della Regione Toscana, Sezione AREA VASTA CENTRO" (SPE 12.630), and adhered to the principles of the Declaration of Helsinki and the Data Protection Act.

Microbiota characterization

Total DNA was extracted using the DNeasy PowerLyzer PowerSoil Kit (Qiagen, Hilden, Germany) from frozen (-80 °C) stool samples, according to the manufacturer's instructions. Briefly, 0.25 g of stool samples were added to a bead beating tube and homogenized with TissueLyser II for 5 min at 30 Hz. Genomic DNA was captured on a silica membrane in a spin column format, washed, and subsequently eluted. The quality and quantity of extracted DNA were assessed with a Qubit Fluorometer (Thermo Fisher Scientific, Waltham, United States) and then frozen at -20 °C.

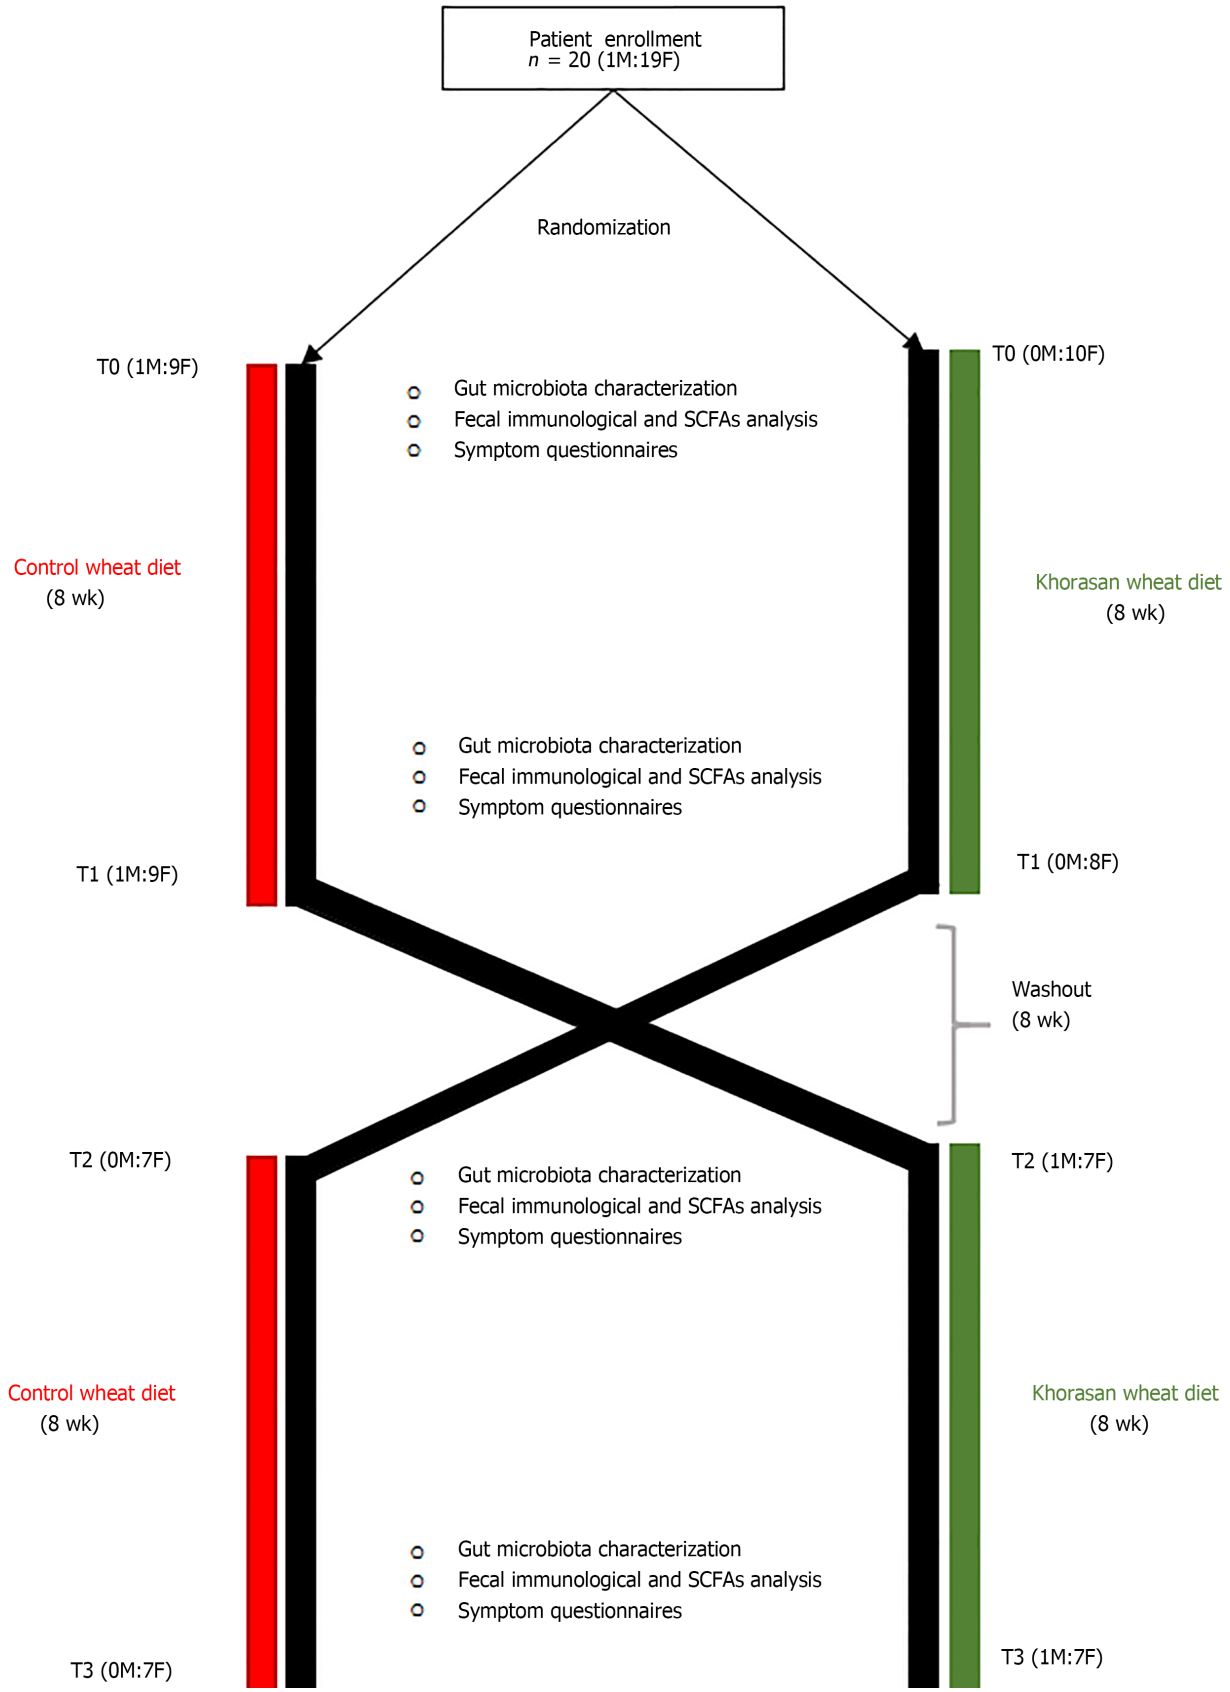

Figure 1 Workflow of the crossover intervention study.

Subsequently, DNA samples were sent to IGA Technology Services (Udine, Italy) where amplicons of the variable V3-V4 region of the bacterial 16S rRNA gene were sequenced by producing paired-end reads (2 × 300 cycles) on the Illumina MiSeq platform, according to the Illumina 16S Metagenomic Sequencing Library Preparation protocol.

Afterwards, the raw data were processed following the software pipeline MICCA (MICrobial Community Analysis) as we previously described[9].

Briefly, paired end reads were assembled, maintaining a minimum overlap of 20 bp and an edit distance in the maximum overlap of 2 bp. Next, the sequences were cut to remove the primers and all the reads having a length lower than 350 bp and with an error rate higher than or equal to 0.5 were removed. The cleaned reads were merged into a single file and transformed into a FASTA file. The operational taxonomic units (OTUs) were generated by setting a 97% identity threshold and performing an automatic removal of chimeras and so the longest sequence of each OTU was used for the taxonomic assignment, *i.e.*, using the Ribosomal Database Project classifier that is able to obtain classification and confidence for taxonomic ranks up to genus.

SCFA determination by gas chromatography-mass spectrometry analysis

The qualitative and quantitative evaluation of fecal SCFAs was performed using the Agilent gas chromatography-mass spectrometry (GC-MS) system composed of a 5971 single quadrupole mass spectrometer, a 5890 gas-chromatograph, and a 7673 autosampler, through our previously described GC-MS method[10].

Just before the analysis, fecal samples were thawed and combined with 10 mM sodium bicarbonate solution (1:1 w/v) in a 1.5 mL centrifuge tube. Then, the obtained suspension was sonicated for 5 min and centrifuged at 5000 rpm for 10 min, and then the supernatant was collected. Finally, SCFAs were extracted as follows: an aliquot of 100 μL of sample solution (corresponding to 0.1 mg of stool sample) was added to 50 μL of internal standards mixture, 1 mL of tert-butyl methyl ether, and 50 μL of 1.0 M HCl solution in a 1.5 mL centrifuge tube. Subsequently, each tube was shaken in a vortex apparatus for 2 min and centrifuged at 10000 rpm for 5 min, and finally the solvent layer was transferred to an autosampler vial and analyzed three times.

Evaluation of fecal molecular inflammatory response

Fecal samples were collected into 1.5 mL centrifuge tubes, added with phosphate-buffer saline w/o calcium w/o magnesium (1:2 w/v), stirred in a vortex apparatus for 2 min, sonicated for 5 min, and then centrifuged at 14000 rpm for 5 min. The supernatants were then transferred in 1.5 mL centrifuge tubes and stored at -20 °C.

The inflammatory response was evaluated through Milliplex custom kit Human Cytokines panel A for Luminex MAGPIX detection system (Affymetrix, eBioscience), following the manufacturers' instructions for supernatants.

In detail, the levels of interleukin (IL)-1α, IL-1β, IL-17A, IL-4, and interferon (IFN)-γ were assessed. Cytokine levels were estimated using a 5-parameter polynomial curve (ProcartaPlex Analyst 1.0) and values under the lower limit of quantitation were considered as 0 pg/mL.

Statistical analysis

Parametric variables are expressed as the mean ± SD whereas non parametric continuous variables are presented as the median and interquartile range. Statistical analyses on the bacterial communities were performed in R using the packages phyloseq 1.26.1, DESeq2 1.22.2, and other packages satisfying their dependencies, in particular, vegan 2.5-5. For the cluster analysis of the entire community, the OTU table was first normalized using the total OTU counts of each sample and then adjusted using square root transformation.

The differential analysis of abundance at the OTUs as well as at different taxonomic ranks (created using the tax_glom function in phyloseq) was performed with DESeq2 using the paired Wilcoxon signed-rank test to compare pre- and post- intervention data. Spearman correlations were performed in R with the package Hmisc 4.5.0, while heatmaps were prepared using the package ggplot2 3.3.5.

Furthermore, GraphPad Prism (v.5) was used for paired statistical analysis of both the fecal molecular inflammatory profile and the SCFA levels before and after each diet.

RESULTS

Characteristics of the study population

Twenty FM patients (1 male and 19 females) with a mean age of 48.9 ± 12.3 years and a mean BMI of 25.30 ± 4.67 kg/m^2 provided written informed consent and were enrolled in this randomized double-blind crossover trial.

As showed in Figure 1, after randomization, ten patients (1M:9F) with a mean age of 51.70 ± 12.93 years and a mean BMI of 25.66 ± 5.59 kg/m^2 were assigned to consume control wheat products while the other ten patients (0M:10F) with a mean age of 46.20 ± 11.52 years and a mean BMI of 24.95 ± 3.81 kg/m^2 were assigned to consume Khorasan wheat products. Subsequently, after the washout period, the intervention groups were crossed and, because of the retirement of five subjects, seven patients (0M:7F) consumed control wheat products and eight patients (1M:7F) consumed Khorasan wheat

products.

Effects of dietary interventions on gut microbiota composition

First of all, aiming to examine the impact of both a control wheat diet (CD) [pre- (CD_0) and post- (CD_1)] and Khorasan wheat diet (KD) [pre- (KD_0) and post- (KD_1)] on the GM composition, we performed the analysis of alpha diversity; however, no significant differences were reported for Shannon index, Chao1 index, or Evenness (data not shown).

Taxonomic analysis, detailed in Table 1, revealed the presence of 14 phyla (> 99% reads), 24 classes (> 99% reads), 35 orders (> 98% of reads), 60 families (> 94% reads), and 142 genera (> 84% reads).

Furthermore, the cluster analysis and the principal coordinate analysis computed using the Bray-Curtis dissimilarity metric did not highlight any clear separation between the pre- and post-CD groups or the pre- and post-KD groups at the phylum level (Figure 2), neither to other taxonomic ranks.

Subsequently, in order to evaluate the impact of both the dietary interventions on microbial abundances, we performed differential analysis at all taxonomic ranks.

In detail, among taxonomic levels, no significant changes were observed except for genus level; in particular, as shown in Figure 3, CD resulted in a significant increase in the abundance of Turicibacter spp. (shrinked FC = 0.969, P = 0.014).

Evaluation of fecal SCFAs profiles before and after dietary interventions

We analyzed the abundances of fecal SCFAs (acetic, propionic, butyric, isobutyric, isovaleric 2-methyl-butyric, and valeric acids) before and after both diets and no influence on their amounts was found after CD or KD (Table 2).

Since these analyses could be in part influenced by the total amount of each SCFA, we repeated the same comparisons on the SCFA percentage compositions and no statistically significant differences were found.

Analysis of fecal molecular inflammatory profile before and after dietary interventions

We evaluated the levels of fecal cytokines (IFN-γ, IL-1α, IL-1β, IL-4, and IL-17A) before and after both dietary interventions (Table 3) and we found that CD only resulted in a significant increase in IL-4 (P = 0.041) while no statistical differences were found after the KD (Figure 4).

Evaluation of impact of dietary interventions on gut microbiota excluding the washout period

Finally, in order to evaluate the impact of both dietary interventions on GM composition excluding eventual "carry-over effects", we focused on each single arm of both KD and CD.

In particular, at the end of the KD first arm (KDT_1), we found a significant increase in members of the phyla candidatus *Saccharibacteria* (log2FC = 2.679, P = 9.95e-06) and *Actinobacteria* (log2FC = 1.384, P = 9.63e-05) (Figure 5A), while at the end of the KD second arm (KDT_3), a reduction of *Enterococcaceae* (log2FC = -4.829, P = 4.97e-04) was reported (Figure 5B).

On the other hand, at the end of the CD first arm (CDT_1), we reported a significant reduction of *Bacteroidales* members (log2FC = -0.916, P = 0.002) (Figure 5C) while the CD second arm (CDT_3) resulted in significantly higher levels of the order *Erysipelotrichales* (log2FC = 1.342, P = 2.03e-5) and the class *Verrucomicrobiae* (log2FC = 1.975, P = 0.005) (Figure 5D).

Fecal SCFA assessment excluding the washout period

The analysis of the fecal SCFAs concentrations displayed an almost significant increase of butyric acid levels (P = 0.054) (Figure 6) at the end of the KDT_1, while no differences were reported after the KDT_3 and after both the CDT_1 and CDT_3.

Evaluation of fecal molecular inflammatory profile excluding the washout period

The assessment of the fecal cytokines concentration excluding eventual "carry-over effects" displayed that the CDT_3 resulted in a significant increase of IL-1β levels (P = 0.031), whereas no significant differences were found at the end of the CDT_1 or at the end of both the KDT_1 and KDT_3 (Figure 7).

Correlation between gut microbiota composition and questionnaire scores

To examine the association between statistically different taxa (post/pre-intervention) and the results of the questionnaire scores (post/pre-intervention), we conducted Spearman correlation for each diet (Figure 8).

In detail, a positive correlation between the phylum *Actinobacteria* and both TSS (P < 0.001) and FOSQ (P < 0.05) scores and between the class *Verrucomicrobiae* and both WPI + SS (P < 0.05) and WPI (P < 0.05) scores was reported in patients following KD. Moreover, a positive correlation between the phylum candidatus *Saccharibacteria* and SS score (P < 0.05) and between the order *Bacteroidales* and SRSBQ score (P < 0.05) was reported after KD. On the other hand, we documented a negative correlation between *Bacteroidales* and FSS score (P < 0.05) and between *Enteococcaceae* and WPI score (P < 0.05).

Table 1 Summary of taxonomic analysis of obtained operational taxonomic units

Rank	Count	Reads	Reads %	OTU	OTU %

IL-17A	17.36 ± 20.39	29.67 ± 50.38	0.155	23.67 ± 12.83	26.03 ± 41.11	0.979

Data are showed as the median (interquartile range). *P* values were calculated using the Wilcoxon signed-rank test. IFN: Interferon; IL: Interleukin; CD_0: Pre-control wheat diet; CD_1: Post-control wheat diet; KD_0: Pre-Khorasan wheat diet; KD_1: Post-Khorasan wheat diet.

In addition, regarding the patients who underwent CD intervention, negative correlations were found between *Actinobacteria* and WPI + SS score ($P < 0.05$) and between *Erysipelothichales* and FSS score ($P < 0.05$).

DISCUSSION

Different nutritional interventions provide benefits in fibromyalgia management[11], and we recently demonstrated that the replacement diet with ancient Khorasan wheat led to an overall improvement in symptom severity and sleep pattern of FM patients[8].

Currently, the relationship between FM syndrome and irritable bowel disease has been confirmed but the link between gut dysbiosis and FM is still poorly understood[4]. Furthermore, it has been documented that the worsening causes for the distinctive musculoskeletal pain associated with FM have

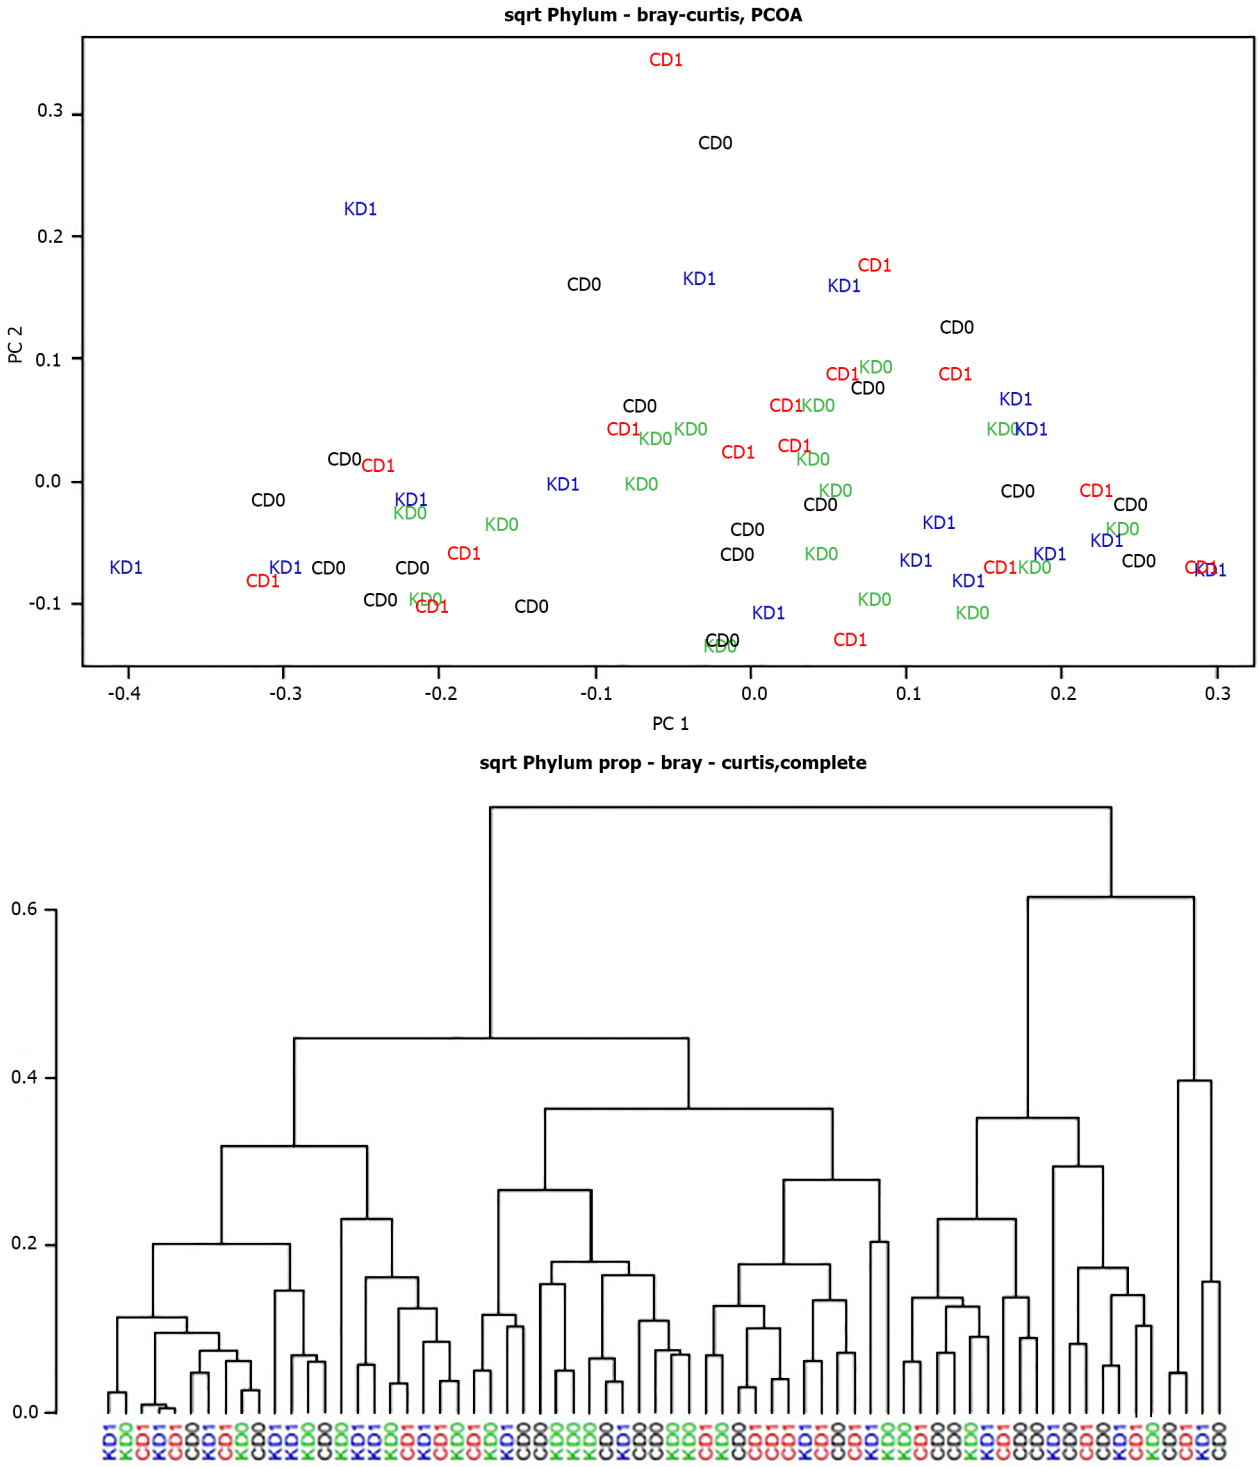

Figure 2 Cluster analysis and principal coordinate analysis of pre- and post-control-wheat-diet samples and pre- and post-Khorasan-wheat-diet samples. A: Cluster analysis; B: Principal coordinate analysis. CD_0: Pre-control wheat diet; CD_1: Post-control wheat diet; KD_0: Pre-Khorasan wheat diet; KD_1: Post-Khorasan wheat diet.

been related to obesity and unhealthy diet[12,13].

Since the whole Khorasan-based diet seems to favor an healthy microbiota[14], the goal of our study was to examine, for the first time, its effects in FM patients.

In detail, we performed a randomized, double blind crossover trial where enrolled FM patients consumed control wheat products or Khorasan wheat products for 8 wk and then crossed.

Then we analyzed the effects of the diets on GM composition, the fecal SCFAs levels, the intestinal inflammatory profile, and symptom improvement in FM patients.

First, concerning the fecal microbiota analysis of FM patients, we found that both 8-wk interventions did not significantly modify either the microbial composition and diversity or the SCFAs levels. Whereas, looking at the changes in microbial abundances produced by each dietary intervention, KD

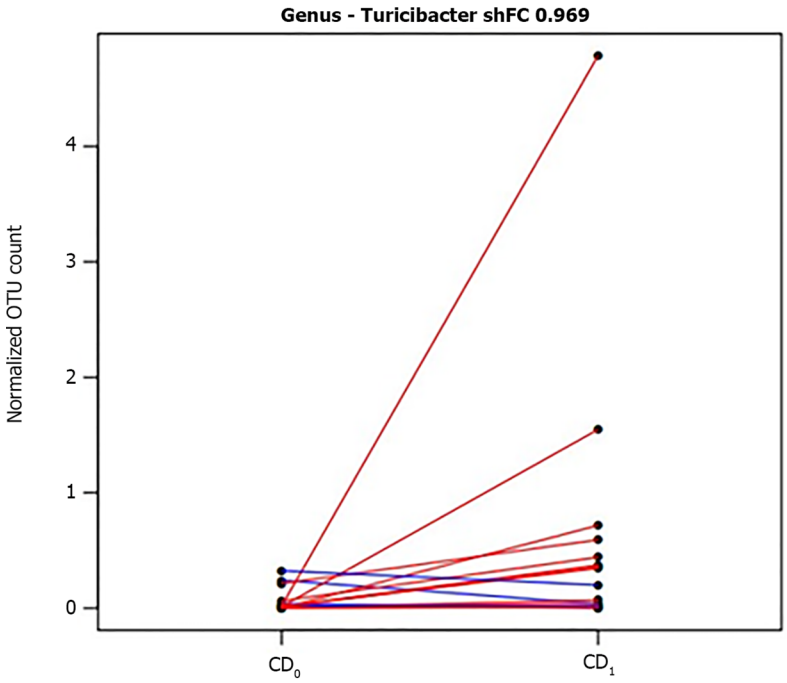

Figure 3 Segment plot showing significantly different taxa between pre- and post-control diet. Lines link paired samples and red or blue colors respectively highlight the increase or decrease of normalized abundance for the indicated rank. Plot title reports shrinked fold change (according to the DESeq2 function lfcShrink) between pre- and post-control-wheat-diet samples. CD_0: Pre-control wheat diet; CD_1: Post-control wheat diet.

did not result in modifications at any taxonomic level; instead, CD was associated with a significant increase of *Turicibacter spp*.

Previous studies documented that the abundance of the genus *Turicibacter* was markedly reduced in mice with high fat feeding[15,16] and recent findings reported its negative correlation with body fat[17, 18]. In addition, Zhong *et al*[19] found a positive correlation between *Turicibacter spp*. and butyric acid, an SCFA famous for its anti-inflammatory properties; hence, CD seems to exert a slight beneficial effect on FM patients.

In addition, the evaluation of the fecal molecular inflammatory profile showed that CD resulted in an increased level of the anti-inflammatory IL-4, while no significant differences were reported after KD.

In contrast, current evidence suggests that, compared to healthy controls, FM patients showed lower plasma levels of IL-4[20,21]. Nevertheless, given its demonstrated role in the transcription enhancement of opioid receptors, a lower IL-4 abundance could be associated with an increase in pain perception[22].

Anyway, in general, both 8-wk dietary interventions displayed modest effects on GM composition and metabolic function (SCFAs) and on the fecal cytokine profile of FM patients.

Nonetheless, our findings are consistent with other previous studies[23,24] which demonstrated the remarkable stability, resilience, and inter-individual variability of the GM in response to short-term dietary modifications.

Finally, although our cross-over study, as it usually is, typically contains a washout period to exclude the repercussion of the modifications (carry-over effect) of one intervention phase on subsequent[25], given that we did not have the possibility to supervise FM patients in the meantime, we repeated all of the analysis at the end of each intervention arm.

Interestingly, the subjects included in the first KD arm, before the unrestricted washout period diet, reported a significant increase of the phyla candidatus *Saccharibacteria* and *Actinobacteria* phyla and a significantly higher abundance of butyric acid.

As previously demonstrated, the *Saccharibacteria* members colonize the human oral cavity and are associated with oral mucosal infectious diseases[26]. However, most members of the *Saccharibacteria* phylum remain uncultivable and no in-depth metabolic analysis of these bacteria is yet available; hence, their potential role in the microbial community has not been fully elucidated[27].

On the other hand, *Actinobacteria*, which play a key role in the maintenance of gut homeostasis by producing SCFAs and modulating the immune response, were reduced in a cohort of FM patients[28, 29].

Concerning the increase of fecal butyric acid abundance after the first KD arm, a recent study reported that FM patients showed lower levels of butyrate-producing bacteria, such as many members of the *Lachnospiraceae* family, than healthy subjects[30]. In addition, comparing the effect of a Kamut-based diet *vs* a modern wheat-based diet in healthy subjects, Saa and colleagues reported that the concentration of butyrate and its esters in stool and urine samples were increased after the Kamut-diet [31].

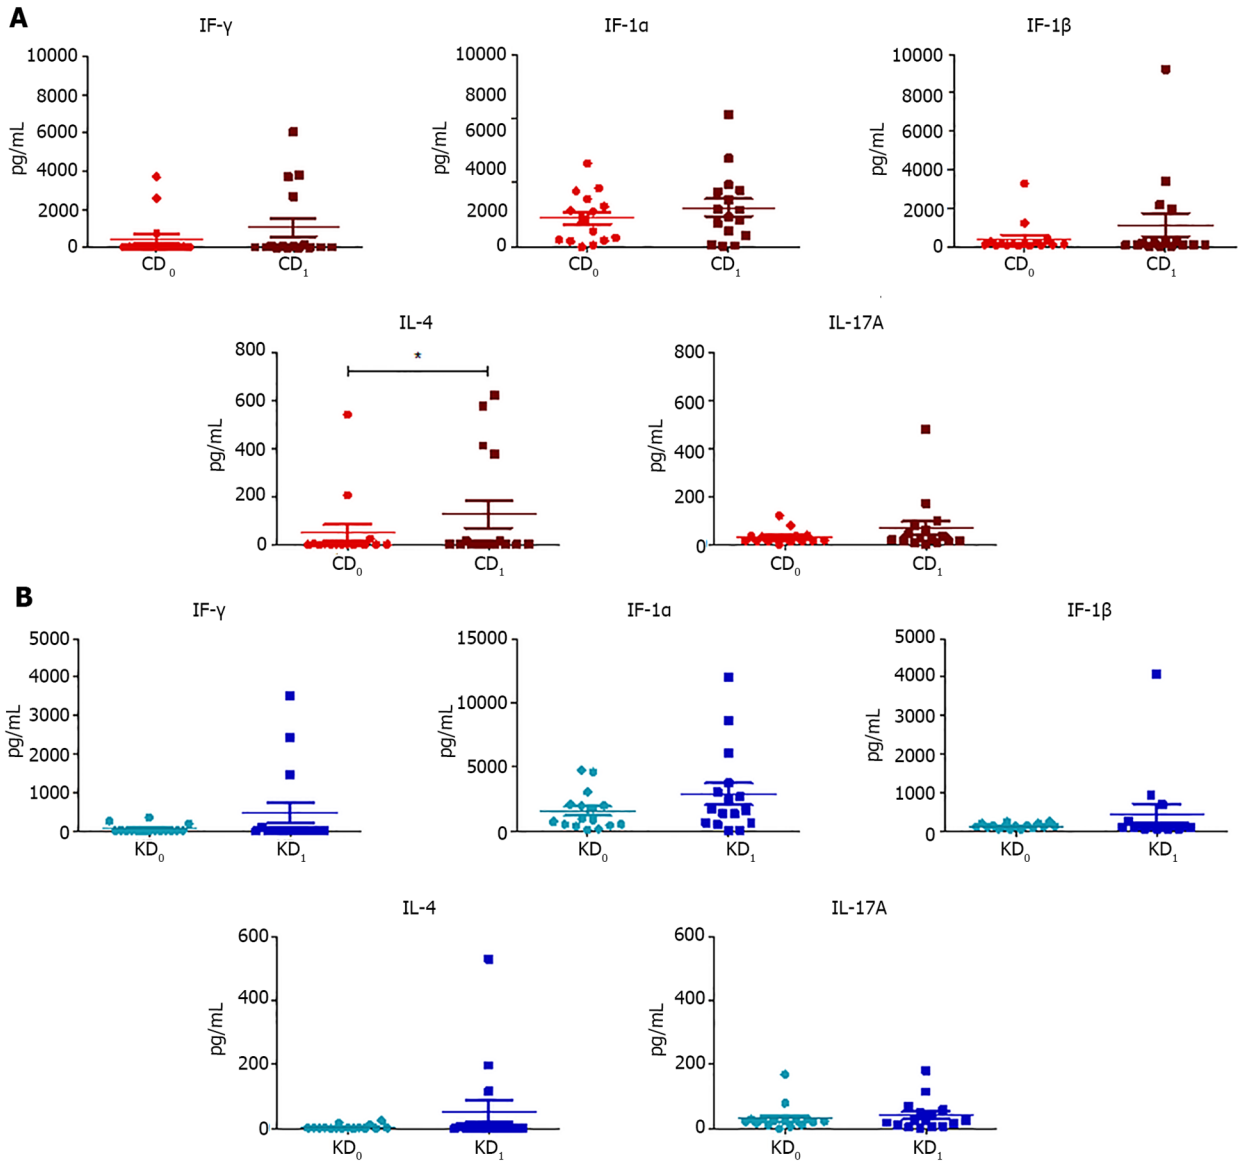

Figure 4 Scatter plots representing the fecal concentrations of interferon-γ, interleukin-1α, interleukin-1β, interleukin-4, and interleukin-17A evaluated before and after control wheat diet and before and after Khorasan wheat diet. A: Before and after control wheat diet; B: Before and after Khorasan wheat diet. Analyses were assessed using the paired Wilcoxon signed-rank test and *P* values less than 0.05 were considered statistically significant. [a] *P* < 0.05, [b]*P* < 0.01, [c]*P* < 0.001. CD_0: Pre-control wheat diet; CD_1: Post-control wheat diet; KD_0: Pre-Khorasan wheat diet; KD_1: Post-Khorasan wheat diet; IL: Interleukin.

Butyric acid, which is secreted by the GM and absorbed in the blood stream, exerts anti-inflammatory effects and induces naive T cell differentiation into regulatory T cells (Tregs)[30]. Furthermore, it acts as a potent histone deacetylase inhibitor, thus exerting analgesic and antidepressant effects[32,33]. In addition, reports suggest that butyric acid improves pain behaviors in models of nerve injury-induced pain and ameliorates neuropathic pain by acting directly on the peripheral nerve system[34,35].

The KDT_3 only resulted in a significant reduction of the *Enterococcaceae* family, whose members were instead over-represented in patients with chronic fatigue syndrome[36].

Given these different findings between the two arms of KD interventions, the possible carry-over effects of the washout period or of the CD intervention cannot be excluded.

In contrast, at the end of the CDT_1, we found a significant decrease of *Bacteroidales* members; a reduction of this order was strongly associated with different disorders, especially in Crohn's disease [37].

On the other hand, the CDT_2 was surprisingly associated with a significant increase of the order *Erysipelotrichales* and the class *Verrucomicrobiae*, which have been respectively associated with irritable bowel syndrome and chronic pain severity[38,39].

Moreover, the CDT_3 showed a significant increase of IL-1β, a potent pro-inflammatory cytokine that acts on nociceptors and results in an improvement in the transduction of pain through various ion channels. But, the IL-1β overexpression is also involved in many autoimmune disorders featuring pain such as inflammatory bowel disease, multiple sclerosis, and rheumatoid arthritis[40,41].

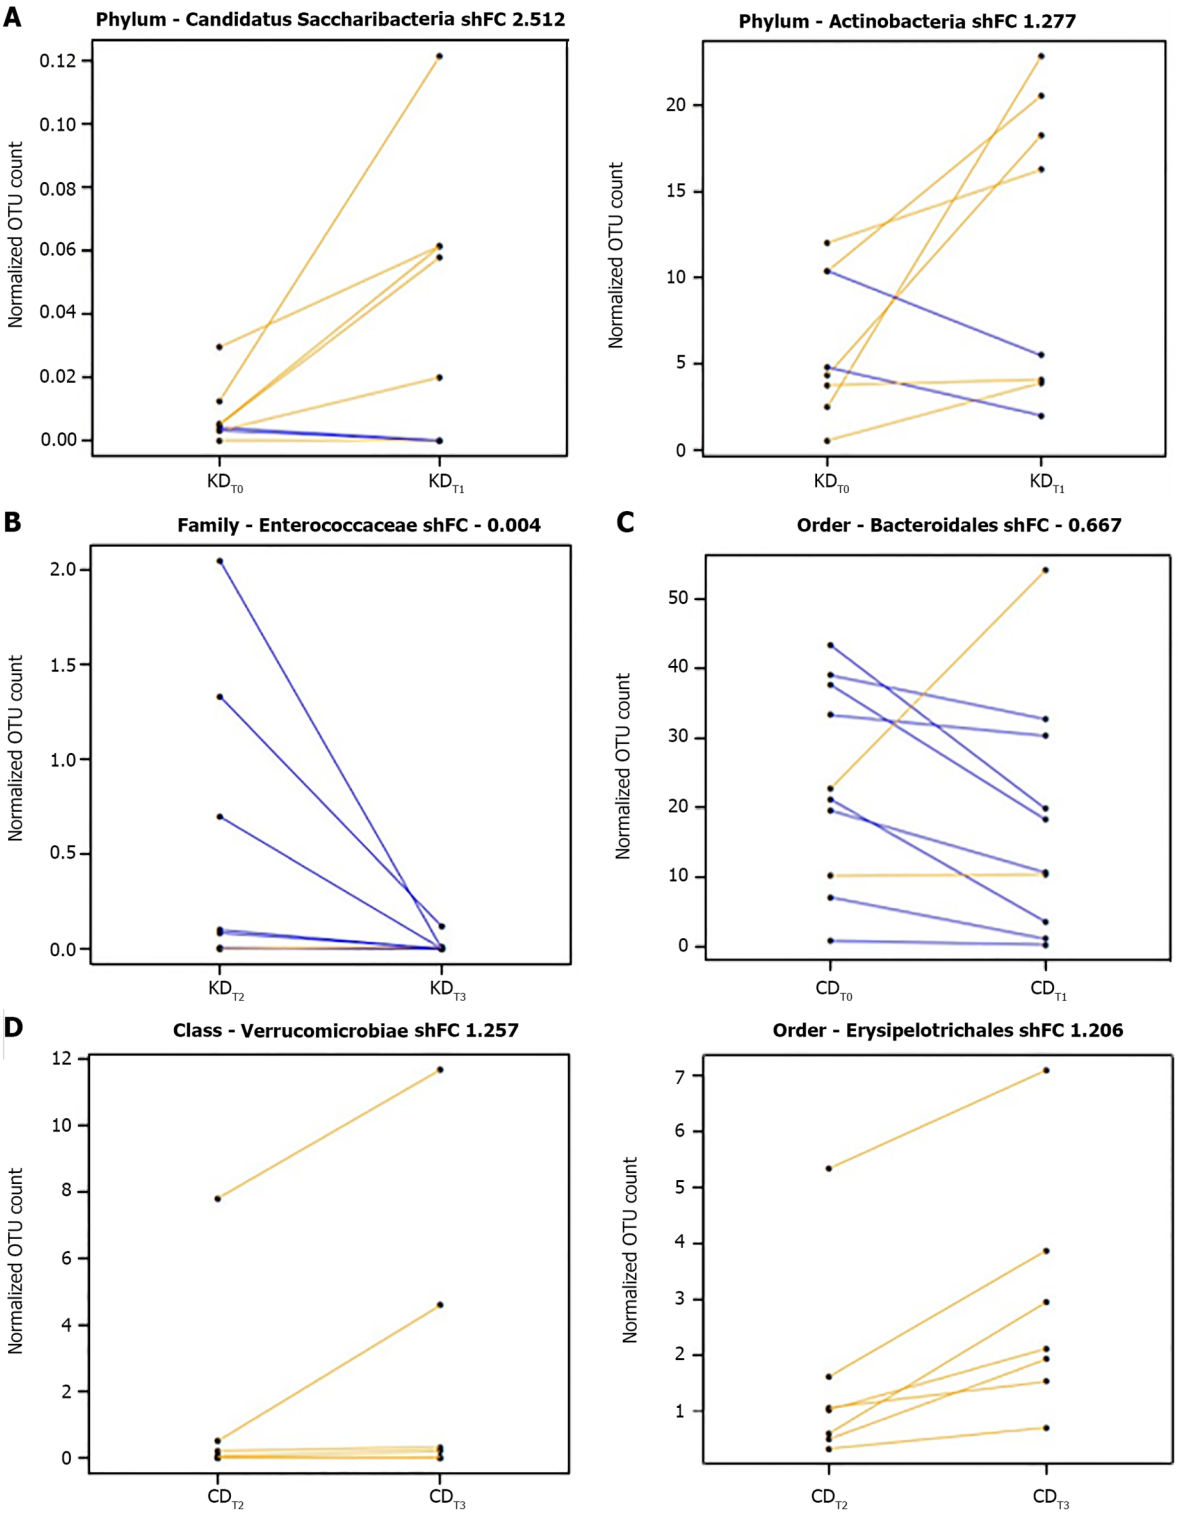

Figure 5 Segment plots showing significantly different taxa during the first arm or the second arm of the Khorasan wheat intervention and over the first arm or the second arm of the control wheat intervention. A: The first arm of the Khorasan wheat intervention; B: The second arm of the Khorasan wheat intervention; C: The first arm of the control wheat intervention; D: The second arm of the control wheat intervention. Lines link paired samples and yellow or blue colors respectively highlight the increase or decrease of normalized abundance for the indicated rank. Plot title reports Shrinked fold change (according to the DESeq2 function lfcShrink) between pre- and post-diet groups included in the two arms of either Khorasan wheat or control wheat interventions. CDT_0: Pre-control-wheat-diet first arm; CDT_1: Post-control-wheat-diet first arm; CDT_2: Pre-control-wheat-diet second arm; CDT_3: Post-control-wheat-diet second arm; KDT_0: Pre-Khorasan-wheat-diet first arm; KDT_1: Post-Khorasan-wheat-diet first arm; KDT_2: Pre-Khorasan-wheat-diet second arm; KDT_3: Post-Khorasan-wheat-diet second arm.

In addition, several studies have shown increased levels of IL-1β in FM patients compared to healthy controls, suggesting an association between IL-1β and some FM symptoms such as hyperalgesia, fatigue, sleep disorders, cognitive dysfunctions, and stress[42,43].

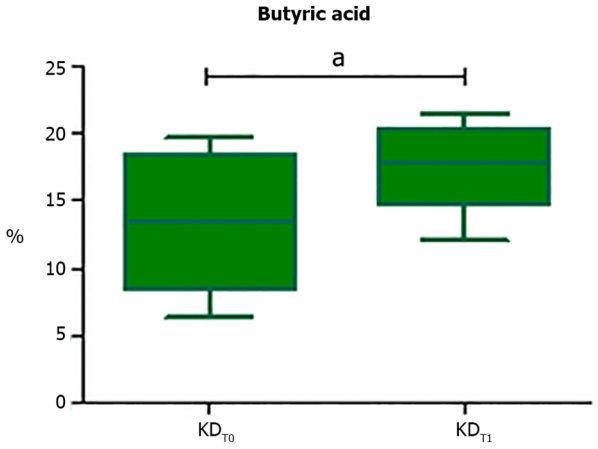

Figure 6 Box plot reporting statistically significant different butyric acid contents at the end of the Khorasan-wheat-diet first arm. Analyses were assessed using the paired Wilcoxon signed-rank test and *P* values less than 0.05 were considered statistically significant. $^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$. KDT$_0$: Pre-Khorasan-wheat-diet first arm; KDT$_1$: Post-Khorasan-wheat-diet first arm.

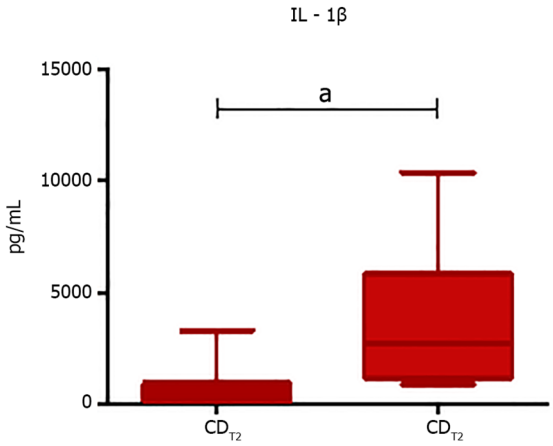

Figure 7 Box plot representing statistically significant different IL-1β levels at the end of the second control wheat diet arm. Analyses were assessed using the paired Wilcoxon signed-rank test and *P* values less than 0.05 were considered statistically significant. $^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$. IL: Interleukin; CDT$_2$: Pre-control-wheat-diet second arm; CDT$_3$: Post-control-wheat-diet second arm.

Finally, to evaluate the association between GM composition and FM symptoms, we performed Spearman correlations between the self-administered questionnaires and the differentially abundant taxa before and after both diets.

In detail, after KD, FM patients reported a positive association between an increasing abundance of *Actinobacteria* and the improvement of the TSS and FOSQ scores. In addition, we documented a positive correlation between the phylum candidatus *Saccharibacteria* and SS scores and a negative association between a reduced abundance of *Enterococcaceae* and an improved WPI score.

On the contrary, FM patients in the CD intervention reported a detrimental negative correlation between increasing *Erysipelothichales* and the amelioration of FSS score.

A significant relationship between the differential abundances of several gut bacteria and FM symptom indices such as pain intensity, WPI score, cognitive deficits, and fatigue was reported by Minerbi *et al*[44]. Moreover, Clos-Garcia *et al*[29] showed a correlation between some genera and FM pain indicators. Finally, several studies suggest that increased reactive oxygen species in FM patients, resulting in impaired mitochondrial function and reduced ATP in muscle and neural cells, might lead to chronic widespread pain in these patients[45]. Therefore, the improvement of various FM symptoms along with the variation of some gut bacteria after the KD intervention could be related to the reported antioxidant effects of the ancient Khorasan wheat[46].

Despite our present study having some limitations such as the limited number of enrolled patients, the low taxonomical resolution of 16S rRNA sequencing, the short period of dietary administrations, and the lack of patients' supervision during the washout period, our study suggest that a replacement diet with Khorasan wheat products improves the symptoms of patients with fibromyalgia.

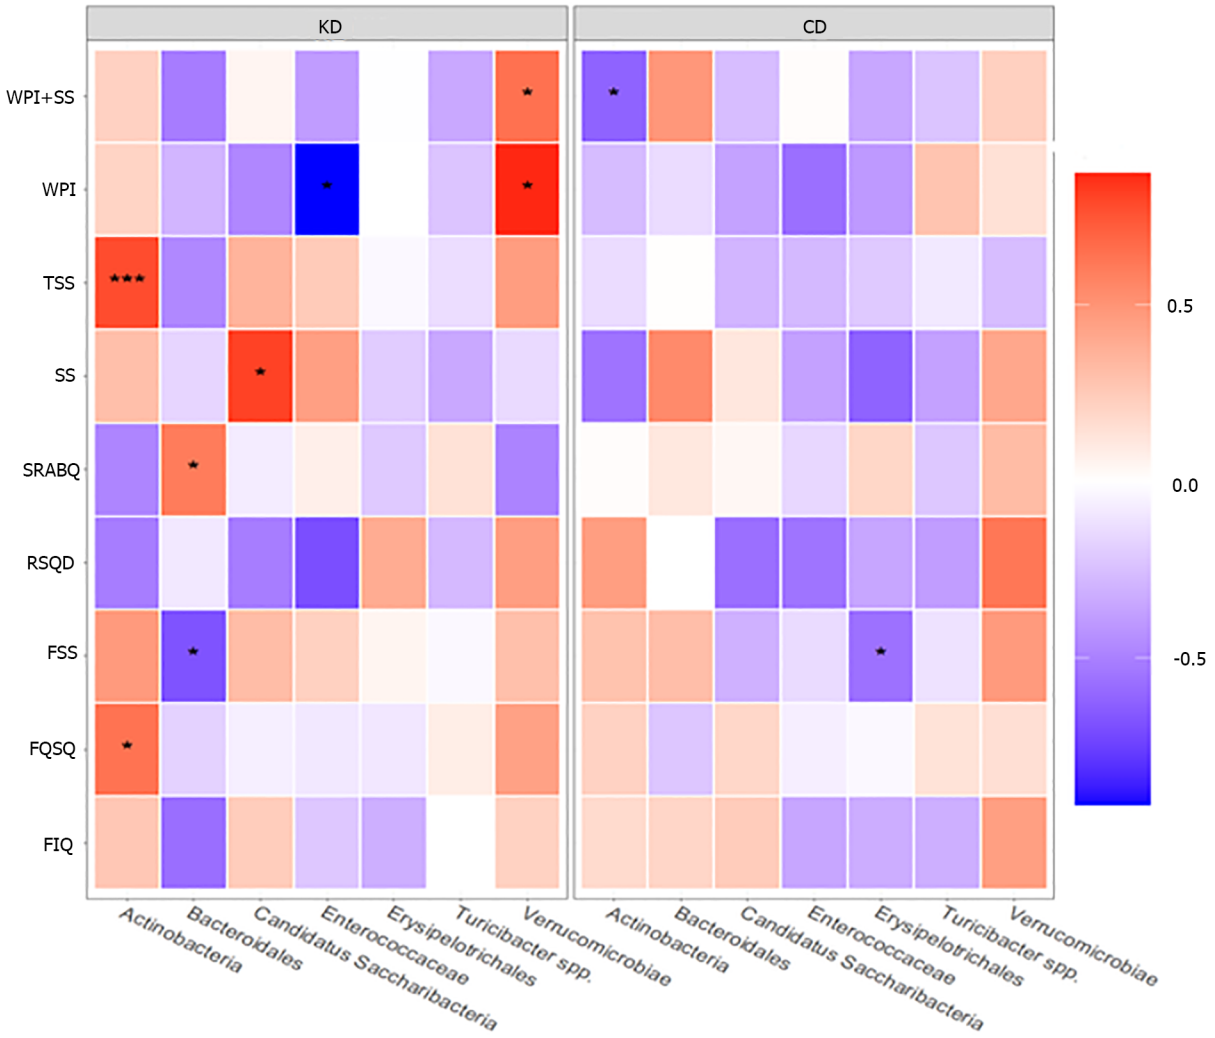

Figure 8 Heatmap of Spearman correlations between statistically significant different taxa (post-pre) and changes in questionnaire scores (post-pre), according to the Khorasan wheat diet or control wheat diet. Red shades indicate positive correlations, whereas blue shades indicate negative correlations; the intensity of colors represents the degree of association. *P* values less than 0.05 were considered statistically significant. [a]*P* < 0.05, [b]*P* < 0.01, [c]*P* < 0.001. KD: Khorasan wheat diet; CD: Control wheat diet.

CONCLUSION

In conclusion, although further studies with a long-term administration of Khorasan wheat products in high numbers of FM patients are necessary, we demonstrated for the first time that an ancient Khorasan wheat diet results in some beneficial GM compositional and functional modifications that positively correlate with an improvement of fibromyalgia symptomatology.

ARTICLE HIGHLIGHTS

Research background

Fibromyalgia (FM) is a syndrome characterized by widespread pain, sleeping disorders, fatigue, and cognitive dysfunction. Frequently, gastrointestinal distress is also reported, suggesting the potential pathogenic role of the gut microbiota (GM).

Research motivation

The GM is deeply influenced by several factors, including diet, and recent findings highlighted a significant symptom improvement in FM patients following various nutritional interventions such as vegetarian diet, low-fermentable oligosaccharides, disaccharides, monosaccharides, and polyols based diets, gluten-free diet, and an ancient grain supplementation. Therefore, a replacement diet with ancient Khorasan grain could improve FM symptomatology.

Research objectives

The main objective of our study was to examine the effects of ancient Khorasan wheat on GM composition, fecal molecular immune profile, and short-chain fatty acids (SCFAs) production in FM patients.

Research methods

In this randomized, double-blind crossover trial, 20 FM patients were randomly assigned to consume either Khorasan or control wheat products for 8 wk and then, after an 8-wk washout period, crossed. At the beginning and at the end of each intervention period, symptom questionnaires and stool samples were collected and GM characterization was performed by 16S rRNA sequencing, while the fecal molecular inflammatory response and the SCFAs were respectively determined with a Luminex MAGPIX detection system and a mass chromatography-mass spectrometry method.

Research results

The Khorasan wheat replacement diet exhibited positive effects on GM composition and on both the fecal immune and SCFAs profiles. Moreover, we documented the improvement of various FM symptoms along with the variation of some gut bacteria after the Khorasan wheat diet.

Research conclusions

An ancient Khorasan wheat diet represents a good strategy to result in positive GM compositional and functional modifications that positively correlate with an improvement of FM symptomatology.

Research perspectives

We demonstrated that a replacement diet based on ancient Khorasan wheat seems to represent a non-invasive successful strategy to ameliorate FM patient's symptomatology. We believe that our data will be a starting point for future studies on FM, especially with a long-term administration of Khorasan wheat products in high numbers of FM patients.

Abstract

BACKGROUND

Fusobacterium nucleatum (*F. nucleatum*) has long been known to cause opportunistic infections and has recently been implicated in colorectal cancer (CRC), which has attracted broad attention. However, the mechanism by which it is involved in CRC development is not fully understood.

AIM

To explore its potential causative role in CRC development, we evaluated the colon pathology, mucosa barrier, colon microbiota and host transcriptome profile after *F. nucleatum* infection in an azoxymethane/dextran sulfate sodium salt (AOM/DSS) mouse model.

METHODS

Three groups of mice were compared to reveal the differences, *i.e.*, the control, AOM/DSS-induced CRC and AOM/DSS-FUSO infection groups.

RESULTS

Both the AOM/DSS and AOM/DSS-FUSO groups exhibited a significantly reduced body weight and increased tumor numbers than the control group, and AOM/DSS mice with *F. nucleatum* infection showed the highest tumor formation ratio among the three groups. Moreover, the colon pathology was the most serious in the AOM/DSS-FUSO group. We found that the structure of the colon

microbiota changed considerably after *F. nucleatum* infection; striking differences in mucosal microbial population patterns were observed between the AOM/DSS-FUSO and AOM/DSS groups, and inflammation-inducing bacteria were enriched in the mucosal microbiota in the AOM/DSS-FUSO group. By comparing intestinal transcriptomics data from AOM *vs* AOM/DSS-FUSO mice, we showed that transcriptional activity was strongly affected by dysbiosis of the gut microbiota. The most microbiota-sensitive genes were oncogenes in the intestine, and the cyclic adenosine monophosphate signaling pathway, neuroactive ligand–receptor interaction, PPAR signaling pathway, retinol metabolism, mineral absorption and drug metabolism were highly enriched in the AOM/DSS-FUSO group. Additionally, we showed that microbial dysbiosis driven by *F. nucleatum* infection enriched eight taxa belonging to Proteobacteria, which correlates with increased expression of oncogenic genes.

CONCLUSION

Our study demonstrated that *F. nucleatum* infection altered the colon mucosal microbiota by enriching pathogens related to the development of CRC, providing new insights into the role of *F. nucleatum* in the oncogenic microbial environment of the colon.

Key Words: *Fusobacterium nucleatum*; Mucosal microbiota; Transcriptome; Colorectal cancer; Inflammation-inducing bacteria

INTRODUCTION

Colorectal cancer (CRC) is the third most common cancer and the fourth leading cause of cancer death worldwide[1]. The incidence of CRC in China has increased dramatically during the past decade[2].

Fusobacterium nucleatum (*F. nucleatum*), a gram-negative anaerobe, was recently identified as an emerging pathogen that has been frequently found in CRC[3-5]. Importantly, overload of *F. nucleatum* was found to be associated with an advanced tumor stage and a poor prognosis in CRC[6]. Accumulating evidence has revealed that *F. nucleatum* influences different stages of CRC progression. *F. nucleatum* can promote the initiation and development of CRC by adhering to epithelial cells through its unique FadA protein[7], which can bind vascular endothelial cadherin and alters endothelial integrity [8]. The activation of oncogenic miR21 under *F. nucleatum* stimulation results in the overexpression of TLR-4/nuclear factor-kappaB, increasing the proliferation of CRC cells and promoting tumor development[9]. Once a colon tumor has developed, *F. nucleatum* can adhere to Gal-GalNAc-expressing tumor cells by binding to the Fap2 Lectin, leading to enrichment of *F. nucleatum*[10]. *F. nucleatum* infection was also proven to increase the expression levels of inflammatory genes, transcription factors, and oncogenes[8,11]. These studies enhance our knowledge of the mechanisms by which *F. nucleatum* shapes the tumor microenvironment.

Evidences have revealed that the local microbiota is also an important part of the tumor microenvironment. Gut microbiota dysbiosis can reshape the tumor microenvironment and make it favorable for tumor growth[12]. The mechanisms involved include increasing mutagenesis, regulation of oncogenic pathways, and modulation of host immune system[13]. These oncogenic functions of gut microbiota are probably due to the microbial products or metabolites they produce when the community structure

balance is disrupted and a resulting overgrowth of specific bacteria. For example, the overload of colibactin-producing *Escherichia coli* and other Enterobacteriaceae can induce DNA damage of host cells and exert tumorigenic effect[14]. These facts suggest a close relationship between gut microbiota, the tumor microenvironment, and CRC. However, the regulatory role of *F. nucleatum* in the "oncogenic microbial environment" of the colon remains mostly unknown. Revealing the effects of *F. nucleatum* infection on the changes of mucosal microbiota will help to provide further insight into the mechanisms of the tumorigenic effect of *F. nucleatum*.

In the present study, we explored the role of *F. nucleatum* in the development of CRC and in altering the mucosal microbial community structure and investigated the association between microbial dysbiosis and the expression of oncogenic signaling pathways. *F. nucleatum* strain ATCC 25586 was gavaged into azoxymethane/dextran sulfate sodium salt (AOM/DSS) mice to explore the role of *Fusobacterium* overload in the progression of intestinal adenoma against a background of environmental inflammatory factors. RNA-seq transcriptomic analysis was used to identify the differentially expressed gene (DEG) signatures driven by *F. nucleatum* infection, and integrated network analysis was conducted to reveal the relationship between microbial dysbiosis and the DEGs. Our study lays a foundation for understanding the regulatory role of *F. nucleatum* in the oncogenic microbial environment of the colon.

MATERIALS AND METHODS

Bacterial strain and culture conditions

The *F. nucleatum* strain ATCC 25586 was purchased from American Type Culture Collection (ATCC) and was cultured as described previously[3]. In brief, *F. nucleatum* was grown in Columbia blood agar supplemented with 5 mg/mL haemin, 5% defibrinated sheep blood, and 1 mg/mL Vitamin K1 in an anaerobic condition with 85% N_2, 10% H_2, and 5% CO_2 at 37 °C. And 10^9 colony-forming units *per* mL (CFU/mL) were prepared for *F. nucleatum* colonization.

Animal model

Thirty-six conventional C57BL/6J wild-type male mice (4 wk of age) were obtained from the Beijing Animal Study Centre and maintained in the Laboratory Animal Services Centre at the Chinese Center for Disease Control and Prevention. The Institutional Animal Care Committee of the Peking University People's Hospital approved all animal experimentation.

To create the mouse model of colon neoplasia induced by AOM/DSS-induced colon neoplasia[15], 24 mice at 6 wk of age were injected intraperitoneally with a single dose of 10 mg/kg AOM (Sigma), designated week 0. DSS (MP Biochemicals; 36000-50000 mw) was dissolved in filtered drinking water and administered to the mice for 7 d during the following weeks: Weeks 1 (1% DSS), 3 (1% DSS), and 5 (1% DSS). After 1 wk of AOM/DSS treatment, the 24 mice were divided into 2 groups, each with 12 mice. At week 7 they were orally gavaged daily with 10^9 CFU/mL (in 100 μL volume for each mouse) *F. nucleatum* (AOM/DSS-FUSO group) or phosphate-buffered saline (AOM/DSS group) for two weeks. The 12 mice in the control group were sibling littermates and received no treatment.

After 2 wk after *Fusobacterium* inoculation as previous study described[16], the mice were sacrificed, colon mucosal contents were collected for microbiota profiling, the colons were dissected, and the polyps were counted. For a subset of the samples, the distal portion of the colon was fixed in 4% paraformaldehyde, paraffin-embedded, and sectioned for hematoxylin and eosin staining. The remaining colon tissue was then prepared for RNA sequencing.

The body weight, colon length, colorectal tumor formation ratio, immune cell patterns, gut microbiota structure and intestine transcriptomics were assessed to explore the potential role of ATCC 25586 in the carcinogenesis/development of CRC.

Histological evaluation

The colon segments were submitted for histological processing. All slides were stained with hematoxylin and eosin. Dysplasia was assessed by the presence of hyperchromasia, nuclear pleomorphism, and increased nuclear-to-cytoplasmic ratios.

Immunohistochemical staining

The expression of E-cadherin and Ki-67 was determined by immunohistochemistry staining. Serial 3 mm sections of the formalin-fixed paraffin-embedded colon tissues on the slides were heated in a microwave with sodium citrate for antigen repair, followed by 2% goat serum for blocking. The slides were then treated with mouse anti-E-cadherin (BD Biosciences, catalog 610181) and anti-Ki-67 (Cell Signaling Technology, catalog 9192) overnight at 4 °C, visualized with diaminobenzidine, counter-stained with hematoxylin, dehydrated and mounted. Staining index of Ki-67 immunostaining was determined by percentage of positive cells having brown nuclear staining from three randomly selected fields at 400 × magnification.

Microbial DNA extraction and 16S rRNA gene sequencing

Microbiota DNA from the colon mucosal contents was extracted using the QIAamp DNA Stool Mini Kit (Qiagen, catalog 51604). For all samples, polymerase chain reaction (PCR) amplification of the 16S rRNA gene with the V3-V4 variable regions was performed using the primers 341F (5′-CCTAYGG-GRBGCASCAG-3′) and 806R (5′-GGACTACNNGGGTATCTAAT-3′)[17]. The pooled library was sequenced on the Ion S5™ XL System (Thermo Fisher Scientific). Single-end reads were assigned to the samples based on their unique barcodes and trimmed by removing the barcodes and primer sequences. Raw fastq files were quality-filtered using fastp[18]. Chimeric sequences were detected and removed by vsearch software[19]. Operational taxonomic units (OTUs) were clustered with 97% identity using UPARSE v7.0.1001[20]. The most frequent sequences were selected as the representative sequences for each OTU. Representative sequences for each OTU were annotated using Mothur software at Threshold: 0.8-1 against the SILVA V132 database (http://www.arb-silva.de/) at each taxonomic rank (kingdom, phylum, class, order, family, genus and species)[21]. OTU abundance information was normalized using a standard sequence number corresponding to the sample with the fewest sequences. To avoid biases, the normalized data were subjected to alpha diversity and beta diversity analyses. Alpha diversity indices (Chao1, ACE, Shannon index, Simpson) and UniFrac distance were calculated by QIIME v1.9.1[22,23]. Beta diversities were visualized by principal coordinate analysis (PCoA) and nonmetric multidimensional (NMDS) based on Bray–Curtis dissimilarity.

Quantitative real-time PCR for F. nucleatum

The Q-PCR assay was performed to determine the colonization of *F. nucleatum*. The 16S primers for *F. nucleatum* quantification were F-TGCGATAAGCCTAGATAAGTTGCA and R-CTTAATAGAT-TGCTCCATTCGGAAA. Primers for total bacterial DNA were F-ACTCCTACGGGAGGCAGCAGT and R-GTATTACCGCGGCTGCTGGCAC[16]. The level of *F. nucleatum* was evaluated by the following formula: The relative value (RV) of *F. nucleatum* was determined by the $2^{-\Delta ct}$ method using total bacterial level as a normalizer. The relative abundance (RA) of *F. nucleatum* was scaled to a reasonable range with the following equation: $RA = \log_2(RV \times 10000 + 1)$.

RNA extraction and RNA sequencing

Total RNA was isolated using TRIzol reagent (Invitrogen, Carlsbad, CA) according to the manufacturer's recommendations. A total of 3 μg RNA *per* sample was used as the input material for the RNA sample preparations. Sequencing libraries were generated using the NEBNext® UltraTM RNA Library Prep Kit for Illumina® (NEB, United States) following the manufacturer's recommendations. The library preparations were sequenced on an Illumina platform, and 150 bp paired-end reads were generated.

The raw reads were first processed through in-house Perl scripts. Adaptor sequences, duplicated sequences, poly-N reads containing more than 10% "N", and low-quality reads containing more than 50% bases with Q ≤ 5 were removed to obtain high-quality clean reads. Clean reads were aligned to the reference genome using Hisat2 v2.0.5[24]. FeatureCounts v1.5.0-p3 was used to count the read numbers mapped to each gene[25]. Then, the FPKM of each gene was calculated based on the length of the gene and the read count mapped to this gene. Prior to the differential gene expression analysis, for each sequenced library, the read counts were adjusted by the edgeR package. Differential gene expression analysis of the two conditions was performed using the edgeR package v3.18.1. The *P* values were adjusted using the Benjamini & Hochberg method[26]. A corrected *P* value of 0.05 and absolute fold change of 2 were set as the thresholds for significantly DEGs. Gene Ontology (GO) enrichment analysis of the DEGs was implemented by the clusterProfiler R package. GO terms with corrected *P* values less than 0.05 were considered significantly enriched by the DEGs. We used the clusterProfiler R package to test the statistical enrichment of the DEGs in the KEGG pathways[27].

Statistical analysis and visualization

The Kruskal–Wallis test was performed when comparing samples from more than two groups. The difference in ratio of diarrhea and bloody was assessed using Chi-square measure. Permutational multivariate analysis was applied with a parameter of 999 permutations in R[28]. Linear discriminant analysis effect size (LEfSe) was used to estimate which microbiome attributes differed significantly by treatments[29]. The relationship between the gut microbiota and DEGs was determined by calculating Spearman's correlations, and then network visualization was performed using Cytoscape v3.6.1[30]. Heatmaps were generated using the R package pheatmap (https://github.com/raivokolde/pheatmap). The relationship between the different gut microbiota and the pathways was determined by calculating Spearman's correlations. The R package ggplot2 was used for the other data visualization in the figures in the present study.

Ethics statement

All animal protocols were approved by the Animal Experimentation Ethics Committee of the Peking University People's Hospital in China. The experiments were conducted in accordance with the Animal Research: Reporting of in Vivo Experiments (ARRIVE) guidelines.

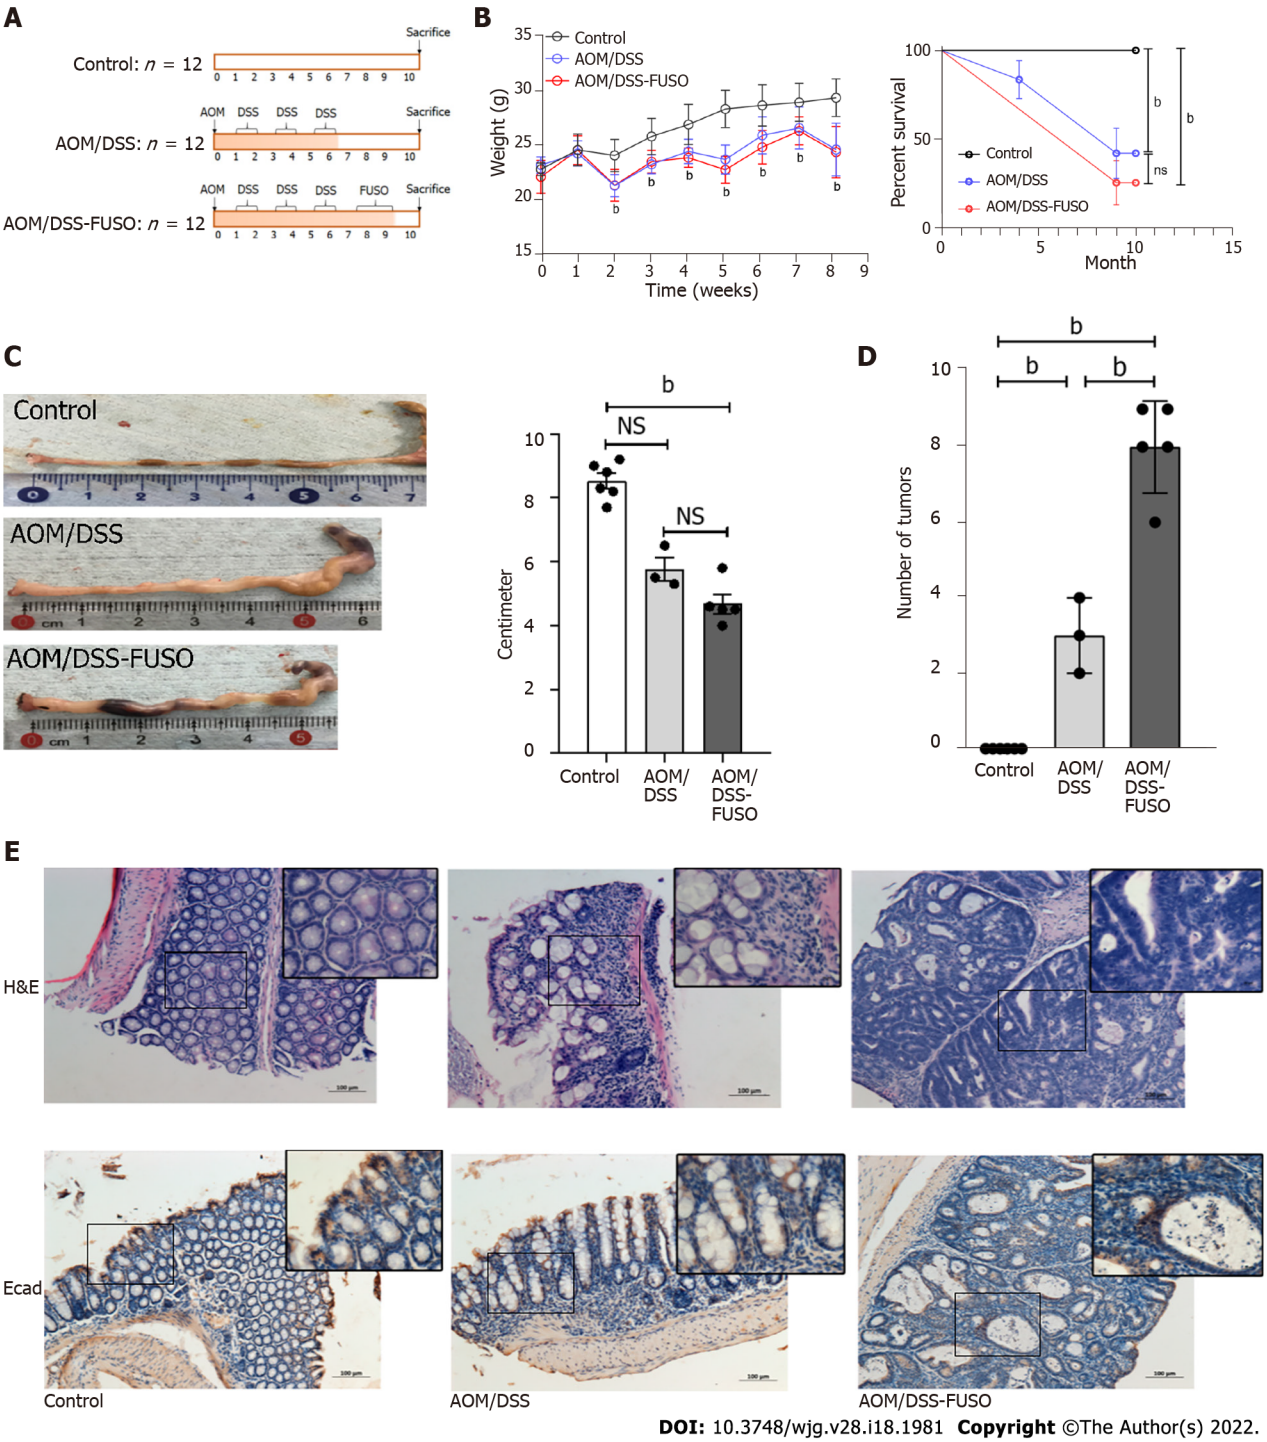
RESULTS

F. nucleatum infection promotes the development of CRC

A flow chart illustrating the *F. nucleatum* infection strategy combined with AOM/DSS treatment is shown in Figure 1A. The colonization of *F. nucleatum* was confirmed by 16S-sequencing and Q-PCR (Supplementary Figure 1). The body weight of the mice in each group increased slowly (Figure 1B), and it differed significantly between the control mice and the AOM/DSS models (two-way ANOVA, $P < 0.05$). After AOM/DSS treatment for six weeks, four mice in the AOM/DSS group and six mice in the AOM/DSS-FUSO group developed diarrhea and bloody stools (Chi-square, $P > 0.05$). No bloody stool was observed in the control group. Over the eight-week treatment, only three mice in the AOM/DSS group and five mice in the AOM/DSS-FUSO group survived.

The AOM/DSS-FUSO group had a trend but not significantly reduced colon length than the AOM/DSS group (Figure 1C), and AOM/DSS-FUSO had the highest tumor formation ratio among the three groups (Figure 1D). The AOM/DSS mice exhibited histological inflammation. In addition, the colon pathology was the most serious in the AOM/DSS-FUSO group, which was confirmed by hematoxylin-eosin (H&E) staining (Figure 1E). The presence of hyperchromasia and nuclear pleomorphism were observed in the AOM/DSS-FUSO group. We also found increased epithelial cell proliferation in the colons of AOM/DSS-FUSO mice, as indicated by a higher expression of Ki-67 than in the other two groups (Supplementary Figure 2). The abnormal expression of E-cadherin in the AOM/DSS-FUSO mice reflected the impaired function of the intestinal barrier.

Aberrant activation of epithelial-mesenchymal transition (EMT) is considered an important trigger of cancer invasion and metastasis[31]. The AOM/DSS-FUSO colon tissues showed morphological features of partial EMT, which was not observed in the AOM/DSS model (Figure 1E). In addition to the morphology-based analysis of colon tissue by H&E staining, the assessment of E-cadherin expression by immunohistochemistry can support the evaluation of partial EMT[31]. The expression of the barrier protein E-cadherin was modestly reduced in the AOM/DSS-FUSO group. Loss of the prototypical epithelial barrier protein E-cadherin is an additional sign of partial EMT[32]. The abnormal histology changes and the reduction of E-cadherin in AOM/DSS-FUSO mouse colons indicated that the AOM/DSS mice with *F. nucleatum* infection had undergone partial EMT, which is critical for CRC progression.



F. nucleatum infection changes the mucosal microbiota community structure

To investigate the effect of *F. nucleatum* infection on the mucosal microbiota, we compared the mucosal microbial composition of the three groups. The β diversity was very different among the three groups. The control group was clearly separated from the AOM/DSS-FUSO and AOM/DSS groups, as shown in the NMDS analysis (Figure 2A). This trend was also found in the PCoA analysis and was confirmed by the weighted UniFrac distance (Figure 2B and C). Around 12.8% of the bacterial composition variance could be explained by the addition of *F. nucleatum* (Permutation based analysis of variance). In AOM/DSS models, AOM/DSS-FUSO and AOM/DSS mice developed different mucosal microbiota with *F. nucleatum* infection as a significant factor in driving the differences. We then assessed the shared and unique OTUs in the AOM/DSS and AOM/DSS-FUSO groups to detect the effect of *F. nucleatum* infection. We observed that the AOM/DSS-FUSO group had more unique OTUs, approximately 44.9% (1117/2490), than the AOM/DSS group, 24.9% (456/1829), signifying that *F. nucleatum*-infected mice largely harbor unique inhabitant niches (Figure 2D). The Shannon, Simpson, observed species, and Chao1 indices for alpha diversity showed no significant differences among the three groups (Supplementary Figure 3).

Differentially abundant mucosal microbial taxa driven by *F. nucleatum* infection

We then explored the specific microbial members related to *F. nucleatum infection*. First, we compared the bacterial RA between groups at different taxa levels. We showed that the phylum Proteobacteria and eight other potential pathogens belonging to Proteobacteria (LEfSe, Figure 3A and B) were the dominant taxa in AOM/DSS-FUSO mice. Meanwhile, the phylum Bacteroides and the family Bacteroidaceae were enriched in AOM/DSS mice, which were evident CRC signature taxa[33]. The enrichment of potential pathogenic taxa and depletion of probiotic bacteria such as Lactobacillales were features of the mucosal microbiota caused by *F. nucleatum* infection (Figure 3C). Comparing the two CRC model groups, the mucosal microbiota in the control mice was dominated by the phylum Firmicutes and the probiotic taxa (Figure 3A and B).

We further compared the distribution of the top 50 most abundant taxa among the three groups. We found that the mucosal microbial population patterns were different in the three groups; the structure of the colon mucosal microbiota changed considerably after *F. nucleatum* infection in the AOM/DSS-FUSO mice (Figure 3D). Inflammation-inducing bacteria were significantly enriched in the mucosa microbiota of AOM/DSS-FUSO group compared with AOM/DSS group, such as *Denitratisom*, *Stenotrophomonas* and unidentified Enterobacteriaceae ($P = 0.036$, 0.018, and 0.048, respectively, wilcon rank-sum test, one-sided), while the potential probiotic genera were remarkably less abundant in AOM/DSS-FUSO group, such as unidentified Ruminococcaceae, unidentified Lachnospiraceae, and *Akkermansia* ($P = 0.036$, 0.036,

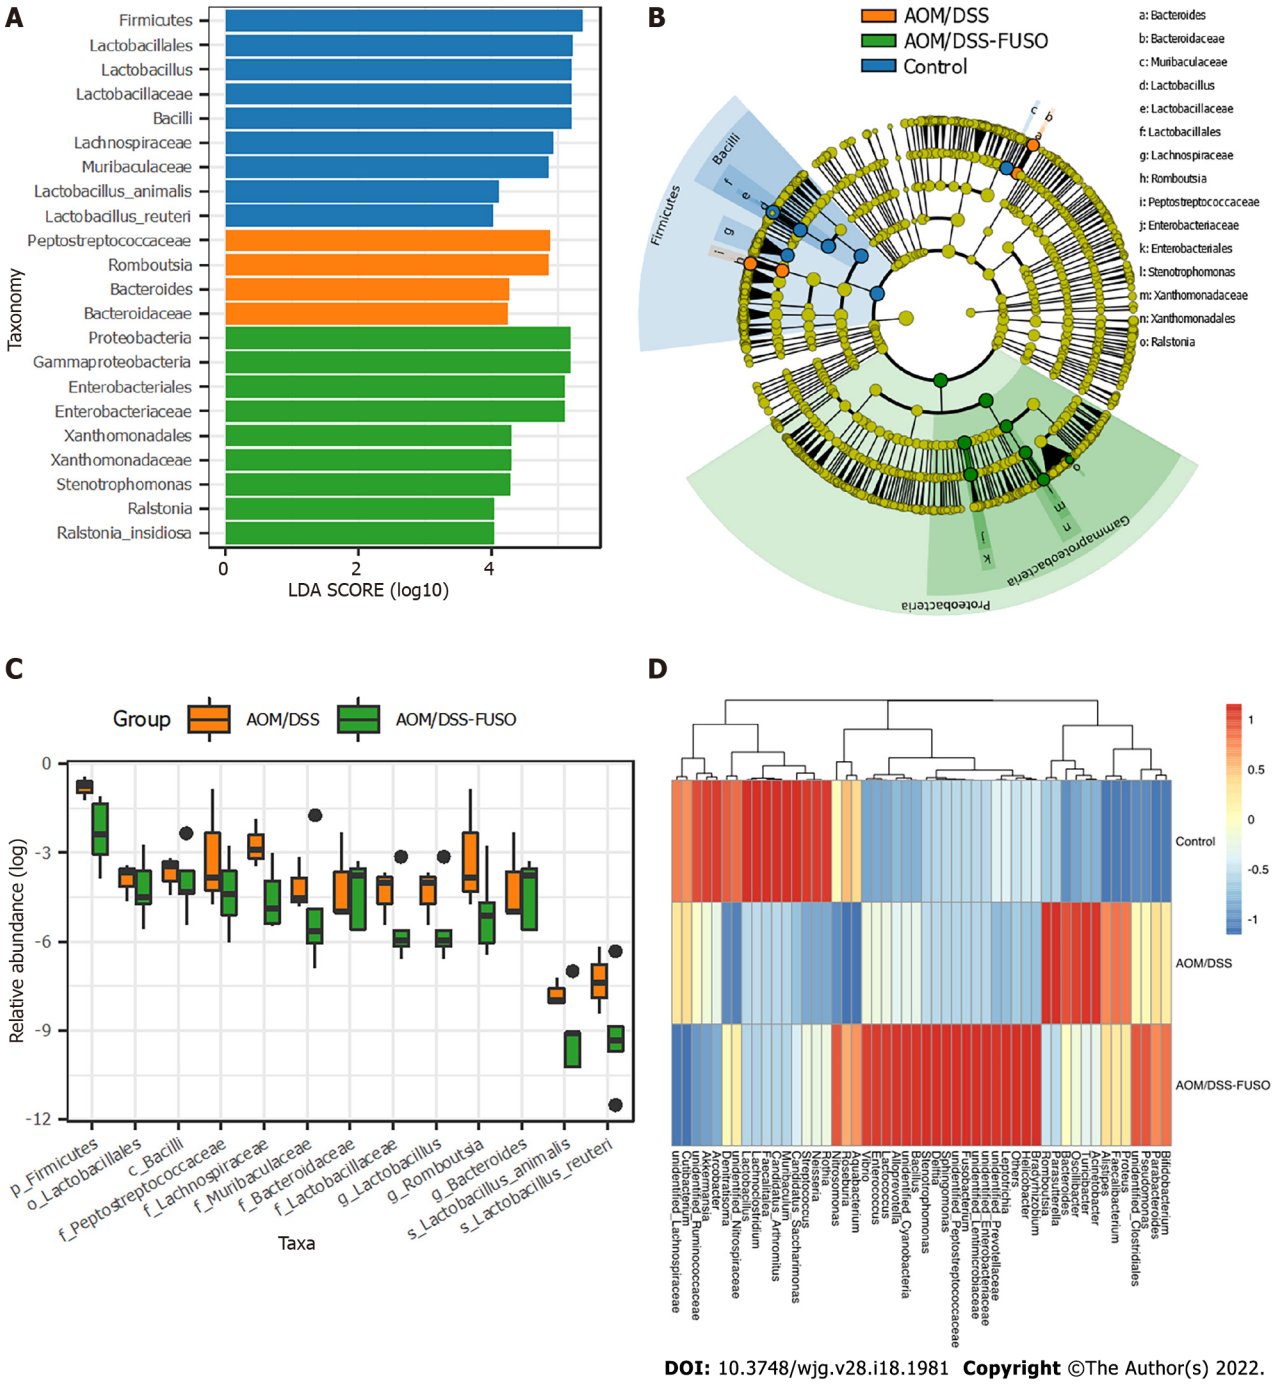
A: Experimental design illustrating the *F. nucleatum* infection strategy combined with azoxymethane/dextran sulfate sodium salt treatment; B: The body weight and survival curve of the three groups during the experiment was evaluated with two-way ANOVA; C: The colon lengths of the three groups were compared using a t-test; D: The numbers of tumors in the colon of the three groups were compared using a t-test; E: Hematoxylin-eosin staining and immunohistochemistry of E-cadherin-positive cells in the colon of the three groups. $^{a}P < 0.05$; $^{b}P < 0.01$. NS: No signification; AOM: Azoxymethane; DSS: Dextran sulfate sodium salt.

and 0.071, respectively, wilcon rank-sum test, one-sided). Taken together, these results suggested that *F. nucleatum* infection further worsens the dysbiosis of the colon mucosal microbiota by increasing the abundance of pathogenic bacteria while reducing probiotics.

Altered host signaling pathways in colon tissue under F. nucleatum infection



To gain insights into the molecular basis underlying the protumorigenic effect of *Fusobacterium* infection, RNA-seq was performed to reveal the transcriptomic changes driven by *F. nucleatum*. We observed different number of DEGs in the three comparions, *i.e.*, AOM/DSS *vs* Control, AOM/DSS-FUSO *vs* Control, and AOM/DSS-FUSO *vs* AOM/DSS (Figure 4A-C), and compared with the

Figure 2 Diversity and shared operational taxonomic units of the gut microbiota in different groups. A: Nonmetric multidimensional plot of the cecal microbiota from the 14 samples based on Bray-Curtis similarities; B: Principal coordinate analysis plot of the cecal microbiota from the 14 samples based on Bray-Curtis similarities; C: Weighted UniFrac distance of the samples from different groups. Kruskal-Wallis test: $P = 6.12 \times 10^{-7}$; D: Number of shared operational taxonomic units between the samples from the azoxymethane-dextran sulfate sodium salt (AOM/DSS)-FUSO group and the AOM/DSS group. AOM: Azoxymethane; DSS: Dextran sulfate sodium salt.

AOM/DSS mice, there were 231 upregulated genes and 92 downregulated genes in the AOM/DSS-FUSO mice (Figure 4C). The heatmap of DEGs showed the distinct gene expression profile between AOM/DSS-induced CRC models with or without overloaded *F. nucleatum* treatment (Figure 4D). These upregulated genes included FABP1 (fatty acid binding protein 1)[34], sucrase isomaltase, defensin, ATP-binding cassette[35], homeobox C6[36] and tolloid-like 2 (NETO2)[37], all of which were overexpressed more than 3-fold and were correlated with a poor prognosis of colorectal carcinoma in previous studies (Supplementary Table 1). KEGG pathway enrichment analysis suggested that the microbiota-transcriptome interaction significantly upregulated neuroactive ligand–receptor interaction, cyclic adenosine monophosphate (cAMP) signaling pathway, PPAR signaling pathway, steroid hormone biosynthesis, retinol metabolism, mineral absorption and drug metabolism in the AOM/DSS-FUSO group (Figure 5), and 36 DEGs were included in these KEGG pathways (Supplementary Figure 4). Among them, several CRC-related DEGs, PPARα[38], PCK1[39,40], GCG[41], VAV2[42], and ANGPTL4 [43] were also revealed to be correlated with the CRC prognosis in previous studies. These results

suggested that dramatic changes occurred in the host signaling pathways that are related to the tumorigenesis of CRC after *F. nucleatum* infection and the resulting disturbance of the mucosal microbiota.

Hub bacteria and key genes involved in the carcinogenesis/development of CRC

To further explore the hub bacteria and the hub DEGs, MCODE plugged in Cytoscape was used to explore the key modules involved in CRC development (Figure 6). The differential bacterial taxa identified by LEfSe analysis and the genes involved in the top seven significantly differential KEGG pathways were processed. The results showed that seven potentially harmful hub taxa were closely related to the overexpression of 12 hub genes. These taxa, *Stenotrophomonas*[44], Xanthomonadaceae, Xanthomonadales, Enterobacteriaceae, Enterobacteriales, Gammaproteobacteria, and Proteobacteria, have been shown to exhibit proinflammatory and procarcinogenic properties. This key module with the

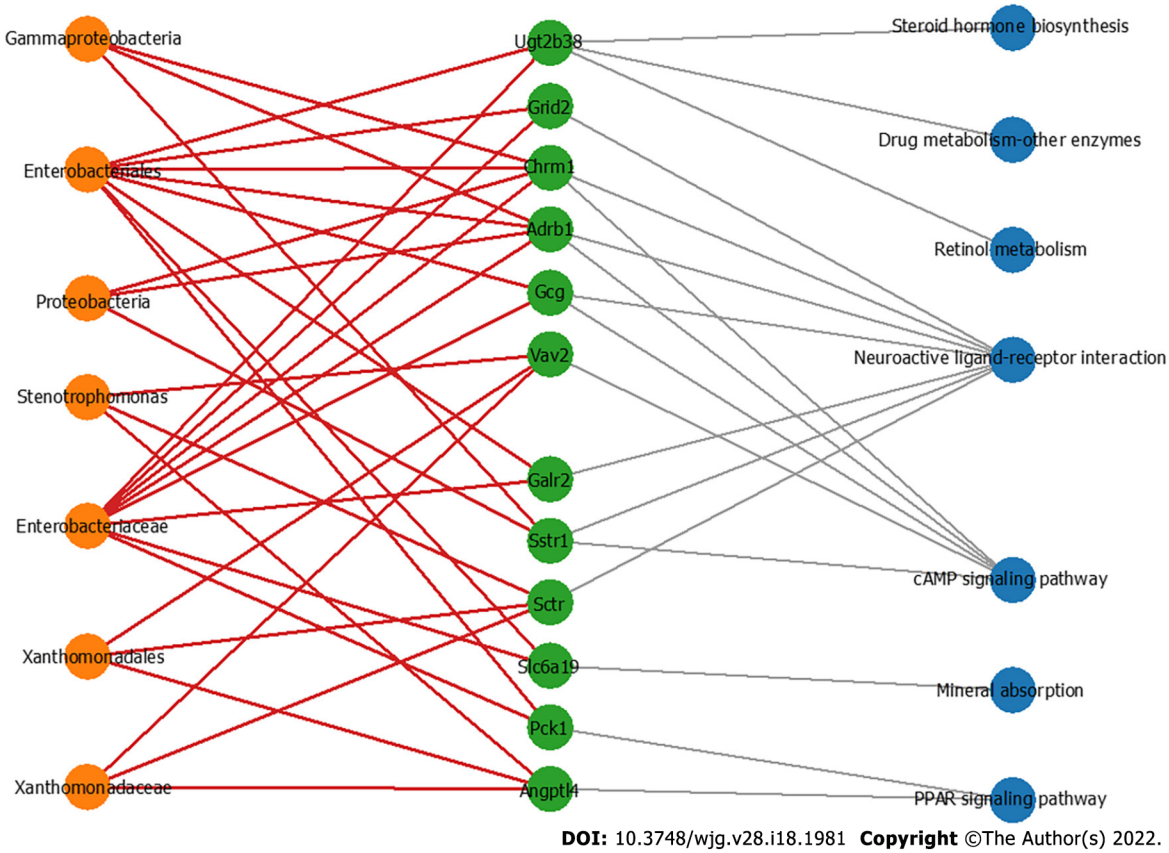
Figure 4 The differentially expressed genes of the mucosa. A: Volcano plot showing the differentially expressed genes between the azoxymethane/dextran sulfate sodium salt (AOM/DSS) group and the control group; B: Volcano plot showing the differentially expressed genes between the AOM/DSS-FUSO group and the control group; C: Volcano plot showing the differentially expressed genes between the AOM/DSS-FUSO group and the AOM/DSS group. Significantly upregulated genes are shown in red ($P < 0.05$ and $\log_2FC \geq 1$). Significantly downregulated genes are shown in blue ($P < 0.05$ and $\log_2FC \leq -1$). The numbers of significantly upregulated genes were 1374 for (A), 1939 for (B) and 231 for (C). The numbers of significantly downregulated genes were 1050 for (A), 1104 for (B) and 92 for (C); D: Patterns of the abundance of all of the differentially expressed genes in the upper panels. The colors indicate the Z scores of the mean abundance in each group. AOM: Azoxymethane; DSS: Dextran sulfate sodium salt.

seven hub microbial taxa and 12 hub genes may regulate the occurrence and development of CRC through CRC-related pathways such as the cAMP and PPAR signaling pathways. Enterobacteriaceae correlated with eight oncogenes, *i.e.*, *PCK1*, *GalR2*, *GCG*, *SLC6A19*, *CHRM1*, *ADRB1*, *UGT2B38*, and *GRID2*, and three taxa (Xanthomonadales, Xanthomonadaceae and *Stenotrophomonas*) were positively correlated with *VAV2*, *SCTR* and *ANGPTL4*. These results suggested that the dysbiosis of gut microbes driven by *F. nucleatum* infection may have the potential to affect the transcriptional activity of tumor-related metabolic pathways, especially those containing oncogenes.



DISCUSSION

F. nucleatum has long been known to cause opportunistic infections and has recently been implicated in CRC, which has attracted broad attention. Previously, we found that the RA of *F. nucleatum* in the fecal microbiota was significantly increased in CRC patients[33]. However, the effect of *F. nucleatum* infection on the mucosal microbiota and the resulting relationship between gut microbiome alterations and CRC development are still open questions. AOM/DSS mice can spontaneously develop multiple intestinal adenomas and have been used extensively as a model of colorectal carcinogenesis inflammation-associated tumors[45]. We showed that AOM/DSS mice with *F. nucleatum* infection have a higher burden of intestinal adenoma and worse colon histology. At the same time, an impaired mucosal barrier as shown by E-cadherin expression and increased epithelial cell proliferation by Ki-67 in the AOM/DSS-FUSO group were observed.

Figure 6 The co-occurrence network shows the correlations of the colon mucosa microbiota with the differentially expressed genes. Edges: Correlations with *P* values < 0.01; red edges: Positive correlations; gray edges: Relationship between the genes and the pathways; green nodes: Genes involved in the top seven significantly differential KEGG pathways in the azoxymethane/dextran sulfate sodium salt (AOM/DSS)-FUSO group compared with the AOM/DSS group; orange nodes: The differential bacterial taxa identified by LEfSe analysis; blue nodes: Related pathways of defferentially expressed genes.

After the introduction of *F. nucleatum*, we propose that *F. nucleatum* needs to adapt to and change the symbiotic microbial environment, which could activate and promote the progression of colorectal carcinogenesis. In this study, three increased inflammation-inducing bacteria and three decreased probiotic genera in the top 50 differentially expressed genera were recognized as dysbiotic mucosal taxa after *F. nucleatum* stimulation. Furthermore, changes in the structure of the mucosal microbiota among the three groups were identified. Proteobacteria and eight other pathogenic bacterial taxa (Figure 3A)

were the dominant taxa in the AOM/DSS-FUSO mice compared with the AOM/DSS group. In agreement with previous studies, gut microbial comparisons of CRC patients and non-CRC subjects are characterized by a high prevalence of pro-inflammatory bacteria (mostly Proteobacteria) and a decrease in commensal beneficial bacteria (mostly Firmicutes)[33,46,47]. Notably, the transfer of two Enterobacteriaceae species (*Klebsiella pneumoniae* and *Proteus mirabilis*) was sufficient to provoke colitis in the recipient mice[48]. The overload of Proteobacteria promoted intestinal inflammation in a T-bet$^{-/-}$ Rag2$^{-/-}$ mouse model of colitis[48-50]. Similar to studies in mice, microbiota studies in humans have shown that the gut microbial structure of inflammatory bowel disease patients is characterized by an expansion of Proteobacteria, particularly Enterobacteriaceae. Consistent with previous studies, we observed that the RA of Enterobacteriaceae in the mucosal microbiota was positively correlated with the expression of key oncogenes. Moreover, three other taxa, *Stenotrophomonas*, Xanthomonadales, and Xanthomonadaceae, were positively correlated with ATGPTL4 (angiopoietin-like 4), the VAV2 oncogene, and SCTR (secretin receptor), as shown in Figure 6. *Stenotrophomonas* was proven to be significantly increased during the exacerbated phase of UC compared to the remission phase[51]. Based on the above evidence, we propose that abnormal expansion of Proteobacteria, especially Enterobacteriaceae and *Stenotrophomonas*, is the signature of microbial dysbiosis driven by *F. nucleatum*.

To further reveal the effects of *F. nucleatum* infection and microbial dysbiosis on the transcriptome of AOM/DSS mice, RNA-seq was performed, and 323 DEGs were identified that were influenced by the oncogenic microbial environment. Interestingly, we found that the *F. nucleatum*-driven DEGs were significantly enriched in cancer-related KEGG signaling pathways. The neuroactive ligand–receptor interaction, cAMP signaling pathway, and PPAR signaling pathway were significantly overexpressed in the AOM/DSS-FUSO group. Among them, ANGPTL4, VAV2, and PCK1 were significantly highly expressed in the AOM/DSS-FUSO groups and positively correlated with the Proteobacteria taxa. In CRC cell lines, Zheng *et al*[52] found that *F. nucleatum* infection provoked glucose uptake and subsequently promoted glycolysis activity of CRC cells *via* ATGPTL4, which could in turn facilitate its own colonization in CRC cells[52]. *F. nucleatum*-mediated glycolysis activation *via* ATGPTL4 plays important roles in the pathogenesis of CRC and subsequently provides a beneficial environment for the outgrowth of CRC-related taxa.

Consistent with our results, other recent studies have demonstrated that *F. nucleatum* provokes glycolysis by upregulating lncRNA ENO-1[53], and an increase in cellular metabolic activity provides ample cellular energy for EMT-mediated metastasis[54]. Another oncogene, *VAV2*, related to three Proteobacteria taxa, is a member of the VAV guanine nucleotide exchange factor family of oncogenes and is one of the five combined prognostic genes that was identified to form a prognostic mutation panel for predicting cancer recurrence in stage II and III CRC[55]. Loss of VAV2, VAV3 and TIAM1 is sufficient to strongly suppress the cancer phenotypes and tumorigenesis induced by APC loss[56].

It is important to note that the eight upregulated hub genes shown in the microbiota-transcriptome network were positively correlated with high levels of Enterobacteriaceae, *e.g.*, PCK1, GalR2, GCG, SLC6A19, CHRM1, ADRB1, UGT2B38, and GRID2. Among them, PCK1 enhanced liver metastatic growth by driving pyrimidine nucleotide biosynthesis under hypoxia[40]. G-protein-coupled receptor galanin receptor 1 (GalR1) was identified as a novel regulator of drug resistance[57]. Notably, silencing either GalR1 or its ligand, galanin, induced apoptosis in both drug-sensitive and drug-resistant cell lines and synergistically enhanced the effects of chemotherapy. Mechanistically, GalR1/galanin silencing resulted in downregulation of the endogenous caspase-8 inhibitor FLIP(L), resulting in induction of caspase-8-dependent apoptosis. *Galanin* mRNA was found to be overexpressed in colorectal tumors, and importantly, high galanin expression was correlated with poor disease-free survival of patients with early-stage CRC. In the future, additional studies need to be performed to explore the effect of *F. nucleatum* on Proteobacteria-related oncogenes to clarify the roles of *F. nucleatum* in CRC diseases.

Therefore, our data present the key microbial signature after *F. nucleatum* infection, which may provide new insights into the role of dysbiosis in the mucosal microbiota driven by *F. nucleatum* in promoting CRC. We provide direct evidence that Proteobacteria expansion, in particular Enterobacteriaceae and *Stenotrophomonas*, occurs during *F. nucleatum* infection, leading to the differential expression of oncogene transcriptomes in the AOM/DSS model. We provide evidence that *F. nucleatum* interacts with other species, how it remodels the microbiota, and how it alters the tumor microenvironment. Furthermore, we revealed the dysbiosis signature of the colon mucosa microbiota driven by *Fusobacterium* and the interaction between the hub microbial taxa and the host transcriptome. A deeper understanding of CRC etiology will also help identify new targets for prevention and treatment.

CONCLUSION

In conclusion, these data extend our previous work to provide evidence for microbial dysbiosis in CRC and suggest the existence of a defined set of microbiota whose composition is essential. Our study is also distinct in taking a holistic approach, given the observation of important bacterial-host networks and evidence for an oncogenic microbial environment of the colon promoting the formation of CRC. Our study is limited by: (1) The lack of time-course experiments to validate the effects of *F. nucleatum* on

the symbiotic microenvironment; and (2) The limited sample size due to the deaths of mice when establishing the disease model. Therefore, further studies using more mice to establish the disease model are required to confirm the findings here and to disentangle the defined role of the Proteobacteria-related oncogenes driven by *F. nucleatum* during the progression of colorectal adenomas.

ARTICLE HIGHLIGHTS

Research background

Fusobacterium nucleatum (*F. nucleatum*) has long been known to cause opportunistic infections and has recently been implicated in colorectal cancer (CRC), which has attracted broad attention. Exploring the roles and underlying mechanism of *F. nucleatum* has important theoretical and practical significance for diagnosis and targeted therapy of CRC.

Research motivation

The aim of this study is to reveal the effect of *F. nucleatum* infection on the changes of mucosal microbiota, and investigate the regulatory role of *F. nucleatum* in the CRC progression.

Research objectives

The azoxymethane/dextran sulfate sodium salt (AOM/DSS)-induced mice were used to investigate the role of *F. nucleatum* in the "oncogenic microbial environment" of the colon.

Research methods

The mucosal microbial composition and RNA-seq transcriptomic analysis were used to identify the differentially expressed gene (DEG) signatures driven by *F. nucleatum* infection, and integrated network analysis was conducted to reveal the relationship between microbial dysbiosis and the DEGs.

Research results

We provide direct evidence that *F. nucleatum* interacts with other species, remodels the microbiota, and alters the tumor microenvironment. In addition, we revealed the dysbiosis signature of the colon mucosa microbiota driven by *F. nucleatum* and the interaction between the hub microbial taxa and the host transcriptome.

Research conclusions

Dysbiosis in the mucosal microbiota driven by *F. nucleatum*, in particular Enterobacteriaceae and *Stenotrophomonas*, occurs during *F. nucleatum* infection, leading to the differential expression of oncogene transcriptomes in the AOM/DSS model.

Research perspectives

Our study provides a deeper insight into CRC etiology driven by *F. nucleatum* infection and the mechanisms of the tumorigenic effect of *F. nucleatum*. Targeting *F. nucleatum* infection is a potential treatment for CRC.

Abstract

BACKGROUND

Incidental gallbladder cancer (IGBC) represents 50%-60% of gallbladder cancer cases. Data are conflicting on the role of IGBC diagnosis in oncological outcomes. Some studies suggest that IGBC diagnosis does not affect outcomes, while others that overall survival (OS) is longer in these cases compared to non-incidental diagnosis (NIGBC). Furthermore, some studies reported early tumour stages and histopathologic characteristics as possible confounders, while others not.

AIM

To investigate the role of IGBC diagnosis on patients' overall survival, especially after surgical treatment with curative intent.

METHODS

Retrospective analysis of all patient referrals with gallbladder cancer between 2008 and 2020 in a tertiary hepatobiliary centre. Statistical comparison of patient and tumour characteristics between IGBC and NIGBC subgroups was performed. Survival analysis for the whole cohort, surgical and non-surgical subgroups was done with the Kaplan-Meier method and the use of log rank test. Risk analysis was performed with univariable and multivariable Cox regression analysis.

RESULTS

The cohort included 261 patients with gallbladder cancer. 65% of cases had NIGBC and 35% had IGBC. A total of 90 patients received surgical treatment (66% of IGBC cases and 19% of NIGBC cases). NIGBC patients had more advanced T

stage and required more extensive resections than IGBC ones. OS was longer in patients with IGBC in the whole cohort (29 *vs* 4 mo, $P < 0.001$), as well as in the non-surgical (14 *vs* 2 mo, $P < 0.001$) and surgical subgroups (29 *vs* 16.5 mo, $P = 0.001$). Disease free survival (DFS) after surgery was longer in patients with IGBC (21.5 mo *vs* 8.5 mo, $P = 0.007$). N stage and resection margin status were identified as independent predictors of OS and DFS. NIGBC diagnosis was identified as an independent predictor of OS.

CONCLUSION

IGBC diagnosis may confer a survival advantage independently of the pathological stage and tumour characteristics. Prospective studies are required to further investigate this, including detailed pathological analysis and molecular gene expression.

Key Words: Gallbladder cancer; Incidental gallbladder cancer; Non-incidental gallbladder cancer; Gallbladder cancer survival

Core Tip: Data are conflicting on the role of incidental gallbladder cancer (IGBC) diagnosis in oncological outcomes. Some studies suggest that IGBC diagnosis does not affect outcomes, while others that overall survival (OS) is longer in these cases compared to non-incidental diagnosis (NIGBC). In our study, IGBC diagnosis conferred better OS in all patients with gallbladder cancer, as well as within the surgical and non-surgical groups. Similarly, disease free survival was significantly longer in patients with IGBC. NIGBC diagnosis was identified as an independent predictor of OS along with N stage and resection margin status.

INTRODUCTION

Gallbladder cancer (GBC) is associated with poor prognosis even after treatment, with median overall survival (OS) ranging in the literature between 3 and 22 mo[1,2]. Incidental gallbladder cancer (IGBC) discovered on routine histological examination of gallbladder specimens after cholecystectomy is more common than non-incidental gallbladder cancer (NIGBC) and represents 50%-60% of all cases[3-5]. The prognostic implication of incidental or non-incidental diagnosis in oncological outcomes is still a matter of debate as is the effect of the timing of curative intent resection which is performed as a secondary operation in IGBC.

Published evidence are contradictory with some studies suggesting that incidental diagnosis does not affect survival[5-8], while others showed longer survival with IGBC[9-11]. Earlier tumour stages in the IGBC group have been suggested as a confounding factor for any potential survival benefit[5]. On the contrary, other studies identified a survival benefit in IGBC even after controlling for tumour stage and degree of differentiation[9,10].

The aim of this study was to investigate the role of IGBC diagnosis in patient OS and especially after surgical treatment with curative intent.

MATERIALS AND METHODS

This is a retrospective single tertiary centre cohort study between January 2008 and December 2020. The sample included all patients with a histological diagnosis of GBC obtained by surgery or biopsy. The management of all patients was discussed and agreed in the hepatobiliary multidisciplinary (MDT) meeting. IGBC diagnosis was established after histopathological examination of specimens following cholecystectomy for benign aetiology. This was followed by complete staging with a computerized tomography scan of the thorax, abdomen and pelvis (CT-TAP) with subsequent curative intent resection if appropriate. NIGBC diagnosis was made based on imaging and/or biopsy after MDT discussion of referred patients. All patients had staging with CT-TAP, followed by surgery if clinically appropriate. In

patients with locally advanced disease, neoadjuvant chemotherapy was administered and resection was contemplated after restaging. Liver magnetic resonance imaging and positron emission tomography scans were used selectively in both groups if liver metastases or extrahepatic disease was suspected on CT. Following surgical resection all patients were referred to oncology for assessment of adjuvant chemotherapy (AC).

Data were collected and recorded for patient's demographics, American society of anesthesiology (ASA) score, extent of surgical resection, histology, chemotherapy, recurrence and survival. The extent of surgery was defined as minor if radical cholecystectomy, gallbladder (GB) bed resection or liver segments IVb/V resection with or without bile duct resection was performed. It also included patients who only had bile duct resection. The resection was defined as major if a major hepatectomy (three or more liver segments) or multi-visceral resection was performed. Recurrence was defined as local/regional (GB bed, hilar lymph nodes), distant or both. The primary outcome of the study was difference in OS between IGBC and NIGBC and the secondary outcome was difference in disease-free survival (DFS).

T-test, Chi-Square, Fisher's Exact and Mann-Whitney U tests were used as appropriate to compare variables and outcomes between the two groups, with statistical significance set at $P < 0.05$. Survival analysis was performed with the Kaplan-Meier method and log rank test was used to compare survival curves between the study groups. Univariable and multivariable time to event analyses were performed using the Cox proportional hazard model to determine risk factors for OS and DFS. Variables were subjected to a univariable analysis first and those with $P < 0.2$ were introduced into a multivariable model. Hazard ratios (HR) and associated 95% confidence intervals (CI) were calculated. A two-tailed *P* value < 0.05 was considered statistically significant. All statistical analyses were performed using the software package SPSS Statistics for Windows (version 25.0; SPSS Inc., Chicago, IL, United States).

RESULTS

Cohort characteristics and management pathway

The study cohort comprised of 261 patients, with 35% presenting as IGBC and 65% had non incidental presentation (NIGBC) at the time of diagnosis (Figure 1). Median age was 69 years [interquartile range (IQR) 61-77] and male to female ratio was 1:3. Eighty-one percent of NIGBC and 34% of IGBC patients did not undergo resection. For the majority of these (82%) locally advanced or metastatic disease was the main reason. Other causes included patient's choice, poor medical status and pathological stage < 1b (where resection is not indicated) (Table 1). Reasons for not having AC after resection were patients' choice or comorbidities and early tumour stages (CIS, T1/T2, N0) with negative resection margins.

Patient and tumour characteristics of surgical patients

A total of 90 patients had curative intent resection. The type of resection depended on IGBC *vs* NIGBC diagnosis, pre-operative staging, intra-operative findings, cystic duct margin status and the T stage of IGBC patients. Hepatoduodenal (portal) lymphadenectomy was performed in all patients. For IGBC cases, the median time from the time of the index cholecystectomy to the curative resection was 13.5 wk (IQR: 11-16 wk).

Patient and tumour characteristics are shown on Table 2. Patients with NIGBC had more advanced T stage and underwent more extensive resections compared to those with IGBC. Similarly, N stage approached but did not reach significance. The types of procedures performed are shown on Table 3.

Survival analysis

For the whole cohort, median OS was longer in patients with IGBC diagnosis, (29 *vs* 4 mo, $P < 0.001$). OS of IGBC patients was significantly longer compared to NIGBC patients in the non-surgical group (14 *vs* 2 mo, $P < 0.001$), as well as the surgical group (29 *vs* 16.5 mo, $P = 0.001$). Similarly, DFS was significantly longer in patients with IGBC (21.5 mo *vs* 8.5 mo, $P = 0.007$) (Figure 2).

Risk analysis

Univariable Cox regression analysis (Table 4) identified that age, ASA, T stage, N stage, resection margin status and NIGBC diagnosis were significantly related to OS ($P < 0.05$). On multivariable analysis, N stage, resection margin status and NIGBC diagnosis were identified as independent predictors of survival, increasing the risk of mortality by 3, 5 and 2 times respectively (Table 4).

Similarly, T stage, N stage, resection margin status and NIGBC diagnosis were identified to be associated with worse DFS on univariable analysis, however only N stage and resection margin status were found to be independent predictors on multivariable analysis (Table 5).

In an effort to statistically investigate if NIGBC diagnosis acted as a confounding factor for the T stage of the disease despite the use of time-dependent regression analysis, models without this parameter were produced. Again, only N stage and margin status were identified as independent prognostic factors for OS and DFS, while T stage was not (Tables 4 and 5).

DISCUSSION

GBC is a rare malignancy with unfavorable prognosis despite the advances in oncological treatments[1,2,12]. The timing of GBC diagnosis, whether incidental after cholecystectomy for benign causes or pre-operative on imaging and/or biopsy, has been previously under investigation for the potential effect in outcomes, however evidence is scarce. Violation of the anatomical planes around the tumour and incomplete clearance during the index laparoscopic cholecystectomy with residual disease in 35%-46% of the patients have been proposed as factors responsible for adverse oncological outcomes in IGBC patients[13-15]. Furthermore, inadvertent GB perforation during cholecystectomy has been reported in up to 22%[16,17], and this could theoretically lead to tumour seeding and metastatic disease. Interestingly, the site of invasion of local disease has also been shown to play an important role in T2 disease[15]. Nonetheless, some published evidence suggested that IGBC diagnosis confers favourable survival, regardless of the stage or degree of differentiation of the disease[9,11]. On the other hand, in other studies, NIGBC diagnosis did not adversely affect survival[5-8]. In a meta-analysis of 51 studies by Pyo *et al*[18], IGBC patients had favorable survival in comparison to NIGBC. However, not all studies included in this meta-analysis were able to show the same difference between both groups.

Sixty five percent of referred patients in our cohort had a preoperative radiological diagnosis of GBC. Sixty six percent of all patients did not proceed to an oncological resection (81% of NIGBC and 36% of IGBC patients), 16% of these due to locally advanced disease (all NIGBC patients) and 38% due to metastatic disease on staging imaging (23% of IGBC and 46% of NIGBC patients). Only 3% of IGBC were stage T1a or below and therefore, no further resection was indicated. Of note only 7% of patients were deemed unfit for surgical treatment. It is clear that the majority of the patients that did not proceed to management with curative intent were due to the late presentation of the disease, a fact that is well described for GBC[19]. The percentage of patients who had AC after curative intent surgery was low (22%). This is comparable with the published literature of around 24%[20]. The reasons for this may include patients' choice and comorbidities, however, may also be attributed to the change in recommended best practice over the years of the study. According to a previously published expert consensus statement, AC was considered only in patients with high risk pathologic features: T3-T4 stages, metastatic lymph nodes and positive resection margins[21]. However, after the BILCAP trial showing improved survival with capecitabine (36.4 mo to 51.1 mo; P = 0.028), it is currently recommended that all patients with resected biliary tract malignancy, including GB cancer, receive 6 mo of adjuvant capecitabine[22]. The results of the currently ongoing ACTICCA-1 trial are eagerly awaited and will provide further evidence if the combination chemotherapy of gemcitabine and cisplatin is

superior to capecitabine monotherapy in the adjuvant setting.

Our data suggests that NIGBC diagnosis adversely affected oncological outcomes. NIGBC patients were more likely to have higher stages of the disease (T3/4), consequently undergoing more extensive resections. The range of oncological procedures for selected cases included multi-visceral resections and major hepatectomies to achieve histologically clear resection margins. Routine performance of such procedures is not associated with survival benefit and has high morbidity rates; however, it is still indicated when the vascular inflow or resection margins are/may be compromised[23-25]. Positive lymph node status was more common in patients with NIGBC with the difference approaching statistical significance. OS of all patients with NIGBC diagnosis was substantially worse than those with IGBC and this was also noted in both surgical and non-surgical subgroups. Furthermore, in the surgical

subgroup, NIGBC diagnosis was identified as an independent predictor of OS; doubling the risk of mortality. Stronger predictors were pN stage and margin status, increasing the risk by 3 and 5 times respectively. These findings persisted when models computed that accounted for the possibility of NIGBC diagnosis acting as a confounding factor for T stage (by not including this parameter in the analysis), indicating that it is not true. This seemingly paradoxical observation may be explained by the presence of micro-metastases in early stages of GBC [26], which would affect and in the end dictate OS and DFS, rather than pT stage. Similar were the results for DFS, with N stage and margin status

conferring higher relative risk of recurrence, while NIGBC diagnosis approached but did not reach significance.

Lymph node status is an important prognostic factor in GBC. Widmann *et al*[27] in a meta-analysis of 18 observational studies which included more than 27000 patients, has shown that lymph node involvement has significant effect on OS and DFS. Lymphadenectomy also was associated with better OS and DFS in patients with T1b, T2 and T3 disease. This was not clearly demonstrated with T4 disease due to the low number of cases undergoing curative resection in this stage. Lymph node micrometastases, defined as disease detected on immune-histochemical staining, have also been described to correlate with the pathologic N stage of the disease and disease prognosis[28]. Nonetheless, the significance of the extent of lymphadenectomy and lymph node yield is controversial in the published literature, with data from two studies suggesting that harvesting more than four lymph nodes during surgery is associated with improved survival[29,30], whilst a third study concluded that lymph node yield does not correlate with improved survival[31]. These differences may be explained by the differences in pathological reporting (higher lymph node yield may result in more accurate pN staging) and/or variations in the non-surgical part of the patients' management, such differences in the administration of neoadjuvant and adjuvant chemotherapy, regimens, duration *etc*.

Overall, our data suggest that the timing of diagnosis of GBC may play a significant role in the oncological outcomes. Due to the retrospective nature of the study and the long study period, data on the site of invasion (hepatic *vs* peritoneal) were not available, hence this could not be investigated as a possible explanation[32,33]. Another possibility is a difference in the genetic profile of the tumours which could account for different behavior, such as early micrometastases, that cannot be captured by the common radiological investigations and standard pathological parameters of stage and differen-

tiation [34]. However, this cannot be investigated by the current study and would require a prospective molecular study design.

The limitations of the study include its single centre retrospective methodology. The long study period also included differences and evolution in the surgical approach during the oncological resection, with more bile duct resections done during the early study period to achieve a negative margin and a greater lymph node yield. In the later years, bile duct resection was only performed in the presence of a positive cystic duct margin. Nonetheless, this is the first study to include all patients referred for GBC to a tertiary regional centre, rather than only the ones receiving surgical treatment, therefore providing outcome data in an intention to treat basis over the whole referral cohort including the patients that did not receive surgical treatment. It is also one of few studies to demonstrate the effect of non-incidental diagnosis on the oncological outcomes.

CONCLUSION

Conclusively, the presented data suggest that IGBC diagnosis may confer a survival advantage, including patients that received surgical treatment, independently of the pathological stage and tumour characteristics. Prospective studies are required to investigate the reasons behind this, including detailed pathological analysis and molecular gene expression.

ARTICLE HIGHLIGHTS

Research background

Incidental gallbladder cancer (IGBC) represents 50%-60% of gallbladder cancer cases. Data are conflicting on the role of IGBC diagnosis in oncological outcomes. Some studies suggest that IGBC diagnosis does not affect outcomes, while others that overall survival (OS) is longer in these cases compared to non-incidental diagnosis (NIGBC). Furthermore, some studies reported early tumour stages and histopathologic characteristics as possible confounders, while others not.

Research motivation

GB cancer is an uncommon malignancy with poor survival. Data suggest whether the diagnosis is incidental or not may play a role in the oncological outcomes. Confirmation of this observation may lead in further research aiming to better identify the reasons and refining the treatment strategy based on the presenting diagnosis.

Research objectives

This study aimed to investigate the role of IGBC diagnosis on patients' overall survival, especially after surgical treatment with curative intent.

Research methods

This is a retrospective analysis of all patient referrals with gallbladder cancer between 2008 and 2020 in a tertiary hepatobiliary centre. All patients had complete staging and were discussed in the multidisciplinary meeting prior to deciding on the treatment plan. Demographic, surgical and tumour variables were collected and compared between patients with IGBC and NIGBC using the appropriate statistical tests. Survival curves for OS and DFS were created using Kaplan-Meier method and compared with the log rank test. Risk analysis for independent predictors of OS and DFS was performed with univariable time to event analysis using the Cox proportional hazard model. Factors with a P value of < 0.200 were entered into a multivariable model and independent predictors (those with $P < 0.05$) were indentified. All statistical analysis was done using the software SPSS for Windows (Version 25.0, SPSS Inc., Chicago, IL, United States).

Research results

261 patients with GB cancer were included. Almost one-third pf patients had IGBC (91/261 patients) and two-thirds had NIGC. A total of 90/261 (34%) patients proceeded to have oncological resection. Metastatic disease was the most common reason for not having oncological resection. Patients with NIGBC were more likely to have advanced T stages of the disease and required more extensive resections than patients with IGBC. Survival analysis shows that patients with IGBC had better OS than patients with NIGBC in the whole cohort (29 *vs* 4 mo, $P < 0.001$), as well as in the non-surgical (14 *vs* 2 mo, $P < 0.001$) and surgical subgroups (29 *vs* 16.5 mo, $P = 0.001$). DFS was similarly better in patients with IGBC who underwent oncological resection (21.5 mo *vs* 8.5 mo, $P = 0.007$). After univariable and multivariable risk analysis, N stage, resection margin status and non-incidental diagnosis were identified as independent predictors of OS. N stage and resection margin status were also independent

predictors of DFS. Within the limitations of a retrospective single centre study, our data suggest that difference in the oncological outcomes between the two groups cannot be solely explained by differences in pathologic or tumour features.

Research conclusions

Our study suggests that IGBC diagnosis may confer a survival advantage, including patients that received surgical treatment, independently of the pathological stage and tumour characteristics. Prospective studies are required to investigate the reasons behind this, including detailed pathological analysis and molecular gene expression.

Research perspectives

Published evidence is still contradicting. The theory that IGBC and NIGBC are two distinct variants of the same disease remains to be proven by detailed pathologic assessment and research in cancer molecular genetics.

Abstract

BACKGROUND

Data on non-drug related risk-factors for gastrointestinal bleeding (GIB) in the general population are limited, especially for life-style factors, clinical measurements and laboratory parameters.

AIM

To identify and investigate non-drug risk factors for major GIB in the general population of Finland.

METHODS

We performed a retrospective cohort study using data from the FINRISK health examination surveys, which have been conducted every 5 years across Finland from 1987 to 2007. Participants were adults aged 25 years to 74 years, excluding those with a previous hospitalization for GIB. Follow-up from enrollment was performed through linkage to national electronic health registers and ended at an event of GIB that led to hospitalization/death, death due to any other cause, or after 10 years. Covariates included demographics, socioeconomic and lifestyle factors, clinical measurements, laboratory parameters and comorbidities. Variable selection was undertaken using Least Absolute Shrinkage and Selection Operator

(LASSO) and factors associated with GIB were identified using Cox regression.

RESULTS

Among 33,508 participants, 403 (1.2%) experienced GIB [256 men (63.5%); mean age, 56.0 years (standard deviation (SD) ± 12.1)] and 33105 who did not experience GIB [15768 men (47.6%); mean age, 46.8 (SD ± 13) years], within 10 years of follow-up. Factors associated with a significantly increased risk of GIB were baseline age [per 10-year increase; hazard ratio (HR) 1.62, 95% confidence interval (CI): 1.42-1.86], unemployment (HR: 1.70, 95%CI: 1.11-2.59), body mass index (BMI) (HR: 1.15, 95%CI: 1.01-1.32), gamma-glutamyl transferase (GGT) (HR: 1.05, 95%CI: 1.02-1.09), precursors of GIB (HR: 1.90, 95%CI: 1.37-2.63), cancer (HR: 1.47, 95%CI: 1.10-1.97), psychiatric disorders (HR: 1.32, 95%CI: 1.01-1.71), heart failure (HR: 1.46, 95%CI: 1.04-2.05), and liver disorders (HR: 3.20, 95%CI: 2.06-4.97). Factors associated with a significantly decreased risk of GIB were systolic blood pressure (SBP) (HR: 0.78, 95%CI: 0.64-0.96), 6-10 cups of coffee a day (HR: 0.67, 95%CI: 0.46-0.99), or > 10 cups (HR: 0.43, 95%CI: 0.23-0.81).

CONCLUSION

Our study confirms established risk-factors for GIB and identifies potential risk-factors not previously reported such as unemployment, BMI, GGT, SBP and coffee consumption.

Key Words: Risk factors; Gastrointestinal hemorrhage; General population; Finland; Life style; Population health

Core Tip: This retrospective study of 33508 Finnish survey participants aimed to identify and investigate non-drug factors associated with the risk of major gastrointestinal bleeding (GIB) in the general population in Finland. Aside from established risk factors, our study identified unemployment, body mass index and gamma-glutamyl transferase enzyme were all associated with increased risk of major GIB. Systolic blood pressure and coffee consumption were associated with a decreased risk of major GIB.

INTRODUCTION

Gastrointestinal bleeding (GIB) is one of the most frequent types of major bleeding events seen in clinical practice and it can be potentially life-threatening if not managed appropriately[1]. Although several studies have investigated risk factors of GIB, these have largely evaluated associations with medications[2-5] or have been conducted in specific population groups, such as those who were critically ill[6-8]. Only a few have investigated potential associations with lifestyle factors such as smoking, alcohol consumption, and physical activity or laboratory parameters[9-11]. Furthermore, several studies on this topic have lacked information on lifestyle factors, clinical measurements, and laboratory parameters as well as long longitudinal follow-up. To identify independent risk factors for GIB, it is important to understand the association of these additional parameters on the risk of GIB when taken in account together with demographic data and comorbidities in the general population. Establishing independent risk factors for GIB is important because it will help to identify patients at high risk of GIB and to better target preventative interventions. In addition, it would be particularly relevant for designing future studies on GIB. Using data from FINRISK surveys and national health registers, we aimed to identify and investigate risk factors for major GIB in the general population of Finland.

MATERIALS AND METHODS

Ethics statement

The National FINRISK Study surveys (started in 1972) followed the EHES (European Health Examination Survey)[12] and the MONICA (Monitoring of Trends and Determinants in Cardiovascular

Disease)[13] project protocols and were approved by the ethics committee of the Finnish Institute of Health and Welfare and the Coordinating Ethical Committee of Helsinki and Uusimaa Hospital District in Finland (THL/66/0.05.00/2015). All participants in the FINRISK surveys provided their informed consent at the time of enrollment and the study was conducted following the principles of the Declaration of Helsinki. Data from the participants was pseudonymized for this study and the secondary use of the survey data was approved by the Finnish Institute of Health and Welfare in 2017.

Study design, data source, and study population

This retrospective cohort study used data from the FINRISK health examination surveys - a series of large population-based, cross-sectional surveys (with 6000 to 8800 participants per survey) carried out every 5 years to determine the risk factors for chronic, noncommunicable diseases. Survey participants were randomly chosen using the population register of Finland to obtain a representative sample of individuals across several geographic regions of Finland; those who responded to the invitation were subsequently enrolled in the study as participants in the first quarter of each survey year. From each geographical area, the surveys enrolled at least 250 subjects of each sex and 10-year age group. From the 1972 survey to the 2007 survey, the participation rate gradually decreased from approximately 80% to 65%[14].

Using data from the 1987, 1992, 1997, 2002, 2007 FINRISK survey cohorts, we identified 33796 unique participants aged 25 years to 74 years. Of these, 288 were excluded due to having hospitalization for GIB before baseline, resulting in a final cohort of 33508 individuals. Using record linkage of FINRISK participants to nationwide electronic health care registers, including the hospital discharge register and causes of death register, we identified incident cases of major GIB. These national registers cover virtually all persons living in Finland. The possibility of linking demographics, lifestyle factors, clinical measurements and laboratory parameters collected in the FINRISK surveys with national health registers increased the granularity of the dataset. The follow-up period was from the date of enrollment in the FINRISK survey to the incidence of GIB that led to hospitalization/death, death from any cause, or a maximum of 10 years, whichever occurred first. The overall design of the study is presented in Supplementary Figure 1.

Study outcome

Major GIB was defined as GIB that led to hospitalization or GIB-specific death (see Supplementary Table 1 for codes), recorded as either the main or the top three contributing factors for the hospitalization, or the underlying, direct, or contributing cause of death. We followed participants from survey enrollment for a maximum of 10 years to allow equal follow-up time for all survey cohorts to observe GIB. In the previous analyses, we have shown that the overall age standardized incidence rate of GIB in the FINRISK cohorts to be 2.10 per 1000 person-years [men: 2.62 per 1000 person-years (95%CI: 2.40-2.86) and women: 1.62 per 1000 person-years (95%CI: 1.45-1.81)][15].

Covariates

Baseline data collected at enrollment into FINRISK surveys included demographic data (age, sex, year of enrollment and region); socioeconomic factors (marital status, occupation, education); lifestyle factors (smoking status, alcohol consumption, coffee consumption, body mass index [BMI], waist hip ratio [WHR], physical activity); blood pressure measurements (systolic [SBP] and diastolic blood pressure [DBP]); and laboratory parameters (total cholesterol, high density lipoprotein cholesterol [HDL], gamma-glutamyl transferase enzyme [GGT]).

Morbidities were identified in the participant's history any time before the GIB or any time before the end of follow-up for participants without GIB. These were obtained from the hospital discharge register, causes of death register, as well as from drug reimbursement register, and prescription register using drugs as proxies for chronic conditions. Conditions were identified using the International Classification of Diseases, Ninth Revision (ICD-9) or the International Statistical Classification of Diseases and Related Health Problems, Tenth Revision (ICD-10) codes as well as prescription codes identified using Anatomical Therapeutic Chemical (ATC) codes and database specific codes of the Finnish Social Insurance. Morbidities included any cancer diagnosis, any psychiatric illness, cardiovascular diseases (stroke, venous thromboembolism, ischemic heart disease, valvular heart disease, atrial fibrillation, peripheral artery disease, heart failure, high blood pressure), a composite of precursors of GIB without bleeding (including gastritis, intestinal diseases, esophageal varices, esophagitis, hemorrhoids, colitis and Crohn's disease), osteoarthritis, connective tissue disorders, diabetes, chronic obstructive pulmonary disease, asthma, liver disorders and anemia (see Supplementary Table 2 for codes).

Statistical analyses

Participants' characteristics were summarized using counts and percentages for categorical variables and means with standard deviation (SD) for continuous variables. We conducted univariate Cox regression using all covariates. We used the Least Absolute Shrinkage and Selection Operator (LASSO) method for variable selection, which provides a relevant and interpretable group of variables from a larger set of covariates including potentially multicollinear variables[16]. LASSO regression maximizes

the partial likelihood of the regression coefficients by imposing a constraint on the sum of the absolute value of all regression coefficients in the model producing coefficients that are exactly zero, thereby regulating the impact of a coefficient in the regression[16]. This effectively excludes some variables which are unnecessary/uninfluential without the need for formal statistical testing thereby reducing the likelihood of overfitting using cross validation. Moreover, the LASSO method is less variable than the stepwise approach and yields interpretable models. The Cox LASSO regression including all the available variables showed the best model could be fitted between 12 to 39 variables (see Supplementary Figure 2). Further, we fitted a Cox proportional hazards model using variables selected by LASSO, *i.e.*, we did not include variables whose coefficients shrank towards zero. Using this approach, we obtained hazard ratios (HRs) with 95% confidence intervals (CI) for the variables in the final model[17]. Using statistical tests and graphical diagnostics, we checked the proportional hazards assumption on the *scaled Schoenfeld residuals*. Continuous variables in the Cox model were standardized by subtracting the value of the variable from its mean and dividing by its SD. For interpretation, it provides a change in risk when the value of the variable changes by one SD. There were few participants with missing baseline data (< 3%); they were excluded from the analysis and no imputations were performed. All statistical analyses were done with R, version 3.6.1 using 'glmnet' package (R Foundation for Statistical Computing).

RESULTS

Characteristics

Of the total 33508 participants, 403 (1.2%) experienced at least one GIB within the maximum 10 years of follow-up. Baseline characteristics of the study cohort are summarized in Table 1. The mean age at enrollment was 56 years (SD ± 12.1) for participants with an incident of GIB and 46.8 years (SD ± 13.0) for those who did not experience GIB. Of the participants experiencing GIB compared to those who did not have GIB, the majority were male (63.5% *vs* 47.6%), from the western region (40.4% *vs* 38.0%), single (31.0% *vs* 26.0%), a current/ex-smoker (56.1% *vs* 46.2%), a heavy alcohol drinker (25.1% *vs* 20.8%), consumed 6-10 cups of coffee per day (21.3% *vs* 27.2%) and undertook moderate-to-heavy physical activity (12.9% *vs* 21.4%). Overall, participants with GIB had a higher prevalence of comorbidities than participants without GIB as seen in Table 2, except osteoarthritis (5.0% *vs* 6.2%) which was lower. Participants developing a GIB also had a higher mean BMI (28.3 kg/m^2, SD ± 5.19 *vs* 26.6 kg/m^2, SD ± 4.61), mean WHR (0.93, SD ± 0.1 *vs* 0.88, SD ± 0.1), and mean SBP (141 mmHg, SD ± 21.7 *vs* 136 mmHg, SD ± 19.8) than those who did not experience a GIB. Of the laboratory parameters, GGT appeared to be higher in participants with GIB (59.5 U/L, SD ± 141 *vs* 31.2 U/L SD ± 45). Participants with GIB had more precursors of GIB (11.9% *vs* 4.5%) compared to participants without GIB. The results of univariate analyses showing each variable's association with the risk of major GIB are presented in Table 3.

Risk factors for major GIB

The LASSO method identified the most important predictors from larger set of variables. Variables with negative coefficients exhibit decreased risk, positive coefficients exhibit increased risk, and coefficient with value zero are the least important predictor variables in the model to predict gastrointestinal bleeding and can be removed from the final model. The aim of LASSO method is model prediction by selecting the most important predictor variables and therefore statistical significance of regression coefficients is not computed here (see Supplementary Table 3). Using these results from LASSO, we excluded variables such as DBP, HDL, VTE and Inflammatory connective tissue diseases from the final Cox model. Categorical variables for which one of the strata had a zero coefficient were kept in the final model.

Increased risk of major GIB

In terms of socio-demographics and lifestyle factors, the Cox regression showed that baseline age (HR: 1.62, 95%CI: 1.42-1.86, per 10-year increase), unemployment (HR: 1.70, 95%CI: 1.11-2.59), and higher BMI (HR: 1.15, 95%CI: 1.01-1.32) were all associated with an increased risk of GIB (Table 3). Among clinical variables, higher GGT levels (HR: 1.05, 95%CI: 1.02-1.09), having ≥ 1 precursor of GIB (HR: 1.90, 95%CI: 1.37-2.63), previous cancer (HR: 1.47, 95%CI: 1.10-1.97), psychiatric disorders (HR: 1.32, 95%CI: 1.01-1.71), heart failure (HR: 1.46, 95%CI: 1.04-2.05), and liver disorders (HR: 3.20, 95%CI: 2.06-4.97) were all associated with an increased risk of GIB. There was no clear evidence that history of cardiovascular disease was associated with the risk of major GIB.

Decreased risk of major GIB

SBP (HR: 0.78, 95%CI: 0.64-0.96) as well as drinking 6-10 cups of coffee a day (HR: 0.67, 95%CI: 0.46-0.99) or more than 10 cups of coffee a day (HR: 0.43, 95%CI: 0.23-0.81), and history of osteoarthritis (HR: 0.39, 95%CI: 0.24-0.65) were all associated with a decreased risk of GIB.

Table 1 Baseline characteristics for participants with and without major gastrointestinal bleedings during follow-up

Baseline characteristics	GIB, *n* = 403	No GIB, *n* = 33105	Overall, *n* = 33508
Age at baseline, mean (SD)	56.0 (12.1)	46.8 (13.0)	46.9 (13.0)
Sex

DISCUSSION

Our large population-based study enabled the evaluation of a wide range of potential risk factors for GIB in the general population, including demographics, socioeconomic and lifestyle factors, comorbidities, clinical measurements and laboratory parameters. Aside from confirming previously known risk factors for major GIB, we also identified unemployment, higher BMI, and higher levels of GGT as associated with a significantly increased risk of GIB, whereas increased daily coffee consumption (> 5 cups) as well as higher SBP were associated with a significantly decreased risk of GIB.

While many studies have investigated the effect of coffee on GI tract including GI cancer prevention, we believe ours is the first to investigate its association with GIB, with 29% of our study population with daily coffee consumption of > 5 cups[18]. A recent review by Iriondo-DeHond *et al*[18], outlined potential mechanisms and summarized the current evidence on the effects of individual coffee components on GI tract concluding that support for a possible causal association is insufficient. Nonetheless, several meta-analyses have reported a protective effect of coffee consumption on colon cancer[19-24] which is a major cause of GIB. A few studies[25-28] have shown that low SBP is associated with an increased risk of GIB, which supports the protective effect of high SBP seen in our study. Our results indicated that approximately 22 units decrease in SBP would increase the risk of GIB by 15%. Therefore, apart from diagnosis of hypertension, SBP values should be considered and included in the analyses of GIBs whenever available. Level of education was not associated with an increased risk for major GIBs, in contrast to being unemployed which is in line with previous research consistently showing that unemployment is associated with poor health[29,30]. Increase in age has been consistently associated with increased risk of major GIBs in the literature as in our study[28,31]. In relation to anthropometric measures, higher BMI was associated with an increased risk of GIB but not WHR or low physical activity and we are unaware of any other studies that have evaluated these variables in this context. We found no association between alcohol consumption and the risk of major GIB, in contrast to previous studies on upper GIBs[32,33]. However, association with an increased risk of major GIB were seen with a history of liver disorders as well as high levels of GGT which can be caused by chronic

heavy alcohol consumption and is in line with the components of some GIB-risk scores[28].

Very few studies mostly focusing on upper GIBs have shown increased risk associated with smoking [32,34], however our multivariate analyses showed no association between self-reported smoking (ex- or current) and major GIB. In terms of morbidities, consistent with previous studies[28,35], a history of heart failure was associated with an increased risk of GIB. This could be related to the treatments and to the fact that heart failure often coexists with atrial fibrillation which is treated with anticoagulants. As medications commonly used to treat osteoarthritis - non-steroidal anti-inflammatory drugs (NSAIDs) and corticosteroids - are thought to increase the risk of GIB[36,37], a number of possible explanations could account for our finding that osteoarthritis was associated with a decreased risk for GIB including that the patients with osteoarthritis were actively monitored, received better care and management of the disease, were prescribed PPI to prevent GIBs, or used other available treatments[38]. Although medications such as antiplatelet agents and anticoagulants, which are associated with an increased risk of GIBs[9] are often used to treat cardiovascular diseases, our study did not find an association between history of cardiovascular diseases and GIB. Our study suggests that the predictors of major GIBs in the general population might be slightly different than in critically ill populations or comorbid patients using multiple medications[3,4,6-8,11].

Strengths and limitations

Our study has several strengths. A key strength was the long follow-up (up to 10 years) of individuals from a large representative sample of the general population of Finland enabling identification of more than 400 incident cases of GIB. The loss to follow-up was minimal, and the data sources enabled us to incorporate a wide range of potential risk factors in our analyses. Missing data amongst the participants

'-' indicates that the variable was not included in the final multivariate Cox model based on the results from LASSO.
CI: Confidence Interval; GIB: Gastrointestinal bleeding; HR: Hazard ratio; SAH: Subarachnoid hemorrhage.

was also minimal. Compared to stepwise selection of variables into the regression model, the LASSO method helped to address multicollinearity and to avoid overfitting. The LASSO approach also performed an internal validation by inbuilt cross-validation techniques, although an external validation of the newly proposed risk factors is still warranted. A small degree of misclassification of GIB is possible because the electronic health register data was collected for administrative purposes, however the magnitude is likely to be very small. We used hospital diagnoses as well as drug prescriptions to identify chronic conditions. Further, NSAIDs can be obtained over the counter and not recorded in the data sources, hence could not be included in our analyses. Also, due to the insufficient numbers of cases, factors such as hemophilia, thyroid disorders, pancreatitis and chronic kidney failure could not be investigated. Information on lifestyle factors such as smoking, and alcohol consumption are self-reported and might be under-reported. Lastly, the data on demographic, lifestyle, and laboratory parameters were only collected at baseline and no repeated measurements were conducted during the study period. Therefore, we could not account for lifestyle modifications on the risk of GI bleeding in our analyses.

Clinical implications and future research

In addition to previously established risk factors for GIB, we have identified additional potential independent risk factors for major GIB, further helping build the knowledge base on this topic. This will support in identifying patients at high risk of GIB. Further, this will support early interventions or counseling to prevent incident or recurrent GIBs as well as help in monitoring the prevalence of these risk factors. The results from our study are exploratory and future studies are required to establish causal associations and hopefully stimulate research of these factors in the general population which currently is scarce.

CONCLUSION

Our study showed that older age, unemployment, higher BMI, higher GGT levels, history of precursors of GIBs, cancer, psychiatric illness, heart failure and liver disorders were associated with an increased risk of major GIBs. Moreover, higher coffee consumption (> 5 cups per day) and higher SBP showed an inverse association with major GIB. These associations in the general population need to be confirmed by future research and other epidemiological studies.

ARTICLE HIGHLIGHTS

Research background

Limited information is available on the risk factors of gastrointestinal bleedings (GIB) in the general population. Previous research mainly focused on the population using specific medications such as antiplatelets, anticoagulants *etc.* or the critically ill population such as hospitalized patients or elderly. Therefore, we investigated the risk factors for major GIB using data representative of the general population having a high granularity of the data source and long-term follow-up of participants.

Research motivation

Many studies investigating risk factors of GIB lacked information on lifestyle factors, clinical measurements and laboratory parameters. We wanted to better understand the effect of these additional variables on GIB as well as how this affects established risk factors. Additionally, to better understand the factors that predict the risk of GIB in the presence of a multicollinear set of variables [*e.g.*, Body mass index (BMI), Waist-hip ratio (WHR) or physical activity].

Research objectives

The overall objective of the study was to identify and investigate new risk factors of major GIB in the general population of Finland considering established risk factors as well as demographics and morbidities. We were able to identify new risk factors of major GIB together with established risk factors which needs to be evaluated and confirmed by further research.

Research methods

We conducted a retrospective cohort study using record linkage of data from the FINRISK health examination surveys which are representative of the general population of Finland to the national electronic health registers with 10 years of follow-up. This linkage enabled us to include and investigate demographics, socioeconomic and lifestyle factors, clinical measurements, laboratory parameters, and comorbidities on the risk of major GIB. We further implemented Least Absolute Shrinkage and Selection Operator (LASSO) to select the most important predictor variables for model prediction and association of these predictor variables were evaluated using Cox regression. The novelty of using LASSO is that it helps in the variable selection and in excluding unnecessary/uninfluential variables from the model thus reducing the likelihood of overfitting a model. It also helps to address multicollinearity that can be problematic in the traditional forms of regression.

Research results

The main results of the study showed that baseline age, unemployment, and higher BMI, higher gamma-glutamyl transferase (GGT) levels, having ≥1 precursor of GIB, previous cancer, psychiatric disorders, heart failure and liver disorders were all associated with an increased risk of GIB. Systolic blood pressure, above average coffee consumption per day, and history of osteoarthritis were all associated with a decreased risk of GIB. This study adds to the scarce literature on risk factors on gastrointestinal bleeding in the general population. Additionally, results are hypothesis generating for the new risk factors identified in this study which must be confirmed by future mechanistic and epidemiological studies.

Research conclusions

This study identified new risk factors associated with major GIB which are unemployment, BMI, GGT, SBP and coffee consumption. Accounting for physical activity and waist-hip ratio, our study suggests that BMI is a better predictor of major GIB. Above average coffee consumption per day, which seems to be more common in Finland with the highest per capita coffee consumption in the world, was associated with a decreased risk of major GIB. Our study suggests that the risk factors of major GIBs might be slightly different in the general population than the at-risk population.

Research perspectives

Future mechanistic and epidemiological studies should evaluate these risk factors in different study populations or countries across the world to establish causal associations. This will further support in complementing and refining existing risk scores for major GIBs.

Abstract

BACKGROUND

Autoimmune hepatitis-primary biliary cholangitis (AIH-PBC) overlap syndrome has a worse prognosis than AIH or PBC alone. Therefore, accurately staging liver fibrosis and dynamically monitoring disease progression are essential.

AIM

To investigate the performance of two-dimensional shear-wave elastography (2D-SWE) for noninvasively staging liver fibrosis and assessing the clinical utility of repeated 2D-SWE for monitoring treatment response in AIH-PBC overlap syndrome.

METHODS

A total of 148 patients diagnosed with AIH-PBC overlap syndrome were retrospectively enrolled. Among them, 82 patients had a 2D-SWE follow-up time of more than 1 year. The Scheuer scoring system was used to evaluate stages of hepatic inflammation and liver fibrosis. The performance of 2D-SWE for staging liver fibrosis was evaluated with the liver biopsy. Changes in liver stiffness (LS) measured by 2D-SWE in patients with or without complete biochemical remission were evaluated.

RESULTS

LS value was strongly correlated with liver fibrosis stage (Spearman $r = 0.84$, $P < 0.0001$). The areas under the receiver operating characteristic curves of LS for

diagnosing significant fibrosis (≥ S2), severe fibrosis (≥ S3), and cirrhosis (S4) were 0.91, 0.97, and 0.96, respectively. Patients with complete biochemical remission had a considerable decrease in LS values (P < 0.0001). More importantly, the declined LS in patients with S0-S2 was significantly lower than that in patients with S3-S4 (P = 0.0002). In contrast, patients who failed to achieve biochemical remission had a slight but not significant decrease in LS (P = 0.37).

CONCLUSION

LS measured by 2D-SWE is an accurate and reliable method in assessing liver fibrosis, especially for diagnosing severe fibrosis (≥ 3) and monitoring treatment response in patients with AIH-PBC overlap syndrome.

Key Words: Liver fibrosis; Liver biopsy; Diagnostic tests; Autoimmune hepatitis; Primary biliary cholangitis; Inflammation

INTRODUCTION

Autoimmune hepatitis-primary biliary cholangitis (AIH-PBC) overlap syndrome is defined as presenting features of AIH and PBC simultaneously or sequentially. AIH is a progressive inflammatory liver disorder characterized histologically by interface hepatitis, serologically by high levels of transaminases and immunoglobulin G (IgG) and the presence of autoantibodies. PBC is progressive autoimmune liver disease with nonsuppurative destructive cholangitis and interlobular bile duct destruction[1]. AIH-PBC overlap syndrome has a worse prognosis than AIH or PBC alone[2]. Therefore, accurately assessing stage of liver disease and dynamically monitoring the progression of disease are essential for some AIH-PBC overlap syndromes with rapid disease progression.

Liver biopsy still remains the gold standard for establishing the diagnosis, assessing disease severity and determining treatment. According to the most recent guidelines, long-term treatment with immunosuppressants in combination with ursodeoxycholic acid is recommended when AIH-PBC overlap syndrome is established[3,4]. Frequent biochemical markers measurement during the follow-up was necessary to monitor the therapeutic response. However, they cannot monitor the histologically progression and reflect the severity of liver fibrosis. Furthermore, hepatic histological remission usually lagged behind biochemical remission by several months[5]. Therefore, detecting the severity of histology at the beginning of treatment and frequent monitoring during long-term follow-up are important for management of AIH-PBC overlap syndrome. Liver biopsy is still the gold standard for diagnosing AIH-PBC overlap syndrome and staging liver fibrosis, and can be accepted by most patients, but the second or repeated liver biopsy cannot be easily performed due to its costly and invasive procedure during the long-term follow-up.

During the past decades, several noninvasive markers are found to have high accuracy for detecting liver fibrosis and disease progression. 2D-SWE by using the supersonic shear imaging technique is an ultrasound-based real-time imaging method with the following advantages for assessing liver disease: (1) nontarget structure and elastic artifacts can be effectively avoided to improve reliability by integrating B-mode imaging and color-coded tissue stiffness maps in real time; (2) it is widely applied to measure liver stiffness in the whole world; and (3) there is no limitation in patients with ascites[6]. Our previous studies showed that 2D-SWE has a great performance for staging liver fibrosis in AIH[7] and PBC patients[8]. However, the utility of 2D-SWE in monitoring treatment response remains blank.

The aim of this study was to evaluate the clinical utility of 2D-SWE in evaluating liver fibrosis and to assess the usefulness of repeated 2D-SWE for monitoring treatment response in AIH-PBC overlap syndrome.

MATERIALS AND METHODS

Patients

This is a single-center retrospective study, which was approved by the ethics committee of our hospital, and due to the retrospective feature, the patients informed consent was waived. Patients was strictly diagnosed according to the Paris criteria[9,10]. The presence of at least two of the three accepted criteria was required for the diagnosis of AIH and PBC. The AIH criteria were as follows: (1) Alanine aminotransferase (ALT) levels at least five times higher than the upper limit of normal (ULN); (2) Serum IgG levels at least two times higher than the ULN or a positive test for anti-smooth muscle antibodies; and (3) Moderate or severe periportal or periseptal piecemeal lymphocytic necrosis in liver biopsy. PBC criteria were as follows: (1) Alkaline phosphatase (ALP) levels at least two times higher than the ULN or γ-glutamyltranspeptidase (GGT) levels at least five times higher than the ULN; (2) A positive test for anti-mitochondrial antibodies; and (3) Florid bile duct lesions in liver biopsy. Among them, moderate interfacial inflammation of the liver was necessary for diagnosis of AIH-PBC overlap syndrome. The patients between September, 2016 and April 2021 in West China hospital were enrolled. The inclusion criteria were as follows: (1) Patients met the diagnosis criteria of PBC-AIH overlap syndrome with liver biopsy; and (2) Age was adults with lower than 75 years old. The exclusion criteria were as follows: (1) Patients with overlapping etiologies of liver disease, such as virus, alcohol liver disease[11], non-alcoholic fatty liver disease[12], drug-induced liver disease[13], hereditary metabolic liver disease or other causes of liver damage; (2) Patients with primary hepatic carcinoma or other malignant tumors; (3) 2D-SWE measurement after liver biopsy for more than 1 mo and with treatment; (4) Patients without 2D-SWE results or serological data; (5) Patients with ascites, varices bleeding, esophageal variceal ligation (EVL) or splenectomy; and (6) Patients with severe systemic disease. Among them, the follow-up time with 2D-SWE greater than 1 year was subsequently analyzed to evaluate the changes of LS values after standard treatment. Complete biochemical remission was defined by normalization of serum AST, ALT, ALP and IgG levels[14].

2D-SWE measurement

2D-SWE measurements were obtained by using the Aixplorer system (SuperSonic Imagine, Aix-en-Provence) with a SC6-1 (frequency of 1-6 MHz) convex probe. Two experience radiologists independently performed the procedures according to the guidelines developed by the World Federation for Ultrasound in Medicine and Biology[15]. The 2D-SWE measurements were performed following our previous study[8], Briefly, the elasticity image box, approximately 4 cm × 3 cm, was placed 1-2 cm under the liver capsule in the parenchyma area of the right hepatic lobe. At least three valid measurements were obtained in each patient. The median LS value was recorded (in kPa)[16]. When less than two-thirds of the signal filled in the 2D SWE region of interest or the large vessels and biliary tracts were not avoided, measurements were considered failed or unqualified[17].

Liver biopsy and histologic stages

Ultrasound-guided liver biopsy was performed in the right liver lobe. Quality of the liver specimen was evaluated. All specimens were analyzed by one experienced pathologist. The Scheuer scoring system, a common scoring system in clinical practice, evaluates liver fibrosis and necroinflammatory activity. Liver fibrosis was scored as follows the previous studies[7]: the liver fibrosis was staged from stage 0 (S0) to stage 4 (S4) cirrhosis (S0-S4). Necroinflammative was also scored from grade 0 (G0), no portal or periportal and lobular necroinflammatory activity to grade 4 (G4), severe piecemeal portal or periportal necrosis and severe or diffuse hepatocellular damage inside the lobule (G0-G4). Significant fibrosis was liver fibrosis stage ≥ S2; severe fibrosis was liver fibrosis stage ≥ S3 and cirrhosis was liver fibrosis stage = S4. Mild liver necroinflammation was defined as necroinflammatory activity lower than G2 (G0–G2), and significant liver necroinflammation was defined as necroinflammatory activity higher than G2 (G3-G4).

Statistical analysis

Statistical analyses were performed in SPSS Statistics version 24.0 (IBM Corporation, Armonk, NY), MedCalc software version 19.1.0 (MedCalc Software, Mariakerke, Belgium). A P value lower than 0.05 was considered statistically significant. Descriptive statistics were summarized as the median and interquartile (25%-75%). One-way ANOVA analysis or the Mann-Whitney test was used to compare quantitative variables. Correlations between LS values and biochemical biomarkers and histological features were evaluated with the Spearman correlation test, and those with $P < 0.05$ were subsequently included in multiple regression analysis. The performance of noninvasive methods in the assessment of liver fibrosis stages was determined by using the area under the receiver operating characteristic curve (AUC). Optimal cutoff values to predict different fibrosis stages were identified with the highest Youden's index. The corresponding sensitivity, specificity, negative predictive value, positive predictive value and accuracy were calculated. The cutoff values of LS for ruling out and ruling in were defined with sensitivity > 95% and specificity > 95%, respectively. The AUCs of noninvasive biomarkers were compared with the DeLong test. The Z test was used to compare the AUCs of LS for predicting liver

fibrosis in the G0-G2 subgroups and G3-G4 subgroups. Two-way ANOVA was used to evaluate the changes in LS. Wilcoxon matched pairs test was used to compare the LS values before treatment and each follow-up.

RESULTS

Patients' characteristics

A total of 177 patients considered AIH-PBC patients were enrolled. Eight patients without 2D-SWE results or liver biopsy, 2 patients of with the 2D-SWE measurements after liver biopsy for more than 1 mo and with treatment, 15 patients with varices bleeding or EVL, 1 patient with splenectomy, 1 patient with portal venous thrombosis, 1 patient with age < 18 years old, and 1 patient with hepatic carcinoma were excluded. Finally, 148 patients were included to analyze the LS for staging liver fibrosis in this study (Figure 1). Among them, 82 patients had a 2D-SWE follow-up of more than 1 year, 36 patients had complete biochemical remission, and 46 patients had no biochemical remission. The characteristics of the patients are described in Table 1. The numbers of patients with S0–S1, S2, S3 and S4 were 25 (15.4%), 48 (30.2%), 13 (9.9%) and 62 (44.4%), respectively.

Correlation of liver stiffness and serum biomarkers, histological features

LS had a strong correlation with serum biomarkers and histological features (Table 2). PLT (Spearman r = -0.43, P < 0.0001), total bilirubin (Spearman r = 0.60, P < 0.0001), AST (Spearman r = 0.33, P < 0.0001), albumin (Spearman r = -0.67, P < 0.0001), and IgG (Spearman r = 0.38, P < 0.0001) had significant correlations with LS values. The necroinflammatory activity grades (Spearman r = 0.32, P < 0.0001) and fibrosis stages (Spearman r = 0.84, P < 0.0001) also had a significant correlation with LS. In multiple regression analysis, only total bilirubin (P = 0.005) and fibrosis stages (P < 0.0001) had strong correlations with LS values (Supplementary Table 1). In addition, LS values in patients were increased with fibrosis stage S0-S1 [7.2 (6.3-9.9) kPa], S2 [10.7 (8.6-12.2) kPa], S3 [13.8 (12.0-20.8)], S4 [21.1 (17.1-28.4) kPa] (P < 0.0001) (Figure 2).

Diagnostic utility of 2D-SWE for assessing liver fibrosis stages

The utility of LS measured by 2D-SWE for staging liver fibrosis is shown in Table 3. For diagnosing significant fibrosis (≥ S2), the AUC of LS was 0.91 (95%CI: 0.85-0.96). The optimal cutoff value of LS was 12.1 kPa with the highest combined sensitivity (67.5%) and specificity (96.0%). The cutoff values of LS for ruling out and ruling in significant fibrosis (≥ S2) were 7.9 kPa and 12.1 kPa, respectively. For assessing severe fibrosis (≥ S3), the AUC of LS was 0.97 (95%CI: 0.94-0.99). The optimal cutoff value of LS was 15.0 kPa with the highest combined sensitivity (85.3%) and specificity (95.9%). The cutoff values of LS for ruling out and ruling in severe fibrosis (≥ S3) were 11.9 kPa and 15.0 kPa, respectively. For diagnosing cirrhosis (S4), the AUC of 2D-SWE was 0.96 (95%CI: 0.92-0.99). The optimal cutoff value of 2D-SWE was 18.0 kPa with the highest combined sensitivity (90.3%) and specificity (91.9%). The cutoff values of LS for ruling out and ruling in liver cirrhosis were 13.9 kPa and 19.4 kPa, respectively.

Effects of different degree of necroinflammation on LS measured by 2D-SWE

The effects of necroinflammatory activity on LS measured by 2D-SWE were evaluated. LS values in the subgroup of patients with G0-G2 and the subgroup of patients with G3-G4 showed no significant difference for staging liver fibrosis S0-S1 (P = 0.57), S2 (P = 0.51), S3 (P = 0.62) and S4 (P = 0.77) (Supplementary Table 2). The effect of necroinflammatory activity on the accuracy of LS values for staging liver fibrosis is shown in Supplementary Table 3. The AUCs of LS for diagnosing significant fibrosis (≥ S2) (P = 0.57), severe fibrosis (≥ S3) (P = 0.89), and cirrhosis (S4) (P = 0.06) were not significantly different between subgroups of patients with G0-G2 and G3-G4 necroinflammatory activity.

Accuracy of liver stiffness for evaluating liver fibrosis

The cutoff values for ruling out significant fibrosis (≥ S2), severe fibrosis (≥ S3) and cirrhosis (S4) were 7.9 kPa, 11.9 kPa and 13.9 kPa, respectively. The accuracy of these cutoff values for predicting each stage of liver fibrosis is listed in Supplementary Table 4. In patients with S0–S1, S2, S3 and S4, 15/25 (60.0%), 26/48 (54.2%), 4/13 (30.8%) and 58/62 (93.5%) of them were correctly classified, respectively. The accuracy of 2D-SWE for predicting severe fibrosis (≥ S3) was 71/75 (94.7%).

Complete biochemical remission is associated with changes in LS values

Eighty-two patients with 2D-SWE follow-up time of more than 1 year were evaluated. The total median follow-up time of these patients was 3.3 (2.2-4.1) years. The median follow-up time of 2D-SWE in these patients was 2.5 (1.5-3.5) years. Among these patients, 36 patients had complete biochemical remission, and 46 patients had no biochemical remission. The baseline characteristics of patients with or without complete biochemical remission were shown in Table 4. Total bilirubin (P = 0.009), ALP (P = 0.0005) and

Data are presented as median and interquartile range, number (percentage). The reference laboratory parameter value: Total bilirubin: 5-28 μmol/L; alanine aminotransferase < 50 IU/L; aspartate aminotransferase < 40 IU/L; albumin: 40-55 g/L; platelet count: 100-300 × 10^9/L; alkaline phosphatase: 51-160 IU/L; gamma-glutamyl transpeptidase: < 60 IU/L; immunoglobulin G: 8-15.5 g/L; immunoglobulin M: 700-2200 mg/L. BMI: Body mass index; TB: Total bilirubin; ALB: Albumin; PLT: Platelet count; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; ALP: Alkaline phosphatase; GGT: Gamma-glutamyl transpeptidase; IgG: Immunoglobulin G; IgM: Immunoglobulin M; LKM: Liver-kidney microsomal antibody; AMA: Antimitochondrial antibodies; ANA: Antinuclear antibody; LS: Liver stiffness.

GGT (P = 0.005) in patients with biochemical remission were lower than those in patients without biochemical remission. The change of LS values in patients with biochemical remission was significantly more than that in patients without biochemical remission (P < 0.0001). LS values in patients with complete biochemical remission present a considerable decrease (P < 0.0001). The LS values in all follow-up time points were lower than control point (all P < 0.01). In contrast, LS values in patients who failed to achieve complete biochemical remission showed a slight but not significant decrease (P = 0.37) (Figure 3). In patients with complete biochemical remission, the changes in LS in patients with S0-S2 fibrosis stages were significantly lower than those in patients with S3-S4 fibrosis stages (P = 0.0002) (Figure 4A). However, there was no similar change in patients without biochemical remission (Figure 4B).

DISCUSSION

AIH-PBC overlap syndrome is a special clinical subgroup of chronic liver disease with poor clinical prognosis and higher risk of liver related complications than AIH or PBC alone. Therefore, disease progression needs intensive follow-up and dynamic monitoring in a timely manner. Noninvasive methods for staging liver fibrosis and monitoring disease progression are worthy of more concern. In this study, we assessed the clinical utility of 2D-SWE for staging liver fibrosis and evaluated the usefulness of repeated 2D-SWE to monitor disease progression in patients with AIH-PBC overlap syndrome.

2D-SWE is equal or superior to TE in staging liver fibrosis[18-21]. A meta-analysis study reported 2D-SWE had an excellent performance for staging fibrosis in common causes of liver disease, such as hepatitis C, hepatitis B, and nonalcoholic fatty liver disease, the AUCs were ranged from 86% to 96%. Autoimmune liver disease (AILD) is a rare group of liver diseases in the whole world, especially AIH-PBC overlap syndrome. Few studies have assessed the performance of 2D-SWE to evaluate severity of AILD. Our studies reported that the AUCs of LS measured by 2D-SWE for staging liver fibrosis were ranged from 0.88-0.99 in patients with PBC and 0.84-0.94 in patients with AIH, respectively. Recently, Janik *et al*[22] showed that the AUC of 2D-SWE for diagnosing cirrhosis was 0.93 in patients with AIH. In addition, Wu *et al*[23] reported that the AUCs of LS measured by TE for diagnosing F ≥ 2, F ≥ 3, and

F4 were 0.84, 0.91, and 0.97, respectively, in patients with AIH-PBC overlap syndrome. In this study, the AUCs of LS measured by 2D-SWE in detecting significant fibrosis (S ≥ 2), severe fibrosis (S ≥ 3), and cirrhosis (S4) were 0.91, 0.97, and 0.96, respectively, which showed a broadly consistent accuracy with previous studies. 61/114 (53.5%) patients with AILD, 68/103 (66.02%) patients with AIH, 116/157 (73.9%) patients with PBC, respectively, can be correctly classified[7,8,24]. 105/148 (69.6%) patients with AIH-PBC overlap syndrome can be correctly classified in this study. These results suggest that LS measured by 2D-SWE is reliable method for staging liver fibrosis in patients with AIH-PBC over syndrome, even in patients with AILD.

The cutoff value of LS may vary among different etiologies and should be considered in diagnosing liver fibrosis[18,25,26]. The LS values ranged from 7.0 kPa to 8.3 kPa, 8.2 kPa to 9.2 kPa, and 9.9 kPa to 13.3 kPa for detecting significant fibrosis (S ≥ 2), severe fibrosis (S ≥ 3) and cirrhosis (S = 4), respectively. Patients with hepatitis B or C viruses have lower LS values for detecting corresponding fibrosis stages [25]. A study including 114 patients with AILD concluded that the optimal LS values for detecting significant fibrosis (S ≥ 2), severe fibrosis (S ≥ 3) and cirrhosis (S = 4) were 9.7 kPa, 13.2 kPa, and 16.3 kPa, respectively[24]. Our previous study showed that the optimal LS values for diagnosing significant fibrosis (S ≥ 2), severe fibrosis (S ≥ 3) and cirrhosis (S4) were 10.0 kPa, 15.8 kPa and 19.3 kPa, respectively in patients with AIH and 10.7 kPa, 12.2 kPa and 14.1 kPa, respectively in patients with PBC[7,8]. In this study, the optimal cutoff values of LS for staging significant fibrosis (S ≥ 2), severe fibrosis (S ≥ 3) and

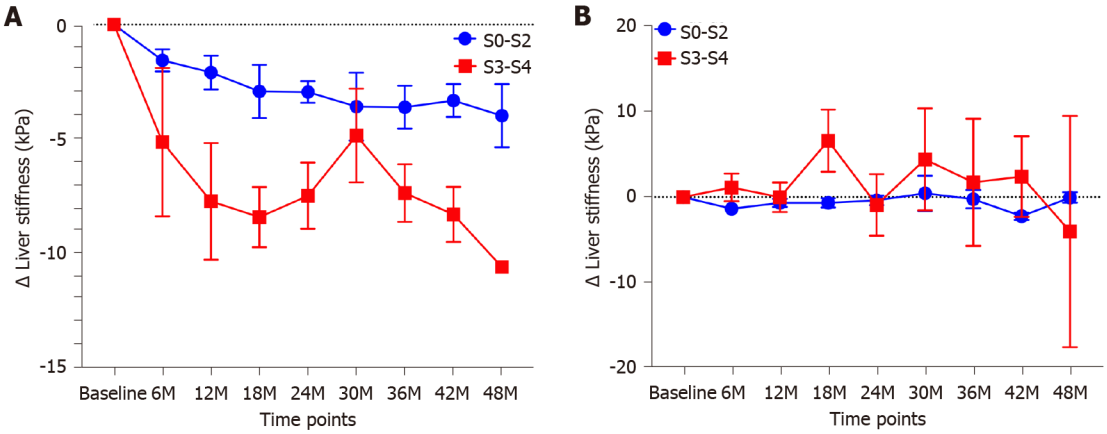
Figure 2 Liver stiffness values of different liver fibrosis stages in patients with autoimmune hepatitis-primary biliary cholangitis overlap syndrome.



cirrhosis (S4) were 12.1 kPa, 15.0 kPa and 15.1 kPa, respectively in patients with AIH-PBC overlap syndrome. The cutoff values of LS for ruling out significant fibrosis (S ≥ 2), severe fibrosis (S ≥ 3) and cirrhosis (S4) were 7.9 kPa, 11.9 kPa and 13.9 kPa, respectively. According to these current studies, we try to draw a conclusion that the causes of liver disease might affect the LS values and that AIH-PBC over syndrome might have higher cutoff values than other causes of liver disease for diagnosing liver fibrosis.

As discussed in the current European Association for the Study of the Liver Clinical Practice Guidelines, the active liver inflammation may affect the LS values. The increased transaminase and total bilirubin might lead to overestimation of LS measurements[27,28]. In this study, LS showed a strong correlation with several serum biomarkers, such as PLT, total bilirubin, AST, albumin and IgG (P < 0.0001). However, in the multiple regression analysis, only liver fibrosis stages and total bilirubin were

Figure 4 In patients with complete biochemical remission, the change of liver stiffness in patients with S0-S2 and S3-S4. A: Change of liver stiffness in patients with S0-S2; B: Change of liver stiffness in patients with S3-S4.

associated with the LS values. These findings were consistent with previous studies[28-31], and the LS values might be influenced by elevated total bilirubin. Therefore, considering the feature of AIH-PBC over syndrome, the cutoff values for diagnosing liver fibrosis could be higher than other causes of liver disease. The treatment history may affect the diagnostic accuracy of 2D-SWE for staging fibrosis. ALT could affect the LS values measured by TE, which are mainly reported in patients with chronic hepatitis B[32-34]. However, the ALT did not associate with LS in this study. Xu *et al*[35] also reported that in patients with AIH, ALT cannot affect the LS values measured by transient elastography. Therefore, whether the level of ALT can represent liver histological inflammatory activity needs more study to validate it.

Hartl *et al*[29] reported a significant decrease in LS measured by TE in AIH patients with complete biochemical remission, especially in subgroups of patients with S3-S4 fibrosis stages. The declines in LS measured by TE may reflect the remission of both liver inflammation and fibrosis[36,37]. In this study, the LS values were significantly decreased in patients with complete biochemical remission. In addition, the changes in LS values in patients with S3-S4 were more than those in patients with S0-S2. However, there was no significant change in LS values in patients without biochemical remission. These results demonstrate that LS measured by 2D-SWE can monitor the therapeutic effect. Due to the lack of liver biopsy after treatment, there was no definite correlation between the decline in LS values and remission of liver inflammation or fibrosis.

This study has some limitations that warrant discussion: (1) The patient cohort was small, which can be understood that the prevalence of AIH-PBC overlap syndrome also very low; (2) There is no detailed information on the failure rate of 2D-SWE; (3) In this cohort, we did not acquire the TE data, therefore, we cannot compare the performance of 2D-SWE with TE for diagnosing fibrosis and monitoring treatment due to the retrospective features of this study; and (4) There was no liver biopsy after

treatment with complete biochemical remission.

CONCLUSION

In conclusion, LS measured by 2D-SWE is a potential noninvasive method for staging liver fibrosis, especially for diagnosing severe fibrosis (≥ 3) in patients with AIH-PBC overlap syndrome. The diagnostic performance of 2D-SWE is superior to that of serum fibrosis models for staging liver fibrosis. More importantly, 2D-SWE can monitor the treatment response in patients with complete biochemical remission with a significant decline in LS values.

ARTICLE HIGHLIGHTS

Research background

Autoimmune hepatitis-primary biliary cholangitis (AIH-PBC) overlap syndrome has a worse prognosis than AIH or PBC alone. Therefore, accurately diagnosing liver fibrosis and dynamically monitoring disease progression are essential.

Research motivation

The evaluation of two-dimensional shear-wave elastography (2D-SWE) in detecting liver fibrosis and monitoring treatment response in patients with AIH-PBC overlap syndrome remains blank.

Research objectives

To evaluate the diagnostic utility of 2D-SWE in staging liver fibrosis and assess the usefulness of repeated 2D-SWE for monitoring treatment response in AIH-PBC overlap syndrome.

Research methods

Patients with biopsy-proven AIH-PBC overlap syndrome were retrospectively enrolled. The performances of 2D-SWE and serum indexes for staging liver fibrosis were evaluated. The Scheuer scoring system was used to evaluate hepatic inflammation and liver fibrosis. Changes in liver stiffness (LS) measured by 2D-SWE in patients with or without complete biochemical remission were measured.

Research results

LS was strongly correlated with liver fibrosis stage (Spearman $r = 0.84$, $P < 0.0001$). The areas under the receiver operating characteristic curves of LS for significant fibrosis, severe fibrosis, and cirrhosis were 0.91, 0.97, and 0.96, respectively. Patients with complete biochemical remission showed a considerable decrease in LS values ($P < 0.0001$). More importantly, the decline in LS in patients with S0-S2 was significantly lower than that in patients with S3-S4 ($P = 0.0002$). In contrast, patients who failed to achieve biochemical remission showed a slight but not significant decrease in LS ($P = 0.37$).

Research conclusions

2D-SWE is an accurate and reliable method in assessing liver fibrosis and monitoring treatment response in patients with AIH-PBC overlap syndrome.

Research perspectives

2D-SWE can monitor the treatment effect in patients with AIH-PBC overlap syndrome.

ABOUT COVER

Editorial Board Member of *World Journal of Gastroenterology*, Cheng-Fu Xu, MD, Chief Physician, Department of Gastroenterology, The First Affiliated Hospital, Zhejiang University School of Medicine, No. 79 Qingchun Road, Hangzhou, Zhejiang Province 310003, China. xiaofu@zju.edu.cn

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, and Scopus. The 2021 edition of Journal Citation Report® cites the 2020 impact factor (IF) for *WJG* as 5.742; Journal Citation Indicator: 0.79; IF without journal self cites: 5.590; 5-year IF: 5.044; Ranking: 28 among 92 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2020 is 6.9 and Scopus CiteScore rank 2020: Gastroenterology is 19/136.

Abstract

The coronavirus disease 2019 (COVID-19) is known to cause gastrointestinal symptoms. Recent studies have revealed COVID-19-attributed acute pancreatitis (AP). However, clinical characteristics of COVID-19-attributed AP remain unclear. We performed a narrative review to elucidate relation between COVID-19 and AP using the PubMed database. Some basic and pathological reports revealed expression of angiotensin-converting enzyme 2 and transmembrane protease serine 2, key proteins that aid in the entry of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) into the pancreas. The experimental and pathological evaluation suggested that SARS-CoV-2 infects human endocrine and exocrine pancreas cells, and thus, SARS-CoV-2 may have a direct involvement in pancreatic disorders. Additionally, systemic inflammation, especially in children, may cause AP. Levels of immune mediators associated with AP, including interleukin (IL)-1β, IL-10, interferon-γ, monocyte chemotactic protein 1, and tumor necrosis factor-α are higher in the plasma of patients with COVID-19, that suggests an indirect involvement of the pancreas. In real-world settings, some clinical features of AP complicate COVID-19, such as a high complication rate of pancreatic necrosis, severe AP, and high mortality. However, clinical features of COVID-19-attributed AP remain uncertain due to insufficient research on etiologies of AP. Therefore, high-quality clinical studies and case reports that specify methods for differential diagnoses of other etiologies of AP are needed.

Key Words: COVID-19; SARS-CoV-2; Pancreatitis; Revised atlanta classification; Prognosis; Etiology

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Several review articles have explored the relationship between coronavirus disease 2019 (COVID-19) and acute pancreatitis (AP). However, due to various etiologies associated with AP, COVID-19-attributed AP is controversially defined. Therefore, this narrative review attempted to reveal clinical features of COVID-19-attributed AP focused on surveillance of the other etiologies of AP. The clinical features of COVID-19-attributed AP remain uncertain due to insufficient data on etiologies of AP. Therefore, prospective cohort studies focused on patients with COVID-19 with idiopathic AP are required, especially to clearly exclude other etiologies of AP.

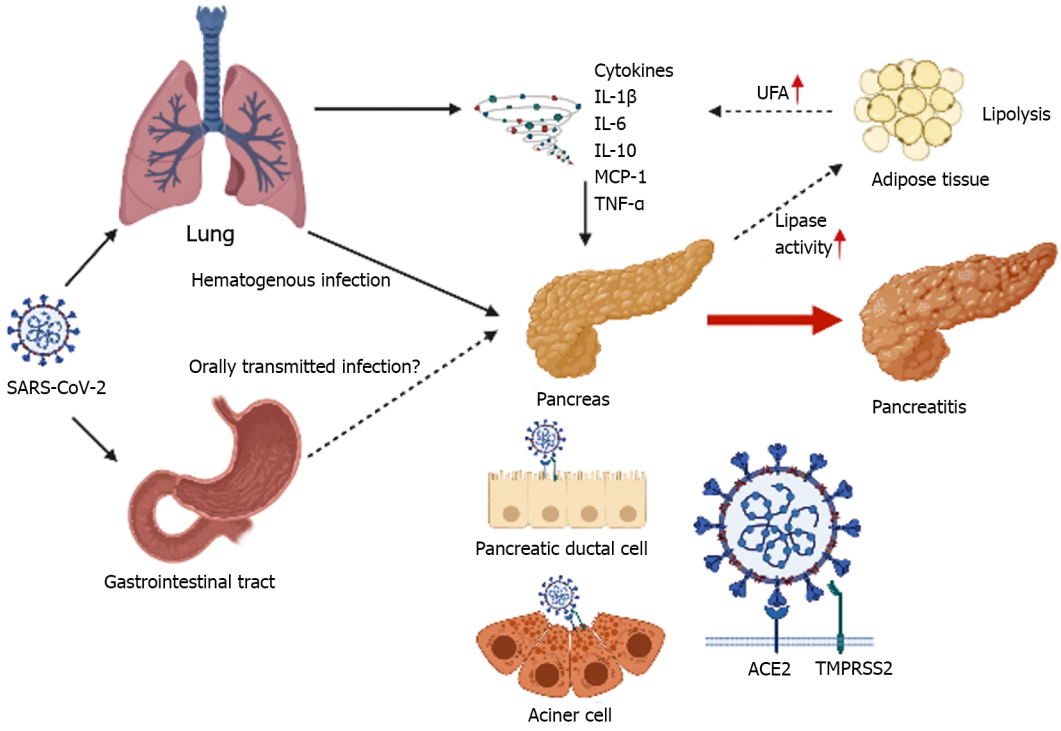
INTRODUCTION



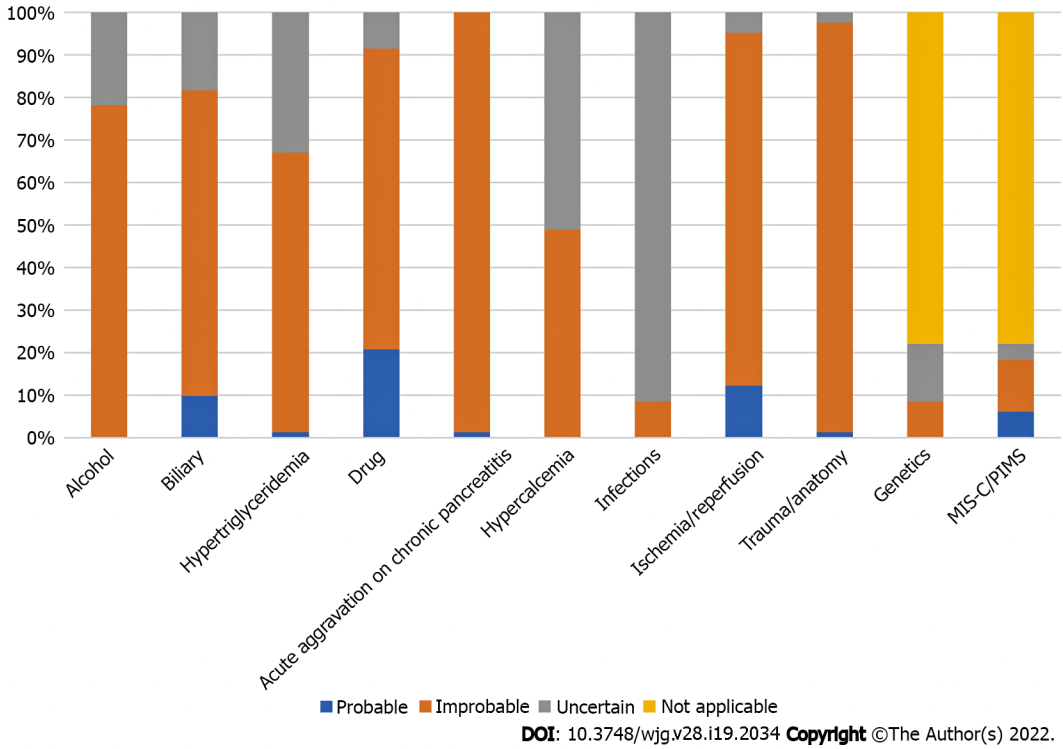
The novel coronavirus disease 2019 (COVID-19), caused by severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2), was declared a pandemic by the World Health Organization (WHO) on March 11, 2020. COVID-19 causes respiratory symptoms, such as cough, fever, sputum production, and shortness of breath, and also leads to gastrointestinal symptoms, such as nausea, vomiting, and diarrhea [1,2]. Some studies revealed that SARS-CoV-2 RNA can be detected in the gastrointestinal tract[3,4]. SARS-CoV-2 binds to angiotensin-converting enzyme 2 (ACE2) protein that serves as an entry point for the virus into epithelial cells[5]. SARS-CoV-2 also invades the gastrointestinal tract *via* ACE2, allowing development of gastrointestinal symptoms[2,6-9]. Recent studies suggest that SARS-CoV-2 infection might induce pancreatic injury or acute pancreatitis (AP)[10,11]. Schepis *et al*[12] identified SARS-CoV-2 RNA in a pancreatic pseudocyst sample collected from a patient with COVID-19[12]. Moreover, ACE2 expressed in the pancreas is associated with pancreatic injury[13]. In experimental system, SARS-CoV-2 infects human endocrine and exocrine cells of the pancreas, *ex vivo* and *in vivo*[14]. However, clinical features of COVID-19-attributed AP remain uncertain. Some systematic reviews have reported COVID-19-attributed pancreatic injury[15,16], but it remains uncertain whether the pancreatic injury is truly caused by SARS-CoV-2 due to insufficient search for the etiology of AP. Gallstones and alcoholism are two common etiological factors of AP[17-19]. Certain medications (valproic acid, azathioprine, and sulfonamides), metabolic disturbances (hypercalcemia and hypertriglyceridemia), and infections are also rare etiologies[19,20]. Trauma, iatrogenic considerations [*e.g.*, endoscopic retrograde cholangiopancreatography (ERCP)], anatomy (*e.g.*, pancreatic tumor or pancreatic divisum), ischemia/reperfusion, and genetic mutation are also reported as etiologies of AP[19,21-23]. Many studies have reported that bacterial, mycobacterial, helminthic, protozoan, and fungal infections are etiologies of AP[24,25]. Furthermore, hepatotropic virus, Coxsackie virus, Echovirus, Cytomegalovirus, human immunodeficiency virus, Herpes simplex virus, mumps virus, measles virus, varicella-zoster virus, and other viruses may cause infectious AP[24-26]. Therefore, the COVID-19-attributed AP should be diagnosed by sufficient exclusion of other etiologies of AP. Additionally, the diagnostic criteria for COVID-19 is reverse transcription-polymerase chain reaction (RT-PCR) or serological test for SARS-CoV-2, and also clinical examinations, such as chest computed tomography (CT) and clinical history. Moreover, the diagnostic criteria for AP and severity of COVID-19 and AP are not unified across reports. Thus, it is required to sufficiently evaluate etiologies of AP, and clearly define diagnostic and severity criteria of COVID-19 and AP for reviewing COVID-19-attributed AP. A sufficient evaluation of etiologies of AP should be performed, especially in case studies.

This study aimed to perform a review of literature to reveal recent findings on the association between AP and SARS-CoV-2. The review also focusses on the real-world data of COVID-19-attributed AP, with surveillance for other etiologies of AP, and reveals some clinical features of COVID-19-attributed AP.

MECHANISMS OF AP WITH COVID-19

Direct association between the pancreas and SARS-CoV-2

Coronaviruses constantly circulate in human populations and usually cause mild respiratory symptoms. The gastrointestinal symptoms, although not as common as respiratory symptoms, have been observed in some patients with COVID-19[2]. The SARS-CoV-2 depends on ACE2, a protein that binds to viral spike (S) protein, to enter epithelial cells[5]. SARS-CoV-2 also invades the gastrointestinal tract *via* ACE2



DOI: 10.3748/wjg.v28.i19.2034 **Copyright** ©The Author(s) 2022.

Figure 1 Direct and indirect pathways of pancreatic injury caused by severe acute respiratory syndrome coronavirus-2. Severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) disseminates through the bloodstream mainly to the pancreas. SARS-CoV-2 may be transported to the pancreas *via* the gastrointestinal tract. The pancreas expresses angiotensin converting enzyme-2 (ACE2) and the transmembrane protease serine 2 (TMPRSS2). SARS-CoV-2 binds to ACE2 after the viral spike (S) protein is primed by TMPRSS2 for cell entry. Therefore, SARS-CoV-2 may potentially cause direct pancreatic injury, including acute pancreatitis. However, indirect pancreatic injury may also be caused by systemic inflammatory responses from respiratory failure induced by SARS-CoV-2 infection. Levels of proinflammatory immune mediators associated with pancreatitis, including interleukin (IL)-1β, IL-6, IL-10, interferon-γ, monocyte chemotactic protein-1, and tumor necrosis factor-α are higher in the plasma of patients with coronavirus disease 2019. These mediators may indirectly cause pancreatic injury. An increase in lipase activity triggers lipolysis in the adipose tissues, and enhances levels of serum unsaturated fatty acids (UFA). UFA may cause an increase in levels of proinflammatory immune mediators that lead to systemic inflammation. SARS-CoV-2: Severe acute respiratory syndrome coronavirus-2; ACE2: Angiotensin converting enzyme-2; TMPRSS2: Transmembrane protease serine 2; IL: Interleukin, IFN-γ: Interferon-γ; MCP-1: Monocyte chemotactic protein-1; TNF-α: Tumor necrosis factor-α; UFA: Unsaturated fatty acids.

and leads to development of gastrointestinal symptoms[2,6-9]. The pancreas also expresses ACE2, with mRNA of ACE2 being expressed in the exocrine glands and islets (Figure 1)[13,27]. The transmembrane protease serine 2 (TMPRSS2), co-expressed with ACE2, is known to be required for virus entry[5,28]. TMPRSS2 is associated with proteolytic cleavage of the viral S protein, and mediates membrane insertion of S protein and viral membrane fusion. TMPRSS2 is also expressed in the pancreas, including the pancreatic ductal epithelial cells, acinar cells, and islet cells[29,30]. According to single cell analysis of human pluripotent stem cells, ACE2 and TMPRSS2 are co-expressed in the acinar cells, ductal cells, alpha cells, and beta cells[31]. Furthermore, ACE2 protein is expressed in the islet and exocrine tissue microvasculature and in a subset of pancreatic ducts, whereas TMPRSS2 is restricted to ductal cells[30]. In tissue sections derived from the pancreas of five healthy humans, the expression of ACE2 was detected in endothelial cells, a subpopulation of ductal cells, and endocrine cells, while TMPRSS2 was detected in beta cells. However, both ACE2 and TMPRSS2 were poorly expressed in acinar cells[14]. Pathological evaluation of patients deceased due to COVID-19 identified SARS-CoV-2 positivity in some ductal cells, a few acinar cells, and endocrine cells. Therefore, SARS-CoV-2 was confirmed to infect human endocrine and exocrine cells of the pancreas, *in vivo*[14]. Moreover, infection with SARS-CoV-2 increases expression of C-X-C motif chemokine ligand 12 (CXCL12), nuclear factor kappa β subunit 1 (NFKβ1), and signal transducer and activator of transcription 3 (STAT3) that are known to be associated with pancreatitis-related inflammation[32]. Therefore, SARS-CoV-2 may directly injure the pancreas. SARS-CoV-2 is considered to primarily disseminate *via* the bloodstream, but there are no data on how SARS-CoV-2 is transported to the pancreas[15]. Some patients with COVID-19 develop AP without any respiratory symptoms at onset[33]. However, it is uncertain whether SARS-CoV-2 is transported to the pancreas *via* the gastrointestinal tract, where SARS-CoV-2 is detected in patients with COVID-19[3].

Pancreatic injury caused by SARS-CoV-2-induced cytokine storm

Recent studies reported that the rate of pancreatic enzyme elevation ranged between 12.1% and 17.3% in patients with COVID-19[10,34,35]. Wang *et al*[10] reported the first case series of COVID-19-attributed

Figure 2 The probability of other etiologies of acute pancreatitis in cases with concurrent coronavirus disease 2019 and acute pancreatitis. The potential of other etiologies, including alcoholism, biliary, hypertriglyceridemia, hypercalcemia, drug-induced, acute aggravation on chronic pancreatitis, ischemia/reperfusion, and trauma/anatomy. In children, the potential of genetic and multisystemic inflammatory syndrome in children/pediatric inflammatory multisystem syndrome-induced acute pancreatitis (AP) are also evaluated. Moreover, these causes are regarded as inapplicable etiologies of AP in adults. The probability of AP is disregarded in cases with insufficient information on the etiologies of AP. Some etiologies of AP, such as alcohol, acute aggravation on chronic pancreatitis, and trauma/anatomy are well verified. Furthermore, the etiological workup for infections and hypercalcemia is insufficient. Moreover, some cases of AP may have been caused by drug and biliary disease as it may be difficult to exclude them from the etiology of AP. MIS-C: Multisystemic inflammatory syndrome in children; PIMS: Pediatrics inflammatory multisystem syndrome; AP: Acute pancreatitis.

pancreatic injury and suggested two pathophysiological theories of how pancreatic injury was caused by SARS-CoV-2[10]. First, viral infection causes direct pancreatic injury, as described above. Second, an indirect pancreatic injury is caused by systemic inflammatory responses to respiratory failure or by harmful systemic immune response induced by SARS-CoV-2 infection (Figure 1). Severe COVID-19, including acute respiratory distress syndrome (ARDS) and multiorgan failure is also known to be associated with cytokine storms in the host[36,37]. Levels of proinflammatory immune mediators associated with pancreatitis, including interleukin (IL)-1β, IL-6, IL-10, interferon-γ (IFN-γ), monocyte chemotactic protein-1 (MCP-1), and tumor necrosis factor-α (TNF-α) are higher in the plasma of patients with COVID-19 than those in healthy controls. Furthermore, in infected patients, levels of MCP-1 and TNF-α are significantly higher requiring admission to intensive care units (ICUs) than those in patients not being treated in ICUs[2,38,39]. Another study suggested that levels of IL-6, IL-10, and TNF-α were increased in patients with severe COVID-19 than in those with non-severe COVID-19[40]. Several points remain unclear in the relationship between proinflammatory immune mediators regulated by the viral effect and AP, but serum amylase and lipase elevation in patients with COVID-19 are associated with severity of COVID-19[41-44]. Additionally, AP is also more complicated in cases with severe COVID-19 than in patients with non-severe COVID-19[45]. These facts may support that cytokine storm caused by SARS-CoV-2 induces AP. In contrast, recent research suggests that the release of pancreatic lipase is associated with an increase in levels of unsaturated fatty acids[46]. It is hypothesized that the intestinal release of pancreatic lipase increases lipolysis and plasma levels of unsaturated fatty acids that may damage mitochondria and cause an increase in proinflammatory immune mediators[47]. This increase in cytokines can accelerate disease pathogenesis and lead to severe COVID-19[41,48]. Additional research and analyses are needed to validate this hypothesis, but it is uncertain whether severe COVID-19 causes AP or complicated AP is associated with increased severity of COVID-19 or both. Moreover, severe COVID-19 may complicate AP with other etiologies, including ischemia, hypercalcemia, and drugs[48]. Corticosteroid is known to induce pancreatitis; but, drug-induced AP is observed in < 5% of total AP cases, and corticosteroid accounts for only 2.8% of the drug-induced AP cases[19,49]. Tocilizumab, an antibody for IL-6 indicated for COVID-19, is also reported as an etiology for AP[50,51].

Further, multisystemic inflammatory syndrome in children (MIS-C)/pediatric inflammatory multisystem syndrome (PIMS), novel multisystem inflammatory conditions with some features similar to those of Kawasaki disease, and toxic shock syndrome leading to multiorgan failure and shock cause gastrointestinal symptoms in children[52-54]. Recent case studies also revealed that MIS-C/PIMS may complicate AP[55-58]. An international survey on children with co-occurrence of COVID-19 and AP showed that 2 of 22 patients had MIS-C/PIMS. The mechanisms of MIS-C/PIMS are unclear, but SARS-CoV-2 may cause AP *via* inflammatory immune mediators.

REAL-WORLD DATA ON COVID-19 AND AP

Cohort and case-control studies on COVID-19 and AP

In a prospective, cohort study in the Netherlands, Bulthuis *et al*[59] confirmed COVID-19 in 433 patients with RT-PCR and/or chest CT scores[59]. Eight of the 433 patients met the Revised Atlanta Classification of AP and all were teetotalers. Three of eight patients had other etiologies (two biliary and one post-ERCP); thus, five (1.2%) were suspected with COVID-19-attributed AP. The median age of the five cases was 60 (range, 47–71) years, and 80% were men. Necrotic changes were not observed in the pancreas of the five patients. All five had organ failures, and three (60%) succumbed to non-pancreatitis-related complications of COVID-19 although their AP was not severe. Vatansev *et al*[60] reported a retrospective cohort study comprising 150 patients, of which 29 had AP, and COVID-19 was confirmed with RT-PCR[60]. The mean age of 29 patients was 64.07 years, and 18 were men. In this study, AP was defined as abdominal pain, increased serum amylase and lipase levels (values not disclosed), and contrast-enhanced abdominal CT findings. Patients with some complications and history of habits, including gallstones, hypercalcemia, hypertriglyceridemia, alcohol consumption, and chronic pancreatitis were excluded from the study. All 29 patients had respiratory failures when diagnosed with AP. According to the Revised Atlanta Classification, the severity of AP was mild and moderate in 19 and 10 cases, respectively. The mortality was 8 of 29 patients (28%) died due to respiratory failure and multiple organ failure. These findings suggest a high mortality rate in patients with COVID-19-attributed AP. However, despite a strict investigation of etiologies of AP in the latter study, the number of patients suspected with COVID-19-attributed AP was higher, although a simple comparison was not possible due to differences in COVID-19 diagnostic criteria. Nevertheless, these studies failed to exclude other etiologies of AP, such as drugs, infections except SARS-CoV-2, and ischemia/reperfusion.

Akarsu *et al*[45] investigated the impact of AP on prognosis of COVID-19 in a prospective study[45]. They included 316 patients with COVID-19, of which 40 had complicated AP with various etiologies. AP was defined according to the Revised Atlanta Classification. The study showed a positive correlation between the severity of pneumonia and AP, and indicated that the frequency of AP increased with severity of pneumonia. Moreover, the mortality rate in patients with COVID-19-attributed AP was higher than that in patients with COVID-19 without AP (32.5% *vs* 7.97%, $P < 0.0001$). These studies showed that the incidence of COVID-19-attributed AP was rare, whereas comorbid COVID-19 was severe and had poor prognosis regardless of the severity of AP. This tendency was identified in suspected COVID-19-attributed AP and also AP with other etiologies. Furthermore, as described above, it is possible that severe conditions that needed treatment at ICU, induced AP in patients with COVID-19. Interestingly, Kumar *et al*[33] focused on the difference in the onset of AP in patients with COVID-19 in a retrospective study[33]. Lipase levels were measured and COVID-19 was confirmed with RT-PCR in 985 patients; of these, 17 cases were diagnosed with AP according to the Revised Atlanta Classification. Eight of these 17 presented with typical symptoms of AP on admission. The others developed AP after the onset of COVID-19 pneumonia and treatment with mechanical ventilation for ARDS. The number of patients were less, but the mortality rate in patients who were primarily admitted for AP was higher than that in patients who developed AP later (12.5% *vs* 33.3%). Several different clinical backgrounds should be considered as the reasons, etiologies of AP also seemed to be one of the causes, and it was not clear in the study. Ischemia/reperfusion and drugs were considered as etiologies of AP in patients who developed AP later, as they were treated with mechanical ventilation for ARDS.

There are several studies on AP and SARS-CoV-2 during the COVID-19 pandemic, and some of them focused on differences in the clinical course of AP, with or without comorbid COVID-19. Pandanaboyana *et al*[61] conducted a prospective, international, multicenter, large cohort study on patients with AP and coexistent SARS-CoV-2 infection[61]. The study, called the COVID PAN collaborative study, comprised 1777 patients with AP with various etiologies, of which 149 were SARS-CoV-2 positive. The study had some limitations, such as the diagnostic criteria of AP was uncertain, although the severity of AP was based on the Revised Atlanta Classification. The most important limitation was that the criteria for diagnosis of COVID-19 was RT-PCR for SARS-CoV-2 and also chest CT images and/or clinical course. The authors performed subgroup analysis to compare outcomes between patients negative for SARS-CoV-2 and those positive for SARS-CoV-2 confirmed by RT-PCR. After exclusion of patients from the subgroup analysis due to missing values, 82 of 909 patients with AP were positive for SARS-CoV-2. The 30-d mortality, rate of persistent organ failure, and acute pancreatic fluid collection were higher, and the length of hospital stay was longer in patients positive for SARS-CoV-2 than in those negative for

SARS-CoV-2. Three retrospective cohort studies also reported results similar to those of the COVID PAN collaborative study[62-64]. Thus, concurrent AP and SARS-CoV-2 infection may lead to worse clinical outcomes, such as prolonged hospital stay, requirement of mechanical ventilation, high incidence of multiple organ failure, and high mortality than that with AP-alone. In contrast, two of three studies also revealed that the incidence of idiopathic AP in patients positive for SARS-CoV-2 was higher than that in patients negative for SARS-CoV-2[62,63]. Interestingly, the COVID PAN collaborative study also revealed that[65] SARS-CoV-2 infection may cause AP similar to other infections. Miró *et al*[66] conducted a retrospective case-control study, called the Unusual Manifestations of COVID-19 (UMC-19) study, comprising emergency units in Spain[66]. The diagnostic criteria for AP were according to the Revised Atlanta Classification. The diagnosis of COVID-19 was based on RT-PCR or antigen detection test, and also on chest image findings and clinical conditions. In 62 emergency departments, of the 1463693 patients tested for COVID-19, 74814 cases tested positive, and 54 of them (0.072%) developed AP. Furthermore, the frequency of non-COVID-19 patients with AP was 0.161% (2231/13888879). To compare outcomes between AP and COVID-19 groups, patients were randomly distributed into two groups-162 patients with AP without COVID-19 and 162 patients without AP with COVID-19. Patients with AP with COVID-19 showed severe clinical courses with high mortality than patients without AP with COVID-19. Moreover, there were no differences in the etiologies of AP with or without concurrent SARS-CoV-2 infections. Additionally, the incidence of AP in patients with COVID-19 was lower than that in patients with AP without COVID-19, consistent with results discussed above (0.072% *vs* 0.161%). In contrast, there were no differences between patients with COVID-19 with AP and those with COVID-19 without AP, except for the length of hospitalization. These results suggest that COVID-19 affects the prognosis of patients with concurrent AP and COVID-19 than those with AP-alone. A recent meta-

RT-PCR: Reverse transcription polymerase chain reaction; IgG: Immunoglobulin G; SARS-CoV-2: Severe acute respiratory syndrome coronavirus-2; COVID-19: Coronavirus disease 2019; AUS: Abdominal ultrasonography; CT: Computed tomography; MRI: Magnetic resonance imaging; NA: Not available.

analysis suggested that patients with AP and COVID-19 were frequently men, had idiopathic etiology of AP, a high rate of pancreatic necrosis, higher severity of AP, and serious clinical courses, such as requirement of ICU admission and mechanical ventilation, and high mortality than patients with AP without COVID-19[67]. The prognoses in patients with COVID-19 with AP and those with COVID-19 without AP were different. It remains unclear whether SARS-CoV-2 infections increase AP, as the incidence of AP is rare, but its severity is high when concurrent with COVID-19. An online survey[68] including 22 children with AP and COVID-19 was reported. They were diagnosed as COVID-19 with RT-PCR or detection of SARS-CoV-2 IgG antibodies, while the diagnostic criteria for AP was unavailable. Children aged 10–14 years accounted for 54.5% of all participants in the study. Their clinical courses were serious-60% of them required treatment in the ICU, 45% had multi-organ involvement, 11% had complicated pancreatic necrosis, and 24% developed shock.

The association of AP with SARS-CoV-2 remains unclear, but patients with concurrent AP and COVID-19 show worse prognoses. The fact that some studies reported idiopathic AP during the COVID-19 pandemic indicates existence of COVID-19-attributed AP. Therefore, prospective cohort

studies focused on patients with COVID-19 with idiopathic AP, especially on how to exclude other etiologies of AP, are needed to clarify the COVID-19-attributed AP.

REVIEW OF CASE REPORTS CONTRIBUTED TO CONCURRENT COVID-19 AND AP

Literature search strategy

We identified relevant studies in the literature by searching the PubMed database. The review was restricted to articles published between December 2019 and October 2021, and selected case reports published in English. The search terms were as follows: COVID-19 pancreatitis AND "2019/01/01" (Date-Publication) to "2021/10/31" (Date-Publication) OR SARS-CoV-2 pancreatitis AND "2019/01/01" (Date-Publication) to "2021/10/31" (Date-Publication). We also screened reference lists of selected studies to manually identify relevant studies and include them in the narrative review.

Diagnosis and severity of AP

AP was defined according to diagnostic criteria of the Revised Atlanta Classification[17]. The presence of two out of three features, including abdominal pain consistent with AP, serum lipase activity (or amylase activity) at least three-times greater than the upper normal limit, and characteristic findings of AP on abdominal imaging, was required for the diagnosis of AP.

The severity (mild, moderately severe, and severe) of AP was also defined according to the Revised Atlanta Classification[17].

Diagnosis and severity of COVID-19

The diagnosis of COVID-19 was defined as a positive RT-PCR result or serological test for SARS-CoV-2. The other methods, such as medical history, or chest CT findings, were excluded.

The severity of COVID-19 (mild, moderate, severe, and critical), as classified by the WHO guidelines, was used to stratify patients in the study (https://www.who.int/publications/i/item/clinical-management-of-covid-19). Critical COVID-19 was defined based on the criteria for ARDS, sepsis, septic shock, or other conditions that would normally require life-sustaining therapies, such as mechanical ventilation (invasive or non-invasive) or vasopressor therapy. Severe COVID-19 was defined based on any of the following criteria: (1) Oxygen saturation < 90% on room air; (2) Respiratory rate > 30 breaths/min in adults and children aged > 5 years, ≥ 60 breaths/min in children aged < 2 mo, ≥ 50 in children aged 2–11 mo, and ≥ 40 in children aged 1–5 years; and (3) Signs of severe respiratory distress (accessory muscle use, inability to complete full sentences, and, in children, very severe chest-wall indrawing, grunting, central cyanosis, or presence of any other general danger signs). Non-severe COVID-19 was defined as the absence of any criteria for severe or critical COVID-19.

The data for some cases was insufficient to confirm the severity of COVID-19, but patients who received oxygen therapy were considered to have severe condition. Nevertheless, the indication for oxygen administration varied with institution. However, oxygen saturation < 90%, a criteria for severe COVID-19, was generally used as an indication for oxygen therapy. Additionally, patients who received oxygen therapy generally required hospitalization. Therefore, patients who received oxygen therapy were considered to have severe condition.

Reports included in the review

The literature search of the PubMed database identified 735 studies that met the criteria. We identified eight additional relevant articles in the references of these studies. We excluded 580 non-case study articles, a study in non-English language, three preprints, and an article that could not be reviewed. Of the remaining 158 case studies, 61 were without pancreatic injury or pancreatitis, and thus, were excluded. Moreover, 16 case reports on AP caused by other etiologies, such as biliary disease, alcohol, acute on chronic pancreatitis, hypertriglyceridemia, cytomegalovirus infection, methanol, lymphoma, and vaccination were excluded. In the remaining 81 case studies, six studies comprised eight cases that were not confirmed for AP based on the Revised Atlanta Classification. Two case studies did not include objective data for COVID-19 diagnosis. After removing these studies, 73 studies that included eight case series and 65 case reports were finally assessed in this review. In three of eight case series, one patient without pancreatitis (but with acute cholecystitis), two with negative RT-PCR test, and eight without RT-PCR test or serological IgG for SARS-CoV-2 were excluded. Eighty-two cases of suspected COVID-19-attributed AP were evaluated. Four of 82 cases were RT-PCR negative, but were serological IgG positive for SARS-CoV-2. However, these studies had a limitation that the etiological search for AP was insufficient in almost all cases. Therefore, we classified the potential of other etiologies for AP as-probable, improbable, and uncertain-for each case. The definition of "probable" for each etiology was as follows: Alcoholic AP, consuming ≥ 60 g of ethanol every day before AP onset; biliary AP, gallstones or biliary tract dilation on the abdominal image findings at AP onset (regarded as biliary AP when any serological hepatobiliary test results exceeded more than three-times the upper normal limit unless endoscopic ultrasonography or ERCP excluded any biliary diseases); hypertriglyceridemia, fasting

triglycerides > 1000 mg/dL (11.3 mmol/L) at AP onset[19]; hypercalcemia, serological calcium > 10.4 mg/dL (2.60 mmol/L) at AP onset; drug-induced AP, new medication within one month before AP onset; acute aggravation on chronic pancreatitis, chronic pancreatitis existed, such as pancreatic calcification, before AP onset; infections, positive serological diagnosis for pathogens at AP onset; ischemia/reperfusion, episodes of hypoxic or hypovolemic status, *i.e.*, cardiopulmonary arrest, shock, or mechanical ventilation, before pancreatitis onset; and trauma/anatomy, history of abdominal trauma or upper abdominal surgery with reconstruction of the gastrointestinal tract. In children, genetic AP was defined as existence of a family history of AP, *i.e.*, ≥ 2 first-degree relatives (or ≥ 3 s-degree relatives) to have unexplained recurrent acute or chronic pancreatitis in ≥ 2 generations[69]. Moreover, in cases aged 0–19 years, MIS-C/PIMS-induced AP was also evaluated. The MIS-C/PIMS was defined according to the WHO definition (https://www.who.int/news-room/commentaries/detail/multisystem-inflammatory-syndrome-in-children-and-adolescents-with-covid-19). In case of insufficient etiological information, the probability of AP was regarded as uncertain.

Reports results

The characteristics of patients with COVID-19-attributed AP are shown in Tables 1–3. The probability of other etiologies for AP in included cases were as follows-alcohol: 0 probable, 64 improbable, and 18 uncertain; biliary AP: 8, 59, and 15; hypertriglyceridemia: 1, 54, and 27; hypercalcemia: 0, 40, and 42; drug-induced AP: 17, 58, and 17; acute aggravation on chronic pancreatitis: 1, 81, and 0; infections: 0, 7, and 75; ischemia/reperfusion: 10, 68, and 4; trauma/anatomy: 1, 79, and 2; genetic AP: 0, 7, and 11; and MIS-C/PIMS: 5, 10, and 3, respectively (Table 3 and Figure 2).

The median age at onset of COVID-19-attributed AP was 42.0 (range, 6–87) years. The men-to-women ratio of COVID-19-attributed AP was 37:44. The patient comorbidities were: Hypertension (22 cases), diabetes (15 cases), heart disease (3 cases), respiratory disease (4 cases), obesity (16 cases), renal dysfunction (5 cases), dyslipidemia (4 cases), hyper/hypothyroidism (4 cases), gastroesophageal reflux disease (2 cases), thrombophilia (1 case), thrombosis (1 case), osteoporosis (1 case), anxiety (2 cases), and malignant disease (2 cases). There were 13 patients with histories of abdominal surgeries, including cholecystectomy, hysterectomy, cesarean section, appendectomy, Whipple procedure, small bowel resection, and renal transplantation. Two pregnant women were also included. Almost all patients had no history of alcohol and cigarette abuse. Abdominal pain was the most frequent symptom (91.5%, 75/82), followed by fever (59.8%, 49/78), vomiting (58.5%, 48/79), nausea (47.6%, 39/66), and cough (34.1%, 28/78). None of the patients had any symptoms. The median levels of white blood cells, platelets, D-Dimer, amylase, lipase, lactate dehydrogenase, and C-reactive protein were 13100/μL (range, 3400–230000), 235500/μL (range, 52000–502000), 4.9 μg/mL (range, 0.3–17.7), 635 U/L (range, 47–4530), 895.5 U/L (range, 35.6–11920.0), 366 U/L (range, 170–3553), and 8.5 mg/dL (range, 0.3–59.7), respectively.

The study included 43 patients (55.8%, 43/77) with severe or critical COVID-19. Oxygen therapy for COVID-19 was required in 42 patients (51.2%, 42/69); of those, 19 were treated with mechanical ventilation. Seventeen patients received antiviral therapy with lopinavir/ritonavir, favipiravir, umifenovir, or remdesivir. One of them was treated with both lopinavir/ritonavir and favipiravir. Moreover, two patients received hydroxychloroquine, an antimalarial drug, for treatment of COVID-19. Two cases were treated with tocilizumab, an anti-IL-6 monoclonal antibody, for COVID-19. Corticosteroids were also administered for the treatment of COVID-19 in 21 patients (39.6%, 21/53).

Abdominal images were evaluated in 75 patients, except in two patients as the pancreases could not be visualized *via* abdominal ultrasonography. Two other patients underwent abdominal CT or magnetic resonance imaging, and the findings were consistent with those of pancreatitis-alone, without details. Of the remaining 71 patients, 48 showed peripancreatic inflammatory changes and 33 had peripancreatic fluid collections. Pancreatic enlargement occurred in 42 patients. Pancreatic ischemic changes, such as decreased contrast enhancement in pancreatic parenchyma on abdominal computed tomography was observed in 12 patients (16.9%, 12/71). However, no change was observed in the abdominal image findings in six patients.

In this review, 28 patients were classified as having severe AP (36.8%, 28/76). Almost all patients with AP received conservative therapy, except for four cases. These four patients underwent invasive treatment; of which, one patient with AP and gastric necrosis underwent drainage of the peripancreatic necrotic collections and total gastrectomy, but failed to recover. The other patient received gastrocolic ligament, necrotic debridement, and drainage placement for acute hemorrhagic necrotizing pancreatitis, and died two days after surgery.

The median period of hospitalization for recovering from COVID-19-attributed AP was 8.0 d (range, 2–76). Ten patients (12.7%, 10/79) died due to critical COVID-19 (median hospitalization, 7.0 d; range, 2–22 d).

In summary, patients suspected with COVID-19-attributed AP were relatively young (median age, 42 years), 36.8% of them had severe conditions, and had a high mortality rate (12.7%) similar to that reported in cohort studies and meta-analyses. However, it cannot be ignored that many AP cases reported in these studies may have occurred due to etiologies other than SARS-CoV-2.

CONCLUSION

It remains controversial whether SARS-CoV-2 infections increase AP, but some basic and pathological approaches suggest mechanisms of direct and indirect involvement of the pancreas caused by SARS-CoV-2. Moreover, there are several clinical data to support existence of COVID-19-attributed AP. First, the incidence of idiopathic AP in patients positive for SARS-CoV-2 is higher than that in patients negative for SARS-CoV-2 in some cohorts with concurrent COVID-19 and AP. Second, SARS-CoV-2 infects pancreatic exocrine and endocrine cells as *per* the pathological evaluation of patients deceased due to COVID-19. Moreover, some clinical features of COVID-19-attributed AP, including various etiologies of AP, are revealed, such as a high rate of pancreatic necrosis, higher severity of AP, and serious clinical courses. However, clinical features of COVID-19-attributed AP remain uncertain. A sufficient investigation on etiologies of AP would improve understanding of the clinical features of COVID-19-attributed AP. High-quality clinical studies and case reports that specify the method for differential diagnoses of the other etiologies of AP, including alcohol, biliary, hypertriglyceridemia, hypercalcemia, drugs, ischemia/reperfusion, trauma, infections, and genetic associations need to be evaluated. The present review of case studies suggests criteria to classify the possibility of other etiologies for AP. The criteria may not be appropriate, but the review highlights the insufficient etiological workup of AP, especially for other infections and hypercalcemia. Moreover, in some cases, it is difficult to completely exclude drug-induced and biliary AP from the etiology of AP. These details may be informative for designing future clinical studies.

Several unsolved questions remain, such as the risk factors of AP in patients with COVID-19. It is also uncertain why some patients with COVID-19-attributed AP become severe while others do not. AP may be a rare complication of COVID-19, but some cases develop severe AP attributed to SARS-CoV-2 infection. Thus, the potential of COVID-19-attributed AP should be thoroughly investigated.

ACKNOWLEDGEMENTS

We thank our colleagues in the Division of Gastroenterology and Nephrology, Department of Multidisciplinary Internal Medicine, Faculty of Medicine, Tottori University (Tottori, Japan) for their support.

Abstract

The anatomical structure of the pancreaticoduodenal region is complex and closely related to the surrounding vessels. A variant of the hepatic artery, which is not a rare finding during pancreatic surgery, is prone to intraoperative injury. Inadvertent injury to the hepatic artery may affect liver perfusion, resulting in necrosis, liver abscess, and even liver failure. The preoperative identification of hepatic artery variations, detailed planning of the surgical approach, careful intraoperative dissection, and proper management of the damaged artery are important for preventing hepatic hypoperfusion. Nevertheless, despite the potential risks, planned artery resection has become acceptable in carefully selected patients. Arterial reconstruction is sometimes essential to prevent postoperative ischemic complications and can be performed using various methods. The complexity of procedures such as pancreatectomy with en bloc celiac axis resection may be mitigated by the presence of an aberrant right hepatic artery or a common hepatic artery originating from the superior mesenteric artery. Here, we comprehensively reviewed the anatomical basis of hepatic artery variation, its incidence, and its effect on the surgical and oncological outcomes after pancreatic resection. In addition, we provide recommendations for the prevention and management of hepatic artery injury and liver hypoperfusion. Overall, the hepatic artery variant may not worsen surgical and oncological outcomes if it is accurately identified pre-operatively and appropriately managed intraoperatively.

Core Tip: Variations in hepatic artery anatomy are not rare during pancreatic surgery and have a significant impact on planning and performance of the procedure. Inadvertent intraoperative injury to hepatic artery may affect liver perfusion and result in ischemic complications. Detailed knowledge and awareness of its anatomical variants are critical, and thorough pre- and intraoperative planning is important to prevent hepatic hypoperfusion. This article comprehensively reviews the hepatic artery anatomy and variations, highlights its impact on surgical and oncological outcomes after pancreatic resection, and discusses prevention and management of hepatic artery injury and liver hypoperfusion.

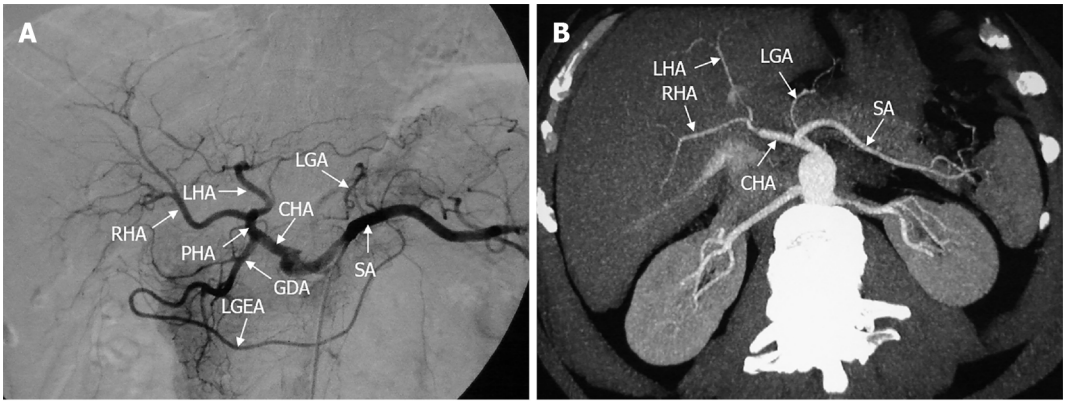
INTRODUCTION

The mortality rate of pancreatectomy has decreased in recent years; however, several complex pancreatic resections such as the pancreaticoduodenectomy (PD), total pancreatectomy (TP), and modified Appleby procedure have high complication rates[1,2]. The anatomy of the pancreaticoduodenal region is complex and closely related to the surrounding blood vessels. Therefore, this region is vulnerable to injury during surgery. Moreover, the presence of vascular anatomical variants makes PD more challenging. Aberrant hepatic artery (AHA) is not rare in patients undergoing PD, with an incidence ranging from 15.1% to 24.8%[3-6]. This variant increases the risk of iatrogenic vascular injury and the incidence of postoperative hepatobiliary ischemic events, inducing complications such as bilioenteric anastomotic leakage and liver abscess[5,7,8]. Therefore, a thorough understanding of the anatomy of the hepatic artery is essential for safer pancreatic resection[9]. Herein, we provide a comprehensive review of the clinical significance of hepatic artery variants in pancreatic surgery.

LITERATURE SEARCH

A thorough search was performed in the PubMed database for relevant studies on hepatic artery variants and pancreatic resection. The search terms used were "aberrant" or "variant" or "anomaly" AND "hepatic artery" AND "pancreaticoduodenectomy" or "pancreatectomy". All available studies published in English or Chinese between January 2000 and November 2021 (131 articles) were screened.



EMBRYOLOGY

It is important to understand the embryology of the hepatic artery to determine the origin of these variants. During embryogenesis, four visceral roots, known as ventral segmental arteries, originate from the dorsal aorta[10]. These ventral vessels are interconnected by longitudinal anastomoses[11,12]. The second and third roots and their connections, usually disappear during embryonic development. Thereafter, the celiac artery (CA) develops from the junction of the first three vessels and forms the left gastric artery (LGA), splenic artery, and common hepatic artery (CHA). The fourth trunk becomes the superior mesenteric artery (SMA). As the embryo grows, the channel between the roots of the CA and SMA fades away, resulting in anatomic division of the CA from the SMA[13]. This process can lead to several abnormalities in the CA and SMA. The associated changes are thought to depend on the degree of degeneration and longitudinal connectivity of primitive splanchnic vessels[10,11,13,14].

In addition, the hepatobiliary-pancreaticoduodenal region has the largest number of organs and the densest vascular branches. It is located at the junction of the foregut and midgut and is bound by the duodenal papilla. The vessels in this region frequently intersect between the CA and SMA, resulting in vascular variations. The three branches of the CA, from anterior to posterior are the LGA, splenic artery, and CHA. The CHA and its branches, which primarily maintain the blood supply between the foregut and midgut, are the most prone to variation.

ANATOMY

The normal anatomy of the hepatic artery refers to the CHA originating from the CA and crossing from

Figure 1 Classic hepatic arterial anatomy. A: Digital subtraction angiography showed normal anatomy of the hepatic arteries; B: Axial maximum intensity projection image showed normal anatomy of the hepatic arteries. CHA: Common hepatic artery; GDA: Gastroduodenal artery; LGA: Left gastric artery; LGEA: Left gastroepiploic artery; LHA: Left hepatic artery; PHA: Proper hepatic artery; RHA: Right hepatic artery; SA: Splenic artery.

the retroperitoneum toward the liver (Figure 1). This gives rise to a branch at the superior margin of the pancreatic head called the gastroduodenal artery (GDA). In this process, the CHA passes in front of the portal vein (PV), which is also known as the preportal route. Subsequently, it gives rise to the right gastric artery (RGA) and becomes the proper hepatic artery (PHA). Thereafter, it bifurcates into the left and right hepatic arteries (LHA/RHA). However, this so-called normal anatomy of the hepatic vessels is observed in only 55%-75.5% of individuals[15].

A series of terms are used to describe hepatic artery anomalies: “Aberrant”, “anomalous”, “accessory”, and “replaced”[16], and the definitions of these terms vary between studies. An aberrant or anomalous hepatic artery originates outside the typical route. It includes “accessory” and “replaced” hepatic arteries[17]. The term "replaced" RHA (rRHA) or LHA (rLHA) is used when the normal artery is absent, and a replaced artery arises from another artery and supplies blood to the corresponding hepatic lobe. The term "accessory" RHA (aRHA) or LHA (aLHA) is used when an additional artery originating from another source and a standard artery is present[16-18].

TYPES AND INCIDENCE

In terms of the anatomical classification of hepatic arteries, the Michels and Hiatt systems are well-established (Figure 2)[19,20]. The Michels system[20] is more extensive, classifying hepatic arteries into 10 types based on their origins. Hiatt *et al*[19] simplified the Michels system into six types. In addition, Garg *et al*[21] advocated a new classification that highlighted the distal branches of the hepatic arteries. However, despite these classifications of the hepatic arteries, several infrequent and unclassified hepatic artery variations have been detected in clinical practice. For example, an aberrant RHA may arise directly from the CA (Figure 3), which is an important anomaly to take note of during hepato-pancreato-biliary surgery because of the high risk of inadvertent injury[22]. More rarely, the origins of the CHA, splenic artery, and SMA mix seamlessly to form a hepato-spleno-mesenteric trunk (Figure 4), with a prevalence ranging from 0.67% to 0.90%[23,24]. The presence of a hepato-spleno-mesenteric trunk implies that only one trunk is responsible for the majority of the blood supply to abdominal organs, complicating operations around it[12].

AHAs can be categorized into three types based on their origin: Type I, an AHA originating from the SMA; type II, an AHA originating from the LGA; and type III, an AHA originating from other arteries such as the GDA, abdominal aorta, and right renal artery. Numerous studies[3,5,7,25] have reported that the most frequently encountered AHA type during PD is type I, with an aberrant RHA from the SMA accounting for most of the cases. This anomalous hepatic artery is of great concern because it can be close to or cross the pancreatic head, and lie posterior to the common bile duct[26]. Most frequently, the aberrant RHA runs from behind the pancreatic head to the posterior and lateral sides of the main PV, before reaching the liver. However, despite the extremely low frequency of intrapancreatic routes, PD becomes complicated when an aberrant RHA or CHA is found traversing the pancreatic parenchyma[27]. Therefore, variants involving the RHA or CHA should be assessed carefully when performing PD[3-5,7,9,17,25,26,28,29], although the incidence may not be high (Table 1)[30-34]. Unfortunately, the actual incidence of AHA may be underestimated because of the limited accuracy of the current preoperative diagnostic methods. Although a preoperative diagnosis of AHA may be negative, its presence should be suspected intraoperatively.

COLLATERAL PATHWAYS

In general, the blood flow in the hepatic artery is predominantly from the CA. However, when the hepatic artery is involved in the tumor, retrograde flow from the SMA may develop (Figure 5). Similarly, celiac artery stenosis (CAS), which is not rare in patients undergoing PD (2%-11%)[35-37], may alter the hemodynamic profile of the hepatic artery. Retrograde blood flow in the CHA is a strong predictor of CAS[38,39]. In patients with CAS, the arterial blood supply to the upper abdominal organs is generally maintained by a steadily growing system of collaterals. Compensatory circulation between the CA and SMA is important in patients with hepatic artery stenosis or CAS because PD may disrupt these collaterals. Four possible collaterals have been reported: The pancreaticoduodenal arcade (key collateral supplying the liver and stomach), the dorsal pancreatic artery, the arc of Bühler, and the connection of the RHA and SMA[35,40-44], as shown in Figure 6. It is noteworthy that the pancreaticoduodenal and right gastroepiploic arcades are vital to the gastric and hepatic blood supply following pancreatectomy with en bloc celiac axis resection[45,46].

However, few studies have focused on collateral circulation in patients diagnosed with both CAS and hepatic artery variants. In patients with an aberrant RHA arising from the SMA, intrahepatic collaterals may develop between RHA and LHA. In cases of PHA or CHA originating from the SMA, the peribiliary vascular plexus in the hepatoduodenal ligament, which connects the central hepatic artery and GDA, is subsequently enlarged. These patients have a compensatory circulation that interconnects the LHA and LGA, and the RGA and LGA[40,43]. During PD, most of these collaterals are sacrificed, inducing an ischemic threat to the midgut viscera, especially to the liver and common bile duct. Thus, the presence of CAS is an important finding during PD, regardless of external compression, which may require preoperative endovascular stenting or intraoperative revascularization[35,36].

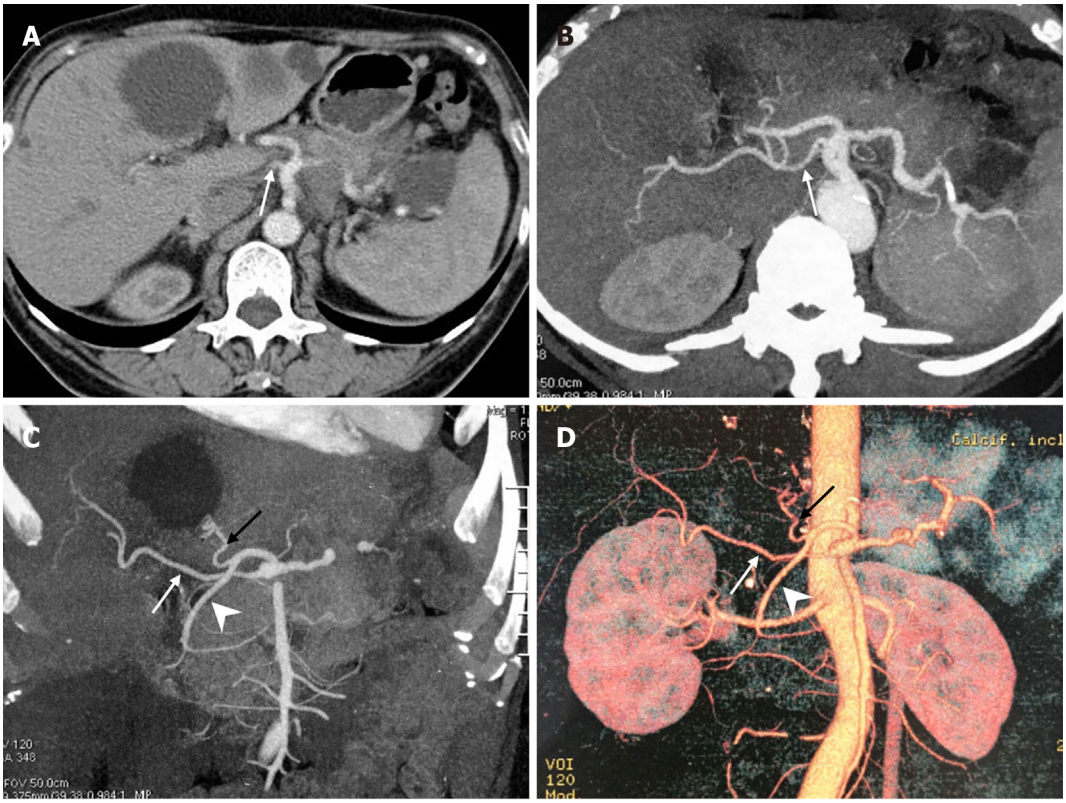

Figure 2 The Michels and Hiatt classifications of hepatic artery. [1]Michels type VIII includes replaced right hepatic artery (rRHA) + accessory left hepatic artery (aLHA) or replaced left hepatic artery (rLHA) + accessory right hepatic artery (aRHA). The common hepatic artery (CHA) from aorta is classified as Hiatt type VI. LGA: Left gastric artery; SMA: Superior mesenteric artery; rRHA: Replaced right hepatic artery; aLHA: Accessory left hepatic artery; rLHA: Replaced left hepatic artery; CHA: Common hepatic artery; aRHA: Accessory right hepatic artery.

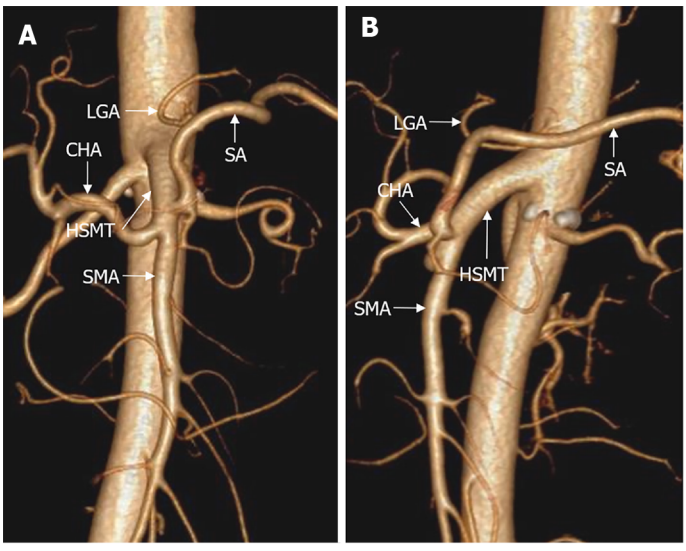
PREOPERATIVE DIAGNOSIS

The importance of preoperative identification of AHA cannot be overemphasized. Although digital subtraction angiography (DSA) is considered the gold standard for the assessment of visceral anatomy and variation, its use is limited because of its invasive nature, minor but non-negligible risk of complications, and high cost[47]. Multidetector computed tomography angiography (MDCTA) is one of the most widely used modalities for diagnosis and identification of AHA and has been shown to reduce the incidence of iatrogenic injuries and postoperative complications[48-51]. Furthermore, magnetic resonance angiography (MRA) provides diagnostic image quality in 72% of the hepatic and visceral arteries and enables the delineation of hepatic arterial anatomical features with high accuracy[47]. Significant advances in computed tomography angiography (CTA) and MRA have led to the marginalization of DSA[52]. However, considering the relatively high human and financial resources required to visualize the vasculature, it is impossible to subject every patient to CTA or MRA. Yang *et al*[32] showed that multidetector computed tomography (MDCT) without arterial reconstruction aided in the evaluation of aberrant RHA for preoperative planning of pancreatic surgery. Therefore, conventional MDCT combined with meticulous analysis may be helpful for preoperative detection of AHA.



SURGICAL AND ONCOLOGICAL OUTCOMES

Studies examining the effect of AHA on the perioperative outcomes of either open PD (OPD) or

minimally invasive PD (MIPD) have reported negative outcomes (Table 2)[3-5,7,17,25,26,30,31,33,34,53]. Although duration of surgery can be prolonged[3,17,26], the AHA does not jeopardize surgical outcomes of PD[5,7,31,33]. Nevertheless, the presence of AHA may predispose patients to intraoperative injury, increasing the risk of hepatic hypoperfusion and ultimately leading to necrosis, liver abscess, and even liver failure. Nearly 10% of patients undergoing PD have a vascular injury, with the incidence of hepatic artery injury ranging from 0.5% to 1.7%[54-56]. Although the PV supply, extrahepatic

collaterals, and interlobular communicating arteries may compensate to some extent for hepatic hypoperfusion, the incidence of catastrophic complications in the postoperative period is approximately 20%[34,57,58]. Liver ischemia after pancreatic resection is classified into four types: Hypoperfusion without major hepatic vessel occlusion, arterial occlusion, PV occlusion, and PV plus arterial occlusion [59]. This classification helps surgeons identify the degree of liver ischemia and escalate treatment appropriately. In addition to the liver, the biliary tree may be involved in an AHA injury. The extrahepatic biliary system receives its blood supply from the retroduodenal artery, RHA, and GDA[26, 60]. After ligation of the GDA in PD, the remaining bile duct relies mainly on the RHA for its blood

Figure 5 Retrograde flow from the superior mesenteric artery due to tumor involvement of the hepatic artery. A: Computed tomography scan showed a low-density mass in the pancreatic head with common hepatic artery involvement (arrow); B: Selective celiacography showed involvement of the hepatic artery from the origin of the celiac artery to the bifurcation of the left and right hepatic arteries, as well as involvement of the gastroduodenal artery. Additionally, an accessory right hepatic artery was seen originating from the gastroduodenal artery; C: Superior mesenteric angiography showed retrograde flow to the liver from the superior mesenteric artery *via* the pancreaticoduodenal arcade.

supply. Therefore, bile leakage may occur because of possible ischemia of the bilioenteric anastomosis [6].

Ischemic complications of PD can occur in patients with hepatic artery injury or CAS. Even in the absence of arterial stenosis or intraoperative arterial trauma, calcified plaques or atherosclerosis in the CHA can cause fatal complications[37]. Compression by a CHA pseudoaneurysm due to postoperative pancreatic fistula may cause ischemia of the abdominal organs, sepsis, and multiorgan dysfunction syndrome, which can be life threatening[61].

Most studies reported no significant differences in R0 resection rates between patients with and without AHA. Furthermore, the median overall survival and number of lymph nodes harvested did not differ significantly between the two groups. Based on these results, the presence of AHA does not seem to affect the radical outcome of pancreatic cancer surgery. The effects of AHA on oncological outcomes in pancreatic cancer, such as R0 resection, median overall survival, and number of lymph nodes harvested, are listed in Table 3[3,4,7,17,25,26,28-31,34,62].

PREVENTION AND MANAGEMENT OF INTRAOPERATIVE AHA INJURY

Among the types of AHA, aberrant RHA or CHA from the SMA may increase the difficulty of PD; therefore, these should be of greater concern during surgery (Figure 7). Even when using radiological techniques with high sensitivity, an AHA may still be missed preoperatively. Hence, the anatomy of the hepatic artery should be determined by performing extended kocherization before dissection. There are various approaches to manage anomalous vessels. Of these, traction away from the ongoing surgical site and revascularization are of paramount importance[17]. Artery-first approaches, such as the posterior and inferior infracolic "SMA first" approach, can be used to identify AHAs[63]. The direct tactile feedback of arterial pulsation is a unique advantage of OPD. For example, normal PHA pulsation can be felt intraoperatively at the left margin of the hepatoduodenal ligament. If an anomaly in this normal condition is detected, surgeons should assess whether an AHA is present. Arterial pulsation behind the pancreatic head or PV may be an aberrant RHA or CHA[64]. The AHA originating from the LGA is vulnerable to injury during partial gastrectomy and may be palpated at the gastrohepatic ligament[18].

Therefore, during distal gastrectomy in PD, the LGA branch should be ligated away from the origin of the aberrant artery or close to the gastric wall[65].

In addition, some specific AHAs may have embarrassing pitfalls. One such AHA is the aberrant RHA arising from the GDA, which has been reported in 3.5% of patients undergoing PD[66]. This variant sets an obstacle to achieving R0 resection because its origin is close to the pancreatic head. It can be accidentally ligated if the GDA is divided close to the CHA. In this case, a clamping test should be performed before transection of the GDA, followed by palpation of the hepatic artery[18]. Another pitfall is the aberrant retropancreatic RHA originating from the SMA. To avoid intraoperative injury to this artery, dissection of the hepatoduodenal ligament above the pancreas is essential after detecting the aberrant RHA by palpation or intraoperative ultrasonography. Skeletonization of the common bile duct may prevent it from being mistakenly ligated[67]. Rarely, an rRHA from the SMA can give rise to GDA after coursing to the right in front of the superior mesenteric vein (Figure 8). This type of aberrant RHA is of real concern because it is vulnerable to pancreatic neck dissection. It can be protected during OPD by accurate preoperative identification, intraoperative tactile feedback of arterial pulsation, and Doppler ultrasonography.

In recent years, with the rapid development of surgical techniques, MIPD has been shown to be as safe as OPD[68]. However, the absence of tactile feedback from arterial pulsation during MIPD complicates the entire procedure, particularly in response to AHA[31]. Can *et al*[69] provided a series of tips to avoid AHA injury during laparoscopic PD (LPD), including the use of the hepatoduodenal ligament as a reliable marker to detect AHA during the dissection of the uncinate process, moderate retraction, and skillful differentiation of the AHA from arterial-like lymphatics and elongated lymph nodes. In terms of the surgical approach, the posterior approach is most often used for LPD[3,65]. This approach can be applied to all patients, regardless of the presence of AHA, because it adheres to the principle of "artery first"[3,65].

Although the feasibility and safety of robotic PD (RPD) have been confirmed[70], a major limitation is the lack of tactile feedback. It has been suggested that aberrant RHA should be suspected when the tissue thickness on the right side of the PV increases or the CHA becomes thin[33]. In such cases, careful dissection is required to prevent vascular injury. During RPD, artery injury can be avoided by strict adherence to the no-touch technique[31]. An additional robotic arm provides sufficient tension to the surrounding tissue to ensure safe dissection. Combining a low-energy robotic hook with a bipolar

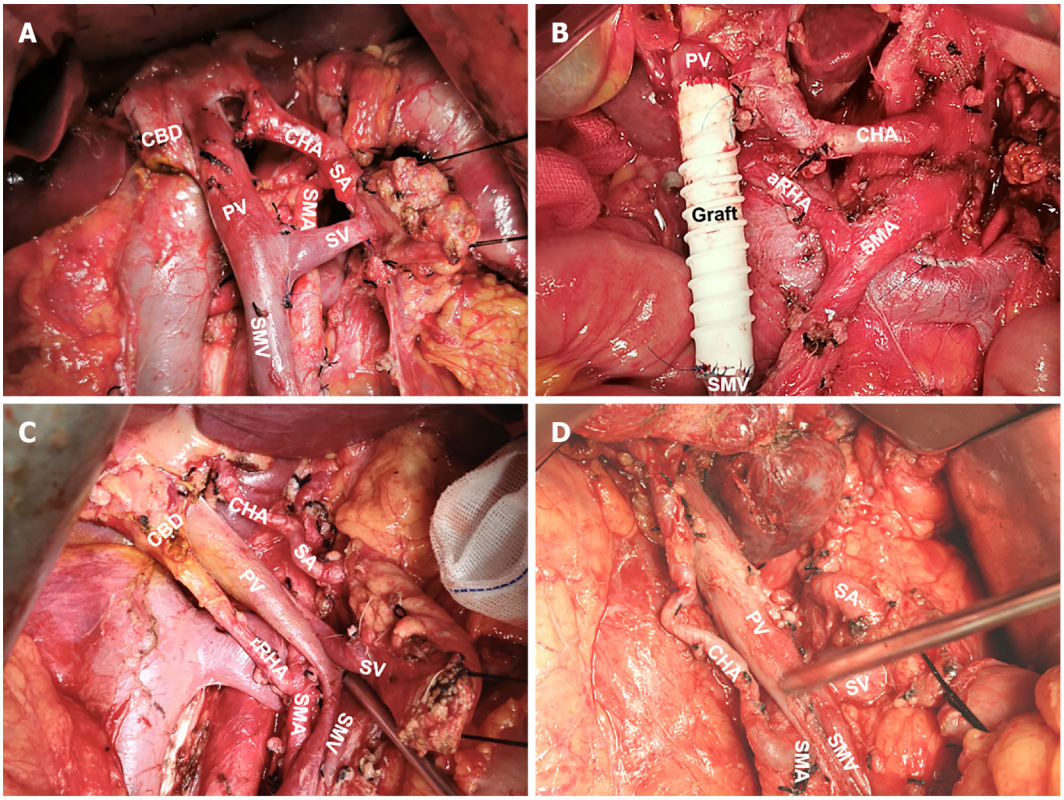
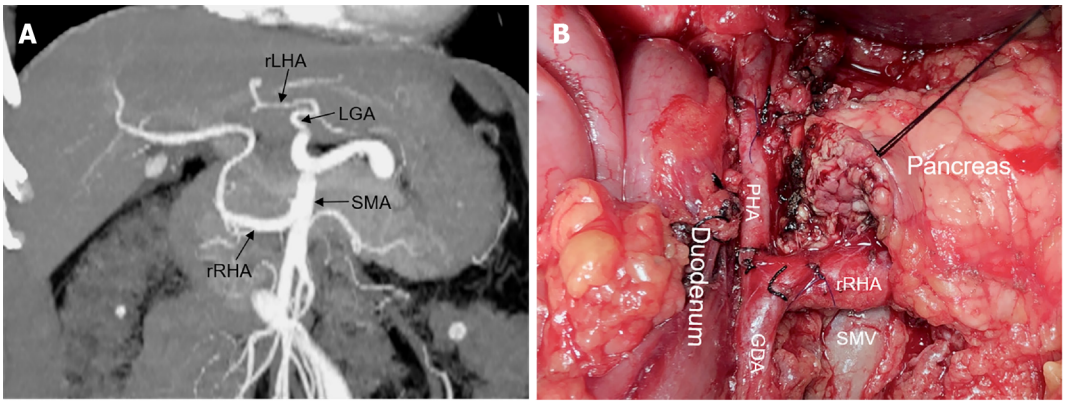
Figure 6 Collateral pathways due to celiac axis stenosis. A: Computed tomography scan showed a mass in the pancreatic head with dilated biliary-pancreatic duct, and celiac axis stenosis (CAS, arrow); B: Sagittal maximum intensity projection image demonstrated CAS (arrow); C: Selective celiac angiographic examination revealed the left gastric artery and splenic artery, with no hepatic arteries depicted, which is compatible with occlusion of the common hepatic artery; D: Superior mesenteric arteriogram demonstrated retrograde filling of the celiac branches *via* the pancreaticoduodenal arcades (arrow) by way of the gastroduodenal artery and anomalous blood vessels traversing the pancreas (arrowhead).



grabber promises effective handling of tiny branches of the uncinate process with minimal heat dissipation to anomalous vessels[31].

Although many studies have analyzed the clinical outcomes of AHA in pancreatic resection, few studies have reported the management of unexpected intraoperative AHA injuries. The early detection of accidental artery injuries is crucial. Remedial reconstruction of a damaged hepatic artery is considered a reliable option[54]. No significant difference in surgical outcomes has been reported between intentional and unintentional revascularization[55]. Ligation of inadvertently injured hepatic arteries may be attempted in view of the presence of collaterals, such as the subcostal arteries and the right inferior phrenic artery. This is like a planned resection of tumor-involved AHA without revascularization[55]. In brief, timely identification and proper management of an inadvertently damaged AHA are important to prevent hepatic hypoperfusion.

MANAGEMENT OF TUMOR INVOLVEMENT OF THE AHA



Intraoperative preservation of the AHA is an ideal surgical option, provided that radical surgical treatment is guaranteed[18]. Vascular invasion is common in patients with pancreatic cancer. In cases where tumor involvement of the AHA is suspected preoperatively, neoadjuvant therapy is recommended to allow translational surgery[71-73]. Unfortunately, even with neoadjuvant chemoradiation, it is sometimes still difficult to preserve the AHA involved in R0 resection[74,75]. However, despite the potential risks, planned artery resection has become acceptable in carefully selected patients [76,77]. If the cancer is located less than 1 cm from the origin of the AHA or if the AHA penetrates through the tumor, it should be resected to achieve R0 resection[7]. After clamping the AHA, intraoperative Doppler ultrasound can be used to assess the hepatic blood supply and determine the requirement for arterial reconstruction[7,78]. Revascularization may not be mandatory in some cases; for example, when an accessory hepatic artery is present, the diameter of the involved branch is thin, and adequate hepatic blood supply is confirmed after dissection[26,55,77].

However, hepatic artery reconstruction is sometimes necessary to prevent postoperative liver ischemia[79]. If the two stumps of the artery are less than 1-2 cm apart, most of them are amenable to

Figure 8 A rare replaced right hepatic artery from the superior mesenteric artery susceptible to injury during pancreaticoduodenectomy. A: Coronal maximum intensity projection image showed Michels type IV hepatic artery variant; B. Intraoperative image showed that replaced right hepatic artery (rRHA) originated from the superior mesenteric artery and traveled to the right behind the inferior margin of the pancreatic neck *via* the superior mesenteric vein anteriorly and gave rise to the gastroduodenal artery and proper hepatic artery. LGA: Left gastric artery; rLHA: Replaced left hepatic artery; SMA: Superior mesenteric artery; GDA: Gastroduodenal artery; SMV: Superior mesenteric vein; PHA: Proper hepatic artery; rRHA: Replaced right hepatic artery.

primary end-to-end anastomosis[18,72,80]. Tension-free anastomosis is necessary because of the potential risk of pseudoaneurysms[18]. If the distance between the stumps is too long to achieve primary anastomosis, transposition or graft interposition may be an option[18,81]. When compared, transposition may be more effective (Figure 9). In addition, the middle colonic, splenic, and dorsal pancreatic arteries are alternative options for anastomosis[81-83]. However, graft interposition is sometimes unavoidable and can be achieved using a saphenous vein or prosthetic graft[80]. In summary, various methods of hepatic artery reconstruction have been reliably performed, as illustrated by Figure 10[71,72,80-83].

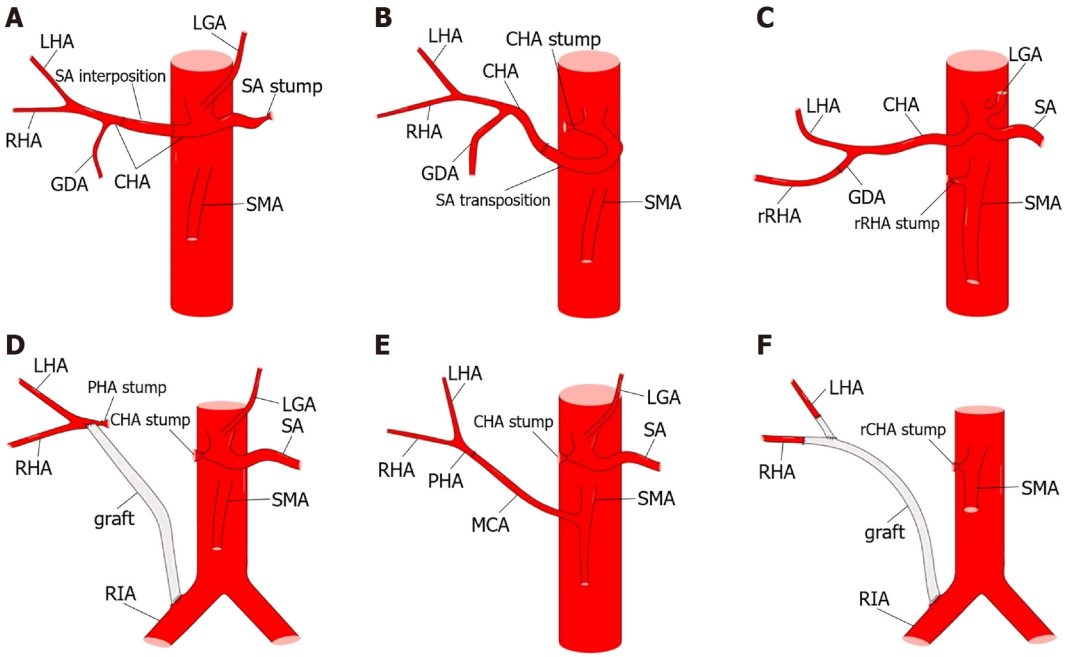

Figure 9 The replaced right hepatic artery reconstruction with gastroduodenal artery remnant during pancreaticoduodenectomy. A and B: Coronal and axial maximum intensity projection images showed the replaced right hepatic artery (rRHA, arrow) originated from the superior mesenteric artery and penetrated through the pancreatic head with tumor invasion resulting in significant stenosis (arrowhead); C: Intraoperative image showed a long length of the gastroduodenal artery (GDA) remnant (black arrow) was available for direct end-to-end anastomosis with the rRHA (white arrow); D: The rRHA-GDA anastomosis is complete.

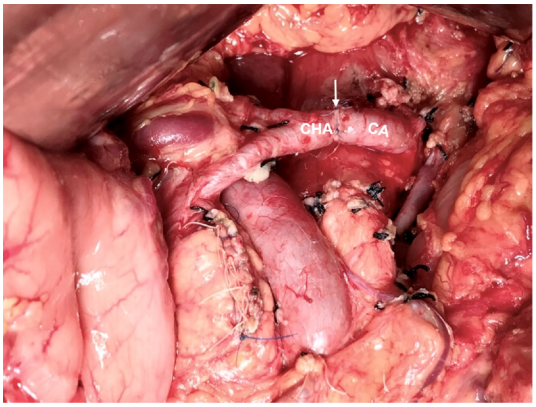
Preoperative arterial embolization is an alternative approach to the prevention of liver ischemia after AHA resection[18,84,85]. Theoretically, preoperative coil embolization may lead to insufficient perfusion of the CHA, causing hepatic artery thrombosis. Migration of embolic material leading to liver ischemia, necrosis, and the risk of bleeding are other possible complications[86]. However, preoperative embolization can improve blood supply to the hepatobiliary system and stomach while providing valuable information to decide whether a partial hepatectomy is required[87]. In short, despite the invasiveness of this approach, it can lead to the prevention of postoperative liver ischemia without causing major complications[18,85].

AHA IN PANCREATECTOMY WITH CELIAC AXIS RESECTION



With the increased use of neoadjuvant chemoradiation, pancreatectomy with en bloc celiac axis resection (CAR) has become more commonly used to treat locally advanced pancreatic cancer[46,88]. Distal pancreatectomy with CAR (DP-CAR), also known as the modified Appleby procedure, is widely used due to its acceptable surgical and oncological outcomes[89-91]. Nevertheless, maintenance of visceral blood supply following DP-CAR, especially in the liver and stomach, remains a hot topic. Preoperative embolization has been recommended because it may reduce the incidence of ischemic complications by promoting associated collaterals[87,91,92]. Nevertheless, this may be avoided when the rRHA or CHA originates from the SMA. However, its application has several limitations, including failure to reduce the incidence of postoperative ischemic complications[84,93], coil migration and secondary ischemia[46,90,94], and complicating revascularization[95].

Hepatic artery reconstruction is an option to prevent postoperative ischemic complications and can be performed by anastomosis with the CA stump[71,86,96], splenic artery interposition[88], abdominal aorta[94,97], middle colonic artery[45], and iliac artery[79,98], as shown in Figures 11 and 12. However, the need for hepatic artery reconstruction remains a controversial issue. Liver perfusion can be intraoperatively assessed by palpation, Doppler ultrasonography, and indocyanine green fluorescence angiography[46,84,90,91,94,99]. Mittal *et al*[86] proposed a novel method to objectively assess liver blood supply by measuring CHA blood pressure. If CHA blood pressure decreases by more than 25% or 18

Figure 11 The common hepatic artery-celiac artery anastomosis during the modified Appleby procedure. Intraoperative image showed direct end-to-end anastomosis between common hepatic artery and celiac artery following distal pancreatectomy with celiac axis resection. The white arrow marks the anastomosis. CHA: Common hepatic artery; CA: Celiac artery.

mmHg, hepatic artery reconstruction should be performed. Although current opinions are not unanimous[79,97], arterial reconstruction may not be required in most cases when liver perfusion is confirmed to be adequate[87,92,94,100].

Unfortunately, despite the increasing detection rate of AHAs, few studies have described the effect of AHA on DP-CAR. In contrast to PD, which requires attention to aberrant RHA or CHA from the SMA, DP-CAR requires caution for aberrant LHA originating from the LGA[18]. This variant may result in left hepatic ischemia when the LGA is transected[101]. Therefore, to prevent aberrant LHA damage and preserve the intact hepatic blood supply, surgeons may preserve the tumor-free LGA or perform anastomosis between the LGA and CHA[84,90,96]. The complexity of the procedure may be mitigated by the presence of an aberrant RHA or CHA from the SMA. For example, the presence of Michels type IV may help avoid arterial reconstruction in TP with en bloc CAR (TP-CAR)[102]. Nevertheless, in the absence of this variant (Michels type IV), TP-CAR should be revascularized[88].

CONCLUSION

In conclusion, AHA is not rare in patients undergoing pancreatic resection, and its clinical significance sometimes resembles a double-edged sword. The presence of AHA does not worsen surgical and oncological outcomes, if it is accurately identified preoperatively and appropriately managed intraoperatively. Given the potential risk of hepatic hypoperfusion caused by AHA injury or resection, hepatic artery reconstruction is sometimes necessary.

Abstract

Mixed neuroendocrine-non-neuroendocrine neoplasms (MiNENs) are rare mixed tumors containing both neuroendocrine (NE) and non-NE components. Each component must occupy at least 30% of the tumor volume by definition. Recent molecular evidence suggests MiNENs are clonal neoplasms and potentially harbor targetable mutations similar to conventional carcinomas. There have been multiple changes in the nomenclature and classification of MiNENs which has created some confusion among pathologists on how to integrate the contributions of each component in a MiNEN, an issue which in turn has resulted in confusion in communication with front-line treating oncologists. This mini review summarizes our current understanding of MiNENs and outline diagnosis, prognosis, and management of these neoplasms. The authors emphasize the importance of treating the most aggressive component of the tumor regardless of its percentage volume.

Key Words: Mixed neuroendocrine non-neuroendocrine neoplasms; Mixed adenoneuorendocrine carcinoma; Mixed neuroendocrine neoplasms; Neuroendocrine; Non-neuroendocrine

Core Tip: Mixed neuroendocrine neoplasms have been referred to by a long list of names. The latest term, mixed neuroendocrine-non-neuroendocrine neoplasm (MiNEN), captures a wider spectrum of neoplasms than did previous nomenclature. This mini review summarizes the development of the term MiNEN and reviews current knowledge about the molecular pathogenesis, diagnosis, prognosis, and management of these neoplasms. MiNENs are viewed as clonal neoplasms and their clinical behaviour and management are ultimately determined by the most aggressive component present.

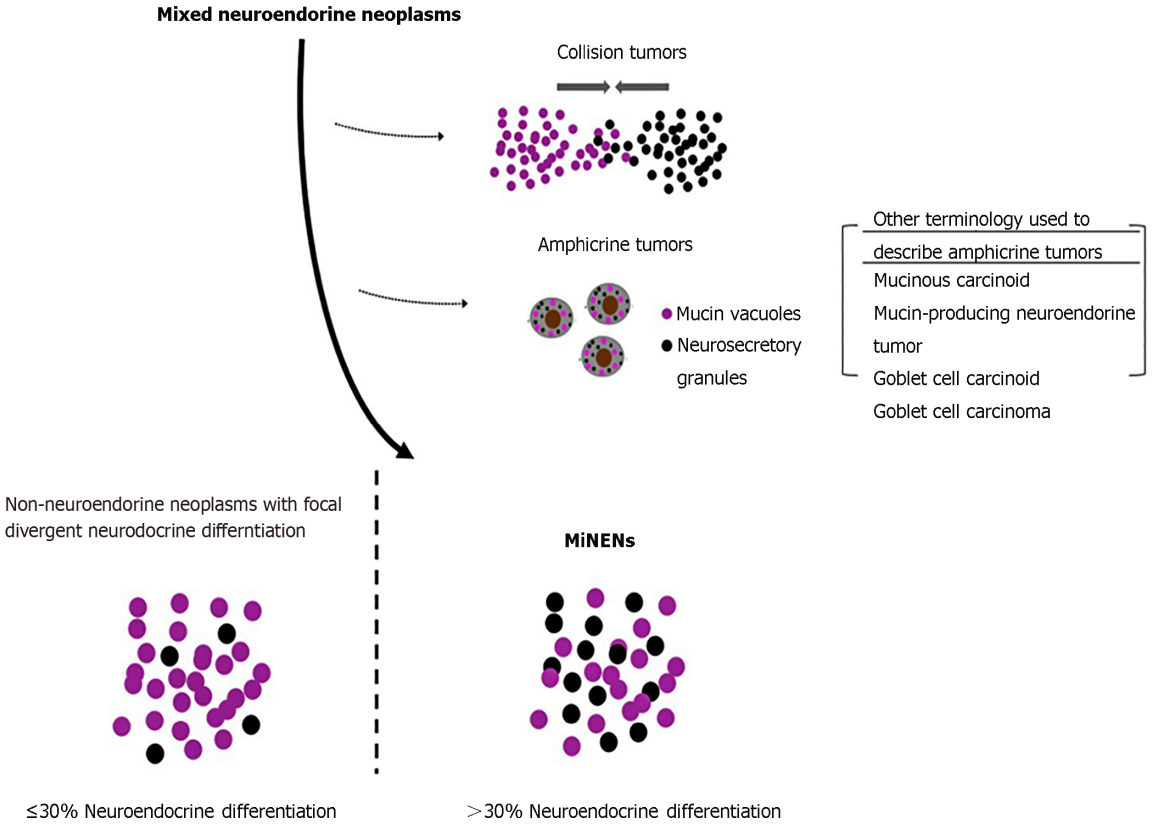
INTRODUCTION

Mixed neuroendocrine-non-neuroendocrine neoplasms (MiNENs) are tumors containing two or more histologically distinct components with one component showing neuroendocrine (NE) differentiation [1]. The non-NE component consists of an adenocarcinoma in over 90% of cases, but it can consist of any other epithelial neoplasm, including squamous cell carcinoma or hepatocellular carcinoma[1,2]. By definition each component must individually comprise > 30% of the total tumor volume in order for the tumor to qualify as a MiNEN[3].



MiNENs are a specific subtype of mixed NE neoplasms (Figure 1)[4]. Traditionally, mixed NE neoplasms include composite tumor, collision tumors, amphicrine tumors and non-NE neoplasms with focal neuroendocrine differentiation (NNE-NEDs). Strictly speaking, in MiNENs the distinct NE and non-NE components are intimately intermingled and both are derived from a common single precursor cell, morphologically expressing usually as composite tumors. Collision tumors consist of two independent primary neoplasms which have grown into the same space by chance. Each neoplasm is derived from a separate precursor cell which has independently undergone its own molecular evolution [5]. Amphicrine neoplasms consist of a single cell type in which each cell displays both NE and non-NE phenotypes simultaneously. For example, electron microscopy may demonstrate both mucous vacuoles and neurosecretory granules in the same cell. These tumors are extremely rare, with approximately only 4 reported in the stomach[6] but are slightly more common in the pancreas. Despite that collision tumors might not come from a common single precursor cell; they have still been referred to as MiNENs by authors based on the traditional practice.

NNE-NEDs are non-NE neoplasms which show NE differentiation but not enough to meet the criteria to be considered MiNENs. The exact percentage threshold of NED required to be considered a MiNEN is artificial and will likely continue to evolve in the future as we learn more about these neoplasms. The current 30% threshold was originally defined arbitrarily in 1987 to recognize and create a new diagnostic entity for truly mixed NE tumors with substantial amounts of both non-NE and NE components, and to exclude non-NE tumors with scattered NE cells of uncertain clinical significance[4,7]. Although it has served a valuable role in the establishment of MiNENs as distinct diagnostic entities, this cut-off does not have a basis in clinical or scientific evidence[1]. Recent studies suggest a lower threshold may be more appropriate, with even 10% NED significantly affecting prognosis, thus raising the possibility the formally defined threshold may change in the future[8,9]. Indeed, poorly differentiated NE or even non-NE components, even when < 5% of the tumor volume, may determine patient outcome. Regardless of what the threshold is, it is important to note neoplasms may show a spectrum of divergent NED, and that only a subset of these neoplasms should be classified as MiNENs.

Other entities which may be confused with MiNENs include usual adenocarcinomas displaying aberrant expression of NE markers (*i.e.*, synaptophysin and chromogranin) but no histologically recognizable NE morphology[7]. These features do not qualify a neoplasm as a MiNEN, and aberrant synaptophysin expression in conventional adenocarcinomas does not affect prognosis[10]. Neoplasms which overgrow and entrap physiologic NE structures, for example acinar adenocarcinoma in the pancreas which can entrap normal physiologic islets of Langerhans, should also not be mistaken for MiNENs despite the pitfall of positive staining for NE markers[7].

NOMENCLATURE

The individual components of MiNENs are common entities which pathologists and oncologists encounter routinely. The major challenge in understanding MiNENs is simply an issue of nomenclature. Unfortunately, the nomenclature has undergone numerous rapid and successive changes over the past 20 years. This has been complicated by substantial changes in the nomenclature for simple pure NE

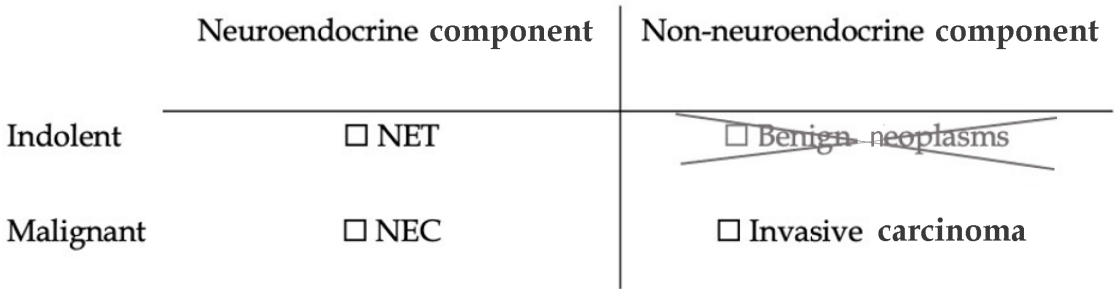
Figure 1 Classification of mixed neuroendocrine neoplasms. Mixed neuroendocrine-non-neuroendocrine neoplasms are specific mixed neuroendocrine tumors, which show an intimate mixture of neuroendocrine and non-neuroendocrine cells and are both derived from a common precursor cell. MiNEN: Mixed neuroendocrine-non-neuroendocrine neoplasms.



neoplasms themselves which have occurred over the same timeframe. The potential clinical confusion which may occur because of these rapid changes is not insignificant. An illustrative example of such potential confusion comes from appendiceal goblet cell neoplasms which have similarly undergone numerous changes in nomenclature. Two cases diagnosed as "goblet cell adenocarcinoma" and "adenocarcinoma ex goblet cell carcinoid" were misinterpreted by oncologists as NE tumors and then considered for inappropriate adjuvant chemotherapy[11].

A conceptual framework for understanding MiNENs is shown in Figure 2. In order to constitute a MiNEN a tumor must show at least two lines of differentiation, one of which is NE and the other of which is epithelial but non-NE. In the digestive system only, there is an additional stipulation that each component of the neoplasm is required to be malignant in order for it to qualify as a MiNEN[3]. Low-grade NE tumors, formerly known as carcinoids, satisfy this "malignant" requirement because of their potential for metastasis, despite their usually indolent behavior[1,3]. However indolent non-NE epithelial tumors, such as adenomas or papillomas, do not metastasize and so would not constitute MiNENs in the digestive system[3]. For example, mixed adenomas well-differentiated NE tumors, or "MANETs", consisting of a composite tubular adenoma-carcinoid tumor, are no longer considered MiNENs with these updated criteria[12]. Similarly, in-situ lesions such as intraductal papillary mucinous neoplasms of the pancreas were formerly included as potential non-NE components of digestive system MiNENs, but now have been excluded by the latest WHO classification[1,3]. The non-NE component is required to be an invasive carcinoma.

Although perhaps daunting, becoming familiar with the host of names that has been used to refer to MiNENs in the past may help reduce confusion in clinical practice. We will attempt to briefly summarize the history of the nomenclature of MiNENs towards this end. We begin by describing the changes in nomenclature of pure NE neoplasms, before moving on to the broader category of MiNENs.

NE neoplasms

The nomenclature of NE neoplasms in the digestive system has undergone a series of changes in the last 20 years. After being first recognized in 1907, NE neoplasms were designated "carcinoid tumors" and referred to as such for almost a century thereafter[8,13]. By 1994 poorly differentiated NE neoplasms were noted to have a drastically worse prognosis than their well-differentiated counterparts[8,14]. The

Figure 2 Conceptual framework for mixed neuroendocrine-non-neuroendocrine neoplasm of the digestive system. The tumor must include one neuroendocrine component and one non-neuroendocrine component. In the digestive system both components must have metastatic potential, excluding benign non-neuroendocrine neoplasms such as adenomas or squamous papillomas. NET: Neuroendocrine tumors; NEC: Neuroendocrine carcinomas.

poorly differentiated neoplasms were designated "small cell carcinomas". The term carcinoid continued to refer to well-differentiated NE neoplasms.

Increasing use of Ki-67 immunohistochemistry revealed a wide spectrum of proliferative rates within carcinoid tumors and small cell carcinomas. A grading system based on Ki-67 index was proposed in 2006 and formally adopted by the WHO classification in 2010[15,16]. NE tumors with low Ki-67 indices (≤ 20%; grades 1 or 2) were called neuroendocrine tumors (NETs) while tumors with high Ki-67 index (> 20%; grade 3) were called neuroendocrine carcinomas (NECs).

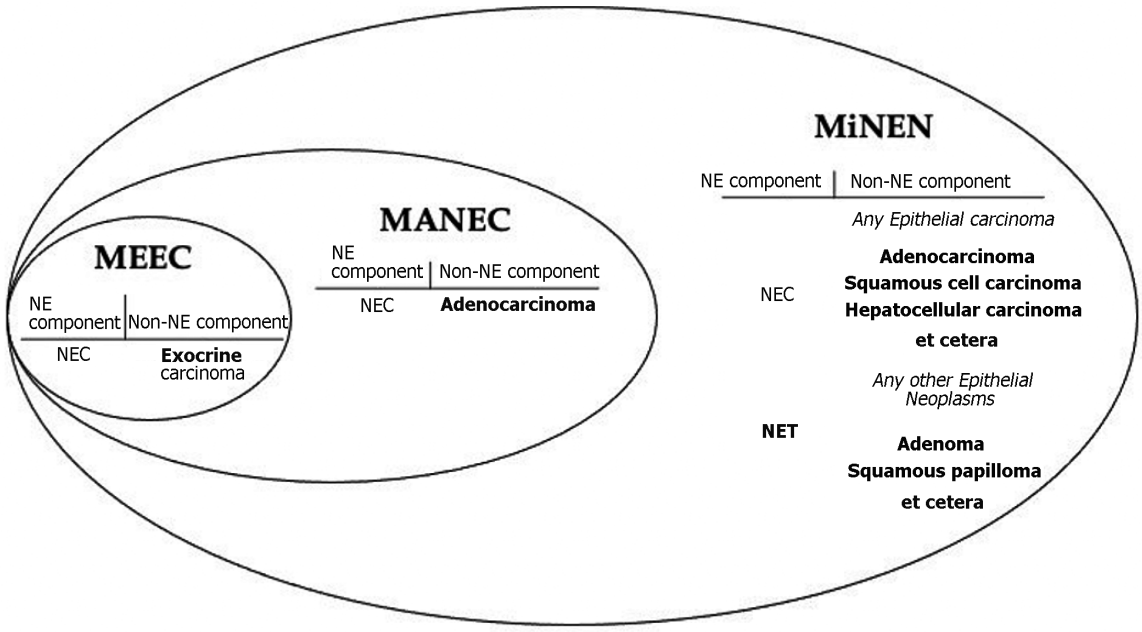
Grade 3 tumors were recently recognized to consist of two types of tumors, although both have increased Ki-67 indices. One type of tumors shows well-differentiated morphology while another type shows poorly differentiated morphology[8]. Further studies have revealed tumors showing poorly differentiated morphology have half the survival of their well-differentiated counterparts[8]. Genetic studies further show the two tumor populations actually develop *via* entirely separate and independent molecular pathways[8,17]. These findings have led to any poorly differentiated tumor being referred to as a NEC, regardless of Ki-67 index. Well-differentiated tumors which are designated NETs and further graded according to their proliferation rate[3].

Any NE neoplasm, either a NET or a NEC, can constitute the NE component of a MiNEN.

Non-NE component

Mixed NE neoplasms were first recognized in 1924, only shortly after pure NE neoplasms themselves were first recognized[7,18]. In 1987 Lewin[4] formally proposed a classification system for mixed NE neoplasms in which he termed what we now call MiNENs as "composite glandular-endocrine cell carcinomas"[4]. His classification system distinguished these tumors from collision tumors and amphicrine tumors, as well as from usual adenocarcinomas with < 30% NED.

In 2000 these neoplasms were adopted into the *WHO Classification of Tumors of the Digestive System* as "mixed exocrine-endocrine carcinomas" (MEECs)[7,19]. This terminology was short-lived and changed to "mixed adenoneuroendocrine carcinoma" (MANEC) in the subsequent 2010 edition of the classification[16].



It soon became apparent adenocarcinomas were not the only non-NE neoplasms observed in mixed NE tumors. Other epithelial neoplasms, such as squamous cell carcinomas and hepatocellular carcinomas, were also observed in mixed NE neoplasms[1,7]. This prompted "mixed adenoneuroendocrine carcinomas" (MANECs) to instead be viewed as "mixed neuroendocrine-non-neuroendocrine carcinomas" (Figure 3).

MiNENs

In 2016, La Rosa *et al*[1] proposed the term "mixed neuroendocrine-non-neuroendocrine neoplasms" (MiNENs)[1]. The intention was to create an umbrella term for mixed NE neoplasms broad enough to encompass all the changes we have discussed so far, while also being generalizable to any mixed NE tumor occurring in any organ in the body. The latter task is difficult considering the heterogeneity in nomenclature for NE neoplasms in different sites such as the lung. It is even more difficult if one anticipates the nomenclature for pure NE neoplasms continuing to evolve in other organs such as it has in the digestive system.

MiNENs are 'neoplasms' instead of 'carcinomas' because benign non-NE components such as adenomas or papillomas can still be a part of MiNENs in sites outside of the digestive system[1]. This had been the case in the digestive system as well until only recently when the latest WHO classification was published in 2019.

The current prevailing view is that MiNENs are clonal neoplasms derived from a single pluripotent stem cell[8]. Multiple studies have compared the mutational landscape in the NE and non-NE

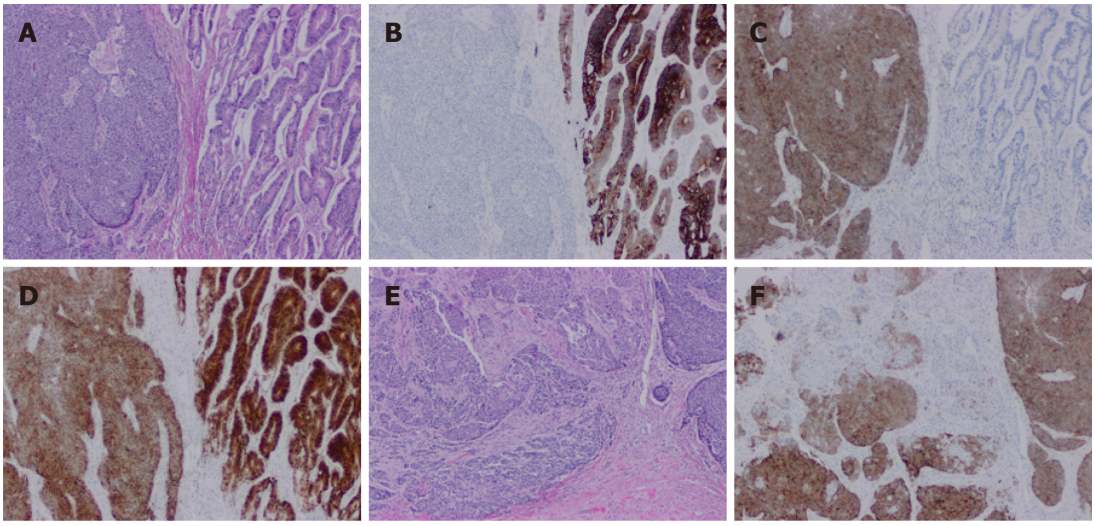
Figure 3 Evolution of the terminology of mixed neuroendocrine-non-neuroendocrine neoplasm. The terminology has been broadened to include other non-neuroendocrine epithelial components beyond adenocarcinoma as well as including indolent or benign tumors such as neuroendocrine tumors. NE: Neuroendocrine; NEC: Neuroendocrine carcinoma; NET: Neuroendocrine tumor; MEEC: Mixed exocrine-endocrine carcinoma; MANEC: Mixed adenoneuroendocrine carcinoma; MiNEN: Mixed neuroendocrine-non-neuroendocrine neoplasm.

components and have demonstrated a common trunk of mutations shared between them, beyond which are further mutations specific to each component[20-22]. Interestingly these shared mutations are very similar to the mutations found in standard pure adenocarcinomas from the same anatomic site[22]. For example, in the colon, MiNENs can show *BRAF*, *KRAS*, and *APC* mutations in both components[22]. The mutated genes are expressed at similar levels in both components, and expression is significantly altered in comparison to normal background tissue[20,21].

Some authors have theorized MiNENs may begin as non-NE tumors and then at some point trans-differentiate to form an aggressive NEC component[2,23-26]. Several reports suggest *c-Myc* and *SMARCA* mutations may play a role in trans-differentiation, with one study even finding only a single additional *SMARCA* mutation in the NE component of a MiNEN[23-25]. Other studies have shown increased chromosomal aberrations and allelic imbalances in the NE component[26].

CHALLENGES IN DIAGNOSIS



Definitive diagnosis of a MiNEN usually follows after surgical resection. The presurgical biopsy diagnoses are roughly evenly split between 1/3 adenocarcinoma, 1/3 NEC, and 1/3 suspicious for MiNEN[2]. The NE component tends to lie deeper in the tumor which can influence the diagnosis on biopsy depending on the depth of tumor sampled[27,28].

Identifying the components

Diagnosing a MiNEN is equivalent to individually diagnosing the constituent components with a few additional steps. Neither the NE nor non-NE components differ from their pure counterparts, including their immunohistochemical profiles.

Figure 4 illustrates a typical MiNEN of colon origin. Both morphologic and immunohistochemical evidence of NED is required to diagnose a NE component in a MiNEN[3,7]. Morphologic evidence is required avoid the pitfall of focal aberrant NE marker expression on immunohistochemistry in otherwise standard non-NE tumors, a commonly recognized phenomenon with no current known clinical significance[10,29]. Common markers of NED that are used include synaptophysin, chromogranin, INSM1, CD56, and neuron-specific enolase. Synaptophysin is traditionally be regarded as the most sensitive and chromogranin as the most specific[30].

The NE component may be either a NEC or a NET[3,7]. Ki-67 proliferative index (or equivalently mitotic rate) should be reported for all NE neoplasms, including the NE component present in MiNENs. NETs are graded as usual by Ki-67 index: Grade 1 tumors are < 3%; grade 2 between 3%-20%; and grade 3 > 20%[3]. Grade 3 NETs usually have a Ki-67 index less than 60%, while the indices for NECs are

Figure 4 Histopathology of a mixed neuroendocrine-non-neuroendocrine neoplasm of colon. A: Hematoxylin and eosin (H&E) stain of mixed neuroendocrine-non-neuroendocrine neoplasm. On the right side is a well-differentiated invasive adenocarcinoma. On the left side is a poorly differentiated neuroendocrine carcinoma (20 ×, H&E); B: The adenocarcinoma component is positive for cytokeratin 20, but the neuroendocrine component is negative (20 ×); C: Positive synaptophysin staining in the neuroendocrine component but negative staining in the adenocarcinoma component (20 ×); D: Positive CDX2 staining in both adenocarcinoma and neuroendocrine carcinoma components (20 ×); E: Merging area of adenocarcinoma and neuroendocrine carcinoma components (20 ×); F: Positive synaptophysin staining of neuroendocrine cells in the merged area (20 ×).

higher, typically more than 50%-60%[8].

Well-differentiated NETs are usually organized in nested, solid, trabecular, ribbon, or insular patterns. Rosette-like formations can be present. Tumors are cohesive without isolated single cells. Granular eosinophilic cytoplasm may be appreciated. Lymphovascular or perineural invasion is allowed in NETs and does not necessitate a diagnosis of NEC. NETs retain immunohistochemical markers from the primary site of origin[8].

The majority of MiNENs do not contain NETs but rather contain poorly differentiated NECs. Tumor cells in NECs show nuclear crowding and pleomorphism. Nuclei are hyperchromatic with increased nuclear membrane irregularity. Single cells are common, and mitoses are obvious. Necrosis can be present, and nuclei display smearing or crush artifact. NE markers remain sensitive, however immunohistochemical markers for the primary site of origin are lost[8,30]. Aberrant expression of TTF-1 and CDX-2 is common, making these markers unreliable and a potential pitfall for mistaking the site of origin[8]. The average Ki-67 proliferative index of NECs in MiNENs is 70%[30].

Morphologically NECs can show either small or large cell patterns. Small cell morphology is similar to traditional small cell carcinoma elsewhere with small uniform round to oval nuclei and evenly distributed finely granular ("salt and pepper") chromatin. Cytoplasm is scant. Cells are crowded with nuclear moulding and indistinct cell membranes. In contrast, large cell NECs (LCNECs) have a larger cell size than small cell carcinoma and a vesicular nucleus with prominent nucleolus. They can have appreciable eosinophilic cytoplasm. Distinguishing LCNECs from small cell carcinoma can sometimes be a difficult task. Ki-67 index can potentially be helpful as the index of LCNECs ranges from 40%-80% while small cell carcinoma averages 80%[31]. In MiNENs the NEC component is more commonly a LCNECs than a small cell carcinoma[32,33].

The non-NE component of MiNENs is adenocarcinoma 92% of the time[2]. Squamous cell carcinoma, hepatocellular carcinoma, and mixed adenosquamous carcinoma make up the majority of remaining non-NE components in reported cases thus far[2].

Extent of NE differentiation

The exact threshold of NED required to define a tumor as a MiNEN *vs* an NNE-NED is an area of current controversy in the literature. As mentioned, the 30% threshold which persists today was originally chosen arbitrarily. A commonly cited and relatively recent study by Park *et al*[9] provides evidence arguing in favor of lowering the threshold to 10%[9]. The authors examined 88 gastric carcinomas with varying degrees of NED and compared overall survival to 650 gastric carcinomas with no NED. NED of just under 10% was associated with worse survival: Overall 5-year survival in cases with < 10% NED was 85.6% compared to only 53.3% survival in cases with ≥ 10% NED.

Another similar study found 20% NED to be associated with significantly worse prognosis in adenocarcinomas, again suggesting the 30% threshold may be too high[34]. The current formal threshold for diagnosing a MiNEN remains 30% but this is likely to be lowered in the future. In the interim while this does preclude a diagnosis of MiNEN in cases with 10%-30% NED, we recommend

always quantifying the percentage of NED in non-NE tumors and informing the oncologist of the possible prognostic impact, for example by making a diagnostic comment citing the studies above. Regardless of how the report is handled, the possible prognostic impact of 10%–30% is an important topic to be raised in multidisciplinary meetings discussing diagnosis and management of these rare tumors.

The significance of divergent differentiation in NECs is a less well explored topic. This may be because even small degrees of NED, beginning at as little as 10% as mentioned above, quickly approach the same dismal prognosis as NECs regardless of the size of the non-NE component (Table 1).

Grading

There is currently no widely accepted system for grading MiNENs. This is somewhat unfortunate because MiNEN is an umbrella term for a wide range of neoplasms whose behaviour can range from indolent (*i.e.*, a MiNEN in which a NET is the most biologically aggressive component) to aggressively malignant, paralleling the prognosis of NECs. Simply designating a tumor as a MiNEN is insufficient and does not convey much useful information. Therefore, it is incumbent upon the pathologist to clearly communicate the nature and aggressiveness of each component present in the tumor to ensure appropriate management.

The original publication by La Rosa *et al*[1] in which the term MiNEN was coined also proposed a grading scheme in which MiNENs were divided into low-grade, intermediate grade, and high grade categories[1]. Tumors with a NEC component, which constitute the vast majority of MiNENs, would be designated high grade neoplasms. Tumors in which the non-NE component was the most aggressive, such as adenocarcinomas with a NET component, would be intermediate grade. Indolent tumors in which a NET was the most aggressive component would be low-grade. This scheme succinctly classifies MiNENs according to their most aggressive component. It is also clinically useful because the most aggressive component usually drives prognosis and management. While the scheme may not be widely used, it still serves as a useful guide as to how to portray grade in MiNENs.

Staging

The fact that MiNENs are considered single clonal neoplasms greatly simplifies staging. The two components do not need to be staged separately as they would in a collision tumor. Standard TNM staging applies as *per* AJCC guidelines, using the same protocols as for other carcinomas from the same body site. For the rare MiNENs in which a NET is the most aggressive component the protocol for NETs from the same body site is used. There does not appear to be literature yet to consider alternative methods for staging MiNENs.

Lymph nodes

While lymph node staging proceeds as *per* staging of the rest of the MiNEN as described above, the composition of lymph node metastases in MiNENs is an interesting issue because of the many different possible scenarios: Only one component may have metastasized, or both may have; the components may metastasize together to the same lymph node, or separately to different lymph nodes. Further it is interesting to consider whether the metastatic component of a MiNEN is a better marker of the biologic behavior of the tumor than the de facto assumption that behaviour is dictated by the worst component found in the primary tumor.

The pattern of metastasis in MiNENs was investigated in a study of 80 patients[35]. In approximately 70% of patients only one component metastasized; this was usually the more aggressive NEC component. In 20% of patients both components metastasized, but none were found together in the same lymph node. In 10% of patients there was lymph node metastasis present containing both components within the same node.

In terms of the components present in metastases, they reflected the composition of the primary tumor; in a tumor composed of 60% NEC and 40% adenocarcinoma, roughly 60% of metastases would be NEC and 40% would be adenocarcinoma[35].

Included in the study were 3 cases of NNE-NEDs. In all 3 of these cases the metastases were composed solely of the NEC component. Notably, by current criteria these tumors would not have qualified as MiNENs, providing further evidence that < 30% NED can be biologically significant.

The question of whether the biologic behaviour of MiNENs is better reflected by the metastatic component or the most aggressive component in the primary tumor is moot since these data show the composition of the metastases simply reflect the composition of the primary tumor; in other words, it is unlikely further useful information will be gained by determining the pattern of lymph node metastasis once the composition of the primary tumor is known. The grading scheme proposed by La Rosa appears to be the most useful gauge of the potential biological behavior of the tumor.

Reporting

'MiNEN' is not a diagnosis but rather an umbrella term for mixed NE neoplasms[1]. The term in and of itself does not convey useful information to the oncologist. The useful information is knowing the components which make up the tumor, and pathologists must ensure these are communicated clearly to

Table 1 Prognostic impact of neuroendocrine differentiation (summarized from Park *et al*[9])

Classification					
Neuroendocrine differentiation (%)	0	< 10	10-30	30-70	> 70
Current classification	Non-NE	Non-NE	NNE-NED	MiNEN	NEC
5-yr overall survival	85	89	17[1]	54	59

[1]The 8 cases of non-NE tumors with NED in this study presented at a higher stage than the other tumors.
NE: Neuroendocrine; NED: Neuroendocrine differentiation; NNE: Non-neuroendocrine; MiNEN: Mixed neuroendocrine-non-neuroendocrine neoplasm; NEC: Neuroendocrine carcinoma.

allow oncologists to stratify risk and plan management accordingly.

Figure 5 shows the example of the pathology report of a MiNEN. The first line of the report should identify that the tumor is a MiNEN. Because there is currently no widely accepted grading system, grade must be conveyed within the next few lines. The most aggressive or high-grade component should be listed first, and the system by La Rosa *et al*[1] serves a useful guide here[1]. A NEC component is the highest possible grade neoplasm found in MiNENs and should always be listed first. Next in the hierarchy of grade usually comes a non-NE carcinoma component, usually an adenocarcinoma, which is then followed by a NET component, and then lastly followed by the lowest grade component possible, a benign epithelial neoplasm such as an adenoma or papilloma. Accordingly, La Rosa's scheme describes tumors driven by a NEC component as high-grade, tumors driven by a carcinoma component intermediate grade, and tumors driven by a NET component low-grade or indolent. For each component listed the histologic subtype and grade should be described the same way they would be as if the component were a pure neoplasm. The percentage of total tumor volume occupied by each component should also be listed.

We recommend designating non-NE tumors with 10%-30% NED (NNE-NEDs) as 'mixed neoplasms' and then reporting them in the same manner as a MiNEN. A diagnostic comment citing the Park *et al*[9] and Jiang *et al*[34] studies mentioning the possible prognostic impact of NE components occupying < 30% of the tumor volume may help provide important background information for these rare tumors[9,34].

Because of their genetic similarity to adenocarcinomas, we recommend performing the same molecular studies on MiNENs as one would perform for an adenocarcinoma from the same anatomic site. Alterations involving MMR, BRAF V600E, and Her-2 have been demonstrated to exist in both components of MiNENs, inviting the exciting possibility of using the same targeted therapies during treatment[22,25,36]. Although ideally both components in a MiNEN would be tested individually to allow for better prediction of how the entire tumor will respond to a targeted therapy, in practice this may be very difficult or impossible to achieve with the closely intermingled components.

PROGNOSIS AND MANAGEMENT

The rarity of MiNENs, combined with their changing terminology over the years, has made it difficult to examine outcomes data. Controversy exists as to whether MiNENs behave better than pure NECs, but ultimately the prognosis appears to be similar[2,30,37,38]. A recently reported survival comparison of 503 NECs, 401 MiNENs, and 2785 adenocarcinomas of the stomach showed that the 5-year disease-free survival (DFS) was 47.5%, 51.1%, and 57.8% respectively[37]. The shorter DFS of NECs and MiNENs compared to adenocarcinoma was statistically significant while the difference between NECs and MiNENs was not.

In the digestive system in general, 82% of MiNENs present with localized disease and 18% present with distant metastases[2]. Patients with localized disease generally proceed to surgical resection. Select patients with advanced disease may undergo palliative resection[38]. The median overall survival for localized MiNENs, including regional lymph node metastases (Stages I-III), is 39 mo. For advanced disease with distant metastasis (Stage IV) median overall survival is 11 mo[38].

MiNENs may be missed in patients with an accessible metastasis that is used for the initial diagnostic biopsy. These cases may be diagnosed as pure NECs or pure adenocarcinomas, if resection is not indicated and further tissue is not sampled, thus may result in under recognition of MiNENs[30]. This leads to bias in outcome data as lower stage tumors are more likely to undergo surgical resection and be diagnosed as MiNENs whereas higher stage tumors are more likely to be missed and labeled pure NECs or pure adenocarcinomas. Thus, MiNENs may appear to have improved prognosis, when in reality they are just more likely to be diagnosed at a lower stage.

Management for these rare tumors is usually discussed at multidisciplinary rounds with the expertise of pathologists and oncologists who have special interest in NE neoplasms. Treatment is tailored

Left colon, hemicolectomy with lymph node dissection:
Mixed neuroendocrine-non-neuroendocrine neoplasms
Component 1: Neuroendocrine carcinoma
(1) Comprises 60% of total tumor volume; (2) Histologic subtype: Small cell carcinoma; and (3) Ki-67 proliferative index: 87%.
Component 2: Intestinal adenocarcinoma
(1) Comprises 40% of total tumor volume; and (2) Tumor grade: Grade 2 (moderately differentiated)
Tumor size: 4.3 cm
Tumor invades serosa and pericolonic tissue (stage pT4a)
Lymphovascular invasion present
Perineural invasion present
No tumor deposits identified
Margins: (1) Proximal margin: Negative; (2) Distal margin: POSITIVE for invasive carcinoma; and (3) Radial margin: Negative.
Total lymph nodes present: 15
Sixlymph nodes POSITIVE for metastatic carcinoma (6/15; stage pN2a): (1) Five lymph nodes are positive for metastatic neuroendocrine carcinoma only; and (2) One lymph node positive for both metastatic neuroendocrine carcinoma and adenocarcinoma.
Ancillary tests: (1) BRAF: POSITIVE for V600E mutation (immunohistochemistry)-Mutation present in both the neuroendocrine carcinoma and adenocarcinoma components; (2) MMR proficient/wild-type (immunohistochemistry); and (3) KRAS, NRAS negative (sanger sequencing)
Final stage: pT4a pN2a MX

Figure 5 Sample pathology report. MiNEN: Mixed neuroendocrine-non-neuroendocrine neoplasm.

towards the most aggressive component of the tumor, which is usually a NEC. MiNENs in which the most aggressive component is an adenocarcinoma (*i.e.*, tumors composed of adenocarcinomas with a NET component) are much rarer, but in these cases treatment is tailored towards the adenocarcinoma component.

No guidelines exist currently for adjuvant or neoadjuvant chemotherapy. NEC driven tumors are usually treated with etoposide and cisplatin-based regimens[2,27,39]. Adenocarcinoma driven cancers are commonly treated with 5-FU based backbones, however treatment options vary based on the site of the primary, with chemotherapies for MiNENs arising from a particular organ mirroring the systemic therapy for adenocarcinomas at that site. The oncologist may attempt a tailored combination of therapy in which the agents employed display efficacy against both components[30]. Radiation therapy has been suggested in tumors from the esophagus, stomach, rectum, and anus[40].

The genetic similarity of MiNENs to adenocarcinomas and reports of *KRAS, BRAF V600E, APC, MMR* , and *HER-2* amplifications occurring in both components of MiNENs invites the possibility of targeted therapies in these tumors[2,22,40,41]. One series of 44 cases found MMR deficiency in 39% of these tumors[40]. While this did not appear to have prognostic impact, it is an exciting finding raising the possibility for potential response to programmed death 1 blockade.

CONCLUSION

Mixed NE neoplasms have a complex history particularly in regard to nomenclature which has evolved alongside our increasing recognition of these tumors. The term 'MiNEN' was created to encompass a broader range of non-NE epithelial components beyond just adenocarcinomas. The term also incorporates updates in terminology used for NE neoplasms. MiNEN can be used to refer to tumors outside of the digestive system as well, although the digestive system has been the leading-edge area for these tumors. Diagnosis is in fact very familiar to both pathologists and oncologists alike, with no significant differences compared to diagnosis of each individual neoplasms. Staging is simplified because MiNENs are considered single clonal neoplasms. Prognosis and management are based on, and in general equivalent to, that of the most aggressive component.

Abstract

Non-alcoholic fatty liver disease (NAFLD) is a disease spectrum caused in part by insulin resistance and genetic predisposition. This disease is primarily characterized by excessive lipid accumulation in hepatocytes in the absence of alcohol abuse and other causes of liver damage. Histologically, NAFLD is divided into several periods: simple steatosis, non-alcoholic steatohepatitis (NASH), hepatic fibrosis, cirrhosis, and hepatocellular carcinoma. With the increasing prevalence of obesity and hyperlipidemia, NAFLD has become the main cause of chronic liver disease worldwide. As a result, the pathogenesis of this disease is drawing increasing attention. Ductular reaction (DR) is a reactive bile duct hyperplasia caused by liver injury that involves hepatocytes, cholangiocytes, and hepatic progenitor cells. Recently, DR is shown to play a pivotal role in simple steatosis progression to NASH or liver fibrosis, providing new research and treatment options. This study reviews several DR signaling pathways, including Notch, Hippo/YAP-TAZ, Wnt/β-catenin, Hedgehog, HGF/c-Met, and TWEAK/Fn14, and their role in the occurrence and development of NASH.

Key Words: Non-alcoholic fatty liver disease; Non-alcoholic steatohepatitis; Ductular reaction; Mechanisms; Signaling pathways

Core Tip: With the increasing prevalence of obesity and hyperlipidemia, Non-alcoholic fatty liver disease (NAFLD) has become the primary cause of chronic liver disease worldwide. Thus, the pathogenesis of non-alcoholic steatohepatitis (NASH) is drawing increasing attention. Ductular reaction (DR) is a reactive bile duct hyperplasia involving hepatocytes, cholangiocytes, and hepatic progenitor cells, that plays an important role in NAFLD pathogenesis and promotes the occurrence and development of NASH and liver fibrosis. This minireview describes the characteristics of DR and summarizes its pivotal mechanisms. A role for DR during NASH is described that supplements current knowledge about the pathogenesis of this disease and informs potential prevention and treatment strategies.

INTRODUCTION

Non-alcoholic fatty liver disease (NAFLD) is defined as the presence of > 5% hepatic steatosis in the absence of significant alcohol consumption or other liver disease-induced steatosis. This is one of the most important causes of liver disease worldwide and will likely emerge as the leading cause of end-stage liver disease in the coming decades. The epidemiology and demographic characteristics of NAFLD vary from country to country, correlating with the prevalence of obesity and risk factors for metabolic comorbidities. The global prevalence of NAFLD is currently estimated to be 29.1%, with more than 240 million individuals in China. NAFLD and its complications inflict a heavy financial burden on the global health system, patients, and their families. Thus, it is critical to conduct more research on NAFLD pathogenesis to inform the development of new prevention or treatment strategies[1,2].

As a result of fat accumulation, insulin resistance, and oxidative stress, a subgroup (approximately 20%-30%) of NAFLD, a relatively benign condition, can develop into non-alcoholic steatohepatitis (NASH) within three years. This is defined as the presence of hepatic steatosis with evidence of hepatocyte damage accompanied by inflammation and regeneration, that can progress into liver fibrosis, cirrhosis, and hepatocellular carcinoma[3,4]. Chronic hepatocyte death often occurs during NASH, and liver regeneration is a common way to restore normal liver structure characterized by phenotypic fidelity of hepatocytes and/or cholangiocytes. There are two primary mechanisms of liver regeneration. Under physiological conditions, liver parenchymal cells are repaired by the division of adjacent resting hepatocytes. During chronic liver diseases, such as NASH, liver regeneration capacity is impaired, activating the alternate regenerative pathway and resulting in ductular reaction (DR). Under these circumstances, macrophages, hepatic stellate cells (HSCs), and the extracellular matrix (ECM) act together to form the inflammatory micro-environment, releasing inflammatory and pro-fibrotic factors and promoting type I collagen deposition. When this occurs, hepatocytes, cholangiocytes, and hepatic progenitor cells (HPCs) in the Hering duct around the portal vein become activated, resulting in DR and eventually leading to liver fibrosis. HPC expansion is shown to occur in NAFLD patients and is strongly correlated with DR[5,6]. This is a common phenomenon during NASH, affecting the stage of fibrosis and disease progression and prognosis[7,8]. In this study, the signaling pathways and the roles of DR during NASH are explored to better understand the pathogenesis of this disease and provide potential treatment strategies to improve NASH outcomes.

DEFINITION OF DR

In 1957, Popper *et al*[9] first characterized DR as a ductular reaction involved in both acute and chronic liver diseases and found that it was associated with recovery from liver homeostasis. Cells involved in DR include pre-existing cholangiocytes, HPCs, and hepatocytes, together known as ductular reaction cells (DRCs) (Figure 1)[10]. However, DR does not just manifest as bile duct hyperplasia but also as liver injury and cell microenvironment-dependent liver regeneration. In diseases involving cholangiocyte damage, biliary cell number and function can be compensated by cholangiocyte and/or HPC proliferation and the transdifferentiation of hepatocytes into biliary-like cells. During hepatocyte injury and other related diseases, cholangiocytes can transdifferentiate into hepatocytes *via* HPCs[10,11]. DRCs exist in a niche with myofibroblasts and macrophages, and can actively promote liver inflammation and fibrosis. In human diseases such as primary sclerosing cholangitis, alcoholic or non-alcoholic steatohepatitis, and viral hepatitis, the number of DRCs in the liver directly correlates with fibrosis severity. In a mouse model, targeted apoptosis of DRCs alleviates fibrosis, while inhibition of DRC apoptosis aggravates liver fibrosis, suggesting that DR correlates with poor prognosis of liver diseases such as

Figure 1 The different compartments of the ductular reaction, including hepatocyte self-proliferation and transdifferentiation, hepatic progenitor cell differentiation, and cholangiocyte proliferation and transdifferention. HPC: Hepatic progenitor cell.

fibrosis and even cirrhosis[12-14]. Thus, research on the mechanism and intervention of DR is of great significance to liver disease treatment. EpCAM and NCAM/SOX9 have been proposed as HPC markers, CK7 and CK19 are used to identify cholangiocytes, and albumin and HNF 4α are regarded as hepatocyte markers (Table 1)[11,15-17]. CK7 immunohistochemistry is positive in HPCs and both initial and late intermediate hepatobiliary cell stages during DR[18]. By calculating the ratio of CK-positive cells in damaged liver tissue using immunostaining, DR can be divided into five grades, and liver injury severity can be predicted. Morphologically DR is divided into three types: (1) Regular bile duct structure commonly seen in biliary obstruction; (2) Incomplete bile duct structure observed in chronic active hepatitis; and (3) Small bile ducts reorganized by bile duct epithelial cells and hepatocytes, seen after submassive liver necrosis[19]. This allows the disease type and degree to be defined through the pathological manifestation of DR and informs disease treatment.

DR AND LIVER FIBROSIS IN NASH

Liver fibrosis is a major complication of almost all types of chronic liver damage including NASH. NAFLD includes three patterns of liver fibrosis according to histological characteristics, portal fibrosis, centrilobular fibrosis, and septal fibrosis[20]. In human liver diseases, fibrosis in the portal area is associated with poor prognosis even when the primary site of injury is lobular hepatocytes. Initially, NASH presents as active lobular necroinflammatory and typical centrilobular fibrosis, characterized by pericentral monocyte infiltration, myofibroblast activation, and localized collagen deposition, that can progress to portal fibrosis, septal fibrosis, and eventually lead to liver cirrhosis[7,21]. The DR correlates closely with fibrosis severity during NASH[6]. A rat model of liver fibrosis induced by chronic 2-acetylaminofluorene showed that HPC expansion aggravated liver fibrosis by driving myofibroblastic transformation of fibroblasts and/or HSCs in the injured liver[22]. However, whether fibrosis aids the regeneration mediated by HPC or DR exacerbates fibrosis remain unclear[7,23].

Periportal DR in NASH

Periportal fibrosis is closely related to NASH progression. Periportal DR is a typical injury response caused by portal inflammatory infiltration that leads to periportal fibrosis[6,24]. Lobular injury activates macrophages to release pro-inflammatory factors such as TNF and IL-1β and promotes formation of the portal inflammatory infiltration microenvironment that is dominated by CD68+ macrophages, CD8+ lymphocytes, collagen I, and laminin, contributing to cell fate. As cell damage increases during NASH, HPC proliferation induces DR around the portal vein. DR activates HSCs and induces HPC differentiation by releasing inflammatory mediators and pro-fibrogenic factors, eventually resulting in

Table 1 Identifying markers of cholangiocytes, hepatic progenitor cells, and hepatocytes

Cell types	Markers	Ref.
Cholangiocytes	CK7/CK19/EpCAM/SOX9/TFF/*etc.*	[15-17]
Hepatic progenitor cells	EpCAM/NCAM/SOX9/MCAM/Foxl1/Lgr5/A6/OV6/NGA2/CXCR4/*etc.*

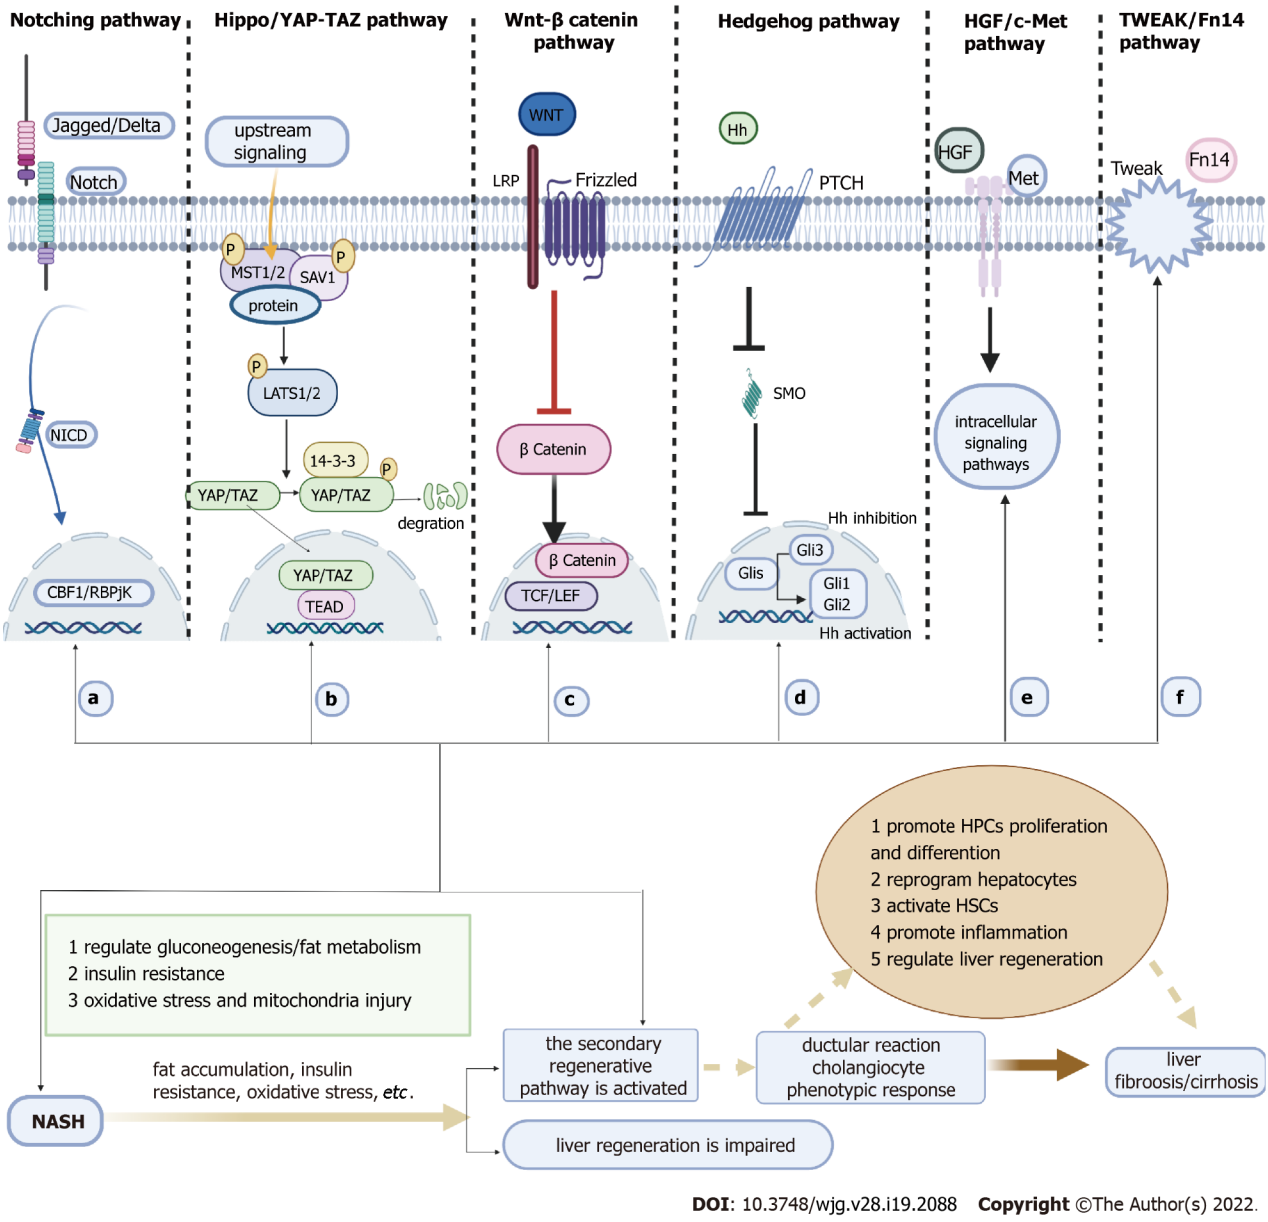
periportal fibrosis that resembles biliary fibrosis[25]. Except for hepatic parenchymal and nonparenchymal cells, current studies have confirmed that mixed infiltration of lymphocytes, neutrophils, monocytes, and a small number of eosinophils participate in DR, but the relative number of different cells and their relationship to disease progression is not fully understood[26].

Studies have shown that DR and portal inflammation are closely related during NASH and are independently related to fibrosis. In the portal vein area, inflammatory cells and their mediators affect HPC differentiation and this process affects the balance between liver regeneration and fibrogenesis. In a rat model using a 3,5-methoxycarbonyl-1,4-dihydrocollidine (DDC)-enriched diet, DRCs proliferated at the capillary bile duct and migrated radially from the portal area to the hepatic parenchymal region [27]. This suggests that the portal DR may interact with the centrilobular DR, leading to progressive fibrosis and even septal fibrosis.

Centrilobular DR in NASH

DR has primarily been described in the periportal compartment. However, a recent study demonstrated that the DR also occurs in the centrilobular regions, suggesting that hepatocytes mount a metaplastic response to chronic injury and/or chronic ischemia, and promote transformation into a more ductular phenotype rather than a progenitor cell reaction[28]. Studies have shown that centrilobular DR is common in NASH and correlates well with lobular inflammation, hepatocellular ballooning degeneration, Mallory-Denk bodies, and necroinflammation. A cross-sectional analysis supported these findings, showing that centrilobular DR is highly correlated with the stage of fibrosis during adult NASH. Moreover, there was a distinct difference in centrilobular DR frequency between patients with progressive and non-progressive fibrosis, suggesting that centrilobular DR can serve as a histologic marker of fibrosis progression[22].



NASH begins with the accumulation of fatty acids and reactive oxygen species in the central area of the lobules, resulting in hepatocyte mitochondrial injury and activation of nearby macrophages and HSCs. Macrophages can release cytokines like TNF-α that promote insulin resistance and inflammation and result in hepatocyte damage. This can promote the transdifferentiation of hepatocytes into DRCs, the expression of inflammatory mediators and pro-fibrotic cytokines, and the activation of nearby HSCs to secrete type I collagen, eventually resulting in peripheral and subsinus fibrosis in the central area of the lobules[20]. Thus, DR in the central area is associated with liver regeneration and repairment of NASH. Centrilobular DR may be an important driver of fibrosis, in which case the degree of centrilobular DR could serve as a histological marker of fibrosis development[22,29].

DR MECHANISMS DURING NASH

During chronic liver diseases such as NASH, an alternative pathway for HPC proliferation is activated when hepatic self-renewal becomes impaired. Persistent HPC activation accompanies the recruitment of pro-inflammatory factors and the production of pro-fibrotic factors and results in DR, aiding pathological repair of the liver. HPCs can proliferate and differentiate into hepatocytes or cholangiocytes, and hepatocytes can further transdifferentiate into cholangiocytes (Figure 1). DR promotes liver and biliary fibrosis using similar mechanisms. A series of highly conservative signaling pathways, including Notch, Hippo/YAP-TAZ, Wnt/β-catenin, Hedgehog (Hh), HGF/c-Met, and TWEAK/Fn14, in the DR play an important role in driving HPC activation and/or HSC activation in chronic liver injury (Figure 2).

Notch signaling during NASH

The Notch ligands, Jagged (Jagged1, 2) and Delta-like (Delta-like, Dll1, 3, and 4), activate Notch receptors (Notch-1, -4) through cell-cell contact, determining cleavage of the Notch intracellular domain (NICD). NICD binds with CBF1/RBPjK in the nucleus and promotes transcription of several genes including the Hes and Hey-related family of transcription factors and SOX9. During embryonic development, Notch signaling can promote HPC differentiation into cells in the biliary lineage and

Figure 2 A series of highly conserved signaling pathways in the ductular reaction which promotes the occurrence of non-alcoholic fatty liver disease and aggravates the prognosis of non-alcoholic steatohepatitis (Created with BioRender.com). A: The Notch signaling pathway regulates expression of genes, such as the Hes and Hey-related family, to determine cell differentiation and function, maintain liver homeostasis, repair liver damage, and regulate liver metabolism, inflammation, and cancer; B: The Hippo/YAP-TAZ signaling pathway can regulate liver size, metabolism, cell proliferation, cell migration, the epithelial-mesenchymal transition, and formation of the extracellular matrix and cytoskeleton formation, *etc*; C: The Wnt/β-catenin signaling pathway affects liver development and physiological functions of all liver disease stages, from initial injury and inflammation to fibrosis, cirrhosis and tumor occurrence; D: The hedgehog signaling pathway affects cell proliferation, migration, and differentiation; E: The HGF/c-Met signaling pathway activates multiple intracellular signaling pathways and affect cell proliferation, migration, and differentiation; F: The TWEAK/Fn14 signaling pathway regulates tissue inflammation and damage repair in addition to cell survival and death. HPC: Hepatic progenitor cell; NASH: Non-alcoholic steatohepatitis.

induce morphogenesis and maturation of the intrahepatic biliary tree. In the DR that occurs during adult liver injury, Notch signaling can determine HPC differentiation into cells in the biliary (Notch activation) or hepatocyte lineage (Notch inhibition). In addition, Notch signaling reprograms hepatocytes into biliary epithelial cells to repair the biliary tract[30,31].

During NASH, inflammatory cells express Notch ligands and promote Notch signaling, increasing FoxO1-induced insulin resistance to regulate glucose production by hepatocytes[32]. The Notch signaling pathway can interact with the mTOR pathway to increase intracellular triglyceride synthesis and lipogenesis by regulating SREBP-1c expression[33]. Thus, it is believed that Notch signaling regulates adipogenesis, steatosis, and insulin resistance, and promotes NAFLD occurrence and progression.

Notch signaling is downregulated following liver cell differentiation in healthy individuals but is upregulated in NASH patients and mice. In Notch-2- and RPB-jK-deficient mice with DDC diet-induced

biliary damage, HPC activation is severely impaired, suggesting that Notch signaling plays an essential role in HPC driven biliary repair and biliary tubule formation[34]. One study indicated that continuous Notch signaling during lipid accumulation could induce liver steatosis and promote fibrogenesis, while suppression of Notch signaling could ameliorate liver fibrosis. Notch signaling also correlates strongly with the NAFLD activity score and alanine aminotransferase level, indicating that its activity is related to NAFLD progression to NASH. Notch signaling can directly promote liver fibrosis by activating HSCs through osteopontin and sinusoidal endothelial cells and can indirectly affect liver fibrosis through inflammation and DR[35,36]. In NASH mice induced using a methionine-choline deficient diet, high Notch ligand levels were found in activated HSCs and HPC activation was linked to inflammation and fibrosis. Liver fibrosis is improved by inhibiting Notch signaling, which reduces HPCs/DR expansion and hepatocyte transdifferentiation. Meanwhile, immunohistochemistry showed that about 2% of CK19+ cells were derived from Notch-1 induced Sox9+ hepatocytes reprogramming[37]. Lineage tracing showed that hepatocytes undergo extensive reprogramming to biliary epithelial cells (BECs) in the DR following chronic injury[38]. In summary, liver cell reprogramming into HPCs during the DR is Notch-dependent, and inhibition of Notch signaling improves fibrosis, providing a potential target for NASH treatment.

Hippo/YAP-TAZ signaling during NASH

In the canonical mammalian Hippo pathway kinase cascade, the tumor suppressor genes, MST1/2 and LATS1/2, are phosphorylated by the upstream kinase tumor suppressor, Hippo, resulting in YAP and TAZ phosphorylation and inactivation. SAV1 and MOB1A/B can act as adaptor proteins to enhance MST1/2 and LATS1/2 phosphorylation and inactivation, respectively. YAP/TAZ interacts with the DNA-binding transcription factors, TEAD (1-4), to regulate target gene expression, and this can be antagonized by TEAD family corepressors such as VGLL4[39].

Hippo-YAP/TAZ signaling participates in various metabolic processes such as liver glycolysis, gluconeogenesis, fatty acid accumulation, and amino acid metabolism. In mice with an MST1 deletion, fasting and high-fat diet aggravated liver metabolic damage. MST1 overexpression is induced by fasting, which decreases SREBP-1c and improves antioxidant genes expression[40]. A previous study demonstrated that AKT overexpression leads to the development of NAFLD by promoting maturation of the transcription factor, SREBP-1c[41]. Studies have shown a positive feedback loop between the Hippo and AKT signaling pathways to promote the development of NAFLD[42]. Thus, regulation of lipid metabolism by Hippo/YAP-TAZ can induce NAFLD. As a result, researchers have turned to the Hippo pathway as a potential therapeutic mechanism for preventing this disease.

Hippo-YAP signaling is related to DR and regulates regeneration of chronic liver disease by determining cellular fates. One study found that YAP levels were increased in NAFLD patients and mice and were primarily localized in the nucleus of DRCs that expressed progenitor markers, correlating with the degree of fibrosis. This suggests that Hippo/YAP signaling is associated with DR and promotes liver fibrosis rather than effective liver regeneration during NASH[43]. In DDC-injured livers, YAP activation occurs in the process of hepatocyte degeneration, and loss of YAP in hepatocytes results in a significant decrease in DR post-DDC injury. In addition, lineage traced hepatocytes in mice showed that YAP was necessary for hepatocytes to form duct-like structures after DDC injury[44]. In several DR mice models, YAP signaling occurred in CK19+ BEC (facultative liver stem cells) and periportal hepatocytes around the portal vein were activated, confirming that YAP was important for BEC expansion and organoid formation and growth. In mice lacking YAP, Sox9 expression in hepatocytes around the portal vein did not increase significantly, and BEC proliferation was significantly reduced. This indicates that YAP mediates the transdifferentiation of Sox9+ hepatocytes and promotes BEC expansion[45]. Another study showed that Hippo signaling could reprogram hepatocytes into ductal cells with characteristics of hepatic progenitors, supporting the idea that YAP could dedifferentiate hepatocytes and reprogram them into cholangiocytes *via* HPCs[46]. Taken together, these findings indicate that the YAP-driven transcriptional program is critical for liver regeneration and hepatocyte reprogramming towards a progenitor, biliary-like fate following liver injury.

In addition, TAZ levels are elevated in NASH patients and mice. When TAZ is silenced, liver inflammation, fibrosis, and cell death are suppressed in NASH mouse models. In contrast, TAZ expression in hepatocytes induces the Indian Hedgehog (Ihh) pathway in mice, promoting pro-fibrotic gene expression in HSCs and mediating the DR process. Both *in vitro* and *in vivo* data indicate that TAZ promotes NASH progression in hepatocytes largely by inducing the Ihh pathway, while silencing TAZ reverses liver inflammation and fibrosis, with the exception of steatosis[47]. In summary, the Hippo-YAP/TAZ signaling pathway provides a potential therapeutic target to prevent the progression of NAFLD to NASH or improve liver fibrosis when NASH is already occurring.

Wnt-β catenin signaling in NASH

Wnt was first discovered in Drosophila, and the canonical Wnt signaling pathway was defined as the Wnt-β-catenin mediated transcription pathway. Wnt ligand binds to Frizzled and co-receptor LRPs and blocks β-catenin degradation, causing the transcription of target genes in a T-cell factor/lymphoid enhancer factor dependent manner[48]. Wnt/β-catenin signaling is important for HPC and hepatoblast

proliferation and final differentiation into mature hepatocytes and for maintaining bile duct homeostasis. In the adult liver, Wnt signaling is only activated in hepatocytes around the central vein, and maintains a static state in other areas of the liver. When hepatocytes are impaired, Wnt-β catenin signaling is activated[49,50]. The β-catenin-T cell factor complex regulates cyclin expression and induces the cell-cycle G1/S transition, promoting liver regeneration[51].

β-catenin induces insulin resistance by interacting with FoxO1 during gluconeogenesis, promoting NASH. Inhibiting Wnt signaling reduces body lipid content, inhibits liver gluconeogenesis, and increases hepatic insulin sensitivity in NASH mice. These findings suggest that Wnt/β-catenin signaling is related to NASH pathogenesis[52]. Wnt/β-catenin signaling may induce DRC differentiation into hepatocytes, and inhibiting this pathway may improve liver cirrhosis. Wnt levels are higher in the area around the portal vein following continuous damage, suggesting that Wnt/β-catenin signaling regulates hepatobiliary repair[53]. Studies indicate that CK19+ DRCs are regulated by Notch signaling and finally differentiate into cells in the biliary system. Wnt/β-catenin signaling may change the fate of biliary-derived DRCs and instead induce their differentiation into hepatocytes, aiding liver regeneration. However, some studies suggest that DRCs make little contribution to liver regeneration, and Wnt/β-catenin signaling cannot alter DRC differentiation[54]. The differentiation of quiescent HSCs into active myofibroblasts is similar to the dedifferentiation of adipocytes into preadipocytes (loss of adipogenic properties), requiring Wnt/β-catenin signaling. In turn, inhibition of Wnt/β-catenin signaling can block liver fibrosis[52]. The effect of Wnt/β-catenin signaling on the repair of liver damage through DRC proliferation provides a new potential research target for hepatobiliary diseases. However, a more comprehensive understanding of the mechanism by which DRCs and Wnt/β-catenin signaling contribute to hepatobiliary regeneration and repair remains unclear, and more studies are needed to determine whether Wnt/β-catenin signaling regulates DRC differentiation[27].

Hh signaling in NASH

Hh was first discovered in drosophila and shown to be critical for promoting tissue development and maintaining homeostasis. There are three Hh ligands, sonic hedgehog (Shh), Ihh, and desert Hh. In the canonical Hh signaling pathway, Hh ligand binding to the transmembrane receptor relieves its inhibitory effect on smoothed, activating the transcriptional mediator glioma-associated oncogene homologues, Glis (Gli1, Gli2, and Gli3). Gli1 is a signal amplifier of Gli2-mediated transcriptional responses, Gli2 is the primary activator of Hh signaling, and Gli3 is responsible for inhibits Hh signaling. Gli1/2 or Gli3 bind to DNA in the nucleus and regulate the transcription of target genes. The Hh pathway plays an important role in hepatic injury repair and fibrogenesis by regulating HPC and mesenchymal cell proliferation and/or differentiation[55,56].

There are multiple mesenchymal cell types that exist in the liver, of which HSCs play a major role in liver fibrosis. In healthy adult liver, liver resident cells produce few Hh ligands and resting HSCs produce Hh inhibitors. As a result, the Hh signaling pathway is relatively quiescent[57,58]. Hh signaling induces HSCs and Gli1+ peribiliary mesenchymal cell proliferation and acquisition of a myofibroblast phenotype responsible for ECM deposition, thus contributing to fibrosis during chronic liver disease[57,59]. Hh signaling recruits bone marrow-derived monocytes to the liver and promotes their transformation into fibrocytes and induces the epithelial-mesenchymal transition in DRCs in response to chronic liver injury[60]. Hepatocytes are the main source of Shh ligands and in the carbon tetrachloride-induced DR model, Shh and Hippo-YAP1 activity are upregulated and correlate with the regulation of DRC fate for liver regeneration. Shh downstream molecular inhibitor, Gant61, can reduce Shh and Yap signaling thereby inhibiting DR and improving liver injury[61]. Thus, Hh signaling is important for the development of antifibrotic therapies because of its potential to regulate the fibrotic process and interact with the Hippo-YAP signaling pathway.

HGF/c-Met signaling in NASH

HGF is a pleiotropic growth factor derived from non-parenchymal cells. HGF combines with the c-Met to activate multiple intracellular signaling pathways that impact cell proliferation, migration, and differentiation. HGF acts as an essential cell mitogen, motogen, and morphogen and plays an important role in mesenchymal-epithelial transformation. C-Met is a receptor tyrosine kinase that activates cell growth and morphogenesis, and HGF/c-Met signaling is strongly associated with epithelial, mesenchymal, and hematological malignancy[62].

HGF expression is upregulated in mice with partial liver excision, promoting liver cell division and maturation. Animal studies have shown that knocking out c-Met during embryonic development hinders liver development and can even result in death. The absence of c-Met and epidermal growth factor receptors arrests liver regeneration and can cause mice to die following partial hepatectomy. These findings highlight the importance of HGF/c-Met signaling in liver regeneration and protection [63,64]. Experiments indicate that HPCs can express c-Met. Inhibiting c-Met phosphorylation inhibits HPC proliferation and the transdifferentiation of hepatocytes into cholangiocytes[65]. HGF also enhances collagenase activity. When the liver is severely damaged, HGF expression is up-regulated, increasing the degradation of collagen fibers and the inhibiting liver fibrosis[66]. HGF induces hepatic progenitor marker gene expression and promotes hepatocyte proliferation and HPC conversion into hepatocytes[67]. These findings suggest that HGF/c-Met signaling can promote regeneration and

improve fibrosis during chronic liver injury.

TWEAK/Fn14 signaling in NASH

TWEAK is a member of the tumor necrosis factor ligand superfamily. Once bound to its receptor, Fn14 participates in many pivotal cellular activities like tissue inflammation, damage repair, cell survival, and death. TWEAK is produced by many myeloid and immune cells and Fn14 is upregulated by fibroblast-like growth factor and other factors associated with injury and inflammation. While the physiological role of the TWEAK/Fn14 axis is to protect against tissue injury, excessive production of TWEAK or Fn14 can drive and orchestrate inflammation, fibrosis, and tissue remodeling[68]. Previous studies show that TWEAK can promote collagen production and pro-inflammatory cytokine secretion and regulate HSC senescence and migration[69].

TWEAK is widely expressed in adult tissue including activated monocytes, natural killer cells, and macrophages in the liver. TWEAK is a direct mitogen to HPCs, and TWEAK/Fn14 signaling can activate NF-κB and STAT3 signaling to increase pro-inflammatory cytokine secretion during liver disease[70]. Fn14 expression is relatively low in resting HSCs, but during chronic liver injury, Fn14 is highly expressed in HPCs and activated HSCs[71]. TWEAK promotes HSC migration through activation of the EGFR/Src and PI3K/AKT pathways, which are important for liver fibrogenesis[69]. One study demonstrated that Fn14-deficient mice treated with a choline-deficient, ethionine-supplemented diet had diminished HPC proliferation, inflammation, collagen deposition, and profibrotic cytokine production that resulted in considerably more mild liver fibrosis[72,73]. Given its effect on pathological remodeling, HSC migration, and pro-inflammatory cytokine expression, TWEAK/Fn14 signaling may serve as a potential strategy of antifibrotic treatment strategy for NASH by regulating HPC proliferation and fibrogenesis.

Signaling pathway crosstalk

Recent studies have supported the view that there is an interactive network between different signaling pathways to regulate DR during NASH. Signaling pathways such as the Hippo/YAP, Wnt/β-catenin, Shh pathway can interact with Notch signaling directly or indirectly to regulate cellular gene expression. Wnt/β-catenin promotes DRCs to differentiate into hepatocytes and inhibits Notch signaling[74]. Both *in vitro* and *in vivo* data indicate that hepatocyte TAZ promotes NASH progression in large part by inducing Ihh signaling, playing an important role in fibrogenesis[47]. Notch signaling is one important downstream YAP target in liver cells[46]. Hippo/YAP-TAZ can upregulate Notch ligands or cooperate with Notch signaling to manipulate target genes in DR[75]. These signaling pathways have distinct roles in DR, including regulating proliferation and transdifferentiation of hepatocytes, cholangiocytes, and HPCs, activating HSCs and fibrogenesis. These pathways can enhance or weaken each other's effects through complicated signaling networks which will require more in-depth understanding and research.

CONCLUSION

In summary, the DR is a response to the bile duct phenotype during liver injury, which aims to restore liver homeostasis and promote regeneration during chronic liver injury by regulating HPC, cholangiocyte, and hepatocyte proliferation and differentiation. The DR plays an important role in NAFLD pathogenesis and promotes the occurrence and development of NASH and liver fibrosis. It is shown that Notch, Hippo/YAP, Wnt/β-catenin, Hh, HGF/c-Met, TWEAK/Fn14, and other intracellular signaling pathways interact with each other to form a crosstalk network, which is related to the DR. In chronic liver disease, these signaling pathways can affect liver inflammation, regeneration, HSC activation, and collagen deposition by regulating corresponding target gene expression. Several molecular inhibitors and modulators are being considered for anti-fibrotic treatment during NASH. While the specific mechanisms for these signaling pathways require more exploration, NASH treatment looks promising in near future.

Abstract

BACKGROUND

The machine perfusion (MP) preservation including hypothermic MP (HMP) and midthermic MP (MMP) has been considered as a promising strategy to preserve the functions of liver donated after cardiac death. The importance of understanding liver sinusoidal endothelial cells (LSEC) damage in regulating liver injury during MP has been emphasized. However, the ultrastructural changes in the LSEC and sinusoids around them after MP are unclear.

AIM

To investigate the ultrastructural changes in the LSEC and sinusoids around them after MP.

METHODS

Porcine liver grafts undergo a warm ischemia time of 60 minutes perfused for 4 h with modified University of Wisconsin gluconate solution. Group A grafts were preserved with HMP at 8 °C constantly for 4 h. Group B grafts were preserved

with a rewarming solution at 22 °C by MMP for 4 h. Then the ultrastructural changes in the LSEC and sinusoids in Group A and B were comparatively analyzed by using osmium-maceration scanning electron microscopy with complementary transmission electron microscopy methods.

RESULTS

An analysis of the LSEC after warm ischemia revealed that mitochondria with condensed-shaped cristae, abnormal vesicles, reduction of ribosomes and the endoplasmic reticulum (ER) surround the mitochondria appeared. The MP subsequent after warm ischemia alleviate the abnormal vesicles and reduction of ribosomes in LSEC, which indicated the reduction of the ER damage. However, MMP could restore the tubular mitochondrial cristae, while after HMP the condensed and narrow mitochondrial cristae remained. In addition, the volume of the sinusoidal space in the liver grafts after MMP were restored, which indicated a lower risk of pressure injury than HMP.

CONCLUSION

MMP alleviates the ER damage of LSEC by warm ischemia, additionally restore the metabolism of LSEC *via* the normalization of mitochondria and prevent the share stress damage of liver grafts.

Key Words: Liver; Sinusoidal endothelial cells; Warm ischemia; Machine perfusion preservation; Transplantation; Ultrastructure

Core Tip: The importance of understanding liver sinusoidal endothelial cells (LSEC) damage in regulating liver injury during machine perfusion (MP) preservation has been emphasized. Here, we comparatively analyzed the ultrastructural changes in the LSEC and sinusoids around them at four hours after hypothermic MP (HMP) or midthermic MP (MMP). MP alleviated the ER damage of LSEC caused by warm ischemia. Moreover, MMP temperature conditions restore the metabolism of LSEC *via* the normalization of cristae of mitochondria and prevent the damage of the liver graft by share stress.

INTRODUCTION

The shortage of brain-dead donors for liver grafts is a serious problem worldwide[1]. One way to expand the donor organ liver pool is by using grafts with extended criteria including liver donated after cardiac death (DCD)[2-4]. However, there is a high risk of acute and chronic liver injury of primary nonfunction caused by ischemia-reperfusion injury after transplantation of DCD liver grafts[5]. Thus, the development of the preservation methods of the liver grafts after cardiac death is required to overcome these problems[1].

The superiority of machine perfusion (MP) preservation to simple cold storage was reported in clinical kidney preservation[6]. Similarly, strategies as MP with oxygen and nutrition-containing solution have also been reported to have numerous advantages to liver transplantation[7,8]. On the other hand, the MP of the DCD grafts has been discussed about the optimal conditions including perfusion temperature, oxygenation, flow rate and pressure, steady or pulsatile flow. Recently, hypothermic machine perfusion (HMP) has been established to preserve the functions of liver grafts, and its application in clinical practice has begun[9].

In addition, the warm MP including midthermic MP (MMP) has also been reported as a promising strategy to maintain the liver graft function to avoid cold ischemic injury and possibly repair the metabolic activity compared to HMP[10,11]. Our previous study also indicated the utilization of MMP reduces the hepatocellular enzyme release to perfusate[12]. We further confirmed that hepatocytes and bile canaliculi of DCD liver grafts after MMP retain a functional ultrastructure compared to HMP, by using scanning electron microscopy after osmium-maceration (OM-SEM) with complementary transmission electron microscopy (TEM)[9,13]. These results showed the practicality of OM-SEM with complementary TEM not only for determining 3D detailed ultrastructure in porcine hepatocytes but in evaluating the function of the transplanted liver which is reflected by ultrastructural characteristics of hepatocytes.

In addition to hepatocyte and bile canaliculi, the importance of liver sinusoidal endothelial cells (LSEC) damage in regulating liver injury during MP has been affirmed[14]. The inferior outcomes following extended criteria donor liver transplantation are thought to be endothelial dysfunction-related, however, it ultimately culminates in early graft dysfunction[14]. Thus, in this study, we comparatively analyzed the ultrastructural changes in the LSEC and sinusoids around them at four hours after HMP or MMP by using OM-SEM with complementary TEM methods. As a consequence, the LSEC that regressed one hour after warm ischemia showed a tendency to recover after MP, especially in MMP, suggesting the preventative effects of HMP and MMP on LSEC-related functions in liver grafts.

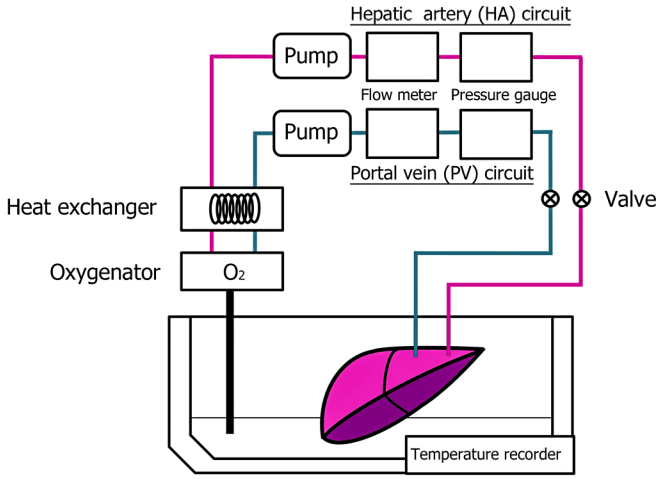
MATERIALS AND METHODS

Antibody

Rabbit anti-ERG monoclonal antibody was purchased from Nichirei Bioscience Corporation (Tokyo, Japan; clone EP111) for chromogenic visualization of viable LSEC in liver grafts and observation by bright field microscopy.

Animals

Domestic female porcine (cross-bred Large White, Landrace, and Duroc pigs; age, 2-3 mo; body weight, approximately 25 kg) from Taisetsusanroku-sya Co., Ltd. (Asahikawa, Japan). The animals were kept in a well-ventilated and temperature/humidity controlled room (in which a light on 12-h cycle), and ad libitum access to food and water. All animal work was performed according to the Guide for the Care and Use of Laboratory Animals at Asahikawa Medical University. All animal studies and procedures were approved by the Institutional Animal Ethics Committee of the Clinical Research Center, Asahikawa Medical University (permit No. 14172).



MP

The harvested porcine liver was perfused with MP systems (Figure 1), as described previously[9,13]. This system consists of 2 separate circulating perfusion circuits for the hepatic artery (HA) and portal vein (PV), where each has a roller pump, a pressure sensor, and a flow meter connected to a separate circulation system *via* plastic connectors, allowing pulsatile and non-pulsatile flow, respectively. A gas blender attached to the oxygenator mixes air with oxygen is installed to the PV and HA circuit. Both circuits were connected to the hepatic vessels *via* plastic connectors and oxygen concentration was perfused and maintained at PO2 200-300 mmHg, where they are monitored by using dissolved oxygen meter installed. Waterproof thermocouples were installed in the perfusion systems to measure the solution temperature, and the heat exchanger was installed in the systems where ice-cold water controls the temperature in the organ chamber. As described previously, the flow rate was controlled as 0.22 mL/min/g for the PV and 0.06 mL/min/g for the HA[9,13].

Preparation and preservation of the liver donated after cardiac death

Pigs weighing approximately 25 kg were used as liver graft donors. In this study, the animals were intubated and ventilated under inhalation anesthesia with isoflurane (Forane; Abbott, Japan), and laparotomized. Immediately after laparotomy, the tissue samples were biopsied from the liver surface as a control. Then the animals were injected with potassium chloride intravenously to induce cardiac arrest followed by the removal of ventilation, as described previously[9,13]. The time of the induction of cardiac arrest was set as the point of 0 min of warm ischemia. During warm ischemia, the HA and PV were isolated from the surrounded tissues to connect with organ flush lines. After 60 min of warm ischemia, the tissue samples of the liver were biopsied from distinct regions of the liver surface. Immediately after tissue sampling, the liver grafts that were procured were initially flushed with a Euro-Collins solution that is less viscous *via* the HA and PV routes at 8 °C as a back table operation. After the operation, the organ flush lines were connected to the perfusion preservation machine systems, and the liver was continuously perfused for 4 h with a modified University of Wisconsin gluconate solution, described previously[9]. The liver grafts were conserved as two groups, A and B. The grafts in group A were perfused at a constant temperature of 8 °C as HMP (n = 3), on the other hand, the grafts in group B were gradually warmed from 8 °C to 22 °C during perfusion as MMP (n = 3), as described previously[13]. After 4 h of MP, liver tissue samples in each group were collected from the well-perfused area of the surface of liver grafts. All the blocks of liver samples were immediately fixed with appropriate fixative for the analysis as described below.

The viability of LSEC in liver grafts preserved for 4 h was evaluated by hyaluronic acid (HyA) levels in perfusate collected from the suprahepatic vena cava as described previously[15]. These results in the text and figures are expressed by the means ± SEM. Comparisons of the significance of differences between each MP group A and B were performed by using unpaired two-tailed *t*-tests.

Figure 1 Schematic representation of the continuous machine perfusion preservation system.

Immunohistochemistry

The tissue samples biopsied from the liver of porcine were immediately immersed into 10% buffered formalin subsequently embedded in paraffin. The paraffin-embedded samples were sectioned into 4 μm slices and mounted on microscope glass slides. After the paraffin was removed by xylene, these tissue slices were rehydrated with series of graded ethanol, subsequently transferred into EDTA (pH 9.0) for antigen retrieval. After washing with PBS, the tissue slices were incubated in 0.3% hydrogen peroxide in methanol for 15 min, subsequently transferred into SuperBlock Blocking Buffer for 20 min as blocking. After these treatments, the tissue slices were incubated in a dilution (1:10) of primary antibody for 1 h at room temperature. Then the tissue slices were visualized by the Envision system (DAKO; Glostrup, Denmark), counterstained by using the hematoxylin. After the dehydration with a series of graded ethanol and xylene, the tissue slices were mounted with Malinol. The sections were observed by light microscopy.

TEM

The biopsied tissue samples from the liver of porcine were cut into small pieces and immersed in the fixative mixture of 2% glutaraldehyde (GA)/2% paraformaldehyde (PFA) in 0.1 M phosphate buffer (PB, pH 7.4) for 2 h at 4 °C. After washing with 0.1 M PB containing 7.5% sucrose, the samples were post-fixed with 1% osmium tetroxide (OsO4) in 0.1 M PB for 2 h at 4 °C. After washing with 0.1 M PB containing 7.5% sucrose, the samples were dehydrated in a series of graded ethanol solutions (starting with 50% and increasing to 100% ethanol). Then the samples were embedded in epoxy resin (Epon 812). Ultrathin sections (80 nm thick) from the embedded samples in Epoxy resin were cut using a diamond knife. The sections were observed by using TEM (HT7700; Hitachi High Technologies Inc., Tokyo, Japan) without staining by uranyl acetate and lead citrate.

OM-SEM

The osmium maceration method was described previously[9,13]. In brief, the biopsied liver tissue samples of porcine were incised into small pieces and fixed with a fixative mixture of 0.5% GA/0.5% PFA in 0.1 M PB (pH 7.4), for 30 min at 4 °C. Then the tissue samples were fixed with 1% OsO4 in 0.1 M PB for 6 h at 4 °C. After washing thoroughly with 0.1 M PB, the samples were immersed into 25% dimethyl sulfoxide (DMSO) for 30 min and subsequently 50% DMSO for 30 min as cryoprotection. Cryoprotected samples were frozen on a precooled aluminum plate chilled with liquid nitrogen. The frozen tissue samples were fractured into two pieces by using a 2.0 mm flathead screwdriver and a hammer. After freeze-fracture, the samples were transferred into 50% DMSO again for thawing, washed with 0.1 M PB, and then immersed into 0.1% OsO4 in 0.1 M PB solution for 96 h at 20 °C under the light for osmium maceration. After osmium maceration, the tissue samples were further fixed with 1% OsO4 in 0.1 M PB for 1 h at 4 °C. The samples were then washed thoroughly with 0.1 M PB before being conductive stained with 1% tannic acid in 0.1 M PB and subsequently with 1% OsO4 in 0.1 M PB. Then the samples were dehydrated in a series of graded ethanol solutions (starting 70% and increasing to 100% ethanol) and immersed in t-butyl alcohol and dried in a freeze dryer (ES2030; Hitachi High Technologies Inc., Tokyo, Japan). The dried specimens were then mounted onto an aluminum plate with silver paste and received the surface coating with platinum-palladium in an ion sputter coating equipment (E1010; Hitachi High Technologies Inc., Tokyo, Japan). After all the processes said were completed, the specimens were evaluated by using a field emission scanning electron microscopy (FE-

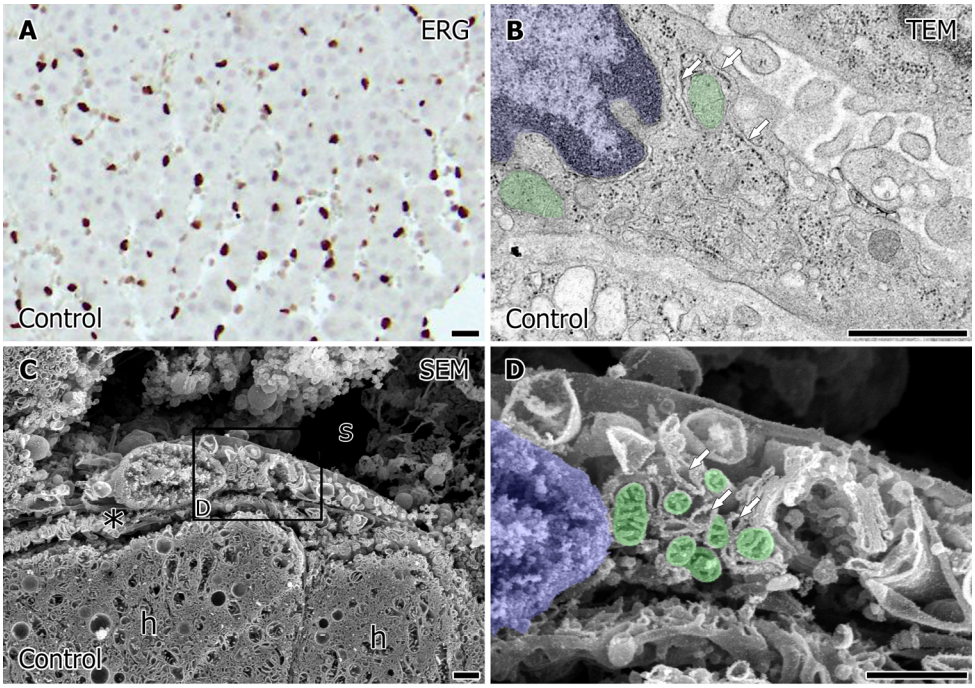
SEM, S4100; Hitachi High Technologies Inc., Tokyo, Japan).

RESULTS

Localization and ultrastructural characteristics of liver sinusoidal endothelial cells in the porcine liver

In the porcine liver, the interspersed ERG positive sinusoidal endothelial cells were observed (Figure 2A). Observation of the intercellular ultrastructure of the sinusoidal endothelial cells by TEM showed that the rough endoplasmic reticulum formed narrow networks of lumens (Figure 2B, arrow), and cytoplasmic vesicles or caveolae occasionally open to the plasma membrane. LSEC had abundant free-ribosome in their cytoplasm and the small sausage-shaped mitochondria (Figure 2B, green) localized around the nucleus (Figure 2B, blue). Observation utilized by SEM revealed more detailed ultrastructural characteristics of LSEC. Low magnified observation showed the flat-shaped LSEC lined the sinusoids (Figure 2C). Also, the space of Disse presented the normal appearance in which apical microvilli of the hepatocytes protruded. In high magnification by SEM, LSEC had the network of rough endoplasmic reticulum and vesicles correspond to TEM observation. In LSEC, mitochondria (Figure 2D, green) had tubular or plate-formed cristae sparsely arranged identified around the nucleus (Figure 2D, blue).

Changes of intracellular ultrastructure in LSEC after warm ischemia



Even after warm ischemia, ERG-positive viable LSEC was detected in liver grafts similar to the samples before warm ischemia (Figure 3A). However, the ultrastructural characteristics of LSEC were substantially changed after warm ischemia. TEM observation revealed that LSEC had a slightly expanded rER, lysosome-like structure, and numerous vesicles. Furthermore, it appears to have a decrease of free ribosomes from the cytoplasm of LSEC (Figure 3B) and membranous structure (Figure 3B, arrowhead) surrounding mitochondria (Figure 3B, green) at the peripheral region from the nucleus (Figure 3B, blue). Low magnified SEM observation showed the LSEC-covered sinusoid in liver grafts after warm ischemia; however, its lumen was reduced reflecting the loss of blood flow (Figure 3C). Additionally, the space of Disse between LSEC and hepatocytes (Figure 3C) was reduced and microvilli were regressed. High magnified SEM observation revealed that a slightly expanded network of rER (Figure 3D, arrow) and numerous vesicles in LSEC. Around the nucleus (Figure 3D, blue), small mitochondria with densely distributed tubular cristae (Figure 3D, green) were surrounded by rER (Figure 3D and D′, arrowhead).

Comparison of ultrastructural changes in LSEC after HMP or MMP

An immunohistochemical study for ERG showed similarly viable LSEC in liver grafts after 4 h for both HMP and MMP (Figures 4A and 5A). The value of HyA in the perfusate did not indicate a significant difference between HMP and MMP. However, there was a trend of improvement in MMP (Supplementary Figure 1, 38.33 ± 8.88 HMP_4h *vs* 26.00 ± 3.46 ng/mL MMP_4h, $P = 0.27$). Furthermore, the ultrastructural characteristics of LSEC after each MP also showed a difference (Figures 4 and 5). TEM observation of LSEC after 4 h of HMP showed that small globular mitochondria and the slightly expanded network formation of rER localized in the cytoplasm (Figure 4B, arrow). Besides, intracellular vesicles and free ribosomes in LSEC after HMP were decreased from the point of warm ischemia 1 h. Low magnified SEM observation showed that the lumen of the sinusoids (Figure 4C) were lined by LSEC, although there were scarcely spaced cavities of Disse between the LSEC and hepatocytes (Figure 4C). At higher magnification, intracellular expanded rER networks were observed in LSEC. Besides, the spherical mitochondria (Figure 4D, green) had densely but shrinking tubular cristae and remained localized around the nucleus (Figure 4D, blue). On the other hand, after 4 h of MMP, expanded rER (Figure 5B, arrow) and the network of endomembranous structures that had a smooth surface and expanded lumen with high electron density simultaneously appeared in LSEC by TEM observation (Figure 5B, red). Moreover, LSEC had the relatively abundant interspersed free-ribosomes in their cytoplasm and mitochondria with sausage-like formation neighboring to the nucleus (Figure 5B). Observation by SEM revealed more detailed intrahepatic ultrastructure containing LSEC. In low magnification, sinusoids of liver grafts after 4 h of MMP tend to enlarge and form the cavity of Disse than that of HMP (Figure 5C). High-magnified SEM observation revealed that LSEC had the expanded rER attached to the surface-smoothed vacuolar structure in the cytoplasm (Figure 5D). Furthermore, the mitochondria with regularly arranged cristae localized around the nucleus in LSEC take a form of sausage-like structure again (Figure 5D, green).

DISCUSSION

In this present study, we confirmed the usefulness of the OM-SEM with complementary TEM for the description of the ultrastructure of organelles in LSEC. Based on this, we revealed the intracellular

ultrastructural characteristics of porcine LSEC post warm ischemia after HMP and MMP preservation by utilizing osmium maceration for SEM and complementary TEM methods.

OM-SEM observation could demonstrate the 3-dimensional architecture of mitochondria cristae in porcine LSEC (Figure 1D). Previous studies using OM-SEM analyzed the intracellular ultrastructure of hepatocytes including bile canaliculi but did not describe the porcine LSEC[9,13,16]. Our data revealed for the first time that the mitochondria in porcine LSEC have tubular cristae with a relative expansion of matrix. The orthodox-shaped mitochondrial cristae are thought to reflect the state of Low ADP[17].

The distribution of anti-ERG antibody-positive cells which indicate viable LSEC in the liver after 60 min of warm ischemia does not differ from normal, which is consistent with our previous report[18]. Nevertheless, the intracellular ultrastructural characteristics of LSEC were altered after warm ischemia. Our data revealed that mitochondria with condensed-shaped cristae, vesicles, and the ER surround the mitochondria appeared in the LSEC after warm ischemia (Figure 3D and D′). It is known that LSECs are specifically sensitive to energy deficiency[19]. The condensed-shaped cristae of mitochondria reflect an energy substrate deficiency[17]. During warm ischemia, the lack of energetic substrate interferes with active transmembrane transport in LSEC[20]. ER injury of LSEC also precedes mitochondrial disintegration in the setting of warm ischemia[4]. Damaged ER may cause the appearance of vesicles and vacuoles in LSEC after warm ischemia[21,22]. These suggest that warm ischemia impaired the membrane transport between the ER and mitochondria consequently caused morphological distortion of ER including vesiculation and membranes surrounding mitochondria.

The MP after warm ischemia alleviates the abnormal vesicles and promotes the reduction of ribosomes in LSEC (Figures 4 and 5). In previous studies, it was indicated that LSEC injury reduces liver viability, and MP protects against and alleviates the effects of endothelial injury at the ultrastructural level[23-25]. One of the potential protective factors of our machine perfusion systems is the early hypothermic period. The lowest degree of damage on LSEC using electron microscopy was seen at the 4 and 25 °C of machine perfusion groups[26]. Hypothermic state of machine perfusion rescue DCD livers subjected to prolonged warm ischemia *via* downregulation of LSEC activation[27]. The flow of machine perfusion is also another potential protective factor. The flow stasis leads to acute endothelial dysfunction and apoptosis *via* rapid loss of shear-stress-dependent KLF2 in LSEC[28]. Machine perfusion which triggers protection of LSEC *via* upregulation of shear stress-sensitive protective genes [29], consequently may alleviate the ultrastructural abnormalities shown by the present study. Furthermore, the high oxygen availability during machine perfusion also maintains the structural integrity of LSEC[30]. Short-term oxygenated perfusion potentially reduces the risk of a possible release

of reactive oxygen species and endothelial shear stress[4]. Consistent with these studies, our present study showed that MP alleviates the ultrastructural abnormalities that appeared in LSEC after warm ischemia.

After warm ischemia, MMP restores the tubular mitochondrial cristae, while after HMP the condensed and narrow mitochondrial cristae remained (Figures 4 and 5). This is consistent with the finding of the previous study that the hepatocyte preserved by HMP has strongly swollen mitochondria, in contrast, MMP could preserve the functional appearance of mitochondria in hepatocytes[13]. These differences of findings rely on the temperature condition during MP. The ultrastructural feature of mitochondria with narrow cristae which appeared after HMP is similar to mitochondria observed in LSEC after cold incubation in UW solution *in vitro*[31]. During hypothermia, LSEC undergoes a cold-induced decrease in mitochondrial membrane potential and finally loses viability and induces apoptosis [31-33]. Similarly, *in vivo*, the HMP compromises liver grafts by prompting cold-induced damage to LSEC[34]. HMP led to a significant slowdown of mitochondrial respiration rate[33], therefore, interrupting the balance of oxygen supply/demand of LSEC. Furthermore, the reduction of membrane fluidity induced by continuous cool perfusion temperatures of HMP was examined in a previous study [35]. Extended times of HMP may also be subject to disadvantages and limitations concerning endoplasmic stress and alteration of LSEC[16].

On the other hand, the controlled oxygenated rewarming, similar to MMP, was reported to significantly increase gene expression and protein levels of the autophagy-related beclin-1 in liver grafts [11]. Electron-dense endomembranous structure that appears in LSEC after MMP resembles autophagolysosome which suggests that the LSEC is protected by autophagy[36]. The restored tubular orthodox-shaped mitochondrial cristae in LSEC after MMP (Figures 5B and D), could supply more appropriate energy to match the demand of intracellular function of LSEC. MMP perfusate tends to have lower HyA levels compared to HMP (Supplementary Figure 1) supports the justification of LSEC has more functional integrity after MMP[15].

In addition to hypothermia, fluid shear stress can further aggravate the damage in LSEC after HMP[7, 37]. It was observed that the reduction of the space of Disse in the liver grafts after HMP may be the cause of the pressure injury (Figures 4 and 5). Liver sinusoids are also known to be very sensitive to endothelial shear stress because LSEC is easily damaged by high pressure[38,39]. Endothelial injury by shear stress is the main risk of HMP[4,24,37,40]. Vascular perfusion of the liver at 4 °C induces vasoconstriction of the hepatic vasculature[41] and alters LSEC, which is vulnerable to hypothermia[31]. Morphological changes in LSEC structures and increased vascular resistance in the liver graft occurred

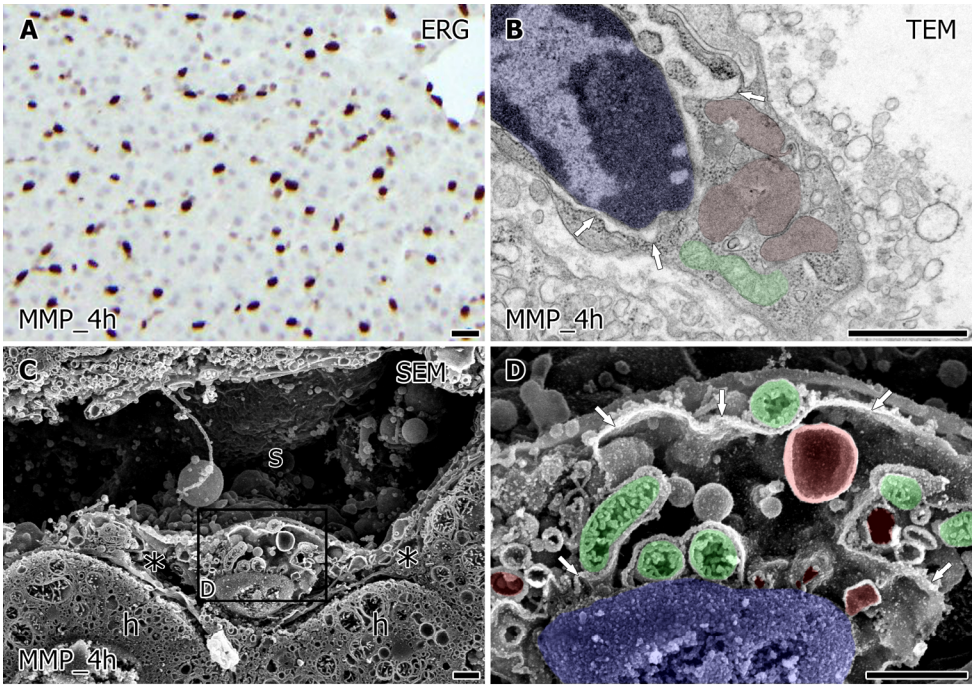
TEM: Transmission electron microscopy; SEM: Scanning electron microscopy.

during HMP, which obstruct the sinusoidal flow[37]. In the present study, the LSEC after HMP was observed as flat-shaped, which consistent with the findings reported by Chai *et al*[42].



In contrast to the HMP, our previous study showed that the pressure transitions of the HA decrease in the initial stage of MMP[12], which suggests the lower risk of shear stress in LSEC after MMP. In the present study, we showed that the volume of the sinusoidal space in the liver grafts after MMP was restored as control liver, which suggests that the decreased vascular resistance *via* sinusoidal space enlargement led to reducing the risk of pressure injury in MMP.

This present study has several limitations. First, the condition of MP including temperature during perfusion should be more refined for clinical application. Similar to the previous study of allogenic transplantation of porcine liver grafts under similar conditions as this study[18], the present MMP condition is not suitable for clinical transplantation. Our previous studies suggested that the liver grafts preserved by MMP suffered damage to some extent[13]. The MP with rewarming gave a more promising alternative, as many results preferring these temperature settings were reported in previous studies[43]. Furthermore, previous studies suggest that oxidative stress and endothelial shear stress can be reduced by modulating the perfusion temperature and oxygenation[44]. However, the rewarming velocity of liver grafts, the critical temperature, and the appropriate period of warm temperature needed to adjust metabolic parameters are yet to be sufficiently defined[43]. Therefore, the ultrastructural characteristics of the LSEC preserved by a better-modified MP method should be analyzed in future studies.

However, this study did not evaluate the ultrastructural characteristics of the LSEC in the liver monitored after MP for evaluation of the ischemic reperfusion injury. The most marked destructive changes of ultrastructure in LSEC are seen during reperfusion[45]. Thus, the results of the present study should be further investigated by future studies utilized normothermic reperfusion ex-situ.

CONCLUSION

In conclusion, MP preservation alleviated the ER damage of LSEC caused by warm ischemia. Moreover, MMP temperature conditions restore the metabolism of LSEC *via* the normalization of cristae of mitochondria and prevent the damage of the liver graft by share stress. In the future, more appropriate MP conditions clinically to preserve the LSEC functions of the liver grafts should be established by

using normothermic reperfusion machine systems. Further analysis of detailed mechanisms of the ultrastructural changes in LSEC under various conditions, including different levels of oxygenation and different temperatures, during perfusion storage, is required for the application of MP to clinical transplantation.

ARTICLE HIGHLIGHTS

Research background

Using liver grafts donated after cardiac death (DCD) is one way to solve the shortage of donors for liver transplantation. Machine perfusion (MP) preservation has been considered as a promising, and the optimal conditions of perfusion temperature of MP of the DCD grafts, including hypothermic MP (HMP) and midthermic MP (MMP) has been discussed.

Research motivation

Recent research showed the practicality of scanning electron microscopy after osmium-maceration (OM-SEM) with complementary transmission electron microscopy (TEM) in evaluating the function of the liver grafts which is reflected by ultrastructural characteristics of hepatocytes. This has prompted the application of this novel strategy for the evaluation of liver sinusoidal endothelial cells (LSEC) damage in regulating liver injury during MP.

Research objectives

The present study aimed to establish the usefulness of the OM-SEM with complementary TEM for the evaluation of LSEC damage, and comparatively investigate the ultrastructural changes associated with LSEC at 4 h after HMP or MMP.

Research methods

Female pigs were intubated and ventilated under anesthesia, and their liver tissues were biopsied immediately after laparotomy, as control, and 60 min of warm ischemia. The liver grafts which had warm ischemia of 60 min were perfused for 4 h with modified University of Wisconsin gluconate

solution by HMP at 8 °C constantly or MMP rewarming up to 22 °C and biopsied at the endpoint of MP. the LSEC in all biopsied liver samples were analyzed by immunohistochemistry and OM-SEM with complementary TEM. The viability of LSEC in liver grafts preserved for 4 h was evaluated by hyaluronic acid levels in the perfusate.

Research results

Immunohistochemistry showed the interspersed viable ERG positive sinusoidal endothelial cells in all biopsied liver samples. After warm ischemia, the LSEC showed the mitochondria with condensed-shaped cristae, abnormal vesicles, reduction of ribosomes and the ER surrounding the mitochondria. Both the HMP and MMP after warm ischemia alleviate the ER damage in LSEC indicated by the abnormal vesicles and reduction of ribosomes. The value of HyA in the perfusate did not indicate a significant difference between HMP and MMP, although there was a trend of improvement in MMP, moreover, only MMP, not HMP, could restore the tubular cristae of mitochondria.

Research conclusions

This research confirmed the usefulness of the OM-SEM with complementary TEM for the evaluation of LSEC damage reflected on the ultrastructure of organelles. MP alleviate the ultrastructural abnormalities indicating ER damage of LSEC caused by warm ischemia. Moreover, MMP temperature conditions restore the metabolism of LSEC *via* the normalization of ultrastructural characteristics of cristae of mitochondria and prevent the damage of the liver graft by share stress.

Research perspectives

The OM-SEM with complementary TEM is applicable for the detailed evaluation of LSEC damage reflected on the ultrastructure of the MP of various conditions, including different temperatures during perfusion storage, for clinically application of the MP for liver transplantation.

ACKNOWLEDGEMENTS

We thank all of the lab members and colleagues for their helpful suggestions and assistance in the experiments. We are extremely grateful to Dr. Hiroyuki Kanazawa for assistance with immunohistochemistry and Mr. Yoshiyasu Satake for assistance with carrying out all of the research.

Abstract

BACKGROUND

Natural orifice transluminal endoscopic surgery (NOTES) gallbladder-preserving surgery by flexible endoscopy is an emerging technology. However, the gallbladder fails to obtain traction and positioning functions during the operation.

AIM

To evaluate the feasibility and safety of a new surgical method, "snare-assisted pure NOTES gallbladder-preserving surgery".

METHODS

Eight miniature pigs were randomly divided into the experimental group [NOTES gallbladder-preserving surgery using the snare device, snare assisted (SA)] and the control group (NOTES gallbladder-preserving surgery without using the snare device, NC), with four cases in each group. The differences between the two groups of animals in operating time, operating workload, complications, adverse events, white blood cells, and liver function were determined.

RESULTS

No differences were found in the surgical success rate, gallbladder incision closure, white blood cell count, or liver function between the two groups. The total operating time, gallbladder incision blood loss, gallbladder disorientation time, gallbladder incision closure time, and workload scores on the National Aeronautics and Space Administration-Task Load Index were significantly reduced in the SA group ($P < 0.05$).

CONCLUSION
These results indicated that snare-assisted pure NOTES gallbladder-preservation surgery using standard endoscopic instruments reduced the difficulty of operation, shortened operation time, and did not increase complications in pigs. A new method for pure NOTES gallbladder-preservation surgery was provided.

Key Words: Snare; Flexible endoscope; Endoscopic gallbladder-preserving surgery; Natural orifice transluminal endoscopic surgery; Transgastric; Minimally invasive

INTRODUCTION

The incidence of benign gallbladder diseases, such as gallbladder stones and gallbladder polyps, has been increasing yearly[1], and the total prevalence of gallbladder stones in adults worldwide has reached 10%–20%[2]. Currently, cholecystectomy is still the main method used for the treatment of gallbladder stones and polyps. However, many complications occur after the patient loses the gallbladder[3,4]; moreover, gallbladder loss leads to an increased incidence of colorectal, pancreatic, esophageal, and liver cancers[5-8]. With the development of medicine, some doctors have realized that gallbladder removal may not be suitable for all patients with benign gallbladder diseases. The operation and concept of preserving the gallbladder and curing benign gallbladder diseases are now widely supported. In addition, some patients refuse open or laparoscopic cholecystectomy because it can cause surgical scars on the abdominal wall. They believe that these scars have a negative impact on their physical and mental health[9]. As an emerging technology, gallbladder-preservation surgery *via* natural orifice transluminal endoscopic surgery (NOTES) has obvious advantages in the complete resection of gallbladder polyps, removal of gallbladder stones, and preservation of gallbladder function. It is minimally invasive, painless, and scar-free. However, there are some technical obstacles to the clinical application of this operation. For example, the gallbladder bed is close to the liver, is obscured by fatty tissue, and has a poor field of vision; therefore, it can be difficult to locate the gallbladder[10]. In addition, the gallbladder collapses and shrinks quickly after incision, and the instruments used for gallbladder operation lose their focus, thereby making the operation very difficult[11]. The single-channel flexible endoscope for gallbladder-preservation surgery *via* NOTES requires additional navigation and traction.

Our inspiration came from the use of snares to assist in traction and exposure of lesions during endoscopic submucosal dissection. We tried a similar surgical method, which involved using a snare to assist in the traction and positioning of the gallbladder. The aim of this study was to evaluate the feasibility and safety of a newly proposed operative method, "a snare-assisted pure NOTES gallbladder-preserving surgery by a single-channel flexible endoscope".

MATERIALS AND METHODS

Animals

Eight Bama mini pigs weighing 15–20 kg that were in good health (with qualified certification) were chosen. The eight animals were randomly divided into two groups: The experimental group [NOTES gallbladder-preserving surgery using the snare device, snare assisted (SA)] and the control group (NOTES gallbladder-preserving surgery without using the snare device, NC). Each group had four animals. This study was conducted in the Experimental Center of the People's Hospital of Guangxi Zhuang Autonomous Region. The study was reviewed and approved by the Ethics Committee of the People's Hospital of Guangxi Zhuang Autonomous Region and the Ethics Committee of the Tongji Medical College, No. KY-LW-2019-4, [2020]-S322.

Equipment

A single-channel flexible endoscope (GIF-Q260J, Olympus, Tokyo, Japan) and an electrosurgical generator (Endocut ICC200; Erbe, Tubingen, Germany) were used. Other equipment included a snare (Boston Scientific, Ref; M00562650), a transparent cap (Olympus), an insulated IT-knife (model KD-610L, Olympus), a hook knife (model KD-620LR, Olympus), an injection needle (model 19G, Olympus), hemostatic clips and a release device (Olympus), and hot hemostatic forceps (KD610, Olympus). All endoscopes and accessories were sterilized prior to use.

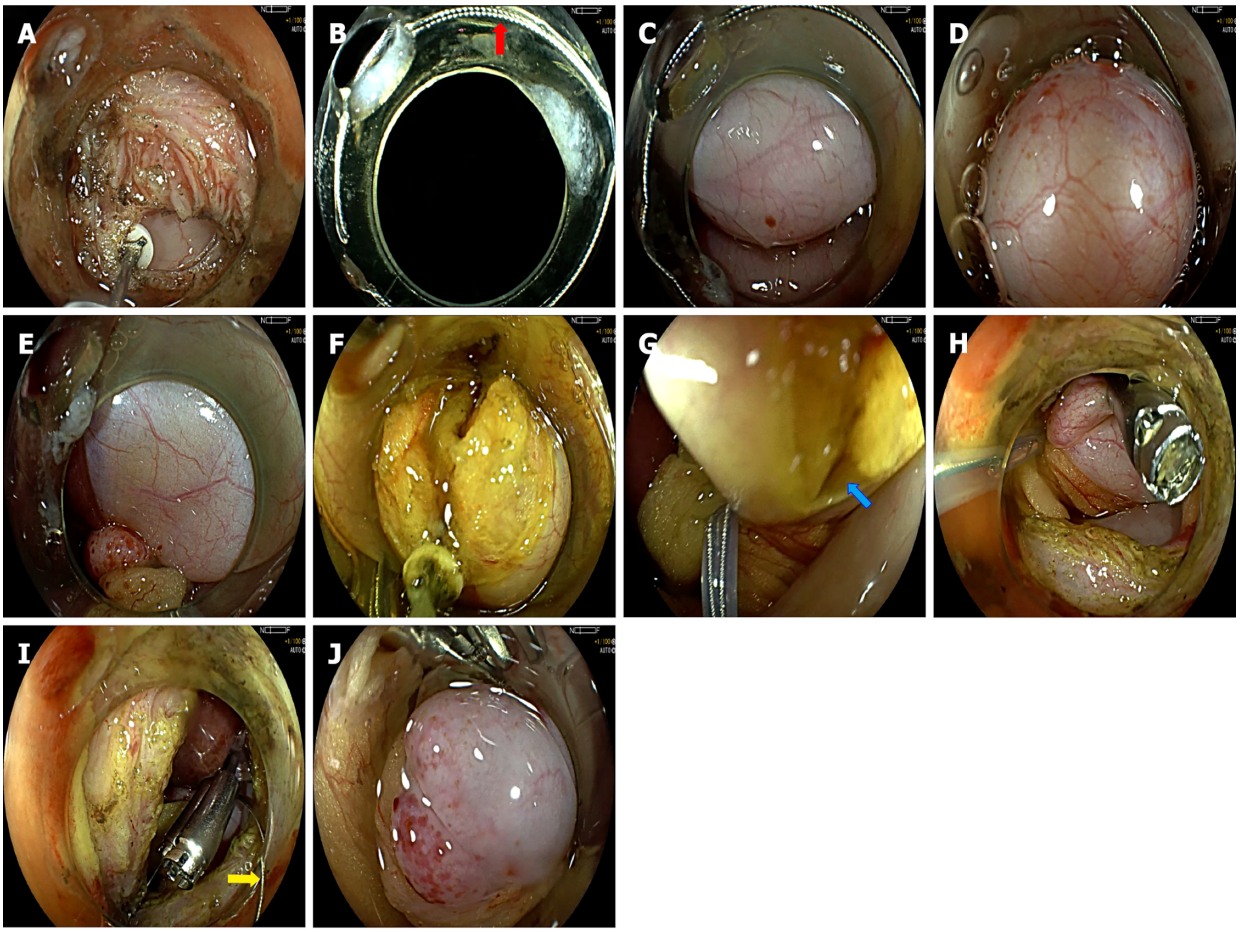
Medications

The medications used in the study included xylazine hydrochloride injection, propofol injection, diazepam, 2% pentobarbital sodium, atropine, cimetidine, and ceftiofur sodium for injection (Chengdu Zhongmu Biological Pharmaceutical Co., Ltd.).

Anesthesia

The pigs fasted for 48–72 h. They were given 200 mL of milk and 500 mL of 50% glucose for their daily drink. Preoperative intramuscular injection of xylazine hydrochloride (2 mL) was completed, after which blood was immediately collected from the anterior vena cava of the neck. Then, an intravenous injection needle was placed in the dorsal ear vein, and intravenous infusion of propofol injection (4 mg/kg/h) was completed to maintain anesthesia. Endotracheal intubation was not performed. The ECG oxygen saturation meter was connected to monitor vital signs, and electrode pads were pasted on the abdominal skin after shaving. Preoperative intramuscular injection of ceftiofur sodium (5 mg/kg) was performed to prevent infection.

Description of technology (pure NOTES gallbladder-preserving surgery)



SA group: Each generally anesthetized pig was placed on its left side on the operating table. Each one wore a sterile mouth ring and was covered with sterile towels. An ordinary gastroscope was preinserted into the stomach. The stomach, esophagus, and duodenum were flushed with normal saline (> 1000 mL). A transparent cap was placed on the front end of the sterile gastroscope, and the anterior wall of the gastric antrum was incised using a hook knife and IT knife (Figure 1A). The snare was placed on the transparent cap and inserted into the abdominal cavity along with the endoscope (Figure 1B). The liver and gallbladder were examined (Figure 1C). The transparent cap clung to the gallbladder wall, and the gallbladder wall was sucked in it. The snare was released, and the gallbladder wall was ligated (Figure 1D). Under this ligation state (Figure 1E), a hook knife and IT knife were used to make an incision of approximately 13 mm in the gallbladder wall (Figure 1F and G). The endoscope entered the gallbladder and was used to observe and flush the gallbladder mucosa. Metal clips were employed to close the gallbladder incision (Figure 1H). The snare was loosened (Figure 1I and J). The abdominal cavity was flushed with normal saline (> 2000 mL). Further observation was performed to ensure that there was no bleeding or bile leakage at the gallbladder incision. Then, the gastric wall incision was closed with clips.

NC group: Except for the fact that the snare was not used, the operating procedures performed for this group were the same as those mentioned above.

During the operation, the intra-abdominal pressure was not measured. The anesthesiologist monitored the abdominal wall pressure and the oxygenation index of the ear skin, which prompted the endoscopist to suck the gas from the abdominal cavity with an endoscope in time to reduce the intra-abdominal pressure.

Video description

The video came from a single surgical procedure in the SA group. A pig model was used to demonstrate snare-assisted pure NOTES gallbladder-preserving surgery by a single-channel flexible endoscope (Videos 1 and 2).

DOI: 10.3748/wjg.v28.i19.2112 Copyright ©The Author(s) 2022.

Figure 1 Snare-assisted flexible endoscope in transgastric endoscopic gallbladder-preserving surgery. A: The anterior wall of the gastric antrum was incised; B: The snare was placed on the transparent cap (red arrow); C: The endoscope was inserted into the abdominal cavity. The gallbladder was located; D: The transparent cap clung to the gallbladder wall, and the gallbladder wall was sucked in it. The snare was released, and the gallbladder wall was ligated; E: This ligation state was maintained; F: The gallbladder wall was incised with the assistance of the snare; G: With the navigation of the snare, the endoscopist quickly found the gallbladder and gallbladder incision again (blue arrow); H: With the help of the snare, clips were used to close the gallbladder wall incision; I: The snare was loosened (yellow array); J: The gallbladder wall returned to normal.

Postoperative follow-up

All pigs were given liquid food after fasting for 24 h. All animals received ceftiofur sodium *via* injection (5 mg/kg, qd, 3 d) to prevent infection. An experienced physician conducted extensive monitoring of these animals daily to observe whether complications or adverse events occurred. Blood was collected at 24 h and 28 d after the operation. Gastroscopy was performed 28 d after the operation.

Animal care and use statement

The animal protocol was designed to minimize pain or discomfort to the animals. All animals were killed by barbiturate overdose (intravenous injection, 150 mg/kg pentobarbital sodium) for autopsy.

Outcome parameters

Changes in the number of white blood cells, blood amylase, and liver function were observed before and after the operation. The operation success rate, operation time, intraoperative and postoperative complications, and animal survival rate were recorded. The National Aeronautics and Space Administration-Task Load Index (NASA-TLX)[12] was used to assess the difficulty of the operation. The conditions of the abdominal cavity, stomach wall, and gallbladder were observed by autopsy.

Statistical analysis

Quantitative data are expressed as the mean ± SD. The results were analyzed by *SPSS* 23.0 statistical software. The significance of the data was determined by Student's *t*-test. P value < 0.05 was considered statistically significant.

RESULTS

Short-term operation outcomes

The operation was completed on all animals, and a success rate of 100% was achieved. It took 10.9 ± 4.3 min to cut the stomach wall, and the bleeding volume was 12.4 ± 6.6 mL. Although entry into the abdominal cavity occurred through the anterior wall of the gastric antrum, which was close to the gallbladder, the mirror body had no bending and showed good mobility. The operation space and visual field were small, and it took 11.0 ± 3.6 min to locate the gallbladder. Fortunately, under the assisted traction and navigation positioning of the snare, blood loss during gallbladder incision was reduced ($P < 0.05$). The total operating time, gallbladder disorientation time during the operation, and gallbladder incision closure time were significantly reduced in the SA group ($P < 0.05$) (Table 1). No differences were found between the two groups in the time involved in gallbladder incision and the number of clips required to close the gallbladder incision ($P > 0.05$), as shown in Table 1. However, removal of the clip was needed in 50% (2/4) of the animals in the NC group due to the incorrect placement of the clip; this situation did not occur in the SA group. The inside of the gallbladder of all animals was fully explored and flushed. None of the animals had bile leakage from the gallbladder incision.

Using the NASA-TLX to evaluate the difficulty of operation, the results showed that under the auxiliary traction and positioning of the snare, the mental demand, physical burden, temporal demand, effort, and frustration of the endoscopist were significantly reduced ($P < 0.05$), as shown in Table 1 and Figure 2.

Operation safety

During the operation, 75% (3/4) of the animals in the NC group showed a significant decrease in the "blood oxygen index" of the ear skin, which returned to normal after the gas in the abdominal cavity was sucked through an endoscope. However, the animals in the SA group did not show these adverse events. In addition, 100% (4/4) of the animals in the NC group had electric burn scars on their livers (Figure 3), whereas only 25% (1/4) of the animals in the SA group showed a similar condition.

All animals survived, and their body weight increased appropriately (an increase of 1.88 ± 0.69 kg) until euthanasia on Day 28. The follow-up found that the animals in the SA group were normal after the operation, and no complications occurred. In addition, no significant differences were found between the groups in the number of white blood cells and neutrophils, liver function, or the amount of amylase in the blood at 24 h and 28 d after surgery ($P > 0.05$) (Table 2).

Gastroscope review and necropsy

The gastric wall incisions of all animals healed without ulcers and incision fistulas (Figure 4A). A small number of omental adhesions existed on the gastric serosal surface of all animals. After the adhesions were released, the gastric wall incisions healed well. The gallbladder incisions of all animals were closed well, and no biliary fistulas, peritoneal effusions, abdominal hematomas, or abdominal abscesses were found. However, there were some adhesions around the gallbladder incisions, and the metal clip was wrapped in it (Figure 4B-D). The gallbladder was opened, and the gallbladder mucosa was smooth, with no formation of stones or polyps. The mucosa at the original incision healed well (Figure 4E), and the local mucosa was slightly edematous (Figure 4F), with an average thickness of 4.2 ± 0.7 mm. However, there was no difference in the thickness of the gallbladder mucosa between the two groups ($P > 0.05$).

DISCUSSION

At present, cholecystectomy is still the gold standard for the treatment of gallbladder stones and polyps. However, the gallbladder has an irreplaceable role in the digestion process of the human body. Many complications and adverse reactions can occur after gallbladder resection[5-8]. Therefore, both physicians and patients expect to find a better treatment that will preserve the gallbladder and cure gallbladder stones and polyps. This paper reports the successful application of flexible endoscopy *via* NOTES gallbladder-preservation surgery. This seems to be a promising new surgery for patients who wish to preserve the gallbladder without scarring of the abdominal wall.

In previous single-channel flexible endoscopy *via* NOTES gallbladder-preservation surgery, the gallbladder was not effectively tracted and navigated, and the gallbladder and gallbladder incision were often lost during the operation, thereby significantly prolonging the operation time and increasing the damage to the surrounding organs[13]. These disadvantages make it extremely difficult to promote this kind of surgery. If the gallbladder and gallbladder incision can be positioned quickly and accurately during the operation and the gallbladder can be pulled safely and effectively, then the difficulty and risk of the operation will be greatly reduced, and the operation time will be shortened. Both physicians and the patients will benefit.

Table 1 Differences in surgical indicators between the two groups of animals

Content	NC group	SA group	*t* value	*P* value
Time required for gallbladder incision (min)	18.5 ± 7.0	10.0 ± 1.8	2.335	0.058

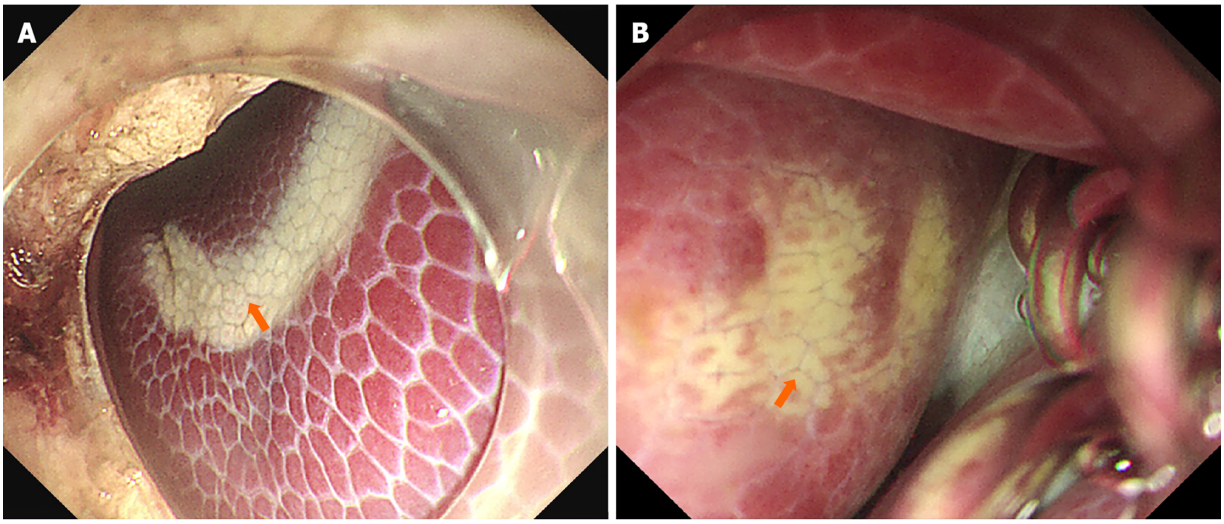
ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; γ-GT: Gamma-glutamyl transpeptidase; NC: Control; SA: Snare assisted.



In recent years, snares have been used in endoscopic submucosal dissection to assist in traction and exposure of lesions[14]. Inspired by this use, we applied the snare device to gallbladder-preserving surgery, which is called "snare-assisted pure NOTES gallbladder-preserving surgery by flexible endoscope". Compared with the non-snare group, the use of the snare significantly reduced the duration and difficulty of the operation. Moreover, the NASA-TLX workload score was significantly reduced, and no adverse reactions or complications occurred.

Although the endoscope enters the abdominal cavity through the stomach, the organs and structures in the four quadrants of the abdominal cavity can be clearly observed[15]. However, this study found that the gallbladder of pigs is deeply buried in the liver lobe and is mostly covered by the surrounding omentum. This affected the surgical vision and caused the disorientation of the gallbladder during the operation. This increased the difficulty of locating the gallbladder and gallbladder incision again and significantly prolonged the operation time. Given the navigation guidance of the snare during the operation, the endoscopist quickly found the gallbladder and gallbladder incision again. Thus, the

Figure 3 The livers of animals in the control group had electric burn scars (arrow). A: The electric burn scars were farther from the gallbladder; B: The electric burn scars were near the gallbladder.

duration of gallbladder disorientation during the operation and the total operation time were significantly shortened.

This study found that after the incision of the gallbladder, the bile flowed out, the gallbladder collapsed and shrank, and the surgical instruments lost their focus, thereby increasing the difficulty of the operation. The use of a snare to pull or drag the gallbladder can significantly reduce the difficulty of operation, shorten the time of gallbladder exploration, and reduce electrical coagulation damage to the nearby liver. Particularly in the case of massive hemorrhage from the gallbladder incision, blood obstructs the vision of the endoscope. The gallbladder is raised or pulled into the stomach by the snare, which can better expose the bleeding point. This is conducive to the electrocoagulation and hemostasis of the hot hemostatic forceps. This study showed that the blood loss from the gallbladder incision in the SA group was smaller than that in the NC group. Another issue is the poor closure of the gallbladder incision, which can lead to a bile fistula[10]. Although metal clips were used in this study to close the gallbladder incision, no complications, such as biliary fistula or peritonitis, occurred after the operation. However, the time involved in closing the gallbladder incision in the SA group was significantly shortened, and there were no adverse events that required the removal of the metal clip due to its incorrect placement.

This study found that 75% of the animals in the NC group experienced a significant drop in the blood oxygen index of the ears during the operation. The abdominal gas was sucked through the endoscope, and the operation was suspended to return to normal. It is possible that the abdominal pressure was too high, which inhibited the animals' breathing and heartbeats[16]. However, the blood oxygen index of the ear skin of the animals in the SA group remained normal. Given the traction and positioning of the snare, it can assist the surgical operation and expose the surgical field without blowing excess air into the abdominal cavity.

Figure 4 Gastroscopic review and necropsy were performed 28 d after the operation. A: The gastric wall incision healed well, with some clips remaining; B-D: A small number of adhesions appeared around the gallbladder incision, and the metal clip was wrapped in it; E: The gallbladder mucosa at the original incision healed well; F: The local mucosa surface was slightly edematous (red circle).

Although there are many microorganisms in the digestive tract, the strong acidity of gastric juice makes it difficult for most microorganisms to survive. Therefore, transgastric NOTES gallbladder-preserving surgery might not increase the risk of infection. A study showed that there was no significant difference in C-reactive protein and tumor necrosis factor-α levels after open surgery, laparoscopic surgery, and pure NOTES[17]. The present study found that although the leukocytes and neutrophils in the blood of all animals increased 24 h after the operation, they quickly returned to normal, and no difference was found between the two groups of animals at 24 h and 28 d after surgery. Therefore, using the snare did not increase the risk of infection during surgery.

The gallbladders of all animals were opened, and their gallbladder mucosae were smooth without the formation of stones and polyps. The mucosal surface at the original incision healed well, and no difference was found in the thickness of the gallbladder healing area between the two groups. The snare did not affect the healing of gallbladder mucosa or gallbladder incision. Moreover, some adhesions appeared around the gallbladder incision in all animals, and the metal clip was wrapped in it. This finding may be due to the body's response to abdominal organ damage and foreign bodies[10]. However, the snare did not aggravate this reaction.

To the best of our knowledge, this is the first experimental study of snare-assisted pure NOTES gallbladder-preserving surgery. However, several limitations of this study bear consideration. First, we only applied snare assistance for endoscopic trans-gastric gallbladder-preserving surgery. Thus, we cannot generalize the efficacy of snare assistance with other surgical paths, such as endoscopic transrectal gallbladder-preserving surgery and endoscopic transvaginal gallbladder-preserving surgery. Studies with other surgery paths are necessary in the future for a complete evaluation of the efficacy and safety of snare-assisted pure NOTES gallbladder-preserving surgery. Second, the number of animals used was small, and more studies with larger sample sizes are needed to confirm these findings. Third, it was undertaken on animals; thus, clinical trials are needed to demonstrate the effectiveness of snare-assisted pure NOTES gallbladder-preserving surgery in humans.

CONCLUSION

In summary, we successfully performed a flexible endoscopic gallbladder-preserving operation on pigs through pure NOTES. The use of a snare to assist the operation can reduce the difficulty of the operation and shorten the operation time; it does not increase the risk of the operation. Translating this new technology to human subjects seems straightforward and has great practical value in the clinic. However, further studies with large sample sizes are needed to confirm its clinical benefits, especially in

humans.

ARTICLE HIGHLIGHTS

Research background

With the development of medicine, the operation and concept of preserving the gallbladder and curing benign gallbladder diseases are now widely supported. As an emerging technology, gallbladder-preservation surgery *via* natural orifice transluminal endoscopic surgery (NOTES) has obvious advantages in the complete resection of gallbladder polyps, removal of gallbladder stones, improvement of gallbladder inflammation, and preservation of gallbladder function. However, there are some technical obstacles to the clinical application of this operation. For example, the gallbladder bed is close to the liver, is obscured by fatty tissue, and has a poor field of vision, indicating that it can be difficult to locate the gallbladder. In addition, the gallbladder collapses and shrinks quickly after incision, and the instruments used for gallbladder operation lose their focus, thereby making the operation very difficult.

Research motivation

The single-channel flexible endoscope for gallbladder-preservation surgery *via* NOTES requires additional navigation and traction. We proposed a new operative method that involved using a snare to assist in the traction and positioning of the gallbladder.

Research objectives

This study aimed to evaluate the feasibility and safety of a new surgical method, "snare-assisted pure NOTES gallbladder-preserving surgery".

Research methods

Eight miniature pigs were randomly divided into the experimental group [NOTES gallbladder-preserving surgery using the snare device, snare assisted (SA)] and the control group (NOTES gallbladder-preserving surgery without using the snare device, NC), with four cases in each group. The differences between the two groups of animals in operating time, operating workload, complications, adverse events, white blood cells, and liver function were determined.

Research results

No differences were found in the surgical success rate, gallbladder incision closure, white blood cell count, or liver function between the two groups. The total operating time, gallbladder incision blood loss, gallbladder disorientation time, gallbladder incision closure time, and workload scores of the National Aeronautics and Space Administration-Task Load Index were significantly reduced in the SA group ($P < 0.05$).

Research conclusions

These results indicated that snare-assisted pure NOTES gallbladder-preservation surgery using standard endoscopic instruments reduced the difficulty of the operation, shortened operation time, and did not increase complications in pigs.

Research perspectives

A new method for pure NOTES gallbladder-preservation surgery was provided. Translating this new technology to human subjects seems straightforward and has great practical value in the clinic.

Abstract

BACKGROUND

Acute respiratory distress syndrome (ARDS) is a major cause of death in patients with severe acute pancreatitis (SAP). Although a series of prediction models have been developed for early identification of such patients, the majority are complicated or lack validation. A simpler and more credible model is required for clinical practice.

AIM

To develop and validate a predictive model for SAP related ARDS.

METHODS

Patients diagnosed with AP from four hospitals located at different regions of

China were retrospectively grouped into derivation and validation cohorts. Statistically significant variables were identified using the least absolute shrinkage and selection operator regression method. Predictive models with nomograms were further built using multiple logistic regression analysis with these picked predictors. The discriminatory power of new models was compared with some common models. The performance of calibration ability and clinical utility of the predictive models were evaluated.

RESULTS

Out of 597 patients with AP, 139 were diagnosed with SAP (80 in derivation cohort and 59 in validation cohort) and 99 with ARDS (62 in derivation cohort and 37 in validation cohort). Four identical variables were identified as independent risk factors for both SAP and ARDS: heart rate [odds ratio (OR) = 1.05; 95%CI: 1.04-1.07; $P < 0.001$; OR = 1.05, 95%CI: 1.03-1.07, $P < 0.001$], respiratory rate (OR = 1.08, 95%CI: 1.0-1.17, $P = 0.047$; OR = 1.10, 95%CI: 1.02-1.19, $P = 0.014$), serum calcium concentration (OR = 0.26, 95%CI: 0.09-0.73, $P = 0.011$; OR = 0.17, 95%CI: 0.06-0.48, $P = 0.001$) and blood urea nitrogen (OR = 1.15, 95%CI: 1.09-1.23, $P < 0.001$; OR = 1.12, 95%CI: 1.05-1.19, $P < 0.001$). The area under receiver operating characteristic curve was 0.879 (95%CI: 0.830-0.928) and 0.898 (95%CI: 0.848-0.949) for SAP prediction in derivation and validation cohorts, respectively. This value was 0.892 (95%CI: 0.843-0.941) and 0.833 (95%CI: 0.754-0.912) for ARDS prediction, respectively. The discriminatory power of our models was improved compared with that of other widely used models and the calibration ability and clinical utility of the prediction models performed adequately.

CONCLUSION

The present study constructed and validated a simple and accurate predictive model for SAP-related ARDS in patients with AP.

Key Words: Acute pancreatitis; Acute respiratory distress syndrome; Nomogram; Calibration; Early identification; Predictive model

Core Tip: Severe acute pancreatitis (SAP)-related acute respiratory distress syndrome (ARDS) affect the mortality of patients with AP. Early identification of patients at high risk for SAP and ARDS can aid clinicians to adopt interventions to stop disease progression. However, current predictive models are either too complicated due to various parameters or unreliable due to lack of validation. This study developed new models to predict SAP and ARDS using only four routine clinical items within 24 h of admission. New models were externally validated and performed as well as or with a higher efficiency than other models.

INTRODUCTION

Acute pancreatitis (AP) is a common event incurring pain, socioeconomic loss, and even death. The majority of the patients who present with mild organ injury and self-limited course are diagnosed with mild acute pancreatitis (MAP) or moderately severe acute pancreatitis (MSAP)[1,2]. However, it is estimated that approximately 20% of patients are critically ill and develop SAP, leading to consistent organ failure and significant mortality[2,3]. Our previous studies indicated that the lung are the most commonly affected organs in SAP[4,5], and acute respiratory distress syndrome (ARDS) is recognized as an important cause of respiratory failure, with a high mortality rate[6-8]. It is reported that 4%-15% of AP patients are complicated with ARDS[9], while this proportion might be as high as one third in SAP [10]. However, to date, the therapeutic options for SAP and ARDS are limited. Therefore, it is necessary to identify patients at risk and adopt interventions to prevent MAP or MSAP from progressing to SAP and ARDS. The protective effect of early intervention for patients with predicted SAP or patients at risk of ARDS has been confirmed by numerous clinical trials and meta-analyses, although the inclusion

criteria for patients have varied according to different studies[11-15].

A plethora of models have been published to predict the risk of SAP in AP patients, including acute physiology and chronic health evaluation II (APACHE-II) score, Ranson criteria, computed tomography severity index (CTSI), and bedside index for severity in acute pancreatitis (BISAP)[16,17]. Lung injury prediction score (LIPS) and other models have also been used to evaluate the risk of ARDS in patients with non-AP[18-20]. However, to date the models used to predict ARDS in AP are scarce. Furthermore, the majority of the SAP predictive models are hard to use in practice due to various parameters, complicated calculation and dependence on radiological assessment. The majority of the models also lack internal or external validation, which reduces their reliability in other cohorts[16]. Therefore, a new concise model may be more practical in the emergency department in order to identify SAP and ARDS in the early course of AP. This model should involve limited available clinical data and should not rely on radiological examinations.

The objective of the present study was to develop and validate models to predict SAP and ARDS in patients with AP based on multicenter retrospective cohorts. The comparison of novel models with quick sequential organ failure assessment (qSOFA), systemic inflammatory response syndrome (SIRS) and BISAP is essential to display the power of different models with a low number of variables. These models usually contain three, four and five items, respectively[21,22].

MATERIALS AND METHODS

Study design and participants

This was a multicenter retrospective study. Sample size was calculated with PASS 11.0. The proportion of SAP was set to 20%, and the incidence of ARDS in SAP and non-SAP patients was set to 1/3 and 4%, respectively. Considering that the dropout rate was low in hospitals, we set it to 5%. In the end, with α = 0.01 and β = 0.10, a total of 211 participants were needed. Patients diagnosed with AP between 1 January 2017 and 31 December 2019 were recruited from different regions of China (Peking Union Medical College Hospital and The Sixth Hospital of Beijing at Northern China, The Fourth Affiliated Hospital of Harbin Medical University at Northeastern China, West China Longquan Hospital Sichuan University at Southwestern China). The patients were categorized into the derivation cohort in order to develop a clinical predictive model. The independent external validation cohort consisted of patients diagnosed with AP between 1 January 2020 and 31 May 2021 at the Peking Union Medical College Hospital. AP was diagnosed if at least two of the three following criteria were met: (1) abdominal pain consistent with AP; (2) serum lipase or amylase levels that were more than three times the upper limit of the normal range; and (3) characteristic radiological findings of AP on computed tomography (CT) and magnetic resonance imaging or ultrasonography[23]. SAP was identified by the presence of persistent organ failure for > 48 h[23]. ARDS was diagnosed based on Berlin definition[24]. Patients aged < 18 years who lacked the necessary information provided by the Atlanta Classification or relevant etiology information were excluded.

Clinical variables

The following demographic and laboratory data were collected from the electronic medical record system within 24 h of admission: age, sex, temperature, heart rate (HR), respiratory rate (RR), systolic blood pressure, Glasgow coma score (GCS), white blood counts, hematocrit, platelet, serum electrolyte concentration (K, Na and Ca), creatine, blood urea nitrogen (BUN) and glucose. Other clinical information, such as, admission date, local complication, length of hospital stay, length of intensive care unit stay, mortality and ventilator use, was also collected. Weekend admission corresponded to admission on Saturday or Sunday and local complication included acute peripancreatitc fluid collection, acute necrosis collection, pseudocyst and walled-off necrosis. The ventilator included invasive or noninvasive mechanical ventilation. qSOFA, SIRS and BISAP scores were calculated based on the aforementioned data. All data were collected and checked by two or more authors independently. Missing items were added following review of the clinical records. The data that could not be completed were removed and the complete-case dataset was finally analyzed.

Statistical analysis

Categorical variables were expressed as frequencies and percentages and compared using χ^2 or Fisher's exact tests. Normally distributed continuous variables were described as the mean ± SD and compared using a two-sided Student's *t* test. Non-normally distributed continuous variables were expressed as the median with the interquartile range and compared using the Mann-Whitney *U* test. Continuous variables were analyzed in their original forms to preserve information[25]. The least absolute shrinkage and selection operator (LASSO) regression method was used to select predictors in the derivation cohort. The predictive models were further built using multiple logistic regression analysis. The nomogram was formulated based on multivariate logistic regression analysis. Receiver operating characteristic (ROC) curve and the area under ROC curve (AUC) were used to evaluate the discriminative power of the predictive model, which referred to the ability of the model to differentiate between

the subjects that did or did not experience the outcome event[25]. The calibration curves were plotted to measure the predictive accuracy of the model, which reflected the agreement between predictions from the model and observed outcomes. A well-calibrated model indicated that the prediction was lying on or around the 45° line of the calibration plot[25]. Hosmer-Lemeshow (H-L) goodness of fit test was used to quantify the calibration curve. The *P* value was determined by the H-L test. $P > 0.05$ suggested an optimal consistency between model prediction and the criteria required for standard diagnosis. Decision curve analysis (DCA) was used to assess the clinical utility of the model, which indicated he relationship between a model-predicted probability threshold and the relative value of net benefit[25].

Statistical analysis was performed using R 4.0.3[26] and MedCalc 15.8 software. A two-side $P < 0.05$ was considered to indicate a statistically significant difference. The nomogram and calibration curve were plotted using rms package and DCA was plotted using rmda package. ROC was plotted with MedCalc 15.8.

RESULTS

Baseline characteristics

Between January 1 2017 and May 31 2021, 628 patients with AP were recruited from four hospitals and reviewed. The exclusion criteria included the following: age < 18 years (2 patients), lack of Atlanta Classification or etiology (26 patients) and incomplete data (3 patients). Following screening, 407 and 190 patients were involved in the derivation and validation cohorts, respectively. The number of participants in each cohort met the requirement of sample size. The detailed demographic and clinical information were described in Tables 1 and 2.

Predictors and model construction

Four variables (HR, RR, Ca and BUN) were extracted as the predictors of SAP through LASSO regression. Supplementary Figure 1 and Supplementary Table 1 show this process in more detail. Multivariable logistic regression revealed that all four variables were independent predictors (Table 3). The probability (PA) of SAP could be calculated according to the following formula: PA = 1/{1 + exp [-(-6.42 + 0.05 × HR + 0.08 × RR - 1.30 × Ca + 0.14 × BUN)]}. Analysis of ARDS obtained similar results (Table 3). The following formula was used for ARDS: PA = 1/{1 + exp [- (-5.46 + 0.05 × HR + 0.10 × RR - 1.78 × Ca + 0.11 × BUN)]}. Two nomogram plots were displayed using prediction models (Figure 1).

Model performance

The new model indicated a great power of discrimination for SAP. Following 1000 interactions of bootstrapping to minimize the risk of overfitting to the original models, the AUC in the derivation cohort was estimated to 0.879 (95%CI: 0.830-0.928), which was significantly superior to that of SIRS (AUC = 0.808, 95%CI: 0.757-0.859, $P = 0.002$) and qSOFA (AUC = 0.730, 95%CI: 0.672-0.789, $P < 0.001$) and not inferior to that of the BISAP score (AUC = 0.888, 95%CI: 0.847-0.929, $P = 0.6629$) (Figure 2A, Table 4). In addition, the model indicated an optimal behavior in the validation cohort (AUC = 0.898, 95%CI: 0.848-0.949) (Figure 2B). The AUC of the new model in derivation was 0.892 (95%CI: 0.843-0.941) for ARDS prediction, which was superior to SIRS (AUC = 0.815, 95%CI: 0.766-0.864, $P = 0.001$) and qSOFA (AUC = 0.742, 95%CI: 0.678-0.807, $P < 0.001$) and not inferior to BISAP (AUC = 0.871, 95%CI: 0.827-0.916, $P = 0.344$) (Figure 2C, Table 4). Despite the assessment of the model in the validation cohort, its performance was moderate (AUC = 0.833. 95%CI: 0.754-0.912) (Figure 2D). When the cut-off value was set as PA > 25% for SAP prediction, the novel model suggested an optimal performance in the combined dataset (sensitivity 0.78, specificity 0.88) (Table 4). The best cut-off value was PA > 18% for ARDS prediction, with a sensitivity of 0.78 and a specificity of 0.85 (Table 4).

Graphical assessment indicated a strong agreement between prediction and observation in both new models (Figure 3). The H-L test indicated that the difference between prediction and observation was not significant both in the derivation ($\chi^2 = 12.675$, $P = 0.124$) and validation cohorts ($\chi^2 = 5.852$, $P = 0.664$) with regard to SAP prediction. The model for ARDS prediction revealed improved performance with regard to the calibration in the derivation ($\chi^2 = 3.753$, $P = 0.879$) and validation cohorts ($\chi^2 = 2.933$, $P = 0.939$).

DCA indicated that if the threshold PA was < 80%, using the new model to recognize and manage SAP had a positive net benefit compared with either the treat-all or treat-none (Figure 4A). In case the threshold probability was set to < 70%, the prediction and intervention for ARDS also produced net benefit (Figure 4B).

DISCUSSION

In the current study, novel prediction models were established for SAP and ARDS in patients with AP. The models were also externally validated and exhibited remarkable discriminative power and high

degree of consistency with the observation both in the derivation and external validation cohorts. These models suggested that patients with AP who manifested a higher heart rate, respiratory rate, blood urea nitrogen concentrations and lower serum calcium concentrations at admission exhibited a higher risk of developing SAP and ARDS.

AP is a major cause of acute abdomen. Patients with AP usually present with multiple organ dysfunction syndrome (MODS). Although organ dysfunction is mild and transient (< 48 h), approximately 20% of patients will proceed to consistent organ failure (> 48 h), leading to SAP and a high risk

ARDS: Acute respiratory distress syndrome; GCS: Glasgow coma score; Tem: Temperature; SBP: Systolic blood pressure; HR: Heart rate; RR: Respiratory rate; WBC: White blood cell; HCT: Hematocrit; PLT: Platelet; Cr: Creatine; BUN: Blood urea nitrogen; Glu: Glucose; ICU: Intensive care unit; qSOFA: Quick sequential organ failure assessment; SIRS: Systemic inflammatory response syndrome; BISAP: Bedside index for severity in acute pancreatitis.

of mortality[27]. AP primarily affects the respiratory system and to a lesser extent the renal and cardiovascular systems[23]. ARDS is the critical event, which is noted during lung injury in AP[28]. Cyclooxygenase-2 inhibitors and enteral nutrition have been shown to prevent SAP, shorten the length of hospital stay and reduce infectious complications and mortality in patients with predicted SAP[11,12,29]. Administration of antiplatelet therapy, withdrawal of prehospital amiodarone treatment and administration of nebulized heparin may decrease the incidence of ARDS, inhibit the progression of lung injury and accelerate the recovery of patients at risk of developing ARDS[13-15,30]. Therefore, early identification of patients at risk of developing SAP and ARDS is clinically significant for improving the prognosis of AP.

Various models have been developed to predict SAP and organ dysfunction for AP management[16]. Although the majority of the models were deficient due to some limitations, such as small sample size, single center studies and lack of internal or external validation, several SAP models have been widely used and validated in different cohorts. These validations were performed using APACHE-II score, Ranson criteria, CTSI and BISAP[31-34]. BISAP contains only five variables and is simpler than APACHE-II score (18 items) and the Ranson criteria (11 items). However, their predictive power is equal [35]. In addition, ultrasound is preferred to CT as an efficient and nonradioactive examination used in the emergency department to initially evaluate potential development of AP. Therefore, pleural effusion and CT presentation could not be evaluated in this case to gain the BISAP and CTSI scores. Although LIPS is a popular model to predict ARDS for patients at risk, its calculation is considerably complicated [18]. In addition, its original developing cohort involved only a small part of patients with AP. LIPS had not been previously validated in patients with AP.

Therefore, a simple model with a low number of parameters and without radiology findings would be more practical. The novel predictive model reported in the current study involved only four parameters for both SAP and ARDS prediction and all these variables were routinely tested. The discriminatory power of the novel model was not inferior to that of BISAP. To the best of our knowledge, the prediction of SAP or ARDS for patients with AP has not been previously assessed by models that were as simple and accurate as this reported in the current study.

Using LASSO regression, calcium was identified as a predictor for both SAP and ARDS. Multiple logistic regression analysis indicated that serum calcium concentration was also the independent predictor. The models of the present study were easier to use than the APACHE-II, Ranson, CTSI and BISAP models and demonstrated improved efficacy than the other two simple models, suggesting their potential clinical significance. ARDS was a non-negligible manifestation of MODS in patients with AP. The majority of the models have mainly focused on the severity classification or mortality prediction of ARDS, whereas the identification of ARDS at an early stage is still challenging. Although LIPS was widely used to predict ARDS, the calculation of the LIPS score was complicated for patients admitted to the emergency department, since certain parameters may be unavailable[18]. The pathogenesis of ARDS

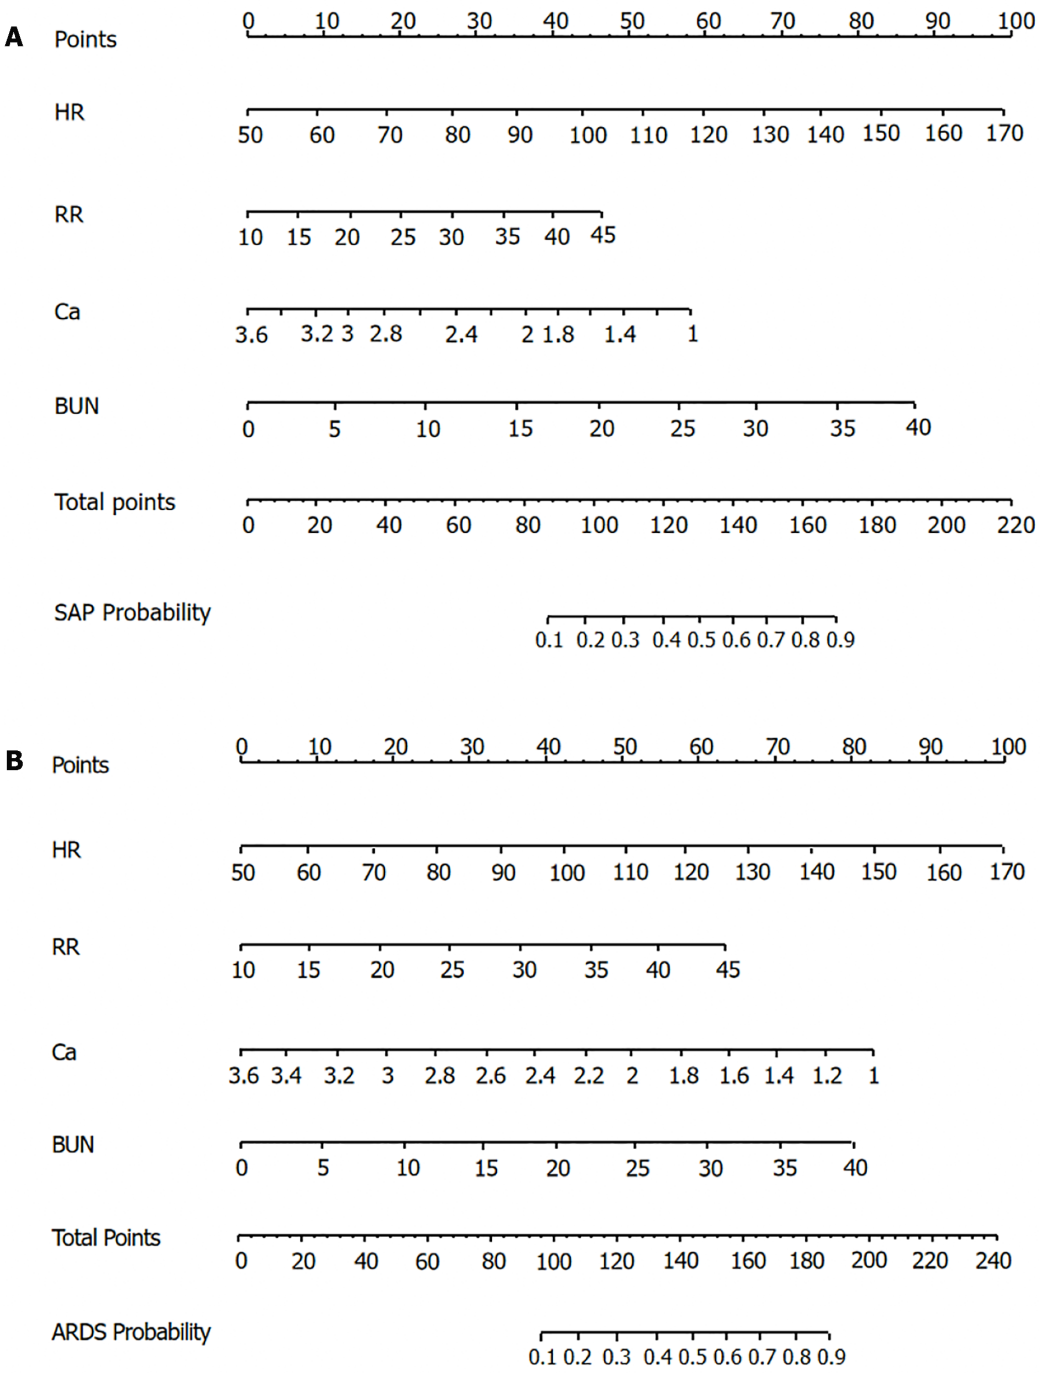

Figure 1 Nomograms of new predictive models. A: Nomogram of severe acute pancreatitis predictive model; B: Nomogram of acute respiratory distress syndrome prediction model. SAP: Severe acute pancreatitis; ARDS: Acute respiratory distress syndrome; HR: Heart rate; RR: Respiratory rate; Ca: Serum calcium concentration; BUN: Blood urea nitrogen.

involves the activation of signaling pathways, which include various cytokines and inflammatory mediators. Certain molecules, such as interleukin (IL)-6, IL-8, protein C, angiopoietin-2 and miRNAs and specific imaging examinations (X-ray and lung ultrasound) were also identified as predictors of ARDS in single or combined forms[8,36-38]. The data indicated that these new predictors seemed promising. However, the molecules and the examinations identified were not part of the routine clinical practice, which limited their clinical utility. Fei *et al*[10] used an artificial neural network algorithm to predict ARDS following SAP. The model by Fei *et al*[10] indicated high accuracy. However, the variable pancreatic necrosis rate was hard to assess when CT was not used and was not evident in the early course of AP.

The pathogenesis of SAP and ARDS involves a series of acute inflammatory reactions[2,39]. SIRS is widely adopted to assess the severity of diseases associated with acute inflammation. Both HR and RR are used in the SIRS model. Therefore, it is reasonable that both HR and RR were identified as predictors of SAP and ARDS. BUN has been shown to reflect volume depletion, renal function, the quality of

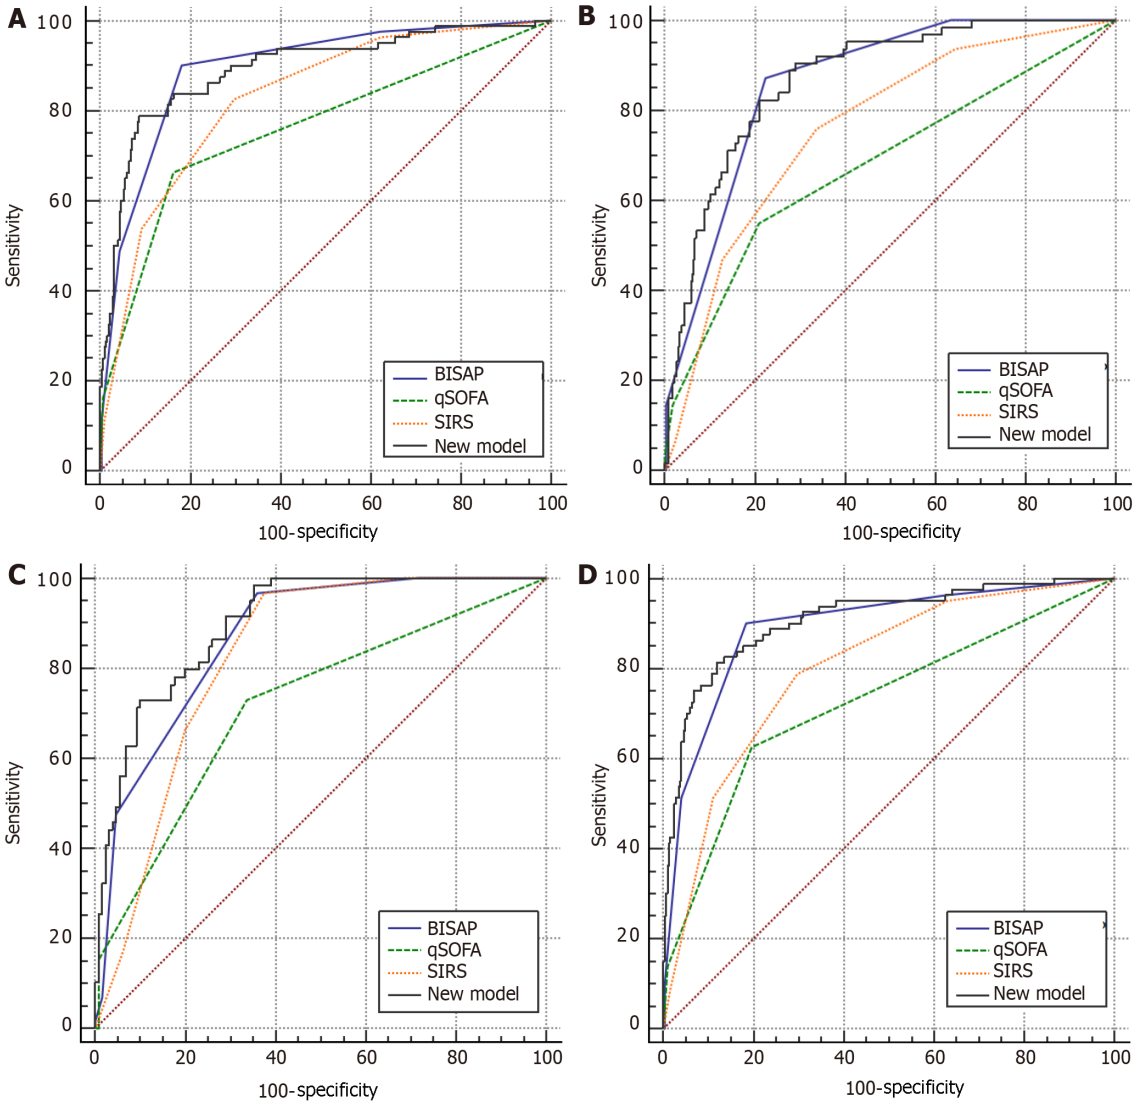

Figure 2 Receiver operating characteristic curves of different predictive models in derivation and validation cohort. BISAP: Bedside index for severity in acute pancreatitis; qSOFA: Quick sequential organ failure assessment; SIRS: Systemic inflammatory response syndrome.

resuscitates and even the ischemic injury of the pancreas during AP[40]. It has been reported that BUN can independently predict both SAP and the mortality of SAP[40-44]. Therefore, BUN was also involved in other predictive models of SAP, such as GCS, Ranson criteria and BISAP, in addition to our new model. The levels of BUN have not been used as a direct predictor of ARDS. However, this marker can be used as a predictor of pathogenesis in association with other risk factors, such as pancreatitis[39]. Calcium concentration has been closely associated with AP[45]. Hypocalcemia was common in the cohort of the present study and in other AP cohorts; notably in critically ill patients[46]. Elevated cytosolic calcium of pancreatic acinar cells causes premature trypsinogen activation, vacuolization and acinar cell death, which play critical roles in the pathogenesis of AP[47]. However, during the development of certain models for the prediction of SAP, serum calcium was excluded for a variety of factors[48]. Calcium is also involved in the pathogenesis of ARDS as a signaling molecule, leading to paracellular hyperpermeability through endothelial junction-cytoskeleton dissociation[49]. The current model suggested that calcium was an independent predictor of SAP and ARDS in AP, indicating the potential of developing novel drugs for the treatment of AP[50]. To the best of our knowledge, the model of the present study was the simplest used to predict SAP and ARDS within 24 h of AP admission. It is also the first model that involved serum calcium concentration to predict ARDS in AP.

The present study had several limitations. Firstly, organ dysfunction occurred mainly in the first week of AP, whereas accurate onset time was not available in the present study. Therefore, certain patients with SAP or ARDS may have been missed. Moreover, the exact onset time of ARDS was not recorded, so the new model only predicted the risk of ARDS during the whole admission (7-15 d) using the scores gained within 24 h of admission. It might not be appropriate, and the new model could not

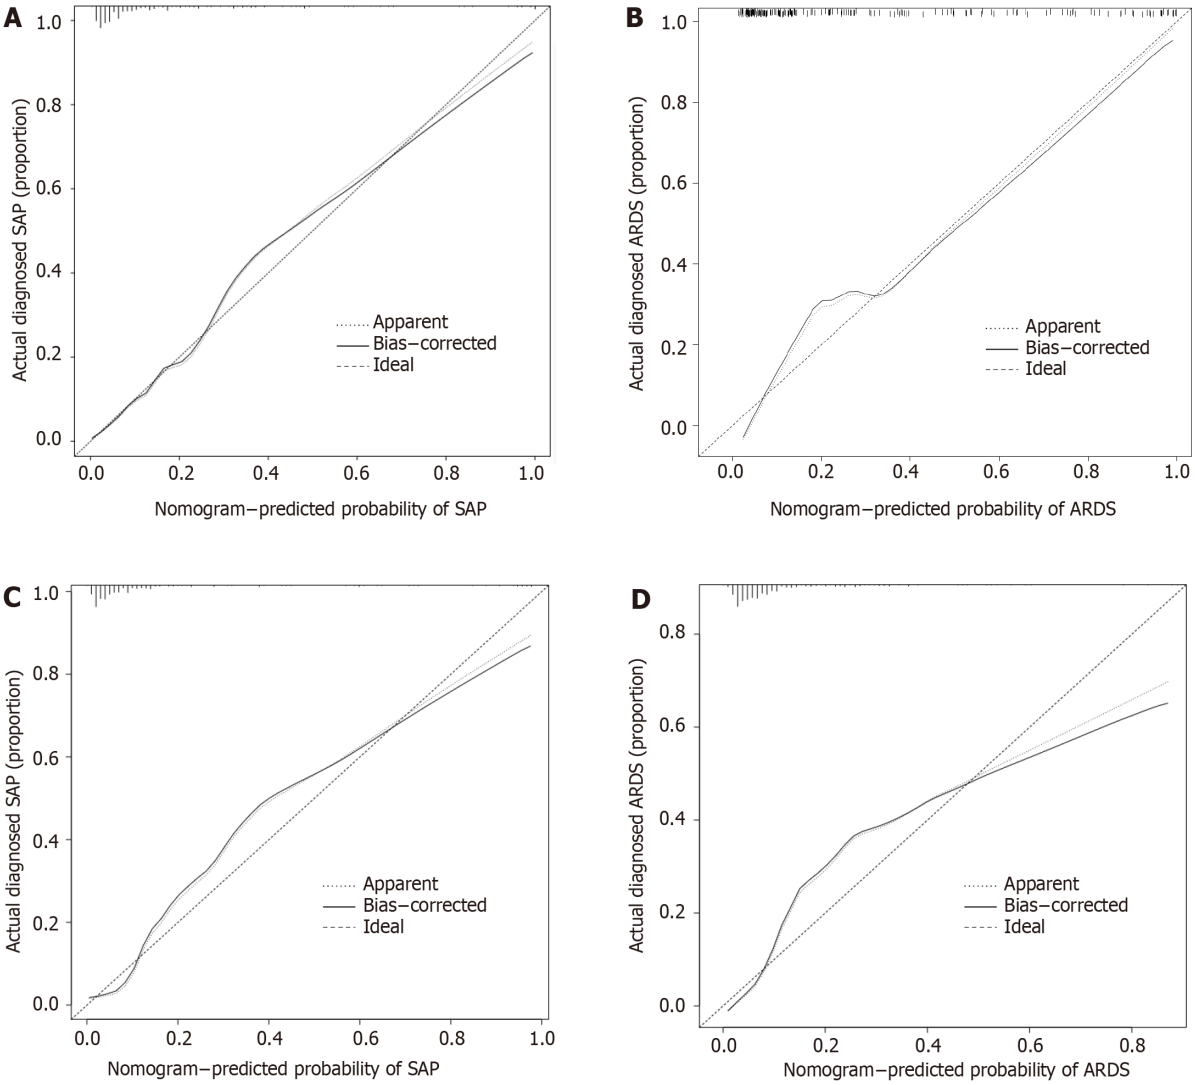

Figure 3 Calibration curves of new predictive models. A: Calibration plot of severe acute pancreatitis (SAP) predictive model in derivation cohort; B: Calibration plot of SAP predictive model in validation cohort; C: Calibration plot of acute respiratory distress syndrome (ARDS) predictive model in derivation cohort; D: Calibration plot of ARDS predictive model in validation cohort.

tell the clinicians when they should prepare for the possible onset of ARDS. Further studies are needed to verify the value of new models on a dynamic timescale. Secondly, the derivation cohort comprised tertiary and secondary hospitals from different regions of China. However, model validation was performed in a tertiary teaching hospital. Although the result of validation was also encouraging, it is hard to ignore that the incidence of SAP and ARDS in the validation cohort was considerably higher than that of the derivation cohort, which could reduce the generalizability in primary or secondary class hospitals, where MAP and MSAP exhibited high proportions. Moreover, certain laboratory examination technologies were different among four hospitals, which increased the systemic error of the data. It must be mentioned that mechanical ventilation will attenuate systemic inflammation of ARDS and the effect varies with patterns[51]. It is unavoidable that new scores to predict ARDS will also be affected. Unfortunately, detailed information of mechanical ventilation was not collected in this study, and further research is needed to investigate the influence of different ventilatory patterns on new models. Thirdly, selection bias was inevitable in a retrospective study. Furthermore, any missing value was deleted to obtain a complete-case dataset for analysis rather than imputating missing data with statistical methods (*e.g.*, multi-imputation), which were not recommended. However, in the present study, only three individuals were removed due to missing data, accounting for a tiny part of the cohort. It was considered that complete data analysis would not affect the overall conclusion. Finally, other common predictive models, such as APACHE-II score, Ranson criteria, CTSI and LIPS were not evaluated due to lack of essential parameters. Therefore, direct comparison among different models was unavailable.

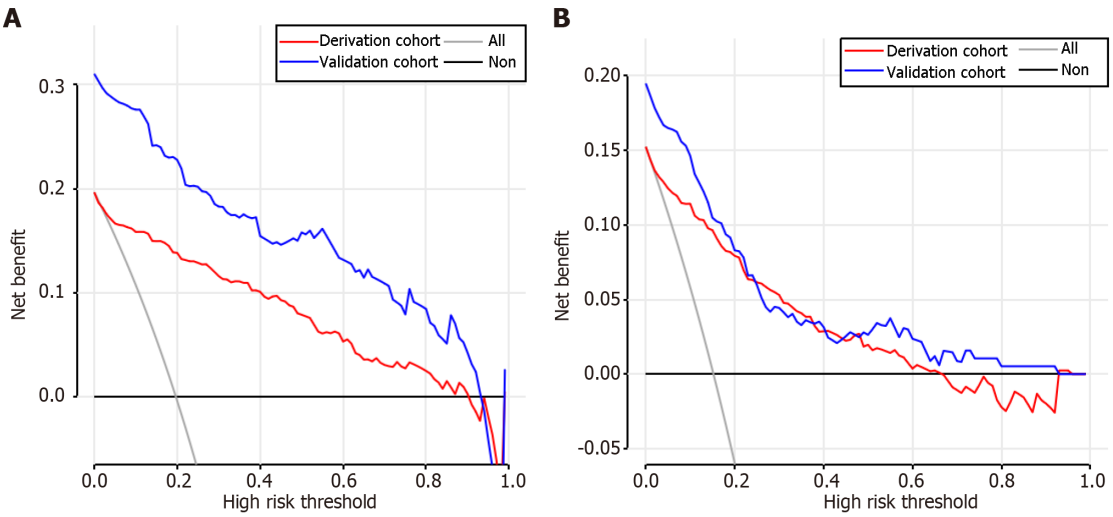

Figure 4 Decision curve analysis of new predictive models. A: Decision curve analysis of severe acute pancreatitis predictive model in derivation and validation cohort; B: Decision curve analysis of acute respiratory distress syndrome predictive model in derivation and validation cohort.

CONCLUSION

Novel models were developed containing only four items to predict SAP and ARDS in patients with AP, which were as accurate as BISAP but simpler. Serum calcium was identified as an important predictor, indicating a potential new strategy for management of AP. Further prospective studies are required to reveal whether early intervention based on novel prediction models could reduce the incidence of SAP and ARDS and finally improve the outcome of patients with AP.

ARTICLE HIGHLIGHTS

Research background

Acute respiratory distress syndrome (ARDS) is a major cause of death in patients with severe acute pancreatitis (SAP), but simple and credible predictive models are absent.

Research motivation

Use of models to predict and identify early patients with SAP and SAP-related ARDS, so that clinicians can manage these patients early to decrease mortality during admission.

Research objectives

To develop and verify new models to predict SAP and SAP-related ARDS.

Research methods

Clinical data from four centers were retrospectively collected. Items selected with least absolute shrinkage and selection operator regression method were involved in multiple logistic regression to develop the final model in development cohort. New models were than verified in validation cohort and assessed with C-index, calibration curve and decision-curve analysis.

Research results

New models could predict SAP and SAP-related ARDS with four easily available items, and performed well.

Research conclusions

We developed and verified simple and reliable models to predict SAP and SAP-related ARDS.

Research perspectives

To verify new models in a larger size of sample, and to investigate the questions raised by reviewer.

Abstract

BACKGROUND

Post-polypectomy surveillance intervals are currently determined based on pathology results.

AIM

To evaluate a polyp-based resect and discard model that assigns surveillance intervals based solely on polyp number and size.

METHODS

Patients undergoing elective colonoscopies at the Montreal University Medical Center were enrolled prospectively. The polyp-based strategy was used to assign the next surveillance interval using polyp size and number. Surveillance intervals were also assigned using optical diagnosis for small polyps (< 10 mm). The primary outcome was surveillance interval agreement between the polyp-based model, optical diagnosis, and the pathology-based reference standard using the 2020 United States Multi-Society Task Force guidelines. Secondary outcomes

included the proportion of reduction in required histopathology evaluations and proportion of immediate post-colonoscopy recommendations provided to patients.

RESULTS

Of 944 patients (mean age 62.6 years, 49.3% male, 933 polyps) were enrolled. The surveillance interval agreement for the polyp-based strategy was 98.0% [95% confidence interval (CI): 0.97–0.99] compared with pathology-based assignment. Optical diagnosis-based intervals achieved 95.8% (95%CI: 0.94–0.97) agreement with pathology. When using the polyp-based strategy and optical diagnosis, the need for pathology assessment was reduced by 87.8% and 70.6%, respectively. The polyp-based strategy provided 93.7% of patients with immediate surveillance interval recommendations *vs* 76.1% for optical diagnosis.

CONCLUSION

The polyp-based strategy achieved almost perfect surveillance interval agreement compared with pathology-based assignments, significantly reduced the number of required pathology evaluations, and provided most patients with immediate surveillance interval recommendations.

Key Words: Colonoscopy; Colorectal pathology; Colorectal adenomas; Endoscopy; Surveillance; Optical diagnosis

Core Tip: Background current post-polypectomy surveillance intervals are based on pathology outcomes. Our aim was to test a novel polyp-based resect and discard model that assigns surveillance interval based on number and size of polyps. Findings Surveillance interval based on a polyp-based strategy achieved 98.0% (95% confidence interval: 0.97–0.99) agreement with pathology-based intervals when applied according to the current surveillance guideline. Implications for patient care the polyp-based strategy can easily be implemented without any requirement for specialist devices and training. The majority of patients can be provided with immediate surveillance interval recommendations, without having to wait for results of pathology analysis.

INTRODUCTION

Screening colonoscopy and removal of detected polyps has been utilized to reduce colorectal cancer (CRC) morbidity and mortality[1]. The majority (90%) of polyps found during colonoscopies are less than 10 mm in size, with diminutive polyps (< 5 mm) accounting for about 70%–80%[2]. Most of these small polyps have been shown to be at very low risk for progression towards CRC. Advanced histology is found in only 0.5% of diminutive polyps and 1.5% of small polyps[2]. Histopathologic evaluation of small polyps can incur significant costs, therefore alternative modalities have been proposed, such as image-enhanced endoscopy-assisted optical polyp diagnosis (the "resect and discard" strategy)[3-5].

While optical diagnosis has achieved high level of accuracy in academic settings[6,7], reports from general clinical practice have not been able to reproduce these results, with accuracies ranging between 75% and 85%, and surveillance interval assignment agreement with pathology of only 81%[8,9]. In a recent survey study, 59.9% of endoscopists reported that optical diagnosis was not feasible for clinical implementation, and 84.2% were not using the strategy in their current clinical practice[10]. Limitations of the resect and discard strategy included fear of making an incorrect optical diagnosis, assigning incorrect surveillance intervals, and training requirements[10]. Therefore, we aimed to develop a resect and discard model that did not require optical diagnosis to assign colonoscopy surveillance intervals. A retrospective study using this model, named the polyp-based resect and discard (PBRD) strategy, showed an 89.3% agreement with pathology-based surveillance recommendations[11]. This current study aimed to evaluate the PBRD model in a prospective clinical study comparing the strategy with optical polyp diagnosis using pathology-based surveillance interval recommendations as the reference standard.

MATERIALS AND METHODS

Methods

Patients (aged 45–80 years) undergoing elective screening, surveillance, or diagnostic colonoscopies between May 2017 and December 2018 at the Centre Hospitalier de l'Université de Montréal (CHUM) were included. Exclusion criteria were known inflammatory bowel disease, active colitis, coagulopathy, familial polyposis syndromes, American Society of Anesthesiologists classification score of > 3, emergency colonoscopies, personal history of CRC, hospitalized patients, and presence of CRC during colonoscopy. The study was planned and conducted as a sub-study in patients enrolled in two prospective clinical studies (NCT04032912 and NCT03515343, respectively). The study protocol and data collection were approved by the local institutional research board as an amendment to the two prospective clinical studies (17.135 and 16.367, respectively).

Colonoscopy procedures

Colonoscopy procedures were performed as *per* the standard of care. Adequate bowel preparation was determined by a Boston Bowel Preparation Score (BBPS) of ≥ 6. Location, size, and morphology according to the Paris classification were documented for each polyp. All polyps were removed and sent for histopathology evaluation. Polyps 1–10 mm were optically diagnosed using either i-Scan or Optivista image-enhanced endoscopy (Pentax, Montvale, NJ, United States) and classified using the Narrow-band imaging international colorectal endoscopic (NICE) classification system[4,12]. Endoscopist level of confidence (low or high) in optical histology prediction was documented. Endoscopists then used the PBRD strategy to assign the next surveillance interval immediately after colonoscopy (real-time application). Then, a research assistant (MT) used the PBRD strategy (post hoc) to determine whether endoscopists had deviated from the intended PBRD strategy and assessed the PBRD model results when used without deviations.

The PBRD model

The PBRD strategy was developed by the research group and previously tested in a pilot study[11]. There was no overlap between the cohort enrolled in the pilot study and the cohort presented herein. The PBRD uses number and size of polyps, and first-degree family history of CRC to predict the next surveillance interval. At the time of the study, the 2012 United States Multi-Society Task Force (USMSTF) guidelines[13] were the most current guidelines used to develop the PBRD strategy (Table 1). With the publication of the updated 2020 USMSTF guidelines[14] during the course of the study, we adapted the PBRD model to reflect those changes through consensus between two researchers (RD and DvR), and tested its performance post hoc (Table 1). Since the 2020 guidelines are the most contemporaneous, the 2020-based analysis was used as the primary outcome of the study. Pathology-based surveillance intervals were therefore determined using 2012 or 2020 USMSTF guidelines as appropriate [13,14]. In cases of multiple recommended intervals (for example, 7–10 years), the longest interval was chosen to compare the strategies.

Study outcomes

The primary outcome was the agreement between PBRD-based surveillance intervals and pathology-based surveillance intervals and agreement between updated PBRD-based surveillance intervals and pathology-based surveillance intervals. Secondary endpoints were: Agreement between optical diagnosis-based surveillance intervals and pathology-based intervals; agreement between real-time endoscopist allocation of intervals based on PBRD compared with pathology-based intervals; proportion of immediate post-colonoscopy surveillance recommendations provided to patients based on both PBRD (real-time and post hoc) and optical diagnosis; proportion of required histopathology evaluations when using PBRD and optical diagnosis. Other secondary outcomes included the proportion of patients with findings that could have been provided with immediate surveillance interval recommendations: no polyps detected; inadequate bowel preparation; polyps sized 1–10 mm that were all optically diagnosed with high confidence (for the optical diagnosis strategy); patients fitting scenarios 1, 2, 3, and 6 (for the PBRD strategy) (Table 1). Polyps undergoing low-confidence optical diagnosis, polyps > 10 mm in size, and all polyps in patients fitting scenarios 4 and 5 (for the PBRD strategy) required histopathology evaluation.

Statistical analysis

Patient, procedure, and polyp characteristics were presented as crude numbers and frequency for categorical variables, and mean ± SD or median (range) for continuous variables. Agreements between the PBRD model, optical diagnosis, and pathology-based surveillance recommendations were presented as proportions with two-tailed 95% confidence interval (CI). For secondary outcomes, proportional estimates with two-tailed 95%CI were presented. A chi-squared test or a two-tailed Fisher's exact test was used to compare proportions. SPSS version 26.0 (IBM Corp., Armonk, New York, United States) and MedCalc version 19.4 (MedCalc Software bv, Ostend, Belgium; https://www.medcalc.org) were used for analyses.

Table 1 The polyp-based resect and discard strategy

Scenario	Rule		If family history of CRC (first-degree relative)
		Surveillance interval recommendation based on 2012 guidelines, yr	
1	No polyp	10	5
2	1–2 diminutive polyps (largest polyp max 5 mm)	10	5
3	1–3 small polyps (all polyps 1–9 mm and the largest polyp max < 10 mm)	5	5
4	≥ 4 polyps, any size	Follow-up pathology results	-
5	At least 1 polyp ≥ 10 mm	Follow-up pathology results	-
6	Insufficient or inadequate bowel preparation	1	-
7	Unclear	-	-
		Surveillance interval recommendation based on 2020 guidelines, yr	
1	No polyp	10	5
2	1–3 diminutive polyps; or 2 diminutive polyps and 1 small polyp	10	5
3	1–2 small polyps exclusively	10	5
4	> 3 polyps, any size, or > 2 polyps 6–9 mm	Follow-up pathology results	–
5	≥ 1 polyp ≥ 10 mm	Follow-up pathology results	–
6	Insufficient or inadequate bowel preparation	1	1

CRC: Colorectal cancer.

RESULTS

Patient and polyp characteristics

A total of 1157 patients were screened, and 944 patients with 933 polyps were included in the final analysis (mean ± SD age 62.6 ± 8.6 years; 49.3% male) (Supplementary Figure 1). Most colonoscopies were performed for screening and surveillance. Among all detected polyps, 819 (87.8%) were either diminutive or small (1–9 mm). Table 2 shows the details of patient, procedure, and polyp characteristics.

PBRD strategy surveillance intervals

The PBRD strategy based on the 2020 guidelines reached 98.0% (95%CI: 0.97–0.99) agreement with pathology-based surveillance intervals (Figure 1). Based on the 2012 guidelines, surveillance interval agreement between real-time PBRD strategy and pathology was 76.4% (95%CI: 0.74–0.79). Endoscopists using the PBRD strategy assigned shorter and longer surveillance intervals in 15.4% and 8.3% of patients, respectively. When applied post hoc, the PBRD strategy based on the 2012 guidelines reached 90.7% (95%CI: 0.89–0.92) agreement with pathology-based recommendations, with shorter and longer intervals assigned in 5.8% and 3.5% of patients, respectively. The proportion of endoscopist assigned surveillance intervals that adhered to pathology-based intervals was significantly lower than those assigned post-hoc using the same strategy ($P < 0.0001$) (Table 3). None of the patients that should have received shorter surveillance intervals through the post-hoc PBRD model had a polyp with advanced histology. Only 3/145 patients that should have been assigned to shorter surveillance intervals by endoscopists had polyps with advanced histology. Deviations from the strategy decreased as the study progressed (Figure 2).

Optical diagnosis-based surveillance intervals

A total of 842 (90.2%) polyps ≤ 10 mm were optically diagnosed using NICE; of those, 648 (69.5%) were classified with high confidence (Table 2). The agreement between surveillance intervals assigned by optical diagnosis and pathology-based intervals using 2012 guidelines was 95.8% (95%CI: 0.94–0.97) (Figure 1). The agreement with pathology for surveillance intervals assigned by optical diagnosis was significantly higher than that for both the PBRD strategy used by endoscopists ($P < 0.0001$) and the PBRD strategy calculated post-hoc based on 2012 ($P < 0.0001$). Supplementary Table 1 shows allocation of surveillance intervals between optical diagnosis and pathology.

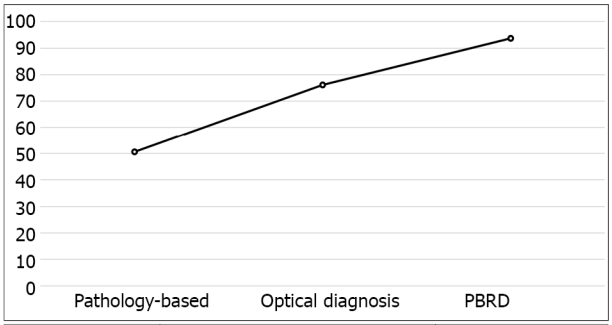
Figure 1 Surveillance agreement of optical diagnosis and polyp-based resect and discard strategy compared with histopathology. The dashed black line represents the 90% agreement of surveillance interval. PBRD: Polyp-based resect and discard.

Histopathology evaluations and immediate surveillance recommendations



When using the standard clinical approach, 50.6% of patients could have been given an immediate surveillance recommendation post-colonoscopy. The PBRD strategy (based on 2020 guidelines) and optical diagnosis would have allowed for immediate surveillance interval recommendation in 93.7% (95%CI: 0.92–0.95, and 76.1% (95%CI: 0.73-0.79) of patients, respectively (Figure 3A). The PBRD strategy reduced 87.8% of histopathology evaluations compared with 70.6% for optical diagnosis (Figure 3B).

A: Proportion of immediate surveillance interval recommendations provided to patients; B: Proportion of pathology examinations, the black bars represent the 95%CI. PBRD: Polyp-based resect and discard.

DISCUSSION

Our study found that surveillance interval assignment using the PBRD strategy based on the 2020 USMSTF guidelines reached 98.0% agreement with pathology. This agreement was significantly higher compared to optical diagnosis-based strategies. In contrast to optical diagnosis, the use of the PBRD strategy is independent of operator skill, leading to increased reproducibility in routine endoscopic practice.

Interestingly, we found that when the PBRD strategy was used in real-time by endoscopists, adherence to guideline recommendations was lower; endoscopists chose a different surveillance interval than the PBRD strategy in 20% of patients, possibly due to clinical information not reflected in the strategy, such as second-degree relatives with CRC or other individual factors. Our findings also reflect previously described practice patterns where endoscopists often assigned shorter surveillance intervals for low-risk lesions and normal colonoscopies, with highly variable but often low (< 50%) adherence to guidelines. Reasons for non-adherence stated in the literature included disagreement with guidelines, inadequate or suboptimal bowel preparation, and concern for missed polyps[15,16]. These factors potentially played a role in endoscopist deviations from the PBRD strategy in our study. Another explanation to these deviations could be the learning curve for PBRD implementation. We found that as the study progressed, the percentage of deviations from the PBRD strategy decreased (Figure 2).

Agreement between pathology-based and post-hoc allocation of surveillance intervals using the PBRD strategy based on 2020 USMSTF guidelines was significantly higher than the agreement between pathology-based and optical-based allocation of surveillance intervals [98.0% (95%CI: 0.97–0.99) *vs*

95.8% (95%CI: 0.94–0.97); P = 0.005]. Additionally, the agreement between optical diagnosis-based surveillance intervals and pathology surpassed the American Society for Gastrointestinal Endoscopy Preservation and Incorporation of Valuable endoscopic Innovations 90% benchmark[3]. However, agreement between surveillance interval assignments using real-time application of PBRD by endoscopists, and pathology was significantly lower than for optical diagnosis. In our study, 70% of polyps were optically classified with high confidence, similar to the rates reported by other studies[17]. Increasing the rate of high-confidence optical diagnosis would contribute to the acceptance of this technique in routine endoscopic practice, particularly for non-academic endoscopists. However, endoscopists are often reluctant to use optical diagnosis due to concerns of incorrect diagnosis, inappropriate surveillance interval assignment, and fear of potential medicolegal repercussions[10]. As our adaptation of the PBRD strategy to reflect the updated 2020 USMSTF guideline resulted in a significantly higher agreement compared with the 2012-based PBRD model [98.0% (95%CI: 0.97–0.99) *vs* 90.7% (95%CI: 0.89–0.92); P < 0.0001], we believe that the PBRD strategy may be a safe alternative that can be easily applied by endoscopists pending further research confirming efficacy in real-time endoscopic practice, and gastroenterology society endorsements. The PBRD strategy and optical diagnosis resulted in significant reductions in required histopathology evaluations, and increased the percentage of patients with same-day surveillance interval assignment. A significant proportion of post-colonoscopy colorectal cancers (PCCRCs) are due to administrative or decision-making errors[18]. Fail-safe mechanisms are therefore needed to ensure the assignment of an appropriate surveillance interval during the index session for follow-up examination. For instance, histopathology might not be followed up adequately, or patients might fail to receive their surveillance interval after pathology results are available. This would exacerbate loss to follow-up and increase the chance of PCCRC. The PBRD strategy could offer a simple solution for endoscopists to communicate the appropriate time for the next surveillance colonoscopy without requiring histopathology evaluation.

Another advantage of the PBRD strategy is that very high agreement with pathology-based surveillance intervals can be achieved without any specialized training, skill, or dedicated equipment. The PBRD strategy might be easier to implement and may address fears cited by endoscopists. As the fear of discarding polyps with advanced histology remains a significant concern and could limit the widespread adoption of resect and discard strategies, revised versions of PBRD could exclude polyps with morphology of potentially advanced lesions (*e.g.*, Paris IIc or III). Furthermore, it might be beneficial to limit the use of the PBRD strategy to diminutive polyps only, which would reduce the risk of assigning polyps with high-grade dysplasia or serrated adenomas to longer surveillance intervals, as advanced pathology occurs more frequently in polyps of 6–9 mm. Notably, the post hoc application of the PBRD strategy did not result in discarding any polyp with advanced histology in our study. Limiting this strategy to 1–3 mm polyps could also be feasible, especially when optical diagnosis is not possible and pathology examination to determine the histology of these polyps not reliable. Approaches to replace pathology for these polyps are likely safe as a recent study showed that advanced histologic features in diminutive polyps did not contribute towards metachronous CRC[19].

The emergence of new modalities such as artificial intelligence (AI)-assisted classification could provide an alternative to the proposed approach in the future. However, the accuracy of AI-based optical diagnosis in broader clinical practice with different endoscopists, platforms, and settings remains to be evaluated, with widespread clinical implementation far from reality. Furthermore, it is unlikely that every endoscopy unit could implement this cutting-edge technology immediately or at all once available. Therefore, the PRBD strategy could be used as a bridge or complementary system to AI. The current strategy of resection and histopathologic analysis of all polyps is associated with high costs. Previous studies estimated that the annual cost saving in the United States population following the adoption of a resect and discard policy for diminutive polyps ranges from United States $33 million to $1 billion annually[20]. By reducing such costs, healthcare systems could increase efficiency and reallocate savings to other resources in CRC prevention, such as screening in younger age groups.

Several limitations should be discussed. Patient recruitment was at a single academic center, limiting the generalizability of our results. Future research should assess PBRD in multicentered studies and community-based practices. The PBRD strategy could be improved by considering other important clinical factors, such as in-depth family and personal history of CRC and/or polyps, suboptimal bowel preparation score (*e.g.*, BBPS of 5 or 6), or offering more granular choices to clinicians. Furthermore, results of this study may have been improved if PBRD was limited to diminutive or 1–3 mm polyps only, due to the low prevalence of advanced histology in such polyps at the expense of lower proportion of patients with same day surveillance interval assignment and higher proportion of required pathology examinations[2].

CONCLUSION

In conclusion, the PBRD strategy reached 98.0% agreement with surveillance intervals assigned through pathology using the 2020 USMSTF guidelines. Performance with the 2012 guidelines was lower when implemented correctly but still surpassed the 90% benchmark. Optical diagnosis also performed above

the 90% benchmark in our study. Therefore, the PBRD strategy may be a feasible alternative to resect and discard that can be used without specialized equipment, training, or optical diagnosis skills.

ARTICLE HIGHLIGHTS

Research background

The majority (90%) of polyps found during colonoscopies are less than 10 mm in size, with diminutive polyps (< 5 mm) accounting for about 70%–80%. Advanced histology is found in only 1.7% of diminutive polyps and 10.1% of small polyps. Current post-polypectomy surveillance intervals are based on pathology outcomes. However, histopathologic evaluation of small polyps can incur significant costs.

Research motivation

Alternative modalities have been proposed, such as image-enhanced endoscopy-assisted optical polyp diagnosis. Limitations of the optical diagnosis included fear of making an incorrect optical diagnosis, assigning incorrect surveillance intervals, and training requirements.

Research objectives

We aimed to develop a novel resect and discard model that did not require optical diagnosis to assign colonoscopy surveillance intervals, and assigned surveillance interval based on number and size of polyps, so-called the polyp-based resect and discard (PBRD) strategy.

Research methods

In a clinical prospective study, all patients undergoing elective colonoscopies were enrolled. The polyp-based strategy was used to assign the next surveillance interval using polyp size and number. Surveillance intervals were also assigned using optical diagnosis for small polyps (< 10 mm). The primary outcome was surveillance interval agreement between the polyp-based model and the pathology-based reference standard using the 2020 United States Multi-Society Task Force guidelines.

Research results

Surveillance interval based on a polyp-based strategy achieved 98.0% (95% confidence interval: 0.97–0.99) agreement with pathology-based intervals when applied according to the current surveillance guideline.

Research conclusions

The polyp-based strategy can easily be implemented without any requirement for specialist devices and training. The majority of patients can be provided with immediate surveillance interval recommendations, without having to wait for results of pathology analysis.

Research perspectives

Future research should assess PBRD in multicentered studies and community-based practices.

Abstract

The association between type 2 diabetes mellitus (DM) and colorectal cancer (CRC) has been thoroughly investigated and reports have demonstrated that the risk of CRC is increased in DM patients. The association between DM and the survival of patients with CRC is controversial. Evidence suggests that metformin with its anti-inflammatory effects is a protective factor against the development of CRC among DM patients and that metformin therapy is associated with a better prognosis in patients with DM. In our cohort, we did not find any associations between the presence of DM or metformin and cancer specific survival or any relation to plasma levels of a panel of 40 inflammatory factors and irisin. On the other hand, we identified that the insulin-like growth factor binding protein 7 single nucleotide polymorphism rs2041437 was associated with DM in CRC patients. The dominance of the T bearing genotypes in patients with DM was statistically significant (P = 0.038), with an odds ratio of 1.66 (95% confidence interval: 1.03-2.69).

Key Words: Diabetes; Metformin; Cytokines; Survival; Colorectal cancer; Polymorphism

Core Tip: Type 2 diabetes mellitus (DM) or metformin treatment does not influence mortality in colorectal cancer (CRC). Type 2 DM or metformin does not influence the levels of inflammatory factors in plasma in patients with CRC. Single nucleotide polymorphisms of insulin-like growth factor binding protein 7 are associated with type 2 DM in patients with CRC.

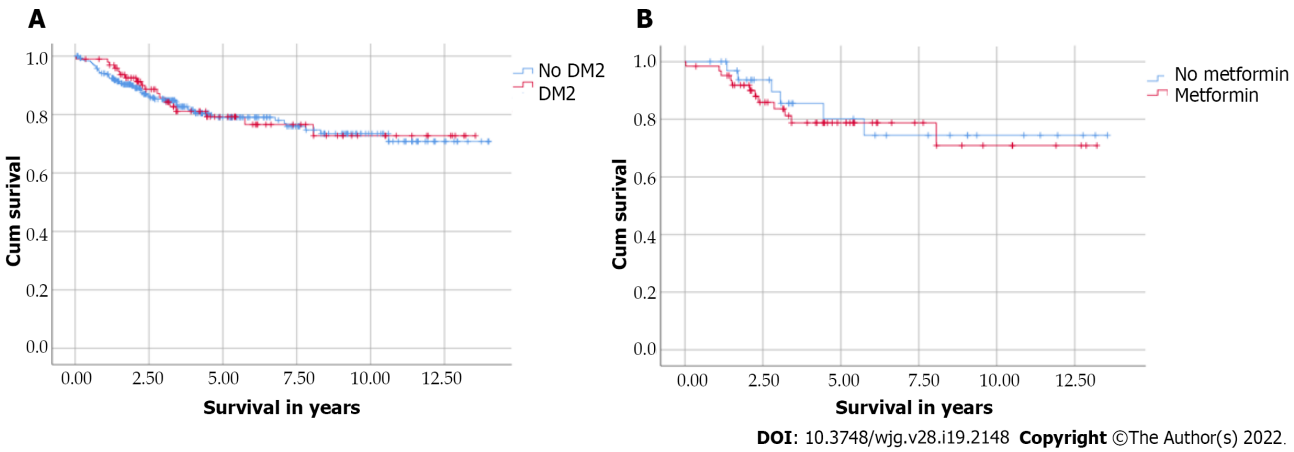
TO THE EDITOR

Having read the article "How far along are we in revealing the connection between metformin and colorectal cancer?" by Cigrovski Berkovic *et al*[1] in *World Journal of Gastroenterology* 2021, we want to contribute with some aspects and data on this matter.

Colorectal cancer (CRC) is one of the most common cancer types worldwide and several genetic pathways affecting CRC initiation and progression have been described[2]. The association between type 2 diabetes mellitus (DM) and CRC has been thoroughly investigated and reports have demonstrated that the risk of CRC is higher in DM patients[3]. However, the association between DM and the survival of patients with CRC is controversial[4,5].

Metformin is an oral glucose-lowering agent used to treat DM. It has also been reported to possess properties that inhibit the proliferation and growth of certain types of cancer[6]. Moreover, recent studies show that metformin has anti-inflammatory effects, a property that can be beneficial in conditions other than DM, such as cardiovascular disease and cancer[7].

Overall, evidence suggests that metformin could protect against the development of CRC among DM patients and that metformin therapy is associated with a better prognosis in patients with DM[1,6,8]. However, this protective role of metformin in CRC remains controversial[1,8]. In light of the above and with special reference to a report by Cigrovski Berkovic *et al*[1], we here add our observations of CRC patients (n = 408) without DM (n = 310) or with DM (n = 98), treated with metformin (n = 63) or not (n = 35), and any associations of these factors with cancer-specific survival, inflammatory factors, or single nucleotide polymorphisms (SNPs).



Blood samples were obtained from all consecutive CRC patients who underwent surgical resection for primary colorectal adenocarcinomas between 2006 and 2019 at the Department of Surgery, Ryhov County Hospital, Jönköping, Sweden. Follow-up for the estimation of cancer-specific survival ended on the date of death or on February 23, 2021. The patient data have been prospectively recorded in a database, comprising 236 males and 172 females with a mean age of 71 years. The study included 172 patients with rectal cancer and 236 patients with colon cancer, based on the primary tumor site. The tumors were classified as stage I in 63 patients, stage II in 148, stage III in 148, and stage IV in 49. The study was approved by the Regional Ethical Review Board in Linköping, Sweden, and informed consent was obtained from each participant.

We did not find any relationships between the presence of DM or metformin and cancer-specific survival in patients with CRC in our cohort, as demonstrated by Kaplan-Maier curves (Figure 1). Receiver operating characteristic curve analysis confirmed this result (data not shown).

Against the background that inflammation has a driving force in carcinogenesis of CRC[2] and that metformin has anti-inflammatory effects, we have applied data that we have previously published in *World J Gastroenterology*[9] regarding a panel of 40 circulating inflammatory factors in a cohort of 174 CRC patients, of whom 44 had DM and 17 were treated with metformin. We found that plasma levels of these factors did not differ between CRC patients with or without DM, whether treated with metformin or not (data not shown). This was also the case when similar analyses were performed regarding carcinoembryonic antigen (CEA) levels, which were available for 332 of the patients.

Irisin is a relatively recently discovered hormone (myokine) that is involved in the regulation of metabolic processes such as stimulation of glycogenesis and inhibition of glycogenolysis and has been suggested to play an important role in DM[10]. However, studies have reported both decreased and increased irisin levels in DM patients[10]. In a clinical study, Zhu *et al*[11] showed reduced serum levels of irisin in CRC patients and suggested that irisin might be used as a serum diagnostic marker. In our analysis, we found no general difference in cancer-specific survival depending on the levels of irisin. Nor were differences in cancer-specific survival observed in those with or without DM and with or without metformin treatment.

Insulin-like growth factor-binding protein 7 (IGFBP 7) binds strongly to insulin and has been found, by us[12] and others[13], to be increased in CRC tissue. Moreover, we have investigated the IGFBP 7 SNP rs2041437 (C > T) in relation to CRC development[12]. When adding further CRC patients (n = 340)

Figure 1 Kaplan-Meier curves. A: Kaplan-Meier curves for colorectal cancer patients with and without type 2 diabetes, revealing no statistically significant differences; B: Kaplan-Meier curves for patients with colorectal cancer and type 2 diabetes using or not using metformin, revealing no statistically significant differences.DM: Diabetes mellitus.

to the earlier study, we found that the rate of the CC genotype was 45.4% and that of CT/TT was 54.6% among patients without DM, while they were 33.3% and 66.7%, respectively, in patients with DM. The dominance of the T-bearing genotypes in patients with DM was statistically significant (P = 0.038), with an odds ratio of 1.66 (95% confidence interval: 1.03-2.69).

In summary, our data do not support the hypothesis that DM increases mortality in CRC or that metformin prevents death from CRC, at least in patients in Swedish healthcare. We could not see any association between circulatory inflammatory factors, irisin, or CEA levels and DM or metformin among CRC patients. On the other hand, we identified that the IGFBP 7 SNP rs2041437 was associated with DM in CRC patients. It should be pointed out that patients with metformin treatment were relatively few, rendering interpretation of data regarding this group uncertain.

FOOTNOTES

Author contributions: Dimberg J and Wågsäter D designed and coordinated the study; Shamoun L performed the experiments, and acquired and analysed the data; Dimberg J, Shamoun L, Landerholm K, and Wågsäter D interpreted the data; Landerholm K recruited the patients; Dimberg J, Landerholm K, and Wågsäter D wrote the manuscript; all authors made critical revisions to the manuscript and approved the final version of the article.

ABOUT COVER

Editorial Board Member of *World Journal of Gastroenterology*, Donatella Barisani, MD, MSc, Associate Professor, School of Medicine and Surgery, University of Milano Bicocca, Via Cadore 48, Monza 20900, Italy. donatella.barisani@unimib.it

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, and Scopus. The 2021 edition of Journal Citation Report® cites the 2020 impact factor (IF) for *WJG* as 5.742; Journal Citation Indicator: 0.79; IF without journal self cites: 5.590; 5-year IF: 5.044; Ranking: 28 among 92 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2020 is 6.9 and Scopus CiteScore rank 2020: Gastroenterology is 19/136.

Abstract

Given the breakthroughs in key technologies, such as image recognition, deep learning and neural networks, artificial intelligence (AI) continues to be increasingly developed, leading to closer and deeper integration with an increasingly data-, knowledge- and brain labor-intensive medical industry. As society continues to advance and individuals become more aware of their health needs, the problems associated with the aging of the population are receiving increasing attention, and there is an urgent demand for improving medical technology, prolonging human life and enhancing health. Digestive system diseases are the most common clinical diseases and are characterized by complex clinical manifestations and a general lack of obvious symptoms in the early stage. Such diseases are very difficult to diagnose and treat. In recent years, the incidence of diseases of the digestive system has increased. As AI applications in the field of health care continue to be developed, AI has begun playing an important role in the diagnosis and treatment of diseases of the digestive system. In this paper, the application of AI in assisted diagnosis and the application and prospects of AI in malignant and benign digestive system diseases are reviewed.

Key Words: Artificial intelligence; Digestive disease; Convolutional neural network; Deep learning; Review

Core Tip: With the continuous development of artificial intelligence, its integration in the field of medical and health care has received increasing attention, allowing the development and application of medical expert systems and artificial neural networks in the medical field. The development of artificial intelligence has resulted in not only more accurate diagnoses of digestive system diseases but also new treatments. Further research on the progress of artificial intelligence in digestive system diseases is needed to better serve patients.

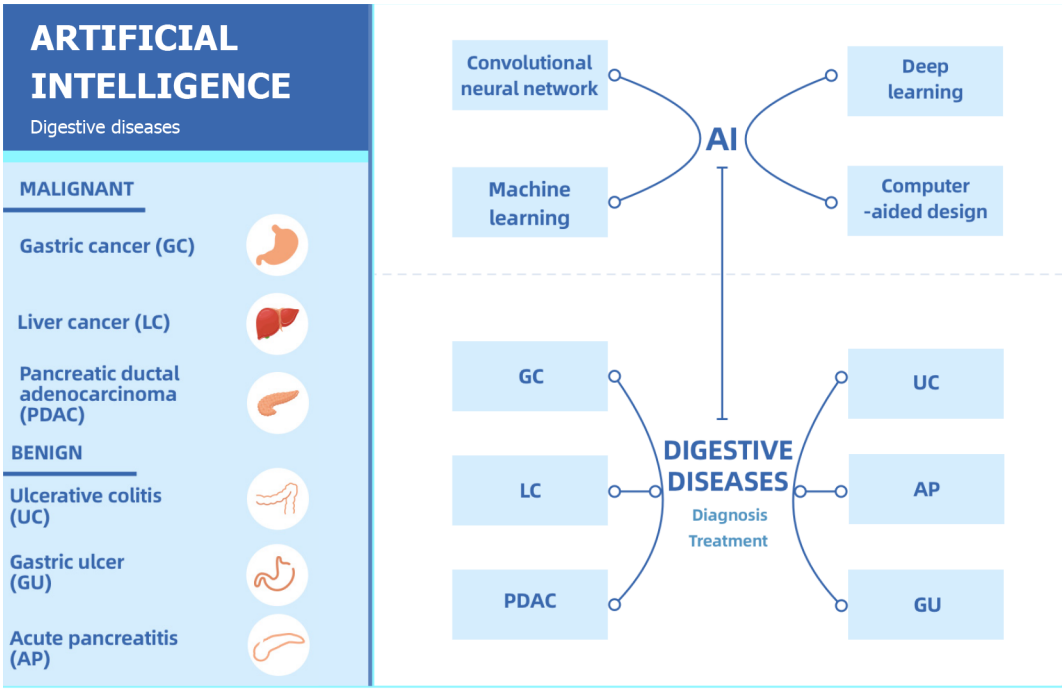
INTRODUCTION



Artificial intelligence (AI) is a branch of computer science[1] inspired by human intelligence that operates in a different way. AI can be considered a set of computing techniques that allow machines to sense, learn, reason, act, *etc.* AI was first used at the Dartmouth AI Conference in the summer of 1956, which is considered the official birth of AI. In the 1990s, as technology continued to improve, hardware became more affordable, performance became more reliable, computing power, storage capacity and the ability to process data were greatly improved, and AI returned to life. In recent years, the application of AI in the medical field has reached an unprecedented height and scale. To date, great progress has been achieve in the use of AI in medicine and health, including speech recognition, medical imaging, wearable devices, risk management, pathology, *etc*[2].

The digestive system contains the largest number of organs in the human body and can be divided into the digestive tract and digestive glands. The digestive tract includes the oral cavity, pharynx, esophagus, stomach, duodenum, small intestine, large intestine, colon, *etc*. The digestive glands comprise the salivary glands, liver, pancreas, *etc.* The digestive system digests food, takes up nutrients and eliminates waste. The coordination of gastrointestinal physiological activities depends on the completion of the normal physiological function of the digestive system. Digestive system diseases, which are the most common clinical diseases, have complicated clinical manifestations, are interrelated with each other, and form a hot spot in the medical field[3]. The incidence of digestive system diseases is high, and often, there are no obvious symptoms in the early stage. Consequently, most digestive diseases are first noted in the middle and late stages; at this point, the prognosis is poor. As AI technology has continued to be developed, its strong computing power and learning ability have been gradually applied to solve complex medical problems. In the field of digestive diseases, such as gastric, liver, and pancreatic cancer and ulcerative colitis, AI can help improve the accuracy and sensitivity of the diagnosis and provide treatment options (Figure 1). AI not only improves the diagnostic accuracy of the disease but also provides a plan for clinical treatment.

In this review, we discuss AI and related technologies, their applications in digestive diseases and their future developments. We used PubMed and Google to search for relevant articles by using the keywords “digestive system diseases”, “artificial intelligence”, “machine learning”, “deep learning”, “computer-aided diagnosis”, “convolutional neural network”, and “endoscopy and endoscope images” for this review.

AI AUXILIARY DIAGNOSIS

In China, the development of AI has received considerable attention, particularly in the application of AI in the medical field. The development of AI has laid a solid foundation for precision medicine. In 2017, the China State Council announced that AI application should be promoted in the health care system. Subsequently, hundreds of new companies dedicated to the application of medical AI have emerged in China, promoting the development of AI in the medical field[4]. AI effectively improves the uneven allocation of medical resources, reduces medical costs and enhances medical efficiency. AI algorithms improve the ease of medical work and lead to not only technological innovations but also a transformation of the medical service mode. AI is applied in all fields of medicine and health, especially in the auxiliary diagnosis of diseases, and includes the following three aspects: intelligent guidance, electronic health records and risk monitoring of diagnosis and treatment.

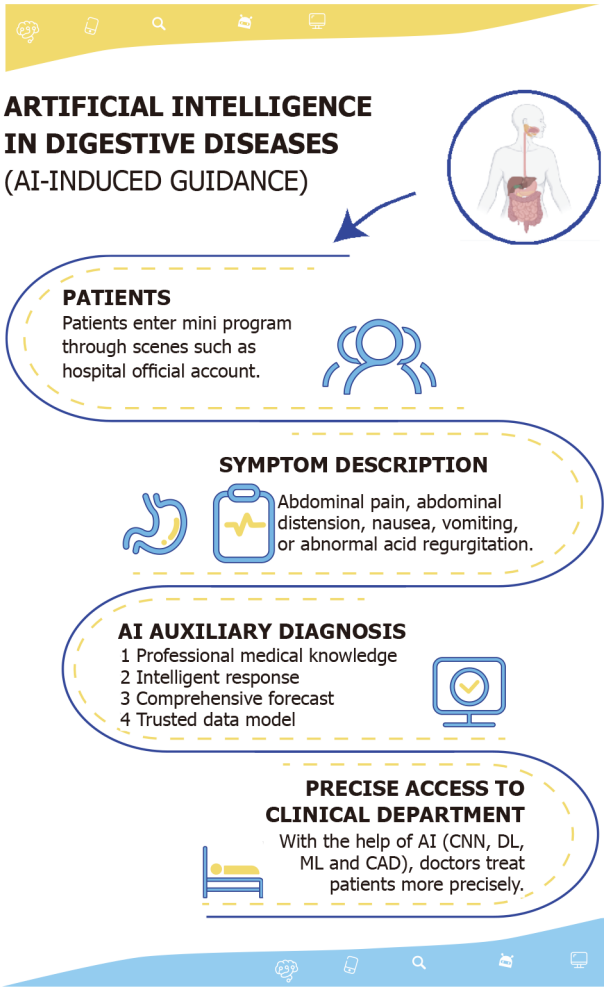
Intelligent guidance



Outpatient triage has gradually transitioned from a traditional manual system to an internet- and intelligence-based system. Most admitted patients lack an understanding of their disease and the hospital. To improve the efficiency and experience of the patients, intelligent guidance systems have been developed. Patients enter the Mini Program through screens on official hospital accounts to describe symptoms or diseases, and guidance assistants intelligently follow up and guide the patients to provide symptoms to accurately match departments, recommend doctors with the most consistent professional direction, and perform online guidance registration in one step. The research and development leading to intelligent guidance systems has led to a reduction in not only the workload of outpatient staff but also the human resource needs and costs of hospitals. These systems can guide patients to seek medical treatment quickly and accurately, improve the accuracy of patient registration and the efficiency of the physician response, increase efficiency at all steps of the patient stay, and effectively provide accurate medical treatment (Figure 2).

Electronic health record

Traditional health records are typically kept on paper, which tend to be scattered in hospital archives, limiting their value. The widespread use of the internet has facilitated the creation of electronic health records (EHRs), which are currently widely used worldwide[5]. EHRs can improve management processes, overcome problems with paper documentation, and ensure the quality of treatment. Both theoretically and practically, EHRs have guiding and economic value, while their applicative value continues to improve. In addition, EHRs can improve clinical decision-making, collaboration between health care teams, and medical efficiency.

Risk monitoring of diagnosis and treatment

Diagnostic risk monitoring systems can improve the diagnostic accuracy and greatly reduce the risk of misdiagnosis, and in this regard, AI has significant advantages over clinical experience. Compared with the United States, domestic equipment is used much more frequently under the same resource allocation[6]. This is the main point of medical care in China. Additionally, the large associated workload and high repeatability result in a cumbersome manual analysis and diagnosis. An accurate diagnosis rate is important for ensuring that radiologists can provide high-quality care to patients. A report in 1999 showed that 98000 people die of misdiagnosis each year, and diagnostic errors by radiologists are a key contributor[7]. Under a heavy workload, the diagnosis results can only be judged and analyzed by subjective individual experience, leading to high misdiagnosis and missed diagnosis rates. The large market demand for pathologists and diagnostic efficiency have also led to new challenges in the medical service industry. However, digestive system diseases increasingly depend on auxiliary diagnoses based on medical images while continuing to demonstrate a yearly increase in

Figure 2 Artificial intelligence and Intelligent guidance. CNN: Convolutional neural network; DL: Deep learning; ML: machine learning; CAD: Computer-aided design.

incidence.

The emergence of AI has led to its gradual use in digestive diseases. Machine learning (ML) is a branch of AI that aims to predict results by analyzing existing data and performing calculations based on an understanding of these data. Deep learning (DL) is a relatively new branch of ML that imitates learning through machine algorithms and provides a set of possible and reasonable solutions[8,9]. In esophageal cancer, van der Sommen *et al*[10] developed an automatic algorithm to distinguish early neoplastic lesions. Huang *et al*[11] used 84 images from 30 patients to train an AI-based neural network model to predict Helicobacter pylori infection. DL can be used to share more comprehensive medical diagnosis and treatment information with doctors with lightweight methods. At a higher level, we can comprehensively manage and guide the overall diagnosis and treatment level of the physician team to build a more scientific, accurate and friendly diagnosis and treatment risk monitoring system.

MALIGNANT DIGESTIVE DISEASES

The digestive system is a common site for malignant tumors, particularly gastric cancer, liver cancer, colorectal cancer and pancreatic cancer. Given the changes in lifestyle, diet and disease spectrum of the population, the incidence of malignant tumors of the digestive system continues to rise[12]. The early diagnosis of malignant tumors is critical for treatment, but patients with malignant tumors often have no obvious symptoms at the early stage, leading to difficulties in early diagnosis. This section summarizes the application of AI in the following three types of malignant tumors with high morbidity and mortality: gastric, liver and pancreatic cancer. The latest clinical studies concerning AI, gastric cancer, liver cancer, and pancreatic ductal adenocarcinoma are summarized in Table 1.

Table 1 Recent researches on artificial intelligence in malignant digestive system diseases

AI and gastric cancer

Gastric cancer (GC) is the fifth most common cancer and ranks third in cancer mortality worldwide, with more than 1 million new cases and 780000 deaths each year[13]. The stage at which GC is diagnosed can greatly affect the prognosis, with a poor prognosis typical in the late stage and a 5-year survival rate of early GC (EGC) exceeding 90%[14]. There are two difficulties in the early diagnosis of GC. First, EGC is difficult to detect, often presenting with slight reddish bulges or depressions under endoscopy that are not easily distinguished from inflammatory lesions. The second difficulty lies in judging the depth of the invasion of GC. In general, intramucosal GC or GC invading the superficial submucosal layer should be resected endoscopically, while GC invading the deep submucosal layer should be resected with open surgery; otherwise, there could be a risk of lymph node and distant metastasis. However, it is difficult to distinguish among these three forms of GC. The rapid development of DL and ML has led to great progress in AI, whose image recognition has transcended that of humans. By reviewing the published literature, this section discusses the diagnosis, treatment and prognosis of GC with AI.

Hirasawa *et al*[15] constructed a diagnostic system based on a convolutional neural network (CNN). The authors used 13584 endoscopic images to train the web-based learning model and 2296 GC images from 69 patients to evaluate its performance. The model took 47 s to analyze 2296 images and correctly diagnosed 77 GC lesions with a total sensitivity of 92%. This web-based learning model for the detection of EGC processes a large number of stored endoscopic images with clinical-related diagnostic capabilities in a very short time and may play a role in real-time gastroscopy[15].

Kubota *et al*[16] used a back propagation neural network algorithm to analyze the depth of gastric wall infiltration in endoscopic images of 344 GC patients and developed a computer-aided design (CAD) system. The cross-validation results revealed that the diagnostic accuracy of T1, T2, T3 and T4 GC was 77%, 49%, 51% and 55%, respectively. The accuracy in detecting intramucosal carcinoma (T1a) and submucosal invasive carcinoma (T1b) is 69%[16]. This study may be used to screen for EGC in the near future.

AI and liver cancer

Liver cancer (LC) is the second leading cause of death worldwide, and its incidence continues to increase[17]. In recent years, AI has been used in various aspects of LC diagnosis and treatment, especially in the field of imaging. However, individual differences in liver morphology and the internal anatomy and the highly heterogeneous molecular and pathological features of LC lead to great challenges in the implementation of AI, ML and DL for the diagnosis and treatment of this disease[18].

The following two modes of AI application are commonly used in the diagnosis of LC: DL and radiomics. Imaging plays a key role in the identification and diagnosis of hepatobiliary diseases and the establishment of surgical treatment plans. Radiologists and surgeons demarcate organs and diagnose diseases based on their experience and judgment, which can be subjective, time consuming and unreproducible; AI can address these limitations. DL is mainly used for the diagnosis of LC *via* traditional machine learning (TML) and CNNs. In TML, a well-developed anatomical model must be established in advance and manually corrected in the later stages[19], while the application of CNNs allows images to be directly used in the learning process, allowing the extraction and utilization of all information contained in the image for DL[20]. Shaw Hospital of Zhejiang University developed a DL system for liver tumor diagnosis through a CNN. In addition to learning more than 30000 magnetic resonance (MR) images, the system incorporates patient clinical data (medical records, examination results, etc.) and demonstrates excellent diagnostic performance with a coincidence rate with a final pathological result of 92%[17].

The application of AI in the treatment of LC has led to new opportunities and challenges, promoting the standardization and intelligence of LC management. Hu *et al*[21] used 3D visualization to evaluate the spatial relationship between tumors and surrounding blood vessels before hepatectomy, which serves as a suitable guide for surgical resection. In the treatment of LC by radiofrequency ablation, fusion imaging can integrate enhanced computed tomography (CT)/MR images with real-time ultrasound imaging by electromagnetic tracking to accurately locate the target lesions[22-24]. AI has been applied to all aspects of LC treatment and auxiliary diagnosis, but further prospective research is needed.

AI and pancreatic ductal adenocarcinoma

Pancreatic ductal adenocarcinoma (PDAC) is a rapidly progressive and highly malignant tumor of the digestive tract[25]. Although many methods have been developed for the diagnosis and treatment of PDAC in recent years, the effective rate of treatment and prognosis remain poor (the 5-year survival rate is only 9%[26]). The early detection and accurate treatment of PDAC are important directions requiring urgent solutions.

Recently, rapid developments have been achieved in the AI-based screening and diagnosis of PDAC, leading to acceptable effects. Ansari *et al*[27] applied artificial neural networks (ANNs) to a long-term survival prediction of patients after radical surgery for PDAC for the first time and achieved a consistency index of 0.79, indicating that their ANN could predict the survival rate of PDAC patients after radical surgery. Fine needle aspiration (FNA) biopsy is an elaborate approach used to diagnose solid masses of the pancreas. Due to the small number of cases, its development is limited. Momeni-Boroujeni *et al*[28] used a multilayer-perceptron neural network (MNN) to evaluate 277 cell mass images from 75 pancreatic FNA patients and achieved an accuracy of 100% in the classification of benign and malignant tumors. In particular, the sensitivity and specificity of MNN in identifying atypical cases were 80% and 75%, respectively. Intraductal papillary mucinous neoplasm (IPMN), a papillary mucinous tumor with many subtypes, has particular malignant potential. Endoscopic ultrasonography (EUS) can reveal the structure of the pancreas and the dilation of the pancreatic duct and can be used to evaluate the degree of malignancy of IPMN. Indeed, Kuwahara *et al*[29] used AI to build a system to perform this function. The authors uploaded 3970 EUS images of 50 patients to the system for DL analysis. The endpoint of their system was the accuracy in diagnosing the malignancy degree of IPMNs by AI. The results showed that the AI system had significantly better value in diagnosing malignant IPMNs than benign IPMNs, with an area under the receiver operating characteristic curve of 0.91 in diagnosing malignant IPMNs. In addition, a three-dimensional depth supervised segmentation network has been developed to classify CT images from PDAC patients and control groups. Chu *et al*[30] standardized the number of cases, the sizes of the segmented images, and the selection of organs and then segmented the boundaries of the abdominal organs and pancreatic tumors in 575 control subjects and 750 patients with PDAC. The results showed that the sensitivity and specificity of the algorithm in detecting PDAC in patients were 94.1% and 98.5%, respectively. The early diagnosis of PDAC is a problem that many physicians find difficult. Appelbaum *et al*[31] developed a risk model for the prediction of PDAC based on patient EHRs that could identify high-risk groups one year in advance,

suggesting that their risk scores could also be used as an initial filter for PDAC.

BENIGN DIGESTIVE DISEASES

In addition to gastric cancer, liver cancer and other malignant tumors, other digestive system diseases include ulcerative colitis, pancreatitis, gastric ulcer, gastritis, intestinal polyp and other benign digestive system diseases. We summarize the application of AI for the benign digestive system diseases discussed below. The latest applications of AI in ulcerative colitis, severe acute pancreatitis, gastric ulcers, gastritis and intestinal polyps are summarized in Table 2.

AI and ulcerative colitis

Ulcerative colitis (UC) is a common chronic intestinal disease; however, there is no single gold standard for the diagnosis of this disease. Combining clinical, laboratory, imaging, endoscopic and histopathological findings, the diagnosis is made by excluding infectious and other noninfectious forms of colitis [32]. Endoscopy is essential, but the accuracy and precision of the diagnosis are limited by doctors' subjectivity. Yao *et al*[33] established a fully automatic endoscopic disease grading video analysis system through AI. These authors used a CNN to train models to predict the amount of information in still images and, thus, determine the severity of the disease. Then, the authors examined 51 and 264 videos from developed high-resolution and multicenter clinical trial test sets, respectively. The results showed that the static image information classification system had good performance, with a sensitivity of 0.902 and specificity of 0.870. For the high-resolution videos, the fully automated methods correctly predicted the Mayo endoscopic score (MES) in 78%. The automated MES grading of the clinical trial videos (often low resolution) correctly distinguished remitted *vs* active disease in 83.7%. To analyze endoscopic images of UC more accurately, Takenaka *et al*[34] developed a deep neural network system and tested 40758 colonoscopy images and 6885 biopsy results from 2012 UC patients. The results identified endoscopic remission with 90.1% accuracy and histologic remission with 92.9% accuracy. In addition, Maeda *et al*[35] developed a CAD system to predict persistent histologic inflammation using endocytoscopy and evaluated its accuracy using 12900 endocytoscopy images. The results showed that the CAD system provided a diagnostic sensitivity, specificity, and accuracy of 74%, 97% and 91%, respectively. In recent years, great progress has been achieved in the treatment of UC, but surgery remains important [36]. These results show that AI has great potential in the diagnosis and treatment of UC.

AI and pancreatitis

Acute pancreatitis (AP) is a common clinical acute abdomen disease with a complex and variable presentation. Severe AP (SAP) is often life threatening, with multiple organ dysfunction induced by SAP being a particularly difficult clinical problem[37]. Qiu *et al*[38] developed three ML algorithms to predict the risk of organ failure in moderate SAP (MSAP) and SAP. These authors inputted 16 parameters from 263 patients with MSAP and SAP into a support vector machine (SVM), logical regression analysis (LRA) and ANN models. The results showed that the SVM, LRA and ANN models could effectively predict the risk of multiorgan failure in MSAP and SAP. Respiratory failure is the main cause of early death in SAP. The early prediction of acute lung injury (ALI) is beneficial for reducing mortality from SAP. The ANN model established by Fei *et al*[39] can effectively predict the occurrence of ALI induced by SAP, with the accuracy of predicting severe acute respiratory distress syndrome reaching 82.8%. Abdominal infection is an important risk factor for organ failure induced by SAP. Compared with logistic regression analyses, the ANN model developed by Qiu *et al*[40] can more accurately predict abdominal infection in MSAP and SAP, with a sensitivity and specificity of 80.99% and 89.44%, respectively. Fei *et al*[41] constructed and verified an ANN model based on clinical and laboratory data from 72 patients with AP. Notably, the sensitivity, specificity, positive predictive value and negative predictive value of the ANN model for portosplenomesenteric venous thrombosis (PSMVT) were 80%, 85.7%, 77.6% and 90.7%, respectively. Thus, this model provides a good reference for the clinical prediction of the occurrence of PSMVT. The recurrence rate after the first attack of AP is approximately 22%, but few indicators can predict this recurrence. Chen *et al*[42] developed a quantitative radiology model based on contrast-enhanced CT. The results of the verification analysis showed that the model can predict the recurrence of AP well in the main and verification populations, with accuracies of 87.1% and 89.0%, respectively. This finding suggests that their model may be a good quantitative method for the prediction of recurrence in patients with AP. Chronic pancreatitis (CP), which is another common clinical digestive system disease, is an important factor in inducing pancreatic cancer. Although traditional pancreaticoduodenectomy, distal pancreatectomy, and the Frey and Beger procedures have achieved considerable success in relieving CP pain, the approaches are often accompanied by serious complications. Therefore, minimally invasive surgery and robot platforms are gradually being applied in the surgical treatment of CP. A retrospective study based on 812 cases of robotic pancreatectomy and reconstruction showed that the robotic platform is safe and feasible in performing complex pancreatectomy to alleviate the sequelae of CP[43]. Autoimmune pancreatitis (AIP) is a rare and special type of chronic pancreatitis, and its diagnosis is clinically challenging. Marya *et al*

Table 2 Recent researches on artificial intelligence in benign digestive system diseases

Ref.	Study design	Study population	Year	Disease	Country/Region	Number of cases	Methods	Results
Maeda *et al*[35]	Retrospective	Hospital	2019	UC	Japan	12900 Images	CAD	Sensitivity: 74%; Specificity: 97%; Accuracy: 91%
Popa *et al*[56]	Retrospective	Hospital	2020	UC	Romania	55 Cases	ML	Accuracy: 90%; AUC: 0.92
Tong *et al*[57]	Retrospective	Hospital	2020	UC	China	6399 Cases	RF, CNN	Sensitivity: RF (0.89); Sensitivity: CNN (0.90)
Qiu *et al*[38]	Retrospective	Hospital	2019	SAP	China	263 Cases	ANN	Sensitivity: 80.99%; Specificity: 89.44%
Chen *et al*[42]	Retrospective	Hospital	2019	SAP	China	389 Cases	LR	Accuracy: 87.1%
Namikawa *et al*[45]	Retrospective	Hospital	2020	Gastric ulcer	Japan	720 Images	A-CNN	Sensitivity: 93.3%; Specificity: 99.0%; PPV: 99.1%
Steinbuss *et al*[46]	Retrospective	Hospital	2020	Gastritis	Germany	1230 Images	CNN	Accuracy: 84%; Sensitivity: 100%; Specificity: 93%
Ozawa *et al*[47]	Retrospective	Hospital	2020	Colorectal polyps	Japan	16418 Images	CNN	Sensitivity: 92%; PPV: 86%

UC: Ulcerative colitis; SAP: Severe acute pancreatitis; CAD: Computer-aided diagnosis; ML: Machine learning; RF: Random forest; CNN: Convolutional neural network; ANN: Artificial neural networks; LR: Logistic regression; A-CNN: Advanced convolutional neural network; AUC: Area under the curve; PPV: Positive predictive value.

[44] developed and validated a CNN model based on a database containing 174461 EUS images and videos from 583 patients. After training, the model could accurately distinguish AIP from PDAC and other benign pancreatic diseases with a sensitivity and specificity of 90% and 85%, respectively.

AI and other diseases

AI has been used in numerous applications for other diseases, such as gastric ulcers, gastritis and colorectal polyps. Namikawa *et al*[45] developed an advanced CNN (A-CNN) based on the original convolutional neural network and evaluated its applicability in the classification of gastric ulcers. These authors used 720 images from 120 patients with gastric ulcers to evaluate the diagnostic performance of the A-CNN. The results showed that the sensitivity, specificity, and positive predictive value of the A-CNN in classifying gastric ulcers were 93.3%, 99.0%, and 99.1%, respectively. There are several subtypes of gastritis, including autoimmune, bacterial, and chemical. Steinbuss *et al*[46] evaluated the ability of a CNN to classify the common gastritis subtypes using a small data set of 1230 gastric antrum and corpus biopsy images. The results showed that the overall accuracy in the test set was 84%, and the sensitivity and specificity for bacterial gastritis were 100% and 93%, respectively. Ozawa *et al*[47] constructed a deep CNN architecture and trained the CNN using 16418 images from 4752 colorectal polyps and 4013 normal colorectal images. Then, the performance of the trained CNN was verified with 7077 additional colonoscopy images. The results showed that the sensitivity of the CNN was 92%, and the positive predictive value was 86%, proving that it has excellent potential as a colonoscopy CP-diagnosis support system based on AI.

CONCLUSION

With the steady development of AI and its heavy integration in the medical industry, AI has received increasing attention in the fields of medicine and health. Digestive system AI technology differs from other AI technologies because of the nonstandard nature of most digestive endoscopic images and the large number of influencing factors, resulting in difficulty in developing such technology. Currently, AI plays an important role in digestive system diseases, particularly in its gradual application in diagnosis and treatment in the clinic. AI has broad prospects in the field of medicine and health, but the cooperation of medical workers and computer experts is needed to develop more intelligent applications and higher-quality services for patients. In summary, as an emerging player, AI will continue to play an increasingly important role in future development. The close combination of AI and medicine can address problems, such as the insufficient supply and uneven distribution of medical resources and

low degree of medical efficiency. More in-depth research should be performed to investigate the application of AI in digestive system diseases from various perspectives to obtain additional diagnosis and treatment measures, promote diagnosis, optimize treatment, improve patient prognosis, and gradually achieve intelligent and accurate medical treatment.

Abstract

Pancreatic neuroendocrine neoplasms (PanNENs) are rare neoplasms with strong heterogeneity that have experienced an increasing incidence rate in recent years. For patients with locally advanced or distant metastatic PanNENs, systemic treatment options vary due to the different differentiations, grades and stages. The available options for systemic therapy include somatostatin analogs, molecularly targeted agents, cytotoxic chemotherapeutic agents, immune checkpoint inhibitors, and peptide receptor radionuclide therapy. In addition, the development of novel molecularly targeted agents is currently in progress. The sequence of selection between different chemotherapy regimens has been of great interest, and resistance to chemotherapeutic agents is the major limitation in their clinical application. Novel agents and high-level clinical evidence continue to emerge in the field of antiangiogenic agents. Peptide receptor radionuclide therapy is increasingly employed for the treatment of advanced neuroendocrine tumors, and greater therapeutic efficacy may be achieved by emerging radiolabeled peptides. Since immune checkpoint inhibitor monotherapies for PanNENs appear to have limited antitumor activity, dual immune checkpoint inhibitor therapies or combinations of antiangiogenic therapies and immune checkpoint inhibitors have been applied in the clinic to improve clinical efficacy. Combining the use of a variety of agents with different mechanisms of action provides new possibilities for clinical treatments. In the future, the study of systemic therapies will continue to focus on the screening of the optimal benefit population and the selection of the best treatment sequence strategy with the aim of truly achieving individualized precise treatment of PanNENs.

Key Words: Pancreatic neuroendocrine neoplasms; Advanced neuroendocrine tumors; Medical treatment; Peptide receptor radionuclide therapy; Advances

INTRODUCTION

Neuroendocrine neoplasms (NENs) are a group of rare neoplasms originating from neuroendocrine cells. However, with the development of diagnostic techniques and improvements in the clinical understanding of these tumors, the incidence is increasing yearly. Based on the United States Surveillance, Epidemiology, and End Results database, the age-adjusted incidence of NENs has increased nearly 6.4-fold from 1.09 per 100000 persons in 1973 to 6.98 per 100000 in 2012. The pancreas (0.84 per 100000 persons) is one of the most common primary sites of NENs, ranked after the lung, small intestine, and rectum[1]. In countries such as China and India, pancreatic NENs (PanNETs) are the most common gastroenteropancreatic neuroendocrine tumors (GEP-NETs) and have the highest morbidity [2].

PanNENs are highly heterogeneous neoplasms that appear as various clinical manifestations and biological behaviors. PanNENs can be classified as nonfunctional PanNENs (60%-90%) or functional PanNETs based on the absence or presence of symptoms associated with the overproduction of specific hormones, respectively[3]. The most common functional PanNETs are gastrinomas and insulinomas; less frequent are glucagonomas, somatostatinomas, vasoactive intestinal polypeptide-secreting tumors, and adrenocorticotropic hormone-secreting tumors[4-7]. The majority of PanNETs are sporadic, although PanNETs can occur as part of hereditary multiple tumor syndromes, such as multiple endocrine neoplasia type 1 and von Hippel-Lindau (VHL) disease[8]. PanNENs are classified into three main histological categories according to the 2019 World Health Organization Classification of Tumors of the Digestive System (5th edition): well-differentiated neuroendocrine tumors (NETs), poorly differentiated neuroendocrine carcinomas (NECs), and mixed neuroendocrine-non-neuroendocrine neoplasms. NETs are further classified into three grades (G1, G2, and G3) according to their mitotic rate (mitoses/2 mm^2) and Ki-67 proliferation index[9]. PanNENs clinical staging is currently based on the eighth edition of the American Joint Committee on Cancer tumor node metastasis (TNM) staging system. Well-differentiated PanNETs are staged by PanNENs TNMs, whereas poorly differentiated PanNECs are staged according to the TNM staging of pancreatic cancer[10].

Therapeutic strategies vary due to the different grades and stages of PanNENs. Radical surgery is the primary treatment option for patients with locally resectable PanNENs; however, 40%-50% of NENs present with distant metastases at the time of initial diagnosis, limiting the opportunity for surgical resection. Moreover, many patients with resected PanNENs will develop recurrence with distant metastases[11,12]. Systemic therapeutic options for patients with locally advanced or distant metastatic PanNENs involve somatostatin analogs (SSAs), molecularly targeted agents, cytotoxic chemotherapeutic agents, immune checkpoint inhibitors, and peptide receptor radionuclide therapy (PRRT) (Figure 1).

The therapeutic goals for patients with locally unresectable and metastatic PanNENs include both hormone control and anti-tumor therapy. The scope of this article does not include medical treatments for the control of functional PanNENs hormone-related symptoms, but rather focuses on anti-tumor therapy. Despite the multiple systemic therapeutic options for PanNENs, problems such as drug resistance, adverse side effects and limited scope of application still exist, and clinical needs have not been met. Thus, conquering drug resistance, expanding the scope of application and developing new clinical drugs have been the main focus of researchers in recent decades. This article reviews the clinical development of existing drugs, focusing on ongoing clinical studies and the development of novel targeted drugs, to provide a reference for addressing the current clinical treatment dilemma and the future direction of PanNENs drug research.

ADVANCES IN CHEMOTHERAPY

Systemic treatment with chemotherapy is one of the main therapies for advanced PanNENs. Appropriate chemotherapy regimens are delivered according to pathological classification and grades, mainly including temozolomide-based combination regimens and platinum-based regimens. Among them, temozolomide-based combination chemotherapy (CAPTEM and STEM) regimens can be used for the first-line treatment of patients with advanced PanNETs G2/G3[19-21] and for the second-line treatment of patients with PanNECs[22,23]. The synergistic effect of capecitabine in combination with temozolomide chemotherapy may be due to its ability to deplete O6-methylguanine DNA methyltransferase (MGMT) levels in tumor cells, thereby enhancing the alkylating effect of temozolomide[24]. The association between MGMT expression status and temozolomide efficacy has been demonstrated in other tumor types, and several studies in NENs have suggested that MGMT promoter methylation or low protein expression correlates better with a favorable therapeutic response to temozolomide and that MGMT status can be used as a biological indicator of the response to alkylating agent treatment in NENs[25,26]. However, because most of the current studies on the relationship between MGMT status and temozolomide efficacy are small-sample, retrospective studies, there is some controversy. A prospective study (NCT03217097) of the relationship between MGMT status and temozolomide efficacy in NETs is underway in which patients with advanced NETs have been divided into two groups according to whether they have MGMT methylation and are receiving temozolomide or oxaliplatin-based chemotherapy at a 1:1 (unmethylated group) and 2:1 (methylated group) ratio, respectively. ORR was used as the primary outcome indicator[27]. Additional prospective studies (NCT02698410, NCT01824875, NCT01525082) have evaluated MGMT status as a secondary outcome.

In clinical practice, drug resistance is one of the major obstacles to the effective treatment of temozolomide-based chemotherapy in PanNENs. Current studies on temozolomide resistance mechanisms are mainly conducted in the field of glioma. In addition to the overexpression of MGMT, the overexpression of the base excision repair (BER) pathway, alteration of autophagy, and activation of the phosphoinositide 3-kinase/protein kinase B/mammalian target of rapamycin (PI3K/AKT/mTOR) pathway contribute to acquired temozolomide resistance[28]. Wu *et al*[29] found enhanced temozolomide sensitivity in a preclinical study of glioblastoma multiforme (GBM) that poly (ADP-ribose) polymerase (PARP) inhibitors, particularly in MGMT-unmethylated GBM, and this effect may be mediated by inhibition of MGMT-mediated repair by abolishing MGMT function and inhibition of BER-mediated repair (Figure 2). Therefore, the combination of PARP inhibitors and temozolomide may be one solution for overcoming temozolomide resistance, and clinical trials applying this combination regimen in patients with small-cell lung cancer have yielded good clinical results[30]. A phase II clinical trial (NCT04394858) is currently evaluating the efficacy of single-agent temozolomide *vs* the combination of temozolomide and olaparib in patients with advanced pheochromocytoma and paraganglioma; however, no clinical trials of temozolomide in combination with PARP inhibitors for PanNENs have been conducted. Temozolomide resistance has also been observed to be associated with activation of the PI3K/AKT/mTOR pathway, and inhibition of the PI3K/AKT/mTOR pathway sensitizes tumor cells to apoptosis upon temozolomide treatment[31]. In a prospective phase II clinical trial, temozolomide in combination with everolimus as second-line therapy for advanced PanNETs resulted in an ORR of 40%

and a median PFS of 15.4 mo, with no synergistic toxicity observed[32].

The most frequent chemotherapy schemes in advanced PanNECs are platinum-based (EP, EC) regimens for first-line therapy and FOLFOX, FOLFIRI, or CAPTEM regimens for second-line therapy [19,33,34]. For other options of first-line treatment regimens for PanNECs, a prospective study (NCT04325425) is evaluating the mFOLFIRINOX regimen *vs* the EP/EC regimen for advanced gastroenteropancreatic neuroendocrine carcinomas (GEP-NECs) as first-line therapy. Another study (NCT03387592) is evaluating the efficiency of the CAPTEM regimen *vs* the FOLFIRI regimen as second-line therapy for advanced NECs. These prospective clinical studies provide additional treatment options for patients with advanced PanNECs and high-level evidence for clinical decision-making.

ADVANCES IN SOMATOSTATIN ANALOGS

SSAs, with their antisecretory and antiproliferative effects, are some of the most common first-line treatments for patients with advanced PanNENs and can be used to control hormonal symptoms in patients with functional PanNETs[35] and for patients with advanced nonfunctional PanNENs to play an antiproliferative role. SSAs are primary treatment options for patients with PanNETs-G1/G2, Ki-67 < 10%, SSTR-positive, and slow-growing tumors[11-14,19,36]. The most widely used clinical SSAs include octreotide LAR and lanreotide autogel, both of which bind primarily to SSTR2 and SSTR5.

Several investigators have also evaluated the efficacy of SSAs in exerting antitumor effects in PanNENs with Ki-67 ≥ 10%. A multicenter retrospective study included advanced, well-differentiated PanNETs with Ki-67 of 10%-35% receiving first-line, long-acting SSAs and observed that SSAs still exert antiproliferative activity against PanNETs with Ki-67 ≥ 10% but have limited effect in PanNETs with high grade (G3) and hepatic tumor load > 25%[37].

In clinical practice, using SSAs at nonconventional high doses (increased administered dose or reduced administration interval) is a common empirical option in patients with progression PanNETs on a standard SSA first-line treatment[38]. A multicenter retrospective study of nonconventional doses of SSAs for GEP-NETs showed that in well-differentiated G1/G2 GEP-NETs, the overall median PFS was 31 mo with high-dose SSA (HD-SSA) therapy after progression on a standard SSA therapy, suggesting that HD-SSAs are active and safe treatment options in patients with progressive well-differentiated GEP-NETs[39]. A prospective single-arm phase II study (NCT02651987) assessed the efficacy of increasing the dose frequency of 120 mg lanreotide autogel (LAN) in 48 patients with progressive G1/G2 PanNETs and showed that 120 mg LAN every 14 d in PanNETs (progressive on standard 120 mg LAN every 28 d) produced promising PFS and DCR, especially in patients with Ki-67 ≤ 10%[40].

In addition, SSAs in combination with other agents (chemotherapy agents, antiangiogenic therapies, everolimus, immune checkpoint inhibitors, *etc.*) are also frequent second-line treatment options in real-world studies[41]. SSA combination therapy may have better efficacy in well-differentiated PanNETs with Ki-67 > 10% or high tumor burden, and a prospective multicenter phase II clinical study (NCT02231762) evaluating the efficacy of the combination of LAN and temozolomide in patients with advanced GEP-NETs is being conducted.

The efficacy of SSAs is correlated with the expression of somatostatin receptors on the tumor cell surface[38]. DNA methyltransferase inhibitors and histone deacetylase inhibitors were observed to upregulate SSTR2 expression in NET cell lines in some preclinical studies and could potentially be an option for overcoming SSA resistance, but the lack of progress in clinical studies requires further validation[42,43]. In clinical management, it is essential to identify the population favorable for SSA therapy, and SSAs in combination with other agents are expected to be synergistic in patients with higher grade, higher tumor load, and SSTR-positive PanNETs.

ADVANCES IN TARGETED THERAPIES

The targeted therapies currently used in PanNETs mainly include mammalian target of rapamycin (mTOR) inhibitors and antiangiogenic agents. FDA-approved target agents for the treatment of PanNENs include everolimus (mTOR inhibitor) and sunitinib (tyrosine kinase inhibitor)[12,19], and the recommendation of surufatinib (tyrosine kinase inhibitor) has been added to the Chinese guidelines for the diagnosis and treatment of pancreatic neuroendocrine neoplasms (2020)[36].

Everolimus, a mTOR inhibitor, has been shown to inhibit tumor cell growth through suppression of the PI3K/AKT/mTOR pathway. The primary results of the RADIANT-3 trial reported that patients with advanced PanNETs in the everolimus group had a median PFS of 11 mo, with a 6.4-mo increase *vs* the placebo group, and the safety profile of everolimus was good[16]. Everolimus resistance is thought to be related to its ability to inhibit only partial mTORC1 but not mTORC2, thus causing over-activation of upstream signaling, including PI3K/AKT[44]. Thus, both the dual PI3K/mTOR inhibitor BEZ235 and the dual inhibitor of mTORC1 and mTORC2, CC-223, are thought to have the potential to overcome everolimus resistance, but the phase II clinical trial of BEZ235 failed due to severe adverse effects[45]. The results of a phase II clinical trial of CC-233 in nonpancreatic NETs patients who failed first-line therapy suggested a DCR of 90% (95%CI: 76.9-97.3%) and a median PFS of 19.5 mo (95%CI: 10.4-28.5 mo), with a safety profile comparable with that of everolimus, but its use in PanNET patients still needs to be prospectively explored[46].

Several preclinical studies suggest that SSAs can inhibit insulin-like growth factor-1 (IGF-1), an upstream signal of the PI3K/AKT/mTOR pathway (Figure 2), and LAN was observed to reduce the survival rate of everolimus-resistant cell lines. SSAs may be able to overcome resistance to everolimus [38,47]. Unfortunately, in the COOPERATE-2 study of everolimus in combination with pasireotide LAR *vs* everolimus monotherapy in patients with advanced PanNETs, no prolongation of PFS was observed in the combination group *vs* the monotherapy group[48]. However, the trial extension results of the LUNA study of everolimus in combination with pasireotide LAR for advanced pulmonary and thymic NETs suggested that the everolimus combined with pasireotide group had a significantly longer median PFS than the pasireotide monotherapy group and the everolimus monotherapy group (8.51 mo *vs* 12.48 mo *vs* 16.53 mo)[49]. The Japan Clinical Oncology Group is also conducting a multicenter, randomized, controlled, phase III trial (jRCT1031200023) to confirm the superiority of combined everolimus plus lanreotide therapy over everolimus monotherapy for advanced GEP-NETs[50].

Resistance to everolimus may also be overcome by combined metformin therapy. Pusceddu *et al*[51] conducted a retrospective analysis of 445 patients with advanced PanNETs treated with everolimus and/or SSAs in 24 medical centers in Italy and observed that the median PFS of 44.2 mo was significantly longer in patients treated with metformin glucose-lowering therapy than in nondiabetic patients (15.1 mo) and longer than that in diabetic patients receiving other glucose-lowering treatments (20.8 mo). Metformin is associated with increased PFS in patients treated with SSA and in patients treated with everolimus (with or without SSAs). A preclinical study showed that metformin may induce more effective mTOR blockade through its effects on IGF-1 and adenosine 5'-monophosphate-activated protein kinase and may counteract the resistance mechanism triggered by everolimus (Figure 2)[52].

Because both metformin and SSA were observed to have the potential to overcome everolimus resistance in preclinical studies, a prospective study evaluating the efficacy of the triple-drug combination of everolimus, octreotide, and metformin for the treatment of advanced PanNENs (NCT02294006) is underway.

Antiangiogenic agents include tyrosine kinase inhibitors (TKIs) and non-TKI agents such as bevacizumab [anti-vascular endothelial growth factor (VEGF) monoclonal antibody]. PanNETs are highly vascularized with overexpression of proangiogenic factors such as VEGF, so antitumor angiogenesis is an effective therapeutic approach[53]. Antiangiogenic agents have evolved rapidly in the field of PanNET therapy in recent years, with new agents and high-grade clinical evidence emerging. Sunitinib, a polytyrosine kinase inhibitor, became the first antiangiogenic agent approved by the FDA for the treatment of patients with advanced PanNETs based on favorable results from a randomized double-blind phase III clinical trial[15]. Surufatinib is a new multitargeted TKI that blocks tumor angiogenesis by inhibiting both vascular endothelial growth factor receptor-1/2/3 (VEGFR-1/2/3) and fibroblast growth factor receptor-1 (FGFR-1) (Figure 2) and regulates tumor-associated macrophages to promote the immune response of the body to tumor cells by inhibiting colony-stimulating factor-1 receptor[54]. The SANET-p study, a phase III clinical trial of surufatinib in patients with advanced PanNETs, suggested a significant prolongation of median PFS (10.9 mo *vs* 3.7 mo) and improvement of ORR (19% *vs* 2%) in the surufatinib group compared with the placebo group[17]. The results from the PanNET cohort of the phase II cohort study (NCT01466036) of cabozantinib, a multitargeted tyrosine kinase inhibitor targeting VEGFR2 and cellular-mesenchymal epithelial transition factor, suggested a median PFS of 21.8 mo (95%CI: 8.5-32.0 mo) and an ORR of 15% (95%CI: 5%-36%)[55]. This result has raised expectations for the publication of the results of the ongoing randomized, double-blind phase III clinical trial of cabozantinib (NCT03375320). The TALENT study (GETNE1509) is a phase II clinical study of the VEGFR1-3 and FGFR1-4 inhibitors lenvatinib in which good clinical efficacy was observed in the PanNET cohort with a tolerable safety profile[56]. In addition, the TALENT study quantified a series of proangiogenic factors, such as VEGF-A, angiopoietin-2 (Ang2), and VEGFR-2. The results suggested that high Ang2 Levels and low FGF2 Levels were significantly associated with ORR, and Ang2 and VEGFR-2 Levels in patients treated with sunitinib could predict the efficacy of lenvatinib, confirming that biomarkers can not only predict drug efficacy but also provide a reference for patient sequential therapy selection[57]. Axitinib[58] and pazopanib[59] have also demonstrated efficacy in phase II clinical trials for the treatment of NETs. Clinical advances in antiangiogenic agents have brought more new options for the treatment of advanced PanNETs.

ADVANCES IN IMMUNOTHERAPY

With the advent of the immunotherapy era, phase I/II clinical trials of various immune checkpoint inhibitors such as programmed cell death-ligand 1 (PD-L1) inhibitors, programmed cell death-1 (PD-1) inhibitors and cytotoxic T-lymphocyte antigen 4 inhibitors have been widely conducted and rapidly developed in the PanNEN field. The results of a phase Ib study of toripalimab as a second-line regimen for the treatment of patients with advanced NENs suggested an ORR of 22.2% and a DCR of 55.5% in the PanNEN subgroup and observed that patients with positive PD-L1 expression, TMB-H (top 10%) and/or MSI-H positivity may preferentially benefit from the treatment[60]. The results of some current clinical trials have shown no significant benefit observed in patients with NENs treated with immune checkpoint inhibitors alone[61,62], and dual immunotherapy with PD-L1/PD-1 inhibitors in combination with CLTA-4 inhibitors is starting to gain interest. The DUNE study (GETNE 1601) is a phase II multicohort clinical study assessing the efficacy of durvalumab in combination with tremelimumab for the treatment of advanced GEP-NENs and pulmonary NETs, with recent results suggesting an ORR of 6.3% for the G1/G2 grade PanNET cohort, 9.1% for the G3 grade GEP-NEN cohort, and 7.4% and 0% for the pulmonary NET and giNET cohorts respectively[63]. A multicohort phase II clinical trial (NCT02923934) assessed the efficacy of ipilimumab in combination with nivolumab in NETs, with the latest results suggesting an ORR of 25% for the NET cohort (20 pts), and the study is still ongoing[64]. Clinical trials of immune checkpoint inhibitors in combination with other agents (antiangiogenic agents, chemotherapy, PRRT, and SSAs) continue to emerge, and some current clinical studies of immunotherapy in combination with antiangiogenic agents suggest better efficacy. An ORR of 20% and a median PFS of 3.94 mo were observed in a phase II clinical trial of toripalimab in combination with surufatinib in patients with advanced NECs after the failure of first-line chemotherapy. Surufatinib in combination with toripalimab has been suggested as a second-line treatment option for patients with advanced NECs[65], and a phase III clinical trial (NCT05015621) is evaluating the efficacy of the combination of surufatinib and toripalimab versus FOLFIRI regimen as a second-line treatment option for patients with advanced NECs. Clinical trials of immunotherapy in combination with other therapies being conducted in patients with NENs are shown in Table 1.

Table 1 Ongoing clinical trials of immune checkpoint inhibitors in combination with other therapies for the treatment of neuroendocrine neoplasms

Drugs	Population	*n*	Phase	Primary outcomes	NCT number
Surufatinib + toripalimab *vs* FOLFIRI	NEC	194	III	OS	NCT05015621
Penpulimab + anlotinib	NET	150	II	ORR	NCT04207463
Pembrolizumab + liver-directed/PRRT	NET	32		ORR	NCT03457948
Nivolumab + chemotherapy	NEN G3	38	II	OS	NCT03980925
Toripalimab + FOLFSIM *vs* EP/EC	Advanced NEC	336	II/III	OS	NCT03992911
Nivolumab + ipilimumab + cabozantinib	PD-NET	30	II	ORR	NCT04079712
Pembrolizumab + lanreotide depot	GEP-NET	22	Ib/II	ORR	NCT03043664

FOLFIRI: Folinic acid, fluorouracil and irinotecan regimen; FOLFSIM: Simmtecan and 5-FU/LV regimen; EP: Etoposide and cisplatin regimen; EC: Etoposide and carboplatin regimen; PD-NET: Poorly differentiated neuroendocrine tumor; ORR: Objective response rate; OS: Overall survival.

ADVANCES IN PEPTIDE RECEPTOR RADIONUCLIDE THERAPY

PRRT has been widely used in the treatment of NETs in Europe, the USA and Asia[66]. ^{177}Lu-DOTATATE has been used for more than a decade, but clinical studies of PRRT are still dominated by phase I/II clinical trials, and there is a lack of phase III clinical trials with large samples for NETs. The NETTER-1 study, a pivotal phase III clinical study of PRRT, treated two groups of midgut NETs with ^{177}Lu-DOTATATE combined with long-acting octreotide (30 mg every 28 d) and high-dose long-acting octreotide (60 mg every 28 d) and observed that ^{177}Lu-DOTATATE significantly increased the ORR (18% *vs* 3%) and prolonged the median OS of patients (48 *vs* 36.3 mo)[18,67]. Unfortunately, the NETTER-1 study, while suggesting good efficacy of PRRT, did not involve PanNETs, and the subsequent NETTER-2 study (NCT03972488), which is still ongoing enrolled SSTR+ G2/G3 GEP-NETs to evaluate the efficacy of ^{177}Lu-DOTATATE in combination with long-acting octreotide (30 mg every 28 days) compared with a high dose of long-acting octreotide (60 mg every 28 d). Prior to the results of the NETTER-2 study, the results of the multicenter retrospective NETTER-R study, which provided evidence for the use of PRRT in PanNETs, suggested that ^{177}Lu-DOTATATE had a median PFS of 24.8 (95%CI: 17.5-34.5) months and an ORR of 40.3% (95%CI: 28.1-53.6) in patients with advanced SSTR-positive PanNETs[68]. ^{177}Lu-DOTA-JR11 is a novel radiolabeled SSTR2 antagonist, and its application in SSTR-positive NETs in phase I/II clinical trials resulted in a DCR (12 mo) of 90% and an acceptable safety profile, suggesting that ^{177}Lu-DOTA-JR11 has good research potential[69]. Among emerging α-emitters, ^{225}Ac-DOTATATE, ^{213}Bi-DOTATOC and ^{212}Pb-DOTAMTATE have also shown good results in small samples of NETs, and clinical trials are underway[70].

NEW TARGETED AGENTS

In addition to common targets such as SSTR2, mTOR, and VEGFR, researchers are actively exploring new targeted agents for clinical application in the field of PanNENs. Cyclin-dependent kinases (CDKs), which regulate cell cycle progression, have been considered promising new targets for tumor therapy. Palbociclib, a small molecule compound that specifically inhibits CDK4 and CDK6, induced G1 phase blockade in Rb-positive CDK4-overexpressing PanNET cell lines in an *in vitro* assay, blocking and inhibiting the growth of PanNET cell lines[71,72]. However, the results of a phase II clinical trial of palbociclib for G1/G2 grade PanNETs suggested a median PFS of only 2.6 mo (95%CI: 0-14.4)[71]. ONC201, an agent with specific targeting of the dopamine-like DRD2 receptor and the mitochondrial protease ClpP, inhibits the growth of PanNET cell lines by TRAIL/DR5 upregulation, dual AKT/ERK pathway inhibition and promotion of a comprehensive stress response to exerting anticancer effects. The phase II study of ONC201 for NETs (NCT03034200) included 10 patients with metastatic PC-PGs (Group A) and 12 patients with other neuroendocrine tumors (Group B), and the latest results of this study suggested 5 PRs and 2 SDs in Group A and 1 PR and 2 SDs in Group B. A full outcome report is still pending[73]. Antibody-coupled drugs developed against SSTR targets have received much attention. PEN-221, an antibody-drug conjugate (ADC) targeting SSTR2, connects the cytotoxic microtubule protein inhibitor DM1 to Tyr3-octreotate and can rapidly internalize DM1 into SSTR2-expressing cells and exert cytotoxic effects after binding to SSTR2[74]. A phase II clinical study of PEN221 in SSTR2-positive gastrointestinal NETs is ongoing, and the latest results suggested that 23

Table 2 Ongoing clinical trials of new targeted agents

Drugs	Targets	Population	*n*	Phase	Primary outcomes	NCT number
Ribociclib + Everolimus	CDK4/6 Inhibitor	Advanced NET	21	II	PFS	NCT03070301
Abemaciclib	CDK4/6 Inhibitor	Advanced GEP-NET	37	II	ORR	NCT03891784
BAY 1895344	ATR Kinase Inhibitor	SCLC/PD-NEC/PDA	87	I	MTD, AEs	NCT04514497
Lurbinectedin, berzosertib	ATR Kinase Inhibitor	SCLC/HGNEC	75	I/II	MTD, ORR	NCT04802174
BI 764532	DLL3 Inhibitor	SCLC/NEN Expressing DLL3	110	I	MTD	NCT04429087
Entinostat	HDAC Inhibitor	Abdominal NET	40	II	ORR	NCT03211988
Niraparib + dostarlimab	PARP Inhibitor	SCLC/HGNEC	48		PFS, ORR	NCT04701307

SCLC: Small-cell lung carcinoma; PD-NEC: Poorly differentiated neuroendocrine carcinoma; PDA: Pancreatic adenocarcinoma; HGNEC: High-grade neuroendocrine cancer; CDK: Cyclin-dependent kinase; ATR kinase: Ataxia telangiectasia and RAD3-related kinase; DLL3: Delta-like protein 3; HDAC: Histone deacetylase; PARP: Poly (ADP-ribose) polymerase; PFS: Progression-free survival; MTD: Maximum tolerated dose; ORR: Objective response rate; AEs: Adverse events.

(88.5%) of 26 evaluable patients were assessed as SD, with a median PFS of 9 mo[75]. Belzutifan is a second-generation small-molecule hypoxia-inducible factor (HIF)-2α inhibitor, which is recommended in the latest NCCN guidelines for advanced PanNET patients with germline VHL alteration[19]. In a phase II, open-label, single-group trial of belzutifan in patients with renal cell carcinoma associated with VHL disease, 22 patients with PanNETs were included, among them 20 patients (91%) had a confirmed response (including 3 patients (14%) who had a complete response)[76]. Phase I/II clinical trials of new targeted agents such as ATR inhibitors, DLL3 inhibitors, HDAC inhibitors, and PARP inhibitors applied to NETs are currently underway (Table 2), but there is still a long way to go before clinical application.

CONCLUSION

Although there are various treatments for PanNENs, choosing appropriate therapeutic schemes for different patients in terms of pathological classification, grades and stages is still difficult. The selection of a cytotoxic chemotherapy regimen is a concern of researchers, and the results of prospective studies may help to address it. First, the problem of drug resistance facing CAPTEM regimen, the most widely used plan, will probably be solved by the combination of PARP inhibitors and mTOR inhibitors, although more evidence is needed. Due to the limited effect of SSAs on inhibiting cancer cell proliferation, progress has mainly been made in the selection of appropriate patients and the synergistic effect of combination therapy. Many new antiangiogenic agents and high-level clinical evidence have emerged, and the reversal of drug resistance to everolimus has also advanced. The use of PRRT in the treatment of NETs is increasingly common, and new radiolabeled peptides appear to be more effective. Immunotherapy faces challenges, and the better curative effect of dual immune checkpoint inhibitor therapies and the combinations of immune checkpoint inhibitors plus other agents need further investigation. Although there are limited choices in the treatment of PanNENs, the combination of common medicines such as SSAs, cytotoxic chemotherapy, everolimus, sunitinib and immune checkpoint inhibitors can have synergistic effects or alleviate drug resistance, thus bringing new vitality to the treatment of PanNENs. The development of biomarkers in clinical research provides a reference for the prediction of curative effects and the selection of sequential therapy, and biomarker-directed therapy helps in choosing appropriate medicines for different people. Advances in the search for new targets and the use of new medicines on common targets will provide more choices for the treatment of PanNENs, but applying them in clinical practice will still take time. Further investigation of PRRT and immunotherapy and the development of new targeted agents will be the focus of future research, and the progress made in the reversal of drug resistance will help clinical practice. In addition, the selection of appropriate therapeutic schemes for different patients and the execution of individualized and precise therapy will be a continuous concern for researchers.

Abstract

Hepatocellular carcinoma (HCC) is the most common primary liver cancer, accounting for about 90% of liver cancer cases. It is currently the fifth most common cancer in the world and the third leading cause of cancer-related mortality. Moreover, recurrence of HCC is common. Microvascular invasion (MVI) is a major factor associated with recurrence in postoperative HCC. It is difficult to evaluate MVI using traditional imaging modalities. Currently, MVI is assessed primarily through pathological and immunohistochemical analyses of postoperative tissue samples. Needle biopsy is the primary method used to confirm MVI diagnosis before surgery. As the puncture specimens represent just a small part of the tumor, and given the heterogeneity of HCC, biopsy samples may yield false-negative results. Radiomics, an emerging, powerful, and non-invasive tool based on various imaging modalities, such as computed tomography, magnetic resonance imaging, ultrasound, and positron emission tomography, can predict the HCC-MVI status preoperatively by delineating the tumor and/or the regions at a certain distance from the surface of the tumor to extract the image features. Although positive results have been reported for radiomics, its drawbacks have limited its clinical translation. This article reviews the application of radiomics, based on various imaging modalities, in preoperative evaluation of HCC-MVI and explores future research directions that facilitate its clinical translation.

Core Tip: Hepatocellular carcinoma-microvascular invasion (HCC-MVI) is closely related to the prognosis of patients, so accurate and individualized prediction of MVI status before treatment is very important. Radiomics is a non-invasive method for predicting HCC-MVI status preoperatively. The standardization of relevant implementation processes of radiomics, such as the delineation of the region of interest, the improvement of algorithms, and the combination of liver imaging reporting and data system, will all contribute to the accurate prediction of MVI. In addition, the introduction of the biological significance of the disease can make up for the shortcomings of the clinical transformation of radiomics to a certain extent.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the most common primary liver cancer, accounting for about 90% of liver cancers cases[1]. According to the World Health Organization, HCC is currently the fifth most common cancer in the world and the third leading cause of cancer-related mortality[2]. The rate of HCC occurrence varies with geographic regions. It is more commonly observed in the underdeveloped regions of the world; for example, its annual incidence rate in East Asia and Sub-Saharan Africa is higher, exceeding 15 per 100000 individuals. Nonetheless, the incidence of HCC is rising rapidly in Europe and the United States, and is expected to continue to rise over the next 10 years[3-5]. Although various treatment modalities are available for different stages of HCC, recurrence is common in the following types of HCC patients: patients with single masses with preserved liver function, no portal hypertension, and treated with resection; patients with multiple intrahepatic tumors or poor liver function, no major comorbidities, and listed for transplantation; patients with up to three tumors (each 4 cm or smaller), not eligible for transplantation, and treated with ablation; patients not eligible for ablation and receiving embolization; and some patients subjected to systemic and radiation treatments [6-8]. According to a previous study, about 70% of HCC patients relapse within 5 years after surgical resection and 35% relapse within 5 years after liver transplantation[9]. Microvascular invasion (MVI) is defined as the invasion of tumor cells into the vascular endothelial cell space, including microvessels of the portal vein, hepatic artery, and lymphatic vessels[10]. Previous studies[11,12] demonstrated that MVI is the strongest independent predictor of early HCC recurrence. It is primarily detected through immunohistochemical and pathological analyses of postoperative tissue specimens[13]. The inability to identify MVI preoperatively leads to incomplete surgical resection and increases the risk of postoperative recurrence. This limits the effectiveness of treatment and affects the long-term survival of liver cancer patients. Although conventional imaging examinations, such as computed tomography (CT)-based quantitative image analysis and dynamic contrast enhanced ultrasound (CEUS)[14,15] can predict MVI preoperatively, routine analyses of these images provide insufficient information, such as two-dimensional analysis of lesion morphology, size, *etc* based on conventional images.

Radiomics is an emerging, powerful, and non-invasive tool that uses a series of data mining algorithms and statistical analysis tools for the high-throughput analysis of image features. It can detect delicate features from conventional radiological images that are invisible to the naked eye and has been increasingly adopted to predict MVI. This enables extraction of many features at the whole lesion level. These features may provide information regarding heterogeneity and invasiveness of the disease that can be of predictive or prognostic value, thus leading to the selection of the best possible treatment[16]. HCC shows a large amount of intra- and inter-tumor heterogeneity at the biological level[17-20]. Biopsy, which is the main method for diagnosing HCC, usually involves removal of only a small part of the tumor, thus excluding the possibility of assessing intratumoral heterogeneity. Hence, in recent years, research pertaining to HCC using radiomics has attracted increasing attention[21]. Quantitative radiomics data, along with models or nomograms based on multiple imaging modalities including CT, magnetic resonance imaging (MRI), ultrasound (US), and positron emission tomography (PET), demonstrate high accuracy in predicting HCC-MVI preoperatively. In this review, we discuss the

applications of radiomics based on various imaging modalities in the preoperative detection of HCC-MVI (Table 1). In addition, future research directions are explored.

CT-BASED RADIOMICS

Liver cirrhosis or hepatitis B-related HCC can be diagnosed highly accurately through non-invasive approaches based on multi-phase CT/MRI imaging features, such as hyperenhancement in the arterial phase (AP) and hypoenhancement in the portal venous phase (PVP)[22]. For example, Peng *et al*[23] constructed a radiomics model based on hepatic AP and PVP images to delineate tumor regions and extract radiomic features to predict the preoperative MVI status of HCC related to hepatitis B. They found that radiomics signature, the alpha-fetoprotein (AFP) level, hypoattenuating halo, internal arteries, and non-smooth tumor margins are independent predictors of MVI. This model showed good correction and discrimination capabilities in the training and validation cohorts. The C indices for the training and validation cohorts were 0.846 and 0.844, respectively, and the area under the curve (AUC) of the radiomics nomogram in the MVI risk analysis was 0.845. In a similar study, Ma *et al*[24] found that the radiomics features of PVP were better than those of the AP and delayed phase (DP); the C index and AUC values of the model, combined with radiomic features and clinical factors, were close to those reported by Peng *et al*[23]. In a recent study based on AP and PVP images, Xu *et al*[9] marked the tumor regions and regions 5 mm away from the tumor surface, as regions of interest (ROI) to extract radiomic features to predict the HCC-MVI status and long-term clinical outcomes of patients with HCC. It was found that aspartate aminotransferase (AST) and AFP levels, tumor margin, growth pattern, capsule, peritumoral enhancement, radio-genomic venous invasion (RVI), and the radiomic score (R-score) were all predictors of MVI. The AUC of this model was 0.909, and the progression-free survival and overall survival of the MVI group were significantly lower than those of the non-MVI group. This showed that combining large-scale clinical radiology and radiomics analyses could reliably predict MVI and clinical outcomes.

MRI-BASED RADIOMICS

Although both conventional multi-phase contrast enhanced CT and MRI can be used to obtain the unique image features of HCC, MRI provides many additional imaging sequences that are helpful in diagnosing HCC without radiation damage; the additional sequences include T2-weighted imaging (T2WI), diffusion weighted imaging (DWI), and enhanced scanning by combined use of some extracellular and hepatocyte contrast agents, such as gadoxetic acid, that have the ability to distinguish relatively small and subtle lesions through the hypointensity received in the hepatobiliary phase (HBP)[25]. Moreover, a combination of MRI parameters can facilitate early diagnosis of small HCC. For example, double hypointensity in the portal/venous phase and HBP can be considered an MRI pattern that is highly suggestive of hypovascular HCC[26]. Thus, MRI-based radiomics provides more possibilities for HCC-MVI assessment. Feng *et al*[27], based on a gadolinium-ethoxybenzyl-diethylenetriamine (Gd-EOB-DTPA) MRI HBP image, delineated the tumor and designated a 1-cm area around it as the ROI. The combined intratumoral and peritumoral radiomics model presented in that study predicted the AUC value of MVI to be 0.85. In another study, Yang *et al*[28] used gadoxetic acid-enhanced MRI to delineate the tumor, which was then used as the ROI. They found that the AFP level, non-smooth tumor margins, arterial peritumoral enhancement, and radiomics signatures of HBP T1WI and HBP T1 maps could all be used as predictors of MVI. The prediction model that combined clinical radiation factors and fusion radiomic features from HBP images predicted the AUC of MVI to be 0.943, which was higher than that reported by Feng *et al*[27]. Meanwhile, the C indices of the generated nomograms in the training and validation groups were 0.936 and 0.864, respectively. This may stem from the varied delineation of the ROIs and the construction of models based on different sequences. Recently, Nebbia *et al*[29] devised a method based on radiomics through multi-sequence and traditional Gd-DTPA MRI for preoperative detection of MVI. It was found that the T2 and PVP sequences were superior to other MRI sequences in single-sequence models (*i.e.* T1, DWI, and late AP). The combination of these two sequences obtained the highest AUC value of 0.867 in predicting MVI, indicating that preoperative liver MRI scans are promising for predicting MVI and that the information obtained from a multi-parameter MRI sequence is crucial in identifying MVI.

US-BASED RADIOMICS

Compared with CT/MR, US is radiation-free, easy to implement, and simple to use for liver examinations. If potential predictors can be identified, US/CEUS may become an alternative technique to provide additional information for the detection of MVI. Hu *et al*[30], based on US images, outlined the

Table 1 Based on various imaging modalities radiomics in the application of microvascular invasion

Ref.	Modality/images/patients/ROI	Software	Predictors of MVI
Peng *et al*[23]	CT/AP and PVP CT images/304/tumor	IBEX software package	Radiomics signature, AFP level, hypoattenuating halo, internal arteries, and nonsmooth tumor margin

AFP: Alpha-fetoprotein; A.K. software: Artificial Intelligence Kit, version 1.1, GE Healthcare; AP: Artery phase; AST: Aspartate aminotransferase; CT: Computed tomography; DP: Delay phase; DWI: Diffusion weighted imaging; [^{18}F]FDG PET: 18-fluorodeoxyglucose positron emission tomography; Gd-DTPA: Gadopentetic acid; Gd-EOB-DTPA: Gadolinium-ethoxybenzyl-diethylenetriamine; HBP: Hepatobiliary phase; MITK: Medical Imaging Interaction Toolkit; MRI: Magnetic resonance imaging; MTD: Maximum tumour diameter; MVI: Microvascular invasion; NA: Not available; PP: Portal-venous phase imaging; PVP: Portal venous phase; ROI: Region of interest; R-score: Radiomic score; RVI: Radiogenomic venous invasion; SUV_{max}: Maximum standard uptake value; TLR: Maximum SUV of the tumor/mean SUV of the normal liver; US: Ultrasound; VOI^{entire}: Entire-volumetric interest; $VOI^{50\%}$: 50% of the entire tumor volume; $VOI^{penumbra}$: A region with 5 mm distance to tumor surface.

tumor region as the ROI to extract radiomic features and constructed a US-based radiomics score for preoperative prediction of HCC-MVI. The study showed that an AFP level > 400 ng/mL and tumor size > 5 cm were significantly related to MVI. The AFP level, gray-scale US-based tumor size, and radiomics score were identified to be independent predictors of MVI. The radiomics-based nomogram (AUC: 0.731) showed better performance in MVI detection than the clinical nomogram (AUC: 0.634). However, there was no significant difference between the MVI-positive and -negative groups in terms of other clinical and pathological features, as well as CEUS features. Similarly, Dong *et al*[31] envisaged that radiomic algorithms based on US images might have potential predictive value in the detection of MVI in patients with HCC. Unlike Hu *et al*[30], Dong *et al*[31] delineated the gross-tumor region (GTR) and the peri-tumoral region (PTR, the uniform dilated half of the tumor radius) and showed that the AUC of the radiomic nomogram, combined with the AFP level, characteristics of the tumor, and the area around the tumor, was 0.744, which was slightly higher than that reported by Hu *et al*[30]. This also supports the idea that the peritumoral area is an onset area of MVI. It is thought to be the main blood transmission route of portal vein thrombosis and the main route for intra- and extra-hepatic metastases [32]. This signifies that, when evaluating HCC-MVI based on radiomics, the area around the tumor also needs to be evaluated.

PET-BASED RADIOMICS

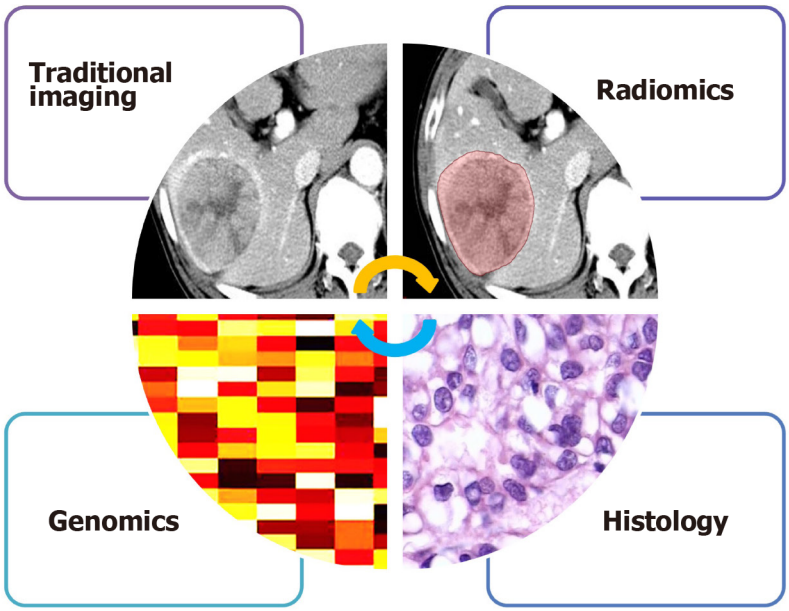
High glucose consumption by the tumor cell microenvironment, including that in HCC, can be reflected in 18-fluorodeoxyglucose PET (^{18}FDG-PET). Although the tumor detection efficiency is affected by liver cirrhosis and a high background signal, studies have confirmed that the maximum standard uptake value (SUVmax) of ^{18}FDG-PET is related to the recurrence rate of HCC and patient survival, and that the combination of MRI and ^{18}FDG-PET can improve the accuracy of HCC histopathological grading[33,34]. In a recent study[35], the PET/CT model, after integrating the radiomic features composed of five PET- and six CT-derived texture features, showed an AUC of 0.891 in the training cohort. The prediction of disease-free survival (DFS) was also more accurate (C index of 0.831). This study indicated that the newly developed [^{18}F]FDG PET/CT radiomics feature is an independent biomarker for evaluating MVI

and DFS in patients with ultra-early and early HCC.

LIMITATIONS

Although radiomics has achieved some exciting results in evaluating the HCC-MVI status, many limitations still exist. The current lack of standardization in image acquisition schemes, segmentation methods, and radiomics tools used for analysis may lead to differences in the measurement of radiomic features that do not stem from biological differences[16]. Existing studies[36] have shown varied reproducibility in extracting quantitative imaging features from tumor regions segmented by different methods. Fortunately, the radiomics quality score (RQS) has been proposed to assess whether radiomics research meets best practices[37]. In addition, there are huge challenges in interpreting the correlation between radiomics features and their biological significance, especially that of the texture features obtained from high-level analysis. This leads to restrictions on the use of radiomics in clinical applications[38].

FUTURE DIRECTIONS



Every step involved in radiomics-based analyses needs to be optimized and standardized, including the adjustment of imaging schemes and parameters, development of (semi-) automated segmentation methods, and refinement of algorithms and high-throughput analysis modeling methods. In addition, in the process of establishing a radiomics model, potential independent variables should be included in the multivariate analysis (such as protein induced by vitamin K absence or antagonist-II), which will help improve the sensitivity, specificity, and predictive ability of the model[39]. In addition, the imaging characteristics of certain liver nodules in patients with chronic liver disease are complex and diverse. For example, the imaging manifestations of primary and recurrent cirrhosis nodules are different[40], and tuberculosis nodules are easily misdiagnosed as HCC[41]. Through targeted collection of a large number of these different liver nodules, corresponding predictions can also be made using radiomics. Furthermore, due to the complexity and similarity in imaging characteristics of certain hepatic nodules in high-risk HCC, the American College of Radiology (ACR) has issued a diagnostic program, namely the liver imaging reporting and data system (LI-RADS, https://www.acr.org). Several studies[42-44] have indicated that ACR CT/MRI LI-RADS and CEUS LI-RADS possess high application value in identifying primary hepatic nodules in patients with high-risk HCC, and especially display high diagnostic performance with LR-5 and LR-M nodules. In a recent study, Zhou *et al*[45] observed that the model incorporating CEUS LR-M and clinical features was able to predict the MVI status of HCC. Therefore, undoubtedly, LI-RADS combined with radiomics using various imaging modalities shows promise in the prediction of HCC-MVI.

Although radiomics can predict MVI and determine related predictors, there are differences between groups. With the exponential growth of interest in the development of artificial intelligence (AI)-based applications, there is now an opportunity to apply AI in radiomics analyses. Deep learning, especially convolutional neural networks (CNNs), can capture texture information in the initial convolution layer. CNNs may replace several current radiomics-based analysis methods[46]. Recently, a new concept of "deep radiomics" was proposed. This technique combines radiomics and deep learning analysis by creating feature images based on texture features and then using them as input for CNNs to classify the images. Therefore, along with the prediction of MVI, the use of AI-based technology is also expected to identify individual MVI.
