Abstract

BACKGROUND

Helicobacter pylori (*H. pylori*) infects about 50% of the world population and is the major cause of chronic gastritis, peptic ulcers, and gastric cancer. Chronic *H. pylori* infection induces gastric mucosal precancerous lesions mostly in adulthood, and it is debatable whether these pathological conditions can occur in childhood and adolescents as well. Since this is a critical issue to determine if intervention should be offered for this population group, we investigated the gastric mucosal precancerous lesions in pediatric patients in an area in central China with a high prevalence of *H. pylori* and gastric cancer.

AIM

To investigate the relationship of *H. pylori* infection and gastric mucosal precancerous lesions in children and adolescents in central China.

METHODS

We screened 4258 ward-admitted children and adolescent patients with upper gastrointestinal symptoms, and finally enrolled 1015 pediatric patients with *H. pylori* infection and endoscopic and histological data. *H. pylori* infection status was determined by rapid urease test and histopathological examination. Both clinical and pathological data were collected and analyzed retrospectively. Occurrence of gastric mucosal precancerous lesions, inflammatory activity and degree of inflammatory cell infiltration between *H. pylori*-positive and -negative groups were compared.

RESULTS

Among the 1015 eligible children and adolescents, the overall *H. pylori* infection rate was 84.14% (854/1015). The infection rate increased with age. The incidence of gastric mucosal precancerous lesions in *H. pylori*-infected children was 4.33% (37/854), which included atrophic gastritis (17 cases), intestinal metaplasia (11 cases) and dysplasia (9 cases). In *H. pylori*-negative patients, only 1 atrophic gastritis case [0.62%, (1/161)] was found ($P < 0.05$). Active inflammation in *H. pylori*-infected patients was significantly higher than that in non-infected patients, and the *H. pylori*-infected group showed more severe lymphocyte and neutrophil granulocyte infiltration ($P < 0.001$). In addition, endoscopy revealed that the most common findings in *H. pylori*-positive patients were antral nodularity, but in *H. pylori*-negative patients only superficial gastritis was observed.

CONCLUSION

In children and adolescents, gastric mucosal precancerous lesions occurred in 4.33% of *H. pylori*-infected patients in central China. These cases included atrophic gastritis, intestinal metaplasia, and dysplasia. The data revealed an obvious critical issue requiring future investigation and intervention for this population group.

Key Words: *Helicobacter pylori*; Gastric cancer; Precancerous lesions; Inflammation; Children and adolescents

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: *Helicobacter pylori* (*H. pylori*) infection induces gastric mucosal precancerous lesions mostly in adulthood. Whether these lesions can also occur in children and adolescents remains controversial. Our study showed that in a region in central China with a high prevalence of *H. pylori* and gastric cancer, the incidence of gastric mucosal precancerous lesions was 4.33% among *H. pylori*-infected children and adolescents, which is significantly higher than the non-infected pediatric patients. The precancerous lesions included atrophic gastritis, intestinal metaplasia, and dysplasia. These data provide an alarming alert and call for further investigation and intervention for this population group.

INTRODUCTION

Helicobacter pylori (*H. pylori*) has infected about 50% of the Chinese population and is responsible for 90% of non-cardia gastric cancer incidences. It is reported that one-third of asymptomatic or healthy children have serologically-confirmed *H. pylori* infection worldwide[1-3]. Although most *H. pylori*-infected children do not have obvious clinical symptoms, studies have shown that children with gastrointestinal symptoms have a higher rate of *H. pylori* infection, and the infection rates are affected by socioeconomic status, living habit, sanitary conditions, geographic region, *etc.*[4,5]. Despite the overall infection rate has slowly declined in China, the infection rate in rural areas is still much higher over that of city residents [6,7].

A recent meta-analysis in China in 2022 has indicated that *H. pylori* prevalence in children and adolescents is 28%[7]. Infection by *H. pylori* is closely associated with gastric mucosal inflammation and extra-gastrointestinal diseases[8-10]. A small portion of infected patients will follow Correa's cascade

and develop severe gastric mucosal lesions, such as atrophic gastritis, intestinal metaplasia (IM), and gastric cancer[11]. *H. pylori* CagA has been shown to be associated with gastric mucosal precancerous lesions in several epidemiological studies[5,12].

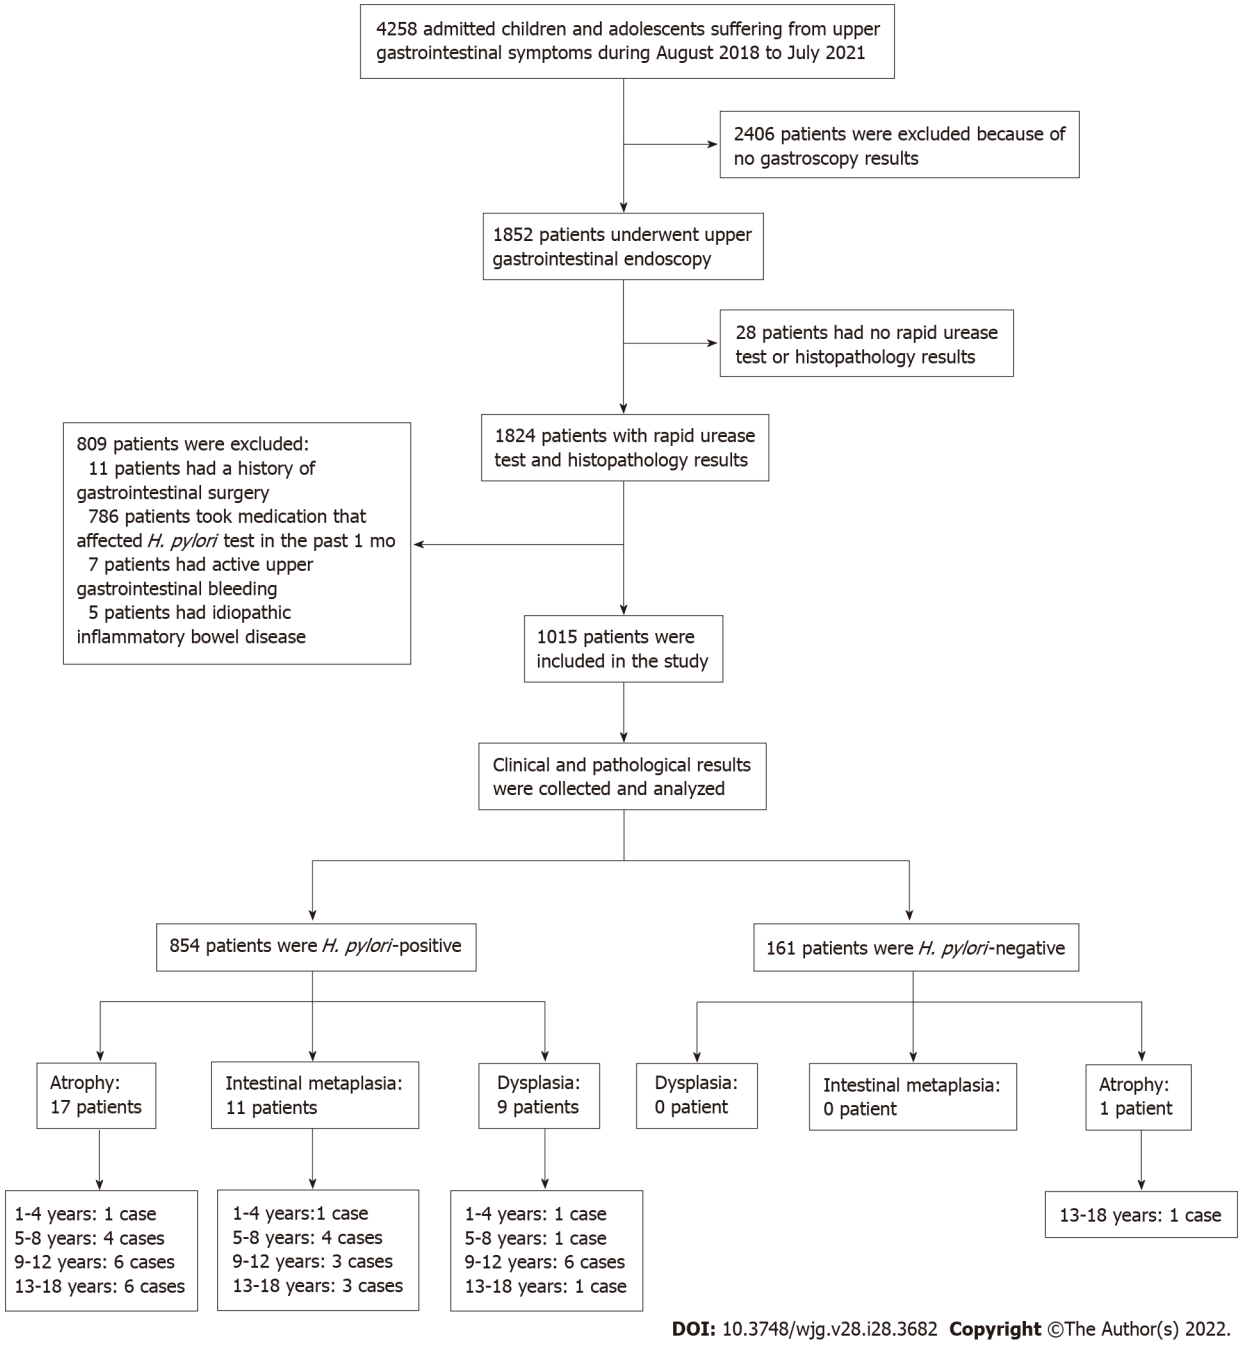
One 2006 review summarized the prevalence of gastric mucosal precancerous lesions in children and adolescents, ranging from 0% to 72% in *H. pylori*-infected patients[13]. Prevalence of gastric atrophy in different populations may also vary depending on different geographic/genetic origins or environmental factors in the pediatric population. For example, one Tunisian study in 2009 found that atrophic gastritis accounted for 9.3% (32/354) of enrolled children; of the 32 children with atrophic gastritis, 30 were infected with *H. pylori*[14]. In 2014, a Mexican study of 82 children with chronic gastritis found that 8.5% (7/82) children had antral atrophy and 6.1% (5/82) had IM; among the 7 children with atrophy, 6 had *H. pylori* infection[15]. Other studies carried out in different countries reported gastric atrophy was present in 4.4% to 10.7% of *H. pylori*-positive children[16,17]. However, large-scale investigation is lacking in this area.

H. pylori has the characteristics of family cluster infection and is transmissible among family members, including spouses and siblings[8,9,18]. The infected parents, especially mothers, play a major role in its transmission[19-21]. Most *H. pylori* infection is acquired during childhood and adolescents, and the infection will persist for decades unless proper treatment is offered. Because *H. pylori* infection usually does not cause or only causes mild gastric mucosal lesions in children and adolescents[22-24], the consequences were thought not to be as important as they were in adulthood. Hence, very few studies have focused on the relationships between *H. pylori* infection and gastric mucosa precancerous lesions in children and adolescents. Recent reports have begun to show that gastric mucosal atrophy and IM are also found in children and even in very young children, as mentioned above[13-15].

In this work, we retrospectively investigated a cohort of *H. pylori*-infected symptomatic pediatric inpatients on gastric mucosal inflammation status, incidence and pattern of gastric mucosal precancerous lesions in a major hospital in central China, which is an area with a high prevalence of *H. pylori* and gastric cancer (*H. pylori* infection rate is 49.6%[6], and gastric cancer incidence is 42.52/100000[25]). Studies in this area will be helpful to understand the pattern and prevalence of gastric mucosal precancerous lesions in pediatric patients and provide evidence for future *H. pylori* eradication recommendation and related disease prevention.

MATERIALS AND METHODS

Study population and patient enrollment



From August 1, 2018 to July 31, 2021, 4258 pediatric patients with an age less than 18-years-old who had upper gastrointestinal symptoms were admitted to the Department of Pediatrics, People's Hospital of Zhengzhou University; among them, 1852 underwent upper gastrointestinal endoscopy examination due to disease complaints, such as abdominal pain, abdominal distension, nausea, vomiting, hiccups, heartburn, *etc*. Patients who had taken biopsy specimens from the gastric mucosa for histopathological examination and rapid urease test were enrolled into the study. Exclusion criteria were as follows: (1) Use of antibiotics, bismuth salts, proton pump inhibitors, H2-receptor blockers, immunosuppressants and steroids over the past 1 mo; (2) History of gastrointestinal surgery; (3) Active upper gastrointestinal bleeding; and (4) Idiopathic inflammatory bowel disease.

The study finally enrolled 1015 eligible children and adolescents. Patient information was collected only for the purpose of disease analysis and were kept confidential. As this is a retrospective study, no informed consent was required. The research protocol was approved by the Ethics Committee of People's Hospital of Zhengzhou University (2019-KY-No. 10). The flow chart of study design and patients' enrollment is shown in Figure 1. Patients were classified into four groups according to age: (1) 1-4 years; (2) 5-8 years; (3) 9-12 years; and (4) 13-18 years.

Endoscopic and histological evaluation of patients

At least two biopsy specimens were collected from the antrum or angulus during endoscopic examination. One biopsy sample was used for immediate rapid urease test. The other was oriented, fixed in formalin and embedded in paraffin blocks. After samples were sectioned, hematoxylin and eosin staining was applied for histological analysis. *H. pylori* infection was detected by immunohistochemical staining. Due to technique limitations, all patients were not given ^{13}C-urea breath test, serological *H. pylori* antibody test or stool antigen test to determine *H. pylori* infection status at the time of their tests. Therefore, a patient was considered *H. pylori*-infected if either histological staining or rapid urease test was positive or if both were positive. Conversely, a patient was considered to be *H. pylori*-uninfected if either histological staining or rapid urease test was negative or if both were negative.

Histological variables (the activity of inflammation, lymphocyte and neutrophil granulocyte infiltration, glandular atrophy, IM and hyperplasia) were analyzed according to visual analog scale of the updated Sydney system[26]. Gastric mucosa changes were classified into absent, mild, moderate and severe levels according to the histological situation of each sample. Severity of lesions was determined by the most severe lesion in each patient. Atrophy of gastric mucosa was indicated by the destruction

Figure 1 Flow chart of patient enrollment on gastric mucosal precancerous lesions in children and adolescents in central China. There were 4258 patients with upper gastrointestinal symptoms under 18 year of age, 2406 patients were excluded for no gastroscopy examination, and the remaining 1852 children had underwent upper gastrointestinal endoscopy. Among these patients, 809 were excluded due to either surgery, medication, bleeding or idiopathic inflammatory bowel disease, and 28 patients were excluded due to no rapid urease test or histopathology test; the final enrolled patient number was 1015. In 854 *Helicobacter pylori* (*H. pylori*)-positive patients, 17 patients had atrophy, 11 patients had intestinal metaplasia and 9 patients had dysplasia, and only 1 of the 161 *H. pylori*-uninfected patients had atrophic gastritis. *H. pylori*: *Helicobacter pylori*.

and reduction in gastric glands of the stomach. IM is a condition in which cells that create the lining of the stomach are changed or replaced by intestinal cells. In many cases, when gastric atrophy and IM coexist, they were allocated into either the atrophy or IM category based on the major pathological presentations of the specific patients. Dysplasia refers to a proliferative lesion, abnormal hyperplasia of the gastric gland basement membrane epithelium and abnormal changes in morphology and structure. These specimens were evaluated by two pathologists in a blinded fashion.

Statistical analyses

Data were analyzed using SPSS for Windows version 25 (IBM Corp., Armonk, NY, United States). Continuous variables were described as mean ± SD or median (interquartile range), while categorical variables were described as percentages or frequencies. The χ^2 test or Fisher's exact test were used to

compare pathological changes of gastric mucosa, including activity of inflammation, presence of precancerous lesions and endoscopic pattern of gastric mucosa between patients with *H. pylori* infection and those without *H. pylori* infection. Grade data were analyzed using Wilcoxon signed-rank test, including degrees of inflammatory cell infiltration. A P value less than 0.05 (derived from two-tailed tests) was considered statistically significant.

RESULTS

Patients' demographic characteristics and clinical data

A total of 1852 selected patients were further examined from a pool of 4258 pediatric ward patients (Figure 1). Then, 809 patients were excluded due to surgery, medication, idiopathic inflammatory bowel disease or bleeding, and 28 more patients were excluded because of no rapid urease test or histopathological test. The remaining 1015 eligible patients were enrolled and analyzed. Patient demographic data were summarized in Table 1. Among the 1015 enrolled patients, 604 were males and 411 were females, with median age of 11-years-old, and 854 patients were infected by *H. pylori*, while 161 patients were not infected. The mean age of *H. pylori*-infected patients was significantly older than those of non-infected subjects (11 years *vs* 9 years, $P < 0.05$). There were no significant differences in sex distribution between the *H pylori*-infected and non-infected groups.

The clinical characteristics of patients are also presented in Table 1. For endoscopic manifestations, superficial gastritis was observed in 255 (29.86%) cases among the *H. pylori*-positive patients and 76 (47.20%) cases among the *H. pylori*-negative patients ($P < 0.05$). There was no significant difference in the proportion of superficial gastritis with erosion, superficial gastritis with bile reflux and esophagitis regardless of the status of *H. pylori* infection ($P > 0.05$). Antral nodularity was observed in 131 (15.34%) *H. pylori*-positive patients and 4 (2.48%) *H. pylori*-negative patients ($P < 0.05$). In both *H. pylori*-infected and non-infected patients, most patients were clinically diagnosed with non-atrophic gastritis, and only a small percentage of patients developed atrophic gastritis or peptic ulcers.

H. pylori infection status in different age groups

In the 1-4 years, 5-8 years, 9-12 years and 13-18 years age groups (Table 2), the *H. pylori* infection rates were 40.74%, 78.39%, 88.05% and 89.60%, respectively. The trend of infection rate increasing as age increased was noted. Patient infection rates of the 5-8 years, 9-12 years and 13-18 years age groups were significantly higher than that of the 1-4 years age group. Infection rates of the 9-12 years and 13-18 years age groups were also significantly higher than that of the 5-8 years age group, but the infection rates had no significant difference between the 9-12 and 13-18 years age groups.

Gastric mucosal precancerous lesions in different age groups

Patient gastric mucosal precancerous lesions are shown in Table 3. Among the 854 *H. pylori*-infected patients, 4.33% (37/854) had gastric mucosa precancerous lesions; among which, 17 patients had atrophy, 11 patients had IM, and 9 patients had dysplasia. Only 1 of the 161 *H. pylori*-uninfected patients (0.62%) had atrophic gastritis. The incidence of precancerous lesions of gastric mucosa in *H. pylori*-infected patients was significantly more than those uninfected patients ($\chi^2 = 5.178$, $P = 0.023$). Among the *H. pylori*-positive patients, there were gastric mucosal precancerous lesions in each age group, whereas among the *H. pylori*-negative patients, only 1 patient with atrophic gastritis was found in the 13-18 years age group. Representative pictures of normal, gastritis, and gastric mucosal precancerous lesions are shown in Figure 2.

Active inflammation in H. pylori-infected and -uninfected patients

As described in Table 4, active inflammation was observed in 16.04% (137/854) of the *H. pylori*-infected patients and only 3.73% (6/161) of the -uninfected patients. A significant difference was noticed between these two groups ($\chi^2 = 16.975$, $P < 0.001$). But in the 1-4 years age group, there was no significant difference in inflammatory activity between the *H. pylori*-infected and -uninfected patients (13.64% *vs* 6.25%, $\chi^2 = 0.196$, $P = 0.658$). Whereas in the 5-8 years, 9-12 years and 13-18 years age groups, the proportion of active inflammation in the *H. pylori*-positive patients was significantly higher than that in the *H. pylori*-negative patients ($\chi^2 = 4.901$, $P = 0.027$; $\chi^2 = 3.987$, $P = 0.046$; $\chi^2 = 6.012$, $P = 0.014$).

Characteristics of inflammatory cell infiltration in H. pylori-infected and -uninfected groups

The degree of neutrophil granulocyte infiltration with different *H. pylori* infection status is shown in Table 5. For the 854 infected patients, the proportions of absent, mild and moderate neutrophil granulocyte infiltration were 83.96%, 13.58% and 2.46%, respectively. While for the -uninfected patients, they were 96.27%, 3.73% and 0%, respectively. Compared with *H. pylori*-infected patients, the prevalence of neutrophil granulocyte infiltration in gastric mucosa was significantly higher than that in uninfected patients ($Z = 4.319$, $P < 0.001$). This difference between *H. pylori*-positive and -negative patients was also indicated in different age groups, with the exception of the 1-4 years age group.

Table 1 Demographic and clinical data of patients

[b]$P < 0.05$: When *H. pylori* infection rates were compared with the 5-8 years age group.
H. pylori: *Helicobacter pylori*.

As for lymphocyte infiltration, patients with *H. pylori* infection had more severe lymphocyte infiltration than uninfected patients ($Z = 3.997$, $P < 0.001$). In the *H. pylori*-positive group, 40.98%, 50.59% and 8.43% of mild, moderate and marked lymphocyte infiltration, respectively, were found, while in the *H. pylori*-negative group, the rates were 56.52%, 40.99% and 2.48%, respectively. In *H. pylori*-infected patients, the 9-12 years and 13-18 years age groups also showed more severe lymphocyte infiltration compared to the uninfected patients ($Z = 2.539$, $P = 0.011$; $Z = 2.164$, $P = 0.030$), but this difference was not significant between the 1-4 years and 5-8 years age groups ($Z = 0.570$, $P = 0.569$; $Z = 1.737$, $P = 0.082$) (Table 6). Representative pictures of gastric mucosal inflammatory cell infiltration are shown in Figure 2.

DISCUSSION

In the current study, we investigated gastric mucosal inflammation and precancerous lesions in pediatric patients who were hospitalized for gastrointestinal symptoms. Among the 1015 children in our study who underwent upper gastrointestinal endoscopy, gastric mucosa precancerous lesions occurred

Figure 2 Representative pictures of normal and pathological gastric mucosa manifestations in children and adolescents. A: Normal gastric mucosa; B: Chronic inflammation of the gastric mucosa; C: Active inflammation of the gastric mucosa; D: Gastric mucosal atrophy; E: Intestinal metaplasia; F: Mild dysplasia. Hematoxylin and eosin, × 400.

in 4.33% of *H. pylori*-infected children, in which the proportions of atrophy, IM and dysplasia were 1.99%, 1.29%, 1.05%, respectively, significantly higher than findings from *H. pylori*-negative patients.

Under endoscopy evaluation, *H. pylori*-positive children presented more nodular gastritis, which is an important feature of *H. pylori* infection in children. But, the proportions of esophagitis, chronic superficial gastritis with erosions, chronic superficial gastritis with bile reflux and esophagitis were not significantly different between the infected and non-infected groups. The results also showed that children with *H. pylori* infection had a significantly higher incidence of gastric mucosal inflammation, and the degrees of neutrophil and lymphocyte infiltration were also much more serious than in *H. pylori*-negative children. These results are in line with previous studies that showed various degrees of inflammation in *H. pylori*-infected pediatric patients. For example, in 2017, Broide *et al*[27] showed that monocyte and neutrophil infiltration was more severe in the infected children group with chronic gastritis in Israel. One retrospective study of 196 children in Japan in 2006 also reached a similar conclusion[17].

The above results indicate that *H. pylori* infection is closely related to gastric mucosal inflammation, which might be the basis for development of gastric precancerous lesions, as both basic experiments and clinical investigations have confirmed that certain bacterial components, such as CagA and VacA, have detrimental effects on gastric epithelial cells. In addition, CagA is a bacterial oncoprotein, which can cause epithelial cell oncogenic transformation *in vivo*[28-30]. Therefore, future experiments for more

detailed analysis of the *H. pylori* component on the pathogenesis of gastric precancerous lesions in children will be very helpful to understand the carcinogenesis and provide more rational for precise intervention and prevention.

The significance of this study is that it provides evidence to demonstrate that *H. pylori* infection is associated with the occurrence of precancerous lesions in pediatric patients, and these lesions increase with increase in age. Furthermore, the pediatric population might present in a similar way to adults with *H. pylori* infection, suggesting a healthcare threat to the pediatric patients. As eradication of *H. pylori* has been shown to prevent the development of atrophic gastritis, IM and gastric malignancy in adults[31,32], it is expected that proper intervention in pediatric patients could prevent the development of future diseases. Future investigation on the rationale and health economic evaluation would be required to provide more supporting evidence.

These results are also in line with previous reports. For example, in 2006, a study of 131 *H. pylori*-infected children in Japan showed that the proportion of gastric antrum atrophy was 10.7%[17]. In a 2020 study in Romania, the *H. pylori* infection rate was 33.06% (82/248); among 82 infected children, 9 (11%) had atrophic gastritis and 2 (2.4%) had IM[33]. A survey of 1634 children in China in 2014 found that atrophic gastritis accounted for 4.4% (23/524 cases) of the *H. pylori*-infected children[16]. However, one Austrian study in 2011 found gastric atrophy was rare (1/84) in children infected with *H. pylori*[34]. In addition, no gastric atrophy was found in 66 French children infected with *H. pylori* in 2009[35], and no precancerous lesions were found in 132 gastric biopsies from 22 symptomatic *H. pylori*-infected children in a 2009 study in Brazil[36].

As *H. pylori*-induced disease presentations are mostly present in adulthood, the presence of precancerous lesions in children unveiled a critical issue that was largely neglected previously[13,15,37]. Although there are still controversies on the significance and consequence of *H. pylori*-induced serious gastric mucosal lesions in children[13], current consensus reports from the Asia-Pacific region[38], China[8,39] and Japan[18] have indicated that *H. pylori* should be eradicated when such conditions are present, and their family members should also receive screening and treatment if confirmed positive. It is hypothesized that gastric mucosal atrophy and IM in children and adolescents might be present in a similar way to adult *H. pylori* infection and is probably more common in areas with high *H. pylori* infection rates than previously thought.

One of the major shortfalls of this retrospective study is that the rapid urease test was the primary test used to detect *H. pylori* infection because ^{13}C-urea breath test, serological *H. pylori* antibody tests and stool antigen tests were not available for more accurate diagnosis. This could result in the underestimation of *H. pylori* infection rates or have false negative results in the uninfected children group. Two perplexing results might be attributed to these drawbacks as there are 8 duodenal ulcer patients (Table 1) and few patients had active gastric inflammation (Tables 4 and 5) in the *H. pylori*-negative group. Due to the strong relationship of *H. pylori* in causing these diseases, it is unlikely these patients were not infected by *H. pylori*. Furthermore, it is likely because of the limitation of the rapid urease test, which is unable to detect patchy distribution of *H. pylori* in the stomach. Therefore, future studies will be required to confirm these discrepancies. Even with these drawbacks, the overall conclusions and significance of the investigation were not affected.

Although the current work provides novel points on *H. pylori*-induced gastric mucosal precancerous lesions in children, due to its retrospective nature, the investigation has limitations. First, this study only discussed the relationship between *H. pylori* infection and gastric mucosa precancerous lesions and was unable to analyze the effects of different genotypes of infected *H. pylori* strains. Therefore, more detailed information on *H. pylori* strains are not available. Nonetheless, our previous work demonstrated that type I *H. pylori* (CagA- and VacA-positive) is the primary type of *H. pylori* infection in this region[40]. It is expected that the pediatric population is similar to the adult population. Second, not all cases had biopsy specimens from both the gastric antrum and body. Some of the precancerous lesions and *H. pylori* infection may have been missed due to histopathological presentation of the stomach, and patchy *H. pylori* infection status in other places of the stomach were unable to be examined. In the future, multiple biopsies might be helpful to overcome these drawbacks. Third, this was a single-center, retrospective analysis, and all the children were hospitalized due to gastrointestinal symptoms, which may be the reason why the infection rate was much higher than among the general population. In the future, large-scale investigations in the general public and multi-center, prospective and randomized control analyses are needed to comprehensively assess the risk of *H. pylori* infection and precancerous lesions in children and adolescents in order to understand the overall precancerous lesions of *H. pylori*-infected pediatric patients.

CONCLUSION

Our results show that *H. pylori*-infected children have more active inflammation and inflammatory cell infiltration in the gastric mucosa, and infection rate increases with patient age. The incidence of precancerous lesions in *H. pylori*-infected patients is also significantly higher compared to that in -uninfected patients. Although the percentage is only 4.33%, it provides an alarming alert and call for further invest-

igation and intervention for this population group.

ARTICLE HIGHLIGHTS

Research background

Chronic *Helicobacter pylori* (*H. pylori*) infection causes gastric mucosal precancerous lesions and gastric cancer in adult patients. It remains to be determined, however, whether gastric mucosal precancerous lesions may also occur in children and adolescents, as this remains an important issue for clinical intervention.

Research motivation

Investigating the relationship between *H. pylori* infection and gastric mucosal precancerous lesions in pediatric patients will provide important evidence on whether intervention should be offered to prevent related disease development in this population group.

Research objectives

H. pylori infection status, gastric mucosal inflammation and gastric precancerous lesions in hospitalized pediatric patients were investigated in central China.

Research methods

We retrospectively enrolled 1015 symptomatic pediatric patients to analyze their clinical and pathological data. The endoscopic and histological findings, occurrence of gastric mucosal precancerous lesions, inflammatory activity and degree of inflammatory cell infiltration were analyzed between *H. pylori*-positive and -negative patient groups.

Research results

The overall *H. pylori* infection rate was 84.14% for the 1015 enrolled pediatric patients, and infection rate increased with age. The incidence of gastric mucosal precancerous lesions in *H. pylori*-infected children was 4.33%, which was significantly higher than that in *H. pylori*-negative children. Infected patients showed more active inflammation as well as more severe inflammatory cell infiltration compared to the non-infected patients. Additionally, endoscopy revealed that the most common presentation was antral nodularity in *H. pylori*-positive patients, whereas superficial gastritis was a marked feature for *H. pylori*-negative patients.

Research conclusions

In children and adolescents, gastric mucosal precancerous lesions occurred in 4.33% of *H. pylori*-infected patients in central China. The data revealed an obvious critical issue that requires future investigation and intervention for this population group.

Research perspectives

The results provide insights on *H. pylori* infection status and its relationship with gastric mucosal precancerous in symptomatic pediatric patients in central China. Further investigation and intervention for related disease prevention are required in this population group.

ACKNOWLEDGEMENTS

The authors are grateful to the staff of the Department of Gastroenterology and Hepatology, People's Hospital of Zhengzhou University for their valuable assistance in this work.

Abstract

BACKGROUND

Intrahepatic cholangiocarcinoma (ICC) is one of the most aggressive malignancies. However, because of its scarcity there are limited population-based data available for investigations into its epidemiologic characteristics. In Taiwan, we have a national cancer registry database that can be used to evaluate the secular trends of ICC.

AIM

To evaluate secular trends of ICC according to age, sex, and risk factors in Taiwan.

METHODS

In this population-based study, we used the national Taiwan Cancer Registry database. Age-standardized and relative percent changes in incidence rates were used to describe secular trends in incidence rates and sex ratios of ICC in Taiwan.

RESULTS

The age-standardized ICC incidence rate among males increased from 1.51 per 100000 in 1993-1997 to 4.07 per 100000 in 2013-2017 and among female from 1.73

per 100000 to 2.95 per 100000. The incidence in females tended to plateau after 2008-2012. For males, the ICC incidence increased as age increased. In the long-term incidence trend of ICC in females, the incidence of the four age groups (40-44, 45-49, 50-54 and 55-59 years) remained stable in different years; although, the incidence of the 60-64 group had a peak in 2003-2007, and the peak incidence of the 65-69 and 70-74 groups occurred in 2008-2012. Among males, beginning at the age of 65, there were increases in the incidence of ICC for the period of 2003-2017 as compared with females in the period of 2003-2017.

CONCLUSION

Increased incidence of ICC occurred in Taiwan over the past two decades. The increased incidence has progressively shifted toward younger people for both males and females.

Key Words: Intrahepatic cholangiocarcinoma; Incidence; Secular trend; Sex ratio; Risk factor

Core Tip: It is important to evaluate the secular trends of intrahepatic cholangiocarcinoma (ICC) incidence and to determine insightful etiological clues in a population with a high incidence of liver cancer. Using the national Taiwan Cancer Registry, we observed an increased incidence of ICC for both males and females. Our observations should be taken in the context of other studies conducted on secular trends of ICC.

INTRODUCTION

Intrahepatic cholangiocarcinoma (ICC) is one of the most aggressive malignancies, and its mortality rates are 1–2 per 100000[1]. After surgery, patients with ICC have 5-year survival rates of approximately 60%, and the rates of recurrence are 60%-65%[2]. In the United States, there were 1.18 new cases per 100000 in 2012[3]. ICC is the second most commonly diagnosed liver cancer[4], and the incidence of ICC continues to increase[5]. Florio *et al*[5] reported that the incidence rate of ICC has regional differences. For example, the incidence rate of ICC in 2008-2012 was 2.80 per 100000 in South Korea [95% confidence interval (CI): 2.68 to 2.93], 2.19 per 100000 in Thailand (95%CI: 2.01-2.36), 0.58 per 100000 in Italy (95%CI: 0.48-0.69), 0.78 per 100000 in the United States (95%CI: 0.74-0.82), and 1.15 per 100000 in the United Kingdom (95%CI: 1.12-1.18)[5]. The average annual percent change (AAPC) of ICC in 2008-2012 also exhibits regional differences. In particular, the AAPC of ICC in 2008-2012 was 4.5% in South Korea (95%CI: 3.0-5.9), -1.0% in Thailand (95%CI: -3.8-1.9), 3.3% in Italy (95%CI: 1.5-5.2), 2.0% in the United States (95%CI: -2.3-6.5), and 4.6% in the United Kingdom (95%CI: 3.2-6.1)[5]. Although these previous studies show that the threat of ICC is rising in many parts of the world[4,5], few studies have used nationwide incidence data to study the epidemiology of ICC.

Moreover, this population-based data facilitates an unbiased estimate of the burden of ICC into the near future. We aimed to evaluate the current trends of ICC in Taiwan. We investigated secular trends in the incidence of ICC to provide insightful etiological analyses, particularly for the variations by age and sex.

MATERIALS AND METHODS

Incidence data from 1993–2017 were obtained from the Taiwan Cancer Registry (TCR). We extracted incidence data on ICC [topography code of International Classification of Diseases for Oncology (ICD-O-FT: T-155.1 before 2002 and ICD-O-3: C22.1, M code 9590-9993 was excluded)]. TCR is organized and funded by the Health Promotion Administration, Ministry of Health and Welfare, Taiwan. In 1979, TCR began to register all cancers nationwide[6,7].

Statistical analysis

In 1995, Taiwan launched the National Health Insurance system[8]. Since that time, the health status of the Taiwanese population has been fully registered[7]. The incidence data were grouped into 17 5-year age groups (0-4, 5-9, 10-14, 15-19, … to 80+ years) and 5 periods (1993–1997, 1998–2002, …, and 2013–2017). Therefore, the data design comprised 14 birth cohorts (the oldest: 1908-1912 to the youngest: 1973-1977). In this study, we reasoned the choice of 1993-1997 as the beginning of the analytical year to avoid incomplete records of incidence data, and the quality of diagnosis in 1993 was similar to that after 1995.

We calculated the incidence rates by sex for each age group by dividing the number of cases by the corresponding population size[9]. Age-standardized incidence rates by sex were calculated using the direct method with the 2000 world standard population as reference[10]. The male-to-female incidence ratios were calculated by dividing the rate in males by that in females for each age group.

All statistical analyses were performed using SAS version 9.4 (SAS Institute Inc., Cary, NC, United States). The research protocol was approved by the Institutional Review Board of Fu-Jen Catholic University (No. C107099).

RESULTS

Age-standardized incidence rates

Figure 1 shows the trend of age-standardized rate (ASR) of ICC in men and women in Taiwan from 1993-1997 to 2013-2017. The incidence of ICC in men increased linearly. The ASR increased from 1.51 per 100000 in 1993-1997 to 4.07 per 100000 in 2013-2017, and its relative percent change was 169%. The incidence of ICC in women tended to plateau after 2008-2012. The ASR increased from 1.73 per 100000 population in 1993-1997 to 2.95 per 100000 in 2008-2012. The relative percentage change was 70%. From 1993-1997 to 2013-2017, the ASR incidence of ICC in men increased more rapidly than that in women.

Age-specific incidence rates

Figure 2A showed the age-specific rates of ICC per 100000 men in Taiwan. For males, the incidence of ICC increased as age increased. The age-specific rate of ICC in seven age groups (40-44, 45-49, 50-54, 55-59, 60-64, 65-69, and 70-74) increased steadily between 1993-1997 and 2013-2017. The respective relative percent changes were 372%, 265%, 156%, 124%, 153%, 231%, and 139%. The 70-74 age group had a larger growth between 1993-1997 and 2003-2007, and its relative percent change was 114%. Then, it increased more slowly between 2003-2007 and 2013-2017, and its relative percent change was only 5%. The 80+ age group showed a trend from rising to declining, with peaks occurring in 2008-2012. Compared to 1993-1997, its relative percent change was 175%. From 2008-2007 to 2013-2017, the incidence decreased 4%.

Figure 2B shows the age-specific rates of ICC per 100000 women in Taiwan. The age-specific rates of the four age groups of 40-44, 45-49, 50-54, and 55-59 remained stable in different years. The incidence of the 60-64 age group had a peak in 2003-2007, and the incidence increased by 69% compared with 1993-1997. The peak incidence of the 65-69 and 70-74 age groups occurred in 2008-2012 compared with the incidence of 1993-1997. The respective relative percent change was 111% and 136%. The incidence of the 75-79 age group increased steadily from 1993-1997 to 2013-2017, with an increase of 121%. The incidence of the 80+ age group peaked in 2008-2012 compared with that in 1993-1997, and the relative percentage change was 227%. Then, the incidence decreased by 11% between 2008-2012 and 2013-2017.

Figure 3 showed the age-specific rates of men and women in different birth cohorts. The incidence of ICC increased as the birth year increased for both males and females. For example, in the 70-74 age group, the incidence of males born in 1943-1947 was 8.41 times of those born in 1913-1917, and the incidence of women born in 1943-1947 was 16.11 times of those born in 1913-1917.

Sex ratios of age-standardized incidence rates

Figure 4 shows the sex ratio of the ASR of ICC in Taiwan from 1993 to 2017. A turning point was apparent at 1998-2002. Before that period, the incidence of ICC in women was higher than that in men. In 1998-2002, the sex ratio of the incidence of ICC was 1.02, which means that the incidence of ICC in men and women was almost the same. After 2002, the incidence of ICC in men was higher than that of women. From 1993-1997 to 2013-2017, the sex ratio of the incidence of ICC increased from 0.87 to 1.52, and the relative percent change was 75%, which indicates a trend of an increasing gap in the incidence of ICC between men and women.

Sex ratios of age-specific incidence rates

Figure 5 shows the sex ratio of the age-specific rates of ICC in Taiwan by diagnostic period. For ICC patients younger than 70-year-old, the sex ratio of age-specific rates increased with year. For example, in the 40-44 age group, the sex ratio was 0.72 in 1993-1997 and 2.98 in 2013-2017. Its relative percent change was 314% from 1993-1997 to 2013-2017. In the age group over 70-years-old, the sex ratio showed a stable

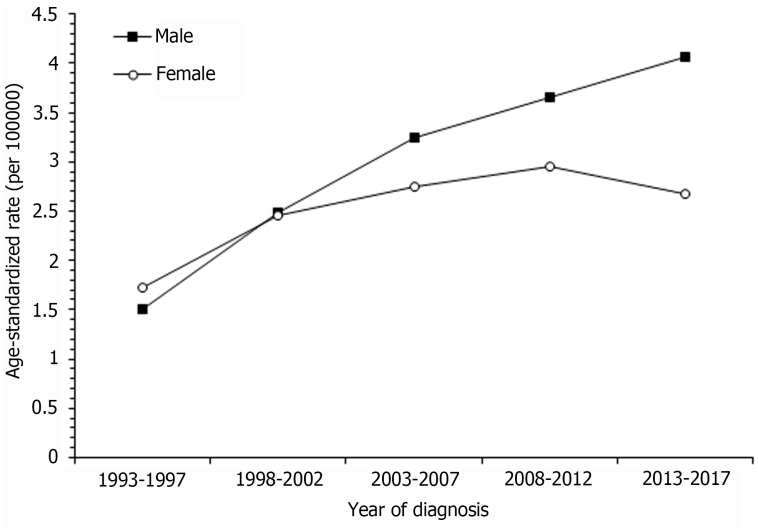

Figure 1 Secular trend in age-standardized incidence rates of intrahepatic cholangiocarcinoma in Taiwan, 1993–2017.

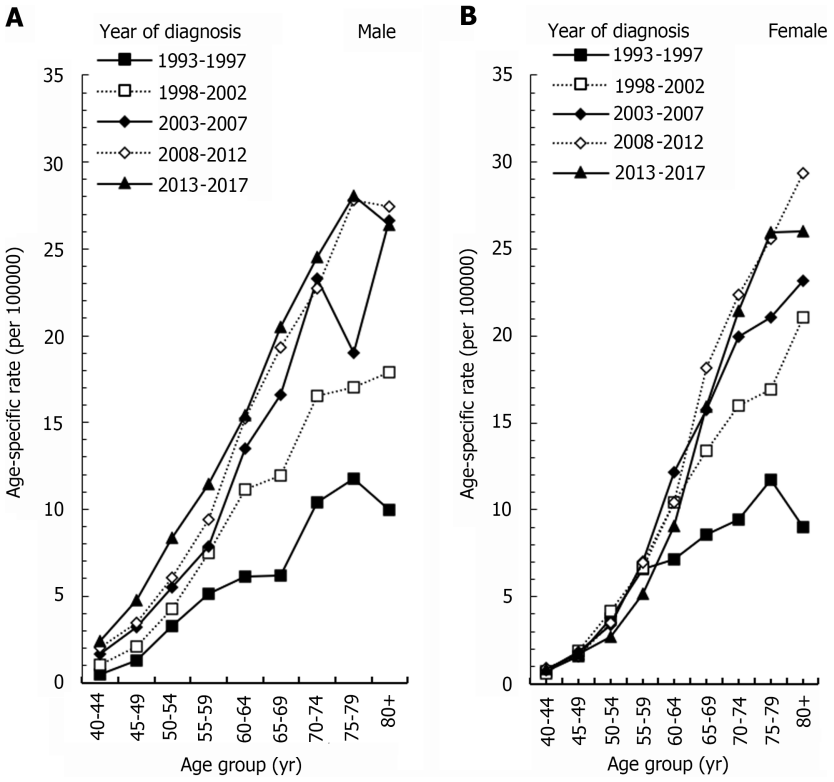

Figure 2 Age-specific incidence rates of intrahepatic cholangiocarcinoma by year of diagnosis and sex. A: Male age-specific rate; B: Female age-specific rate.

baseline in different years, which meant that the incidence of ICC was similar in men and women.

DISCUSSION

This population-based study showed that the incidence of ICC has rapidly increased in Taiwan. This increase remained after stratification by age, sex, diagnosis period, and birth cohort. These results, which highlight the current and projected incidence of ICC, suggest that there is a need for more research to prevent the burden of this cancer in Asian countries.

The incidence rate of ICC varies among different regions of the world[4]. Globally, the ASR is 0.85 per 100000[11]. In Asia, the highest ASR was 2.80 per 100000 in South Korea, and the lowest was 0.26 per 100000 in Israel during 2008-2012[5]. According to our result, the ASR in Taiwan was about 3.3 per

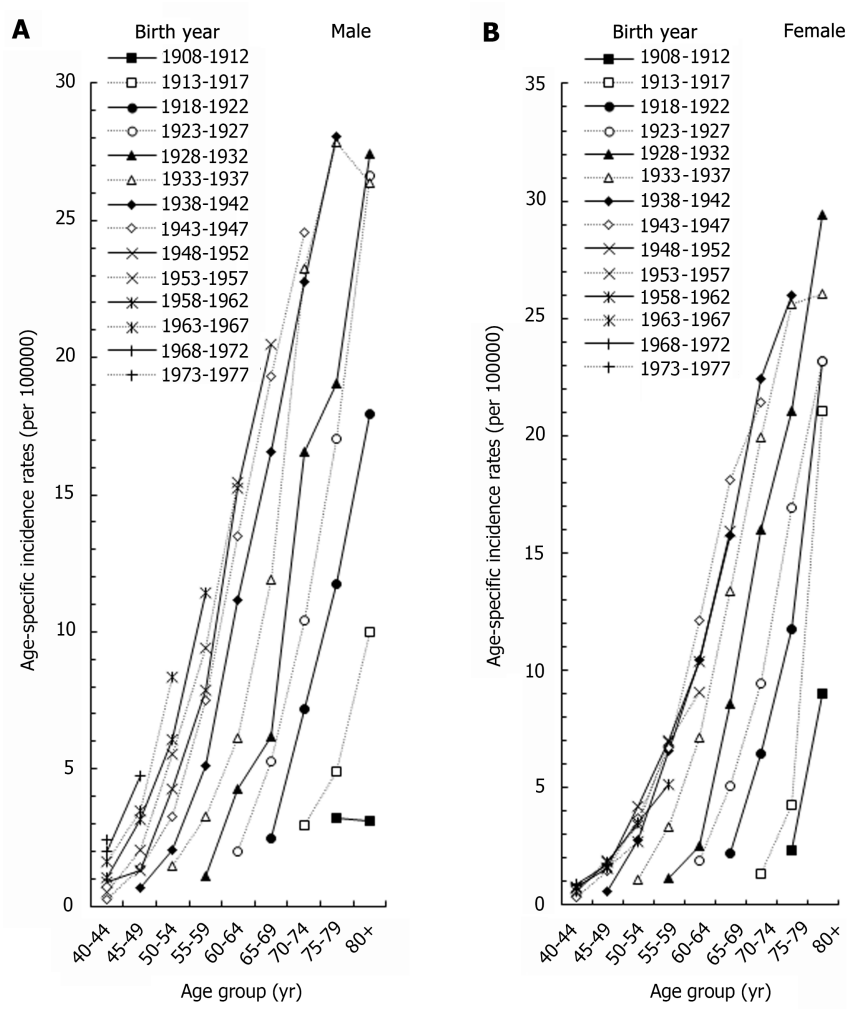

Figure 3 Age-specific incidence rates of intrahepatic cholangiocarcinoma by birth year and sex.

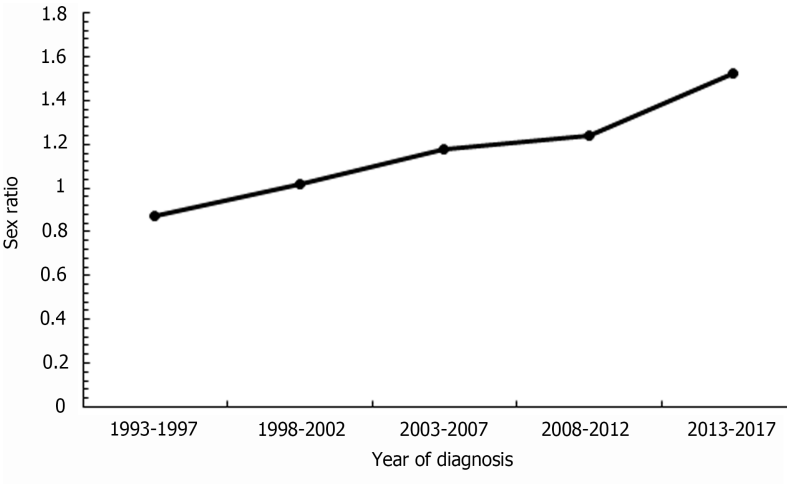

Figure 4 Sex ratio for age-standardized incidence rate of intrahepatic cholangiocarcinoma by year of diagnosis.

100000 during 2008-2012, which means that Taiwan is a high-risk region of ICC. Higher incidence of ICC in Asian countries is likely due to the presence of more risk factors[4,12].

Changes in the incidence of ICC also differs among different countries[5]. Overall, the incidence of ICC has increased in most of the countries in the world[5]. However, the incidence of ICC was higher in Asia, and the increase-rate was higher in Europe and North America[13]. The AAPC of ICC incidence from 1993 to 2012 was 5.0% in Canada, 6.1% in Costa Rica, 6.5% in France, 7.5% in Germany, 8.7% in Poland, 10.5% in Ireland, and 20.1% in Latvia[5]. In Asian countries, the AAPC of ICC incidence was -

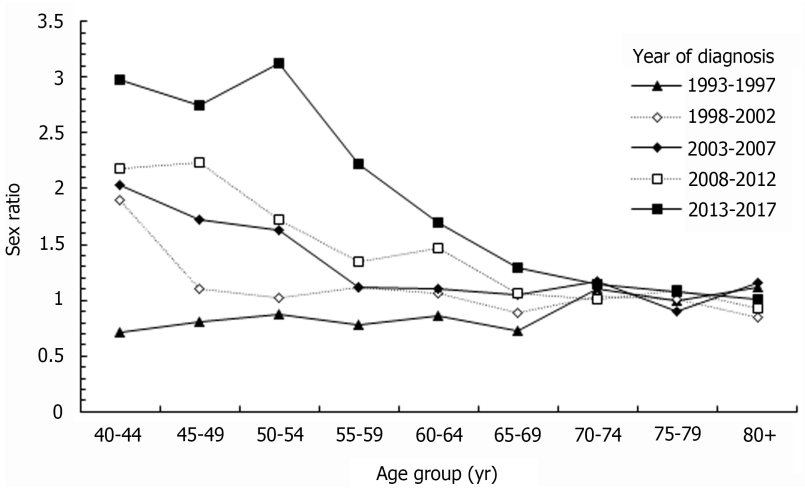

Figure 5 Age-specific sex ratio of intrahepatic cholangiocarcinoma by year of diagnosis and age groups.

0.7% in Japan, -1.0% in Thailand, -2.4% in Philippines, 4.5% in South Korea, and 11.1% in China[5]. In some Asian countries, such as Philippines, Thailand, and Japan, the incidence of ICC showed a nonsignificant decline[5]. In contrast to other studies, our results indicate a rising burden of ICC in the Asia-Pacific area.

A previous study attempted to report the population-based incidence rate of ICC[14]. A study conducted in the United States found that ICC incidence increased from 0.44 per 100000 in 1973 to 1.8 per 100000 in 2012. The AAPC from 2001 to 2012 was 2.3%, and AAPC was 4.36% from 2003 to 2012[3]. In this study, we used the national registry system, which provides comprehensive coverage of the entire population, to make an unbiased estimation of ICC incidence. We found that the incidence of ICC in Taiwan increased from 1.04 per 100000 to 3.36 per 100000 from 1988-1992 to 2013-2017.

An expert consensus document reported that ICC has several risk factors, such as aging of the population, smoking, obesity, diabetes mellitus (DM), hepatitis B virus (HBV) infection, and hepatitis C virus (HCV) infection[4], which may account for this projected increasing incidence. However, due to the number of risk factors of ICC, the phenomenon of the increasing trend of the ICC incidence in Taiwan cannot be explained by a single risk factor.

Aging is an established risk factor for ICC[4]. A study published in 2016 found that the median age at diagnosis among patients in the United States diagnosed with ICC was 67 years between 2008 and 2012 [3]. More than 73% of those patients with ICC were older than 60 years[15], which was similar to our results. We found that the incidence rate was low before age 60 and increased dramatically thereafter. The proportion of people in the population aged 60 and above increased from 13.6% in 2007 to 23.2% in 2020 in Taiwan[9]. A previous study found that the aging of populations in developed countries contributes to the increasing incidence of ICC[15]. Nevertheless, we found the age-adjusted incidence increased gradually over time, and the trend remained consistently elevated, even after stratification by age. This implies that population aging has contributed to the increasing ICC incidence in Taiwan.

A previous meta-analysis showed that DM significantly increased the risk of ICC independent of various confounding factors (relative risk: 1.97, 95%CI: 1.57-2.46; P = 0.025 for heterogeneity)[16]. A previous study reported an increasing prevalence of DM for both sexes in Taiwan from 1992 to 1996 [17], while the incidence remained stable at 6.9–7.7 per 1000 person-years from 1999 to 2004[18]. From 2000 to 2007, the ASR of type 2 DM remained high, at 8.7–9.8 per 1000[19]. In the elderly age group (≥ 65 years), the incidence rate in women (873.2/100000) was higher than that in men (721.4/100000)[20].

Smoking is the most comprehensive environmental factor responsible for ICC. A study based on the National Cancer Institute's SEER 18 database reported that smoking increases the risk of ICC by 46% (95%CI: 1.28-1.66)[20]. A cohort study that included 1518741 individuals showed that current smokers have a 47% greater risk of ICC compared to non-smokers (95%CI: 1.07-2.02)[21]. Taiwan has a high prevalence of smoking. The smoking rate among adult men increased from 59% in 1986 to 63% in 1990, which resulted from the cigarette market opening[22]. A study based on the National Health Interview Survey of Taiwan was conducted in 2001. The prevalence of smokers was 46.8% and the prevalence of ex-smokers was 6.8% in Taiwanese adult males in 2001. The prevalence of smoking was 4.3% and the prevalence of ex-smokers was 0.5% in Taiwanese adult females in 2001[23]. In 2009, a new anti-smoking law was established in Taiwan. Despite the efforts of the Taiwan government, a cross-sectional study that included 961 adults found that up to 42% of sampled Taiwanese adults had smoked cigarettes after that new law had been implemented[24]. The high prevalence of smoking among the early birth cohort in Taiwan may partly explain its high incidence of ICC and seemed to have a cohort effect on ICC.

Obesity was found to increase the risk of ICC by a previous meta-analysis [odds ratio (OR): 1.56, 95%CI: 1.26-1.94][25]. Recently, the prevalence of obesity in Taiwan has increased rapidly. More specifically, a study based on the Nutrition and Health Surveys in Taiwan reported that the prevalence of obesity in men increased from 10.5% in 1993–1996 to 17.0% in 2005. The prevalence of obesity tripled for elementary school boys from 1993 to 2002. Due to the consumption of high-fat foods and lack of physical activity, the prevalence of obesity is likely to increase further in Taiwan[26]. The aforementioned phenomenon may contribute to the increasing prevalence of ICC.

A previous study reported that ICC incidence rates were higher in males than in females in most countries in the world[5]. The sex ratio of the incidence of ICC was 2.9 in Malta, 1.9 in South Korea, 1.9 in Thailand, 1.9 in Japan, 1.9 in Spain, 1.6 in Slovakia, and 1.6 in France[5]. A study based on the SEER database reported that the incidence of ICC was higher in males than in females, and the sex ratio of the age-specific rates of ICC decreased in the aging group[27]. Our results also showed similar outcomes, and this phenomenon may be due to the different hormone profiles of males and females[28]. A study reported that estrogen may modulate cholangiocyte proliferation in nude mice[29]. A previous study used chromatography-tandem mass spectrometry and competitive electrochemiluminescence immunoassay to analyze the relationship between sex steroid hormones and ICC. In that study, a high level of estradiol was found to increase the risk of ICC (OR: 1.40, 95%CI: 1.05-1.89)[30]. A previous study in Taiwan reported that women born in younger cohorts had a later age at natural menopause (hazard ratio: 0.87 per 10-year difference, 95%CI: 0.81-0.95)[31]. The lower ICC incidence of females in our study may be attributed to decreasing estrogen levels in elderly and postmenopausal women. The lower prevalence of smoking among women (4%-8%) than men (47% in 2001)[22] may also contribute to their lower incidence of ICC.

A previous study found that hepatitis B surface antigen (HBsAg) and HCV antibodies had a high association with ICC[32]. A meta-analysis reported that HBV and HCV infection increased the risk of ICC (OR: 3.17, 95%CI: 1.88-5.34 and OR: 3.42, 95%CI: 1.96-5.99, respectively)[33]. Previously, Taiwan was classified as a high-risk region for HBsAg[34]. A study found that HBV DNA could interrupt seven genes (*TERT*, *CEACAM20*, *SPATA18*, *TRERF1*, *ZNF23*, *LINC01449*, and *LINC00486*) in ICC tissue, which may indicate a potential mechanism for the increased risk of ICC in HBV carriers[35].

A retrospective multicenter study in Taiwan reported that the HBsAg prevalence in hepatocellular carcinoma from 1981 to 2001 decreased from 81.5% to 61.2% in males and decreased from 66.7% to 41.4% in females[36]. The sex ratio of HBsAg prevalence of hepatocellular carcinoma increased from 1.22 to 1.61[36], which was consistent with the increasing trend of the sex ratio of the ICC incidence in our study. A previous review hypothesized that HCV could induce the transformation of hepatocytes into cholangiocyte precursors[37]. The HCV antibody prevalence in hepatocellular carcinoma was 31.5% (95%CI: 30.4%-32.6%) in Taiwanese males and 56.7% (95%CI: 54.4%-59.0%) in Taiwanese females[36]. A retrospective cross-sectional study in Taiwan reported that in patients with HCV infection, visceral obesity was significantly associated with waist-to-height ratio, body fat percentage, fat-free mass/body weight, and muscle mass/body weight[38]. Thus, we assumed that HBV and/or HCV infection may be at least partially explain why the incidence of ICC in Taiwan was high.

We found that the sex ratio of the incidence of ICC increased as the diagnostic year increased. In the group over the age of 70 years, the sex ratio of the incidence of ICC between men and women was close to 1, which meant that there was almost no difference in the incidence of ICC between men and women. The proportion of women with ICC increases with age. Another population-based study in the United States showed the proportion of females with ICC was 38.9% for those aged 40-59 years, 45.8% for those aged 60-79 years, and 56.3% for those aged ≥ 80 years[27]. The aforementioned research results are consistent with our study outcome. However, another study based on the Italian National Institute of Statistics A in Italy, another country with a high risk of ICC, reported that the incidence of ICC in males was always higher than that in females[39], which was different from our study outcome. Due to the variety of risk factors of ICC, it is difficult to identify the cause of this difference. A study based on the Netherlands Cancer Registry reported that the incidence of ICC in a low endemic area significantly increased in older populations, especially in in the 45–59 years age group[40]. Interestingly, we also found a similar pattern.

Assessing the temporal trends in the sex difference of ICC incidence has useful implications. Any temporal changes in the sex difference reflect the contributions from environmental and extrinsic risk factors, while a stable sex difference indicates the role of intrinsic exposures or environmental risk. The increase of the sex difference in the incidence of ICC may be explained by the decreasing prevalence of smoking, particularly in men with a historically higher prevalence[23,24]. The decline in smoking prevalence in Taiwan, which has been more rapid for men than for women, may have also contributed to the decreased sex difference in ICC[23,24]. In addition, we noted an increased sex difference in the incidence of ICC since 2008, which warrants confirmation through continued monitoring and investigations.

We found that the gap in the sex ratio between the 40-44 age group and the 80+ age group increased as the diagnostic year increased. In age groups younger than 70 years, the sex ratio increased as the diagnostic year increased. However, in the age groups over 70 years, the sex ratio was similar during each diagnostic period. In our cohort, we found that the incidence of ICC in males and females was higher in the elder birth cohort, which resulted in the aforementioned phenomenon.

Surgery is the only curative treatment for ICC[4]. A previous study found the incidence of sarcopenia among ICC patients following receipt of liver resection to be 50%. Preoperative nutritional evaluation is important for ICC[41]. In addition, nutritional factors may affect the disease incidence. Indeed, a population-based cohort study found that regular use of oil supplement lowered the risk of total liver cancer to 44% (95%CI: 25%-59%) and risk of ICC to 40% (95%CI: 7%-61%)[42]. A meta-analysis suggested that vegetable and fruit consumption may reduce the risk of ICC; specifically, the reported ORs of mixed vegetables, mixed fruits, and combined fruits and vegetables were 0.61 (95%CI: 0.50-0.75), 0.79 (95%CI: 0.65-0.96), and 0.68 (95%CI: 0.57-0.80), respectively[43]. A multi-center study determined that high dietary fiber intake could be associated with a lower risk of intrahepatic bile duct cancer[44]. Finally, an animal model-based study in Taiwan provided further evidence of a relationship between ICC and nutrition; vitamin D supplementation lead to significant suppression of ICC initiation and progression in the rat model *via* regulation of gene expression (*e.g.*, of lipocalin 2)[45].

This study has several limitations. As seen in other studies based on cancer registry databases[46], a substantial portion of cases did not receive histological verification. Old age and advanced tumor stage at presentation likely prohibited this verification. Nevertheless, integrity of the TCR database was 98.4% [47]. The morphological verification percentage of the TCR database is 93.0%[47], which minimizes the misdiagnosis of cancer incidence. In addition, quality and accuracy of clinical diagnosis in our databases has been validated, and the percentage of death certificate-only data is 1%[47]. In addition, we extracted the ICD-O-FT: T-155.1 before 2002 and ICD-O-3: C22.1 from 2003–2017, which may misclassify some diagnostic cases. However, due to the rarity of ICC cases in Taiwan, this deviation did not affect the statistical trend outcomes in our study. In addition, restriction to cases with histological proof would have introduced selection bias. Ultimately, although our study found that there are various risks associated with ICC, including sex, age, DM, HBV and/or HCV infection, obesity, nutritional factors, and smoking, the results need to be validated in larger cohorts, exploring the risk of ICC development in a high incidence area in particular.

CONCLUSION

The incidence of ICC continues to rise in Asia. The etiological role of ICC is still unclear. However, future prospective evaluations are warranted to explore potential risk factors of ICC. The assessment of their independent and/or interactive effects are suggested, which could lead to prevention of ICC, development of early detection methods for early curative surgery, and identification of potential prognostic factors related to improved therapy and outcomes.

ARTICLE HIGHLIGHTS

Research background

Intrahepatic cholangiocarcinoma (ICC) is one of the most aggressive malignancies. However, because of its scarcity few population-based studies have explored its epidemiology. In Taiwan, we have a national cancer registry database, which can be used to evaluate the epidemiology of ICC.

Research motivation

To discover the secular incidence trends and associated risk factors of ICC in Taiwan.

Research objectives

To observe secular trends in ICC incidence according to age, sex, and risk factors in Taiwan.

Research methods

In this population-based study, we used the national Taiwan Cancer Registry database. Relative percent change in incidence rates were used to describe secular trends in incidence rates and sex ratios of ICC in Taiwan.

Research results

The age-standardized ICC incidence rate among males increased from 1.51 per 100000 in 1993-1997 to 4.07 per 100000 in 2013-2017 and among females from 1.73 per 100000 to 2.95 per 100000. ICC incidence rates in females tended to plateau after 2008-2012. For males, the incidence of ICC increased as age increased. In the long-term incidence trend of ICC in females, the incidence of the four age groups of 40-44, 45-49, 50-54, and 55-59 years remained stable in different years, the incidence of the 60-64 age group had a peak in 2003-2007, and the peak incidence in the 65-69 and 70-74 age groups occurred in 2008-2012.

Research conclusions

An increased incidence of ICC has occurred in Taiwan over the past two decades. The increased sex ratios has progressively shifted toward younger people.

Research perspectives

Further long-term cohort studies are needed to investigate the relationship between ICC and its risk factors.

Abstract

BACKGROUND

Helicobacter pylori (*H. pylori*) has characteristics of family cluster infection; however, its family-based infection status, related factors, and transmission pattern in central China, a high-risk area for *H. pylori* infection and gastric cancer, have not been evaluated. We investigated family-based *H. pylori* infection in healthy households to understand its infection status, related factors, and patterns of transmission for related disease prevention.

AIM

To investigate family-based *H. pylori* infection status, related factors, and patterns of transmission in healthy households for related disease prevention.

METHODS

Blood samples and survey questionnaires were collected from 282 families

including 772 individuals. The recruited families were from 10 selected communities in the greater Zhengzhou area with different living standards, and the family members' general data, *H. pylori* infection status, related factors, and transmission pattern were analyzed. *H. pylori* infection was confirmed primarily by serum *H. pylori* antibody arrays; if patients previously underwent *H. pylori* eradication therapy, an additional ^{13}C-urea breath test was performed to obtain their current infection status. Serum gastrin and pepsinogens (PGs) were also analyzed.

RESULTS

Among the 772 individuals examined, *H. pylori* infection rate was 54.27%. These infected individuals were from 246 families, accounting for 87.23% of all 282 families examined, and 34.55% of these families were infected by the same strains. In 27.24% of infected families, all members were infected, and 68.66% of them were infected with type I strains. Among the 244 families that included both husband and wife, spouse co-infection rate was 34.84%, and in only 17.21% of these spouses, none were infected. The infection rate increased with duration of marriage, but annual household income, history of smoking, history of alcohol consumption, dining location, presence of gastrointestinal symptoms, and family history of gastric disease or GC did not affect infection rates; however, individuals who had a higher education level showed lower infection rates. The levels of gastrin-17, PGI, and PGII were significantly higher, and PGI/II ratio was significantly lower in *H. pylori*-infected groups than in *H. pylori*-negative groups.

CONCLUSION

In our study sample from the general public of central China, *H. pylori* infection rate was 54.27%, but in 87.23% of healthy households, there was at least 1 *H. pylori*-infected person; in 27.24% of these infected families, all members were infected. Type I *H. pylori* was the dominant strain in this area. Individuals with a higher education level showed significantly lower infection rates; no other variables affected infection rates.

Key Words: *Helicobacter pylori*; Atrophic gastritis; Family clustering infection; Gastric cancer; Gastrin; Pepsinogen

Core Tip: *Helicobacter pylori* (*H. pylori*) has characteristics of family cluster infection. However, few studies have investigated family-based infection status and pattern of intrafamilial transmission in the general public of central China. In our study, *H. pylori* infection rate was 54.27%, but in 87.23% of healthy households, there was at least 1 *H. pylori*-infected person; in 27.24% of these infected families, all members were infected. Type I *H. pylori* was the dominant strain in this area. Intrafamilial infection status and patterns of transmission represent one important source of *H. pylori* spread, indicating the urgent need for family-based infection control and related disease prevention.

INTRODUCTION

Chronic *Helicobacter pylori* (*H. pylori*) infection is the major cause of chronic gastritis, peptic ulcers, and gastric cancer (GC), and is also closely associated with a number of extra-gastrointestinal (GI) diseases [1-3]. *H. pylori* infection rate in China is about 50%, but the infection rate varies widely in different regions due to economic development, age, lifestyle habit, and sanitary conditions[4-6]. *H. pylori* has characteristics of family cluster infection[7]. Most *H. pylori* infections are acquired during childhood and adolescence, and infection will persist for decades unless proper treatment is offered.

Mounting evidence has demonstrated that transmission of *H. pylori* is mainly by oral-oral and fecal-oral routes, and water sources[8,9], and intra-familial spread is the major source of *H. pylori* transmission[10-12]. The infected parent, especially the mother, is thought to play an important role in its transmission[9,11]. When parents are infected with *H. pylori*, the infection rates of their children

markedly increase; spread has also been demonstrated between spouses and among siblings[13-17]. Therefore, diagnosis and treatment of the whole family have important clinical implications for preventing related diseases[18]. Recently, the notion of "family-based *H. pylori* infection control and management" has been introduced to China as a practical strategy to curb *H. pylori* intra-familial transmission[3]. However, relatively few studies have been performed to investigate the family-based infection status, related factors, and pattern of intrafamilial transmission in the general population.

Type I [cytotoxin-associated protein-positive (CagA+), vacuolating cytotoxin-positive (VacA+)] *H. pylori* infection causes severe gastric inflammation and is prone to induce carcinogenesis[19,20]. Our previous study of 3572 patients admitted to the hospital showed that the *H. pylori* infection rate was 75.9% in this area of central China. The infection rate was further confirmed by investigation of 523 endoscopy-confirmed patients (76.9%), of whom 72.4% (291/402) had type I *H. pylori* infection and 27.5% had type II *H. pylori* infection. Importantly, 88.4% of GC patients were *H. pylori*-positive, of whom 84.2% had type I infection; only 11.6% of GC patients were *H. pylori*-negative[21]. At present, the genotype of family based-*H. pylori* infection in the healthy household is unclear, as well as its relationship with GC epidemiological markers such as gastrin-17 (G-17), pepsinogen (PG) level, and PG I/II ratio (PGR).

Henan province in central China is one of the high-risk areas for *H. pylori* and GC, with an *H. pylori* infection rate of 49.6%[22] and GC incidence of 42.52/100000[23]. The capital city, Zhengzhou, has a population of 12 million, but there has been no large-scale family-based *H. pylori* intrafamilial transmission survey, and the factors that affect *H. pylori* spread and cause disease are also unclear.

Therefore, we investigated family-based *H. pylori* infection status, factors related to bacteria spread, bacteria genotype, and patterns of transmission for the residents in this area, and analyzed their impact on GC epidemiological markers including G-17, PGI, PGII, and PGR. The results of this study will provide information on *H. pylori* infection status in the household and help to refine eradication strategies for the prevention of related diseases.

MATERIALS AND METHODS

Study population and data collection

From September 2020 to April 2021, blood samples and questionnaires were collected from family members of 10 selected communities in greater Zhengzhou area; each community enrolled 20-30 families, with all members participating. The 10 communities were selected based on high, middle, and low living standards to prevent biased selection of the population; these included two high-income communities, six middle-class communities, and two communities originating from rural areas. Specifically, the study included two communities located in Guancheng District, namely Lufu Pavilion and Houjiadong Street communities; three communities located in Jinshui District, namely Chengbei Road, Jiagang, and Huilong Digital City communities; four communities in New East Zhengzhou District, namely Hanhai Qingyu, Zhengzhou Academy of Aviation Administration, Henan University of Finance, Economics and Law, and Nanxi Fudi communities; and one community in Central Zhengzhou District, namely Kowloon City community.

A total of 282 families (family size ≥ 2 persons) including 772 individuals participated in the survey. Inclusion criteria were: Family members being long-term residents living in Zhengzhou area, with no age limit; all family members being willing to participate by providing blood samples and filling out the questionnaire; at least 2 people composing the family unit, but with no limitation on how many people are living in the same household; and all family members being willing to provide written informed consent. An infected family was defined as a household with various family members infected with *H. pylori*, ranging from only 1 person to all family members being infected, and a family could be composed of only a couple, with or without children. Exclusion criteria were: Pregnant and breast-feeding females; people with mental illness; or people who refused to fill out the questionnaire or sign the consent form.

This study was approved by the Ethics Committee of People's Hospital of Zhengzhou University (No. 53, 2021). All subjects provided written informed consent; for minor subjects, written informed consent was given by their legal guardian. This study was registered in the China Clinical Trial Registry (www.chictr.org.cn; No. ChiCTR2100052950), and the protocol is freely available from the website after registration.

Subject enrollment and questionnaire

Before and during enrollment, an introduction brochure or information booklet for the study was distributed to the community center staff, who were responsible for distributing and helping recruit community family members for onsite registration. A registration website was also open to community members for whole family-based registration; registration for only a single individual was declined. A questionnaire was filled out either online or onsite by each of the participating family members. Blood samples were collected from each participating member for *H. pylori*, gastrin, and PG analyses; if necessary, ^{13}C-urea breath test (UBT) was subsequently performed by appointment.

Based on the purpose of this study, questionnaire included the following 17 items: Age; sex; family ethic; number of family members; professions; marriage status; socioeconomic data; dining history; living habits; lifestyle; disease history; medication history; presence of GI symptoms; *H. pylori* eradication history; history of gastroscopy; infection history of other family members; and treatment history (Table 1).

H. pylori infection status, gastrin, and PG analyses

Three milliliters of fasting venous blood were collected from all subjects in the morning. Blood samples were centrifuged at 1000 × *g* for 10 min, (80-2 centrifuge; Jiangsu Zhongda Instrument Technology Co., Ltd., Jiangsu, China), and samples were either analyzed on ice on the same day or stored at -80 °C for subsequent analyses. Serum anti-*H. pylori* antibodies [detecting CagA, VacA, UreA, UreB *via H. pylori* enzyme-linked immunosorbent assay (ELISA) kit (Blot Biotech Co., Ltd., Shenzhen, Guangdong, China)] and G-17, PGI, PGII levels, as well as PGR (*via* PGI, PGII, G-17 ELISA kits; Biohit Biotechnology, Helsinki, Finland) were measured by an ELISA kit following manufacturer's instructions as previously reported[22]. If patients had previously undergone *H. pylori* eradication therapy, an additional ^{13}C-UBT was performed to obtain their current infection status (^{13}C-UBT Diagnostic Kit; Beijing Boran Pharmaceutical Co., Ltd., Beijing, China).

Statistical analyses

Data were analyzed using SPSS for Windows version 25 (IBM Corp, Armonk, NY, United States). Continuous variables are expressed as mean ± SD, whereas categorical variables are described as percentages or frequencies. The measurement data were compared by *t*-test, and the enumeration data were compared by χ^2 test or Fisher's exact test. $P < 0.05$ was considered statistically significant.

RESULTS

Demographic information of the enrolled families

As shown in Table 1, a total of 282 families including 772 members participated in this study. Among them, 419 had *H. pylori* infection, giving an overall infection rate of 54.27% (419/772); among the infected individuals, 328 (42.49%, 328/772) were infected with type I strains and 91 (11.79%, 91/772) were infected with type II strains. Type I strains accounted for 78.28% (328/419) of cases, and type II strains accounted for 21.7% (91/419) of infected individuals (Figure 1A).

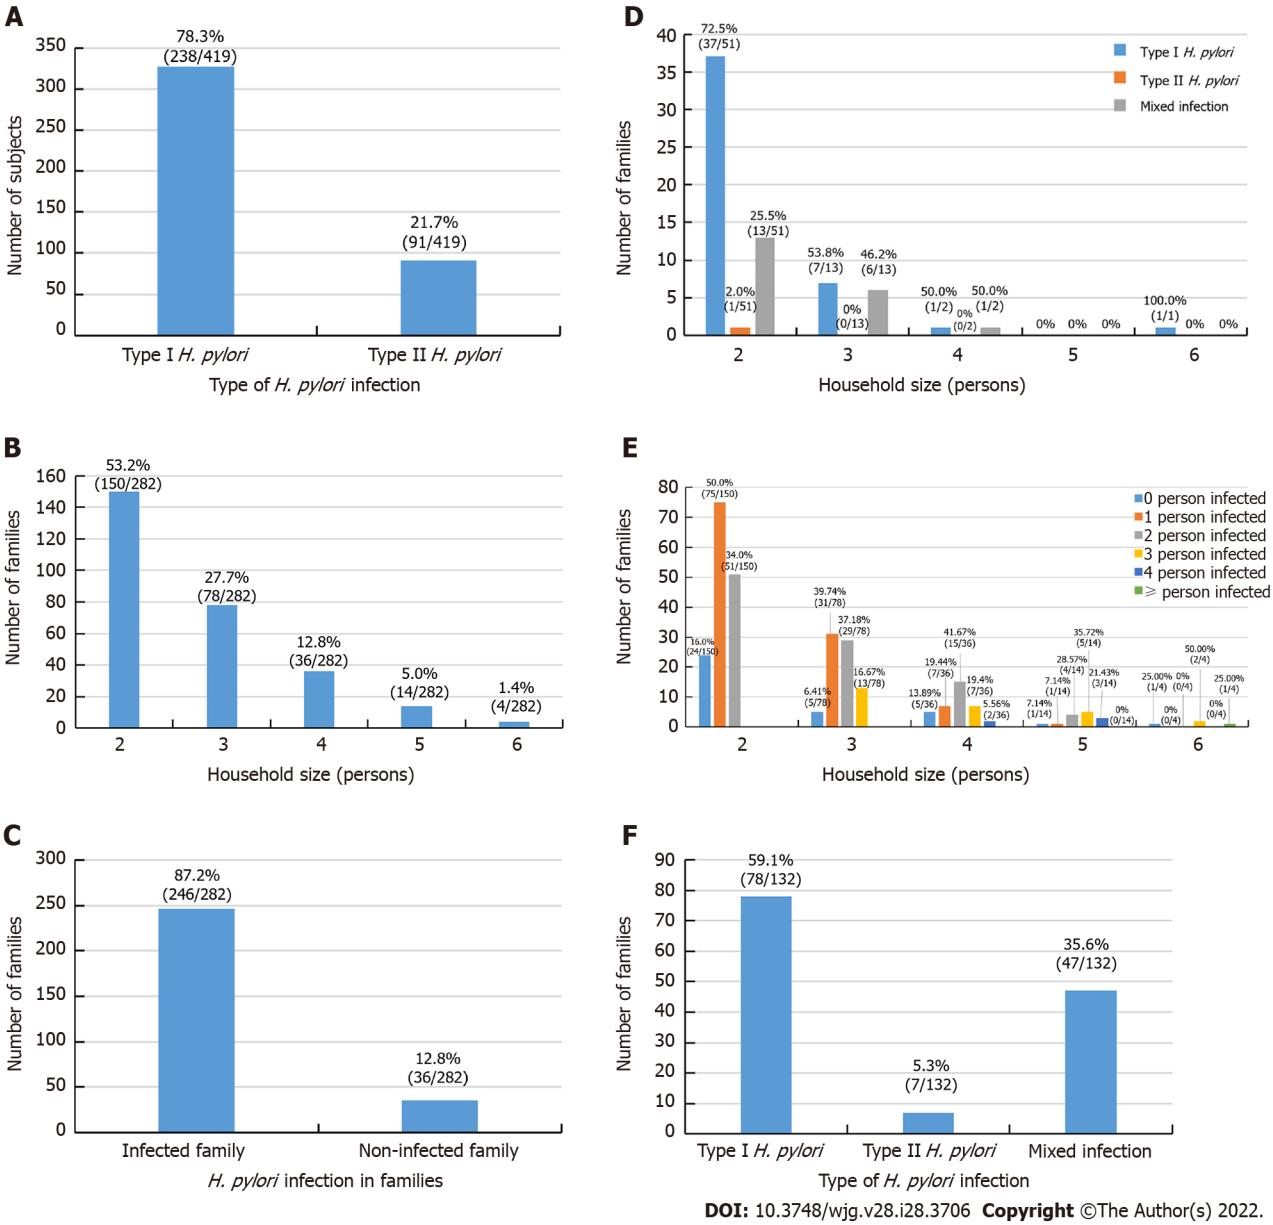
In total, 330 (42.75%) of the study participants were male, with an average age of 44.56 ± 20.19 years, and 442 (57.25%) were female, with an average age of 45.95 ± 18.74 years ($P > 0.05$). The age range of the enrolled individuals was 3 years to 90 years, with the youngest and oldest infected individuals aged 5 years and 87 years, respectively.

As shown in Figure 2, stratified age and *H. pylori* genotype infection were further analyzed, type I strains was the dominant strains for all age groups. The infection rates of individuals under the age of 18 were 23.26% (20/86), and the age groups of 51-60 and 61-70 years had the highest infection rates of 63.01% (92/146) and 65.95% (93/141), respectively. Compared with age groups under 18-years-old, the infection rate was significantly higher in groups above 18-years-old ($P < 0.05$), but there was no difference in infection rates among groups above 18-years-old ($P > 0.05$).

Among questionnaire variables (Table 1), annual household income, history of smoking, history of alcohol consumption, dining location, presence of GI symptoms, and family history of gastric disease and GC did not affect infection rates ($P > 0.05$), but individuals with a higher education level showed significantly lower infection rates ($P < 0.05$).

H. pylori infection status of the enrolled families

The average family size of the study cohort was 2.74 persons *per* households, and family size ranged from as few as 2 persons *per* family to as many as 6 *per* family (Figure 1B). In this survey, 2- and 3-person households accounted for 80.85% (228/282) of the families enrolled.



As shown in Figure 1C-F, *H. pylori*-infected individuals were distributed in 246 of the 282 families with varying numbers of members infected, ranging from only 1 person to all family members infected. The family infection rate was 87.23% with at least 1 person infected in a family unit (246/282), in 12.77% of the 282 households, no family members were infected (36/282) (Figure 1C). In 67 of the 246 infected families, all members were infected (27.24%, 67/246), among these 67 all member-infected households, 46 households were infected with the same type I strains (68.66%, 46/67), 1 household was infected with type II strains (1.49%, 1/67), and 20 households had mixed type I and II strain infection (29.85%, 20/67) (Figure 1D). The data of the stratified family member infection rate of 282 households were shown in Figure 1E. In 53.66% (132/246) of families with at least 2 members infected, 59.09% (78/132) of these families were infected with type I strains, 5.30% (7/132) were infected with type II strains, and 35.61% (47/132) were infected with mixed type I and II strains (Figure 1F).

Figure 1 *Helicobacter pylori* infection status of the 282 enrolled families. Values above each column are the case number and percentages of each group. A: Genotype pattern of the 419 infected subjects in the enrolled families; B: Distribution pattern of the 282 enrolled families ranged from 2-6 people; C: General *Helicobacter pylori* (*H. pylori*) infection status of 282 families; D: Genotype pattern of the 67 all member-infected families from the enrolled 282 families; E: Distribution pattern of the *H. pylori* infection status of the 282 enrolled families; F: Genotype pattern of the 132 *H. pylori*-infected families with ≥ 2 persons infected from the 282 enrolled families. Infected family: At least 1 person in a family was infected; Non-infected family: All members in a family were not infected; Type I *H. pylori*: *H. pylori* infection with type I strains; Type II *H. pylori*: *H. pylori* infection with type II strains; Mixed infection: *H. pylori* infection with type I and type II strains.

H. pylori infection status between couples

H. pylori infection status between couples is shown in Figure 3. In all, 244 of the 282 families had both spouses, and infection rate of both spouses was 34.84% (85/244); further, 17.21% (42/244) couples were not infected, and 47.95% (117/244) had only a single spouse infection (Figure 3A). Among 117 families with infection of only 1 spouse, 75.21% (88/117) were infected with type I strains and 24.79% (29/117) were infected with type II strains (Figure 3B). Of these spouses, the husband was infected in 49.57% (58/117) of cases and the wife was infected in 50.53% (59/117) of cases ($P > 0.05$), they were further stratified into type I and type II strains infections (Figure 3C). Furthermore, among the 85 families with both husband and wife co-infected with *H. pylori*, 68.24% (58/85) were infected with the same type of strain, of whom 63.53% (54/85) were infected with type I strains, 4.71% (4/85) were infected with type II strains, and 31.76% (27/85) had mixed type I and type II infection (Figure 3D). Significantly more couples were infected with the same type of strain than with mixed strains ($P < 0.05$). In addition, with the increase in marriage duration, infection rate of both husband and wife was significantly increased ($r = 0.98$, $P < 0.05$; Figure 3E).

Parental infection and infection status of children and adolescents

In 51 families with both parents and children younger than 18 years of age, as shown in Table 2, the infection rate of children was 23.08% (6/26) when both parents were *H. pylori*-infected; however, when both parents were not infected, the infection rate of children was 18.18% (2/11) ($P > 0.05$). When only mother was infected, the infection rate of children was 45.45% (5/11); no child was infected (0/9) when only father was infected ($P > 0.05$).

Table 3 shows infection status of the 51 families comprising both parents and children, for a total of 190 individuals. Among these family members, the infection rates were as follows: Father, 62.75% (32/51); mother, 62.75% (32/51); grandfather, 50.00% (2/4); grandmother, 66.67% (8/12); maternal grandfather, 25.00% (1/4); maternal grandmother, 37.50% (3/8); and other relatives, 66.67% (2/3).

Comparison of G-17, PGI, and PGII levels, and PGR with different types of *H. pylori* infection

To determine the impact of *H. pylori* infection on common GC epidemiological markers (*e.g.*, G-17, PGI, PGII, and PGR) in healthy households, we assayed their levels during *H. pylori* infection. As shown in Table 4, compared to *H. pylori*-negative groups, PGI levels were significantly higher and PGR was significantly lower in *H. pylori* type I infections compared with *H. pylori*-negative groups ($P < 0.05$). However, there were no differences in G-17, PGII level, and PGR between type II *H. pylori* infection and *H. pylori*-negative groups ($P > 0.05$). The levels of G-17, PGI, and PGII were significantly higher, and PGR was significantly lower in *H. pylori*-infected groups than in *H. pylori*-negative groups ($P < 0.05$).

DISCUSSION

H. pylori infection rates vary greatly among different countries and regions[24]. Although numerous studies have demonstrated that intrafamilial transmission is one of the most important sources of *H. pylori* spread[2,18,24], there are few studies on the characteristics and pattern of family-based *H. pylori* infection for disease prevention and control[9,25,26]. Therefore, focusing on family-based *H. pylori* infection control and management would be a novel approach to reduce the related diseases and GC burden in a society.

In this work, we analyzed *H. pylori* infection status in a total of 772 individuals from 282 families in the Zhengzhou area. The results showed that despite an overall infection rate of only 54.27%, in as high as 87.23% of the surveyed families (246/282), there was at least 1 person infected, and in 27.07% (67/246) of these infected families, all family members were infected; further, 34.55% (85/246) of these families were infected with the same type of strain. Therefore, this study provides new evidence showing the importance of family-based *H. pylori* infection control, which has substantive public health implications, and suggests that intrafamilial infection is a major source of *H. pylori* transmission. Thus, preventing intrafamilial spread is critical to eliminate the source of infection in order to prevent the related diseases.

Over the past several decades, the social and family structure in China has changed dramatically. The latest national statistics[27] (2020) revealed that the nation has a population of 1.41 billion and 492 million families with an average family size of 2.62 persons/family, which is much smaller than it was in 1990, when China had 1.13 billion citizens and 278.6 million families, with an average family size of 4.05 persons/family[27]. Due to the previous nationwide "one-children-per-family policy" (between 1982 and 2016), most families in China only have 1 child and two generations. As these children do not have siblings, transmission among siblings within a family unit did not appear to be the major route of transmission in the current analysis. *H. pylori* spread from parent or grandparent to children is probably more important for bacteria transmission. Although the current results provide a snapshot of *H. pylori* infection status in the general public, a nationwide large-scale investigation is needed to explore the nationwide infection status and develop policies for related disease prevention.

Table 2 Parental infection and infection status of children and adolescents in 51 families

Parental infection (Household numbers)	Children infection (57)		Infection rate (%)	*P* value
	H. pylori+ (*n*)	*H. pylori*- (*n*)		
Neither parent infected (11)	2	9	18.18	
Both parent infected (21)	6	20	23.08	0.109[a]
Only father infected (9)	0	9	0	
Only mother infected (10)	5	6	45.45	
Total (51)	13	44	22.81	

[a]*P* > 0.05 when both parents infected group were compared with neither parent infected group.
n: Person *per* group; Infection rate (%): Infection rate of children in different groups; *H. pylori*+: *H. pylori*-positive; *H. pylori*-: *H. pylori*-negative.

Table 3 *Helicobacter pylori* infection status in 51 families with children and other relatives

Family members (N)	*H. pylori* positive			*H. pylori* negative, *n*	Infection rate (%)
	Sub total, *n*	Type I *H. pylori*, *n*	Type II *H. pylori*, *n*		
Total (190)	93	66	27	97	48.95
Father (51)	32	23	9	19	62.75
Mother (51)	32	22	10	19	62.75
Grandfather (4)	2	1	1	2	50.00
Grandmother (12)	8	6	2	4	66.67
Maternal grandfather (4)	1	0	1	3	25.00
Maternal grandmother (8)	3	2	1	5	37.50
Other relatives (3)	2	2	0	1	66.67
Child (57)	13	10	3	45	22.81

[a]*P* < 0.05 when type I *Helicobacter pylori* (*H. pylori*)-infected groups were compared with *H. pylori*-negative groups.
[b]*P* < 0.05 when type II *H. pylori*-infected groups were compared with *H. pylori*-negative groups.
[c]*P* < 0.05 when type I *H. pylori*-infected groups were compared with type II *H. pylori*-infected groups.
[d]*P* < 0.05 when *H. pylori*-infected groups were compared with *H. pylori*-negative groups.
Data are presented as mean ± SD. G-17: Gastrin-17; PG: Pepsinogen; PGR: PG I/II ratio; Type I *H. pylori*: *H. pylori* infection with type I strains; Type II *H. pylori*: *H. pylori* infection with type II strains; *H. pylori*: *Helicobacter pylori*; *H. pylori*+: *H. pylori*-positive; *H. pylori*-: *H. pylori*-negative.

In single factor analysis, we noted that the highly infected age groups were between 31 years and 70 years, and infection rates increased along with age and duration of marriage. Annual household income, history of smoking, history of alcohol consumption, dining location, and family history of gastric disease or GC were not different between the infected and non-infected groups, but individuals with a higher education level showed a lower infection rate. A 2020 all-ages population-based cross-sectional study[28] in Wuwei county in northwestern China showed that the prevalence of *H. pylori*

DOI: 10.3748/wjg.v28.i28.3706 **Copyright** ©The Author(s) 2022.

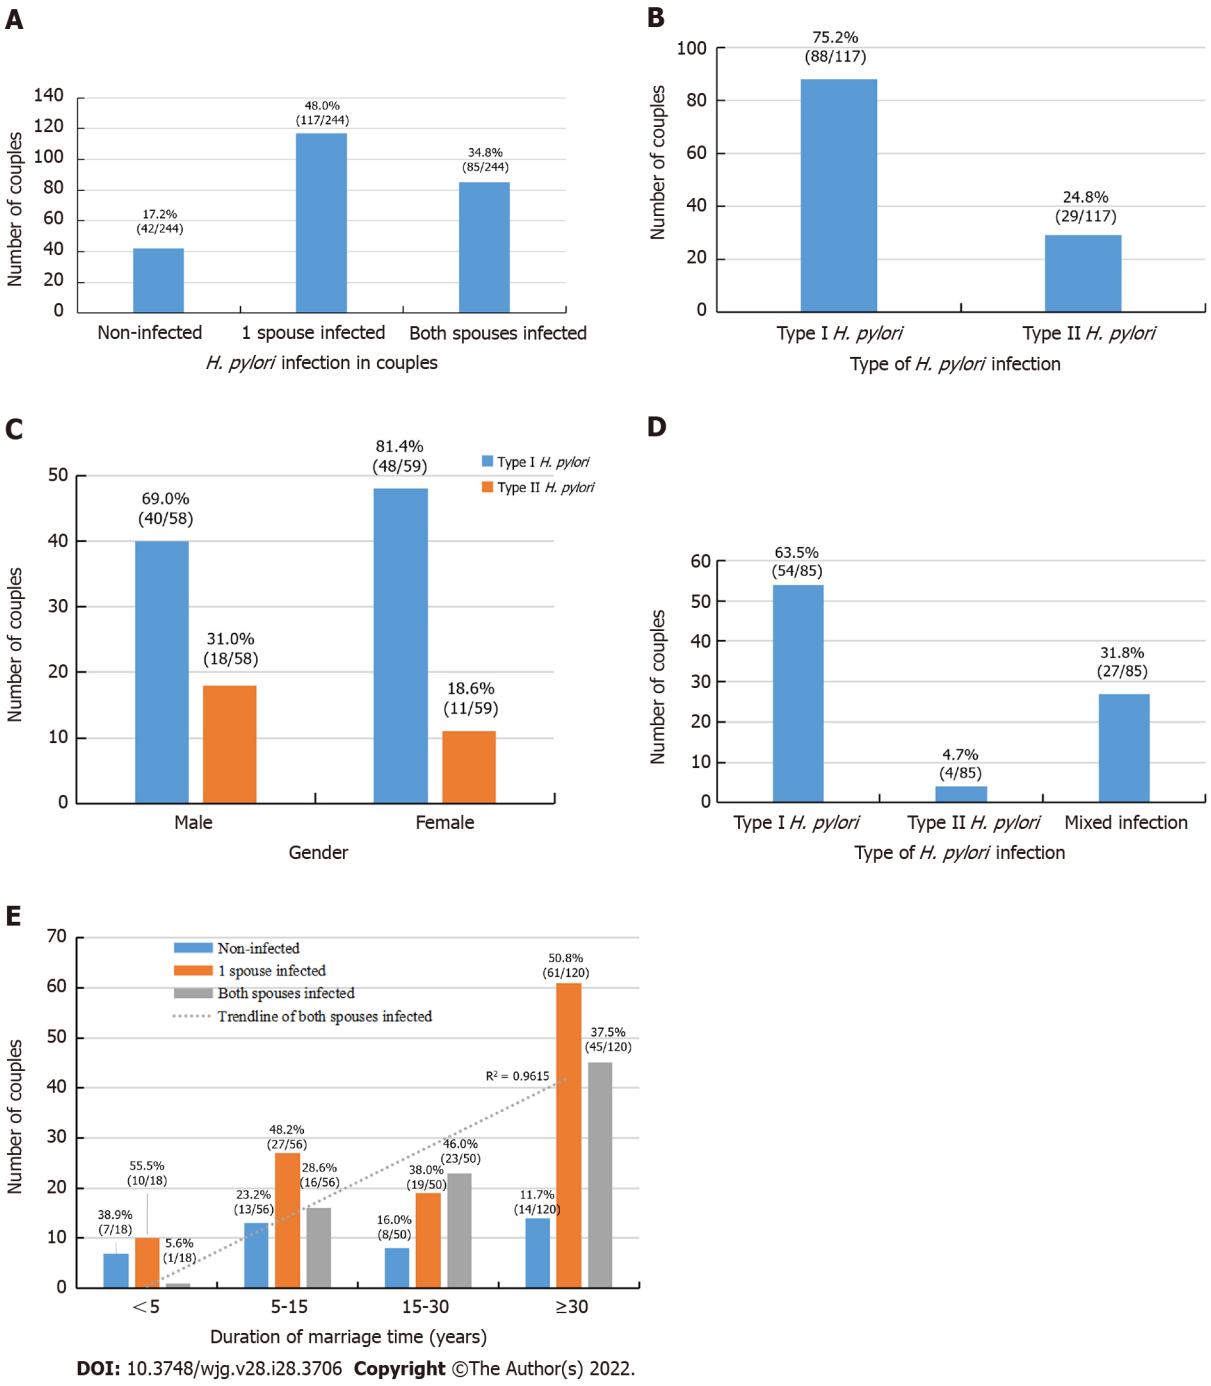

Figure 2 *Helicobacter pylori* infection status of 772 subjects in different age groups. Values above each column are the case number and its percentages in each specific age group. $^aP < 0.05$ when *Helicobacter pylori* (*H. pylori*) infection rate in the age group of ≤ 18 yr was compared with other age groups. Type I *H. pylori*: *H. pylori* infection with type I strains; Type II *H. pylori*: *H. pylori* infection with type II strains.

infection was closely associated with socioeconomic conditions, sanitary situations, dietary habits of the participants in the city. Boarding, eating at school, and drinking untreated water were main factors explaining the rising infection rate in junior-senior high school students. The results indicated that close contact is associated with increased infection risk. In addition, differences in geographic location, study population, lifestyle habit, and sanitary conditions are important factors that greatly contribute to *H. pylori* infection[22,29,30].

Similar results were obtained from other regions, such as one community-based study[31] in Vietnam in 2017 on familial clustering in a multiple-generation population. The study showed that high monthly income, not regularly being fed chewed food, and being breastfed were protective factors against *H. pylori* infection. Risk factors for *H. pylori* infection in children were not regularly handwashing after defecation, *H. pylori*-infected mother and grandfather, father's occupation, mother's education, and household size. Other factors such as number of siblings, infected fathers, regularly sharing a bed, group living, and antibiotic use were not found to be significant risk factors for infection.

H. pylori-infected family members are a possible source of continued transmission, which is an important health threat for uninfected family members[7,32,33]. A 2003 study[9] in the Stockholm area of Sweden using bacterial isolates for family-based DNA fingerprinting technique demonstrated a high proportion of shared strains among siblings, and between spouses, but also showed different strains in a portion of subjects (8%). Similar results were also reported by a 2009 study in Bangladesh[26]. In the current analysis, we found that among the 67 all member-infected households (Figure 1F), 68.66% (46/67) were infected with *H. pylori* type I strains, 1.49% (1/67) were infected with type II strains, and 29.85% (20/67) had mixed type I and II strain infection. These data support the notion that intrafamilial transmission is the primary transmission route, but exogenous infection outside the family can occur, indicating that there may be multiple sources of transmission. In 244 couples comprising both husband and wife, 34.84% (85/244) of them were co-infected, and 68.24% (58/85) of households were infected with the same strain. With an increase of marriage duration, the infection rate of both husband and wife was significantly increased, suggesting that there was also cross-infection between husband and wife.

One unexpected result was that when both parents were infected, the infection rate of children was 23.08% (6/21), whereas when both parents were not infected, the infection rate of children was 18.18% (2/11), and the difference did not reach statistical significance. This result was slightly different from our previous concept that parental *H. pylori* infection is an independent factor for infection in young children, and that mothers play an important role in *H. pylori* transmission to their descendent[13-15,26]. However, the current results likely reflect the current infection status in this region, as the gradually improved living standard, sanitary condition, use of tap water, and avoiding chewing food to feed children over the past several decades in China's urban family have resulted in a reduced infection rate. This is in line with the fact that the overall *H. pylori* infection rate is declining in most of China's urban

DOI: 10.3748/wjg.v28.i28.3706 **Copyright** ©The Author(s) 2022.

Figure 3 *Helicobacter pylori* infection status between 244 couples. Values above each column are the case number and percentages of each group. A: *Helicobacter pylori* (*H. pylori*) infection status of 244 couples; B: Type I and II *H. pylori* genotype status of the 117 couples with 1 spouse infected; C: *H. pylori* genotype and sex of 117 couples with 1 spouse infected; D: *H. pylori* genotype status in 85 couples with both spouses infected; E: Relationship between infection and marriage duration in 244 couples. The dashed line across the figure is the trendline of both spouses infected, $r = 0.98$. Non-infected: All members in a couple were not infected; one spouse infected: Only 1 in a couple was infected; Type I *H. pylori*: *H. pylori* infection with type I strains; Type II *H. pylori*: *H. pylori* infection with type II strains; Mixed infection: *H. pylori* infection with type I and type II strains.

areas[3,22]. Another possibility is that the current cohort had relatively small numbers of children and adolescents, which may not have generated enough power for statistical significance. In addition, we were unable to perform bacterial DNA fingerprinting to confirm if the strains were identical, so the genotype that precise bacterial strains transmit within a family unit has yet to be determined. Future large-scale investigations are needed to confirm the current conclusion.

Type I *H. pylori* strain accounted for 78.28% of the infected population in this survey, similar to the results of our previous study in patients admitted to the hospital, which showed that type I *H. pylori* infection accounted for 72.4% (291/402) of the infected patients, and type II was 27.6%[21]. When compared to *H. pylori*-negative groups, G-17, PGI, and PGII levels were higher in *H. pylori*-infected groups. G-17, PGI, and PGII levels were significantly higher and PGR was significantly lower in the

type I *H. pylori*-infected groups than in *H. pylori*-negative groups. The levels of G-17 and PG II were significantly higher, and PGR was significantly lower in type I *H. pylori*-infected groups than in type II-infected groups. These results are in line with our previous endoscopy results from inpatients, and indicate that both type I and type II *H. pylori* strains increase G-17 Level, whereas only type I *H. pylori* infection affects PGI and PGII levels and the PGR in this geographic area[21].

Type I infection and reduced PGR are risk factors for gastric mucosal precancerous lesions and GC [19,21]. Therefore, these results have important clinical implications, as the abnormal expression of gastric markers was noted in a portion of individuals in healthy households infected with *H. pylori* before they sought medical examinations. It was unclear if this group of individuals had gastric mucosal precancerous lesions; thus, further examinations by endoscopy may be required for confirmation. The results of this study also provide another line of support showing that family-based *H. pylori* infection control and management would be an important strategy for infection control and related disease prevention[3,18,34,35].

Although this pilot work provides novel information regarding family-based *H. pylori* infection status, it had some limitations. First, the investigation was performed with a relatively small number of families, and in some groups, especially children and adolescents, the number of samples was not large enough to reach statistical significance; thus, future large-scale, multiple region sampling would provide more convincing data. Second, this was a cross-sectional study without data from endoscopy to confirm *H. pylori* infection-related disease status and pathological changes in gastric mucosa; therefore, some in-depth information was missing, and the work was performed in a Chinese setting, which may not be suitable to other areas. Third, type I and II *H. pylori* genotype concordance through antibody array analysis only provided a very general evaluation. As we did not obtain bacteria strain culture and DNA fingerprinting data, *H. pylori* intrafamilial transmission was unable to be evaluated precisely to assess the heterogeneity of *H. pylori* strains within families. Thus, future studies are needed to evaluate the *H. pylori* DNA fingerprinting pattern for more precise evaluation. Even with these limitations, this study provides novel points and information on family-based *H. pylori* infection characteristics, which merit further large-scale exploration.

CONCLUSION

The current results provide snapshots of family-based *H. pylori* infection status in central China. The high infection rate and coincidence of people infected with *H. pylori* within a family unit indicate the status and pattern of intrafamilial transmission, which provide a novel option for family-based *H. pylori* infection control and related disease prevention. The concept is applicable not only to Chinese residents but also to other communities with high infection rates.

ARTICLE HIGHLIGHTS

Research background

Helicobacter pylori (*H. pylori*) has characteristics of family cluster infection; however, its family-based infection status, related factors, and transmission pattern in central China have not been evaluated.

Research motivation

We evaluated family-based *H. pylori* infection status, related factors, and interfamilial transmission pattern in healthy households in central China, a high-risk area for *H. pylori* and gastric cancer (GC).

Research objectives

To investigate family-based *H. pylori* infection and identify a better approach for *H. pylori* infection control and related disease prevention.

Research methods

H. pylori infection was confirmed primarily by serum antibody arrays in 282 enrolled families, including a total of 772 family members. If patients previously underwent *H. pylori* eradication therapy, an additional ^{13}C-urea breath test was performed to obtain their current infection status. Serum levels of gastrin and pepsinogens (PGs) were also analyzed.

Research results

In our study sample from the general public of central China, *H. pylori* infection rate was 54.27%. In 87.23% of healthy households, there was at least 1 *H. pylori*-infected person, and in 27.24% of these infected families, all members were infected. Type I *H. pylori* was the dominant strain in this geographic area. Among many variables, only individuals with a higher education level showed lower infection

rates. *H. pylori* infection was also correlated with abnormal gastrin-17, PGI, and PGII levels and PGI/PGII ratio.

Research conclusions

H. pylori infection in healthy households is very common in central China, and poses an important health threat to uninfected family members. The intrafamilial infection status and patterns of transmission represent one important source of *H. pylori* spread, and indicate the urgent need for family-based infection control and related disease prevention.

Research perspectives

The results of this study provide new information on family-based *H. pylori* infection status in central China, and support the novel concept of family-based *H. pylori* infection control and management. This notion is also likely to benefit other *H. pylori* and GC prevalent areas.

ACKNOWLEDGEMENTS

The authors are grateful to the staff of the Department of Gastroenterology and Hepatology, People's Hospital of Zhengzhou University, for their valuable assistance in this work.

Abstract

BACKGROUND

Clostridioides (Clostridium) difficile (*C. difficile*) is still the most common cause of healthcare-associated diarrhoea and is increasing in prevalence as a community-acquired infection. In addition, the emergence of antibiotic resistance in *C. difficile* can increase the likelihood of the disease developing and/or spreading.

AIM

To provide an up-to-date picture of the trends in publications related to *C. difficile* infection, together with specific insights into hot-button issues in this field.

METHODS

Publications on *C. difficile* infections in the field of microbiology between 2001 and 2020 were identified from the Scopus database and Reference Citation Analysis. Bibliometric indicators were determined, including the number and type of publications, countries, affiliations, funding agencies, journals and citation patterns. VOSviewer was used to determine research areas and hot-button issues by identifying recurring terms with a high relative occurrence in the title and abstract.

RESULTS

A total of 8127 documents on '*C. difficile*-associated diarrhoea' published between 2001 and 2020 were retrieved from the Scopus database. In the last decade, there has been a significant almost fourfold increase in the number of published papers on this topic. The United States was among the countries (44.11%) with the most publications, and the most involved institution was the *University of Leeds* in the

United Kingdom (2.50%). Three clusters of research were identified and included 'illness spectrum and severity, as well as the signs, symptoms and clinical pathogenesis of *C. difficile*'; 'laboratory diagnosis and characterization of *C. difficile*' and 'risk factors for *C. difficile* infection'.

CONCLUSION

This study contains the most up-to-date and comprehensive data ever compiled in this field. More international research and cross-institutional collaborations are needed to address more global *C. difficile* concerns and to benefit from greater sharing of expertise, which will result in higher quality or more effective studies in the future. Promising research avenues in the near future may draw the attention of relevant scientists and funding organizations and open up novel *C. difficile* infection–based diagnosis and treatment approaches.

Key Words: *Clostridioides*; *Clostridium difficile*; Bibliometric; Scopus; VOSviewer; Diarrhoea

Core Tip: The significance of this study lies in the fact that, to our best knowledge, there are no previous bibliometric studies on *Clostridioides (Clostridium) difficile* (*C. difficile*) infection research. This study presents the evolution of *C. difficile* infection-related publications over time. This bibliometric study will provide clinicians and researchers in gastroenterology and microbiology with a quantitative and timely summary of *C. difficile* infection-related publications. Promising research avenues in the near future may draw the attention of relevant scientists and funding organizations and open up novel *C. difficile* infection–based diagnosis and treatment approaches.

INTRODUCTION

Clostridium difficile (*C. difficile*) has been reclassified as *Clostridioides difficile*, although the preferred term remains *C. difficile*. *C. difficile* infections are increasing in prevalence and are among the most common healthcare-associated illnesses globally[1-3]. *C. difficile* infections, also known as *C. difficile*-associated diarrhoea, are the most common signs of clinical infection and can range from mild diarrhoea to fulminant colitis[4]. *C. difficile* is frequently linked to the use of antibiotics. *C. difficile* was once thought to be predominantly a nosocomial illness; however, community-acquired *C. difficile* has already been identified[3].

Metronidazole and vancomycin have been the primary treatments for *C. difficile* infections for more than three decades. However, the low number of sustained cures and the rising incidence of *C. difficile* infections, as well as the accompanying morbidity and death, have necessitated the development and investigation of novel treatment approaches[1,5]. Despite ongoing attempts to enhance *C. difficile* prevention and treatment, *C. difficile* continues to be a major public health concern. In both hospitals and the community, *C. difficile* infection is still a prevalent and dangerous problem. In recent years, faecal microbial transplantation has been developed as a safe and successful method of treatment for recurrent infections[6-11]. Therefore, faecal microbial transplantation will most likely become the standard therapy for recurrent infection as a novel technique[6-11].

Bibliometrics and research performance assessments have been performed in a broad range of health areas[12,13], particularly to address environmental[14-17], and toxicological[18] issues. Yet, to our knowledge, a large number of bibliometric studies noticeably focused on microbiology[19-23] have been conducted by using different databases for data analysis. Because of these studies[19-23], microbiology research has recently been given increased scientific attention worldwide. Still, more research efforts are needed to thoroughly review and identify the existing literature related to *C. difficile* infection from different aspects, including authorships, country, affiliation, journals, citation patterns, and content analysis, to determine the research areas that are hot-button issues in this field.

C. difficile infection is considered one of the most debated topics in this era. Using the bibliometric approach to *C. difficile* infection would affect how scientists design and conduct studies and the selection of models that estimate risk. Using a bibliometric analysis of publications in Scopus, this study provides an up-to-date picture of the trends in publications related to *C. difficile* infection, together with specific insights into hot-button issues in this field. The significance of this study lies in the fact that, to our best

knowledge, there are no previous bibliometric studies on *C. difficile* infection research. Therefore, this study presents the evolution of *C. difficile* infection-related publications over time. This bibliometric study will provide clinicians and researchers in gastroenterology and microbiology with a quantitative and timely summary of *C. difficile* infection-related publications. Furthermore, it aims to provide clinicians and researchers with a resource for principles and current evidence. A detailed understanding of the historical trends in this field of research and its obstacles may help to establish a framework for future gastroenterology scholarship.

MATERIALS AND METHODS

Data acquisition

The research data were taken from the Scopus bibliographic database and Reference Citation Analysis (RCA) (https://www.referencecitationanalysis.com/). Scopus was chosen because it has a larger number of indexed journals than other databases (*e.g.* PubMed or Web of Science) and is completely inclusive of all journals in Medline[24-26]. Scopus is the most popular set of scientific publications used in bibliometric and scientometric studies, together with PubMed or Web of Science[27]. In addition, Scopus contains indexed journals in the health, social, physical and life sciences. This enhances the likelihood of retrieving as many relevant publications as is feasible. Baishideng Publishing Group Inc. owns RCA, which is an open transdisciplinary citation analysis database (Pleasanton, CA 94566, United States)[28].

Search strategy

To identify studies related to *C. difficile*-associated diarrhoea, we took the following steps.

Step 1: Data extraction was performed on July 25, 2021 and the results obtained within one day to avoid potential bias due to the regular updating of the database. The terms used in the search engines were applied in Title ((TITLE (Clostrid* difficile) OR TITLE('C. diff*') OR TITLE('Cl. diff*')))) AND Title/Abstract (TITLE-ABS(diarrh*) OR TITLE-ABS(Antibiotic) OR TITLE-ABS(infection) OR TITLE-ABS(AAD)). More precisely, in the results, the search strategy for research related to *Clostridium difficile* terms was limited to the title only to eliminate false-negative results. Search terms with different suffixes were truncated using an asterisk (*). The keywords used were chosen because they are commonly used in the literature related to *C. difficile*-associated diarrhoea[3,29-31].

Step 2: The year 2021 was omitted because the database records for this year would not have been completed at the time of the search.

Step 3: All retrieved documents were reviewed and analysed with respect to the following different bibliometric indicators, as in previous bibliometric studies[13,32-34]: (1) The annual number of publications on *C. difficile*-associated diarrhoea indexed in Scopus and published from 2001 to 2020; (2) Prolific countries, journals, and authors in this field in relation to the number of publications; (3) Research collaboration among the most productive countries; (4) The most frequently cited publications. It is likely that certain articles were cited more frequently than others due to the considerable period that had passed since their publication. Therefore, a citation index was generated for each article to overcome the bias caused by the period that had passed since publication. The citation index is derived by dividing the average number of citations by the number of years since the article was first published; (5) Hot-button issues in this field; and (6) RCA was used to determine the impact index *per* article for the top ten most-cited publications.

Step 4: A network visualization map based on the publications retrieved from the Scopus database was created using VOSviewer (version 1.6.16) software (www.vosviewer.com). The output results from VOSviewer are displayed in clusters. The existing connections between the bibliometric data can be clearly visualized to analyse collaboration between countries. Furthermore, it illustrated the terms widely used in the titles and abstracts of the publications collected, showing the hot research topics.

RESULTS

General description of the retrieved publications

A total of 8127 documents on '*C. difficile*-associated diarrhoea' published between 2001 and 2020 were retrieved from the Scopus database. From these publications, articles (n = 6062) were the most often published documents, comprising 74.59% of the total, followed by reviews (n = 1016; 12.50%) and letters (n = 384; 4.72%).

The trend of global publications

As shown in Figure 1, there was a growing trend in the number of publications on *C. difficile*-associated diarrhoea in the Scopus database between 2001 and 2020. It is obvious that there was an increasing number of publications mostly during two periods: From 2006 to 2013 and from 2014 to 2020. Since 2006, the number of relevant articles grew significantly, which is notable. Papers published during the last seven years (2014 to 2020) accounted for 60.16% of the total publications. As a result of these findings, the number of yearly publications grew progressively from 2014 to 2020, showing that the amount of research output increased steadily over that period.

Contributions by country

Table 1 shows that the United States was the most prolific country, whose authors published the most documents (n = 3585), followed by the United Kingdom (n = 1013), Canada (n = 556), and Germany (n = 434). The first 10 countries in Table 1 produced 89.84% of the documents published related to *C. difficile*-associated diarrhoea. Analysis of international collaboration was conducted on the downloaded data based on co-authorship relationships between countries (Figure 2).

Contributions by institution

The top 10 most productive institutes in terms of total papers are listed in Table 2. The major academic contributions mainly originated from *University of Leeds* (2.50%), *Leiden University Medical Center* (2.35%) and *Harvard Medical School* (2.25%).

Contributions by funding agency

Table 3 lists the top 10 global funding agencies that sponsored research output on *C. difficile*-associated diarrhoea. Among them, eight agencies were from the United States, and two were from the United Kingdom. The *National Institutes of Health* ranked first, supporting the highest number of studies at 884. The *U.S. Department of Health and Human Services* ranked second (n = 841), and the *National Institute of Allergy and Infectious Diseases* ranked third (n = 539).

Most active journals

The 10 most prolific journals are presented in Table 4. The most productive journal was *Infection Control and Hospital Epidemiology* (n = 304), followed by *Anaerobe* (n = 276), *Clinical Infectious Diseases* (n = 251) and *Journal of Hospital Infection* (n = 212). Thus, the first 10 journals in Table 4 produced 23.97% of the documents published related to *C. difficile*-associated diarrhoea.

Most cited documents

Table 5 presents the 10 most often cited articles published on *C. difficile*-associated diarrhoea[35-44]. Furthermore, the ten most cited articles have an impact index *per* article of 45.6 to 313.9 (Table 5).

Most frequent topics

We studied the distribution of co-occurrence terms using VOSviewer software (the minimum number of occurrences of a term in all publications is 100 times in titles and abstracts) to detect directions and topics in *C. difficile*-associated diarrhoea research and understand the growth of this discipline. The size of the circle or node of a term equals that particular term's number of occurrences. For example, in Figure 3, of the 84961 terms, 385 terms occurred at least 100 times, distributed in three clusters: Cluster 1, shown by green dots, includes those terms commonly found in studies related to clinical features of *C. difficile*, including the illness spectrum and severity, as well as the signs, symptoms and clinical pathogenesis of *C. difficile*. Cluster 2, shown by blue dots, includes those terms commonly found in laboratory diagnosis and characterization studies of *C. difficile*. Cluster 3, indicated by red dots, includes terms commonly found in studies related to risk factors for *C. difficile* infections. To investigate the changes in hotspots over time, a network visualization map of the most frequent terms in the titles/abstracts of the retrieved documents was generated using VOSviewer software, and the results revealed that the topic 'risk factors for *C. difficile* infection' began to appear more frequently in the last five years (Figure 4).

DISCUSSION

The current study was a descriptive study on global research output of publications related to *C. difficile* infection. It is important to examine the quantity and quality of research in this field, given the changing epidemiology of *C. difficile* morbidity and mortality, worldwide escalation of antibiotic resistance and limited alternative preventive strategies for *C. difficile* infection. This bibliometric analysis will aid in revealing key milestones and progressions in this field, detecting current shortages and developing trends and directing the field's future research path. The current study showed a fourfold increase in publications in the last decade. These results reflect those of Balsells *et al*[45] and Ofosu[46], who also

[1]The impact index *per* article is presented based on Reference Citation Analysis [Source: Baishideng Publishing Group Inc. (Pleasanton, CA 94566, United States)].

The United States was the leading country in *C. difficile* infection-related publications, contributing about half of all Scopus publications in this field. This is presumably due to economic prosperity and population growth, and the large number of microbiology researchers[47,48]. The economic basis plays an essential part in supporting scientific research in the current study. The majority of the top 10 funding agencies were based in the United States. High-income countries have published most *C. difficile* infection-related publications, with limited input from low- and middle-income countries. An analysis of the countries that generated the most *C. difficile* infection-related publications indicates that

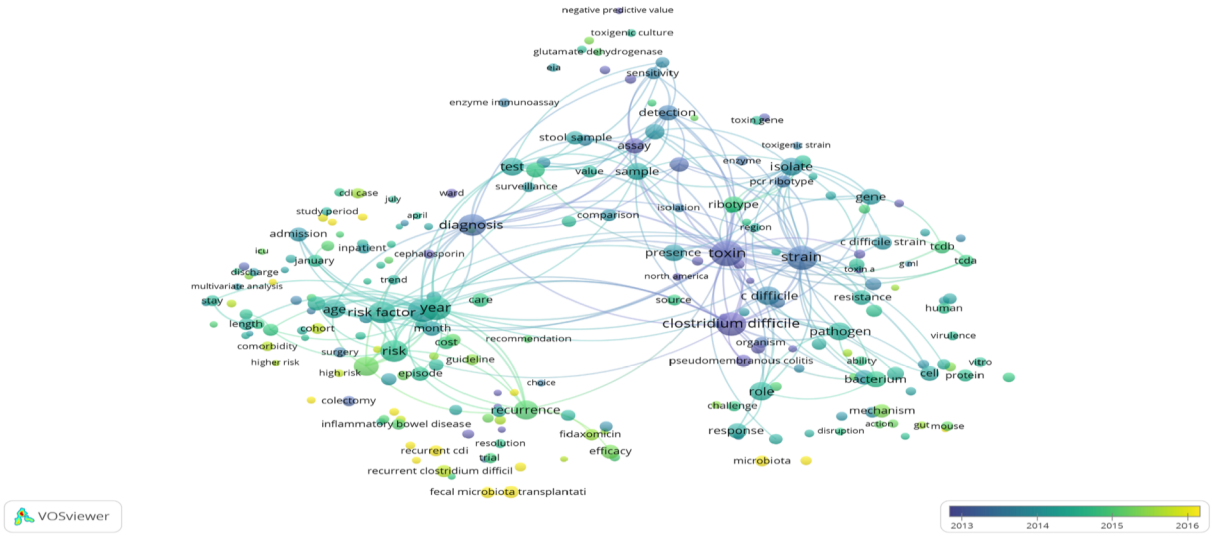
Figure 2 Network visualization map of country co-authorships. Of the 103 countries, 31 had at least 50 publications.

countries with economic power indicators have the greatest say in this field. This finding broadly supports the work of other studies in different areas linking scientific research output with geographical location and financial growth[12,49,50]. Various bibliometric analysis studies have also shown that the United States is the most prolific country in microbiology research output[19,20,23,51].



The current study showed that the most frequently cited article on *C. difficile*-associated diarrhoea, written by Cohen *et al*[35] and published in 2010, with 2370 citations, is a guideline that updates the recommendations for epidemiology, diagnostics, therapeutics, infection control, and environmental management. The second most frequently cited paper has 2140 citations and addresses the effect of duodenal infusion of donor faeces in patients with recurrent *C. difficile* infection; this article, published in 2013, was written by van Nood *et al*[42]. These two papers receive approximately 237 and 305.7 citations *per* year on average, respectively. However, the article with the second-highest number of citations *per* year, placed fourth in the ranking, was published in 2015 and was written by Lessa *et al* [44]. This paper aimed to produce more accurate national estimates the burden of illness, incidence, recurrence and death by collecting data from a variety of health care delivery and community contexts. Note that five papers published after 2010 appear in the top 10 most cited publications between 2001 and 2020 in *C. difficile*-associated diarrhoea.

Although it is challenging to reveal the quality or impact of publications through bibliometric analysis, to some degree, citations are considered an indirect measure of an article's contribution to the knowledge generated in the field, *i.e.* the connection between the research finding and its significance

Figure 3 Network visualization map of the most frequent terms in the titles/abstracts of the retrieved documents. Of the 84961 terms, 385 had at least 100 publications. Terms with the same color represent a separate cluster (research theme).

DOI: 10.3748/wjg.v28.i28.3720 **Copyright** ©The Author(s) 2022.

Figure 4 Overlay network visualization map of the most frequent terms in the titles/abstracts of the retrieved documents. The colors on the map reflected the period of emergence in the literature, with yellow representing terms that were relatively recent in the literature.

for science[52,53]. However, these analyses of the top 10 most cited publications will guide microbiologists interested in further studies by updating knowledge of current developments in *C. difficile* infection-related publications and potential future directions for study.

Analysis of the frequencies of occurrence of terms in publications can offer insights into certain fields' main and hot topics[54]. The current study found that highly cited literature focused on the signs, symptoms and clinical pathogenesis of *C. difficile* concepts and risk factors for *C. difficile* infections. A clear theme to emerge from the results is that the most frequently cited publications on *C. difficile* infections highlighted a range of subtopics similar to the hot research topics. A recent bibliometric study [55] was defined to assess global research activity on antimicrobial stewardship as one measure for efforts dedicated to containing antimicrobial resistance. This study found that *C. difficile* was frequently encountered as author keywords in the retrieved literature on antimicrobial stewardship. The United States Centers for Disease Control and Prevention has considered *C. difficile* infection an urgent danger in its 2019 Antibiotic Resistance Threats Report[56]. In a European point prevalence study, *C. difficile* was rated sixth among bacteria responsible for healthcare-associated illnesses[57]. The majority of *C. difficile* infections in the United States are considered hospital acquired[58].

Strengths and limitations

This study offered the first bibliometric analysis of *C. difficile* infections from the unique perspective of its research hotspots to determine the influential scientific areas and global trends. *C. difficile* infection-based publications in microbiology were collected in the online Scopus database and analysed comprehensively, thoroughly and objectively. As with all previous bibliometric studies[13,31,32,59], the current study has some limitations. First, we preferentially selected English articles from the database but lost some articles that were not in English. Second, we chose Scopus alone as the data source for *C. difficile* infection research because it presented the most reliable and credible information. Inevitably, any useful information from other medical sources such as PubMed and Web of Science would be overlooked. On the other hand, Scopus remains the best database available for analysing research activity and identifying research hotspots on a certain topic. Given these limitations, we believe that this study offers a qualified global view of *C. difficile* infection-based publications in the field of microbiology from 2001 to 2020.

CONCLUSION

The current study used a bibliometric analysis of *C. difficile* infection-based publications in the fields of microbiology and gastroenterology during the period 2001–2020 to determine research hotspots for possible future directions. The results showed that *C. difficile*-based publications have grown rapidly since 2006. Research activity on *C. difficile* infections has been an emerging topic during the last two decades and has been developed predominantly by scientists from the United States of America, the United Kingdom, Canada, Germany, France and China. Risk factors for *C. difficile* infection, laboratory diagnosis and characterization of *C. difficile*, signs, symptoms and clinical pathogenesis of *C. difficile* concepts were the main research hotspots in *C. difficile* infection, and related studies should pioneer these fields in the future. Promising research avenues in the near future may draw the attention of relevant scientists and funding organizations and open up novel *C. difficile* infection–based diagnosis and treatment approaches.

ARTICLE HIGHLIGHTS

Research background

Clostridioides (Clostridium) difficile (*C. difficile*) infections are growing more prevalent and are now one of the most often encountered healthcare-associated infections worldwide.

Research motivation

To our best knowledge, however, a large number of bibliometric studies notably focused on microbiology have been undertaken by using various databases for data analysis. More research efforts are still required to thoroughly analyse and identify the existing literature related to *C. difficile* infection from many perspectives in order to identify study area hot issues in this field.

Research objectives

This study gives an up-to-date picture of the trends in publications linked to *C. difficile* infection, as well as unique insights into hot topics in this field.

Research methods

This study was based on a bibliometric analysis of Scopus and Reference Citation Analysis publications.

Research results

Three clusters of research were highlighted as hot topics: 'illness spectrum and severity, as well as signs, symptoms and clinical pathogenesis of *C. difficile*'; 'laboratory diagnosis and characterization of *C. difficile*' and 'risk factors for *C. difficile* infection'.

Research conclusions

The current study conducted a bibliometric analysis of *C. difficile*-related publications in the disciplines of microbiology and gastroenterology from 2001 to 2020 to identify research hotspots for potential future directions. Results revealed that the topic 'risk factors for *C. difficile* infection' began to appear more frequently in the last five years.

Research perspectives

This bibliometric study will provide clinicians and researchers in gastroenterology and microbiology with a quantitative and timely summary of publications linked to *C. difficile* infection. It also intends to

be a resource for clinicians and researchers on principles and current evidence.

Abstract

BACKGROUND

Secondary sclerosing cholangitis, characterized by biliary obstruction, can be caused by drugs such as immune checkpoint inhibitors (ICIs). While there a few reports of sclerosing cholangitis after immune checkpoint inhibitor administration, no case has been reported after discontinuation of such drugs.

CASE SUMMARY

A 68-year-old man who underwent chemotherapy for lung adenocarcinoma with bone metastasis presented with abdominal pain and fever 4 mo after the final administration of pembrolizumab. Computed tomography revealed thickening of the gallbladder wall and dilatation of the common bile duct. Endoscopic retrograde cholangiopancreatography revealed an irregularly narrowed intrahepatic bile duct. Biopsy of the bile duct demonstrated that $CD8^+$ T cells were predominant over $CD4^+$T cells. Liver biopsy showed dominant infiltration of $CD8^+$T in the portal tract, but onion-skin lesions were not observed. The patient was diagnosed with immune-related sclerosing cholangitis induced by pembrolizumab. Administration of methylprednisolone and endoscopic nasobiliary drainage were performed, but the cholangiography and laboratory test findings did not improve. No further treatment was administered due to disease progression, and the patient was referred for palliative care.

CONCLUSION

Immune-related sclerosing cholangitis may have a late onset, and such cases occurring after discontinuation of ICIs should be carefully managed.

Key Words: Immune-related adverse events; Sclerosing cholangitis; Delayed immune-related events; Case report

Core Tip: Immune checkpoint inhibitors have become a new standard in cancer treatment, but have often been reported to induce adverse events, called immune-related adverse events (irAEs). Biliary system complications, such as irAEs, remain rare, and the management strategy remains unclear. We present herein, a rare case of delayed immune-related sclerosing cholangitis (SC) after discontinuation of pembrolizumab. Our case emphasizes that immune-related SC can occur later, but the mechanisms have not yet been elucidated. As such, our case contributes to new knowledge in the hopes of being able to establish proper diagnostic criteria and management strategies for similar patients.

INTRODUCTION

Secondary sclerosing cholangitis (SC) is a chronic disease characterized by biliary obstruction and can be caused by a variety of specific etiologies such as infections, immune-related factors, toxicity, obstruction, ischemic injury, or drugs, including immune checkpoint inhibitors (ICIs)[1]. ICIs have transformed the treatment landscape for patients with many advanced malignancies but have often been reported to induce adverse events, called immune-related adverse events (irAEs)[2]. The irAEs differ from toxicities caused by cytotoxic or molecularly targeted agents, and the time to toxicity may be delayed and not follow a cyclical pattern, as observed with conventional cytotoxic agents[3]. Biliary system complications, such as irAEs, remain rare, and the management strategy remains unclear. There are a few reports of SC induced by ICIs; however, no cases developed immune-related SC after discontinuation of ICIs. Herein, we report a case of delayed immune-related SC caused by pembrolizumab.

CASE PRESENTATION

Chief complaints

A 68-year-old male patient was admitted to our hospital with abdominal pain and fever.

Imaging examinations

Contrast-enhanced computed tomography and endoscopic ultrasonography revealed swelling and wall thickening of the gallbladder and dilatation of the common bile duct without obstruction (Figure 1A-D). Endoscopic retrograde cholangiopancreatography revealed a dilated common bile duct and irregularly narrowed right intrahepatic bile duct (Figure 1E). Intraductal ultrasonography demonstrated diffuse wall thickening from the right bile duct to the common bile duct (Figure 1F).

Laboratory examinations

Laboratory tests revealed increased levels of white blood cells [10100/μL (3300-8600/μL)], C-reactive protein [4.88 mg/dL (0.00-0.18 mg/dL)], aspartate transaminase [31 U/L (13–30 U/L)], alanine transaminase (ALT) [50 U/L (7–23 U/L)], gamma-glutamyl transpeptidase [205 U/L (13-64 U/L)], and alkaline phosphatase (ALP) [996 U/L (38-113 U/L)]. Total bilirubin was within the normal range [0.7 mg/dL (0.4-1.5 mg/dL)], and blood cultures showed no bacterial infection. The serum immunological markers, including antinuclear antibody, antimitochondrial antibody, and anti-smooth muscle antibody were negative, and the immunoglobulin G4 Level (59 mg/dL) was within the normal range.

Physical examination

The patient's body temperature was 38.9 °C, but the other vital signs were stable. Regarding the pulmonary and cardiac examination, no obvious abnormality was observed. Physical examination revealed epigastric tenderness without rebound tenderness or Murphy's sign. No jaundice or palpable masses were observed.

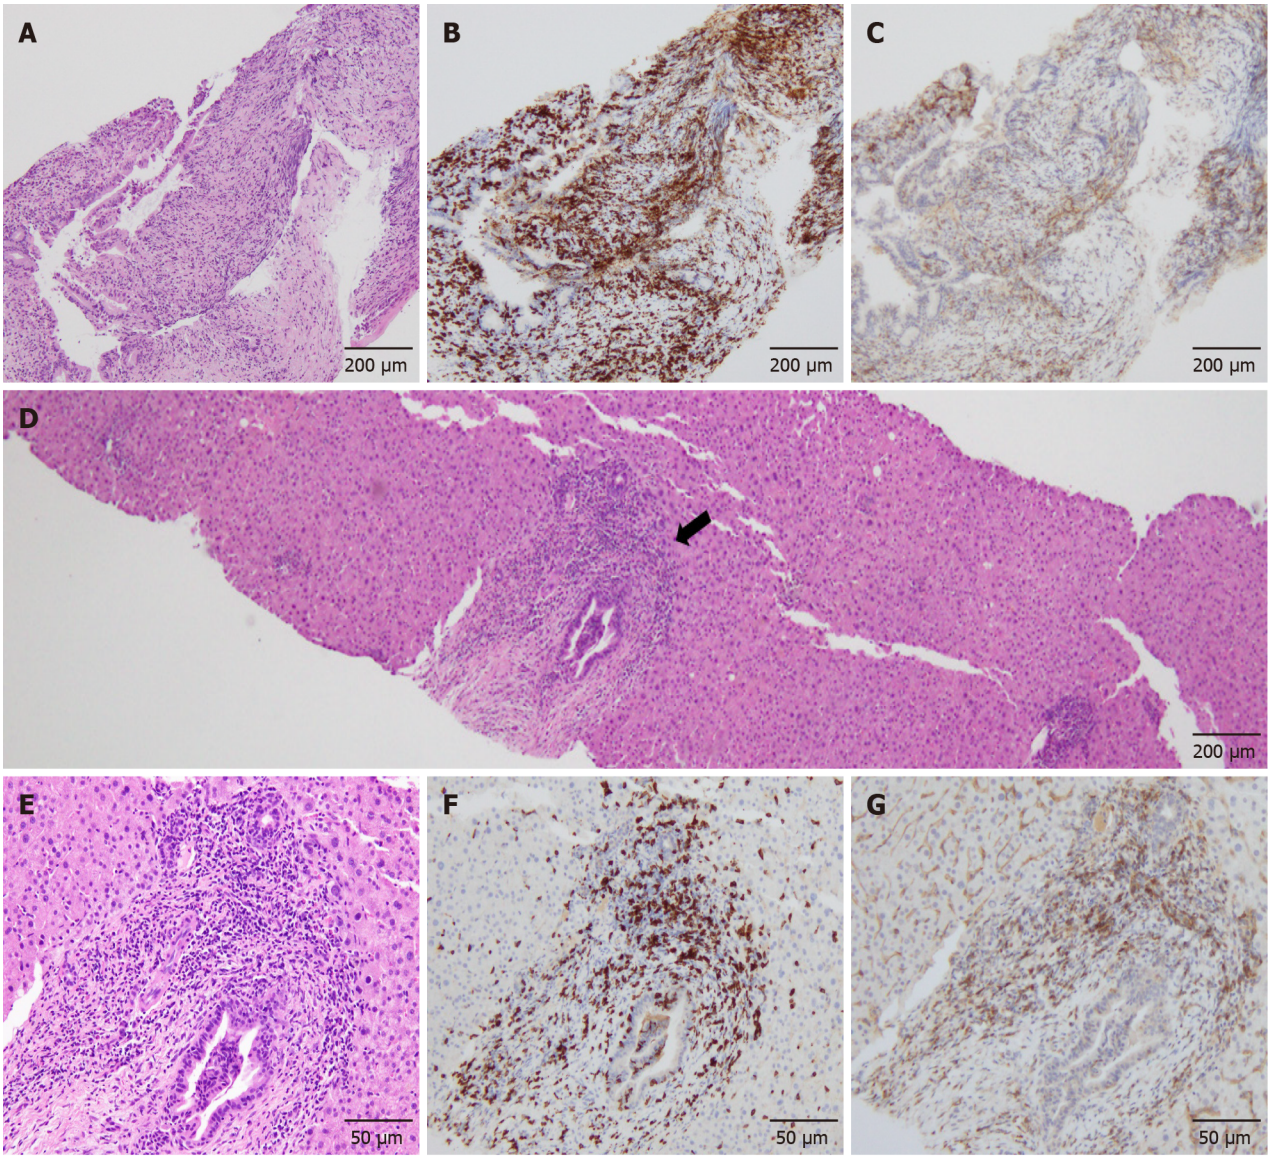
Figure 1 Imaging examinations of the gallbladder and common bile duct. A, B: Contrast-enhanced computed tomography shows swelling and wall thickness of the gallbladder and common bile duct; C, D: Endoscopic ultrasonography shows dilatation of the common bile duct without obstruction and wall thickness of the gallbladder; E: Endoscopic retrograde cholangiopancreatography shows a dilated common bile duct and irregularly narrowed right intrahepatic bile duct (white arrow); F: Intraductal ultrasonography shows the wall thickness from the right bile duct to the common bile duct (white arrowhead).

Personal and family history

No information was available regarding his family history.

History of past illness



The patient has laparoscopic inguinal hernia repair twenty years ago.

History of present illness

The patient was diagnosed with stage IV lung adenocarcinoma (wild-type epidermal growth factor receptor and anaplastic lymphoma kinase, programmed death ligand 1 positive expression) and received first-line treatment with cisplatin and pemetrexed sodium hydrate. Four months after the initiation of first-line chemotherapy, the patient received second-line treatment with pembrolizumab because of disease progression. Three months later (three cycles of pembrolizumab), carboplatin and nab-paclitaxel were administered as third-line treatments. Four months after discontinuation of pembrolizumab (3 mo after initiation of third-line chemotherapy), the patient was admitted to our hospital with abdominal pain and fever.

FINAL DIAGNOSIS

The common bile duct biopsy showed intraepithelial infiltration of lymphocytes, and $CD8^+$ T cells were more predominant in the biliary epithelium than $CD4^+$ T cells (Figure 2A-C). Percutaneous ultrasonography-guided liver biopsy was also performed for differential diagnosis of other liver diseases. The liver biopsy showed infiltration of predominantly $CD8^+$ T cells in the portal area, but the periductal "onion-skin" fibrosis characteristic of primary sclerosing cholangiopathies, and panlobular hepatitis or isolated central zonal necrosis characteristic of acute hepatitis were not detected (Figure 2D-G). According to these imaging and pathological findings, the patient was diagnosed with immune-related SC induced by pembrolizumab.

Figure 2 Pathological findings of the common bile duct and liver. A: Hematoxylin–eosin staining (× 40): Intraepithelial infiltrations of lymphocytes are observed; B and C: CD8 (B) and CD4 (C) staining (× 40): Infiltration of $CD8^+$ T cells are predominant in the biliary epithelium compared to $CD4^+$ T cells; D and E: Hematoxylin–eosin staining: On liver biopsy, inflammation of the hepatic parenchyma is not observed. The periductal "onion-skin" fibrosis is not observed in the portal area (black arrow); F and G: CD8 (F) and CD4 (G) staining (× 200): In a zoomed-in view of the portal area, predominant infiltration of $CD8^+$ T cells, compared with $CD4^+$ T cells, is observed.

TREATMENT

Endoscopic nasobiliary drainage was performed and administration of 25 mg (0.5 mg/kg) of methylprednisolone was initiated. However, grade 3 elevation of ALP and grade 1 elevation of ALT were still present, and the cholangiography findings did not improve.

OUTCOME AND FOLLOW-UP

Because of disease progression, no further treatment was administered, and the patient was referred for palliative care.

DISCUSSION

ICIs enhance antitumor immunity by blocking negative regulators of T cell function that exist on both

immune and tumor cells. Although these agents can lead to remarkable responses, their use may also be associated with irAEs. A previous study showed that most irAEs occur in the first few months of treatment, but late-onset toxicity even after ICI discontinuation is also possible[4]. To the best of our knowledge, no case of immune-related SC after pembrolizumab discontinuation has been reported.

Kawakami *et al*[5] revealed that immune-related cholangitis was characterized by: (1) Localized extrahepatic bile duct dilation without obstruction; (2) Diffuse hypertrophy of the extrahepatic bile duct wall; (3) A dominant increase in the biliary tract enzymes ALP and gamma-glutamyl transpeptidase relative to the hepatic enzymes aspartate and alanine aminotransferase; (4) Normal or reduced levels of the serum immunological markers antinuclear antibody, antimitochondrial antibody, smooth muscle antibody, and immunoglobulin G4; (5) Pathological findings of biliary tract cluster of differentiation $CD8^+$ T cell infiltration from liver biopsy; and (6) A moderate to poor response to steroid therapy. The present case met all these characteristics of immune-related cholangitis.

In contrast, SC developed while carboplatin and nab-paclitaxel were administered. Previous studies reported that chemotherapy-induced SC and drug-induced SC appeared to be one or more strictures of the large bile ducts, mainly the common hepatic duct and the right and left hepatic ducts, usually sparing the common bile duct and smaller intrahepatic ducts[6,7]. Histologically, Weber *et al*[8] showed that a shift in the $CD4^+/CD8^+$ cell ratio in favor of $CD8^+$ cytotoxic T lymphocytes is useful in discriminating irAEs from other conditions (*e.g.*, autoimmune diseases and drug-induced injury). In our case, an irregularly narrowed right intrahepatic bile duct and infiltration of predominantly $CD8^+$ T cells were observed. Therefore, we diagnosed the patient with SC induced by pembrolizumab on the basis of the imaging and pathological findings of previous reports.

Recently, new reports of irAEs emerging after discontinuation of immunotherapy, a clinical diagnostic complex termed delayed immune-related events (DIRE), have surfaced[9]. The first case of DIRE after discontinuation of pembrolizumab was reported in 2013[10], and various late-onset irAEs have also been reported in the literature[11]. Anti-PD-1 antibodies continue to bind to lymphocytes several weeks after the last infusion of PD-1 inhibitors, which explains the development of irAEs after discontinuation of ICI therapy[12]. Although there have been some reports of DIRE after discontinuation of pembrolizumab, no cases of delayed immune-related SC induced by pembrolizumab have been reported.

Previous studies showed that steroid therapy was recommended for the treatment of irAEs, but was not useful for the treatment of immune-related SC[4,13]. Ursodeoxycholic acid (UDCA) and other anti-inflammatory agents, including immunomodulators and infliximab, have been considered for the treatment of irAEs, but their efficacy and response have been reported to be insufficient for the treatment of immune-related SC[14,15], and more cases may be needed to evaluate the usefulness of these drugs for immune-related SC. Biliary drainage has been reported to be ineffective for immune-related SCs[5,16,17]. It remains uncertain why there is a poor response to steroid therapy and biliary drainage for immune-related SC, and further studies are necessary to establish the treatment for immune-related SC.

This indicates that immune-related SC can occur later, similar to other hepatic irAEs. The imaging features and pathological findings of immune-related SC have become almost clear, but the mechanism and onset time of immune-related SC have not been elucidated. Further studies and accumulation of cases are necessary to establish appropriate diagnostic criteria and management strategies, and caution should be exercised for late-onset irAEs after discontinuation of ICIs.

CONCLUSION

Immune-related sclerosing cholangitis may have a late onset, and such cases occurring after discontinuation of immune checkpoint inhibitors should be carefully managed.

Abstract

Pneumatosis intestinalis (PI) is defined as the presence of gas within the submucosal or subserosal layer of the gastrointestinal tract. It is a radiologic sign suspicious for bowel ischemia, hence non-viable bowel must be ruled out in patients with PI. However, up to 15% of cases with PI are not associated with bowel ischemia or acute abdomen. We described an asymptomatic patient with prednisolone-induced PI and modified the Naranjo score to aid in a surgeon's decision-making for emergency laparotomy *vs* non-operative management with serial assessment in patients who are immunocompromised due to long-term steroid use.

Figure 1 Computed tomography of abdomen and pelvis and serial erect abdominal radiographs showing interval improvement in pneumatosis coli and resolution of pneumoperitoneum. A: First admission day. Pneumatosis coli from cecum to transverse colon; B: 2 wk after admission. Progression of pneumatosis coli and pneumoperitoneum; C: 2 wk Post-hyperbaric oxygen therapy. Resolution of pneumoperitoneum and pneumatosis coli.

clinical case with prednisolone-induced pneumatosis coli and propose a modified Naranjo score for prednisolone-induced pneumatosis.

A 71-year-old lady with dysphagia and diplopia symptoms was diagnosed with Neuromyelitis Optica (NMO). Treatment with prednisolone 20 mg once daily improved her diplopia. Nasogastric tube (NGT) feeding was commenced due to malnourishment from dysphagia. The chest radiograph for NGT placement showed pneumoperitoneum, and she was referred urgently to the surgical unit. She was asymptomatic, afebrile with normal hemodynamics. Abdomen was soft and non-tender. Leukocyte count, procalcitonin, lactate, and arterial blood gas were normal. A computed tomography of abdomen and pelvis (CTAP) with intravenous and NGT contrast confirmed pneumoperitoneum and pneumatosis coli from cecum to splenic flexure (Figure 1). There was no contrast extravasation, portal venous gas, inflammatory pathology, or mesenteric ischemia. Non-operative management with nil enteral feeding, serial abdominal examination, serum tests, and abdominal radiographs (AXR) was done. The patient remained asymptomatic with normal serum tests. A repeat CTAP showed minimal improvement of pneumoperitoneum. A follow-up AXR two weeks later showed worsening of pneumatosis coli. Hyperbaric oxygen therapy (HBOT) was arranged. Five HBOT sessions were performed at 2.2 atmospheric pressure for 90 min. Her abdominal girth reduced from 79 to 73 cm with minimal AXR improvement. Prednisolone was weaned over next five days and she was discharged well on oral diet. At two-weeks outpatient follow-up, AXR showed improvement (Figure 1).

Corticosteroid therapy remains the cornerstone for the treatment of autoimmune diseases. The true incidence of benign PI as an ADR secondary to corticosteroids is unknown[2,3]. The hypothesis is due to atrophy of lymphoid follicles in the bowel wall. Although PI occurred after prednisolone's commencement in our patient, we did not initially stop prednisolone in balancing risk *vs* benefits for NMO therapy. When PI worsened, HBOT was offered due to concerns for secondary bowel ischemia from PI. The HBOT regimen was similar to that described by Feuerstein *et al*[4], who suggested at least three sessions. As our patient's PI improved but did not resolve fully after 5 HBOT sessions, we reduced prednisolone dose. After two weeks of cessation, PI resolved, similar to a report described by Choi *et al* [5].

According to the Naranjo score (adverse drug reaction probability scale) of 6, PI was probably caused by prednisolone in our patient. Naranjo score recommends isolation of drug in toxic concentrations in body fluid, response to placebo administration, and drug rechallenge to evaluate for the occurrence of symptoms. These three criteria are not routinely done due to practical and safety reasons[6]. We propose a modified Naranjo score (Tables 1 and 2) for prednisolone-induced pneumatosis which replaces these three criteria with the following: (1) No symptoms or signs of abdominal pathology; (2) Serum investigations for inflammatory markers (*e.g.*, C-reactive protein and procalcitonin) must be normal; and (3) Imaging studies should rule out hollow viscus perforation or inflammatory abdominal pathology as a cause for PI. With the modified Naranjo score, the causal link of PI due to prednisolone becomes definite. We propose validation of modified Naranjo score.

Table 1 Modified Naranjo score-pneumatosis intestinalis specific score

Question	Yes/No/Do not know	Score
Are there previous conclusive reports on this reaction?	Yes	1
Did the adverse event appear after the suspected drug was administered?	Yes	2
Did the adverse reaction improve when the drug was discontinued, or a specific antagonist was administered?	Yes	1
Are there alternative causes (other than the drug) that could on their own have caused the reaction?	No	0
Was the reaction more severe when the dose was increased or less severe when the dose was decreased?	Yes	1
Did the patient have a similar reaction to the same or similar drugs in any previous exposure?	No	0
Did any objective evidence confirm the adverse event?	Yes	1
Were there any symptoms or signs of abdominal pathology? (instead of isolation of drug in toxic concentrations in body fluid)	No	1
Were the serum inflammatory markers normal? (instead of drug rechallenge to evaluate for reoccurrence of symptoms)	Yes	1
Did imaging studies rule out hollow viscus perforation or inflammatory abdominal organ pathology? (instead of response to placebo administration)	Yes	1
Total score		**9 (definite)**

Table 2 Interpretation of scores

Total score	Interpretation of scores
≥ 9	Definite
5 to 8	Probable
1 to 4	Possible
≤ 0	Doubtful

Abstract

Endoscopic anti-reflux treatment is emerging as a new option for gastro-esophageal reflux disease (GERD) treatment in patients with the same indications as for laparoscopic fundoplication. There are many techniques, the first of which are transoral incisionless fundoplication (TIF) and nonablative radio-frequency (STRETTA) that have been tested with comparative studies and randomized controlled trials, whereas the other more recent ones still require a deeper evaluation. The purpose of the latter is to verify whether reflux is abolished or significantly reduced after intervention, whether there is a valid high pressure zone at the gastroesophageal junction, and whether esophagitis, when present, has disappeared. Unfortunately in a certain number of cases, and especially in the more recently introduced ones, the evaluation has been based almost exclusively on subjective criteria, such as improvement in the quality of life, remission of heartburn and regurgitation, and reduction or suspension of antacid and antisecretory drug consumption. However, with the most studied techniques such as TIF and STRETTA, an improvement in symptoms better than that of laparoscopic fundoplication can often be observed, whereas the number of acid episodes and acid exposure time are similar or higher, as if the acid refluxes are better tolerated by these patients. The suspicion of a local hyposensitivity taking place after anti-reflux endoscopic intervention seems confirmed by a Bernstein test at least for STRETTA. This examination should be done for all the other techniques, both old and new, to identify the ones that reassure rather than cure. In conclusion, the evaluation of the effectiveness of the endoscopic anti-reflux techniques should not be based exclusively on subjective criteria, but should also be confirmed by objective examinations, because there might be a gap between the improvement in symptoms declared by the patient and the underlying pathophysiologic alterations of GERD.

Key Words: Endoscopic anti-reflux treatment; Transoral incisionless fundoplication; Nonablative radio-frequency; Anti-reflux mucosectomy; Gastro-esophageal reflux disease; Laparoscopic Nissen fundoplication

Core Tip: Endoscopic anti-reflux treatments are being increasingly used instead of anti-reflux surgery. However, most of them have been evaluated only on the ground of subjective symptoms, without performing any objective examination. Furthermore, some also appear to be more effective than surgery in improving acid reflux symptoms, even if their acid exposure is worse, suggesting a reduced sensitivity. The Bernstein test performed after nonablative radio-frequency seems to confirm this hypothesis. Hence, to verify the effectiveness of these esophageal anti-reflux interventions, in addition to evaluating the symptoms before and after the intervention, it is necessary to perform objective examinations.

TO THE EDITOR

In the past few years, endoscopic anti-reflux treatments have increasingly caught the attention of many gastroenterological centers, as they offer a minimally invasive option for patients with gastroesophageal reflux disease (GERD) who show refractoriness or intolerance to proton pump inhibitors (PPI), or who refuse to take lifelong medication, but want to avoid a surgical intervention, such as the classical laparoscopic fundoplication (LF). A recent article[1] has provided an up-to-date review of the technical aspects, clinical effectiveness, and safety of the main endoscopic anti-reflux procedures including transoral incisionless fundoplication (TIF), nonablative radio-frequency (STRETTA), and Medigus ultrasonic surgical endostapler (MUSE), together with the following still experimental techniques, such as full-thickness endoscopic plication device, anti-reflux mucosectomy (ARMS), anti-reflux mucosal ablation, and band-assisted ligation techniques. However, two observations can be made after consulting the literature studies on the effectiveness of these systems.

First, in most studies the efficacy of an endoscopic anti-reflux technique has been evaluated almost exclusively considering subjective symptoms, such as the improvement in quality of life, remission of heartburn and regurgitation, and reduction or suspension of antacid and antisecretory drugs consumption, to the extent that it has been deemed a success when the patient halved the dose of PPI used prior to intervention.

Second, in most studies where these endoscopic interventions are compared with LF or PPI therapy, symptom improvement after endoscopic treatments is frequently greater than that obtained with LF, even when the 24 h pH recording shows a worse result.

This statement can be easily verified in the systematic review and network meta-analysis of Richter *et al*[2] from seven randomized controlled trials (RCTs) with a total of 1128 patients, concerning a comparison of laparoscopic Nissen fundoplication (LNF) *vs* TIF or PPI treatment. The results indicate that TIF has the highest likelihood of increasing the patient's health-related quality of life (HRQL) followed by LNF, whereas the LNF has the highest likelihood of increasing the percentage of time with distal esophageal pH > 4, followed by PPI and then by TIF, which, in addition, has a higher likelihood than LNF for persistent esophagitis.

Also in the randomized controlled trial of Witteman *et al*[3] performed in 60 patients to evaluate the effectiveness of TIF in comparison with the PPI treatment, GERD symptoms after 6 mo are significantly more improved in the TIF group than in the PPI group, despite the similar improvement in distal esophageal acid exposure, whereas the pH normalization for TIF group is 50% with respect to 63% for the PPI group.

A systematic review and network meta-analysis[4] comprising 516 patients from 10 RCTs compared the anti-reflux efficacy of Stretta, TIF, and PPI. Both STRETTA and TIF are significantly superior to PPI in improving GERD-HRQL and heartburn scores, whereas PPI is better in decreasing the percentage of time with pH < 4.0 when compared with TIF.

Also in the study of He *et al*[5], the symptom score improvement was significantly higher in the STRETTA group of 26 patients compared with the PPI group of 21 patients after 6 mo, whereas both interventions improved, without significant differences, the 24 h pH parameters, including the number of acid episodes, acid exposure time, and DeMeester score.

Furthermore, the absence of correlation between the improvement in GER symptoms and the decrease in acid reflux in patients treated with STRETTA is highlighted by the following two studies.

Coron *et al*[6] in an article comparing the results in 20 patients undergoing STRETTA and 16 patients treated with PPI report that GERD-HRQL scores do not differ between groups, whereas no significant

change in esophageal acid exposure is noted between baseline and 6 mo after STRETTA treatment. So they came to the conclusion that the efficacy of the STRETTA treatment does not seem to be related to a decrease in esophageal acid exposure. In addition, the study of Arts *et al*[7] shows that 3 mo after STRETTA procedure on 11 patients, the symptom score was significantly improved, whereas no changes were observed in esophageal acid exposure.

In view of all these results, we may be led to believe that the greater improvements in GER symptoms observed after TIF and STRETTA applications as compared with LF and PPI treatments, despite the scarce improvement in GER objective parameters, likely depend on another factor, that could be identified with a decreased visceral sensitivity. The hypothesis that symptom improvement in these patients depends on a decreased esophageal acid sensitivity is confirmed, at least for STRETTA, by the study of Arts *et al*[8]. They found that 6 mo after the STRETTA procedure in 13 patients, the mean time needed to induce heartburn during esophageal acid perfusion of the Bernstein test increased from 9.5 ± 2.3 (mean ± SD) to 18.1 ± 4.4 min ($P < 0.01$) , whereas five had become insensitive to 30 min acid perfusion, *vs* none at baseline ($P = 0.04$).

Also in the case of TIF, the dissociation between symptoms and objective parameters, if compared with those of LF and PPI, suggests the post-intervention appearance of a hyposensitive condition, similar to that of STRETTA, although a Bernstein test is necessary to confirm this supposition.

The cause of this local hyposensitivity could lie in an effect of radiofrequency (RF) energy of STRETTA on the myenteric and submucosal nervous plexuses carrying sensory receptors, acetylcholine stimulatory and non-adrenergic, non-cholinergic (NANC) inhibitory neurons, as well as on the two branches of the vagus nerve, which pass in the subadventitial space at the esophagogastric junction level. RF energy inducing a thermal injury promoting submucosal fibrosis and muscularis propria hypertrophy, should also act on nervous tissues impairing the inhibitory NANC neurons with a decrease in transient LES relaxations, while increasing its yield pressures[9]. It is likely that RF energy could also act on sensitive neurons of the esophageal wall. In addition, a slight excess of RF energy or a tissue weakness may also cause damage to the vagus nerve passing below, causing delayed gastric emptying and gastroparesis reported by some authors[10-13]. With regard to the other endoscopic procedures, there are no appropriate comparative studies with LNF and PPI treatments, except for the study of Wong *et al*[14], who compared Nissen fundoplication with ARMS. But they did not perform objective measurements for reflux and only evaluated GERD-HRQL and reflux symptoms up to 2 years, without observing any difference between the two groups.

In conclusion, the evaluation of the effectiveness of any endoscopic anti-reflux technique should not be based exclusively on subjective criteria, such as a good response to PPI suspension, remission of heartburn, and GERD-HRQL improvement, but should also be established with objective examinations, such as 24 h pH monitoring, and, if possible, manometric measurement of the high pressure zone in the distal esophagus, besides endoscopy for the assessment of esophagitis. The good capacity of TIF and STRETTA to improve the reflux symptoms and the quality of life more than LF and PPI treatments, is a double-edged weapon, because a scarce prevention of acid reflux in the long term may expose the patient to the risk that more or less serious alterations will pass unnoticed. This risk could also be taken with the other more recent endoscopic techniques, which, as previously mentioned, should be compared with LF or PPI treatments and possibly examined by the Bernstein test.

Abstract

Anastomotic leakage (AL) has a wide range of clinical features ranging from radiological only findings to peritonitis and sepsis with multiorgan failure. An early diagnosis of AL is essential in order to establish the most appropriate treatment for this complication. Despite AL continues to be a dreadful complication after colorectal surgery, there has been no consensus on its management. However, based on patient's presentation and timing of the AL, there has been a gradual shift to a more conservative management, keeping surgery as the last option Reoperation for sepsis control is rarely necessary especially in those patients who already have a diverting stoma at the time of the leak. A nonoperative management is usually preferred in these patients. There are several treatment options, also for patients without a stoma who do not require a reoperation for a contained pelvic leak, including recently developed endoscopic procedures, such as clip placement or endoluminal vacuum-assisted therapy. More conservative treatments could be an option in patients who are clinically stable or in presence of a small defect.

Key Words: Anastomotic leakage; Colorectal cancer; Colorectal surgery; Mortality; Morbidity

TO THE EDITOR

We were pleased to read the high-level article on treatment of colorectal anastomotic leakage (AL) with endoluminal vacuum therapy (EVT), published by Vignali and De Nardi[1]. The authors have a remarkable clinical experience and scientific authority in colorectal surgery and related complications[2-4].

We agree with the authors that AL is still the worst complication of colorectal surgery today. The consequences of AL can severely alter functional outcomes and oncological results[5]. In the case of AL, the severity of the clinical picture is extremely variable. Some AL have no impact on the patient, while others present with sepsis and can be fatal[6-8].

The incidence of AL is variable[1,5,9]. We believe that this variability in incidence is related to several factors. In accordance with the literature data, we believe that variables such as neoplastic or inflammatory disease, timing of the operation, the distance of the tumor from the anal merge, the clinical presentation with signs of visceral perforation or intestinal obstruction, the local characteristics of the tumor and the surgery performed are important for the postoperative onset of AL. In this context, the need for a common definition appears to be fundamental. AL occurs when a surgical anastomosis fails. In this circumstance, the intestinal contents leak out of the surgical connection. A pelvic abscess close to the anastomosis must be considered as AL. The classification of severity degrees proposed by the International Study Group of Rectal Cancer (ISREC)[10] is the most widely adopted. ISREC[10] proposes a classification of AL into three types (A, B and C) of increasing severity according to the therapeutic management it requires (conservative management in type A; non-surgical management in type B; surgical treatment in type C).

We believe that the onset of AL is important. The time to onset of AL affects both the severity of the complication and also the treatment of the complication itself. Colonic or rectal stump ischemia due to excessive preparation of the stump itself with consequent interruption of the perianastomotic supply of microvascular blood or tension in the anastomotic site is usually responsible for the early onset of AL [11]. On the other hand, the late presentation of AL is not linked to surgical technique problems but rather to clinical conditions of impaired tissue healing, such as local sepsis, malnutrition, the intake of immunosuppressive drugs, severe obesity and exposure to radiation[9,12]. In most patients, AL that occurs early is associated with more severe clinical symptoms. Faecal contamination of the peritoneum is frequently observed in these patients and the incidence of emergency laparotomies is higher. In conditions of worsening sepsis, mortality rates increase. By contrast, in late forms of AL, clinical manifestations will be characterized by the appearance of a pelvic abscess[13,14].

Furthermore, we believe that early diagnosis of AL is essential in order to establish the most appropriate treatment for this complication[15]. Despite AL continues to be a dreadful complication after colorectal surgery, there has been no consensus on its management[5]. Today, however, there is an increasing use of more conservative management. It is preferred to keep surgery as a last resort. Obviously this attitude is related to the presentation of the patient and the timing of the AL[16-18]. In agreement with Vignali and De Nardi[1], we believe that saving the anastomosis through the use of conservative treatments represents a valid therapeutic option to be used especially in clinically stable patients or in the presence of a small defect.

The authors focus their attention on EVT. Its principle is based on the application of topic negative pressure to drain the cavity and to prevent the development of chronic sinus. The paragraph on the description of the device is interesting and exhaustive, too. We agree with Vignali and De Nardi[1] that several reviews, and meta-analyses have been published so far with promising results. Nevertheless, the analysis of most documents yields mixed results, especially when the success rate, anastomosis salvage rates, and long-term outcomes are taken into account. Furthermore, the paucity of comparative studies does not allow definitive conclusions to be drawn, as pointed out by the authors in their narrative review.

There are several treatment options, including recently developed endoscopic procedures, such as stent or clip placement or EVT. These procedures can be used primarily in patients who already have a diverting stoma at the time of the leak. These treatments also find application in patients with extraperitoneal anastomosis and in those without ostomy who do not require further surgery due to a contained pelvic loss (type B of the ISREC classification). EVT is performed endoscopically. An open-pored polyurethane sponge is positioned in the leakage cavity through the anastomotic defect. The main advantages of the treatment are represented by a less invasive approach and continuous drainage. Treatment favors granulation and vascularity; furthermore, it determines a mechanical reduction in the size of the abscess cavity[19-21]. The main indication for the use of the EVT are extraperitoneal, low leaks that are difficult to drain. A disadvantage to the systematic adoption of EVT is the fact that the sponges must be periodically changed, usually more than 8 times in 4-6 wk. Anastomotic necrosis and stricture are the most common complications of the procedure.

The AL treatment should be tailored taking into consideration many factors, giving that there is no universally accepted management flowchart for the optimal treatment of this complication. Non-operative management is usually preferred in patients with extraperitoneal anastomosis without sepsis and peritonitis and in those who underwent proximal faecal diversion at the initial operation[5]. Excluding complications directly related to the endoluminal device, the factors associated with the failure of a conservative approach using EVT are mainly represented by neoadjuvant therapy, lack of a protective stoma before treatment and male sex. However, it must be emphasized that most of these are well known risk factors for AL in general. The timing of EVT can influence success, significantly. A high success rate occurs when endoluminal therapy is started early (within 6 wk) after the onset of AL[22, 23]. Riss *et al*[24] found that 25% of patients assessed after primary successful EVT in a multicentre study developed recurrent abscesses after a median follow-up of 17 mo. No study in the literature has focused attention on oncological and functional outcomes.

It seems obvious to us that in case of AL it is better to prevent its complications rather than treat them once they have arisen. Unfortunately, we believe that complications after colorectal surgery are still inevitable. We are sure that also Vignali and De Nardi[1] agree with our orientation.

Moreover, surgeons have employed several intraoperative techniques to assess integrity of the colorectal anastomoses in order to minimize the risks of postoperative complications. Basic mechanic patency tests (traditional air leak testing, saline leak, and methylene blue leak tests), endoscopic visualization techniques, and more recently, micro perfusion assessment technology are the most commonly used methods. Other methods commonly adopted to evaluate the blood perfusion of the intestinal segments to be used for the creation of the anastomosis are the visual evaluation of the color of the intestinal wall, the presence of visible peristalsis and bleeding from the marginal arteries. These tests are limited. None of these tests allow viewing of the lumen. The anastomosis is assessed by occluding the proximal lumen and then filling the intraluminal cavity with air or fluid and checking for leakage[2,25].

Intraoperative endoscopy was used to visualize the anastomosis. However, the use of the method is not so widespread. Furthermore, the results of intraoperative endoscopy are not of univocal interpretation. A recent systematic review evaluating the results of five non-randomized controlled trials, in which a total of over 900 patients were enrolled, documented an incidence rate of AL of 7.7% in patients with documented AL at intraoperative endoscopy, with no significant difference in postoperative AL rate compared to patients with negative intraoperative endoscopy for AL[26].

Nowadays, a promising and increasingly used new technology is intra-operative fluorescence angiography with indocyanine green[2,27-29]. Evidence for the impact of intraoperative fluorescence angiography in reducing AL after colorectal anastomosis is growing. The procedure allows direct visualization of tissue perfusion. It may help to prevent AL. The use of indocyanine green fluorescence angiography leads to a significant reduction in AL compared to standard intraoperative methods to assess anastomotic blood perfusion in colorectal surgery. Moreover, especially in patients with low or ultra-low rectal resection, the use of indocyanine green fluorescence decreases the need for surgical reintervention for AL.

A diverting stoma ideally protects a low colorectal anastomosis. However, there is a lot of controversy surrounding the use of a protective stoma. The first controversy is certainly about which is the most optimal type of ostomy, an ileostomy or a colostomy[30]. We believe that ostomy is useful to reduce clinical symptoms of AL by increasing the percentage of sub-clinical dehiscence, but not modifying the overall percentage. Moreover, no significant benefit of a diverting stoma for reducing the risk of AL has been showed in some large-volume studies. Usually, we tend to protect with an ostomy the patients who underwent neoadjuvant radiotherapy and those with an ultralow colorectal anastomosis. In recent years, this dogma has been challenged. Several authors questioning the need of an ostomy for all patients with an ultralow anastomosis.

We believe that the use of a transanastomotic drainage tube (TDT) may be useful in preventing the onset of AL. Regarding the TDT, several studies showed no difference in AL rate between patients with and without one[31]. Other literature observations, instead, have documented a reduction in frequency of AL in patients with TDT[32-35]. Prophylactic TDT presents fewer risks of complication than derivative stoma. It was thought to lower the risk of AL, *per* as documented in a systematic review and meta-analysis pooling 1772 patients undergoing rectal anterior resection[36]. The same conclusions were obtained in another systematic review and meta-analysis, including patients with diverting stoma[37].

Therefore, prophylactic TDT could constitute an efficient method to prevent AL in high-risk patients without exposing them to the complications of a diverting stoma. However, it is necessary to conduct an RCT on a large number of patients in order to obtain definitive results from the comparison of the two techniques.

AL after rectal surgery is a fearsome complication with considerable mortality and morbidity. Many factors are related to the onset of AL in the postoperative period. Some of these factors cannot be changed in the least by medical intervention. It is paramount to identify leaks early to minimize the potential morbidities of this complication. Despite advances in combating surgical infections, new devices for bowel reapproximation, better understanding of risk factors for anastomotic complications, and improved perioperative care, we continue to struggle with the occurrence and management of this complication. Technology will likely never be developed that would allow surgeons to prevent the onset of AL in the postoperative period. The use of the TDT prevents the formation of AL. This is a simple method that could avoid performing diverting ileostomies. AL can be further reduced by fluorescence angiography. This method, while bringing significant intraoperative changes in surgical strategies, allows the direct evaluation of the vascularization of the intestinal segments. In the meantime, it's necessary promptly diagnose AL. Likewise, the knowledge of all the therapeutic possibilities, from the least invasive ones to surgery, is necessary in order to treat AL and improve patient outcomes by reducing the incidence of functional disorders or the impact on survival.

FOOTNOTES

Author contributions: Chiarello MM and Brisinda G conceived the original idea; Fransvea P and Bianchi V performed a comprehensive review of all available literature and summarized the data; Brisinda G and Chiarello MM meet the criteria for authorship established by the International Committee of Medical Journal Editors and verify the validity of the results reported; all authors read and approved the final manuscript.

Conflict-of-interest statement: All the authors report no relevant conflicts of interest for this article.

ABOUT COVER

Editorial Board Member of *World Journal of Gastroenterology*, Nikolaos Papadopoulos, MD, PhD, Consultant, The First Department of Internal Medicine, 417 Army Share Fund Hospital, Monis Petraki 10-12, Athens 11521, Greece. nipapmed@gmail.com

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 edition of Journal Citation Reports® cites the 2021 impact factor (IF) for *WJG* as 5.374; IF without journal self cites: 5.187; 5-year IF: 5.715; Journal Citation Indicator: 0.84; Ranking: 31 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. Abstract

Pancreatic ductal adenocarcinoma (PDAC) is one of the most lethal neoplasms worldwide and represents the vast majority of pancreatic cancer cases. Understanding the molecular pathogenesis and the underlying mechanisms involved in the initiation, maintenance, and progression of PDAC is an urgent need, which may lead to the development of novel therapeutic strategies against this deadly cancer. Here, we review the role of SET and MYND domain-containing protein 2 (SMYD2) in initiating and maintaining PDAC development through methylating multiple tumor suppressors and oncogenic proteins. Given the broad substrate specificity of SMYD2 and its involvement in diverse oncogenic signaling pathways in many other cancers, the mechanistic extrapolation of SMYD2 from these cancers to PDAC may allow for developing new hypotheses about the mechanisms driving PDAC tumor growth and metastasis, supporting a proposition that targeting SMYD2 could be a powerful strategy for the prevention and treatment of PDAC.

Key Words: Pancreatic ductal adenocarcinoma; Protein lysine methyltransferase; Histone/non-histone methylation; Oncogenic signaling pathways; Methyltransferase inhibitors

Core Tip: The broad substrate specificity of SET and MYND domain-containing protein 2 (SMYD2) and its involvement in diverse oncogenic signaling pathways in numerous cancers have provided a wealth of information that could be extrapolated to the pancreatic ductal adenocarcinoma (PDAC) research field to expand our understanding of SMYD2 in PDAC development. This review not only discusses the known roles of SMYD2 in PDAC initiation and progression, but also aims to capitalize on a rich body of knowledge with respect to SMYD2's involvement in various signaling cascades to develop new hypotheses about the mechanisms of driving PDAC tumor growth and metastasis.

INTRODUCTION

Pancreatic cancer is one of the top ten leading causes of cancer-related mortality worldwide, accounting for about 448000 new cases and 441000 deaths in 2017[1]. Pancreatic cancer comprises several types of tumors that arise from the endocrine or exocrine components of the pancreas. The vast majority of pancreatic tumors arise from the exocrine cells, which make up the exocrine gland and the ducts of the pancreas. Pancreatic ductal adenocarcinoma (PDAC) is the most common and aggressive form of pancreatic cancer, which represents about 85% of pancreatic cancer cases[2]. The incidence and mortality rates of pancreatic cancer have dramatically increased over the past few decades and vary considerably across regions and populations, with the highest trends being recorded in developed countries[3]. Although the causes and mechanisms that initiate the formation and development of pancreatic cancer are still largely unknown, the variation in regions and populations may be attributed to the variance in some of the risk factors and the socioeconomic lifestyle identified for this disease, such as obesity, diabetes, and smoking. In the United States, the incidence of pancreatic cancer continues to increase, with an estimation of 60430 new cases and 48200 deaths in 2021, and it has become the fourth leading cause of cancer-related mortality[4]. Pancreatic cancer has the poorest prognosis among the top ten common cancers, with the current 5-year survival (OS) rate of just 10%[4], and it is expected to be the second most common cause of cancer death by 2030[5].

Diagnosis and treatment of PDAC are still challenging due to its multifactorial nature. It is predominantly diagnosed in advanced stages with unresectable tumors due to several reasons, including the lack of early detection methods, the lack of specific PDAC biomarkers and simple examinations, the retroperitoneal location of the pancreas, and the nonspecific symptoms due to its highly metastatic nature early in the disease course[6]. Also, PDAC incidence is significantly associated with age, with the highest incidence rates being in elderly people[1]. Given the poor overall health of the elderly, the surgical resection is not feasible for the majority of elderly PDAC patients, especially for those who have metastatic cancers that have spread to the nearby abdominal vessels and critical organs at diagnosis[7]. Only a small fraction of PDAC patients diagnosed in the early stage have resectable tumors. Although the surgery in combination with adjuvant therapy remains the only cure for PDAC patients, the overall survival rate of PDAC patients is poor, even for those PDAC populations who have undergone surgery [8-10]. PDAC patients, after surgical resection, usually develop acquired chemoresistance, with a high rate of recurrence due to the very heterogeneous biology of PDAC and the aggressive clinical behavior of this disease[6]. These factors may explain the high mortality in PDAC patients; therefore, it is of great importance to identify the molecular mechanism of PDAC pathogenesis and the involved signaling pathways in order to discover novel targets and potential biomarkers for PDAC diagnosis and therapy.

SET and MYND domain-containing protein 2 (SMYD2) has been linked with tumor progression, poor prognosis, or a worse malignant outcome in multiple human cancers including PDAC[11-16]. This protein belongs to a special class of protein lysine methyltransferases and is characterized by a conserved catalytic SET domain split by an MYND domain[11]. The MYND domain of SMYD2 is a zinc finger motif that facilitates the protein-protein interaction, while the SET domain, an evolutionarily conserved motif, catalyzes the transfer of methyl groups to lysine residues of target proteins using S-adenosylmethionine (SAM) as a donor substrate[12]. The carcinogenic potential of SMYD2 is exemplified by its ability to methylate a broad spectrum of proteins involved in cellular signaling, cell cycle control, and cell differentiation and proliferation[17-20]. SMYD2 is an epigenetic regulator that has histone lysine methyltransferase activity and can methylate histones H3K36 and H3K4[11,12]. Through the dimethylation of histone H3 at Lys36 (H3K36me2), SMYD2 was reported to downregulate gene transcription, which is further enhanced by Sin3A-mediated deacetylation to suppress cell proliferation [11]. On the other hand, methylation of histone H3K4 by SMYD2 is usually associated with gene activation, yet the exact underlying mechanism by which this SMYD2-mediated methylation regulates

cell proliferation is not well understood[12,21]. Several investigations revealed multiple nonhistone substrates of SMYD2, including the tumor suppressor p53, retinoblastomaassociated protein (RB), ERα, HSP90, PARP1, and PTEN (Table 1)[22-27]. For instance, the tumor suppressor p53 is an important nonhistone target that is monomethylated by SMYD2 at Lys370 located in the regulatory domain of p53, repressing the p53's transcriptional regulatory activity and promoting cancer initiation and growth[22]. It has also been shown that through its broad methyltransferase activity on nonhistone proteins, SMYD2 impacts various signaling pathways required for the development and progression of the malignancies [17,28-32]. These pathways include the critical signaling cascade RTK/Ras, the downstream signaling cascades of the RTK/Ras pathway, such as the mitogen-activated protein kinase (MAPK) pathway, and the PI3K/AKT pathway[16,27,28,30,31]. As dysregulation of these signaling pathways is an almost universal phenomenon in cancer, it is not surprising that SMYD2 overexpression has been linked with tumor development and progression in multiple human cancers, such as gastric cancer[33], esophageal squamous cell carcinoma[34], breast cancer[30], bladder cancer[23], colon cancer[31,35], colorectal cancer[36], hepatocellular carcinoma[14], acute lymphoblastic leukemia[37,38], hematopoietic leukemias [39], head and neck squamous cell carcinoma[15], lung adenocarcinoma[13], papillary thyroid carcinoma[40], cervical cancer[41,42], ovarian clear cell carcinoma[43,44], and renal cell carcinoma[45,46] (Table 2).

Because of SMYD2 overexpression in numerous human tumors (Figure 1A), understanding the molecular mechanisms of SMYD2 in cancer initiation and development, and validating its therapeutic potential as a drug target to inhibit abnormal cell proliferation, have gained increasing interest in recent years; currently, SMYD2 is one of the most extensively studied protein lysine methyltransferases in the context of cancer. However, the involvement of SMYD2 in PDAC initiation and progression has not yet been fully explored. The overexpression of SMYD2 has been reported in PDAC by a study that showed methylation of the human MAPK activated protein kinase 3 (MAPKAPK3) by SMYD2 promotes tumor growth and progression[16]. Another investigation identified that the SMYD2 Locus is among the active chromatin sites unique to the genomes of the adenosquamous cancer of the pancreas (ASCP) and is associated with the active H3K4me1 histone mark[47]. These pioneering works, despite being limited in scope, demonstrate that SMYD2-mediated methylation of both histone and nonhistone proteins could also be an important tumorigenic event contributing to PDAC initiation and development. On the other hand, a rich body of knowledge available in many other human cancers with respect to the roles of SMYD2 in cell cycle control and various signaling cascades provides a wealth of information that could be extrapolated to the PDAC research field to expand our understanding of SMYD2 in PDAC development. Here, we review the known roles of SMYD2 in PDAC initiation and progression, and through capitalizing on the current knowledge about its known cancer-related functions in other human cancers, we propose there existing additional SMYD2-mediated methylation events involved in diverse signaling pathways that control and coordinate different cellular processes in PDAC.

CURRENT EVIDENCE OF SMYD2 INVOLVEMENT IN PANCREATIC CANCER

One study aimed to investigate the function of SMYD2 in PDAC using mouse and cellular models found evidence that SMYD2 plays a pivotal role in the development of this deadly pancreatic cancer[16] (Figure 1B). In other human cancers, SMYD2 usually exerts its tumorigenic effects through methylating cell signaling-related proteins and through the effect of such methylation on the targets' activity, stability, or subcellular localization[13,27,42,48]. Such a methylation-oriented mechanism has been instrumental for the initial development of a mechanistic hypothesis of SMYD2 involvement in PDAC and for the subsequent success of establishing a novel link of SMYD2 to promoting PDAC growth and progression[16]. Using an *in vitro* protein-array system, which consists of about 9500 human proteins, 159 proteins were identified as SMYD2 substrates in this study. Among these hits, MAPKAPK3 was selected for further analysis due to being implicated in cancer and being linked to Ras signaling, a key driver of PDAC[16,49-52]. Although the roles of MAPKAPK3, like those of SMYD2, in PDAC were unknown at the time of the study, MAPKAPK3 has been known as a mediator in the MAPK/ERK cascade that is responsible for regulating a wide variety of stimulated cellular processes[53-55]. It has also been shown that MAPKAPK3, phosphorylated by ERK1/2, p38 kinase, and SAPK/JNK, plays a role in inflammation and stress responses[56-59]. Therefore, the identification of MAPKAPK3 as a new SMYD2 substrate suggested a novel regulatory axis in PDAC progression.

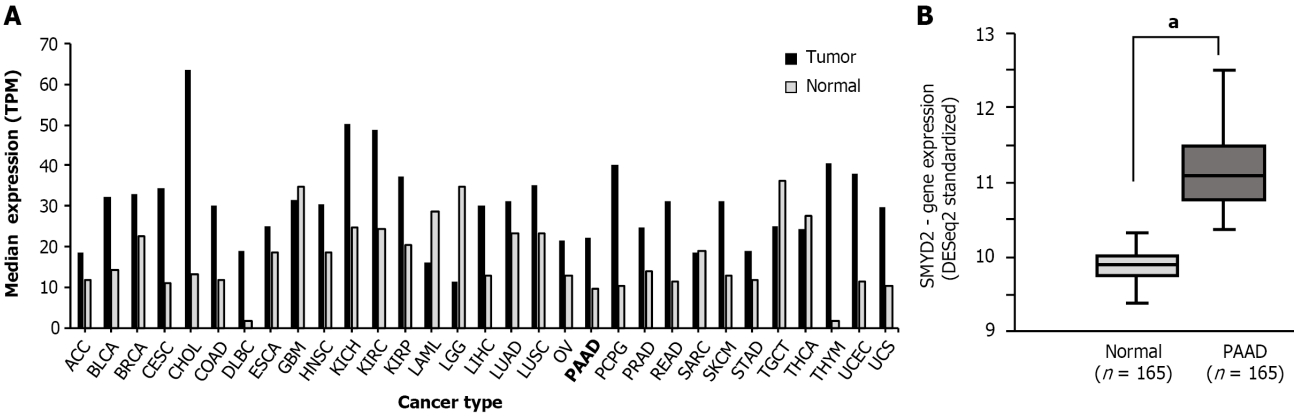
Further characterization confirmed that the SMYD2-MAPKAPK3 axis is required for efficient PDAC development and that SMYD2-mediated methylation of MAPKAPK3 is a key event during the K-Ras-driven transformation of PDAC cells *in vivo*[16]. Lys355 of MAPKAPK3 was identified as a site of methylation targeted by SMYD2 using a mutagenesis approach and an LC-MS/MS analysis. Specificity analyses using an MS approach showed that the related protein MAPKAPK2, which shares about 75% sequence identity with MAPKAPK3, as well as other MAPKAPK proteins, are not substrates of SMYD2. On the other hand, none of the eight active lysine methyltransferases, including SMYD3 and SET8, could methylate MAPKAPK3 *in vitro*. Co-expression of SMYD2 and MAPKAPK3 in PDAC cells identified MAPKAPK3-K355me1 in a SMYD2-dependent manner, demonstrating that only SMYD2 can

Table 1 Major SET and MYND domain-containing protein 2 nonhistone substrates

Substrate	Methylation site	Methylation effect	Affected pathways	Role of substrates in PDAC	Ref.
ALK	K1451; K1455; K1610	Promotes EML4-ALK phosphorylation and NSCLC cell growth	PI3K/AKT; JAK/STAT; RTK/Ras	ALK rearrangement-positive cancer correlates with better response to chemotherapy	[28, 96]
β-catenin	K133	Promotes β-catenin nuclear translocation	Wnt/β-catenin/TCF	Mediates EMT; promotes cell proliferation, migration, and invasion	[48, 97]
BMPR2	Kinase domain	Stimulates BMPR2 kinase activity; SMAD1/5 phosphorylation; BMP pathway activation	BMP	Promotes tumor growth *via* GRB2/PI3K/AKT pathway	[98, 99]
ERα	K266	Suppresses ERα target gene activation	PI3K/AKT; MAPK-ERK	ERα expression correlates with tumor progression; endocrine therapies	[100, 101]
EZH2	K307	Promotes EZH2 stability; cell proliferation; EMT;invasion in BC	RB-E2F	Linked to an aggressive phenotype	[102, 103]
HSP90AB1	K531; K574	Enhances dimerization; chaperone complex formation of HSP90AB1; promotes cancer cell proliferation	PI3K/AKT	Targeting HSP90 decreases GEM chemores-istance	[25, 104]
MAPKAPK3	K355	Promotes pancreatic ductal adenocarcinoma	RTK/Ras; MAPK-ERK	Interacts with HSP27; mediates gemcitabine toxicity	[16]
p53	K370	Inhibits p53 and p53-mediated transcrip-tional regulation	p53	p53 methylation correlates with aggressive tumors; poor prognosis	[16, 22]
PARP1	K528	Enhances poly (ADP-ribosyl) ation enzymatic activity; promotes apoptotic escape of cancer cells	Base excision repair	Promotes tumorigenesis and resistance	[26, 105]
PTEN	K313	Inactivates PTEN; promotes BC cell prolif-eration	PI3K-AKT	Loss of PTEN enhances activation of PI3K-AKT; NF-κB and MYC; promotes tumor cell growth and survival	[27, 74]
RB	K810; K860	Enhances Ser 807/811 phosphorylation of RB1; enhances E2F transcriptional activity; cell cycle progression	RB-E2F pathway	Reduced expression of RB correlates with cancer progression	[23, 76,78]
STAT3	K685	Activates and phosphorylates STAT3; promotes cell proliferation and survival in triple-negative BC	JAK2/STAT3	Suppress apoptosis *via* regulation of BCL-2 family; promotes tumorigenesis	[30, 106]
P65	K310	Activates and phosphorylation p65; represses tumor cell apoptosis in triple-negative BC	NF-κB pathway	-	[30]

PDAC: Pancreatic ductal adenocarcinoma; MAPKAPK3: Mitogen-activated protein kinase activated protein kinase 3; RB: Retinoblastomaassociated protein; BC: Breast cancer; STAT3: Signal transducer and activator of transcription 3; BCL-2: B cell lymphoma-2.

monomethylate MAPKAPK3 at Lys355 both *in vitro* and *in vivo*. Moreover, depletion of SMYD2 led to a decreased expression of endogenous methylation of MAPKAPK3 at Lys355 in the human SW1990 PDAC cell line, indicating that SMYD2 is required for the physiological levels of MAPKAPK3-K355me1 in these cells. Additional experiments further confirmed MAPKAPK3 as a cancer-relevant cytoplasmic target of SMYD2, as determined by a decreased stromal response and a diminished inflammation in *K-Ras* mutant mice, as well as by the cytoplasmic co-localization of SMYD2 and MAPKAPK3 in human and murine PDAC cell lines[16].



PDAC is one of the Ras-driven carcinomas, where *K-Ras* mutation is a key player in triggering the pancreatic intraepithelial neoplasia (PanIN) and tumor development[16,52]. The overexpression of SMYD2 in PDAC samples, as well as the methylation of the Ras-signaling kinase MAPKAPK3, support the idea that targeting the catalytic activity of SMYD2, or the SMYD2-MAPKAPK3 axis, may be therapeutic in the Ras-driven PDAC. SMYD2 expression was not detectable in normal pancreas tissue sections, while sections from murine and human PanIN and PDAC specimens revealed elevated expression of SMYD2[16]. Notably, an increase in the expression of SMYD2 is correlated with the cancer progression in samples from *K-Ras* mutant mice. Loss of SMYD2 resulted in a reduction in the acinar-to-ductal metaplasia (ADM)[16], an early event in PDAC development triggered by the activation of the RTK/Ras signaling pathway[60]. Consistently, a reduction in the development of the precancerous lesions PanINs and a decreased proliferation ability were also observed upon depletion of SMYD2, as determined by using MUC5AC, pERK1/2, Ki67, cleaved-Caspase-3, and αSMA as markers for PanIN lesions, Ras pathway activation, proliferation, apoptosis, and stromal response, respectively. These

Table 2 SET and MYND domain-containing protein 2 involvement in human cancers

Cancer type	Findings	Ref.
Acute lymphoblastic leukemia	SMYD2 overexpression; worse OS and EFS; higher WBC counts; a higher percentage of high-risk disease; prognostic factor	[38]
Bladder cancer	Higher expression of SMYD2; promotes cell cycle progression of cancer cells; methylation of RB	[23]
Breast cancer	SMYD2 overexpression; worse RFS; prognostic factor	[107]
	SMYD2 overexpression; poor survival	[30]
Cervical cancer	Higher expression of SMYD2; worse OS; advanced FIGO stage; larger tumor size; poor prognosis	[41]
Chronic lymphocytic leukemia	Higher expression of SMYD2; high WBC counts; complex karyotype; tumor progression	[108]
Clear cell renal cell carcinoma	SMYD2 overexpression; worse OS and DFS; high TNM stage; early tumor relapse	[46]
Colon cancer	SMYD2 overexpression; upregulation MDR1/P-glycoprotein; poor prognosis; enhances oxaliplatin resistance	[31]
Colorectal cancer	SMYD2 overexpression; activates the Wnt/β-catenin pathway; worse OS and DFS; worse oncologic outcomes	[36]
Esophageal squamous cell carcinoma	Higher expression of SMYD2; worse OS; enhances venous invasion; higher pT category and recurrence	[34]
Gastric cancer	SMYD2 overexpression correlates with larger tumor size; aggressive invasion; more lymph node metastasis; recurrence; poor OS	[33]
Hematopoietic leukemias	Higher expression of SMYD2; promote Wnt-β-Catenin signaling; poor OS	[39]
Hepatocellular carcinoma	SMYD2 overexpression correlates with tumor size; vascular invasion; differentiation; TNM stage; worse OS; poor prognosis	[14]
HPV-unrelated, non-multiple head and neck cancer	Higher expression of SMYD2; worse OS; prognostic biomarker	[15]
Lower-grade gliomas	Poor OS; prognostic biomarker	[109]
Lung adenocarcinoma	Overexpressed SMYD2 correlates with shorter OS and DFS; promotes proliferation, migration, and invasion of cancer cells	[13]
Non-small cell lung cancer	Overexpressed SMYD2 enhances cisplatin resistance; downregulates the p53 pathway	[32]
Ovarian clear cell carcinoma	Shorter OS and DSS; prognostic biomarker	[43]
Pancreatic cancer	SMYD2 overexpression; methylation of MAPKAPK3; enhances precancerous lesions; poor OS	[16]
Papillary thyroid carcinoma	SMYD2 overexpression correlates with PTC progression; poor prognosis and DFS; worse clinical outcomes	[40]
Renal cell tumor	Low expression of SMYD2 correlates with shorter DSS and DFS; prognostic biomarker	[45]

SMYD2: SET and MYND domain-containing protein 2; OS: Overall survival; EFS: Event-free survival; DFS: Disease-free survival; DSS: Disease-specific survival.

results have led to pharmacological inhibition experiments aimed to evaluate the therapeutic potential of targeting the SMYD2-MAPKAPK3 axis in Ras-driven pancreatic cancer[16]. The compound PF-3644022, which inhibits the kinase activity of MAPKAPK3, was found to suppress the expansion of PDAC cells in culture[16]. Also, treatment with PF-3644022 caused inhibition of PDAC growth in *K-Ras* mutant mice, as well as resulted in fewer PanIN, reduced cell proliferation, an elevated level of apoptosis, attenuation of the Ras pathway, and a reduced level of inflammatory cytokines. Treatment with the SMYD2 small molecule inhibitor BAY598[61] inhibited the methylation of MAPKAPK3 by SMYD2 and decreased the growth of *K-Ras*/*TP53* mutant PDAC cells, whereas the growth of *K-Ras*/*TP53*/*SMYD2* mutant cells was not significantly impacted. On the other hand, the chemotherapeutic gemcitabine had a stronger inhibitory effect on the clonal expansion of *K-Ras*/*TP53* mutant PDAC cells when combined with BAY598[16]. Gemcitabine also inhibits the growth of *K-Ras*/*TP53*/*SMYD2* mutant cells, suggesting that SMYD2 inhibition along with chemotherapy treatment cooperate to target PDAC cells. Such a notion was further supported by the fact that co-treatment of gemcitabine with either SMYD2 inhibition or its deletion resulted in much greater suppression of the growth of PDAC xenografts in mice when compared with any single-agent treatments. Another combination treatment with low-dose doxorubicin and BAY598 revealed similar results in inhibiting PDAC cell growth[16]. These studies together demonstrated that the efficacy of chemotherapy for the treatment of PDAC patients could be significantly improved by a combination of SMYD2 inhibition and effective chemotherapy agents, underscoring the therapeutic potential of targeting the SMYD2-MAPKAPK3 axis

in PDAC.

FUNCTIONAL EXTRAPOLATION OF SMYD2 FROM OTHER CANCERS TO PANCREATIC CANCER

SMYD2 involvement in many other human cancers (Table 2) through regulating the oncogenic signaling pathways provides a conceptual foundation for extrapolating the known functions of SMYD2 to the less studied pancreatic cancer. SMYD2 is highly expressed in breast tumor tissues relative to normal breast tissues[30]. Inhibition of SMYD2 by RNAi-mediated knockdown or through the specific inhibitor AZ505 significantly decreased tumor growth *in vivo*, indicating that SMYD2 may be involved in the initiation and development of breast cancer (BC) *via* methylation of proteins required for BC cell survival. Indeed, the contribution of SMYD2 to BC development depends on its ability to methylate four protein targets including the NF-κB p65 subunit, signal transducer and activator of transcription 3 (STAT3), histone H3, and PTEN; the activation/inactivation of these protein targets by the methylation affects a wide range of cancer cell behaviors, including cell proliferation, migration, invasion, and survival (Figure 2). SMYD2-mediated methylation of the NF-κB p65 subunit resulted in NF-κB activation and repressed apoptosis of human breast cancer cells[30]. SMYD2-mediated methylation of STAT3 contributes to STAT3 activation in triple-negative breast cancer cells, which in turn increases SMYD2 expression, leading to increased methylation of H3K4 and H3K36 by SMYD2, thereby linking SMYD2 to several BC-associated signaling cascades, including JAK2/STAT3, ERK, and AKT signaling[11,27,30,62]. SMYD2-mediated methylation of PTEN at Lys313 was shown to downregulate the expression of PTEN and to suppress PTEN activity through inducing phosphorylation at serine 380 of PTEN[27,30]. PTEN is a dual lipid and protein phosphatase; as a negative regulator of PI3K/AKT signaling, it downregulates signal transduction initiated by growth factors and hormones through dephosphorylating phosphatidylinositol 3,4,5-triphosphate (PIP3) produced by PI3K[63]. Since PI3K/AKT signaling is a crucial intracellular pathway in human cancers and is frequently upregulated in multiple types of cancer including PDAC[64], the link of SMYD2 to this signaling pathway *via* the methylation-induced repression of PTEN activity suggests a possible new mechanism by which SMYD2 contributes to PDAC development. Several reports have shown the constitutive activation of Ras/ERK and PI3K/AKT signaling and PTEN downregulation being involved in the pathogenesis and progression of pancreatic cancer[65-70]. PTEN was shown to be abundantly expressed in the cytoplasm of non-tumor pancreatic tissues but to be significantly downregulated in PDAC tissues[71]. The downregulation of PTEN has been associated with a high rate of tumorigenesis and a poor prognosis for PDAC patients[71-73]. One important mechanism by which aberrant PTEN expression contributes to PDAC development is the activation of

Figure 2 A schematic model for SET and MYND domain-containing protein 2 driving pancreatic cancer development *via* methylation of nonhistone proteins. SET and MYND domain-containing protein 2 (SMYD2) can methylate several nonhistone proteins that may be involved in pancreatic cancer tumorigenesis, including p53, PTEN, retinoblastomaassociated protein (RB), and mitogen-activated protein kinase activated protein kinase 3 (MAPKAPK3). SMYD2 methylates and inactivates p53 to promote cell proliferation. PTEN is downregulated by SMYD2-mediated methylation, which promotes cell proliferation through activation of PI3K signaling. Methylation of RB by SMYD2 enhances RB phosphorylation, which allows E2F to disassociate from the RB-E2F complex and enhances E2F activity to promote cell cycle progression. SMYD2 impacts the RTK/Ras pathway through methylation of MAPKAPK3 to promote cell growth. MAPKAPK3: Mitogen-activated protein kinase activated protein kinase 3; RB: Retinoblastoma-associated protein.

the PI3K/AKT signaling pathway, which promotes PDAC cell growth, survival, and angiogenesis[74,75]. Therefore, in addition to promoting PDAC growth *via* methylation of MAPKAPK3, it is possible that the tumor-promoting activity of SMYD2 in PDAC is attributable to its methyltransferase activity on PTEN, which subsequently causes the activation of the oncogenic PI3K/AKT signaling pathway. In order to prove this hypothesis, future investigation should be directed towards assessing whether Lys313 of PTEN, which is methylated by SMYD2 in BC, can be methylated by SMYD2 in the context of PDAC, and whether such methylation represses the tumor-suppressor activity of PTEN, leading to the activation of PI3K/AKT signaling.

Methylation of RB by SMYD2[76], which is involved in the development of bladder cancer[77], suggests another potential mechanism by which SMYD2 contributes to PDAC progression. SMYD2 is overexpressed in bladder cancer cell lines and primary bladder tumor samples and plays a role in promoting bladder cancer cell proliferation[23]. One mechanism for the SMYD2's bladder cancer-promoting role is the methylation of the tumor suppressor RB, which contributes to the hyperphosphorylation of RB, leading to RB inactivation, and thereby bypassing the regulatory action of RB on cell proliferation[23]. In the case of pancreatic cancer, RB protein levels were significantly lower in PDAC tumor tissues than those in adjacent normal tissues; the low protein levels of RB have been associated with PDAC progression[78]. Another study showed that RB depletion promotes PanIN and rapid malignant transformation in *K-Ras*-induced PDAC, being associated with an impaired p53 activity[79]. This result suggests the importance of RB function in suppressing PDAC progression through mediating the cellular senescence and enhancing p53 function. However, little is known about the methylation status of RB in pancreatic cancer, how such posttranslational modification regulates RB activity, and what are the downstream effects of the methylation on cellular functions and PDAC progression. Given the role of the SMYD2-mediated RB methylation in bladder cancer, one can speculate that there might exist an analogous cancer-promoting mechanism, where SMYD2 mediates the inactivation of RB through direct methylation of RB, resulting in bypassing cell cycle restrictions and promoting PDAC cell growth.

Because of the broad substrate specificity of SMYD2 (Table 1), with most of its substrates being tumor suppressors or oncogenic proteins, the mechanistic link of SMYD2 to PDAC proliferation is expected to be complex, involving the interconnected signaling pathways that regulate the cell cycle, apoptosis, as well as energy metabolism. The tumor suppressor p53 is another important methylation target of SMYD2[22], and this methylation has been shown to promote the tumorigenesis of cervical cancer through an alternative metabolic strategy, shifting the major production of cellular metabolism to lactate production[42]. p53 exerts its tumor-suppressive function in response to severe DNA damage and

inhibits the onset and progression of tumors[80]. p53 is a master regulator of the cell cycle and apoptosis and is involved in the regulation of metabolic pathways to maintain the metabolic homeostasis of cells [81,82]. It has been reported that SMYD2 monomethylates p53 at Lys370, which led to p53 inactivation by decreasing the binding activity of p53 to its target genes[22]. Loss-of-function and gain-of-function experiments revealed that SMYD2 depletion not only significantly reduced the p53K370me level but also increased the p53 reporter activity in cervical cancer cell lines; in contrast, overexpression of SMYD2 in the same cell lines led to an increased level of p53K370me[42]. It has also been shown that the knockdown of p53 in SMYD2-overexpressing cervical cancer cells compromised the increase in glucose uptake and lactate production induced by SMYD2[42]. Moreover, hijacking tumor glycolysis by the glucose analog 2-deoxy-D-glucose (2-DG) significantly repressed SMYD2-dependent tumor growth. These findings together indicate that SMYD2 is a positive glycolytic mediator and plays a promoting role in enhancing tumor growth in a glycolysis-dependent manner, likely through SMYD2-mediated methylation of p53 to promote aerobic glycolysis and tumorigenesis in cervical cancer[42]. Although the role of SMYD2-mediated p53 methylation in PDAC has not yet been explored, dysregulation of the p53 pathway is one of the primary molecular pathological events in PDAC, which promotes the development and progression of pancreatic tumors[83]. In a cohort of 272 PDAC patients, an aberrant alteration rate of the *TP53* gene was about 38%[84], consistent with earlier reports demonstrating 40% and 47% of PDAC samples having p53 mutations[85,86]. It was shown that the inactivation of p53 occurs during the progression of PanIN to invasive tumors[87], while activation of the mitochondrial p53 was shown to restore the apoptotic pathway and inhibit PDAC growth *in vitro* and *in vivo*[88]. These studies demonstrate that p53 dysfunction has a strong association with the progression of pancreatic cancer. As an upstream regulator of the p53 pathway, SMYD2 monomethylates p53 and deactivates the transcriptional activity of p53, and it is thus possible that its ability to block the p53-tumor suppressor activity is another mechanism by which SMYD2 contributes to PDAC progression. It would also be interesting to investigate whether SMYD2-mediated silencing of p53 is also involved in the metabolic reprogramming of pancreatic tumors and promotes the aerobic glycolysis of cancer cells.

CURRENT CHALLENGES IN THE MOLECULAR THERAPEUTIC TARGETING OF SMYD2

Because of the tumor-promoting role of SMYD2 in numerous cancers including PDAC, the development of selective small-molecule inhibitors against SMYD2 could offer a substantial opportunity for targeted medicine with a broad therapeutic benefit. Great progress in crystal structure analysis of SMYD2 has allowed for the development of multiple selective and potent SMYD2 inhibitors over the past decade [89]. The first SMYD2 inhibitor AZ505 was identified in 2011 after screening over one million-compound library[90]. AZ505 is a competitive inhibitor and has high selectivity for SMYD2, with an inhibitory potency at IC_{50} of 0.12 μM. This landmark discovery opened avenues for structure-based drug discovery for SMYD2 and led to the development of more potent SMYD2 inhibitors. A systematic structure-activity relationships (SAR) study on the AZ505 structure has identified the small molecule A893 as a highly selective SMYD2 inhibitor and being more potent in inhibiting p53 methylation than AZ505[91]. LLY507, another selective SMYD2 inhibitor, was developed and validated not only by a biochemical assay but also by the cell-based assays, and this inhibitor was found to strongly inhibit SMYD2-mediated p53 methylation in several cancer cell lines[92]. Using a modified high-throughput binding assay, BAY598 was identified as one of the most selective and potent SMYD2 inhibitors, with promising pharmacokinetic properties and capable of inducing SMYD2 inhibition *in vivo*[61]. BAY598 showed more than 100-fold selectivity towards SMYD2 relative to other SMYD proteins, and it had a preferred binding to the SMYD2-SAM substrate complex. In cell-based assays, BAY598 was able to inhibit the methylation of p53 by SMYD2, and it can also lead to a slight reduction of tumor area in mice[61]. Further studies identified additional potent and selective inhibitors with suitable pharmacokinetic properties, namely AZ931 and AZ506, though these inhibitors showed no effect on the proliferation of either *TP53* wild-type or *TP53*-deficient cell lines[93]. Recent studies presented new SMYD2 inhibitors, including EPZ033294, EPZ032597, MTF1497, and MTF9975[89,94]. It is noteworthy that EPZ033294 was the first SMYD2 inhibitor acting as a non-competitive inhibitor for the substrate peptide, with a low nanomolar inhibitory activity[94]. However, all these SMYD2 inhibitors are still at a research level and have not undergone clinical trials as therapeutic agents against tumors.

It is widely accepted that the cancer-promoting role of SMYD2 is dependent on its ability to methylate histone and nonhistone proteins, which has significant functions in the development and progression of malignancies. However, targeting the methyltransferase activity of SMYD2 has not yet achieved great outcomes in current cancer studies. This lack of success may be attributed to traditional SMYD2 inhibitors that usually inhibit the evolutionarily conserved cofactor binding site, as well as the complexity of the SMYD2 broad substrate specificity and its involvement in multiple signaling pathways that are essential for both normal and cancerous cells. Targeting the cofactor binding site of SMYD2 is a straightforward strategy, as the methyltransferase activity of SMYD2 relies on the methyl donor SAM being bound at the cofactor binding site. However, the highly conserved nature of this SAM binding site across the entire SET domain-containing protein lysine methyltransferase superfamily

makes designing a highly selective inhibitor with minimum cross-reactivity a challenge. Although a great selectivity has been achieved by some SMYD2 inhibitors, the current specificity analysis is limited to a handful number of SET domain-containing proteins that are closely related to SMYD2, and the full spectrum of the specificity profiles of these inhibitors across the genome is unknown. Consequently, some reports pointed out a potent inhibition of cell proliferation by some of the SMYD2 inhibitors, such as LLY507, being independent of SMYD2 inhibition, rather targeting several other unrelated enzymes to exert their inhibitory effects[94]. Similar conflicting data was also obtained about the effect of the SMYD2 inhibitor BAY598[61]. As a result of these conflicting data, some reports concluded that SMYD2 might not be required for *in vitro* cell line proliferation, though such a claim needs to be further studied [94]. The broad substrate specificity of SMYD2 represents another significant challenge in targeting SMYD2 for cancer therapy. In the past two decades, many nonhistone substrates of SMYD2 have been reported, suggesting that the functional impact of inhibiting SMYD2 will be very complex, involving different mechanisms and affecting various cellular pathways in both normal and pathological conditions. The lack of understanding of how SMYD2 inhibition affects the physiological behavior of normal cells is a major issue of current SMYD2 inhibitors. Another issue is that, for example, SMYD2 inhibition leading to the restoration of the p53 tumor suppressor activity has been well characterized, but how this inhibition affects the function of p53 gain-of-function mutants is unknown. Many mutant p53 proteins promote tumorigenesis through the gain-of-function mechanism[95]. The activity of such p53 mutants could be enhanced by targeting SMYD2 in a similar way as it does to wild-type p53, leading to unwanted outcomes and adverse effects. This is consistent with the evidence that SMYD2 is not always a poor prognostic marker for cancer patients, and the overexpression of SMYD2 has been shown to be a favorable prognostic marker for patients with renal cell tumors[45]. Nonetheless, given that the cancer-promoting role of SMYD2 has been confirmed in multiple types of cancers, it is worthwhile to continue to exploit SMYD2 as a drug target for cancer treatment, with more attention being paid to new inhibition strategies, such as targeting protein-protein interactions and targeting additional functional sites that are less conserved but have substrate-specific functions.

CONCLUSION

In the past few decades, there have been huge improvements in our understanding of the complex molecular nature of pancreatic cancer and progress in the available therapy options, including surgery, chemotherapy, radiotherapy, immunotherapy, and targeted therapies. Although these therapy options have resulted in a slight improvement in the overall 5-year survival rate of patients, pancreatic cancer remains a difficult disease to treat. SMYD2 could be a promising target for the development of a novel PDAC therapy, given its involvement in diverse oncogenic signaling pathways to control multiple cellular processes like cell proliferation, apoptosis, and energy metabolism (Figure 2). SMYD2 is overexpressed in PDAC and serves as an important regulatory molecule through the interplay with the RTK/Ras signaling pathway and the PI3K-AKT signaling pathway to drive PDAC cell growth and metastasis. The projected role of SMYD2 in repressing the activity of the tumor suppressors p53 and PTEN in PDAC development further implies that SMYD2 is a key player in promoting the cell cycle, cell growth, and cell survival. Therefore, targeting SMYD2 could be a powerful strategy for the prevention and treatment of PDAC, in particular with consideration of tumor subtypes and genetic backgrounds.

Abstract

Mastocytosis is a rare and heterogeneous disease characterized by various clinical and biological features that affect different prognoses and treatments. The disease is usually divided into 2 principal categories: cutaneous and systemic disease (SM). Clinical features can be related to mast cell (MC) mediator release or pathological MC infiltration. SM is a disease often hard to identify, and the diagnosis is based on clinical, biological, histological, and molecular criteria with different specialists involved in the patient's clinical work-up. Among all manifestations of the disease, gastrointestinal (GI) symptoms are common, being present in 14%-85% of patients, and can significantly impair the quality of life. Here we review the data regarding GI involvement in SM, in terms of clinical presentations, histological and endoscopic features, the pathogenesis of GI symptoms, and their treatment.

Key Words: Systemic mastocytosis; Gastrointestinal involvement; Gastrointestinal symptoms

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Gastrointestinal (GI) involvement is frequent in systemic disease (SM); GI symptoms are frequent (second in frequency only to itching), being the main culprits of chronic disorders, and are a major determinant of quality of life. GI symptoms could be secondary both to mast cell (MC) mediator release and MC infiltration in the GI tract, causing organ dysfunction. Diagnosis of GI involvement in SM is based on clinical and endoscopic suspicion and histologic demonstration of MC infiltration in GI mucosa, using immunohistochemistry (*i.e.,* CD117, tryptase, CD25). Symptomatic treatment is used to control mediators-release symptoms while cytoreductive therapies are necessary to reduce organ dysfunction secondary to MC infiltration and proliferation.

INTRODUCTION

Mastocytosis is a rare type of myeloid neoplasm characterized by clonal expansion and accumulation of morphologically and immune-phenotypically abnormal mast cells (MCs) in one or more organ systems [1]. Clinical presentation in mastocytosis patients is heterogeneous[1,2]. Cutaneous mastocytosis (CM) is the skin-limited presentation; it is most common in children, who experience spontaneous regression of skin lesions during their growth. Systemic mastocytosis (SM) is, on the contrary, a condition of MCs proliferation associated with extra-cutaneous involvement, and it is more frequent in adult patients. Neoplastic MCs form focal and/or diffuse infiltrates in various internal organs, including the bone marrow (BM), spleen, liver, and gastrointestinal (GI) tract[2-4]. Regardless of the type of SM, the BM is involved in virtually all patients.

In 2016, the World Health Organization (WHO) classification of SM identified 5 clinical variants with different prognoses: indolent SM (ISM), smoldering SM (SSM), aggressive SM (ASM), SM with associated hematological neoplasm (SM-AHN), and mast cell leukemia (MCL)[5,6]. Advanced SM (ASM, SM-AHN, and MCL) is generally associated with a poor outcome, whereas ISM patients usually have a comparable life expectancy in comparison with the general population[1,2].

In recent years, knowledge of the pathophysiology of mastocytosis has improved. Particularly, research has found that a recurrent activating D816V KIT mutation, located in the phosphor-transferase domain (PTD) of the receptor, is detectable in more than 80% of adult patients with SM[7,8]. Further genetic alterations, usually involved in myeloid malignances pathogenesis, are often found in advanced forms of SM. These mutations are associated with aggressive disease and poor prognosis[9].

For many years, mastocytosis has been considered an orphan disease, and this might be an explanation for the difficulty in estimating its prevalence. The reported prevalence of SM of 9.56 per 100000 persons[10] is probably underestimated; in the last few years, improved knowledge of the disease and availability of diagnostic tests suggested a higher prevalence, with the newer prevalence reported to be 21 per 100000 inhabitants in the adult population[11].

Mastocytosis diagnosis is based on the identification of atypical MCs in the affected tissue, according to the well-established WHO criteria, based on morphological, histological, cytofluorimetric, and molecular features[5,6] (Table 1). When the major and at least one minor SM criterion or three minor SM criteria are detected, the diagnosis SM is established. SM patients can be further sub-classified depending on the presence of B (organ involvement without organ failure) or C (organ involvement with organ dysfunction) findings, defining MCs burden or disease aggressiveness, respectively[1,5,6] (Table 2).

The severity of the symptoms associated with mastocytosis may vary from mild to life-threatening [2]. In general, symptoms occurring in SM are mainly due to the release of chemical mediators from the MCs, such as histamine, heparin, and eosinophil chemotactic factor, and thus produce symptoms associated with an allergic reaction, although a true allergic trigger may not be identified. In ASM, where MCs infiltration occurs, a decrease in blood cells (cytopenia), break-down of bones (osteolysis), swelling of the lymph nodes (lymphadenopathy), swelling of the liver (hepatomegaly), impaired liver function, ascites or portal hypertension, and malabsorption may occur[1,12,13].

Symptom-directed treatment should be considered in all SM patients[2]. Supportive therapies for SM are directed at MC's degranulation symptoms [histamine-receptors 1 (H1) and 2 (H2) antagonists, proton pump inhibitors (PPI), leukotriene antagonist, sodium cromolyn, corticosteroid], symptomatic skin disease (Psolaren plus ultraviolet A photo-chemotherapy, corticosteroids), and/or osteopenia/osteoporosis/pathologic fractures (bisphosphonate, cytokine/ immunomodulatory drugs) [2,14,15]. Treatment goals for ISM patients are primarily directed towards anaphylaxis prevention and

Table 1 Systemic mastocytosis criteria according to World Health Organization 2016

Major SM criterion	Multifocal dense infiltrates of MCs (≥ 15 MCs in aggregates) in BM biopsies and/or in sections of other extracutaneous organ(s)
Minor SM criteria	(a) > 25% of all MCs are atypical cells (type I or type II) on BM smears or are spindle-shaped in MC infiltrates detected on sections of visceral organs
	(b) KIT point mutation at codon 816 in the BM or another extracutaneous organ
	(c) MCs in BM or blood or another extracutaneous organ exhibit CD2 and/or CD25
	(d) Baseline serum tryptase level >20 ng/mL (in case of an unrelated myeloid neoplasm, item d is not valid as an SM criterion)

If at least 1 major and 1 minor or 3 minor systemic mastocytosis (SM) criteria are fulfilled, the diagnosis of SM can be established. BM: Bone marrow; MCs: Mast cells; SM: Systemic mastocytosis.

Table 2 B and C Findings in systemic mastocytosis

B and C Findings in systemic mastocytosis
B Findings
BM biopsy showing > 30% infiltration by MCs (focal, dense aggregates) and serum total tryptase level > 200 ng/mL
Myeloproliferation or signs of dysplasia in non-MC lineage(s), no prominent cytopenias; criteria for AHN not met
Hepatomegaly and/or splenomegaly on palpation without impairment of organ function and/or lymphadenopathy on palpation/imaging (> 2 cm)
C Findings[1]
Cytopenia(s): ANC < 1 × 10^9/L, Hb < 10 g/dL, or platelets < 100 × 10^9/L
Hepatomegaly on palpation with impairment of liver function, ascites, and/or portal hypertension
Skeletal lesions: Osteolyses and/or pathologic fractures
Palpable splenomegaly with hypersplenism
Malabsorption with weight loss from gastrointestinal tract MC infiltrates

[1]Must be attributable to the mast cell infiltrate. AHN: Associated hematological neoplasm; ANC: Absolute neutrophilic count; BM: Bone marrow; MCs: Mast cells.

symptom control/osteoporosis treatment. Patients with advanced SM frequently need MCs cytoreductive therapy to ameliorate disease-related organ dysfunction[2]. High response rates have been seen with small-molecules inhibitors that target mutant-KIT, including midostaurin (Food and Drug Administration and European Medicine Agency approved) or avapritinib (Food and Drug Administration approved)[2,16-19].

In this review, we sought to focus on clinical, pathophysiological, histological, and therapeutic aspects of GI tract involvement in SM.

GI CLINICAL MANIFESTATIONS OF SM

GI involvement in the clinical presentation of SM has been reported to vary from 15% to 85%. The wide range of variability is probably due to variable definitions of GI symptoms and differences in the attention on GI involvement in the case series available in the literature[20]. However, among all clinical manifestations, GI symptoms appear to be second in frequency only to itching[21] and are the main culprits of chronic disorders being a major determinant of quality of life (QoL)[20-22].

GI symptoms can be varied and may be independent of a clear GI involvement with mastocytes' infiltration[23]. In addition, GI manifestations may occur in the absence of typical cutaneous manifestations, with GI dysfunction being observed in both cutaneous mastocytosis and SM[24]. Although the gastro-enteric tract involvement has been described in all SM variants, both the frequency and the type of GI symptoms vary according to the SM subtype.

GI symptoms associated with SM are often non-specific and mimic common conditions, such as irritable bowel syndrome, inflammatory bowel disease, or celiac disease, with recurrent abdominal pain, nausea, vomiting, gastro-esophageal reflux disease, diarrhea, and bloating, until more severe pictures characterized by long-standing, persistent, and intractable diarrhea with malabsorption occurs[23]. Also, peptic ulcer disease represents a GI manifestation of SM, causing gastro-duodenal ulceration in up

to 50% of cases[25], with possible severe GI bleeding sustained by the large amount of histamine released by mast cells (Table 3).

PATHOPHYSIOLOGY OF GI INVOLVEMENT

From the pathophysiological point of view, these symptoms are caused by several mechanisms. Activation of MCs causes alteration in epithelial and neuromuscular function. MCs represent 2% of the cells present on the intestinal mucosa of the GI tract[26]: They are responsible for a series of regulatory functions concerning the barrier functions and vascular mucosal permeability, regulating the secretion of GI hormones, modulating peristalsis and the pain perception threshold, and regulating the endothelial barrier and chemotaxis of immune cells. They, therefore, intervene in the regulation of the inflammatory response and, as recently described, they drive the immune response by attracting both granulocytes and lymphocytes and triggering innate defense mechanisms, such as enhanced epithelial secretion, peristalsis, and alarm programs of the enteric nervous system[26,27].

Activated MCs release various inflammatory mediators, which determine intestinal motility alteration, visceral sensitivity alteration, and mucosal and epithelial gut barrier function alteration. Furthermore, MCs inflammatory mediators determine hypersecretion and increased motility, causing diarrhea and abdominal pain. In the more advanced and aggressive stages, there is a direct MC infiltration of the GI tract and the pathogenic mechanisms change. The GI tract can be involved in any phase of SM and the pathophysiological mechanisms are different. As well as reported for other extra-hematological manifestations of SM, in the initial and indolent forms of SM, the gut is a target of mediators released by MCs and functional disorders are more expressed, with mediator-related functional diarrhea, abdominal pain, and motor dyspepsia.

Thereafter, with the massive and persistent mediators' release, organic lesions appear, such as peptic disease. The main mediator released by MCs is histamine which exerts different effects on both the upper and lower gastrointestinal tract. Histamine interacts with H2 receptors, promoting the secretion of hydrochloric acid, resulting in gastroesophageal reflux disease, gastritis, and peptic ulcer.

The peptic ulcer due to the increase in histamine-related acid secretion is a condition not rarely observed in SM, and it is largely underestimated: It is reported in up to 40% of patients with SM. It does not correlate with circulating markers, in particular with circulating histamine; therefore, it has to be hypothesized with a low threshold of suspicion and then investigated with gastroscopy. Moreover, peptic ulcer bleeding in MS is also reported in up to 11% of patients[25]. Histamine also interacts with the H1 receptors, regulating the gut smooth muscle contraction, causing impaired peristalsis and motility disorders, clinically resulting in the dysmotility-like dyspepsia and functional diarrhea observed in patients in the early stages of SM.

Besides the GI effects of histamine, other transmitters are released in the course of SM, including prostaglandins and serotonin, which have various effects, including effects mainly on the neuromuscular junction of the GI tract, with consequently impaired motility and visceral hypersensitivity. Again, patients present with nausea, vomiting, and abdominal pain worsened by the reduction of the pain threshold. In the course of mastocytosis, diarrhea is often associated with flushing. Therefore, is important to distinguish "wet flushing", associated with profuse sweating, and "dry flushing", without sweating (Table 3). In SM, dry flushing is observed, whereas "wet flushing" is more related to physiological or para-physiological causes.

In the more advanced and aggressive stages of MS, the manifestations are mainly related to the gut MC infiltration of the GI wall, which impairs both the barrier functions and the absorbing functions, and the pathogenic mechanisms of diarrhea change from a functional to organic diarrhea. As the disease progresses, the clinical picture evolves into malabsorption, progressive caloric-protein malnutrition, vitamin deficiency, deterioration of the patient's condition, worsening of osteoporosis (already present in these patients), and finally anasarca, due to a complete impaired gut absorption and barrier function.

Mast cell mediators-related GI abnormalities

The release of a great amount of histamine and other peptides contained in MC granules has been implicated in the pathogenesis of a variety of functional GI manifestations in SM, including diarrhea, bloating, nausea, vomiting, abdominal pain, peptic ulcer disease, and related GI bleeding.

A recent multicenter French study analyzing a cohort of 83 patients affected by SM has demonstrated that GI symptoms are more frequent in SM patients compared to matched healthy subjects. Moreover, SM is correlated with a significantly greater risk of developing peptic ulcer disease, especially duodenal ulcers[28]. Diarrhea, bloating and abdominal pain have been reported as the most frequent SM-associated GI disturbances in several studies[20,22,25,29].

Abdominal pain has been described in different case series with a wide range of frequency from 12% to 100%. Of note, Cherner and colleagues[25] identified two different types of abdominal pain. The majority of SM patients suffered from an abdominal pain of dyspeptic nature, defined as an epigastric pain responsive to antacids and histamine type 2 receptor antagonists and with a high incidence of peptic disease on upper gastrointestinal endoscopic examination. A minority of patients complained of

Table 3 Differential diagnosis between systemic mastocytosis and gastrointestinal diseases

Symptoms	Differential diagnosis
Chronic diarrhea	Irritable bowel syndrome; Inflammatory bowel disease; Celiac disease; Thyreopathies (*i.e.* hyperthyroidism, medullary thyroid cancer); Pancreatopathyes
Epigastric pain, dyspepsia, heartburn	Functional dyspepsia; Peptic ulcer; Gastroesophageal reflux disease; H. pylori related gastritis; Zollinger-Ellison Syndrome
Flushing	Neuroendocrine neoplasms
Hepato-splenomegaly, portal hypertension	Cirrhosis; Non cirrhotic portal hypertension

non-dyspeptic pain associated with bloating that does not benefit from histamine 2 receptor antagonists and antacids and was associated with normal endoscopic investigations. While the pathogenesis of the first pain type may be easily correlated to increased acid secretion, the non-dyspeptic pain type is more likely related to intestinal motility disturbances and a lower pain threshold caused not only by an increased release of histamine but also by other mediators, such as serotonin, prostaglandins, and neuropeptides.

Functional diarrhea has been reported in several series of SM patients with a range from 14% to 100%. The presence of diarrhea has been described as an episodic increase in bowel movements with subsequent emission of liquid stool that may or may not be associated with a fecal weight > 200 g/d [20]. It may be related to increased gastric acid secretion with mechanisms similar to Zollinger Ellison syndrome and/or to increased bowel motility induced by prostaglandin D2 secretion, as there is evidence of cases of diarrhea responsive to aspirin administration[30]. In contrast, the presence of steatorrhea has been correlated with a condition of malabsorption characteristic of advanced mastocytosis with extensive mucosal and submucosal infiltration with MCs.

Nausea and vomiting have been described less frequently and usually as components of syndromic disorders that also include palpitations, flushing, abdominal cramps, and diarrhea, generally exacerbated by the ingestion of certain substances, such as alcohol and medications, or contact with inflammatory mediators, which stimulate MCs degranulation. The absence of specific colonic symptoms does not mean that the colon or rectum are not involved. In particular, rectal manometric studies show a lower distention threshold to induce pain or rectal urgency; patients complain of reduced rectal compliance or overactive rectal contractility.

Peptic ulcer disease

One of the most common mediator-related clinical signs, which over time can generate organic lesions and GI organic damage, is related to gastric acid hypersecretion secondary to the hyper-histaminic state, which leads to dyspeptic pain and digestive ulcer disease.

A prospective study shows that peptic ulcers in SM are common, present in up to 50% of patients [25]. It is usually symptomatic and associated with gastric acid hypersecretion and elevated basal acid output (BAO)[31]. In some patients, BAO can reach the Zollinger-Ellison range, so that may even cause the signs and symptoms of the syndrome itself[20]. Of interest, a particular form of CM, the so-called *telangiectasia macularis eruptiva perstans*, also known as paucicellular mastocytosis, has been associated with peptic giant gastro-duodenal ulcers[32]. Other acid-related complications have been reported, such as ulcer perforation and severe esophagitis. Moreover, up to 11% of SM-affected patients will manifest peptic ulcer bleeding during the disease course. However, so far there has been no evidence of a consistent relationship between the level of serum histamine and the presence of ulcer disease or gastric acid output. However, despite the increased circulating histamine level, many patients have normal acid secretion and in some cases, even achlorhydria has been observed[31]. The variability in the response to circulating histamine may relate to partial inactivity of circulating histamine, differences between circulating histamine and gastric tissue histamine, and the intervention of unknown cofactors in the stimulation of oxyntic cells, as well as the theory of possible desensitization of parietal cells that can justify the rare cases of complete achlorhydria[20].

Mast cell infiltration-related GI abnormalities

In patients with advanced SM, the B and C findings (Table 2) become prevalent to functional GI symptoms. B GI findings indicate organ involvement without organ dysfunction, while C GI-findings refer to the advanced stage where both organ infiltration and dysfunction coexist, being associated with a poor prognosis[6]. They include malabsorption, weight loss, and organomegaly (spleen, liver) until full-blown organ dysfunction leads to hepatic failure and ascites.

Malabsorption based on quantitative stool fat analysis, D-xylose, and Schilling tests has been found to occur in one-third of SM patients and is usually mild[32]. Thus, it is important to consider mastocytosis in the diagnostic work-up of chronic and intractable diarrhea, especially when the endoscopic presentation seems to be suggestive. Both the small and the large intestine can undergo permanent

alterations, which contribute to the genesis of diarrhea and malabsorption. Over time, patients could develop real intestinal malabsorption syndrome with vitamins A and D deficiency, overt osteomalacia and osteoporosis, protein-energy malnutrition, and anasarca. The whole gastrointestinal tract may be involved in SM with varying degrees.

Liver involvement in SM can range from an abnormal liver function test alone to hepatomegaly due to MC and eosinophil infiltrates in portal triads. Initial fibrosis can evolve in cirrhosis with worsening portal hypertension sustained by simultaneous splenomegaly, with or without hypersplenism, and ultimately ascites and upper digestive bleeding from esophageal varices. Of note, mastocytosis is one of the causes of non-cirrhotic portal hypertension[33], sustained by pre-sinusoidal and sinusoidal mechanisms through the infiltration of inflammatory mast cells within the portal vein and obstruction of the sinusoids[34]. In this setting, we can also observe vascular alterations, like portal hypertension, veno-occlusive disease (8%), and Budd-Chiari syndrome.

No studies have identified how many patients with SM develop portal hypertension, but in real medical practice, clinicians have to keep in mind that it can occur without associated advanced liver disease, further increasing the risk of upper GI bleeding. A study of 24 cases of SM involving the GI tract found only 3 patients with liver involvement; however, liver involvement correlates with more aggressive disease[23]. Moreover, as liver failure occurs, it contributes to worsening malnutrition and hypoalbuminemia that are already determined by intestinal insufficiency.

ENDOSCOPIC FINDINGS IN SM

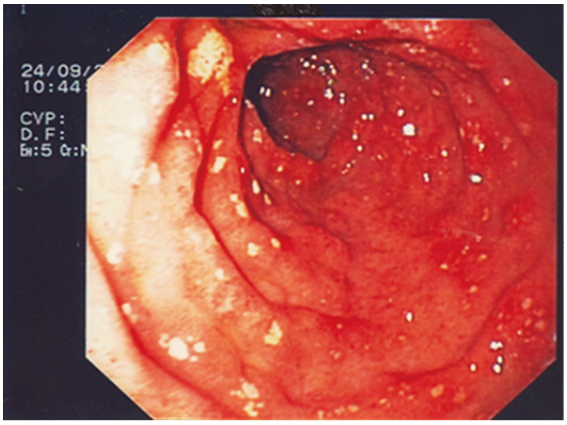
Even though no remarkable endoscopic findings could be found[4], there are several endoscopic pictures described in SM, and endoscopic findings could be secondary both to MC mediator release and to MC infiltration in the GI wall or liver.

Upper gastrointestinal endoscopy

At upper GI endoscopy, peptic disease (esophagitis, esophageal strictures, peptic ulcer) is one of the most frequent findings in patients with SM[21].

According to the literature, upper GI involvement could be found in up to 40% of SM patients undergoing endoscopy[25] and may be sustained by chlorhydric acid hypersecretion. However, its pathogenesis is still uncertain: Peptic disease is thought to be secondary to gastric acid hypersecretion sustained by elevated histamine plasma levels, but data from literature are controversial: Hypersecretion-n of gastric acid does not seem to be consistently related to the level of serum histamine levels measured. It may, however, be possible that a relationship between tissue concentration of histamine and GI manifestations can exist[25].

While esophagitis and, when untreated, esophageal strictures are thought to be secondary to mediator release, esophageal varices could be accounted for SM endoscopic findings when liver infiltration is present; this infiltration determines intrahepatic portal hypertension with esophageal and gastric varices development[33-35].



Exploration of the stomach and duodenum could show urticaria-like lesions in the antrum of the stomach, diffuse telangiectasia, multiple erosions of gastric and/or duodenal mucosa (Figure 1) and peptic ulcer; these findings are thought to be secondary to MCs mediators' release (*i.e.*, histamine, serotonin, prostaglandins, and neurotensin). When atypical mastocyte infiltration occurs, nodular mucosal lesion of the stomach and/or duodenum can be found[21,36,37].

Small bowel endoscopy and colonoscopy

Small bowel, as well as other digestive tract components, could be involved by SM. From the review of literature, the most common findings during small bowel exploration are diffuse telangiectasia, thickened jejunal folds, scalloped folds, and diffuse nodularity[21,36]. As for the upper GI tract, diffuse telangiectasia and thickened jejunal folds are thought to be secondary to MC mediator release, while scalloped folds and diffuse nodularity are thought to be secondary to MC infiltration in the GI wall[21].

Colonoscopy in patients with SM can reveal diffuse telangiectasia and/or urticarial lesion, patchy mucosal erythema, as well as mucosal edema, mucosal friability, loss of vascular patterns, and diffuse nodularity. Moreover, adding indigo carmine dye spraying could be useful to enhance yellowish-white polypoid lesions and yellowish-white nodular or granular mucosal lesions[36,38,39].

As for the other GI tracts, mucosal erythema and edema, mucosal friability are thought to be secondary to MC mediator release, while loss of vascular patterns and nodular and /or polypoid lesions are thought to be secondary to MCs infiltration into the bowel wall[21]. Unfortunately, none of these endoscopic signs is specific for GI involvement of SM; hence, biopsy specimens of the GI wall should always be performed in order to have histological diagnostic confirmation of GI involvement.

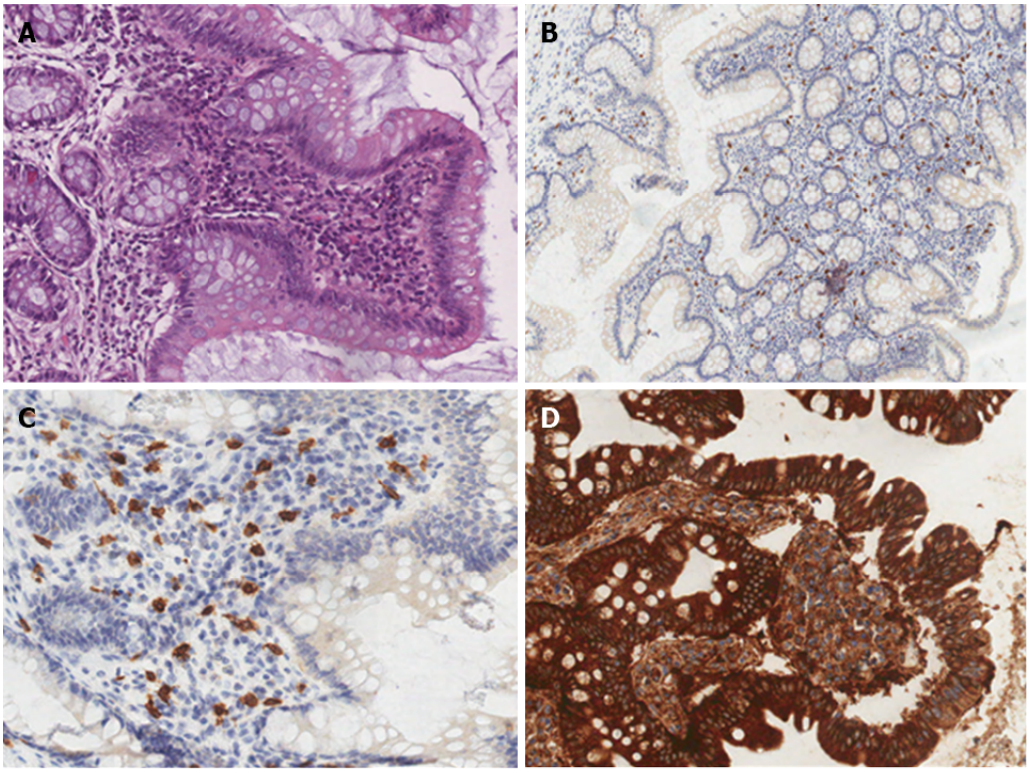
Figure 1 Endoscopic pictures of second portion of the duodenum. The mucosa appears to be erythematous, hyperemic, and covered with diffuse erosions.

HISTOPATHOLOGICAL ASPECT IN SM

Mast cells (MCs) are unique granulated cells (approximately 20 μm) that are absent in peripheral blood. They develop *in situ* from CD34-positive or c-Kit– positive progenitor cells[40]. MCs are distributed throughout many tissues, including the gastrointestinal mucosa. They enable an immune function in response to a diversity of exogenous substances in the gut lumen[41].

Within the gut, two subpopulations can be distinguished: the mucosal reactive MCs, which may dramatically increase in response to immune stimuli and are dependent on T lymphocytes[42,43], and the submucosal MCs, which can act in the regulation of intestinal permeability, secretion, peristalsis, nociception, immunity, and angiogenesis[44]. The histologic appearances of the GI mucosa in SM patients are incompletely described[45]. Results of mucosal mast cell quantitation have similarly been mixed with some studies reporting increased, decreased, and normal numbers of mucosal mast cells in patients with SM compared with controls[46].

The mean normal value of MCs count in normal GI mucosa is yet to be validated in large patient cohorts; most studies consider a cutoff of 20 MCs per high-power field within the lamina propria, this value being 2 standard deviations above that found in the general population[47,48]. As MC infiltrate can be focal and mild, the diagnosis of mastocytosis in GI mucosal biopsies can be challenging; hence, multiple biopsies are necessary in order to improve diagnostic yield[28].



In almost all cases of SM involving the GI tract, the number of intramucosal MCs is substantially increased[23], and MCs group together forming pathognomonic compact micronodular or band-like infiltrate. Tiny clusters of cells, with a predominant sub-epithelial distribution, appear in different shapes, varying from rounded cells with a moderate amount of pale and eosinophilic cytoplasm to ovoid and spindle-shaped cells with scant cytoplasm. Those diagnostic infiltrates may be small but should consist at least of 15 clusterings[23].

Hematoxylin and eosin staining are not a definitive method for MCs detection, hence special staining is required, such as toluidine blue staining and immuno-histo-chemical panels using tryptase, CD117, and CD25[49]. Comparison between these techniques confirmed a stem cell factor receptor kit (testing for c-kit and CD117) is the most accurate technique[50]. CD117 is expressed on all types of MCs independent off maturation and activation status; in SM, c-Kit is often expressed in MCs in a mutated and constitutively activated form. In these patients, MCs aberrantly display CD25, a diagnostic marker of neoplastic MCs in all SM variants[51]. Therefore, CD117 is sensitive, but not specific for MCs; tryptase is less sensitive but more specific. Both CD117 and tryptase are not diagnostic of the neoplastic nature, whereas CD25 expression is considered a hallmark of MCs atypia[4] (Figure 2).

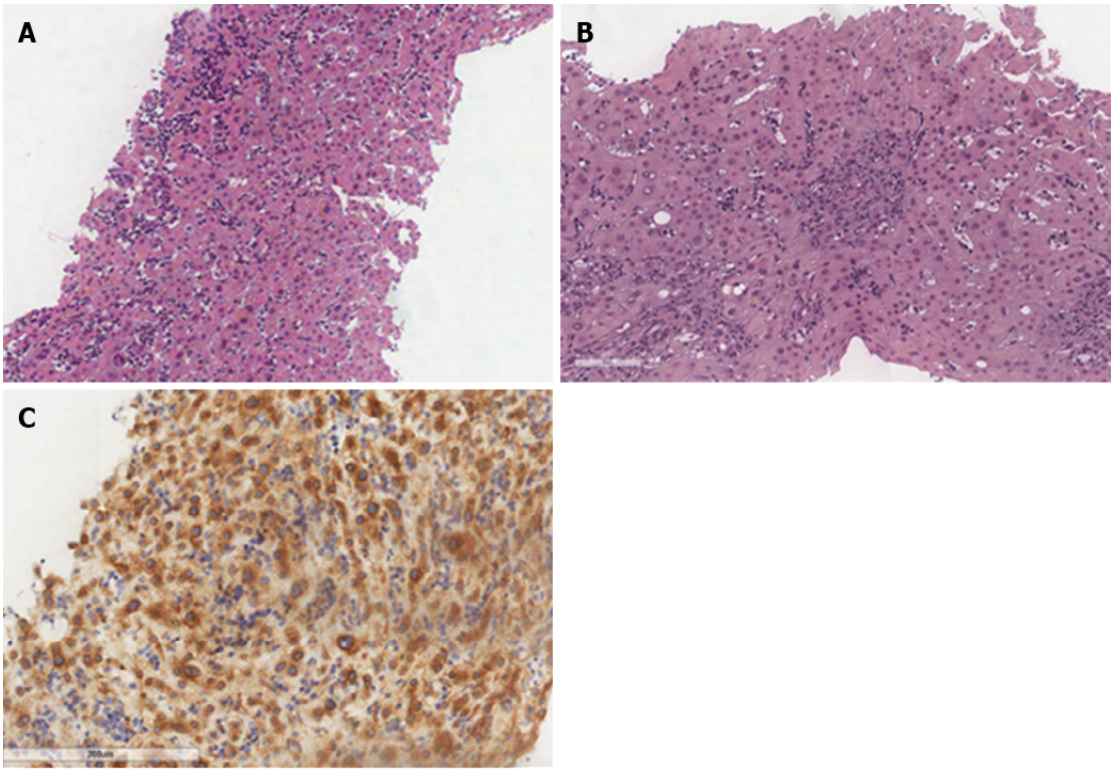
SM may involve other GI organs like the liver. The main site of liver involvement is the portal tract, where MCs may form groups of dense infiltrates within the fibrotic portal triads; because MCs are normally absent in the sinusoid, the presence of scattered MCs in liver sinusoids is also consistent with SM (Figure 3).

TREATMENT OF GI SYMPTOMS

Symptom-directed treatments should be considered in all SM patients and are directed at MC degranulation symptoms (*i.e.* nausea, vomiting, abdominal pain, peptic disease, diarrhea)[2].

DOI: 10.3748/wjg.v28.i29.3767 **Copyright** ©The Author(s) 2022.

Figure 2 Spectrum of histologic findings in patients with intestinal involvement of systemic mastocytosis. A: A mild initial finding with mast cells arranged in sheets and micro aggregates (hematoxylin-eosin, × 10). A heavy eosinophil infiltrate frequently dominates the picture. Crypt architectural distortion, without any other evidence of inflammatory bowel disease. Scattered lymphocytes and plasma cells often accompanied the mast cell and eosinophil infiltrates; B-C: The mast cells show expression of c-kit (B; CD117, × 2) and tryptase (C; × 10); D: CD25 positive cells in a clearcut and spread duodenal mastocytosis (CD25, × 10).



As first step, patients must recognize and avoid general and specific individual factors that trigger symptoms. These can commonly include physical factors such as heat, temperature changes, some forms of exercise, emotions, stress, sleep deprivation; diagnostic and therapeutic agents (such as opiates, NSAIDs, succinylcholine, and agents with tetrahydroisoquinoline, atracuronium, rocuronium, and quinolones), foods, alcohol and Hymenoptera venoms[52].

Different symptomatic drugs have been proposed for the control of GI symptoms: H2- antagonists (*i.e.*, Famotidine 10 mg BID, Cimetidine 400 mg BID) are the first-line therapy[2]. They act as inverse agonists that combine with and stabilize the inactive conformation of the histamine-receptor, shifting the equilibrium toward the inactive state; in a concentration-dependent manner, they inhibit MC activation and histamine release. However, although,the mechanisms involved have not yet been delineated fully, downregulation of intracellular calcium ion accumulation seems to play a role[53]. Inactivation of histamine receptors reduces the histamine effect along the GI tract, hence reducing histamine-related symptoms (*i.e.*, diarrhea, abdominal pain, peptic disease).

When histamine-receptor blockers are poorly effective or ineffective, proton pump inhibitors (PPIs, *i.e.*, Omeprazole 20 mg/d, Rabeprazole 20 mg/d, Pantoprazole 40 mg/d) represent second-line therapy [2]. Hydrochloric acid is secreted by parietal cells in the oxyntic mucosa that lines the body and the fundus of the stomach as a response to different mediators (*i.e.*, histamine, gastrin, acetylcholine), that activate H+/K+ ATP-ase (*i.e.*, the proton pump) that pumps hydrogen ions (protons) into the lumen in exchange for potassium ions. PPIs block this final step in gastric acid secretion by blocking H+/K+ ATP-ase irreversibly. They are remarkably effective in the inhibition of gastric acid secretion[54]. Considering SM as a hypersecretory condition, it is clear that reducing hydrochloric acid secretion is beneficial in SM patients because it reduces peptic symptoms, peptic disease, and/or diarrhea.

Sodium cromolyn (100-200 mg QID 30 minutes before meals and bedtime) represents the third-line therapy when H-2 antagonists and PPIs are ineffective[2]. It works as an inhibitor of histamine release and cell membrane stabilizer: cromolyn sodium caused weak inhibition of histamine release. However, different studies have shown its action on other mediators involved in mast cells' degranulation by inhibiting prostaglandin D2 release and TNFα release from mast cells, hence reducing MC degranulation and mediator release[55]. Reducing mediator release should help reduce GI symptoms.

Pardanani[2] has proposed systemic corticosteroid (*i.e.* prednisone 0.5-1 mg/kg/d starting dose; taper as feasible based on response/tolerance), as the fourth line of therapy for GI symptoms resistant to previous symptomatic therapies. Corticosteroids are potent anti-inflammatory drugs widely used in the treatment of allergic and inflammatory diseases. They also showed an in-vitro inhibition of MCs

DOI: 10.3748/wjg.v28.i29.3767 **Copyright** ©The Author(s) 2022.

Figure 3 Frustules of hepatic parenchyma with substantially preserved structure, with trabeculae with 2-cell spinnerets with no significant steatosis, but focal balloon-like degeneration associated with biliary stasis phenomena. A: Biliary spaces with preserved ducts, with ductular regeneration and bilio-hepatocyte metaplasia (hematoxylin-eosin, × 4); B: Some phenomena of hepatitis with aggression of the biliary epithelium are observed (hematoxylin-eosin, × 20). Portal spaces enlarged due to the presence of mixed inflammatory infiltrates, mainly consisting of T lymphocytes (CD3 +) with initial fibrotic expansion and formation of porto-portal bridges; C: In this context, scattered CD117 +, tryptase + cells (× 20) referable to mast cells.

mediators' release. Systemic administration of corticosteroids has been used in patients with mastocytosis. While this treatment appears to improve control of some mediator-release symptoms, it has not been proven to reduce MC numbers significantly in patients with mastocytosis[56]. Of note, systemic corticosteroids have been useful in decreasing the malabsorption and ascites in some of these patients[57].

In advanced SM, treatments interfering with MC proliferation and survival are used[2]. GI symptoms secondary to organ infiltration could also benefit from cytoreductive therapies, such as 2-chlorodeoxy-adenosine (cladribine or 2-CdA) or interferon-alfa[58]. In young and otherwise healthy ASM patients, allo-SCT is the only option for a sustained response[59]. Promising effects have been seen with the use of targeted therapy on mutated-KIT, which occurs in most SM patients[2]. Midostaurin (PKC412) is the first kit-inhibitor recent approved by the United States Food and Drug Administration (FDA) and European Medicines Agency (EMA) for the treatment of Advanced SM[16,17]. It has *in vitro* activity against kinase domain KIT mutants (D816Y and D816V). In the global Phase 2 CPKC412D2201 trial[18], 116 patients with advanced SM were enrolled; patients were treated with PKC412 at 100 mg BID. The overall response rate (ORR) per conventional criteria was 60% with 45% having a major response and 15% having a partial response, but it is often not sustained. In particular, concerning GI involvement, reversal of organ damage was reflected by normalization of hypoalbuminemia (58%), improvement in liver function test abnormalities (44%-58%), and/or reversion of weight loss (25%). Patients reported improvement of disease-related symptoms with treatment. Therefore, the most common drug side effects (all grades/grades 3-4) were nausea (79%/6%), vomiting (66%/6%), diarrhea (54%/3%), and fatigue (28%/9%), in addition to hematological toxicity, in terms of grade 3-4 of neutropenia, anemia, and thrombocytopenia, occurring in 24%, 41%, and 29% of patients, respectively.

Avapritinib[19], a KIT and PDGFRA inhibitor, showed promising results; other medications potentially effective for SM patients are under investigation[2]. Further optimization of treatment with tyrosine-kinase inhibitors in order to improve patients' quality of life is still needed.

CONCLUSION

Mastocytosis is a rare and heterogeneous disease characterized by various biological and clinical

features with different prognosis and treatments. The disease is usually divided into 2 principal categories: CM and SM. Clinical features can be related to MCs mediators release or pathological MCs infiltration. The diagnosis of SM is based on clinical, biological, histological, and molecular criteria, according to WHO 2016 classification. A proper patient's workup requires a multidisciplinary approach including gastroenterologists, endoscopists, hematologists, and pathologists. Among all manifestations of the disease, GI symptoms are common, being present in 15%-85% of the patients and can significantly impair the quality of life. Here, we review the data regarding GI involvement in SM, in terms of clinical presentations, histological features, pathogenesis of GI symptoms and their treatment. The most frequent GI symptoms are abdominal pain, diarrhea, nausea, and vomiting. GI lesions may involve all the digestive tract, from the esophagus to the rectum. The histological diagnosis of GI involvement is difficult. The treatment of GI symptoms aims to prevent and limit MCs degranulation and/or its consequences and more rarely to control tumoral mast cells infiltration. The diagnosis of mastocytosis should be considered in the case of unexplained severe GI disorders.

Abstract

The liver is the site of synthesis of the majority of circulating proteins. Besides initial polypeptide synthesis, sophisticated machinery is involved in the further processing of proteins by removing parts of them and/or adding functional groups and small molecules tailoring the final molecule to suit its physiological purpose. Posttranslational modifications (PTMs) design a network of molecules with the common protein ancestor but with slightly or considerably varying activity/localization/purpose. PTMs can change under pathological conditions, giving rise to aberrant or overmodified proteins. Undesired changes in the structure of proteins most often accompany undesired changes in their function, such as reduced activity or the appearance of new effects. Proper protein processing is essential for the reactions in living beings and crucial for the overall quality control. Modifications that occur on proteins synthesized in the liver whose PTMs are cirrhosis-related are oxidation, nitration, glycosylation, acetylation, and ubiquitination. Some of them predominantly affect proteins that remain in liver cells, whereas others predominantly occur on proteins that leave the liver or originate from other tissues and perform their function in the circulation. Altered PTMs of certain proteins are potential candidates as biomarkers of liver-related diseases, including cirrhosis. This review will focus on PTMs on proteins whose structural changes in cirrhosis exert or are suspected to exert the most serious functional consequences.

Core Tip: Chronic liver diseases and cirrhosis are accompanied by various metabolic disorders, some of which affect proteins. Besides changes in the concentration, structural alterations of proteins occur, mostly at the level of posttranslational modifications (PTMs). Five frequent cirrhosis-related PTMs are oxidation, nitration, glycosylation, acetylation, and ubiquitination. Some are more specific for the circulating proteins, whereas others are more specific for liver tissue-residing proteins. PTMs influence folding, stability, half-life, aggregation, and function of proteins. Modified proteins with altered function contribute to further progression of liver pathology. An overview of cirrhosis-related alterations of PTMs of specific proteins is the topic of this article.

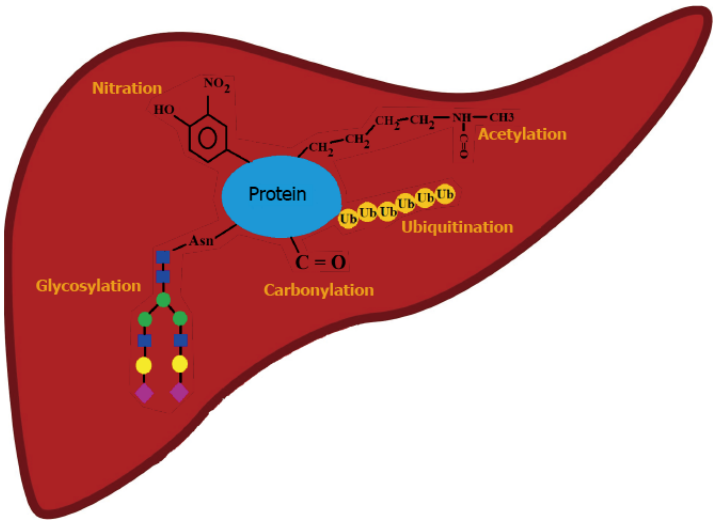
INTRODUCTION

Liver cirrhosis is an end-stage condition of chronic liver disease[1]. The speed of progression from chronic disease to cirrhosis depends on multiple factors. Cirrhosis may develop due to toxic, infectious, immunopathological, or vascular processes. Alcoholic fatty liver disease (AFLD) and non-AFLD (NAFLD), and hepatitis B- and hepatitis C-induced diseases are the most common causes of cirrhosis, with AFLD being the most frequent.

The liver is the site of synthesis of the majority of circulating proteins. Besides initial polypeptide synthesis, sophisticated machinery is involved in the further processing of proteins by removing parts of them and/or adding functional groups and small molecules tailoring the final molecule to suit its physiological purpose. Changes that occur after formation of the polypeptide chain are known as cotranslations and posttranslational modifications (PTMs). PTMs enlarge the genome coding capacity by several orders of magnitude, designing a network of molecules with the common protein ancestor but with slightly or considerably varying activity/Localization/purpose. According to review articles of Ramazi and Zahiri[2] and Khoury *et al*[3], more than 400 different PTMs have been discovered to date.

When talking about PTMs, one should bear in mind the dynamic nature of the protein structure, which can be seen, among other ways, in different modifications at different moments of the protein lifespan. Each modification is expected to suit or respond to certain (patho)physiological needs of an organism. Furthermore, one protein can have more than one type of PTM simultaneously and at several molecular sites. Multiple PTMs are highly dependent on conformational and steric factors. A vast number of PTMs on proteins have been experimentally detected, but in the era of computational omics and bioinformatics, the prediction of PTMs based on the structure of proteins is an additional tool in the investigation of PTMs and their consequences on protein function.



PTMs that occur under physiological conditions regulate the proper functioning of the organism. PTMs can, however, change under pathological conditions giving rise to aberrant or overmodified proteins. Undesired changes in protein structure most often accompany undesired changes in their function. Such modifications can reduce the initial activity of proteins or their lifespan with an overall outcome experienced as a decreased effect. Other modifications can, however, contribute to the appearance of new effects; these include misfolded proteins, previously unseen interactions, unusual molecular trafficking and localization, altered gene expression, creation of neoantigens, and stimulation of the immune system (which may lead to autoimmunity), protein aggregation followed by tissue deposition, prolonged half-life, impaired clearance and initiation of additional pathological processes. Thus, PTMs are essential for the reactions in living beings and crucial for the overall quality control.

Huang *et al*[4] reported more than 80 modification sites in proteins that were experimentally confirmed and named 24 major PTMs. Phosphorylation of the amino acid serine (Ser) is the most frequent modification, followed by phosphorylation of other amino acids, and then acetylation and ubiquitination. Lysine (Lys) is the amino acid that can be modified in the greatest number of different ways, resulting in as many as 15 types of altered species. Modifications that occur on proteins synthesized in the liver whose PTMs were found to be cirrhosis-related (Figure 1) are oxidation, nitration, glycosylation, acetylation, and ubiquitination[5-8].

MECHANISMS UNDERLYING PTMS IN CIRRHOSIS

Oxidation

Oxidative stress plays a major role in the development of liver pathology, regardless of etiology. The

liver, being a central organ of homeostasis, regulates metabolism, biosynthesis, and storage of carbohydrates, proteins, lipids, and vitamins. Due to such performances, it has intensive metabolic activity and is a site of a considerable free radical generation[9]. Any molecule possessing an unpaired electron is a free radical and is highly reactive. The most important free radicals produced by living organisms are reactive oxygen species (ROS) and reactive nitrogen species (RNS). Kupffer cells, neutrophils, and hepatocytes (mitochondria and cytochrome P450 enzymes) are involved in ROS generation during processes such as signal transduction, apoptosis, proliferation, growth, and defense against microorganisms[10]. Excessive quantities of ROS and RNS are toxic. They can induce tissue damage and are generally recognized as oxidative/nitrosative stress initiators. Cell type, intensity, and duration of the stress govern the outcome, which may be positive (beneficial) or negative (damaging). Some products of protein oxidation are chemically stable and present in large quantities, thus enabling their consideration as potential biomarkers of oxidative damage to be applied in clinical practice[11].

As mentioned before, cirrhosis usually occurs due to AFLD, NAFLD, and viral infection. The intersection point of all these conditions is oxidative stress. Alcohol in the case of AFLD, fatty acids in the case of NAFLD, and viral proteins in the case of hepatitis are the initiators of oxidative stress in these diseases. Different cellular compartments including mitochondria, cytoplasm, and endoplasmic reticulum are the sites of ROS production. Alterations in signaling pathways also play an important role in free radical induction. Detailed mechanisms underlining or assisting in oxidative stress generation in AFLD, NAFLD, and hepatitis B and C are reviewed in several papers[12-14]. Oxidation damages liver tissue by modifying proteins, DNA, and lipids. Once modified, these biomolecules gain altered structure, their function may be reduced to a different extent, their clearance rate may be increased or decreased, modified molecules may be involved in the activation of the immune system, or they alter signaling pathways contributing to further liver damage. Oxidative stress plays a role in both the initiation and progression of liver diseases[15].

Nitration

Nitric oxide (NO) is a signaling molecule that can be synthesized in either enzymatically or non-enzymatically driven reactions in many cells. NO itself is not very reactive and has a short half-life. However, highly reactive peroxynitrite ion (NO_3^-) may form in the reaction of NO with ROS. This ion can further react with tyrosine (Tyr) residues in a process called nitration, creating 3-nitroTyr[16], and with cysteine (Cys) residues in a reaction called S-nitrosylation, creating nitrosothiols[17]. Interaction with tryptophan (Trp) also occurs[18]. These nitration modifications affect not only proteins but also DNA and lipids. If not controlled, RNS may cause progressive damage to cells, tissues, and organs. Both ROS and RNS levels increase in liver diseases, as does the activity of inducible nitric oxide synthase. Mitochondria are particularly sensitive to nitro-oxidative damage since they have lower anti-oxidative capacity than the cytoplasm[19], rendering mitochondrial proteins and DNA vulnerable to nitration. Prolonged exposure of mitochondria to nitro-oxidation deteriorates their function, affecting both mitochondrial proteins and DNA[20-22].

When immunohistochemical detection of nitroproteins was performed in liver sections from patients with cirrhosis, a significant increase in nitrated proteins was observed[23]. Changes were more significant in patients with grade C (according to Child-Pugh classification) cirrhosis than in patients with grade A or B. A positive correlation was found between the level of nitrite and the level of nitroproteins with the progression of cirrhosis.

Glycosylation

Glycosylation is one of the major posttranslational modifications that affects most secretory proteins. This modification introduces a higher level of diversity in the protein population due to the covalent addition of specific sugar moieties. Glycosylation influences both structural and functional properties of proteins. The overall glycome is affected by genetic and environmental factors, and changes may suggest the presence of inflammatory or other pathological events in the organism[24]. Glycosylation is an enzymatically regulated process that depends on several glycosyltransferases and glycosidases. Many factors including the activity of enzymes involved, substrate availability, and localization of enzymes within organelles affect the final glycosylation pattern of the protein. Unlike the genome and proteome, glycome is produced without a template. In the O-glycosylation of proteins, glycan attachment occurs at amino acid residues Ser and threonine (Thr). N-glycosylation involves asparagine (Asn) residues but only in a specific sequence, Asn-X-Ser/Thr, where X represents any amino acid except proline[25].

Several liver diseases are accompanied by alterations in protein glycosylation: NAFLD, liver fibrosis, cirrhosis, and hepatocellular carcinoma (HCC)[7,26-28]. A number of common glycosylation changes were noted as a general pattern in liver diseases, regardless of the disease type. They include increased fucosylation (Fuc), increased branching, and an appearance of a bisecting N-acetylglucosamine (GlcNAc). Additional analyses of the responsible glycosyltransferases documented that their levels were altered, underlining the mechanism of detected changes[7]. When the overall N-glycan structure was examined in immunoglobulin (Ig)G-deprived sera from patients with cirrhosis, two general trends emerged: an increase in bisecting GlcNAc structures and a decrease in fully galactosylated (Gal) bi- and triantennary N-glycans. The ratios of certain glycans were suggested to serve as potential biomarkers of a specific stage of liver fibrosis or cirrhosis[27]. Data reported in that study confirmed the correlation between the detected glycan changes and the levels of the corresponding glycosyltransferases.

Acetylation

Acetylation is one of the key PTMs involved in the regulation of many proteins. It influences their stability, activity, localization, and interactions with other proteins. Metabolic pathways, including fatty acid metabolism and the Krebs cycle, are regulated by protein acetylation. This modification assumes the addition of an acetyl group from acetyl-coenzyme A on Lys residues[29]. Acetylation seems to play a significant role in liver diseases, as the pattern of protein acetylation in fatty liver is significantly different from the pattern in the healthy liver[30].

Ubiquitination

Ubiquitin and its related pathways are closely connected to chronic liver disease. Dysfunctional ubiquitination was detected in liver tissue in different stages of chronic liver disease. Ubiquitin is a protein that consists of 76 amino acids and has seven Lys and N-terminal methionine (Met) residues that can form *iso*-peptide-linked ubiquitin chains. It binds to substrates by a three-step enzymatic mechanism involving activating enzyme (E1), conjugating enzyme (E2) and ligase (E3)[31]. Receptors with ubiquitin-binding domains can recognize ubiquitinated substrates[32]. On the other hand, deubiquitinases remove ubiquitin from modified molecules, making this PTM a reversible, dynamic process with a plethora of diverse cellular effects[33]. Ubiquitinated proteins may be taken by proteasome which destroys them, thus controlling their lifespan and activity.

Some of the aforementioned PTMs predominantly affect proteins that remain in liver cells (ubiquitination, acetylation, and nitration), whereas others predominantly occur on proteins that leave the liver and exert their functions in the circulation (oxidation and glycosylation). Additionally, there are proteins not originating from the liver whose structure changes in cirrhosis. Some of these modifications have the potential to serve as biomarkers of liver-related diseases.

This review mostly focuses on PTMs on the circulating proteins originating from the liver whose structural changes in cirrhosis exert the most serious functional consequences. Modifications of Igs and liver tissue proteins will be also briefly mentioned.

PROTEINS FROM THE CIRCULATION AFFECTED BY SPECIFIC PTMS IN CIRRHOSIS

Fibrinogen

Fibrinogen is a large, fibrillar glycoprotein with a molecular mass of 340 kDa. This protein is involved both in primary (interaction with platelets) and secondary hemostasis (fibrin formation). N-glycosylation analysis using lectin microarray with 15 Lectins demonstrated that cirrhosis induces changes in its glycans[34]. Based on the interactions with lectins *Pholiota squarrosa* (PhoSL), *Maackia amurensis* lectin I (MAL-I), *Maackia amurensis* lectin II (MAL-II), *Galanthus nivalis* lectin (GNL), *Phaseolus vulgaris* leucoagglutinin (PHA-L), and *Phaseolus vulgaris* lectin E (PHA-E), an increased content of the following carbohydrate moieties was observed: terminal α-2,3 sialic acid (Sia) and α-1,3 mannose (Man), a disaccharide composed of Gal and N-acetyl galactosamine (Galβ-1,4GlcNAc) and tri/tetra-antennary

N-glucan structures. Core α-1,6 (Fuc) and bi-antennary galactosylated N-glycans with the bisecting GlcNAc were, on the other hand, reduced. An increase in the number of Sia residues on fibrinogen as a consequence of cirrhosis was confirmed by several researchers[35,36]. Sialic acid is negatively charged and is a weak binding site for calcium ions[37]. Taking into consideration that advanced chronic liver disease is characterized by hypercalcemia[38], interactions between calcium ions and an increased number of Sia residues may be seen as a modulator of fibrinogen action in cirrhosis[37]. "Proper" glycosylation of fibrinogen is essential for its function. Alterations in this PTM may even lead to complete dysfunction of the protein[39-42].

Increased oxidation of fibrinogen from patients with cirrhosis was detected as well[34,43]. Dinitrophenyl-hydrazide (DNP)-reactive sites on fibrinogen were investigated using anti-DNP antibodies to analyze protein carbonyls and it was discovered that the Aα-chain was dominantly carbonylated, followed by the Bβ-chain. It seems that the γ-chain of fibrinogen is not carbonylated in patients with cirrhosis. Carbonylation affects the function of fibrinogen[44-46], as both Aα- and Bβ-chains contain cleavage sites for thrombin action. Oxidation of αC domains on Aα-chains also affects their mutual interaction and lateral association of fibrin monomers[47]. Generally, residues that may be affected by oxidation/carbonylation are located in all structural elements of fibrinogen. Thus, alterations in the secondary and tertiary structures of fibrinogen also accompany cirrhosis[34]. Reduced content of its α-helical subunits was observed, which coincided with the formation of denser clots[46]. Although the structure of fibrinogen is altered in cirrhosis, Hugenholtz *et al*[43] did not detect significant structural changes in fibrin clots, even though clots formed from samples originating from patients with cirrhosis had reduced porosity. Subtle alterations, not visible by scanning electron microscopy, are most likely sufficient to influence porosity. Furthermore, carbonylated sites on fibrinogen are hydrophobic regions which prevent efficient liquid flow through the fibrin clot, increasing its resistance towards lysis by plasmin[36]. Overall, changes in fibrinogen structure due to cirrhosis are complex and lead to the formation of a molecule acquiring thrombogenic characteristics. Other factors that participate in coagulation or fibrinolysis are altered as well, defining a general pro-coagulant state in liver cirrhosis [48].

Albumin

Albumin is the major plasma protein, constituting approximately 50% of the total protein content. It is a globular, single-chain, α-helicoidal protein, organized into three domains. This protein exhibits many physiological roles, such as maintenance of osmotic pressure and transport of various metal ions and biomolecules (fatty acids, metabolites, and drugs), providing anti-oxidative, anti-inflammatory, and hemostatic activities[49].

Cirrhosis is accompanied by reduced albumin concentration and its significant structural changes [49]. Oxidation of free Cys-34 residue is one of the most notable changes in albumin structure due to cirrhosis. This residue strongly contributes to the anti-oxidative capacity of albumin. Oxidized albumin differs from the native molecule pharmacokinetically and conformationally, negatively influencing its function[50]. Quantities of albumin oxidative forms, assessed by measuring the level of carbonyl groups and oxidation of free Cys-34 residue, correlate with the severity of liver failure[51]. Oxidative stress triggers the dimerization of albumin molecules (through free Cys residues) in patients with cirrhosis, with significant reduction in native albumin required for the physiological functions[52]. Furthermore, matrix-assisted laser desorption/ionization time of flight (MALDI-TOF) mass spectrometry (MS) detects cysteinylation of Cys-34 in cirrhosis, followed by other molecular changes, such as truncation of N-terminal portion and glycosylation[53]. Oxidative stress also induces structural changes of the N-terminus and the reduced capacity of albumin to bind cobalt ions. Albumin modified in that way is called ischemia-modified albumin (IMA)[50]. The cobalt-binding assay revealed increased IMA levels in patients with advanced cirrhosis[54]. Additionally, the electron paramagnetic resonance study, using 16-doxyl stearic acid as a spin probe, confirmed that the ligand-binding capacity of albumin is significantly reduced in cirrhosis[55]. A small-angle X-ray scattering study demonstrated that albumin in patients with liver disease has an altered, more open conformation compared to control samples[56]. To summarize, posttranslational alternations of albumin in cirrhosis influence its conformation, which further decreases its ligand binding.

Therefore, reduced level of serum albumin in patients with cirrhosis, as well as its substantial structural change, have important and clinically relevant consequences, such as alterations in the redox balance, hemostatic disorders, modifications in the transport of endogenous and exogenous ligands, acid-base imbalance, reduced detoxification capacity, and antioxidant activity[49].

Transferrin

Human transferrin (Tf), an iron-binding protein, is a 76-kDa glycoprotein produced in the liver[57,58]. The Tf molecule contains two lobes at the N- and C-termini, and each binds one Fe^{3+} ion[58]. Tf is stabilized by 19 intrachain disulfide bonds and is modified by three carbohydrate side chains; two of them are N-linked (Asn-413 and Asn-611) and the third one is O-linked (Ser-32)[57]. The glycosylation profile of Tf changes significantly in liver diseases. A carbohydrate-deficient Tf (CDT) is found in AFLD, and it is characterized by a loss of terminal sialic acids[59]. Lectin affinity electrophoresis of CDT also confirmed the absence of Asn-linked oligosaccharides in AFLD and cirrhosis[60]. Both Tf and iron

uptake capacity of deglycosylated Tf are significantly reduced by the human hepatoma cell line PLC/PRF/5[61], suggesting impaired function of Tf in liver cirrhosis. A less advanced liver disease can be discriminated from cirrhosis by studying disialotransferrin isoforms. Poor chromatographic resolution of disialotransferrin from trisialotransferrin (the so-called "di-tri bridging") was seen for samples originating from patients with cirrhosis[62,63]. This abnormal pattern could be ascribed to the presence of higher mass disialotransferrin isoforms due to an increased branching and fucosylation of the carbohydrate moiety[64]. This phenomenon was not seen in less-advanced liver diseases[63].

Besides changes in the glycosylation profile, the lower concentration of Tf is also related to cirrhosis, and it represents a good indicator of the survival rate of patients[65]. Lower serum Tf concentration is accompanied by higher hepatic iron concentration and lipid peroxidation levels compared to healthy subjects. In this context, Tf exerts a protective role in maintaining liver function[66].

Hemopexin

Hemopexin (HPX) is secreted mainly by hepatocytes and binds free heme in the circulation. The formed complex is cleared from the circulation by a hepatocyte-specific membrane receptor. The serum concentration of HPX does not significantly vary in liver diseases[67]. However, significant alterations in the glycosylation profile of HPX occur in patients with cirrhosis. Lectin chemiluminescence-linked immunosorbent assay demonstrated a higher level of N-glycosylation (fucosylation) in samples from patients with cirrhosis and HCC than in samples from patients with hepatitis and healthy individuals [68]. A study using liquid chromatography-tandem MS with multiple reaction monitoring (LC-MS/MS MRM) assay revealed a nearly five-fold increase in the sialylation of site-specific Oglycoforms of HPX in cirrhosis[67]. Since HPX is an important anti-oxidative protein, its altered N-glycosylation in cirrhosis possibly interferes with the redox balance in organisms.

Haptoglobin

Haptoglobin (Hp) is a glycoprotein secreted by the liver into the plasma. Its major biological role is to capture released hemoglobin during intravascular hemolysis and prevent kidney damage by the released iron[69]. Hp is composed of two α and two β chains linked by disulfide bonds in a quaternary structure[70,71]. All four N-glycosylation sites are located in the β subunit and glycoforms are known to create additional phenotypic variants[69,72]. Many studies have reported glycan changes of Hp in diseases. MALDI-TOF MS analyses revealed N-linked glycan alterations (increased fucosylation) of serum Hp β chain in patients with cirrhosis[69,71]. Zhu *et al*[73] applied a similar approach to distinguish the N-glycan profile of Hp in patients with cirrhosis from those with hypophosphatasia. A degree of bifucosylation was higher in samples from patients with an early-stage HCC than in samples from patients with cirrhosis, regardless of the etiology. Thus, monitoring alterations in the glycosylation profile of the Hp β chain may become a valuable approach for detection and distinction between HCC and cirrhosis. The observed changes of Hp at the N-glycosylation level most likely affect its functional properties, including interactions with binding partners, as was suggested in the case of progressive liver diseases[69].

Ferritin

Ferritin plays an important role in storing intracellular iron and its segregation in a non-toxic form[74, 75]. It is a 24-mer globular protein that is made up of heavy (H) and light (L) subunits, with molecular masses of 21 kDa and 19 kDa, respectively[74]. Subunits surround the central hollow core, capable of binding up to 4500 iron ions[76]. Ferritin concentration in the circulation is relatively low (< 1 μg/mL) [74]. However, it is increased in conditions such as iron overload, infection, inflammation, malignancy, diabetes and liver diseases, including NAFLD and cirrhosis[77]. Besides changes in ferritin concentration, liver cirrhosis is also accompanied by the derangement of the ordered secondary structure of the protein[78].

Approximately 50%-80% of serum ferritin is glycosylated[79]. There is no strong evidence of the connection between ferritin glycosylation and cirrhosis. Some studies have reported a decrease in glycosylated ferritin in liver necrosis[79]. On the other hand, Chapman *et al*[80] demonstrated that the measurement of the fraction of glycosylated serum ferritin does not provide any advantage over the estimation of the total serum ferritin concentration in the assessment of iron stores in patients with liver cirrhosis.

Insulin-like growth factor binding protein 3

Insulin-like growth factors (IGFs), namely IGF-I and IGF-II, are peptides that exert growth-promoting, endocrine and cytokine effects[81,82]. They are synthesized in many tissues locally, but the liver is the origin of IGFs that enter the circulation. IGF-I is the mediator of the growth hormone (GH) action. The activity of IGFs is regulated by a network of insulin-like growth factor binding proteins (IGFBPs) and is most often inhibited when IGFs are in complexes with IGFBPs. To perform their physiological roles, IGFs need to be released from complexes and interact with IGF receptors, which are predominantly found on cell membranes. IGFs are liberated from complexes by the proteolysis of IGFBPs. The synthesis of several IGFBPs occurs in the liver, under the control of GH. IGFBP-3 is the major binding

protein in the circulation and is synthesized in Kupffer cells. It forms ternary complexes with IGFs, which also contain an acid-labile subunit. These complexes are large (150 kDa), remain within blood vessels, and bind 75%-90% of the circulating IGFs, serving both as a reservoir and a guardian of the IGF activity.

IGFBP-3 has three N-glycosylation and two phosphorylation sites[83,84]. It is present in the circulation as two major glycoforms of 40 kDa and 44 kDa, although a non-glycosylated form (29 kDa) can also be detected. Diethylaminoethyl ion-exchange chromatography was shown to fractionate at least 12 IGFBP-3 species that are isoforms with different charges due to PTMs[85]. Three of these isoforms exhibited significant reactivity with lectin concanavalin A (Con A), specific for Man residues and to a lesser extent for glucose (Glc) and GlcNAc residues. In patients with alcoholic liver cirrhosis, two of these glycoforms had an increased reactivity with Con A, whereas the third one had decreased reactivity, compared to molecules originating from healthy persons. Furthermore, some differences were also detected between different stages of liver cirrhosis. IGFBP-3 from patients with Child score A stage exhibited similar isoform distribution and reactivity as in healthy persons. Child score B seems to be the turning point in the progression of cirrhosis, after which considerable changes in the concentration of IGFBP-3 and its structure occur. A reduced reactivity of IGFBP-3 due to cirrhosis was also noted with wheat germ agglutinin, specific for GlcNAc, and breadfruit lectin, specific for Gal and GalNAc residues[86]. These alterations affect the conformation of IGFBP-3 and its susceptibility to proteolytic cleavage, thus influencing its half-life and the entire mechanism that controls IGFs' activity. Since IGFBP-3 can also perform IGF-independent roles after binding to its cell surface or nuclear receptors, changes in IGFBP-3 glycosylation can contribute to the pathophysiology of several diseases such as diabetes, obesity, NAFLD, and cancer[87,88].

Sex hormone-binding globulin

Sex hormone-binding globulin (SHBG) is a 90-kDa to 100-kDa homodimeric glycoprotein, mainly produced by the liver[89]. It is a transporter of sex hormones, capable of binding to them with high affinity[90]. SHBG is both N- and mucin-type O-glycosylated[90,91]. Comprehensive LC-MS/MS analysis revealed that fucosylation of N-glycoforms increases in liver cirrhosis. Additionally, the same pathology was related to an increase of the α-2−6 sialylated glycoform of the O-glycopeptide of SHBG [67]. Glycosylation of SHBG does not seem to influence binding of steroid hormones[92]. However, it is suspected that higher content of sialic acid increases the half-life of SHBG[93], elevating the total concentration of this protein in patients with cirrhosis[94]. An increased concentration of SHBG may influence the equilibrium between protein-bound and free, physiologically active steroid hormones, particularly testosterone. Consequently, SHBG seems to play an important role in the occurrence of feminization in male non-alcoholic liver cirrhosis by reducing free testosterone level[95]. On the other hand, higher concentrations of this protein were reported to possibly exert protection against NAFLD [96]. The exact effect of altered glycosylation of SHBG on is function is still not known.

IgG

Igs are principle components of the defense system known as immunity. Although Ig are not synthetized in the liver, their aberrant glycosylation has been linked to various liver diseases[97]. A study combining LC-MS/MS analysis with lectin fluorophore-linked immunosorbent assay identified changes in the glycosylation of anti-Gal IgG molecules in the sera of hepatitis C virus-infected individuals with fibrosis and cirrhosis[98]. The most prominent change was agalactosylation of heavy chains of anti-Gal IgG. The same study also revealed that truncation of Gal residues induced alterations in the tertiary structure of IgG molecules originating from patients with cirrhosis[98]. Yuan *et al*[97] confirmed agalactosylation of IgG molecules in cirrhosis and reported an increased degree of fucosylation in IgG1 and IgG3 glycoforms. Cirrhosis is also accompanied by Gal deficiency and decreased sialylation of IgA molecules, as well as by an increased amounts of abnormally glycosylated polymeric IgA molecules[99]. Furthermore, concentrations of IgG and IgA are increased in the circulation of patients with cirrhosis[97]. Altered glycosylation could influence the ability of IgG to bind and activate complement system. It was discovered that alpha-Gal IgG antibodies from patients with cirrhosis have reduced complement-mediated killing ability[100]. This issue is important since bacterial infection in one of the major complications in patients with cirrhosis and alpha-Gal epitope is abundantly synthetized by bacteria.

LIVER TISSUE PROTEINS AFFECTED BY SPECIFIC PTMS IN CIRRHOSIS

Proteins remaining in liver cells are mostly modified by ubiquitination, nitration and acetylation. Ubiquitination and associated processes play important roles in the development of cirrhosis affecting many proteins. E3 ubiquitin ligase promotes, for example, NF-E2-related factor 2 ubiquitination and degradation, disrupting the anti-oxidative pathway. The same ligase promotes the accumulation of extracellular matrix by inducing ubiquitination of procollagen1 to mature collagen1[101,102]. Sumoylation and neddylation, ubiquitin-like modifications, also play roles in liver cirrhosis. It was

discovered that *in vivo* reduction of neddylation ameliorates liver fibrosis[103]. Sumoylation affects, for example, promyelocytic leukemia protein and nuclear factor-kappa B (NF-kB)[104]. Modification of these proteins leads to cell proliferation and fibrosis in the liver. A detailed overview of ubiquitination and its implications in chronic liver disease is given in the 2021 review paper of Park *et al*[33].

Transcription factors, sterol regulatory element-binding transcription factor (SREBP), and carbohydrate-response element-binding protein (ChREBP) regulate fatty acid metabolism in the liver, promoting lipogenesis. These factors are active when acetylated. Sirtuins 1 and 3 (SIRT1 and SIRT3) are deacetylases that regulate their activity. High-fat diet and obesity reduce the expression of SIRT 1 and SIRT 3, thus promoting acetylation and activation of ChREBP and SREBP, followed by an increase in the uptake of fatty acids by the liver. Liver lipid load induces inflammation and the NF-kappa B pathway, and reduces mitophagy, altogether leading to mitochondrial and liver damage and advancement towards NAFLD. Calorie restriction and exercise upregulate SIRT1 and SIRT3, thus, preventing and ameliorating NAFLD[29]. ATP-citrate lyase, microtubules, heat shock protein 90 and CCAAT/enhancer binding protein α are differently modified by acetylation in different liver diseases preceding cirrhosis. Aberrant acetylation of the mentioned proteins leads to their functional alterations and subsequently different metabolic responses, further contributing to the liver pathology[105-108].

There are many hepatic proteins with confirmed nitration status in liver diseases, whose functions are either augmented or reduced[109]. Decreased function of glutamine synthetase, 3-ketoacyl-CoA thiolase, aldehyde dehydrogenase 2, complexes I and V of oxidative phosphorylation, cytochrome p450 2E1 and B6, superoxide dismutase 1 and 2, and cluster of differentiation 95 contribute to decreased energy production, ROS leakage, steatosis, decreased anti-oxidant defense capacity, ethanol- and drug-induced toxicity, apoptosis and necrosis. Nitration of glutathione-S-transferase, however, potentiates the function of this enzyme, leading to an increased hepatic anti-oxidative defense capacity[110].

CONCLUSION

Liver disease can progress from mild damage, over moderate with a certain degree of compensation, to severe, which cannot be compensated and may lead to organ failure. While still able to compensate for tissue damage, the liver produces scars of fibrotic tissue, which reduce its function. The persistent presence of agents and/or events that cause liver damage leads to decompensated cirrhosis, resulting in several pathological outcomes, including liver cancer, and finally, functional arrest.

Early diagnosis of chronic liver disease is critical since the etiology of the disease can be discovered in this stage. When cirrhosis progresses, the etiology of a disease is very hard to determine. Appropriate treatment administered on time can prevent and reverse the progression of cirrhosis which leads to irreversible changes. Avoiding or minimizing contributing harmful factors is recommended[1]. For example, persons with chronic liver disease should avoid alcohol intake and smoking[111]. On the other hand, consumption of coffee is associated with a slower progression of liver fibrosis[112]. There are no specific curative strategies targeting alterations in PTMs in cirrhosis.

Since oxidative stress is one of the causes involved in the etiology and development of liver diseases, supplementation of vitamins and minerals, which act as anti-oxidants and/or cofactors of enzymes and other molecules that participate in anti-oxidant defense, may be recommended. However, one should bear in mind that some substances are stored in the liver and may act as pro-disease agents[113]. For example, lipophilic vitamin A is stored in liver stellate cells. If overloaded with vitamin A, these cells start to produce collagen, leading to liver fibrosis. The beta-carotene form, however, causes no such effects and is safe to consume. Iron ions can induce oxidative stress by participation in the generation of free radicals. As already said, the liver is the site of iron storage, in association with the protein ferritin. Patients with alcoholic liver cirrhosis often have an increased intrahepatic iron concentration, which is highly correlated with mortality rates[114]. Thus, when considering management strategies to treat cirrhosis, one should have in mind the complexity and limitations of interconnected metabolic pathways.

Abstract

Chronic Hepatitis B is a highly prevalent disease worldwide and is estimated to cause more than 800000 annual deaths from complications such as cirrhosis and hepatocellular carcinoma (HCC). Although universal hepatitis B vaccination programs may have reduced the incidence and prevalence of chronic hepatitis B and related HCC, the disease still imposes a significant healthcare burden in many endemic regions such as Africa and the Asia-Pacific region. This is especially concerning given the global underdiagnosis of hepatitis B and the limited availability of vaccination, screening, and treatment in low-resource regions. Demographics including male gender, older age, ethnicity, and geographic location as well as low socioeconomic status are more heavily impacted by chronic hepatitis B and related HCC. Methods to mitigate this impact include increasing screening in high-risk groups according to national guidelines, increasing awareness and health literacy in vulnerable populations, and developing more robust vaccination programs in under-served regions.

Key Words: Hepatitis B; Epidemiology; Hepatocellular carcinoma; Socioeconomic status; Healthcare disparity; Hepatitis B vaccine

Core Tip: While many studies in the past have analyzed the impact of various epidemiological and socioeconomic factors on viral hepatitis and hepatocellular carcinoma (HCC), this minireview is the first to adopt a global perspective in highlighting the impact of both epidemiologic and socioeconomic factors on current trends in chronic hepatitis B and related HCC. We highlight trends in incidence, prevalence and mortality of chronic hepatitis B seen throughout the world in the past few decades and the disparity in healthcare distribution and outcomes between different populations.

INTRODUCTION

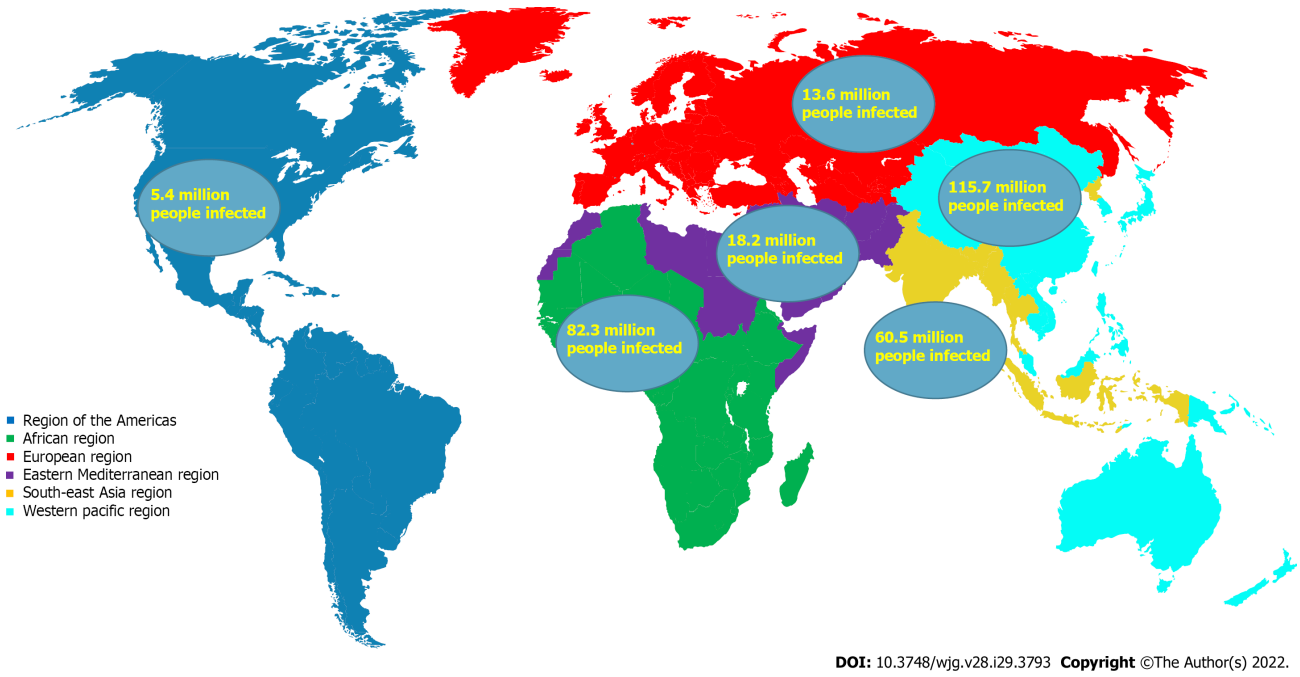
In 2019, the World Health Organization (WHO) estimated the worldwide prevalence of chronic hepatitis B virus (HBV) to be around 296 million with the incidence of new HBV infection to be 1.5 million each year. HBV is more prevalent with high burden of disease in the regions of Africa, Western Pacific and South-East Asia compared to North America and Europe. Furthermore, fewer people in the African and South-East Asian regions knew about their HBV status and had access to treatment compared to the latter regions[1].

Hepatocellular carcinoma (HCC) in unsuspected HBV patients is a major cause of increased morbidity and mortality in low-income countries with limited resources[2,3]. While it may be too early to see the true impact of the global HBV vaccination initiative led by the WHO or treatment efforts for HBV-related HCC, evidence thus far demonstrates decreased burden of HBV and HCC in children and suggests treatment with antivirals can reduce HCC risk in some patients[4-8]. There continues to be great disparity in access to vaccines, treatment, and screening programs worldwide, however. Even where there is access, the risk of HCC in treated chronic HBV is not fully mitigated[9,10]. While concomitant liver diseases are certainly at play including co-infection with hepatitis C, aflatoxin exposure, metabolic syndrome, and alcohol use disorder, chronic HBV-related HCC has a significant global disease burden that disproportionately impacts people of different regions and demographics[9,11]. The aim of this review is to examine the impact of epidemiologic and socioeconomic factors on chronic HBV-related HCC from a global perspective. Strategies to address the resulting disparities in disease outcomes will also be discussed.

DEMOGRAPHIC FACTORS

Geographic variations

There is significant global variation in the prevalence of chronic HBV between regions. As a result, the incidence and prevalence of HBV related HCC are also quite variable between regions and correlate with rate of HBV infection[12]. About 50%-80% of HCC can be linked to HBV worldwide, and the high-risk HCC regions represent 80% of the global burden of HCC[13]. Regions such as Africa, Southeast Asia, and the Western Pacific, are considered high-risk HCC regions owed partially due to high seroprevalence of chronic HBV which is estimated at 5%-10%. On the contrary, North America and Western Europe are low-risk HCC regions with an HBV prevalence of < 1%. The Middle East and the Indian subcontinent are intermediate-risk regions with HBV prevalence of 2%-5%[14]. Data illustrating the geographic distribution of chronic HBV by prevalence is seen in Table 1 and Figure 1.



Asia and Africa

Prevalence of HBV in Asia and Africa within high-risk regions is not uniform. In Africa, particularly West Africa and Sub-Saharan Africa, complications of chronic HBV including cirrhosis and HCC are frequent and fatal due to a relative lack of vaccination, surveillance and treatment[15]. Sub Saharan Africa had an estimated vaccination rate of less than 10% and fewer than 1% of HBV infections were diagnosed in 2019[9].

In East Asia, China has a high prevalence of HBV-related HCC, estimated to be 50% of the world's burden of HCC. Mongolia has the highest incidence rate of HCC in the world at 93.7 per 100000 with HBV being the predominant risk factor[9]. However, countries of low HCC incidence also exist in the Asia-Pacific region such as Japan, India, Singapore, and Pakistan. Interestingly, Japan has a low incidence of HBV where hepatitis C virus (HCV) is the major contributor of HCC, estimated to account for 80%-90% of cases[11,14,16].

Table 1 Geographic distribution of Chronic hepatitis B virus by estimated disease burden in 2019

Geographic region[22,40]	People living with hepatitis B infection
African region	82.3 million (62.1-114.7 million)
Region of the Americas	5.4 million (3.1-12.0 million) (2.1 million in Latin America and the Caribbean)
Eastern Mediterranean region	18.2 million (14.4-23.8 million)
European region	13.6 million (10.2-22.1 million)
South-East Asia region	60.5 million (45.3-120.9 million)
Western Pacific region	115.7 million (95.2-141.9 million)

Figure 1 Geographic distribution of chronic hepatitis B virus.

Data from Asian nations such as India, China, Thailand and Nepal show that there are evident disparities in HBV prevalence within population sub-groups[17,18]. Surveys of the Tibetan population in Nepal's Kathmandu valley showed prevalence of chronic HBV of 10%-20% compared to the overall prevalence of 0.9% in Nepal[18]. The general population of China has an estimated HBV prevalence of 6.89% while Western provinces have a higher prevalence at 8.92%[19]. The hill tribe of Chiang Rai province in Thailand see a significantly higher prevalence of chronic HBV at 26.6% while the overall prevalence in Thailand is 5.1%[17,20]. Although Southeast Asia as a region has a higher prevalence of HBV infection at 3.0%, there are variations in prevalence between ethnicities within the region. Given the relatively high prevalence rate of chronic HBV infection in Southeast Asia compared to Europe and the Americas, the incidence of liver cancer being highest in these regions is not surprising[11,21]. Some explanations for the disparities seen in the various regions and ethnic groups include unequal access to vaccines, limited health care programs, lack of health literacy, and elements of culture and religion that also serve a role[17,19,21].

United States

Immigration from endemic countries is the main contributor to chronic HBV cases in the United States, which has a prevalence rate of 0.5% compared to 3.8% globally[21]. An estimated 70% of HBV infections in the United States are among foreign-born individuals with an estimated 730000 to 2.2 million living with chronic HBV[22]. Screening studies of foreign-born immigrants from Africa, the Middle East, and Asia have shown a higher chronic HBV prevalence rate of 10%-15% compared to 0.27%-0.50% for the general population[11,12,23,24]. Chronic HBV infection is disproportionately higher amongst Asian Americans in the United States[25]. Asian Americans comprise roughly 5%-6% of the population in the United States but 50% of the cases of chronic HBV[22].

Studies have also shown ethnic variation in HBV-related HCC within the United States, owing to differing sizes of immigrant populations from endemic countries. While rates of HCC in Asian and Pacific Islanders, once elevated are now declining, the incidence of HCC in Hispanics, Whites and African Americans continues to increase, driven mainly by HCV and non-alcoholic steatohepatitis (NASH) related cirrhosis[7,23,26-28]. Southern and Western states have the highest incidence rates of HCC in the United States[28]. While Asian Americans have the lowest mortality rates from HCC of all ethnicities, the highest mortality rates are seen in African Americans[29,30]. This apparent disparity may be partially explained by the etiology of HCC which include alcohol use disorder and HCV related cirrhosis, as well as health care disparities and access to quality care among African Americans. Recent studies show a disparity even after liver transplantation in patients with HCC, with African Americans consistently having worse survival than Asian Americans and White American patients[31].

Europe

Western Europe, like the United States, has a growing diversity in its population. Most chronic HBV infections in Western European countries are due to migrant populations, with an HBV prevalence estimated to be around 4% for migrant populations and < 1% for the general population[23,27]. There is also a greater prevalence of cirrhosis and HCC in the foreign-born population[32]. A population-based study of HCC in England found a higher proportion of HCC in non-white ethnicities, particularly due to viral hepatitis-related HCC[33]. Similar findings are reported in studies of other low HCC risk countries such as Austria, Finland, Netherlands, Germany, the United Kingdom and Denmark in which migrant populations are over-represented in cases of chronic HBV and HCC[32,34].

Latin America

There is a reported heterogeneous distribution in chronic HBV prevalence amongst Latin American countries. Owed to variation in the endemicity of HBV and underreporting, some studies report an estimated 7-12 million people infected in Central and South America and the Caribbean[35]. In contrast, a report by the Pan American Health Organization and the WHO in 2016 suggested chronic HBV seroprevalence in Latin America being 0.33% with an estimated 2.1 million infected in the general population. However, the variation in HBV serum antigen (HBsAg) seroprevalence ranged from 0.20% to 13.55% among the numerous countries[36].

In the majority of Latin America, HCV and alcoholic liver disease are the leading causes of HCC. HBV is more endemic to certain countries such as Brazil, Argentina, and Peru.

Systematic reviews and retrospective studies have shown HBV-related HCC accounting for 12%-14% of HCC in South and Central America with the countries Peru and Brazil having 20%-60% of their HCC cases related to HBV infection[37-39].

Although Latin American countries are more varied in HBV prevalence and range from low to high prevalence, overall HCC risk and burden is similarly as low as the rest of the Americas in a global context[11,36].

Gender

Chronic HBV has a greater prevalence in males than females across all geographic regions[13]. Males also have a greater incidence, prevalence, and mortality from HCC than females across geographic location and age; studies have reported a 2 to 3 times increased risk of developing HCC in males compared to females[26,27,40,41].

Regions of higher chronic HBV prevalence such as sub-Saharan Africa and Southeast Asia, tend to also have a higher male to female ratio of HCC incidence. In the United States, both sexes have shown a trend of rising incidence rates of HCC since 1975, with HBV estimated to account for 10%-15% of HCC cases[42]. The gender disparity is not completely understood but is believed to be partially due to many overlapping risk factors that are more common in males, including alcoholism, diabetes, viral hepatitis, and tobacco use[43]. In the United States, heavy alcohol usage and tobacco use is much more common in males with both being independent risk factors for incidence of HCC[43,44]. In contrast, metabolic syndrome is more common in women, with one retrospective study reporting it accountable for 32% of HCC burden in the United States[27,44].

Despite controlling for other risk factors, male sex continues to remain an independent risk factor for HCC. Studies have linked higher testosterone levels to greater incidence of HCC in chronic HBV patients and estrogen replacement therapy to reduced risk of developing HCC[42,45,46]. Serum testosterone level has been associated with upregulated inflammatory activity while estrogen has shown to have an anti-inflammatory effect by inhibition of the NF-kB pathway[46-48]. Estrogen may be protective against development of HBV-related HCC through decreasing HBV RNA transcription which could explain higher viral loads seen in male carriers of HBV[12,47]. However, studies have failed to demonstrate a benefit in survival from hormonal therapy such as flutamide, an anti-androgen, and leuprorelin, a gonadotropin-releasing hormone agonist which has anti-androgen effects[48].

Age

The average age of chronic HBV patients has continued to increase over time. A study comparing

chronic HBV patients derived from an insurance claims database of Medicaid and Medicare patients found that the median age had risen from 44.1 to 50.2 years for Medicaid patients and 48.1 to 51.8 for Medicare patients[49]. This trend has also been seen in studies from other countries. A large territory-wide cohort study conducted in Hong Kong found the mean age for Chronic HBV had increased from 41 in 2000-2004 to 55 in 2014-2017[50]. Chronic HBV is now presenting at an older median age due to longer life expectancy, under diagnosis of HBV, under screening, and delayed treatment[21,51]. There is also improved vaccine-induced immunity in the 20-49 years age group which is predicted to cause a continual upward shift in the median age of diagnosis[49].

In populations at low risk for HBV infection, such as in Western Europe and the United States where HBV in not endemic, HCC is rarely seen before the fourth decade of life with a mean age of diagnosis around 65 years[12]. In contrast, endemic regions such as Southeast Asia and sub-Saharan Africa, where > 80% of HCC cases occur, have mean ages of diagnosis about one decade earlier[42]. China has a mean age of diagnosis of HCC around 55-59 years[12]. In countries in Sub-Saharan Africa, mean age of diagnosis of HCC is 35-50 years, and found to be almost 20 years later in those Black Africans who migrate from a rural to city setting[12,52].

With the advent of the HBV vaccine in 1981, and the universal vaccination programs that began in the 1990s, there was a new focus on vaccination of newborns. As of 2020, 190 WHO member countries vaccinated newborns as part of their routine vaccination schedules, and global coverage with all 3 doses of HBV vaccine was estimated to be 83%[53]. This campaign also included recommendations to vaccinate high-risk adult populations, adolescents who had missed immunization, and advocated for societal awareness of the risks and consequences of HBV[22]. Asian males who are HBV carriers continue to present with HCC at a relatively young age[54]. This may be related to viral factors such as genotype. Genotype B is more commonly seen in the Asian demographic and has been associated with onset of HCC in patients under 50 years of age, with one study from Taiwan finding that more than 90% under 35 years of age had genotype B HBV[47,55]. Genotype C is associated with the highest risk of developing HCC in patients aged > 50 years[56]. Genotype F has been seen in Alaskan Native populations to have the greatest risk of developing HCC at a lower median age, with the annual incidence rate amongst men at 387/100000 and 63/100000 for women[57]. In contrast, genotypes A, D are less frequently associated with development of HCC and more common in North American and European populations[58].

Socioeconomic status

Patients belonging to low socio-economic status are at significant disadvantage due to low health literacy, limited healthcare resources and access-including lack of insurance or ability to pay for care, especially for care of preventable diseases such as HBV. Hepatitis B is very infectious as it can be transmitted by contact with blood or bodily fluids, sexual intercourse and vertically from mother to baby. Vertical transmission is the most common mode of transmission in the developing world and can be dramatically reduced by HBV vaccination and use of anti-viral medications during third trimester [7]. Horizontal transmission seems to be more common in low prevalence regions[13,22]. While Hepatitis B viral load is considered one of the strongest predictors of HCC risk and can be managed with anti-viral medications, unfortunately, even in low-risk regions such as United States, roughly 3% of people currently living with chronic HBV are on treatment[14,21]. Several studies have shown the impact of socioeconomic status (SES) on health outcomes in cancer with populations of lower SES and less wealthy nations having significantly lower survival rates[32,59-61]. One retrospective analysis of European nations found nearly 20% variation in all-cancer relative survival between the least wealthy and most wealthy nations[61]. Similarly, low SES groups are associated with a variety of risk factors for poor outcomes in chronic HBV-related HCC. Despite 5-year survival rate for HCC in the United States increasing to 18% in 2019, the greatest benefits in survival and mortality are seen in groups with higher SES, while higher HCC incidence, later stage of diagnosis, and lower survival rates are seen in low-SES status groups[28,40]. Disadvantaged groups are typically minority ethnic groups such as African Americans and Hispanics as they tend to live in areas with the highest rates of family poverty, unemployment and high-school dropouts and thus may be associated with greater risk for HCC due to less access to screening and treatment[62].

Among patients with Medicaid insurance, the presence of comorbidities such as obesity, diabetes, alcohol, and tobacco use disorders combined with lower educational attainment contribute to liver disease such as alcoholic and NASH (ASH/NASH) and significantly overlap with liver disease from chronic HBV[63,64].

METHODS TO ADDRESS DISPARITIES

Targeted screening and prevention

Globally, chronic HBV and HCC cases are underdiagnosed. The 2016 Polaris Observatory study estimated that only 10% of infected people were diagnosed with HBV[51]. Chronic HBV infection is often asymptomatic and requires greater emphasis on screening, especially considering that HBV can

lead to HCC in patients without cirrhosis[13,42,65]. There is a geographic disparity in screening: About 2% of people with HBV knew their status in 2019 in Africa *vs* 22% in the Americas and 19% in the European region[21]. Additionally, there is likely underestimation of the true number of chronic HBV in the United States and other regions because high-risk populations have historically been under-represented in national surveys and surveillance studies, especially considering the large influx of yearly immigration to the US[24].

Early detection of tumors from screening in chronic HBV improves overall survival. A Randomized Controlled Trial study in Shanghai found that biannual screening in chronic HBV patients reduced HCC mortality by 37%[66]. An estimated 70% of liver cancer cases are preventable with risk factor modification and screening, thus judicious screening of high-risk populations with use of evidence-based guidelines can significantly reduce mortality from chronic HBV-related HCC[40]. The the American Association for the Study of Liver Diseases (AASLD) recommends HCC surveillance with ultrasound with or without AFP for all patients with diagnosed cirrhosis, and chronic HBV carriers who are high risk including African Americans older than 20 years, Asians older than 40 years, and those with family history of HCC. However, less than 1 in 5 high-risk patients are regularly screened[67]. Although greater than 90% of patients with acute HBV experience resolution of disease and the small minority develop chronic HBV infection, 40% of chronic HBV patients go on to develop cirrhosis, liver failure and HCC, and up to 25% of patients with chronic HBV end up dying from cirrhosis or HCC; thus HCC screening has been found cost-effective in patients with HBV even without cirrhosis when incidence of HCC is greater than 0.2% per year[67,68].

Health literacy

Lack of health literacy is particularly apparent in vulnerable and underserved populations such as immigrant populations, Mexican Americans, and African Americans, who already disproportionately bear the burden of chronic HBV and HCC[69,70]. Increasing social awareness of risk factors and protective factors of chronic HBV can be an avenue to improve health literacy. Social media is used by much of the developed world. For example, World Hepatitis Day is an annual health education campaign led by the WHO in July that heavily utilizes social media to make a call to action to bolster efforts in prevention, screening, treatment and to spread awareness of viral hepatitis[71]. Culturally sensitive approaches are necessary with an increasingly diverse population of the United States, to effectively communicate with various ethnic groups. One such example is "photo novels" developed to cater to specific cultures which have been shown to be effective in increasing HBV awareness and screening in underserved populations[72].

In many developing countries, such as those in Sub-Saharan Africa and the Asia-Pacific region where the majority of global chronic HBV and HCC cases occur, there is limited knowledge of hepatitis B and the benefits of the HBV vaccine[1,11,12,73]. Only two percent of the patients in African and Southeast Asian regions were aware of their chronic HBV status in 2019[1]. There is a dire need for informational campaigns in these endemic regions to increase awareness and health education amongst vulnerable populations in addition to the national immunization programs that must be initiated at the federal level with support from international health organizations.

CONCLUSION

Chronic HBV infection continues to have significant impact globally despite escalating vaccine coverage, screening techniques and availability of anti-viral medications. The close geographic relationship between endemic chronic HBV and increased burden of HCC remains to this day in Africa and the Asia-Pacific regions comprising the vast majority of HBV-related HCC in the world. HBV and HCC disproportionately affect certain ethnic groups within the United States and worldwide, many of which are of low SES. Men and the elderly are disproportionally affected at greater rates. To mitigate this largely preventable disease, enhanced access to screening, vaccinations, surveillance, and treatment must be achieved to reduce the burden of chronic HBV and HCC worldwide.

Abstract

Therapeutic endoscopic retrograde cholangiopancreatography (ERCP) begins with successful biliary cannulation. However, it is not always be successful. The failure of the initial ERCP is attributed to two main aspects: the papilla/biliary orifice is endoscopically accessible, or it is inaccessible. When the papilla/biliary orifice is accessible, bile duct cannulation failure can occur even with advanced cannulation techniques, including double guidewire techniques, transpancreatic sphincterotomy, needle-knife precut papillotomy, or fistulotomy. There is currently no consensus on the next steps of treatment in this setting. Therefore, this review aims to propose and discuss potential endoscopic options for patients who have failed ERCP due to difficult bile duct cannulation. These options include interval ERCP, percutaneous-transhepatic-endoscopic rendezvous procedures (PTE-RV), and endoscopic ultrasound-assisted rendezvous procedures (EUS-RV). The overall success rate for interval ERCP was 76.3% (68%-79% between studies), and the overall adverse event rate was 7.5% (0-15.9% between studies). The overall success rate for PTE-RV was 88.7% (80.4%-100% between studies), and the overall adverse event rate was 13.2% (4.9%-19.2% between studies). For EUS-RV, the overall success rate was 82%-86.1%, and the overall adverse event rate was 13%-15.6%. Because interval ERCP has an acceptably high success rate and lower adverse event rate and does not require additional expertise, facilities, or other specialists, it can be considered the first choice for salvage therapy. EUS-RV can also be considered if local experts are available. For patients in urgent need of biliary drainage, PTE-RV should be considered.

Key Words: Difficult biliary cannulation; Endoscopic ultrasound; Rendezvous; Endoscopic retrograde cholangiopancreatography; Percutaneous transhepatic biliary drainage; Interval

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Three endoscopic salvage therapies are available for endoscopic retrograde cholangiopancreatography (ERCP) cannulation failure, but consensus is lacking. This review found that interval ERCP had an overall success rate of 76.3% and an adverse event rate of 7.5%. Percutaneous-transhepatic-endoscopic rendezvous procedure (PTE-RV) had an overall success rate of 88.7% and an adverse event rate of 13.2%. Endoscopic ultrasound-assisted rendezvous procedures (EUS-RV) had an overall success rate of 82%-86.1% and an adverse event rate of 13%-15.6%. Interval ERCP may be preferred, but EUS-RV may also be considered if a local expert is available. PTE-RV is reserved for patients requiring urgent biliary drainage.

INTRODUCTION

Endoscopic retrograde cholangiopancreatography (ERCP) has become the treatment of choice for biliary tract diseases in recent decades. Selective biliary cannulation (SBC) is a critical step in the success of therapeutic ERCP; however, it is not always successful, even for experienced endoscopists[1]. The failure to achieve SBC during the initial ERCP can be attributed to two main aspects: an endoscopically inaccessible papilla/biliary orifice; and an endoscopically accessible papilla/biliary orifice but failed SBC with available cannulation methods. Management of initial ERCP failure constitutes a major clinical challenge for endoscopists. This review focuses on the endoscopic management of initial SBC failure in patients with an accessible papilla/biliary orifice.

When the major papilla is accessible, SBC typically begins with standard cannulation methods through a cannula or sphincterotome using either guidewire-assisted or contrast-guided techniques[2]. Using standard cannulation techniques, SBC fails in approximately 5% to 15% of cases[3]. This condition is often referred to as difficult biliary cannulation, although definitions have varied widely between endoscopists or studies[4,5]. In this case, depending on the experience or preference of the endoscopist, a variety of advanced techniques can be applied as a means of rescue. In general, when unintentional pancreatic guidewire insertion has been achieved, a double guidewire cannulation approach can be attempted[1]. Alternately or sequentially, transpancreatic sphincterotomy can be performed[6]. However, some endoscopists might prefer to perform needle-knife precut papillotomy (NKP) or needle-knife fistulotomy (NKF), especially after the placement of a pancreatic stent[2,7]. If the pancreatic duct is not cannulated, however, only NKP or NKF can be applied[4]. The application of these advanced technologies does not require additional facilities. Today, most qualified ERCP endoscopists can master at least some of these advanced cannulation techniques, so these procedures can often be performed by the same endoscopist during the same endoscopic session[8]. Despite these rescue techniques, failed biliary cannulation can occur[9]. Therefore, in this review, difficult biliary cannulation was defined as failure to achieve SBC using the advanced techniques described above[10,11]. In the setting of difficult bile duct cannulation, there is currently no consensus on the next steps in treatment[9]. Because endoscopic therapy has the advantage of a broader range of treatment options and no need for external drainage, this review aims to propose and discuss potential endoscopic options, alone or in combination with the percutaneous procedure, for patients who have failed initial ERCP due to difficult bile duct cannulation. These endoscopic options include interval ERCP, percutaneous-transhepatic-endoscopic rendezvous procedures (PTE-RV), and endoscopic ultrasound (EUS)-guided procedures. We also propose a potential treatment algorithm to provide practical advice.

INTERVAL ERCP

In a literature search in early 2022, we were only able to find 7 studies (371 patients in total) reporting interval ERCP[9,12-17]. All of these studies were retrospective. There were no review/meta-analysis articles on this topic. However, when SBC cannot be achieved by advanced cannulation techniques,

Table 1 Summary of studies on reporting interval endoscopic retrograde cholangiopancreatography

Ref.	Study design (patient number)	Percentage[1]	Median time interval[2] (range)	Pre-cut during interval ERCP	Technical success rate	Factors associated with success	Overall complication rate
Kevans *et al*[12] (2010)	Retrospective (*n* = 19)	53% (19/36)	6 d (1-21 d)	0%	68% (13/19)	NA	0

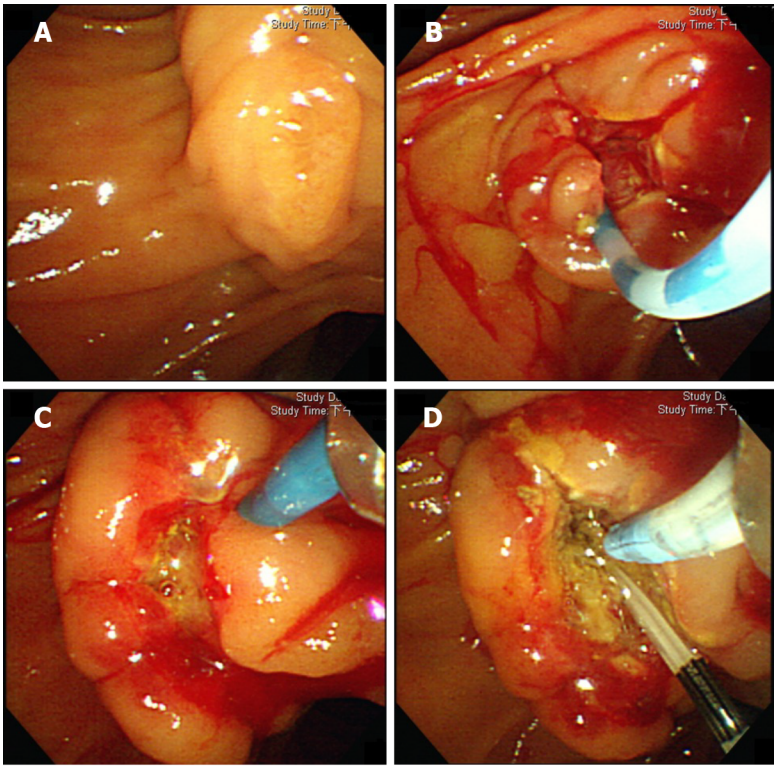
ERCP: Endoscopic retrograde cholangiopancreatography; NA: Not available; IQR: Interquartile range.

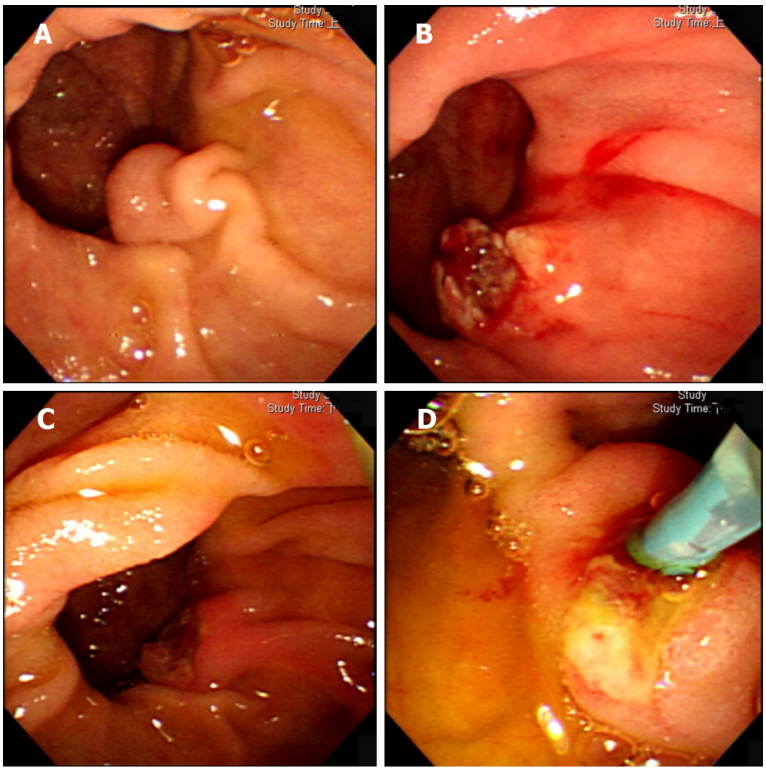
such as NKP or NKF, these studies have shown that interval ERCP is a viable treatment option (Table 1) [9,12-17]. The overall success rate of interval ERCP was 76.3% (68%-79% between studies). The time interval between the initial ERCP and the interval ERCP varies greatly from study to study (median, 3-8 d)[9,12,13,15-17]. Three studies reported that 0%, 16%, and 28% of patients required a second precut procedure during the interval ERCP, respectively[9,12,14].



Interestingly, the timing to perform interval ERCP appeared to affect the success rate of interval ERCP[9,13,14,16]. The edema, tissue necrosis, and even bleeding of the major papilla caused by cannulation and/or NKP/F improved over time, resulting in an open and easily accessible papilla (Figures 1 and 2). Therefore, the success rate of interval ERCP could increase if it could be delayed for a couple of days. Donnellan *et al*[13] reported a significantly longer median time interval between initial and interval ERCP in the successful cannulation group compared to the failed cannulation group (6.0, 1-28 d *vs* 3.0, 1-8 d; $P = 0.02$). Kim *et al*[14] studied only patients who received interval ERCP within 3 d [14]. They reported that the success rate of interval ERCP after one day was significantly lower than after 2-3 d (65.7% *vs* 88.2%, $P = 0.027$). Except for the time interval, no other factor was significantly associated with the success of interval ERCP in their study. Colan-Hernandez *et al*[16] performed univariate and multivariate analyses of factors associated with interval ERCP cannulation failure. They found that the ERCP interval within 4 d after the initial precut was the only significant factor (cannulation success rate of 44.4% *vs* 79.4%, $P = 0.024$ for univariate and 0.026 for multivariate analysis). However, in our study, we did not find any factors associated with interval ERCP failure in either the univariate or multivariate analysis[9].

Adverse events of interval ERCP were reported in five studies involving a total of 254 patients[9,12-14,16]. These adverse events included pancreatitis, bleeding, perforation, and cholangitis. The overall adverse event rate was 7.5% (0-15.9% between studies). Pancreatitis occurred in 1.6% (0-2.9%); all cases were mild. The bleeding rate was 2.8% (0-5.8%). Approximately half of the bleeding was mild, and the other half was moderate. The perforation rate was 1.2% (0-2.9%); all cases were mild. The cholangitis rate was 2.0% (0-4.7%). Two studies compared adverse event rates for initial and interval ERCP and found no significant difference[14,15].

In these studies, only 38%-82% of patients received interval ERCP when initial NKP/F failed to achieve SBC[9,12-17]. This result could reflect that some other salvage treatments, such as percutaneous or EUS-guided drainage, are still applicable in this situation[18].



PERCUTANEOUS-TRANSHEPATIC-ENDOSCOPIC RENDEZVOUS PROCEDURES

Percutaneous transhepatic biliary drainage (PTBD) remains possibly the most widely used salvage

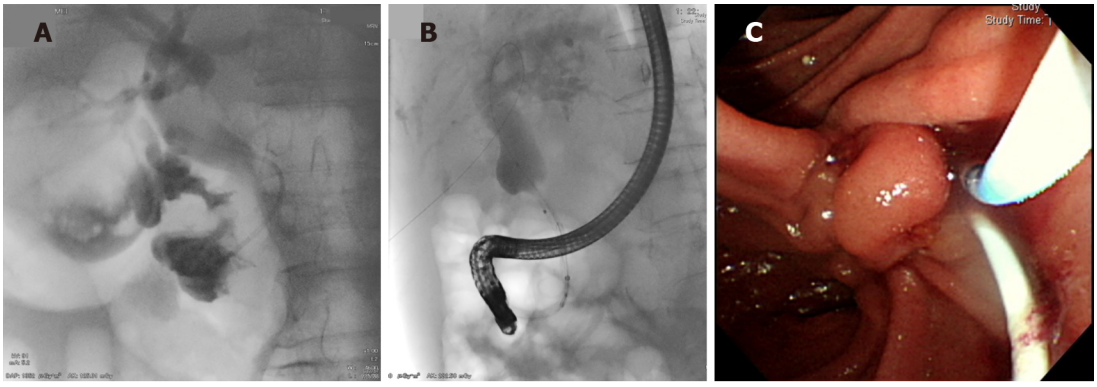
A: The original papilla in the initial endoscopic retrograde cholangiopancreatography (ERCP); B: Post-precut papilla, at the end of initial ERCP; C: post-precut papilla, at the beginning of interval ERCP. Papillary edema due to pre-cut has disappeared; D: Deep bile duct cannulation is successful during the interval ERCP.

therapy in the setting of initial ERCP failure[19]. However, PTBD has some drawbacks, including a high rate of adverse events, decreased patient quality of life, and most importantly, providing of somewhat limited options for therapeutic maneuvers[3]. In addition, external drainage can cause discomfort and pain and often requires reintervention[20]. Therefore, an improved technique combining percutaneous and endoscopic approaches, known as percutaneous-transhepatic-endoscopic rendezvous procedures (PTE-RV), seems preferable to PTBD[21]. PTE-RV have been around for more than three decades[22]. They have several advantages over PTBD alone: (1) PTE-RV allow for transhepatic puncture using only small-caliber catheters, thereby reducing complications. Bokemeyer *et al*[21] reported significantly fewer complications with PTE-RV than in PTBD (16.6% *vs* 26.4%; $P = 0.037$); (2) PTE-RV allow endoscopists to perform therapeutic ERCP in the usual manner through rendezvous access; and (3) Although PTBD is part of PTE-RV, once the biliary obstruction is resolved, the percutaneous access is closed[23].

PTE-RV can be executed as a one-stage procedure or a two-stage procedure[23]. The advantage of the one-stage procedure is that there is no need to insert a PTBD catheter. The two-stage procedure includes PTBD during the first session and internalization of the drain using an endoscope during the second session. These two steps are usually separated by a few hours to a few days[24]. Wayman *et al*[25] compared one-stage ($n = 19$) and two-stage PTE-RV ($n = 22$) and found that the technical success rates were comparable (94.7% *vs* 95.5%), but adverse events were more common in the two-stage group (37% *vs* 73%, $P < 0.05$), mainly due to complications related to external drainage.

For the following purposes, we recommend the insertion of a percutaneously placed hydrophilic-coated catheter (*e.g.*, angiocatheter) before the endoscopic rendezvous procedure (Figure 3A). First, the hepatic capsule and parenchyma, which could be damaged by the antegrade-introduced guidewire (AGW), were protected. Second, to ensure percutaneous access, once the AGW is lost incidentally during PTE-RV, it can be reintroduced into the biliary tree. Third, to facilitate the movements of AGW. After the AGW is introduced into the duodenum, there are several ways to achieve SBC[23,26]. The first and most classic technique is to grasp the distal end of the AGW with a snare and then pull the wire through the working channel of the endoscope. Retrograde bile duct cannulation can then be achieved over the wire (Figure 3B). This technique is particularly useful for patients with tight biliary strictures since the guidewire can be secured at both sides of percutaneous and endoscopic routes to facilitate retrograde passage of a catheter or stent through the stricture (push-pull technique). However, this technique might be limited by the difficult capture of the AGW and laborious guidewire manipulation, the potential for kinking or accidental loss of the AGW during withdrawal, and the risk of hepatic capsule/parenchymal tearing during AGW manipulation. The second and parallel technique is to use a standard ERCP cannulation method alongside the AGW or the percutaneously introduced catheter (Figure 3C). The advantage of this technique is that it is simple and perhaps time saving while avoiding the limitations of classical techniques. However, in some cases, it can be difficult. In such cases, retrograde biliary cannulation can be performed after antegrade balloon dilation of the biliary orifice. The other adjunctive maneuvers include insertion of a retrograde guidewire into a percutaneously placed catheter exiting the ampulla or insertion of a sphincterotome into the AGW exiting the ampulla [26].

PTE-RV has been relatively less investigated. In a literature search in early 2022, we found no review/meta-analysis articles on this topic. We were only able to find six studies (441 patients in total) over the past decade; all of them were retrospective (Table 2)[21,23,24,26-28]. The reason for PTE-RV in the searched studies was the failure of the initial ERCP. All but one study on the management of biliary strictures after living-donor liver transplantation included patients with malignant biliary strictures[28], ranging from 38% to 100% of study patients. PTE-RV is effective, with a technical success rate of 88.7% (80.4%-100% between studies). PTE-RV is also safe, with an overall adverse event rate of 13.2% (4.9%-19.2% between studies). Most studies reported no deaths from procedure-related mortality, except for one study that reported a 3.5% mortality rate possibly related to the PTE-RV procedure[23,24,27,28].



EUS-ASSISTED OR GUIDED BILIARY DRAINAGE

EUS-assisted or guided biliary drainage (EUS-BD) includes the EUS-assisted rendezvous technique (EUS-RV), EUS-guided choledochoduodenostomy (EUS-CDS), EUS-guided hepaticogastrostomy (EUS-HGS) and other procedures[29]. EUS-RV is designed to facilitate ERCP and does not involve tract dilation or stent placement and is therefore more physiologically and minimally invasive among the existing EUS-guided procedures[30]. Indications for EUS-RV include benign or potentially resectable malignant cases and unresectable malignant cases not suitable for other EUS-BD methods[31,32]. EUS-CDS and EUS-HGS involve direct transmural biliary drainage, so there could be some serious adverse events[33]. Therefore, both techniques are currently indicated for unresectable malignant cases[29-31, 33]. EUS-HGS and EUS-CDS are mainly used in patients in whom access to the papilla is not possible, such as in cases of duodenal obstruction or surgically altered anatomy. Therefore, they are beyond the scope of this review and are not included. However, indications for EUS-BD might change over time as technology advances, and improvements in devices/stents could increase technical success rates and reduce adverse event rates[34-37].

Table 2 Summary of studies on reporting percutaneous-transhepatic-endoscopic rendezvous procedures

Ref.	Study design (patient number)	Malignant biliary obstruction	One-stage *vs* two-stage	Technical success rate	Adverse events	PTE-RV related mortality
Chivot *et al*[23] (2021)	Retrospective (*n* = 84)	78.5%	One-stage	95.2% (80/84)	19% (16/84); Cholangitis: 9.5%; Pancreatitis: 3.5%; Hemorrhage: 2.3%; Pneumoperitoneum: 3.5%	3.5%
Bokemeyer *et al*[21] (2019)	Retrospective (*n* = 163)	71.3%	NA	80.4% (131/163)	16.6% (27/163); Procedure-related complications: 8.6%; Drainage-related complications: 8%	NA
Yang *et al*[26] (2017)	Retrospective (*n* = 42)	38%	Two-stage	92.9% (39/42)	7.1% (3/42)	NA
Tomizawa *et al*[24] (2014)	Retrospective (*n* = 26)	91%	One-stage (73%) or two-stage	88% (23/26)	19.2% (5/26)	0
Neal *et al*[27] (2010)	Retrospective (*n* = 106)	100%	Two-stage	92.5% (98/106)	4.9% (5/106)	0
Chang *et al*[28] (2010)	Retrospective (*n* = 20)	0	Two-stage	100% (20/20)	10% (2/20); Pancreatitis: 5%; Cholangitis: 5%	0

EUS-assisted rendezvous technique

In EUS-RV, the bile duct is punctured under EUS guidance, followed by the introduction of an AGW into the duodenum (Figure 4). The EUS endoscope is then switched to a duodenoscope, with eventual ERCP (SBC is achieved over the AGW or in parallel to the AGW). There are three puncture routes for EUS-RV[11,31,38]: (1) The intrahepatic bile duct (IHBD) route: Either transesophageal puncture of B2 or transgastric puncture of B2 or B3 can be performed. If the target is the right IHBD, it can be punctured from the duodenal bulb (D1). Transgastric puncture of B2 is most frequently performed; (2) The extrahepatic bile duct (EHBD)/D1 route, with puncture from D1: In this route, the endoscope is usually in the push position (long position), and the proximal EHBD is punctured; and (3) The EHBD/second portion of the duodenum (D2) route, with puncture from D2. In this route, the endoscope is usually in a short position, and the distal EHBD is punctured.

Two studies proposing treatment algorithms suggested using the EHBD/D2 route as a first-line approach[10,31]. They reported that the EHBD/D2 route was feasible in 50%-62.5% of patients, with EUS-RV success rates of 100% in both studies. Iwashita *et al*[10] found that the EUS-RV success rate *via* the EHBD/D1 and IHBD routes was only 66.7%. Matsubara *et al*[31] found that the time between puncture and guidewire placement with the DEHBD/D2 route was significantly shorter than that with other methods (3.5 min *vs* 14.0 min, P = 0.014). Therefore, EUS-RV *via* the EHBD/D2 route can be

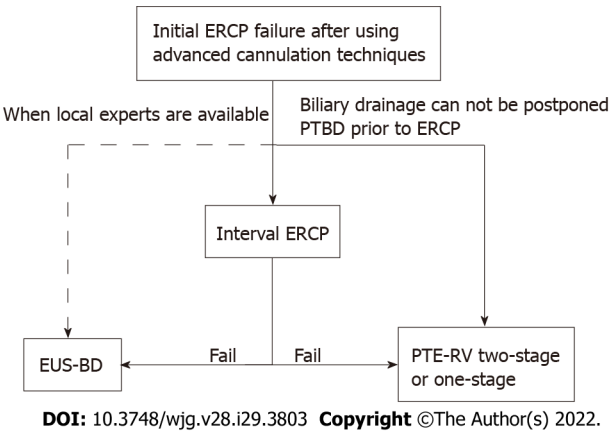
Figure 4 Endoscopic ultrasound-assisted rendezvous procedures. A: Under endoscopic ultrasound, the proximal extrahepatic bile duct is punctured through the duodenal bulb. The sonoendoscope is in a long position; B: The guidewire is delivered antegradely to the duodenum through the puncture route; C: Switch to a duodenoscope to grasp the antegradely introduced guidewire.

considered a first-line approach when feasible, although the route of access should be chosen on a patient-by-patient basis[10,31,32]. In the case of the IHBD approach, Iwashita *et al*[39] reported a hybrid rendezvous technique, in which a 6-French dilator was inserted into the biliary system for better guidewire manipulation, which could improve the technical success rate.

EUS-RV has been increasingly used in patients with SBC failure in initial ERCP[11,30]. A review by Tsuchiya *et al*[11] in 2016 (15 studies, 382 patients) reported that EUS-RV had an overall success rate of 82% (50%-100% between studies) and a complication rate of 13% (0-23% between studies). They also found that the IHBD puncture route had a lower success rate than the EHBD route (76% *vs* 85%). Therefore, in this review, we performed a literature search in Medline and included studies published after 2015 (7 studies, 177 patients; Table 3)[10,31,32,40-43]. The proportion of patients with malignant biliary obstruction was 43.5% (0-68.8% between studies). The results showed an overall EUS-RV success rate of 84.4% (78.6%-100% between studies) and a complication rate of 15.6% (6.3%-23.3% between studies) for EUS-RV. These results are similar to those in the aforementioned review article. Furthermore, we found that the IHBD puncture route also had a lower success rate than the EHBD route (74.2% *vs* 84.9%). The associated complications included pancreatitis (6.7%), cholangitis (1.7%), bile leak/peritonitis (3.3%), hematoma (0.6%), perforation (0.6%), pneumomediastinum (1.7%), aspiration pneumonia (0.6%), and gastric mucosal laceration (0.6%). In a recent meta-analysis (12 studies, 342 patients), Klair *et al*[30] further reported that, if only patients with normal anatomy (without surgical alterations) were included in the analysis, the technical success rate would have improved from 86.1% to 88.3%. The pooled clinical success rate was 80.8% (95%CI: 64.1-90.8). The pooled overall adverse event rate was 14% (95%CI: 10.5-18.4), including pancreatitis (7.2%), cholangitis (2.3%), bile leak (3.3%), bleeding (2.1%), perforation (2.7%), and peritonitis (2.3%). However, all of the studies included in this meta-analysis were retrospective.

Some unanswered questions remain; for example, does early switching to EUS-RV without spending too much time on advanced cannulation techniques improve technical success rates and reduce complication rates[44]? Further studies are required to clarify this issue.



CONCLUSION

Based on this review, interval ERCP appears to have the lowest technical success rate and overall complication rate of the three endoscopic salvage methods. Given the acceptably high success rates and low complication rates, and without the need for additional expertise, facilities (*e.g.*, EUS), or other specialists (*e.g.*, radiologists), interval ERCP can be considered the first choice when SBC is not feasible with advanced cannulation techniques[4]. In this way, more invasive alternative interventions can be avoided in approximately three-quarters of patients. However, the main limitation of interval ERCP is that it must be delayed by a few days to improve the success rate. Therefore, patients in urgent need of biliary drainage (*e.g.*, uncontrolled cholangitis) should undergo other, more invasive therapies. In this setting, since percutaneous biliary puncture is a more widespread technique than EUS-BD, and most ERCP endoscopists can perform rendezvous procedures, two-stage PTE-RV can be considered because PTBD can achieve early bile drainage. Of course, if both interventional radiologists and endoscopists are available, one-stage PTE-RV is welcome because it reduces complication rates. Another situation in which PTE-RV can be considered a first choice is when the patient has a PTBD drainage tube before the initial ERCP. EUS-BD is a relatively new technique and requires additional technical expertise/facilities, and as such, its use has been limited to some ERCP endoscopists at some advanced endoscopy centers.

Table 3 Summary of studies on reporting endoscopic ultrasound-guided rendezvous procedures

Ref.	Study design (patient number)	Malignant biliary obstruction	Success rate *via* EHBD	Success rate *via* IHBD	Overall technical success rate	Overall complication rate

Figure 5 The proposed treatment algorithm. ERCP: Endoscopic retrograde cholangiopancreatography; PTBD: Percutaneous transhepatic biliary drainage; PTE-RV: Percutaneous-transhepatic-endoscopic rendezvous procedure; EUS-BD: Endoscopic ultrasound-assisted or guided biliary drainage.

When local experts are available, EUS-BD could serve as a first-line salvage technique before considering PTBD, as recommended by recently issued ESGE guidelines[29]. If not, it might be performed in a second endoscopic session by another endoscopist with dual endoscopic techniques. Based on the current review, we propose a treatment algorithm to provide practical recommendations, as shown in Figure 5. Since there have been no comparative studies between treatments, the suggested practice should be validated by further studies.

FOOTNOTES

Author contributions: Tsou YK conceptualized and designed the review and wrote the manuscript; Pan KT was

responsible for the data acquisition/analysis of the percutaneous-transhepatic-endoscopic rendezvous procedures; Lee MH was responsible for the data acquisition/analysis of the endoscopic ultrasound-assisted or guided procedures; Lin CH contributed to revising and validating the manuscript.

Abstract

Early detection of pancreatic cancer has long eluded clinicians because of its insidious nature and onset. Often metastatic or locally invasive when symptomatic, most patients are deemed inoperable. In those who are symptomatic, multi-modal imaging modalities evaluate and confirm pancreatic ductal adenocarcinoma. In asymptomatic patients, detected pancreatic lesions can be either solid or cystic. The clinical implications of identifying small asymptomatic solid pancreatic lesions (SPLs) of < 2 cm are tantamount to a better outcome. The accurate detection of SPLs undoubtedly promotes higher life expectancy when resected early, driving the development of existing imaging tools while promoting more comprehensive screening programs. An imaging tool that has matured in its reiterations and received many image-enhancing adjuncts is endoscopic ultrasound (EUS). It carries significant importance when risk stratifying cystic lesions and has substantial diagnostic value when combined with fine needle aspiration/biopsy (FNA/FNB). Adjuncts to EUS imaging include contrast-enhanced harmonic EUS and EUS-elastography, both having improved

the specificity of FNA and FNB. This review intends to compile all existing enhancement modalities and explore ongoing research around the most promising of all adjuncts in the field of EUS imaging, artificial intelligence.

Key Words: Pancreatic ductal adenocarcinoma; Pancreatic cancer; Endoscopic ultrasound; Contrast-enhanced endoscopic ultrasound; Endoscopic ultrasound contrast agents; Endoscopic ultrasound elastography; Artificial intelligence; Fractal analysis; Endoscopy; Imaging

Core Tip: Several reviews have evaluated the use of contrast-enhanced endoscopic ultrasound (CE-EUS), EUS-elastography (EUS-E), and artificial intelligence in separation. Not many have reviewed all three modalities' strengths in a single article. This article elaborates on current methods and outcomes of CE-EUS and EUS-E while reviewing the impact of artificial intelligence on the field of EUS imaging.

INTRODUCTION

Pancreatic ductal adenocarcinoma (PDAC) is the 5th most fatal cancer globally, and those receiving a diagnosis have only a 6% 5-year survival rate[1]. Fortunately, early detection of a PDAC, especially when smaller than 1 cm, along with timely resection can aggrandize 5-year survival rates by up to 80.4% [2]. This disease's increasing incidence and mortality trend have brought different specialists (*i.e.* radiologists and gastroenterologists) together to create a framework to enhance early detection. Computed tomography (CT), magnetic resonance imaging (MRI), and endoscopic ultrasound (EUS) have all emerged as essentials in the multidisciplinary diagnostic approach of PDAC. EUS images of the pancreas are distinct from all modalities above because of their increased spatial resolution, making it 94% sensitive for PDAC detection[3]. Successive generations of EUS imaging transducers and post-processing software have markedly improved the spatial resolution of conventional B-mode EUS images. When used alone, it boasts a superior diagnostic accuracy over multidetector CT and MRI, singularly for solid pancreatic lesions (SPLs), but a meager specificity when differentiating pancreatic cancer from other pathologies[3,4]. However, with the advent of image-enhancing technologies such as contrast-enhanced EUS (CE-EUS) and EUS-elastography (EUS-E), there is evidence to suggest that even smaller SPLs are now detectable with good sensitivity and specificity[5-7]. Although promising, these advances' overarching impact in the face of early pancreatic cancer detection and diagnosing benign pancreatic diseases is still largely underwhelming. Pancreatic cancer remains a leading cause of death in industrialized populations, and the new case burden is estimated to grow steadily for the next 20 years [8]. Thus far, we know that the diagnostic accuracy of EUS, when coupled with EUS-guided tissue sampling, holds good outcomes, but reproducing its performance with ease remains a global challenge. The learning curve to master and competently perform an EUS examination is steep[9,10]. In this context, the introduction of artificial intelligence (AI), alone or in combination with existing enhanced EUS imaging technologies, may contribute to filling the gaps in accurately and consistently diagnosing pancreatic diseases[11]. This commentary highlights existing enhanced EUS imaging technologies while paving the way for AI, postulating its possible role in this arena.

EUS-E

Elastography is an ultrasonographic tool to measure the stiffness of the desired study area. The desired study area for a suspicious pancreatic lesion is also known as a region of interest (ROI). Akin to the clinical aspect of palpating a mass by hand and describing its characteristics, elastography does this similarly, but instead for deeper structures[12]. The two types of elastography include strain elastography (SE) and sheer wave elastography (SWE). However, SWE is still unstable in its use to measure the elasticity of SPLs and will not be discussed further in this article[13].

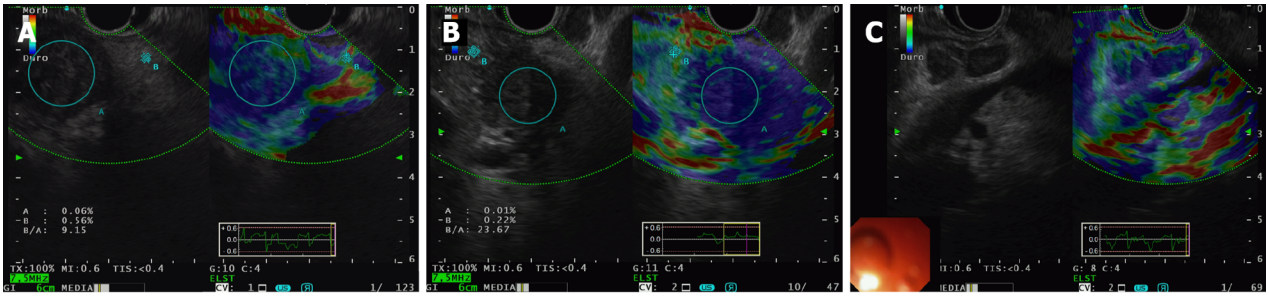
The type of elastography used in EUS is quasi-static or SE. It measures tissue displacement from a compressive force generated internally by the patient's physiology like breathing and vascular pulsations or externally by the tip of the echoendoscope pressing against the GI wall[14]. The compressive force deforms the tissue momentarily. The amount the tissue deforms or the degree to which it gets displaced is known as strain. Softer or more elastic tissue, *i.e.* more benign, will have more displacement while stiffer, inelastic, and generally more malignant tissue, will have less strain[15]. The images can be seen side by side on the EUS display, with the EUS-E overlayed on the B mode image.

We present examples for PDAC (Figure 1A and B) and for a metastatic lymph node (Figure 1C). The color spectrum represents a qualitative measurement, blue being the hardest and red being the softest. Quantitative measurements are seen on the strain histogram or valued as the strain ratio (SR; the strain of the larger round-shaped ROI area A divided by the strain of smaller round-shaped region of surrounding normal tissue area B). Suggested surrounding normal homogenous tissue to be used as reference include either healthy surrounding pancreatic parenchyma (pSR) or healthy GI tract wall (wSR). Suggested elastography SR values are automatically computed and estimated using the built-in software found in the Olympus EU-ME2 processor and the Hitachi United States machines. However, the reference areas have yet to be standardized.

Outcomes

One of the earliest prospective multicenter studies by Giovannini[16] evaluated the elastography of pancreatic masses from 121 patients on initial EUS referenced against final histological diagnoses. Elastography successfully demonstrated "intense blue" on qualitative measurement for all PDAC, endocrine tumors, pancreatic metastasis, and pancreatic sarcomas. According to his scoring system of 1 through 5 (5 being the stiffest and most intense blue), scores 1 and 2 had a negative predictive value (NPV) of 77.4%, whilst scores 3 and 4 had a positive predictive value (PPV) for malignancy of 92.8%[16].

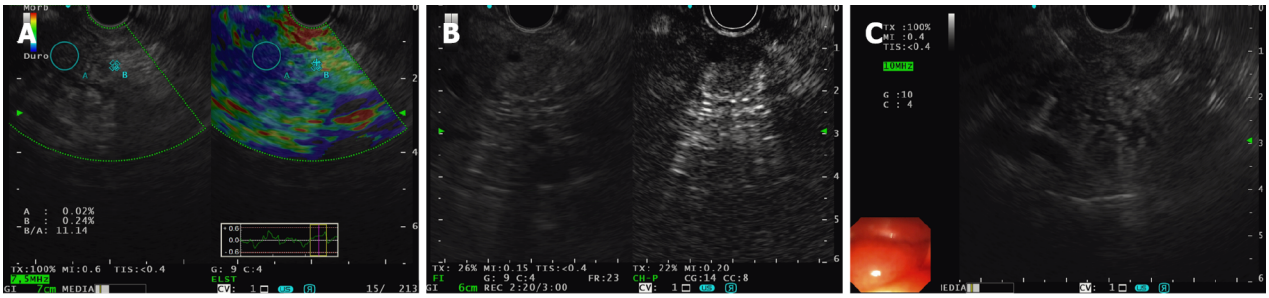
In the interest of detecting smaller ductal adenocarcinomas (< 15 mm), which if resected earlier, have shown a 5-year survival mark in PDAC survivors to exceed 30%-60%, Ignee *et al*[7] evaluated SRs for SPLs of < 15 mm from 218 patients across 13 international centers. They found that EUS-E patterns of a small lesion (average size 11 ± 3 mm), if found to be soft, could confidently rule out malignancy (NPV 98%). Although PDAC was diagnosed in these small lesions with a sensitivity of 96%, elevated stiffness in a detected lesion had a specificity of only 67% with a PPV of 56% when diagnosing malignancy[7]. These small lesions' final etiological percentage breakdown was 66% benign, while 52% were neuroendocrine tumors (NETs). Notably, 36% of the NETs were stiff lesions, while 64% were soft compared to surrounding tissue. The remaining 23% were PDAC, 17% other entities, and 8% metastasis (which showed stiffness only 59% of the time)[7].



In 2012, Pei *et al*[17] and in 2013, Ying *et al*[18], the Asian groups conducted separate metanalyses, but with additions to pooled data on the subject matter of EUS-E's diagnostic accuracy, a more recent meta-analysis of 17 studies analyzing 1544 lesions from 1537 patients was conducted in 2017. From their pooled results, EUS-E reported an accumulated sensitivity of 97% (95%CI: 95%-99%) and a sensitivity of 67% (95%CI: 59%-74%) for qualitative methods; 97% sensitivity (95%CI: 95%-98%) and 67% specificity (95%CI: 61%-73%) for Strain Histograms, and lastly, 98% specificity (95%CI: 96%-99%) and 62% sensitivity (95%CI: 56%-68%) for strain ratios, suggesting its value as a complement to EUS-guided tissue sampling, *i.e.* EUS-FNA[19].

Similarly, guidelines proposed by the European Federation of Societies for Ultrasound in Medicine and Biology (EFSUMB) advocate using elastography as a complementary tool for focal pancreatic lesion characterization[20]. When a EUS-FNA sample is negative, but the index of suspicion for malignancy remains, the EFSUMB recommends using elastography and CE-EUS for repeat tissue sampling or referring the patient directly to the surgeons for operative intervention without further delay[20]. We demonstrate the clinical application of EUS-E (with CE-EUS) to target FNB sampling in a patient with a degenerated intraductal papillary mucinous neoplasm (IPMN) under our surveillance (Figure 2). This patient had positive cytology, warranting early surgery. Although documented to be helpful in the diagnosis of early autoimmune pancreatitis due to an idiosyncratic distribution of tissue stiffness, the guidelines cannot recommend the use of elastography in differentiating advanced chronic pancreatitis from pancreatic cancer[20].

One of EUS-E's many inherent limitations is evident here: Its low specificity and inability to consistently distinguish between pancreatic diseases (inflammatory *vs* neoplastic) or even types of pancreatic malignancies.



Inbuilt elastography software reduces intra-observer variability by overcoming the selection bias of images by providing the operator with a real-time movie of all recorded frames. However, there remains significant inter-observer variability when differentiating NETs from normal pancreatic parenchyma, as both may appear green *i.e.* soft.

Here are a few other scenarios where misdiagnoses occur: (1) If the endoscopist places too much compressive pressure between the probe and the examined tissue; and (2) False image reconstruction due to the heterogeneity of the examined tissue *i.e.* in the case of pancreatic cancer where some areas within the lesion are either necrotic, fibrous from desmoplasia, or have become inhomogeneous from vessel infiltration.

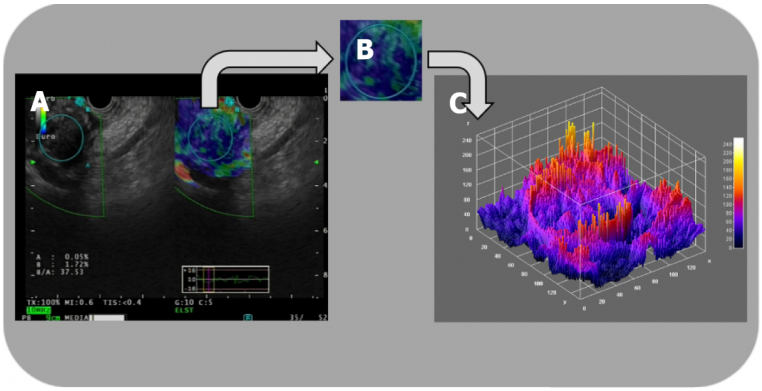
Figure 2 The clinical application of endoscopic ultrasound-elastography (with contrast-enhanced endoscopic ultrasound) to target fine needle biopsy sampling in a patient with a degenerated intraductal papillary mucinous neoplasm under our surveillance. A: Case demonstration of a degenerated intraductal papillary mucinous neoplasm and combination use of endoscopic ultrasound-elastography (EUS-E) to direct fine needle biopsy (FNB) sampling. Pre-EUS-E, the area of concern was iso-echoic, resembling normal parenchyma; however, under EUS-E, the area is stiff (blue); B: Contrast use post-FNB showing hypo-enhancement of the area of concern, confirming the area previously highlighted by EUS-E; C: Post-EUS-E and contrast-enhanced EUS guided FNB sampling in the same patient, allowing targeted sampling of the hard area.

Other pitfalls include: (1) A lack of standardization for cut-off values for strain ratios, although some experts propose using parenchyma-to-lesion SR of > 9.10 (PPV 89.7%; NPV 76.9%) or the gastric wall-to-lesion SR of > 16.2 (PPV 86.5%; NPV 80%)[21]; (2) Border delineation once the lesion becomes larger [22]; (3) Inability to measure strain if the lesion is too far away from the probe, and lastly; and (4) Image acquisition when fluid is present, *i.e.* with cysts[22].



Carrara *et al*[21] demonstrated the use of fractal geometry analysis (Figure 3) to quantify the surface roughness of 2 tissues that share the same mechanical properties on elastography, and in doing so, overcome a significant limitation of EUS-E, but further trials are required[21]. Studies are also underway to evaluate the use of EUS-E in differentiating actual vessel wall infiltration by tumor tissue from that caused by an inflammatory reaction. The European Elastography Group, amongst others, is also designing and training deep learning platforms for future use in reducing inter-operator variability.

CE-EUS IMAGING

CE-EUS imaging is a non-invasive technique that utilizes a contrast agent during a EUS examination to improve diagnostic imaging. Contrast use in ultrasound imaging was first pioneered in 1986 by Matsuda and Yabuuchi with the infusion of CO_2 as a medium. Kato heralded its subsequent application into EUS in 1991, confined only to angiographic examinations[23]. In the mid-1990s, the use of Doppler function and sonicated serum albumin expanded the application of CE-EUS beyond the premise of angiographic studies[24].

In CE-EUS, the mechanical index (MI) alludes to the reaction of microbubbles in response to a stimulus in the form of an acoustic wave[25]. From this response, CE-EUS is typed into two: (1) Contrast-enhanced high-MI EUS (CEHMI-EUS), not requiring specific interpretive software; and (2) Contrast-enhanced low-MI EUS (CELMI-EUS), requiring a contrast-specific software mode.

A significant advantage of CELMI-EUS over CEHMI-EUS is its higher resolution and visibility of the contrast enhancer bubbles. In contrast, CEHMI-EUS's ability to display pancreatic macro-vessels (vessels with a diameter of approximately 0.2 mm and higher) comes at the expense of microbubble destruction

Figure 3 Three-dimensional surface fractal dimension estimate. A and B: Endoscopic ultrasound-elastography images (A) are used to highlight representative parenchymal regions (B) of solid pancreatic lesions; C: A computer-aided image analysis system generates an irregularly-shaped three-dimensional surface as a "shape matrix" of points with the column and row numbers proportional to the x and y coordinates and with the depth information z (x, y) stored as a matrix element. The three-dimensional fractal dimension, which is an index of the "surface roughness", is automatically determined using the box-counting algorithm. The fractal dimension of a surface is expressed by a real number greater than 2 (the Euclidean dimension of a two-dimensional surface) and less than 3 (the Euclidean dimension of a solid). A surface with a higher surface fractal dimension is wrinkled than one with a lower dimension.

and, as a result, CEHMI-EUS's use for Doppler enhancement is preferred[26].

In collaboration with European experts in a recently issued guideline, the Asian Federation of Societies for Ultrasound in Medicine and Biology (AFSUMB) concluded that the MI should be between 0.2 and 0.4. They added that the 0.1 to 0.4 range used in published reports was influenced by several factors, including EUS probe type (radial or linear), image processing hardware, and software, phase-inversion harmonics, amplitude modulations, and focal points[27].

Contrast-enhanced harmonic EUS imaging

Tissue harmonic imaging (THI) is an ultrasonographic technique, first introduced in 1997, that utilizes nonlinear propagation of ultrasound (US) waves to generate images that are superior in quality to the fundamental B-mode imaging mode[28]. This tool was incorporated into the EUS imaging arsenal approximately a decade later[29].

The two image processing techniques developed to generate harmonic images were the band filtering method and phase inversion method. The ability of harmonic imaging to improve signal-to-noise ratio and reduce artifacts produced by side lobes, grating lobes, and reverberation allowed it to outperform earlier imaging applications, such as Color Doppler and power Doppler, which were susceptible to motion artifacts[30]. Furthermore, this modality allowed for visualization of parenchymal perfusion and microvasculature of the pancreas[31].

AFSUMB, in their summary recommendations, alluded to the benefit of contrast-enhanced harmonic EUS (CH-EUS) for characterization of solid pancreatic masses, pancreatic cancer staging in patients with suspected major vessel involvement, identification of mural nodules in cystic pancreatic lesions, and detection of subtle pancreatic lesions[27].

Nevertheless, THI is saddled with certain intrinsic technical limitations. The narrow bandwidth decreases axial resolution when applying the band filtering method. This limitation gave rise to the conception of the phase inversion method. However, the latter method necessitates the transmission of two US pulses, thus decreasing the frame rate and raising the possibility of motion artifacts[30].

Contrast agents

The first reported use of intravenous ultrasound contrast agents (UCAs) in ultrasonography was for image enhancement during echocardiography. Its adoption followed this in transabdominal ultrasonography before it was eventually introduced in EUS[32]. EFSUMB's recommendation on contrast for CE-EUS in non-liver applications highlighted its similarity to its use in transabdominal CEUS[33]. Worth noting is that the modalities, as mentioned earlier, represent the only imaging techniques that allow a dynamic observation of the CE phases[34]. UCAs are used to augment their ability in lesion characterization and intervention guidance.

During the evolutionary phase of CE-EUS, various agents were explored to advance the diagnostic performance of this modality. To render stability and durability, all commercially available agents are composed of gas-filled microbubbles encapsulated by a phospholipid or albumin shell. Each agent is aptly categorized based on its half-life and ability for transpulmonary passage[32].

The AFSUMB working group strongly recommends the following for use as UCAs: SonoVue (Lumason, sulfur hexafluoride micro-bubbles; Bracco, Milan, Italy; available in Europe, China, India, Korea, Hong Kong, New Zealand, Singapore, and Brazil); Definity (octafluoropropane microbubbles;

Bristol- Myers Squibb Medical Imaging, New York, NY, United States; available in the United States, Canada, and Australia), and Sonazoid (perfluorobutane microbubbles; GE Healthcare, Chicago, IL, United States; Daiichi Sankyo, Tokyo, Japan; available in Japan, South Korea, Taiwan and Norway). They further stated that neither of the agents had a superior diagnostic ability over the other[27].

Outcomes

A significant emphasis has been placed on researching the adjunctive role of CE-EUS in evaluating solid pancreatic masses. The result is a wealth of data that supports its use in assessing the pancreas and related pathologies[33]. Mei *et al*[35] affirmed this in a recent meta-analysis (n = 1497) to evaluate the accuracy of CE-EUS in discriminating between benign and malignant pancreatic masses with a reported pooled sensitivity, specificity, and diagnostic odds ratio of 0.91, 0.86, and 69.50, respectively[35].

Another meta-analysis that included 1139 patients across 12 studies highlighted that both high and low MI techniques had a 94% sensitivity and 89% specificity in differentiating pancreatic adenocarcinoma from other pathologies, with an area under the receiver operating characteristic curve of 0.9732. Subgroup analysis by excluding the outliers provided a sensitivity and specificity of 93%[36].

Săftoiu *et al*[37] analyzed the diagnostic accuracy of combining CE-EUS and elastography to differentiate focal pancreatic masses and highlighted its influence in decision making when confronted with a negative EUS-FNB result with a strong clinical suspicion of malignancy. A similar study by the same authors assessed the "synergistic" performance of CE-EUS with EUS-EG in 50 patients with a negative FNA of pancreatic masses. The results determined 19 to be pancreatic adenocarcinoma and 31 to be pseudo-tumoral chronic pancreatitis. CE-EUS reported a specificity of 100% and an accuracy of 93% in the cohort of 25 patients where EUS-EG demonstrated high lesion stiffness, diagnosing malignancy[38].

Buxbaum *et al*[39], in a prospective tandem-controlled trial involving 101 cases of focal pancreatic lesions, concluded that CE-EUS increased the diagnostic yield compared to conventional B-mode EUS with an odds ratio of 7.8 (95%CI: 2.7-30.2). Ninety-one percent of lesions were correctly characterized in the validation cohort, with an improved yield compared to unenhanced EUS[39]. In a real-life clinical setting, we demonstrate its use in a case of a degenerated IPMN showing how its use allows differentiation of tumor vegetation from mucus within a cyst (Figure 4).

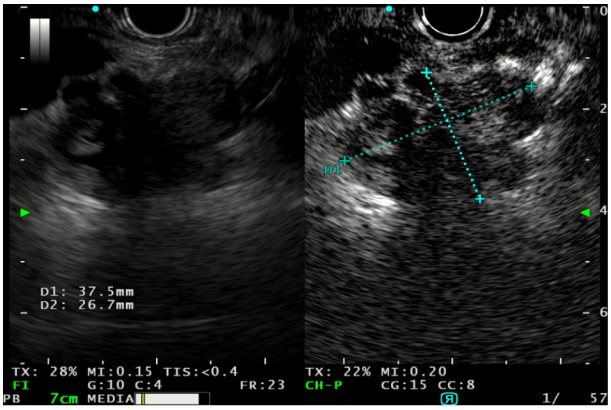
AI

AI can level the playing field for endoscopists globally by making this highly sensitive and specific, but technically challenging, diagnostic tool we know as EUS more user-friendly and quicker to master.

The existing image enhancing techniques, CH-EUS and EUS-E, are available to the endoscopist currently as stand-alone software plug-ins. They require prior training before use with a low to moderate learning curve to master given that the user is already proficient with an echoendoscope.

The potential of AI is seen here in its ability to harness the diagnostic power of EUS while unifying all existing and future image-enhancing techniques "under one roof." This unifying software can aid the endoscopist by highlighting areas of concern while prompting suitable image-enhancing methods.

This added edge of diagnostic confidence can help overcome lesion ambiguity and improve lesion specificity, regardless of the years of prior endosonographic training.



Principle of AI

AI is a divaricate under the broader umbrella of computing methodology and information sciences. It utilizes autonomous properties from rapidly advancing technological developments in deep learning as a segue to mimic human behavior ultimately. Over the last decade, AI applications have quickly matured. Their iterations in the daily practice of various fields within medicine are expanding with success.

The development and training of computer-aided diagnosis (CAD) systems revolve around the aim of autonomously distinguishing features that the human eye and mind may unintentionally miss. Identifying and interpreting changes of varying subtleties, particularly in medical images, has been the high point of AI. The objectivity of a trained CAD system could potentially seek to overcome one of the most significant limitations of any physician or endoscopist: The lack of an intra- and inter-observer agreement. Suppose an AI system can distinguish between neoplastic and non-neoplastic lesions with near perfection after training, it would seem reasonable to imagine that the burden from pathological examinations may be considerably relieved very soon. Thus far, colonic adenoma detection and differentiation have gained tremendous attention from several CAD systems utilizing deep learning and Artificial Neural networks. Due to their promising results, these systems have gained popularity in day-to-day endoscopy usage[40-43].

AI and EUS

The most common application of AI in EUS is creating machine learning architectures that extract EUS images and analyze them for their textures (boasting accuracy of up to 93%-94%) to create an artificial neural network that can ultimately serve as a clinical decision support tool. It can do one of 2 things: (1)

DOI: 10.3748/wjg.v28.i29.3814 **Copyright** ©The Author(s) 2022.

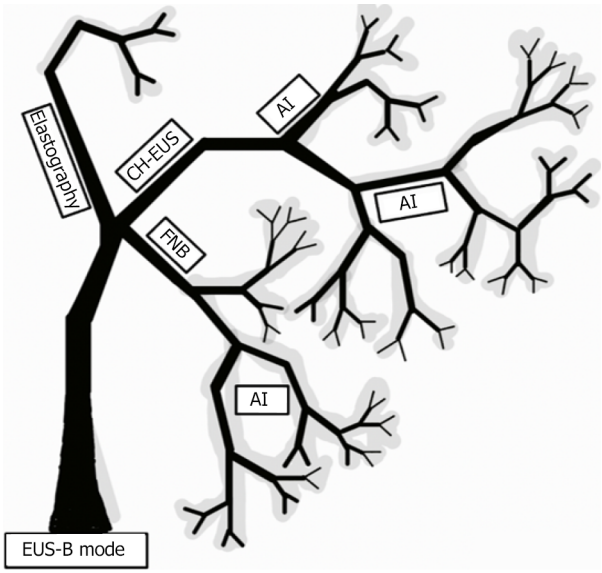
Figure 4 Use of contrast-enhanced endoscopic ultrasound to study the evolution of a degenerated intraductal papillary mucinous neoplasm and the vegetations within, allowing differentiate between mucus and vegetations as only tumor vegetations will show inhomogeneous enhancement.

Using the station approach to familiarize the endoscopist with normal anatomy, as demonstrated by Kanno *et al*[44]; and (2) Non-invasively differentiating pancreatic parenchymal pathologies when EUS-FNB may not be clinically feasible or have a poor diagnostic yield in the case of cysts or AIP[40].

In 2008, two studies emerged providing the diagnostic ability of AI integrated EUS in reporting pancreatic diseases. Săftoiu *et al*[45] reported 68 cases in a prospective study using a neural network EUS to compare PDAC and chronic pancreatitis. The authors reported 95% accuracy in the system's diagnostic ability. In the second study, Das *et al*[46] reviewed 319 images with a neural network system and performed a principal component analysis to compare acute and chronic pancreatitis, from pancreatic carcinoma. The study reported the area under the curve indicating the systems' diagnostic ability to be 93%. In 2013, Zhu *et al*[47] studied 288 cases retrospectively with a support vector machine and reached an accuracy of 94%.

Additionally, Săftoiu *et al*[48], in a prospective multicenter study, reported 167 cases using a neural network system, reaching a diagnostic accuracy of 94%. Ozkan *et al*[49] reported an accuracy of 93% in reviewing 332 images in retrospect using a neural network. A deep learning architecture specific to EUS noteworthy of mentioning is one used to differentiate high-grade dysplasia *vs* malignancy for IPMN with an accuracy of 94%[42]. In a single-center retrospective study that trained a deep learning algorithm using 3970 still images, deep learning was superior to human ability in its diagnostic accuracy (95% *vs* 56%), proving an objective method such as is this is more accurate in diagnosing malignancies of IPMN origin in comparison to conventional EUS features[42].

AI demonstrates its usefulness again in increasing diagnostic specificity using occlusion heatmap analysis to differentiate AIP from PDAC. The result is overcoming a delay in diagnosis, initiating immunosuppressive or chemoradiotherapy early, and preventing unwarranted resections (90% sensitive, 85% specific)[50]. It is worth mentioning that these studies use a cross-validation method with an internal control check, thus inflating the actuality of the diagnostic accuracy. In its applications to actual EUS fine-needle biopsy histopathological samples, AI was able to bring diagnostic clarity to difficult-to-analyze samples with an accuracy of 94.1% despite cellular paucity and contamination.



In centers with a lack of dedicated GI pathologists, AI software can quickly close this gap of diagnostic delay and eliminate repeat sampling at second or third centers[11]. One setback of AI is the black-box phenomenon, which can cause judgment errors without an explanatory basis. That said, a trained convolutional neural network model with extracted visual features from various pancreatic diseases, namely chronic pseudo-tumoral pancreatitis, NET, and PDAC, can accurately produce a real-time diagnosis[51].

SUMMARY RECOMMENDATIONS

For a suspected pancreatic mass, we propose utilizing both EUS-E and CE-EUS to augment conventional B-mode imaging (Figure 5).

Their advantages in defining nodules and ambiguous ROIs allow FNA/FNB sampling precision, making them crucial adjuncts in day-to-day practice, whether for first encounters or follow-up visits.

Validation studies are still underway to evaluate promising non-contrast-based high-definition imaging modalities. The modalities are in-built into the echo processor for ease of microvasculature study. They carry great potential in supplementing and possibly surrogating UCAs in conditions, such as pregnancy or compromised cardiopulmonary status[52]. However, until then, EUS-E and CE-EUS

Figure 5 Graphical representation of existing diagnostic applications to endoscopic ultrasound imaging in the form of a fractal tree, fractal analysis with artificial intelligence being the possible future of enhanced endoscopic ultrasound imaging. AI: Artificial intelligence; CH-EUS: Contrast-enhanced harmonic endoscopic ultrasound; FNB: Fine needle biopsy.

coupled with B-mode imaging will remain the choice stratagem in improving the early detection of pancreatic cancer.

CONCLUSION

In the EUS world of greys, colors emerged from elastography and patterns from contrast use, improving the overall accuracy of pancreatic mass differentiation. AI could be the rainbow that bridges us to a more precise diagnosis.

Abstract

BACKGROUND

Recent studies have demonstrated that dysfunction of the intestinal barrier is a significant contributing factor to the development of severe acute pancreatitis (SAP). A stable intestinal mucosa barrier functions as a major anatomic and functional barrier, owing to the balance between intestinal epithelial cell (IEC) proliferation and apoptosis. There is some evidence that calcium overload may trigger IEC apoptosis and that calcineurin (CaN)/nuclear factor of activated T-cells (NFAT) signaling might play an important role in calcium-mediated apoptosis.

AIM

To investigate the potential mechanisms underlying the therapeutic effect of Qingyi decoction (QYD) in SAP.

METHODS

A rat model of SAP was created *via* retrograde infusion of sodium deoxycholate. Serum levels of amylase, tumor necrosis factor (TNF-α), interleukin (IL)-6, D-lactic acid, and diamine oxidase (DAO); histological changes; and apoptosis of IECs were examined in rats with or without QYD treatment. The expression of the two subunits of CaN and NFAT in intestinal tissue was measured *via* quantitative real-time polymerase chain reaction and western blotting. For *in vitro* studies, Caco-2 cells were treated with lipopolysaccharide (LPS) and QYD serum, and then cell

viability and intracellular calcium levels were detected.

RESULTS

Retrograde infusion of sodium deoxycholate increased the severity of pancreatic and intestinal pathology and the levels of serum amylase, TNF-α, and IL-6. Both the indicators of intestinal mucosa damage (D-lactic acid and DAO) and the levels of IEC apoptosis were elevated in the SAP group. QYD treatment reduced the serum levels of amylase, TNF-α, IL-6, D-lactic acid, and DAO and attenuated the histological findings. IEC apoptosis associated with SAP was ameliorated under QYD treatment. In addition, the protein expression levels of the two subunits of CaN were remarkably elevated in the SAP group, and the NFATc3 gene was significantly upregulated at both the transcript and protein levels in the SAP group compared with the control group. QYD significantly restrained CaN and NFATc3 gene expression in the intestine, which was upregulated in the SAP group. Furthermore, QYD serum significantly decreased the LPS-induced elevation in intracellular free Ca^{2+} levels and inhibited cell death.

CONCLUSION

QYD can exert protective effects against intestinal mucosa damage caused by SAP and the protective effects are mediated, at least partially, by restraining IEC apoptosis *via* the CaN/NFATc3 pathway.

Key Words: Severe acute pancreatitis; Intestinal epithelial cell; Apoptosis; Calcineurin/nuclear factor of activated T-cells pathway; Qingyi decoction

Core Tip: This manuscript investigated the role of the calcineurin (CaN)/nuclear factor of activated T-cells (NFATc3) pathway in the apoptosis of intestinal epithelial cells (IECs) in severe acute pancreatitis (SAP) and the potential mechanisms underlying the therapeutic effect of Qingyi decoction (QYD). QYD significantly restrained CaN and NFATc3 gene expression in the intestine, ameliorated IEC apoptosis associated with SAP, and decreased the lipopolysaccharide-induced elevation in intracellular free Ca^{2+} levels and cell death. These findings suggest that the protective effects of QYD might be mediated, at least partially, by downregulating IEC apoptosis *via* the CaN/NFATc3 pathway.

INTRODUCTION

Severe acute pancreatitis (SAP) is a severe acute abdominal disease characterized by high morbidity and mortality that can occur as a consequence of systemic inflammatory response syndrome (SIRS) and multiple organ dysfunction syndrome (MODS)[1]. A considerable amount of literature has been published on SAP. These studies have demonstrated that dysfunction of the intestinal barrier is a significant contributing factor to the development of SAP. Disruption of the intestinal barrier can give rise to gut bacteria and endotoxin translocation, thus creating secondary infections, SIRS, and MODS, leading to SAP[2]. A stable intestinal mucosa barrier functions as a major anatomic and functional barrier, owing to the balance between intestinal epithelial cell (IEC) proliferation and apoptosis. Recent research has revealed that IEC apoptosis plays an essential role in the development of SAP, and increased IEC apoptosis has been confirmed to contribute to intestinal injury, mucosal atrophy, bacterial translocation, and barrier dysfunction in SAP[3-5].

As a ubiquitous second messenger, Ca^{2+} has a significant impact on a variety of cellular processes in nearly all cell types. Calcineurin (CaN), a unique calcium-activated serine/threonine phosphatase, is a dominant factor in calcium-dependent signal transduction pathways. Nuclear factor of activated T-cells (NFAT) is a substrate phosphorylated by CaN, that is completely dependent on Ca^{2+}/CaN signaling; thus, NFAT is remarkably responsive to intracellular Ca^{2+} oscillations[6]. There is some evidence that calcium overload may trigger IEC apoptosis and that CaN/NFAT signaling might play an important role in calcium-mediated apoptosis[7,8].

Qingyidecoction (QYD), a Chinese herbal medicine consisting of Radix Bupleuri (Chaihu, *Bupleurum scorzonerifolium* Willd.), Scutellariae Radix (Huangqin, *Scutellaria baicalensis* Georgi.), Aucklandiae Radix (Muxiang, *Aucklandia lappa* Decne.), Rhizoma Corydalis (Yanhusuo, *Corydalis acropteryx* Fedde), Coptidis Rhizoma (Huanglian, *Coptis chinensis* Franch.), Radix Paeoniae Alba (Baishao, *Paeonia lactiflora* Pall.), Rhei Radix Et Rhizoma (Dahuang, *Rheum palmatum* L.) and Natrii Sulfas (Mangxiao, *Mirabilite*) has been widely utilized for several decades in the treatment of acute pancreatitis in China[9]. QYD, as an organic combination of many effective components, plays a multitarget role in acute pancreatitis treatment through multiple pathways, including protecting the intestinal barrier. The efficacy of QYD has been demonstrated to involve its ability to moderate endotoxin generation, restrict excessive neutrophil activation, minimize the release of inflammatory cytokines, and inhibit IEC apoptosis[10]. The present study aimed to investigate the role of the CaN/NFATc3 pathway in the apoptosis of IECs in SAP and explore the potential mechanisms underlying the therapeutic effect of QYD.

MATERIALS AND METHODS

Animal preparation and experimental protocols

Male Sprague-Dawley (SD) rats, 180-220 g, were obtained from the specific-pathogen-free Animal Center of Dalian Medical University. This study was approved by the Ethics Committee of Dalian Medical University. Thirty male SD rats were randomly divided into an SAP group, a QYD treatment group, and a control group, with ten rats per group. The SAP model was established using a method previously described[9]. The rats in the QYD group were gavaged with three doses of QYD (10 mL/kg body weight/dose, the First Affiliated Hospital of Dalian Medical University, Dalian, China) 0.5 h before and 6 and 12 h after surgery. The rats in the control group received only sham surgery[9]. The rats were anesthetized with 10% chloralhydrate *via* intraperitoneal injection at 3 mL per kg bodyweight 24 h post operation. Abdominal aorta blood samples and tissue samples were collected immediately.

Measurement of serum amylase, interleukin-6, tumor necrosis factor-α, D-lactic acid, and diamine oxidase

Serum amylase was detected using a spectrophotometric method with a commercial kit (Jiancheng, Nanjing, China). Briefly, 0.5 mL of starch reagent and 0.10 mL of serum samples were added to a 5 mL graduated tube. After incubating for 7.5 min at 37 °C, 0.5 mL of iodine reagent and 3.0 mL water were added immediately. The absorbance was measured at 660 nm. Enzyme-linked immunosorbent assay (ELISA) kits for tumor necrosis factor (TNF-α) (Lengton, Shanghai, China), D-lactic acid (Goybio, Shanghai, China), diamine oxidase (DAO) (Jiancheng, Nanjing, China), interleukin (IL)-6 (Lengton, Shanghai, China) were used to evaluate the levels in rat serum according to the manufacturer's instructions.

Histological examination

Pancreatic and intestinal tissues were fixed in 10% formaldehyde. After dehydration in gradient alcohol and transparentizing in xylene, the tissues were embedded in paraffin and cut into 5 μm thick slices. The slices were stained with hematoxylin and eosin for histological examination. The tissues were scored under an optical microscope (Leica, Solms, Germany) by a pathologist blinded to the experimental design. Five histopathological parameters (edema, inflammatory infiltration, hemorrhage, and acinar necrosis) of the pancreatic tissue were evaluated, each on a scale of 0-4 using a previously described method[11]. Mucosal injury, inflammatory infiltration, and hemorrhage were graded, each on a scale of 0-5, using a method described in a previous article to assess intestinal tissue[12].

Apoptosis detection

Fixed rat intestinal sections with 10% formaldehyde were deparaffinized in xylene and rehydrated through a graded ethanol series. A terminal deoxynucleotidyl transferase-mediated dUTP nick-end labeling (TUNEL) assay kit (Keygen, Nanjing, China) was applied to assess apoptosis in intestinal tissue. Briefly, rat intestinal sections were treated with 50 μL of the TUNEL reaction mixture and then incubated at 37 °C for 60 min. After rinsing with phosphate buffer solution, tissue sections were stained with 4′,6-diamidino-2-phenylindole (DAPI) and observed with fluorescence microscopy.

Immunofluorescence analysis

For immunofluorescence analysis, intestinal sections were incubated in a xylol-ethanol gradient to remove the paraffin. The slides were incubated with primary antibody against NFATc3 (Santa Cruz, CA, United States) and subsequently incubated with Alexa Fluor goat anti-rabbit immunoglobulin G (Life Technologies), and then observed using fluorescence microscopy following staining of the nuclei with DAPI (Sigma-Aldrich, St. Louis, MO). The specificity of the signals was monitored by blank staining without primary antibodies.

Western blot analysis

Western blotting was performed as previously described[13]. Total protein from intestinal tissue was extracted with a protein extraction kit (KeyGen, Nanjing, China). Protein was separated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis and then transferred onto a nitrocellulose membrane. After nonspecific binding was blocked, the membranes were incubated with primary antibodies against calcineurin A (CnA, 1:2000, Abcam, United Kingdom), calcineurin B (CnB, 1:500, Abcam, United Kingdom), and β-actin (1:1000). Immunoreactive proteins were visualized using enhanced chemiluminescence detection (Bioworld Technology, Nanjing, China). ImageJ software was used for statistical analyses of the band intensities normalized to β-actin.

Quantitative real-time polymerase chain reaction

Total RNA extraction from intestinal tissue was performed with NAiso Plus (TaKaRa, Dalian, China), and then a PrimeScriptTMRT MasterMix kit (TaKaRa, Dalian, China) was used to synthesize cDNA. Quantitative real-time polymerase chain reaction (qRT-PCR) was carried out in a 7300 Real-time PCR System using a SYBR® Premix Ex Taq™IIKit (TaKaRa). The primer sequences were as follows: NFATC3 forward 5′-GGTGGCCATCCTGTTGTGAA-3′ and reverse 5′-CAGTAATGCGATGCACCTGGTAA-3′; β-actin forward 5′- GGAGATTACTGCCCTGGCTCCTA-3′ and reverse 5′-GACTCATCGTACTCCT-GCTTGCTG-3′. The $2^{-\Delta\Delta Ct}$ method was used for statistical analyses of the mRNA levels normalized to β-actin.

Preparation of QYD serum

Drug-containing serum was prepared as described previously[14]. Ten SD rats were divided into two groups: A normal group and a QYD serum group. In the QYD serum group, QYD (the First Affiliated Hospital of Dalian Medical University, Dalian, China) was administered to SD rats *via* gavage at 10 mL/dose/kg body weight twice per day for 5 d. The rats in the normal group were treated with the same volume of saline. After 5 d of treatment, blood samples were extracted from the abdominal arteries. Under anesthesia, serum was isolated from both the normal group and the QYD group based on a previously described method[15].

Cell experimental design

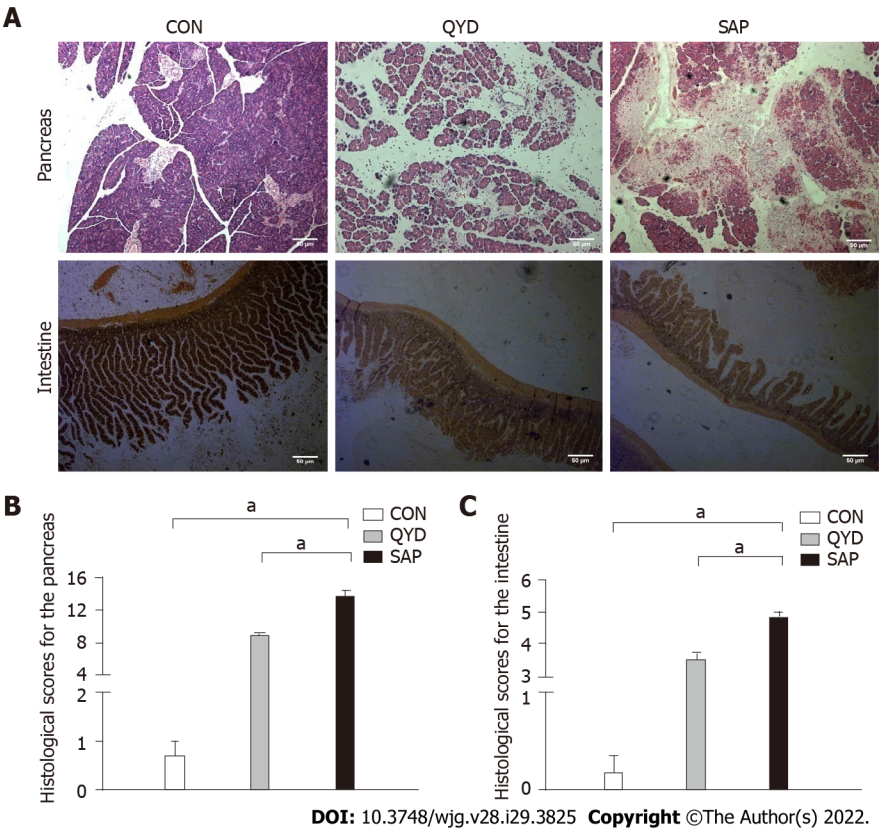
Caco-2 cells were randomly divided into the following groups: The rat serum group, in which the cells were treated with 10% normal rat serum for 24 h; the rat serum + lipopolysaccharide (LPS) group, in which the cells were exposed to 100 ng/mL LPS and 10% normal rat serum for 24 h; and the QYD serum + LPS group, in which the cells were treated with 100 ng/mL LPS and 10% QYD serum for 24 h.

Cell viability analysis

Caco-2 cell viability was assessed using MTT assays (Sigma, St Louis, MO, United States). After incubation with MTT dye (5 mg/mL) for 4 h at 37 °C, DMSO (150 μL/well) was added. The optical absorbance was evaluated with a microplate reader at 490 nm to measure cell viability.

Measurement of intracellular calcium levels

Intracellular Ca^{2+} levels were monitored using the Ca^{2+}-sensitive fluorescent indicator Fluo-3. Flou-3 can enter cells through the medium of lipophilic AM and combine with intracellular free Ca^{2+}. The fluorescence intensity of Flou-3 is positively correlated with the concentration of intracellular free Ca^{2+}. Caco-2 cells were seeded in HBSS buffer with Fluo-3/AM at 5 μmol/L for 30 min. The cells were washed twice in fresh HBSS and then treated with 0.5 mL of HBSS buffer. Finally, a confocal laser scanning microscope (BioRad Radiance 2100) was used to assess the fluorescence intensity.



Statistical analysis

Data are expressed as the mean ± SD. SPSS v16.0 software was used for data analysis. One-way ANOVA was applied to assess significant differences between groups; $P < 0.05$ was considered to indicate a statistically significant difference.

RESULTS

Histological changes in the pancreas and intestine

As shown in Figure 1A, edema, inflammatory infiltration, hemorrhage, and acinar necrosis were observed in the pancreas as the characteristic morphological features of SAP. Interstitial edema, irregular villi, mucosal erosion, and inflammatory infiltration were exhibited in the SAP group, with necrosis and shedding of the intestinal epithelium. The pancreatic and intestinal histological scores were significantly higher according to the standards of Anthony and Chiu, respectively. However, QYD treatment significantly ameliorated the pancreatic and intestinal pathology caused by SAP (Figures 1B and 1C).

Figure 1 Histological changes in pancreatic and intestinal tissues. A: Slight edema was detected [pancreas control (CON) group]; broad necrosis of acinar cells and interstitial edema were observed [pancreas severe acute pancreatitis (SAP) group]; only local necrosis, slight interstitial edema, and few inflammatory cell infiltrates were observed [pancreas Qingyi decoction (QYD) group]. Slight interstitial edema was detected (intestine CON group); irregular villi, mucosal erosion, and inflammatory infiltration were observed (intestine SAP group); edema and mild mucosal erosion were observed (intestine QYD group); B: Histological scores for the pancreas; C: Histological scores for the intestine. The histological scores for the pancreas and intestine were significantly ameliorated in the QYD treatment group compared with the SAP group. $^{a}P < 0.05$, 100 ×. CON: Control; QYD: Qingyi decoction; SAP: Severe acute pancreatitis.

Serum levels of amylase, IL-6, TNF-α, D-lactic acid and DAO

It can be seen from the data in Figure 2 that the serum levels of amylase (Figure 2A), IL-6 (Figure 2B), and TNF-α (Figure 2C) were increased significantly in the SAP group compared with the control group. Consistent with previous research results, QYD treatment ameliorated the increases in amylase, IL-6, and TNF-α serum levels observed in the SAP group. D-lactic acid and DAO, which can serve as markers of intestinal barrier dysfunction and tissue injury, were significantly increased in the SAP group compared with the control group. However, the levels of serum D-lactic acid and DAO in the QYD group were significantly decreased compared with those in the SAP group (Figures 3A and 3B).

CnA and CnB expression in intestine

Following QYD treatment, the expression levels of CnA and CnB were detected *via* western blot analysis. The results, shown in Figure 4A, demonstrated that the expression levels of CnA and CnB were increased in the SAP group. The band intensities of CnA and CnB in the SAP group were 2.78 and 1.24, respectively, normalized to β-actin. QYD treatment significantly reduced the protein expression levels of CnA and CnB (Figures 4B and 4C).

NFATc3 expression in the intestine

Furthermore, we examined NFATc3 protein expression in intestinal tissues using immunofluorescence. NFATc3 was highly expressed in the SAP group compared with the control group but significantly downregulated under QYD treatment (Figure 5A). Semiquantitative analysis showed that the relative integral optical density (IOD) value was higher in the SAP group than in the control group. However, the relative IOD value was lower in the QYD group than in the SAP group (Figure 5B).

Transcription of NFATc3 mRNA in intestinal tissue

Compared with the control group, qRT-PCR analysis revealed that the level of NFATc3 mRNA transcription was obviously increased in the SAP group. QYD treatment decreased the mRNA level compared with that in the SAP group (Figure 6).

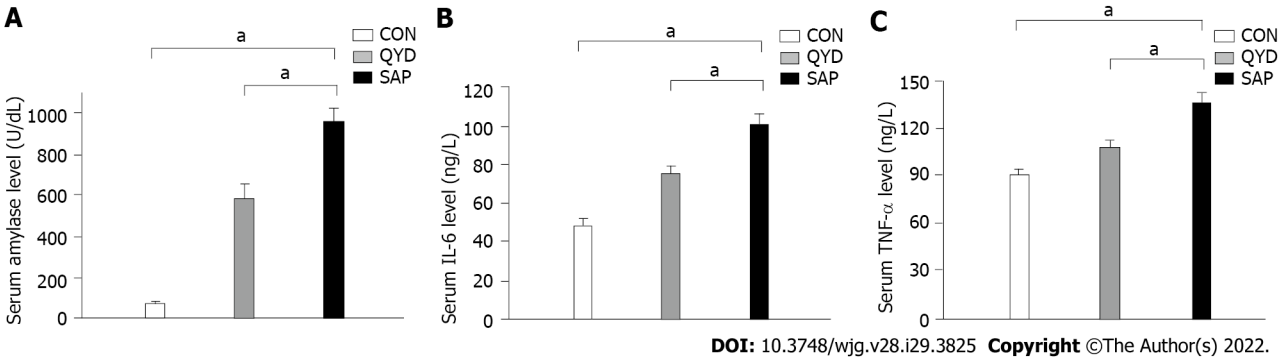

Figure 2 Serum levels in the different experimental groups. A: Amylase; B: Interleukin-6; C: Tumor necrosis factor-α. $^{a}P < 0.05$. CON: Control; QYD: Qingyi decoction; SAP: Severe acute pancreatitis; TNF: Tumor necrosis factor; IL: Interleukin.

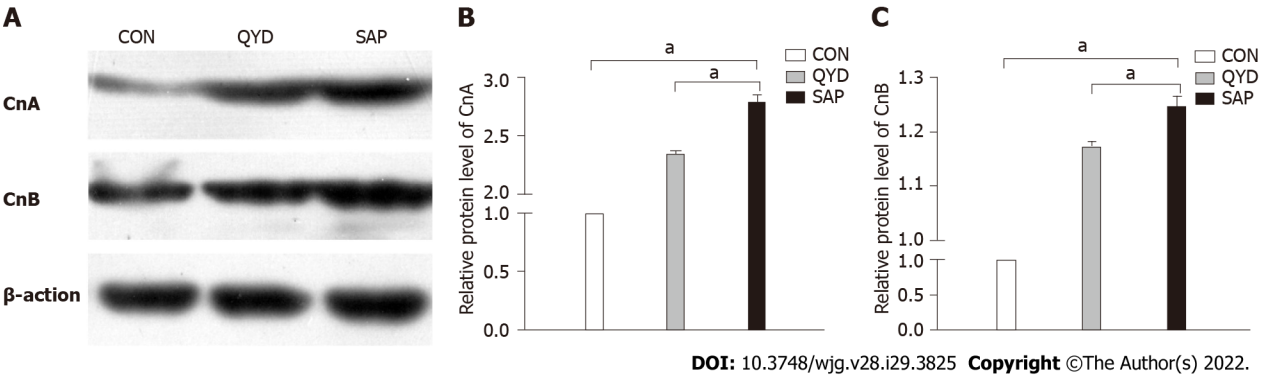

Figure 4 Expression of calcineurin subunits in the intestine. A: Calcineurin A (can) and calcineurin B (CnB) protein expression in the intestine; B: Qingyi decoction (QYD) treatment significantly inhibited the elevatcanCnA protein expression in the intestine observed in the severe acute pancreatitis (SAP) group; C: QYD treatment significantly inhibited the elevated CnB protein expression in the intestine observed in the SAP group. $^{a}P < 0.05$. CON: Control; QYD: Qingyi decoction; SAP: Severe acute pancreatitis; CnA: Calcineurin A; CnB: Calcineurin B.

ICE apoptosis

TUNEL staining results of rat intestinal tissue slices revealed that retrograde infusion of sodium deoxycholate increased ICE apoptosis compared with the control rats (Figure 7). However, compared with that in the SAP group, the level of ICE apoptosis in the QYD groups was significantly lower.

Effect of QYD serum on cell viability and intracellular calcium

A significant decline in cell viability after LPS treatment was verified by MTT assays (Figure 8), but QYD serum inhibited LPS-induced cell death. LPS induced a significant increase in Ca^{2+} levels. Treatment with QYD serum significantly attenuated the increase in Ca^{2+} levels caused by LPS-induced

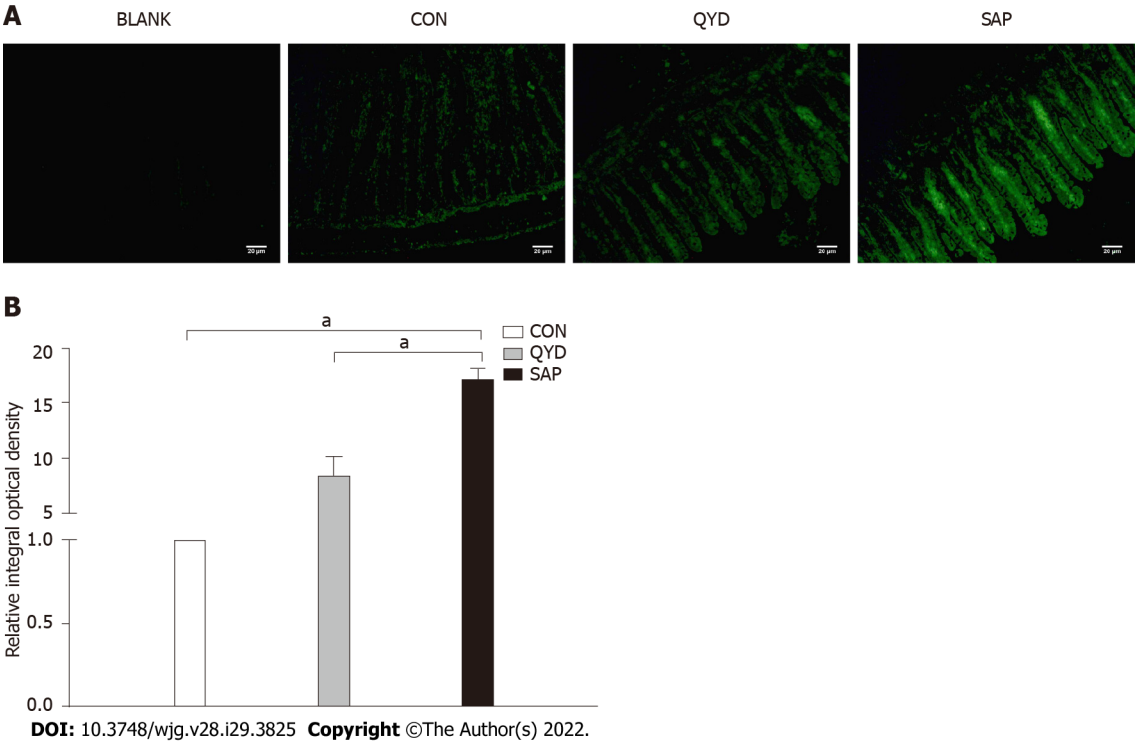

Figure 5 Immunofluorescence and semiquantitative analysis of nuclear factor of activated T-cells c3 expression. injury (Figure 9A). The relative mean optical density value was higher in the LPS group than in the control group, but QYD serum treatment decreased the relative mean optical density induced by LPS (Figure 9B).

DISCUSSION

SAP refers to an acute abdominal disease characterized by rapid onset, rapid progression, and a high fatality rate. Prior studies have noted the importance of the intestinal barrier in the progression of SAP, which involves alterations in its mechanical, immune, chemical, and biological barriers[16]. Bacterial and/or endotoxin translocation from the gut lumen caused by intestinal barrier functional disturbance has a major influence on the prognosis of SAP[17]. The intestinal epithelium functions as the first barrier

to defend against the invasion of overcrowded intestinal bacteria owing to intestinal motor dysfunction in SAP. Therefore, conservation and renovation of the intestinal epithelial function may have a positive effect on SAP and reduce SAP-mediated septic morbidity and mortality[18]. As a specific form of cell death in terms of its morphology and biochemistry, apoptosis has been thought of as a key factor in the physiological processes of IEC biology[19]. Recently, investigators have examined the effects of IEC apoptosis on intestinal integrity[18]. TNF-α, secreted from pancreatic acinar cells, monocytes and macrophages, not only mediates primary inflammation directly but also contributes to the occurrence of secondary inflammation[20,21]. High concentrations of TNF-α can be detected in serum as well as in pancreatic parenchyma, ascitic fluid, and lymphatic drainage in the early stages of AP. Many studies have confirmed that high serum levels of TNF-α are related to the severity of AP[22,23]. IL-6 is a phosphorylated glycoprotein of 185 amino acids encoded by the human IL-6 gene. The IL-6 gene has been mapped to human chromosome 7p21-24[24]. Current evidence has clarified that IL-6 is a vital cytokine in AP development; moreover, the serum level of IL-6 is associated with AP severity[25]. DAO is an intestinal mucosal enzyme that plays a key role in digestion and absorption and maintenance of the mucosal barrier. DAO activity in the mature upper villus cells of the intestinal mucosa is high, but it is very low in all other tissues under normal physiological conditions. However, DAO activity increases in the blood plasma and intestinal lumen when the intestinal mucosa is damaged[26,27]. D-lactic acid is a metabolite produced by the fermentation of intestinal bacteria. When the permeability of the intestinal mucosa increases as a result of infection with bacteria, D-lactic acid can enter the blood circulation and be detected in the peripheral blood. Consequently, D-lactic acid can be used as an early indicator of intestinal mucosa damage with high specificity[28]. In accordance with previous studies, the present results confirmed that retrograde infusion of sodium deoxycholate successfully created a rat model of SAP. Retrograde infusion of sodium deoxycholate increased the severity of pancreatic and intestinal

pathology and the levels of serum amylase, TNF-α, and IL-6. Moreover, both the indicators of intestinal mucosa damage (D-lactic acid and DAO) and the levels of IEC apoptosis were elevated in the SAP group.

CaN, a serine/threonine phosphatase, can be defined as a central calcium-responsive signaling molecule that has a significant impact on immune responses. CaN contains two subunits, CnA (the large catalytic subunit) and CnB (the smaller regulatory subunit). As a result, the formation of a heterodimer determines the activity of CaN[29]. It is now well established based on a variety of studies that CaN is a significant contributing factor to the development of acute pancreatitis as a unique target of aberrant calcium signaling[30-32]. For example, bile acid-induced pancreatic injury, transient high ductal pressure-induced pancreatic inflammation, and pancreatic inflammation caused by radiocontrast agents are all dependent on CaN activation[31,33]. CaN can dephosphorylate several substrates; one of the most important of these substrates is NFATc[34]. CaN/NFAT signaling can accurately adjust gene expression to alter cell differentiation and development, dependent on its remarkable ability to sense Ca^{2+} oscillations in cells[35]. When phosphorylated, all NFAT members reside in the cytosol of resting cells. However, upon dephosphorylation in response to high intracellular levels of Ca^{2+}, cytosolic CaN binds to NFAT, leading to nuclear translocation and transcription. The calcium-CaN-activated NFAT family contains four members (NFATc1, NFATc2, NFATc3, and NFATc4), among which the NFATc3 gene has been identified to be expressed in mammalian intestinal tissues[36]. The effects of NFATc3 in AP were described in a report by Awla *et al*[37]. Their results demonstrated that NFATc3 could adjust to trypsinogen activation, inflammation, and pancreatic tissue damage during the process of AP. Consequently, NFATc3 activity might be a therapeutic target[37]. In this study, we found that the protein expression levels of the two subunits of CaN were remarkably elevated in the SAP group. Furthermore, we examined NFATc3 expression using qRT-PCR and immunofluorescence analyses. The results suggested that the NFATc3 gene was significantly upregulated at both the transcript and protein levels in the SAP group compared with the control group.

The therapeutic effects and associated mechanisms of QYD may lie in clearing fever, detoxifying, soothing the liver, regulating the flow of vital energy and removing obstructions, invigorating the circulation of blood, dissipating blood stasis, and dredging urination and defecation, according to traditional Chinese medicine's holistic thoughts[38]. QYD, as an organic combination of many effective components, plays a multitarget role in acute pancreatitis treatment through multiple pathways, including defending the intestinal barrier. It has been proven that QYD can suppress intestinal bacterial translocation, moderate inflammatory factor release, and prohibit intestinal mucosa destruction by inhibiting the expression of intestinal secreted phospholipase A2[39], suppressing the Toll-like receptor 4/nuclear factor-kappa B signaling pathway and stimulating Zona occludens 1 expression[9]. Serum

pharmacology, first brought forward by the famous Japanese medical scientist Masakazu Tashiro, was introduced into the field of TCM medical research in 1997[40]. Serum pharmacology can broadly be defined as a new experimental method in which the target drug is administered orally to experimental animals, and then the serum is separated for *in vitro* pharmacological testing after a certain period[41]. Currently, rabbits and rats are mainly chosen for the preparation of drug-containing serum as a result of their biological characteristics similar to those of humans[42]. After investigation of many of the pharmacokinetic parameters of TCM, an optimal medication plan (medicating 2 times a day, 3 d to 5 d continuously, and exsanguination 1 h after the last medication) was proven feasible. Owing to better reflecting the metabolism of TCM in the human body, serum pharmacology can provide new directions for pharmacological analysis of TCM[43]. In this study, the severity of SAP in the QYD group was attenuated compared with that in the untreated SAP group. In addition, the levels of IEC apoptosis declined in the QYD group relative to the untreated group. QYD significantly alleviated the upregulation of CaN and NFATc3 gene expression in the intestine in the SAP group. Further study indicated that QYD serum significantly decreased the LPS-induced elevation of intracellular free Ca^{2+} levels and cell death.

CONCLUSION

In summary, the results of this research demonstrated that the CaN/NFATc3 pathway might play a key role in IEC injury caused by SAP and that QYD can exert protective effects. Moreover, QYD can regulate CaN and NFATc3 gene expression. The findings suggest that the protective effects of QYD might be mediated, at least partially, by restraining IEC apoptosis *via* the CaN/NFATc3 pathway.

ARTICLE HIGHLIGHTS

Research background

Severe acute pancreatitis (SAP) is a severe acute abdominal disease characterized by high morbidity and mortality. A considerable amount of literature has demonstrated that intestinal barrier dysfunction is a significant contributory factor to SAP development. Qingyi decoction (QYD) has been used to treat acute pancreatitis in China for many years.

Research motivation

The protective functions of QYD against intestinal mucosa injuries caused by SAP will provide new therapeutic information on SAP.

Research objectives

To research the function and mechanism of QYD in treating intestinal mucosa injuries caused by SAP.

Research methods

A rat model of SAP was created. Hematoxylin and eosin staining of pancreatic and intestinal tissue was performed. Enzyme-linked immunosorbent assay was used to estimate the concentrations of tumor necrosis factor (TNF-α), interleukin (IL)-6, D-lactic acid, and diamine oxidase (DAO). Terminal deoxynucleotidyl transferase dUTP nick-end labeling was carried out to assess intestinal epithelial cell (IEC) apoptosis. Quantitative real-time polymerase chain reaction, western blotting, and immunofluorescence were used to determine the expression of calcineurin (CaN) and nuclear factor of activated T-cells (NFATc3). MTT and confocal laser scanning microscope were used to detect cell viability and intracellular calcium levels *in vitro* studies.

Research results

In this study, the severity of SAP in the QYD group was attenuated. In addition, the levels of IEC apoptosis declined in the QYD group. QYD significantly restrained CaN and NFATc3 gene expression in the intestine. Further study indicated that QYD serum significantly decreased the lipopolysaccharide-induced elevation in intracellular free Ca^{2+} levels and cell death.

Research conclusions

This research demonstrated that the CaN/NFATc3 pathway might play a key role in IEC injury caused by SAP and that QYD can exert protective effects, at least partially, by restraining IEC apoptosis *via* the CaN/NFATc3 pathway.

Research perspectives

This study provides insight into the function and mechanism of QYD in the treatment of intestinal

mucosa injuries caused by SAP *in vivo* and *in vitro* experiments, thereby providing theoretical support for the clinical application of QYD.

Abstract

BACKGROUND

Obesity is associated with an increased risk of developing Crohn's disease (CD), higher disease activity, and comparatively worse clinical outcomes.

AIM

To investigate the role of mesenteric adipose tissue-derived exosomes in the pathogenesis of CD aggravation in obese individuals.

METHODS

First, we induced colitis in mice initiated on high-fat and normal diets and compared the severity of colitis. We then extracted and identified exosomes from mesenteric adipose tissue and determined the levels of metastasis-associated lung adenocarcinoma transcript 1 (MALAT1) in mesenteric adipose tissue-derived exosomes and the colon. Next, we demonstrated an interaction between MALAT1 and the miR-15a-5p/activating transcription factor 6 (ATF6) axis. Finally, we explored the effects of mesenteric adipose tissue-derived exosomes extracted from mice fed a high-fat or normal diet on the severity of 2,4,6-trinitrobe-nzenesulfonic acid (TNBS)-induced colitis and ATF6-related endoplasmic reticulum stress

pathways.

RESULTS

High-fat diet was found to aggravate TNBS-induced colitis in mice. The expression of MALAT1 in mesenteric adipose tissue-derived exosomes of high-fat diet-fed mice increased. The increased expression of MALAT1 in colon tissue exacerbated TNBS-induced colitis and activated the ATF6 endoplasmic reticulum stress pathway. This effect was partially reversed by the reduced expression of MALAT1 and overexpression of miR-15a-5p.

CONCLUSION

Mesenteric adipose tissue-derived exosome-encapsulated long noncoding RNAs MALAT1 targets the colon and aggravates TNBS-induced colitis in obese mice, which may potentially act on the miR-15a-5p/ATF6 axis and activate endoplasmic reticulum stress.

Key Words: Metastasis-associated lung adenocarcinoma transcript; Crohn's disease; miR-15a-5p; Mesenteric adipose tissue; Obesity; Colitis; Inflammatory bowel disease

Core Tip: A higher visceral adipose tissue ratio has been associated with increased disease activity in patients with Crohn's disease. However, the mechanisms underlying this effect remain unclear. Our study indicates that a high-fat diet increases the mesenteric adipose tissue content and aggravates colitis in mice. Mesenteric adipose tissue-derived exosome long noncoding RNAs metastasis-associated lung adenocarcinoma transcript 1 can be absorbed by the colon, leading to the activation of the endoplasmic reticulum stress pathway by targeting the miR-15a-5p/activating transcription factor 6 axis to aggravate colitis.

INTRODUCTION

Crohn's disease (CD) is a chronic relapsing inflammatory disease of the gastrointestinal tract that results from the interplay between genetic susceptibility and various environmental exposures[1]. The incidence of CD is higher in developed countries and urban areas than in developing and rural areas[2]. Similarly, the prevalence of CD is increasing in areas with rapid urbanization[3], paralleling the obesity epidemic, possibly in conjunction with western-style diets characterized by high fat content.

The conventional understanding is that CD is a chronic disease characterized by wasting, low weight, and malnutrition. Nevertheless, based on real world data, 15%-40% of patients with inflammatory bowel disease (IBD), including CD and ulcerative colitis (UC), are obese and 20%-40% are overweight [4]. Several studies have shown that obesity is associated with an increased risk of developing CD[5,6], a higher disease activity, and comparatively worse clinical outcomes[7]. For instance, Jain *et al*[8] observed that obesity was not only associated with an increased risk of persistent disease activity and relapse in patients with IBD but also with higher rates of anxiety, depression, fatigue, pain, and inferior social function scores. Although these studies on the association between obesity and the course of CD have some limitations, and the above-mentioned outcomes have not been observed consistently, accumulating evidence indicates that visceral adiposity better captures the association between obesity and CD than body mass index[4]. A higher baseline visceral adipose tissue/total fat mass ratio was found to be associated with increased disease activity[9]. Although the influence of obesity on the course of CD has been confirmed, the underlying mechanism remains elusive.

Significant expansion of adipose tissue is a common phenomenon in obese individuals. In addition to storing energy, adipose tissue is an endocrine organ that secretes various adipokines, lipokines, and exosomes, contributing to the state of chronic inflammation in obese individuals[10]. Localized mesenteric fat accumulation in CD patients, known as creeping fat, is not only related to overall obesity but also has a systemic pro-inflammatory effect[11]. Adipose tissue and visceral adipose tissue-derived endocrine hormones are involved in multiple diseases, including cancer[12], cardiovascular disease[13], and nonalcoholic steatohepatitis (NASH)[14]. Exosomes are extracellular vesicles secreted by various cells, including adipocytes[15]. Visceral adipose tissue-derived exosomes display tissue affinity, prefer-

entially targeting the colonic lamina propria[16]. Mesenteric adipose tissue can directly invade the lamina propria. Therefore, we hypothesized that obesity exacerbates IBD, partially due to mesenteric adipose tissue-derived exosomes.

Previous studies have indicated that exosomes contain multiple non-coding RNAs such as circular RNAs, long noncoding RNAs (lncRNAs), and microRNAs, which serve as messengers in cell-to-cell communication. Among these, lncRNAs are non-coding RNAs containing more than 200 nucleotides [17]. LncRNAs can interact with transcription factors to regulate transcription, bind to proteins to promote the formation of ribonucleoproteins, guide chromatin-modifying protein complexes targeting genes, and act as sponges for downstream microRNAs, participating in a variety of pathophysiological processes[18]. To our knowledge, few studies have explored the potential functions and mechanisms of adipocyte-derived exosomal lncRNAs in the exacerbation of CD.

The present study aimed to investigate the role of lncRNAs transferred by mesenteric adipose tissue-derived exosomes in obesity aggravated CD, and thereby assess the potential of these lncRNAs as therapeutic targets for the treatment of CD in this subpopulation.

MATERIALS AND METHODS

Construction of obesity mouse model and colitis mouse model

C57BL/6 mice (6-8 wk old) were purchased from Chengdu Dossy Experimental Animals Co.,Ltd. and fed either a normal diet (ND) (#D12451, Research Diets, United States) or a high-fat diet (HFD) (#D12492, Research Diets, United States) for 12 wk. To induce acute experimental colitis, 2,4,6-trinitrobenzenesulfonic acid (TNBS) (Beyotime, China; 100 μg/g, 175 μL) was injected into the colon for 4 d. The daily disease activity index (DAI) score was calculated in mice in accordance with a well-established method[19]. The body weight of the mice in each group was also recorded. On day 8, the mice were sacrificed for colon and mesenteric adipose tissue collection. Rectum tissue, 3 cm away from the anal margin, was collected for hematoxylin and eosin (HE) staining and inflammatory pathological score determination using the following steps. Briefly, mouse colon tissue was fixed in 10% formaldehyde, embedded in paraffin, sectioned, and stained with HE. Details of histological scoring have been described previously[20]. The remaining colon tissue was placed in liquid nitrogen for subsequent analyses. Mice were randomly divided into the following four groups (n = 6 each): ND + control, HFD + control, normal diet + TNBS, and HFD + TNBS.

RNA Extraction and real-time reverse transcription-PCR

Total RNA was isolated using Trizol (Invitrogen, United States) and reverse-transcribed into cDNA using the First Strand cDNA Synthesis Kit (TransGen, China), in accordance with the manufacturer's instructions. Real-time reverse transcription-PCR (qRT-PCR) was performed using the SYBR Premix Ex Taq qPCR kit (TaKaRa, Japan). Primer sequences used are listed in Supplementary Table 1.

Enzyme linked immunosorbent assay and Western blotting

The concentrations of mouse interleukin 1β (IL-1β), tumor necrosis factor α (TNF-α), and interleukin 6 (IL-6) were detected using enzyme linked immunosorbent assay (ELISA) kits (Elabscience, China) according to the manufacturer's instructions. Additionally, total protein was isolated using radioimmune precipitation assay (RIPA) buffer (TaKaRa, Japan) supplemented with a protease inhibitor (Roche, Switzerland). After quantification using the BCA Protein Assay Kit (Thermo, United States), the proteins were separated by SDS-PAGE and transferred onto polyvinylidene fluoride (PVDF) membranes. The membranes were blocked and incubated overnight with antibodies against activating transcription factor 6 (ATF6) (ab227830, Abcam, United Kingdom), p-PERK (MA5-15033, Thermo, United States), p-IRE1 (CSB-RA00,7795A724phHU, CUSABIO, China), GRP78 (MA5-27687, Thermo, United States), p-EIF2α (51995, CST, United States), CHOP (5554T, CST, United States), and GAPDH (ab8245, Abcam, United Kingdom) at 4 °C. The membranes were then incubated with HRP-conjugated secondary antibodies (Multi Sciences, China). Finally, the protein bands were detected using enhanced chemiluminescence (ECL) kits (Thermo, United States).

Isolation and primary culture of adipocytes

Mesenteric adipose tissue (25 g) was isolated and placed into a sterile 50 mL polypropylene test tube containing 15 mL of collagenase [1 mg collagenase/1 mL phosphate belanced solution (PBS); 3 mL solution/1 g tissue]. After grinding, the solution was swirled for 20 s and the test tube was incubated at 37 °C in a rocking water bath at 100 rpm for 40 min. The solution was vortexed and filtered through a funnel containing a double gauze. Thereafter, the homogenate was centrifuged at 1000 rpm for 10 min, followed by collection of the top fat layer, which was washed three times with PBS. The precipitate was then resuspended in 10 mL of RBC lysis buffer (154 mmol/L NH_4Cl, 10 mmol/L $KHCO_3$, 1 mmol/L EDTA) in a water bath at 37 °C and 100 rpm for 5 min, followed by centrifugation at 1000 rpm for 10 min. The precipitates were resuspended in 10 mL of plate culture medium (DMEM, 0.1 mmol/L

penicillin, 0.06 mmol/L streptomycin, 10% HI-FBS, pH 7.4), swirled, spread on 100 mm culture dishes, and incubated at 37 °C. After 20 h, the cells were washed with 10 mL of PBS three times, and supplemented with 1 mL of trypsin. Finally, the cells were resuspended and subcultured for further analysis.

Isolation and confirmation of exosomes

The supernatant of adipocytes was collected and centrifuged at 2000 × g for 30 min, followed by filtration through a 0.22 μm membrane to remove apoptotic cells, debris, and large particles. Exosomes were extracted from the filtrate according to the manufacturer's instructions as described previously [21]. For further confirmation, the diluted exosomes were subjected to NanoFCM (China) for transmission electron microscopy and size distribution analysis.

Luciferase reporter assay and RNA pull-down assay

The luciferase reporter assay was performed using the Dual-Luciferase Reporter Assay System (Promega, United States), as described previously[22]. The RNA pulldown assay was performed using the Pierce Magnetic RNA-Protein Pull-Down Kit (Thermo, United States). Briefly, miR-15a-5p was biotinylated and transfected into the Caco-2 cells. Cultured cells were collected for lysis 48 h later. Thereafter, the RNA bound to miR-15a-5p was captured using Pierce nucleic acid-compatible streptavidin magnetic beads. Finally, qRT-PCR was performed to determine the expression of metastasis-associated lung adenocarcinoma transcript 1 (MALAT1).

Transfection of shMALAT1 and miR-15a-5p mimic

Adipocytes were transfected with shMALAT1 and miR-15a-5p using Plko.1-EGFP-puro. ShMALAT1 was designed based on information from Thermo Fisher (http://rnaidesigner.thermofisher.com/rnaiexpress/). The sequence of shMALAT1 was 5'-TGTACTATCCCATCACTGAAG-3'.

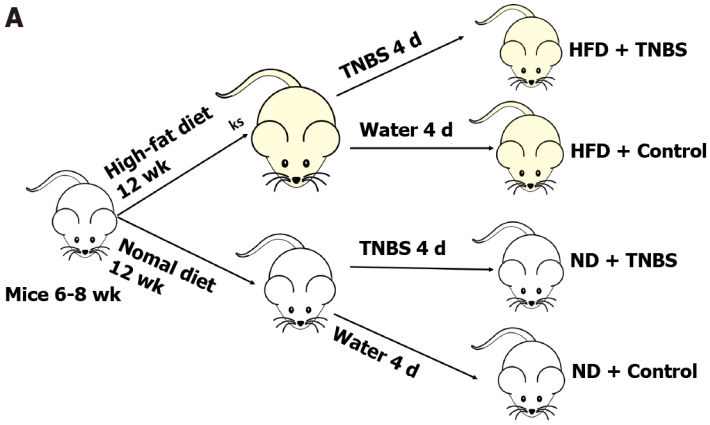
Statistical analysis

All data are presented as mean ± SD. Differences between two groups were analyzed using the Student's *t*-test. Two-way analysis of variance was used to compare the differences between multiple groups with two factors. All statistical analyses were performed using GraphPad 9.0.2 software, and $P < 0.05$ was considered to indicate a significant difference between groups.

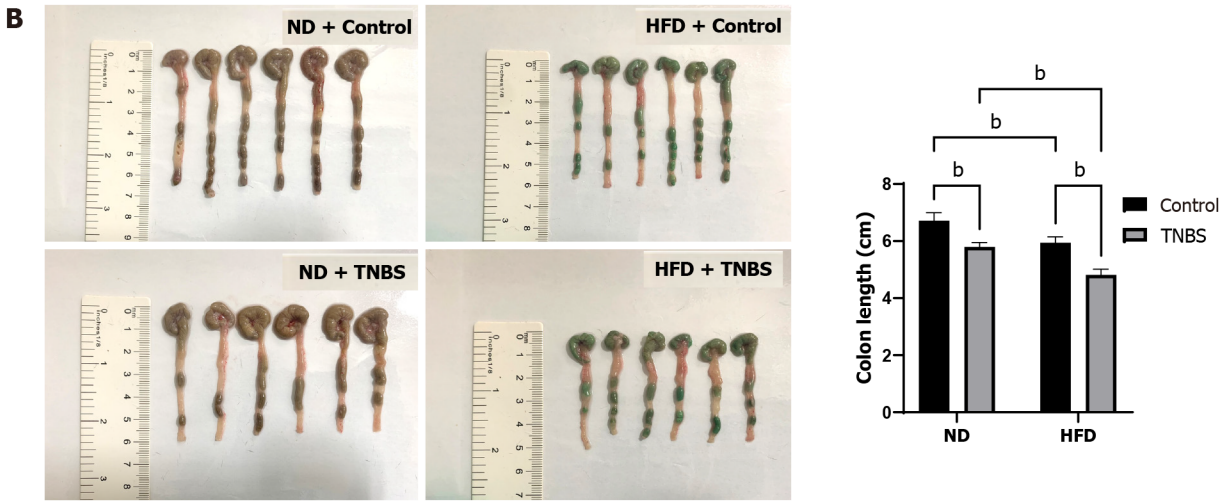
RESULTS

High-fat diet aggravated TNBS-induced colitis

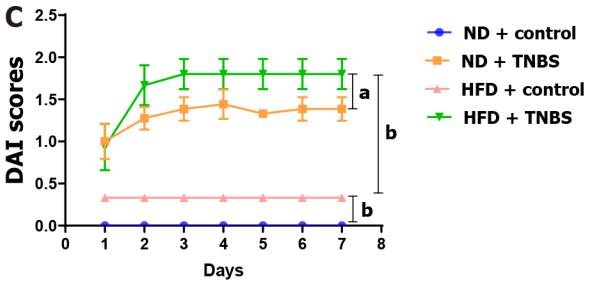
Accumulating evidence has shown that CD is more severe in obese individuals. We established a model of obesity in mice fed a HFD for 12 wk, while mice on a ND were used as controls. Thereafter, TNBS was used to induce colitis in the mice (Figure 1A). Compared with the control group, colon length was significantly shortened in the TNBS treatment group and the effect was further exacerbated by HFD (Figure 1B). To determine the degree of colitis activity index in different groups of mice, the DAI score was calculated daily for 8 d after starting TNBS treatment. HFD mice had a higher DAI score than the ND mice (Figure 1C). In addition, HFD significantly aggravated the TNBS-induced weight loss in mice (Figure 1D). To observe the degree of tissue damage in the mouse colon more intuitively, we used the colon tissue for HE staining and determined the histological injury scores (Figure 1E and F), which showed that HFD aggravated TNBS-induced colitis and tissue damage.



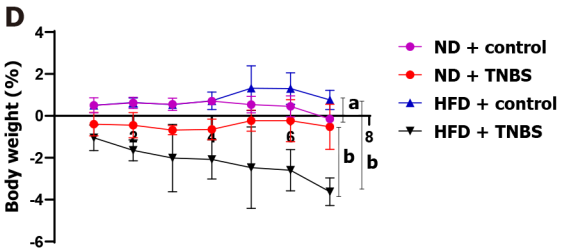
In addition, we measured the expression levels of pro-inflammatory cytokines in the colon tissues of mice in each group. The expression of TNF-α, IL-1β, and IL-6 in the colon of HFD mice treated with TNBS was significantly higher than that in ND mice treated with TNBS (Figure 1G-I). Notably, HFD itself increased the levels of pro-inflammatory cytokines in the colon of mice, which may be related to chronic inflammatory states in the body caused by obesity. These results suggest that HFD aggravates the severity of TNBS-induced colitis.



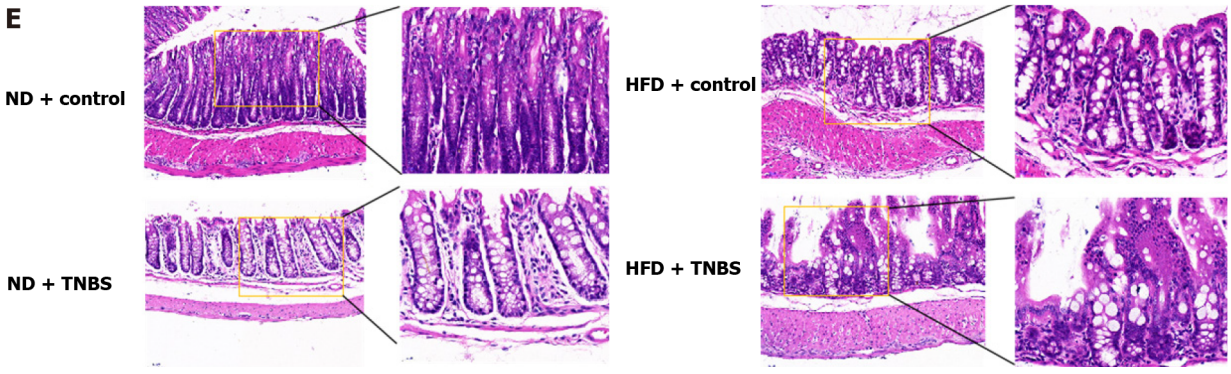
Successful extraction and identification of mesenteric adipose tissue derived exosomes (MAT-Exos)



The mesenteric adipose tissue index was significantly increased in HFD mice (Figure 2A). MAT-Exos were isolated from mesenteric adipose tissue cultured in vitro, and the typical mitochondrial morphology was observed using transmission electron microscopy (Figure 2B). Using Western blotting, we demonstrated that the isolated exosomes expressed exosomal marker proteins CD63 and TSG101 and the adipocyte exosomal membrane protein HSP70 (Figure 2C). The properties of exosomes were further demonstrated by particle size analysis (Figure 2D). In summary, we successfully harvested and identified exosomes from mesenteric adipose tissue.



Partial contribution of MAT-Exo to increased colon lncRNA MALAT1 Levels in HRD-fed mice



Existing literature indicates increased levels of lncRNA MALAT1 in HFD-fed mice[23]. In this study, the expression of lncRNA MALAT1 in MAT-Exos was found to be significantly increased in HFD-fed mice

using qRT-PCR (Figure 3A). The relative expression of lncRNA MALAT1 in mesenteric adipose and colon tissue in HFD mice treated with TNBS was significantly increased compared to that in ND mice treated with TNBS (Figure 3B and C). Therefore, we focused our attention on lncRNA MALAT1 and speculated that the increase in the relative expression of MALAT1 in the colon tissue of HFD mice may be partially attributed to exosomes from the mesenteric adipose tissue.

For further verification, MAT-Exos labeled with a PKH26 marker were incubated with Caco2 cells in vitro. PKH26 fluorescence in Caco2 cells was detected using a laser scanning confocal microscope, indicating that Caco2 cells can absorb MAT-Exos (Supplementary Figure 1). In addition, exosomes isolated from the mesenteric adipose tissue of HFD-fed and ND mice were injected into the mice *via* the tail vein, followed by lncRNA MALAT1 detection in the mouse colon tissue. MAT-Exos of HFD-fed mice increased the relative expression of lncRNA MALAT1 in the colon tissues of recipient mice (Figure 3D). We speculate that in HFD mice, the MAT-Exos-encapsulated lncRNA MALAT1 might target the colon to increase its local expression.

LncRNA MALAT1 targetes the miR-15a-5p/ATF6 axis

Numerous miRNAs with the ability to interact with lncRNA MALAT1 have been reported in literature [24], among which miR-15a-5p has attracted our attention. After searching miRDB (http://mirdb.org) [25] and TargetScan, we identified many potential mRNAs downstream of miR-15a-5p. Combining the literature review and bioinformatic prediction (Figure 4A), we chose ATF6 as the target mRNA of miR-15a-5p. ATF6 is an important molecule associated with endoplasmic reticulum (ER) stress[26] involved in gut homeostasis and IBD processes[27-29]. Western blotting was used to detect ATF6 expression in the colon tissues of mice in each group. The ATF6 Levels in the colon tissues of ND mice treated with TNBS were higher than those in ND mice without TNBS treatment. In addition, HFD was found to upregulate the expression of ATF6 in the colon tissues (Figure 4B). Subsequently, we used a dual-luciferase assay to confirm the interaction between ATF6 and miR-15a-5p. Compared with the control group, miR-15a-5p reduced the relative expression of ATF6 when placed downstream of the wild-type 3′ untranslated regions (3′ UTRs), but not when it was downstream of the mutant 3′ UTR, indicating a regulatory relationship between miR-15a-5p and ATF6 (Figure 4C). We then verified the interaction between miR-15a-5p and MALAT1 using RNA pull-down assays. We found that miR-15a-5p could bind to MALAT1, whereas the mutant miR-15a-5p could not pull down MALAT1 (Figure 4D). Based on these direct and indirect evidences, we can conclude that lncRNA MALAT1 can act on the miR-15a-5p/ATF6 axis.

LncRNA MALAT1 binds miR-15a-5p to aggravate TNBS-induced colitis in HFD-fed mice

We designed animal experiments to further demonstrate that mesenteric adipose tissue derived exosomes and their encapsulated lncRNA-MALAT1 can aggravate TNBS-induced colitis in HFD mice. First, MAT-Exos from HFD mice were isolated, and treated with either a short hairpin RNA targeting MALAT1 (shMALAT) or a miR-15a-5p mimic before injection. MAT-Exos from ND mice were used as a control. Thereafter, the mice were randomly divided into four groups and treated with ND-MAT-Exos, HFD-MAT-Exos, HFD-MAT-Exos + shMALAT1, or HFD-MAT-Exos + miR-15a-5p mimic, *i.e.*, A, B, C, and D groups, respectively. Mice were injected with MAT-Exos (100 μg/mouse) *via* the tail vein on days 1, 4, and 8. On day 3, TNBS was administered to induce colitis. On day 9, the mice were sacrificed and the colon tissue was collected. Compared to MAT-Exos from ND mice, MAT-EXOSs from HFD mice significantly increased the body weight loss (Figure 5A), DAI (Figure 5D), and histological damage

score (Figure 5E and F), and decreased colon length (Figure 5B and C). Transfection with shMALAT1 to knockdown the expression of MALAT1 or treatment with the miR-15a-5p mimic to enhance the function of miR-15a-5p partially reversed the effects of MAT-Exos on HFD mice. In conclusion, lncRNA MALAT1 may sponge miR-15a-5p and aggravate TNBS-induced colitis in HFD mice.

LncRNA MALAT1 acted on the miR-15a-5p/ATF6 axis to exacerbate colitis in response to ER stress

To further investigate whether lncRNA MALAT1 encapsulated within MAT-Exos of HFD mice aggravated TNBS-induced colitis *via* the miR-15a-5p/ATF6 axis, we detected the protein content of ATF6 in the colon tissue of mice in each group. MAT-Exos of HFD mice increased ATF6 expression in the colon tissue, whereas transfection with shMALAT1 or (A6) treatment with the miR-15a-5p mimic resulted in reduced expression of ATF6 in the colon tissue (Figure 6A). ATF6 is involved in IBD that develops in response to ER stress[30]. We further examined the expression of proteins associated with the ATF6-related ER stress pathway in the colon tissue. The expression of GRP78 and XBP-1 was increased in the colon of mice injected with MAT-Exos from HFD mice, a phenomenon that was antagonized by shMALAT1 and the miR-15a-5p mimic (Figure 6B; Supplementary Figure 2). In addition, the expression of other ER stress pathway related proteins, such as p-PERK, p-IRE1, p-eIF2α, and CHOP, also increased upon injecting MAT-Exos into HFD mice (Figure 6B). Previous studies have shown that ER stress activates NF-κB signaling to induce an inflammatory response[31,32]. Therefore, we also detected inflammatory factors associated with the NF-κB pathway (Figure 6C) using ELISA. The observed changes were consistent with the expression of proteins associated with the ATF6-related ER stress pathway.

DISCUSSION

Currently, almost one-third of the patients with IBD are obese and have a poor quality of life[8], great difficulty in inducing remission[33-35], increased risk of disease recurrence[8], and a higher burden of hospitalization and disease expenditure[36]. Therefore, it is necessary to explore the mechanism by

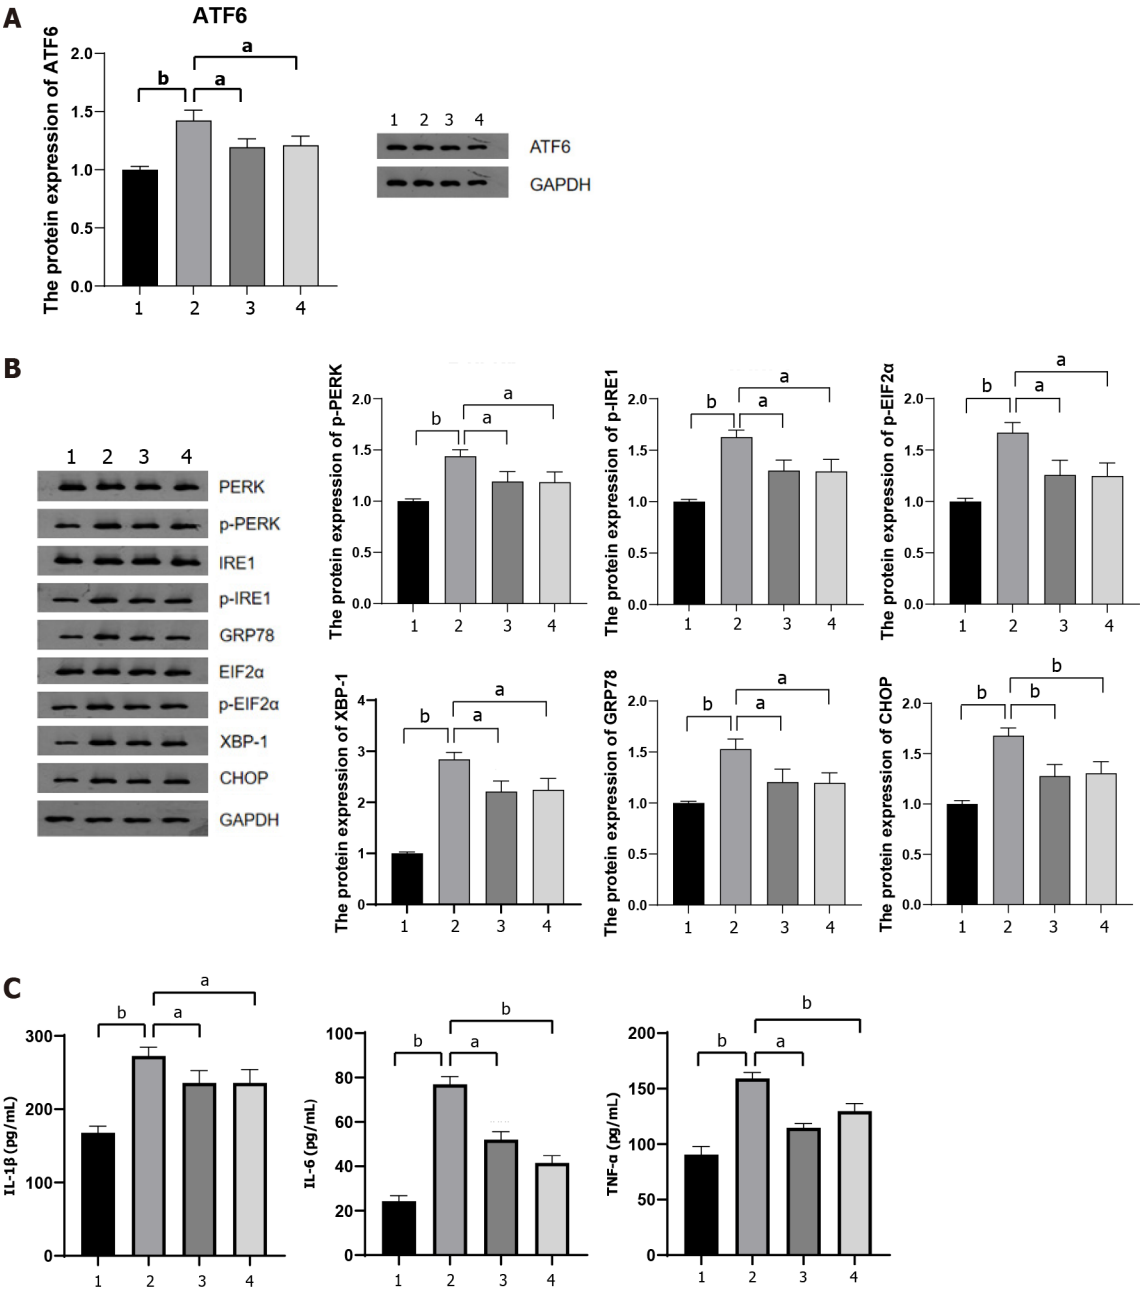

Figure 6 Long noncoding RNAs metastasis-associated lung adenocarcinoma transcript 1 acted on the miR-15a-5p/activating transcription factor 6 axis to activate the endoplasmic reticulum stress signaling pathway. which obesity is induced in IBD to improve its treatment. Previous studies have shown that the increased severity of IBD in obese patients is related to increased intestinal permeability, intestinal microflora translocation, and changes in the intestinal microflora spectrum[37,38]. In addition, the increase in plasma leptin levels and decrease in adiponectin levels were also found to be involved in obesity-mediated IBD aggravation, but the mechanisms underlying these processes need further exploration[39]. In this study, we propose a novel mechanism through which obesity aggravates IBD *via* exosome-secreted lncRNAs.

First, we demonstrated that a high-fat diet could aggravate TNBS-induced colitis in mice and explored the underlying mechanisms. One of the main characteristics of obesity is the accumulation of adipose tissue. As adipose tissue is an endocrine organ, it plays an important role in a variety of metabolism-related diseases, especially visceral adipose tissue[40]. We focused our attention on the mesenteric adipose tissue, a type of visceral adipose tissue, as it is closest to the colon tissue and can communicate with the colon in various ways. In patients with CD, the lesion is often surrounded by a

special type of mesenteric adipose tissue called creeping fat, which is associated with the translocation of gut microbiota[41]. These findings suggest that the mesenteric adipose tissue may play an important role in IBD progression. We further found that TNBS treatment reduced the content of the mesenteric adipose tissue. However, the content of the mesenteric adipose tissue in HFD mice treated with TNBS was still significantly higher than that in ND mice treated with TNBS.

Exosomes serve as important means of intercellular communication. Previous reports have shown that exosomes secreted by visceral fat could target the colon tissue[16]. Therefore, we hypothesized that mesenteric-derived exosomes in obese mice may aggravate TNBS-induced colitis. Exosomes from the mesenteric adipose tissue were isolated and identified. Subsequently, exosomes extracted from the mesenteric adipose tissue of HFD and ND mice were separately injected into TNBS-treated ND mice *via* the tail vein. The results showed that exosomes from the mesenteric adipose tissue of HFD mice aggravated TNBS-induced colitis.

We then investigated the molecular mechanism by which exosomes derived from the mesenteric adipose tissue of HFD mice aggravated TNBS-induced colitis. A recent study indicated that visceral adipose tissue-derived exosomes can exacerbate colitis severity through proinflammatory noncoding RNAs such as miR-155[16]. In this study, we focused on the lncRNAs in exosomes. Using qRT-PCR, we identified that lncRNA expression is strongly associated with HFD in mesenteric adipose exosomes, as well as mesenteric adipose and colon tissues. In the same structures or tissues, the expression of MALAT1 was higher in TNBS-treated HFD mice than in TNBS-treated ND mice. An additional injection of MAT-Exos from HFD mice *via* the tail vein increased the relative expression of MALAT1 in the colon tissue, indicating that the increased expression of lncRNA MALAT1 in the colon tissue can be partially attributed to MAT-Exos arising from increased creeping fat. In fact, shMALAT1 partially reversed the effect of exosomes derived from the mesenteric adipose tissue in HFD mice, suggesting that exosomes derived from the mesenteric adipose tissue in HFD mice aggravated TNBS-induced enteritis in part due to the high expression of lncRNA MALAT1 in exosomes.

The mechanism by which lncRNA aggravates colitis was further investigated. We revealed that lncRNA MALAT1 could bind miR-15a-5p in vivo, and that the miR-15a-5p mimic could reverse the aggravation of colitis. Furthermore, the miR-15a-5p mimic and sh-MALAT1 reversed the HFD mice MAT-Exos-induced increase in the expression of ER stress-related proteins, including ATF6. We further verified the interaction between miR-15-15p and ATF6 using a dual-luciferase reporter assay. These results indicate that lncRNA MALAT1 may activate the ATF6-related ER stress signaling pathway by binding miR-15a-5p.

MALAT1 is abundantly expressed and highly conserved in 33 species of mammals, with the earliest study linking it to metastasis in non-small cell lung cancer[42]. However, recent studies have shown that MALAT1 plays an important role in a variety of tumors[18] as well as in a variety of autoimmune[43], infectious[44,45], and metabolism-related diseases[46]. Previous studies have shown that MALAT1 Levels are reduced in the plasma of patients with CD[47], suggesting that MALAT1 may be a protective factor with respect to the occurrence and development of CD. The results of our study indicated that TNBS treatment decreased the expression of MALAT1, in accordance with finding of previous reports, but the differences were not significant. Moreover, Li *et al*[48] indicated that MALAT1 targets intestinal epithelial cells and enhances the intestinal epithelial barrier, which plays a protective role by sequestering miR-146b-5p and maintaining the expression of AJC proteins, NUMB, and CLDN11 in IBD. However, they did not demonstrate an effect of MALAT1 overexpression on colitis in vivo.

Intriguingly, our study showed that obesity-induced increases in MALAT1 expression in colon tissue can aggravate colitis, suggesting that MALAT1 may be a double-edged sword with respect to IBD. Mechanistically, the contrary effect of MALAT1 in colitis was mainly due to the fact that exosomes derived from the mesenteric adipose tissue targeted the lamina propria of the colon rather than intestinal epithelial cells[16]. Many immune cells are distributed within the lamina propria of the colon, including dendritic cells, macrophages, and lymphoid cells, which supplement the barrier function of intestinal epithelial cells[49]. In addition, many adaptive immune system-related lymphocytes are recruited from peripheral circulation to the lamina propria and are involved in the onset and progression of IBD. LncRNA MALAT1 encapsulated in exosomes from the mesenteric adipose tissue may act on the abovementioned immune cells in the lamina propria and activate the ATF6-related ER stress pathway to promote the release of pro-inflammatory cytokines[50].

ER stress plays a role in the occurrence and development of metabolic syndrome-related diseases in the obese population[51]. Our study demonstrates that ER stress is one of the potential mechanisms by which obesity aggravates IBD, thereby highlighting the importance of weight loss in obese patients with IBD and the treatment of metabolic syndrome-related diseases. In addition, we preliminarily identified a new signaling pathway, namely, the MALAT1-miR-15a-5p/ATF6 axis, revealing a new regulatory mechanism, *i.e.*, the ATF6-related ER stress signaling pathway. Whether this signaling pathway plays a role in other tissues or diseases requires further investigation.

This study has several limitations that should be acknowledged. First, the effect of exosomes derived from the mesenteric adipose tissue was only studied in the colon as a whole, and the specific target cell types remain unclear and require further elucidation. Second, it would be more beneficial if the regulation of the lncRNAMALAT1-miR-15a-5p-ATF6 pathway could be confirmed in a more in-depth investigation. Finally, we speculated that the divergent effect of lncRNA MALAT1 on IBD severity may

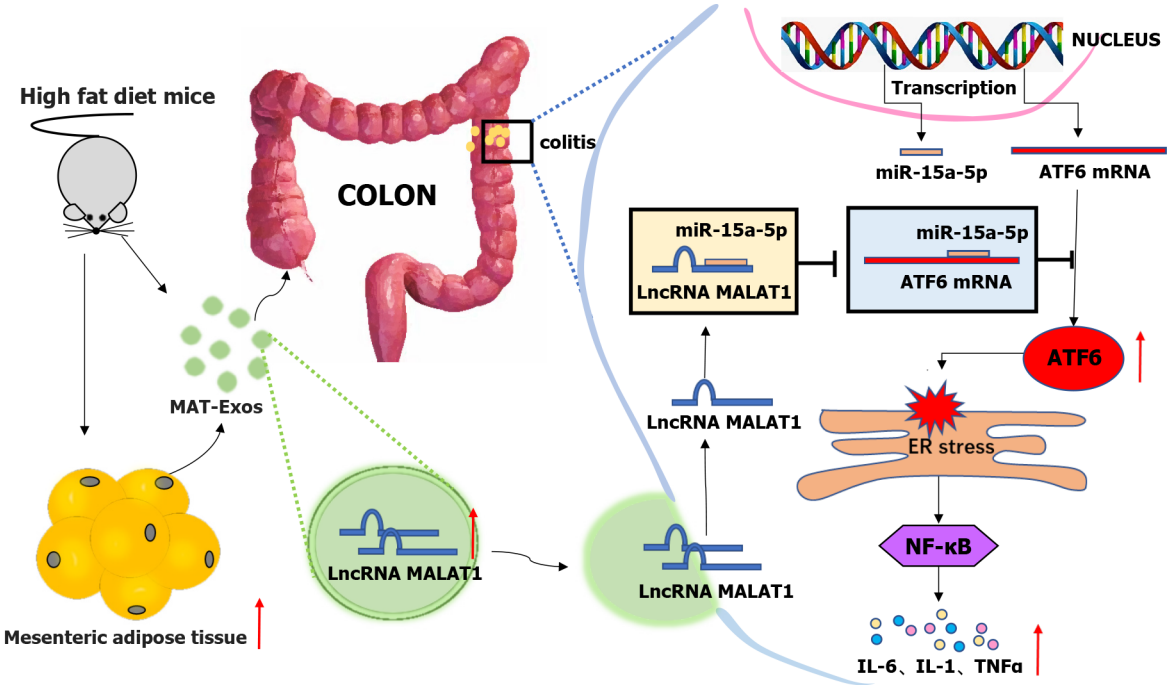

Figure 7 Long non-coding RNA metastasis-associated lung adenocarcinoma transcript 1 encapsulated by mesenteric adipose tissue-derived exosomes targets the colon to aggravate colitis *via* the microRNA-15a-5p/activating transcription factor 6 axis in response to endoplasmic reticulum stress. ATF-6: Activating transcription factor 6; LnRNA: Long non-coding RNA; IL: Interleukin; TNF-α: Tumor necrosis factor-α; ER: Endoplasmic reticulum; MAT-Exos: Mesenteric adipose tissue derived exosomes; MALAT1: Metastasis-associated lung adenocarcinoma transcript 1.

be due to its various targeting areas, where endogenous MALAT1 may exert its effect on intestinal epithelial cells, while extrinsic mesenteric adipose tissue-derived EXO-MALAT1 may act on the intestinal lamina propria through its gut-homing property. However, this theory requires further exploration in the future.

Overall, HFD increased the content of the mesenteric adipose tissue and associated EXO lncRNA MALAT1, which was then absorbed by the colon where it targeted the miR-15a-5p/ATF6 axis, thereby leading to the activation of the ER stress pathway. Further, downstream activation of the inflammatory factor signaling pathway may partially contribute to the aggravation of colitis in obese IBD patients.

CONCLUSION

A higher visceral adipose-tissue ratio was associated with an increased disease activity in CD patients. But the underlining mechanism still remains elusive. Our study indicated that high-fat diet increased the content of mesenteric adipose tissue and aggravated colitis in mice. Mesenteric adipose tissue derived exosome lncRNA metastasis-associated lung adenocarcinoma transcript 1 can be absorbed by the colon leading to activation of the endoplasmic reticulum stress pathway by way of targeting the miR-15a-5p/ATF6 axis to aggravate colitis (Figure 7).

ARTICLE HIGHLIGHTS

Research background

Obesity is associated with an increased risk of developing Crohn's disease (CD), higher disease activity, and comparatively worse clinical outcomes, especially in CD patients with a high visceral adipose tissue ratio. However, the underlying mechanisms remain unclear.

Research motivation

Exosomes contain multiple non-coding RNAs such as long non-coding RNAs (lncRNAs), which serve as messengers in cell-cell communication. Visceral adipose tissue derived exosomes display tissue affinity and preferentially target the colonic lamina propria. We hypothesized that obesity exacerbates inflammatory bowel disease, partially through mesenteric adipose tissue-derived exosomes.

Research objectives

To investigate the role of mesenteric adipose tissue-derived exosomes in CD aggravation through obesity, thereby providing a potential therapeutic target for CD in this subpopulation.

Research methods

A 2,4,6-trinitrobe-nzenesulfonic acid (TNBS) was used to induce colitis in mice fed a high-fat diet (HFD) and normal diet (ND). Exosomes from the mesenteric adipose tissue were extracted and identified, followed by the investigation of lncRNA metastasis-associated lung adenocarcinoma transcript 1 (MALAT1) expression. Luciferase reporter and RNA pull-down assays were performed to verify the interaction between MALAT1 and miR-15a-5p/activating transcription factor 6 (ATF6) axis. Finally, mesenteric adipose tissue-derived exosomes extracted from HFD-fed mice were isolated and treated with either a short hairpin RNA targeting MALAT1 (shMALAT) or an miR-15a-5p mimic before being injected into mice to explore their influence on TNBS-induced colitis.

Research results

HFD can aggravate TNBS-induced colitis in mice, and increase the expression of MALAT1 in mesenteric adipose tissue-derived exosomes. Increased expression of MALAT1 in the colon tissue exacerbated TNBS-induced colitis and activated the ATF6-related endoplasmic reticulum stress pathway. Moreover, this effect was partially reversed by the reduced expression of MALAT1 and overexpression of miR-15a-5p.

Research conclusions

Mesenteric adipose tissue-derived exosome-encapsulated lncRNA MALAT1 targets the colon and aggravates TNBS-induced colitis in obese mice, which may potentially act on the miR-15a-5p/ATF6 axis and indice endoplasmic reticulum stress.

Research perspectives

Obesity-mediated aggravation of colitis might involve the mesenteric adipose tissue-derived exosome lncRNA MALAT1, but the specific cells of the intestine targeted by MALAT1 deserve further exploration.

FOOTNOTES

Author contributions: Jin X designed the report; Chen D performed experiments and statistical analysis; Lu MM wrote the paper and assisted to design the report; Wang JH, Ren Y, Wang SS, Xu LL, Cheng XF, Cheng WX, Gao JG, and Li XL assisted to perform experiments and analyzed data; Kalyani FS assisted with paper writing; all authors had access to the study data and reviewed and approved the final manuscript.

Abstract

BACKGROUND

The mechanisms underlying gastrointestinal (GI) dysmotility with ulcerative colitis (UC) have not been fully elucidated. The enteric nervous system (ENS) plays an essential role in the GI motility. As a vital neurotransmitter in the ENS, the gas neurotransmitter nitric oxide (NO) may impact the colonic motility. In this study, dextran sulfate sodium (DSS)-induced UC rat model was used for investigating the effects of NO by examining the effects of rate-limiting enzyme nitric oxide synthase (NOS) changes on the colonic motility as well as the role of the ENS in the colonic motility during UC.

AIM

To reveal the relationship between the effects of NOS expression changes in NOS-containing nitrergic neurons and the colonic motility in a rat UC model.

METHODS

Male rats (n = 8/each group) were randomly divided into a control (CG), a UC group (EG1), a UC + thrombin derived polypeptide 508 trifluoroacetic acid (TP508TFA; an NOS agonist) group (EG2), and a UC + NG-monomethyl-L-arginine monoacetate (L-NMMA; an NOS inhibitor) group (EG3). UC was induced by administering 5.5% DSS in drinking water without any other treatment (EG1), while the EG2 and EG3 were gavaged with TP508 TFA and L-NMMA, respectively. The disease activity index (DAI) and histological assessment were recorded for each group, whereas the changes in the proportion of colonic nitrergic neurons were counted using immunofluorescence histochemical staining, Western blot, and enzyme linked immunosorbent assay, respectively. In addition, the contractile tension changes in the circular and longitudinal muscles of the rat colon were investigated *in vitro* using an organ bath system.

RESULTS

The proportion of NOS-positive neurons within the colonic myenteric plexus (MP), the relative expression of NOS, and the NOS concentration in serum and colonic tissues were significantly elevated in EG1, EG2, and EG3 compared with CG rats. In UC rats, stimulation with agonists and inhibitors led to variable degrees of increase or decrease for each indicator in the EG2 and EG3. When the rats in EGs developed UC, the mean contraction tension of the colonic smooth muscle detected *in vitro* was higher in the EG1, EG2, and EG3 than in the CG group. Compared with the EG1, the contraction amplitude and mean contraction tension of the circular and longitudinal muscles of the colon in the EG2 and EG3 were enhanced and attenuated, respectively. Thus, during UC, regulation of the expression of NOS within the MP improved the intestinal motility, thereby favoring the recovery of intestinal functions.

CONCLUSION

In UC rats, an increased number of nitrergic neurons in the colonic MP leads to the attenuation of colonic motor function. To intervene NOS activity might modulate the function of nitrergic neurons in the colonic MP and prevent colonic motor dysfunction. These results might provide clues for a novel approach to alleviate diarrhea symptoms of UC patients.

Key Words: Nitrergic neurons; Nitric oxide; Nitric oxide synthase; Ulcerative colitis; Colonic motility; Colonic myenteric plexus

Core Tip: This study focused on the effects of nitrergic neurons in the myenteric plexus (MP) on colonic motor function in rats with ulcerative colitis (UC). The results suggest that an increased number of nitrergic neurons in the colonic MP of the UC rats leads to reduced colon contractile function. Therefore, the regulation of the activity of nitrergic neurons in the colonic MP through interference with the activities of nitric oxide synthase might be a novel potential and prospective way to reduce the diarrhea symptoms in UC patients.

INTRODUCTION

Ulcerative colitis (UC) is a nonspecific inflammatory disorder of the intestine that primarily involves the rectum, sigmoid colon, and/or, the whole colon, in severe cases. Clinical features include recurrent episodes of abdominal pain, diarrhea, and mucopurulent stools[1]. Unfortunately, the disease course is permanent and causes great suffering to the patients. UC can occur at any age (mainly in young adults), and in recent years, its incidence has increased worldwide[2]. The etiology of UC is complex, and its pathogenesis might be related to genetics[3], immunological factors, psychiatric depression and anxiety [4], environmental factors[5], dietary allergy, intestinal flora[6], and other factors. Therefore, it leads to treatment difficulty and a prolonged treatment course, and recurs easily. Although current pharmacological treatments in the clinic might improve patient's symptoms, they still cannot achieve satisfactory results. In recent years, the research on the aspects of gastrointestinal (GI) motility disorders in UC patients has advanced, and the abnormal intestinal dynamics has become a focus of research on the pathogenesis of UC [7-9].

The enteric nervous system (ENS), including the submucous plexus (SP) and myenteric plexus (MP) [10,11], as an essential component of the peripheral nervous system (PNS), is independent of the central nervous system (CNS) and is involved in the regulation of intestinal secretion, absorption, and motility [12]. Neurons in the ENS, depending on their neurotransmission function, are divided into sensory neurons, motor neurons, and interneurons. Further, motor neurons are divided into excitatory and inhibitory ones, regulating the systolic and diastolic function of the intestine, respectively. Typically, the ENS plays a vital role in maintaining gut homeostasis; however, gut motility gets impaired once the relaxation and contraction functions of the gut become imbalanced.

As the primary inhibitory gas neurotransmitter within the ENS, nitric oxide (NO) regulates several GI functions, such as vascular permeability, mucosal defense, immune regulation, and GI motility[13]. Nitric oxide synthase (NOS), the rate-limiting enzyme of NO synthesis, is widely distributed in endothelial cells, macrophages, neuro-phagocytes, and neuronal cells. NOS can be divided into neural NOS (nNOS), endothelial NOS (eNOS), and inducible NOS (iNOS). Out of these, nNOS is located within the nervous tissue of both the CNS and PNS. NO is one of the major inhibitory neurotransmitters of non-adrenergic noncholinergic (NANC) nerves in the ENS and its release by NOS-positive neurons plays an essential role in stimulating GI secretion and relaxing GI smooth muscle. Changes in the NOS expression level cause alterations in GI motility; however, the impact of such changes in UC on colonic motility has not been clearly defined. Therefore, this study aimed to observe the changes of NOS within the colonic MP in dextran sulfate sodium (DSS)-induced UC rats, to further understand the underlying mechanisms of colonic motility in UC for delineating a new direction for the treatment of UC.

MATERIALS AND METHODS

Reagents

Dextran sulfate sodium (DSS; PC-99017), NG-monomethyl-L-arginine monoacetate (L-NMMA; PC-45273), and thrombin derived polypeptide 508 trifluoroacetic acid (TP508TFA; PC-50991) were purchased from PlantChemMed Co., Ltd (Shanghai, China). Rabbit Anti-HuD + HuC (ab184267) and Goat Anti-nNOS (ab1376) were purchased from Abcam (Cambridge, United Kingdom). Donkey Anti-Goat Alexa Fluor 488 (a11055) and Donkey Anti-Rabbit Alexa Fluor 594 (A21207) were purchased from Invitrogen Co., Ltd (Carlsbad, United States). Mouse Anti-β-Actin monoclonal antibody (A1978) and Immobilon Forte western HRP substrate (Cat. No. WBLUF0020) were purchased from Merck KGaA (Darmstadt, Germany). HRP-Labeled Goat Anti-Rabbit IgG (H + L) (ZB-2306) and HRP-Labeled Goat Anti-Mouse IgG (H + L) (ZB-2305) were purchased from ZhongShan GoldBridge Biotechnology Co., Ltd (Beijing, China). SDS-PAGE Gel Preparation Kit (P0012A) was purchased from Beyotime Biotechnology Co., Ltd (Shanghai, China). BCA Protein Concentration Assay Kit (AR0146) was purchased from BOSTER Biological Technology Co., Ltd (Wuhan, China). NOS1/nNOS ELISA Kit (E-EL-R1438C) were purchased from Elabscience Biotechnology Co., Ltd (Wuhan, China). All other reagents and chemicals used in this study are commercially available.

Animals and animal tests

Thirty-two 8-wk-old male Sprague-Dawley rats weighing 200 ± 20 g were housed in a specific pathogen-free animal house. The animals were kept at a standard room temperature of 24 °C, with 40%-60% relative humidity, 12 h light-dark alternation, and a standard laboratory diet containing 23% protein and water. All animals were provided by the Animal Center of the Fourth Military Medical University and divided into four major groups. All experimental procedures were conducted in accordance with the Principles of Laboratory Animal Care and approved by the University Ethics Committee and performed as per institutional guidelines. Efforts were made to minimize the number of animals used.

The rats were randomly divided into four groups (n = 8/each group), including the control (CG), UC (EG1), UC + NOS agonist TP508TFA (EG2), and UC + NOS inhibitor L-NMMA (EG3) groups. The CG group was housed as described above, whereas the animals in the three experimental groups (EG1-3)

were given tap water containing 5.5% DSS. The CG group was fed in the same way as the experimental groups except that DSS was not added in the tap water. All animals were given free access to water for 7 d, and the water was changed to tap water at day 15. Further, EG2 rats were treated with 3 mL of 0.01 mmol/L TP508 TFA i.g. daily for 15 d and EG3 rats were treated with 3 mL of 0.01 mmol/L L-NMMA i.g. daily for 15 d. Animals were regularly monitored for the general conditions, body weight, stool characteristics, occult blood, and hematochezia for the evaluation of the disease condition. The scoring criteria of the disease activity index (DAI) were as follows[14]: Body weight: No loss, 0 points; loss by 1%-5%, 1 point; loss by 6%-10%, 2 points; loss by 11%-15%, 3 points; loss by more than 15%, 4 points; stool characteristics: Normal (well-shaped), 0 points; bondless (mushy and semi-formed stool that does not adhere to the anus), 2 points; loose (watery stool that can adhere to the anus), 4 points; fecal occult blood or macroscopic hematochezia: Normal, 0 points; occult blood (+), 2 points; macroscopic hematochezia, 4 points. DAI score was calculated as equal to the average value of the sum of the above scores.

Rats in each group were individually subjected to the open field test on day 14 of the experiment. The rats were randomly placed into boxes with a height of 30-40 cm and a length of 100 cm on the bottom side. The box's inner walls were darkened, and the bottom surface was divided on the average 25 squares (4 cm × 4 cm) with a digital camera set 2 m above each side. The data was acquired automatically and recorded for 15 min. This technique was used to test the spontaneous activity of the animals and their anxious behavior in an open environment.

On the 15th day of the experiment, rats in each group were anesthetized with an intraperitoneal injection of 7% chloral hydrate (0.4 mL/100 g). The whole colon was removed to compare the colon length for rats in each group.

Histological evaluation of the colon

Eight rats in each group were used for histological evaluation of the colon. Following the whole colon removal, the intestinal lumen was flushed using 0.01 mmol/L PBS buffer, and transected 6-9 cm from the anus. Colons were fixed in 4% paraformaldehyde, dehydrated in graded alcohols, and then embedded in the paraffin. The block was cut into 5 μm thick sections and hematoxylin-eosin stained. Afterwards, the slides were mounted with neutral gum and dried at 37 °C overnight. A whole slide was observed under a scanning biomicroscope (SLIDEVIEW VS200, Olympus, Tokyo, Japan). Histological changes were recorded based on the staining results, and the histological index (HI) scoring was performed, with the following criteria[15]: 0 points for no damage; 1 point for disappearance of basal 1/3 crypts; 2 points for disappearance of basal 2/3 crypts; 3 points disappearance of crypts with intact epithelial cells; and 4 points for crypt and epithelial cell disappearance.

Immunofluorescence histochemical staining

The distal colons of eight rats in each group were dissected separately. The intestinal lumens were flushed in 0.01 mol/L PBS buffer, then a colonic strip with a width of approximately 0.5-1.0 cm was cut along the travel direction of the circular muscle (CM). Afterwards, the dissected colon was fixed in 4% paraformaldehyde. The mucosal layer was fixed upward and horizontally in PBS buffer (pH = 7.4). The mucosal, submucosal, and CM layers were removed with the help of filament forceps to preserve the longitudinal muscle (LM) layer. The tissues were blocked in 10% donkey serum for 30 min and then incubated with Rabbit-Anti-HuD + HuC (1: 500) and Goat-Anti-nNOS (1: 300) in a shaker overnight at 4 °C. Slides were incubated with Donkey Anti-Goat Alexa Fluor 488 (1: 500) and Donkey Anti-Rabbit Alexa Fluor 594 (1: 500) for 4 h. Eight different fields (approximately 1.0 cm × 1.0 cm) of the specimens were observed using confocal microscopy (FV-1000, Olympus, Tokyo, Japan) with the appropriate laser beams and filter settings for Alexa 488 (excitation, 488 nm; emission, 510-530 nm) and Alexa 594 (excitation, 543 nm; emission, 590-615 nm). Digital images were captured with an FV10-ASW 4.2 from Olympus, and these images eventually saved as TIFF files to calculate changes in the proportion of colon nitrergic neurons.

Western blot analysis

Four rats in each group were anesthetized and perfused with pre-cooled PBS buffer, and the terminal colon was transected. The mucosa and submucosa were separated with silk tweezers. The muscle layer was put into a pre-cooled EP tube. The tissue was homogenized using an ultrasonic grinder, in the lysis buffer (RIPA: protease inhibitor: phosphatase inhibitors = 100:1:1). After standing for 10 min on ice, the supernatant was centrifuged at 12000 rpm (10008 × *g*) for 10 min. The protein concentration was measured using a BCA protein concentration assay kit and FC microplate reader (1410101, Thermo Fisher Scientific, Shanghai, China). The protein samples were kept at -80 °C for further use.

Gels were made using the SDS-PAGE gel preparation kit, and the samples were electrophoresed at a constant voltage of 80 and 120 V. Membrane transfer was achieved at a constant current of 300 mA. First, the PVDF membranes were blocked with Western blocking solution (P0252, Beyotime Biotechnology Co., Ltd., Shanghai, China) for 15 min and then incubated with Rabbit Anti-nNOS (1:1000) and Anti-β-Actin antibody (mouse monoclonal; 1:5000) on a shaker overnight at 4 °C. The PVDF membranes were then incubated with HRP-labeled Rabbit Anti-Goat IgG (H + L) (1:10000) and HRP-labeled Goat

Anti-Mouse IgG (H + L) (1:10000) for 2 h. After three rinses (10 min each) in TBST, the membranes were probed by Immobilon™ Western chemiluminescent HRP substrate (WBKLS0050, Merck KGaA, Darmstadt, Germany) and placed into ECL for the detection. The proteins were analyzed using Image-Pro Plus software (Image-Pro Plus Version 6.0, Media Cybernetics, Maryland, United States).

ELISA

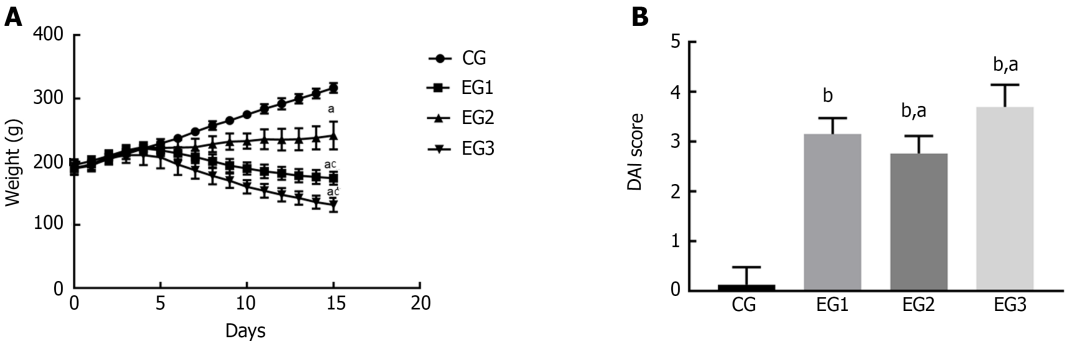
Whole blood from four rats in each group were kept for 2 h at room temperature and then centrifuged at 3800 rpm (1000 × *g*) for 20 min, followed by the removal of supernatant. Next, the terminal colon tissues were grounded and disrupted with an appropriate volume of PBS (usually at a weight to volume ratio of 1:9), homogenized using a glass homogenizer, and then centrifuged at 8460 rpm (5000 × *g*) for 5 to 10 min. Afterwards, the supernatant was collected. The NOS1/nNOS ELISA kit was used to determine the concentration of NOS in the colon as well as in the serum.

In vitro gut colonic tension detection

Four rats in each group were used to explore the changes of *in vitro* gut colonic tension, including eight circular and eight longitudinal colon muscle strips. Rats were anesthetized, and the abdominal cavity was exposed. Then, the intestinal tube was carefully separated with the forceps and quickly freed. The colon was excised and placed in Krebs' fluid at 37 °C with a continuous supply of 95% O_2 and 5% CO_2 mixture. Then, 3 mm × 10 mm circular and LM strips were cut, where both ends were anchored to tension receptors and platinum rings at the lower end, respectively. The signals acquired by the tension receptors were recorded and processed with a multi-channel physiological signal acquisition and processing system (RM6240E, INSTRUMENT FACTORY, Chengdu, China). The mean amplitude of spontaneous contractions was recorded in circular and LM strips obtained from control and UC rats at rest, when the muscle strips were allowed to rest in the incubation solution for 30 min. After 10 min of recording, TP508TFA (1×10^{-4} mol/L) was added to the bath of the UC group, and the mean amplitude changes of circular and LM strips were recorded, respectively. The liquid in the bath was replaced after 10 min, and the bath was washed. After resting for 30 min, L-NMMA (1×10^{-4} mol/L) was added, and the corresponding mean amplitude changes were re-recorded.

Statistical analysis

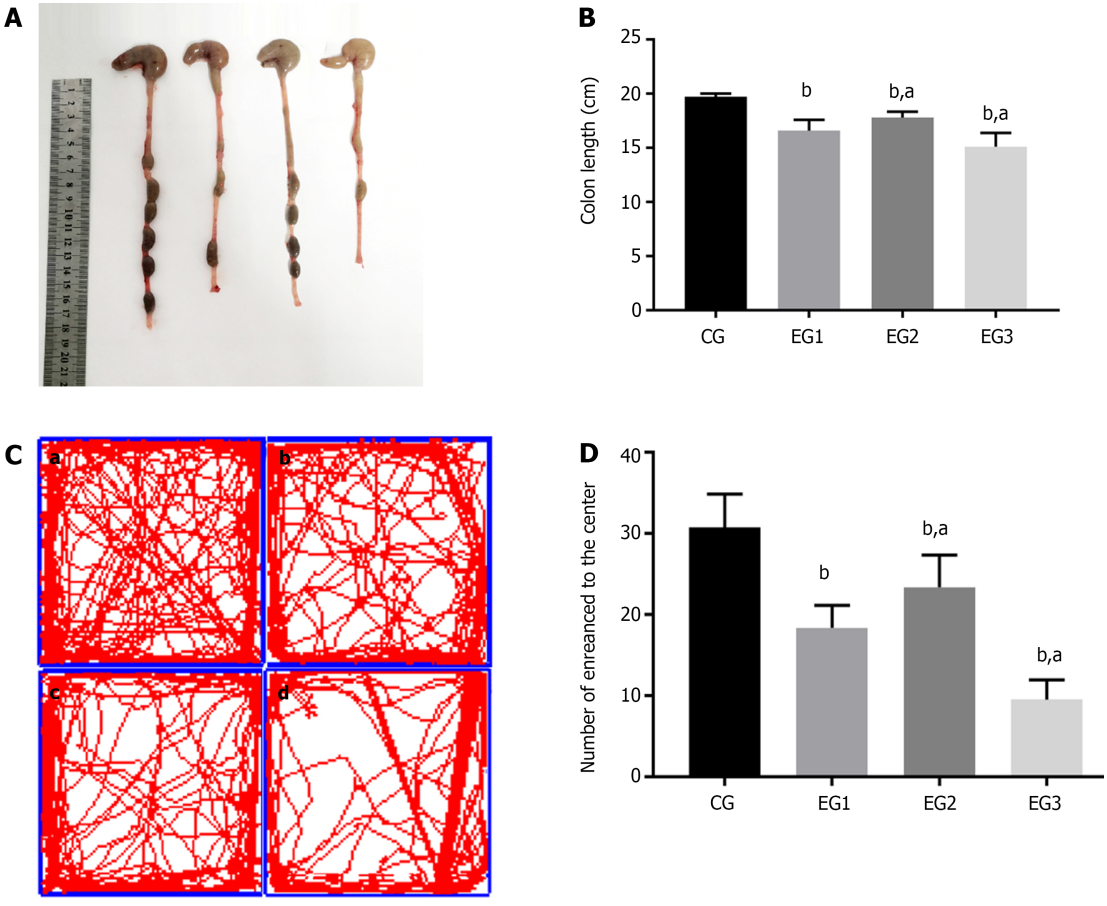
SPSS version 23.0 statistical software (SPSS Inc, Chicago, United States) was used for statistical analyses. Data are expressed as the mean ± SD, and comparisons between groups were performed by one-way ANOVA. A P value of < 0.05 was considered statistically significant.



RESULTS

DAI scores

Sloth, anorexia, emaciation, decreased fur gloss, and higher stool frequency were found in all EG rats, with some developing mucopurulent bloody stools. From days 0 to 5, animals in all groups gained weight (CG group: 28.90 ± 2.43 g; EG1 group: 18.10 ± 3.23 g; EG2 group: 17.00 ± 6.17 g; EG3 group: 21.80 ± 3.63 g). The body weight of rats in each group was not significantly different ($P > 0.05$); however, the body weight of rats in the EG1-3 groups began to decrease from day 6. Until day 15, the CG group (116.60 ± 2.76 g) and EG2 group (58.60 ± 7.79 g) gained weight, while the EG1 group (26.00 ± 3.69 g) and EG3 group (60.40 ± 3.99 g) lost weight. The decrease in body weight was statistically significantly different between the EG groups and CG group ($P < 0.05$); the differences in weight change between the EG2-3 groups and EG1 group were also statistically significant ($P < 0.05$) (Figure 1A). As for the stool profiles of all the groups, two rats in the CG group exhibited bondless and loose stools without hematochezia. For the EG1 group, it took 3.25 ± 0.31 d to the occurrence of loose stools, 3.37 ± 0.37 d to fecal occult blood, and 4.1 2 ± 0.39 d to macroscopic hematochezia; the corresponding values in the EG2 and EG3 groups were 3.85 ± 0.50 d, 4.00 ± 0.37 d, and 4.62 ± 0.41 d, and 2.87 ± 0.29 d, 2.62 ± 0.26 d, and 3.37 ± 0.32 d, respectively. Regarding the DAI scores, no statistically significant differences was found from day 0 to day 5 for any group ($P > 0.05$). After day 5, the intergroup differences in DAI scores were significantly increased. The DAI scores were (0.12 ± 0.12), (3.15 ± 0.11), (2.67 ± 0.12), and (3.69 ± 0.15) for the CG, EG1, EG2 and EG3 groups, respectively, at day 15. Moreover, the scores were significantly different between the EG groups and CG group ($P < 0.0001$), and between the EG2-3 groups and EG1 group ($P < 0.05$) (Figure 1B).



Comparison of colon length and behavior

The colonic morphology of rats from each group was compared during the dissection (Figure 2A). Compared with the CG group, the colon length in the EG groups showed various degrees of shortening, and the differences were statistically significant ($P < 0.0001$). The difference was also significant between the EG2-3 groups and EG1 group ($P < 0.05$) (Figure 2B).

Figure 2 Colon length in each group and results of the open field test. A: Colon length of rats in the four groups; B: Comparison of colon length in CG (19.71 ± 0.11 cm), EG1 (16.59 ± 0.35 cm), EG2 (17.80 ± 0.19 cm), and EG3 (15.11 ± 0.44 cm) groups. There were statistically significant differences between EG groups and CG group ($^{b}P < 0.0001$), and between EG2-3 groups and EG1 group ($^{a}P < 0.05$); C: Movement trajectories of rats. a: CG; b: EG1; c: EG2; d: EG3; D: Results of the open field test. There were statistically significant differences between EG groups and CG group ($^{b}P < 0.0001$), and between EG2-3 groups and EG1 group ($^{a}P < 0.05$). CG: Control group; UC: Ulcerative colitis; NOS: Nitric oxide synthase; L-NMMA: NG-monomethyl-L-arginine monoacetate; EG1: UC group; EG2: UC + NOS agonist TP508TFA group; EG3: UC + NOS inhibitor L-NMMA group.

On the 14th day of the experiment, the behavior of rats was examined using an open field test. The number of times that the rats passed through the center of an open box within 15 min period is shown as follows: 30.75 ± 1.46 for the CG, 18.38 ± 0.98 for EG1, 23.38 ± 1.40 for EG2, and 9.50 ± 0.86 for EG3 group. Differences were statistically significant between the EG groups and CG group ($P < 0.0001$).

Additionally, the EG2-3 groups showed statistically significant differences compared with the EG1 group ($P < 0.05$) (Figure 2C and D).

Colonic histological damage assessment

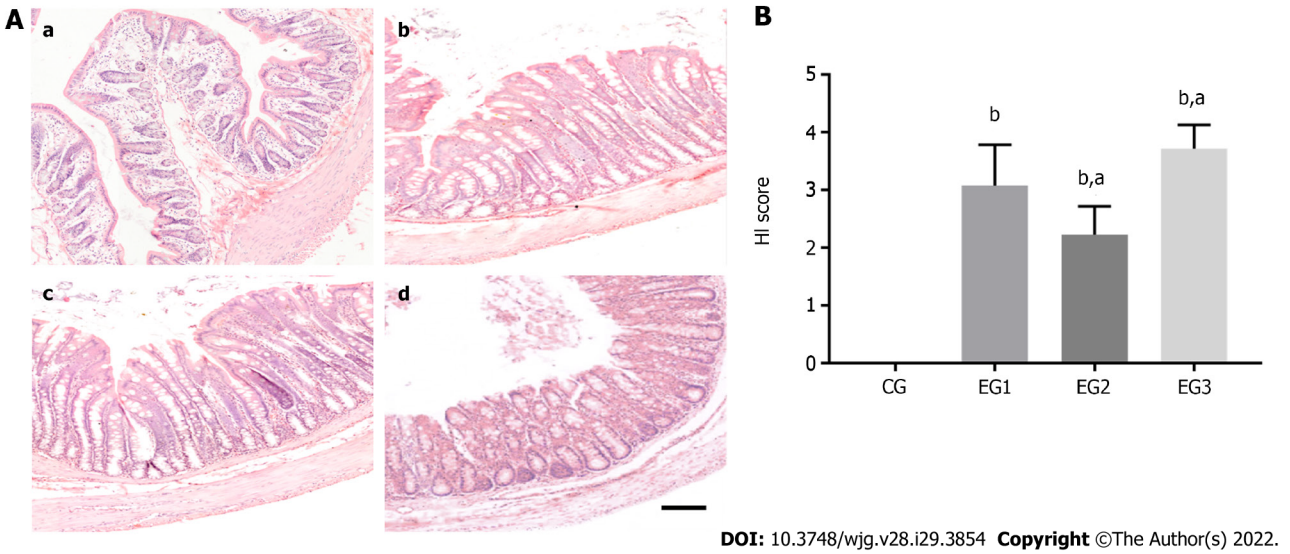
The results of HE staining indicated that the colonic tissue structure of CG rats was normal, with the mucosal layer showing a well-arranged monolayer of columnar epithelial cells, clear intestinal glands, morphologically normal goblet cells, and no inflammatory cell infiltration. In the colon of EG1 rats, most crypts disappeared, with some broken or disappearing epithelia, accompanied by inflammatory cell infiltration. In the colon of EG2 rats, 1/3-2/3 of basal crypts disappeared, with the occasional destruction of epithelial cells. In the colon of EG3 rats, crypts completely disappeared, with some broken or disappearing epithelia, accompanied by massive inflammatory cell infiltration (Figure 3A). The HI scores for the colons of the rats in the CG, EG1, EG2, and EG3 groups were 0.00 ± 0.00, 3.07 ± 0.25, 2.22 ± 0.17, and 3.71 ± 0.14, respectively. The differences were statistically significant between the EG groups and CG group ($P < 0.0001$), and between the EG2-3 groups and EG1 group ($P < 0.05$) (Figure 3B).

Changes in proportion of NOS-positive colonic myenteric neurons

The distal rat colons were double-stained by immunofluorescence histochemistry to observe the distribution and expression of NOS-positive neurons within the colonic MP. Within the colonic MP of rats, the proportion of these neurons in each group was counted. Enteric neurons exhibited a reticular distribution in the colonic MP (Figure 4B). NOS-positive neurons accounted for 31.38 ± 0.94% in the CG group (Figure 4C) but were more distributed within the marginal side of the ganglia (Figure 4A). They were fusiform or star-shaped, and their nuclei were round with several elongated protrusions. The protrusions of these neurons were interconnected with each other to form a dense and complex neural network. In the EG1 group, the percentage of NOS-positive neurons in colonic neurons (Figure 4E) increased to 42.25% ± 0.88% under disease conditions (Figure 4F). The distribution of these neurons was no longer confined to the edges of the ganglia and began to appear elsewhere within the ganglia (Figure 4D). Moreover, the proportion of NOS-positive neurons in the EG2 group increased to 51.75% ± 1.22% (Figure 4I and H). These neurons in the ganglia were disorganized and widely distributed within the ganglia (Figure 4G). Compared with the EG1 group, the proportion of NOS-positive neurons in the EG3 group decreased to 37.25% ± 1.09% (Figure 4L and K), with their distribution within the ganglia being predominantly marginal (Figure 4J). The changes in the proportion of NOS-positive neurons to colonic neurons in the EG groups were statistically significant in comparison to the CG group ($P < 0.0001$); however, the EG2 and EG3 groups were also significantly different from the EG1 group ($P < 0.05$) (Figure 4M).

NOS protein expression level in colonic MP

The expression level of NOS protein in the colonic MP of EG1 rats was higher than that in the CG group. The NOS expression in the EG2 rat colon was further increased, while the expression in the EG3 rat colon was lower than that in the EG1 group. The differences were statistically significant between the EG groups and CG group ($P < 0.0001$) and between the EG2-3 groups and EG1 group ($P < 0.05$) (Figure 5A and B).



Concentration of NOS in colonic myenteric tissue and serum

The concentration of NOS was significantly increased in the colonic myenteric tissue in the EG groups compared with the CG group ($P < 0.0001$); the EG2 group had a higher NOS concentration, whereas the EG3 group had a lower concentration than the EG1 group, and the difference between the EG2-3 groups and EG1 group was also statistically significant ($P < 0.05$) (Figure 6A). In addition, serum concentrations of NOS were significantly increased in the EG group compared with the CG group ($P < 0.0001$); however, the EG2 group had a significantly higher NOS concentration, whereas the EG3 group had a significantly lower concentration than the EG1 group ($P < 0.05$) (Figure 6B).

Comparison of contraction tension of isolated rat colonic smooth muscle

At rest, the contraction of the LM in the colon of CG rats appeared as a regular and sine wave-like curve with relatively neat amplitude (Figure 7A). In EGs rats, the contraction was significantly more frequent, with the increased amplitude (Figure 7B-D). The contraction tension of the LM of the colon was considerably more significant in EG rats than in CG rats ($P < 0.0001$). However, the contraction tensions of the colonic LM were significantly weakened and increased in EG2 and EG3 rats, respectively, when compared with EG1 rats ($P < 0.001$) (Figure 7E).

At rest, the contraction of the colonic CM in CG rats appeared as a regular and triangular wave-like curve. The amplitude was neat, with a contraction interval between the adjacent two waves (Figure 8A). In EGs rats, contraction of the CM of the colon was significantly accelerated, and its amplitude was increased (Figure 8B-D). The contraction tension of the colonic CM was significantly larger in EG rats than in CG rats ($P < 0.0001$). The contraction tension of the colonic CM appeared significantly weakened and increased in EG1 rats compared with EG2 and EG3 rats, respectively ($P < 0.0001$) (Figure 8E).

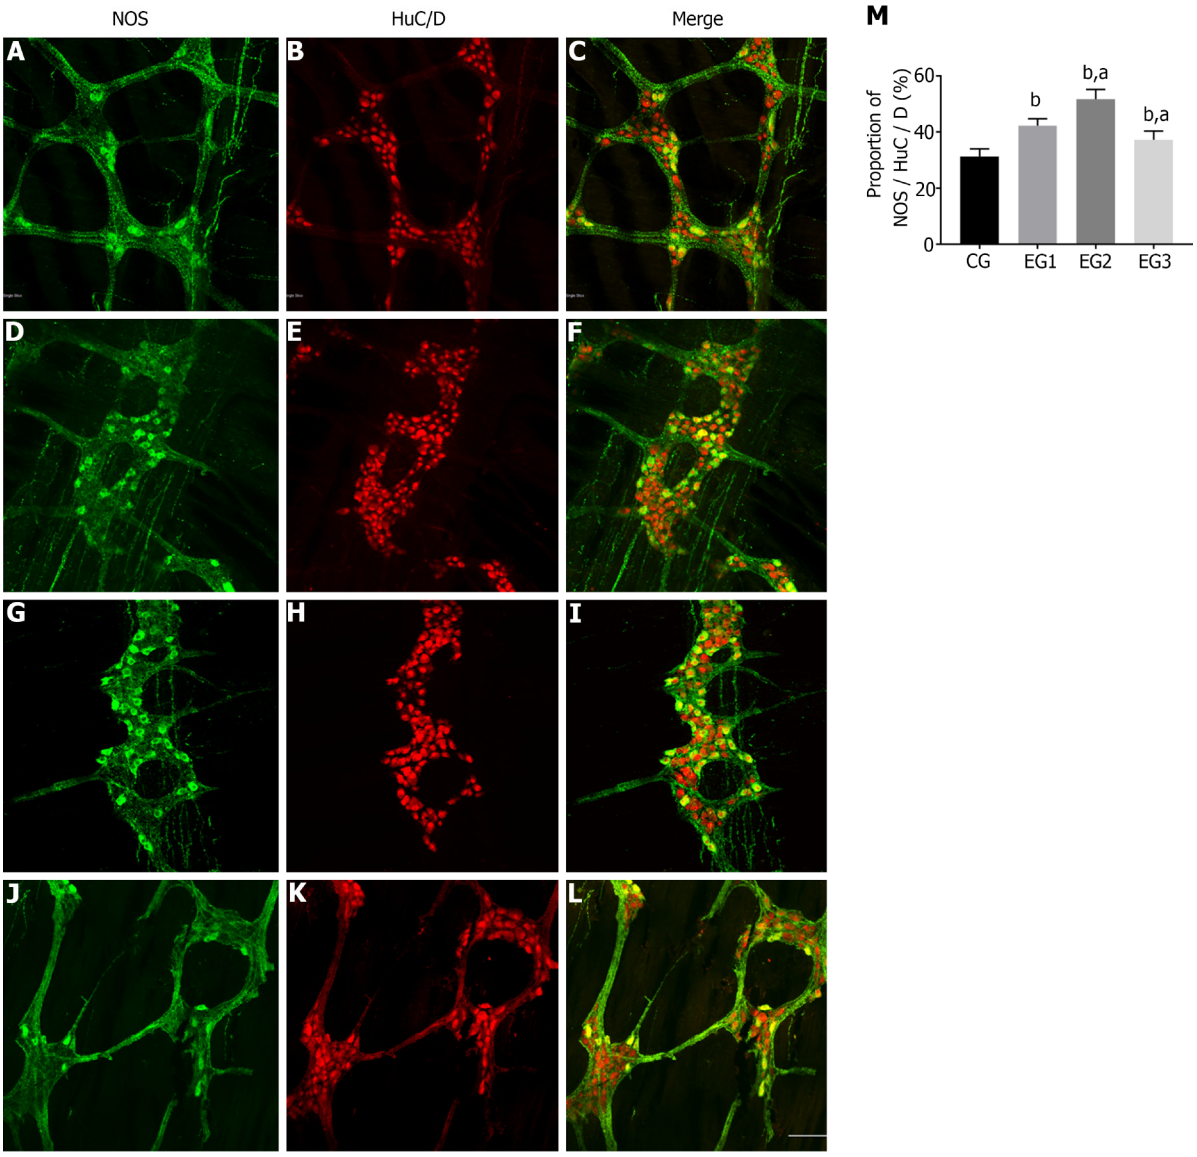
DISCUSSION



An increase or decrease in the number of neurons and/or neuronal degeneration in the ENS can lead to various diseases. For instance, congenital dysplasia of the ENS leads to congenital megacolon (Hirschsprung disease) and primary achalasia, whereas neurodegenerative ENS alterations can lead to the disorders such as Alzheimer, Huntington, and Parkinson diseases[16,17]. The secondary alterations in the ENS also result in inflammatory infiltrates or immune system pathologies such as irritable bowel syndrome[18], idiopathic enteric gangliosidosis[19], paraneoplastic syndrome[20], slow transit constipation[21], severe acute pancreatitis[22], diabetes mellitus[23,24], and UC[25].

The different types of ENS neurons have significantly different morphology and structure associated with the synthesis and secretion of neurotransmitters. However, by forming complex synaptic connections, these neurons participate in the structural basis that mainly underlies the relatively independent reflex activity of the gut and can also regulate the diverse motor and sensory activities of the digestive tract.

Despite the unclear etiology of UC, numerous studies have shown that its pathogenesis might be associated with the interactions between genetic susceptibility, environmental provoking factors, and immune-mediated tissue damage. Additionally, the relationship between abnormal intestinal motility and UC has also gained attention. Abnormal ENS is an important mechanism contributing to the abnormal colonic motility of UC, which is an important factor causing diarrhea in UC patients.

The onset of UC has a complex genetic background. Based on the gene polymorphism and heterogeneity, the impaired local barrier function of the intestinal mucosa can be the result of a combination of factors, such as altered epithelial permeability, neuroendocrine regulation, and intestinal flora translocation[26]. This, in turn, provokes the inflammatory response with symptoms such as abdominal pain, diarrhea, and colonic motor dysfunction. As the rate-limiting enzyme of NO synthesis in the body, NOS has three sub-types: iNOS, eNOS, and nNOS. Histological studies have identified intense focal iNOS expression by the inflamed bowel epithelium and in the mononuclear cell infiltrate in the intestinal tissues of both Crohn's disease and UC patients[27]. A great number of studies suggest that iNOS in the ENS may play a part in preventing activation of mast cells, reducing leukocyte adhesion to the endothelium and protecting the host from being invaded by colonic bacteria[28-30]. In normal and UC states, eNOS expression is limited to colonic vascular endothelium[31]. Baker *et al*[32] confirmed that during DSS-induced UC, eNOS KO mice suffered less tissue damage and inflammation than wild-type mice, suggesting that eNOS is essential for maintaining the integrity of the GI mucosa. nNOS is one of the specific markers for nitrergic neurons within the ENS, the primary inhibitory neurons of the colonic MP[33]. By releasing inhibitory neurotransmitter NO, nitrergic neurons can regulate GI motility. The changes in expression of nNOS in the colonic MP of UC rats indicate that nitrergic neurons may be involved in NO-based neurotransmission and regulate GI motility in UC state.

Research has shown that NO is the second messenger in the smooth muscle cells (SMCs) or interstitial cells of Cajal (ICCs)[34]. NO is highly lipid-soluble and reaches target ICCs in a freely diffusible manner after synthesis. It binds to the soluble guanylyl cyclase in the cells to increase the enzymatic activity by altering its spatial configuration, which further leads to an increase in cyclic guanosine monophosphate

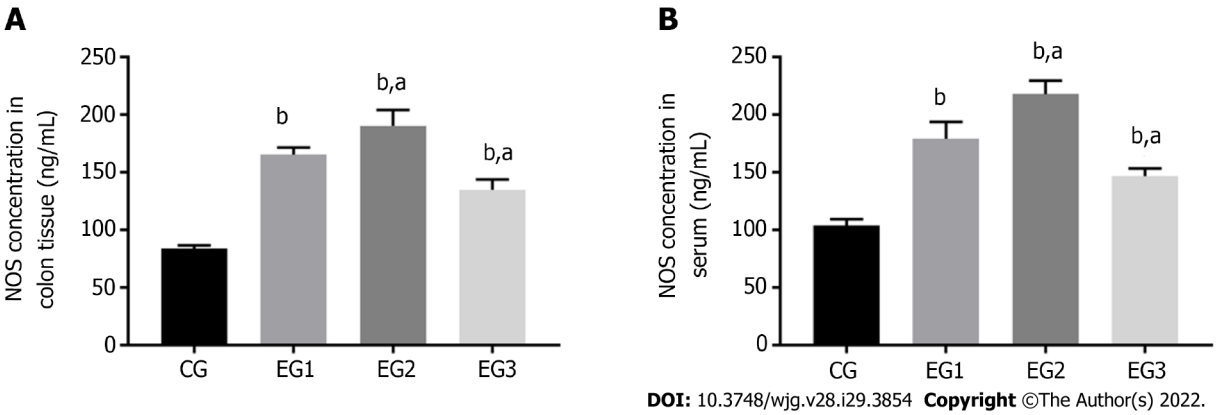
Figure 4 Changes in the number of nitric oxide synthase-positive neurons in the colonic myenteric plexus. A-L: Immunofluorescent histochemical double-staining of the rat colonic myenteric plexus (MP) for nitric oxide synthase (NOS; green) and HuC/D (red) in CG (A-C), EG1 (D-F), EG2 (G-I), and EG3 (J-L) rats. Scale bar = 30 μm; M: Comparison of the proportion of NOS-positive neurons in the colonic MP showing statistically significant differences between EG groups and CG group ($^{b}P < 0.0001$), and between EG2-3 groups and EG1 group ($^{a}P < 0.05$). CG: Control group; UC: Ulcerative colitis; NOS: Nitric oxide synthase; L-NMMA: NG-monomethyl-L-arginine monoacetate; EG1: UC group; EG2: UC + NOS agonist TP508TFA group; EG3: UC + NOS inhibitor L-NMMA group; MP: myenteric plexus.



(cGMP) within the cells, activating the cGMP protein kinase-dependent calcium pumps, and therefore finally participates in intercellular information transmission[35]. Therefore, it could be concluded that as a messenger of information transmission between the NOS-positive neurons and GI SMCs, increased NO can reduce the Ca^{2+} influx and directly promotes smooth muscle relaxation. In addition, studies have confirmed that NO can inhibit muscle contraction by inhibiting the release of excitatory transmitters[23,36]. Therefore, NO-mediated reduced contractility of the intestinal smooth muscle might be one of the important mechanisms contributing to colonic dysmotility[9,37].

In the present study, DSS was applied to induce the UC rat model successfully. For the first time, the finding of a secondary increase in NOS expression in the colonic MP of UC rats, combined with altered *in vitro* colonic contraction tension, suggests that the increased NOS expression is associated with the altered colonic motility in UC rats. Increasing (or decreasing) the number of NOS-positive neurons might enhance (or attenuate) the diastolic function of the colonic smooth muscle regulated by these neurons. However, the change in the number of NOS-positive neurons is often due to changes in the concentration and release of neurotransmitters caused by changes in the amount of NOS contained in neurons under pathological conditions, rather than caused by neuronal degeneration and regeneration. The results of *in vitro* studies of the colon using both agonists and inhibitors of NOS further confirmed that the altered NOS expression regulate the colonic motility in UC. A previous similar study

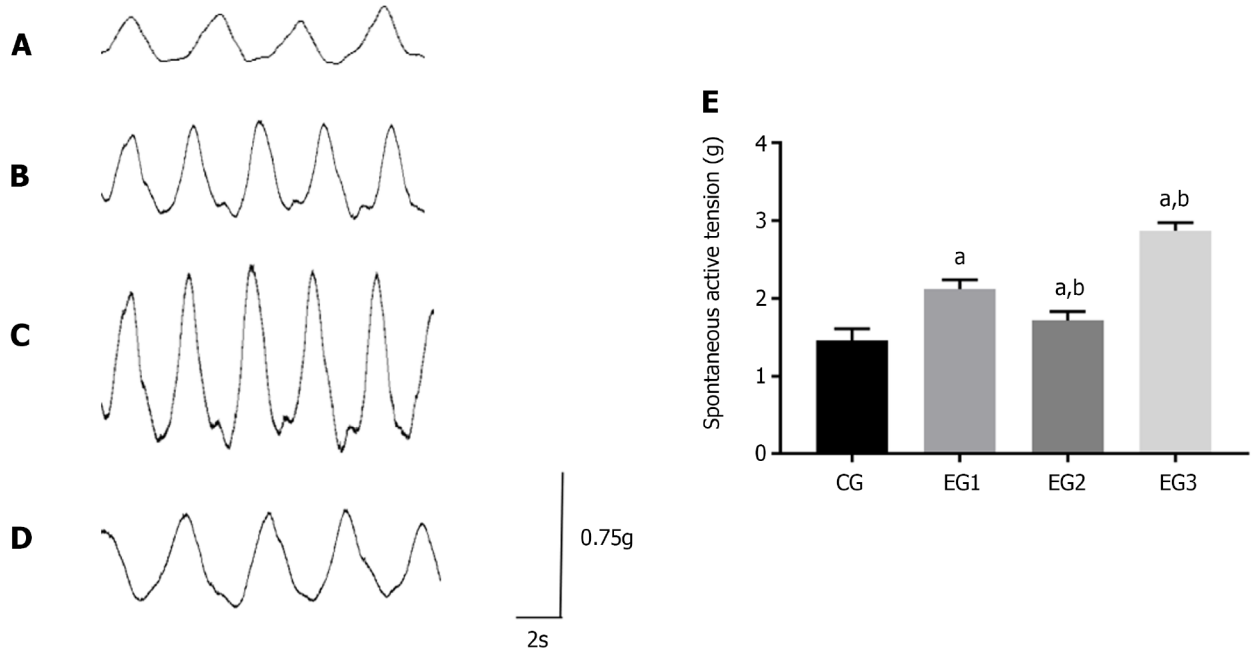
demonstrated that the NOS expression and NO concentration within the muscular layer of the stomach and small intestine were increased in an animal model of chronic pancreatitis[38]. These results suggest that the reduced contractility of the gastric CM because of NO inhibition might be an important mechanism underlying gastric motor dysfunction in chronic pancreatitis[36,38]. Moreover, these findings can provide an interesting insight into the role of the ENS during GI dysmotility.

The initiation of colonic dysmotility in UC may be related to the structural alterations and abnormal number of ICCs, disturbed intestinal electrophysiology, changes in colonic pressure, and abnormal expression of gut-related neurotransmitters. Our present results have demonstrated that the increased NOS expression inhibits the contraction motility of the colonic smooth muscle. Therefore, appropriate adjustment of NOS levels can alter the expression of nitrergic neurons, control the motor movement of the intestinal smooth muscle, and improve the UC colonic motor function. Of note, this could improve the symptoms of UC patients, providing a basis for the screening of novel agents against UC.



CONCLUSION

The increased number of nitrergic neurons in the colonic MP of UC rats, both *in vitro* and *in vivo*, diminishes the colonic motor function. In contrast, activation and inhibition of NOS activity could induce and diminish the colon motor function, respectively. Further, an increased number of nitrergic neurons in the colonic MP of UC rats leads to reduced colon contractile function. Therefore, the

regulation of nitrergic neurons in the colonic MP through interference with the activity of NOS might be a novel potential and prospective way to reduce diarrhea symptoms in UC patients.

ARTICLE HIGHLIGHTS

Research background

Ulcerative colitis (UC) is a nonspecific inflammatory intestinal disorder with a complex etiology and poorly understood pathogenesis. The association between abnormal intestinal motility and UC has gained increasing attention over the past years. The enteric nervous system (ENS) regulates gut motility and based on their functions, has been divided into inhibitory and excitatory neurons, which mainly regulate the gut motility in terms of relaxation and contraction *via* different neurotransmitters. Nitrergic neurons are typical inhibitory neurons in the ENS and act through the neurotransmitter nitric oxide, which is synthetized by the rate-limiting enzyme nitric oxide synthase (NOS), whose expression changes might affect the motor function of the gut.

Research motivation

UC is an intestinal disease with abdominal pain and diarrhea as the main symptoms, which are associated with abnormal gastrointestinal motility. Alterations in the amount of enteric neurotransmitters may change the number of enteric neurons. Nitrergic neurons are well-established enteric inhibitory neurons, and modification of its expression may interfere with its regulatory effect on intestinal motility and improve the symptoms of abdominal pain and diarrhea in UC.

Research objectives

This study aimed to investigate the relationship between colonic NOS expression changes and colonic motility in dextran sulfate sodium (DSS)-induced UC rats, and to explore the effects of nitrergic neurons on colonic motility in UC rats to discover the potential mechanisms for the treatment of UC.

Research methods

UC was induced in adult male rats with 5.5% DSS, and part of them were administered with NOS agonists and inhibitors. The rats were divided into control (CG), UC (EG1), UC + agonist (EG2), and UC + inhibitor (EG3) groups. The changes in tissue expression, relative protein expression, and concentration of NOS in rats were detected by immunofluorescence histochemical double staining, Western blot, and ELISA techniques, respectively. The effect of nitrergic neurons on colonic motility was examined by the changes in colonic circular muscle (CM) and longitudinal muscle (LM) contraction tension *in vitro*.

Research results

Compared with CG rats, the proportion of NOS positive neurons within the colonic myenteric plexus (MP), the relative expression of NOS, and the concentration of NOS in both serum and colonic tissue were significantly higher in EG rats. After administration of NOS agonists and inhibitors, various degrees of increase and decrease were observed in EG2 and EG3 rats, respectively. The contraction amplitude and mean contraction tension of the CM and LM in rat colon after administration of agonists and inhibitors were attenuated and enhanced *in vitro*, respectively. For UC, regulating the expression of NOS within the MP may improve intestinal motility, thereby favoring the recovery of intestinal function.

Research conclusions

Nitrergic neurons within the rat colonic MP are involved in the regulation of colonic motility. Increased NOS in the colonic MP of UC rats causes nitrergic neurons amplification, leading to decreased colonic contraction function. Modulation of NOS levels within colonic MP can alter nitrergic neuron expression and adjust the motor activity of the intestinal smooth muscle, which can further improve colonic motor function, moderate UC symptoms, and provide evidence for the development of new drugs against UC.

Research perspectives

This study demonstrated increased NOS expression in the colonic MP of UC rats, with a possible corresponding increase in nitrergic neuron expression and a decrease in colonic contraction function in UC rats. Thus, by regulating the expression of NOS in the colonic MP, colonic motor function and interruption in the pathogenesis of UC can be achieved, thus providing a novel insight into the treatment of UC.

Abstract

BACKGROUND

Mass spectrometry-based proteomics and glycomics reveal post-translational modifications providing significant biological insights beyond the scope of genomic sequencing.

AIM

To characterize the N-linked glycoproteomic profile in esophageal squamous cell carcinoma (ESCC) *via* two complementary approaches.

METHODS

Using tandem multilectin affinity chromatography for enrichment of N-linked glycoproteins, we performed N-linked glycoproteomic profiling in ESCC tissues by two-dimensional gel electrophoresis (2-DE)-based and isobaric tags for relative and absolute quantification (iTRAQ) labeling-based mass spectrometry quantitation in parallel, followed by validation of candidate glycoprotein biomarkers by Western blot.

RESULTS

2-DE-based and iTRAQ labeling-based quantitation identified 24 and 402 differentially expressed N-linked glycoproteins, respectively, with 15 in common, demonstrating the outperformance of iTRAQ labeling-based quantitation over 2-DE and complementarity of these two approaches. Proteomaps showed the distinct compositions of functional categories between proteins and glycoproteins with differential expression associated with ESCC. Western blot analysis validated the up-regulation of total procathepsin D and high-mannose procathepsin D, and the down-regulation of total haptoglobin, high-mannose clusterin, and GlcNAc/sialic acid-containing fraction of 14-3-3ζ in ESCC tissues. The serum levels of glycosylated fractions of clusterin, proline-arginine-rich end leucine-rich repeat protein, and haptoglobin in patients with ESCC were remarkably higher than those in healthy controls.

CONCLUSION

Our study provides insights into the aberrant N-linked glycoproteome associated with ESCC, which will be a valuable resource for future investigations.

Key Words: Esophageal squamous cell carcinoma; N-linked glycoprotein; Post-translational modification; Lectin; Cathepsin D; Haptoglobin; 14-3-3ζ

Core Tip: The N-linked glycoproteome was comprehensively profiled by two-dimensional gel electrophoresis-based and isobaric tags for relative and absolute quantification (iTRAQ) labeling-based mass spectrometry quantitation in parallel after N-linked glycoprotein enrichment by a tandem of multilectin affinity chromatography. The iTRAQ labeling-based quantitative proteomic profiling outperformed protein spot intensity quantification used by two-dimensional gel electrophoresis. A total of 411 N-linked glycoproteins were identified, including 128 up-regulated and 283 down-regulated glycoproteins with differential expression, which provide the scientific community with a dataset of glycoproteins associated with esophageal squamous cell carcinoma for in-depth investigation.

INTRODUCTION

Esophageal cancer is a severe global health issue with 572000 new cases and 509000 deaths in 2018, half of which occur in China[1]. The two most common histological subtypes of esophageal cancer are esophageal squamous cell carcinoma (ESCC) and esophageal adenocarcinoma, with ESCC being the predominant histological subtype both in China and worldwide[2,3]. The long-term outcome of ESCC is correlated with clinical stage at diagnosis with the best outcome in the early stages[4-6]. Unfortunately, the current endoscopic screening for ESCC suffers from low patient compliance and high cost despite the fact that an early detection rate of 70% was achieved in a high-risk region in northern central China [7]. Furthermore, serum biomarkers for ESCC, including squamous cell carcinoma antigen, carcinoembryonic antigen, CYFRA21-1, and carbohydrate antigen 19-9, lack sufficient sensitivity and specificity for early detection[8-11]. The overall 5-year survival rate ranges from 15% to 25% because most cases of ESCC present at an advanced stage[6,12]. It is well accepted that novel biomarkers would hold great promise to improve the clinical outcome of ESCC.

Recent large-scale "omics" studies in ESCC have identified a myriad of aberrations at the levels of genome, epigenome, transcriptome, proteome, *etc*., revealing the high molecular heterogeneity of ESCC [13-17]. Beyond the scope of other techniques, mass spectrometry (MS)-based proteomics has the ability to measure post-translational modifications that provide additional significant biological insights, for example, therapeutically targetable signaling proteins and pathways[18,19]. To date, comprehensive glycoproteomic studies of ESCC are lacking. Glycosylation is present on more than 50% of human proteins and aberrant glycosylation has been implicated in the development and progression of various cancers[20-24]. The sugar chains of glycoproteins are involved in numerous physiological and pathological functions including cell growth, adhesion, differentiation, migration, signal regulation, immune responses, and tumor invasion[20,25,26]. Notably, the clinical prognosis of cancer has been correlated with certain structures of glycans attached to proteins[27,28]. The bisecting GlcNAc structure

catalyzed by N-acetylglucosaminyltransferase III plays crucial roles in suppression of cancer metastasis, which contrasts with the tumor-promoting role of β1, 6-branched N-glycan catalyzed by N-acetylglucosaminyltransferase V[29]. It has been reported that E-cadherin modified by complex N-glycans exhibits weakened adherens junctions, whereas high mannose or less N-glycans attached to E-cadherin produces stable adherens junctions[30]. Furthermore, N-acetylglucosaminyltransferase III modified α3β1 integrin suppresses cell spreading and migration and focal adhesion kinase activity[31]. The fraction of ConA-binding procathepsin D in the serum of hepatocellular carcinoma patients is significantly increased and shows a sensitivity of 85% and specificity of 80% for hepatocellular carcinoma diagnosis [24]. Not surprisingly, over 50% of current cancer biomarkers are glycoproteins, such as AFP, AFP-L3, CA19-9, CA125, and CEA[32-35].

In this study, we used MS-based proteomic analysis to identify N-linked glycoproteins associated with ESCC after isolation of N-linked glycoproteins using tandem multilectin affinity chromatography. Our study unraveled a comprehensive landscape of N-linked glycosylation dysregulation associated with ESCC and bioinformatics analysis provided insights into the functional significance of such aberrant glycosylation. The glycosylated fractions of procathepsin D, clusterin, 14-3-3ζ, proline-arginine-rich end leucine-rich repeat protein (PRELP), and haptoglobin may play important roles in malignant progression of ESCC and are potential diagnostic biomarkers for ESCC, suggesting that N-linked glycosylation aberrations may promote the malignant progression of ESCC.

MATERIALS AND METHODS

Clinical samples

All patients provided written informed consent, and the study was approved by the Ethics Committee of the Medical School, Henan University, China (ethics ref: 108) and conducted in accordance with the ethical guidelines of the 1975 Declaration of Helsinki. Forty-seven pairs of resected ESCC and adjacent normal esophageal mucosa tissue samples, and ten pre-operative serum samples were collected at Linzhou Cancer Hospital, Henan, China between 2010 and 2011 and stored in liquid nitrogen or at -70 ℃ prior to protein extraction. Among the tissue samples, 15 pairs served as a discovery set and the other 32 pairs as a validation set. All tissues were histopathologically confirmed as normal esophageal mucosa or ESCC. The adjacent non-cancerous samples were at least 3 cm distant from the edge of neoplastic mass. No patient in this study had received preoperative radiotherapy or chemotherapy.

Isolation of N-linked glycoproteins by lectin affinity chromatography

Extraction of total tissue proteins and N-linked glycoproteins was performed as previously reported with modifications[24]. Briefly, the esophageal tissue was homogenized in lysis buffer (50 mmol/L Tris, 150 mmol/L NaCl, 1% NP-40, pH 7.2) supplemented with complete proteinase inhibitor cocktail (Roche Diagnostics GmbH, Mannheim, Germany) followed by centrifugation and supernatant collection. Enrichment of N-linked glycoproteins for three pairs of pooled protein samples from 15 ESCC and adjacent non-tumor tissues (five samples for each pair) was performed by tandem lectin affinity chromatography. The multilectin affinity chromatography used a combination of three agarose-bound lectins, Con A (Vector Laboratories, AL-1003), lentil lectin (LCH, Vector Laboratories, AL-1043), and snowdrop lectin (GNA, Vector Laboratories, AL-1243), and a combination of wheat germ agglutitin lectin (WGA, Vector Laboratories, AL-1023) and elderberry lectin (SNA, Vector Laboratories, AL-1303) for the first and second affinity chromatography, respectively. Sixty milligrams of pooled proteins were diluted with binding buffer (30 mmol/L Bis-Tris, 150 mmol/L NaCl, 1 mmol/L $CaCl_2$, 1 mmol/L $MnCl_2$, pH 7.2) and incubated with the lectins in the first affinity chromatography columns at room temperature for 2 h. After incubation, 200 mmol/L methyl-α-D-mannopyranoside was used for elution of high-mannose N-linked glycoproteins. The flowthrough of the first three-lectin column was subjected to the second chromatography for isolation of GlcNAc/sialic acid-containing N-linked glycoproteins using 200 mmol/L N-Acetyl-D-glucosamine as elution buffer. The eluted samples were desalted and concentrated by acetone precipitation.

Two-dimensional gel electrophoresis and image analysis

Two-dimensional gel electrophoresis (2-DE) was performed as previously reported[24,36]. Fifty micrograms of glycoproteins were used for the first-dimension isoelectrofocusing electrophoresis using IPG strips with a linear pH range of 3-10, followed by the second dimension separation using 15% SDS-PAGE gels. Silver stained gels were scanned with an ImageScanner. Image analysis was carried out with ImageMaster 2-D Elite software 4.01.

In-gel digestion and MS identification

The excised protein spots with differential expression were reduced with DTT, alkylated with iodoacetamide, dried in a speedvac, and digested with trypsin (12.5 μg/mL in 50 mmol/L ammonium bicarbonate). LC-MS/MS analysis of tryptic peptides was performed using a Maxis Impact Q-TOF mass

spectrometer (BrukerDaltonics, Bremen, Germany). The MS/MS data were searched against the SwissProt human sequence database using MASCOT *via* Proteinscape (BrukerDaltonics, Bremen, Germany) and reverse database searching was used for estimating the false discovery rate. All proteins were identified by ≥ 2 unique peptides.

Isobaric tags for relative and absolute quantification labeling and MS identification

Isobaric tags for relative and absolute quantification (iTRAQ) labeling of tryptic peptides was performed according to the protocol provided by the supplier. The iTRAQ labeled peptides derived from pooled protein samples of ten ESCC and adjacent non-tumor tissues as previously described in duplicate[37] were separated into 16 fractions by mixed-mode anion exchange/reverse-phase chromatography. Each fraction was dried, dissolved in 0.1% formic acid, and analyzed by LC-MS/MS using a Maxis Impact Q-TOF mass spectrometer (BrukerDaltonics, Bremen, Germany). Data were searched against the SwissProt human sequence database using MASCOT and expression ratios calculated by WARP-LC *via* Proteinscape (BrukerDaltonics, Bremen, Germany). The false discovery rate was estimated using a reverse database search strategy. All proteins were identified by ≥ 2 unique peptides. The data have been deposited at https://www.iprox.cn/ with Project ID IPX0004371000.

Functional enrichment analysis

Gene-set enrichment analyses of differentially expressed glycoproteins (DEGs) and previously identified differentially expressed proteins (DEPs)[37] were performed using Enrichment Map, which organizes the enriched gene-sets into a network with links representing the overlap of member genes [38]. The gene-sets with a P value < 0.001 and false discovery rate < 5% were selected for display in the enrichment map. To gain an insight into the functional makeup of DEGs and DEPs, Proteomap was used to visualize the functional distribution of DEGs or DEPs in cellular processes, including genetic information processing, metabolism, cellular processes, signaling, and others[39].

Western blot analysis

Total tissue proteins were extracted using radioimmunoprecipitation assay lysis buffer, and glycoproteins were isolated by lectin affinity chromatography. Total proteins or glycoproteins were separated by SDS-PAGE and then transferred to PVDF membranes. The blots were blocked in 5% non-fat milk, incubated with primary antibodies and then corresponding secondary antibodies, and visualized using Supersignal West chemiluminescent substrate (Pierce Biotechnology, Rockford, IL, United States). Semi-quantitation of the band intensity was performed using image analysis software and corrected by reference to GAPDH. The antibodies used in this study were: Haptoglobin (1:2000, 16665-1-AP, Proteintech), cathepsin D (1:2500, ab75852, Abcam), clusterin (1:5000, 12289-1-AP, Proteintech), SOD3 (1:1500, T1799, Epitomics), PRELP (1:2000, AP6665b, Abgent), and 14-3-3-ζ (1:2500, ab85268, Abcam).

Statistical analysis

All statistical analyses were performed with SPSS 24.0 software (SPSS, Chicago, IL, United States). Comparisons of quantitated protein band density between ESCC and adjacent non-cancerous tissues were done by paired Student's t-tests or Wilcoxon signed-rank sum tests. All statistical tests were two-sided, and P < 0.05 was considered statistically significant.

RESULTS

N-linked glycoprotein profiling by two-dimensional gel electrophoresis

This study utilized two rounds of multilectin affinity chromatography to isolate N-linked glycoproteins. The first multilectin affinity column comprised Con A, LCH, and GNA lectins to isolate high-mannose N-linked glycoproteins, and the second affinity column included WGA and SNA lectins for GlcNAc/sialic acid-containing glycoprotein enrichment. 2-DE was used to separate the isolated N-linked glycoproteins. Figure 1A and B shows the representative 2-DE images of high-mannose glycoproteins isolated from ESCC and non-cancerous tissues. An average of 742 ± 45 protein spots could be detected on each 2-DE gel analyzed by Image Master 2-D Elite. A total of 35 differential protein spots with ≥ 1.5 fold-changes in protein spot intensities (P < 0.05) were identified, including 20 up-regulated and 15 down-regulated protein spots in ESCC compared with corresponding non-cancerous tissues, respectively. For GlcNAc/sialic acid-containing glycoprotein profiling, the patterns of protein spots on 2-DE gels were markedly different compared with those of high-mannose glycoproteins (Figure 1C and D). There were 23 protein spots with differential expression, including 5 up-regulated and 18 down-regulated protein spots in ESCC compared to non-cancerous tissues.

These protein spots were identified by LC-MS/MS of the trypsin-digested spots excised from preparative gels. The identities of proteins are shown in Tables 1 and 2, in which 22 proteins and 23 proteins were derived from the first and second lectin affinity chromatography, respectively. There

Figure 1 Representative two-dimensional gel electrophoresis images of N-linked glycoproteins from esophageal squamous cell carcinoma (ESCC) and adjacent non-cancerous tissues (N), in which the denoted numbers represent protein spots with differential expression. A and B: Representative two-dimensional gel electrophoresis (2-DE) images of high-mannose glycoproteins from ESCC (A) and N (B); C and D: Representative 2-DE images of GlcNAc/sialic acid-containing glycoproteins from ESCC (C) and N (D). ESCC: Esophageal squamous cell carcinoma; N: Non-cancerous tissues.

were six proteins in common between these two isolated fractions. In agreement with our previous reports[24,36], many gel spots were identified as the same protein, indicating the presence of different proteoforms due to post-translational modifications. Using NetNGlyc (http://www.cbs.dtu.dk/services/NetNGlyc) to predict the glycosylation sites on proteins, 72.7% (16/22) of high-mannose N-linked glycoproteins and 56.5% (13/23) of GlcNAc/sialic acid-containing glycoproteins were found to have potential glycosylation sites, indicating some non-specific binding to lectins by non-glycosylated proteins.

N-linked glycoprotein profiling by iTRAQ labeling

To comprehensively characterize the N-linked glycoproteome in ESCC, we further performed iTRAQ-based analysis of the N-linked glycoproteome in ESCC and non-cancerous tissues. One pair of protein pools from ten ESCC and matched non-cancerous tissues, respectively, were subjected to tandem lectin affinity chromatography enrichment, in-solution digestion with trypsin, iTRAQ labeling, and LC-MS/MS identification in duplicate. In total, 1464 and 1298 proteins from the first affinity column were identified in the two technical replicates (Figure 2A, Supplementary Tables 1 and 2). Using the cut-off criteria of ≥ 2 unique peptides and a fold-change of 1.5, 189 and 138 proteins with differential expression were identified from the first and second independent pools, respectively, with 65 proteins in common, resulting in identification of 262 differentially expressed proteins in total from the high-mannose binding lectin affinity chromatography, of which 203 (77.5%) have predicted N-linked glycosylation sites (Figure 2B). For N-linked glycoproteins enriched by the downstream GlcNAc/sialic acid binding lectin chromatography, two independent iTRAQ-labeled pools produced 1174 and 936 proteins following isolation of high-mannose glycoproteins (Figure 2C, Supplementary Tables 3 and 4). There were 237 of 1174 and 154 of 936 proteins with differential expression, respectively, with 74 proteins in common (Figure 2D). A total of 317 unique proteins, of which 246 (77.6%) were predicted to be N-linked glycoproteins, were identified from the GlcNAc/sialic acid binding lectin chromatography enrichment.

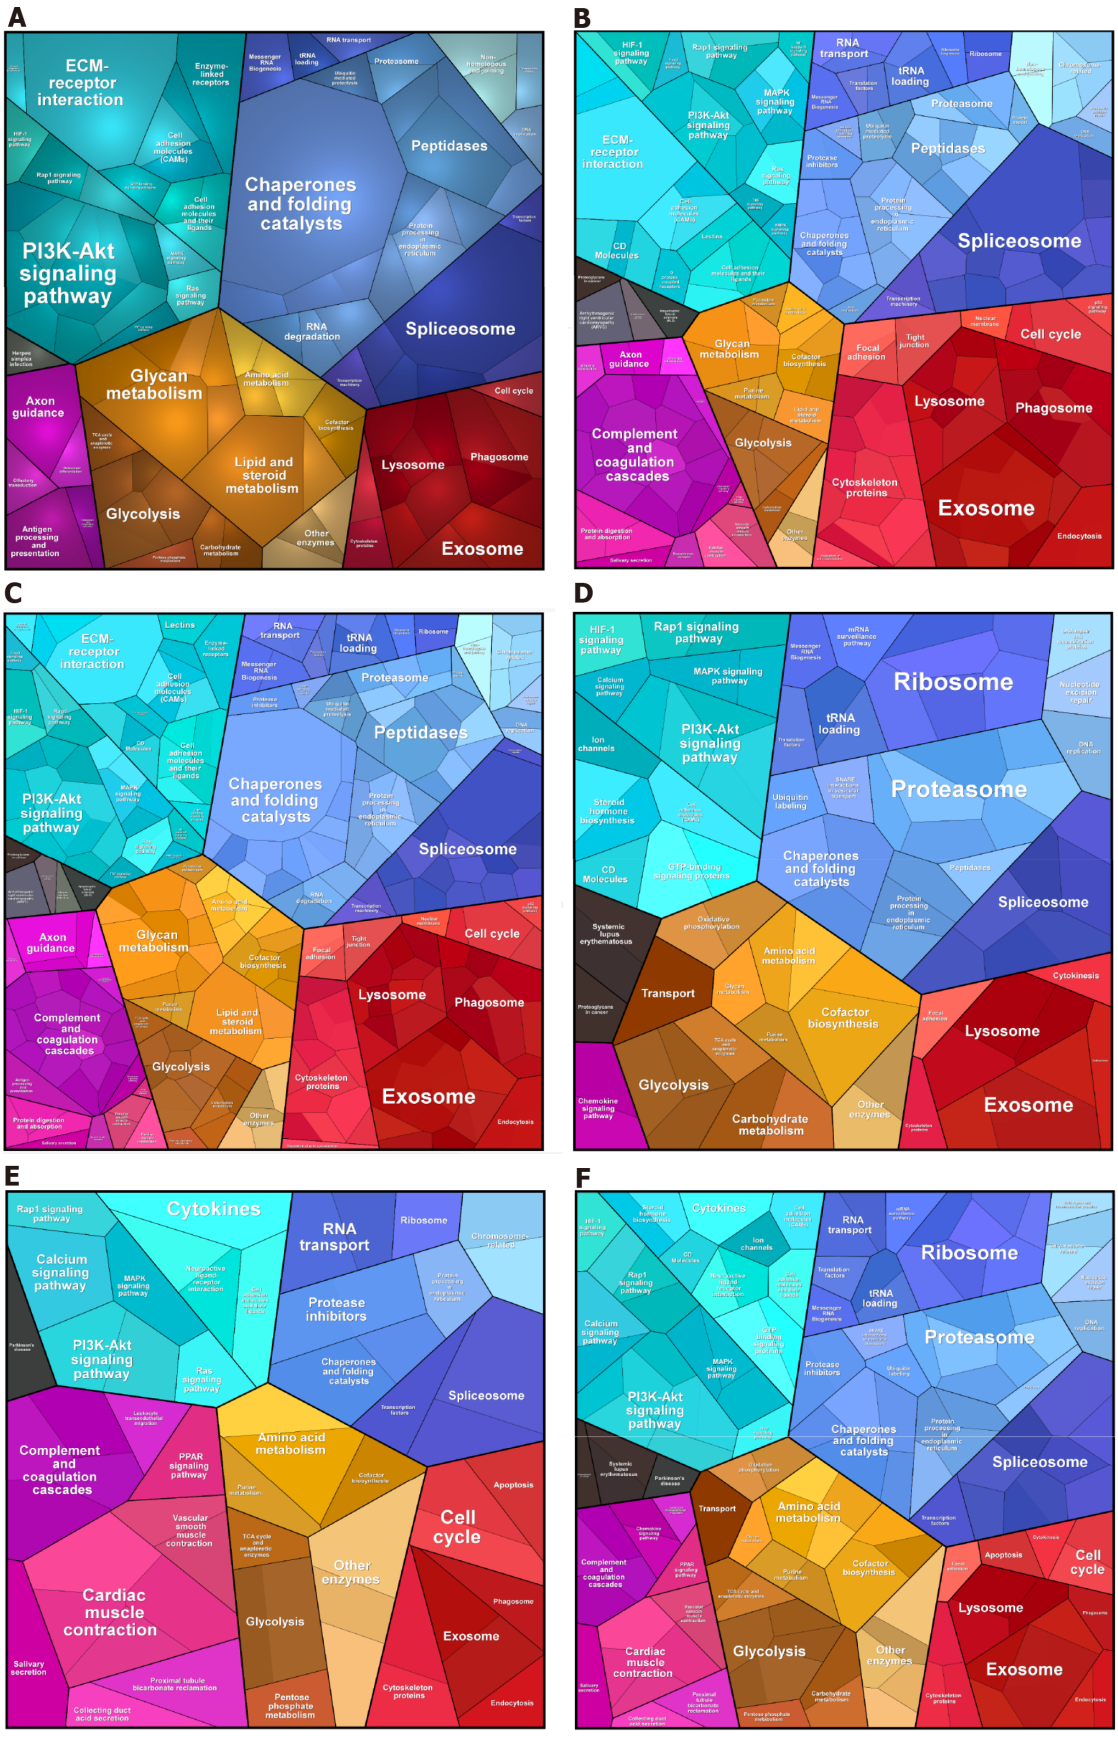
There were 58 overlapping glycoproteins found between 262 high-mannose glycoproteins and 317 GlcNAc/sialic acid-containing glycoproteins.

Comparison of two-dimensional gel electrophoresis-based and iTRAQ labeling-based profiling

In this study, two protocols for identifying N-linked glycoproteins based on different quantitative methods yielded quite different results. There were only 11 high-mannose glycoproteins and 4 GlcNAc/sialic acid-containing glycoproteins in common between 2-DE-based and iTRAQ-based glycoproteomic profiling. Our results demonstrate that iTRAQ-based quantitative proteomic profiling outperformed protein spot intensity quantification by 2-DE. There were, however, common glycoproteins found by both approaches. Therefore, the combination of these four fractions produced 411 unique N-linked glycoproteins. These findings indicate that a combination of these two complementary protocols could generate a more comprehensive landscape of N-linked glycoproteome implicated in ESCC because iTRAQ-based and 2-DE-based methods were able to isolate unique glycoproteins, thus providing a good representation of the N-linked glycoproteome.



Functional analysis of differentially expressed glycoproteins

To explore the biological function of the 411 DEGs associated with ESCC, KEGG pathway enrichment analysis was initially performed using Enrichment Map. Figure 3A-C shows the 64 enriched pathways, which include complement and coagulation cascades, focal adhesion, ECM-receptor interaction, cellular interactions, immune response and infection, metabolism of fructose and mannose, glycolysis and gluconeogenesis, splicesome, and PI3K-Akt and HIF-1 signaling pathways. In addition, proteomaps were constructed to visualize the composition of these DEGs in the five functional categories, which comprise genetic information processing, environmental information processing, cellular processes, metabolism, and organismal systems. Figure 4A-C shows that the genetic information processing accounts for the largest component of the DEGs, with protein processing, translation, and transcription being the biggest contributors to this functional category. In the category of signaling events, both the up-regulated and down-regulated DEGs were involved in PI3K-Akt, MAPK, Ras, Rap1, and HIF-1 signaling pathways (Figure 4A and B). The layouts of cellular process between up-regulated and down-regulated DEGs were different, with common components of exosome, lysosome, phagosome, cytoskeleton, and cell cycle, whereas the down-regulated DEGs are implicated in focal adhesion, tight

Differentially expressed glycoproteins; DEPs: Differentially expressed proteins.

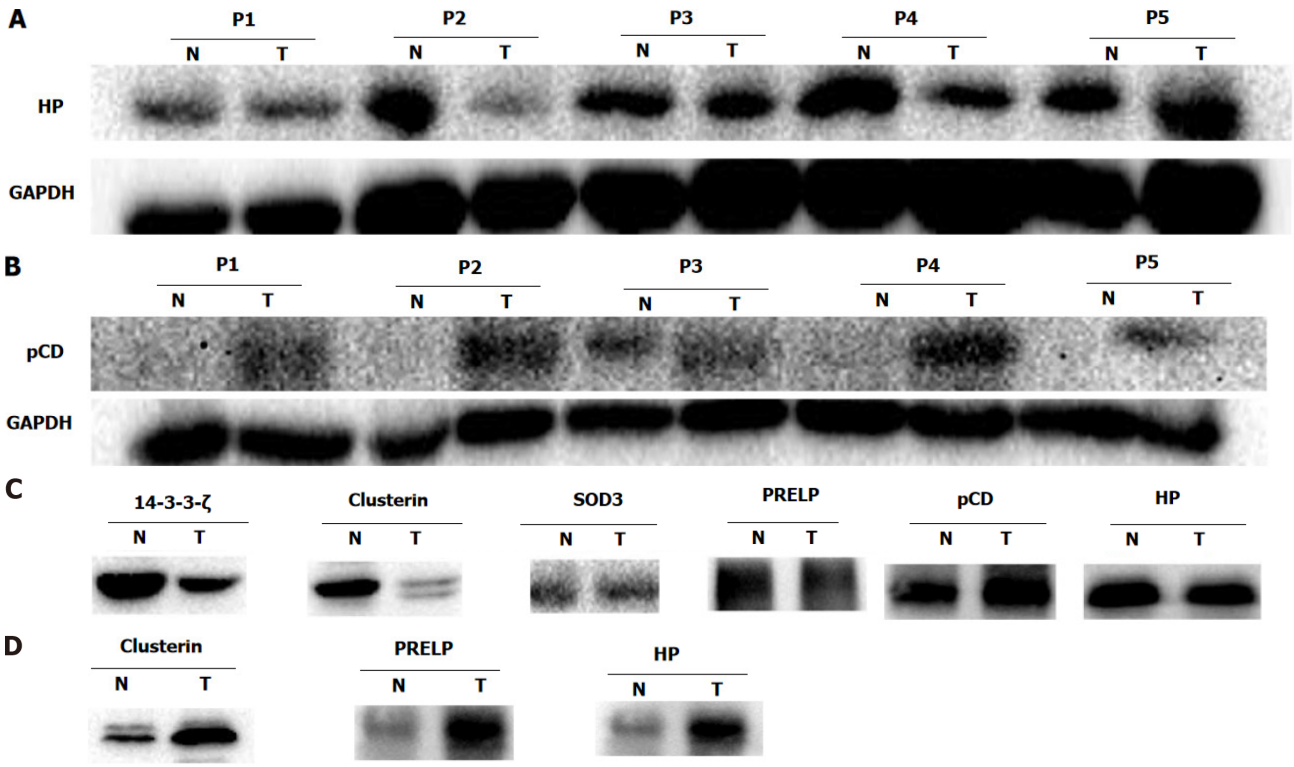
junction, endocytosis, and p53 signaling pathway (Figure 4A and B). In glycolysis, there were more up-regulated than down-regulated DEGs. Notably, the complement and coagulation cascades in the immune system include exclusively down-regulated DEGs (Figure 4A and B).

Functional comparison between glycoproteins and proteins with differential expression

Because there were only 82 overlapping proteins between DEGs and DEPs, the distinct subproteomes in each functional category may affect the structure of proteomaps. As shown in Figure 4, the compositions of proteomaps differ. In the category of genetic information processing, the chaperones, spliceosome, and peptidases are the predominant components in DEGs whereas the spliceosome, proteasome, and ribosome are the main contributors in DEPs. Although there are some signaling pathways (PI3K/Akt, MAPK, HIF1, Ras, and Rap1) in common in DEGs and DEPs, distinct components (neuroactive ligand-receptor interaction, calcium signaling pathway, GPT-binding signaling proteins, steroid hormone biosynthesis, and cytokines in DEPs *vs* NF kappa B pathway, FoxO pathway, ECM-receptor interaction, CD molecules, lectins, and enzyme-linked receptors in DEGs) are present in environment interaction (Figure 4C and F). Along with these differences, distinct compositions of the other three categories were found as well, in agreement with uniquely characterized proteomes. Likewise, Enrichment Map analysis showed that marked differences were found between DEGs and DEPs (Figure 3C and F). In the same line, there were remarkable distinctions between DEGs and DEPs identified using iTRAQ-based quantitation of Indian ESCC samples (data not shown)[40].

Validation of potential glycoprotein biomarkers

Western blot analysis was performed to validate the differential expression of potential glycoprotein biomarkers for ESCC, including haptoglobin, cathepsin D, clusterin, superoxide dismutase 3 (SOD3), PRELP, and 14-3-3ζ. Consistent with the corresponding protein spots of 748 and 1001 on 2-DE images, haptoglobin expression in ESCC was significantly down-regulated in tumor compared with adjacent non-cancerous tissues (Figure 5A). In contrast, the expression of procathepsin D instead of mature cathepsin D was remarkably enhanced in ESCC compared with the corresponding non-cancerous tissues (Figure 5B). There were no significant differences in the expression levels of the other four selected proteins (Supplementary Figure 1). These data suggest that the differential expression of glycoproteins identified in this study could be caused by up-regulation of protein expression, or up-regulation of N-linked glycosylation due to aberrant expression or activities of certain glycosyltransfereases.



To assess the contribution of high-mannose or GlcNAc/sialic acid components attached to the selected glycoproteins, enrichment of corresponding glycoproteins *via* glycan chain binding to specific lectins was performed followed by Western blot detection. Consistent with the up-regulation of procathepsin D protein, the high-mannose subtype of procathepsin D was pronouncedly increased in ESCC as well (Figure 5C). In contrast to the expression pattern of total clusterin protein, the high-mannose fraction of clusterin was markedly down-regulated in ESCC as compared with non-cancerous tissues (Figure 5C). However, the glycosylated fractions of SOD3, PRELP, and haptoglobin did not show significant differences between ESCC and non-cancerous tissues after enrichment of high-mannose glycan structure of glycoproteins using lectin affinity chromatography. In agreement with the quantitative result of glycosylated 14-3-3ζ, the GlcNAc/sialic acid-containing fraction of 14-3-3ζ was strongly reduced in ESCC (Figure 5C).

Serum levels of potential glycoprotein biomarkers

As isolation of N-linked glycoproteins from serum reduces the high-complexity of the serum proteome, we characterized the serum levels of potential glycoprotein biomarkers in patients with ESCC. As expected, the total protein levels of the six selected proteins were not significantly different in the serum of ESCC patients and healthy controls (Supplementary Figure 2). In contrast, the serum levels of glycosylated forms of clusterin, PRELP, and haptoglobin in ESCC patients were much higher than those of healthy controls (Figure 5D).

DISCUSSION

Aberrant glycosylation of proteins, which is not correlated with mRNA levels, has been linked to a variety of cancers and reflects disease status and progression[20,41-44]. MS-based proteomics and glycomics hold considerable potential to identify novel glycosylation-based biomarkers. To the best of our knowledge, this study is the first to use tandem lectin affinity chromatography to enrich N-linked glycoproteins, followed by 2-DE-based and iTRAQ labeling-based proteomic quantitative profiling, and protein identification by MS. In total, 411 differentially expressed N-linked glycoproteins were

Figure 5 Western blot validations of potential glycoprotein biomarkers. A and B: Representative Western blot results show haptoglobin (HP) (A) and procathepsin D (pCD) (B) with differential expression between esophageal squamous cell carcinoma (ESCC/T) and adjacent non-cancerous tissues (N); C: Representative Western blot results show the N-linked glycosylated fraction of HP, pCD, clusterin, superoxide dismutase 3 (SOD3), proline-arginine-rich end leucine-rich repeat protein (PRELP), and 14-3-3ζ in ESCC/T and N enriched by corresponding lectins; D: Representative Western blot results show the N-linked glycosylated fractions of clusterin, PRELP, and HP in serum of patients with ESCC/T and healthy controls. The results are representative of three independent experiments. ESCC/T: Esophageal squamous cell carcinoma; HP: Haptoglobin; pCD: Procathepsin D; SOD3: Superoxide dismutase 3; PRELP: Proline-arginine-rich end leucine-rich repeat protein.

identified, including 128 up-regulated and 283 down-regulated DEGs. These DEGs provide the scientific community a dataset of glycoproteins associated with ESCC for in-depth investigation.

Depending on the linkage of carbohydrate to the protein backbone, glycoproteins fall into two main types, N-glycosylated and O-glycosylated, in which glycans are covalently attached to the amide nitrogen of asparagine residues and to the hydroxyl group of serine or threonine residues, respectively [45]. Lectins are defined as proteins that bind to the particular oligosaccharide epitope structures attached to proteins or lipids *via* selective affinities[46]. Due to these natural features, lectins are frequently used to isolate glycoproteins from a variety of origins, in particular from blood, to reduce sample complexity and to enrich low-abundance proteins. Using three lectins in parallel, *i.e.*, ConA, WGA, and Jacalin, a total of 423 proteins were fractionated from membrane proteins, among which 202 (71%) have predicted N-linked glycosylation sites[47]. As expected, there were unique and shared proteins enriched by these three lectins. To comprehensively isolate N-linked glycoproteins involved in ESCC, five lectins allocated to two sequential affinity chromatographies were used in this study to increase the coverage of captured N-linked glycoproteins. In addition, two complementary methods for quantitative profiling of enriched glycoproteins were used. In total, 262 and 317 nonredundant DEPs were identified by iTRAQ labeling-based profiling from the first and second lectin affinity chromatography, respectively. 2-DE-based MS/MS profiling led to fewer DEPs being identified compared with the iTRAQ labeling-based approach. Under a high stringency of selection criteria (foldchange ≥ 1.5, unique peptides ≥ 2), 519 proteins were identified in total, of which 402 (77.5%) carry predicted N-linked glycosylation sites. Identification of a large number of proteins without predicated glycosylation sites indicates the existence of non-specific binding to certain lectins needing further in-depth study to elucidate.

Functional analysis based on KEGG pathway annotations by Proteomap revealed that there were striking differences in the compositions of DEGs distributed in five functional entities. In line with previous findings, the DEGs in genetic information processing account for the largest fraction of N-linked glycoproteome, supporting the survival and rapid growth of cancer cells[39]. In further support of this, a number of signaling pathways, including PI3K-Akt, MAPK, Rap1, and HIF-1 pathways, which play important roles in oncogenesis and progression, were significantly enriched. In metabolism, glycolysis was significantly enriched in DEGs identified in this study. The increased rate of glucose

metabolism and aerobic glycolysis, also known as the Warburg effect, are recognized hallmarks of cancer[48]. In agreement with this, HIF signaling proteins were over-represented in ESCC and may contribute to increased glycolysis. Besides energy generation, aerobic glycolysis enhances rapid growth and unlimited proliferation of cancer cells through providing precursors for certain biosynthetic processes as well as alteration of the tumor microenvironment[49]. Moreover, extracellular lactate has inhibitory effects on human cytotoxic T lymphocytes[50,51]. Furthermore, metabolic phenotype of cancer stem cell seems distinct from bulk cancer cells and is characterized by glycolysis and/or XoPhos [49]. The increased expression of fructose-bisphosphate aldolase A, triosephosphate isomerase, alpha-enolase, all-trans-retinol dehydrogenase [NAD(+)] ADH1B, and glyceraldehyde-3-phosphate dehydrogenase in ESCC may contribute to the progression of ESCC *via* increased glycolysis and could serve as therapeutic targets for the management of ESCC. All together, these distinct functional categories and related effector molecules may represent potential therapeutic targets in ESCC.

Cathepsin D, a lysosomal protease, is expressed in nearly all cells and tissues of mammals. However, pro-cathepsin D but not mature cathepsin D is reportedly associated with the development and progression of a variety of cancers[52]. In line with up-regulation of ConA-binding cathepsin D and procathepsin D, glycosylated procathepsin D was increased in ESCC as well, suggesting it as a potential biomarker for ESCC. In addition, we also demonstrated that both total haptoglobin and N-linked haptoglobin in serum were differentially expressed in ESCC, as seen in other malignancies[41,53,54]. Although there were no alterations in the levels of total protein expression, the high-mannose clusterin and sialic acid glycoforms of 14-3-3ζ were down-regulated in ESCC but need further study to characterize their glycan moieties. After probing the serum levels of these candidate biomarkers, we provide several potential biomarkers for ESCC diagnosis. Additionally, our findings reveal that differential protein expression is a confounding factor for identification of aberrant glycosylation.

The current study has several limitations. First, the main limitation is that sample pooling used in this study may cause a loss of inter-individual information. However, this is partly compensated by the validation of candidate biomarkers using individual tissue samples. Second, affinity chromatography comprising multiple lectins for glycoprotein isolation yielded different subglycoproteomes. Further studies should characterize the composition and structure of glycans associated with proteins. Nevertheless, our study represents, to our knowledge, the first study to characterize the glycoproteome associated with ESCC, and thus provides the scientific community a resource of glycoproteins for in-depth investigation.

CONCLUSION

In conclusion, this study catalogued a total of 411 N-linked glycoproteins implicated in ESCC after glycoprotein enrichment using two stage multilectin affinity chromatography and MS/MS identification. Proteomap analysis revealed the distribution of differential glycoproteins in five functional categories. A preliminary validation demonstrated the differential expression of glycoprotein biomarker candidates, including total procathepsin D and haptoglobin in ESCC, high-mannose fractions of procathepsin D, clusterin and sialiated 14-3-3ζ in ESCC, and glycosylated fractions of clusterin, PRELP, and haptoglobin in serum. Consequently, this study yielded a comprehensive landscape of N-linked glycoproteome associated with ESCC for further characterization.

ARTICLE HIGHLIGHTS

Research background

Recent large-scale "omics" studies in esophageal squamous cell carcinoma (ESCC) have identified a myriad of aberrations at the levels of genome, epigenome, transcriptome, proteome, *etc*., revealing the high molecular heterogeneity of ESCC. However, protein post-translational modifications, such as glycosylation and phosphorylation, which provide additional significant biological insights, are missing.

Research motivation

The sugar chains of glycoproteins are involved in numerous physiological and pathological conditions. More than 50% of current cancer biomarkers are glycoproteins.

Research objectives

To identify N-linked glycoproteins associated with ESCC after isolation of N-linked glycoproteins using tandem multilectin affinity chromatography.

Research methods

N-linked glycoproteins were isolated from ESCC and adjacent non-tumor tissue samples using multilectin affinity chromatography. Two-dimensional gel electrophoresis (2-DE)-based and isobaric tags for relative and absolute quantification (iTRAQ) labeling-based mass spectrometry quantitation were performed in parallel to profile the N-linked glycoproteome in ESCC, followed by validation of candidate glycoprotein biomarkers using Western blot.

Research results

A total of 411 differentially expressed N-linked glycoproteins (DEGs) with potential glycosylation sites on proteins were identified by 2-DE-based and iTRAQ labeling-based quantitation, demonstrating the outperformance of iTRAQ labeling-based quantitation over 2-DE. These DEGs exhibited distinctive compositions in functional categories from differentially expressed proteins in ESCC. Western blot analysis validated the up-regulation of total procathepsin D and high-mannose procathepsin D, and the down-regulation of total haptoglobin, high-mannose clusterin, and GlcNAc/sialic acid-containing fraction of 14-3-3ζ in ESCC tissues. The serum levels of glycosylated fractions of clusterin, proline-arginine-rich end leucine-rich repeat protein, and haptoglobin in patients with ESCC were remarkably higher than those in healthy controls.

Research conclusions

This study identified the aberrant N-linked glycoproteome associated with ESCC, which will be a valuable resource for future investigations.

Research perspectives

In-depth characterization of the composition and structure of glycans associated with proteins can shed more lights on biological insights and clinical relevance of the identified DEGs in ESCC.

Abstract

BACKGROUND

The high prevalence and persistence of *Helicobacter pylori* (*H. pylori*) infection, as well as the diversity of pathologies related to it, suggest that the virulence factors used by this microorganism are varied. Moreover, as its proteome contains 340 hypothetical proteins, it is important to investigate them to completely understand the mechanisms of its virulence and survival. We have previously

reported that the hypothetical protein HP0953 is overexpressed during the first hours of adhesion to inert surfaces, under stress conditions, suggesting its role in the environmental survival of this bacterium and perhaps as a virulence factor.

AIM

To investigate the expression and localization of HP0953 during adhesion to an inert surface and against gastric (AGS) cells.

METHODS

Expression analysis was performed for *HP0953* during *H. pylori* adhesion. *HP0953* expression at 0, 3, 12, 24, and 48 h was evaluated and compared using the Kruskal-Wallis equality-of-populations rank test. Recombinant protein was produced and used to obtain polyclonal antibodies for immunolocalization. Immunogold technique was performed on bacterial sections during adherence to inert surfaces and AGS cells, which was analyzed by transmission electron microscopy. HP0953 protein sequence was analyzed to predict the presence of a signal peptide and transmembrane helices, both provided by the ExPASy platform, and using the GLYCOPP platform for glycosylation sites. Different programs, *via*, I-TASSER, RaptorX, and HHalign-Kbest, were used to perform three-dimensional modeling.

RESULTS

HP0953 exhibited its maximum expression at 12 h of infection in gastric epithelium cells. Immunogold technique revealed HP0953 localization in the cytoplasm and accumulation in some peripheral areas of the bacterial body, with greater expression when it is close to AGS cells. Bioinformatics analysis revealed the presence of a signal peptide that interacts with the transmembrane region and then allows the release of the protein to the external environment. The programs also showed a similarity with the Tip-alpha protein of *H. pylori*. Tip-alpha is an exotoxin that penetrates cells and induces tumor necrosis factor alpha production, and HP0953 could have a similar function as posttranslational modification sites were found; modifications in turn require enzymes located in eukaryotic cells. Thus, to be functional, HP0953 may necessarily need to be translocated inside the cell where it can trigger different mechanisms producing cellular damage.

CONCLUSION

The location of HP0953 around infected cells, the probable posttranslational modifications, and its similarity to an exotoxin suggest that this protein is a virulence factor.

Key Words: Hypothetical protein HP0953; Adherence; *Helicobacter pylori*; Glycocalyx; Virulence factor; Persistence

Core Tip: The high prevalence and persistence of *Helicobacter pylori* infection and the diverse pathologies associated with it suggest that the virulence factors of this microorganism are varied. Moreover, its proteome contains 340 hypothetical proteins, so it is crucial to investigate them to elucidate the mechanisms of its virulence and survival. We studied the hypothetical protein HP0953, its location around infected cells, and the probable posttranslational modifications. Its similarity to an exotoxin suggests that HP0953 is a virulence factor.

INTRODUCTION

The estimated prevalence of *Helicobacter pylori* (*H. pylori*) infection is 70% in developing countries and 30%-40% in the United States and other industrialized countries[1]. However, not all people infected with this bacterium have symptoms. *H. pylori* has been associated with gastroduodenal diseases and it is

considered the major risk factor for the development of gastric cancer[2]. *H. pylori* colonizes the gastric mucosa, adhering to the mucous epithelial cells and to the mucous layer that covers the gastric epithelium. Adherence to gastric cells is the first step in establishing an infection and for successful colonization, the bacterium releases various effector proteins/toxins[3-5].

Upon colonization, the pathogenic mechanism of *H. pylori* is mediated by virulence factors such as flagella and the ability to form a biofilm (both *in vitro* and *in vivo*)[6]. Biofilm formation enhances the ability of microorganisms to survive in a hostile environment, which would cause and exacerbate infections, rather than extend them, resulting in chronicity[7]. The glycocalyx participates in adhesion to inert surfaces, allowing biofilm formation but also participates in cell attachment; the major components of the glycocalyx are glycans and may contain digestive proteins or secreted virulence factors[8,9]. *H. pylori* secretes various virulence factors, including urease, cag pathogenicity island proteins, hemagglutinin, Lewis antigens (Le^x and Le^y), BabA CagA, and VacA[10-12]. All these virulence factors have been extensively investigated elsewhere.

Furthermore, *H. pylori* contains hypothetical proteins, some of which are secreted particularly in the context of interactions with the host. The bacterium uses a set of secreted and translocated proteins to adapt itself to the mucosal environment[13]. *H. pylori* possesses a relatively small genome of < 1.6 Mb [14,15] compared with other gram-negative prokaryotes, such as *Escherichia coli*, whose genome is > 4.5 Mb[16]. Despite its small size, an ineligible fraction of *H. pylori* proteins, possibly 30%-40%, are annotated as "hypothetical proteins". Using bioinformatics tools, Naqvi *et al*[17] and Zanotti and Cendron[18] respectively analyzed 340 hypothetical proteins of *H. pylori* 26695. The function of some of these proteins can be hypothesized based on a weak homology with proteins of other bacteria, whereas most proteins do not exhibit similarities with others, and their function cannot be predicted[17,18].

HP0953 is a hypothetical and uncharacterized protein of *H. pylori* secretome; it lacks conserved domains but, interestingly, is present in all *H. pylori* strains whose genomes have been sequenced, as well as in *H. acinonychis* that colonizes the gastric mucosa of large felines. The closely related *H. hepaticus* and *Campylobacter jejuni* lack HP0953 homologs, suggesting that HP0953 is unique to the gastric *Helicobacter* species[11]. Moreover, we previously observed that this protein is overexpressed during adhesion to inert surfaces under stress conditions. Most of the possible effects of secreted proteins on the host have yet to be discovered. In addition, secreted factors represent eligible proteins for identifying promising targets for the development of new antimicrobial drugs[17,18].

In recent years, there has been an increasing importance on *H. pylori*; on the one hand when it is present, it is associated with gastric disease, and on the other hand, it is associated with gastroduodenal reflux, food allergy, and asthma when it is absent[19]. This dual role in the human microbiota emphasizes the need for further characterization of the hypothetical proteins already described. In this study, the location of the protein is determined for the first time, inside and outside the bacterium, and we predict some biochemical characteristics, through *in silico* analysis that contribute toward understanding the importance of this hypothetical protein to the microorganism in the establishment of infection, its role in such infection, or colonization of the host.

MATERIALS AND METHODS

In silico analysis of HP0953 protein

We obtained the amino acid sequence of HP0953 (accession number NP_207745) from the National Center for Biotechnology Information database[20]. Then, we used the Pfam database to analyze the HP0953 sequence and search for conserved domains or homologous regions present in other proteins [21].

Signal peptide prediction

The amino acid sequence of HP0953 was analyzed using the SignalP-4.1 tool provided by the ExPASy platform to predict the presence of a signal peptide[22].

Prediction of transmembrane helices and glycosylation sites

The amino acid sequence previously obtained was analyzed to predict transmembrane helices using the TM pred tool provided by the ExPASy platform[23,24]. The glycosylation sites were investigated using the GLYCOPP platform[25].

Three-dimensional modeling of HP0953 protein

To explore the remote homologs that could be used as a template for modeling, we used the HHpred tool that uses the HMM comparison[26]. Different programs such as I-TASSER[27], RaptorX[28], and HHalign-Kbest[29] were used to perform three-dimensional (3D) modeling.

Strain, cell culture, and extraction of genomic DNA from H. pylori

H. pylori strain 26695 was cultured on Casman agar (Dibico; Mexico) supplemented with 5% sheep

erythrocytes and incubated in an atmosphere of 50 mL/L CO_2 and 37 °C for 48 h. The culture was harvested for infected human against gastric (AGS) cell-line assay and genomic DNA extraction. Genomic DNA extraction was performed according to the protocol established for the Wizard kit (Promega; United States) by its manufacturer.

Amplification and purification of HP0953

HP0953 was amplified by polymerase chain reaction (PCR) using *H. pylori* genomic DNA as the template. To amplify the complete gene, 50 µL of reaction mixture was prepared as follows: 1.25 U polymerase GoTaq®, 0.2 mmol/L dATP, 0.2 mmol/L dGTP, 0.2 mmol/L dCTP, 0.2 mmol/L dTTP, 1.5 mmol/L $MgCl_2$ (Promega), HP0953F oligonucleotide (25 pmol) (5'-GGGGGATCCATG-GTTTTAATCGCTCTTTTAGGGGTG-3'), HP0953R oligonucleotide (25 pmol) (5'-GGGGTCGACCCT-TAACGCACAAACGCTACC-3'), and *H. pylori* 26695 DNA (250 ng). For amplification of the gene without the signal peptide, the same PCR was performed substituting the oligonucleotide HP0953F by HP095WSPF (5'-GGGGGATCCGTCTCTGATTTAAAGGGCATG-3'). The amplification cycle consisted of 94 °C for 1 min, followed by 30 cycles at 94 °C for 30 s, 68.4 °C for 30 s, 72 °C for 1 min, and a final step at 72 °C for 7 min. Both PCR products (555 and 474 bp) were purified using the protocol established by Promega for using the Wizard® SV gel and the PCR Clean-Up System (Promega).

Cloning of the complete and without-signal peptide hp0953

Complete *HP0953* and its version without the signal peptide were inserted into the vector pJET1.2 (Thermo Scientific; Lithuania) according to the manufacturer's instructions to obtain the recombinant pJET-HP0953 and pJET-HP0953WSP plasmids, respectively. Chemically competent DH5α cells of *Escherichia coli* (*E. coli*) were transformed with each plasmid by thermal shock[30,31]. The recombinant colonies were selected in LB agar (Sigma-Aldrich; MO) containing 100 µg/mL ampicillin. The plasmids were extracted using the illustra™ plasmidPrep Mini Spin Kit (GE Healthcare; United Kingdom).

The pJET-HP0953 and pJET-HP0953WSP plasmids were digested with the fast restriction enzymes BamHI and Sal I according to the manufacturer's instructions (Thermo Scientific) to free both versions of *HP0953*. Restriction products were purified using the protocol established by Promega for the Wizard® SV gel and the PCR Clean-Up System. DNA fragments were ligated into the expression vectors pET28a(+) (Novagen, United States) for the complete *HP0953* and pGEX-6p-2 (GE Healthcare) for the version without the signal peptide. The vectors were digested with the same enzymes and treated with alkaline phosphatase (Thermo Scientific). The Rapid DNA Ligation Kit (Thermo Scientific) was used to obtain the recombinant pET-HP0953 and pGEX-HP0953WSP plasmids. Chemically competent DH5α cells of *E. coli* were transformed with each plasmid by thermal shock. The recombinant colonies were selected in LB agar containing 50 µg/mL kanamycin for pET-HP0953 or 100 µg/mL ampicillin for pGEX-HP0953WSP. The plasmids were extracted using the illustra™ plasmidPrep Mini Spin Kit (GE Healthcare) and analyzed by PCR. DNA inserts in the recombinant plasmids were characterized by sequencing; for this purpose, PCRs were performed as described earlier using the following primers: T7F (5'-TAATACGACTCACTATAGGG-3') and T7R (5'-GCTAGTTATTGCTCAGCG-3') for pET-HP0953 and HP095WSPF (5'-GGGGGATCCGTCTCTGATTTAAAGGGCATG-3') and HP0953R (5'-GGGGTCGACCCTTAACGCACAAACGCTACC-3') for pGEX-HP0953WSP. The annealing temperature was 68.4 °C for pET-HP0953 and 60 °C for pGEX-HP0953WSP. The PCR products were purified as described earlier and sequenced by Synthesis and Sequencing Unit, Institute of Biotechnology, Universidad Nacional Autónoma de México. Chemically competent BL21 pLysS cells of *E. coli* were transformed with each recombinant plasmid and the empty plasmids by thermal shock[31]. The recombinant colonies were selected in LB agar containing the corresponding antibiotic.

Expression and purification of HP0953 protein

The HP0953 protein was expressed according to the manufacturer's instructions for pET28a(+) and pGEX-6p-2 vectors using 1 mmol/L IPTG (Sigma-Aldrich) and incubating the *E. coli* pET28a(+)/pET-HP0953-transformed cells for 16 h at 30 °C to obtain the recombinant protein His-HP0953 and the *E. coli* pGEX-6p-2/pGEX-HP0953WSP-transformed cells for 3 h at 37 °C to obtain the recombinant protein GST-HP0953WSP. The inclusion bodies were extracted as described in the inclusion body preparation method without solubilizing the inclusion bodies in a denaturing agent[32]. The cell pellet was resuspended in 1 mL of 4 × sample buffer. Aliquots were collected throughout the process and analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and western blot assays. The inclusion bodies were electrophoresed on SDS-PAGE, and the recombinant protein band was purified by electroelution. The glutathione-S-transferase (GST)-HP0953WSP recombinant protein was used to produce polyclonal antibodies, as described later, and the His-HP0953 protein was used to purify antibodies.

Production of polyclonal anti-GST-HP0953WSP

Anti-GST-HP0953WSP antibodies were obtained by immunization of a New Zealand rabbit (2 mo age) according to the Howard and Bethell method[33] (approved by the Bioethics Committee of the Hospital Infantil de México Federico Gómez).

Purification of polyclonal anti-HP0953

Purification of polyclonal antibody was performed by immunoadsorption. The His-HP0953 protein was subjected to SDS-PAGE on preparative gels. The bands were transferred onto a polyvinylidene fluoride (PVDF) membrane (Millipore; United States), which was blocked with 0.5% bovine serum albumin (BSA) and washed with phosphate buffer solution (PBS)-Tween. Serum was diluted 1:100 in PBS-Tween, incubated with the membrane for 2 h under stirring at room temperature, and washed with PBS-Tween; then, the membrane was incubated with 0.02 M glycine-HCl (pH 2.2) for 10 min at room temperature. Finally, 1 M Tris base (pH 9.1) was added. The antibody was recovered and stored at -20 °C. Nonpurified antisera and purified antibodies were tested against a total extract of *H. pylori*, and the two purified recombinant proteins were evaluated by western blotting using the same PVDF membrane, which was stripped between each test[34].

Construction of plasmid pBlue-5CM3 for site-directed mutagenesis of the HP0953 gene in H. pylori

The chloramphenicol resistance gene was obtained from the pLysS plasmid of the *E. coli* BL21 (DE3) pLysS strain by PCR, for which 50 µL of reaction mix was prepared, consisting of 1 × HF Fusion buffer (Thermo Scientific); 0.2 mmol/L each of dATP, dGTP, dCTP, and dTTP (Promega); 6 pmol each of primer CMF (5′-GGG AGATCTTTACGCCCCGCCCTG-3′) and CMR (5′-GGGCATATGATG-GAGAAAAAAATCACTGG-3′); plasmid pLysS (250 ng); and Phusion DNA Polymerase (1 U) (Thermo Scientific). The CMF and CMR primers contain restriction sites for *Bgl*II and *Nde*I, respectively. The amplification program consisted of initial denaturation at 98 °C for 30 s; 35 cycles of denaturation at 98 °C for 10 s, primer annealing at 65 °C for 30 s, and extension at 72 °C for 1 min; and a final extension at 72 °C for 7 min.

The 5′ and 3′ fragments of the *HP0953* gene were obtained from the plasmid pJET-HP0953, constructed above by PCR. To amplify the 5′ fragment, 50 µL of the reaction mixture was prepared, consisting of GoTaq DNA polymerase (Promega) (1.25 U); 0.2 mmol/L each of dATP, dGTP, dCTP, and dTTP; 1.5 mmol/L $MgCl_2$ (Promega); primer HP0953F (25 pmol) (5′-GGGGGATCCATG-GTTTTAATCGCTCTTTTAGGGGTG-3′); primer HP0953R (5′-GGGAGATCTCATGGAATTGCTCCAT-GAAGCG-3′); and plasmid DNA from pJET-HP0953 (250 ng). The amplification program consisted of initial denaturation at 94 °C for 1 min; 35 cycles of denaturation at 94 °C for 30 s, primer annealing at 68.4 °C for 30 s, and extension at 72 °C for 30 s; and a final extension at 72 °C for 7 min. To amplify the 3′ fragment, PCR was performed under the same conditions but using the primers HP0953F (5′-GGGCATATGAGTCCGAGCAGACGACTACG-3′) and HP0953R (5′-GGGGTCGACCTACCT-TAACGCACAAACGCTACC-3′). Amplicons of 304 and 248 bp were obtained, respectively.

We subjected 5 µL of each amplification product to 1.5% agarose gel electrophoresis at 85 volts for 75 min. Then, we stained the gel with ethidium bromide (Sigma-Aldrich) and observed the bands under ultraviolet light. Upon confirmation of the amplified product, the remainder was purified using a Wizard SV Gel and PCR Clean-up System, as per the manufacturer's protocol. Each fragment was inserted into a pJET1.2 vector. The ligation reaction of each fragment in the pJET1.2 vector consisted of 1 × reaction buffer, 0.15 pmol purified PCR product (5′ fragment, 3′ fragment, or chloramphenicol resistance gene; 0.15 pmol), pJET1.2/Blunt Cloning Vector (0.05 pmol), and T4 DNA ligase (5 U). The reaction mixture was incubated at 22 °C for 20 min.

After ligation, we used heat shock treatment to transform 50 µL of competent *E. coli* DH5α cells with each plasmid[31]. Then, they were centrifuged at 5000 × g for 1 min, the supernatant was decanted, and the pellet was resuspended in the residual medium. Subsequently, the bacterial suspension was seeded on LB agar plates containing ampicillin (100 µg/mL; Sigma-Aldrich) and incubated at 37 °C for 18-24 h to select the recombinant clones. Following incubation, we selected five colonies from the plate and resuspended them in 2 mL of LB broth (Sigma-Aldrich) containing ampicillin (100 µg/mL), and the plasmid was extracted using the alkaline lysis method[35]. We quantified the plasmid DNA using an Epoch microplate spectrophotometer (Biotek Instruments, Inc.; United States) and stored it at -20 °C.

We performed three PCR assays to verify the sequence of the cloned fragments. Each PCR reaction was performed in a final volume of 20 µL, consisting of 1 × HF Fusion buffer (Thermo Scientific); 0.2 mmol/L each of dATP, dGTP, dCTP, and dTTP (Thermo Scientific); primer pJET1.2F (0.2 µM) (5′-CGACTCACTATAGGGAGAGCGGC-3′) (Thermo Scientific); primer pJET1.2R (0.2 µM) (5′-AAGAACATCGATTTTCCATGGCAG-3′) (Thermo Scientific); plasmid DNA (100 ng/µL) (pJET-CM, pJET-5′ or pJET-3′); and Phusion DNA polymerase (Thermo Scientific) (0.4 U). The amplification program consisted of initial denaturation at 98 °C for 30 s; 35 cycles of 98 °C for 10 s, 68 °C for 30 s, and 72 °C for 30 s; and a final extension at 72 °C for 7 min. The PCR products were sequenced by Macrogen (Seoul, Korea).

The 5′ fragments, 3′ fragments, and the chloramphenicol resistance gene were obtained from the plasmids previously constructed by enzymatic digestion. *Bam*HI and *Bgl*II were used for the 5′ fragment, *Nde*I and *Sal*I for the 3′ fragment, and *Bgl*II and *Nde*I for the chloramphenicol resistance gene, according to the above-described digestion protocols. The fragments were inserted into the pBluescript II KS+ vector (Agilent Technologies, Inc.; United States), which allows for the synthesis of ssDNA and has an ampicillin resistance gene to facilitate selection following the above-described protocols.

E. coli XL1-blue MRF' cells were transformed with the constructed vector (pBlue-5CM3) using heat shock treatment and selected following culture on LB agar plates (Sigma-Aldrich) with 100 μg/mL of ampicillin[31]. The plasmid was extracted using alkaline lysis[35], and fragment insertion was verified by automated sequencing. *H. pylori* was transformed with the plasmid using electroporation[36]. The mutant *H. pylori* strain was cultured on Casman agar supplemented with 5% sheep erythrocytes and incubated in an atmosphere of 50 mL/L CO_2 at 37 °C for 48 h.

Identification of HP0953 in H. pylori

The purified antibody was used for identifying the protein HP0953 in *H. pylori* 26695 by western blotting. A total extract obtained from *H. pylori* adhesion test (see below) was used, and soluble and insoluble fractions were separated according to the inclusion body preparation method[32]. These fractions were subjected to SDS-PAGE (50 mg of protein) and transferred onto a PVDF membrane, where western blotting was performed using the purified antibody diluted 1:2 in PBS-Tween and incubated overnight under stirring at 4 °C and the secondary antibody diluted 1:10000 [anti-rabbit immunoglobulin G (IgG) horseradish peroxidase (HRP)-conjugated antibody] (Santa Cruz Biotechnology; United States)[34]. Washing was done with TBST (2 mmol/L Tris, 15 mmol/L NaCl, 0.1% Tween 20, pH 7.6). Finally, the membrane was visualized using Immobilon Western Chemiluminescent HRP substrate (Millipore).

Adhesion test of H. pylori

A suspension (6×10^8) of *H. pylori* 26695 culture in Brucella broth (Dibico) supplemented with 1% yeast extract was prepared. Next, 50 mL of the suspension was placed in cell culture bottles and incubated at 37 °C in an atmosphere of 50 mL/L CO_2 for 0, 1, 3, 12, and 24 h; these time points are the first hours of biofilm formation where adherence occurs. After the incubation period, the supernatant was removed, and the bottle walls were scraped to obtain adherent cells, which were resuspended in 1 mL of sterile 1 × PBS.

Thawing and seeding of AGS cells

First, 1 mL of AGS cell suspension was placed in a 15 mL conical tube. Subsequently, 2 mL of DMEM-F12 (Gibco, Life Technologies; United States) medium was added for washing by centrifugation at 1500 rpm for 5 min. A second washing step was performed, and the cells were resuspended again in DMEM-F12 medium. Next, 1 mL of the cell suspension was taken to seed into cell culture bottles. The bottles were incubated in a CO_2 chamber for 24 h at 37 °C.

AGS cell infection assay by H. pylori

The gene expression assay during biofilm formation was performed in duplicate in ten cell culture bottles of 225 mL each. A suspension of *H. pylori* (strain 26695, previously cultured for 24 h in a plate with Casman medium) was prepared in DMEM-F12 culture medium. The cells were washed by centrifugation at 3000 rpm for 15 min. After washing, the cell pellet was used to prepare a bacterial suspension in 300 mL of DMEM-F12 culture medium inside a flask until the growth level reached similar to that in tube number 2 on the McFarland scale. To each bottle, 30 mL of the bacterial suspension similar to McFarland tube 2 suspension was added, and then 20 mL of DMEM-F12 medium without the bacteria was added to complete 50 mL. One bottle was not infected with the bacterial strain and was used as the control for the transmission electron microscopy (TEM) assay. The bottles were incubated at 3, 12, 24, and 48 h post-infection. Time 0 was taken as the culture of the bacterial strain with no contact with AGS cells for the expression assay. After each time point of incubation, the supernatant was discarded, and 1 mL of sterile 1 × PBS was added for washing the cells. Subsequently, the wall of the bottle was scraped with a gendarme to detach the cells and remove the adhered biofilm. Each sample was processed for RNA extraction assay. An aliquot was taken for use in TEM, and the remainder was centrifuged at 7000 rpm for 15 min. The test was conducted in triplicate.

Immunogold technique for TEM

First, 500 μL of the samples obtained from the adhesion test was centrifuged at 2500 rpm for 10 min and fixed with 4% paraformaldehyde (MP Biomedicals; United States) in 1 × PBS (pH 7.4) for 1 h at 4 °C. Then, three washes were performed with 1 × PBS (pH 7.4), and the sample was dehydrated by adding 50% ethanol (Merck; IRL) for 10 min, followed by two washes with 70% ethanol for 15 min at room temperature. The inclusion was done using the LR-White method as described by Vázquez and Echeverría[37], and ultrathin sections of 60-90 nm were obtained. The sections were placed on nickel grids, blocked with 5% BSA for 20 min, and incubated with the purified polyclonal antibody overnight at 4 °C. The sample was then washed with TBST and incubated with the secondary antibody (goat anti-rabbit IgG coupled to 10-nm colloidal gold particles, 1:5, Sigma-Aldrich) diluted in deionized water for 1 h at room temperature. The grids were rinsed with TBST. Finally, they were observed under a transmission electron microscope (JEM 1010 JEOL Ltd. Japan) equipped with a TEM Imaging Systems AMT (Woburn; United States).

Table 1 Prediction of glycosylation sites

Position		Residue score	Prediction
Probable N-linked glycosylation sites			
68	NNK	-0.20374993	Non-glycosylated
69	NKY	-0.11718906	Non-glycosylated
80	NAK	-0.46398761	Non-glycosylated
113	NIS	0.031759513	Potentially glycosylated
120	NYL	-0.12578944	Non-glycosylated
130	NTY	-0.42088241	Non-glycosylated
134	NLK	-0.028092183	Non-glycosylated
164	NLN	0.45527702	Potentially glycosylated
166	NDN	-0.14904342	Non-glycosylated
168	NEI	0.2906731	Potentially glycosylated
Probable O-linked glycosylation sites			
15	S	0.3493683	Potentially glycosylated
16	S	-0.20711247	Non-glycosylated
18	S	-0.033164353	Non-glycosylated
20	S	-0.066886402	Non-glycosylated
23	S	0.33910492	Potentially glycosylated
33	S	-0.58418843	Non-glycosylated
40	S	-0.76207501	Non-glycosylated
43	S	0.16899016	Potentially glycosylated
78	T	-0.75721234	Non-glycosylated
84	S	-0.20144186	Non-glycosylated
107	S	-0.2527357	Non-glycosylated

There are three probable N-linked and six probable O-linked glycosylation sites.

Quantitative SYBR-Green real time-PCR analysis for hp0953 expression during H. pylori infection of AGS cells

Expression analysis was performed by real time-PCR (RT-qPCR). The glutamate racemase (*glmM)* gene was used as an internal control for the bacterial cell, and the *β-globin* gene was used as an internal control for human AGS cells. *HP0953* expression was evaluated at different time points (0, 3, 12, 24, and 48 h). Time 0 was taken as the culture of the bacterial strain with no contact with AGS cells.

Gene-specific primers were developed for *HP0953* and *glmM* using the Primer3 software, v.0.4.0[38, 39]. The sequences of all the primers were as follows: *HP0953* (5′-CATATGCCGAGCAGACGACTACG-3′; 5′-GTCGACCTACCTTAACGCACAAACGCTACC-3′), *glmM* (5′-ACCGACGCTCTCACCCACTT-3′; 5′-AGCGCGAGCCACAACCCTTT-3′). Total RNA was isolated from the AGS cell cultures with and without *H. pylori* at a multiplicity of infection of 1:100. RNA was extracted using TRIzol® Reagent (Ambion RNA, Life Technologies; United States), followed by phenol:chloroform extraction. The quality and amount of the resulting RNA were evaluated using a Nano-Drop spectrophotometer (The Epoch™ Multi-Volume Spectrophotometer System; United States) at 260 and 280 nm, respectively.

Reverse transcription reaction and SYBR-Green PCR were performed as described below. To initiate the first-strand cDNA synthesis, 1 mg of total RNA was treated with 500 μL of DNAse I (10 U/mL; Invitrogen; United States). Then, it was incubated for 30 min at 37 °C and 5 min at 75 °C with 4 μL of 5 × RT buffer, 2 μL of 25 mmol/L $MgCl_2$, 2 μL of 10 mmol/L dNTP mix, 2 μL of 50 mmol/L random hexamer primers, 1 μL of RNAse inhibitor (20 U/μL), and sufficient H_2O for a final volume of 20 μL. The mixture was then incubated for 10 min at 25 °C and 30 min at 48 °C with 2 μL of MultiScribe reverse transcriptase (50 U/mL; Applied Biosystems; United States). The reaction was terminated by heating the sample at 95 °C for 10 min. Aliquots of 200 ng of cDNA were used in the SYBR-Green PCR analysis according to the manufacturer's protocol. RT-PCR amplification was performed in triplicate under the

following conditions: 2 min at 50 °C (for UNG activation) and 10 min at 95 °C (for polymerase activation), followed by 40 cycles of denaturation and alignment/extension at 95 °C for 15 s and 60 °C for 1 min, respectively, using the Stratagene Mx3005p qPCR System and MxPro-Mx3005p software (Santa Clara; United States). Relative quantification of HP0953 RNA expression was performed using the comparative CT method. The Δ Ct (difference in CT values) between HP0953 and the *glmM* internal control and the Δ Δ Ct were calculated to normalize the differences in cDNA concentrations for each reaction. The RNA expression level was calculated using the equation $2^{-(\Delta\Delta Ct)}$[40]. The Kruskal-Wallis equality-of-populations rank test was used to compare the expression of the gene at all study time points. Differences were considered to be significant when the *P* value was < 0.05.

RESULTS

In silico analysis of HP0953 protein features

In silico analyses allow us to foresee probable protein maturation. The analysis conducted using the SignalP 4.1 tool revealed that HP0953 protein loses a signal peptide after excision between amino acids 21 and 22 which could lead to extracellular release (Figure 1). This region is also believed to present a transmembrane helix (Figure 2). The protein modifications provided us an insight into their probable function. Tables 1 and 2 show the predicted modification sites for HP0953. There are three predicted N-linked glycosylation sites in amino acid positions 113, 164, and 168 and six predicted O-linked glycosylation sites in positions 15, 23, 43, 111, 115, and 183. Moreover, there are four predicted myristoylation sites in positions 12-17, 29-34, 73-78, and 182-187 and one predicted prenylation site in the position 185-188.

To predict the structural model, we used different programs such as I-TASSER, RaptorX, and HHalign-Kbest, the latter being the one that generated a better quality model (Figures 3 and 4). The HHpred program disclosed a similarity with the Tip-alpha protein of *H. pylori*; thus, it was used as a template for modeling. Additionally, no conserved domains were found or matches with other proteins.

Site-directed mutagenesis of HP0953 gene

Plasmid pBlue-5CM3 was constructed for *HP0953* site-directed mutagenesis (Supplementary Figure 1). Sequencing the D*hp0953::Cm* Blue-5CM3 construction multiple cloning site corresponded to inserted *HP0953* and *Cm* cassette. However, we were unable to propagate the *H. pylori*-transformed strain.

HP0953 is detected in the insoluble fraction of H. pylori protein extract

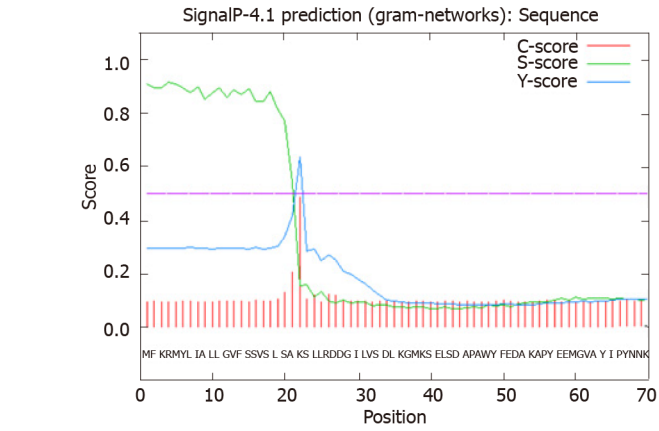
For *H. pylori* HP0953 protein identification, insoluble and soluble fractions were obtained and resolved by SDS-PAGE assay. HP0953 protein was not detected in the soluble fraction, and its total concentration was very low in the insoluble fraction (data not shown). Interestingly, HP0953 was expressed constitutively at all the tested time points (Figure 5).

HP0953 is located in the cytoplasm and the peripheral zone of H. pylori

Protein location is indicative of its function. HP0953 was identified in the insoluble fraction of *H. pylori* lysates, which probably implies that the function of HP0953 is elicited in the vicinity of the outer membrane. To examine this hypothesis, we performed the immunogold technique on bacterial sections that were analyzed by TEM. The micrographs showed that HP0953 protein is located in the cytoplasm and accumulated in some peripheral areas of the bacterial body (Figure 6A), as well as in bacteria-bacteria contact areas (Figures 6B, 6C and 6D). Furthermore, there was a large accumulation of the protein in the bacterial debris (Figure 6E). Interestingly, the presence of this protein was also observed in the area of the glycocalyx that covers *H. pylori* (Figure 7), and accumulated where said coating spreads, producing a type of net, perhaps indicating the formation of a biofilm. Interestingly, a large amount of HP0953 protein was secreted during the infection of gastric cells because it was found in the *H. pylori*-AGS cell contact area (Figure 8).

Higher expression of HP0953 is required in the early stages of H. pylori-AGS cell interaction

RT-qPCR was performed to elucidate the behavior of *HP0953* during the contact of *H. pylori* with AGS cells. Figure 9 shows a comparison of the expression ratios of the treated and untreated cultures. *HP0953* expression was observed at all the tested time points; however, higher expression values were observed after 12 h of infection. *glmM* was the prokaryotic constitutive gene that was used as an internal control (Figure 9).



DISCUSSION

The high prevalence of *H. pylori* infection and its significant persistence in the gastrointestinal tract in the population with limited economic resources, as well as the diversity of related pathologies, the

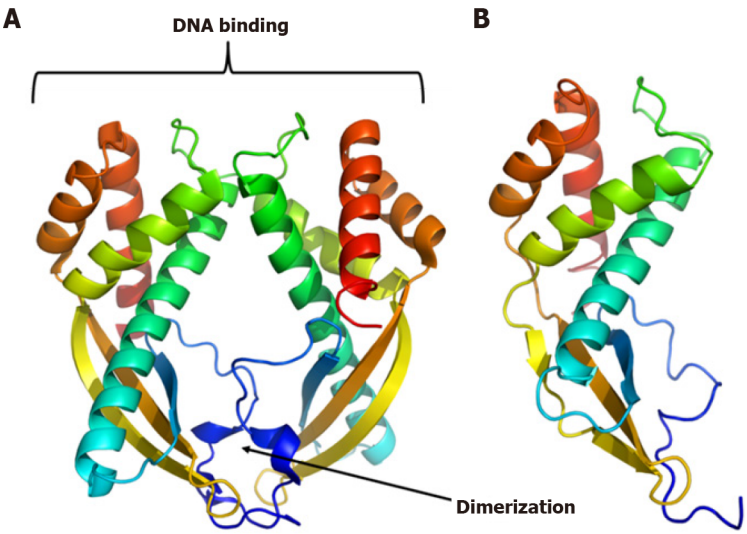

Figure 1 Prediction of a signal peptide for HP0953 protein. The green line that represents the S-score indicates a high probability that the first 20 amino acids conform a signal peptide that can be removed by a cut between amino acids 20 and 21, as marked by the tallest red line indicating the C-score.

environment, and the genetics of the host, suggest that the pathogenicity mechanisms used by this microorganism are numerous. The different bacterial strains express variations in their virulence factors, including those associated with the colonization process (*e.g.*, urease, flagella, a chemotaxis system, and adhesins), immune response evaders (*e.g.*, lipopolysaccharide and flagella; CagA and the type IV secretion system, VacA; gamma-glutamyl transpeptidase, and catalase superoxide dismutase), and disease inducers (*e.g.*, VacA, BabA, IceA, HtrA, CagA, and the type IV secretion system, DupA, and OipA)[41]. Furthermore, the *H. pylori* proteome consists of 340 proteins that are described as hypothetical, implying that their structure or function is unknown, thus indicating that some proteins may be related to pathogenicity mechanisms or are important to adapt to the surrounding environment. The HP0953 protein exhibited its maximum expression at the first 12 h of infection in a culture of gastric epithelium cells; this finding along with its location near the infected cells and the predicted prenylation and myristoylation sites suggest that it is an important protein during the bacterium's colonization phase of the gastric epithelium.

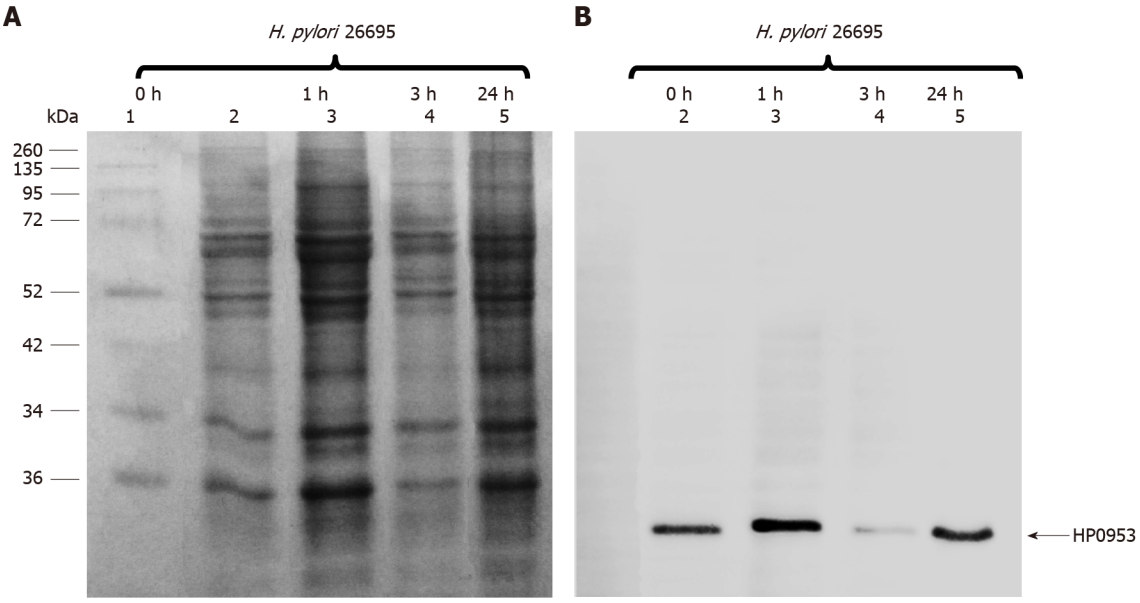
Figure 3 Three-dimensional models of proteins. A: Tip-alpha protein from *Helicobacter pylori* (*H. pylori*); B: HP0953 protein from *H. pylori*. Tip-alpha acquires a dimer arrangement that could also be present in the HP0953 protein due to its structural similarity in the position of the alpha helices and beta sheets.



Although various studies, such as those conducted by Naqvi *et al*[17] in 2016 and Park *et al*[42] in 2012, have performed *in silico* analyses to determine the probable structures and functions of the hypothetical proteins of *H. pylori*, none of them evaluated the probable function of HP0953[17,42]. Furthermore, the bioinformatics analysis performed in this study highlighted the presence of a signal peptide that may anchor at the transmembrane region and then allow the release of the protein to the external environment after its excision. The analyses also revealed some probable glycosylation sites, which suggests that HP0953 is a protein from the glycocalyx. The glycocalyx is defined as any glycoprotein-associated polysaccharide that contains bacterial surface structures and is distant from the outer membrane or cell wall surface[43]. Bacterial glycocalyx generally has protection functions that allow bacterial survival and persistence in the natural environment and cell attachment[44].

Different modification patterns are found within the HP0953 sequence, such as the myristoylation pattern. This modification is essential for the removal of membrane proteins[45]; the existence of these putative sites provides an idea about its pathogenicity. Importantly, these bacteria lack the enzyme N-myristoyl transferase (NMT) required for producing this modification; hence, the proteins that are myristoylated are processed by the NMT of their eukaryotic hosts[46]. NMT is a suitable therapeutic target in opportunistic infections in humans; in fact, it has been associated with carcinogenesis, in

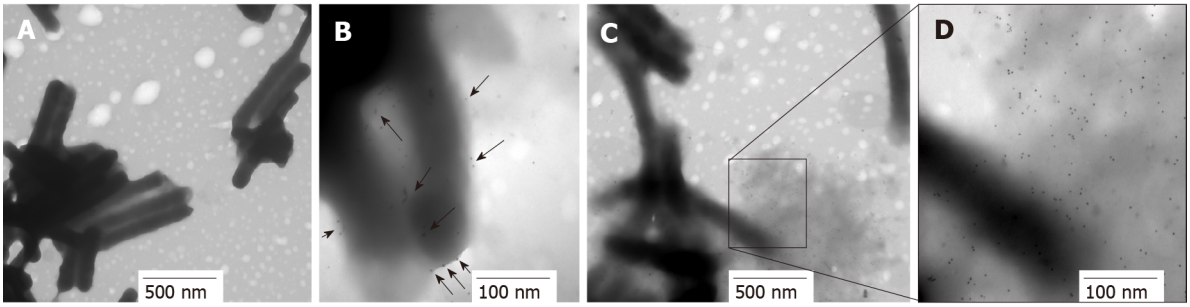
The arrow indicates the presence of the native HP0953 protein. *H. pylori*: *Helicobacter pylori*.



particular colon cancer[47]. Myristoylation has been suggested to occur as part of the secretory machinery[48,49]. Hypothetical patterns of prenylation were also detected, which is a class of modification involving the addition of isoprenoids or geranylgeranyl, and it is involved in membrane interactions due to the hydrophobicity of these lipids[50]. This modification is often a step to target the affected proteins to specific membranes[51]. As this modification was predicted in HP0953 by the ProtComB tool, it could be relevant for its function.

Extracellular proteins can play a vital role in bacterial pathogenesis[11], which correlates with our findings of the similarity between the HP0953 protein and the Tip-alpha protein, which is described as the only virulence factor secreted by all *H. pylori* strains[52]. Moreover, its overexpression has been related to the development of gastric cancer. Tip-alpha is an exotoxin that penetrates cells and induces the production of tumor necrosis factor alpha[53]. HP053 protein could have a similar function because probable posttranslational modification sites related to bacterial pathogenesis were also found. It has been reported that some bacteria secrete effectors through the type III or type IV secretion systems, mimicking the functions of eukaryotic proteins to evade the defense systems. Subsequently, they

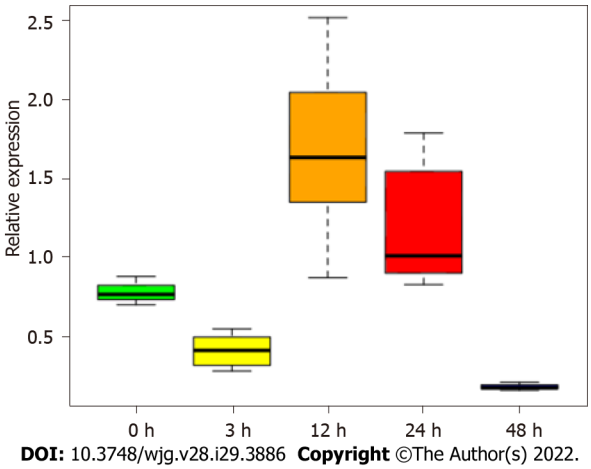
undergo a posttranslational modification mediated by the same host enzymes to become biologically active[54], stimulating or inhibiting the immune response, interfering signaling pathways, affecting T-cell activation, or whatever their function may be[55]. Among these posttranslational modifications are myristoylation and prenylation[56,57], which were also detected in the *in silico* analysis conducted in this study. These modifications added lipid residues that allow the protein to anchor to the cell membrane to exert some unknown function.



HP0953 lacks homologous proteins outside *H. pylori*, and this absence limits comparisons and the elucidation of its potential role. X-ray crystallography analysis can be performed to determine its 3D structure, which could then be used in comparisons with other proteins in the database. However, it was observed that HP0953 is an insoluble protein, which makes it difficult to purify in its native form.

The persistence of *H. pylori* in an environment where there are peristaltic movements and cell shedding is mediated by a variety of adhesins present on the bacterial surface[10,58], and the adhesion of *H. pylori* can be achieved by a connection of the plasma membrane through filamentous materials. However, it is known that glycocalyx preferentially adheres to the surfaces of biomaterials and compromised tissues, forming biofilms[55]. Research on biofilm composition has shown that a

Figure 9 Expression of HP0953 increases significantly after 12 h of infection of against gastric cells. The Kruskal-Wallis equality-of-populations rank test was used to compare the expression of the gene at all study time points. $P = 0.0006$.

pericellular matrix, also known as the glycocalyx, develops to preserve and concentrate the lytic enzymes secreted by bacteria, which, in turn, increases their metabolic efficiency[8]. This suggests that the hypothetical protein HP0953 could be involved in lytic processes by being present in the glycocalyx and concentrated in the bacterial debris; however, functionality studies are still required to elucidate the role of this protein in the persistence of *H. pylori* in the human stomach. Smith *et al*[11] suggested that this protein could be involved in the survival of the bacterium in the gastric environment based on their finding that it is also present in *H. acinonychis*, which colonizes the gastric mucosa of felines. Nevertheless, other closely related ε-proteobacteria, such as *H. hepaticus* and *C. jejuni*, lack sequences that are homologous to HP0953, thus suggesting that this protein is unique to the gastric *Helicobacter* species[11], suggesting an important role of HP0953 in *H. pylori* gastric pathogenesis.

In our previous study, we observed the overexpression of HP0953 protein during the first hours of adherence to inert surfaces and AGS cells[59], suggesting its involvement in the survival of *H. pylori* in the environment or in its pathogenic mechanisms. In the present study, we found that initial levels of *HP0953* expression become diminished, perhaps as a result of the adaptation of *H. pylori* to its environment. The levels of HP0953 rise after 3 h, indicating that this protein is required for the interaction of *H. pylori* with AGS cells, and the maximum level of *HP0953* expression occurred 12 h after the infection of AGS cells. Genetic regulation in pathogens allows for fluctuation in the expression of constitutive genes following initial contact with the target cells[60,61]. The immunogold assay demonstrated that HP0953 protein was located in the cytoplasm, accumulated in some peripheral areas of the bacterial body, and exhibited a greater expression when it is close to AGS cells. These data suggest that HP0953 protein is synthesized in the cytoplasm and subsequently exported to the outer membrane, where it is involved in adhesion functions as its agglomeration was detected at the binding sites between the bacterium and in the space between the bacterium and gastric cells. Similarly, the immunogold assay of HP0953 protein in the whole bacterium revealed that the protein was primarily located in the bacterial coat or glycocalyx, which is consistent with the finding reported by Smith *et al*[11], who investigated the proteins secreted by *H. pylori* and found that HP0953 protein was a

component of this set of proteins.

Furthermore, we altered *HP0953* to obtain a mutant strain. Unfortunately, we were unable to propagate the resultant *HP0953* mutant clone, but we are continuing with our efforts to modify the methodology to obtain a mutant strain that can be successfully propagated. Further studies are necessary to determine the structure and function of hypothetical proteins of *H. pylori*, such as HP0953, which may be associated with the disease pathology.

CONCLUSION

HP0953 protein exhibited its maximum expression during the first 12 h of infection in a culture of gastric epithelium cells. This finding indicated its location surrounding the infected cells, and the predicted presence of prenylation and myristoylation sites suggests that HP0953 is a relevant protein during the bacterium's colonization phase of the gastric epithelium. HP0953 was also found to be strikingly similar to an exotoxin, possibly associating it with the development of gastric cancer.

ARTICLE HIGHLIGHTS

Research background

Helicobacter pylori (*H. pylori*) is a bacterium of clinical relevance. Approximately 50% of the worldwide human population is colonized by this bacterium, where up to 3% can develop gastric cancer. Several environmental conditions such as the genetic predisposition of the host, and bacterial virulence factors are directly associated.

Research motivation

H. pylori is a bacterium associated with gastric diseases. This microorganism owns more than 200 hypothetical proteins with functions yet unknown. Some of them could be related to the disease or adaptation to gastric microenvironment. However, in a short-term future, they can be considered as therapeutic targets.

Research objectives

The objective was to characterize the hypothetical protein HP0953, such as structure, location, and expression, to determine if it is a virulence factor employed by *H. pylori* during infection of against gastric (AGS) cells.

Research methods

Several bioinformatic platforms (SignalP, Expasy, GLYCOPP, I-Tasser) were employed to predict some features of the hypothetical protein HP0953, such as peptide-signaling, three-dimensional structure, and possible post-translational modifications. HP0953 was located during *H. pylori* infection to AGS cells by transmission electron microscopy, employing a specific antibody for said protein and immunogold technique. The expression of HP0953 during the infection of AGS cell cultures by the bacterium was evaluated by real-time polymerase chain reaction.

Research results

The hypothetical protein HP0953 was observed in the cytoplasm and embedded in the glycocalyx secreted by the bacterium, as well as in the space between the bacterium and the AGS cell. The overexpression of the protein was observed at 12 h of infection. HP0953 was predicted to possess a signal peptide, which can interact with transmembranal regions for its secretion. Additionally, the HP0953 protein acts as like an exotoxin, which can then undergo post-translational modifications, which might then require the eukaryotic cell to be carried out.

Research conclusions

The hypothetical protein HP0953 is a protein located in the periphery of infected cells. It is overexpressed during infection. The *in silico* analysis revealed prenylation and myristoylation sites. These findings suggest that the protein has a relevant function during the colonization or infection of *H. pylori* into gastric epithelium.

Research perspectives

Propagate a *H. pylori* modified strain, which lacks the HP0953 protein. The study will define its functions and establish a new precedent for the study of the pathogenesis of the disease, and its relevance in the adaptation process in the gastric microenvironment.

Abstract

BACKGROUND

Chronic abdominal pain is the most common cause for gastroenterology consultation and is frequently associated with functional gastrointestinal disorders including irritable bowel syndrome and inflammatory bowel disease. These disorders present similar brain/gut/microbiota trialogue alterations, associated with abnormal intestinal permeability, intestinal dysbiosis and colonic hypersensitivity (CHS). Intestinal dysbiosis can alter colon homeostasis leading to abnormal activation of the innate immunity that promotes CHS, perhaps involving the toll-like receptors (TLRs), which play a central role in innate immunity.

AIM

To understand the mechanisms between early life event paradigm on intestinal permeability, fecal microbiota composition and CHS development in mice with TLRs expression in colonocytes.

METHODS
Maternal separation model (NMS) CHS model, which mimics deleterious events in childhood that can induce a wide range of chronic disorders during adulthood were used. Colonic sensitivity of NMS mice was evaluated by colorectal distension (CRD) coupled with intracolonic pressure variation (IPV) measurement. Fecal microbiota composition was analyzed by 16S rRNA sequencing from weaning to CRD periods. TLR mRNA expression was evaluated in colonocytes. Additionally, the effect of acute intrarectal instillation of the TLR5 agonist flagellin (FliC) on CHS in adult naive wildtype mice was analyzed.

RESULTS
Around 50% of NMS mice exhibited increased intestinal permeability and CHS associated with intestinal dysbiosis, characterized by a significant decrease of species richness, an alteration of the core fecal microbiota and a specific increased relative abundance of flagellated bacteria. Only TLR5 mRNA expression was increased in colonocytes of NMS mice with CHS. Acute intrarectal instillation of FliC induced transient increase of IPV, reflecting transient CHS appearance.

CONCLUSION
Altogether, these data suggest a pathophysiological continuum between intestinal dysbiosis and CHS, with a role for TLR5.

Key Words: Chronic abdominal pain; Colonic hypersensitivity; Toll-like receptors; Intestinal microbiota; Early life events

Core Tip: Neonatal maternal separation (NMS) model mimic deleterious events in childhood, which can induce a wide range of chronic disorders during adulthood. Herein, around 50% of NMS mice exhibited increased intestinal permeability and colonic hypersensitivity (CHS) associated with intestinal dysbiosis. Only toll-like receptor 5 (TLR5) mRNA expression was increased in colonocytes of NMS mice with CHS and acute intrarectal instillation of flagellin transiently increased intracolonic pressure variations, reflecting transient CHS appearance. Together, those findings suggest a pathophysiological continuum between intestinal permeability, intestinal dysbiosis and CHS, with a previously undescribed role for TLR5 in CHS.

INTRODUCTION

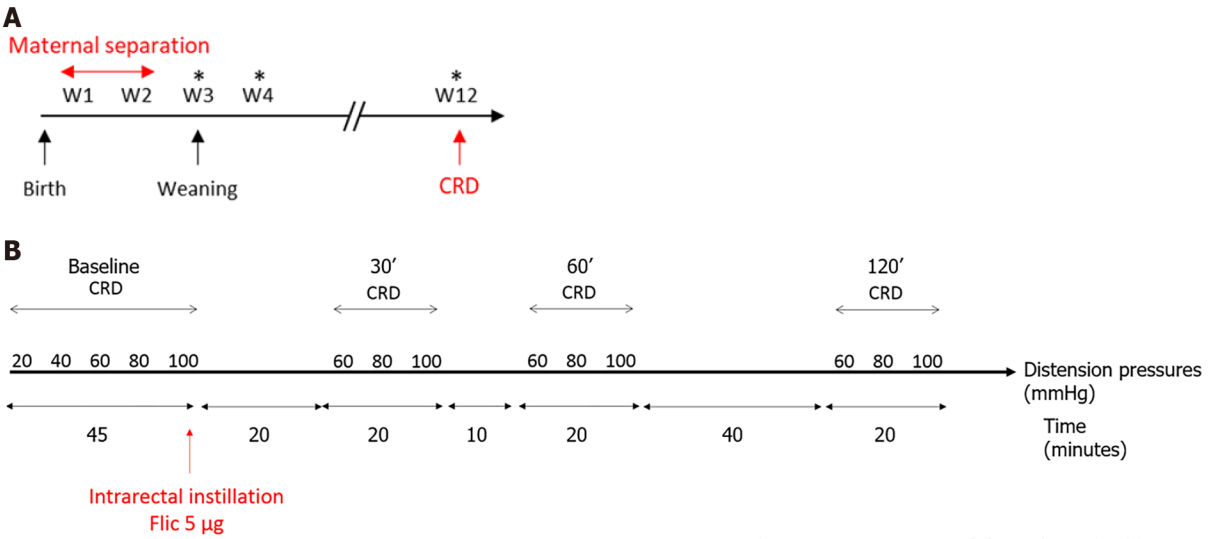
Irritable bowel syndrome (IBS) is one of the major chronic gastrointestinal disorders, strongly related to stress. It is characterized by abdominal pain, changes in bowel habits and increased intestinal permeability without macroscopic organic alterations. Such changes has been hypothesized to trigger impairment of life's quality and the development of comorbidities such as anxiety and depression[1]. A worldwide prevalence of 3%-5% has been reported and today, efficient pharmacological treatments are limited to relieve symptoms[2]. Colonic hypersensitivity (CHS), frequently associated with abdominal pain, has been described as the main cause of medical consultation in IBS patients with a prevalence ranging from 33% to 90%[3]. This symptom is defined by an altered sensation in response to colorectal stimuli and is clinically revealed by enhanced perception of mechanical triggers applied to the bowel. The common hypothesis is that CHS may result from colonic homeostasis changes and/or alterations of the brain-gut connection. In fact, the brain-gut axis has been shown to be impacted by inflammation and immunological factors, psychological factors, dysregulation of the hypothalamic-pituitary-adrenal (HPA) axis, abnormal activation of the vagus nerve and the enteric nervous system and intestinal dysbiosis[4].

Qualitative and/or quantitative alterations of the intestinal microbiota has been characterized in most of the functional gastrointestinal disorders including IBS[5]. Despite the numerous studies carried out, data on specific bacterial groups altered in IBS patients are still inconclusive. However, *Enterobacteriaceae*

family, *Lactobacillaceae* family, and *Bacteroides* genus seem to be increased in patients with IBS compared with controls, whereas uncultured *Clostridiales* I, *Faecalibacterium* and *Bifidobacterium* genus were decreased in IBS patients[6]. Furthermore, it has been described that some IBS patients with chronic abdominal pain present specific intestinal microbiota dysbiosis, allowing considerations of the gut microbiota as a potential therapeutic target[7].

In healthy conditions, the interaction between gut microbiota and pattern recognition receptors (PRRs), especially local toll-like receptors (TLRs), allow maintenance of intestinal barrier in a homeostatic state. Indeed, TLRs, mostly present on the membrane of immune and epithelial cells, identify pathogen-associated molecular patterns (PAMPs) and induce intracellular signaling cascade resulting in the production of cytokines and chemokines important for colonic homeostasis. The mammalian TLRs family consists of 13 members (TLR1-10 in humans, TLR1-9 and TLR11-13 in mice) and each TLR responds to distinct PAMPs leading to the activation of specific signaling pathway. For example, TLR4 recognizes lipopolysaccharide (LPS) and TLR5, which is expressed in the basolateral membrane of the intestinal epithelium, detects flagellin (FliC)[8]. In a dysbiotic state, alterations in the signature of microbial molecules sensed by the host can lead to abnormal activation state of the immune system and induce a low-grade intestinal inflammation[9].

The breakdown of the symbiotic relationship between TLRs and gut microbiota could contribute to the development of various multifactorial intestinal diseases, such as IBS. Previous studies have reported modifications of TLRs expression and activation in intestinal biopsies of IBS patients[10-15]. Furthermore, a preclinical study assessed the effect of neonatal maternal separation (NMS) in rats on TLRs expression, showing an upregulation of TLRs in colonic mucosa[16]. In this context, because of correlation between IBS and early life adverse events[17], this study investigated the impact of NMS paradigm on intestinal permeability, fecal microbiota composition and CHS development in mice as well as the association with TLRs expression.



MATERIALS AND METHODS

Animals

Seven-week-old wild type C57Bl/6J males and females mice were purchased from Janvier Laboratories (Le Genest Saint Isle, France). They were mated to obtain male pups for the NMS protocol. After birth, wild-type C57Bl/AJ pups were isolated from their mother from post-natal days P2 to P14, three hours per day (from 9:00 a.m. to 12:00 p.m.). These mice were named NMS mice. Pups were then left with their mothers up to weaning (P21) (Figure 1A). Control wild-type C57Bl/AJ pups were co-housed in the animal facility and were called non-handled (NH) mice. In addition, ten-week-old wild type C57Bl/6J males were purchased from Janvier Laboratories and used for FliC intrarectal instillation experiment. Animals were given access to food and water *ad libitum* and housed with a 12 h light-dark cycle. All experiments were performed on twelve-week-old male mice and were performed according to the ethical guidelines set out by the International Association for the Study of Pain (IASP), complied with the European Union regulation and were approved by ethics committees: The local committees C2EA-02 of Clermont-Ferrand (approvals CE110-12 and CE111-12).

Colorectal distension test

Colorectal distension test (CRD) was performed using the non-invasive manometric method described [18]. A miniaturized pressure transducer catheter (Mikro-Tip SPR-254; Millar Instruments, Houston, TX, United States) equipped with a custom-made balloon (length: 1.5 cm) prepared from a polyethylene plastic bag which avoid any colonic compliance effect. On the day of the experiment, the mice were accustomed to the holding device for 1 h before the CRD. Then, under mild anesthetic (2.5% isoflurane), the balloon was inserted into the rectum such that the distal end of the balloon was 5 mm from the anal margin. Subsequently, the animals were placed in the holding device and allowed to recover for 30 min prior to CRD. The balloon was connected to an electronic barostat (Distender Series II, G&J Electronics, Toronto, Canada) and a preamplifier (PCU-2000 Dual Channel Pressure Control Unit, Millar Instruments, Houston, TX, United States) connected to the PowerLab interface (AD Instruments, Dunedin, New Zealand). The barostat enabled the control of the balloon pressure. The distension protocol consisted of a set of increasing distension pressures (20, 40, 60, 80 and 100 mmHg), each of which was repeated twice, which was applied for 20 s with a 4 min inter-pressure interval. The signal was acquired and analyzed using LabChart 7 software (ADInstruments, Dunedin, New Zealand). After intracolonic pressure recording for each animals along the CRD protocols and signal treatment as previously described[18], intracolonic pressure variation (IPV), reflecting the colonic sensitivity, was calculated as previously described[19] for each distension pressure. Briefly, IPV was calculated by subtracting the integral (area under the curve) of the treated signal corresponding to the 20 s preceding the CRD from the integral (area under the curve) of the treated signal during the 20 s of CRD stimulation. Therefore, two groups of NMS mice were defined: NMS non-sensitized (NMS NS) and NMS sensitized (NMS S) mice. The NMS S animals are distinguished according to the area under the curve (AUC) value in response to the distention pressures from 60 to 100 mmHg during CRD procedure

Figure 1 Time course protocols used in this study. A: Time course protocol for neonatal maternal separation experiment; B: Time course protocol for flagellin intrarectal instillation experiment. ∗Feces sample collection for Next Generation Sequencing; CRD: Colorectal distention test.

[20]. Briefly, if this value is higher than the average AUC of the NH control animals plus twice the SEM value ($AUC_{NMS\,S} \geq AUC_{NH} + 2 \times SEM_{NH}$), this mouse is considered as hypersensitive and are placed in the NMS S group. Others are considered as NMS NS. For FliC intrarectal instillation experiment, the distension protocol was the same before intrarectal instillation and, only a set of distension pressure 60, 80 and 100 mmHg was used 30 min, 60 min and 120 min after intrarectal instillation.

In vivo intestinal permeability

In vivo intestinal permeability was assessed using fluorescein dextran (FITC- dextran 3000-5000 Da, TdB Consultancy AB, Uppsala, Sweden) as previously described[21]. Briefly, before CRD, NMS and NH mice were orally gavaged with 0.6 g/g body weight of FITC-dextran and blood samples were obtained from the retro-orbital venous plexus 3 h after this administration. Plasma FITC levels were determined by fluorometry at 488 nm using a microplate reader (Tecan, Lyon, France).

Fecal pellets collection, DNA extraction and microbiota sequencing

Fecal pellets were collected from mice at week 3, 4 and 12 and stored at -80 °C prior to DNA extraction. Bacterial DNA was extracted from fecal bacteria following the protocol of NucleoSpin® Soil kit (Macherey-Nagel, Düren, Germany). DNA concentrations and purity were then assessed using Take3 micro-volume plate and Epoch Microplate Spectrophotometer (BioTek, Winooski, VT, United States). The 16S rRNA gene V4 variable region polymerase chain reaction (PCR) primers 515/806 with barcode on the forward primer were used in a 30 cycles PCR using the HotStarTaq Plus Master Mix Kit (Qiagen®, Germantown, MD, United States). Next generation sequencing (NGS) was performed at Molecular Research DNA (MR DNA - Shallowater, TX, United States) on a MiSeq following the manufacturer's guidelines. Sequences data analysis was performed using the quantitative insights into microbial ecology pipeline (QIIME)[22]. The analysis was carried out on the core microbiota *i.e.* the operational taxonomic units (OTUs) present in the fecal microbiota of 90% of the mice.

FliC intrarectal instillation

FliC from wildtype *Salmonella enterica* serovar typhimurium (SL3201, fljB−) was provided by Pr. A. Gewirtz (Center for Inflammation, Georgia State University, Atlanta, GA, United States). Briefly, FliC was purified through sequential cation- and anion-exchange chromatography and purity was verified as described previously[8]. Intrarectal instillation was performed under mild anesthetic (2.5% isoflurane) using orogastric feeding tube and inserted 2.5 cm up the colon (Figure 1B). At this point, 50 µL of FliC diluted in PBS, corresponding to 5 µg was slowly administered over 30 s while pressure was applied to the anal area to prevent leakage. Following the injection of the solution, the tube was slowly removed and the rectal pressure was maintained for a further 30 s.

Colonocytes extraction

Following mice euthanasia, fragments of colon (3-4 cm) were flushed and opened longitudinally along the mesentery and homogenized in cold PBS to remove feces. Then, these fragments were incubated into HBSS containing EDTA solution (2 mmol/L) 30 min at 37 °C with strong agitation every 10 min. After HBSS/EDTA incubation, colons were removed and samples were centrifuged at 2000 g for 10 min.

Then, HBSS/EDTA was removed and colonocytes were deep-frozen in liquid nitrogen and stored at -80 °C for further analysis.

RNA extraction, reverse transcription and quantitative PCR

Total RNA from mice colonocytes was extracted using the RNeasy Plus Mini Kit (Qiagen®, Germantown, MD, United States) according to the manufacturer's protocol. After RNA extraction, reverse transcription was performed with the High Capacity cDNA RT Kit (Applied Biosystems, Foster City, CA, United States) with 500 ng of RNA, followed by a qPCR using LightCycler FastStart DNA Master SYBR Green Kit (Roche Applied Science, Penzberg, Germany). The primers used for TLRs expression analysis are described in Table 1. All results were normalized to the *HPRT* gene. Samples were tested in duplicate, and the average values were used for quantification by using 2-ΔΔCt method.

Fecal FliC and LPS load quantification

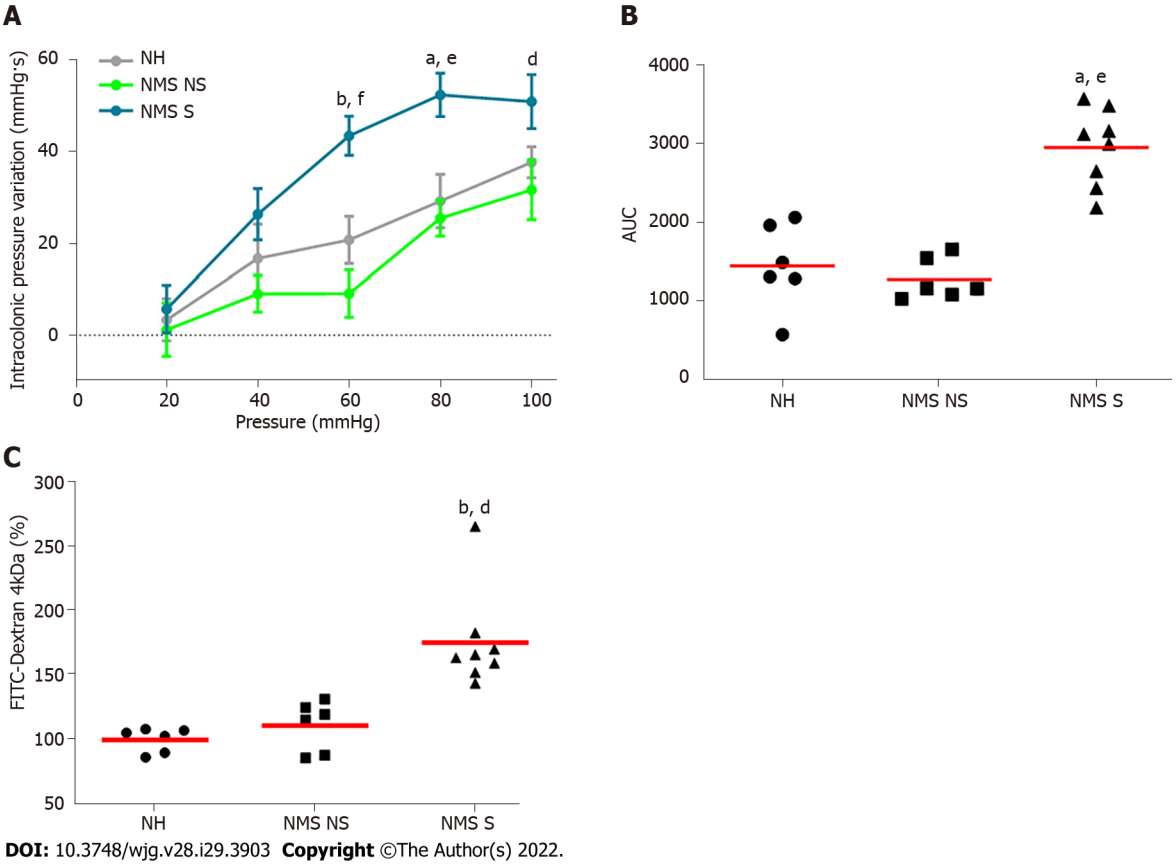
FliC and LPS were quantified using human embryonic kidney (HEK)-Blue-mTLR5 and HEK-Blue-mTLR4 cells, respectively (Invivogen, San Diego, California, United States). Fecal material was resuspended in PBS to a final concentration of 100 mg/mL and homogenized for 10 s using a Mini-Beadbeater-24 without the addition of beads to avoid bacteria disruption. The samples were then centrifuged at 8000 g for 2 min and the resulting supernatant was serially diluted and applied to mammalian cells. Purified *Escherichia coli* FliC and LPS (Sigma, St Louis, Missouri, United States) were used for standard curve determination using HEK-Blue-mTLR5 and HEK-Blue-mTLR4 cells, respectively. After 24 h of stimulation, cell culture supernatant was applied to QUANTI-Blue medium (Invivogen, San Diego, California, United States) and alkaline phosphatase activity was measured at 620 nm after 30 min.

Statistical analysis

Statistical analyses were performed with Prism 7 software (GraphPad, La Jolla, CA, United States). The Kolmogorov-Smirnov test has been used to check if data follow a normal distribution. One-way ANOVA, Kruskal-Wallis test or two-way ANOVA (more than two groups) were used for intergroup-comparisons with Tukey's, Dunn's and Dunnett's test for the post-hoc analysis. Correlation was assessed using Pearson's test. ANOSIM method followed by Monte-Carlo permutation test was performed to assess the significativity of beta-diversity analysis of fecal microbiota using the QIIME. A P value ≤ 0.05 was considered statistically significant.

RESULTS

NMS paradigm induces CHS and intestinal permeability increase in a subset of mice



In order to evaluate colonic sensitivity, a CRD test was performed on twelve-week-old NH or NMS mice (Figure 1A). As previously described[23], among NMS mice only a subset developed CHS in comparison to NH mice Therefore, two groups of NMS mice were defined: NMS NS and NMS S mice. In fact, colorectal distension assessment revealed significant increase of IPV for the highest distension pressures 60, 80 and 100 mmHg in the NMS S group in comparison to NMS NS and NH groups (Figure 2A). Analysis of the areas under the curve (AUC) for each mouse confirmed this significant difference between NH, NMS NS and NMS S groups (Figure 2B). Intestinal permeability assessment revealed significant increase of FITC-Dextran plasma levels in the NMS S group compared to NH and NMS NS groups (Figure 2C).

Fecal microbiota dysbiosis is associated with CHS in neonatal maternal separated mice

Illumina sequencing of the 16S rRNA gene was performed on fecal pellets DNA extracts from NH, NMS NS and NMS S mice at W3, W4 and W12 (just before the CRD test) according to the time course protocol for NMS experiment (Figure 1A). Alpha-diversity analysis (number of observed OTUs) of the core fecal microbiota revealed no statistical difference between NH, NMS NS and NMS S animals at week 3, before weaning (Figure 3A-left panel). However, a significant decrease of species richness appeared at W4 in NMS S mice in comparison to NH or NMS NS animals and persisted at adulthood (W12, time point of CRD test), even if NMS NS and NMS S mice were co-housed in the same cage during all the experiment (Figure 3A-middle and right panels). In addition, a significant decrease of the observed OTUs number was present in NMS NS at adulthood (W12) in comparison to NH mice. Principal coordinates analysis based on unweighted UniFrac distances confirmed the alteration of the core fecal microbiota. It enabled to significantly (ANOSIM method followed by the Monte-Carlo permutation test, $P < 0.05$) identify the three animals' groups from W3 to W12 (Figure 3B). The taxonomic analysis of the fecal core microbiota composition in the NMS S group revealed in twelve weeks old mice a decreased relative abundance of bacteria belonging to the phylum *Bacteroidetes* and an increase in *Firmicutes* in comparison to the NMS NS group (Figure 3C). At lower taxonomic levels, NMS S mice were characterized by a decreased abundance of bacteria from the genera *Allobaculum* and *Barnesiella* compared to

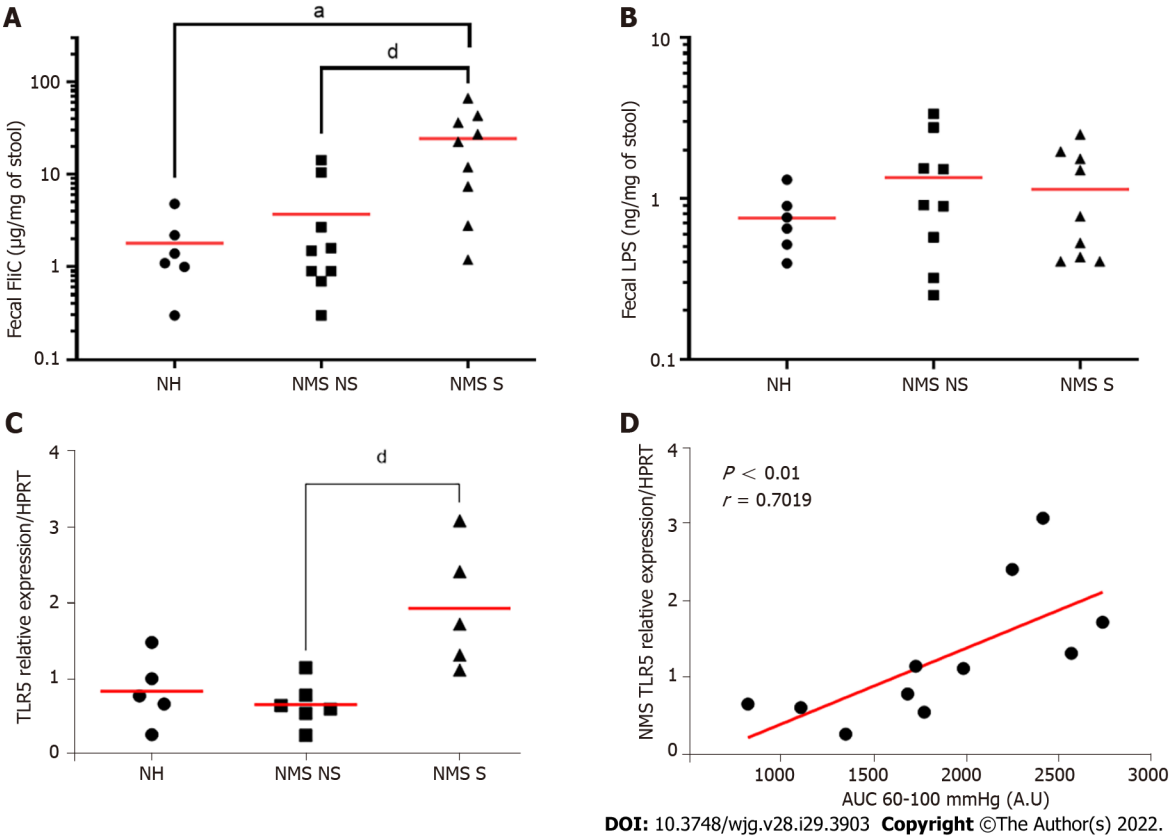
Figure 2 Neonatal maternal separation induces colonic hypersensitivity and increases intestinal permeability in mice. A: Intracolonic pressure variation (IPV) in response to colorectal distension in non-handled (NH), neonatal maternal separated non-sensitized (NMS NS) and neonatal maternal separated sensitized (NMS S) mice; B: Area under the curve (AUC) of the IPV relative to colorectal distension for each NH, NMS NS and NMS S mouse; C: FITC-dextran 4 kDa plasmatic concentrations, 3 h after oral gavage with 15 mg of FITC-dextran of NH, NMS NS and NMS S mice. Values are expressed as a percentage of FITC-dextran per mL of plasma in comparison to the NH group mean. NH: $n = 6$; NMS NS: $n = 6$; NMS S: $n = 8$. $^{a}P < 0.05$ and $^{b}P < 0.01$ *vs* NH group; and $^{d}P < 0.05$, $^{e}P < 0.01$ and $^{f}P < 0.001$ *vs* NMS NS group. For IPV to CRD test, dots represent means and error bars represent SEM. For AUC and FITC-dextran, each dot represents one mouse and red lines represent means.

control NH mice, and a decreased abundance of bacteria from the genera *Bacteroides* compared to NMS NS mice. The relative abundances of *Lachnoclostridium, Clostridium* and *Lactobacillus* were increased in these NMS animals with CHS in comparison to NMS mice without CHS. Surprisingly, the relative abundance of *Lactobacillus* was decreased in NMS NS animals compared to NH group (Figure 3D).

CHS induced by NMS exposure increased fecal level of FliC and is related to TLR5 overexpression in colonocytes



To understand potential mechanisms between fecal microbiota dysbiosis and CHS induced by NMS, quantification of two different PAMPs, FliC and LPS, was performed in feces from twelve-week-old NH, NM NS and NMS S mice. Exposure to NMS paradigm increased significantly fecal level of FliC (Figure 4A) rather than fecal LPS which is not significant better between different animal (Figure 4B).

Figure 3 Neonatal maternal separation paradigm induces alterations of core fecal microbiota related to colonic hypersensitivity. A: Alpha-diversity analysis of the core microbiota. Number of observed operational taxonomic units according to the number of sequences per samples of fecal samples from non-handled (NH), neonatal maternal separated non-sensitized (NMS NS) and neonatal maternal separated sensitized (NMS S) at week 3 (W3), week 4 (W4) and week 12 (W12); B: Beta-diversity analysis of the core microbiota. Principal coordinates analysis (PCoA) of unweighted UniFrac distances of NH, NMS NS and NMS S mice at W3, W4 and W12; C and D: Mean relative abundances of bacterial phyla (C) and genera (D) significantly altered by the NMS paradigm between NH, NMS NS and NMS S mice at W12. NH: n = 6; NMS NS: n = 6; NMS S: n = 8. $^{a}P < 0.05$, $^{b}P < 0.01$ and $^{c}P < 0.001$ *vs* NH or $^{d}P < 0.05$, $^{e}P < 0.01$ and $^{f}P < 0.001$ *vs* NMS NS groups respectively. For alpha-diversity analysis, dots represent means and error bars represent SEM. For PCoA analysis each dot represents one mouse.

As TLRs are the main receptors of PAMPs, the TLRs mRNA expression in colonocytes from NH, NMS NS and NMS S mice was quantified in adult (W12) mice. As previously described, three mouse groups were defined, based on the CHS (Supplementary Figure 1A and B). In those mouse groups, the TLR2, 3, 4 and 9 mRNA were not modified between NH, NMS NS and NMS S animals (Supplementary Figure 1C), whereas TLR5 mRNA expression is significantly increased only in NMS S subgroup (NH: 0.836 ± 0.200, NMS NS: 0.662 ± 0.120, NMS S: 1.925 ± 0.363, $P < 0.05$ *vs* NMS NS) (Figure 4C). AUC corresponding to the IPV for highest colorectal distension pressures (60, 80 and 100 mmHg) significantly correlated with the mRNA expression level of TLR5 in colonocytes of NMS mice ($P < 0.01$) (Figure 4D).

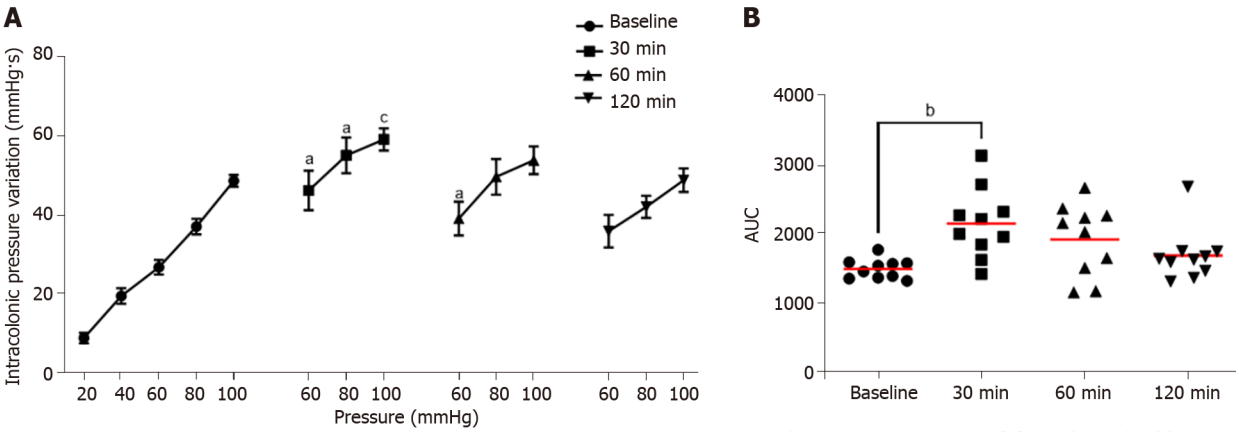
Figure 4 Neonatal maternal separation induced colonic hypersensitivity is associated with increased flagellin fecal content and colonocytes toll-like receptor 5 expression. A: Levels of fecal flagellin (FliC) assayed with toll-like receptor 5 (TLR5) reporter cells; B: Levels of fecal lipopolysaccharide assayed with TLR4 reporter cells; C: Colonocytes mRNA expression of TLR5 in non-handled (NH), neonatal maternal separated non-sensitized (NMS NS) and neonatal maternal separated sensitized (NMS S) mice at week 12. Values are expressed as relative expression of TLR5 mRNA compared to *HPRT* expression; D: Correlation between NMS colonocytes TLR5 expression and area under the curve (AUC) corresponding of the intracolonic pressure variation (IPV) for highest colorectal distension pressures (60, 80 and 100 mmHg). A and B: NH: $n = 6$; NMS NS: $n = 9$; NMS S: $n = 9$. $^{a}P < 0.05$ *vs* NH group; and $^{d}P < 0.05$ *vs* NMS NS group. C and D: NH: $n = 5$; NMS NS: $n = 6$; NMS S: $n = 5$. $^{d}P < 0.05$ *vs* NMS NS. For FliC quantification TLR5 mRNA relative expression, each dot represents one mouse and red lines represent means and for correlation between TLR5 expression and AUC of IPV, each dot represents one mouse and red line represents the linear regression curve.



FliC intrarectal instillation is associated with a transient increase of colonic sensitivity

Intrarectal instillation of FliC, agonist of the receptor TLR5, significantly increased IPV at the 60, 80 and 100 mmHg distension pressure 30 min and 60 min post-instillation (Figure 5A). The increase in the response to CRD test was transient and did not persist 120 min after FliC instillation. AUC confirmed this significant increase of IPV 30 min after intrarectal instillation of FliC (Figure 5B).

DISCUSSION

Abdominal pain, frequently associated with CHS, has been shown to be a common feature of IBS patients. It also strongly impacts on patient's quality of life, leading to an important rate of consultation in Gastroenterology[24]. According to clinical studies, 33% to 90% of IBS patients exhibit CHS[3,25]. IBS presents a poorly first line treatment efficacy, especially regarding the treatment of abdominal pain[26]. Thus, in accordance with the aim of our study, a better characterization of mechanisms associated with CHS is important for the establishment of new potential pharmacological targets.

The etiology of this condition, resulting in various symptoms, remains unclear even if biological, psychological and social factors seem to be involved. Indeed, several studies reported an increased risk of IBS associated with early adverse life events[17,27-29]. These events refer to traumatic experience during childhood such as physical, sexual or emotional abuse as well as discordant relationship with primary caretaker. Using NMS stress animal model[30], our study demonstrates the impact of early adverse life events on colonic sensitivity of adult mice. Interestingly, only a subset of NMS mice presented CHS, revealed by CRD test, compared to control non-handled mice. These results were consistent with data obtained in previous studies carried out in both rats and mice[23,31,32].

Figure 5 Evaluation of the impact of intrarectal instillation of flagellin on colonic sensitivity. A: Intracolonic pressure variation (IPV) in response to colorectal distension in males mice before (Baseline) and after (30, 60 and 120 min) intrarectal instillation of flagellin (5 µg); B: Area under the curve (AUC) of the IPV relative to highest colorectal distension pressures (60, 80 and 100 mmHg). For each mouse and each time point, $n = 10$. $^{a}P < 0.05$, $^{b}P < 0.01$ and $^{c}P < 0.001$ respect to Baseline. For IPV to colorectal distension test, dots represent means and error bars represent SEM. For AUC, each dot represents one mouse and red lines represent means.

Many studies reported an association between activation of the HPA axis, the major neuroendocrine system regulating various bodily processes in response to psychological or physical stressors, and intestinal permeability increase[33,34]. Furthermore, alteration of the intestinal barrier is a key clinical feature of IBS and it has been related to CHS[35]. In our study, assessment of intestinal permeability was carried out by measurement of FITC-dextran plasma level. Only NMS animals with CHS exhibited high plasmatic levels of FITC-dextran, suggesting that NMS paradigm induced CHS is associated with altered intestinal barrier. This result is in accordance with previous reports showing increased intestinal permeability following NMS paradigm or chronic stress exposure[34,36,37]. In addition, the link between the weakness of the intestinal mucosa barrier and CHS has been demonstrated in a mouse model of post-infectious IBS[20].

Consistent studies reported intestinal dysbiosis in IBS patients[6]. The main distinguishing feature of IBS patients compared to heathy volunteers is on one hand the increased abundance of bacteria belonging to the *Firmicutes* phylum and on the other hand, the decreases abundance of bacteria belongs to the *Bacteroidetes* phylum. Implication of the intestinal microbiota in CHS and associated chronic abdominal pain was also suggested[38]. In the present study, the characterization of the fecal microbiota composition using high-throughput sequencing of the 16S rRNA revealed the presence of a dysbiotic state making it possible to discriminate NH, NMS NS and NMS S mice. Indeed, the beta-diversity analyses showed that the composition of the fecal microbiota is different between NMS and NH control mice but also between NMS NS and NMS S mice while these animals came from the same litters and were co-housed. Changes in intestinal microbiota composition associated with NMS and CHS appeared very early, before weaning the animals (week 3) and persisted over time up to 12 wk. These alterations in the fecal microbiota composition were also characterized by a decreased bacterial richness in NMS S mice from week 4 to week 12. In general, this decrease was associated with a physiological disorder in the host, which seemed to be in agreement with the results obtained in this model[39]. A reduction in the bacterial diversity of the intestinal microbiota has notably been demonstrated in IBD and IBS patients but also in stress animal models[40-44]. *Clostridium* and *Lachnoclostridium*, flagellated bacteria, are among the genera whose abundance was increased in NMS S mice, at W12, the time of colonic sensitivity assessment, compared to NMS mice without CHS. Studies carried out in animals subjected to stress during the neonatal period have also shown an increase in the relative abundance of the *Clostridium* genus[43,45,46]. Furthermore and interestingly, Luna *et al*[47] highlighted an increased relative abundance of different species of *Clostridium* and *Lachnoclostridium* within the mucosa-associated microbiota in children with an autistic disorder associated with functional gastrointestinal disorders and in particular abdominal pain. These findings suggest an implication of the intestinal microbiota in the development of CHS in the NMS model.

In a dysbiotic state, particularly associated with an increase in intestinal permeability, alterations in the signature of microbial molecules sensed by the host can lead to a different activation state of the immune system[9]. Indeed, PAMPs, such as LPS or FliC, are sensed by PRRs including TLRs, which are expressed on the host cell surface or in the cytosolic compartment of numerous cell types. In this context, the aim of our study was to characterize the expression of different TLRs in colonocytes from our different animal subgroups after NMS paradigm. It is important to note that NMS paradigm is not associated with a modification of the intestinal inflammation status[23,36]. An increased TLR5 expression was observed only in animals presenting CHS after NMS paradigm, moreover, correlation

between gene expression of TLR5 and AUC from 60 to 100 mmHg (corresponding to nociceptive stimulation) in NMS mice. These findings are in line with some reports showing upregulation of TLRs in IBS patient's colonic biopsies[10-12,15]. An increased expression of some TLRs was also observed in NMS model but without association with visceral pain[11]. Few publications have indicated TLRs implication in animal pain model, especially inflammatory and neuropathic pain[48,49]. In visceral pain context, Tramullas *et al*[50] in 2014 demonstrated involvement of TLR4 in visceral sensitivity in a chronic stress model. Furthermore, Luczynski *et al*[51] demonstrated increased colonic sensitivity to colorectal distention in germ free mice, associated with an increase of TLRs expression in spinal cord. Finally, in 2018, a study published by Zhou *et al*[52] established TLR4 implication in inflammatory visceral pain in animals with high-fat diet. Following the demonstration of FliC increase in NMS S mice fecal content and the upregulation of TLR5 expression in the NMS S mouse colonocytes, the effect of FliC was assessed on visceral sensitivity in naïve animals. We highlighted a transient increase of colonic sensitivity between 30 min and 60 min after FliC intra-rectal instillation. These results are the first to demonstrate potential FliC and TLR5 involvement in CHS in a non-inflammatory IBS-like animal model. Indeed, only Das *et al*[53] have shown that TLR5 signaling mediates hypersensitivity in a model of allodynia and that sensitivity was reversed by blocking TLR5 with a specific antagonist. Moreover, Dlugosz *et al*[54] has found a significantly higher serum level of antibodies to FliC patients with IBS. Our data, associated with the results of previous studies suggest that TLR5, through its activation by FliC, could play a key role in CHS induced by dysbiosis related to the NMS paradigm and more generally, in the pathophysiology of IBS.

CONCLUSION

In conclusion, our results demonstrated the association of fecal dysbiosis, characterized especially by an increased abundance of flagellated bacteria, with impaired intestinal permeability, increased TLR5 expression and induced CHS. Taken together, TLR5 signaling upon recognition of FliC is relevant in visceral pain through both direct and indirect mechanisms, and application of TLR5-specific antagonists could potentially reversed CHS in non-inflammatory visceral pain context[23,36].

ARTICLE HIGHLIGHTS

Research background

Chronic abdominal pain associated to irritable bowel syndrome (IBS) is strongly related to stress and is the most common cause for gastroenterology consultation. Brain/gut/microbiota trialogue alterations are suspected to be involved in colonic hypersensitivity (CHS), responsible for chronic abdominal pain. It is also associated with abnormal intestinal permeability and intestinal dysbiosis, which can alter colon homeostasis leading to abnormal activation of the innate immunity that promotes CHS, perhaps involving the toll-like receptors (TLRs), which play a central role in innate immunity.

Research motivation

The breakdown of the relationship between TLRs and gut microbiota could contribute to the development of IBS. Thus, because of correlation between IBS and early life adverse events, our study investigated the impact of neonatal maternal separation (NMS) paradigm on intestinal homeostasis, fecal microbiota composition and CHS development in mice as well as the association with TLRs expression.

Research objectives

A better characterization of mechanisms associated with CHS is important for the establishment of new potential pharmacological targets.

Research methods

In our study, we used a referenced CHS animal model, the NMS paradigm, which mimics deleterious events in childhood that can induce a wide range of chronic disorders during adulthood. In addition, we have evaluated colonic sensitivity of NMS mice by colorectal distension (CRD) coupled with intracolonic pressure variation measurement. Fecal microbiota composition was analyzed by 16S rRNA sequencing from weaning to CRD periods. TLR mRNA expression was evaluated in colonocytes.

Research results

This study, based on the preclinical mouse model of NMS, demonstrated that around 50% of NMS mice exhibited increased intestinal permeability and CHS associated with intestinal dysbiosis. In particular, a significant increased amount of flagellated bacteria was observed in the NMS mice with CHS. In

association, only tlr5 mRNA expression was increased in colonocytes of NMS mice with CHS.

Research conclusions

Taken together, our results suggest a pathophysiological continuum between intestinal dysbiosis and CHS, with a role for TLR5.

Research perspectives

TLR5 signaling upon recognition of flagellin is relevant in visceral pain through both direct and indirect mechanisms, and application of TLR5-specific antagonists could potentially reversed CHS in non-inflammatory visceral pain context.

Abstract

BACKGROUND

Hepatocellular carcinoma (HCC) is the most common type of primary liver cancer. Current guidelines for HCC management recommend surveillance of high-risk patients every 6 mo using ultrasonography. Serum biomarkers, like alpha-fetoprotein (AFP), protein induced by vitamin K absence/antagonist-II

(PIVKA-II) and lectin-reactive AFP, show suboptimal performance for detection of HCC, which is crucial for successful resection or treatment. Thus, there is a significant need for new biomarkers to aid early diagnosis of HCC. Studies have shown that the expression level of human microRNAs (miRNAs), a small, non-coding RNA species released into the blood, can serve as an early marker for various diseases, including HCC.

AIM

To evaluate the diagnostic role of miRNAs in HCC as single markers, signatures or in combination with known protein biomarkers.

METHODS

Our prospective, multicenter, case-control study recruited 660 participants (354 controls with chronic liver disease and 306 participants with HCC) and employed a strategy of initial screening by two independent methods, real-time quantitative PCR (n = 60) and next-generation sequencing (n = 100), to assess a large number of miRNAs. The results from the next-generation sequencing and real-time quantitative PCR screening approaches were then combined to select 26 miRNAs (including two putative novel miRNAs). Those miRNAs were analyzed for their diagnostic potential as single markers or in combination with other miRNAs or established protein biomarkers AFP and PIVKA-II *via* real-time quantitative PCR in training (n = 200) and validation cohorts (n = 300).

RESULTS

We identified 26 miRNAs that differentiated chronic liver disease controls from (early) HCC *via* two independent discovery approaches. Three miRNAs, miR-21-5p (miR-21), miR-320a and miR-186-5p, were selected by both methods. In the training cohort, only miR-21, miR-320d and miR-423 could significantly distinguish (Q < 0.05) between the HCC and chronic liver disease control groups. In the multivariate setting, miR-21 with PIVKA-II was selected as the best combination, resulting in an area under the curve of 0.87 for diagnosis and area under the curve of 0.74 for early diagnosis of HCC. In the validation cohort, only miR-21 and miR-423 could be confirmed as potential HCC biomarkers. A combination of miRNAs did not perform better than any single miRNA. Improvement of PIVKA-II performance through combination with miRNAs could not be confirmed in the validation panel. Two putative miRs, put-miR-6 and put-miR-99, were tested in the training and validation panels, but their expression could only be detected in very few samples and at a low level (cycle threshold between 31.24 and 34.97).

CONCLUSION

miRNAs alone or as a signature in combination with protein biomarkers AFP and PIVKA-II do not improve the diagnostic performance of the protein biomarkers.

Key Words: Carcinoma; Hepatocellular; MicroRNAs; Biomarkers; Alpha-fetoprotein; Protein induced by vitamin K absence-II; Diagnosis

Core Tip: Hepatocellular carcinoma (HCC) is the most common type of primary liver cancer and has a high mortality rate, making early diagnosis essential for better treatment outcomes. Studies have shown microRNAs to be early markers for HCC; we evaluated the potential diagnostic role of microRNAs alone and in combination with known protein biomarkers (alpha-fetoprotein, protein induced by vitamin K absence/antagonist-II) in samples from HCC-affected individuals and controls using real-time quantitative PCR and next-generation sequencing. MiR-21 and miR-423 demonstrated significant differential expression between the HCC and control groups. MicroRNAs alone or as a signature in combination with protein biomarkers did not improve diagnostic performance of the protein biomarkers.

INTRODUCTION

According to the World Health Organization report of cancer cases worldwide, hepatocellular carcinoma (HCC) was the sixth most common cancer in terms of new cases and the fourth most common cause of cancer-related deaths in 2018[1]. HCC accounts for 85%-90% of all primary liver cancers[2], and in most cases develops in cirrhotic livers. Cirrhosis arises as a consequence of chronic liver injury and inflammation caused by viral and non-viral factors. About 70% of all HCC cases are caused by viral liver infections like hepatitis B virus (HBV) and hepatitis C virus (HCV)[3]. Approximately 80% of HCC cases occur in eastern Asia and sub-Saharan Africa, where the dominant risk factor is chronic infection with HBV and exposure to aflatoxin B1. In contrast, the main risk factors for HCC development in North America, Europe and Japan are infection with HCV or alcohol misuse, diabetes and obesity[4]. The mortality rate of HCC is high, with 5-year overall survival rates of 19.5%[5].

Limited treatment options exist for patients with HCC when diagnosed at advanced stages, so early detection is crucial to reduce mortality. If diagnosed early, treatment options such as resection, local ablation and liver transplantation are available and increase the 5-year overall survival rate for very early HCC [Barcelona-Clinic Liver Cancer (BCLC) stage 0] to 70%-90% and for early HCC (BCLC stage A) to 50%-70%. Intermediate to end-stage HCCs are unresectable and have a median survival of 16 mo for intermediate HCC (BCLC stage B), 6 mo for advanced HCC (BCLC stage C) and 3-4 mo for end-stage HCC (BCLC stage D)[6].

HCC is often asymptomatic, making its early diagnosis challenging. Major international guidelines recommend surveillance of high-risk patients [patients with severe chronic liver disease (CLD) such as chronic HBV or HCV infections, alcohol abuse or non-alcoholic steatohepatitis, leading to cirrhosis of the liver) at 6-mo intervals using abdominal ultrasound (US) with (The Asian Pacific Association for the Study of the Liver, American Association for the Study of Liver Diseases) or without (European Association for the Study of the Liver-European Organisation for Research and Treatment of Cancer) measurement of alpha-fetoprotein (AFP) levels in serum[7-9]. Japanese guidelines on HCC management propose the use of US and measurement of AFP, lectin-reactive AFP and protein induced by vitamin K absence/antagonist-II (PIVKA-II; also known as des-gamma-carboxy prothrombin) for routine follow-up in patients at high risk for developing HCC[10]. Other recommended imaging methods are computed tomography (CT) and magnetic resonance imaging; however, these are very cost-intensive, not easily accessible and have potential adverse effects like radiation exposure (CT)[6-8,11]. US use is also not without problems, as its performance is operator-dependent[12] and is limited in the setting of non-alcoholic steatohepatitis[13]. Adjunctive use of AFP may improve HCC detection rates. Although it has limited sensitivity for early-stage HCC, its addition to US improved sensitivity from 45% to 63% (P = 0.002)[11,14]. PIVKA-II is more sensitive but less specific than AFP for diagnosis of HCC in patients affected by chronic HCV infection[15]. Thus, there is a great need for new, non-invasive diagnostic tools to improve the detection of early HCC and eliminate operator-dependent variability.

MicroRNAs (miRNAs) are small (approximately 22 nucleotides), non-coding RNA molecules that post-transcriptionally modify gene regulation by base-pairing to mRNA[16]. The target mRNA is then either degraded (complementary or near-perfect complementary binding) or the translation is inhibited (partial complementarity), thus inhibiting protein expression[17].

In the cancer research field, the role of miRNAs has been discussed extensively. In the context of human cancers, miRNAs are associated with cell proliferation, genomic instability, tissue invasion, metastasis, angiogenesis, evasion of apoptosis and immune response. They can also act as oncogenes or tumor suppressor genes[18]. Clinical applications of miRNAs have been studied in various malignant tumors, such as lung, breast and prostate cancers[19]. Primarily, miRNAs from serum and plasma are of particular interest for diagnosis of cancer and the study of disease prognosis. The main advantage of miRNA-based diagnosis is the high stability of these molecules in blood and other biological fluids that can be easily sampled[20-22].

In HCC, the role of miRNAs for diagnosis and therapy has been exhaustively analyzed, although with contradictory results[23]. The expression of several miRNAs in different HCC tumor tissue samples was both elevated and decreased compared with a control group (non-tumorous tissue) in different studies[24]. Additionally, numerous circulating miRNA candidates or signatures composed of several miRNAs have been published as biomarker candidates for HCC (*e.g.*, hsa-miR-206, hsa-miR-141-3p and hsa-miR-433-3p)[25]. In some cases, both increases and decreases in the expression of the same miRNA (*e.g.*, hsa-miR-143, hsa-miR-155, hsa-miR-195) have been reported[26]. While previous studies have given some indication that miRNAs may be useful biomarkers for HCC, no miRNA has been found as a reliable biomarker in the diagnosis of early-stage HCC. To date, studied cohorts have been small, or control cohorts contained only one group of patients with a disease having a high risk for HCC [27], only healthy individuals[28] or did not include patients with early HCC[29]. A large cohort is necessary to obtain statistically significant results[30], and an HCC biomarker should show high sensitivity and specificity in patients at risk for HCC (including those with HBV, HCV and cirrhosis).

The aim of this study was to identify and clinically validate potential miRNAs for the early detection of HCC in human plasma samples through a comprehensive, prospective, multicenter, case-control study. To this end, a large cohort including 660 HCC (early and late stage) and CLD patients was studied. The potential improvement of the diagnostic performance of already established protein

biomarkers for HCC (AFP and PIVKA-II) in combination with miRNA biomarkers was also assessed.

MATERIALS AND METHODS

Patient sample collection

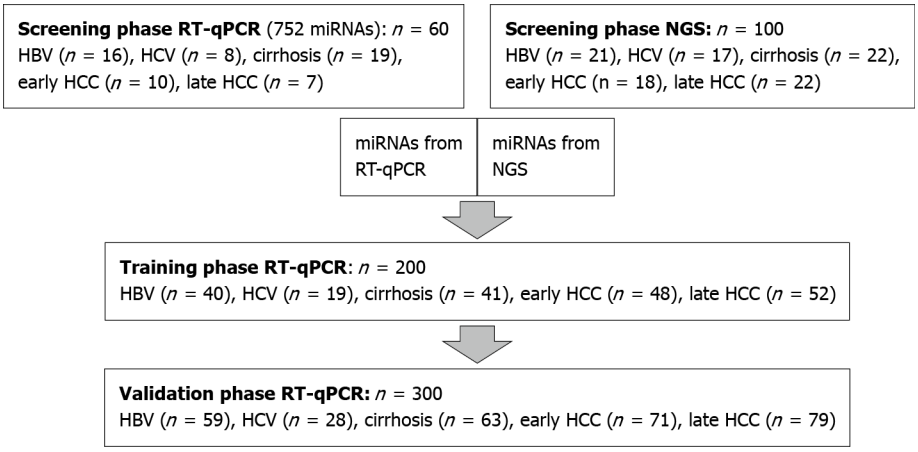
Between 2014 and 2016, EDTA-plasma samples from 354 CLD controls, including HBV and HCV with and without cirrhosis, and 306 HCC (early and late stage) patients were provided by the following institutions: Maharaj Nakorn Chiang Mai Hospital, Chiang Mai, Thailand; Siriraj Hospital, Bangkok, Thailand; Songklanagarind Hospital, Hat Yai, Thailand; Srinagarind Hospital, Khon Kaen, Thailand; Prince of Wales Hospital, Shatin, Hong Kong; NCT University Hospital Heidelberg, Heidelberg, Germany; and Vall d'Hebron University Hospital, Barcelona, Spain. Full inclusion and exclusion criteria have been previously described[31].

Written informed consent was obtained from all participants. The study was conducted in full conformance with the principles of the Declaration of Helsinki and with approval of independent ethics committees. Plasma samples were collected before treatment (surgery, percutaneous ethanol injection, chemotherapy, radiotherapy) according to the appropriate standard operating procedures and stored at -70 °C until analysis. Repeated freeze-thaw cycles were avoided. HCC diagnosis was verified using imaging (ultrasonography, CT, magnetic resonance imaging) or biopsy, followed by histopathological analysis.

Description and clinical data of patients

The demographic and clinical characteristics of the study participants are presented in Supplementary Table 1. All diagnosed HCC cases were classified according to BCLC guidelines upon sample collection. Early-stage HCC was defined as BCLC 0 and A and late-stage HCC as BCLC B, C and D. CLD controls were individuals with HBV or HCV with or without cirrhosis. Some patients had additional underlying diseases, which were not considered when distributing them into the four groups. All clinical data, including the patients' diagnoses, were blinded to laboratory operators to avoid measurement bias.

Study design



CLD and HCC patient samples were randomly distributed into four panels: a screening panel for real-time quantitative (RT-q) PCR (n = 60), a screening panel for next-generation sequencing (NGS) (n = 100), a training panel (n = 200) and a validation panel (n = 300) (Supplementary Table 1). Comparisons were made for: (1) All HCC (early + late stages) *vs* controls (HBV and HCV, with and without cirrhosis); (2) Early HCC *vs* controls; and (3) Early HCC *vs* cirrhosis (Figure 1).

miRNA isolation

The following methods for miRNA isolation from plasma were validated: TaqMan miRNA ABC Purification Kit, mirVana PARIS Kit (both LifeTechnologies, Carlsbad, CA, United States) and the miRCURY RNA Isolation Kit-Biofluids (Exiqon, Vedbaek, Denmark). The best performance for the isolation of small RNA was found using the last method; therefore, all isolation experiments were performed using the miRCURY RNA Isolation Kit-Biofluids. The starting material was 250 µL of EDTA-plasma per patient. Handling was according to the manufacturer's protocol with the following adaption: after adding the protein precipitation solution and subsequent centrifugation, only 200 µL of supernatant was transferred into a new tube; the remaining volume was discarded. For quality control, spike-ins UniSp2, UniSp4 and UniSp5 from the miRCURY Universal RT microRNA PCR, RNA Spike-in kit (Exiqon) were added to all samples prior to isolation. Isolated small RNA (including miRNA) was stored at -80 °C until analysis.

NGS

NGS of miRNAs from EDTA-plasma samples was performed by Exiqon. Briefly, RNA was isolated following quality control by RT-qPCR. Next, the miRNA library was prepared, followed by quality control *via* RT-qPCR and bioanalyzer. Finally, miRNAs were sequenced on a Nextseq500 (Illumina, San Diego, CA, United States) with 10 million reads per sample and 50 nucleotide single-end read. The annotation reference used was miRBase 20 (http://mirbase.org/). In the following data analyses, the reads were mapped and classified based on their sequence as: (1) Known miRNA; (2) Predicted (putative) miRNA; (3) Outmapped; (4) Unmapped; (5) Genome; and (6) Small RNA. In the NGS report from Exiqon, putative miRNAs were described as miRNAs predicted from the sequences that do not map to any organism found in miRBase or to other known RNA sequences. miRPara was used to analyze the potential folding of these sequences[32]. These results were combined to identify putative novel miRNAs. The differential expression analyses were done using the trimmed mean of M-value normalization method in the EdgeR statistical software package.

Putative miRNA primer design

For the evaluation of the putative miRNA (put-miRs), the following RT-qPCR primers were designed using the Exiqon tool for primer design: put-miR-25, put-miR-46, put-miR-56, put-miR-66, put-miR-79, put-miR-99, put-miR-83, put-miR-86, put-miR-91, put-miR-100, put-miR-118 and put-miR-128. Three primer sets for each put-miR were tested in the three EDTA-plasma samples that had shown the highest expression for the respective put-miR in NGS. The put-miRs that showed a cycle threshold (Ct) lower than 35 were selected for clinical validation. The primer set with the lowest Ct of all three primer sets was used for the following RT-qPCR analyses. Details on the put-miRs and their corresponding chromosome location, chromosome strand, start and stop position, sequence and primer design-IDs from Exiqon can be found in the Supplementary materials (Supplementary Table 2).

Reverse transcription and RT-qPCR

Reverse transcription and RT-qPCR were carried out using the Universal complementary DNA synthesis kit II for reverse transcription and the ExiLENT SYBR Green master mix kit for RT-qPCR (Exiqon) according to the manufacturer's protocol. For quality control, spike-ins UniSp6 and cel-miR-39-3p from the miRCURY LNA Universal RT microRNA PCR, RNA Spike-in kit were added to all samples prior to reverse transcription. RT-qPCR analysis was performed for: (1) Individual miRNA primer sets; (2) Commercially available predefined ready-to-use panels: Human miRNome panel I and II, V4 which included primers for 752 known miRNAs; and (3) Customized ready-to-use panels [all primer sets and panels from miRCURY LNA Universal RT microRNA PCR Biofluids (Exiqon)]. RT-qPCR was performed on a LightCycler® 480 (Roche Diagnostics International Ltd, Rotkreuz, Switzerland). The following modifications to the manufacturer's protocol were made: (1) In both customized and predefined ready-to-use panels the amount of complementary DNA was doubled; and (2) After adding the PCR mastermix-complementary DNA mix to each well and centrifuging the plate, the reagents in the plate were mixed on a shaker for 20 s and then centrifuged again.

Normalization and miRNA expression

Pre-processing of RT-qPCR data from the ready-to-use and customized panels was done using GenEx (MultiD Analyses AB, Gothenburg, Sweden) following the Exiqon Data Analysis Guide for the miRCURY LNA Universal RT microRNA Ready-to-Use PCR panels, V3. All Ct values < 35 were considered valid and included in further analyses. Normalization was done by applying the global mean (Human miRNome panel I and II, V4) or by normalizing to the expression of reference genes (customized panels). When conducting RT-qPCR analysis with only a small number of miRNAs, global mean normalization was not applicable. Therefore, a normalization to endogenous control miRNAs that show equal expression throughout all sample groups was necessary. Reference genes for normalization of customized panels were selected with GenEx NormFinder software by comparing their standard deviation (SD) and accumulated SD (accumulated SD = $\frac{1}{n}\sqrt{\sum_{i=1}^{n} SD_i^2}$. Relative miRNA expression was calculated using a $2^{-\Delta\Delta Ct}$ method.

Serum protein assays measurements

AFP and PIVKA-II were measured using microchip capillary electrophoresis and a liquid-phase binding assay on the uTASWako i30 automated analyzer (Fujifilm Wako Pure Chemical Industries, Osaka, Japan).

Biostatistical analyses

The statistical methods and analyses of this study were performed and reviewed by biostatisticians Dr. Martin Klammer and Vinzent Rolny of Roche Diagnostics GmbH.

Univariate analysis

For each miRNA, two-sample Wilcoxon rank-sum testing was performed, and the *P* value was reported. Subsequently, the *P* values were corrected by means of Benjamini-Hochberg false discovery rate correction to account for multiple hypothesis testing (referred to as '*Q*-values' in the tables).

In the initial global discovery of differentially expressed miRNAs, the raw *P* values (without false discovery rate correction) were used. Here, a higher false-positive rate was deliberately accepted for the sake of minimizing the risk of missing a potential biomarker candidate (*i.e.*, minimizing the false-negative rate).

Multivariate analysis

To discover the optimal bivariate biomarker combination and reliably estimate its performance in future samples, a two-tier cross-validation workflow employing logistic regression was established. In the first (outer) tier with 200 Monte-Carlo cross-validation runs, the data set was randomly split into training and test set (80% and 20%, respectively) in each run, while maintaining the ratio of cases and controls. The optimal feature combination was then searched for in the second (inner) tier with five-fold cross-validation, where the training data were again split into an inner training and an inner test set. All possible two-marker combinations (exhaustive search) were then assessed by training a logistic regression model on the inner training data containing only information of the respective two markers (inner selected training data) and testing their performances by means of area under the curve (AUC) of the receiver operating characteristics curve with the respective inner test set (inner selected test data). The combination showing the best inner cross-validation results (*i.e.*, maximum mean AUC across the five cross-validation runs) was then selected and used to train a model in the outer tier. As with the inner tier, logistic regression was used, and the performance of the test set (selected test data) for each of the 200 Monte-Carlo cross-validation runs was then assessed; the mean AUC represented the estimated overall performance.

Since the feature selection procedure was part of the outer cross-validation tier, it was possible that different marker pairs were selected in the 200 Monte-Carlo cross-validation runs. However, it was necessary to select the one pair that would be used to train a model to predict future samples. This was achieved by subjecting the entire data set to the inner cross-validation tier (not only the training data, as was done for the performance evaluation) and receiving the final biomarker pair, which was subsequently used to train the final logistic regression model on the entire data set (Figure 2).

In the case of searching for a miRNA that best complements the protein marker (AFP or PIVKA-II), the protein marker itself was fixed as first feature in the feature selection process, and the optimal partner was determined as described above.

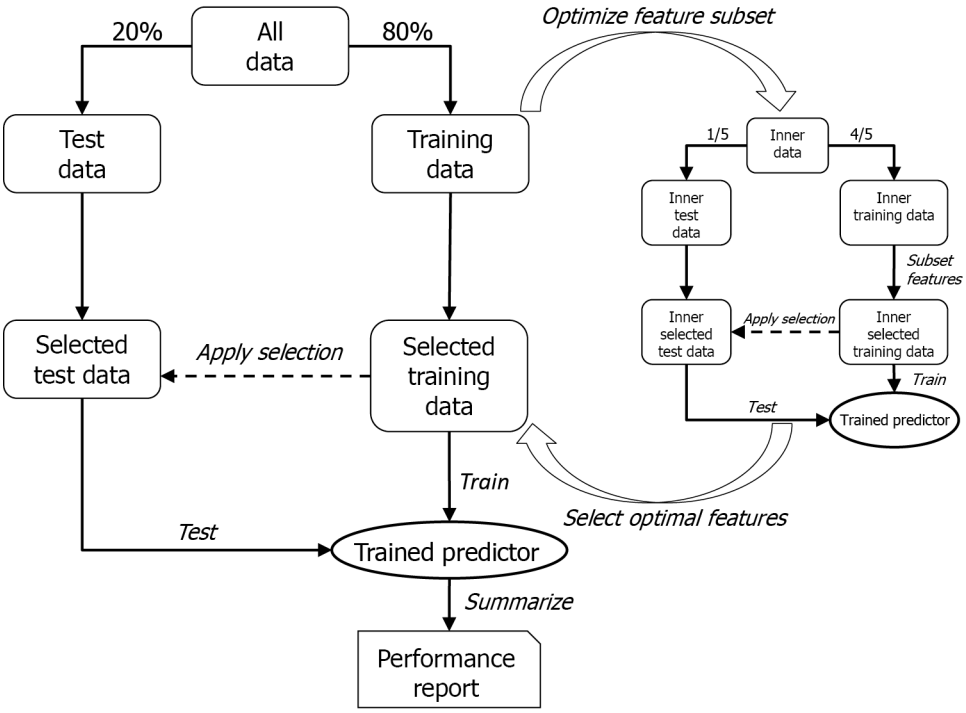
RESULTS

Analysis of differentially expressed miRNAs yielded 26 potential biomarker candidates

To find a suitable biomarker for the (early) diagnosis of HCC, a large number of miRNAs were screened, using two independent methods: RT-qPCR (752 predefined miRNAs) and NGS (resulting in 244 miRNAs). We analyzed whether miRNAs were differentially expressed between a group with (early stage) HCC and a control group with CLD (including patients with hepatitis B, hepatitis C and cirrhosis). The miRNAs identified in the screening were then analyzed as potential biomarkers for (early) diagnosis of HCC in an independent training panel using RT-qPCR and validated in an independent panel.

Global miRNome analysis of miRNAs by NGS and human miRNA panels

Compared with RT-qPCR, NGS can identify all known and unknown miRNAs. First, miRNA was isolated from the plasma of 60 patients from the CLD control group (HBV, HCV and cirrhosis; see Supplementary Table 1) and 40 patients from the HCC groups (early and late stages), followed by a quality control *via* RT-qPCR. Six control samples did not pass the quality control and were excluded from NGS. Illumina Nextseq500 sequencing of the prepared library produced an average of 10.9 million accepted reads per sample. After data analysis, two additional outlier control samples were identified and excluded from further analysis. The miRNA expression was compared for the following groups: all HCC *vs* CLD and early HCC *vs* CLD, for known and unknown miRNAs, respectively (Supplementary Table 3). The 13 miRNAs with the smallest *P* value, highest AUC and largest fold change (approximately 1.2 or higher) were selected for validation *via* RT-qPCR (Table 1).



In the second discovery approach, RT-qPCR panels of preassigned assays for 752 known human miRNAs were applied for the screening of miRNA expression. miRNAs were investigated in the

independent sample panel (n = 60, see Supplementary Table 1). After global mean normalization, the miRNA expression was compared between the following groups: (1) All HCC *vs* CLD; and (2) Early HCC *vs* CLD (Supplementary Table 4). The 16 miRNAs with the smallest *P* value, highest AUC and largest fold change were selected for further analysis *via* RT-qPCR (Table 1). The AUCs and fold changes for the comparison of early HCC *vs* CLD were generally higher than the AUCs and fold changes when comparing all HCC *vs* CLD. Twenty-six miRNAs with the highest AUCs and fold changes, resulting from both discovery methods, were selected for further evaluation. Three miRNAs,

Figure 2 Overview of the two-tier cross-validation workflow employing logistic regression.

hsa-miR-320a (miR-320a), hsa-miR-421 (miR-421) and hsa-miR-21-5p (miR-21-5p), were identified by both independent methods (Supplementary Table 3).

Selection of five endogenous control miRNAs for normalization

The 26 selected miRNAs were then analyzed by RT-qPCR in an independent sample panel. As the number of examined miRNAs was very small, the normalization could not be based on the global mean value, which was used for the screening. To select endogenous miRNAs that could be used for normalization, GenEx software (MultiD) was used. Five miRNAs with the lowest SD and SDacc, hsa-let-7i-5p, hsa-miR-222-3p, hsa-miR-23a-3p, hsa-miR-30e-5p and hsa-miR-191-5p, were selected as endogenous controls for normalization (Table 2).

Putative miRNA primer selection

During NGS, sequences that could be potential miRNAs based on their length and structure were identified (= put-miR; Supplementary Table 2). Some showed different expression between the all/early-stage HCC and CLD groups. The 15 potential miRNAs with the smallest *P* values, highest AUCs and largest fold changes detected in the NGS were validated by RT-qPCR in an independent sample panel. For all 15 put-miRs identified, the three plasma samples with the highest expression of the respective put-miR in the NGS were selected, and RNA was isolated with the miRCURY isolation kit and subject to RT-qPCR analysis. In the RT-qPCR, two put-miRs (put-miR-6 and put-miR-99) reached Cts below the cut-off of 35, and their best primer pairs showed a mean Ct of 33.54 (put-miR-6) and 34.17 (put-miR-99). The remaining 13 put-miRs showed no expression. Put-miR-6 and put-miR-99 were further analyzed in the training and validation cohorts (Table 1).

RT-qPCR analysis of training cohort: univariate analysis

The 26 (24 known and 2 putative) miRNAs showing the best diagnostic performance and expression fold change in the NGS and RT-qPCR analysis (Table 1) were further validated by RT-qPCR in two independent sample panels: training cohort (200 samples) and validation cohort (300 samples). From the 24 previously selected known miRNAs, only three candidates (miR-21-5p, miR-320a and miR-186-5p) revealed themselves as potential biomarkers through both NGS and RT-qPCR analysis. miRNAs were analyzed alone (univariate) and as a combination of several miRNAs (signature, multivariate). miRNAs were also combined with known protein markers PIVKA-II and AFP (multivariate).

The training cohort consisted of the following plasma samples: HCC group (48 early stage and 52 late stage) and control group (100 HCV and HBV patients with and without cirrhosis). When comparing all HCC *vs* CLD controls in a univariate analysis, three miRNAs, namely miR-21-5p, hsa-miR-320d (miR-320d) and hsa-miR-423-5p (miR-423), could significantly distinguish ($Q < 0.05$) between those two groups (Table 3, Supplementary Figure 1).

Table 2 Individual standard deviation and accumulated standard deviation for consecutive microRNA reference genes

miRNA	SD	SD_{acc}
hsa-let-7i-5p	0.49	0.49
hsa-miR-222-3p	0.57	0.37
hsa-miR-23a-3p	0.63	0.33
hsa-miR-30e-5p	0.65	0.29
hsa-miR-191-5p	0.79	0.28

The lower the standard deviation/accumulated standard deviation, the more applicable microRNA/microRNA combination was as reference gene. These miRNAs were used as endogenous controls for the normalization of real-time quantitative PCR data. SD: Standard deviation; SD_{acc}: Accumulated standard deviation; miRNA: MicroRNA; miR: MicroRNA.

For the comparison of early HCC *vs* CLD, none of the 26 miRNAs could significantly distinguish between early HCC and the control group. After a refined analysis of the control groups, hsa-miR-652-3p (miR-652) demonstrated itself to be a marker significantly distinguishing early HCC from the cirrhosis group (mixed HBV and HCV) (Table 3, Supplementary Figure 1).

RT-qPCR analysis of training cohort: multivariate analysis and combination with protein biomarkers

A combination of several miRNAs did not perform better than the single miRNAs (data not shown). MiRNA marker candidates from the univariate analysis of all HCC *vs* CLD were then combined with the protein marker PIVKA-II, which is a widely used marker for HCC[33]. As a result, two-tier cross-validation workflow (see Methods for details) was established, which employed logistic regression and combined two features (PIVKA-II and one of the 26 miRNAs) repeatedly to investigate the potential improvement of the diagnostic performance of PIVKA-II alone. The combined approach resulted in a higher AUC and specificity at 90% sensitivity than PIVKA-II or miR-21-5p alone (Table 4, Supplementary Figure 2A). miR-21-5p was selected as the best PIVKA-II partner in 86% of the cross-validation runs (Table 5), and PIVKA-II + miR-21-5p was selected as the final biomarker pair.

In the next step, the specificity of the combined approach was tested for early HCC *vs* CLD. The three best partners for PIVKA-II were miR-21-5p in 60%, miR-320d in 18% and miR-652 in 16% of the cross-validation runs (Table 5, Supplementary Figure 2B), and PIVKA-II + miR-21-5p was selected as the final biomarker pair.

For the differentiation between early HCC and cirrhotic control patients, the AUC and specificity at 90% sensitivity of the combination PIVKA-II with miRNAs was higher than for single markers (Table 4, Supplementary Figure 2C). The two best miRNA partners for PIVKA-II were miR-652 in 64% and hsa-miR-221 in 26% of the cross-validation runs (Table 5), and PIVKA-II + miR-652 was selected as the final biomarker pair.

The multivariate analyses of the miRNA marker candidates combined with protein marker AFP did not show any improvement in diagnostic performance (Supplementary Figure 3).

RT-qPCR analysis of validation cohort: univariate analysis

The validation cohort consisted of the following plasma samples: all HCC group (71 early stage and 79 late stage) and CLD control group [63 cirrhosis (HBV, HCV), 59 HBV and 28 HCV). When comparing all HCC *vs* CLD, miR-21-5p and miR-423 were confirmed as possible biomarker candidates for the diagnosis of HCC. The performance of miR-21-5p was slightly worse in the validation cohort compared with the training cohort; miR-423 performance remained almost unchanged. The results from the training cohort for miR-320d could not be confirmed (Table 6, Supplementary Figure 4).

For the comparison of early HCC *vs* CLD with cirrhosis, miR-652 could not be confirmed as a possible biomarker, as seen in the training cohort (Table 6, Supplementary Figure 4).

RT-qPCR analysis of validation cohort: multivariate analysis and combination with protein biomarkers

As no combination of miRNAs could be identified in the training analysis, only PIVKA-II + miRNA combinations were validated here. However, the performance of PIVKA-II as a single marker could not be improved through combination with miRNAs selected in the training cohort for all data sets (Figure 3).

No confirmation of put-miRs as potential biomarkers for HCC

Put-miRs (put-miR-6 and put-miR-99) were tested in the training and validation panels. Put-miR-6 could only be detected in 2 samples, with a Ct of 31.24 in 1 of 200 samples in the training panel and a Ct of 34.00 in 1 of 300 samples in the validation panel. Put-miR-99 Cts between 34.00 and 34.97 (mean value

DISCUSSION

HCC is a severe disease of the liver and one of the leading causes of cancer-related deaths worldwide [5]. As with all other cancers, early detection is crucial for successful treatment. Recommended detection methods include US, CT, magnetic resonance imaging and measurement of AFP and PIVKA-II. However, these methods are either cost-intensive, operator-dependent or not suitable for the detection of early HCC[6-8,11-13,15]. Previous publications show that single miRNAs, like miR-21, hsa-miR-26a and hsa-miR-101[34,35], as well as miRNA signatures (*e.g.*, hsa-miR-3677, miR-421, hsa-miR-326, hsa-miR-424 and hsa-miR-511-2)[36,37] can improve detection of HCC. While these results are promising, the studies were conducted in small cohorts and/or the control group included healthy individuals who were not being screened regularly for HCC.

CLD: Chronic liver disease; HCC: Hepatocellular carcinoma; PIVKA-II: Protein induced by vitamin K absence/antagonist-II; miR: MicroRNA.

Therefore, we carried out a comprehensive, prospective, multicenter, case-control study including patient samples with early-stage (n = 147) and late-stage HCC (n = 160), HBV (n = 136), HCV (n = 72) and cirrhosis with HBV and HCV (n = 145). We analyzed plasma samples to evaluate the utility of circulating miRNAs alone and in combination with two established protein markers, PIVKA-II and AFP, as biomarkers for detection (including early detection) of HCC and performed multivariate analysis on the included miRNAs. When compared with other studies of circulating miRNAs, our study is unique for the following reasons. First, we screened a large number of plasma miRNAs *via* NGS and RT-qPCR, which enabled us to identify potential diagnostic markers independently of the detection method. Second, we included early-stage and late-stage HCC and for the control cohort included HBV and HCV patients with and without cirrhosis to find a miRNA that can diagnose HCC at an early stage and to validate a biomarker that would be applicable for most of the at-risk population. Third, we used a large sample size of 660 samples with four different independent sample panels to increase statistical power. Finally, we employed an empirically validated set of endogenous reference genes for the normalization of our data.

To find reliable miRNA biomarkers for HCC that were unbiased with respect to the detection method, we followed two different screening approaches (RT-qPCR and NGS) to assess a large number of miRNAs isolated from patient plasma. For each method, we used a different set of plasma samples to receive reproducible results by two independent techniques in a large set of samples. These factors

could explain why we obtained only three miRNAs (miR-21-5p, miR-320a and miR-421) that showed high potential as diagnostic biomarkers for HCC in both screening approaches.

The 26 best miRNAs selected by both screening methods, including the three overlapping miRNAs, were then analyzed in two different sample panels (training and validation) and combined with the established protein markers PIVKA-II and AFP. In the training panel, miR-21-5p, miR-320d and miR-423 were the best single markers for distinguishing between the HCC and CLD groups. For the early detection of HCC, our data showed that miR-21-5p has the potential to improve the diagnostic performance of PIVKA-II. In the validation panel, the results from the training panel for the comparison of HCC *vs* CLD for miR-21-5p (AUC = 0.65) and miR-423 (AUC = 0.59) could be confirmed. However, the hypothesis of finding a miRNA signature specific for the detection of early HCC could not be confirmed, and the combination of all 26 miRNAs and AFP did not reveal greater diagnostic potential than AFP alone.

MiR-21-5p was one of the two miRNAs with significantly higher expression in the HCC group compared with the CLD group in both the training and validation cohorts. Other publications have shown similar results. Amr *et al*[38] demonstrated that the expression of serum miR-21 was increased in HCC compared with chronic hepatitis, while Gedawya *et al*[39] revealed overexpression of plasma miR-21 in an HCC group ($P < 0.05$) compared with both CLD and healthy subjects from a cohort in Egypt. However, miR-21 was also reported as a circulating diagnostic biomarker for various other cancers[40] such as breast cancer[41], glioma[42] and non-small cell lung cancer[43]. MiR-21 has been described as an oncogene, targeting tumor suppressors like TP63, TP53, TGF-β and PTEN, leading to the inhibition of apoptosis[44,45]. Furthermore, miR-21 contributes to the epithelial-to-mesenchymal transition in cervical cancer by modulating the expression of the *Rasa1* gene (RAS p21 protein activator 1). Therefore, by indirectly influencing the activity of Ras, miR-21 contributes to the migration potential of these cells. Another described oncogenic effect is that miR-21 modulates angiogenesis in prostate cancer cells[46]. Thus, the underlying biology of miR-21 supports its role in HCC development and its potential diagnostic value in HCC as well as other cancers.

MiR-423 also showed differential expression when comparing HCC and CLD in both the training and validation groups. Previously, it was revealed that the expression of miR-423 was significantly increased in HCC tissues compared with adjacent normal tissues[47,48]. In serum samples from HCC patients, miR-423 was also found to be significantly upregulated compared with a control group consisting of patients with cirrhosis or chronic hepatitis[49]. In the training and validation panels (total of 500 independent samples), miR-423 levels were elevated in the HCC group. MiR-423 expression has also been found to be upregulated in breast cancer tissue[50], human prostate cancer tissues and prostate cancer PC3 cells[51] and plasma of patients with oral squamous cell carcinoma[52]. This indicates that miR-423 is not limited to the detection of HCC and can also detect several other cancer types. It can act as an oncogene by enhancing the proliferation and migration of gastric cancer cells *in vitro* and *in vivo* when overexpressed[53]. Furthermore, when knocking down miR-423, proliferation of PC3 cells was inhibited, and apoptosis was promoted[51]. In summary, although miR-21 and miR-423 are upregulated in several diseases, their overexpression in a high-risk population could be indicative of early HCC development.

Our results indicate that miR-320d and miR-652 might not be robust biomarkers to diagnose (early) HCC as the results from the training cohort could not be validated. However, they seem to play a role in the development of cancer in general, which requires further investigation.

The 15 putative miRNAs detected by NGS in the screening phase that were differentially expressed between HCC and CLD could not be confirmed as potential biomarkers by RT-qPCR in the training and validation panel. Nonetheless, they could be detected in a small number of samples by both NGS and RT-qPCR. Though the putative miRNAs only showed a relatively low expression, they could be novel miRNAs and should be considered in further investigations.

In the training panel, the combination of the HCC biomarker PIVKA-II with the 26 miRNAs selected in the screening phase improved diagnostic capability, and AUC was increased compared with PIVKA-

II alone. However, this could not be confirmed in the validation panel, which included more samples than the training panel. The combination of AFP and miRNA also did not show any improvement in AFP diagnostic capability in the training panel and was therefore not analyzed in the validation panel. We observed that individual miRNAs identified the same set of patients as those identified by AFP, thus the miRNAs did not add any significant value in this case. However, as the performance of PIVKA-II in the same cohort was between 5% and 20% lower than the performance of AFP, the miRNAs therefore had higher additive value when combined with PIVKA-II. Our results demonstrate that the protein markers AFP and PIVKA-II are more robust biomarkers for HCC than miRNAs.

CONCLUSION

In conclusion, our study found that two miRNAs (miR-21-5p and miR-423) demonstrated significant differential expression between the HCC group and CLD control group. However, the combination of miRNAs with established protein biomarkers (AFP and PIVKA-II) did not improve diagnostic performance of either protein. Further investigation of the molecular mechanisms by which miRNAs, specifically miR-21-5p and miR-423, support HCC development may help in diagnosing and treating this highly malignant tumor.

ARTICLE HIGHLIGHTS

Research background

Hepatocellular carcinoma (HCC) is the sixth most common cancer worldwide and a leading cause of cancer-related mortality. Current guidelines recommend the surveillance of high-risk patients every 6 mo using ultrasonography, but early-stage HCC detection is limited.

Research motivation

Previous reports show that the expression level of human microRNAs (miRNAs) can serve as an early marker for HCC, even outperforming established biomarkers like alpha-fetoprotein (AFP) and protein induced by vitamin K absence/antagonist-II (PIVKA-II).

Research objectives

To evaluate the diagnostic role of miRNAs in HCC as single markers, signatures or in combination with known protein biomarkers AFP and PIVKA-II in a prospective, multicenter, case-control study.

Research methods

We employed two independent methods, real-time quantitative PCR and next-generation sequencing, to investigate miRNAs levels in the discovery cohort of 160 HCC and control patients. Selected miRNAs were subsequently analyzed for their univariate and multivariate performance in independent training (n = 200) and validation cohorts (n = 300).

Research results

Real-time quantitative PCR and next-generation sequencing identified 26 miRNAs differentiating between HCC and chronic liver disease controls. Three miRNAs (miR-21, miR-320a and miR-186-5p) were selected by both methods. In the training cohort, only miR-21, miR-320d and miR-423 could significantly distinguish (Q < 0.05) between the HCC and control groups. In the multivariate setting, miR-21 with PIVKA-II was selected as the best combination, resulting in an area under the curve of 0.87 for diagnosis and 0.74 for early diagnosis of HCC. miR-21 and miR-423 were confirmed as potential HCC biomarkers in the validation cohort. A combination of miRNAs did not perform better than any single miRNA. Improvement of AFP or PIVKA-II performance through combination with miRNAs was not confirmed in the validation panel.

Research conclusions

Selected miRNA candidates in standalone or signature settings or in combination with biomarkers AFP and PIVKA-II did not improve the diagnostic performance of the protein biomarkers in identification of early-stage HCC.

Research perspectives

Diagnostic superiority of microRNAs for detection of early HCC could not be confirmed, which was primarily due to the excellent and robust performance of the protein biomarkers AFP and PIVKA-II for this intended use. Therefore, miRNAs still carry diagnostic potential for application in other oncological diseases.

Abstract

BACKGROUND

Biliary decompression is well known to greatly decrease the risks of mortality in acute cholangitis (AC). Although early biliary drainage is recommended by the treatment guidelines for AC, the best time for performing this procedure is yet to be established. Furthermore, since the clinical outcomes of patients with severe AC vary dramatically, screening for patients that could benefit the most from early drainage would be more beneficial than the drainage performed based on the severity grade criteria.

AIM

To investigate the optimal drainage timing for AC patients with each disease severity grade and organ dysfunction.

METHODS

In this retrospective monocenter cohort analysis, we reviewed 1305 patients who were diagnosed with AC according to the Tokyo guidelines 2018 at a Chinese tertiary hospital between July 2016 and December 2020. Demographic characteristics including age and sex, clinical and laboratory characteristics, and imaging findings of each patient were obtained from electronic medical records. We investigated the all-cause in-hospital mortality (IHM), hospital length of stay (LOS), and hospitalization costs associated with the timing of biliary drainage according to the severity grading and different dysfunctioning organs and predictors [age, white blood cell (WBC) count, total bilirubin, albumin, lactate, malignant obstruction, and Charlton comorbidity index (CCI)].

RESULTS

Biliary drainage within 24 or 48 h in Grade III AC patients could dramatically decrease IHM (3.9% *vs* 9.0%, $P = 0.041$; 4% *vs* 9.9%, $P = 0.018$, respectively), while increasing LOS and hospitalization costs. Multivariate logistic analysis revealed that neurological, respiratory, renal, and cardiovascular dysfunctions, hypoalbuminemia, and malignant obstruction were significantly associated with IHM (odds ratio = 5.32, 2.541, 6.356, 4.021, 5.655, and 7.522; $P < 0.001$, $P = 0.016$, $P < 0.001$, $P = 0.012$, $P < 0.001$, and $P < 0.001$; respectively). Biliary decompression performed within 12 h of admission significantly decreased the IHM in AC patients with neurological dysfunction (0% *vs* 17.3%, $P = 0.041$) or with serum lactate > 2 mmol/L (0% *vs* 5.4%, $P = 0.016$). In the subgroup of AC patients with renal dysfunction, abnormal WBC count, hyperbilirubinemia, or hypoalbuminemia, early drainage (< 24 h) reduced the IHM (3.6% *vs* 33.3%, $P = 0.004$; 1.9% *vs* 5.8%, $P = 0.031$; 1.7% *vs* 5.0%, $P = 0.019$; 0% *vs* 27%, $P = 0.026$; respectively). The IHM was lower in patients with AC combined with hepatic dysfunction, malignant obstruction, or a CCI > 3 who had undergone biliary drainage within 48 h (2.6% *vs* 20.5%, $P = 0.016$; 3.0% *vs* 13.5%, $P = 0.006$; 3.4% *vs* 9.6%, $P = 0.021$; respectively).

CONCLUSION

Biliary drainage within 12 h is beneficial for AC patients with neurological or cardiovascular dysfunction, while complete biliary decompression within 24 h of admission is recommended for treating patients with Grade III AC.

Key Words: Acute cholangitis; Endoscopic retrograde cholangiopancreatography; Mortality; Biliary drainage; Organ dysfunction

Core Tip: This study aimed to investigate the optimal timing of drainage for patients with acute cholangitis (AC) with each grade and organ dysfunction. We first attempted to study whether AC patients with different organ dysfunction should undergo biliary drainage at distinct times. We believe that our study makes a significant contribution to the literature because we found that patients with severe AC should complete biliary decompression within 24 h of admission, while biliary drainage within 12 h was beneficial for AC patients with neurological or cardiovascular dysfunction.

INTRODUCTION

Acute cholangitis (AC) is a life-threatening condition that occurs in the presence of biliary obstruction. Although growing evidence confirms that biliary decompression can dramatically decrease the mortality rates associated with AC, the optimal time for biliary drainage remains controversial[1-3]. Most experts agree that the timeframe for biliary decompression is distinct for different severity grades based on the Tokyo guidelines 2018/2013 (TG18/13), which recommend early biliary drainage for Grade II AC and urgent biliary drainage for Grade III AC; however, the exact timeframe is unclear[4]. Moreover, the 2019 European Society of Gastrointestinal Endoscopy guidelines recommend biliary drainage as soon as possible in patients with Grade III AC and within 12 h for patients with septic shock, while within 48–72 h for patients with Grade II AC[2]. Meanwhile, the 2021 American Society of Gastrointestinal Endoscopy (ASGE) guidelines suggest endoscopic retrograde cholangiopancreatography (ERCP) within 48 h in AC patients, regardless of severity[1]. Some studies have demonstrated a "the earlier, the better" approach for the management of AC cases[5-8]. They deemed urgent biliary decompression necessary in severe cases. However, other studies have shown that ERCP can be safely delayed to allow for sufficient resuscitation[9-11]. In our clinical experience, the severity of Grade III AC varies dramatically, and we have observed that the optimal timing of biliary decompression may vary for different organ injuries.

So far, no relevant study has determined whether the clinical outcomes of Grade III AC patients vary with different organ injuries and whether AC patients with different organ dysfunction should undergo biliary drainage at distinct times. Consequently, this single-center retrospective study aimed to

investigate the relationship between drainage timing and in-hospital mortality (IHM) in patients with AC of different severities, and attempted to stratify patients with AC to identify the best decompression time.

MATERIALS AND METHODS

Patients

Ethical compliance: This retrospective cohort study was conducted according to the tenets of the Declaration of Helsinki, and approved by the Bioethics Committee of Beijing Friendship Hospital, Capital Medical University (Certification No. 2020-P2-224-01). After the review conducted by the Ethics Committee, the need for informed consent was waived.

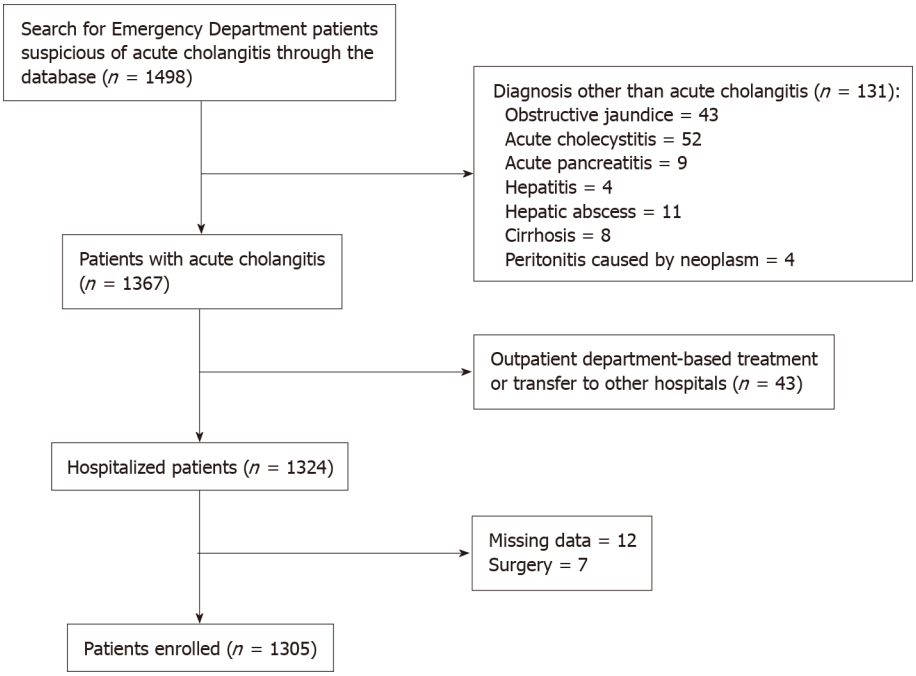
Sample size: Based on the pre-experimental results, which revealed a 0.87% and 3% mortality rates for patients who did and did not undergo biliary drainage, respectively, we calculated the sample size using PASS 15.0 with Power = 0.8, Alpha = 0.05, and N1 = N2. The resultant sample size was 1306. On this basis, we expanded the sample size by 15% to exclude the reduction caused by data deficiency or diagnostic errors.

Enrollment: We searched the electronic medical record database of the Beijing Friendship Hospital for all adult (> 18 years) non-pregnant patients visiting the Emergency Department (ED) between July 2016 and December 2020 who were discharged with a diagnosis of AC. A total of 1498 patients were included in the study. All the medical records were reviewed and a diagnosis of AC was confirmed according to the TG18 diagnostic criteria[12]. Besides pregnant women and patients aged < 18 years, we also excluded patients transferred to other hospitals or outpatient departments for treatment and patients whose medical data were incomplete or missing. Finally, 1305 patients were enrolled (Figure 1).

Data collection

Demographic data, including age and sex, were obtained for each patient. Clinical data, laboratory characteristics, and imaging findings were obtained from the electronic medical records. Clinical data included vital signs, fluid output, Glasgow coma score, the vasoactive drug dose, history of biliary disease, Charlton comorbidity index (CCI), etiology of AC, registration time at the ED, time and type of drainage, discharge time, complications of drainage, hospitalization cost, and IHM. Laboratory findings included white blood cell (WBC) count, platelet count, total bilirubin, albumin, aspartate transaminase, alanine transaminase, creatinine, amylase, prothrombin time-international normalized ratio, arterial blood oxygen pressure, and lactate. Computed tomography, magnetic resonance cholangiopancreatography, or ERCP findings were reviewed to determine the etiology of cholangitis. The time interval for biliary drainage was calculated as the difference between ED registration time and the time of ERCP or percutaneous transhepatic biliary drainage (PTBD). We used the TG18 severity criteria for grading the severity[12].

Definition and indications



Benign stenosis was defined as stenosis in the biliary ducts without radiological findings of metastasis or malignant cells on histological examination. The indications of ERCP were AC combined with persistent extrahepatic biliary obstruction, and cases of anatomical derangement, failed ERCP, intrahepatic biliary obstruction underwent PTBD. The contraindications of ERCP included acute coronary syndrome, acute heart failure (New York Heart Association class III-IV), acute stroke occurring within 2 wk prior to enrollment, and acute pulmonary embolism complicated with the arterial PaO_2 <60 mmHg, while the contraindications of PTBD were platelet count < 50000/mm^3 or prothrombin activity < 60%. The adverse effects after drainage were based on the lexicon guidelines of the ASGE[13]. The second treatment included a second ERCP and a second PTBD for stone removal or stent placement. The need for a second therapeutic ERCP was assessed per the discretion of the experienced operators who performed the intervention and based on 2018 ERCP Guidelines for China[14]. All of the endoscopists had independently completed 300 ERCP interventions per year for 3 years.

Study outcomes

Our primary outcome was IHM, and the secondary outcomes were hospital length of stay (LOS) and hospitalization costs. When analyzing the survivors' LOS and entailed cost, we excluded patients who died or were transferred to other hospitals. We investigated the primary and secondary outcomes relevant to the timing of biliary drainage according to severity grading and some predictors based on TG18 and other previous studies.

Statistical analysis

Continuous variables were reported as medians with interquartile ranges (IQR) for not normally distributed; categorical variables were expressed as numbers and percentages. Comparisons between

DOI: 10.3748/wjg.v28.i29.3934 **Copyright** ©The Author(s) 2022.

Figure 1 A flowchart of the study population.

groups for continuous variables were evaluated using the Kruskal–Wallis test and Mann–Whitney *U* test, and for categorical variables, Fisher's exact test was used. Univariate logistic regression analysis and multivariate logistic regression with stepwise variable selection were used to analyze the relationship between organ dysfunction or predictors and IHM. Odds ratios (ORs) and 95% confidence intervals were calculated. Statistical significance was set at $P < 0.05$. Statistical analyses were conducted using SPSS v22.

RESULTS

The characteristics of the study population are shown in Tables 1 and 2. This cohort included 1305 patients, the majority of whom were men (60%). The median age of the group was 74 years (IQR, 63-82 years), and patients with Grade I AC were significantly younger ($P < 0.001$). The CCI of individuals with Grade III cholangitis was significantly higher than that of patients with Grade I or II cholangitis ($P < 0.001$). Choledocholithiasis (69.4%) was the most common cause of cholangitis, followed by malignant obstruction (18.5%). Among patients with cholangitis caused by malignancy, the number of patients with Grade II cholangitis was higher than that of patients with Grade I or III cholangitis. More patients with Grade II AC underwent biliary decompression ($P = 0.006$), while the IHM and hospitalization costs were significantly higher in the Grade III AC group than in the Grade I and II AC groups (IHM: $P < 0.001$, hospitalization costs: $P < 0.001$). Deaths tended to occur earlier in the disease course in patients with Grade III AC (median time 6 d).

A total of 915 patients in this cohort (70.1%) underwent biliary decompression, most of whom underwent endoscopic interventions (90.7%), while more patients underwent PTBD in the severe AC groups (Grade II: 37 cases, Grade III: 35 cases *vs* Grade I: 13 cases, $P = 0.001$). One hundred and sixty patients with Grade III were treated with antibiotics and fluid infusion only (disagreement about procedures = 35 cases, including two of mortality; with contraindications = 24 cases, including five of death; not tolerable conditions = 14 cases, including eight of death; obstruction spontaneous relief = 67 cases, including seven of mortality; not persistent biliary obstruction with high risk to stone removal by ERCP = 15 cases without death; not persistent biliary obstruction with selective cholecystectomy = five cases without death). The median drainage time was 24 h. Nearly half of the patients underwent biliary drainage within 24 h (445/915, 48%), while 89 patients with Grade III underwent drainage within 12 h (29%), which was significantly higher than that in Grades I and II ($P = 0.04$). Among the patients who underwent biliary drainage, more patients in Grade III underwent biliary drainage outside regular working hours (31.9%) and 478 patients (52.2%) required a second intervention for stone removal or stent placement, which exhibited no relationship with severity ($P = 0.688$). Post-ERCP pancreatitis was the major adverse event (8.2%), and the incidence of adverse events was not significantly different among the three severity grades.

IQR: Interquartile range; CCI: Charlton Comorbidity Index; LOS: Length of stay; CNY: Chinese Yuan; IHM: In-hospital mortality; WBC: White blood cell count; T-Bil: Total bilirubin.

The association of the IHM, LOS, and hospitalization costs with the timing of biliary drainage in each severity grade has been presented in Table 3. Biliary drainage significantly decreased the IHM in all AC patients (13/915 *vs* 28/390, $P < 0.001$). Among individuals with Grade III cholangitis, the IHM rate was significantly decreased in patients who had biliary drainage within 24 h or 48 h ($P = 0.041$, $P = 0.018$), while the LOS was significantly increased among those patients who underwent drainage within 12 h, 24 h, or 48 h ($P < 0.001$, $P < 0.001$, and $P < 0.001$, respectively). Hospitalization costs significantly increased for all patients with biliary drainage, regardless of severity criteria. For patients with Grade I AC, IHM was not affected by the timing of drainage and there was no relationship between LOS and the timing of biliary drainage for the survivors, but LOS was significantly extended in all the patients who underwent biliary drainage within 24 h or 48 h ($P = 0.004$, $P = 0.002$).

Univariate and multivariate analyses of predictors, including TG18 severity grading factors, lactate, CCI, and etiology of malignant obstruction, are shown in Table 4. In the univariate analysis, organ dysfunction, abnormal WBC count, hypoalbuminemia, CCI > 3, and etiology of malignancy were significantly associated with IHM. In a multivariate analysis of organ dysfunction, only neurological, respiratory, renal, and cardiovascular dysfunction, hypoalbuminemia, and malignant obstruction were significantly positively associated with IHM (OR = 5.32, 2.541, 6.356, 4.021, 5.655, and 7.522; $P < 0.001$, $P = 0.016$, $P < 0.001$, $P = 0.012$, $P < 0.001$, and $P < 0.001$, respectively).

IQR: Interquartile range; ERCP: Endoscopic retrograde cholangiopancreatography; PTBD: Percutaneous transhepatic biliary drainage.

From the data presented in Table 4, the association between IHM and the timing of biliary drainage for each clinical predictor is reflected. Among patients with AC complicated with neurological dysfunction or hyperlactatemia, the IHM rate was significantly decreased in individuals who underwent biliary decompression within 12 h (P = 0.041, P = 0.016), while those patients complicated with neurological dysfunction who had drainage within 24 h or 48 h could not improve prognosis compared with those who underwent drainage after 24 or 48 h, as well as those who did not undergo biliary drainage after admission (P = 0.175, P = 0.304). In patients with renal dysfunction, abnormal WBC count, hyperbilirubinemia, hypoalbuminemia, or hyperlactatemia, who had biliary decompression within 24 h or 48 h, there were significantly lower IHM rates than those of the remaining patients in each subgroup. Among patients with AC complicated with hepatic dysfunction, higher CCI (> 3), or malignancy, a lower IHM rate was significantly associated with early drainage (< 48 h) (P = 0.016, P = 0.006, P = 0.021).

DISCUSSION

In this retrospective monocenter cohort analysis including 1305 AC patients stratified according to TG18 severity criteria, early drainage (< 24 h) in Grade III AC patients had the greatest benefit, which could significantly reduce the all-cause IHM. It is worth noting that, in this subgroup, patients complicated with neurological dysfunction should be drained as early as possible (< 12 h). Moreover, early drainage was also required for AC patients with lactate more than 2 mmol/L, abnormal WBC count, hyperbilirubinemia, or hypoalbuminemia. Although these patients may have no severe cholangitis, early drainage could significantly reduce IHM and benefit the most. However, it should be noted that our results did not prove that drainage reduced hospitalization costs compared to conservative treatment. Furthermore, early drainage increased hospitalization costs and LOS.

AC is a clinically heterogeneous disease with recent mortality rates ranging from 2.7% to 10%, which is considered as an improvement since these rates were as high as 50%-60% in severe cases[15,16]. Although it is well-accepted that biliary decompression can significantly decrease the mortality of AC, it is highly debatable as to what the optimal strategy is for performing biliary drainage procedures. Should drainage occur as early as possible or should the procedure be delayed until stabilization after adequate resuscitation, especially for Grade III AC patients? Our study showed that biliary drainage could significantly decrease the IHM of AC patients (1.4% *vs* 7.2%, P < 0.001), and AC patients of Grade

III underwent decompression within 24 h or 48 h had lower IHM (3.9% *vs* 9.0%, $P = 0.041$; 4% *vs* 9.9%, $P = 0.018$). These findings are in line with the results of a large sample size retrospective study, which showed that drainage within 48 h was associated with improved IHM (3.4% *vs* 10.2%, $P = 0.019$)[17], although it did not discuss drainage within 24 h. Another retrospective study of 6063 patients with AC conducted by Kiriyama *et al*[3] reported a distinct result: decompression within 24 h or 48 h improved the 30-d mortality rate only among Grade II patients (drainage within 24 h *vs*. after 24 h or no drainage: 1.7% *vs* 3.4%, $P < 0.05$; drainage within 48 h *vs* after 48 h or no drainage: 2.0% *vs* 3.7%, $P < 0.05$), and the drainage timing did not influence 30-d mortality in patients with Grade I and Grade III. This dissimilarity may be because we reviewed the all-cause IHM, while Kiriyama *et al*'s study observed 30-d cholangitis-caused mortality, and the mortality rate of Grade III AC patients was lower than that in our study (5.1% *vs* 9.4%), especially for subgroups of delayed decompression in which more patients died from malignancy[3]. In addition, as the number and grade of patients without drainage were not shown in the results of Kiriyama *et al*[3], the proportion of patients without drainage in our study may be different from the group studied by Kiriyama *et al*[3]. Since then, few researchers have tried to examine

the possibility of improving the prognosis of Grade III AC patients by undergoing biliary drainage more immediately[6,8]. Unfortunately, consistent with our results, there was no evidence that earlier decompression (within 12 h) benefited these severe patients.

Another multicenter retrospective net cohort study reported a novel finding in which delayed biliary decompression (> 12 h) was significantly associated with increased mortality in AC patients combined with septic shock [OR 3.40 (1.12-10.31)][7]. These results suggest that it may be necessary to approach each organ's failure separately and that different types of organ dysfunction should be considered when determining the optimal drainage timing. This was verified by our multivariable analysis which showed that neurological, respiratory, renal, and cardiovascular dysfunction were significantly associated with IHM (OR = 5.32, 2.541, 6.356, 4.021, respectively), whereas hepatic and hematological dysfunction did not influence IHM. In addition to indicators affecting mortality recommended in TG18, we also analyzed CCI, malignancy, and lactate levels, which were previously reported to have an impact on the death rate[5,7,18]. Multivariate regression analysis showed that, in addition to organ dysfunction, hypoproteinemia and malignant obstruction significantly increased IHM. These outcomes were similar to those reported in a previous review[3].

In this study, we first attempted to stratify Grade III AC patients according to organ dysfunction to identify patients whose prognosis could most likely be improved by earlier decompression. According to our clinical experience, neurological dysfunction was the most severe complication and might affect drainage operation; therefore, AC patients with altered mental status require immediate biliary decompression. This was verified by our data that only undergoing drainage within 12 h could greatly improve IHM in this subgroup of individuals (0% *vs* 17.3%, P = 0.041). For AC patients with renal dysfunction, performing drainage within 24 h could decrease the IHM. As a result, the renal injury was not only caused by infection but also induced by hypovolemia, which was provoked by fever, decreased appetite, early initiation of antibiotics, and aggressive fluid resuscitation to improve renal flow were more valuable for these patients. Unlike previous studies[7], we did not observe an association between drainage and IHM in AC patients with cardiovascular dysfunction. This may be because only 39 patients were included in this subgroup. Drainage within 12 h significantly reduced mortality in AC patients with increased lactate levels (≥ 2 mmol/L), suggesting that decompression within 12 h might be beneficial for patients with cardiovascular dysfunction. Performing drainage within 48 h greatly reduced mortality in AC patients with hepatic dysfunction, because the amelioration of biliary stasis after drainage could directly rescue hepatic function and diminish inflammatory reaction, even if no significant association between hepatic injury and IHM was observed.

The influence of abnormal WBC count and hyperbilirubinemia on outcomes in AC has been previously described[9]. The underlying pathophysiologic mechanisms are known to result from sepsis; therefore, abnormal WBC count and hyperbilirubinemia are linked with an increased likelihood of poor prognosis. Hypoalbuminemia refers to malnutrition, which is linked to life-threatening infections and poor outcomes. For individuals in these subgroups, undergoing drainage within 24 h indicated a lower IHM.

Decompression within 12, 24, or 48 h in Grade III AC patients would extend the LOS, which was contrary to the findings of Aboelsoud *et al*[19] who demonstrated that drainage within 24 h or 48 h could decrease the LOS, compared with drainage after 24 h or 48 h (drainage within 24 h *vs* after 24 h: mean 7.71 *vs* 13.57 d, P = 0.001; drainage within 48 h *vs* after 48 h: mean 8.61 *vs* 14.24 d, P = 0.002). This was because their study only reviewed patients who underwent drainage, whereas our study included both patients who underwent drainage and those who did not. In addition, most of the Grade II and Grade III patients in this study received only endoscopic nasobliary drainage or endoscopic retrograde biliary drainage treatment at the first ERCP intervention because of their serious condition, and 52.2% of them received a second endoscopic intervention for biliary stone removal or stent placement when their condition stabilized, thus increasing the LOS. Drainage within 12, 24, or 48 h was associated with increased hospital costs despite the severity of AC since endoscopic operation itself was expensive, and the delayed-drainage group contained non-drainage ones who spent little.

Limits of study

Our analysis had certain limitations. First, it was retrospective in design, and as such, was susceptible to record bias and incomplete data. Second, because it is a single-center study, the study results only reflect the clinical status of our center and cannot represent the situation of all hospitals. Third, due to the limited sample size, especially the limited number of patients with cardiovascular dysfunction who underwent drainage within 48 h, some results were not statistically significant. In addition, the time from onset to initial treatment and the antibiotics and fluid resuscitation before admission to our hospital were not evaluated, which may have an impact on the outcome. A prospective multicenter study will be conducted to further explore a precise stratified model to guide drainage timing rather than TG18.

CONCLUSION

To our knowledge, this is the first study to stratify patients with Grade III AC according to different organ dysfunctions and to recommend the optimal timing of biliary drainage accordingly. Biliary decompression significantly decreases the all-cause IHM rates in AC, and early biliary drainage (< 24 h) was shown to be beneficial for AC patients with Grade III severity. Severe cases with different organ dysfunctions have distinct prognoses, and cases complicated with either neurological or cardiovascular dysfunction should undergo drainage within 12 h of admission. For patients with mild or moderate cholangitis, early drainage increases the probability of a second treatment and increases the patients' injury, hospitalization cost, and LOS. A further multicenter prospective cohort study will be conducted to verify the result and investigate whether the optimal timing of drainage based on different organ dysfunctions can increase the 30-d mortality rates and decrease the readmission rate.

ARTICLE HIGHLIGHTS

Research background

Acute cholangitis (AC) is a life-threatening condition that occurs in the presence of biliary obstruction. Biliary decompression is well known to greatly decrease the risks of mortality in AC. Although early biliary drainage is recommended by the treatment guidelines for AC, the exact timeframe is yet to be established.

Research motivation

We have observed that the clinical outcomes of severe AC patients vary dramatically. So, we first attempted to study whether AC patients with different organ dysfunction should undergo biliary drainage at distinct times and try to screen out patients that could benefit the most from earlier drainage.

Research objectives

To investigate the optimal drainage timing for AC patients with each disease severity grade and organ dysfunction.

Research methods

In this retrospective monocenter cohort analysis, we reviewed 1305 patients who were diagnosed with AC according to the Tokyo guidelines 2018 at a Chinese tertiary hospital for four years. We investigated the all-cause in-hospital mortality (IHM), hospital length of stay (LOS), and hospitalization costs associated with the timing of biliary drainage according to the severity grading and different dysfunctioning organs and critical predictors [age, white blood cell (WBC) count, total bilirubin, albumin, lactate, malignant obstruction, and Charlton comorbidity index (CCI)].

Research results

Biliary drainage within 24 h in Grade III AC patients had the greatest benefit, which could significantly reduce the all-cause IHM, while increasing LOS and hospitalization costs. Multivariate logistic analysis revealed that neurological, respiratory, renal, and cardiovascular dysfunctions, hypoalbuminemia, and malignant obstruction were significantly associated with IHM. Furthermore, AC patients complicated with neurological dysfunction or with serum lactate > 2 mmol/L should be drained as early as possible (< 12 h) for it could significantly decrease the IHM. In the subgroup of AC patients with renal dysfunction, abnormal WBC count, hyperbilirubinemia, or hypoalbuminemia, drainage within 24 h reduced the IHM, while in the subgroup of AC patients with hepatic dysfunction, malignant obstruction, or a CCI > 3, biliary drainage should be performed within 48 h.

Research conclusions

Biliary drainage within 12 h is beneficial for AC patients with neurological or cardiovascular dysfunction, while complete biliary decompression within 24 h of admission is recommended for treating patients with Grade III AC.

Research perspectives

A further multicenter prospective cohort study will be conducted to verify the result and investigate whether the optimal timing of drainage based on different organ dysfunctions can increase the 30-d mortality rates and decrease the readmission rate.

Abstract

BACKGROUND

The incidence of hypertriglyceridemic acute pancreatitis (HTG-AP) has increased yearly, but updated population-based estimates on the incidence of HTG-AP are lacking. Reducing serum triglyceride (TG) levels quickly is crucial in the early treatment of HTG-AP. Decreased serum TG levels are treated by non-invasive methods, which include anti-lipidemic agents, heparin, low-molecular weight heparin, and insulin, and invasive methods, such as blood purification including hemoperfusion (HP), plasmapheresis, and continuous renal replacement therapy. However, authoritative guidelines have not been established. Early selection of appropriate treatment is important and beneficial in controlling the development of HTG-AP.

AIM

To evaluate the effect between patients treated with intravenous insulin (INS) and HP to guide clinical treatment.

METHODS

We retrospectively reviewed 371 patients with HTG-AP enrolled in the Department of Fujian Provincial Hospital form April 2012 to March 2021. The inpatient medical and radiologic records were reviewed to determine clinical features, severity, complications, mortality, recurrence rate, and treatment. Multivariate logistic regression analyses were used to analyze risk factors for

severe HTG-AP. Propensity score matching was used to compare the clinical outcomes of INS and HP.

RESULTS

A total of 371 patients met the HTG-AP criteria. The incidence of HTG-AP was increased by approximately 2.6 times during the 10 years (8.4% in April 2012-March 2013 and 22.3% in April 2020-March 2021). The highest incidence rate of acute pancreatitis was observed for men in the age group of 30-39 years. The amylase level was elevated in 80.1% of patients but was only three times the normal value in 46.9% of patients. The frequency of severe acute pancreatitis (26.9%), organ failure (31.5%), rate of recurrence (32.9%), and mortality (3.0%) of HTG-AP was high. Improved Marshall score, modified computed tomography severity index score, baseline TG, baseline amylase, C-reactive protein (CRP), albumin, aspartate aminotransferase, low-density lipoprotein cholesterol, urea nitrogen, creatinine, calcium, hemoglobin, free triiodothyronine, admission to intensive care unit, and mortality were significantly different between patients with different grades of severity ($P < 0.050$). Multivariate logistic regression analysis confirmed that high CRP [$P = 0.005$, odds ratio (OR) = 1.011, 95%CI: 1.003-1.019], low calcium ($P = 0.003$, OR = 0.016, 95%CI: 0.001-0.239), and low albumin ($P = 0.023$, OR = 0.821, 95%CI: 0.693-0.973) were risk factors of severe HTG-AP. After propensity score matching adjusted by sex, age, severity of HTG-AP, and baseline TG, the serum TG significantly decreased in patients treated with INS ($P < 0.000$) and HP ($P < 0.000$) within 48 h. However, the clearance rate of TG (57.24 ± 33.70% *vs* 56.38 ± 33.61%, $P = 0.927$) and length of stay (13.04 ± 7.92 d *vs* 12.35 ± 6.40 d, $P = 0.730$) did not differ between the two groups.

CONCLUSION

The incidence of HTG-AP exhibited a significant increase, remarkable severity, and recurrent trend. Patients with mild and moderately severe acute pancreatitis can be treated effectively with INS safely and effectively without HP.

Key Words: Hypertriglyceridemic acute pancreatitis; Triglyceride; Improved Marshall score; Severity of acute pancreatitis; Intravenous insulin; Hemoperfusion

INTRODUCTION

Acute pancreatitis (AP) is an inflammatory condition of the pancreas that originates within the pancreatic acinar cells and causes pancreatic necrosis, systemic inflammatory response syndrome, and multiple organ failure[1], with a mortality rate for severe cases as high as 20%-25%[2]. The great majority of AP is driven by gallstones (40%-70%) and alcohol (25%-35%)[3]. With the change of people's diet structure and lifestyle, the incidence and mortality of hypertriglyceridemic (HTG)-AP are increasing year by year and has surpassed alcohol as the second leading cause of AP in China[4]. The standardized incidence rate of HTG-AP increased from 0.7 to 1.7 per 100000 person-years from 2008 to 2019 in Denmark[5], and the incidence has increased by 2.4 times in 10 years. However, the increasing number of HTG-AP incidence remains unclear in China.

The mechanism by which severe HTG precipitates to AP remains unknown. Studies have shown that pancreatic lipase hydrolyses excess triglyceride (TG) with accumulation of free fatty acids, thereby inducing the production of acinar cell and pancreatic capillary injury; chylomicrons lead to increased blood viscosity and local tissue ischemia[6,7]. Therefore, early detection of serum TG and active treatment measures to reduce serum TG are crucial for the prognosis of AP. Some scholars believe that

rapid reduction of serum triglyceride levels within 48 h before the onset of HTG-AP is the key to treatment[8]. Effective treatments of reducing serum TG levels include anti-lipidemic agents, insulin, heparin, low-molecular weight heparin, and blood purification, such as hemoperfusion (HP), plasmapheresis (PE), and continuous renal replacement therapy[6,9]; however, no HTG-AP treatment guideline has been established. At present, selecting routine treatment or blood purification for patients with HTG-AP after admission remains controversial.

In view of the increasing incidence of HTG-AP in recent years and its short and long-term harmful effects on patients, families, and society, scholars have focused on preventing and effectively blocking HTG-AP as well as on its diagnosis and treatment. However, the causes remain unknown[10-12]; the low elevation of amylase (AMY) levels[13] and other characteristics[14] lead to the early misdiagnosis of HTG-AP. In addition, HTG-AP is prone to young age of onset[10], many complications[15], higher chance of systemic inflammatory response syndrome and cardiopulmonary and renal insufficiency[16], severe tendency[17], and lack of unified clinical treatment standards, which bring some difficulties to clinical treatment.

This study aims to improve the clinical diagnosis rate of HTG-AP by summarizing the clinical characteristics of HTG-AP and developing appropriate and cost-effective treatments for patients with HTG-AP.

MATERIALS AND METHODS

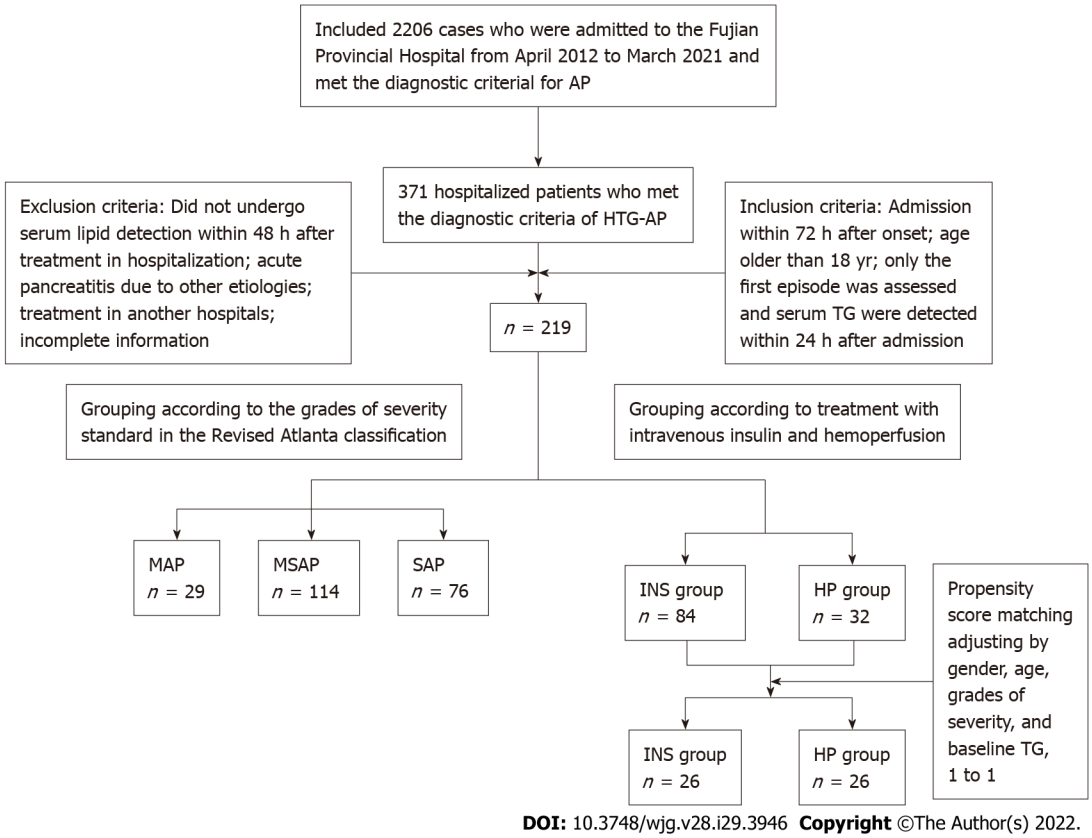
Patients

From April 2012 to March 2021, AP was diagnosed in 2206 patients in the Fujian Provincial Hospital. A total of 371 hospitalized patients who met the diagnostic criteria of HTG-AP were retrospectively studied, and 219 patients met the inclusion and exclusion criteria that were used to explore risk factors for severe HTG-AP. Fifty-two patients were included after propensity score matching (PSM) was adjusted by sex, age, grades of severity, and baseline TG. Clinical outcomes were compared between the 52 patients treated with intravenous insulin (INS) and HP (Figure 1). The Ethics Committee of Fujian Provincial Hospital approved the study (K2021-02-007).

The inclusion criteria were as follows: (1) Diagnosis of HTG-AP; (2) Admission within 72 h after onset; (3) Age older than 18 years; (4) Assessment of the first episode (for patients with multiple episodes of AP); and (5) Serum TG detected within 24 h after admission.

The exclusion criteria were as follows: (1) Did not undergo serum lipid detection within 48 h after treatment upon hospitalization; (2) AP due to other etiologies (including gallstones, alcohol, autoimmune, drug-induced, hypercalcemia, hyperparathyroidism, pancreatic tumor-related etiology of AP); (3) Treatment in another hospital; and (4) Incomplete information.

Grouping methods



According to the grades of severity standard in the Revised Atlanta Classification, patients were classified into the mild acute pancreatitis (MAP) group, moderately severe acute pancreatitis (MSAP) group, and severe acute pancreatitis (SAP) groups.

Patients were divided into the INS group and HP group according to treatment method. All patients were given basic support treatment including abrosia, gastrointestinal decompression, enema, fluid resuscitation, water maintenance, electrolyte and acid-base balance, lactulose to improve intestinal function, low molecular weight heparin, proton pump inhibitors for gastric acid secretion, and somatostatin/octreotide inhibitor pancreatic secretion. The INS group was given INS. The HP group was treated with HP. Blood access was established by puncture of the femoral vein or internal jugular vein. HP was performed with a resin irrigator (HA330, Zhuhai Lizhu Group, Biological Material Co, Ltd., China) for 2 h every 24 h with a blood flow of 150-250 mL/min. During the procedure, heparin was used to flush the infusion tube. After the procedure, coagulation markers were monitored. For those with prolonged coagulation times, 10-15 mg protamine was given to neutralize the effect of heparin. For patients with bleeding tendency, low molecular weight heparin was chosen, or the dose of heparin was appropriately reduced.

Definition

The diagnosis of AP was in accordance with the Revised Atlanta Definitions[18]. AP was diagnosed when two of the following three characteristics were met: (1) Abdominal pain consistent with AP (acute onset of a persistent, severe, epigastric pain often radiating to the back); (2) At least three times higher levels of AMY and/or lipase above the upper limit of the normal value; and (3) Abdominal imaging (including computed tomography, magnetic resonance imaging, or transabdominal ultrasonography) consistent with changes in AP.

HTG-AP was considered in patients with AP when the level of serum TG was: (1) Over 1000 mg/dL; and (2) Between 500 and 1000 mg/dL with lactescent serum at admission[19].

DOI: 10.3748/wjg.v28.i29.3946 **Copyright** ©The Author(s) 2022.

Figure 1 Research sample screening and grouping process. HTG-AP: Hypertriglyceridemic acute pancreatitis; MAP: Mild acute pancreatitis; MSAP: Moderately severe acute pancreatitis; SAP: Severe acute pancreatitis; TG: Triglyceride; INS: Insulin; HP: Hemoperfusion; AP: Acute pancreatitis.

The severity of AP was graded according to the Revised Atlanta Definitions[18]: MAP, MSAP, and SAP. MAP was defined by the absence of organ failure and the absence of local or systemic complications. MSAP was defined by the presence of transient (< 48 h) organ failure or local or systemic complications in the absence of persistent organ failure. SAP was defined by persistent (> 48 h) organ failure.

Organ failure was determined according to the improved Marshall score standard in the Revised Atlanta classification[18]. Three organ systems were assessed to define organ failure: respiratory, cardiovascular, and renal. For respiratory (PaO_2/FiO_2), 301 mmHg ≤ PaO_2/FiO_2 ≤ 400 mmHg was scored as 1 point, 201 mmHg ≤ PaO_2/FiO_2 ≤ 300 mmHg was scored as 2 points, 101 mmHg ≤ PaO_2/FiO_2 ≤ 200 mmHg was scored as 3 points, and PaO_2/FiO_2 ≤ 101 mmHg was scored as 4 points. For renal serum creatinine (SCR), 134 μmol/L ≤ SCR ≤ 169 μmol/L was scored as 1 point, 170 μmol/L ≤ SCR ≤ 310 μmol/L was scored as 2 points, 311 μmol/L ≤ SCR ≤ 439 μmol/L was scored as 3 points, and SCR > 439 μmol/L was scored as 4 points. For cardiovascular systolic blood pressure (BP), BP < 90 mmHg and fluid responsive was scored as 1 point, BP < 90 mmHg without fluid responsive was scored as 2 points, BP < 90 mmHg and pH < 7.3 was scored as 3 points, and BP < 90 mmHg and pH < 7.2 was scored as 4 points. A score of 2 or more in any system defined the presence of organ failure.

Data collection

Data were obtained from the patients' medical records and hospital electronic database records. Sex, age, and comorbidities were collected. Clinical manifestations, improved Marshall score[18], modified computed tomography severity index (MCTSI) score[20], organ failure[18], laboratory and imaging data, treatments, intensive care unit admission, length of stay, and prognosis during hospitalization were recorded. All laboratory data were measured within 24 h after admission. Baseline TG and serum AMY were measured using the first tested values since onset. Serum lipids were reviewed within 48 h after administering lipid-lowering treatment.

Statistical analysis

SPSS 25.0 (IBM Corp., Armonk, NY, United States) was used for data analysis, and GraphPad Prism7.0 was used for mapping. Measurement data in normal distribution were expressed as mean ± SD and analyzed with Student's *t*-test or analysis of variance. Otherwise, variables were described as medians and interquartile ranges and analyzed by Mann-Whitney *U* test or Kruskal-Wallis test. Categorical variables were presented as absolute numbers and proportions and tested by χ^2 or Fisher's exact test.

Paired *t* test was used for continuous variables before and after treatment. Multivariate logistic regression analysis was used to identify independent risk factors with odds ratios (ORs) and 95%CIs. In addition, 1-1 PSM was performed, followed by univariate analysis. $P < 0.05$ was considered statistically significant.

RESULTS

Trends in incidence of HTG-AP

For nearly a decade, 371 patients were diagnosed with HTG-AP in Fujian Provincial Hospital. The total number of patients with HTG-AP in our hospital increased, and the incidence of HTG-AP was increased by approximately 2.6 times over the past 10 years and ranged from 8.4% to 22.3% (Figure 2).

Clinical characteristics of HTG-AP

A total of 371 patients were diagnosed with HTG-AP, the mean age of the patients with HTG-AP was 39.86 ± 10.20 years, and most of the patients (approximately 93.8%) were young and middle-aged individuals, with a male/female ratio of 2.0 (247/124). The highest incidence rate of AP was observed for men in the age group of 30-39 years (Figure 3).

The mean serum baseline TG values in HTG-AP were significantly high (2544.59 ± 2305.37 mg/dL). The serum AMY elevated levels were higher than normal in 80.1% of the patients with HTG-AP but only three times greater than normal in 46.9% of patients (Table 1).

About 90.6% of patients with HTG-AP had comorbidity with fatty liver disease, and 11 women (3.0%) had an HTG-AP attack during pregnancy. About 54.7% of the cases were related to diet (high fatty acid) and/or drinking (beer). Patients with HTG-AP had a high frequency of SAP (100, 26.9%), organ failure (117, 31.5%), recurrence (122, 32.9%), and high MCTSI score (5.00 ± 1.83). Eleven patients (3.0%) died during hospitalization (Table 1).

Comparisons of different grades of severity of HTG-AP

A total of 219 patients met the inclusion and exclusion criteria divided into the MAP group ($n = 29$), MSAP group ($n = 114$), and SAP group ($n = 76$).

Table 2 shows that the more severe HTG-AP was, the more frequent blood purification was used. Improved Marshall score ($P < 0.000$), MCTSI score ($P < 0.000$), baseline TG ($P = 0.035$), baseline AMY ($P < 0.000$), CRP ($P < 0.000$), albumin ($P < 0.000$), aspartate aminotransferase ($P < 0.000$), low-density lipoprotein-cholesterol ($P = 0.003$), urea nitrogen ($P < 0.000$), creatinine ($P < 0.000$), calcium ($P < 0.000$), hemoglobin ($P = 0.010$), free triiodothyronine ($P = 0.018$), admission to the intensive care unit ($P < 0.000$), and mortality ($P < 0.000$) were significantly different between patients with different grades of severity.

Multivariate logistic regression analysis confirmed that high CRP ($P = 0.005$, OR = 1.011, 95%CI: 1.003-1.019), low calcium ($P = 0.003$, OR = 0.016, 95%CI: 0.001-0.239), and low albumin ($P = 0.023$, OR = 0.821, 95%CI: 0.693-0.973) were risk factors of severe HTG-AP (Table 3).

Comparisons between INS and HP treatments

Of the 219 patients, 84 patients were treated with INS in the INS group and 32 patients were treated with HP in the HP group. The entire cohort showed that the grades of severity of HTG-AP ($P = 0.002$) and baseline TG ($P = 0.037$) were significantly different between patients treated with INS and HP (Table 4).

Given the large severity and baseline TG gap between the two groups, patients were selected for further analysis using PSM, adjusted by sex, age, grades of severity, and baseline TG. After matching, 26 patients were in the INS group and 26 patients were in the HP group (1:1, match tolerance = 0.02). No significant differences in sex ($P = 0.184$), age ($P = 0.895$), grades of severity ($P = 0.755$), improved Marshall score ($P = 0.186$), MCTSI score ($P = 0.127$), and baseline TG ($P = 0.734$) were found between the two groups (Table 4).

In patients with MAP and MSAP, the serum TG level significantly decreased in patients treated with INS ($P < 0.000$) and HP ($P < 0.000$) within 48 h (Figure 4). The clearance rates of TG were 57.24% ± 33.70% and 56.38% ± 33.61%, respectively ($P = 0.927$). However, the clearance rate of TG ($P = 0.927$) and length of stay (13.04 ± 7.92 d *vs* 12.35 ± 6.40 d, $P = 0.730$) did not differ between the two groups (Table 4).

DISCUSSION

Trends in incidence of HTG-AP

AP has many etiologies, and previous studies reported that HTG as an etiologic factor is between 1.3% and 6.9%[21,22]. However, HTG-AP increased at a fast rate in the Asian region during recent years. Taiwan reported that the frequency of HTG as an etiologic factor in patients with AP ranged from 6.3% to 12.3%[23]. A study reported that the incidence of HTG-AP reached 25.6% in 2013[14]. Zheng *et al*[24]

retrospectively analyzed 2461 patients with AP in Beijing during a 5-year period and reported that the causes of AP included biliary (55.75%), alcoholism (10%), hypertriglyceridemia (10.36%), and others (23.89%); however, this work did not mention the rate of increase in HTG-AP.

The standardized incidence rate of HTG-AP increased from 0.7 to 1.7 per 100000 person-years from 2008 to 2019 in Denmark, and the incidence has increased by 2.4 times over the past 10 years[5]. Another study from Guangdong showed that the incidence of HTG-AP in 2000 to 2005 was 2.6 times higher than that in 1990 to 1994 (8.9% *vs* 3.4%, $P < 0.05$)[25]. Based on recent observations from China[26], the

Figure 2 The total number of patients with hypertriglyceridemic acute pancreatitis and other acute pancreatitis in Fujian Provincial Hospital increased significantly during nearly 10 years. HTG-AP: Hypertriglyceridemic acute pancreatitis.

proportion of patients with HTG-AP increased from 14.0% to 34.0% during a 16-year period in a tertiary hospital setting. Our study found that the incidence of HTG-AP increased by approximately 2.6 times and ranged from 8.4% to 22.3% during nearly 10 years, with a significant increase detected after 2017. Our results are similar to previously reported data.

At present, updated population-based estimates on the incidence of HTG-AP are lacking. Some studies have shown that the incidence and mortality of HTG-AP were increasing year by year, which was related to the change of people's diet structure and lifestyle[4]. At the same time, the availability of the detection of serum TG also improved the diagnosis of HTG-AP. For example, the emergency of our hospital began testing serum TG in 2017, and Figure 1 shows the incidence of HTG-AP has increased since 2017.

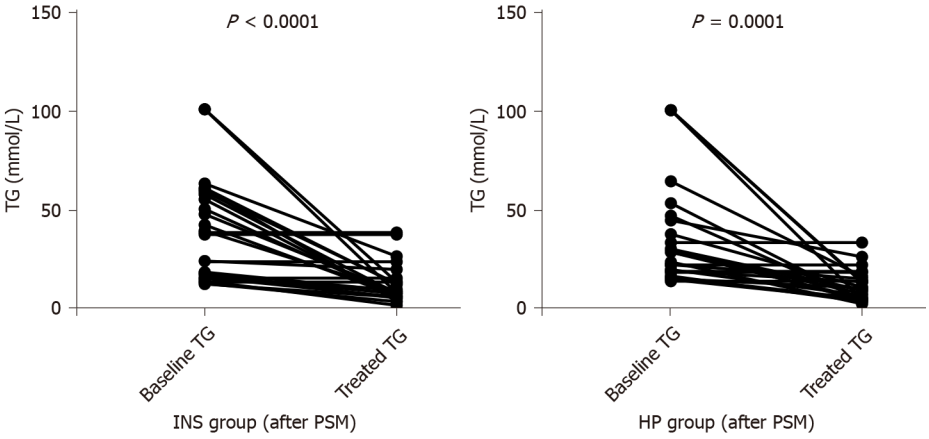
Figure 1 showed the decrease in the incidence of HTG-AP from April 2016 to March 2017 and from April 2019 to March 2020, which coincided with the opening of the South Hospital of Fujian Provincial Hospital and the outbreak of coronavirus disease 2019 in China, leading to the diversion and reduction of the number of patients with AP and HTG-AP.



Clinical feature of HTG-AP

This study also found that the clinical manifestations of patients with HTG-AP included the most common abdominal pain and abdominal distension as well as nausea, vomiting, and anhelation without

Figure 4 Changes of serum triglyceride levels in both groups before and after treatment. TG: Triglyceride; INS: Insulin; PSM: Propensity score matching; HP: Hemoperfusion.

specificity. However, patients with HTG-AP have some clinical characteristics, such as serum TG level (2544.59 ± 2305.37 mg/dL) that was significantly higher than normal values at the onset of disease. Hence, serum TG level ≥ 1000 mg/dL is the most important characteristic of HTG-AP[19]. Thus, we can improve the diagnosis rate of HTG-AP by improving the early detection rate of serum TG in clinical work.

We found that the mean age of patients with HTG-AP was 39.86 ± 10.20 years. The highest incidence rate of AP was observed for men in the age group of 30-39 years, and the male/female ratio was 2.0 (247/124). Li *et al*[10] reported that patients with HTG-AP were younger (40 *vs* 51, $P < 0.01$) and were mostly males (214/91 *vs* 242/183, $P < 0.01$) compared with patients with biliary AP.

Sekimoto *et al*[27] stated that the average age for HTG-AP was lower than that for other causes. Zheng *et al*[24] reported a higher proportion of alcoholic and HTG-AP in men than in women and in patients younger than 50 years. Olesen *et al*[5] reported that the highest incidence rate of severe HTG was observed for men in the age group of 40-49 years, and severe HTG is a well-known risk factor for AP. Therefore, HTG-AP is becoming more prevalent among younger individuals.

AMY was elevated to levels higher than the normal value in 80.1% of patients but only three times higher than the normal in 46.9% of patients. About 50% of patients with HTG-AP showed no significant increase in serum and urine AMY levels[13], which may be due to the presence of AMY activity inhibitors in their plasma; these inhibitors can enter the urine through the kidneys and inhibit urinary AMY activity. In addition, increased TG levels directly affected the determination of AMY. Therefore, the early diagnosis of HTG-AP is more difficult. The diagnostic accuracy of lipase for HTG-AP was 91.83%, while that of AMY was only 40.38%[14]. Thus, we can improve the diagnosis rate of HTG-AP by combining serum AMY and lipase.

In this study, the frequency of SAP (26.9%), organ failure (31.5%), rate of recurrence (32.9%), and mortality (3.0%) of HTG-AP was high. A large multicenter study in China showed higher incidences of

local complication (34.13% *vs* 15.72%, $P < 0.000$) and MSAP (28.85% *vs* 12.95%, $P < 0.000$) in patients with HTG-AP than in patients without HTG-AP[14]. HTG-AP varied in severity between mild (41%), moderate (26%), and severe (33%)[17]. A foreign study showed that patients with HTG-AP had significantly higher percentages of multiple organ dysfunction syndrome (24.1% *vs* 12.1%, $P = 0.009$) and cardiovascular failure (17.6% *vs* 4.6%, $P < 0.001$) compared with biliary AP[26].

Some reports showed a more severe course of AP induced by HTG compared with other causes, whereas other scholars seemed to favor no significant difference in disease severity[28]. Vipperla *et al* [17] reported that the risk of recurrent AP attacks was 32%, often in patients with poorly controlled diabetes, alcoholism, and TG levels. Our study showed that the recurrence rate of MSAP was higher than that of SAP, which may be due to insufficient attention and medical care. Different studies reported that the mortality rate of HTG-AP ranged from 0.48% to 7.9%[10,14,26], but the mortality rate for severe cases reached as high as 20%-25%[2].

The high frequency rates of fatty liver disease, diabetes mellitus, and hypertension were found in patients with HTG-AP, with values of 90.6%, 31.0%, and 16.7%, respectively. Patients with HTG-AP were often complicated with metabolic diseases such as diabetes mellitus and obesity, and patients with type 2 diabetes mellitus had an elevated risk of AP compared with patients without diabetes[15].

Comparisons of different grades of severity of HTG-AP

A comparison was conducted among patients with MAP, MSAP, and SAP to investigate the association of the severity of HTG-AP with clinical data and laboratory indicators. Table 2 showed that age and sex had no difference among the three groups (all $P > 0.050$). Improved Marshall score, MCTSI score, baseline TG, baseline AMY, CRP, albumin, aspartate aminotransferase, low-density lipoprotein-cholesterol, urea nitrogen, creatinine, calcium, hemoglobin, and free triiodothyronine were significantly different among patients with different grades of severity of HTG-AP (all $P < 0.050$). Multivariate logistic regression analysis confirmed that high CRP ($P = 0.005$, OR = 1.011, 95%CI: 1.003-1.019), low calcium ($P = 0.003$, OR = 0.016, 95%CI: 0.001-0.239), and low albumin ($P = 0.023$, OR = 0.821, 95%CI: 0.693-0.973) were risk factors of severe HTG-AP.

CRP, serum calcium, and serum albumin are well-known predictors of severe AP with non-HTG-AP and are widely used in its early detection. Experts suggested that CRP levels > 150 mg/L 48 h after the onset of symptoms have a high sensitivity for predicting the severity of AP[29]. Yu *et al*[30] reported that patients with HTG-AP had lower serum ionized calcium associated with a higher risk of developing SAP. Chen *et al*[31] confirmed that low serum albumin ($P = 0.004$, OR = 3.362, 95%CI: 1.492–8.823) and high CRP ($P = 0.005$, OR = 3.061, 95%CI: 1.407–6.659) were risk factors of moderately severe to severe HTG-AP.

Our study showed that the predictors of SAP with HTG-AP were similar to those of AP with other etiologies including alcoholic and biliary AP.

Comparisons among different treatments

Reducing serum TG levels quickly is crucial in the early treatment of HTG-AP. This method mainly includes two categories of routine treatment, and blood purification had been implemented for the patients with HTG-AP. Currently, the TG levels should be reduced to below 500 mg/dL as soon as possible; when follow-up TG levels were < 500 mg/dL, an associated reduction in the risk of clinical events and decrease in health care resource use and costs were observed[32]. However, selecting routine treatment or blood purification for patients with HTG-AP after admission to obtain economic cost effectiveness remains controversial. Routine treatments, such as insulin, heparin, and anti-HTG drugs, are effective in reducing TG and have the advantages of non-invasiveness and low cost.

Blood purification includes HP, PE, and continuous renal replacement therapy, which have the disadvantages of invasiveness and expensive. Compared with HP and PE, continuous renal replacement therapy can not only reduce TG rapidly but also remove inflammatory mediators and is more accurate for systemic inflammatory response syndrome control[9]. However, selecting routine treatment or blood purification for patients with HTG-AP after admission in order to obtain economic cost effectiveness remains controversial. Therefore, this study mainly compared the effect of INS and HP on lowering serum TG.

Among patients with MAP and MSAP, a significant decrease in serum TG was found in patients treated with INS ($P < 0.000$) and HP ($P < 0.000$) within 48 h. The clearance rates of TG were 57.24% ± 33.70% and 56.38% ± 33.61%, respectively ($P = 0.927$). This rate of decline was similar to a report[33] wherein 22 episodes of HTG-AP had a calculated fall in serum TG of 69.8% within 48 h by conservative management. This finding is also similar to that reported in an HP case series, which demonstrated 49%-80% reductions in serum TG after a single session[34,35]. These reports showed no difference in the rate of TG decline between patients managed with or without HP. This study also showed that length of stay (13.04 ± 7.92 d *vs* 12.35 ± 6.40 d, $P = 0.730$) did not differ between the two treatments. A large multicenter retrospective study collected 1159 patients with SAP, which included 30 patients with HTG-AP, and 10 patients treated with PE compared with 20 patients treated with routine therapy; no additional reduction in TG levels and no improvement in clinical outcomes were detected[36].

Study strengths and limitations

The strengths of this study are the high accuracy of data due to the strict inclusion and exclusion criteria and the use of PSM to avoid test errors. At present, few studies have reported on how to choose the treatment mode of HTG-AP, which is the innovation of this study.

Our study has some important limitations. This study adopted a single-center retrospective design. The incidence of HTG-AP is not universal and can only reflect the situation of our hospital. Data such as body mass index, urine AMY, blood lipase, and blood gas analysis were missing. The choice of treatment had selection bias.

CONCLUSION

The incidence of HTG-AP exhibited a significant increase, remarkable severity, and recurrent trend. By understanding the characteristics of HTG-AP, we can improve the clinical diagnosis rate and identify patients who are likely to develop severe disease early. Patients with MAP and MSAP can be treated with INS safely and effectively without HP. This work provides a basis for doctors to choose an appropriate treatment plan for patients.

ARTICLE HIGHLIGHTS

Research background

The incidence of hypertriglyceridemic acute pancreatitis (HTG-AP) has increased yearly, but updated population-based estimates on the incidence of HTG-AP are lacking. Reducing serum triglyceride (TG) levels quickly is crucial in the early treatment of HTG-AP. Currently, there are many treatments to reduce TG levels, but there is still a lack of authoritative guidelines.

Research motivation

We wanted to explore appropriate treatments to block the progression of HTG-AP.

Research objectives

To explore the clinical characteristics to reduce the missed diagnosis rate of HTG-AP and to identify the patients who would develop severe acute pancreatitis early. To compare the clinical outcomes of intravenous insulin (INS) and hemoperfusion (HP) and guide the choice of treatment for patients.

Research methods

We retrospectively reviewed the incidence and clinical characteristics of 371 patients with HTG-AP in our hospital from the past 10 years. Then, 219 patients who met the inclusion and exclusion criteria were further screened and divided to different groups according to grades of severity of HTG-AP and treatments. Multivariate logistic regression analyses were used to identify the independent risk factors for severe HTG-AP. Propensity score matching was used to compare the clinical outcomes of INS and HP.

Research results

The incidence of HTG-AP increased by approximately 2.6 times during the 10 years and ranged from 8.4% to 22.3% (8.4% in April 2012–March 2013 and 22.3% in April 2020–March 2021). Multivariate logistic regression analysis confirmed that high C-reactive protein [P = 0.005, odds ratio (OR) = 1.011, 95%CI: 1.003-1.019], low calcium (P = 0.003, OR = 0.016, 95%CI: 0.001-0.239), and low albumin (P = 0.023, OR = 0.821, 95%CI: 0.693-0.973) were risk factors of severe HTG-AP. After propensity score matching with sex, age, grades of severity, and baseline TG, there was a significant decrease in serum TG in patients treated with INS (P < 0.0001) and HP (P = 0.0001) within 48 h. However, the clearance rate of TG and length of stay did not differ between the two groups.

Research conclusions

The incidence of HTG-AP exhibited a significant increase. Patients with mild and moderately severe acute pancreatitis can be treated with INS safely and effectively without HP.

Research perspectives

Identifying patients with a severe tendency at the early stage of HTG-AP and choosing cost-effective treatments is the future direction of this research.

Abstract

BACKGROUND

Tumor deposits (TDs) are not equivalent to lymph node (LN) metastasis (LNM) but have become independent adverse prognostic factors in patients with rectal cancer (RC). Although preoperatively differentiating TDs and LNMs is helpful in designing individualized treatment strategies and achieving improved prognoses, it is a challenging task.

AIM

To establish a computed tomography (CT)-based radiomics model for preoperatively differentiating TDs from LNM in patients with RC.

METHODS

This study retrospectively enrolled 219 patients with RC [TDs^+LNM^- (n = 89); LNM^+ TDs^- (n = 115); TDs^+LNM^+ (n = 15)] from a single center between September 2016 and September 2021. Single-positive patients (*i.e.*, TDs^+LNM^- and LNM^+TDs^-) were classified into the training (n = 163) and validation (n = 41) sets. We extracted numerous features from the enhanced CT (region 1: The main tumor; region 2: The largest peritumoral nodule). After deleting redundant features, three feature selection methods and three machine learning methods were used to select the best-performing classifier as the radiomics model (Rad-score). After validating Rad-score, its performance was further evaluated in the field of diagnosing double-positive patients (*i.e.*, TDs^+LNM^+) by outlining all peritumoral nodules with diameter (short-axis) > 3 mm.

RESULTS

Rad-score 1 (radiomics signature of the main tumor) had an area under the curve (AUC) of 0.768 on the training dataset and 0.700 on the validation dataset. Rad-score 2 (radiomics signature of the largest peritumoral nodule) had a higher AUC (training set: 0.940; validation set: 0.918) than Rad-score 1. Clinical factors, including age, gender, location of RC, tumor markers, and radiological features of the largest peritumoral nodule, were excluded by logistic regression. Thus, the combined model was comprised of Rad-scores of 1 and 2. Considering that the combined model had similar AUCs with Rad-score 2 (P = 0.134 in the training set and 0.594 in the validation set), Rad-score 2 was used as the final model. For the diagnosis of double-positive patients in the mixed group [TDs^+LNM^+ (n = 15); single-positive (n = 15)], Rad-score 2 demonstrated moderate performance (sensitivity, 73.3%; specificity, 66.6%; and accuracy, 70.0%).

CONCLUSION

Radiomics analysis based on the largest peritumoral nodule can be helpful in preoperatively differentiating between TDs and LNM.

Key Words: Radiomics; Tumor deposits; Lymph node metastasis; Rectal cancer; Computed tomography; Differential diagnosis

Core Tip: In this study, a radiomics model based on the largest peritumoral nodule was developed to preoperatively differentiate tumor deposits (TDs) from lymph node (LN) metastasis in patients with rectal cancer. This model demonstrated good performance in both the training and validation cohorts. However, its performance decreased with the diagnosis of the double-positive patients. In summary, this model can be helpful for differentiating TDs from LN metastasis.

INTRODUCTION

Colorectal cancer (CRC) ranks third in terms of incidence and second in terms of mortality[1], and RC accounts for approximately 30% of CRC[2]. Tumor deposits (TDs) in RC are defined as discontinuous extramural extensions or focal aggregates of adenocarcinoma located in the perirectal region, without histological evidence of residual lymph node (LN) or vascular/neural structures[3,4]. As a factor for poor prognosis, TDs have attracted widespread attention in recent years[4,5]. A review published in 2017 confirmed that TDs were independently associated with lower overall and disease-free survival according to data available in the literature[4].

Clearly, TDs are not equivalent to LN metastasis (LNM) in terms of biology and prognosis. Among patients with LNM, the occurrence of TDs can lead to a worse prognosis[4,5], strongly indicating that their impact on prognosis is independent and additive. Therefore, TDs must be reported separately from LNM[6]. However, TDs and LNM can only be determined through pathological examinations of surgical specimens[7]. Presently, it is difficult to preoperatively differentiate TDs from LNM using computed tomography (CT).

Radiomics is a rapidly developing field of research that involves the extraction of numerous quantitative features from medical images. These features can capture characteristics of volume of interest (VOI), such as heterogeneity, and it may, alone or in combination with other data, be used to solve clinical problems[8]. Recently, some studies have reported the involvement of TDs in RC[6,9,10]. However, some previous studies did not focus on the differentiation of TDs from LNM[9,10], and Atre *et al*[6] used only texture analysis and lacked the construction and validation of a model. Therefore, we aimed to establish a CT-based radiomics model to preoperatively differentiate TDs from LNM in patients with RC.

MATERIALS AND METHODS

Patients

This retrospective study was approved by the institutional review board (No. 1159) of the authors' hospital. Given the retrospective design and use of anonymized patient data, requirements for informed consent were waived.

Patient data collected between September 2016 and September 2021 were reviewed by searching radiological and pathological databases. A total of 219 patients [single-positive, 112 male, 92 female; mean ± SD age, 60 ± 12 years (range, 32-92 years); double-positive, 6 male, 9 female; mean age, 60 ± 13 years (range, 37-83 years)] were enrolled. The inclusion criteria were as follows: Diagnosis of rectal adenocarcinoma on pathology; single positive result (*i.e.*, TDs^+ or LNM^+); and 15 randomly selected patients who were TDs^+LNM^+. The exclusion criteria were as follows: No peritumoral nodules with short-axis diameter > 3 mm on enhanced CT images (n = 22); incomplete clinical data, such as tumor markers (n = 36); patients who did not undergo surgery (n = 5); treatment before CT examination (n = 2); and poor-quality CT images (n = 4). Figure 1 shows the flow diagram of patient recruitment. Figure 2 shows the workflow of this radiomics study. Clinical characteristics, including age, gender, location of RC, tumor markers, pTN stage, extramural vascular invasion (EMVI), histological grade, and radiological features of the largest peritumoral nodule, are summarized in Table 1.

Reference standard

Pathological confirmation reports based on surgically resected specimens were obtained from the hospital's electronic medical database. From these reports, pathological information about the main tumor and peritumoral nodules (status and number of TDs and LNMs) were obtained.

Image acquisition and evaluation

Chest-abdomen-pelvis enhanced CT can detect not only the primary tumor but also suspected metastases. The main scanning parameters of CT are described in the Supplementary Table 1.

Two experiential radiologists reviewed the CT images and recorded the radiological features while blinded to clinical and pathological information. As shown in Table 1, the tumor location and radiological features of the largest peritumoral nodule, such as size, morphology, spiculation, and CT value, was confirmed by summarizing the results of these two radiologists (disagreements were resolved by consensus discussion).

Feature extraction and model-building

The reliability of the radiomics features was tested in twenty patients. The features with intra-/inter-class correlation coefficients (ICCs) > 0.75 were considered stable[11]. Thereafter, the radiologists independently segmented the main tumor and largest peritumoral nodule by manually drawing three-dimensional VOI (Figure 2). All images were resampled to pixel spacing of 1 mm in all three dimensions. Several transformation methods, such as wavelet filter and Laplace of Gaussian filter, were applied to the original images. PyRadiomics was used to extract features from the original and filtered images[12]. Figure 2 shows the types of the features. The correlation analysis was performed to remove redundant features. In detail, if the correlation coefficient between two features was > 0.4, the one with a lower coefficient was removed. Subsequently, three feature selection methods and three machine learning methods were tested to select the best performing classifier as the radiomics model (*i.e.*, Rad-score). Statistically significant factors from univariate and multivariate logistic regression analyses were used to develop the combined model.

Model evaluation

Receiver operating characteristic (ROC) curves of the models were performed to assess and compare their performance in identifying TDs^+LNM^- patients. Moreover, the performance of the models in diagnosing double-positive (*i.e.*, TDs^+LNM^+) patients were further evaluated by outlining all peritumoral nodules with short-axis diameters > 3 mm in the mixed group [TDs^+LNM^+ (n = 15); randomly selected single-positive patients from the training or validation sets (n = 15)]. If there were two different results (TD^+ or LNM^+) in all the outlined peritumoral nodules of each patient, double-positive patients were considered to be diagnosed correctly.

Statistical analysis

Statistical analyses were performed using SPSS (IBM Corporation, Armonk, NY, United States), Stata (StataCorp LP, College Station, TX, United States), and MedCalc software. In Table 1, continuous variables were analyzed using t-test or Mann-Whitney U test, and categorical variables were compared using the chi-squared test or Fisher's exact test. The areas under the curve (AUCs) of the models were compared using DeLong's test.

Table 1 Baseline and clinical characteristics of the included patients

Characteristics	TDs^+LNM^- (n = 89)	LNM^+TDs^- (n = 115)	P value	Training set (n = 163)	Validation set (n = 41)	P value

RESULTS

Patient characteristics

A total of 219 patients with RC [TDs^+LNM^- (n = 89); LNM^+TDs^- (n = 115); TDs^+LNM^+ (n = 15)] were enrolled in this study. Clinical factors, including pathological N stage, pathological EMVI, and the size and shape of the largest peritumoral nodule, were found significantly different between the TDs^+LNM^- group and LNM^+TDs^- group. No statistical differences were found in age, gender, location of RC, tumor markers, pathological T stage, histological grade, and other features of the peritumoral nodule (spiculation and CT values) between the TDs^+LNM^- group and LNM^+TDs^- group. The patients were classified into a training set (n = 163) and a validation set (n = 41). Except for carcinoembryonic antigen (P = 0.012), no significant differences were found in the other clinical factors between the training and validation sets (Table 1).

Feature selection and model building

After evaluating the reliability, a large number of radiomics features remained (n = 1490 extracted from the tumor and 1252 from the largest peritumoral nodule), with ICCs of > 0.75. After excluding redundant radiomics features, we selected features using the L1-based method and established Rad-score using a logistic regression analysis. Features included in Rad-score are reported in the Supplementary Tables 2 and 3. Rad-score of the main tumor (Rad-score 1) and that of the largest peritumoral nodule (Rad-score 2) were independent risk factors for differentiating TDs from LNM [odds ratio (OR) = 3.267 and 14.396, respectively]. Regarding clinical factors, although the size and shape of the largest peritumoral nodule had significant difference between the TDs^+ group and LNM^+ group, they were all deleted in the logistic regression (P = 0.314 and 0.948, respectively; Table 2). Furthermore, a combined model integrating Rad-scores of 1 and 2 was established using the logistic regression.

Model evaluation

For classification results, the AUC for Rad-score 1 was 0.768 [95% confidence interval (CI): 0.695-0.830] in the training set and 0.700 (95%CI: 0.537-0.833) in the validation set. Rad-score 2 achieved improved performance, with an AUC of 0.940 (95%CI: 0.892-0.971) in the training set and 0.918 (95%CI: 0.789-0.981) in the validation set. The combined model (Rad-scores 1 + 2) had similar AUCs to Rad-score 2 in both the training and validation sets, as shown in Table 3 and Figure 3A and B. Thus, Rad-score 2 (Rad-

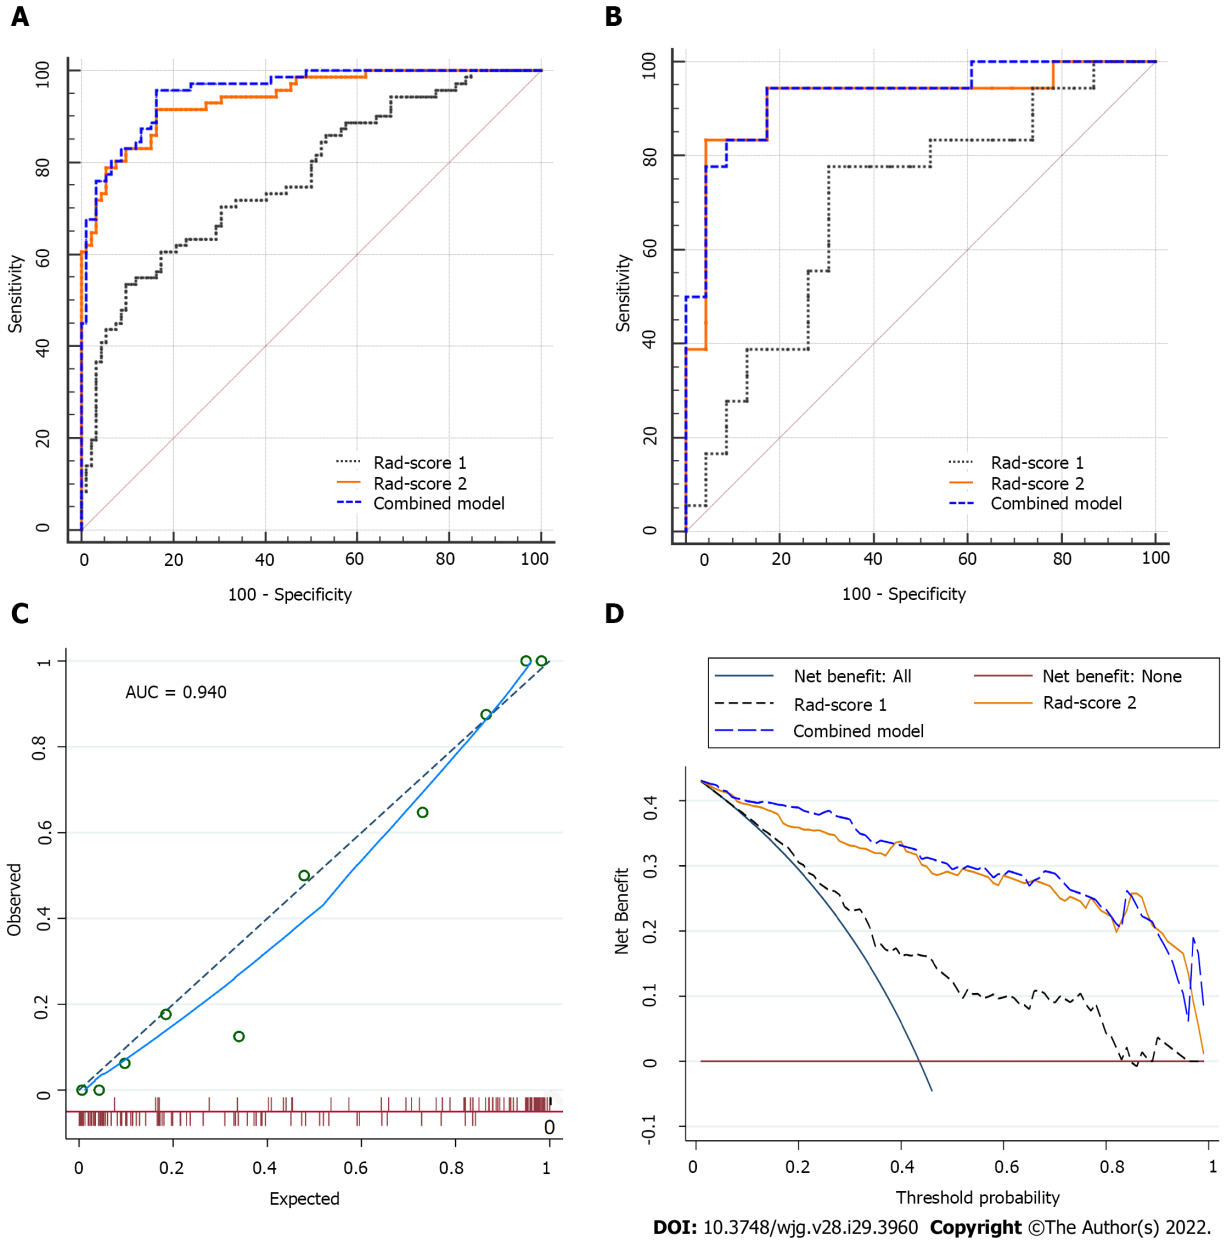
Figure 2 Radiomics workflow. 3D VOI: Three-dimensional volume of interest; GLCM: Gray level co-occurrence matrix; GLSZM: Gray level size zone matrix; GLRLM: Gray level run length matrix; GLDM: Gray level dependence matrix; NGTDM: Neighbouring gray tone difference matrix; ROC: Receiver operating characteristic curve.



score of the largest peritumoral nodule) was used as the final model owing to its simplicity.

In the calibration curve for Rad-score 2, the solid line was close to the reference line (dotted line), indicating that Rad-score 2 demonstrated good agreement between the prediction (x-axis) and observation (y-axis) (Figure 3C). However, Rad-score 2 still overestimated the actual risk for TDs^+ (approximately 10%, at most). A decision curve was constructed to evaluate the clinical utility of Rad-score 2 in differentiating TDs from LNM. The net benefit can be measured along the y-axis. Figure 3D shows that Rad-score 2 yielded more benefit than "treat all", "treat none", and Rad-score 1. A case example is shown in Figure 4.

Moreover, all peritumoral nodules with short-axis diameter > 3 mm were delineated in each patient in the mixed group [TDs^+LNM^+ (n = 15); single-positive (n = 15)] to evaluate the performance of the models in predicting double-positive (*i.e.*, TDs^+LNM^+) patients. Of the 30 patients, 134 peritumoral nodules were delineated. Rad-score 2 had a moderate accuracy of 70% (sensitivity, 73.3%; specificity, 66.6%). Because the combined model had the same accuracy of 70% as Rad-score 2, it confirmed the use of Rad-score 2 as the final model.

Subgroup analysis

In view of the prognostic difference between the upper and middle-lower RC[13], we performed a subgroup analysis indicating that Rad-score 2 had high AUCs in both the upper [0.941 (95%CI: 0.853-

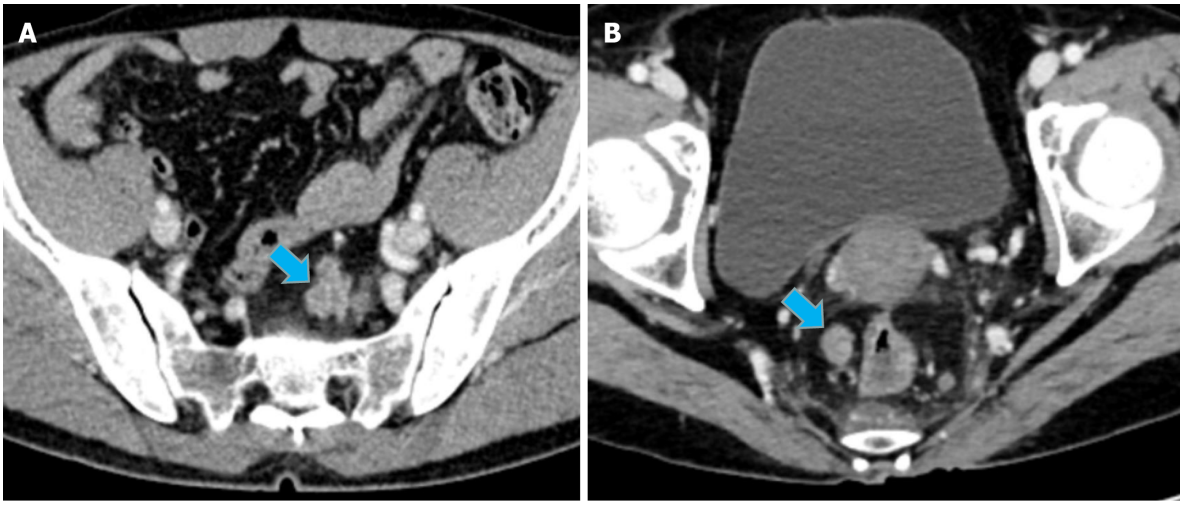
Figure 3 Comparisons of the receiver operating characteristic curves, and fit and usefulness evaluation of Rad-score 2. A: In the training set: Area under the curve (AUC) = 0.768 for Rad-score 1, 0.955 for the combined model, and 0.940 for Rad-score 2; B: In the validation set: AUC = 0.700 for Rad-score 1, 0.930 for the combined model, and 0.918 for Rad-score 2; C: The calibration curve of Rad-score 2 shows good agreement between the predicted and observed risks in the training cohort; D: The decision curve demonstrates that Rad-score 2 obtains more benefit than "treat all", "treat none", and Rad-score 1. Rad-score 1: Rad-score of the main tumor; Rad-score 2: Rad-score of the largest peritumoral nodule; AUC: Area under the curve.

0.984)] and middle-lower [0.931 (95%CI: 0.875-0.967)] RC groups. For patients receiving neoadjuvant chemoradiotherapy (nCRT), Rad-score 2 also had high AUCs, as shown in Table 4. In these subgroup analyses, Rad-score 2 outperformed Rad-score 1.

The American Joint Committee on Cancer (AJCC) tumor-node-metastasis (TNM) staging system has not correlated a higher number of TDs with staging, unlike LNs (*e.g.*, N1, 1-3 and N2, ≥ 4 regional LNs) [14]. Several authors have found that patients with ≥ 3 TDs have a significantly worse prognosis than those with 1-2 TDs[15]. However, in this study, the values of Rad-scores 1 and 2 were not significantly different between the ≥ 3 TDs group and the 1-2 TDs group (P = 0.838 for Rad-score 1, and P = 0.309 for Rad-score 2) (Table 4).



DISCUSSION

Our study established a new radiomics signature (Rad-score 2) based on 11 features extracted from the largest peritumoral nodule, demonstrating the potential for preoperatively differentiating TDs from

Figure 4 Case presentation. A: A 56-year-old man with upper RC, the nodule of TDs (size: 24 mm × 16 mm) had an irregular shape; B: A 44-year-old man with lower RC, the nodule of TDs (size: 14 mm × 11 mm) had a regular oval shape. It is difficult to distinguish TDs and LNM from conventional imaging findings. For these two patients, Rad-score of the largest peritumoral nodule achieved correct diagnosis (values = 0.98 and 0.97, respectively). RC: Rectal cancer; TDs: Tumor deposits; LNM: Lymph node metastasis.

LNM. Moreover, Rad-score 2 outperformed Rad-score 1 (based on the main tumor) in this field [0.918 *vs* 0.700 (P = 0.032) in the validation set]. However, this model had a minor overestimation of TDs^+ probability for most of the included patients.

The 8th AJCC TNM staging system incorporates a N1c category for RC patients with TDs^+LNM^-. The N1c category represents 5% to 10% of RC with TDs (TDs^+LNM^- and TDs^+LNM^+) observed in approximately 20% of all rectal adenocarcinomas[5]. Although many authors have speculated on the origin of TDs, the phenomenon remains unclear. However, some authors have found that a significant proportion of TDs cannot be traced back to the LN[16]. Goldstein *et al*[17] reported that, after performing experiments on deeper sections, most TDs (up to 90%) exhibited signs of > 1 origin. Currently, the only method to determine the status of peritumoral nodules is the histopathologic examination of the resected specimens. The preoperative differentiation of TDs and LNM facilitates the design of individualized treatment strategies and evaluation of prognosis.

Unlike CT and magnetic resonance imaging (MRI), radiomics may solve clinical problems by extracting an enormous number of features which can quantify invisible differences in tissues for the human eye. Several radiomics studies investigating TDs[6,9,10] and LNM[18-21] have been reported in

RC. There were, however, some differences in our study. First, in contrast to most previous models (predicting single factor positive TDs[9,10] or LNM[18-21]), our model can be used to predict the status of both TDs and LNM. When a peritumoral nodule with a short-axis diameter > 3 mm was found on CT images, we could then use our model to predict the classification of this nodule (TDs^+ or LNM^+) and further identify the patient as TDs^+ only, LNM^+ only, or double positive. Second, we delineated the main tumor and the largest peritumoral nodule, while previous authors delineated the tumor and whole peritumoral fat[10] or only the main tumor[9]. Third, our study included a larger sample size of TDs^+ patients (n = 89) and had a higher AUC (0.918 in the validation set) than those reported by Chen *et al*[10] [TDs^+ (n = 40); AUC 0.795], Yang *et al*[9] [TDs^+ (n = 23); AUC 0.820], and Atre *et al*[6] [TDs^+ (n = 25); AUC 0.810]. Finally, although Atre *et al*[6] could also predict both TDs^+ and LNM^+, they only performed texture analysis, which was clearly different from the analysis in our study.

Notably, double-positive patients had a worse prognosis than those with TDs^+ or LNM^+ only. One positive LN 5-year survival rate was 62% without TDs, *vs* 44% with TDs[4]. Thus, preoperative diagnosis of double-positive patients is of great clinical significance. However, the performance of the model decreased (accuracy, 70%) when used to diagnose double-positive patients. We speculated that this may be related to the following factors. First, we established a model based on the largest peritumoral nodule. When diagnosing double-positive patients, we used all peritumoral nodules (> 3 mm). Thus, the mean size in the mixed group was smaller than that in the training set. Second, the sample size of the mixed group was small. Third, among the double-positive patients, some LNMs were incorrectly evaluated as TDs. In these lesions, the value of wavelet-HLH_firstorder_Median (a radiomics feature) decreased. In the future, we will include a larger sample to improve the applicability of the model in double-positive patients.

Nevertheless, the nature of TDs after neoadjuvant therapy remains unclear. Regarding the 77 patients who underwent nCRT in our study, the AUC for the Rad-score 2 did not decrease significantly (0.897), indicating that the model was stable. Regarding the tumor location, the AUCs of the model were also similar between the upper and middle-lower RC. Our model failed to differentiate between groups with ≥ 3 TDs and 1-2 TDs (P = 0.309).

Our study had several limitations. Firstly, because this was a retrospective study, selection bias may have been introduced. Secondly, to directly compare peritumoral nodules, we especially selected a sample comprising TDs^+LNM^- and LNM^+TDs^- and outlined the largest peritumoral nodule. However, it was still possible to identify benign peritumoral nodules. Thirdly, this was a single-center analysis. In the future, it will be necessary to conduct an external validation to confirm the versatility of the model.

CONCLUSION

A radiomics signature based on the largest peritumoral nodule is established in this article. This signature can facilitate the preoperative differentiation of TDs from LNM.

ARTICLE HIGHLIGHTS

Research background

Tumor deposits (TDs) are not equivalent to lymph node (LN) metastasis (LNM) but have become independent adverse prognostic factors in patients with rectal cancer (RC). If TDs can be differentiated from LNM before therapy, individualized treatment and patient prognosis may greatly improve.

Research motivation

Currently, preoperative differentiation of TDs and LNM can be challenging.

Research objectives

To establish a radiomics model for preoperatively differentiating between TDs and LNM in patients with RC.

Research methods

The present study retrospectively enrolled 219 patients with RC [TDs^+LNM^- (n = 89); LNM^+TDs^- (n = 115); TDs^+LNM^+ (n = 15)] from a single center between September 2016 and September 2021. Single-positive patients (TDs^+LNM^- and LNM^+TDs^-) were classified into training (n = 163) and validation (n = 41) sets. Rad-scores were established based on the main tumor and largest peritumoral nodule. After validating Rad-score, we further evaluated its performance for diagnosing double-positive patients (*i.e.*, TDs^+LNM^+) by outlining all peritumoral nodules with diameters > 3 mm (short axis).

Research results

Rad-score 1 (radiomics signature of the main tumor) had an area under the curve (AUC) of 0.768 on the training dataset and 0.700 on the validation dataset. Rad-score 2 (radiomics signature of the largest peritumoral nodule) had a higher AUC (training set: 0.940; validation set: 0.918) than Rad-score 1. For the diagnosis of double-positive patients in the mixed group [TDs^+LNM^+ (n = 15); single-positive (n = 15)], Rad-score 2 demonstrated moderate performance (sensitivity, 73.3%; specificity, 66.6%; and accuracy, 70%).

Research conclusions

The radiomics signature of the largest peritumoral nodule could provide individualized preoperative differentiation of TDs and LNM. Moreover, it was helpful in diagnosing patients who were TDs^+LNM^+.

Research perspectives

To improve the model, surgeons, radiologists, and pathologists should collaborate through prospective research to achieve node-to-node correspondence between CT images and pathological examinations in the future.

Abstract

BACKGROUND

Microwave ablation (MWA) is an effective treatment option for patients with primary liver cancer. However, it has been reported that the MWA procedure induces a hepatic inflammatory response and injury, which may negatively affect the efficacy of MWA. As such, the discovery of reliable markers to monitor the patient's response to MWA is needed. Golgi protein 73 (GP73) has been shown to be associated with chronic liver disease. To date, the potential value of serum GP73 in the dynamic monitoring during MWA of liver cancer remains unclear.

AIM

To examine the effects of MWA on the serum levels of GP73 in patients with primary liver cancer.

METHODS

A total of 150 primary liver cancer patients with a single small lesion (≤ 3 cm in diameter) were retrospectively enrolled spanning the period between January 2016 and October 2018. All of the patients received MWA for the treatment of primary liver cancer. Serum GP73, alpha-fetoprotein (AFP), and widely used liver biochemical indicators [serum albumin, total bilirubin (TBIL), alanine aminotransferase (ALT), and aspartate aminotransferase (AST)] were compared before MWA and at different time points, including 1, 2, and 4 wk following the ablation procedure.

RESULTS

Complete tumor ablation was achieved in 95.33% of the patients at 1 mo after MWA. The 1-, 2-, and 3-year disease-free survival rates were 74.67%, 59.33%, and 54.00%, respectively. The serum AFP levels were significantly decreased at 1, 2, and 4 wk after MWA; they returned to the normal range at 12 wk after MWA; and they remained stable thereafter during follow-up in those cases without recurrence. In contrast, the serum GP73 levels were significantly increased at 1 and 2 wk after MWA. The serum GP73 levels reached the peak at 2 wk after MWA, started to decline after hepatoprotective treatment with glycyrrhizin and reduced glutathione, and returned to the pretreatment levels at 12 and 24 wk after MWA. Notably, the changes of serum GP73 in response to MWA were similar to those of TBIL, ALT, and AST.

CONCLUSION

Serum GP73 is markedly increased in response to MWA of liver cancer. Thus, serum GP73 holds potential as a marker to monitor MWA-induced inflammatory liver injury in need of amelioration.

Key Words: Liver cancer; Microwave ablation; Ablation therapy; Golgi protein 73; Biomarker; Liver injury

Core Tip: Microwave ablation (MWA) has become an effective modality of cancer treatment, including primary liver cancer. However, the MWA procedure induces a hepatic inflammatory response and injury, which may diminish the efficacy of MWA. Therefore, the discovery of reliable markers to monitor the response to MWA is still needed. In this study, we examined the effects of MWA on the serum levels of Golgi protein 73 (GP73). The resulting data suggest that serum GP73 is markedly elevated in response to the MWA procedure. Importantly, our novel findings may have the clinical implication that serum GP73 could be a potential marker to monitor MWA-induced inflammatory liver injury.

INTRODUCTION

Liver cancer is one of the most common malignant tumors throughout the world, and its incidence is relatively high in Asian countries and Pacific islands[1,2]. In China, nearly 500000 cases of primary liver cancer are newly diagnosed annually, accounting for approximately 50% of all new primary liver cancer cases worldwide, mainly due to a particularly high prevalence of hepatitis B virus (HBV) infection[1-3]. Primary liver cancer mainly includes hepatocellular carcinoma (HCC), intrahepatic cholangiocarcinoma (ICC), and combined hepatocellular-cholangiocarcinoma, of which HCC makes up 75%-85% and ICC accounts for 10%-15% of all primary liver cancer cases[4]. For patients with primary liver cancer at an early stage, ablation therapy has been shown to be an effective treatment option. Microwave ablation (MWA) is an ablation modality that destroys cancer cells by using heat from microwave energy. Over the last decade, extensive studies have shown that MWA is effective and safe for treating small primary liver cancer, which is usually less than 3 cm in diameter[5-9]. However, it has been reported that the MWA procedure induces a hepatic inflammatory response and injury, which may negatively affect its efficacy[10]. Therefore, the discovery of reliable markers to monitor the patient's response to MWA is still needed.

Golgi protein 73 (GP73) is a transmembrane glycoprotein with a molecular weight of 73 kDa. Under normal conditions in the liver, GP73 is mainly expressed in the epithelial cells of the bile duct, while its expression in hepatocytes is considerably lower[11]. Previous studies have shown that hepatic GP73 expression is upregulated in a variety of acute and chronic liver diseases[12]. Our previous study also has demonstrated that GP73 is expressed in the cytoplasm of hepatocytes, but not in the infiltrating inflammatory cells in patients with chronic HBV infection, and that changes in the hepatic and serum levels of GP73 are positively correlated with hepatic necroinflammatory activity in CHB patients[13]. Few hepatocytes expressed GP73, and the serum GP73 levels were low in patients with chronic HBV infection but without indications of liver injury. However, once hepatic necrosis was triggered, the affected hepatocytes started to release more GP73 into the blood, resulting in elevated hepatic and

serum levels of GP73. Our previous study also found that elevated serum GP73 levels were positively associated with a higher hepatic necroinflammatory activity grade[14]. To date, the potential value of serum GP73 in the dynamic monitoring and assessment of patient response to MWA during the treatment of liver cancer remains to be further investigated.

Intrigued by our previous findings, we aimed to examine the effects of MWA of liver cancer on the serum GP73 levels before and at different time points after ablation therapy in patients with primary liver cancer. The findings may help to identify potential markers to be used in the dynamic monitoring of the response to MWA for the treatment of primary liver cancer.

MATERIALS AND METHODS

Study subjects

A total of 150 patients with primary liver cancer were retrospectively enrolled from the Liver Disease Center at the 910th Hospital of the PLA Logistics Support Force between January 2016 and October 2018. All of the study subjects were diagnosed as having primary liver cancer, in accordance with the Guidelines for the Diagnosis and Treatment of Primary Liver Cancer in China (2019 edition) issued by the National Health and Health Commission of the People's Republic of China[15], and fulfilled the following inclusion criteria: (1) Age > 18 years old; (2) A single lesion ≤ 3 cm in diameter; and (3) No invasion into the portal vein, hepatic vein, or extrahepatic distant metastasis on imaging examinations [*e.g.*, color Doppler ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI)]. All of the 150 patients with primary liver cancer had a history of HBV infection. Chronic hepatitis B (CHB) and CHB-associated liver cirrhosis were diagnosed in accordance with the diagnostic criteria as reported in the Guidelines of Prevention and Treatment for Chronic Hepatitis B (2019 version)[16]. The exclusion criteria were as follows: (1) Age ≤ 18 years old; (2) The number of lesions ≥ 2 or the size > 3 cm in diameter; (3) The tumor invaded adjacent organs or extrahepatic metastases occurred; (4) Child–Pugh score of grade C; (5) Uncorrectable coagulation dysfunction; (6) Complicated with active infection; (7) Massive ascites and cachexia; (8) Major organ failure (heart, brain, lung, kidney, or other important organs); (9) Eastern Cooperative Oncology Group (ECOG) score > 2; and (10) Disorders of consciousness or inability to cooperate with medical treatments. Among the 150 patients with primary liver cancer, 143 patients with space-occupying lesions with typical imaging features of liver cancer did not receive a liver biopsy, and the remaining 7 patients underwent a liver biopsy and had a pathological diagnosis of primary HCC. In terms of the status of the background liver, 115 patients had background liver cirrhosis, and 35 patients showed no clinical signs of liver cirrhosis.

This study was approved by the Ethics Committee of the 910th Hospital of the PLA Joint Logistics Support Force (Quanzhou, Fujian Province, China). All of the patients provided a signed informed consent.

MWA of liver cancer

All of the patients refused liver resection surgery and were willing to undergo MWA of liver cancer on a microwave therapeutic apparatus (Nanjing, Jiangsu Province, China). The procedure was performed under the guidance of CT or color Doppler ultrasound. The power and ablation time were designed for each patient based on the size of the liver cancer and the surrounding tissues. The ablation zone size was 0.5-1 cm to the margin of the tumor.

Effectiveness of MWA and follow-up

Enhanced CT or MRI examinations were performed on the patients at 1 mo after MWA to determine the complete or partial tumor ablation rate. The patients were followed up for more than 3 years, during which the patients were scheduled for enhanced CT or MRI to determine the cumulative recurrence rate, survival time, local tumor progression, presence of new tumors, disease-free survival (DFS), and overall survival (OS). Complete tumor ablation was defined as no residual tumor on enhanced CT or MRI within the ablation zone and adequate ablation margins of 0.5-1.0 cm. Partial tumor ablation was defined as the presence of a residual tumor on enhanced CT or MRI in the zone of ablation.

Quantitative enzyme-linked immunosorbent assay of serum GP73 levels

Enzyme-linked immunosorbent assay (ELISA) was performed to determine the serum GP73 levels at the Laboratory of Liver Diseases, the 910th Hospital of the PLA Joint Logistics Support Force. The GP73 ELISA detection kit was purchased from Hotgen Biotech Co. Ltd. (Beijing, China) and used for the determination of serum GP73 levels on a Model 680 Microplate Reader (BIO-RAD, United States), according to the manufacturer's protocol. A serum GP73 concentration of 45 mg/L was used as a cut-off value for the general healthy population.

Serum alpha-fetoprotein and liver biochemical tests

Serum alpha-fetoprotein (AFP) was examined using an AFP detection kit (Roche Diagnostics, Basel,

Switzerland), and a value of < 7 mg/L was considered to be normal. Liver biochemical tests, including serum albumin (ALB), total bilirubin (TBIL), alanine aminotransferase (ALT), and aspartate aminotransferase (AST), were determined on a TBA120FR automatic biochemistry analyzer (Toshiba Medical System Co., Ltd., Japan) in the Clinical Laboratory of the 910th Hospital of the PLA Joint Logistics Support Force (Quanzhou, Fujian Province, China).

Statistical analysis

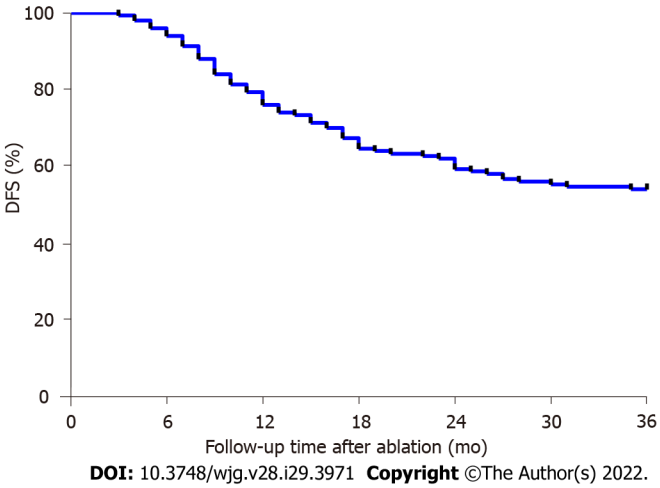
Statistical analysis was performed using GraphPad Prism 5.0 software (Graphpad Software Inc., La Jolla, CA, United States). Count data were expressed as percentages (%). Continuous variables were presented as the median (25%, 75%). For paired data following a normal distribution, a paired *t*-test was used to evaluate differences between the pairs. For non-normally distributed data, a paired Wilcoxon signed-rank test was applied to determine the difference between matched samples. The Kaplan–Meier method was used for survival analysis. $P < 0.05$ indicated that the difference was statistically significant. The statistical methods of this study were reviewed by Zhu YL from the Department of Medical Statistics, Huaqiao University.

RESULTS

Characteristics of the enrolled patients with primary liver cancer

The study cohort was comprised of 150 primary liver cancer patients with one small lesion (average size, 2.03 cm in diameter; range, 0.7-3 cm), including 130 men (86.67%) and 20 women (13.33%), and the median age was 56.00 years old. All of the enrolled patients had a medical history of chronic HBV infection, of which 97 patients (97/150, 64.7%) were positive for the HBV e antigen. Of note, 91 patients (91/150, 60.7%) received antiviral treatment with entecavir or tenofovir disoproxil fumarate for more than 1 year before undergoing MWA and had an HBV DNA concentration of < 500 IU/L, while the remaining 59 patients (59/150, 39.33%) who did not receive the antiviral treatment had an average HBV DNA level of 6.32 (4.52, 7.15) log10 IU/L. Of the enrolled primary liver cancer patients, 115 patients had compensated liver cirrhosis, accounting for 76.7% of the study subjects. Prior to MWA, the 150 patients with primary liver cancer had an ECOG Performance Status score of 0 and a Child–Pugh classification of Class A. The majority of the patients with primary liver cancer had abnormally high levels of AFP, accounting for 68.00% (102/150) of the study subjects. The liver biochemical characteristics, including serum ALB, TBIL, ALT, and AST, as well as the AFP and serum GP73 Levels of the study subjects before MWA are summarized in Table 1.

All of the patients received MWA for primary liver cancer, and the effectiveness was evaluated, including the complete tumor ablation rate at 1 mo after MWA, recurrence rate, and survival time. At 1 month after MWA, enhanced CT/MRI examinations showed that 143 patients (143/150, 95.33%) achieved complete tumor ablation. A small proportion of the patients (7/150, 4.67%) who had partial tumor ablation underwent reablation treatment with MWA and achieved complete tumor ablation. All of the 150 patients were followed up for more than 3 years, and the results were as follows: 134 patients (134/150, 89.33%) survived and 16 patients (16/150, 10.67%) died due to gastrointestinal bleeding in 5 patients (5/150, 3.33%) and liver failure in 11 patients (11/150, 7.33%). The OS rates at 1, 2, and 3 years after MWA were 100.00%, 96.00%, and 89.33%, respectively. In terms of tumor recurrence, cumulative recurrence occurred in 69 patients (69/150, 46.00%) at 3 years after MWA, including 13 patients (13/150, 8.67%) with local tumor progression and 57 patients (57/150, 37.33%) with a new tumor. Among the 69 patients with tumor recurrence, the overall 1-, 2-, and 3-year recurrence rates after MWA were 55.07% (38/150), 33.33% (23/150), and 11.59% (8/150), respectively. As presented in Figure 1, the 1-, 2-, and 3-year DFS rates after MWA were 74.67%, 59.33%, and 54.00%, respectively, in the patients with MWA treatment of primary liver cancer.



Changes of liver biochemical indicators before and after MWA in the enrolled patients with primary liver cancer

MWA for primary liver cancer may cause some adverse effects, including inflammatory injury in the liver. We analyzed the effects of MWA treatment on the widely used liver biochemical indicators ALB, TBIL, ALT, and AST by comparing their values of the enrolled patients before MWA and at different time points (1, 2, and 4 wk) after the treatment procedure. As shown in Table 1, the serum levels of ALB were significantly decreased, while the levels of serum TBIL, ALT, and AST were significantly increased at 1 wk after MWA treatment compared with those levels prior to MWA as a control (all $P < 0.001$). We found that increases in the biochemical indicators (TBIL, ALT, and AST) were related to the hepatocyte injury in response to MWA treatment. There were no significant differences in ALB, TBIL, ALT, or AST between before and at 2 or 4 wk after the MWA treatment (Table 1), which was mainly attributed to the implementation of hepatoprotective therapy using the active compounds glycyrrhizin and reduced glutathione for nearly 2 wk.

Table 1 Liver biochemical tests in the primary liver cancer patients before and after microwave ablation treatment

Figure 1 Disease-free survival rates of the patients with primary liver cancer after treatment with microwave ablation. The disease-free survival (DFS) rates were analyzed at 6, 12, 18, 24, 30, and 36 mo after microwave ablation (MWA) for primary liver cancer in the patients. The 1-, 2-, and 3-year DFS rates after MWA were 74.67%, 59.33%, and 54.00%, respectively. DFS: Disease-free survival.

Changes of serum AFP before and after MWA treatment in the enrolled patients with primary liver cancer

We examined the effects of MWA on the serum AFP levels before and after MWA treatment in the enrolled patients with primary liver cancer. As illustrated in Figure 2 and Table 1, the patients had an abnormally high AFP level of 110.40 (32.71, 267.30) mg/L before MWA treatment (pre-MWA), which was decreased sharply to 37.61 (23.30, 95.48) mg/L at 1 wk after MWA treatment. Notably, the AFP level continued to decrease at 2 and 4 wk, returned to the normal range at 12 wk after MWA, and remained stable thereafter during follow-up in those cases without recurrence (Figure 2, Table 1). Statistical analysis revealed that the serum AFP levels at all time points after the MWA treatment were significantly lower compared with the value prior to MWA treatment as a control (all $P < 0.001$). For the recurrent cases with primary liver cancer, however, the serum AFP levels started to increase at 12 wk post MWA; the values were 75.85 mg/L (range, 38.32-86.70 mg/L), 54.17 mg/L (range, 37.83-82.60 mg/L), 67.80 mg/L (range, 37.67-97.32 mg/L), 43.20 mg/L (range, 29.80-58.96 mg/L), 38.05 mg/L (range, 30.85-93.93 mg/L), and 66.73 mg/L (range, 51.90-81.56 mg/L) at 24, 48, 72, 96, 120, and 144 wk following the MWA treatment, respectively (Figure 2).

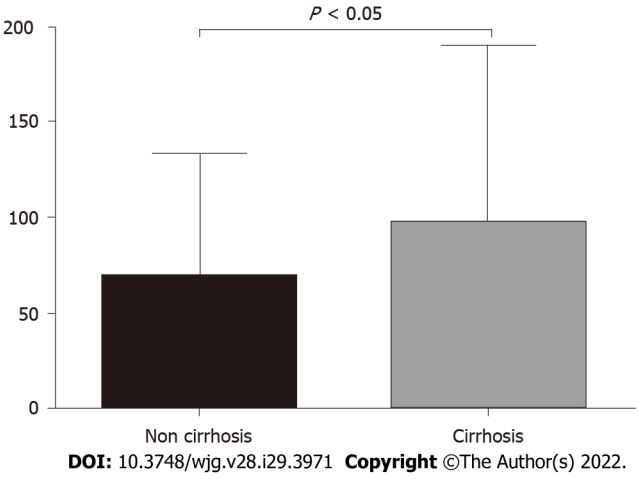
Figure 2 Effects of microwave ablation treatment on the serum alpha-fetoprotein levels in patients with primary liver cancer. The serum alpha-fetoprotein (AFP) levels were examined in the primary liver cancer patients before microwave ablation (MWA) treatment and at different time points after the treatment. The average serum AFP level was 110.4 mg/L before MWA treatment (pre-MWA), decreased sharply to 37.61 mg/L at 1 wk after MWA treatment, continued to decrease, returned to the normal range at 12 wk after MWA, and remained stable thereafter during follow-up in those cases without recurrence. For the recurrent cases with primary liver cancer, however, the serum AFP levels started to increase at 12 wk following the MWA treatment. AFP: Alpha-fetoprotein.

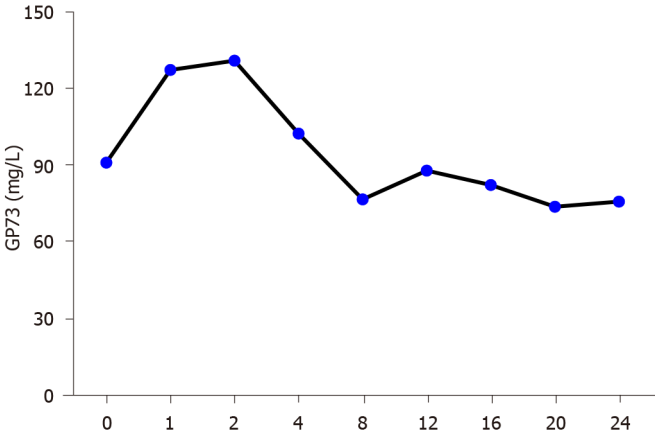
Comparison of serum GP73 levels in the primary liver cancer patients with or without liver cirrhosis



We compared the serum GP73 levels in the enrolled liver cancer patients with *vs* without background liver cirrhosis. As shown in Figure 3, the average level of serum GP73 in the 115 patients with liver cirrhosis was 97.76 mg/L (range, 70.65-133.10 mg/L), which was significantly greater than 69.02 mg/L (range, 45.48-101.40 mg/L) in the 35 patients without liver cirrhosis ($t = 2.477$, $P < 0.05$) (Figure 3).

Changes of serum GP73 before and after MWA treatment in the enrolled patients with primary liver cancer

To evaluate the potential value of serum GP73 measurement for inflammatory injury associated with MWA treatment, we analyzed the serum GP73 levels in the primary liver cancer patients before and at different times after the MWA treatment. As shown in Figure 4 and Table 1, the average serum GP73 level was 90.83 mg/L (range, 54.49-110.6 mg/L) before MWA, which was increased to 127.1 mg/L (range, 84.66-175.50 mg/L) and 130.70 mg/L (range, 88.39-163.60 mg/L) at 1 and 2 wk following the MWA treatment, respectively. Notably, the serum GP73 level started to decline after hepatoprotective treatment with glycyrrhizin and reduced glutathione at 4 wk post MWA; the values were 102.20 mg/L (range, 59.15-121.90 mg/L), 85.73 mg/L (range, 61.42-105.70 mg/L), and 76.09 mg/L (range, 59.26-102.66 mg/L) at 8, 12, and 24 wk following the MWA treatment, respectively (Figure 4). Statistical analysis revealed that the serum GP73 levels were significantly greater at 1 and 2 wk after the MWA procedure *vs* before MWA (1 wk after MWA *vs* before MWA: $t = 5.150$, $P < 0.001$; 2 wk after MWA *vs* before MWA: $t = 6.182$, $P < 0.001$) (Figure 4). It is worth noting that the serum GP73 level reached the peak at 2 wk after MWA and then started to decline at 4 wk after MWA (Figure 4). During the follow-up of the patients at 12 and 24 wk following the MWA treatment, the serum GP73 levels were similar to the pretreatment level (Figure 4).



DISCUSSION

This retrospective study has the following major findings: (1) MWA was highly efficacious in treating patients with small primary liver cancer, with as high as 95.33% of the patients achieving complete tumor ablation at 1 mo after MWA; (2) The serum AFP level was significantly decreased following the MWA treatment and returned to the normal range at 3 mo after MWA, which was in agreement with the observation for the complete tumor ablation rate; (3) The serum GP73 levels were significantly elevated at 1 and 2 wk following MWA, with the peak reached at 2 wk after completion of the treatment; (4) The serum GP73 level declined starting at 4 wk after MWA and continued to decrease to the pretreatment level at 12 and 24 wk after MWA; and (5) The effect of MWA on the serum GP73 level was similar to those of TBIL, ALT, and AST. These findings suggest that measurement of the serum GP73 level has the potential to monitor MWA-mediated inflammatory injury in patients with primary liver cancer.

Figure 4 Effects of microwave ablation treatment on serum Golgi protein 73 levels in the enrolled patients with primary liver cancer. The serum Golgi protein 73 (GP73) levels were examined in the primary liver cancer patients before and after microwave ablation (MWA) treatment. The serum GP73 levels were increased 1 and 2 wk after MWA. The serum GP73 levels reached the peak at 2 wk after MWA, then progressively decreased, and returned to the pretreatment levels 12 and 24 wk following the MWA treatment. GP73: Golgi protein 73.

In the last decade, percutaneous ablation therapy has been used as a radical treatment method for treating patients with liver cancer[6,17]. In contrast to other types of ablation therapy, MWA has a number of advantages (*e.g.*, a faster ablation time, the capability of simultaneous ablation of multiple lesions, and larger tumor ablation volumes)[18]. Compared with traditional radiofrequency ablation for the treatment of small primary liver cancer nodules, MWA is less affected by the heat sink effect[19-21]. Therefore, MWA is widely accepted as an effective nonsurgical treatment option for liver cancer of a small size and at an early stage[19-23]. Of note, MWA has been demonstrated to completely destroy tumor cells and has been proposed as a radical treatment for small primary liver cancer (≤ 3 cm in diameter) with a single lesion[6,22,24]. In addition, Zhang *et al*[25] performed a meta-analysis of 1480 patients and showed that the therapeutic effectiveness of MWA was superior to that of surgical resection for the treatment of small liver cancer (< 3 cm in diameter). There were no significant differences in the OS, DFS rate, and recurrence rate between MWA and surgical resection for small liver cancer. Our results revealed a high therapeutic effectiveness of MWA for primary liver cancer as supported by several lines of evidence, including 95.33% of patients reaching complete tumor ablation at 1 mo after MWA, high OS rates (1- and 3-year OS rates of 100.00% and 89.33%, respectively), and high DFS rates (1-, 2-, and 3-year DFS rates of 74.67%, 59.33%, and 54.00%, respectively), which were similar to those values previously reported for surgical resection[26]. Despite the high therapeutic effectiveness of MWA for small primary liver cancer, the procedure may trigger an inflammatory response and cause liver injury, which will need to be monitored and alleviated properly.

It merits attention that the serum GP73 level in the present study was significantly elevated at 1 wk after MWA, reached the peak at 2 wk after completion of the procedure, and then declined at 4 wk following MWA. During follow-up of the patients with primary liver cancer at 12 and 24 wk after MWA, the serum GP73 levels nearly returned to the pretreatment level. Consistent with the increase of the serum GP73 levels at 2 and 4 wk after MWA, the serum TBIL, ALT, and AST levels were also significantly increased. Moreover, previous studies have reported that MWA is associated with liver injury due to the high temperature generated in the procedure, induction of hepatocyte apoptosis, and stimulation of the intrahepatic macrophage-related inflammatory response[10,21]. After the MWA-mediated liver injury was alleviated with the implementation of hepatoprotective therapy using the active compounds glycyrrhizin and reduced glutathione for nearly 2 wk, the serum GP73 level was significantly decreased and returned to a level similar to that before MWA. The change of the serum GP73 level in the early response to MWA as well as anti-inflammatory and hepatoprotective therapy using glycyrrhizin and reduced glutathione suggests that serum GP73 is related to the aseptic inflammatory injury of hepatocytes after MWA. The results of this study are also in agreement with those of our previous study demonstrating that the serum GP73 level is increased in liver inflammatory injury [13,14]. Therefore, these findings suggest that the serum GP73 level could be a useful diagnostic approach to monitor the liver inflammatory injury caused by MWA during the treatment of primary liver cancer.

This study does have some limitations that must be addressed. For instance, this was a retrospective study that selected liver cancer patients with one small lesion (≤ 3 cm); therefore, bias in patient selection may have occurred. In addition, due to the retrospective nature of this study, we were unable to examine the correlation between the initial level of GP73 after MWA and the AFP level, recurrence rate, or survival rate. Further prospective studies are needed in the future to validate the interesting findings and to assess the diagnostic accuracy of serum GP73 for monitoring liver injury following MWA treatment for primary liver cancer.

CONCLUSION

Taken together, this study demonstrated that serum GP73 is markedly elevated in response to MWA treatment for primary liver cancer. Therefore, the findings have a clinical implication that measurement of serum GP73 holds promise for monitoring MWA-induced inflammatory liver injury that requires alleviation.

ARTICLE HIGHLIGHTS

Research background

Microwave ablation (MWA) has been proven to be highly effective in treatment of small primary liver cancer. However, the procedure may trigger an inflammatory response and cause liver injury in primary liver cancer patients undergoing MWA. As such, it is needed to find reliable markers to monitor and evaluate patient response to MWA. Previous studies have shown that Golgi protein 73 (GP73) are associated with liver inflammatory injury.

Research motivation

This study was designed to test our hypothesis that serum GP73 levels altered in response to MWA in patients with primary liver cancer, and thereby could be used as a potential marker for MWA-induced liver inflammation and injury.

Research objectives

The main objective of this study was to examine effects of MWA on the serum levels of GP73 before and at different time points after the ablation procedure in patients with primary liver cancer.

Research methods

Patients with primary liver cancer (≤ 3 cm in diameter) receiving MWA were retrospectively enrolled in this study. Serum GP73 levels were compared before and 1, 2, and 4 wk after the ablation procedure.

Research results

The serum GP73 levels were significantly elevated at 1 and 2 wk after MWA with the peak at 2 wk after completion of the treatment. The serum GP73 levels decreased starting at 4 wk after MWA and continued to decline to the pretreatment level at 12 and 24 wk after MWA. It was worthy to note that the alterations of serum GP73 levels in response to MWA were similar to those of liver biochemical indicators.

Research conclusions

The findings of this study have demonstrated that serum GP73 levels altered in response to MWA in patients with primary liver cancer, and thereby measurement of serum GP73 level holds potential as a biomarker for monitoring and assessment of MWA-mediated inflammatory injury in patients with primary liver cancer.

Research perspectives

Future prospective studies are needed to validate the findings and to assess the diagnostic accuracy of serum GP73 for monitoring liver injury following MWA treatment for primary liver cancer.

Abstract

BACKGROUND

Hepatocellular carcinoma (HCC) is a common tumour often diagnosed with a multifocal presentation. Patients with multifocal HCC represent a heterogeneous group. Although Trans-Arterial ChemoEmbolization (TACE) is the most frequently employed treatment for these patients, previous data suggested that liver resection (LR) could be a safe and effective procedure.

AIM

To compare LR and TACE in patients with multifocal HCC in terms of procedure-related morbidity and oncologic outcomes.

METHODS

All patients with multifocal HCC who underwent LR or TACE as the first procedure between May 2011 and March 2021 were enrolled. The decision to perform surgery or TACE was made after a multidisciplinary team evaluation. Only patients in Child-Pugh class A or B7 and stage B (according to the Barcelona Clinic Liver Cancer staging system, without severe portal hypertension, vascular invasion, or extrahepatic spread) were included in the final analysis. Propensity score matching was used to adjust the baseline differences between patients undergoing LR and the TACE group [number and diameter of lesions, presence of cirrhosis, alpha-fetoprotein (AFP) levels, and Model for End-Stage Liver Disease score]. The Kaplan-Meier method was used to estimate overall survival (OS) and disease-free survival (DFS). The outcomes of LR and TACE were compared using the log-rank test.

RESULTS

After matching, 30 patients were eligible for the final analysis, 15 in each group. Morbidity rates were 42.9% and 40% for LR and TACE, respectively (P = 0.876).

Median OS was not different in the LR and TACE groups (53 mo *vs* 18 mo, $P = 0.312$), while DFS was significantly longer with LR (19 mo *vs* 0 mo, $P = 0.0001$). Subgroup analysis showed that patients in the Italian Liver Cancer (ITA.LI.CA) B2 stage, with AFP levels lower than 400 ng/mL, less than 3 lesions, and lesions bigger than 41 mm, benefited more from LR in terms of DFS. Patients classified as ITA.LI.CA B3, with AFP levels higher than 400 ng/mL and with more than 3 lesions, appeared to receive more benefit from TACE in terms of OS.

CONCLUSION

In a small cohort of patients with multifocal HCC, LR confers longer DFS compared with TACE, with similar OS and post-procedural morbidity.

Core Tip: Hepatocellular carcinoma (HCC) is a leading cause of death and often presents in a multifocal form. Trans-Arterial ChemoEmbolization (TACE) is the most frequently employed treatment for this patient category. As patients with multifocal HCC are a heterogeneous group, previous data suggested that liver resection (LR) could be a safe and effective procedure. A propensity score-matched analysis has been performed to compare LR and TACE in terms of post-procedure morbidity and survival. Despite the limited number of patients, LR conferred longer disease-free survival with similar overall survival compared to TACE. Subgroup analyses identified the patients benefiting more from a specific treatment.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the most frequent primary liver cancer worldwide, accounting for approximately 90% of cases[1]. HCC incidence has grown over the last two decades, with more than 900.000 new cases *per* year. Moreover, it is expected to further increase in the next few years due to the exponential growth in nonalcoholic fatty liver disease[2]. Despite the improvements in diagnosis and management, HCC is detected in a multinodular form in 35%-40% of cases[3,4] with a reported 5-year survival rate of 19.5%[5].

Over the years, various staging systems have been proposed to overcome the limitations of the tumour-node-metastasis system, which only considers tumour burden[6]. Currently, the Barcelona Clinic Liver Classification (BCLC) is one of the most widely used staging systems for HCC, and includes variables related to tumour status, liver function, and performance status (PS), and recommends one or more specific treatment modalities for each disease stage[7].

Several additional efforts have been made to deal with the heterogeneity of the BCLC-B or intermediate stage of this classification. The Italian Liver Cancer (ITA.LI.CA) group recently proposed a new staging system and prognostic score, based on the BCLC staging system, which includes tumour burden, liver function, and other patient-related variables, and provides a subclassification of this stage [8].

Surgical treatments, including liver resection (LR) and liver transplantation, are considered the best choice for survival and quality of life whenever feasible, while Trans-Arterial ChemoEmbolization (TACE) is not a curative treatment and should be used for patients with well-defined, multifocal HCC, a preserved portal flow, and adequate liver function and PS. TACE outcomes are poor, and several lines of information about the safety and effectiveness of surgery in selected patients for whom TACE is usually recommended have been reported[9-12]. Finally, liver transplantation could also have a central role for these patients, especially after successful downstaging[7], but organ shortage and increased demand for organ transplantation could lead to high drop-out rates.

The debate concerning whether selected patients with multinodular HCC may benefit from surgery rather than TACE remains unsolved.

In this study, a propensity-score matching analysis was used to compare procedure-related morbidity and oncological outcomes in multifocal HCC patients classified as BCLC-B who underwent LR or TACE to determine if one treatment should be given priority over the other.

MATERIALS AND METHODS

Study design and patients

A retrospective analysis was conducted on patients with multifocal HCC who had undergone surgical resection or TACE as first-line treatment between May 2011 and March 2021. The following exclusion criteria were considered: Age < 18 years, Child-Pugh score > 7, vascular invasion or extrahepatic spread, and hepatic venous pressure gradient > 15 mmHg. HCC was diagnosed histologically or by imaging techniques [magnetic resonance imaging and/or triphasic computed tomography (CT)] according to the available EASL guidelines version. Before LR or TACE, an evaluation of age, comorbidities, blood chemistry, tumour number and size (major radiological diameter of the largest lesion from the last available imaging test), ITA.LI.CA. stage and Eastern Cooperative Oncology Group PS.

The decision to perform surgery or TACE was taken by the local multidisciplinary team who considered patients and tumour features, including lesion location and relation with the pedicles, and the volume of the future liver remnant. During surgery, intraoperative ultrasound sonography (IOUS) was routinely performed to confirm preoperative planning. Whenever feasible, anatomic resections were preferred. Both conventional, lipiodol-based TACE and TACE with drug-eluting beads were included. The patients' response was evaluated one month after the procedure with a CT scan. For patients who did not achieve a complete response, data and the effectiveness of each subsequent TACE were also recorded.

Post-treatment morbidity was evaluated according to the Clavien-Dindo (CD) classification[13].

All patients underwent a standardised follow-up programme that included blood tests with alpha-fetoprotein (AFP), and a triple phase-contrast enhanced CT scan every three months for the first year and then biannually for 5 years after surgery (starting 3 mo after surgery or 1 mo after TACE). Recurrence was diagnosed in the case of radiological evidence of HCC.

Statistical analysis

Quantitative data were expressed as mean ± SD or median and range, as appropriate. Qualitative data are reported as absolute and relative frequencies. Satterthwait's test or the Mann-Whitney test was used according to the Shapiro-Wilk test and F-Test, respectively, for normality distribution and homoscedasticity to assess the difference in quantitative variables between treatment groups t-test. The chi-square test or Fisher's test were used as appropriate to verify the association between qualitative variables and treatment groups. The propensity score matching (PSM) method was used to compare similar treatment groups for known prognostic factors (AFP levels as a dichotomous variable with a cut-off set at 400 ng/dL, presence or not of cirrhosis, Child-Pugh and Model for End-Stage Liver Disease (MELD) score, number, and diameter of lesions). An AFP level > 400 ng/mL was considered a prognostic factor of poor outcome, as suggested by recent guidelines[14]. A diagnosis of cirrhosis was established based on the presence of one or more of the following: Compatible histology, imaging showing compatible hepatic morphology, liver stiffness > 15 kPa by vibration-controlled transient elastography, clinical or endoscopic or imaging signs of portal hypertension. The propensity score was calculated by a multiple logistic regression model with a backward selection method. The nearest neighbour method was used to match the two groups with a 1:1 ratio.

Overall survival (OS) was calculated from the date of the first treatment to death of any cause or the last follow-up. As TACE patients could need more than one treatment to achieve a complete response, disease-free survival (DFS) was calculated from the date of the effective treatment to the date of first radiological recurrence. Survival was expressed as the median and 95% confidence interval.

The Kaplan-Meier curve method and the log-rank test were used to evaluate the difference in OS and DFS between the groups.

Subgroup survival analyses were performed comparing the results of the different treatment modalities and stratifying patients by the different grades of the ITA.LI.CA classification, the AFP levels (using 400 ng/mL as cut-off), and by the different number and size of HCC (dividing them into two groups using the median value as a cut-off). A P value < 0.05 was considered statistically significant.

All the analyses were conducted using SAS, version 9.2 (SAS Corporation, Cary, NC, United States), and revised by a biomedical statistician.

RESULTS

Patient clinical characteristics

A total of 50 patients with multifocal HCC were included in the study, 25 underwent LR while 25

underwent TACE. The distribution of the factors used for the PSM in the general population is reported in Table 1. All patients belonging to the TACE group had cirrhosis, whereas, among those who underwent LR, cirrhosis was absent in 36% of cases (P = 0.002). The number of lesions was higher among patients who underwent TACE, whereas resected patients usually had more extensive tumours. No significant differences were found between the two groups regarding Child-Pugh score and AFP levels. In contrast, the MELD score tended to be higher in patients who underwent TACE compared with the resected patients. After the PSM, only 30 patients were eligible for the final analysis, 15 from each subgroup.

The general baseline clinical characteristics are shown in Table 2, while data regarding liver function aspects, tumour characteristics, and patient distribution according to the Up-to-7 criteria[15] and ITA.LI.CA classification are reported in Table 3. No statistical differences were found in baseline characteristics. The median age was 69 years, and more than two/thirds of patients were male. The most common cause of liver disease was viral hepatitis, followed by NASH and alcohol use disorder. Lower platelet counts and higher bilirubin levels were present in the TACE group. There was also a trend towards a higher presence of varices in the TACE group. No significant differences across the Up-to-7 criteria in or out and ITA.LI.CA. staging distribution were found.

Postoperative short-term outcomes and survival analysis

Patients in the TACE group received a significantly higher number of treatments (Table 4, P = 0.001). Post-procedure complications were not significantly different between patients who underwent LR and TACE (Table 4). In the surgery group, complications classified as grade 1 and 2 of CD included fever, pneumonia, or the need for blood transfusion. Only one patient developed bile leakage classified as grade 3 according to CD and was treated with percutaneous drainage.

In the TACE group, complications classified as grade 1 and 2 of CD included mostly transient alterations in liver biochemistry and/or fever. Only one patient developed temporary liver failure and required percutaneous drainage due to an abdominal effusion.

The median follow-up was 19 mo (range 3-62). The estimated global median OS and DFS were 31 and 5 mo, respectively (Figure 1). There were no significant differences in OS and DFS for the global population stratified by the ITA.LI.CA classification. Median OS for B1, B2, and B3 groups were 31, 31, and 14 mo, respectively (P = 0.803), while median DFS for B1, B2, and B3 groups were 5, 14.5, and 1.5 mo, respectively (P = 0.516).

No differences in OS were observed when the two treatment groups were compared. A significantly longer DFS was found in resected patients compared with those undergoing TACE (19 mo *vs* 0 mo, respectively, P = 0.0001) (Figure 2).

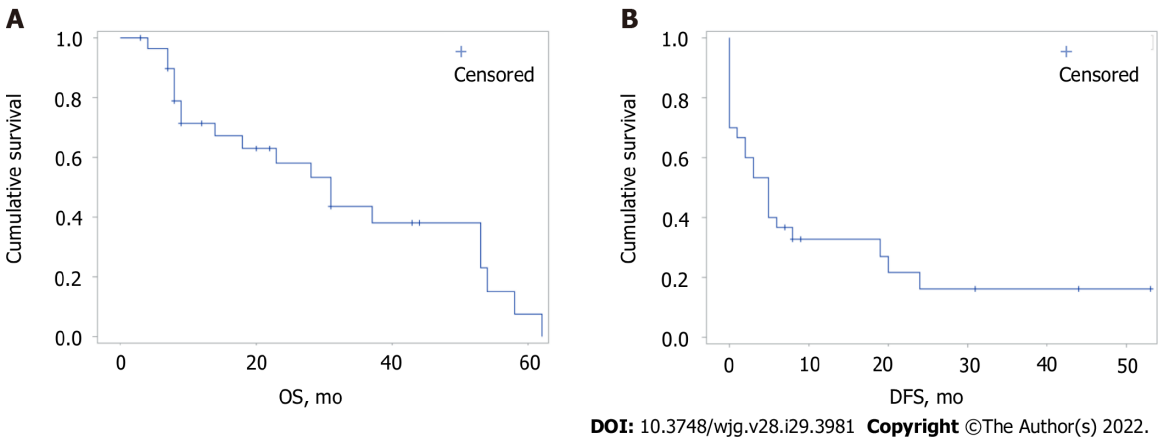
Subgroup analyses were also performed to evaluate the possible differences in OS or DFS according to AFP levels, size, lesion number, Up-to-7 criteria, and ITA.LI.CA staging between each treatment group.

A significant difference was found in both OS and DFS (P < 0.0001 and P = 0.0001, respectively, Figure 3A), with patients presenting with lower levels of AFP showing the best prognosis, in both treatment groups. Furthermore, patients with AFP levels higher than 400 ng/mL and receiving surgery showed a poor OS compared to the TACE group.

No difference in OS was found when comparing treatment modalities in patients stratified according to the Up-to-7 criteria. On the contrary, DFS was higher in the LR group (P = 0.002) (Figure 3B).

The results of different treatment modalities for patients stratified by the ITA.LI.CA classification are reported in Figure 3C. Similar to the previous analysis, a significant difference was found in both OS and DFS (P = 0.047 and P = 0.001, respectively), with patients classified as B2 and receiving resection, showing the best prognosis, while those classified as B3 and receiving resection had the worst prognosis.

Although no significant differences were found in OS, the 4 patients with more than 3 lesions receiving TACE showed a 1, 3, and 5-year OS of 75%, 25%, and 25%, respectively. Among the surgery group, patients with less than 3 lesions had a significantly higher DFS compared with those with 3 or more lesions (P = 0.001). Conversely, no differences in terms of OS and DFS were found in the TACE group stratified by the number of lesions (Figure 3D). Similar results were obtained when the treatment groups were stratified according to the size of the more extensive lesion (Figure 3E). Patients with smaller lesions in the surgery group had a better DFS.



DISCUSSION

HCC is the most common primary liver tumour. Despite recent advantages in terms of follow-up, early diagnosis, and treatment, a considerable percentage of patients are still diagnosed in multiple or advanced forms and global mortality remains high with poor long-term prognosis[16]. The term multifocal HCC comprises patients presenting with a broad disease spectrum, ranging from small, oligonodular tumours to diffuse disease. The accompanying liver cirrhosis, portal hypertension, and liver function impairment should be considered, as they are related to high post-procedure morbidity

and mortality. Therefore, a tailored approach is mandatory for each patient, and the decisional role of a specialised multidisciplinary team has been highlighted and encouraged in the last version of the BCLC classification[7].

The BCLC algorithm recommends TACE as the primary treatment modality for multinodular HCC, but whether a subset of patients may benefit from a surgical approach remains unestablished. We conducted a retrospective analysis using the PSM, a method that may provide high-quality evidence in conditions when randomised clinical trials are unethical or unfeasible. For the PSM analysis, both indicators of liver function and tumour burden and aggressiveness were used. Although the Child-Pugh and MELD scores could be considered outdated after the last published version of the BCLC staging system[7], these data are still commonly used in clinical practice. Wang *et al*[5] showed that patients with gradual deterioration in CP score had shorter survival times and worse prognosis (5-year OS rates of 31.1%, 2.4%, and 0.9% for CP A, B, and C, respectively). AFP is a well-established independent risk factor for survival in HCC patients and levels greater than 400 ng/mL are generally considered diagnostic for HCC, in the presence of appropriate radiologic findings[5,17]. Finally, the number and dimension of the nodules are two of the major prognostic factors, and the most used guidelines underscore their importance in treatment allocation[7,8,14,18].

Figure 2 Kaplan–Meier curves of overall and disease-free survival comparing the results of the different treatment modalities (*P* = 0.312 and *P* = 0.0001, respectively). Median overall survival (OS) and disease-free survival (DFS) for the resection group were 53 [95% confidence interval (CI): 31-53] and 19 mo (95%CI: 3-Not Evaluable), respectively. Median OS and DFS for the Trans-Arterial ChemoEmbolization group were 18 (95%CI: 8-31) and 0 (95%CI: 0-2) months, respectively. A: OS; B: DFS. OS: Overall survival; DFS: Disease-free survival; TACE: Trans-Arterial ChemoEmbolization.

TACE is considered the standard treatment for BCLC-B patients, as evidence from randomised clinical trials and meta-analyses indicates that TACE provides better survival outcomes compared to the best supportive care with a 1-year mortality rate of 34.1%[19-21]. On the other hand, guidelines do not recommend LR for BCLC-B patients, due to the unfavourable prognostic impact of multinodular presentation and high postoperative morbidity[18]. Moreover, LR for multifocal HCC is a challenging

surgery as wide and/or multiple resections are needed, possibly leading to bile leaks and/or postoperative liver failure.

Advances in surgical techniques, including extensive use of IOUS, better coagulation devices, and wider application of minimally invasive surgery, together with better perioperative management, have contributed to improving the results of LR in this difficult-to-treat population. Remarkably, the comparison between different studies is limited by variations in the modalities of detection and reporting of post-procedural complications.

In the present series, we did not find any differences in post-procedure morbidity when comparing resection and TACE. According to the CD classification, only three patients undergoing LR and one patient in the TACE group had a clinically relevant event. However, it should be documented that TACE patients often required more than one treatment to achieve the best response, thus partially explaining the lower morbidity rate of the procedure. Conflicting results on morbidity were previously reported. Zhong *et al*[22] showed a complication rate of 35% and 21% for resection and TACE, respectively[22]. On the contrary, a meta-analysis did not find any difference in post-procedure morbidity between these two treatment modalities[23].

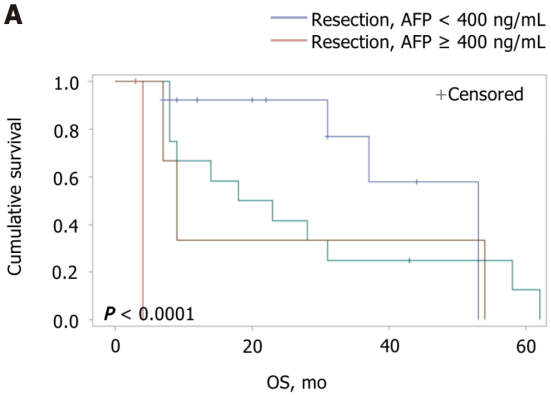
TACE: Trans-Arterial ChemoEmbolization; CD: Clavien-Dindo classification grade.

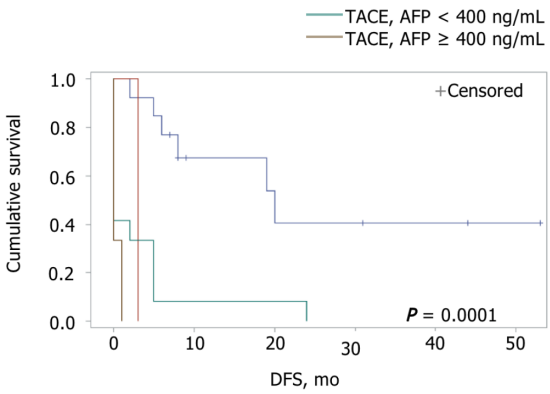
While only a nonsignificant trend towards better OS was observed with surgery, we found that DFS was significantly longer in resected patients. These results confirm and extend previous studies conducted on patients with multinodular HCC. Favourable results with surgery were originally reported by non-controlled studies[10,24]. In a multicentric study including 736 BCLC-B patients, Torzilli *et al*[24] reported a 5-year survival rate of 57% and a DFS of 27%. The survival benefit of LR compared with TACE in BCLC-B patients has been previously reported in the meta-analysis by Liu *et al*[23], and similar conclusions were reached in a randomised controlled trial enrolling 173 patients[25].

Considering the marked population heterogeneity of patients with multinodular HCC, subgroup analyses may provide additional clues for better selection of the treatment modality. Not surprisingly, patients with lower AFP levels had the best prognosis. An exciting result was the observation that patients with high AFP levels benefit more from TACE in terms of OS, and further studies are needed to confirm these data and investigate the possible mechanisms thereof. Another aspect which deserves further investigation is to what extent some of these patients with multinodular HCC could benefit from new systemic combination treatments which include the use of immunotherapy with excellent results [26].



Interesting results were also provided by patient stratification according to the ITA.LI.CA classification. Patients in the B2 subgroup, characterised by nodules of smaller size or lower number, showed the best prognosis when receiving LR. In contrast, those classified as B3, *i.e.*, with larger nodules and higher numbers, had the worst prognosis when resected. Patients with two HCC nodules had a more significant benefit from LR compared with TACE in terms of DFS. These data emphasise the relevance of the number of nodules, which is considered a poor prognostic factor and a predictor of early recurrence.

Nonetheless, a clear cut-off value for the number of nodules beyond which resection is contraindicated has not been determined[10,12,25,27]. Furthermore, although using the same parameters of the Up-to-7 criteria (number of lesions and a maximum diameter of the bigger lesions), the ITA.LI.CA. classification showed better ability in patient stratification.



We also evaluated the impact of nodule size on survival in our series. Interestingly, patients with lesions larger than 41 mm had an even more significant benefit from LR in terms of DFS. Previously published studies reported that patients with large solitary HCC had better survival rates when treated with resection than TACE[28,29]. Furthermore, conflicting results have been reported regarding the potential role of tumour diameter as a prognostic factor. While some studies indicated that tumour size alone was not a predictor of poor prognosis[24,30], other reports mentioned tumour dimension as a predictor of survival[31-33]. In particular, in the analysis of 2887 HCC patients, tumour size was an independent prognostic factor of poor survival at multivariate analysis[5], and Wada *et al*[12] concluded that while size alone was not a contraindication for resection, a diameter lower than 5 cm was a favourable factor[12].

Several limitations of this study must be acknowledged, including its retrospective nature with the inherent selection bias. Moreover, the fact that a limited number of patients from a single centre were enrolled should lead to caution in the general applicability of the results. In addition, the relatively long period of enrollment could have been associated with differences due to modifications in the HCC

Figure 3 Kaplan–Meier curves of overall and disease-free survival comparing the results of the different treatment modalities for patients stratified by different parameters (n = 30). A: Stratification by alpha-fetoprotein levels, lower or higher than 400 ng/mL [overall survival (OS): P < 0.0001 and disease-free survival (DFS): P = 0.0001]; B: Stratification by the Up-to-7 criteria, in or out (OS: P = 0.612 and DFS: P =0.002); C: Stratification by the ITA.LI.CA classification (OS: P = 0.047 and DFS: P = 0.001); D: Stratification by the number of lesions, 2 lesions or more than 3 lesions (OS: P = 0.310 and DFS: P = 0.001); E: Stratification by the maximum diameter of the lesion, smaller or bigger than 41 mm (OS: P = 0.215 and DFS: P = 0.001). Median survival is expressed as months and 95% confidence interval. OS: Overall survival; DFS: Disease-free survival; AFP: Alpha-fetoprotein; N.E.: Not Evaluable; TACE: Trans-Arterial ChemoEmbolization.

management. On the other hand, we performed a rigorous matching using a powerful statistical tool such as the propensity score, although some additional variables not included in the score could have influenced the outcomes.

CONCLUSION

Although the small sample analysed should lead to careful interpretation of the results, after a propensity score matching analysis, patients with multinodular HCC appear to significantly benefit from a surgical approach over TACE in terms of DFS. These results are more evident in the sub-population belonging to the less advanced B2 subgroup according to the ITA.LI.CA. classification, with AFP levels lower than 400 ng/mL, 2 lesions, and with lesions bigger than 41 mm. Patients classified as

ITA.LI.CA B3, with AFP levels higher than 400 ng/mL, and more than 3 lesions had higher benefits from TACE in terms of OS. Future studies are needed to confirm these results in a larger population and to identify other HCC subgroups of patients who would benefit from personalised treatment.

ARTICLE HIGHLIGHTS

Research background

Hepatocellular carcinoma (HCC) is the most frequent primary liver tumour and a leading cause of death. Despite follow-up programmes for cirrhotic patients, HCC is diagnosed in a multifocal form in up to 40% of the patients. Although being a heterogeneous group, the existing classifications consider together the patients with multifocal HCC and generally recommend Trans-Arterial ChemoEmbolization (TACE) as the main treatment. Considering the progress in perioperative care, a growing body of literature has started to propose liver resection (LR) in selected cases, which has shown the best long-term oncological results.

Research motivation

A consensus and detailed guidelines that also consider LR for these patients have not yet been proposed. Moreover, the characteristics of the patients that could benefit more from LR have still to be determined. Defining these aspects could help clinicians in patient management and potentially improve their prognosis.

Research objectives

A comparison between LR and TACE as the first main treatment in terms of post-procedural results and long-term oncological outcomes was performed in patients with multifocal HCC.

Research methods

To reduce the influence of the well-known prognostic factors [*i.e.*, Alpha-fetoprotein (AFP) levels as a dichotomous variable with a cut-off set at 400 ng/dL, presence or absence of cirrhosis, Child-Pugh and Model for End-Stage Liver Disease score, number, and diameter of lesions], a propensity score-matched analysis was performed. Two homogeneous groups (with a 1:1 ratio) were compared to assess the difference in short- and long-term post-procedural results.

Research results

After matching, 30 patients were eligible for the final analysis. Morbidity rates were 42.9% and 40% for LR and TACE, respectively (P = 0.876). Median overall survival (OS) was not different when comparing LR and TACE (53 mo *vs* 18 mo, P = 0.312), while disease-free survival (DFS) was significantly longer with LR (19 mo *vs* 0 mo, P = 0.0001). Subgroup analysis showed that patients in the Italian Liver Cancer (ITA.LI.CA) B2 stage, with AFP levels lower than 400 ng/mL, 2 lesions, and lesions bigger than 41 mm benefited more from LR in terms of DFS. Patients classified as ITA.LI.CA B3, with AFP levels higher than 400 ng/mL and more than 3 lesions appeared to receive more benefit from TACE in terms of OS. However, not all patients with multifocal HCC are amenable to treatment with LR or TACE. Consequently, only a small sample of patients resulted in being eligible for the analysis. Therefore, these results should be considered with caution and further studies are needed.

Research conclusions

There are subgroups of patients with multifocal HCC that seem to benefit more from LR than TACE.

Research perspectives

Further studies are needed to include LR in the guidelines as a potential treatment to be offered to specific subgroups of patients with multifocal HCC.

FOOTNOTES

Author contributions: All authors contributed to the conceptualization and design of the study; Risaliti M, Bartolini I and Campani C wrote the original draft; all authors contributed to critical revision of the article and final approval of the version to be published; Amedei A, Batignani G and Marra F supervised the work.

Institutional review board statement: The study was approved by the Ethical Committee Area Vasta Centro (Florence), No. 12254/22.

Informed consent statement: All study participants or their legal guardian provided informed written consent for

personal and medical data collection prior to study enrolment.

Conflict-of-interest statement: All the authors report no relevant conflicts of interest for this article.

Data sharing statement: No additional data are available.

STROBE statement: The authors have read the STROBE Statement—checklist of items, and the manuscript was prepared and revised according to the STROBE Statement—checklist of items.

Abstract

BACKGROUND

The enteric nervous system (ENS) is situated along the entire gastrointestinal tract and is divided into myenteric and submucosal plexuses in the small and large intestines. The ENS consists of neurons, glial cells, and nerves assembled into ganglia, surrounded by telocytes, interstitial cells of Cajal, and connective tissue. Owing to the complex spatial organization of several interconnections with nerve fascicles, the ENS is difficult to examine in conventional histological sections of 3-5 μm.

AIM

To examine human ileum full-thickness biopsies using X-ray phase-contrast nanotomography without prior staining to visualize the ENS.

METHODS

Six patients were diagnosed with gastrointestinal dysmotility and neuropathy based on routine clinical and histopathological examinations. As controls, full-thickness biopsies were collected from healthy resection ileal regions after

hemicolectomy for right colon malignancy. From the paraffin blocks, 4-μm thick sections were prepared and stained with hematoxylin and eosin for localization of the myenteric ganglia under a light microscope. A 1-mm punch biopsy (up to 1 cm in length) centered on the myenteric plexus was taken and placed into a Kapton® tube for mounting in the subsequent investigation. X-ray phase-contrast tomography was performed using two custom-designed laboratory setups with micrometer resolution for overview scanning. Subsequently, selected regions of interest were scanned at a synchrotron-based end-station, and high-resolution slices were reported. In total, more than 6000 virtual slices were analyzed from nine samples.

RESULTS

In the overview scans, the general architecture and quality of the samples were studied, and the myenteric plexus was localized. High-resolution scans revealed details, including the ganglia, interganglional nerve fascicles, and surrounding tissue. The ganglia were irregular in shape and contained neurons and glial cells. Spindle-shaped cells with very thin cellular projections could be observed on the surface of the ganglia, which appeared to build a network. In the patients, there were no alterations in the general architecture of the myenteric ganglia. Nevertheless, several pathological changes were observed, including vacuolar degeneration, autophagic activity, the appearance of sequestosomes, chromatolysis, and apoptosis. Furthermore, possible expulsion of pyknotic neurons and defects in the covering cellular network could be observed in serial slices. These changes partly corresponded to previous light microscopy findings.

CONCLUSION

The analysis of serial virtual slices could provide new information that cannot be obtained by classical light microscopy. The advantages, disadvantages, and future possibilities of this method are also discussed.

Core Tip: Full-thickness biopsies of 1 mm diameter and up to 1 cm length from the human ileum were scanned using two laboratory-based μ-computed tomography setups to study the architecture of the enteric nervous system (ENS) and further scanned by a synchrotron-based end-station for histopathological studies, without any staining. Several pathological neuronal changes, such as vacuolar degeneration, autophagic activity, appearance of sequestosomes, chromatolysis, and apoptosis, were identified in diseased patients. Phenomena that were undetectable by light microscopy were observed. The relationships among various tissue components could be followed in all directions. Thus, this method provides a unique analysis of the ENS.

INTRODUCTION

The neurons of the enteric nervous system (ENS) assemble into ganglia, forming the submucosal and myenteric plexuses[1]. The ganglia, which also contain glial cells, are connected by nerve fascicles and are surrounded by telocytes and interstitial cells of Cajal (ICC), as well as by other cells and fibers of connective tissue. Various diseases of the ENS may lead to severe bowel motility dysfunction in the form of chronic intestinal pseudo-obstruction (CIPO) and enteric dysmotility (ED)[2,3]. Enteric neuropathy is seldom studied because only a few centers are available for the evaluation of gastrointestinal motility, access to the myenteric plexus requires full-thickness bowel biopsies, and pathologists subspecializing in neuromuscular diseases of the ENS are scarce. Subsequently, the neuropathy diagnosis may be ignored or delayed for several years, which prevents proper healthcare of the patients[4].

We recently presented a methodology to use X-ray phase-contrast nanotomography to study the volume and structure of the ENS[5]. Neurons and surrounding structures are visible using this method without any prior staining, allowing the possibility to study large sample volumes[5,6]. The aim of the present qualitative analysis of virtual slices was to describe in detail the structure of human ileal myenteric ganglia in the normal human ileum as well as in patients with CIPO or ED.

MATERIALS AND METHODS

Patients and samples

Six patients with severe gastrointestinal pain and dysmotility were examined using esophageal manometry, gastric emptying scintigraphy, antroduodenojejunal manometry, and colonic transit time, after exclusion of organic disease. Patients were diagnosed with CIPO when they fulfilled the following three criteria: a medical history compatible with pseudo-obstruction, documented events or chronic signs mimicking mechanical obstruction (bowel dilatation and/or air/fluid levels), and absence of mechanical obstruction or other organic causes for these symptoms and findings[3]. The criteria for ED were documented abnormal contractile activity, but no history of episodes or current signs mimicking mechanical obstruction and the absence of any medication that could lead to the observed motor abnormalities[2].

A previously described laparoscopy-assisted technique for ileal full-thickness biopsies and the preparation of biopsies was used[4,7]. Briefly, 1.0 cm × 1.5 cm large full-thickness biopsies were cut from the ileum and embedded in paraffin. Transversal and horizontal 3-5-mm thick serial sections were stained according to the protocol for CIPO analysis[8]. Histopathological findings were evaluated by a pathologist (B.V.) and classified as previously described[9]. The criteria for neuropathies were based on criteria suggested by the Gastro 2009 International Working Group for Gastrointestinal Neuromuscular Pathology[10]. The histopathological diagnoses and various stains, such as CD117 for ICC, CD34 for telocytes, S100 for Schwann cells, periodic acid-Schiff (PAS) with or without diastase (PAS-D) for carbohydrates or their compounds (*e.g.*, glycogen and mucin), and p62 for sequestosome, were obtained from the medical records (Table 1). For all patients, the disease initially presented when they were adults without any known heredity. Genetic analysis was not performed. There was no correlation between the varying histopathological findings described in Table 1 and the clinical presentation or other functional findings of patients (data not shown).

Three men aged 45, 54, and 82 years were used as controls, all of whom had undergone hemicolectomy due to malignancy in the right colon. A full-thickness biopsy specimen was collected and stained from the healthy resection region of the ileum. The sample size was adopted based on the beam time available in the laboratory.

Sample preparation

From the paraffin blocks of these nine individuals, 4-μm thick sections were prepared and stained with hematoxylin and eosin (H&E) for the localization of the myenteric ganglia under a light microscope. A biopsy punch of 1 mm diameter and up to 1 cm in length centered on the myenteric plexus was taken from the paraffin blocks of patients and controls and placed into a Kapton® tube (Paramount, Indiana, United States) for mounting in the subsequent tomographic investigation[11].

X-ray phase-contrast tomography

X-ray phase-contrast tomography was performed on two custom-designed laboratory setups with micrometer resolution, located at the Institute for X-Ray Physics, University of Göttingen, Göttingen, Germany[11] and a Gottingen Instrument for Nano-Imaging with X-rays (GINIX), installed at the P10/PETRAIII beamline (Hamburg, Germany) with sub-micron resolution[12]. All setups used propagation-based, phase-contrast methods, in which the sample is placed between the source and detector, and the phase information is obtained by free-space propagation and self-interference of the coherent X-ray beam without the need for additional optical elements. Phase retrieval is necessary to correctly extract phase information before tomographic reconstruction[13-15].

The two laboratory setups were installed at a liquid metal jet source (Excillum, Kista, Sweden) or a microfocus rotating anode (mm007, Rigaku, Austin, TX, United States). Both setups used high-resolution scintillator-based detectors (Xsight, Rigaku) and employed broad bandpass radiation peaking at the characteristic lines of Ga Ka (9.25 keV) and Cu (8.05 keV) for the liquid jet and rotating anode sources, respectively. Phase retrieval was performed using the Bronnikov-aided correction algorithm[11,15,16]. As a result, these home-built setups allowed us to image the whole 1-mm wide and several-mm long sample with an isotropic effective voxel size of approximately 1 μm (approximately 15 h scan time per sample), enabling identification of the neural tissue structure (further information about the experimental parameters is provided in (Table 2). The two systems could run in parallel and were used to optimize time consumption.

Table 1 Basic characteristics of subjects

Age, sex	Disease (years)	Clinical diagnosis	Histopathological findings	Histopathological diagnosis	X-ray
45, M	NA	Control	Normal neurons	Healthy	Healthy
54, M	NA	Control	Normal neurons	Healthy	Healthy
82, M	NA	Control	Normal neurons	Healthy	Healthy
27, W	4	ED/type 1 diabetes	Vacuolated, apoptotic neurons, chromatolysis	Lymphocytic ganglioneuritis	Vacuolated, shrunken neurons, chromatolysis, autophagia
27, W	6	Idiopathic ED	Vacuolated neurons, chromatolysis	Degenerative neuropathy	Pre-apoptotic and dead nucleus
32, W	2	Drug-induced CIPO	Vacuolated, shrunken, chromatolysis, hyperplasia ICC	Visceral degenerative neuropathy with axon vacuolization, hyperplasia, and vacuolization of ICCs, and hypertrophy of the longitudinal and internal circular muscle layers	Only fascicle, no ganglia for evaluation
43, W	3	Idiopathic ED	Amphophilic shrunken neurons, Vacuolated neurons, chromatolysis	Lymphocytic ganglioneuritis with neurondegeneration	Amphophilic degeneration, vacuolated neurons
52, W	4	Idiopathic ED	Vacuolated, shrunken neurons, hypoplasia of ICC	Lymphocytic ganglioneuritis	Vacuolated, shrunken neurons, chromatolysis
56, W	50	ED/Ehlers-Danlos	Vacuolated neurons, chromatolysis, hyperplasia ICC	Lymphocytic ganglioneuritis with vacuolar neurodegeneration and hyperplasia of the ICC	Severe atrophy with reduced volume

Data obtained from the medical records; disease duration assessed in years. CIPO: Chronic intestinal pseudo-obstruction; ED: Enteric dysmotility; ICC: Interstitial cells of Cajal; M: Man; W: Woman; NA: Not available.

Table 2 Experimental and reconstruction parameters

Scan configuration	Effective pixel size (μm)	Energy (keV)	Number of projections[1]	Phase retrieval scheme	Phase retrieval parameter	Ring removal algorithm
Laboratory setup (liquid metal jet)	0.920[2]	9.25 (Kα)	1 × 1000 (50 s) or 1 × 700 (40 s)	BAC	α = 0.008, β = 0.160	Wavelet
Laboratory setup (rotating anode)	1.072	8.05 (Kα)	1 × 1000 (50 s) or 1 × 700 (40 s)	BAC	α = 0.07, β = 0.16	Wavelet
GINIX waveguide (all samples except for ED/Ehlers-Danlos patient)	0.169	8.00	4 × 1500 (1 s) or 3 × 1500 (1 s)	Non-linear Tikhonov[3]	δ/β = 50, lim1 = 8e-3, lim2 = 0.5	Additive
GINIX waveguide (ED/Ehlers-Danlos patient)	0.176	7.50	4 × 1000 (2 s)	Non-linear Tikhonov[3]	δ/β = 50, lim1 = 1e-4, lim2 = 0.1	Additive

[1]Due to time constraints, some samples were scanned with a lower number of projections and shorter exposure times (in the overview scans) or with less distances (in the high-resolution scans of the drug-induced chronic intestinal pseudo-obstruction patient and of the 40 years old control).
[2]After voxel binning of 2 × 2 × 2.
[3]No support, no restriction on phase shift.
GINIX: Gottingen Instrument for Nano-Imaging with X-rays; ED: Enteric dysmotility.

Selected regions of interest (ROIs) of 320 μm × 320 μm × 320 μm were scanned with an isotropic effective voxel size of 169 nm at the synchrotron-based end-station (approximately 2.5-3.0 h scan time), using inline holography based on a coherent divergent beam [8 keV, Si (111) monochromator] exiting from an X-ray waveguide[11,12]. Holographic phase retrieval based on contrast-transfer-function (CTF) approach, ring removal, and tomographic reconstructions were performed using in-house reconstruction pipelines[16]. Further details can be found in Table 2.

Complete information regarding the experimental setups and reconstruction pipelines, which were performed by physicists unaware of the diagnosis, is provided in a previous publication[5]. The analysis of the slices reported in this paper was performed on the data acquired at the synchrotron end-station, on the high-resolution scans.

Image analysis

All the obtained volumetric datasets were digitally sectioned along any arbitrary slicing plane, enabling virtual histology of the samples. In the histological evaluation, the term "spindle-shaped cells" was used to describe the cells around the ganglia, which represented either telocytes, ICCs, or fibroblasts/cytes because no differentiation could be made without immunohistochemistry. In cases where identification can be made from double immunohistochemical staining of the same regions[17], the cells are called telocytes or ICC. In total, more than 6000 virtual slices were analyzed from the nine samples.

RESULTS

In the overview scans performed with the laboratory setup, the general architecture of the bowel samples was examined with respect to the quality of the sample and the presence and localization of the myenteric plexus. High-resolution scans revealed details of the myenteric plexus, including the ganglia, interganglional nerve fascicles, and surrounding tissue.

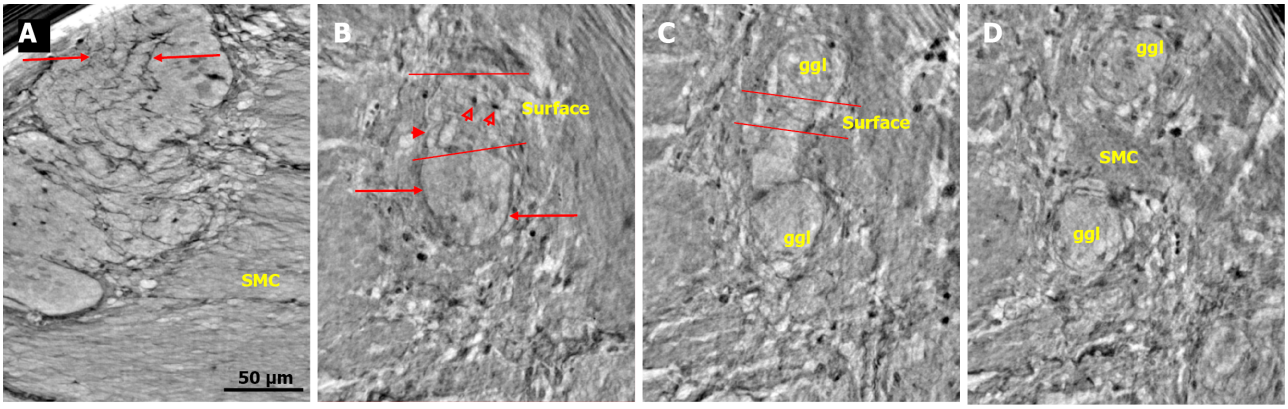
Normal structure of the ileal myenteric plexus

Ganglion: The shape of the ganglia was uneven toward both the muscle layers and interganglional nerve fascicles. The smaller or larger irregularities contained one or more neurons and glial cells (Figures 1, 2A, 4A-D, and 5).

In the surface view of the ganglia, a parallel arrangement of telocytes with long thin "primary" telopodes originating directly from the cellular bodies could be observed, from which shorter "secondary" telopodes radiated sidewise, building up a network (Figures 1A-C, 3B, 4A and B). Occasionally, at the optimal transverse view of the ganglion, a double layer of thin cytoplasmic projections was present (Figure 2B), corresponding to the immunohistochemical demonstration of telocytes and ICCs[17].

Both larger and smaller neurons had mostly rounded nuclei and nucleoli, where larger neurons had finely granulated cytoplasm with a paler network between the granules, whereas the smaller neurons had slightly denser and more homogeneous cytoplasm (Figures 2B and 3B-D). Axons were occasionally observed (Figure 2A). Small glial cells were present around and between the neurons (Figures 2A, 3C and D). No degenerating neurons were found in either of the two younger individuals. In the 82-year-old control, however, one neuron with a shrunken, dark body, pyknotic small almost black nucleus and larger autophagic vacuoles could be observed in addition to numerous normal neurons (not shown).

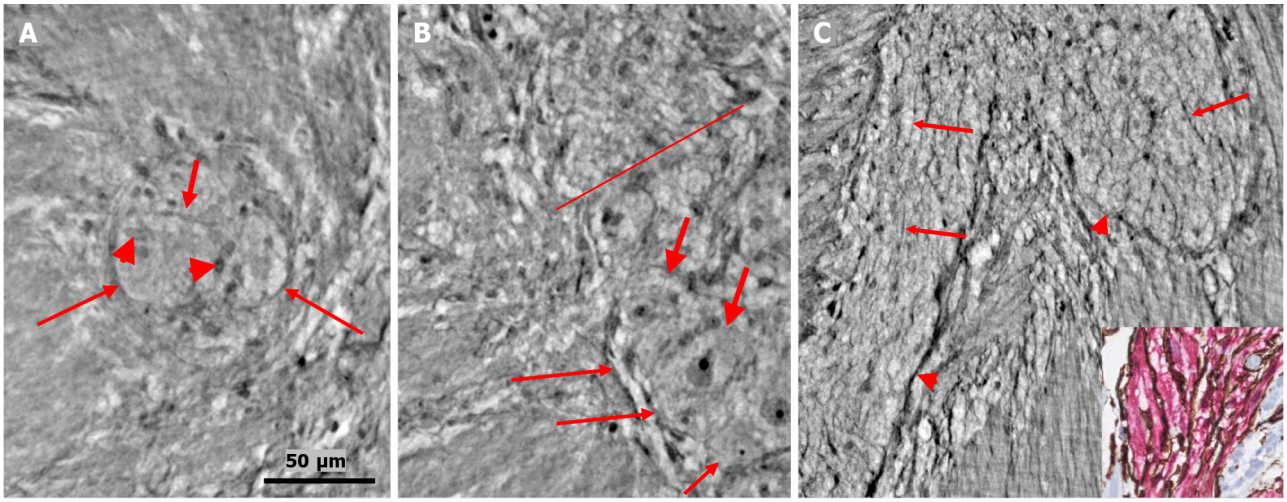
Nerve fascicles and spindle-shaped cell layer



The nerve fascicles had normal architecture. Parallel thin telopodes separated the individual axons (Figures 2C and 3A-C). Some spindle-shaped cells had very thin, dark nuclei, whereas the nuclei of others were larger and cigar-like.

Pathological findings of the ileal myenteric plexus

Four patients had lymphocytic ganglioneuritis or lymphocytic neuritis, and two patients had only visceral degenerative neuropathy. No alterations were observed in the general architecture of the myenteric ganglia. Nevertheless, several pathological changes could be observed, partly corresponding to the light microscopic findings, as shown in the insets of the figures. Cellular changes occurred in all six patients with dysmotility. Suspected lymphocytes were found within the ganglion only in one patient. The lack of lymphocytic attack on the ganglion in other patients can be explained by the focal nature of inflammation.



Pathological neuronal changes

The cytoplasm of several neurons contained vacuoles. Many of the vacuoles contained small dark granules (Figure 5A, C, and D) (autophagic vacuoles/Lipofuscin; 5D-inset: PAS-D$^+$). In one patient, several neurons exhibited pale cytoplasm (Figure 4A-D) (chromatolysis), and a large homogeneous irregular dark area was present (Figure 4F) (4F-inset: Sequestosome p62$^+$). Apoptotic shrunken neurons had compact, dark cytoplasm with small, irregular, pyknotic nuclei (Figures 4C-E, 5B and 6) (4E-inset H&E; 5B-inset: Apoptosis H&E). These neurons were observed in three patients at the ganglion border without telopodes in a few virtual slices (Figure 4B-D), possibly representing the ejection of a dead neuron (Figures 4B-D and 6). Very dense dark inclusions with similar substructures were found in two patients, which are foreign structures for the normal ganglion; one of these bodies is shown in serial virtual slices (Figure 4A-C) (4A-C: Hyaline bodies; 4A and B-insets: PAS-D$^+$). At 6.8 μm in Figure 4A, an inner structure with a central pale area surrounded by an irregular dark ring can be seen within the body (Figure 4B). When viewing 4.0 μm deeper, there is a semi-dense "half-moon" at the edge of the hyaline body (Figure 4C).

Figure 1 Ganglion from healthy human ileum. A: Part of the myenteric ganglion in two portions. Quite regular, almost parallel, thin cytoplasmic projections of telocytes (telopodes) with short, thin "spines" on the surface are observed (between arrows). The scale bar (50 µm) was applied to all subfigures; B: A small portion of the ganglion containing two neurons. On the surface of the ganglion (between the two lines), the cellular nuclei of the two telocytes were observed as dark spots (empty arrowheads). Telopodes radiate from their body. Arrows indicate the telopodes around the ganglion. A telopode can be followed toward the surface (arrowhead); C: 16.9 µm deeper from Figure B, two portions appeared with thin telopodes on the surface; D: 10.1 µm deeper from Figure C, SMCs are observed between the two portions. B-D are representative virtual slices from a series covering 27.0 µm thickness of the ganglion. Ggl: Ganglion; SMC: Smooth muscle cells.

DOI: 10.3748/wjg.v28.i29.3994 **Copyright** ©The Author(s) 2022.

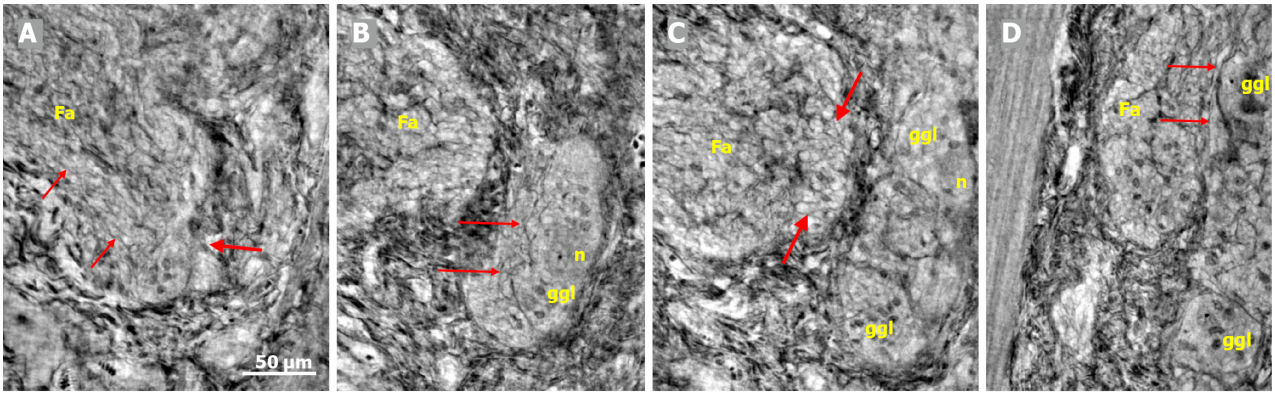

Figure 2 Ganglion and fascicle from healthy human ileum. A: Within a portion of the ganglion, there is a neuron with an axon (thick arrow). Arrowheads indicate glial cells. Thin arrows indicate a single layer of telopodes at the border of the ganglion. The scale bar (50 µm) was applied to all subfigures; B: Part of a ganglion with several large (thick arrows) and medium-large (short thin arrow) neurons. The nuclei contain dark nucleoli. The cytoplasm is slightly granulated. Above the straight line, a small area of the neuropil was observed. Long thin arrows indicate the double-cell layer at the border; C: Normal nerve fascicle and thicker nerve with telopodes separating axons (arrows). Note the single layer of telopodes around the fascicle and nerve (arrowheads). Inset: Normal nerve fascicles stained with double immunohistochemistry. Telocytes run parallel to Schwann cells (light microscopy; S100: Schwann cells red; CD34: Telocytes brown).

Pathological change of the nerve fascicles and perigangliональ spindle-shaped cell layer

In one patient who was diagnosed with lymphocytic ganglioneuritis, a segment of the perigangliональ spindle-shaped cell layer showed vacuolization and/or was absent within a 19.9 µm distance along the length axis of the bowel sample (Figure 5). The largest window in this absence was 16.1 µm in the virtual slices (Figure 5B). At a 7.8 µm deeper level (Figure 5C), a double layer of thin cellular projections appeared at the border of the defect, whereas at an additionally 4.7 µm deeper, one intact layer of cellular projections was again present between the ganglion and the surrounding tissue (Figure 5D).

Video-film

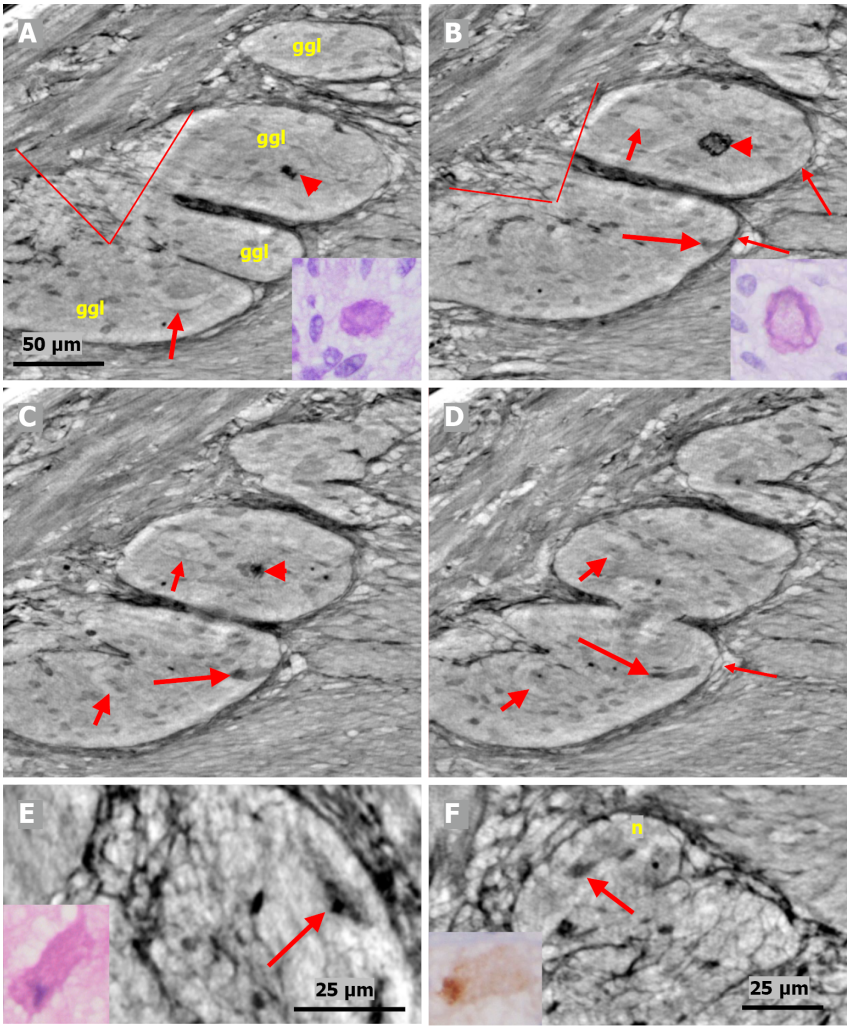
In the video film from one patient, more than one dozen neurons and glial cells could be observed (Supplementary material). Almost all the neurons showed various types of degeneration. Furthermore, one pre-apoptotic neuron in the lower part of the ganglion was probably in contact with the tip of the incomplete septum, and hence, extended into the surrounding tissue (Supplementary material).

DOI: 10.3748/wjg.v28.i29.3994 **Copyright** ©The Author(s) 2022.

Figure 3 Series of virtual slices covering 113.6 µm thickness at the border between the nerve fascicle and the ganglion. A: Thick fascicle with parallel telopodes (thin arrows). There is a small peripheral part of the ganglion (thick arrow); B: 62.2 µm deeper from Figure A. Connective tissue cells between the fascicle and the superficial part of the ganglion. Normal large neurons and nuclei of several glial cells in the ganglion. A network of telopodes is present on the surface of the ganglion (arrows); C: 11.5 µm deeper from Figure B. The thickness of the connective tissue is diminished between the fascicle and the periphery of the ganglion, with two neurons and small glial cells. Transversally cut vesicle-like axons (between the arrows) on the right end of the fascicle; D: 39.9 µm deeper from Figure C, the fascicle and ganglion are united. Thin arrows show telopodes. The scale bar (50 µm) applies to all the subfigures. Fa: Fascicle; ggl: Ganglion; n: Neuron.

DISCUSSION

The main qualitative finding in the present study was that X-ray phase-contrast nanotomography could analyze the different cellular components of the myenteric plexus in more than 6000 serial virtual slices, which could reveal minor changes not seen under the light microscope. We could image large volumes with finer sampling resolution with shorter distances between sections along the sample direction, that is, below the standard thickness of a histological scan.



A study of the normal ganglia revealed that their shape is not usually seen in the transverse sections under a light microscope with a well-defined border. In serial virtual slices, the ganglia have smaller or larger irregularities, with one or a few neurons and glial cells protruding into the muscle layers or the intermyenteric connective tissue. Within the ganglia, neurons of various sizes and glial cells could be clearly differentiated. The absence of thin cytoplasmic projections in the neuropil corroborates our previous finding in the ileal ganglia, namely the lack of telopodes in the ileum in contrast to the colon [17]. The presence of one degenerating neuron in the 82-year-old control may be the result of aging starting at around 40-50 years of age[18].

The optimal transverse sections showed two clear layers of cellular projections surrounding the ganglion, in accordance with our previous immunohistochemical findings[17]. The inner layer consisted of cytoplasmic projections of telocytes called telopodes, which were situated almost parallel to each other, in agreement with immunohistochemical observations[17]. The outer layer is composed of an ICC [17].

Pathological changes from the patients revealed different types of neuronal degeneration (vacuolization, autophagic vacuoles/Lipofuscin, chromatolysis, and apoptosis) and the presence of a hyaline body within the ganglion, as observed under a light microscope by the golden standard of various staining techniques[8]. Furthermore, p62+ sequestosomes were also observed in accordance with the findings of Alafuzoff *et al*[19].

Three new phenomena were discovered with the present phase-contrast nanotomography, which cannot be observed under a light microscope because of the thickness of the paraffin sections. First, the presence of a semi-dense "half-moon" attached to the hyaline body could hypothetically be one of the end stages of cellular death. Second, the phenomenon of a probable expulsion of dead neurons could be followed in the virtual serial slices because of the occurrence of a short "opening" of the telopode-layer between the surrounding connective tissue and shrunken apoptotic neurons. Third, the total absence of the single telopode layer within the 16.1 µm "window" could possibly have negatively affected the stability of the ganglion.

The virtual histology of the myenteric ganglion using X-ray nanotomography has advantages, disadvantages, and future possibilities. The main advantage is that the method can exactly measure the volumes of chosen tissue components following segmentation, as have been previously published[5]. The second advantage is the possibility to analyze several hundred serial virtual slices at subcellular, isotropic resolution, and through this, discover "nano-changes" which cannot be seen using the light microscope. Because the neuron size is 15-40 µm, the ENS is difficult to examine in conventional histological sections of 3-5 µm. Slow videos make it possible to follow the relationships between the various tissue components. The third advantage is the flexibility in sample preparation; samples can be examined with or without paraffin embedding (*e.g.*, in liquid or epoxy resin) or staining. Thus, the

Figure 4 Series of virtual slices covering 17.2 µm thickness of the ganglion from one patient. A: Four portions of the ganglion. There is a dark body at the center of one of these areas (arrowheads). An arrow indicates a neuron with a very pale homogeneous cytoplasm below the nucleus. Between the straight lines, a network of telopodes is observed on the ganglion surface. Incomplete septa between portions. Scale bar (50 µm) is applied to subfigures A-D. Inset: Hyaline body in the ganglion [1st level of serial sections; light microscopy; periodic acid-Schiff with diastase (PAS-D) staining]; B: 6.8 µm from Figure A., three portions of the ganglia are completely separated, and the surface area is smaller (between straight lines). The central dark body shows an irregular dense outer layer and central light area (arrowhead). A new neuron with pale cytoplasm is seen in the middle portion (short arrow). Intact telopodes form the border between the ganglion and the periganglional connective tissue rim (thin arrows). An almost triangle-shaped moderately dense area is seen below the telopode telopode corresponding to an apoptotic neuron (long arrow; see also C and D). Inset: The central region of the hyaline body is negative, whereas the outer layer is positive with PAS-D staining (2nd level of serial sections, light microscopy; PAS-D); C: 4.0 µm from Figure B. The hyaline body is without a central pale area (arrowhead), with a semi-dense irregular half-moon to the left. The two neurons had a pale cytoplasm (short arrows). A dark pyknotic nucleus appeared in the semi-dense cytoplasm at the border showing an apoptotic neuron corresponding to the "dark triangle" in Figure B (long arrow); D: 6.4 µm deeper from Figure C. Two of the portions are united. Nuclei are present in neurons with pale cytoplasm (short arrows). Intact telopodes are present between the degenerated apoptotic cells (long arrow) and the periganglional space (thin arrow); E: Digital magnification of a shrunken neuron with a darker cytoplasm, small vacuoles, and enlarged nucleolus. Scale bar: 25 µm Inset: Pre-apoptotic neurons with pyknotic nucleus and vacuole-containing amphophilic cytoplasm (light microscopy; H&E staining); F: There is a homogeneous circumscribed "inclusion" in the neuron, suggesting a sequestosome, as seen in the inset (arrow). Scale bar: 25 µm. Inset: Large p62+ aggregates in neurons (arrow; light microscopy; p62 immunohistochemistry). Scales bars of 50 or 25 µm included. Ggl: Ganglion; n: Neuron; PAS-D: Periodic acid-schiff with diastase.

samples require less handling and fewer preparation steps[20].

The current established method to diagnose enteric neuropathy uses immunohistochemistry with a wide range of staining according to a standardized protocol[8,21]. The strength of this method lies in the exact identification of different cell types and tissue structures. The weakness is that there is a wide range of different molecules and structures that can vary in abundance among different patients with the same diagnosis. We do not know whether these changes are causal or primary, or whether they are secondary or compensatory. Due to the large variation between patients, no uniform pattern has been determined for the diagnosis of enteric neuropathy, and thus, some of the information did not add substantial value to the examination. The current description of neurons, glial cells, and spindle-shaped cells appears to be sufficient for diagnosis.

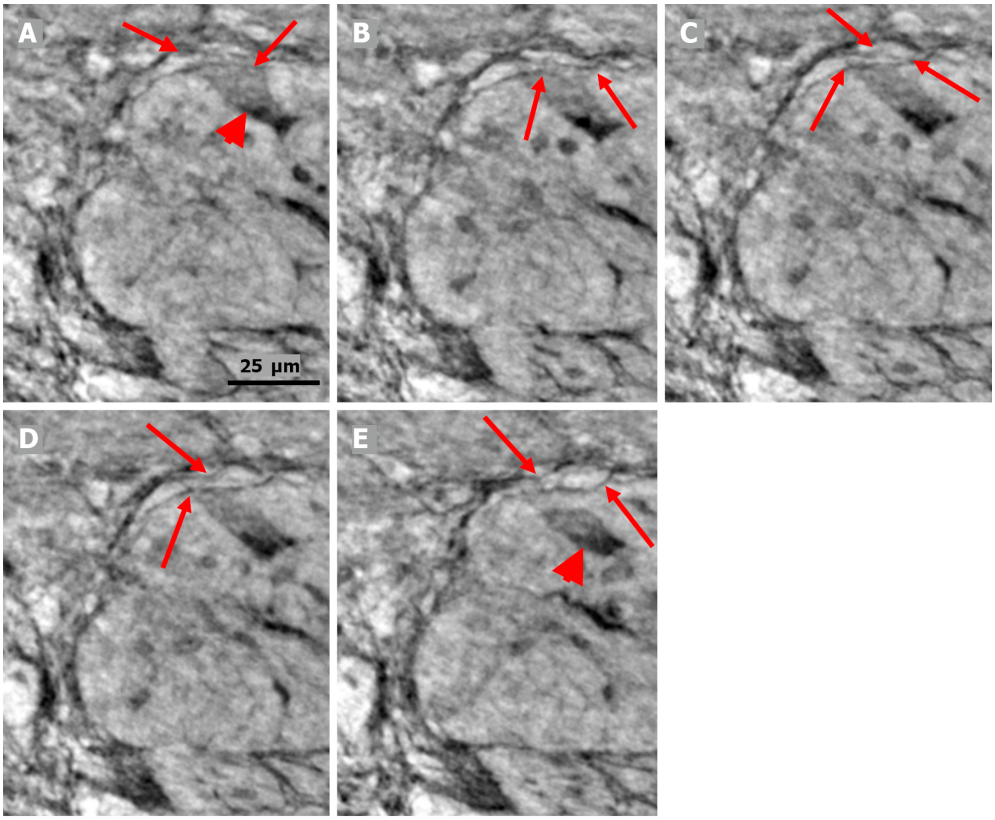
Figure 5 Series of virtual slices covering 19.9 µm thickness of the ganglion from one patient. A: Two portions of the ganglion with smooth muscle cells between them. Long arrows indicate the continuous layer of telopodes with tiny vesicles bordering the ganglion. A string of glial cell nuclei was present within the left portion. The thick arrow shows the vacuole above the nucleus of the neuron. Four small dark granules were present in the other neurons. Inset: Several vacuoles fill the cytoplasm of the two degenerating neurons (light microscopy and H&E staining); B: 7.4 µm deeper from Figure A. Between the thin arrows there is no continuous layer of telopodes, instead some vesicles are seen. The left portion has disappeared. The remaining portion is part of a pre-apoptotic neuron with a dark cytoplasm and pyknotic nucleus (arrowhead). Above this neuron is the nuclei of normal glial cells. The thick arrow indicates a vacuole in the neuron. Inset: Apoptotic neurons with strongly amphophilic cytoplasm and rest of the pyknotic nuclei (light microscopy; H&E staining); C: 7.8 µm deeper from Figure B. The defect of the telopodes (between the thin arrows) was shorter. Double layer of telopodes below the defect. In the upper part of the ganglion, there is a large neuron with a few small dark, dense dots, whereas the pre-apoptotic neuron from the middle of the ganglion is no longer present; D: 4.7 µm deeper from Figure C. There is a continuous layer of telopodes (between arrows) with a "remnant" of the double layer, as shown in Figure C. The dark granules in the neurons were larger and more numerous. Arrowhead shows a neuron with both dark granules and vacuoles. Inset: The cytoplasm of the neurons was filled with diastase-resistant PAS+ lipofuscin granules (light microscopy; PAS-D staining). The scale bar (50 µm) applies to all the subfigures. Ggl: Ganglion; H&E: Hematoxylin & eosin; n: Neuron; PAS: Periodic acid-Schiff; PAS-D: Periodic acid-Schiff with diastase; SMC: Smooth muscle cells.



Fluorescence confocal microscopy has been performed with serial sectioning to mimic three-dimensional (3D) imaging; however, the maximal thickness of viewing is still limited, and the space between sections is larger[22-25]. Recently, another method using immunohistochemistry and confocal microscopy was developed for the quantitative analysis of full-thickness bowel biopsies[26]. These different efforts to improve the analysis of ENS prove the importance of clinicians obtaining more information about the function and dysfunction of the gastrointestinal tract.

Among the disadvantages were the limited access to synchrotron beamtime and the cost of the entire process in terms of money and manpower. Furthermore, because the ganglia of the ENS are very sparse, especially in patients with dysmotility, and the myenteric plexus can fold and curve beneath what is visible on the surface of the block, it is very difficult to correctly punch the tissue of interest based on a histological section. Hence, multi-scale X-ray phase-contrast tomography, which involves scanning a tissue block with a mm-sized field-of-view at µm-resolution and then imaging specific features of interest in greater detail using local nanotomography on the full block (instead of extracting biopsy punches as in this work), would be preferable and has been proven to be feasible at different synchrotron beamlines, such as TOMCAT[27,28] and P10/GINIX[29-31].

In the future, the combination of immunohistochemistry with X-ray phase-contrast nanotomography, such as immuno-electron microscopy[32], or with joint X-ray phase-contrast tomography and focused ion beam scanning electron microscopy (FIB-SEM) could provide unique possibilities to study targeted cells and their internal and external relationships[33]. In addition, this technique can determine the exact volume of the target tissue components[5].

CONCLUSION

Virtual sectioning by X-ray phase-contrast nanotomography is a method that provides a unique analysis of the myenteric ganglion, revealing minor pathological changes that cannot be discovered using light microscopy or other two-dimensional scanning methods to study the relationship between various tissue components.

Figure 6 Series of virtual slices covering 6.4 μm thickness of the ganglion from one patient. A: Neuron with shrunken pyknotic nucleus and dark cytoplasm containing vacuoles at the edge of the ganglion (arrowhead). A part of the cytoplasm of the pre-apoptotic neuron is present between the telopodes (arrows); B: 2.0 μm deeper from Figure A. The lower telopode was discontinuous (arrows); C: 0.7 μm deeper from Figure B. The two telopodes are intact, and almost all of the cytoplasm between them has disappeared; D: 0.7 μm deeper from Figure C. Pre-apoptotic neurons seem to be in contact with the lower telopode; E: 3.0 μm deeper from Figure D. The pre-apoptotic neuron (arrowhead) lies within the ganglion, without contact with the telopodes. Arrows point to two telopodes on the figures. The scale bar (25 μm) applies to all the subfigures.

ARTICLE HIGHLIGHTS

Research background

The enteric nervous system (ENS) is difficult to study because of its deep localization in the intestinal wall. The limited sections visualized by light microscopy cannot show the size of the neurons or the interconnection between different parts of the ENS or different cell types.

Research motivation

Since the ENS is difficult to examine, patients with gastrointestinal dysmotility are not properly examined, diagnosed, and treated. They can experience symptoms for several years before a proper diagnosis is established.

Research objectives

The main objective of this study was to examine whether X-ray phase-contrast tomography could improve the visualization of the ENS. We realized that the ENS could be visualized without any prior staining, and the information provided was superior to conventional light microscopy in some respects. Thus, this method should be further evaluated in future studies.

Research methods

Full-thickness biopsies from the ileum of patients with dysmotility and controls were examined using X-ray phase-contrast tomography. For comparison, the same samples were examined using immunohistochemistry. This is the first time that bowel biopsies have been examined using X-ray tomography, and the histopathology has been described in detail.

Research results

This study showed that X-ray phase-contrast tomography can be used to study the ENS in detail to describe normal and pathological cells and tissue structures. The interconnections between the cells and

structures can be visualized. Some new findings could not have been observed using conventional light microscopy.

Research conclusions

Virtual sectioning by X-ray phase-contrast nanotomography provides a unique analysis of the myenteric ganglion, revealing minor pathological changes that cannot be discovered by light microscopy, to follow the relationship between various tissue components.

Research perspectives

This method needs to be further studied in larger cohorts, with scanning of whole paraffin blocks combined with different staining methods to try to improve the identification of different cell types and tissue structures. More healthy controls should be examined to obtain reference values for health and disease.

ACKNOWLEDGEMENTS

The authors thank Maria Teresa Moreira Jara and Maria Nilsson for their technical assistance and the pathologists for control sample collection. The valuable discussion with Anca Dragomir, MD, PhD, Uppsala University, regarding possible artifacts, is greatly appreciated.

Abstract

BACKGROUND

Complete polyp resection is the main goal of endoscopic removal of large colonic polyps. Resection techniques have evolved in recent years and endoscopic submucosal dissection (ESD), endoscopic mucosal resection (EMR) with margin ablation, cold snare polypectomy (CSP), cold EMR, and underwater EMR have been introduced. Yet, efficacy of these techniques with regard to local recurrence rates (LRRs) *vs* traditional hot snare polypectomy and standard EMR remains unclear.

AIM

To analyze LRR of large colonic polyps in a systematic review and meta-analysis.

METHODS

MEDLINE, EMBASE, EBM Reviews, and CINAHL were searched for prospective studies reporting LRR or incomplete resection rate (IRR) after colonic polypectomy of polyps ≥ 10 mm, published between January 2011 and July 2021. Primary outcome was LRR for polyps ≥ 10 mm.

RESULTS

Six thousand nine hundred and twenty-eight publications were identified, of which 34 prospective studies were included. LRR for polyps ≥ 10 mm at up to 12 mo' follow-up was 11.0% (95%CI, 7.1%-14.8%; 15 studies; 4904 polyps). ESD

(1.7%; 95%CI, 0%-3.4%; 3 studies, 221 polyps) and endoscopic mucosal resection with margin ablation (3.3%; 95%CI, 2.2%-4.5%; 2 studies, 947 polyps) significantly reduced LRR *vs* standard EMR without (15.2%; 95%CI, 12.5%-18.0%; 4 studies, 650 polyps) or with unsystematic margin ablation (16.5%; 95%CI, 15.2%-17.8%; 6 studies, 3031 polyps).

CONCLUSION
LRR is significantly lower after ESD or EMR with routine margin ablation; thus, these techniques should be considered standard for endoscopic removal of large colorectal polyps. Other techniques, such as CSP, cold EMR, and underwater EMR require further evaluation in prospective studies before their routine implementation in clinical practice can be recommended.

Key Words: Colonoscopy; Adenoma; Polyp; Endoscopic mucosal resection; Colorectal cancer

INTRODUCTION

Complete endoscopic polyp removal is especially important for large colorectal polyps in order to prevent local polyp recurrence and progression to colorectal cancer[1]. Evidence is growing that polyp removal is frequently incomplete, putting patients at risk of developing post-colonoscopy cancer[2-4]. A meta-analysis published in 2020 found that after snare resection, 15.9% of diminutive and small polyps and 20.8% of polyps 10–19 mm are removed incompletely[5]. For polyps 20 mm or larger, a meta-analysis published in 2014 demonstrated a recurrence rate of 15% after endoscopic mucosal resection (EMR)[6].

In recent years, different techniques for endoscopic resection of large colorectal polyps have evolved or been developed. Cold snare polypectomy (CSP) has been introduced and its use expanded to include the removal of large colorectal polyps[7]. Endoscopic submucosal dissection (ESD) has gained traction in Western countries and EMR has undergone technical modifications by introducing margin ablation or underwater EMR[8,9].

These developments have sparked our interest in providing an up-to-date meta-analysis of local recurrence rates (LRRs) and incomplete resection rates (IRRs) for large (≥ 10 mm) colorectal polyps, and to evaluate the impact of the novel or modified endoscopic resection techniques on LRRs.

MATERIALS AND METHODS

The analysis was conducted adhering to the Preferred Reporting Items for Systematic Reviews and Meta-analysis statement[10].

Literature search

A systematic literature search was performed within MEDLINE, EMBASE, EBM Reviews, and CINAHL databases. All articles published between January 2011 and July 2021 reporting on IRR and/or LRR for colorectal polyps 10 mm or larger removed by endoscopic resection techniques were included in the search. For specific search terms, see Supplementary Table 1. Additionally, a secondary search was performed to identify further records using article reference crosscheck, manual searching, and expert contact.

Article selection

Articles retrieved by the systematic search were collected and duplicates removed. Two researchers (Rotermund C and Taghiakbari M) assessed all articles independently and decided upon inclusion and exclusion. In cases of disagreement, a third researcher (von Renteln D) was consulted.

Inclusion criteria were full-text articles of prospectively performed clinical studies reporting on either LRR or IRR evaluated by margin assessment or margin biopsy of endoscopically removed polyps ≥ 10 mm. Even though often of larger sample size, publications with retrospective study design were excluded from the analysis, as risk for selection bias and risk for missed data is usually higher.

Exclusion criteria were retrospective study design, polyps < 10 mm, IRR evaluated by visual margin assessment, data from first follow-up that exceeded 12 mo, publications solely evaluating difficult polypectomies, publication languages other than English, articles reporting on training of a certain technique, and articles in which results from different polypectomy techniques were not clearly distinguishable.

Data extraction

Relevant data retrieved from the evaluated study included author, year of publication, country, study type, study quality, polyp size, polyp morphology, polyp histology, polyp resection method and adjunct therapy, LRR, IRR, IRR assessment method, submucosal injection rate and solution, *en bloc* resection rate, and endoscopist number and experience level. For analyses, polyps were subdivided according to size: 10–19 mm, ≥ 20 mm (not including polyps < 20 mm), and all polyps ≥ 10 mm (including polyps ≥ 20 mm). Data were retrieved by one author (Rotermund C) and correct retrieval confirmed by a second author (Djinbachian R).

Outcomes

Primary outcome was LRR for polyps ≥ 10 mm. Local recurrence was defined as the presence of recurrent polyp at the resection site, detected during follow-up examination. Publications, in which the appointments for follow-up examinations exceeded 12 mo between the different patients, were excluded from the analysis. Secondary outcomes were IRR evaluated by either margin assessment or margin biopsy for polyps ≥ 10 mm, as well as factors influencing LRR and IRR, including polyp resection technique [hot snare polypectomy (HSP), CSP, hot and cold EMR, underwater EMR, ESD], adjunct therapy, margin assessment method, submucosal injection status, polyp size, polyp morphology and histology, endoscopist experience and number of endoscopists involved. IRR assessment method was defined as (1) Biopsy from the resection margin (="margin biopsy"); (2) Histologic assessment of polyp margin (= "margin assessment"); and (3) *En bloc* resection and histologic assessment of polyp margin (= "*en bloc* and margin assessment"). Endoscopist experience was defined as (1) Less experienced for EMR, when a fellow was included in the study or < 2000 colonoscopies had been performed by the endoscopist; (2) Experienced for EMR, when only expert endoscopists (> 2000 colonoscopies) were involved; (3) Less experienced for ESD, when fellows for ESD (< 200 cases) were included in the study; and (4) Experts for ESD (> 200 cases).

Quality assessment and publication bias

Study quality was assessed independently by two researchers (Taghiakbari M and Rotermund C). In cases of disagreement, a third researcher (von Renteln D) was consulted. For evaluation, National Institutes of Health quality assessment forms for case series and randomized controlled trials (RCTs) were used[11]. For RCTs (maximum score: 14), a score of 11–14 was rated as good, a score of 8–10 as fair, and a score below 8 as poor quality. For prospective case series (maximum score: 9), a score of 7–9 was rated as good, a score of 4–6 as fair, and a score below 4 as poor quality. Detailed information on criteria for low and high quality are given in Supplementary Tables 2 and 3.

A sensitivity analysis was performed to determine the effects of excluding poor-quality studies and publication bias was assessed using funnel plots (Supplementary Figure 1). The graph was plotted as proportion vs. sample size instead of log odds *vs* 1/standard error, as this method has been shown to be more accurate in predicting risk of publication bias for meta-analyses of proportions[12].

Statistical analysis

Proportions were meta-analyzed using the metaprop command of Stata version 16 (StataCorp, College Station, TX, United States), and tests of heterogeneity were performed using the I^2 statistic. Either a random-effects model or a fixed-effect model was used for the analyses. Proportions were reported with their associated 95% confidence intervals (CIs) with an alpha level of < 0.05 used for statistical significance.

RESULTS

Literature search and study characteristics

Systematic literature search yielded 6922 hits and 6 additional records were identified through reference crosscheck, manual search, and expert contact (Figure 1, Supplementary Table 1). After removal of duplicates, 5010 publications remained. Of these, 4070 were excluded based on title and 672 based on abstract, so that 268 full-text records were evaluated for eligibility. Ultimately, 34 publications were included in the analysis, with 19 reporting on IRR, 13 on LRR, and 2 on both (Figure 1). All studies were prospective and 14 were RCTs.

Quality assessment and publication bias

Included studies showed symmetrical distribution for both assessments of LRR and IRR, with no publication bias detected (Supplementary Figure 1). Quality assessment revealed 23 studies of good quality, 10 studies of fair quality, and 1 study of poor quality (Supplementary Tables 2 and 3). Sensitivity analyses did not show statistically different results or decreased heterogeneity when excluding poor- or fair-quality studies (Supplementary Figures 2 and 3).

Local recurrence rate

A total of 15 studies reported on LRR after removal of large colonic polyps ≥ 10 mm. Of these, 15 studies stated LRR obtained during follow-up examinations up to 12 mo, 7 during follow-up up to 24 mo, and 3 from follow-up after more than 24 mo (Supplementary Table 4). Definitions of LRR given in the original studies are presented in Supplementary Table 5. Mean overall LRR at up to 12 mo' follow-up was 11.0% (95%CI, 7.1%–14.8%; 4904 polyps) (Figure 2A). Overall LRR for follow-up up to 24 mo was 14.6% (95%CI, 8.4%–20.8%; 7 studies) (Supplementary Figure 4).

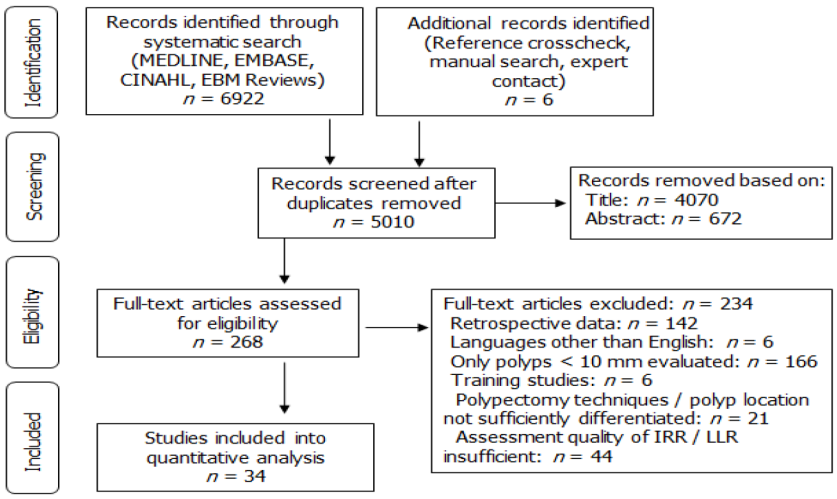
Local recurrence rate up to 12 mo' follow-up: Influence of resection method: Resection method was found to exhibit major influence on LRR of polyps ≥ 10 mm (Figure 2B, Table 1). ESD (1.7%; 95%CI, 0–3.4%; 3 studies) and EMR with margin ablation (3.3%; 95%CI, 2.2%–4.5%; 2 studies) significantly reduced LRR compared with EMR in which margin ablation was not performed (15.2%; 95%CI, 12.5%–18.0%; 4 studies) or only used in some cases (16.5%; 95%CI, 15.2%–17.8%; 6 studies). No prospective studies were found evaluating LRR after HSP, CSP, or cold EMR within the search period. Two studies evaluated LRR after underwater EMR; however, heterogeneity between studies was high, so that a valid analysis could not be performed.

Similarly, when only results for polyps ≥ 20 mm were evaluated, ESD and EMR with margin ablation yielded lower LRRs compared with EMR without margin ablation (Table 1). No prospective studies were found evaluating HSP, CSP, or cold EMR.

Local recurrence rate up to 12 mo' follow-up: further influencing factors: Polyp size did not influence LRR (≥ 10 mm: 11.0%; 95%CI, 7.1%–14.8%; 15 studies *vs* ≥ 20 mm: 11.2%; 95%CI, 6.8%–15.6%; 12 studies) (Table 1). Similarly, expert status of the endoscopist was not found to influence LRR (Table 1); however, as only two expert studies were found, the data set was small. The data set was also insufficient for analysis of the influence of polyp morphology or histology on LRR. Only one study included pedunculated polyps (12.1% of all resected polyps); however, the reported LRR was comparable to the rate observed in other studies[13]. Most studies included sessile serrated adenoma/polyps (SSA/Ps). One study compared LRR after EMR removal of SSA/Ps *vs* conventional adenomas and reported significantly reduced LRR for SSA/Ps[14].

Incomplete resection rate

A total of 21 studies reported on IRR after removal of large colonic polyps ≥ 10 mm, using either margin assessment or margin biopsy for evaluation (Supplementary Table 6). Mean overall IRR for all polyps ≥ 10 mm was 14.9% (95%CI, 11.4%–18.4%; 21 studies; 3563 polyps) (Figure 3). Twelve studies indicated IRR for polyps 10–19 mm, resulting in a mean IRR of 16.0% (95%CI, 10.4-21.7%) (Supplementary Figure 5), and 14 studies reported IRR for polyps ≥20 mm, yielding a mean IRR of 11.7% (95%CI, 7.5%–15.8%; 1739 polyps) (Supplementary Figure 6).



Incomplete resection rate: Influence of resection method: Resection method was not found to significantly influence IRR of polyps 10–19 mm, comparing hot EMR (18.5%; 95%CI, 8.9%–28.1%; 8 studies), HSP (16.2%; 95%CI, 10.6%–21.7%; 2 studies), underwater EMR (25.5%; 95%CI, 18.9%–32.2%; 2 studies), and cold EMR (14.0%; 95%CI, 1.8%–26.3%; 3 studies), with studies on cold EMR exhibiting high variability (Table 2). Only two studies evaluated CSP, showing high heterogeneity, so that a valid analysis could not be performed.

Comparison of ESD and EMR for polyps ≥ 20 mm showed a lower IRR for ESD (12.5%; 95%CI, 6.2%–18.8%; 9 studies) than for EMR (29.3%; 95%CI, 19.3%–39.2%; 3 studies) (Table 2). Only two studies evaluated IRR for polyps ≥ 20 mm with HSP, yielding high heterogeneity, so that a valid analysis could not be performed. No data were found reporting IRR after CSP or cold EMR for polyps ≥ 20 mm.

Table 1 Factors influencing local recurrence for polyps ≥ 10 mm at 0–12 mo' follow-up

Subgroups	LRR % (95%CI)	I^2 %	Studies, *n*	Polyps, *n*
Resection method, polyps ≥ 10 mm				
Hot EMR, no margin ablation	15.2 (12.5–18.0)	0	4	650
Hot EMR, some margin ablation	16.5 (15.2–17.8)	0	6	3013
Hot EMR, with margin ablation	3.3 (2.2–4.5)	NA	2	947
ESD	1.7 (0.0–3.4)	NA	3	221
Resection method, polyps ≥ 20 mm				
Hot EMR, no margin ablation	14.8 (11.0–18.5)	NA	2	334
Hot EMR, some margin ablation	16.5 (15.2–17.8)	0	6	3013
Hot EMR, with margin ablation	3.3 (2.2–4.5)	NA	2	947
ESD	2.4 (0–5.7)	NA	2	83
Polyp size				
≥ 10 mm	11.0 (7.1–14.8)	95.6	15	4904
≥ 20 mm	11.2 (6.8–15.6)	95.8	12	4431
Expert level

Figure 1 Literature search strategy.

Incomplete resection rate: Further influencing factors: For polyps sized 10–19 mm, submucosal injection status did not influence IRR. Mean IRR after resection with submucosal injection was 20.0% (95%CI, 11.9%–28.0%; 10 studies) compared with 14.4% (95%CI, 5.4%–23.3%; 6 studies) after resection without submucosal injection (Table 2). For polyps ≥20 mm, IRR was lower after resection with prior submucosal injection (Table 2). Mean IRR after submucosal injection was 12.6% (95%CI 7.7–17.6; 13 studies), compared to 32.4% (95%CI, 0-76.3%; 3 studies) after resection without injection.

The solution used for submucosal injection was not found to influence IRR, yielding comparable results for saline solution (15.8%, 95%CI, 7.1%–24.8%; 6 studies) and hyaluronic acid (16.3%, 95%CI, 8.5%–24.1%; 8 studies) (Table 2).

Table 2 Factors influencing incomplete resection

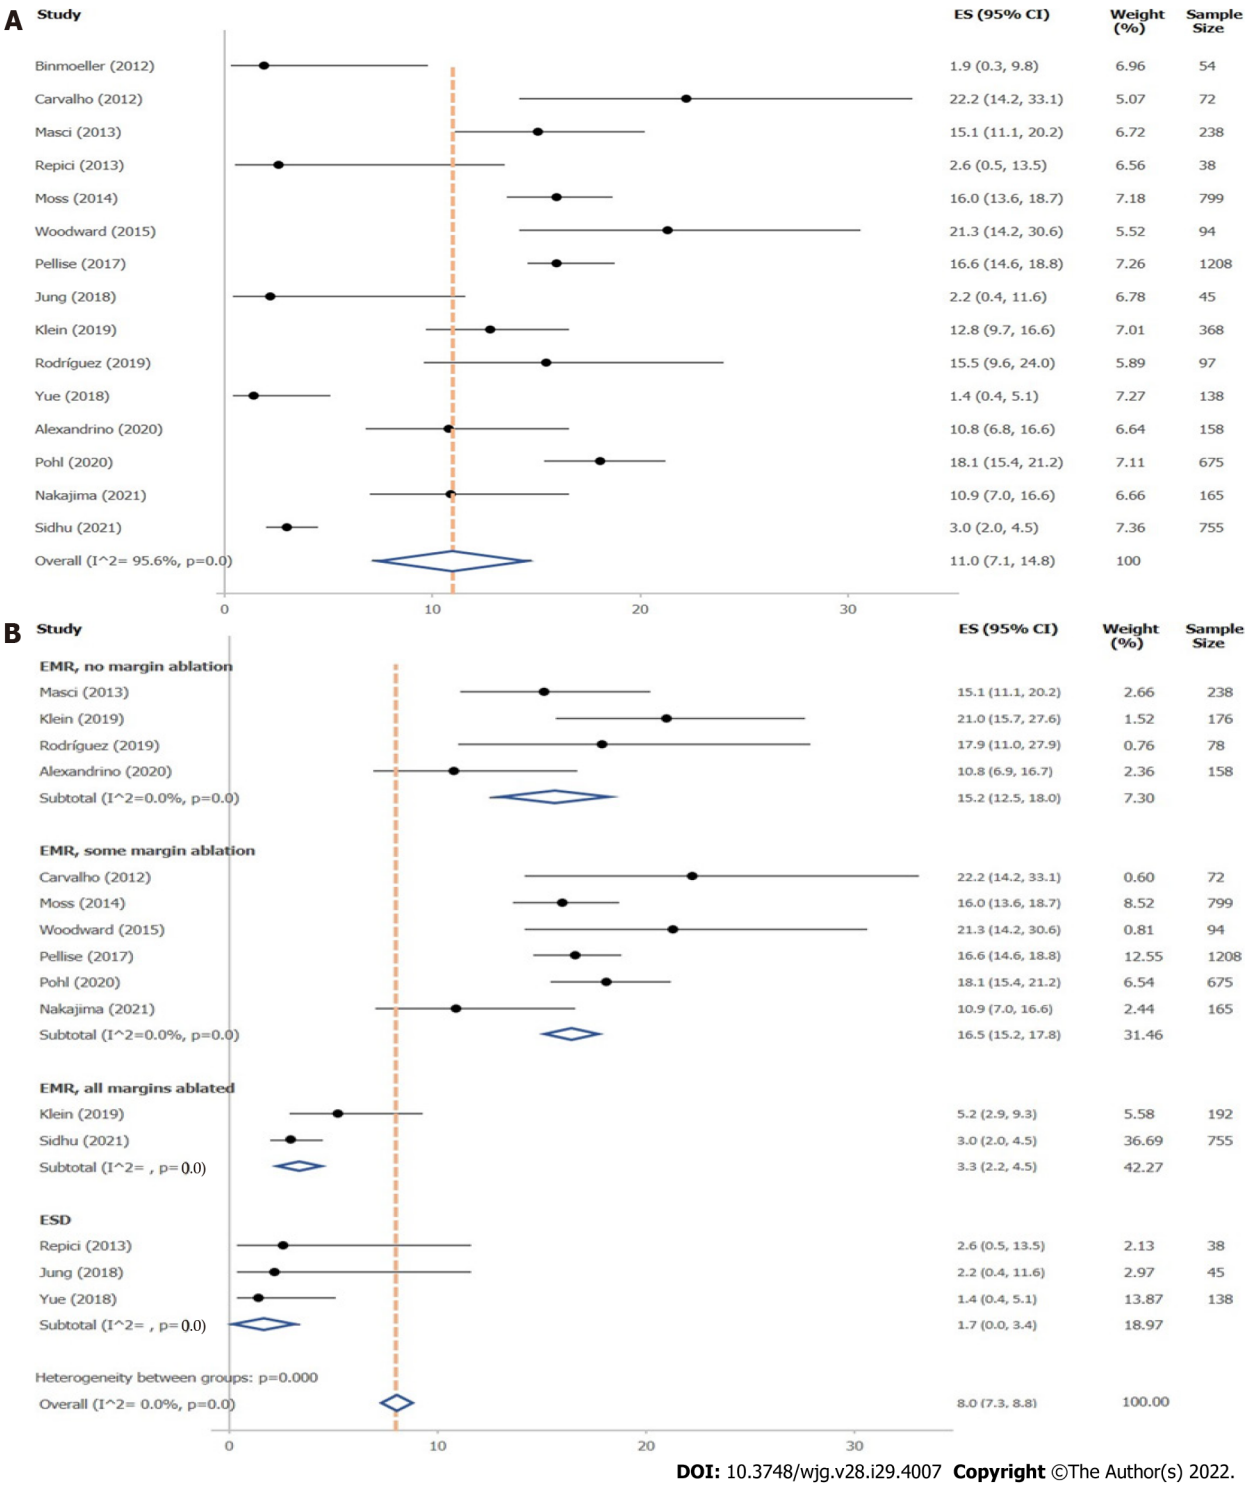
[1]Data exhibit high variance; calculated mean should be handled with care.

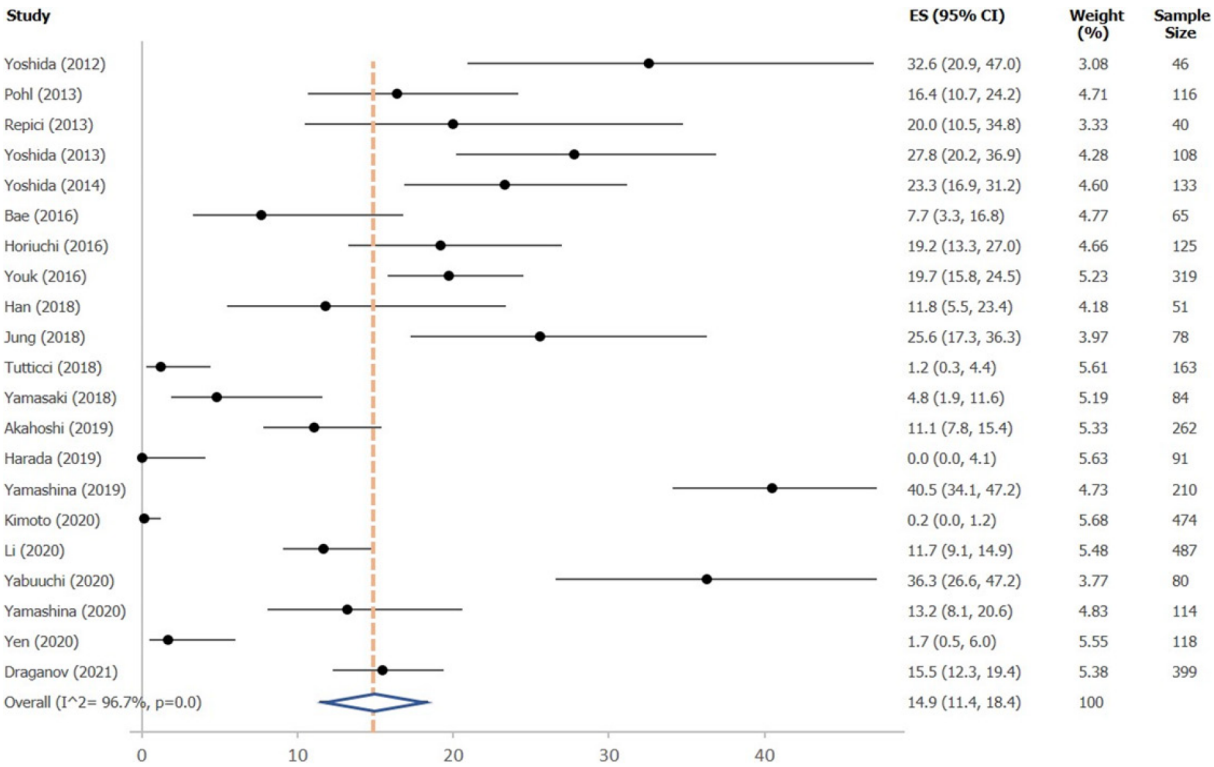


NA: Number of studies insufficient for estimation; EMR: Endoscopic mucosal resection; ESD: Endoscopic submucosal dissection; HSP: Hot snare polypectomy; IRR: Incomplete resection rate; U-EMR: Underwater endoscopic mucosal resection.

There was a strong trend toward lower IRR when considering endoscopist experience (Table 2, Supplementary Figure 7). The mean IRR was 7.0% (95%CI, 3.5%–10.4%; 8 studies) when only expert endoscopists were involved in the study, and 20.3% (95%CI, 13.5%–27.1%; 13 studies) when non-experts were included.

Insufficient data were available for analysis of the influence of polyp morphology or histology on IRR. Three studies included around 50% or more pedunculated polyps; two analyzed hot EMR[15,16] , and the third analyzed hot and cold EMR and CSP[17]. Three further studies included smaller numbers of pedunculated polyps, using cold EMR[18], ESD[19], and underwater EMR[20]. Most studies included 10% or less SSA/Ps, while two studies investigating CSP and cold EMR evaluated results from SSA/Ps only[21,22]. The latter two studies reported exceptionally low IRR of less than 1.5%.

DISCUSSION



This meta-analysis confirms the high risk for recurrence after standard EMR resection of large colonic

DOI: 10.3748/wjg.v28.i29.4007 **Copyright** ©The Author(s) 2022.

Figure 2 Local recurrence rate at < 12 mo' follow-up. A: For polyps ≥ 10 mm; B: For polyps ≥ 10 mm, stratified by resection method.

polyps. When standard EMR without routine margin ablation is used, we found a 12-month recurrence rate of 15.2%. This is comparable to the results found in the two available meta-analyses published in 2014 and 2021, which reported recurrence rates of 15%[6] and 10%[23], respectively. However, since then, many new or modified endoscopic removal techniques have been developed. These novel developments include cold EMR, hot snare with margin ablation, and an increasing body of literature on ESD for colorectal polyps coming from Asian, European and North American centers. We found that two of these modalities resulted in significantly lower LRRs compared with standard EMR. ESD was associated with an LRR of only 1.7%, and the LRR after EMR with routine ablation of the complete margin was 3.3%. However, ESD requires advanced endoscopy skills, adequate training, and the technique is associated with an increased risk for complications[24-26]. Furthermore, significant differences in safety and efficacy of ESD have been shown between Asian and non-Asian countries[27], so that EMR has remained the standard for large polyp resection in Western countries to date.

Figure 3 Incomplete resection rate for polyps ≥ 10 mm, independent of resection method.

The other modality that shows significantly reduced recurrence rates is the combination of hot EMR with routine margin ablation[9,28]. Thus, ESD or EMR with routine margin ablation currently seem to be the best approaches for endoscopic removal of large colorectal polyps in order to avoid recurrence. We found that systematic margin ablation after EMR can reduce the LRR to rates similar to those of ESD. These results originate from two recent Australian prospective studies, in which snare tip soft coagulation (STSC) was routinely performed after EMR[9,28]. As these studies included only polyps ≥ 20 mm further studies evaluating the effect of margin ablation on polyps sized 10-19 mm may be of additional value. The positive effect of margin ablation has also been shown in a retrospective US study, evaluating systematic application of argon plasma coagulation (APC) after EMR in 246 patients[29]. The authors found an LRR of 5% at < 12 mo FU, which is comparable to the rates found by Klein (5%) [9] and Sidhu (3%)[28]. However, the results for using APC margin ablation still need to be confirmed by prospective studies. A recently completed prospective, multicenter study evaluating resection of large colonic lesions ≥ 20 mm in 76 patients using EMR and hybrid APC for margin and base ablation found a LRR of 2.2%[30]. This indicates that APC ablation can reduce local recurrence comparable to ESD and EMR with STSC.

Importantly, margin ablation should be performed systematically and completely, as visual margin assessment may underestimate incomplete resection[4]. This is confirmed by our analysis, which showed that studies using unsystematic or incomplete margin ablation were not able to reduce the LRR [9,14,31].

Notably, even though use of cold snare resection techniques for large colonic polyps is increasingly reported, at present no prospective studies have been published reporting LRR for CSP or cold EMR for large colorectal polyps. Furthermore, recent retrospective studies have indicated that these techniques might potentially increase the risk for local recurrence. In the largest retrospective series published to date, Suresh *et al*[32] reported an LRR of 34.8% after cold EMR. Therefore, caution is warranted for routine use of cold EMR outside of clinical studies until data from ongoing RCTs comparing hot with cold EMR become available.

For polyps 10–19 mm, follow-up examination is often performed years after the index colonoscopy. Therefore, data on LRR for 10–19 mm colorectal polyps are sparse, and we used IRR to estimate the risk of local recurrence for this subgroup. In our analysis, overall IRR for polyps sized 10–19 mm was 16.0%. This rate was similar to the IRR found in a previous meta-analysis (20.8%)[5] and in one of the landmark studies on IRR (CARE study)[4]. The CARE study reported that even though endoscopists rated resection as complete by visual assessment, 10.1% of cases showed residual tissue on margin biopsy. Compared with the previous meta-analysis, our analysis included more data, especially regarding cold snare resection techniques[5]. However, adding the recently published data on cold snare resection did not significantly alter overall IRR of polyps 10–19 mm. Furthermore, IRR of EMR, cold EMR, HSP, and

underwater EMR were similar[17,18,21]. Only two prospective studies evaluated IRR for large colonic polyps after CSP resection[17,21]. These studies showed high variability in IRR, and while one study found rates comparable to those obtained with other techniques[17], rates reported in the second were extremely low[21]. This is likely based on the fact that in this study only expert endoscopists were involved and only SSA/Ps were removed by wide-field style cold snare resection. A previous meta-analysis has already demonstrated that expert endoscopists achieve lower IRRs[5], and this was confirmed in our analysis, with an IRR of 7.0% for expert endoscopists and 20.3% for those studies in which less experienced endoscopists were included. Furthermore, the exclusive inclusion of SSA/Ps introduced a further bias into the study, as removal of SSA/Ps generally yields better results[14]. This renders the generalizability of CSP to general clinical practice difficult, and more prospective studies are needed to establish IRR, and especially LRR risk, after CPS and cold EMR removal of large colorectal polyps including all pathology types.

For polyps ≥ 20 mm, the mean IRR was 11.7% in this analysis. Interestingly, this rate is lower than the results obtained for polyps sized 10–19 mm (16.0%). This effect was based on the good results obtained with ESD, and is most likely also associated with the fact that 10–19 mm polyps are usually resected in general endoscopic practice, whereas polyps ≥ 20 mm are often referred for expert resection.

Recent guidelines recommend HSP, EMR [European Society of Gastrointestinal Endoscopy, American Gastroenterological Association (AGA)][33,34] and CSP (AGA)[34] for resection of 10–19 mm polyps. Our data show that EMR with margin ablation is an important new development that warrants further study. For lesions ≥ 20 mm, guidelines recommend ESD in specific cases, and the need for a skilled endoscopist to perform the procedure is highlighted[25,26,35]. The importance of endoscopist skill level is also supported by our data. Furthermore, our data suggest that EMR with systematic and complete margin ablation may be an appropriate alternative to ESD, especially considering the low complication rates reported in the available studies[9,28,29].

However, safety profiles should also be taken into account when evaluating different polypectomy techniques. Known complications occurring during and after polypectomy are immediate and delayed bleeding as well as perforation and post-coagulation syndrome[33,34]. A meta-analysis from 2016 evaluating endoscopic resection of polyps ≥ 20 mm found perforation occurring in 1.5% and bleeding in 6.5% of polyps. Mortality was indicated as 0.08%[36]. Yet, an up-to-date analysis comparing safety profiles of CSP, HSP, EMR with and without margin ablation, underwater EMR, and ESD still has to be performed.

Our analysis has several strengths, including the robustness of the literature search with a large number of publications screened (6928 publications). Of these, 34 prospective studies with a total of 10268 polyp resections were included. As only prospective data were evaluated, we were able to perform a high-quality analysis, as retrospective studies reporting on LRR and IRR are unsystematic in the ascertainment of the main outcomes, thus having a high likelihood of bias. Furthermore, the retrieval of granular data allowed us to perform multiple analyses.

The main limitation of the study is that by exclusion of retrospective studies, the data set was reduced. Furthermore, publications were excluded in which IRR was determined by visual assessment or in which appointments for follow-up examinations for LRR assessment exceeded 12 mo. While this reduced the amount of studies included into the analysis, it ensured a better overview of the high-quality data available in the literature. Additionally, it shows that for some techniques data of sufficient quality is sparse and that there is a need for further studies. Second, expert endoscopist status was difficult to determine, as there is no published consensus definition, and some studies do not clarify the expertise of the involved endoscopists. However, expert and non-expert status were systematically assessed and discussed for this meta-analysis. Third, as assessment for IRR is not standardized, different methods, including margin assessment and margin biopsy, are used for its estimation. However, margin assessment is likely to overestimate IRR, as lesions resected in piecemeal fashion may be resected completely, but will appear with positive resection margins. Margin biopsy, on the other hand, is likely to underestimate IRR, as only sample parts of the margins are examined[37]. Therefore, true IRR will be located somewhere in between the values found with margin biopsy and margin assessment. Another limitation is the elevated heterogeneity in some reported outcomes. For LRR, most of the observed heterogeneity was due to combining different resection techniques into the same analysis. When stratifying for resection technique and use of margin ablation, we found very low heterogeneity in the reported outcomes. For IRR, the differing use of wide field resection before biopsies and the number of margin biopsies taken could explain some of the heterogeneity reported.

CONCLUSION

In conclusion, we found that local recurrence after resection of large colonic polyps occurs frequently when standard EMR is used. Local polyp recurrence can be reduced by performing ESD or EMR with routine and complete margin ablation. Other techniques, such as CSP, cold EMR, and underwater EMR require further evaluation in prospective studies before their routine implementation in clinical practice can be recommended.

ARTICLE HIGHLIGHTS

Research background

Complete resection is the aim of endoscopic therapy for large colonic polyps. Endoscopic mucosal resection (EMR) is the most common endoscopic treatment for such polyps. In recent years, endoscopic resection techniques have evolved, including cold snare polypectomy (CSP), cold EMR, EMR with margin ablation, underwater EMR, and endoscopic submucosal dissection (ESD).

Research motivation

Efficacy of these newer polypectomy techniques with regard to local recurrence rates (LRRs) *vs* traditional hot snare polypectomy and standard EMR remains unclear.

Research objectives

These developments have sparked our interest in providing an up-to-date meta-analysis of LRRs and incomplete resection rates (IRRs) for large (≥ 10 mm) colorectal polyps, and to evaluate the impact of the novel or modified endoscopic resection techniques on LRRs.

Research methods

A systematic literature search was performed within MEDLINE, EMBASE, EBM Reviews, and CINAHL databases. All articles published between January 2011 and July 2021 reporting on IRR and/or LRR for colorectal polyps 10 mm or larger removed by endoscopic resection techniques were included in the search.

Research results

LRR were lowest when EMR with systematic margin ablation (3.3%) or ESD (1.7%) were used for endoscopic removal of large (> 10 mm) colorectal polyps. When standard EMR (without margin ablation) or with partial margin ablation were used, LRRs were high (15.2% and 16.5%, respectively).

Research conclusions

Local recurrence after resection of large colonic polyps occurs frequently when standard EMR is used, but can be reduced by performing ESD or EMR with routine and complete margin ablation. Other techniques, such as CSP, cold EMR, and underwater EMR require further evaluation in prospective studies before their routine implementation in clinical practice can be recommended.

Research perspectives

ESD or EMR with margin ablation should be considered standard of care for endoscopic removal of large colorectal polyps in order to avoid recurrence. At present, cold snare resection techniques or underwater EMR should only be performed within clinical trials, pending the availability of high-quality evidence.

ABOUT COVER

Associate Editor of *World Journal of Gastroenterology*, Ming-Lung Yu, MD, PhD, Chair Professor, Chief, Hepatitis Research Center, Kaohsiung Medical University, No. 100 Tzyou 1st Road, Kaohsiung 807, Taiwan. fish6069@gmail.com

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 edition of Journal Citation Reports® cites the 2021 impact factor (IF) for *WJG* as 5.374; IF without journal self cites: 5.187; 5-year IF: 5.715; Journal Citation Indicator: 0.84; Ranking: 31 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2021 is 8.1 and Scopus CiteScore rank 2021: Gastroenterology is 18/149.

Abstract

Current histopathological staging procedures in colorectal cancer (CRC) depend on midline division of the lymph nodes (LNs) with one section of hematoxylin and eosin staining. Cancer cells outside this transection line may be missed, which could lead to understaging of Union for International Cancer Control Stage II high-risk patients. The one-step nucleic acid amplification (OSNA) assay has emerged as a rapid molecular diagnostic tool for LN metastases detection. It is a molecular technique that can analyze the entire LN tissue using a reverse-transcriptase loop-mediated isothermal amplification reaction to detect tumor-specific cytokeratin 19 mRNA. Our findings suggest that the OSNA assay has a high diagnostic accuracy in detecting metastatic LNs in CRC and a high negative predictive value. OSNA is a standardized, observer-independent technique, which may lead to more accurate staging. It has been suggested that in stage II CRC, the upstaging can reach 25% and these patients can access postoperative adjuvant chemotherapy. Moreover, intraoperative OSNA sentinel node evaluation may allow early CRC to be treated with organ-preserving surgery, while in more advanced-stage disease, a tailored lymphadenectomy can be performed considering the presence of aberrant lymphatic drainage and skip metastases.

Key Words: Colorectal malignancies; One-step nucleic acid amplification; Diagnostic accuracy; Negative predictive value; Upstaging; Organ-sparing surgery; Tailored lymphadenectomy

Core Tip: Our findings suggest that the one-step nucleic acid amplification (OSNA) assay has high diagnostic accuracy and negative predictive value in detecting metastatic lymph nodes in colorectal cancer (CRC). The short turnaround time renders OSNA an attractive intra-operative method. OSNA results in upstaging in about 25% of stage II CRC cases. Moreover, organ-sparing surgery in early CRC and tailored lymphadenectomy, in more advanced cases, can be performed.

INTRODUCTION

Of the gastrointestinal cancers, the colorectal cancer (CRC) is the most represented. Among the indication criteria for chemotherapy, lymph node (LN) positivity (stage III) is the most important[1]. The histopathological study of the LNs is performed on one or at most two sections of each LN with hematoxylin and eosin (HE). Therefore the conventional study presents the possibility of not detecting micro-metastases (MMs) or macro-metastases leading to an "understaging". The high relapse rates (20%–25%) in patients with negative LNs could be due to this "understaging"[2]. Multilevel LN sectioning combined with immunohistochemistry (IHC) can improve the detection rate of small nodal tumor infiltrates [*i.e.* isolated tumor cells (ITCs) and MMs], although it is a costly and protracted process [3-6].

Tsujimoto *et al*[7] were the first to describe the one-step nucleic acid amplification (OSNA) assay for detecting LN metastases (LNMs) in patients with breast cancer (BC). Numerous studies have followed which have confirmed the high sensitivity of OSNA in detecting LNMs of breast, gastric and CRCs[8-15]. Other studies[16-18] have underlined the usefulness of the OSNA assay as a complementary tool for diagnosing LNMs and upstaging in histologically node-negative stage II CRC.

The sentinel LN (SLN) is gaining more and more consensus because it allows to perform a more conservative surgery with considerable advantages, when applicable for the patient and for the operating times. Obviously in the early stages of CRCs this could play an important role, allowing to realize, in case of absence of lymph node metastases on SLNs, an organ preserving surgery.

In this review, we analyzed the use of OSNA in detecting LNMs in CRC.

LITERATURE SEARCH

Search strategy

After developing and piloting search terms, MEDLINE, SCOPUS, ClinicalTrials.gov, and Cochrane Database were used to conduct a comprehensive computerized literature search for articles pertaining to OSNA use in detecting LNMs in CRC. Medical subject headings terms and keywords were combined: colorectal malignant, cancer, colorectal tumor, colorectal neoplasm, carcinoma, lymph node metastasis, SLN, one-step nucleic acid amplification, OSNA, cytokeratin 19, CK-19, predictive value, upstaging, organ-sparing surgery, and tailored lymphadenectomy. The electronic search was supplemented by reviewing reference lists of included studies and previous systematic reviews. No time limitation was stipulated for the search, which was last updated December 20, 2021. In addition, we retrieved and cited high-quality references using the Reference Citation Analysis database (https://www.referencecitation-analysis.com/).

Study selection, data extraction, and quality assessment

The retrieval of articles was completed in three consecutive stages. Following reduplication of the sum of collected articles, their titles and abstracts underwent further screening and those deemed ineligible were removed. For duplicates, the most recent or complete publication was chosen. The remaining papers were evaluated in full text. Two reviewers (MB, SV) extracted data in duplicate using a standardized data extraction sheet.

LYMPHATIC DRAINAGE IN CRC

The American Joint Committee on Cancer/Union for International Cancer Control (AJCC/UICC) staging score divides the stages according to how many metastatic lymph nodes are present. Based on the location of the primary tumor, those with a course adjacent to the main vascular branches near the affected colon are considered regional lymph nodes. In particular, starting from the rectum up to the right colon, in addition to the peri-colic lymph nodes, regional lymph nodes are considered, those adjacent to the rectal arteries, the sigmoid arteries, the left colonic artery, the inferior mesenteric artery, the middle colic artery, the right colic artery, the ileocolic artery[19].

In AJCC/UICC tumor-node-metastasis (TNM) staging system[20-22], patients with no metastatic LNs are N0, cases with one to three metastatic LNs are N1, and cases with more than three positive LNs are N2. Moreover, the N1 category is subdivided into N1a (1 metastatic LN), N1b (2–3 metastatic LNs), and N1c (no regional LNs are positive but there are tumor deposits in the subserosa, mesentery or non-peritonealized pericolic or perirectal/mesorectal tissues), whereas the N2 category is subdivided into N2a (4–6 metastatic LNs) and N2b (7 or more metastatic LNs). The minimum number of examined LNs needed for adequate staging should not be less than 12 to minimize the possibility of stage migration[19, 23-27].

The Japanese Society for Cancer of the Colon and Rectum (JSCCR) staging score classifies the involved LNs based on location and number. This system divides the regional LNs into three groups: main, intermediate and peri-colic. Regional LNs depend on their adjacency to the blood vessels following the primary tumor site. LNs adjacent to the marginal arcade are pericolic nodes, the LNs along the course of the main vessels of the colon are intermediate nodes (sigmoid arteries, the left colonic artery, the inferior mesenteric artery, the right and left middle colic artery, the right colic artery, the ileocolic artery). Lymph nodes located proximal to the origin of the main colonic vascular branches of the inferior and superior mesenteric artery are the main nodes. LNMs are classified as N1 if up to 3 peri-colic or intermediate LNs are involved, N2 if they are ≥ 4, N3 when the main LNs are involved[28, 29].

ITCs and MMs

When single or few tumor cells smaller than 0.2 mm are found, these are called ITCs, if instead the deposits have a diameter between 0.2 and 2.0 mm these are called MMs. When ITCs or MMs with HE or IHC are found, they are classified as pN0 (i +), if instead the deposits are diagnosed only by reverse transcriptase polymerase chain reaction (RT-PCR), they are classified as pN0 (mol +)[19,20]. MMs, ITCs, and occult metastasis have been reported in 4.2%, 19.3%, and 5% of patients with stage I and II CRC, respectively, and attracted interest as prognostic factors[30-33].

Tumor deposits

In the literature, tumor deposits (TDs) are defined as foci of tumor separated from the main neoplasm and found in peri-rectal or peri-colonic adipose tissue or in mesocolon in the lymphatic drainage area, in the absence of identifiable LN tissue.

It is postulated that they are produced either by discontinuous dissemination of the tumor or by vascular/perineural dissemination. TDs can be found in 10.2%–22% of CRC cases and it has been suggested that TDs may represent a LN, a vascular structure, or a nerve completely replaced by carcinoma[34].

Several studies[35,36] have shown decreased disease-specific survival and overall survival (OS) in the presence of TDs. Moreover, the survival outcomes worsen when TDs occur concomitantly with LNMs. Other studies confirmed this evidence in CRC. It has been suggested that TDs have negative prognostic value but are not sufficiently categorized in the current TNM staging and the number and/or presence of the TD should be added to the number of LNMs to define the final N stage creating a specific category for TDs with LNM, which could be called category N2c or N3[37-41].

CLINICAL STAGE OF NODAL METASTASES

Diagnostic imaging

Diagnostic imaging assessment of lymphadenopathy in CRCs is challenging. Individual imaging modalities face specific intrinsic limitations, for example, transrectal ultrasound is operator-dependent, detrimentally affected by a small field of view, and cannot be employed in stenosing or rectal cancers. Computed tomography (CT) is hampered by its low soft tissue contrast resolution which, besides negatively impacting detection, precludes evaluation of fine LN details and therefore must rely only on LN size for assessing lymphadenopathy. Magnetic resonance imaging (MRI) requires long acquisition times and is prone to artifacts in the case of poor patient cooperation. Fluorodeoxyglucose (FDG)-positron emission tomography (PET)/CT and PET/MRI necessitate exposure to radiation, and its yields are influenced by the amount of metabolically avid cells in the affected LNs.

Size

Lymphadenopathy is also intrinsically challenging. Despite malignant LNs tending to be larger than their benign counterparts, there is wide size superimposition between malignant and benign LNs. In one study that evaluated only LNs ≥ 5 mm, short axis range was 6-12 mm for malignant LNs and 5-13 mm for benign LNs[42,43]. Moreover, the size of metastatic LNs is often at the lower limits of imaging spatial resolution. In a study, median LN short axis was 3.2 mm for malignant LNs and 2.8 mm for benign LNs[44]. Additionally, 30%-94% of metastatic LNs from rectal cancer are < 5 mm in short axis [45-48]. To make things even more challenging, some benign etiologies, especially inflammation, might increase LNs size.

MRI

Due its superior anatomic layout and high soft tissue contrast resolution, MRI can explore LN nature trough size and morphologic criteria. LN size criteria have yielded different results in different studies. However, across studies, the bigger the short axis threshold, the higher the specificity and lower the sensitivity; a 3 mm short axis has been associated with 92% sensitivity, 3% specificity, and 40% accuracy; a short axis threshold of 9 mm has been associated with the opposite trend, giving 8% sensitivity, 100% specificity, and 62% accuracy[42]. Short axis thresholds of 7.2-7.5 mm have reached 32%-87% sensitivity and 70%-94% specificity, with 68% of accuracy[42,43]. However, the most accepted short axis cut off for lymphadenopathy in rectal cancer is 5 mm, yielding sensitivities of 50%-72%, specificities of 46%-60%, and an accuracy of 57%[42,46-50].

Beside size, several other MRI criteria can be used, with diffusion weighted imaging (DWI) believed to be one of the most promising tools. However, DWI has proven inadequate for this purpose so far. High b-value DWI is a powerful tool for LN detection. However, DWI and even apparent diffusion coefficient values[43,51,52] are unable to discriminate benign from malignant LNs (accuracy 40%). Therefore, in our practice, we use DWI just to detect all LNs, relegating the differentiation of benign from malignant ones to morphologic, size and/or metabolic criteria.

Chemical shift effect (CSE) refers to a black or bright border outlining organ contours, including LNs. In the case of neoplastic growth in the subcapsular sinus, the resonance frequencies of hydrogen protons in the subcapsular sinus and in the adjacent fat are similar, resulting in the loss of CSE.

Four patterns of LN CSE have been described: continuous and smooth, continuous, and irregular, discontinuous, and irregular, or absent[44]. Once neoplastic cells have colonized the subcapsular sinus, they easily spread outside of the LN, likely more rapidly than toward the medulla. This results in irregular or obscure LN contours, reported in 60%-65% of malignant LNs and in 16%-20% of benign LNs, leading to sensitivity of 88%, specificity of 23%, and accuracy of 50% in one study. On the other hand, a smooth external contour has been described in 80%-84% of benign LNs and in 34%-40% of malignant LNs[42-44].

The internal structure of LNs may be heterogenous in the settings of metastases; this has been reported in 26%-52% of benign and 54%-91% of malignant LNs, with a sensitivity of 84%, specificity of 31%, and accuracy of 53%; on the other hand, homogeneous internal structure, has been observed in 48%-73% of benign and 8%-46% of malignant LNs[42-44]. The combination of inhomogeneous signal intensity and indistinct/irregular borders has been shown to yield sensitivity, specificity, and accuracy of 56%, 91%, and 77%, respectively[42].

Currently, LN size is the most used criterion to discriminate between malignant and benign LNs on MRI, but given the previously discussed inherent limitations, it is often integrated with the morphologic criteria described above. According to the European Society of Abdominal and Gastrointestinal Radiology (ESGAR) guidelines, a LN is considered metastatic in the case of[53]: Short axis diameter ≥ 9 mm, short axis 5-8 mm plus ≥ 2 morphologic criteria, short axis < 5 mm plus 3 morphologic criteria, or mucinous LN regardless of the size. Morphologic criteria chosen by ESGAR are round shape, irregular borders, and heterogenous signal.

However, despite all of the above efforts, even MRI, the most promising imaging modality for LN evaluation is still inadequate for the scope. A recent study that explored the staging performance of MRI in rectal cancer, using surgical pathology as a standard of reference, showed that MRI LN status was correctly assigned in 68% of cases, overstaged in 28%, and understaged in 4%. Moreover, only 40% of MRI-positive LN cases were pathologically confirmed[54]. These results are in line with a FDG-PET/MRI study where N status was overstaged by MRI in 22.6% of patients and by PET/MRI in 8% of cases; correct N status was assigned by MRI in 58% of patients and by PET/MRI in 79% of patients[55].

PET

FDG-PET, in addition to structural information, includes the advantage of assessing the metabolic activity of colorectal patient LNs. However, even with metabolic information, sensitivity is limited. A recent meta-analysis including 13 studies published between 2007 and 2019 evaluated the pretreatment ability of 18F-FDG PET/CT as a staging modality to detect metastatic LNs in CRC[15]. The pooled sensitivity, specificity, positive and negative likelihood ratios were 65%, 75%, 4.57, and 0.37, respectively. Prospective studies have demonstrated higher sensitivity and specificity compared to retrospective studies, and studies with sample sizes greater than 100 and that used a cut off value of

maximum standardized uptake value (SUV) ≤ 2.5 revealed better accuracy. An older meta-analysis of CRC patients found an even lower pooled sensitivity of 42.9% for detecting LN metastasis, but a higher specificity of 87.9%[56,57]. Differences in meta-analysis outcomes are thought to be due to the heterogeneity of baseline patient characteristics and included article methodologies. Regardless of the variances between the two meta-analyses, FDG-PET has limitations in sensitivity[58-61], likely due to a partial volume effect when assessing the SUV of small LNs (< 10 mm), as well as limitations in spatial resolution when differentiating between extension of primary tumor and adjacent positive LNs[62-64]. Specificity on the other hand is limited by false positives seen most often in reactive LNs.

Innovations

Advancements in the imaging evaluation of LNs in CRC are going to happen in the very near future due to innovative scanning technologies such as PET/MRI, which can investigate tumor biology, phenotypes, improve diagnosis, and impact the management of several solid organ malignancies including CRC[55,65-72], innovative radiopharmaceuticals such as fibroblast activation protein inhibitor (FAPI), which is already outperforming FDG in several settings[73,74], and due to the endless possibilities opened by artificial intelligence. Regarding FAPI, a study[74] comparing 68Ga-FAPI and 18F-FDG uptake in 35 patients with gastric, duodenal, and CRCs, showed a significantly higher sensitivity with 68Ga-FAPI PET/CT compared to 18F-FDG PET/CT (79% *vs* 54%) but an equivalent specificity (82% *vs* 89%). Artificial intelligence is going to play a major role in diagnostic imaging evaluation of LNs. A recently published metanalysis, which focused on LN staging in CRC, showed that deep learning and radiomics outperform radiologists, with deep learning also being superior to radiomics. In rectal cancer, on a per patient basis, pooled area under receiver operator characteristic curve was 0.017 for deep learning, 0.808 for radiomics, and 0.727 for radiologists; and sensitivity and specificity were 89% and 94% for deep learning, 78% and 73% for radiomics, and 68% and 70% for radiologists respectively[75].

CONTROVERSIES IN LN DISSECTION IN CRC

Several studies have shown that in more than 80% of cases, the first metastatic LN in CRC is a paracolic LN located 5 cm or less from the tumor[76-81]. Besides this classic lymphatic drainage, aberrant drainage within the regional LNs can exist. Such drainage leads directly to main LN stations near the superior and inferior mesenteric vessels or to colic and paracolic LNs located a significant distance from the tumor. The prevalence of aberrant lymphatic drainage is reportedly up to 20%[82,83]. Drainage of this nature influences the scope of lymphadenectomy since "aberrant" LNs are potential locations for "skip metastases"[76,77,84-86].

In some individual studies, a higher rate of aberrant lymphatic drainage reaching up to 29% has been observed in patients undergoing lymphatic mapping[87]. There are some different points of view on the resection type between East and West. The Japanese concept is partial resection of the bowel according feeding artery (short bowel specimen, long lymph vascular pedicle), and the opposite European concept is wide resection of the bowel such as hemicolectomy or extended hemicolectomy.

European Society of Medical Oncology (ESMO) recommends that local excision could be considered in the early colon cancer (CC) Stage 0 (Tis) and in selected T1N0M0 (G1-2, N0). ESMO and National Comprehensive Cancer Network (NCCN) recommend wide surgical resection with a safe margin (ESMO suggests at least 5 cm from the tumor), and en bloc removal of LNs with the feeding arterial arcade (regional nodes). NCCN suggests removing only suspicious LNs that are not contained in the arcade[25,26,88,89].

The best results in terms of prognosis after the introduction of the TME concept in the treatment of rectal cancer led to the Hohenberger *et al*[90] hypothesis in which surgical dissection according to embryological planes could lead to a similar improvement also in surgery of the. On this hypothesis is based the complete mesocolic excision (CME) associated with the concept of central vascular ligation (CVL) in which the main blood vessels are tied at the origin after a dissection according to the embryological planes (*i.e.* removing the surgical trunk of Gillot in right-sided CC)[90].

JSCCR provides a detailed description of the extent of surgical lymphadenectomy, based on tumor stage. In brief, JSCCR advocates central (D3) lymphadenectomy in selected T2 and in all T3-T4 cancers, as well as in all N-positive patients.

In the study by West *et al*[91] the CME with CVL does not show significant differences with the Japanese D3 as regards the quality of the mesocolon surgical plan and the free margins. In the Japanese school, as indicated in the JSCCR guidelines, the longitudinal extension is less important; consequently the number of lymph nodes and the mesenteric surface were lower. Even if the operative pieces in western countries have a greater longitudinal extension than in the Asian ones, the TNM system does not include in its nomenclature the localization of regional lymph nodes. The indications to D3 Lymphadenectomy with CVL in the Western countries are still a subject of debate.

CONTROVERSIES IN LN DISSECTION IN RECTAL CANCER

Rectal cancer surgery is based on[92-94] TME or tumor-specific mesorectal excision (TSME). TME is a procedure that resects all of the mesorectum just above the anal canal[92]. TSME is a procedure for partially resecting the mesorectum according to the location of the tumor[94]. In Western countries, in the rectal cancer, lateral LNM is generally considered a metastatic disease and neoadjuvant chemoradiotherapy combined with TME is widely used. By contrast, the Japanese Classification of Colorectal Carcinoma[95-98] defines lateral LNs as regional LNs in the internal iliac, obturator and common iliac subregions. The JSCCR Guidelines for the treatment of CRC[28,29] consider mesorectal excision as D1 resection and recommend a D3 procedure (TME with lateral LN dissection) as standard treatment for T3 or more middle and lower located rectal cancer.

Some studies have shown that extensive lymphadenectomy is associated with improved prognosis in patients with more advanced stage CRC, even though numerous postoperative complications related to this extensive surgery are described.

Among colorectal surgeons, it is now accepted that "one size does not fit all", and there is increasing agreement regarding the need for a more targeted surgery and a tailored lymphadenectomy[98-100]. The real challenge is careful patient selection.

HYSTOPATHOLOGICAL DIAGNOSIS OF LNMs IN CRC

A relevant clinical finding is the fact that up to 30% of patients with CRC diagnosed as pN0 following surgery will die within 5 years due to regional recurrence or distant metastases[87,101-104].

A discussion to establish criteria for defining high-risk stage II patients who could benefit from adjuvant therapy was undertaken by the Multicenter International Study of Oxaliplatin/5-Fluorouracil/Leucovorin in the Adjuvant Treatment of Colon Cancer and National Surgical Adjuvant Breast and Bowel Project studies. Presently, the high-risk group, according to ESMO and NCCN treatment standards, comprises patients with T4 tumors (especially T4b), a high grade of histological malignancy, infiltration of vessels and perineural tissue, tumor budding (TB), a small number of removed LNs (< 12), and emergency surgery[101,105,106]. Several studies have identified prognostic genes that may select high-risk patients for adjuvant treatment[107-112], but only a few are routinely used in clinical practice.

Mismatch repair (MMR) genes act in DNA repair pathways. MMR deficiency results from the loss of function of their products (MMR-D), leading to microsatellite instability (MSI). MSI increases CRC risk by increasing tumor mutational burden and the number of tumor-infiltrating lymphocytes (TILs). There are two categories of CRC with MSI: MSI-high (MSI-H) and MSI-low (MSI-L). Instability in more than 30% of the markers as detected by PCR is defined as MSI-H, and alteration in 10%–30% of the markers is considered MSI-L. The MSI-H is associated with a high mutational burden in DNA.

Frameshift mutations can create antigenic epitopes that make MSI-H/MMR-D tumors more immunogenic compared with microsatellite-stable tumors. MSI-induced frameshift mutations produce a significant number of neoantigens. Accordingly, MSI-H/MMR-D tumors manifest a great number of TILs, many of which can be directed against tumor-related neoantigens[107].

Despite this, the most important risk factor is the presence of unidentified LN MMs and macrometastases. Rahbari *et al*[113] concluded that the presence of LN MMs is associated with poor OS and shorter disease-free survival (DFS) in stage II CRC patients. Therefore, the problem is to identify diagnostic methods that can improve selection based on this criterion in terms of both cost and effectiveness[101,114,115]. The relevant literature shows that examination of only one LN slide using HE staining leaves up to 33% of metastases unidentified. A single slide with HE staining through the center of a node 1 cm in diameter provides information on < 1% of its volume[114-118].

Additional HE histopathologic analyses of serial sections allows for the identification of micrometastatic disease in up to 20% of LNs determined to be negative by standard HE methods[119]. However, performing HE histopathologic analyses of sections can be technically challenging and time consuming, as well as entailing significantly greater cost. Other histopathologic methods utilized for more accurate assessment of the status of the regional LNs, such as IHC using antibodies against human cytokeratin (CK) or RT-PCR, require even more time and incur an even higher cost.

IDENTIFICATION OF AN OPTIMAL mRNA MARKER FOR THE OSNA ASSAY IN CRC METASTATIC NODES

Yamamoto *et al*[13] reported the background for the identification of CK19 mRNA as an optimal marker for the OSNA assay in CRC. Yamamoto *et al*[13] examined 98 candidate mRNA genetic markers, which were from a genome-wide database, by comparing an expression frequency in CC. After four sequencing phases, CK19, carcinoembryonic antigen (CEA), and CK20 mRNAs were evaluated using

the OSNA assay. The expression of CK19 mRNA was observed in all pathologically positive LNs; however, CEA and CK20 mRNAs were not found in metastatic nodes.

DIAGNOSTIC PERFORMANCE OF THE OSNA ASSAY IN CRC

A novel technique for pathological examination, OSNA, uses the reverse transcription loop-mediated isothermal amplification method to amplify CK19 mRNA. In contrast to the current routine histopathological examination, it can examine whole LNs and detect metastases in a sufficiently short time (Table 1). A standard curve previously determined with three calibrators containing different CK19 mRNA copy numbers was used to calculate the amount of CK19 mRNA. Positive and negative control samples were used to ensure the quality of the assay.

A limit value of 250 copies/mL of CK19 mRNA copy had been choosed. A value less than 250 copies/mL was considered negative for metastasis, on the contrary, a value ≥ 250 copies/mL was considered positive. Previous studies defined this by the logarithmic midpoint between the maximum value of the CK19 mRNA copy number in non-metastatic patients and minus 2 or 3 standard deviations (SDs) from the average of CK19 mRNA copy number in node-positive patients. These studies also defined the MM threshold between 250 and 4999 CK19 mRNA copies/mL. LNs with 5000 or more mRNA copies/mL were considered macrometastases[7,120,121]. The utility of conventional OSNA as a molecular staging method has been demonstrated for various cancers[9,17,122-124].

Although most of the studies evaluated in this review were prospective in design, none was a randomized controlled trial (Table 1). The studies comparing the diagnostic performance between OSNA and pathological examination for the detection of LNMs in CRC are shown in Tables 2 and 3. Our review on OSNA and CRC shows high sensitivity, few false negatives results, and a concordance rate with pathological findings ranging from 61.8% to 98.7% (Table 2). Moreover, studies have shown that OSNA results in upstaging in about 25% of initially nodal-negative CRC patients after conventional HE analysis (Table 3). With the OSNA approach, the lymph node is homogenized without the need for other preparations and the results are ready in less than 40 min for 3 or 4 LNs, 20 min for a single LN. The stage of the tumor and the number of lymph nodes analyzed correlates with upstaging. Notably, the OSNA upstaging rate in Croner's investigation for stage UICC I and II patients was 16.2% and 30.3%, respectively. Therefore, it was suggested that stage UICC I and II patients, who suffer from recurrent disease, were understaged by conventional HE analyses[9,124-126].

In a study of Yamamoto *et al*[13] OSNA-positive patients (2.0% of stage I CRC and 17.6% of stage II CRC) had more advanced features of CRC, such as deeper invasion to the colonic wall and severe invasion to lymphatic invasion compared with OSNA-negative cases. They found a 95% concordance rate between OSNA and classical histological analyses with HE and IHC. Yamamoto *et al*[13] concluded that OSNA is comparable to a 2-mm interval histopathological examination in its ability to detect LNMs.

In our previous published study[127], OSNA was superior to HE in identifying LNMs, with a false negative rate of 0% *vs* 44.4% and accuracy of 100% *vs* 76.4%, respectively (Table 2). As represented in Tables 2 and 3, few studies evaluated HE and IHC, few performed multi-sliced tissue sections using HE and the remaining single slice HE tissue section *vs* OSNA[11,128-131]. While the detection of small metastatic foci in LNs is influenced by the skill and experience of the pathologists, the advantage of the OSNA assay is the possibility to perform standard evaluations without being influenced by operator skill or experience. This explains the reason why the use of OSNA has recently garnered interest for detecting MMs[9,16,17,128].

Methods of LN division and pooled OSNA

Previous reports have detailed three major methods to compare LN status between pathological examination and the OSNA assay (Table 3). The first method[14,125] involves dividing LNs in half and sending each 50% portion for pathology and OSNA (half-division method). The second method[11,12,15] involves dividing LNs into four equal sections and sending two of these sections (50%) for pathology and OSNA (four-section method). In the third method[14,124], only 1 mm from the center of LNs are sent for pathological examination and the rest are used for OSNA measurement (center-cut method). The latter two methods described above are thought to be technically difficult for evaluating small LNs. By contrast, dividing in half and sending each 50% portion for pathology and OSNA is the simplest method.

In previous studies using classic OSNA (cOSNA), 50% of each LN was submitted for pathologic examination, followed by evaluation of each remaining half by OSNA. The obstacles for clinical applications of cOSNA include a need to simplify the procedure for halving the dissected LNs and reducing the operating costs associated with the equipment used for OSNA analyses.

Rakislova *et al*[125] conducted a study comparing two methods of LN evaluation by OSNA in CRC: an individual analysis of each LN (cOSNA) and a new approach involving pooling several LNs, known as the "pooling method". The diagnostic performance of pooled OSNA (pOSNA) was comparable to that of cOSNA. In the pOSNA method, the LNs are pooled together in a test tube for OSNA analysis. The weight limitation for the LNs per tube was ≤ 600 mg, with those exceeding this limit placed in another

Table 1 Characteristics of one-step nucleic acid amplification studies in colorectal cancer patients

tube for measurement. In the study by Tani *et al*[33], pOSNA and the half-division method were combined and used in the diagnosis of pericolic LNMs and applied in clinical practice[33]. These results revealed that the pOSNA with the half-division method might be useful as a clinical molecular staging method.

In this study, the upstaging rate for early-stage CC patients was 9.1% (6/66). The upstaging rates of the study by Tani *et al*[33] were slightly lower than those previously reported (Table 3).

COMPARISON OF THE NUMBER OF POSITIVE NODES AND QUANTITATIVE OSNA RESULTS

The OSNA assay of retrieved LNs does not allow the number of involved LNs typically used for TNM staging, and therefore cannot be used for conventional cancer staging. Nevertheless, the OSNA assay can potentially be used to infer the size of metastatic foci based on the detected copy numbers[113,132]. Patient's total tumor load (TTL) resulted from the sum of all CK19 mRNA tumor copies/μL of each positive LN from the colectomy specimen. Yamamoto *et al*[17] found that the sum of CK19 mRNA increased as the number of histologically positive LNs increased. Indeed, the median value of CK19 mRNA was significantly smaller in patients with < 3 regional LNMs than in those with ≥ 4 regional LNMs. The median TTL values of pN0, pN1 (1-3 positive LNs), and pN2 (4 or more positive LNs) were 1550 copies/mL (300-320000 copies/mL), 24050 copies/mL (250-890000 copies/mL), and 90600 copies/mL (7700-1635100 copies/mL), respectively. The TTL significantly increased as the node status increased.

In the study of Aldecoa *et al*[133] the TTL was related to pT stage ($P = 0.01$) and tumor size ($P < 0.01$) in low-grade tumors. In that study TTL, correlated with classical high-risk factors in stage I–II CC patients. These findings indicate that the sum of CK19 mRNA assessed by OSNA displays a trend compatible to the current pathological diagnosis system. These findings suggest the future possibility of novel molecular staging using OSNA, based on metastasis volume (amount of CK19 mRNA) rather than the number of LNMs. It has been suggested a correlation between CRC risk factors[11,12,16,18,122,126,134] such as pN, pT, tumor grade, male sex, tumor size, lymph vascular invasion (LVI), poor prognosis, worse DFS and TTL.

Correlation of node TTL with TB and poorly differentiated clusters

The physiological process that can lead epithelial cells to acquire mesenchymal properties and the potential for migration and stromal invasion, essential for the development of metastases, is the morphological manifestation of the epithelial-mesenchymal transition phenotype that can lead to the formation of TB and clusters poorly differentiated (PDCs). The presence of isolated tumor cells or cell clusters of ≤ 4 cells on the invasive front of the tumor is termed tuberculosis[134]. 5 or more neoplastic cells in the tumor stroma not organized into glandular structures constitute the PDCs. In stage II CC, both PDCs and TB are independent prognostic factors[134-136], associated with LNMs, distant

metastases, extramural vascular invasion, LVI, perineural invasion (PNI), tumor grade and high pT stage[136-142].

International Consortium on TB Recommendations indicates how to count the number of TB at the invasive front of the tumor[135]. The classification for TB was as follows: Bd1/low (≤ 4 buds), Bd2/intermediate (5–9 buds), and Bd3/high (10 one more buds). The classification for PDCs evaluated [143] at the invasive front or in the center of the tumor was as follows: G1 (≤ 4 clusters), G2 (5–9 clusters), and G3 (10 or more clusters). Barresi *et al*[144] suggested not classifying tumor cells within mucin pools in mucinous carcinomas as TB, considering only tumor cells infiltrating the stroma with minimal extracellular mucin. While, the PDCs were evaluated within mucin lakes.

Recently Archilla *et al*[145] suggested the correlation of the TTL with patient outcome, TB, and PDC. The use of molecular methods to assess LN status, together with other pathological risk factors, could help improve risk stratification and management of patients with early-stage CRC.

Indeed, OSNA positivity was found in 38.3% of the cases (131/342) with a mean TTL of 36662 copies/mL among positive cases. The TTL present in the LNs evaluated by the OSNA test correlated positively, with both PDC (r = 0.266 by IHC; r = 0.257 by HE) and TB (r = 0.249 by IHC; r = 0.243 by HE) (P = 0.001). Low and intermediate TB had similar mean TTL (Bd1: 3292 copies/mL and Bd2: 18002 copies/mL), with no significant differences between both groups (*P* = 0.154). The mean TTL of high-Bd3

TB was 45331 copies/mL, and. it was significantly different from Bd1 and Bd2. Likewise, the mean TTL of PDC G1, with 4962 copies/mL and G2, with 13146 copies/mL did not show significant differences (P = 0.068), while PDC G3 had 61108 copies/mL, significantly different than low and intermediate grades. Thus, the authors grouped low and intermediate grades of TB and PDC into one category, obtaining two groups with significant differences for both TB and PDC (P < 0.001) as well. The authors also concluded that TTL can be used as an alternative method to to better stage patients compared to the classic HE because it is able to identify real stage II or III patients, thereby selecting those who are candidates for adjuvant therapy[145].

SURVIVAL ANALYSES

In the meta-analysis of Wild *et al*[146] it is emphasized that long-term outcomes and the use of adjuvant therapy in those upstaged by OSNA should be clarified before routine use of OSNA test.

Itabashi *et al*[18] showed that pStage II patients with OSNA positive LN had a lower 3-year DFS than negative patients (55% *vs* 86%; P = 0.005), with no significant differences in 3-year OS (P = 0.914). In this study, the upstaging occurred for patients with pStage II, of whom 11 of 70 patients (15.7%) were OSNA-positive. Most of the OSNA positive LNs were located in the peri-colic or peri-rectal area (10 out of 11 OSNA-positive stage II CRC patients).

Weixler *et al*[147] showed that the detection of positive LN by HE staining but not by OSNA as significant predictors of cancer-specific survival, cancer-specific and recurrence-free survival, and DFS. He concluded that in patients with CC, OSNA offers no prognostic advantage compared to conventional LN staging with HE contrasting findings in other cancers. It is important to highlight that the methodology of the histopathological evaluation for detection of the LNMs differed among studies. In Weixler's multicenter study[147] all harvested LNs > 3 mm in greatest dimension or a short axis ≥ 10 mm was cut into four slices: two were stored for later OSNA analysis and two were allocated to conventional standard HE staining, multilevel HE staining, and IHC for CK19. Multilevel sectioning with IHC leads to relevant upstaging of 15.4%-26% of otherwise negatively classified patients[148,149]. In addition, stage I-III patients were included in this study, whereas most of the OSNA studies focused on stage I-II patients. Therefore this HE + IHC *vs* OSNA study including stage I-III patients, although well conducted and of great value and interest, is not amenable to a comparison with studies in which HE *vs* OSNA in stage I-II patients are evaluated.

ORGAN-PRESERVING SURGERY

CC

Early CRC can be treated by endoscopic mucosal resection or endoscopic submucosal dissection (ESD). In determining the indication for endoscopic treatment and the treatment method, information on the depth of invasion and morphology of the tumor is essential. Colorectal ESD is an "endoscopic resection technique, which enables en bloc resection of a tumor, regardless of size" and avoids piecemeal resection. It is of great importance to differentiate Tis and T1a cancers from T1b cancers (T1 cancer with ≥ 1000 μm submucosal invasion depth), as the former can be treated by endoscopy while the latter requires surgical operation with nodal status assessment[29,150-154]. Moreover, innovative organ-preserving procedures such as endoscopic full-thickness resection or transanal minimally invasive surgery have been proposed to perform high-quality resections with decreased incidence of specimen fragmentation without resorting to demolitive interventions[155]. Nevertheless, it is estimated that overall 10%–20% of patients in stage T1 will have LNMs, and such patients subjected to a localized resection are undertreated[151].

Laparoscopic endoscopic cooperative surgery (LECS) can also lead to full thickness local resection by means of combined use of laparoscope and endoscope. The development of modified LECS procedures, such as non-exposed endoscopic wall-inversion surgery and closed LECS has almost resolved these drawbacks. This has led to a recent increase in the indication of modified LECS to include patients with gastric epithelial neoplasms. The LECS concept is also beginning to be applied in other organs such as the duodenum, colon and rectum. Further evolution of LECS procedures is expected in the future. SLN mapping could also be combined with LECS, resulting in a portion of early gastrointestinal cancers being treated by LECS with SLN mapping[156].

Rectal cancer

TEM, first described by Gerhard Buess[157-161], due to its ability to perform high-quality resections with decreased incidence of fragmentation, is superior to standard transanal excision for treating benign and malignant rectal lesions, most notably[162,163].

Transanal minimally invasive surgery (TAMIS) was initially born as a fusion between trans anal endoscopic microsurgery (TEM) and single-site laparoscopy. This technique was designed as a cost-

effective and easily reproducible alternative to TEM without specialized equipment.

The indications for TAMIS are similar to standard transanal resection for benign and malignant lesions determined by EUS or MRI[164,165]. TAMIS is also indicated for early malignant neoplasms confined to the submucosa[166]. T1 neoplasms of the rectum can still be divided into low-risk lesions [167] and at high risk for poor histopathological features (TB, poor differentiation, LVI or perineural invasion). Studies[155,168-170] identified a higher risk of LN metastasis in T1 sessile tumors with deeper submucosal invasion (sm^2 or sm^3).

THE OSNA ASSAY FOR THE DETECTION OF CRC METASTASIS IN SLN

LN status plays a crucial role in oncologic therapeutic strategies, and despite the use of increasingly sophisticated imaging techniques, pre-operative metastatic LN identification in patients with CRC is unsatisfactory[171,172].

The study of the SLN is gaining more and more popularity because it can avoid extensive lymphadenectomies, reduce operating times and morbidity. This can change the surgical strategy in patients with an apparent early stage of CRC, as patients with intraoperative positive SLN are submitted, during the same surgical procedure, to an adequate lymphadenectomy, whereas those with negative SLN can be treated with an organ-preserving surgery, avoiding unnecessary lymphadenectomy. The extemporaneous intraoperative examination performed on frozen specimen has a lower sensitivity than the classic postoperative analysis. The problem is mainly due to the low detection rate of MMs and ITC[173,174]. The disease detection rate increased with the technique of multi-step formalin-fixed tissue sections (FFTS) stained by HE with or without IHC[6,175-179]. Nonetheless, a significant number of MMs can still be overlooked, as during histological workup usually only small parts of LNs are screened.

Therefore, there are two methods for SLN mapping: staining and radioguided[180]. Three tracers have been used to detect SLNs: Dye, radioisotope, and indocyanine green (ICG). Each tracer has its respective disadvantages. The use of the ICG fluorescence method has officially been approved in Japan for LNs of BC and malignant melanoma; thus, it appears that ICG can be an acceptable tracer for the detection of LNs in gastric and CC.

ICG tattooing method is very useful for the marking of early gastric and CCs, especially when using a laparoscopic approach[181]. It has been suggested that SLN mapping with fluorescent dye can play an important role in the treatment of CC, particularly those at early stages, and can lead to ultraconservative surgery[182]. Because the results of OSNA are available in a relatively short time compared to the conventional technique, intraoperative OSNA analysis of SLNs may be employed easily in clinical practice.

In the study by Vogelaar *et al*[15] OSNA proved to be a promising method for the detection of SLN metastases in CC patients after *ex vivo* SLN mapping. OSNA appeared to outperform routine pathological examination with HE-stained slides with an upstaging rate of 20.2%. In the study by Yeung *et al*[130] OSNA was used intraoperatively, together with the technique of retrieving colorectal LNs by fluorescence imaging, to analyze the status of these specific LNs. In this study, OSNA is highly concordant with standard histology.

The results of the meta-analysis by Tranoulis *et al*[183] indicate that the the use of OSNA can allow to identify the status of the LNs even when applied intraoperatively. Marhic *et al*[184] proposed that the OSNA technique may be a new method to reduce time to adjuvant chemotherapy after surgery for CC. In this study, SLN status was determined intraoperatively with the OSNA assay; when positive, a port-a-cath was placed during the procedure for upcoming adjuvant chemotherapy. In this study, there was no difference between the groups regarding cancer staging, duration of hospitalization, and major morbidities but the time interval between surgery and adjuvant chemotherapy was significantly shorter in the OSNA group at 35 ± 8 d *vs* 67 ± 36 d ($P = 0.021$).

In our previous study[127], we showed that SLN analysis with OSNA in combination with ICG-near infrared (NIR) lymphangiography is feasible and may allow intraoperative prediction of LN status in patients with CRC (Table 4). Patients with SLN positive by the OSNA method were considered pN-positive and subjected to adjuvant chemotherapy. The time to start chemotherapy was lower in OSNA (+) patients [39.1 ± 1.9 d *vs* 50.2 ± 4.1 d in the OSNA (−) group; $P = 0.01$].

Both *ex vivo* and *in vivo* ICG fluorescence imaging are feasible for the detection of SLNs in CRC. The submucosal injection technique and subserosal were both used. A NIR 30° laparoscope (Olympus, Tokyo, Japan) was used to inspect the mesocolon. The LNs found using fluorescence were considered SLNs and analyzed intraoperatively. More work needs to be done to define protocols, indications for its use, a standard number of LNs that need to be removed and to test its efficacy in larger patient populations.

Implementation SLN analysis with OSNA in combination with ICG-NIR lymphangiography could allow more precise staging, reducing the delay between surgery and the onset of adjuvant chemotherapy. SLN evaluation by intraoperative OSNA analysis combined with a LECS approach may allow, in case of OSNA-negative early CRC, to apply an organ-preserving surgery avoiding the complic-

OSNA: One-step nucleic acid amplification; SLN: Sentinel lymph node.

ations related to an unnecessary lymphadenectomy.

By contrast, in intraoperative OSNA-positive early CRC, a colorectal resection associated with selective lymphadenectomy can be performed, also taking into consideration the presence of aberrant lymphatic drainage and skip metastases. Despite the attractiveness of the previously exposed concept, studies in this field are lacking or very few (Table 4). However, several studies underline the role of OSNA SLN evaluation in more advanced stages and in case of positivity, the consequent upstaging and access to adjuvant treatment (Table 4).

LATERAL PELVIC LNs AND OSNA

There is disagreement in the international literature regarding the use of prophylactic lymphadenectomy in comparison with preoperative radiochemotherapy to improve prognosis in patients with locally advanced rectal cancer, due in part to the complex anatomy of the pelvic floor which makes diagnosis of lateral pelvic LNs (LPLNs) metastasis difficult. In Japan, the evolution in the surgical oncology approach has been toward LN clearance and, as a result, LPLNs have been considered local-regional disease from the outset[185].

Nevertheless, the rate of pathological lateral (Lat) LNM (p-LatLNM) in patients without clinical LatLNM (c-LatLNM) remained low at 7%, and lateral LN dissection (LatLND) is generally considered technically demanding and can prolong the operative time[186-188]. As Sammour *et al*[189] proposed, patients who are candidates for curative-intent treatment should be stratified depending on their risk to have LPLN metastasis in high, moderate, and low risk in order to select the best option to manage the pelvic compartment. Nevertheless, with preoperative images or traditional criteria, it is difficult to predict LatLNM. Obtaining a preoperative or intraoperative diagnosis is essential to select patients with LatLNM.

If SLN navigation surgery could be applied in cases of middle and lower rectal cancer, unnecessary LatLND procedures could be avoided. SLN anlysis may be useful in deciding both the indication of LatLND and which side of the lateral pelvic wall should be dissected[190]. In the study of Noura *et al*[191] the existence of a lateral pelvic region SLN in 53 lower rectal cancer patients was investigated. The lateral pelvic region was observed using a NIR camera system (photodynamic eye) after the ICG has been injected into the submucosa along the dentate line. If SLNs were positive for metastasis a Bilateral LatLND was performed, if instead SLNs were negative for metastasis mesorectal excision only was performed. In 49 (92.5%) of the 53 patients the lateral SLNs were successfully identified, 4 of these patients (8.2%) had lymph node metastases; the mean number of lateral SLNs per patient was 2.0 (range, 1–4).

The results of Yasui *et al*[192] suggested the potential use of SLN with ICG strategy to identify cases with non-metastatic LPLN, and to omit LatLND in such cases, and thereby avoid both LatLND-related surgical complications and radiation-induced adverse events. Moreover, the author suggested that further studies are needed to shorten the required time and improve the accuracy of SLN biopsy by the intraoperative rapid diagnosis with different methods such as molecular biological diagnosis.

Miyake *et al*[193] attempted to perform an intraoperative OSNA assay to detect perirectal LNMs to predict LPLN metastasis in rectal cancer patients undergoing surgical resection plus LatLND. In their study, LPLN metastases were present in 16% of patients (4/25), and all of these patients were positive on an OSNA for perirectal LNMs. The sensitivity of OSNA was 100%, specificity 86%, positive predictive value 57%, and negative predictive value 100% for predicting LPLN metastasis, and the authors concluded that the OSNA of perirectal LNs might be useful for selecting candidates for omission of LatLND in rectal cancer surgery. OSNA can be associated with SLN to intraoperatively identify foci of metastasis in LPLNs.

With respect to risk factors for p-LatLNM, three previous studies reported that pathological mesorectal LN (MesLN) metastasis (p-MesLNM) is a consistent risk factor for p-LatLNM[194-196]. Furthermore, previous studies have shown that p-LatLNM rarely occurs without p-MesLNM[16,197].

Negative OSNA diagnosis for mesorectal LNM (MesLNM) (OSNA-MesLNM) is highly correlated with negative p-LatLNM; hence, negative confirmation of OSNA-MesLNM may be useful in selecting patients in whom LatLND can be omitted[189].

In conclusion, the role of LatLND is still under discussion. Nevertheless, it has been suggested a selective and mono- or bilateral LatLND in advanced low and middle rectal cancer, based on OSNA positive mesorectal nodes or OSNA-positive ICG-stained sentinel LPLNs.

COSTS

A disadvantage of cOSNA is that it is more costly than pathologic examination. Depending on the number of samples analyzed in each lot, there is a variation in the cost of consumables and additional reagents. For example, a 12 LN analysis would have an indicative cost of single use products is £ 550–£ 590 per patient [excluding value added tax (VAT)]. If consumables are maximized and samples from more than 1 patient are tested in one batch, the cost could be as high as £ 33.50 per LN. The annual maintenance contract for the system (which would apply from the 2nd year after installation) is priced at £ 6628.48 (excluding VAT) with a 12 mo warranty.

The lifespan of the OSNA system declared by the manufacturer is at least 6 years. The duration of the analysis is approximately 90 min for 12 LNs, therefore it is possible to analyze samples of approximately 5 patients per day (7.5 h), and 1200 in 1 year (considering 240 annual working days). Average cost per patient (including capital, maintenance and disposable costs) ranges from £ 568 to £ 608, using the standard annuity method with a 3.5% discount rate[198]. Nonetheless, the OSNA use may reduce the reinterventions and allow earlier commencement of adjuvant treatment. The financial implications of OSNA have been previously investigated in BC, with an estimated saving between 400 and 700 £ per patient[199,200].

With pOSNA, only one measurement is required, at a cost of $ 225 (¥ 24000). In contrast, cOSNA requires three or more measurements, at a cost of $ 670 (¥ 72000) or more. In pOSNA, multiple LNs can be measured in one tube, taking into consideration the upper limit of the LN weight that can be assayed in one tube by the OSNA method is 600 mg. However, in cOSNA, only one LN can be measured in a single tube (max 50 mg). Using cOSNA to measure 12 or more halved LNs would require at least 12 tubes and three or more measurements per tube, whereas if 12 pericolic LNs are measured, pOSNA would require only one or two tubes for each case. The OSNA measuring device can measure up to four tubes at once; however, because pOSNA requires only one or two measurements per case, this allows the device to take measurements for two cases simultaneously depending on the number and weight of the removed LNs.

Diaz-Mercedes *et al*[109] analyzed the budget impact of introducing an OSNA assay in early-stage CRC patients and suggested that OSNA might have not only an economic benefit but also a clinical benefit in CRC patients, since it enabled more accurate staging, thereby avoiding unnecessary treatment. The results of Diaz-Mercedes *et al*[109] indicate that the Spanish National Health System would have saved over € 19 million from 2017 to 2019 if OSNA had been introduced in clinical practice for surgically treated CRC patients. In this study, HE-positive patients and OSNA-positive patients, both underwent adjuvant therapy. Savings are explained by the fact that OSNA ensures a more accurate diagnosis in CRC patients, allowing a reduction in treatment costs after initial surgery, as well as costs of adjuvant treatments and surgery after recurrence, compared with HE techniques. Although patients' LN staging is more expensive with OSNA than with HE, savings regarding treatment costs after surgery and treatment costs due to recurrence are high enough to justify the investment in OSNA analysis.

Although the costs of OSNA are high, the speed, simplicity, and reproducibility could allow a reduction in the hours of work of individual pathologists. Furthermore, two cases can be studied during a single procedure using the pOSNA method. Adding, as demonstrated by Diaz-Mercedes *et al*[109], the reduction in treatment costs after surgery and the reduction in costs relating to the treatment of recurrences, this method could be also attractive for developing countries.

ADVANTAGES AND DISADVANTAGES

Advantages

The innovative aspects of OSNA are that unlike standard histopathology, OSNA can analyze the whole LN as well as partial LNs. This may improve cancer staging accuracy. It can detect metastatic foci regardless of their size or location. It is seemingly superior to conventional FFTS in detecting MMs and ITC, as it can identify metastatic foci as small as 0.35 mm[201]. Yamamoto *et al*[17] found that the sum of CK19 mRNA increased as the number of histologically positive LNs increased. Indeed, the median value of CK19 mRNA was significantly smaller in patients with < 3 regional LNMs than in those with ≥ 4 regional LNMs. In the study of Aldecoa *et al*[133], the TTL was related to pT stage (P = 0.01) and tumor size (P < 0.01) in low-grade tumors. In this study, TTL correlates with classical high-risk factors in stage

I–II CC patients. These findings indicate that the sum of CK19 mRNA assessed by OSNA displays a trend compatible to the current pathological diagnosis system. These findings suggest the future possibility of novel molecular staging using OSNA, based on metastasis volume (amount of CK19 mRNA) rather than the number of LNMs.

Archilla *et al*[145] have suggested the correlation of TTL with TB and PDCs. TTL could be used as a new prognostic factor in CRC as it is related to the outcome and. The combination of the TTL as a new prognostic factor, TB and PDC, could help to better stratify and manage patients with early-stage CRC at risk of recurrence.

The application of OSNA in addition to the current standard pathology would likely provide an additional risk factor for disease recurrence regarding patients with stage II CRC. LNM is a reliable prognostic marker of CRC; it is used as the ''gold standard'' for post adjuvant chemotherapy after curative surgery. One may question whether OSNA-positive CRC patients should receive post-adjuvant chemotherapy after curative surgery. Further clinical trials are needed to determine if adjuvant therapy is beneficial in this upstaged group. On the other hand, the short turnaround time renders OSNA an attractive intra-operative method. Based upon the BC accumulated experience, the turnaround time is less than 40 min for one LN, whereas it ranges from 50 to 62 min for assessing four LNs[7]. The OSNA rapid turnover time may potentially be useful in circumventing the major issues associated with SLN biopsy. Moreover, OSNA is automated and the results are quantifiable; hence, easily reproducible, less operator-dependent with short learning curve[201-203]. Therefore, implementation of OSNA in routine clinical practice may ease the burden on pathologists.

Finally, it is laborious and rather expensive to perform molecular tests. Nonetheless, the OSNA use may reduce the re-interventions and could allow earlier commencement of adjuvant treatment. The financial implications of OSNA have been previously investigated in BC[199,200]. The results showed that pOSNA can simplify the process of cutting harvested LNs in half while reducing the equipment-related costs associated with OSNA assays used in clinical practice. Additionally, pOSNA demonstrated an upstaging rate for pNNCC equivalent to that reported in previous studies, suggesting its feasibility for molecular staging in clinical practice. With pOSNA, the possibility of fewer measurements per patient and of studying more cases simultaneously with the same panel further reduces costs[33,125]. In an era of stringent economics, health systems should undergo cost-effectiveness analyses upon which a progressive integration of OSNA in their daily clinical practice could be based on[109,200].

Limitations

The few OSNA limitations should be acknowledged. OSNA can be used to analyze LNs more than 50 mg; if the LN diameter is inferior to 3-4 mm, it cannot be divided and analyzed with OSNA and conventional histology (Table 3). The examination of the whole LN by OSNA inevitably precludes FFTS examination. One limitation of all OSNA studies performed in CRC, is that the analysis has been performed using only a part of the LNs, while using the rest of the LN tissue for conventional histological analysis and pN staging[145].

The technique of nodal division must be taken into account when evaluating the results because it can vary widely between different studies. Discordant results between OSNA and FFTS were reported. The three main reasons for these discrepancies are: tissue allocation bias, low CK19 expression, and tissue contamination. Moreover, discordances may also arise from the presence of metastases from primary tumors that do not express CK19[147]. The latter is considered an important limitation of OSNA. The accuracy of OSNA is seemingly higher amongst CK19 positive primary tumors by IHC compared to those with CK19-negative primary tumors[183]. As such, the positive CK19 IHC in primary tumors has been proposed as a prerequisite for the OSNA use by some authors[183]. An additional challenge is the fact that 36% and 49% of CK19-negative primary tumors have CK19-positive LNs[183]. Peigné *et al*[203] also reported that CK19 mRNA can also be detected by OSNA even in cases with CK19-negative primary lesion.

The tendency toward a loss of CK19 expression in poorly differentiated cancers may represent a challenge for assays using CK19 IHC or PCR for detecting MMs. It is of note that upregulation of CK19 in tumors derived from cells that are CK19-negative can also be linked to unfavorable tumor features. CK19 is highly expressed in positive LNs from BC patients even when its expression is not observed in primary tumors. Targeted studies on the upregulation of CK19 mRNA in LNM of CRC are needed[13].

In light of the potential for false-negative results, the incorporation of additional markers would be a possible direction in improving the diagnostic performance of OSNA. The cut-off point of 250 copies/mL is established in BC and seemingly sensitive in CRC while the optimal diagnostic cut-off point is a matter of debate[184]. The aforementioned pitfalls remain to date a field of contention necessitating a shift in the focus of future research into incorporation of novel biomarkers and evaluation of the optimal diagnostic cut-off point.

At this time there is no exact definition of true LN positives or negatives, cancer-related relapse and death were used as real positive LN indicators, disease-free survival as negative real LN[147]. The false-negative rate of pOSNA is a point to be considered when applying OSNA in clinical practice (Table 2). However, Aldecoa *et al*[133] observed that high-grade (G3) tumors or tumors with vascular invasion presented lower levels of TTL making it not a reliable prognostic tool for these specific pathologic features.

Finally, in this review, we found few reports dealing with CRC and SLN evaluation and there is obviously the need for future research in this field.

CONCLUSION

OSNA analysis is potentially more accurate than conventional pathologic methods for identifying metastasis because it solubilizes the entire LN and analyzes CK19 mRNA levels in the resulting sample. The advantages of OSNA include a short analysis time of approximately 30–40 min from start to completion, and the ability to automate the OSNA assay eliminates interlaboratory differences based on pathologist skill and experience. The short turnaround time renders OSNA an attractive intra-operative method. Patients with pN0 OSNA-positive CRC might also need chemotherapy after curative surgery. To achieve this goal, it needs several studies to compare the recurrence rate between the groups of no treatment or adjuvant chemotherapy after surgery both in OSNA-positive pStage II CRC patients. The result would clarify whether adjuvant chemotherapy is beneficial to patients with OSNA-positive pStage II CRC. Anyway, it can be suggested that OSNA may be considered as the route to tailormade surgery.

Abstract

Langerhans cell histiocytosis (LCH) is a malignant disease of the histiocytes involving various organ systems. The spectrum of liver involvement in LCH ranges from mild transaminitis to end-stage liver disease. The hallmark of hepatic LCH is secondary sclerosing cholangitis, which manifests due to a progressive destruction of the biliary tree by malignant histiocytes. Chemotherapy remains the mainstay of treatment for active LCH. Early recognition, diagnosis and a systematic approach to the management of LCH can ameliorate the disease process. Nonetheless, the liver involvement in these patients may progress despite the LCH being in remission. Liver transplantation (LT) remains central in the management of such patients. Various facets of the management of LCH, especially those with liver involvement remain unclear. Furthermore, aspects of LT in LCH with regards to the indication, timing and post-LT management, including immunosuppression and adjuvant therapy, remain undefined. This review summarises the current evidence and discusses the practical aspects of the role of LT in the management of LCH.

Key Words: Langerhans cell histiocytosis; Liver transplantation; Outcomes; Management; Chemotherapy; Ethics

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Involvement of the liver in Langerhans cell histiocytosis (LCH) is considered a high-risk disease and the management algorithm needs to factor in the malignancy and the severity of liver disease. Liver transplantation (LT) is usually offered to LCH patients in remission with decompensated liver disease. However, given the paucity of currently available literature, the role of LT in LCH remains undefined. There is hence a need for large collaborative, multicentre studies to provide recommendations on the management algorithm for LCH.

INTRODUCTION

Langerhans cell histiocytosis (LCH) is a malignant disease of the histiocytes involving various organ systems including the liver, spleen, skin, bone, lymph nodes, lung, and the gastrointestinal tract[1]. Involvement of the liver in LCH occurs in many ways. The spectrum ranges from mild transaminitis to end-stage liver disease (ESLD). The hallmark of hepatic LCH is secondary sclerosing cholangitis (SSC), which manifests due to a progressive destruction of the biliary tree by malignant histiocytes[2]. Chemotherapy remains the mainstay of treatment for active LCH[3]. However, conventionally used vinblastine-based chemotherapy may not be tolerated by patients with concomitant liver involvement and modified regimens which balance the risk of liver decompensation with the oncological efficacy need to be instituted[3,4].

By the time the bile duct injury presents clinically, the primary disease is usually burnt out and the characteristic histiocytes are absent. ESLD and portal hypertension develop as a sequalae of SSC[5]. These patients are offered liver transplantation (LT) with an intent to cure the liver damage[6,7]. Various facets of the management of LCH, especially those with a liver involvement remain unclear. Furthermore, aspects of LT in LCH with regards to the indication, timing and post-LT management, including immunosuppression and adjuvant therapy, remain undefined. This review summaries the current evidence and discuss the practical aspects of the role of LT in the management of LCH.

LIVER INVOLVEMENT IN LCH

Liver is involved in 20%-60% of patients with LCH and is more common when there is multiorgan involvement[2]. LCH-related liver disease is conventionally divided into two stages: Early infiltrative and late sclerosis[8]. The early stage is characterised by reactions elicited by the malignant histiocytes and other inflammatory cells, manifesting as periportal infiltration and hepatic nodular lesions. In the late fibrous stage, progressive destruction of biliary tree occurs resulting in cirrhosis and portal hypertension[8,9].

Hepatic involvement as defined by the European Consortium for Histiocytosis includes a palpable liver 3 cm below the coastal margin confirmed by ultrasound and liver dysfunction as defined by hyperbilirubinemia (at least 3 times the upper limit of normal) hypoalbuminemia (< 30 g/dL) , alanine transaminase (ALT) and/or aspartate transaminase (AST) (more than 3 times the upper limit of normal), -glutamyl transpeptidase (GGT) over twice the upper limit of normal, ascites, oedema, or intrahepatic nodular mass[3]. Sclerosing cholangitis in LCH is defined as involvement of extrahepatic/intrahepatic biliary tree with strictures, dilatation, pruning detected on imaging (computed tomography or magnetic resonance imaging) and/or on liver biopsy with or without elevated GGT[10,11]. The characteristic features of bile duct injury can be detected by magnetic resonance cholangiopancreatography. It is noteworthy that despite resolution of active malignancy, the biliary injury continues to progress. The major site of LCH involvement is the large bile duct, and hence sites of active disease may be missed on liver biopsy[8].

With a mortality risk of over three times that of patients without liver involvement, hepatic LCH is considered a high-risk disease. In a study of patients with LCH, liver involvement drastically reduced survival from 97% to 52%[12]. SSC may be observed in up to 20%, which invariably progress to ESLD requiring LT[13]. It is noteworthy that an acute hepatic involvement by active LCH may be reversible with timely instituted chemotherapy[12]. Later stages and/or burnt out disease on the other hand may continue to have worsening liver injury. Furthermore, this progression of SSC is more rapid than what is observed in primary sclerosing cholangitis[14]. In a series of adults with LCH, nearly 30% died due to complications of SSC and ESLD[14].

LIVER PATHOLOGY IN LCH

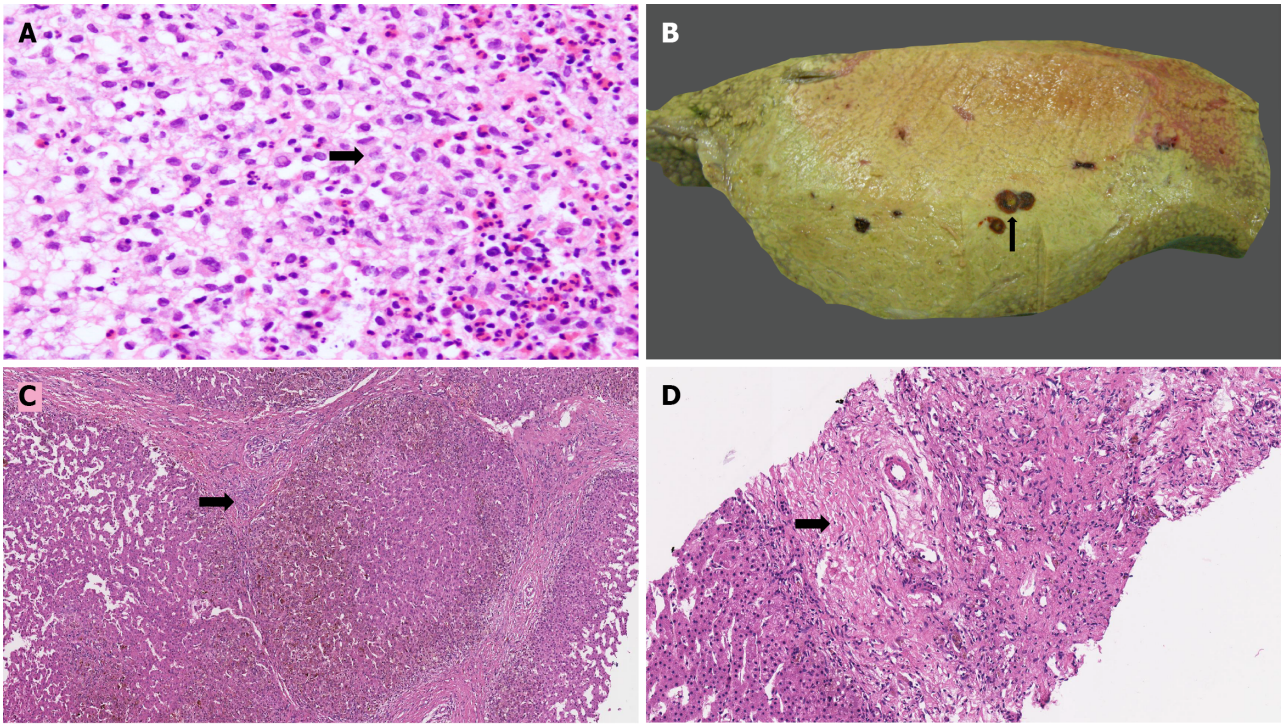
LCH exhibit diverse morphological features in the liver, which vary depending on the phase, stage and activity of the disease. Aggregates of LCs having lobulated, coffee-bean-shaped or contorted nuclei with a fine chromatin pattern and abundant eosinophilic cytoplasm admixed with eosinophils, polymorphs, lymphocytes, plasma cells, non-Langerhans histiocytes and rare multinucleated giant cells forming masses of variable sizes have been described (Figure 1A). Most cases with hepatic infiltration show marked tropism of the bile ducts. Active infiltrations of the bile ducts cause mucosal injury and fibrosis that lead to a progressive pattern of SSC, ultimately resulting in biliary cirrhosis[11,15,16]. There is destruction of the walls of bile ducts which may lead to cystic dilatation with intraluminal biliary sludge and rupture (Figure 1B). LCs can be identified within the basement membrane of the bile ducts, displacing the epithelial cells off the wall. Many cases demonstrate concentric periductal fibrosis. Cholangiopathy causes periportal bile ductular proliferation (Figure 1C), duct loss (Figure 1D), and features of chronic cholestasis with periportal cholestasis and stainable granules of copper and copper-binding protein. It is important to note that, despite evidence of biliary damage, the characteristic LCs may not be detected on liver biopsy. The diagnosis then rests on the presence of a concomitant infiltrate in other sites. Reassuringly, examination of liver explants in patients with LCH-induced biliary cirrhosis usually shows no evidence of active disease[17].

CHEMOTHERAPEUTIC AGENTS IN LCH

Liver, bone marrow and spleen are defined as the high-risk organs and their involvement makes the prognosis worse in patients with LCH[3]. The standard chemotherapy regimen for high-risk LCH as per the LCH IV protocol includes an induction phase of 6 wk with vinblastine (6 mg/m^2) once weekly for 6 wk and prednisolone (40 mg/m^2/d) daily for 4 wk, tapered over the next 2 wk[3,18]. LCH is invariably avid on positron emission tomography (PET), and presence of active disease can easily be ascertained. At the end of 6 wk, a PET scan is recommended, and the maintenance phase of therapy is commenced only after confirmed remission of LCH. Nonresponders conventionally receive another 6-wk cycle of the same regimen. If after the second cycle, remission is not achieved, second-line salvage chemotherapeutic agents are used[3,18].

Maintenance-phase therapy consists of vinblastine (6 mg/m^2) given once in 3 wk along with prednisolone (40 mg/m^2/d) for 5 d in the same week for 1 year. A few other drugs have been tried with doubtful benefit. These include methotrexate, fludarabine, 6-mercaptopurine, cyclophosphamide and etoposide[17,19]. Clinical trials have shown that newer targeted agents like BRAF inhibitors (see below) have shown promise in achieving remission in patients with refractory disease[20].

LT FOR LCH



In contrast to other hepatic malignancies like hepatoblastomas or haematological cancers, hepatic involvement in LCH is unique. While the latter result in cirrhosis progressing to ESLD, the former do not. Hence management of LCH with liver involvement needs a meticulous balance of two major decision domains, *i.e.*, malignancy and ESLD.

In patients who have normal liver function, standard chemotherapeutic regimens (vinca alkaloids and steroids) can be safely used. However, in those with features of decompensated liver disease (DCLD) and/or synthetic failure, these drugs can result in serious adverse effects. Vinblastine is inherently hepatotoxic and can worsen liver dysfunction[16,21,22]. Also, since vinblastine is metabolised in the liver, a failing liver could lead to severe drug-related toxicity (peripheral neuropathy, myelosuppression, *etc.*)[16,21,22]. Nonetheless, a delay in initiating chemotherapy for the fear of compromising liver function potentially worsens the malignant process. Deferring LT may result in morbidity and morbidity from cirrhosis and decompensation[13]. However, premature LT in the presence of active malignancy is not a standard recommended practice, and risks recurrent LCH in the graft.

The oncologist and the transplant clinician are faced with four clinical scenarios in patients who have LCH with liver involvement. These include patients with CLD and LCH in remission, patients with DCLD and LCH in remission, those with CLD and active LCH, and lastly, those with DCLD and active LCH.

Compensated liver disease with LCH in remission

These are a subset of patients who have completed chemotherapy and have the disease in remission. As mentioned above, they could still have progressive liver disease as sequalae of LCH. It could be many years before they present with symptoms of liver disease, which may be in the form of cirrhosis and/portal hypertension[23]. LT is offered to these patients independent of their previous history of LCH. Apart from decompensation, other indications for LT in these patients include, portal

hypertension, intractable pruritus and growth retardation. Nonetheless, irrespective of the lag-time between LCH remission and LT, prior to LT, a PET scan is performed to confirm the absence of active LCH.

Decompensated liver disease with LCH in remission

When indicated, LT may be performed in these patients. Evidence shows that the post-LT outcomes including disease-free survival in these patients is similar to those who have undergone LT for other indications[7].

Compensated liver disease with active LCH

Standard chemotherapeutic regimens (vinca alkaloid based) directed at LCH treatment should be initiated after appropriate staging workup for the disease. If the liver does not show signs of decompensation, patients should complete the full course of chemotherapy (induction and maintenance)[3]. They should however remain on close follow-up for LCH remission, signs of worsening of the liver disease and consequently the need for LT. The total duration of 12 mo chemotherapy is recommended in patients with LCH and an LT is offered after a minimum interval of 3 wk, when indicated[3]. The need for adjuvant chemotherapy in these patients is debatable, and a decision is usually made on a case-by-case basis. There may be a situation wherein the liver decompensates after initiating chemotherapy. In these patients, the severity of liver decompensation and the state of LCH remission guides further course of management.

In patients where the liver decompensation can be managed supportively, chemotherapy is continued with an aim to achieve remission. In this case however, the chemotherapy needs to be switched to relatively nonhepatoxic agents like cytarabine[24]. Once remission is confirmed following induction chemotherapy, these patients may be offered LT. It is nonetheless imperative to complete the full chemotherapeutic course. A chemotherapy-free interval of at least 3 wk is recommended prior to LT. This helps reduce the risk of chemotherapy-related damage to the liver allograft. Evidence is divisive with regards to the timing, dosing and regimen of post-LT chemotherapy. It is nonetheless unequivocally clear that the maintenance phase of chemotherapy needs to be completed. The agents are reintroduced usually 3 wk following LT. This allows for the transplanted liver to cope with the toxic agents better. Furthermore, it is advisable to reintroduce vinca alkaloids when the bilirubin is near normal (< 3 mg/dL)[22].

Decompensated liver disease with active LCH

Striking the balance between achieving remission with chemotherapy, abating worsening liver dysfunction and postponing LT remains a challenge in the management of these patients. The prudent approach would be to attempt achieving remission with relatively nonhepatotoxic, low-dose chemotherapy. Should this be achieved, as mentioned above, LT may be offered following a negative PET scan. A rarer and unfortunate situation is when a patient with active LCH requires LT. While LT may not be justified as per protocol, these are exceptional situations requiring a multi-disciplinary team decision.

ETHICS OF LT IN LCH

LCH is a malignancy; therefore, before offering these patients LT, the ethical aspects need to be debated. Immunosuppressants mute the native immune system's antitumour action, potentially resulting in a higher risk of recurrence. Furthermore, the ideal latency period between disease remission and LT remains undefined. There are also data to suggest that in patients with DCLD, delaying LT may result in worse outcomes[9]. Hence, for selected patients with DCLD, potential benefit and risk must be evaluated on an individual basis[25]. It does however, seem reasonable to indicate LT only when the oncological probability of survival disregarding immunosuppression is at least 50% at 5 years. The caveat in these cases is that the LCH should be amenable to sustained remission prior to LT and there should always remain the option of post-LT adjuvant therapy. Living donor LT (LDLT), especially in regions where deceased donor LT (DDLT) is uncommonly performed, permits optimal timing of the LT and avoidance of delays between the end of chemotherapy and LT.

LCH is a relatively rare oncological condition, and despite advances in medical oncology, there are few approved chemotherapeutic agents and even fewer clinical trials in this regard. An ethical dilemma also arises when despite chemotherapy, disease remission cannot be achieved in patients with DCLD. This subgroup of patients along with those who have active LCH and urgently require LT are outliers who need to have their management tailored according to the disease state; ideally in a clinical trial setting.

Nonetheless, prior to offering LT, it is imperative to satisfy the time-tested tenets of justice, utility and normal feasance for DDLT, and that of balancing the donor risk *versus* recipient benefit (principle of double equipoise) in living donor LT.

OUTCOMES OF LT IN LCH

Paediatric transplant oncology is a niche area that aims at optimising post-LT oncological outcomes. Given that LCH is a rare oncological condition, the literature remains sparse. Earlier series of LCH noted a recurrence of 30%-55% with a patient survival of 60%–67%[26,27]. With advances in immunosuppression, chemotherapeutic agents, and a better understanding of the oncopathology, more recent series including ours, have shown remarkably improved outcomes which are on par with LT for other indications[7,28] (Table 1). In a recent meta-analysis of 60 LT recipients with LCH, the 1-year, 3-year and 5-year patient survival rates were 86.6%, 82.4%, and 82.4%, respectively[25]. Furthermore, a cumulative recurrence of LCH in the grafts was 8%[25].

OUR UNIT POLICY AND OUTCOMES

We offer LT in patients with acute decompensation, portal hypertension with sclerosing cholangitis or growth retardation or intractable pruritus. If any patient decompensates in between chemotherapy, a LT is offered, following which the chemotherapy cycles are completed. A 18-fluorodeoxyglucose (FDG)-PET scan is mandatorily done before considering a LT in these patients. Patients who do not tolerate the full course of chemotherapy are also considered for LT during mid-cycle if the FDG-PET shows disease in remission. An interval of 2-3 wk is considered between the chemotherapy cycle and LT. This is followed by restarting of chemotherapy (if the cycles are not completed prior to surgery) after 3 wk.

Our unit's protocol includes the use of standard chemotherapy regimen in patients who are likely to withstand the full course. We use a modified chemotherapy in patients with liver dysfunction. This regimen includes low-dose cytarabine (100 mg/m^2) every 3 wk along with prednisolone (40 mg/m^2/d) daily for 4 wk tapered over the next 2 wk (each cycle is of 6 wk duration). Maintenance chemotherapy includes the same dose of cytarabine and prednisolone as the standard regimen, administered for 1 year. In our experience of six patients who underwent a LDLT, all are alive after mean follow up 36 mo (18-80 mo).

Table 1 Liver transplantation for Langerhan cell histiocytosis

Author (year)	No. of patients	Age at diagnosis (mo)	Age at transplant (mo)	Immunosuppression (No. of patients)	Surgical complications (No. of patients)	Medical complications (No. of patients)	Survival (follow-up in mo)
Stieber (1990)	3 (1adult/2 paediatric)	-	-	Cyclosporine, steroid	-	Recurrent rejection (3); retransplant (2)	66% (1 adult died of long bone fracture)
Whitington (1992)	2 (paediatric)	36 & 19	60 & 30	Cyclosporine, steroid	Roux-en Y anastomotic leak	CMV hepatitis (2); rejection (2); GI bleed (1)	100% (30-34)
Zandi (1995)	5 (paediatric)	23 ± 13	151 ± 43	Cyclosporine, steroid, azathioprine (3); cyclosporine, steroid (1); OKT3, steroid (1)	-	Rejection (4); CMV infection (2); GI bleed (1); Kidney injury (1)	60% (0.25-88.00)
Newell (1997)	6 (paediatric)	15 (12-30)	36	Cyclosporine, steroid, azathioprine (6)	Nil	PTLD (4); rejection (6); retransplantation (4); recurrence (2)	67% (24-74)
Hazdic (2000)	2 (paediatric)	16 & 17	34 & 14	Cyclosporine, steroid, MMF (1); tacrolimus, steroid (1)	Bowel perforation due to PTLD (1); PVT (1)	Recurrence (2); PTLD (1); rejection (2)	100% (5 & 60)
Braier (2002)	5 (paediatric)	-	-	Cyclosporine, steroid, azathioprine (5)	HAT & Retransplant (1)	CMV (1); rejection (1)	60% (14-37)
Chen (2020)	5 (paediatric)	15 (13-28)	53 (24-81)	Tacrolimus, steroid, MMF (5)	HAT (1)	EBV (4), CMV (1); LCH recurrence (1); DILI (1)	100%: 32 (2-67)
Our experience	6 (paediatric)	25 (9-48)	52.5 (33-204)	Tacrolimus, steroid (6)	Nil	Nil	100%: 36 (18-80)

CMV: Cytomegalovirus; GI: Gastrointestinal; MMF: Mycophenolate mofetil; EBV: Epstein–Barr virus; HAT: Hepatic artery thrombosis.

POST-LT COMPLICATIONS

Patients transplanted for LCH are known to have a higher incidence of rejections and post-transplant lymphoproliferative disorder (PTLD) (0%-67%)[7,8,27]. A purported theory is that of increased release of proinflammatory cytokines from the neoplastic cells predisposing to rejection. There remain concerns that immunosuppression could potentially increase risk an early recurrence of the index cancer, making LT futile. Hence the relative hesitancy at increasing immunosuppression in the early experiences of LT in LCH. There is no evidence till for the role of the mechanistic target of rapamycin inhibitors like sirolimus for preventing the occurrence of PTLD in these patients.

FUTURE DIRECTIONS

There is some encouraging evidence on the use of targeted therapy in LCH refractory to standard chemotherapy. *BRAF* gene mutations are observed in up to 67% of patients with LCH[29]. Vemurafenib and dabrafenib are two such agents that have shown potential in the clinical trial settings. Vemurafenib showed 83% response rate in refractory LCH[30]. In another trial of children with refractory LCH, 65% showed a remission with dabrafenib[31]. While vemurafenib may be hepatotoxic, dabrafenib is safe in patients with liver disease[32]. The authors concluded, that these agents may be used as the second- or third-line therapy for patients with refractory LCH and DCLD.

Another target for such novel therapy is the MEK1 mutation. It is observed in 19% of patients with LCH. Cobimetinib and trametinib are MEK1 inhibitors, and have shown some promise in clinical trials [33]. There however, remains a need for further research especially in those with concomitant liver disease to assess the true efficacy of these novel agents.

There have been studies evaluating the role of PD-1 (programmed cell death-1)/PD-L1 (programmed cell death ligand-1) check points in pathogenesis of LCH, especially when it involves the musculoskeletal system[34]. Hence anti PD-1 immunotherapy (pembrolizumab/nivolumab) may have a role in treating patients of LCH if there is an active musculoskeletal disease[35,36]. The role of anti-PD-1-based immunotherapy in the post-LT population remains a matter of intense debate. Given that these drugs act primarily by potentiating the native immune response, there have been studies demonstrating a high likelihood of rejections and allograft loss[37]. Therefore, the indications of anti PDL-1 therapy in the LCH patients who are likely to need LT remains undefined.

CONCLUSION

Early recognition, diagnosis and a systematic approach to the management of LCH can ameliorate the disease process. Nonetheless, the liver involvement in these patients may progress despite the LCH in remission. LT remains the mainstay in the management of such patients. Over the last decade significant advances in immunosuppression protocols, and availability of effective chemotherapeutic agents, have translated into better long-term allograft and recurrence-free patient survival. The post-LT outcomes are now comparable with those for other indications. However, given the rarity of the disease and the paucity of currently available literature, there is a need for large collaborative international, multicentre, society-based studies to provide recommendations on evidence-based algorithm for LCH, especially in patients with liver involvement.

Abstract

The gut microbiota is a complex community of microorganisms that inhabit the digestive tracts of humans, living in symbiosis with the host. Dysbiosis, characterized by an imbalance between the beneficial and opportunistic gut microbiota, is associated with several gastrointestinal disorders, such as irritable bowel syndrome (IBS); inflammatory bowel disease (IBD), represented by ulcerative colitis and Crohn's disease; and colorectal cancer (CRC). Dysbiosis can disrupt the mucosal barrier, resulting in perpetuation of inflammation and carcinogenesis. The increase in some specific groups of harmful bacteria, such as *Escherichia coli* (*E. coli*) and enterotoxigenic *Bacteroides fragilis* (ETBF), has been associated with chronic tissue inflammation and the release of pro-inflammatory and carcinogenic mediators, increasing the chance of developing CRC, following the inflammation-dysplasia-cancer sequence in IBD patients. Therefore, the aim of the present review was to analyze the correlation between changes in the gut microbiota and the development and maintenance of IBD, CRC, and IBD-associated CRC. Patients with IBD and CRC have shown reduced bacterial diversity and abundance compared to healthy individuals, with enrichment of *Firmicute* sand *Bacteroidetes*. Specific bacteria are also associated with the onset and progression of CRC, such as *Fusobacterium nucleatum*, *E. coli*, *Enterococcus faecalis*, *Streptococcus gallolyticus*, and ETBF. Future research can evaluate the advantages of modulating the gut microbiota as preventive measures in CRC high-risk patients, directly affecting the prognosis of the disease and the quality of life of patients.

Key Words: Gut microbiota; Dysbiosis; Ulcerative colitis; Crohn's disease; Inflammatory bowel disease; Colorectal cancer

Core Tip: Dysbiosis is present in patients with inflammatory bowel disease (IBD) and colorectal cancer (CRC). Dysbiosis can lead to a disruption of the mucosal barrier of the digestive tract lining, resulting in the perpetuation of inflammation and carcinogenesis, thus increasing the risk of developing CRC in IBD patients. Therefore, the aim of this review was to analyze the correlation between changes in gut microbiota and the development of IBD, CRC, and IBD-associated CRC. Further studies should be carried out to identify bacterial species that cause imbalances in the gut microbiota, enabling the development of prevention strategies or treatment of IBD-associated CRC.

INTRODUCTION

The human microbiome is composed of several types of microbes that colonize different niches of the human body, such as the skin, lungs, vagina, and gastrointestinal tract[1]. Of these, the gut microbiota is the most studied, due to the presence of greater diversity and number of microbial species compared to other parts of the body[1,2]. The gut microbiota is a complex community of approximately 100 trillion microorganisms, such as fungi, viruses, and protists, that inhabit the digestive tracts of humans, living in symbiosis with the host[3,4].

Alterations in the gut microbiota are associated with several diseases, including inflammatory bowel disease (IBD) and colorectal cancer (CRC)[2]. Thus, studies aimed at elucidating the role of the microbiota in each phase of each disease are necessary. Based on changes in the intestinal microbiota, new diagnostic tools and possible treatments can be developed. Further, studies aiming to correlate alterations in the microbiota or in specific bacterial populations with the diagnosis, prognosis, and/or treatment of diseases are necessary. Therefore, this mini-review was conducted to determine the correlation between changes in the gut microbiota and IBD, CRC, and IBD-associated CRC.

At birth, the intestinal tract is sterile[2], with bacterial colonization beginning as early as during the passage of the baby through the birth canal[5]. Colonization continues through feeding and other environmental contacts. Several factors are known to influence colonization, including gestational age, mode of delivery (vaginal birth *vs* cesarean delivery), diet (breast milk *vs* formula) and exposure to antibiotics, and sanitation[2].

During the first year of life, the microbial composition of the mammalian intestine is relatively simple and characterized by low diversity with relative dominance of species from the phyla *Proteobacteria* and *Actinobacteria*[2,5]. Over time, the microbiota becomes more diverse, with the *Firmicutes* and *Bacteroidetes* phyla later emerging as the predominant microbes characterizing the adult microbiota[2,6-8].

In an adult individual, over 90% of intestinal bacteria belong to *Firmicutes*, *Bacteroidetes*, *Proteobacteria*, or *Actinobacteria* phyla[4,7]. The gut microbiota can be differentiated into beneficial bacteria and opportunistic bacteria, the latter of which can cause infection[8]. *Lactobacillus*, *Bifidobacterium*, *Enterococci*, and *Propionobacteria* are some of the beneficial microbes, while the opportunistic groups include *Bacteriodes*, *Bacilli*, *Clostridia*, *Enterobacteria*, *Actinobacteria*, *Peptococci*, *Staphylococci*, and *Streptococci*[8].

The benefits of the gut microbiota to the host's physiology are vast, including nutrition, immune development, and host defense[4,7]. In the field of nutrition, some bacterial species, such as *Bifidobacterium*, participate in the biosynthesis of several components as vitamin K and vitamin B[7]. In addition, some can provide short-chain fatty acids (SCFAs) by fermenting dietary fibers[7,9]. SCFAs are a group of small fatty acids (2 to 5 carbons) produced by anaerobic microorganisms that, after absorption, have systemic immunomodulatory and anti-inflammatory properties[9].

The most abundant SCFAs in the colon are acetate, propionate, and butyrate[7,9,10], which promote the proliferation of beneficial bacteria and stimulate regulatory T cells to reduce inflammatory mediators, associated with an increase in colonic oxygen consumption by epithelial cells, and enhancing immune regulation, and gut barrier function[9-11].

Imbalance between the beneficial and opportunistic groups causes dysbiosis, which is associated with gastrointestinal disorders such as IBS, IBD, and CRC[4,7,8].

IBD AND GUT MICROBIOTA

IBD, a heterogeneous chronic and relapsing inflammatory illnesses of the digestive system, is traditionally classified into ulcerative colitis (UC) and Crohn's disease (CD)[4,12,13]. Both UC and CD can cause several symptoms like diarrhea, rectal bleeding, and abdominal pain. However, inflammation in CD is transmural and can involve any part of the gastrointestinal tract. In contrast, inflammation in UC is more superficial and limited to the colon[14].

Although the cause of IBD is not fully known, genetic history is likely involved in the pathophysiology of IBD, thus, several studies have identified a number of susceptible genes[12]. However, environmental factors, such as stress, sleeping patterns, antibiotic use, hygiene, diet, and smoking, are also associated with the development of IBD[4].

While IBD is a disease with the highest rates in industrialized countries, its incidence varies considerably worldwide, and newly industrialized areas such as India and South America presented a rapid increase in case numbers[7,13,14]. This enhancement can be related to dietary habits such as increased consumption of processed foods, sugars, and fats; overutilization of antibiotics; and an overall improvement in sanitary conditions and hygiene[13].

Nevertheless, the exact factors that trigger the first episode of inflammation and subsequent relapse remain unknown, it is now know that inflammatory episodes can result, in genetically predisposed people, from an immune response against intestinal microbial antigens under several environmental conditions[14]. Several IBD-associated susceptible genes are correlated with host responses to gut bacteria, suggesting that the gut microbiota also participate in the pathogenesis of IBD[7]. Dysbiosis is a reduction in microbial diversity, or a combination of the loss of beneficial bacteria and an increase in pathogenic bacteria[15], that may influence the pathogenesis of IBD.

The most prominent changes in the microbiota of IBD patients are the decreased diversity in bacteria species associated with decreased abundance of *Bacteroidetes* and *Firmicutes*[4,7] alongside an increase in the abundance of *Proteobacteria*[4].

In patients with IBD, the mucus layer is compromised, allowing luminal bacteria to penetrate and invade the submucosal layers, leading to the proliferative and inflammatory processes[4,13]. Then, mucosal destruction due to inflammatory injury further exposes the submucosa to more bacteria, leading to a vicious, positive feedback cycle of antigenic exposure and mucosal damage[13].

Faecalibacterium prausnitzii is one of the most abundant human gut bacteria and can be used as synonym of the gut health because of its anti-inflammatory and immunoregulatory properties[14]. One of the its products is butyrate, which is associated with an anti-inflammatory effect[7]. Several authors have correlated decreases in *Faecalibacterium prausnitzii* (*F. prausnitzii*) abundance with CD development [7,14,16] and in UC patients, a decrease was also observed during remission, being the recovery of the *F. prausnitzii* population associated with the maintenance of clinical remission[17].

Roseburia spp, including *Roseburia faecis*, *Roseburia intestinalis* (*R. intestinalis*), *and Roseburia hominis* (*R. hominis*), another genus of butyrate-producing bacteria, were significantly lower in healthy individuals with a high genetic risk for IBD compared to healthy individuals with low genetic risk[7]. *R. hominis*, specifically, was significantly reduced in UC patients, and an inverse correlation was observed between *R hominis* and disease severity[18]. In contrast, *R. intestinalis* supernatant suppressed the expression of interleukin (IL)-6 as well as the signal transducer and activator of transcription 3 (STAT3) *via* macrophage regulation in an *in vitro* experiment. Additionally, in dextran sodium sulfate- and 2,4,6-trinitrobenzene sulfonic acid-induced intestinal inflammation models, *R. intestinalis* supernatant reduced macrophages and Th17 cells in the colon, which was associated with the downregulation of IL-6 and STAT3[19].

In the field of pathogenic bacteria, several authors have described a relative increase in *Proteobacteria*, mainly *Escherichia coli* (*E. coli*), in IBD patients[7,20-22]. The exact mechanisms that lead to an increase in *Proteobacteria* during inflammation are not completely understood; however, Rizzatti *et al*[20] proposed two mechanisms: The oxygen hypothesis and the presence of nitrate. In a normal colon, epithelial cells deplete oxygen in the lumen through beta oxidation, creating an anaerobic environment[23]. In contrast, during an inflammatory episode, the beta oxidation capacity of colonic cells is decreased, thus increasing oxygen availability, which promotes dysbiosis and *Proteobacteria* growth[24]. Nitrate generated as a by-product during the inflammatory process conferred a growth advantage to the commensal bacteria *E. coli* in the large intestine, which then became predominant[25].

The increase in pathogenic bacteria in the digestive tract that can adhere to the colonic mucosa could alters the gut permeability, modifying the diversity and composition of intestinal microbiota, and ultimately leading to intestinal inflammation by regulating inflammatory genes expression[7].

Dysbiosis can further alter bacterial metabolites; decreased concentration of SCFAs has been reported as a result of a diminish in butyrate-producing bacteria like *F. prausnitzii*, in patients with IBD and in animal models of intestinal inflammation[7,9,10]. Decreased levels of SCFAs affects the differentiation and expansion of Treg cells and the growth of epithelial cells[26], leading to the loss of intestinal homeostasis.

CRC AND GUT MICROBIOTA

CRC is the third most common cancer, and the second most frequent cause of cancer deaths worldwide being more common in developed than in developing countries[27,28]. Notwithstanding cases in all countries are on the rise, most CRC cases occur in Western countries, where there is an increase in incidence[28]. CRC rates in older adults in the United States have declined in recent years probably due to increased screening, but rates in younger adults have been rising, which may be correlated with higher incidence of obesity and other diet and lifestyle trends in the western hemisphere[29].

The exact mechanism for CRC onset and progression has not been fully elucidated, but it is generally believed to be the result of extensive and complex interactions between genetic and environmental factors[30]. According to Olovo *et al*[28], the progression of adenoma to carcinoma could be linked to the gut microbiota and conversely, a healthy microbiota is correlated with a minor risk of advanced adenoma[28].

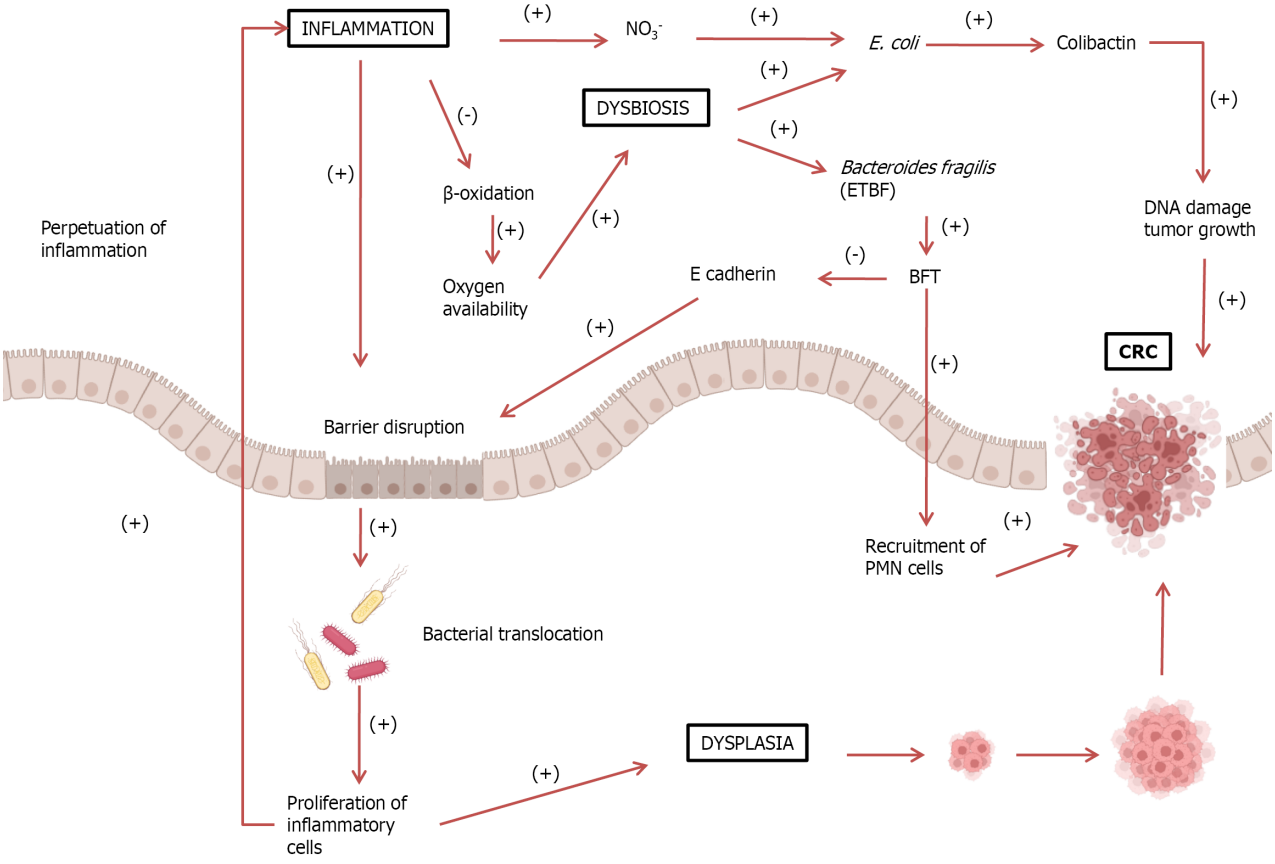
Several factors that affect the gut microbiota are thought to be related to colon carcinogenesis, such as obesity, a high-fat diet, smoking, and frequent consumption of alcohol[30].

Patients with CRC have shown reduced bacterial diversity and abundance compared to healthy individuals, with enrichment of *Firmicutes* and *Bacteroidetes*[31]. Specific bacteria are also associated with the onset and progression of CRC, such as *Fusobacterium nucleatum*, *E. coli*, *Enterococcus faecalis*, *Streptococcus gallolyticus*, and enterotoxigenic *Bacteroides fragilis* (ETBF)[32].

The abundance of *Fusobacterium nucleatum*, an opportunistic pathogen found normally in the oral cavity, is correlated with age and tumor diameter in CRC patients[31,33,34]. Additionally, an overabundance of *F. nucleatum* is associated with poor prognosis in metastatic CRC[32]; thus, *F. nucleatum* could be considered a potential biomarker for predicting the prognosis in patients with proximal colon cancer[34].

There is plenty of evidence of the tumor-promoting effects of *Streptococcus gallolyticus* in colon cells [35-37]. Colonic cells incubated with *Streptococcus gallolyticus* (*S. gallolyticus*) presented increased levels of β-catenin, c-Myc, and proliferating cell nuclear antigen (PCNA), all of which are transcription factors associated with cancer development[35]. In addition, in mice, administration of *S. gallolyticus* leads to more tumors, higher tumor burden, and dysplasia grade, and increased cell proliferation and β-catenin staining in colonic crypts compared to mice incubated with control bacteria[35]. Furthermore, CRC patients present high levels of this bacterium compared to healthy individuals[37]. However, CRC-specific conditions, such as the increased concentration of bile acids, could also promote *S. gallolyticus* colonization, creating a maintenance cycle for high levels of this bacterium in the gut[37].

ETBF is the most frequent anaerobe isolated from cases of diarrhea, peritonitis, intra-abdominal abscesses, and sepsis, and there is a positive correlation between the presence of ETBF and active IBD and CRC[38]. According to Appunni *et al*[39], co-colonization of toxigenic *E. coli* and ETBF in mice resulted in increased production of pro-inflammatory IL-17 and subsequent DNA damage, which could accelerate the development of CRC[39]. In addition, the toxin in ETBF could induce c-myc expression and IL-8 secretion causing oxidative DNA and epithelial barrier damage, and STAT3/Th17 immune responses activation, which are further correlated with an increased risk of CRC[38].



IBD-ASSOCIATED CRC AND GUT MICROBIOTA

Intestinal inflammation is one of the most common risk factors for developing CRC. Besides being two to six times more likely to develop CRC than healthy people, IBD patients with cancer are affected younger than sporadic CRC patients[40]. Disease duration, extension of the lesions, inflammation, sclerosing cholangitis, age at onset and onset in childhood are factors linking IBD with an increased incidence of CRC[41,42].

Chronic inflammation initiates and drives tumorigenesis[42], leading to an "inflammation-dysplasia-carcinoma" sequence, not the "adenoma-sequence" classically described in sporadic CRC[40].

Popov *et al*[43]proposed the three main theories about bacterial involvement in the development of IBD-associated CRC: The alpha-bug hypothesis, driver-passenger hypothesis, and common ground hypothesis. In the alpha-bug hypothesis, a single bacterium (normally ETBF) is thought to cause all modifications and damage that lead to carcinogenesis. The driver-passenger hypothesis is similar, but after the attack by the first bacteria, other opportunistic bacteria start to grow and contribute to cancer development. Finally, in the common ground hypothesis, endogenous and exogenous factors form a "leaky gut," allowing the passage of bacteria into the submucosal tissue, leading to chronic inflammation and the consequent emergence of cancer[43].

It is known that bacteria, through pathogen-associated molecular patterns (PAMPs), are capable of communicating with the tool-like receptors (TLRs), retinoic acid-inducible gene I-like receptors (RLRs), and nucleotide binding oligomerization domain-receptors (NLRs), and trigger an immune response [42]. Nuclear factor kB (NF-kB) can be activated by the TLR and tumor necrosis factor-α (TNF-α), inducing the transcription of several tumorigenesis genes such as COX-2, which then leads to the apoptosis of intestinal epithelial cells *via* tumor suppressor p53 pathways[40] and consequent

Figure 1 Increased inflammatory response can lead to barrier disruption, allowing bacterial translocation into the intestinal lumen. These pathogens trigger an immune and inflammatory response, perpetuating the inflammatory process. Inflammatory cells can also cause dysplasia, leading to the development of colorectal cancer (CRC). Under normal conditions, epithelial cells, during β-oxidation, decrease oxygen availability, thus creating an anaerobic environment. During chronic inflammation, β-oxidation decreases, enhancing oxygen availability. This also leads to an increase in nitrate (NO3-) formation, leading to dysbiosis and growth of proteobacteria such as *Escherichia coli* (*E. coli*). *E. coli* produces colibactin, which could damage DNA and stimulate tumor growth. The growth of Bacteroidetes fragilis may also occur, which produces Bacteroides fragilis toxin (BFT). This toxin cleaves E-cadherin, a major constituent of the zonula adherens, which is responsible for cell adhesion, leading to further barrier disruption. Additionally, BFT also stimulates epithelial cells to recruit polymorphonuclear leukocytes (PMN) cells, promoting the development of CRC. BFT: Bacteroides fragilis toxin; ETBF: Enterotoxigenic *Bacteroides fragilis*; CRC: Colorectal cancer; PMN: Polymorphonuclear leukocytes.

breakdown of the intestinal barrier, allowing microbial translocation.

Increased quantities of *Proteobacteria* are associated with decreased levels of SCFAs and increased colonic inflammation[43]. In addition, intestinal Dysbiosis and barrier defects, associated with alterations in mucin secretion may happen even in the absence of active inflammation[43], perpetuating a favorable environment for the emergence of CRC.

Several studies have demonstrated the participation of bacteria such as *E. coli*, ETBF, and *Fusobacterium nucleatum* in chronic inflammation and cancer development in IBD patients[40,42-45].

A review by Yu *et al*[44] concluded that commensal bacteria, *E. coli* and *E. faecalis*, isolated from healthy subjects are capable of initiating intestinal inflammation in genetically deficient mice, suggesting that opportunistic commensal bacteria may become pathogenic only in genetically predisposed hosts[44]. Nevertheless, some types of *E. coli* can produce colibactin, a genotoxic compound capable of promoting tumor growth, alkylating DNA, and inducing tumorigenic double-stranded breaks[45]. According to Yang *et al*[45], inflammation may upregulate bacterial virulence genes, such as colibactin, and facilitate colonization of the mucosa, leading to increased colibactin-induced DNA damage in colonic epithelial cells, allowing this bacterial strain to exert its carcinogenic activity[42].

The enterotoxin produced by ETBF known as bacteroides fragilis toxin, acted as a metalloprotease cleaving E-cadherin, a major constituent of the zonula adherens, which is responsible for cell adhesion [46]. This toxin can trigger an inflammatory, pro-tumoral signaling caspase in colonic epithelial cells that cause the recruitment of polymorphonuclear immature myeloid cells to promote colon cancers[44].

CONCLUSION

There is a consensus that dysbiosis is present in both IBD and CRC, and that dysbiosis could lead to a disruption of the mucosal barrier with perpetuation of inflammation and carcinogenesis. Dysbiosis with a consequent increase in bacteria, such as *E. coli* and ETBF, is believed to lead to a breakdown of the intestinal mucosal barrier, allowing the translocation of more bacteria from the lumen to the interior of the tissue. This condition leads to chronic tissue inflammation, with the release of inflammatory and pro-carcinogenic mediators increasing the risk of developing CRC. This positive feedback loop of dysbiosis could be the basis for the inflammation-dysplasia-cancer sequence (Figure 1).

Further studies should be carried out to identify which bacteria or which set of bacteria may be responsible for this feedback cycle. Understanding the mechanism behind dysbiosis cycles may be the basis for preventing or treating IBD-associated CRC and CRC. Future research should evaluate the advantages of modulating the intestinal microbiota as a protective factor for the development of IBD-associated CRC; thus, the use of prebiotics, probiotics, or diet-based treatment can be used as preventive measures in CRC high-risk patients, directly affecting the prognosis of the disease and the quality of life of patients living with IBD.

Abstract

Chronic liver disease is characterized by several hematological derangements resulting in a complex and barely rebalanced haemostatic environment. Thrombocytopenia is the most common abnormality observed in these patients and recent advances have led to researchers focus the attention on the multifactorial origin of thrombocytopenia and on the key role of thrombopoietin (TPO) in its physiopathology. Severe thrombocytopenia (platelet count < 50000/μL) complicates the management of patients with chronic liver disease by increasing the potential risk of bleeding for invasive procedures, which may be therefore delayed or canceled even if lifesaving. In the very last years, the development of new drugs which exceed the limits of the current standard of care (platelet transfusions, either immediately before or during the procedure) paves the way to a new scenario in the management of this population of patients. Novel agents, such as the TPO-receptor agonists avatrombopag and lusutrombopag, have been developed in order to increase platelet production as an alternative to platelet transfusions. These agents have demonstrated a good profile in terms of efficacy and safety and will hopefully allow reducing limitations and risks associated with platelet transfusion, without any delay in scheduled interventions. Altogether, it is expected that patients with chronic liver disease will be able to face invasive procedures with one more string in their bow.

Key Words: Thrombocytopenia; Chronic liver disease; Thrombopoietin agonists; Platelet transfusions; Avatrombopag; Lusutrombopag

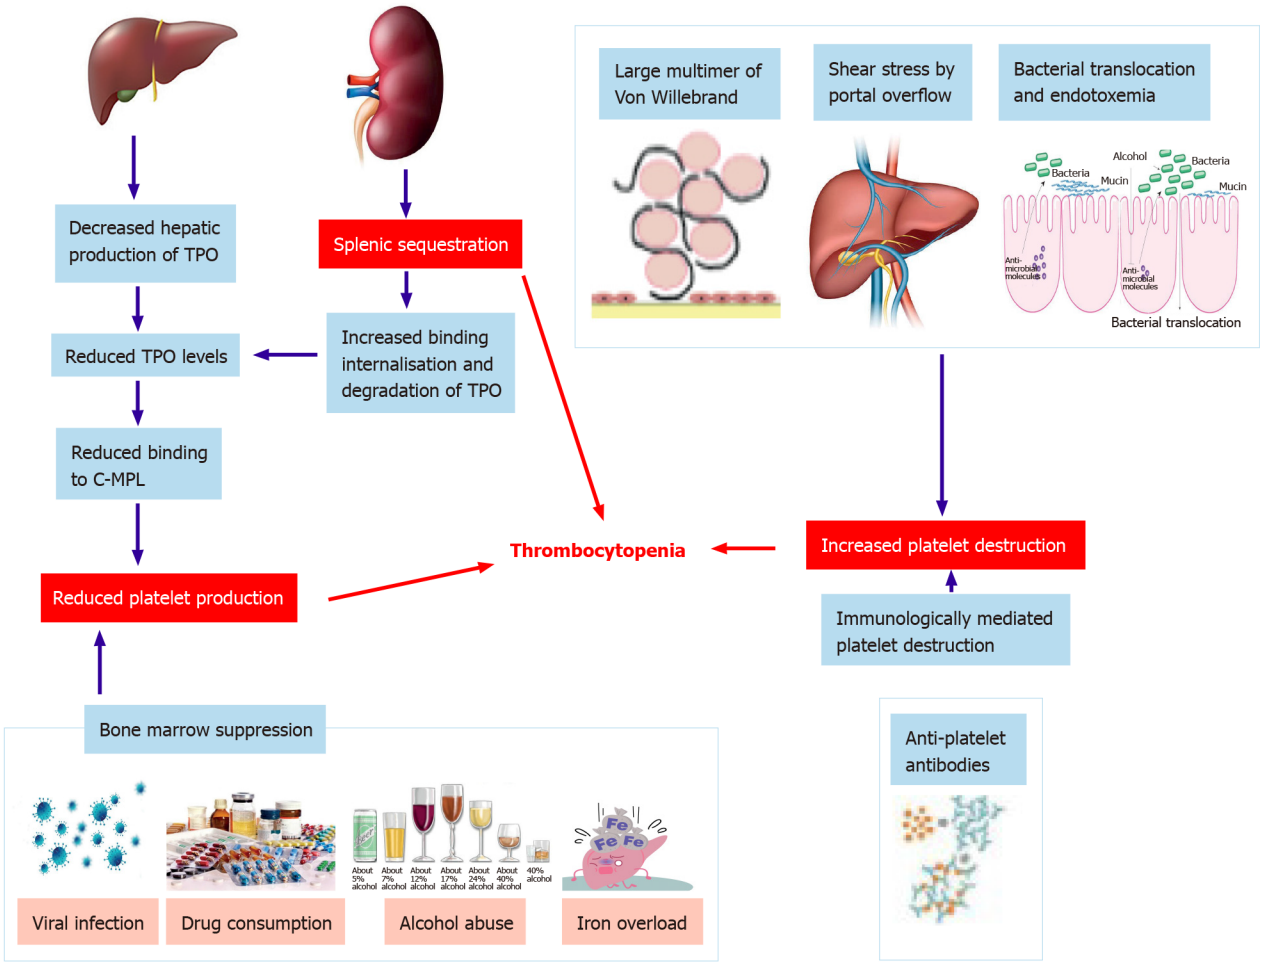
INTRODUCTION

Thrombocytopenia, usually defined as any decrease in platelet count below the lower normal limit of 150000/μL, is the most common haematological abnormality in patients with chronic liver disease[1]. Current data report a prevalence ranging from 6% to 78%, which progressively increases from patients with compensated to those with decompensated cirrhosis[2]. The clinical significance of mild (100000/μL-150000/μL) and moderate (50000/μL-100000/μL) thrombocytopenia is minimal and does not interfere with the regular clinical practice. Otherwise, severe thrombocytopenia (< 50000/μL) can be associated with many sequelae and could have a negative impact on the management of patients with advanced chronic liver disease.

PHYSIOPATHOLOGY OF THROMBOCYTOPENIA IN CHRONIC LIVER DISEASE



In chronic liver disease, thrombocytopenia has been classically attributed to hypersplenism[1,3]. Over the last decades, however, advances in the understanding of thrombopoiesis have led to a wider and better understanding of its physiopathology. As a result, thrombocytopenia is considered a more complex and multifactorial process involving multiple different mechanisms. These are generically divided into those leading to decreased production or increased destruction of thrombocytes and splenic sequestration[1] (Figure 1).

Decreased platelet production

Decreased platelet production is a consequence of decreased production of thrombopoietin (TPO) and direct bone marrow suppression. Currently, the production of TPO is believed to play a pivotal role in thrombopoiesis. TPO is primarily produced in the liver and, after being secreted into the circulation, it binds to the surface of platelets and megakaryocytes through the c-MPL receptor[4]. TPO-receptor ligation activates a number of intracellular signalling pathways *via* Janus kinase type 2 and tyrosine kinase 2[5], which ultimately lead to the differentiation of bone marrow stem cells into mature megakaryocytes and to the production of platelets which are released into the peripheral circulation[6]. Of note, after binding to its receptor, TPO is internalized and destroyed in order to reduce further platelet and megakaryocyte exposure[4]. Platelet production is therefore mainly regulated by platelet levels in the blood through a negative feedback circuit[1]. The role of a decreased hepatic production of TPO in the development of thrombocytopenia in chronic liver disease is supported by the immediate increase in TPO levels and platelet production after liver transplantation[7]. Animal models and human clinical studies have confirmed decreased expression of *TPO* mRNA in liver tissue with the progression of cirrhosis[8], which is probably associated with specific regulatory mechanisms for the expression of *TPO* gene and is not regulated by bone marrow[9]. Moreover, a correlation between reduced c-MPL expression and the progression of liver cirrhosis has been demonstrated and may play an additional role in the development of thrombocytopenia[10]. Some chronic liver diseases may also cause decreased platelet production through direct bone marrow suppression or toxicity, as observed during viral infection (particularly hepatitis C virus (HCV) infection[11], alcohol abuse[12], iron overload[12], and drug consumption[1,13]).

Increased platelet destruction

Increased platelet destruction is a multifactorial process that may involve decreased levels of A disintegrin-like and metalloprotease with thrombospondin type 1 motif 13 (ADAMTS13), immunologically mediated platelet destruction, and bacterial activity. ADAMTS13 is a metalloproteinase

produced by hepatic stellate cells, whose physiological role is to cleave large von Willebrand factor (vWF) multimers[14]. In cirrhosis, decreased levels and activity of ADAMTS13 drive the accumulation of vWF multimers, which mediates an enhancement of shear-stress induced platelet aggregation[14]. Additionally, anti-platelet antibodies are a frequent finding in patients with liver cirrhosis, being detectable in up to 64% of cases[15]. The inverse relationship between platelet-associated immunoglobulin G (IgG) levels and platelet count evidences that immunologic destruction contributes to the genesis of thrombocytopenia at least in some chronic liver diseases[16]. Immune-mediated thrombocytopenia is most likely to occur in the course of autoimmune liver diseases (particularly primary biliary cholangitis) and HCV infection[1,17].

HCV can cause immune-mediated thrombocytopenia through multiple mechanisms[1]. First, it can be associated with idiopathic thrombocytopenic purpura (ITP), as supported by a prevalence of anti-HCV antibodies of approximately 10% in patients with ITP[18]. The virus can also directly bind to platelets interacting with multiple surface receptors, leading to the attachment of anti-HCV antibodies to platelets. This will ultimately determine either platelet phagocytosis by the reticuloendothelial system or alterations in the platelet membrane epitopes that induce the production of anti-platelet antibodies[19]. Finally, HCV infection can be associated with the production of cryoglobulins, which can accelerate platelet clearance by the reticuloendothelial system[20]. Thrombocytopenia can be found in about 48% of patients with bacterial infection and sepsis[21], confirming that the inflammatory cascade plays a role in the development of thrombocytopenia. This is confirmed in the hospitalized cirrhotic population[22]. In sepsis, thrombocytopenia is mainly dependent on the increased activation of the coagulative system, resulting in clot formation and platelet consumption[23].

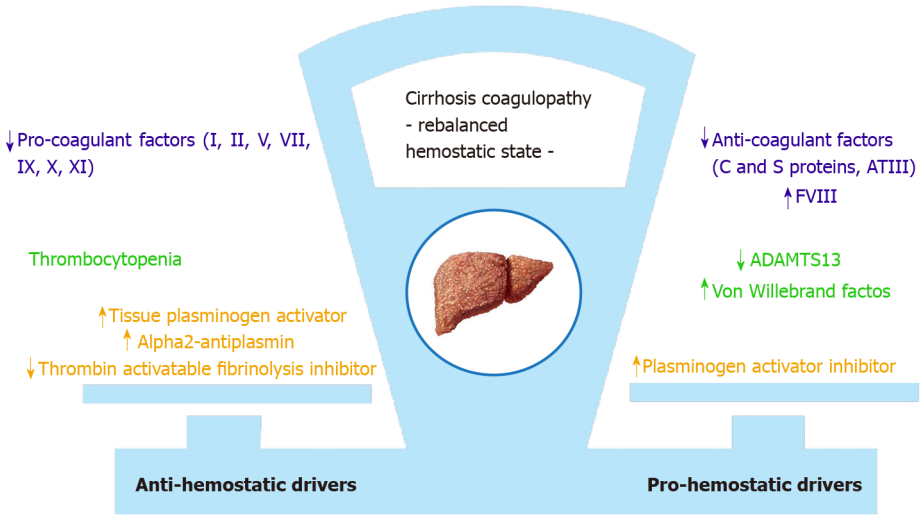
Splenic sequestration

Hypersplenism has been classically considered the main determinant of thrombocytopenia during chronic liver disease[1,3], even after that many other physiopathologic mechanisms have been progressively identified. During chronic liver disease, the inception of portal hypertension causes a redistribution of splanchnic venous blood flow, ultimately responsible for congestion of the spleen and consequent enlargement of the organ, leading to a significant increase of the splenic pool of platelets

[24]. Actually, hypersplenism is the clinical syndrome in which splenomegaly is associated with splenic hyperactivity, *i.e.*, a reduction in one or more peripheral blood cell types, in patients with an appropriate proliferative bone marrow response. This syndrome can be reverted with splenectomy[1,24].

COAGULOPATHY AND HAEMORRHAGIC RISK ASSESSMENT IN CHRONIC LIVER DISEASE

Chronic liver disease is characterized by alterations of the entire hemostatic system[25]. Thrombocytopenia is just one face of a wider coagulation disorder whose relevance is mirrored by the inclusion of coagulation indices in all functional and prognostic scores of liver disease[26]. Traditionally, coagulopathy in cirrhosis was considered as a bleeding diathesis disorder[27], alongside the well-known thrombocytopenia, and the impaired coagulation tests were perceived as indicators of hemorrhagic risk [28]. In the last decades, several studies led to significant changes in knowledge, with a renewed vision concerning the coagulopathy of liver cirrhosis. A new paradigm of a balanced, *albeit* precarious, hemostatic state has emerged and the net effect is a rebalanced equilibrium[26,27], which can be easily disturbed by many different clinical events, alternatively leading to hemorrhagic as well as to thrombotic manifestations, with the latter being even more frequent indeed[27] (Figure 2).



It has been shown that the reduction in liver-derived pro-coagulant factors is counteracted by the concomitant decrease of the liver-derived anti-coagulant ones, especially protein C[28,29]. Thrombocytopenia and platelet abnormal function are offset by increased vWF and decreased ADAMTS13 levels. In cirrhosis, even if diminished in number, platelets are able to support normal thrombin generation at least until they are in the range 50-60000/mL, therefore assuring a normal primary hemostasis. This is possible thanks to the compensatory action of vWF and to the upregulation of intracellular activating signalling pathways[27], leading to an enhanced thrombocyte response. Furthermore, decreased clearance of tissue plasminogen activator and plasminogen activator inhibitor, and decreased synthesis of alpha 2-antiplasmin and thrombin activable fibrinolysis inhibitor are all factors contributing to hyperfibrinolysis. The latter is observed in up to 30% of patients with advanced liver disease[1], confirming a re-arrangement of the whole hemostatic system.

In cirrhotic patients, even though reduced in number, platelets are still able to ensure an adequate haemostatic function. Consequently, the sole platelet count is not able to predict bleeding risk in liver cirrhosis. Actually, for patients with cirrhosis undergoing invasive diagnostic or therapeutic procedures, the risk of procedure-related bleeding remains a clinical issue[30], and risk stratification is a great challenge. This is mainly due to the inaccuracy, in the context of cirrhosis, of the laboratory tests that are routinely used for the assessment of the hemocoagulative system[25,27,30]. Indeed, it is now well established that the standard clotting tests do not reflect the actual bleeding risk[30-32], and current evidence does not support prothrombin time (PT)/international normalized ratio (INR) as clinical targets[25,33]. Conversely, assessing platelet count and fibrinogen levels before high-risk procedures is recommended, as well as it is the pre-procedural correction of these parameters, having these laboratory parameters been proposed as more reliable indicators of the bleeding risk in patients with cirrhosis[34].

Moreover, many studies have shown that cirrhotic portal hypertension and kidney injury are more essential in determining the risk of bleeding[25,35]. As a matter of fact, renal failure can lead to platelet impairment resulting from reduced adhesive and aggregative capacities *via* alterations of serotonin concentration, of calcium flow and of thromboxane metabolism[25]. Patient with cirrhosis can also develop accelerated intravascular coagulation and fibrinolysis, described as a bleeding entity similar to disseminated intravascular coagulation, but different for the imbalance between pro- and anti-fibrinolytic factors, resulting in hyper-fibrinolysis with an increased bleeding risk[35]. Despite all such evidence, most current guidelines still recommend correcting elevated PT/INR values through plasma transfusions, while tests capable of better capturing the hemostatic function of cirrhotic patients (thrombin generation tests, thromboelastography, *etc.*) are not readily available in everyday clinical practice[25].

NON-PHARMACOLOGICAL TREATMENT OPTIONS FOR MANAGEMENT OF THROMBOCYTOPENIA

The management of thrombocytopenia in chronic liver disease has been a primary and challenging endpoint for decades. In the 1960s, surgical splenorenal shunts were performed with this purpose, but they were soon abandoned due to high mortality rates and the risk of liver decompensation[36]. Total and partial splenectomy were therefore developed. They gained popularity in the 1990s thanks to limited complication rates, mainly after the introduction of the laparoscopic technique. Later, less invasive techniques, namely, splenic artery embolization or spleen radiofrequency ablation, opened new scenarios[36].

Figure 2 Pathophysiology of coagulopathy. ATIII: Antithrombin III; FVIII: Coagulation factor VIII; ADAMTS13: A disintegrin-like and metalloprotease with thrombospondin type 1 motif 13.

Splenectomy

In the past, open splenectomy has been considered among the strategies for treating thrombocytopenia. Actually, this procedure was associated with a high risk of bleeding and consequent hepatic decompensation, particularly following the open technique. For these reasons, subsequent studies supported the laparoscopic technique over open surgical splenectomy or the shunt techniques over splenectomy[37,38]. Overall, also with less invasive procedures, the rate of complications range from 2.5% to 17%, and the risk of portal and splenic vein thrombosis is elevated (about 10%)[39]. Altogether, due to their invasive nature and to the high risk of complications, these strategies are restricted to rare and specific cases, while they have been virtually abandoned in the ordinary clinical practice.

Splenic artery embolization

Splenic artery embolization has been introduced since the 1970s as an alternative to splenectomy in surgically unfit patients. For the increased risk of developing splenic abscesses after total embolization, partial splenic embolization has become the preferred option for candidate patients[40], with a lower risk of complications, sepsis and mortality compared to total splenectomy[36,41]. Unfortunately, the extent of the beneficial effect on platelet count depends on the amount of the splenic mass embolized, which is proportional to the complications observed.

Radiofrequency ablation of the spleen

Radiofrequency ablation of the spleen is a minimally invasive procedure with promising results in patients with cirrhosis and severe thrombocytopenia[36]. The main benefits of this minimally invasive procedure are cost-effectiveness and lower complication rates over other invasive procedures. The major side effects are hemorrhagic shock and intra-abdominal bleeding, while complications such as splenic abscess or rupture are not a concern with this procedure[42]. Besides, to date, more clinical trials with longer follow-up would be needed to estimate the effectiveness of this strategy.

Shunt procedures

Shunt procedures [portocaval shunt, splenorenal shunt, and transjugular intrahepatic portosystemic shunt (TIPS)] are other possible techniques which have been experimented in chronic liver disease. They are aimed at decreasing splenic congestion and, therefore, platelet sequestration[36]. To date, however, these approaches are not supported by available studies; indeed, there is an absence of clear benefits on the platelet number and well-known complications. Actually, the use of these procedures, in particular TIPS, is currently restricted to selected cases where the aim is not to increase platelet levels, but to control bleeding from oesophageal varices or to manage refractory ascites[43].

Platelet transfusion

Platelet transfusion has become the mainstay of treatment in patients with chronic liver disease and severe thrombocytopenia who require an invasive procedure[44]. The choice to transfuse platelets is variable and controversial, depending upon patient comorbidities and the risk of bleeding. Most data suggest that invasive procedures may be performed without a significantly increased risk of bleeding in patients with more than 50000/μL platelets, while there is less consensus about the risk in patients with

a lower count, as reflected also in the latest guidelines and a recent retrospective study[45,46]. In a sub-analysis of 2740 liver biopsies from the Hepatitis C Antiviral Long-term Treatment against Cirrhosis trial, there were only 16 bleeding events (0.6%), and the highest bleeding risk (5.3%) was recognized for platelet counts less than 60000/μL[47]. Conversely, in another study evaluating the safety of liver biopsies (177 patients), the frequency of bleeding in patients with a platelet count lower than 50000/μL was not significantly different from that in those with a normal platelet count, and the only independent risk factor for bleeding was an underlying malignancy[32].

Guidelines vary as to the threshold below which periprocedural bleeding risk justifies intervening to treat thrombocytopenia; however, transfusions are more frequently indicated with a platelet threshold < 50000/μL[48]. Although platelet transfusion has been the standard of care for correcting thrombocytopenia for a long time, relevant side effects limit its use. The most common issues include febrile or allergic reactions, risk of infection (even if very low), hemolysis, transfusion-related graft-*versus*-host disease, and alloimmunization[41,49]. Even the procedure of transfusion itself may be critical. Potential risks include errors in patient identification, in blood typing, and in cross-matching[50]. Concerning efficacy, platelet transfusions determine an overall modest increase in platelet count, without a significant impact on the risk of bleeding[51], and treatment effect has a limited duration. Moreover, up to 70% of patients receiving repeated platelet transfusions become refractory to subsequent ones. Finally, platelet transfusions are limited by donor supply, and the reduced availability may have a great impact on the management and clinical outcomes of these patients.

NEW THERAPEUTIC OPTIONS FOR THRMBOCYTOPENIA IN CHRONIC LIVER DISEASE

Recent advances in understanding the physiopathology of thrombocytopenia in chronic liver disease, with the discovery of the central role of TPO in thrombocytopoiesis, has led to the development of many drugs with TPO activity.

Recombinant TPO and human cytokines

Two recombinant TPOs that stimulate platelet production in humans and showed potential promise were recombinant human TPO and pegylated recombinant megakaryocyte growth and development factor[52,53]. They have shown clinical benefits in clinical trials of haematological patients without safety concerns, but have been withdrawn from clinical development for the induction of neutralizing antibodies[53]. Similarly, the use of recombinant human cytokines was limited because of side effects and the occurrence of toxicities as observed after the subcutaneous injection of the recombinant human interleukin-1, approved by the Food and Drug Administration (FDA) for the treatment of the thrombocytopenia induced by chemotherapy for solid tumors, which can cause cardiovascular side effects and flu-like symptoms[54].

TPO agonists

Activation of thrombopoiesis through TPO receptor agonists is an alternative method to stimulate platelet production with the use of drugs, which are not homologous to endogenous TPO but activate the same receptor working on a different site. These drugs have been primarily investigated in patients with chronic ITP and subsequently in chronic liver disease for treating thrombocytopenia before invasive procedures. The effect of TPO agonists is mediated by the interaction with TPO receptors on megakaryocytes, specifically c-MPL ligand-mediated activation of Janus kinases and signal transducer and activator of transcription proteins and mitogen-activated protein kinase pathways[55].

Romiplostin: Romiplostin is a polypeptide linked to an IgG heavy-chain Fc molecule and has no amino acid sequence homology to endogenous TPO. It acts by competing with the same site of the TPO-receptor and activating intracellular transcriptional pathways aimed to increase platelet production[55]. Due to a different molecular structure, its use has not been associated with antibodies reacting against endogenous TPO. This drug is administered subcutaneously once a week, but it is currently approved only for treatment of ITP when refractory to other drugs[54,56].

Indeed, most of the experience with romiplostin was derived from clinical studies in patients with refractory ITP[57], while only anecdotal case reports and small series involved patients with chronic liver disease[58-61]. A single-centre study in Egypt involved 35 patients with HCV-related cirrhosis and severe thrombocytopenia who required elective surgery[60]. Patients received romiplostin once weekly for a maximum of 4 wk. The primary endpoint - achieving a threshold of platelet count of 70000/μL - was reached in 94% of patients, and 20% of them had maintained a count > 50000/μL 3 mo after the last injection. Headache was reported as the only adverse event. In another single centre, prospective, randomized, double-blind study, 65 subjects with chronic liver disease and thrombocytopenia (less than 60000/μL) undergoing percutaneous liver biopsy received a TPO agonist or platelet transfusion[61]. Romiplostin determined significantly higher pre-biopsy and post-biopsy platelet counts compared to eltrombopag and platelet transfusion, and it was cost-effective and safe.

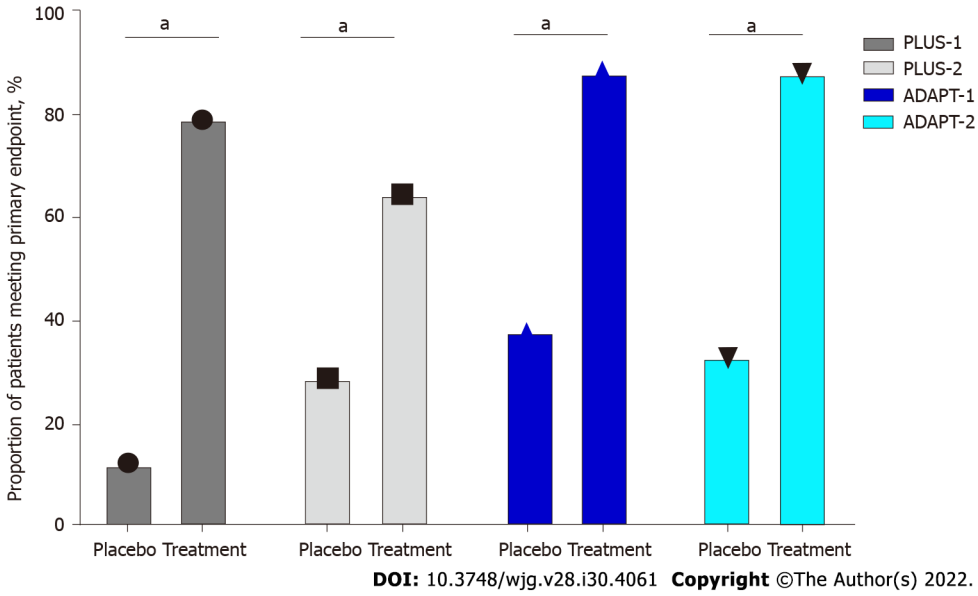
Eltrombopag: Eltrombopag is an orally available, small non-peptide TPO mimetic molecule more largely studied for use in liver disease. Its binding to a specific human transmembrane domain of TPO-receptor induces proliferation and differentiation of megakaryocytes and precursor cells[62]. It is taken orally once daily and is approved for thrombocytopenia: (1) In chronic ITP refractory to other treatments; (2) In HCV chronic hepatitis candidates for treatment with interferon-based regimens; and (3) In patients with severe aplastic anaemia[63].

Eltrombopag safely increased platelet number in patients with cirrhosis and HCV infection[64]. In a phase II multicentre randomized trial, eltrombopag was effective in increasing platelet count to more than 100000/μL at week 4 in 75%-95% of patients, compared to 0% of patients in the placebo group. Consequently, these patients were significantly more likely to initiate and complete 12 wk of antiviral treatment with respect to those on placebo (36%-65% *vs* 6%). In a phase II trial in Japan on 38 patients with chronic liver disease, eltrombopag increased platelet count in a dose-dependent manner[65].

The most recently published data in chronic liver disease are derived from the Eltrombopag Evaluated for Its Ability to Overcome Thrombocytopenia and Enable Procedures study, a phase 3 double-blind, placebo controlled trial that assessed the utility of this drug to increase platelet count and reduce the need for transfusion in patients undergoing elective procedures[66]. In this trial, 86% of patients recruited had liver cirrhosis with a platelet count less than 50000/μL. Patients were randomized to receive 75 mg eltrombopag daily or placebo in the 2 wk preceding the invasive procedure performed within 5 d from the last dose. Primary endpoint was the number of subjects who did not require a platelet transfusion before, during, and up to 7 d after the procedure. This was achieved in 72% (104/145) of subjects who received eltrombopag, compared to 19% (28/147) in the placebo group (P < 0.001). However, this study was prematurely terminated since six patients in the treatment group developed thrombotic events (2 patients in placebo, odds ratio for eltrombopag 3.04, 95% confidence interval: 0.62-14.82). *Post-hoc* analysis suggested an association of platelet count > 200000/μL with the occurrence of portal vein thrombosis[66].

The other two international phase III trials included patients with chronic hepatitis C and platelet counts less than 75000/μL[67]. Eltrombopag to Initiate and Maintain Interferon Antiviral Treatment to Benefit Subjects with Hepatitic C-Related Liver Disease (ENABLE)-1 and ENABLE-2 assessed the ability of eltrombopag to increase platelet count and, so, allow subjects to initiate and maintain antiviral treatment with pegylated interferon and ribavirin. In both trials, significantly more patients on eltrombopag achieved a sustained virological response at 24 wk of antiviral therapy, with similar adverse events. However, the absolute benefit over placebo was less than 10% and the use of this drug was associated with an increased risk of hepatic decompensation (10% *vs* 5% placebo) and thromboembolic events (3% *vs* 1% placebo). The most frequent adverse events reported were anaemia, pyrexia, and neutropenia.

Avatrombopag: Avatrombopag is an orally available drug that has a similar mode of action to eltrombopag, and it does not compete with endogenous TPO for its receptor site-binding. It is taken once daily with food for 5 d a week, with the dose adjusted according to baseline platelet count. Differently from eltrombopag, it exhibits significant drug-drug interactions based on the cytochrome P450 2C9 (CYP2C9) and CYP3A cytochrome systems[68]. In a phase II study, 130 patients with chronic liver disease and platelet count less than 60000/μL received two different formulations of the drug 1 wk prior to an elective invasive procedure, and both groups of avatrombopag-treated patients achieved the primary endpoint of an platelet increase of > 20000/μL from baseline, and to > 50000/μL, at least once during the treatment days 4-8.



After that, avatrombopag was approved by the FDA in 2018 and the European Medicines Agency (EMA) in 2019 for the treatment of severe thrombocytopenia in patients with chronic liver disease undergoing invasive procedures, with the recommendation to take it 10-13 d before the procedure scheduled within 5-8 d from the last dose administration[69]. The safety and efficacy were evaluated in two pivotal randomized phase 3 studies[69]. ADAPT-1 and ADAPT-2 (Table 1) randomized 430 patients with cirrhosis and severe thrombocytopenia undergoing scheduled procedures to receive avatrombopag at different doses (according to platelet baseline count) or placebo for 5 d. The primary endpoint was the need for platelet transfusion or rescue procedures for bleeding in the 7 d after the procedures[70]. Significantly more patients met this endpoint in avatrombopag groups: In ADAPT-1, 65.6% and 88.1% compared to 22.9% and 38.2% of patients receiving placebo; in ADAPT-2, 68.6% and 87.9% compared to 34.9% and 33.3% (P < 0.001 for both) (Figure 3). Overall, the safety profile was similar to placebo and the most frequent adverse events were nausea, fatigue, abdominal pain, pyrexia, and headache. Serious adverse events occurred in 16%-19% of patients with avatrombopag and 6%-14% of those with placebo, including one patient who developed portal vein thrombosis during post-treatment follow-up. Finally, the safety and efficacy of avatrombopag were recently confirmed in a real-world setting, where cirrhotic patients mainly undergoing esophageal varices band ligation received the drug without requiring platelet transfusion, and with a good profile of adverse events[71,72].

Lusutrombopag: Lusutrombopag is an orally administered synthetic small molecule that acts as an agonist of human TPO, activating the signal transduction pathways to upregulate platelet production. Earlier studies have demonstrated that lusutrombopag raises platelet count and is a manageable drug

Table 1 ADAPT 1-2 key characteristics

Key characteristic	ADAPT 1-2
Key inclusion criteria	Chronic liver disease (MELD score ≤ 24) and thrombocytopenia (platelet counts < 50000/μL). Age ≥ 18 yr
Key exclusion criteria	ADAPT-1/2: History of thrombosis or hematologic disorders. Significant cardiovascular disease. Portal or splenic mesenteric system thrombosis at screening; portal vein blood flow < 10 cm/s at screening. Platelet transfusion within 7 d of screening. Use of heparin, warfarin, FANS, aspirin, verapamil, or antiplatelet therapy with ticlopidine or glycoprotein IIb/IIIa antagonists, or erythropoietin-stimulating agents within 7 d of screening. Advanced hepatocellular carcinoma (BCLC C or D)
Dosing	Low baseline platelet count cohort (≤ 40000/μL): 60 mg avatrombopag or placebo once daily with a meal on days 1-5. High baseline platelet count cohort (40000-50000/μL): 40 mg avatrombopag or placebo once daily with a meal on days 1-5
Type of study	ADAPT-1/2: Global, multicenter, randomized, double-blind, placebo- controlled, phase 3 studies
Patients number	ADAPT-1: 231; ADAPT-2: 204
Endpoints	Efficacy assessment: (1) Primary: Proportion of patients not requiring a platelet transfusion or rescue procedure for bleeding bleeding in the 7 d after the procedures; and (2) Secondary: Proportion of patients achieving the target platelet count of 50000/μL on procedure day; the change in platelet count from baseline to procedure day. Safety assessment: The incidence of adverse events adverse drug reactions, treatment-emergent adverse events

MELD: Model for end-stage liver disease.

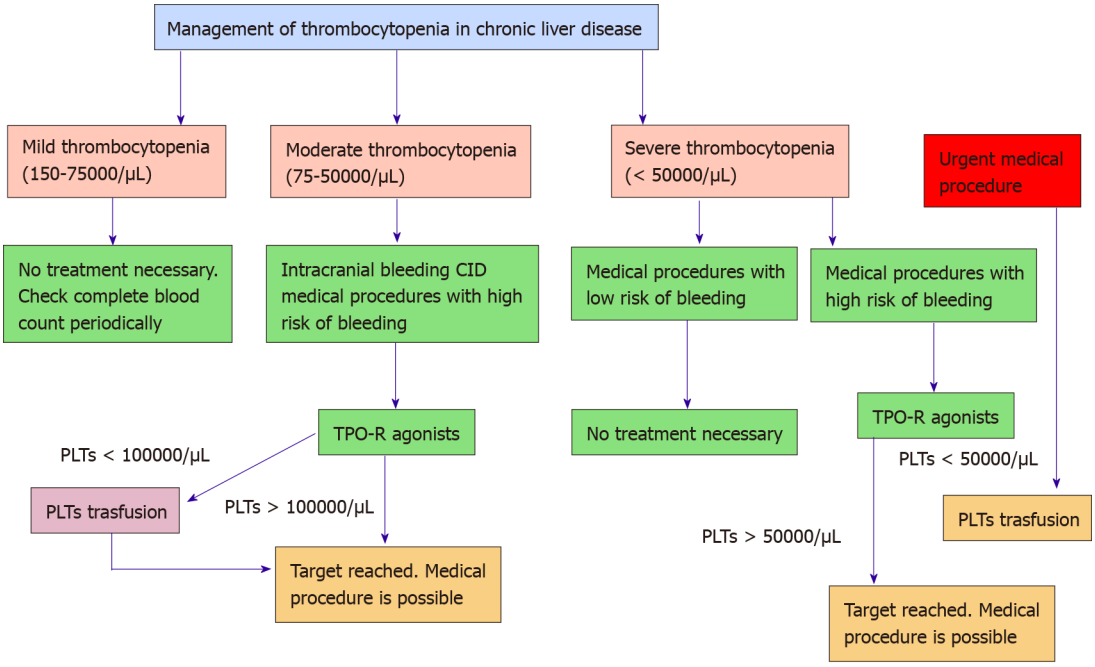
Figure 3 Overview of primary endpoints of phase 3 studies (ADAPT-1, ADAPT-2, L-PLUS 1, and L-PLUS 2). [a]*P* ≤ 0.0001.

that does not require food restrictions, and has no clinically significant drug-drug interactions[73,74]. Furthermore, it has demonstrated a dose-proportional pharmacokinetic with no clinically significant differences in the pharmacokinetic grounded on age, liver function (Child-Pugh classes A and B), and renal function (creatinine clearance greater than 30 mL/min)[75]. It is primarily metabolized by CPY4 enzymes, including CYP4A11, and it is mainly excreted by the faecal route (83% of dose). Moreover, it has a low potential to inhibit or induce transporter systems and CYP enzymes[73]. The recommended dose of the drug is 3 mg once daily for 7 d, beginning 8-14 d prior to the scheduled procedure.

Lusutrombopag was approved in Japan in 2015 for use in patients with thrombocytopenia and chronic liver disease who needed invasive procedures and received a positive opinion from the EMA Committee for Medicinal Products for Human Use in 2018[76]. The approval of this drug was based on the results of Lusutrombopag for the Treatment of Thrombocytopenia in Patients with Chronic Liver Disease Undergoing Invasive Procedures trial (L-PLUS-1), a phase 3 double-blind study, carried out in Japan with 96 patients with chronic liver disease and severe thrombocytopenia (platelet count < 50000/μL) undergoing invasive procedures[77] (Table 2). In this study, the proportion of patients that did not require pre-operative platelet transfusions was significantly greater in the lusutrombopag group *vs* placebo (79.2 % *vs* 12.5%, respectively, $P < 0.0001$) (Figure 3). The median platelet count reached more than 50000/μL after 5 d in the drug group, with the greatest value observed after a mean of 13.4 d.

Table 2 Lusutrombopag for the Treatment of Thrombocytopenia in Patients with Chronic Liver Disease Undergoing Invasive Procedures trial 1-2 key characteristics

Key characteristic	L-PLUS 1-2
Key inclusion criteria	Chronic liver disease (Child Pugh A or B) and thrombocytopenia (platelet counts < 50000/μL). Age ≥ 18 yr (≥ 20 yr in L-PLUS 2)
Key exclusion criteria	L-PLUS 1: (1) Hematopoietic tumors; aplastic anemia, myelodysplastic syndrome, myelofibrosis, congenital, immune, or drug-induced thrombocytopenia; (2) Splenectomy, any other causes of thrombocytopenia; (3) History of portal vein thrombosis; (4) Active malignant tumor other than primary hepatic cancer; (5) Therapies that could influence platelet count (L-PLUS 1); (6) Chronic liver disease with Child-Pugh C; (7) Portal vein tumor embolism; and (8) Past or present thrombosis or prothrombotic condition. L-PLUS 2: (1) Hematopoietic tumors; aplastic anemia, myelodysplastic syndrome, myelofibrosis, congenital, immune, or drug-induced thrombocytopenia; (2) Portal vein thrombosis within 28 d prior to randomization or a history of portal vein thrombosis; absence of hepatopetal blood flow in the main trunk of the portal vein as demonstrated by doppler ultrasonography within 28 d prior to randomization; (3) Chronic liver disease with Child-Pugh C; (4) Portal vein tumor embolism; and (5) Past or present thrombosis or prothrombotic condition, history of splenectomy
Dosing	3 mg lusutrombopag or placebo once daily for up to 7 d
Type of study	L-PLUS 1: Double-blind, parallel-group, phase 3 study; L-PLUS 2: Global, phase 3, randomized, double-blind, placebo-controlled study
Patients number	L-PLUS 1: 96; L-PLUS 2: 215
Endpoints	Efficacy assessment: (1) Primary: Proportion of patients who required no platelet transfusions before the primary invasive procedure and no rescue therapy for bleeding; and (2) Secondary: Rate of response (defined as proportion of patients who achieved platelet count of more than 50000/μL with an increase of ≥ 20000/μL from baseline at any time during the study); the duration of sustained platelet count increase; time courses of changes in platelet count. Safety assessment: The incidence of adverse effects, adverse drug reactions, treatment-emergent adverse effects, bleeding-related adverse effects, and thrombotic events



L-PLUS: Lusutrombopag for the Treatment of Thrombocytopenia in Patients with Chronic Liver Disease Undergoing Invasive Procedures trial.

Moreover, no significant concerns were raised in this study, and no significant adverse drug reactions were observed.

The safety and efficacy of this drug were confirmed in a larger study, the L-PLUS-2[78]: 215 patients with chronic liver disease and a platelet count < 50000/μL were randomly assigned to once-daily lusutrombopag at a dosage of 3 mg or placebo for ≤ 7 d before an invasive procedure. The procedure was performed within 7 d after the last dose. In the intention to treat analysis, significantly more patients in the lusutrombopag group (64.8%) met this endpoint compared with placebo (29%, $P < 0001$). This percentage was greater in the per-protocol analysis, with the endpoint reached in 72.5% of patients in the active drug group *vs* 20% in the placebo group ($P < 0.0001$). The median duration of the achievement of a target of platelet count > 50000/μL was 19.2 d in the lusutrombopag group *vs* 0 d for the patients who received placebo. Moreover, the median maximum change in platelets from baseline was over 4 times higher for patients treated with the active drug, who did not receive platelet transfusions, compared with patients who did receive transfusions (45000 *vs* 11000/μL)[78]. Finally, 47.7% of patients in the lusutrombopag group and 48.6% in the placebo group had at least one adverse event. These side effects were mainly mild or moderate in severity and the most common were headache, abdominal pain, fatigue, peripheral edema, and nausea. There were only three mild bleeding events in three patients in the lusutrombopag group (2.8%) *vs* seven bleeding events (4 moderate and 1 severe; 5.6%) with placebo. Only three thromboembolic events were recorded (1 in the lusutrombopag group), which were not related to platelet count.

The first real-life study in Japan enrolled 25 patients with cirrhosis, who were treated with lusutrombopag prior to invasive treatments (radiofrequency ablation, transarterial chemoembolization, and endoscopic variceal ligation)[79]. In this group, platelet count significantly increased compared with baseline (82000 ± 26000 *vs* 41000 ± 11000 /μL). The proportion of patients who needed platelet transfusions before procedures was very low (only 4, 16%) compared to those not treated with lusutrombopag (69 patients, 54%). Moreover, platelet counts after treatment and before invasive procedures were lower in patients with a count less than 30000/μL, and this cut-off, together with a spleen index > 40 cm^2, was predictive of a lower response rate to the drug[80]. This was probably due to a larger number of platelets sequestered in the spleen in this subgroup of patients. No haemorrhagic complications were observed, and only a single case of recurrent portal vein thrombosis was observed and successfully treated.

Another real-life setting retrospective study was carried out in patients with chronic liver disease and severe thrombocytopenia. In this study[81], 74.2% of patients who received treatment did not require platelet transfusion before invasive procedures. This percentage increased to 82.1% of treatments if patients who repeated lusutrombopag use more times were included, thus demonstrating the efficacy of repeated use of the drug. Furthermore, only one serious adverse event was observed during/after treatment, *i.e.*, one case of portal thrombosis disappearing after anticoagulation. Notably, this study

Figure 4 Operative flow chart for management of thrombocytopenia in chronic liver disease. TPO-R: Thrombopoietin receptor; PLTs: Platelets; CID: Disseminated intravascular coagulation.

confirmed that a lower platelet count at baseline was a predictive factor for failure to reach the target of > 50000/μL platelets. Indeed, median basal platelet count was higher in responders *vs* non-responders (38000/μL *vs* 12000/μL).

Moreover, the safety and efficacy of repeated use of lusutrombopag have been confirmed also in 66 patients who underwent radiofrequency ablation for recurrence of hepatocellular carcinoma[82]. Later, others reports have confirmed the efficacy and safety of lusutrombopag in real life in patients with thrombocytopenia due to chronic liver disease. In a case report, Kaneko *et al*[83] showed lusutrombopag to be a successful substitute for platelet transfusion in a patient with chronic liver disease undergoing endoscopic spinal surgery. Kawata *et al*[84] reported three patients treated with lusutrombopag before tooth extraction: Platelet count increased, preventing the need for transfusion in two of three cases. There were no adverse events. In addition, the efficacy and safety of the drug have been confirmed in a retrospective Japanese study based on hospital administrative databases. Here the incidence of bleeding events was lower in the lusutrombopag group than in the platelet transfusion group (3.7% *vs* 8.2%, $P < 0.001$), with a consequently lower average medical cost[85]. Finally, real-world data for adverse events (spontaneously reported by healthcare professionals and consumers in a database including about 4000 patients exposed to lusutrombopag from December 2015 to April 2018) confirm the efficacy and the safety of the drug (93% of patients did not require pre-procedural platelet transfusion; 1.2% of serious adverse events, with 0.4% cases of portal vein thrombosis)[86].

CONCLUSION

Thrombocytopenia represents one of the main coagulation disorders in patients with chronic liver disease. Recent awareness in its physiopathology shed light on the central role of TPO. The development of TPO receptor agonists has opened a new scenario in the management of patients with liver disease who need invasive procedures (Figure 4). Avatrombopag and lusutrombopag have demonstrated their efficacy and safety in increasing platelet count without an increased risk of thrombosis. Moreover, they reduce the overall clinical risk associated with platelet transfusion without any delay in the management of these patients. With careful logistical planning and coordination between drug availability and medical procedures, patients with chronic liver disease and severe thrombocytopenia should now be able to undergo more easily invasive procedures.

Abstract

BACKGROUND

Clostridioides difficile (*C. difficile*) is the most common pathogen causing health care-associated infections. *C. difficile* TcdA and TcdB have been shown to activate enteric neurons; however, what population of these cells is more profoundly influenced and the mechanism underlying these effects remain unknown.

AIM

To characterize a specific population of TcdA-affected myenteric neurons and investigate the role of the P2X7 receptor in TcdA-induced ileal inflammation, cell death, and the changes in the enteric nervous system in mice.

METHODS
Swiss mice were used to model TcdA-induced ileitis in ileal loops exposed to TcdA (50 μg/Loop) for 4 h. To investigate the role of the P2X7 receptor, Brilliant Blue G (50 mg/kg, i.p.), which is a nonspecific P2X7 receptor antagonist, or A438079 (0.7 μg/mouse, i.p.), which is a competitive P2X7 receptor antagonist, were injected one hour prior to TcdA challenge. Ileal samples were collected to analyze the expression of the P2X7 receptor (by quantitative real-time polymerase chain reaction and immunohistochemistry), the population of myenteric enteric neurons (immunofluorescence), histological damage, intestinal inflammation, cell death (terminal deoxynucleotidyltransferase-mediated dUTP-biotin nick end labeling), neuronal loss, and S100B synthesis (immunohistochemistry).

RESULTS
TcdA upregulated ($P < 0.05$) the expression of the P2X7 receptor gene in the ileal tissues, increasing the level of this receptor in myenteric neurons compared to that in control mice. Comparison with the control mice indicated that TcdA promoted ($P < 0.05$) the loss of myenteric calretinin+ (Calr) and choline acetyltransferase+ neurons and increased the number of nitrergic+ and Calr+ neurons expressing the P2X7 receptor. Blockade of the P2X7 receptor decreased TcdA-induced intestinal damage, cytokine release [interleukin (IL)-1β, IL-6, IL-8, and tumor necrosis factor-α], cell death, enteric neuron loss, and S100B synthesis in the mouse ileum.

CONCLUSION
Our findings demonstrated that TcdA induced the upregulation of the P2X7 receptor, which promoted enteric neuron loss, S100B synthesis, tissue damage, inflammation, and cell death in the mouse ileum. These findings contribute to the future directions in understanding the mechanism involved in intestinal dysfunction reported in patients after *C. difficile* infection.

Key Words: *Clostridioides difficile*; *Clostridioides difficile* toxin A; P2X7 receptor; Enteric nervous system; Enteric neuron; Enteric glia

Core Tip: There is a knowledge gap regarding the population of enteric neurons affected by TcdA and the role of the P2X7 receptor, which is a low-sensitivity adenosine triphosphate-gated cation channel, in TcdA-induced alterations in enteric neurons and enteric glial cell (EGC)-derived mediators, particularly S100B. The findings of the present study demonstrated the mechanism of P2X7 receptor-driven enteric neuronal loss induced by TcdA in the mouse ileum. TcdA promoted the upregulation of the P2X7 receptor, which promoted cell death in enteric neurons and induced the release of proinflammatory mediators, which in turn promoted S100B synthesis in EGCs. However, the blockade of the P2X7 receptor abrogated ileal damage induced by TcdA.

INTRODUCTION

Clostridioides difficile (*C. difficile*) continues to be the leading cause of nosocomial diarrhea worldwide[1]. TcdA, TcdB, and *C. difficile* binary toxin are the main virulence factors of *C. difficile* infection-related intestinal damage. These toxins have been shown to play an important role in secretory diarrhea and inflammation during the infection[2,3]. The clinical disease ranges from mild diarrhea to toxic megacolon, colonic perforation, and death.

Intestinal dysfunction has been identified in patients after the acute phase of *C. difficile* infection[4-7]. Growing evidence suggests that the enteric nervous system (ENS) plays an important role in the regulation of intestinal inflammation. Alterations in the ENS components, including enteric neurons and glia, contribute to the amplification of inflammatory immune response and intestinal dysfunction under inflammatory conditions.

The P2X7 receptor is a low-sensitivity adenosine triphosphate (ATP)-gated cation channel expressed by several cell types, such as macrophages[8], EGCs[9], and enteric neurons[10]. Once activated, the P2X7 receptor increases the intracellular Ca^{2+} concentrations, which in turn promote the release of proinflammatory cytokines and neuromodulators[11,12]. Additionally, high levels of the P2X7 receptor have been reported in enteric neurons during colitis induced by dinitrobenzene sulfonic acid[13] and intestinal ischemia[10].

TcdA and TcdB have been shown to excite enteric neurons, stimulating the release of substance P and vasoactive intestinal peptide *via* the inhibition of noradrenergic transmission and the interleukin (IL)-1β pathway, respectively, resulting in neutrophil recruitment and secretory diarrhea[14-16]. However, there is a knowledge gap regarding the population of enteric neurons affected by TcdA and the role of the P2X7 receptor in TcdA-induced alterations in enteric neurons and enteric glial cell (EGC)-derived mediators, particularly S100B.

In the present study, we characterized the population of myenteric neurons affected by TcdA during ileitis in mice. In addition, we investigated the role of the P2X7 receptor in ileal damage, inflammation, and enteric glial and neuronal changes in TcdA-induced ileitis in mice. Our hypothesis was that TcdA affects specific types of neurons and induces reactive gliosis and that activation of P2RX7 is involved not only in ileal damage and inflammation but also in the activation of enteric glia and neuronal loss induced by this toxin.

MATERIALS AND METHODS

Animals

Swiss mice (8-week-old) were provided by the central vivarium of the Federal University of Ceara. All mice were maintained under standard conditions at 24 °C at a 12-h light-dark cycle, and all groups were provided water and food *ad libitum*. All mouse procedures were conducted according to current regulations regarding animal experiments approved by the local Animals Care and Use Committee (protocol no. 7028200418).

Mouse ileal loop model

A mouse model of TcdA-induced ileitis was established as described previously with[17] some modifications. Swiss mice (n = 5 *per* group) were fasted for 4 h with free access to water and deeply anesthetized with an intraperitoneal injection of ketamine (80 mg/kg) and xylazine (10 mg/kg). After a midline laparotomy, a single 4-cm ileal loop was ligated and injected with 50 μg of TcdA in 100 μL of phosphate-buffered saline (PBS). The control loops were injected with 100 μL of PBS alone. After 4 h, the mice were euthanized, and the ileal loops were removed for subsequent analysis. Alternatively, some mice were injected with Brilliant Blue G (BBG, Sigma–Aldrich, 50 mg/kg, i.p.)[10], a nonspecific P2X7 receptor antagonist, or with A438079 (Abcam, 10 μM/200 μL, i.p.), a competitive P2X7 receptor antagonist[18], one hour prior to PBS or TcdA (50 μg) injection in the ileal loops. The experimental groups were as follows: Control (loops were injected with 100 μL of PBS alone), TcdA (loops were injected with 50 μg of TcdA in 100 μL of PBS), BBG (injected with BBG one hour prior to the injection of 100 μL of PBS in the loop), A438079 (injected with A438079 one hour prior to the injection of 100 μL of PBS in the loop), TcdA + BBG (injected with BBG one hour prior to the injection of 50 μg of TcdA in 100 μL of PBS), and A438079 (injected with A438079 one hour prior to the injection of 50 μg of TcdA in 100 μL of PBS).

TcdA was provided by Prof. Carlos Quesada from the University of Costa Rica. BBG was kindly provided by Dr. Patricia Castelucci from the University of São Paulo. A43807 was kindly provided by Dr. Henning Ulrich from the University of São Paulo.

Analysis of histological damage in the ileum

The ileal samples were fixed in 10% formalin solution for 20 h and processed by the NEMPI-UFC Research Histology Core. The severity of ileal damage was measured by a blinded expert in histopathology based on a scoring system ranging from 0 to 3 as described previously with some modifications as follows: (0) Absence of alterations; (1) Mild loss of the integrity of the villi, mild edema, and neutrophil infiltration; (2) Partial loss of the villi, moderate edema, and neutrophil infiltration; and (3) Complete loss of the villi, extensive edema, and intense neutrophil infiltration[19].

Analysis of enteric neuron population

Fresh ileal samples were flushed with PBS, dissected, and opened along the mesenteric border. Then, the samples were fixed in 4% paraformaldehyde (in 0.2 M sodium phosphate buffer, pH 7.4) overnight at 4 °C. Then, the samples were washed three times with 100% dimethyl sulfoxide for 10 min, followed by three washes with PBS for 10 min each. All samples were stored at 4 °C in PBS containing 0.1% sodium azide. The fixed tissues were dissected to remove the mucosa, submucosa, and circular layers, yielding longitudinal muscle-myenteric plexus whole mounts as described previously[10].

Table 1 Primary and secondary antibodies used

Antigen	Host	Dilution	Manufacturer
nNOS	Sheep	1:2000	Millipore (AB1529/Lot 2488802)
ChAT	Goat	1:50	Millipore (AB144P/Lot 1978747)
P2X7 receptor	Rabbit	1:100	Millipore (AB5246/Lot 2361386)
Calretinin	Goat	1:100	Molecular
Donkey anti-rabbit IgG Alexa 594	Donkey	1:200	Probes (A21206/Lot 1182675)
Donkey anti-sheep IgG Alexa 488	Donkey	1:400	Molecular
			Probes (A11016/Lot93D1-1)

nNOS: Neuronal nitric oxide synthase; ChAT: Choline acetyltransferase; IgG: Immunoglobulin G.

Whole-mount preparations of the ileal myenteric samples were preincubated in 10% horse serum in PBS containing 1.5% Triton X-100 for 45 min at room temperature to reduce nonspecific binding and permeabilize the tissue. The antibodies used in the present study are described in Table 1. Double labeling was achieved using the combinations of primary antibodies (Table 1) overnight at 4 °C. Then, the samples were washed (with PBS three times for 10 min each) and incubated with secondary antibodies (Table 1). After washing with PBS, the samples were mounted in glycerol buffer (in 0.5 M sodium carbonate, pH 8.6). The immunostaining images were acquired using confocal microscopy by a Zeiss confocal scanning laser system installed on a Zeiss Axioplan 2 microscope. The images were acquired at a resolution of 512 × 512 pixels, and the thickness of each optical section was 0.5 μm. The Z-stacks of immunoreactive cells were captured as a series of optical sections with a center spacing of 0.2 μm. Confocal images were collected using Zeiss LSM 5 image processing software and further processed using Corel Photo Paint and Corel Draw software[10].

Quantitative analysis of myenteric neuron immunostaining

The antigen colocalization was determined in fluorescently labeled preparations. Initially, the neurons were identified by immunofluorescence. Then, the filter was switched, and the labeling of the second antigen was evaluated. The proportion of the neurons labeled with the antigen pairs was thus determined. The cohort size was 100 neurons, and the data were collected from the preparations obtained from five mice *per* experimental group. The percentage of double immunoreactive neurons was calculated and is expressed as the mean ± standard error of the mean (SEM). The density of the neurons immunoreactive (neurons/cm^2) to the P2X7 receptor, neuronal nitric oxide synthase (nNOS), calretinin (Calr), and choline acetyltransferase (ChaT) and neuronal morphological profiles were assessed in the whole-mount preparations at 100 × magnification. The number of the cell bodies of immunoreactive neurons in the myenteric ganglia in each visual microscopic field (0.04909 mm^2) was estimated. To quantify two whole-mount preparations (1.0 cm^2 each), the counts were estimated in 40 microscopic fields selected at random for each antigen in each animal. The perikaryon profile areas (μm^2) of 50 randomly selected neurons from each animal were obtained using a semiautomatic morphometry device and measured using the Image-Pro Plus software package.

Immunohistochemistry

Immunostaining of S100B (an enteric glia-derived mediator), HuC/D (a neuronal marker), and the P2X7 receptor was performed in paraffin-embedded ileal formalin-fixed sections (4-μm thick) using the streptavidin-biotin-peroxidase method; the sections were mounted on poly(L)-lysine-coated microscope slides as described previously[20]. Briefly, the samples were deparaffinized and rehydrated by incubation with xylene and graded alcohol solutions, respectively. Then, the samples were immersed in antigen retrieval solution (*EnVision™ FLEX target retrieval solution, pH = 6.0; Dako, Denmark A/S*) for 20 min on a PT Link system (Dako), incubated in 3% hydrogen peroxide (*EnVision™ FLEX peroxidase-blocking reagent; Dako)* to block endogenous peroxidase for 15 min at room temperature, and washed with PBS. Then, the samples were incubated with primary antibodies (rabbit anti-P2X7 receptor (Invitrogen), mouse anti-HuC/D (Invitrogen), or goat anti-S100B (Santa Cruz Biotechnology, 1:100) in antibody diluent solution (*EnVisionTM FLEX antibody diluent; Dako*) overnight at 4 °C. Then, the samples were incubated with *EnVision™ FLEX/HRP (Dako)* as recommended by the manufacturer. P2X7 receptor, HuC/D, and S100B were detected using the chromogen 3,3'-diaminobenzidine (DAB, *EnVision™ FLEX DAB+ chromogen; Dako*). The negative control sections were processed simultaneously as described above; however, the primary antibody was replaced with antibody diluent solution (*EnVision™ FLEX antibody diluent; Dako*). The slides were counterstained with Mayer's hematoxylin. The images were acquired by a Leica DM100 microscope and analyzed using Adobe Photoshop 8.0 software. The

percentages of P2X7 receptor-, S100B- and HuC/D-stained tissue sections were measured by using Adobe Photoshop as described previously[20].

Total RNA extraction, reverse transcription, and real-time polymerase chain reaction

Total RNA was isolated from the ileum using an *Aurum™ total RNA fatty and fibrous tissue* kit (Bio-Rad, CA, United States), and 1 μg of the RNA was reverse transcribed using iScript™ (Bio-Rad) according to the manufacturer's instructions. Real-time polymerase chain reaction (qPCR) was performed on a 7900HT fast real-time PCR system (Applied Biosystems) using the following specific primers (IDT, Coralville, IA): P2X7 receptor (forward: GCACGAATTATGGCACCGTC and reverse: CCCCACCCTCT-GTGACATTCT) and GAPDH (forward: TGCACCACCAACTGCTTAG and reverse: GGATGCAGG-GATGATGTTC)[21]. The reaction mixture was prepared in a final volume of 20 μL as follows: 10 μL of master mix iQTM SYBR® Green (Applied Biosystems), 2 μL of each primer (200 nM), 1 μL of cDNA, and 5 μL of nuclease-free water. The gene amplification included the following steps: 10 min at 95 °C (initial denaturation), 15 s at 95 °C and 60 s at 60 °C for 40 cycles; thus, a melting curve was obtained. Relative gene expression was determined using the 2-Δ Δ Ct method with GAPDH as a housekeeping gene.

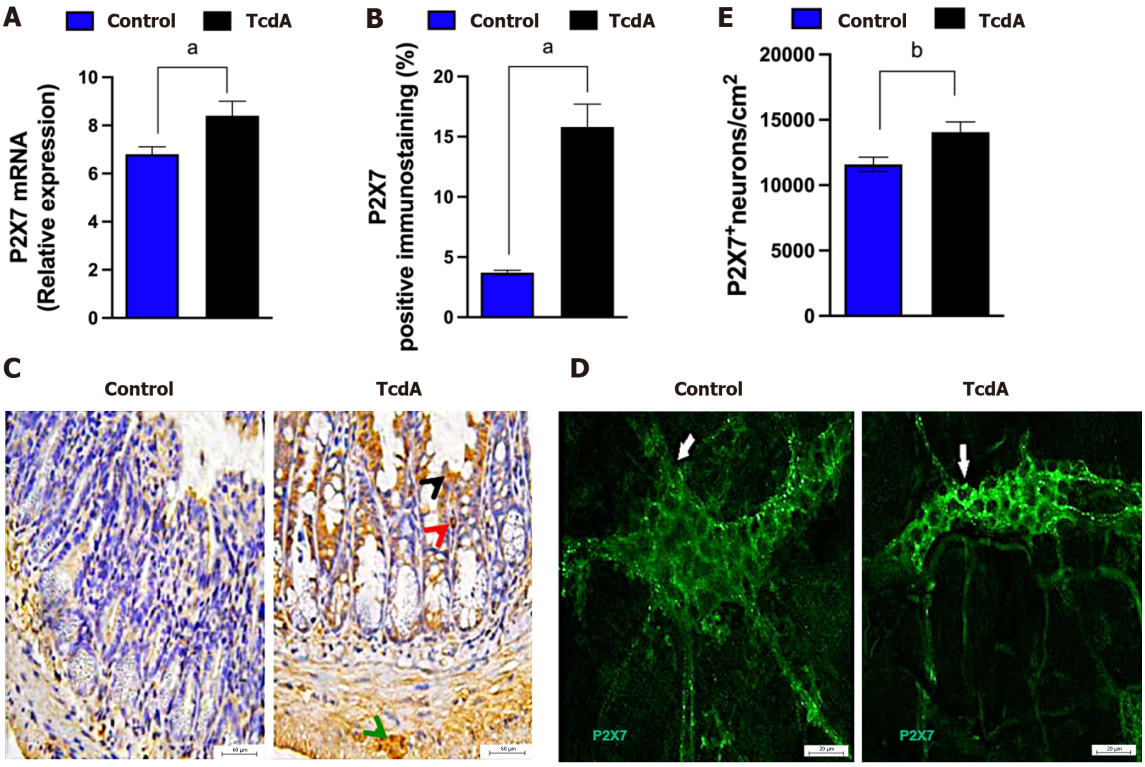
Terminal deoxynucleotidyltransferase-mediated dUTP-biotin nick end labeling assay

Ileal samples were processed for terminal deoxynucleotidyltransferase-mediated dUTP-biotin nick end labeling (TUNEL) using an *ApopTagR S 7100* kit (Merck Millipore, Germany) to quantify apoptotic and necrotic cells. Briefly, paraffin-embedded sections were hydrated and incubated with proteinase K (Sigma, United States, 20 mg/mL) for 15 min at room temperature. Endogenous peroxidase was blocked with 3% hydrogen peroxide in PBS for 5 min at room temperature. After a washing step, the sections were incubated with TdT buffer containing TdT enzyme and reaction buffer in a humidified chamber at 37 °C for 1 h. The specimens were incubated for 10 min at room temperature with stop/wash buffer and then incubated with an anti-digoxigenin–peroxidase conjugate at room temperature in a humidified chamber for 30 min. After washing with PBS, the slides were covered with peroxidase substrate (DAB) to develop the color and were counterstained with methyl green.

Cytokine quantification by enzyme-linked immunosorbent assay

To measure inflammatory markers, the ileal samples were processed to evaluate the levels of IL-1β, IL-6, keratinocyte chemoattractant (KC, a human IL-8 analog), and tumor necrosis factor (TNF)-α by enzyme-linked immunosorbent assay (ELISA) using a mouse cytokine kit (R&D Systems) according to the manufacturer's instructions. The absorbance of the samples was detected at 450 nm using an ELISA plate reader (Biotech Epoch, United States). The data are expressed as pg *per* mg of tissue.

Statistical analysis



The results are expressed as the mean ± SEM calculated by GraphPad Prism version 9.0 (GraphPad Software, San Diego, CA). The differences between more than two experimental groups were evaluated using one-way analysis of variance (ANOVA) with Bonferroni's multiple comparison test. Student's t test was performed to analyze the differences between two groups. The histopathological score data were compared by using Kruskal–Wallis nonparametric test followed by Dunn's test. Statistical significance was defined as $P < 0.05$.

RESULTS

TcdA upregulates the P2X7 receptor transcripts in the ileum of mice and increases the population of myenteric enteric neurons expressing the P2X7 receptor

Initially, we investigated whether TcdA alters the expression of the *P2RX7* gene in the ileum of mice by using qPCR. We demonstrated that TcdA upregulated the P2X7 receptor in the ileum of mice compared with that in control mice ($P < 0.05$, Figure 1A). The data of the assay of the P2X7 receptor protein by immunofluorescence showed an increase in the percentage of positive P2X7 receptor immunostaining in the ileal samples of TcdA-challenged mice compared with that in the control samples ($P < 0.05$, Figure 1B). An increase in the expression of the P2X7 receptor was observed in epithelial cells, the lamina propria, and the myenteric plexus (Figure 1C).

Enteric neurons are an important component of the myenteric plexus, which is a part of the ENS; hence, we investigated whether the level of the P2X7 receptor is increased in these cells in the myenteric plexus by using immunofluorescence analysis. Comparison with the control group indicated an increase in the density of enteric neurons expressing the P2X7 receptor in the ileum myenteric plexus in mice challenged with TcdA ($P = 0.01$, Figure 1D and E).

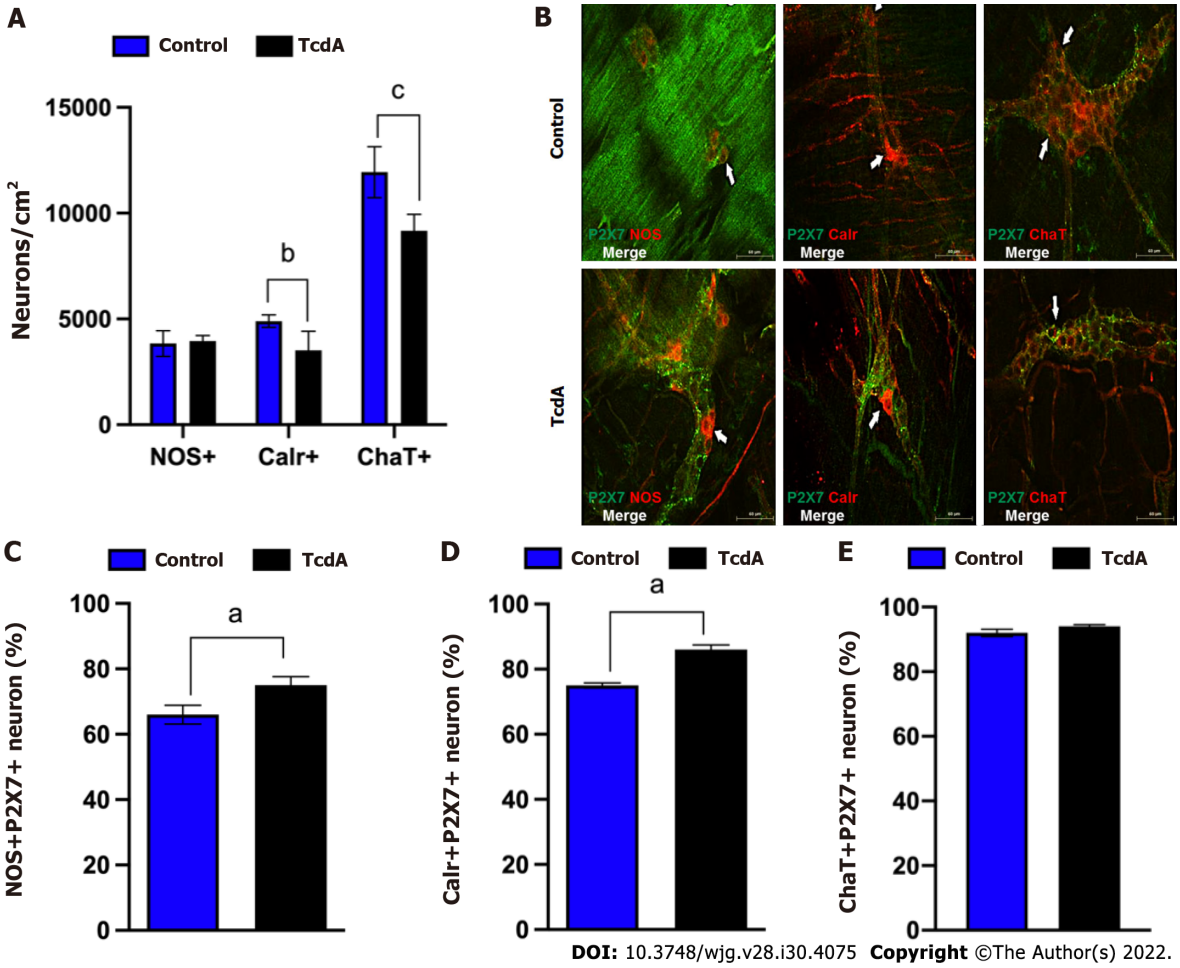
Figure 1 *Clostridioides difficile* toxin A increases the expression of the P2X7 receptor in the ileum myenteric plexus of mice. A: The expression of the *P2RX7* gene [mean ± standard error of the mean (SEM)] assayed by quantitative real-time polymerase chain reaction in the ileal samples of mice injected with TcdA [TcdA, 50 μg in phosphate-buffered saline (PBS)] or PBS alone in the ileal loops (Control) (n = 4); B: Quantification of the percentage (mean ± SEM) of the P2X7 receptor-immunopositive area in the ileum from control and *TcdA*-challenged mice in 5-6 microscope fields *per* sample (n = 4 animals *per* group); C: Representative immunohistochemical images of the expression of the P2X7 receptor in the ileum of control and *TcdA*-challenged mice. Increased expression of the P2X7 receptor (arrowhead) was detected in the intestinal epithelial layer (black arrowhead), lamina propria (red arrowhead), and myenteric plexus (green arrowhead). Scale bars, 50 μm; D: Representative photomicrographs ofimmunostaining of the P2X7 receptor (arrow indicates the region stained green) in the ileum myenteric plexus from control and *TcdA*-challenged mice; E: Quantification of the number of P2RX7$^+$ neurons/cm^2 (mean ± SEM) in the ileum of control and *TcdA*-challenged mice (n = 4 animals *per* group); A, B and E: Unpaired two-tailed Student's t test ($^aP < 0.05$; $^bP = 0.01$).

TcdA decreases the density of enteric Calr+ and ChaT+ neurons in the ileum myenteric plexus of mice



Subsequently, to better understand how TcdA affects the myenteric enteric neuron population, we immunostained the ileum myenteric plexus to detect nNOS, Calr, and ChaT, which were stained in the main population of enteric neurons. As shown in Figure 2A, the density of Calr+ ($P < 0.03$) and ChaT+ neurons ($P < 0.002$) in the ileum myenteric plexus of mice challenged with TcdA was decreased compared to that in control mice. In addition, all these subtypes of the neurons expressed the P2X7 receptor (Figure 2B).

Comparison with the control group of mice indicated that the enteric neuron population expressing the P2X7 receptor in the ileum myenteric plexus had a higher number of nNOS+P2RX7+ and Calr+P2RX7+ neurons, but not of ChaT+P2RX7+ neurons ($P < 0.05$, Figure 2C-E).

Overall, these findings indicated that TcdA decreased the enteric neuron population, specifically Calr+ and ChaT+ cells and upregulated the P2X7 receptor in a specific population (nNOS and Calr) of the neurons in the ileum myenteric plexus in mice.

Blockade of the P2X7 receptor decreases ileal damage induced by TcdA in mice

Then, we blocked the P2X7 receptor by pretreating mice using a pharmacological approach, including administration of BBG and A438079 one hour prior to the challenge with TcdA to determine whether P2X7 receptor activity is required for ileal damage induced by TcdA. Hematoxylin and eosin-stained slides of ileum samples were analyzed for evidence of epithelial damage, edema, and neutrophil infiltration, with a maximal severity score of 3 (Figure 3). TcdA induced complete epithelial disruption, extensive edema, and intense neutrophil infiltration in the ileum of mice, resulting in a high damage score (score = 3) compared with those in the undamaged ileum in control mice ($P < 0.007$, Figure 3). However, both P2X7 receptor antagonists (BBG and 438079) induced a substantial decrease in the ileal damage promoted by TcdA, resulting in a reduction in the damage score (score = 1) compared to that in untreated TcdA-challenged mice ($P < 0.04$, Figure 3).

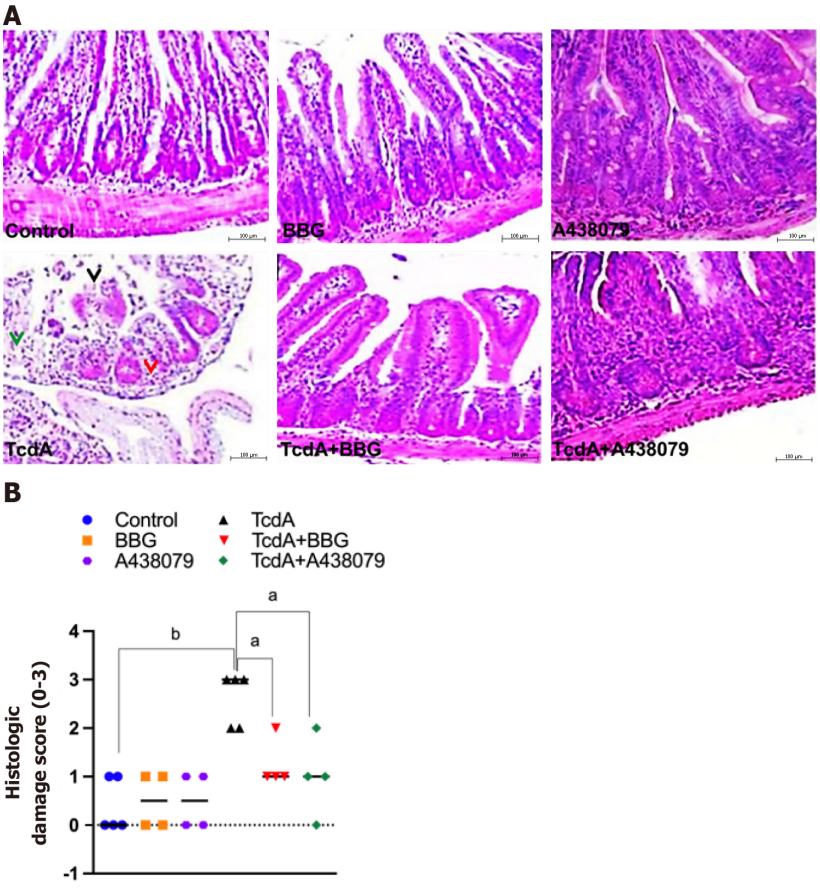
Figure 2 *Clostridioides difficile* toxin A induces alterations in enteric neuronal coding in the myenteric plexus in the ileum of mice. A: Quantification of the number of neuronal nitric oxide synthase+ (nNOS+), calretinin+ (Calr+), and choline acetyltransferase+ (ChaT+) neurons/cm^2 [mean ± standard error of the mean (SEM)] in the ileum myenteric plexus in control and *TcdA*-challenged mice; B: Representative photomicrographs of the P2X7 receptor (green), nNOS (left panels, red), Calr (center panels, red), and ChaT (right panel, red) immunostaining and DAPI (blue) nuclear staining in control and *TcdA*-challenged mice. White arrows indicate positive immunostaining. Scale bars, 50 μm; C-E: Percentage of NOS$^+$P2X7$^+$ neurons (C), Calr$^+$P2RX7$^+$ neurons (D), and ChaT$^+$P2RX7$^+$ neurons (E) (mean ± SEM) in the ileum myenteric plexus of control and *TcdA*-challenged mice (n = 4); A, C, D and E: Unpaired two-tailed Student's t test ($^aP < 0.05$; $^bP < 0.03$; $^cP < 0.002$). NOS: Nitric oxide synthase; Calr: Calretinin; ChaT: Choline acetyltransferase.

Blockade of the P2X7 receptor decreases ileal inflammation and cell death induced by TcdA in mice



Subsequently, we evaluated whether P2X7 receptor activity is involved in ileal inflammation and cell death induced by TcdA in mice. We demonstrated that both P2X7 receptor blockers (BBG and A438079) reversed a TcdA-induced increase in IL-1β (P = 0.008 and P = 0.03, Figure 4A), TNF-α (P = 0.0002 and P = 0.0001, Figure 4B), and IL-6 (P = 0.03 and P < 0.0001, Figure 4C) in the ileal samples of mice. However, comparison with TcdA-challenged mice, which were not pretreated with the blockers, indicated that blockade of the P2X7 receptor by A438079, but not by BBG, decreased the levels of KC (P = 0.01, Figure 4D) and the number of TUNEL+ cells (P = 0.01, Figure 4E) in the ileum of mice challenged with TcdA.

Overall, these data indicated that the P2X7 receptor was involved in intestinal damage, inflammation, and cell death induced by TcdA in mice.

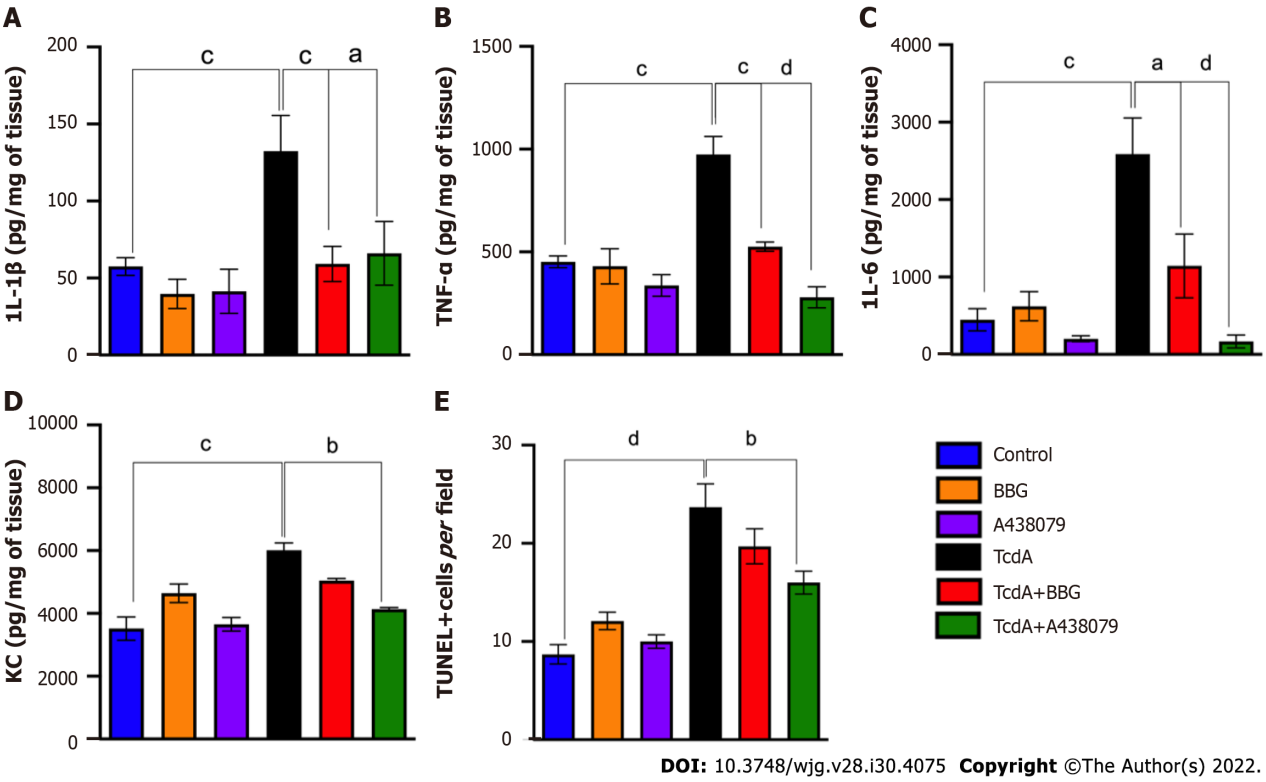
Blockade of the P2X7 receptor decreases enteric neuron loss and S100B synthesis induced by TcdA in mice

Since we demonstrated that TcdA promoted a decrease in ileum enteric neurons in mice, we assessed whether the P2X7 receptor accounts for this alteration. Comparison with TcdA-challenged mice, which were not pretreated with the blockers, indicated that a P2X7 receptor blocker (A438079) increased the percentage of positive immunostaining of HuC/D, which is a pan-marker of enteric neurons, in the ileum of mice challenged with TcdA (Figure 5).

Furthermore, we evaluated whether the activation of the P2X7 receptor is required to induce S100B expression in the ileum of TcdA-challenged mice; high levels of S100B are released by EGCs under inflammatory conditions. As shown in Figure 5, the P2X7 receptor antagonist A438079 induced a

DOI: 10.3748/wjg.v28.i30.4075 **Copyright** ©The Author(s) 2022.

Figure 3 Inhibition of the P2X7 receptor decreases *Clostridioides difficile* toxin A-induced ileal damage in mice. Mouse ileal loops were injected with TcdA [TcdA, 50 μg in phosphate-buffered saline (PBS)] or PBS alone (control) (n = 5), and the animals were pretreated with a P2X7 receptor antagonist [Brilliant Blue G (BBG) or A438079] one hour prior to TcdA challenge. A: Representative histological images (magnification of 200 ×) of TcdA-unchallenged (control, BBG, and A438079) and challenged (TcdA, TcdA + BBG, and TcdA + A438079) mice. TcdA induced epithelial disruption (black arrowhead), edema (green arrowhead), and neutrophil infiltration (red arrowhead); B: Histopathological score (median; 0 corresponds to-no damage and 3 corresponds to intense damage) performed by a blinded histopathological expert and based on epithelial damage, submucosal edema, and infiltration of inflammatory cells. Kruskal–Wallis nonparametric test followed by Dunn's test. $^{a}P < 0.04$; $^{b}P < 0.007$. BBG: Brilliant Blue G.



considerable decrease in the percentage of S100B-positive immunostaining in the ileum of mice challenged with TcdA compared with that in the ileum TcdA-challenged mice, which were not pretreated with the blockers (P = 0.009).

Overall, these data indicated that the P2X7 receptor was involved in enteric neuronal loss and S100B synthesis induced by TcdA in mice.

DISCUSSION

The data of the present study indicated that TcdA upregulated the P2X7 receptor in the ileum of mice. An increase in the expression of P2RX7 has been reported in colonic biopsies from Crohn's disease patients[21] and in preclinical models of intestinal inflammation, such as colitis induced by trinitrobenzene sulfonic (TNBS) acid[22] and sepsis[23]. Thus, the upregulation of the P2X7 receptor is a common phenomenon under inflammatory conditions[24].

In the present study, we also demonstrated that the level of the P2X7 receptor was increased in the epithelial layer, lamina propria, and myenteric plexus. In the myenteric plexus, we detected an increase in the density of neurons expressing the P2X7 receptor, including the nNOS+ and Calr+ subtypes. In addition to enteric neurons, other cell types can express the P2X7 receptors, such as mast cells, T cells, and dendritic cells[21]. However, we focused on enteric neurons in the myenteric plexus because this component of the ENS is a major functional unit of the system that moves the luminal contents along the intestine by coordinating muscle contraction and relaxation[25]. In addition, *C. difficile* infection is characterized by intense diarrhea in the acute phase of the disease, and the mechanism of these events is poorly understood.

Figure 4 P2X7 receptor inhibition abrogates *Clostridioides difficile* toxin A-induced inflammation and cell death in mice. A-D: The levels of interleukin (IL)-1β (A), tumor necrosis factor-α (B), IL-6 (C), and keratinocyte chemoattractant (D) in the ileal samples of TcdA-unchallenged [control, Brilliant Blue G (BBG), and A438079] and challenged (TcdA, TcdA + BBG, and TcdA + A438079) mice measured by ELISA (n = 5); E: The number of TUNEL+ cells *per* field in the ileal samples of TcdA-unchallenged (control, BBG, and A438079) and challenged (TcdA, TcdA + BBG, and TcdA + A438079) mice. The data are expressed as the mean ± standard error of the mean. ANOVA followed by Tukey's test was used (^{a}P = 0.03; ^{b}P = 0.01; ^{c}P < 0.008; ^{d}P < 0.0001). IL: Interleukin; TNF: Tumor necrosis factor; BBG: Brilliant Blue G; KC: Keratinocyte chemoattractant; TUNEL: Terminal deoxynucleotidyltransferase-mediated dUTP-biotin nick end labeling.

We demonstrated that TcdA promoted neuron loss specifically by reducing the density of the Calr+ and ChaT+ neuronal populations. Acetylcholine, which is synthesized in a reaction of choline with acetyl-CoA catalyzed by ChaT, is the primary transmitter in excitatory motor neurons, intrinsic afferent neurons, and interneurons, and Calr is the primary transmitter in excitatory cholinergic neurons[26]. Excitatory motor neurons are involved in coordinated muscle contraction[25]; thus, a reduction in the density of Calr+ and ChaT+ neuronal populations induced by TcdA may be involved in the functional disorders manifested after *C. difficile* infection. Accordingly, a study performed in the United States military personnel reported functional gastrointestinal disorders (including gastroesophageal reflux disease, dyspepsia, irritable bowel syndrome, or constipation) after *C. difficile* infection recovery[6]. In the present study, alterations in the myenteric enteric neuron population induced by TcdA could have been related to these post-*C. difficile* infection-related intestinal dysfunctions. However, more studies are needed to better understand how these alterations specifically contribute to intestinal dysfunction induced by *C. difficile* infection.

In the present study, we also showed that the activation of the P2X7 receptor was involved in the TcdA-induced loss of enteric neurons because inhibition of the receptor by known P2RX7 antagonists (BBG and A438079) resulted in a substantial decrease in the loss of these ENS cells during ileitis induced by TcdA. In agreement with these data of the present study, another study demonstrated that the activation of P2RX7 promotes cell death in mucosal regulatory T cells in colitis induced by TNBS[27]. The P2X7 receptor regulates cell death pathways, such as apoptosis, pyroptosis, necrosis, and autophagy[28].

ATP released from dead cells can increase the activation of the P2X7 receptor and promote the secretion of proinflammatory cytokines, such as IL-1β, which in turn can induce the secretion of other cytokines[29,30]. In the present study, the blockade of the P2X7 receptor markedly decreased IL-1β, IL-6, KC, and TNF-α synthesis in the TcdA-challenged mouse ileum, suggesting that this receptor plays an important role in inflammation induced by *C. difficile* toxin. Similarly, in a model of TNBS-induced colitis, P2X7 receptor blockade reduces the severity of inflammation by decreasing the infiltration of macrophages in the lamina propria[31]. In contrast, deletion of P2RX7 increases the susceptibility to toxoplasmic ileitis[32], suggesting that the activation of this receptor plays a role in the response against intracellular pathogens. In contrast, *C. difficile* releases toxins, which in turn enter the cells to inhibit Rho GTPases, and the P2RX7 antagonists have positive effects in this case.

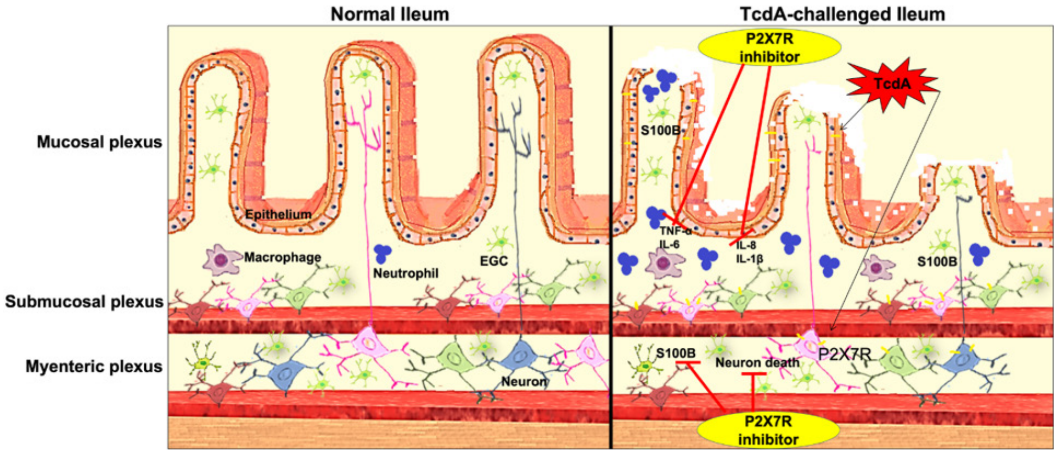

Figure 5 P2X7 receptor inhibition attenuates *Clostridioides difficile* toxin A-induced enteric neuron loss and S100B synthesis in mice. A: Representative immunohistochemical images of the expression of HuC/D (neuronal marker) and S100B (enteric glia marker) in the ileum of TcdA-unchallenged (control and A438079) and challenged (TcdA and TcdA + A438079) mice. Black arrows indicate positive immunostaining. Scale bars, 50 μm; B: Quantification of the percentage (mean ± standard error of the mean) of HuC/D- and S100B-immunopositive areas in the ileum of TcdA-unchallenged (control and A438079) and challenged (TcdA and TcdA + A438079) mice (n = 4 animals *per* group). ANOVA followed by Tukey's test was used (^aP = 0.04; ^bP = 0.01; ^cP < 0.009; ^dP < 0.0001). GFAP: Glial fibrillary acidic protein.

In addition, we demonstrated that blockade of the P2X7 receptor decreased S100B synthesis in the ileum of mice challenged with TcdA. S100B functions as a proinflammatory mediator when released at higher levels by activating the nuclear activation factor-κB[20] and is an important mediator during *C. difficile* infection[33]. In the myenteric plexus, EGCs express S100B[34] and are involved in the control of motility and epithelial barrier[35]. In a rat glioblastoma cell line, IL-6 promotes S100B synthesis[36]. In the present study, a reduction in proinflammatory cytokines related to P2X7 receptor blockade could have contributed to a decrease in S100B synthesis induced by TcdA, which in turn reduced intestinal inflammation and neuronal death.

Additional studies are needed, for example, using a *C. difficile* infection model, to explore how P2RX7 blockage can influence the *C. difficile* infection outcome and to better understand physiological benefits of this blockade for relief of intestinal permeability and dysmotility during the infection. However, it is important to emphasize that investigations of the role of this receptor in the damaging effects induced by one of the main virulence factors released by *C. difficile* will help to understand the pathogenesis of these effects and to develop alternative cotreatments to control the deleterious and exacerbated host response to the *C. difficile* toxins.

CONCLUSION

In conclusion, the results of the present study revealed the mechanism of P2X7 receptor-driven loss of enteric neurons induced by TcdA in the mouse ileum. TcdA promoted the upregulation of the P2X7 receptor, which promoted cell death in enteric neurons and induced the release of proinflammatory mediators (IL-1β, IL-6, KC, and TNF-α) in epithelial/immune cells, which in turn promoted S100B synthesis in EGCs. However, blockade of the P2X7 receptor abrogated ileal damage induced by TcdA (Figure 6). Overall, the findings of the present study open new avenues to better understand how *C.*

Figure 6 Scheme of the hypothetical role of the P2X7 receptor during *Clostridioides difficile* toxin A-induced ileitis. *Clostridioides difficile* TcdA promotes epithelial damage and the upregulation of the P2X7 receptor in enteric neurons, intestinal epithelial cells, and immune cells. Once activated, the P2X7 receptor promotes the death of enteric neurons and the release of proinflammatory mediators by epithelial/immune cells [interleukin (IL)-1β, IL-6, keratinocyte chemoattractant, and tumor necrosis factor-α]. These proinflammatory mediators induce S100B synthesis by enteric glial cells. Blockade of the P2X7 receptor using a pharmacological approach attenuates these deleterious effects of TcdA. IL: Interleukin; TNF: Tumor necrosis factor; EGC: Enteric glial cell.

difficile toxins promote the changes in the ENS components that can be related to intestinal dysfunction after *C. difficile* infection.

ARTICLE HIGHLIGHTS

Research background

The P2X7 receptor, a low-sensitivity adenosine triphosphate-gated cation channel, is expressed in several cell types, including enteric neurons. Once activated, the P2X7 receptor promotes the release of proinflammatory cytokines and neuromodulators. High levels of P2X7 receptor have been reported in enteric neurons during experimental colitis.

Research motivation

There is a knowledge gap regarding the population of enteric neurons affected by TcdA and the role of the P2X7 receptor in TcdA-induced alterations in enteric neurons and enteric glial cell-derived mediators, particularly S100B.

Research objectives

We characterized the population of myenteric neurons affected by TcdA during ileitis in mice. In addition, we investigated the role of the P2X7 receptor in ileal damage, inflammation, and the changes in enteric glia and neurons in TcdA-induced ileitis in mice.

Research methods

Swiss mice were used to model TcdA-induced ileitis in ileal loops exposed to TcdA (50 μg/Loop) for 4 h. To investigate the role of the P2X7 receptor Brilliant Blue G (50 mg/kg, i.p.), which is a nonspecific P2X7 receptor antagonist or A438079 (0.7 μg/mouse, i.p.), which is a competitive P2X7 receptor antagonist, were injected one hour prior to TcdA challenge. Ileum samples were collected to analyze the expression of the P2X7 receptor (quantitative real-time polymerase chain reaction and immunohistochemistry), the population of myenteric enteric neurons (immunofluorescence), histological damage, intestinal inflammation, cell death (terminal deoxynucleotidyltransferase-mediated dUTP-biotin nick end labeling), neuronal loss, and S100B synthesis (immunohistochemistry).

Research results

TcdA upregulated ($P < 0.05$) the expression of the P2RX7 gene in the ileal tissues, increasing the level of this receptor in myenteric enteric neurons compared with that in control mice. Comparison with control mice indicated that TcdA promoted ($P < 0.05$) the loss of myenteric calretinin+ (Calr) and choline acetyltransferase+ neurons and increased the number of nitrergic+ (nitric oxide synthase+) and Calr+ neurons expressing the P2X7 receptor. Blockade of the P2X7 receptor decreased TcdA-induced intestinal damage, cytokine release (interleukin (IL)-1β, IL-6, IL-8, and tumor necrosis factor-α), cell death, enteric

neuron loss, and S100B synthesis in the mouse ileum.

Research conclusions

The findings of the present study demonstrated that TcdA induced the upregulation of the P2X7 receptor, which promoted enteric neuron loss, S100B synthesis, tissue damage, inflammation, and cell death in the ileum of mice.

Research perspectives

These findings contribute to future directions in understanding the mechanism involved in intestinal dysfunction reported in patients after *Clostridioides difficile* infection.

Abstract

BACKGROUND

The healthcare burden of inflammatory bowel disease (IBD) is rising globally and there are limited non-invasive biomarkers for accurate and early diagnosis.

AIM

To understand the important role that intestinal microbiota play in IBD pathogenesis and identify anti-microbial antibody signatures that benefit clinical management of IBD patients.

METHODS

We performed serological profiling of 100 Crohn's disease (CD) patients, 100 ulcerative colitis (UC) patients and 100 healthy controls against 1173 bacterial and 397 viral proteins from 50 bacteria and 33 viruses on protein microarrays. The study subjects were randomly divided into discovery (n = 150) and validation (n = 150) sets. Statistical analysis was performed using R packages.

RESULTS

Anti-bacterial antibody responses showed greater differential prevalence among the three subject groups than anti-viral antibody responses. We identified novel

antibodies against the antigens of *Bacteroidetes vulgatus* (BVU_0562) and *Streptococcus pneumoniae* (SP_1992) showing higher prevalence in CD patients relative to healthy controls. We also identified antibodies against the antigen of *Streptococcus pyogenes* (SPy_2009) showing higher prevalence in healthy controls relative to UC patients. Using these novel antibodies, we built biomarker panels with area under the curve (AUC) of 0.81, 0.87, and 0.82 distinguishing CD *vs* control, UC *vs* control, and CD *vs* UC, respectively. Subgroup analysis revealed that penetrating CD behavior, colonic CD location, CD patients with a history of surgery, and extensive UC exhibited highest antibody prevalence among all patients. We demonstrated that autoantibodies and anti-microbial antibodies in CD patients had minimal correlation.

CONCLUSION

We have identified antibody signatures for CD and UC using a comprehensive analysis of anti-microbial antibody response in IBD. These antibodies and the source microorganisms of their target antigens improve our understanding of the role of specific microorganisms in IBD pathogenesis and, after future validation, should aid early and accurate diagnosis of IBD.

Key Words: Inflammatory bowel disease; Anti-microbial antibody; Protein microarray; Crohn's disease; Ulcerative colitis; Gut microbiome

Core Tip: We performed the largest serological profiling of anti-microbial antibodies to date in using 100 Crohn's disease (CD) and 100 ulcerative colitis (UC) patients. We identified novel anti-microbial antibodies with differential prevalence in inflammatory bowel disease (IBD) patients compared with healthy controls. There was minimal correlation between anti-microbial antibodies and our previously reported autoantibodies in CD patients. We combined novel anti-microbial antibodies to build biomarker panels distinguishing CD *vs* control, UC *vs* control and CD *vs* UC with an area under the curve of 0.81, 0.87, and 0.82, respectively. Subgroup analysis revealed that IBD patients with severe disease had the highest antibody prevalence.

INTRODUCTION

Inflammatory bowel disease (IBD) represents a group of intestinal disorders that causes chronic inflammation in the digestive tract. The two main clinical phenotypes are ulcerative colitis (UC) and Crohn's disease (CD). The public health burden of IBD is rising globally[1]. Early and accurate diagnosis is key to reducing this burden. Gastroenterologists often use a combination of relatively invasive procedures, like ileocolonoscopy with biopsy for diagnosis, and to determine the disease extent and activity. There is a need for serological biomarkers that can reveal the disease state non-invasively. Herein, our objectives were to discover anti-microbial antibody signatures in IBD patients and understand the association of microbial infection with IBD pathogenesis.

IBD is caused by a combination of genetic predisposition, faulty immune responses, and environmental factors[2]. The interaction of microbes with the gut mucosa in a genetically susceptible individual and the corresponding immune response play a pivotal role in the initiation and progression of IBD[3]. After birth, a limited diversity microbial community develops into a complex community due to the influence of diet and environmental factors[4]. During the second or third decade of life, a dysbiosis is observed in IBD patients which leads to an imbalance between commensal and potentially pathogenic microorganisms[5]. The healthy gut microbiota predominately comprises Firmicutes and Bacteroidetes, and to a lesser extent, Actinobacteria and Proteobacteria[6,7]. In IBD, dysbiosis is observed with reduced abundance of Firmicutes and either higher or similar abundance of Proteobacteria. Besides compositional changes, genetic alterations also contribute to gut dysbiosis that leads to disease initiation and progression. For example, NOD2 variants were found in 20%-40% of European and American CD patients[8,9]. NOD2 encodes an intracellular receptor for the bacterial peptidoglycan muramyl dipeptide, which helps maintain the balance of commensal bacterial flora[10].

Immune response to microbes results in the production of antibodies to microbial antigens[11]. Anti-*Saccharomyces cerevisiae* antibodies (ASCA) are associated with CD patients, with sensitivities and specificities ranging between 55% to 65% and 80% to 95%, respectively[12]. Perinuclear antineutrophil cytoplasmic antibodies (pANCA) are associated with UC patients, with sensitivities and specificities ranging between 50% to 71% and 75% to 98%, respectively[13]. Outer membrane protein of *Escherichia coli* (OmpC) and flagellin (CBir1) antibodies are prevalent in CD patients, with prevalence ranging between 24%-55% and 50%-56%[13]. The number and response magnitude of anti-microbial antibodies have previously been shown to indicate the presence of IBD, its severity and its clinical course; however, the clinical utility of available antibodies in diagnosis and clinical management of IBD patients has been limited. The techniques used to discover the known anti-microbial antibodies associated with IBD are of low throughput, and have only been applied to test on small number of candidate microorganisms or microbial antigens[14]. We have performed a large-scale comparative profiling of anti-microbial antibodies in CD and UC patients and healthy controls using an innovative protein microarray technology, namely Nucleic Acid Programmable Protein Array. We selected 1570 microbial proteins from our microbial protein collection (DNASU.org) from 50 bacteria and 33 viruses based on preliminary studies in our laboratory and a review of the literature, displayed them on microarrays and probed them against 100 CD, 100 UC and 100 healthy control serum samples.

MATERIALS AND METHODS

Patients and samples

All the serum samples were acquired from Serum Biobank at Mayo clinic with approval from institutional review board. CD patients were randomly selected, followed by age and gender matched healthy controls and UC patients. The samples (100 CD, 100 UC and 100 controls) were divided evenly into two non-overlapping discovery and validation sets randomly (Table 1). Disease status for study participants was assessed by clinicians at Mayo clinic.

Microbial protein array fabrication

We analyzed 1570 microbial proteins, of which 1173 proteins were from 50 different species of bacteria, 397 proteins were from 33 different species of viruses and the remaining proteins were autoantigens. These proteins were selected from our large collection of microbial antigens (DNASU.org) with reference to our anti-microbial antibody studies on other diseases (unpublished data). Microbial protein arrays were fabricated as described earlier[15,16]. Briefly, plasmids with genes of interest cloned in the pANT7_cGST expression vector were obtained from the DNASU plasmid repository, prepared, and printed into silicon nanowells using a piezoelectric dispensing system to produce microbial protein arrays. On the day of experiment, proteins were freshly expressed from printed plasmids using an *in-vitro* transcription and translation protein expression kit (Fisher Scientific) and captured by anti-GST antibody co-printed in each nanowell. After expression, microarrays were incubated with 1:100 diluted serum samples. We randomized the case and control serum samples while profiling on microarray to reduce bias. IgG and IgA anti-microbial protein antibodies were detected by Alexa-647 goat anti-human IgG (H+L) and Cy3 goat anti-human IgA (Jackson ImmunoResearch). After washing and drying, the microarrays were scanned in a Tecan PowerScanner and the raw fluorescence intensity data were extracted using the ArrayPro Analyzer Software. Raw fluorescence intensity of each protein on the microarray was divided by the median intensity of all the proteins on the microarray for normalization. The normalized value was termed as Median Normalized Intensity (MNI) and used for all analysis. Seropositivity of antibody for a particular antigen was defined as MNI ≥ 2 as we have done for our other studies[17,18].

Statistical analysis

Pairwise comparisons of numbers of IgG or IgA antibodies for each bacterial species among the 3 subject groups were performed using Chi-squared tests to assess statistical significance (Supplementary Figure 1). For each pairwise comparison, the Chi-squared *P* values were adjusted using the FDR (false discovery rate) method to reduce the likelihood of false positives. In addition to the multiple comparison adjustment at the antibody level, we performed adjustment at the species level.

For univariate analysis between two comparison groups, we calculated sensitivity for one group at the 96th percentile of the other group or the MNI of 2, whichever was larger. Antibodies with ≥ 14% sensitivity in the discovery set were selected as candidates for further validation. If an antibody had ≥ 14% sensitivity at 96% specificity in both discovery and validation sets, then it was considered as a "validated marker". Venn diagram for the overlap of microbial antigen targets were plotted using Venny[19].

We used a three-stage approach to build our multi-antibody panels. In the first stage, we selected all candidate biomarkers that passed the criteria above, *i.e.*, sensitivity was greater or equal than 14% at 96% specificity. Next, we applied the minimum redundancy maximum relevance algorithm to further select biomarkers that were possibly the most important and least correlated[20]. In the third stage, we

Table 1 Clinical information of the samples

	Discovery set			Validation set		
	CD	UC	HC	CD	UC	HC
N	50	50	50	50	50	50
Gender (female, male)	29, 21	29, 21	29, 21	28, 22	28, 22	28, 22
Age (median ± SD)	41 ± 17.66	44 ± 17.25	42 ± 18.47	39.5 ± 17.49	44.5 ± 17.23	39.5 ± 16.02
Disease behavior (B1/B2/B3)	9/10/6			16/8/2		
Disease location (L1/L2/L3/L4)	12/6/7/0			12/7/7/0		
Disease extent (E1/E2/E3)		0/32/18			0/34/16	
Surgery (Yes, No)	24, 25	8, 42		22, 27	7, 42	

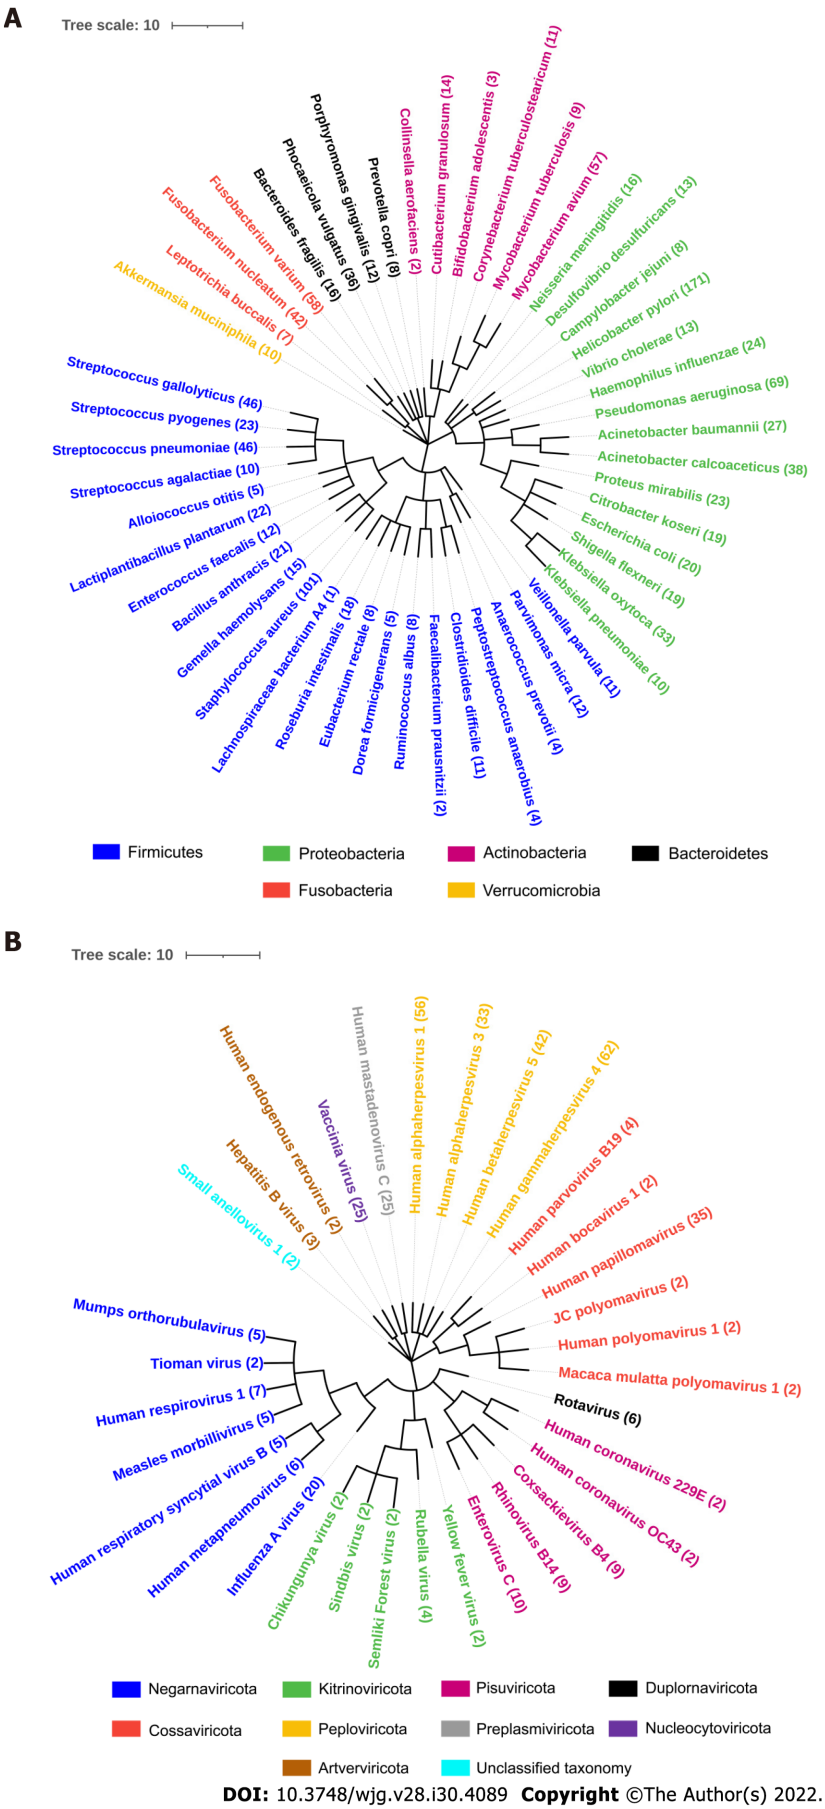
Fischer's exact test *P* value is equal to 1 for the gender difference among CD, UC and HC in both discovery and validation set. Kruskal-Wallis test *P* value for the age difference among CD, UC and HC in discovery and validation set were 0.3159 and 0.1737 respectively. CD: Crohn's disease; UC: Ulcerative colitis; HC: Healthy control.

fit a logistic regression model using the selected biomarkers from the first two stages and generated its receiver operating characteristic curve and AUC value to evaluate the model's discriminatory performance between CD, UC, and healthy controls.

Pair-wise subgroup comparisons based on the Montreal classification were performed for the odds ratio (OR) of each antibody using the seropositivity threshold defined as the maximum of MNI 2 and the 75th percentile of all samples. Chi-squared tests were used to test global significance between all groups with a slight modification by adding 0.5 to each cell of the table to avoid zero cell counts. *P* values from the Chi-squared method were adjusted for each pair of comparisons and for all candidate biomarkers. The number of antibodies with significant difference in prevalence among classifications were counted based on OR > 1 and OR < 1 for each pair of classification of CD behavior, CD location, UC extent and the surgery history of CD patients. The difference in total number of antibodies with significant difference between classification groups were computed using two sample proportion test. We did not perform a subgroup analysis for the UC patients based on the surgery history because most (84 out of 100) had no surgeries (Table 1).

Spearman's rank correlation analysis was performed to assess the correlation between autoantibody and anti-microbial antibody reactivity for CD patients and healthy controls. The R "pheatmap" package was used to generate the heatmap for correlation coefficients.

Bioinformatics analysis



The NCBI Taxonomy browser was used to find the taxonomical details of all the bacteria and viruses used in our study. The taxa were downloaded as phylip tree file and was used as an input in interactive tree of life software. Two phylogenetic trees were created for bacteria and viruses with different colors distinguishing the phylum.

For sequence homology analysis, a pair-wise BLAST analysis was carried out on the antigen protein sequences of validated antibodies for CD *vs* healthy control analysis. E-values were used to generate a heatmap using Python Seaborn package.

RESULTS

Anti-microbial antibody profiling in IBD on microbial protein arrays

We studied IgG and IgA anti-microbial antibody profiles of 100 CD and 100 UC patients and 100 age-gender matched healthy controls (Table 1) against 1570 microbial antigens including 1173 antigens from 50 different bacteria and 397 antigens from 33 different viruses using our protein microarray platform (Figure 1, Supplementary Table 1). This study provided a representative overview of the anti-microbial antibody response in IBD patients (Supplementary Figure 1). The numbers of IgG antibodies against bacterial proteins from *Bacteroidetes vulgatus* (*B. vulgatus*) and *Citrobacter koseri* (*C. koseri*) were significantly higher in CD patients compared with those in healthy controls (Chi-square test, $P < 0.01$) (Supplementary Figure 1). On the contrary, the numbers of IgG antibodies against proteins from several bacteria, such as *Streptococcus pneumoniae* (*S. pneumoniae*), *Haemophilus influenza* (*H. influenzae*), *Staphylococcus aureus* (*S. aureus*), *Helicobacter pylori* (*H. pylori*) and *Parvimonas micra* (*P. micra*) were significantly lower in CD and UC patients compared with those in healthy controls (Chi-square test, $P < 0.05$)

Figure 1 Phylogenetic tree of microbes studied with their corresponding number of proteins analyzed. A: Fifty species of bacteria with 1173 proteins were segregated into 6 phyla; B: Thirty-three species of viruses with 397 proteins were segregated into 10 phyla.

(Supplementary Figure 1). Overall, fewer IgA anti-microbial antibodies were found than IgG antibodies. The numbers of IgA antibodies against *S. pneumoniae*, *H. influenzae*, *S. aureus*, and *H. pylori* were significantly lower in UC patients compared with those in healthy controls (Chi-square test, $P < 0.01$). On the other hand, anti-viral IgG and IgA antibodies showed heterogenous prevalence with no clear trend of differences among CD, UC, healthy controls (data not shown). Therefore, we focused our analysis on anti-bacterial antibodies.

Antibodies distinguishing CD from healthy controls

We compared prevalence for individual anti-microbial antibodies between CD patients and healthy controls. We randomly split samples evenly into discovery and the validation sets (Table 1). For antibodies with elevated prevalence in CD patients, 13 IgG antibodies passed the criteria (sensitivity ≥ 14% at 96% specificity) in both discovery and validation sets (Table 2). Anti-A4-Fla2_IgG, a well-studied anti-bacterial flagellin antibody in CD, had the best performance with 47% sensitivity at 96% specificity in the full sample set (Table 2). Beside the flagellins, we found antibodies to four novel target antigens from *B. vulgatus* (BVU_0562), *P. mirabilis* (PMI_RS06815), *S. flexneri* (SF_Lpp) and *S. pneumoniae* (SP_1992) (Table 2) with no significant sequence homology to flagellins (Figure 2A).

To our surprise, 12 validated IgG antibodies showed elevated prevalence in healthy controls relative to CD patients (Supplementary Table 2). Among these 12 antibodies, anti-bacterial antibodies performed better in differentiating CD patients from healthy controls than anti-viral antibodies (Supplementary Table 2). Antibody against SPy_2009, an anchoring protein located in the cell wall of *Streptococcus pyogenes* (*S. pyogenes*), had the highest sensitivity of 24% at 96% specificity in healthy controls relative to CD patients. Seven validated IgA antibodies showed higher prevalence in healthy controls relative to CD patients (Supplementary Table 4).

Antibodies distinguishing UC from healthy controls

For anti-microbial antibodies with elevated prevalence in UC patients relative to healthy controls, 4 IgG antibodies passed the criteria in both discovery and validation sets (Table 2). Antibodies to A4-Fla2_IgG and a flagellin from *C. koseri* had a sensitivity of 18% and 15% respectively. For IgG antibodies with higher prevalence in healthy controls relative to UC patients, 32 antibodies got validated (Supplementary Table 3). Source microorganisms for the target antigens of these 32 antibodies were enriched for *S. pneumoniae, S. aureus,* and *H. influenzae* (2-sample proportion test, $P < 0.05$). 2.7% of the proteins on the microbial protein microarray were from *S. pneumoniae* while 18.7% of antigens for validated antibodies were from *S. pneumoniae*, 6.1% of the proteins on the microarrays were from *S. aureus* while 18.7% of antigens for validated antibodies were from *S. aureus,* and 1.4% of the proteins on the microarrays were from *H. influenzae* while 12.5% of antigens for validated antibodies were from *H. influenzae*. Nine validated IgA antibodies showed higher prevalence in healthy controls relative to UC patients (Supplementary Table 4).

Fewer anti-viral antibodies than anti-bacterial antibodies were validated comparing CD or UC patients with healthy controls (Table 2, Supplementary Tables 2 and 3). Anti-viral antibodies to Rhinovirus B14, Enterovirus C, Influenza A virus, Human metapneumovirus had higher prevalence in healthy controls compared with CD and UC patients (Supplementary Tables 2 and 3).

Comparison of anti-microbial antibody response between CD and UC

We found 46 IgG and 22 IgA validated anti-microbial antibodies with higher prevalence in CD patients compared to UC patients while 28 IgG and 9 IgA validated anti-microbial antibodies with higher prevalence in UC patients compared to CD patients. There was minimal overlap of the target antigens of these validated IgG and IgA antibodies (Figure 2B).

Multivariate analysis to distinguish CD, UC, and healthy controls

We built multi-antibody panels that could distinguish CD *vs* control, UC *vs* control, and CD *vs* UC with an area under the curve (AUC) of 0.81, 0.87, and 0.82 respectively. For CD *vs* control, antibodies against novel flagellins (HP_0115, CK_LafA, CK_LafA.1, VC_flaD, VC_flaB, VC_flaE, VC_flaA) had an AUC of 0.73, antibodies against non-flagellins (BVU_0562, SP_1992, PMI_RS06815, and SF_Lpp) had an AUC of 0.75 and the combined AUC of antibodies against novel flagellins and non-flagellins was 0.81 (Figure 3A). For UC *vs* control, a combination of seven antibodies, four against *S. pneumoniae* and one each against *S. aureus*, *H. influenzae* and *B. vulgatus* had an AUC of 0.87 (Figure 3B). For CD *vs* UC, combination of seven antibodies, two against *H. pylori* and one each against *E. coli*, *S. pneumoniae*, *S. pyogenes*, *C. jejuni* and *L. bacterium A4* had an AUC of 0.82 (Figure 3C).

Subgroup analysis

We investigated the association of CD behavior (B1, B2, B3), CD location (L1, L2, L3), and UC extent (E1, E2, E3) based on the Montreal classification with the anti-microbial antibody prevalence. We calculated the 4th quartile odds ratio for each antibody between the two classification groups and compared the number of antibodies with significant odds ratio (P value < 0.05) in each group. We found B3 (penetrating) had the highest prevalence of antibodies followed by B2 (stricturing) and B1 (non-

Table 2 Sensitivities of validated IgG antibodies comparing Crohn's disease and ulcerative colitis with healthy controls in the discovery, validation, and the entire set at 96% specificity

		Antigen	Protein name	Organism	Discovery	Validation	Entire

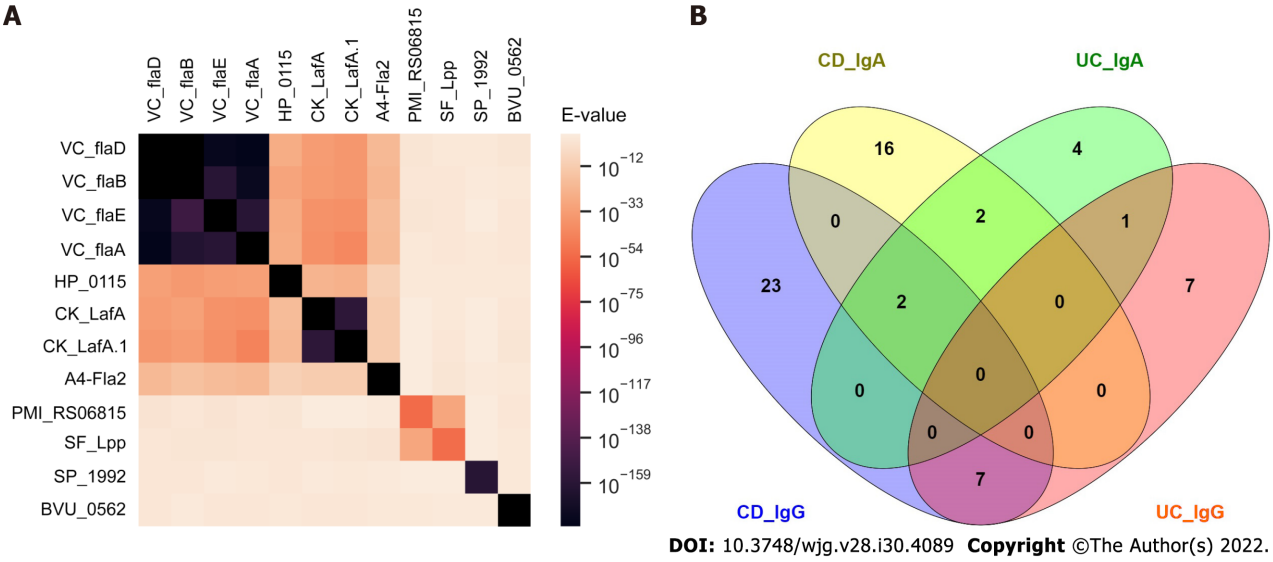
stricturing, non-penetrating) (Table 3). For CD location, we found L2 had the highest prevalence of antibodies followed by L3 (ileocolonic) and L1 (Table 3). For UC extent, E3 (extensive UC) had higher prevalence of antibodies compared to E2 (left sided UC). In addition to the Montreal classification, we also performed subgroup analysis based on the surgery history of CD patients. We found that patients who had surgery possessed higher prevalence of antibodies compared to those without surgery (Table 3).

Correlation of anti-microbial antibodies and autoantibodies in CD patients

We previously reported novel autoantibodies in CD patients using the same set of CD patients and healthy controls[21]. We profiled both IgG and IgA autoantibodies and anti-microbial antibodies in all 100 CD and 100 healthy controls. It is interesting to note the antibodies showing differences for autoantibodies were mostly IgA, but the anti-microbial antibodies were mostly IgG[21]. Anti-SNRPB_IgA had the highest sensitivity of 20% at 96% specificity among all autoantibodies compared with 47% sensitivity at 96% specificity for the best performing anti-microbial antibody, anti-A4-Fla2_IgG.

We compared the novel autoantibodies and validated anti-microbial antibody profiles to determine if correlation existed between their reactivity. Overall, we did not observe high correlation between autoantibodies and anti-microbial antibodies in CD patients (Figure 4). Anti-microbial antibodies formed two clusters, one with anti-flagellin antibodies, and the other with SF_Lpp_IgG and PMI_RS06815_IgG. Five autoantibodies, PRPH_IgA, SNAI1_IgA, PPP1R13L_IgA, SNRPB_IgA and PTTG1_IgA, formed a cluster. The remaining antibodies had relatively unique reactivity patterns.



DISCUSSION

We have performed a microbiomics study to understand the connection between host anti-microbial responses and IBD and to identify antibody signatures that can aid in the accurate diagnosis of IBD. We found antibody responses to novel non-flagellin antigens with elevated prevalence in CD patients compared with healthy controls. On the contrary, we observed many anti-microbial antibodies with

Table 3 Subgroup analysis of inflammatory bowel disease patients

Classification	Comparison	Number of antibodies with		Two sample proportion test
		OR > 1	OR < 1	
Disease behavior: B1: non-stricturing, non-penetrating; B2: stricturing; B3: penetrating	B1 *vs* B2 ($P < 0.05$)	0	32	$P < 0.001$
	B2 *vs* B3 ($P < 0.05$)	0	19	$P < 0.001$
	B1 *vs* B3 ($P < 0.05$)	2	41	$P < 0.001$
Disease location: L1: ileal; L2: colonic; L3: ileocolonic	L1 *vs* L2 ($P < 0.05$)	0	38	$P < 0.001$
	L2 *vs* L3 ($P < 0.05$)	9	5	$P = 0.131$
	L1 *vs* L3 ($P < 0.05$)	5	16	$P < 0.001$
Disease extent: E2: left sided UC; E3: extensive UC	E2 *vs* E3 ($P < 0.05$)	11	39	$P < 0.001$
Surgery in CD patients	No *vs* Yes ($P < 0.05$)	6	25	$P < 0.001$

For each comparison, the number of antibodies with significant difference in prevalence between two classifications were counted based on odds ratio (OR) > 1 and OR < 1. The difference in total number of antibodies for each comparison were computed using two sample proportion test. CD: Crohn's disease; UC: Ulcerative colitis; OR: Odds ratio.

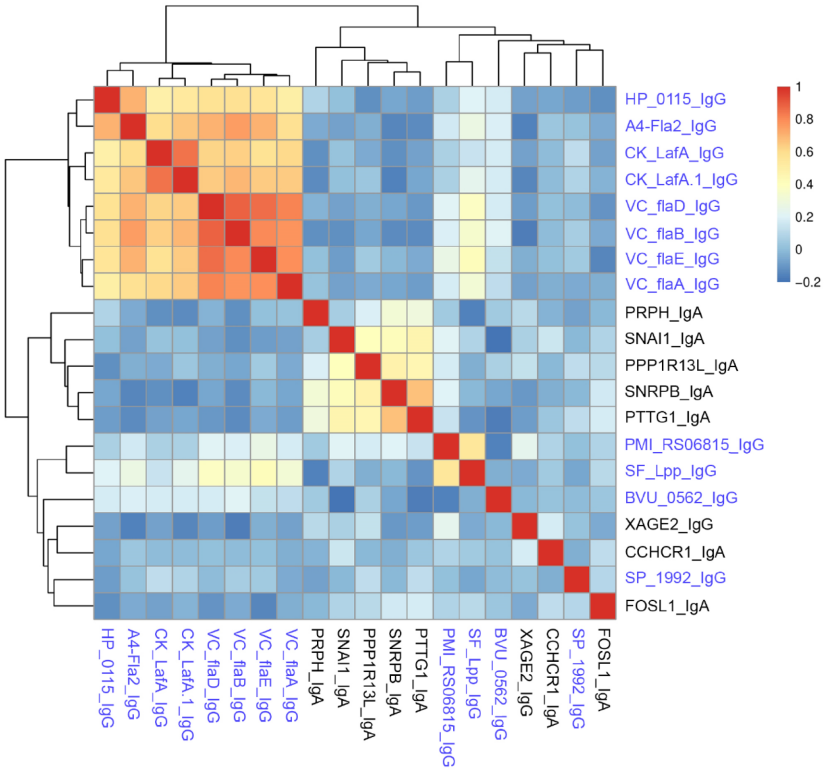
Figure 2 Sequence homology of target antigens of validated antibodies and overlap of antibodies among Crohn's disease and ulcerative colitis. A: Heatmap showing sequence homology among target antigens for antibodies with validated performance of ≥ 14% sensitivity at 96% specificity comparing Crohn's disease (CD) patients with healthy controls; B: CD_IgG, ulcerative colitis (UC)_IgG, CD_IgA and UC_IgG represent the overlap of anti-microbial antibodies of IgG and IgA isotypes in CD and UC patients with ≥ 14% sensitivity at 96% specificity against healthy controls in the discovery set. CD: Crohn's disease; UC: Ulcerative colitis.



lower prevalence in UC patients relative to healthy controls. We built antibody panels that could distinguish CD *vs* control, UC *vs* control and CD *vs* UC with AUCs of 0.81, 0.87, and 0.82, respectively. Lichtenstein *et al*[22] reported an integrated serological (ASCA-IgA, ASCA-IgG, anti-OmpC, anti-CBir1, anti-I2, pANCA) and genetic (SNP8, SNP12, SNP13) marker panel with an AUC of 0.80 to distinguish CD *vs* control. A panel of serological markers (ASCA-IgA, ASCA-IgG, ANCA, pANCA, OmpC, and CBir1) built by Plevy *et al*[23] yields an AUC of 0.78 to distinguish CD *vs* UC. Our novel antibody marker panels had comparable or better performance in IBD diagnosis or distinguishing CD from UC subtypes. We observed a stronger anti-microbial antibody response with more aggressive disease in both CD and UC patients. Finally, we demonstrated that anti-microbial antibodies and autoantibodies had different reactivity patterns in CD patients.

Our comprehensive study of anti-microbial antibodies in IBD patients provided interesting insight into its pathogenesis. Antibody responses to proteins from *B. vulgatus*, *P. mirabilis*, *S. flexneri* and *S. pneumoniae* were elevated in CD patients. *B. vulgatus* has been reported to induce colitis in IBD-susceptible mice[24,25]. *P. mirabilis* in gut can induce inflammation in cells and a colitis mouse model and has been associated with CD pathogenesis[26]. Our results suggest that *B. vulgatus* and *P. mirabilis*

may also play a role in human CD development. We observed reduced antibody responses in UC patients to several genera of the Firmicutes phylum including *P. micra*, *S. pyogenes*, *S. aureus*, which were often reduced in abundance in UC patients' gut microbiota[27]. For several genera belonging to Proteobacteria phylum, such as *H. influenzae*, *H. pylori*, *K. oxytoca*, we observed overall reduced antibody responses; however, their abundance in the gut microbiota of UC patients has been reported to be either increased or remained the same compared with healthy controls[6,28].

Beyond exposure alone, antibody response requires functional immunological interaction between a microorganism and the host; however, anti-microbial antibodies by themselves do not prove causality. As such, source microorganisms whose antibodies show significant changes between IBD patients and healthy controls warrant future confirmation and functional assessment in causing IBD. A4-Fla2

flagellin included in our study showed IBD-specific prevalence with performance similar to that reported in the literature[14,29]. We also identified several antibodies to flagellins with higher prevalence in CD patients relative to healthy controls.

Previous studies mostly focused on antibodies with higher prevalence in IBD patients[30]. Our unbiased data-driven approach revealed the existence of many anti-microbial antibodies with higher prevalence in healthy controls relative to CD and especially UC patients (Supplementary Tables 3 and 4). The reduction observed in CD and UC patients may be attributed to the dysbiosis and reduced diversity of gut microbiota in CD and UC patients[28,31]. It is also possible that the reduction in anti-microbial antibodies in some CD and UC patients was in part because of immunosuppressive therapies they received. The greater number of antibodies having high prevalence in CD patients compared with UC patients indicates stronger anti-microbial humoral immunity in CD than in UC, which is consistent with reports in the literature that most known anti-microbial antibodies, such as ASCA, anti-OmpC, anti-Cbir1, and anti-I2, had higher prevalence in CD patients than in UC patients[30]. This agreement, together with comparable performance of anti-flagellin antibodies in our study and that reported in the literature, suggests that our results reflect the microbial association of IBD etiopathology. However, the use of samples from patients with established disease and the lack of information on immunosuppressive therapies of these patients limited the interpretation of the results.

We studied the association between anti-microbial antibody prevalence and various disease classifications based on Montreal classification and surgery history. We found more antibodies with significantly higher prevalence in patients with more aggressive disease behaviors relative to those with milder disease behavior. We also found more antibodies with significantly higher prevalence in colonic CD patients relative to those in ileal CD patients. Our results were consistent with previous reports that increasing diversity and magnitude of anti-microbial immune response was correlated with increased frequency of penetrating and/or stricturing disease behavior[13,32]. It is known that the colon has a microbial density of 10^{11}-10^{12} anaerobic bacteria/gram while the ileum is colonized by 10^{7}-10^{8} anaerobic bacteria/gram[7]. Kleessen *et al*[33] found higher percentage of bacterial invasion of mucosa in colon compared to ileum. CD patients requiring surgery usually had more severe disease compared with those who did not need surgery. Stronger anti-microbial immune response in patients with severe CD or UC suggests a higher abundance of the source microorganisms for the target antigens of the differential antibodies and/or a stronger more conducive immune microenvironment at the disease site in severe disease.

Both autoantibodies and anti-microbial antibodies associated with IBD have been reported[30]. One popular hypothesis for the autoantibody elicitation is molecular mimicry, where anti-microbial antibodies cross react with human proteins. However, we found minimal correlation between the anti-microbial antibodies and the autoantibody profiles in the same set of CD samples. The lack of correlation suggests that IBD-specific autoantibodies and anti-microbial antibodies are elicited independently through different underlying mechanisms, and cross-reactivity may play less of a role in eliciting CD-associated autoantibodies. The breakdown of immune tolerance to human proteins might have occurred due to the damaged gut epithelial cells and the faulty immunological microenvironment partly caused by microbial infections. In addition, the elicitation of autoantibodies may be associated with the infections of multiple microorganisms, and the correlation with individual anti-microbial antibodies may not be great.

Strengths of our study include the broadest analysis to date of IgG and IgA antibodies against individual antigens from many different microorganisms in both CD and UC patients and the use of a two-stage approach with discovery and independent validation of antibody markers. There are some limitations to our study. Except for a few microbes, the number of proteins studied for each species is small, which might limit our interpretation of antibody response in IBD at the species level. Furthermore, many samples used in studies were collected from patients with established disease. Future studies with access to more clinical information, such as information about the use of immunosuppressive or antibiotics treatment, could aid in the interpretation of our results. In addition, samples collected from newly diagnosed patients will strengthen our ability to identify diagnostic markers and microbial connections for IBD development.

CONCLUSION

In summary, we have demonstrated the power of a microbiomics study of anti-microbial antibodies in IBD for the identification of anti-microbial antibody signatures to improve early accurate diagnosis and help understand IBD etiology. The elucidation of the source microorganisms of the target antigens of the antibody biomarkers could lead to novel strategies for the prevention of IBD.

ARTICLE HIGHLIGHTS

Research background

Early and accurate diagnosis of inflammatory bowel disease (IBD) can benefit the clinical management of IBD patients. The clinical utility of available non-invasive biomarkers is limited.

Research motivation

The gut microbiota plays an important role in the pathogenesis of IBD. Antibody responses to microbial antigens can be exploited to identify better diagnosis markers and improve our understanding of IBD pathology.

Research objectives

This study aimed to compare anti-microbial antibody profiles in Crohn's disease (CD) and ulcerative colitis (UC) patients and healthy controls.

Research methods

We employed an innovative protein microarray platform and profiled antibodies against 1570 microbial antigens in 100 CD, 100 UC, and 100 healthy controls.

Research results

Antibodies to bacterial proteins were better in distinguishing IBD patients from healthy controls compared with antibodies to viral proteins. We identified a set of novel anti-microbial antibodies against the antigens of *Bacteroidetes vulgatus* (BVU_0562) and *Streptococcus pneumoniae* (SP_1992) elevated in CD patients relative to healthy controls. In addition, anti-microbial antibodies against the antigen of *Streptococcus pyogenes* (SPy_2009) were found to be elevated in healthy controls relative to UC patients. We constructed antibody panels that could distinguish CD *vs* control, UC *vs* control, and CD *vs* UC with an AUC of 0.81, 0.87 and 0.82 respectively. Patients with severe disease had higher prevalence of anti-microbial antibodies. There was minimal correlation among the occurrence of autoantibodies and anti-microbial antibodies in CD patients.

Research conclusions

This study discovered novel anti-microbial antibodies with differential prevalence in CD and UC patients relative to healthy controls. In addition, this study revealed the potentially different roles of gut microbiota in CD and UC pathology.

Research perspectives

Our study demonstrated the power of a microbiomics approach to identify biomarkers that could aid in the early and accurate detection of IBD non-invasively, and shed light into the role of various microbes in IBD etiology.

ACKNOWLEDGEMENTS

The authors would like to thank Jessica Friton for her help with patient sample and data acquisition. The authors would like to thank Shehzad Sheikh for helpful suggestions to improve the manuscript.

FOOTNOTES

Author contributions: Shome M and Song L designed and ran the experiment; Williams S and Chung Y performed the statistical analysis; Murugan V and Park JG helped in preparation of clones; Faubion W, Pasha SF and Leighton JA provided the serum samples and also provided intellectual guidance; LaBaer J and Qiu J supervised the project and secured funding; Shome M and Qiu J wrote the original manuscript which was then reviewed by remaining authors.

Institutional review board statement: The authors have taken appropriate steps to protect the rights and welfare of humans participating as subjects in the research (IRB Application #: 13-008267).

Informed consent statement: All study participants or their legal guardian of the study provided informed written consent about personal and medical data collection prior to study enrollment.

Conflict-of-interest statement: All the authors report no relevant conflicts of interest for this article.

Data sharing statement: Data from this study is available on request from the corresponding author.

STROBE statement: The authors have read the STROBE Statement-checklist of items, and the manuscript was prepared and revised according to the STROBE Statement-checklist of items.

Open-Access: This article is an open-access article that was selected by an in-house editor and fully peer-reviewed by external reviewers. Abstract

BACKGROUND

Medications for inflammatory bowel disease (IBD) have changed dramatically over time. However, no study on long-term medication profiles has been conducted in the Chinese population.

AIM

To evaluate temporal changes in medication use and treatment patterns for Chinese patients with IBD.

METHODS

A multicenter retrospective cohort study was conducted among Chinese patients newly diagnosed with Crohn's disease (CD) and ulcerative colitis (UC) between January 1999 and December 2019. Baseline characteristics and drug prescriptions were collected. Trends in medication use and therapeutic patterns were analyzed.

RESULTS

In total, 3610 patients were analyzed. During follow-up, 5-aminosalicylates (5-ASA) and corticosteroids (CS) prescriptions gradually decreased, accompanied by a notable increase in immunosuppressants (IMS) and infliximab (IFX) prescriptions in patients with CD. Prescription rates of 5-ASA and CS were stable, whereas IMS and IFX slightly increased since 2007 in patients with UC. Subgroup (n = 957) analyses showed a switch from conventional medications to IFX in patients with CD, while 5-ASA and CS were still steadily prescribed in patients with UC. Logistic regression analyses revealed that surgical history, disease behavior, and disease location were associated with initial therapeutic strategies in patients with CD. However, medications before diagnosis, disease location, and diagnostic year might affect initial strategies in patients with UC.

CONCLUSION

Long-term treatment strategies analyses has provided unique insight into the switch from conventional drugs to IFX in Chinese patients with CD.

Key Words: Inflammatory bowel disease; Crohn's disease; Ulcerative colitis; Medication trends; Treatment pattern; Infliximab

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Prescriptions of immunosuppressants and infliximab (IFX) increased in parallel with steady or decreasing prescriptions of 5-aminosalicylates and corticosteroids in Chinese patients with inflammatory bowel disease. Furthermore, a switching profile from conventional drugs to IFX was observed in patients with Crohn's disease. This is the first multicenter cohort study to depict temporal trends in long-term medication uses and periodic changes in treatment paradigms in the Chinese population, which may provide evidence for clinical practice in the foreseeable future.

INTRODUCTION

Inflammatory bowel diseases (IBD), consisting of Crohn's disease (CD) and ulcerative colitis (UC), are chronic debilitating disorders characterized by alternating periods of relapse and remission[1,2]. With a growing incidence worldwide, IBD cases in China are expected to exceed 1.5 million by 2025[3]. In light of the need for lifelong medical interventions, IBD poses a global public health challenge.

Owing to the rapid development of new drugs, IBD medications have launched in succession and changed in the past few decades, especially following the discovery of infliximab (IFX), the first anti-tumor necrosis factor agent, which has revolutionized the field[4,5]. Several attempts have been made by Western and other Asian countries to provide rough medication changes. Specifically, increasing proportions of immunomodulators and biological agents have been observed, accompanied by decreasing prescription rates of 5-aminosalicylates (5-ASA) and corticosteroids (CS)[6-8]. A few studies have been carried out on annual changes in IBD medications, including 5-ASA and CS[9,10]. However, no long-term analysis of medication tendency has been conducted in a large population of Chinese patients with IBD.

Drug diversification enables treatment combinations for better therapeutic effects[11]. However, combination treatment also correlates with increasing risks of side effects[12,13]. Therefore, patients might switch treatment strategies to acquire optimal effects from IBD medications under different circumstances. Currently, minimal attention has been paid to periodic changes in IBD treatment strategies. Additionally, initial treatment strategies affect follow-up therapeutic patterns to some extent; thus, investigating the possible predictors for initial treatment strategies may help to better understand periodic changes in therapeutic patterns in patients with IBD.

Therefore, this study aimed to provide fresh insights into temporal trends in medication prescriptions among the Chinese patients with IBD for over 20 years. The study also aimed to investigate long-term periodic changes in treatment paradigms and identify the possible factors that influence initial drug strategies.

MATERIALS AND METHODS

Study design

This multicenter retrospective cohort study included 12 IBD referral centers across all seven administrative regions in China with diverse socioeconomic backgrounds. The study protocol was reviewed and approved by Sir Run Run Shaw Hospital, College of Medicine Zhejiang University Institutional Review Board (Approval No. 20210714-31) with approval for all hospitals involved in the study. The requirement for patient informed consent was waived due to the retrospective nature of this study.

Study population

Incident adult patients with a definite diagnosis of CD or UC according to the Chinese consensus on IBD diagnosis, which was similar to that of the European Crohn's and Colitis Organization (ECCO) consensus, between January 1, 1999 and December 31, 2019 were included[14,15]. Patients were excluded from analyses for medication trends if the cessation date of medications was unclear. Additionally, patients were further excluded from analyses for treatment patterns if: (1) They were followed up for < 3 years since diagnosis; or (2) No prescription of either 5-ASA, CS, immunosuppressants (IMS), or IFX was administered throughout follow-up. Cases were followed from diagnosis until loss to follow-up, or December 31, 2020, whichever came first.

Data collection and definition

Patients were identified using International Classification of Diseases 8th and 10th revision codes for CD (563.00–563.09 and K50) and UC (563.19, 569.04 and K51), respectively. Data regarding baseline characteristics and prescriptions since diagnosis were collected by reviewing medical records and digitized into the Epidata 3.0. Data quality was ensured using standardized case report forms and careful manual scrutinization.

Demographic parameters including sex, date of first IBD-related symptoms, date of initial diagnosis, smoking status, region of urbanization, occupation, and clinical parameters including disease location, disease activity, extraintestinal manifestations (EIMs), IBD family history, gastrointestinal surgical history, and medication use within six months before diagnosis were collected from patients with IBD. Additionally, disease behavior, perianal involvement, and perianal surgical history were also collected from patients with CD. Other relevant variables were calculated, including median age of onset and diagnosis, median interval from onset of symptoms to diagnosis, median follow-up duration, and body mass index (BMI) at diagnosis.

Smoking status was defined by smoking habits at diagnosis. EIMs classification originated from the 2016 ECCO consensus[9]. Disease location for IBD and CD behavior were defined according to the Montreal classification[10]. Disease activity was acquired from medical records using the Crohn's Disease Activity Index (CDAI) and Mayo score for CD and UC, respectively, and was assessed and recorded by IBD nurses when patients were first diagnosed[16,17].

Statistical analysis

Continuous variables are presented as medians with interquartile ranges (IQRs), and categorical variables as numbers with percentages. A T-test or Mann-Whitney U test was used to compare

continuous variables, and Chi-square test or Fisher's exact test was used to compare categorical variables.

The initiation date of medications (including 5-ASA, CS, IMS, and IFX) since diagnosis was set as the first prescription date, and the last date was calculated as the first prescription date plus the number of prescription days. Annual percentage of each drug used among all available patients was plotted against every calendar year to demonstrate medication trends from 1999 to 2020. To conduct subgroup analysis for periodic changes in treatment paradigms, the study period was divided according to the following time points since diagnosis: 1, 3, 6, 12, 24, and 36 mo. The frequency and percentage of different drug combination strategies were plotted against different periods to illustrate periodic changes in drug patterns with a 3-year follow-up. To investigate possible factors for initial treatment strategies, we incorporated drugs into the following combination strategies. For CD, initial medications were classified as: (1) CS (CS monotherapy or combined with 5-ASA); (2) CS + IMS (CS combined with IMS); and (3) IFX [IFX monotherapy or combined with conventional drugs (5-ASA, CS, or IMS)]. For UC, initial medications were classified as: (1) 5-ASA (5-ASA monotherapy); (2) CS (CS monotherapy or combined with 5-ASA); and (3) IFX/IMS (IFX monotherapy, IMS monotherapy, or IFX combined with IMS). Predictors for initial drug strategies were identified using logistic regression analysis and presented as odds ratios and 95% confidence intervals.

P value < 0.05 were considered a statistically significant difference. Statistical analyses were conducted using SAS 9.4 (SAS Institute, Cary NC, United States), and graphs were plotted using R software (version 4.1) with the "ggplot2" and "ggalluvial" packages[18,19].

RESULTS

Baseline characteristics

Altogether, 3610 patients were included in the analysis for temporal changes in medication use (2208 and 1402 patients with CD and UC, respectively). Furthermore, 957 patients were included in the analysis for periodic changes in treatment patterns (686 and 271 patients with CD and UC, respectively), after excluding 2452 patients who were followed up < 3 years since diagnosis, and 201 patients with no prescription of either 5-ASA, CS, IMS, or IFX throughout follow-up (Figure 1).

Patient baseline characteristics are summarized in Table 1. The median (IQR) follow-up duration was 1.6 (0.3-3.8) years, the median (IQR) age at diagnosis was 33.0 (25.0-48.0) years, and male accounted for 46.2% of patients. Similar patterns were found in the region of urbanization and IBD family history between CD and UC, except for male sex (P < 0.0001), median age of onset (P < 0.0001), median age at diagnosis (P < 0.0001), median interval from onset to diagnosis (P < 0.0001), median follow-up duration (P < 0.0001), smoking status (P < 0.0001), occupation (P < 0.0001), BMI category (P < 0.0001), EIM classification (P < 0.0001), gastrointestinal surgical history (P < 0.0001), and drug history (medication use within six months before diagnosis; P < 0.0001).

The differences in baseline characteristics between included and excluded patients in the analysis for periodic changes in treatment patterns are shown in Table 2. Briefly, patients who were included in further analysis were prone to be younger at the age of onset and diagnosis (P < 0.001), accompanied with EIMs (P = 0.0096), and underwent perianal surgeries before diagnosis (P < 0.0001). Moreover, patients with UC had a higher risk of proctitis and left-sided involvement (P = 0.0005), and patients with CD had higher proportion of moderate severity (P = 0.0002).

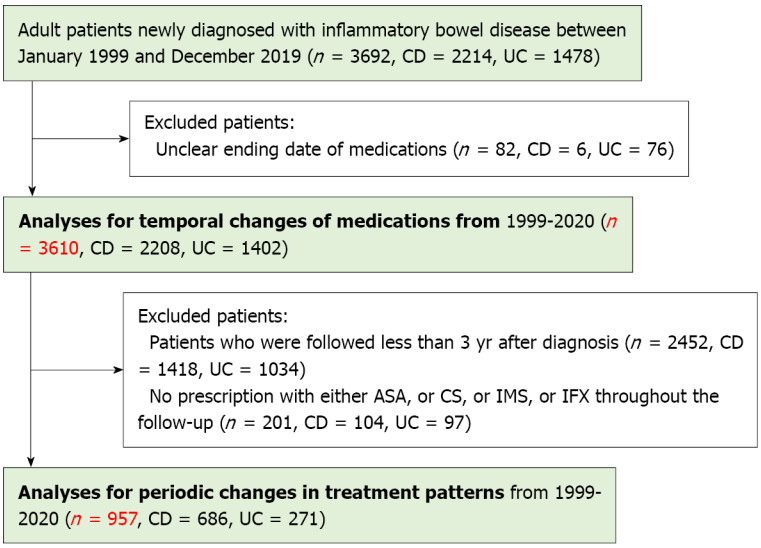
Temporal trends in medication use

Proportions of different prescriptions during the 20-year follow-up of patients with CD are depicted in Figure 2A and Supplementary Table 1. The prescription rate of 5-ASA showed a steady decline from 50.0% in 2002 to 5.5% in 2020, and a similar trend was observed for CS. Meanwhile, the prescription rate of IMS increased prominently from 2005 onwards, but decreased slightly between 2018 and 2020. The prescription rate of IFX has gradually increased since 2008, reaching 60.3% in 2020.

We also reported the proportions of different prescriptions among patients with UC (Figure 2B and Supplementary Table 2). 5-ASA and CS were steadily prescribed between 1999 and 2020. IMS was first prescribed in 2007, increasing slightly to 8.5% in 2020. Parallel to IMS, a gentle increase was observed in the proportion of IFX prescriptions between 2009 and 2020.

Periodic changes in treatment patterns

Therapeutic regimens were evaluated for three consecutive years after diagnosis. As IFX was first prescribed between 2008 and 2009 in China, we further divided the total cohort into Cohorts I (1999–2008) and II (2009-2020), to evaluate the potential impact of IFX availability on therapeutic strategies.



IFX (22.3%), IMS (7.1%), and IMS combined with IFX (12.0%) accounted for nearly half of initial (within the first month after diagnosis) treatment strategies for patients with CD (Figure 3A and Supplementary Table 3). Interestingly, 51.6% of patients ceased medical treatment within 1-3 mo, but 41.7% re-prescribed in the following period. Specifically, a prominent increase in monotherapy or

combination therapy containing IMS and IFX was observed during the subsequent 6-36 mo. Meanwhile, conventional therapies including 5-ASA, CS, and CS combined with IMS were steadily used. When comparing the two cohorts, we found that all initial prescriptions originated from conventional medications in Cohort I, while therapies comprising of IFX or IMS accounted for 45.0% of all initial prescriptions in Cohort II (Supplementary Figures 1 and 2).

Data on UC are presented in Figure 3B and Supplementary Table 4. 5-ASA (56.1%) was the most frequently prescribed medication in initial strategies, followed by CS (20.7%). Similar to CD, 60.1% of patients stopped medications within 1-3 mo, but 38.7% were put back on the same or other drugs for treatment progression, resulting in a steady increase of 5-ASA, CS, and IFX/IMS prescriptions in the following period. Compared with Cohort I in initial strategies, we still found 5-ASA and CS comprised a majority of prescriptions in Cohort II (Supplementary Figures 3 and 4).

Factors associated with initial drug strategies

Since initial therapeutic regimens may affect follow-up strategies to some extent, we further invest-

The classification of body mass index: Underweight: < 18.5; Normal: 18.5-23.9; Overweight: 24-28; Obese > 28. Disease behavior was not available in 1407 patients. IQR: Interquartile ranges; BMI: Body mass index; CDAI: Crohn's disease Activity Index; CD: Crohn's Disease.

igated potential factors impacting initial drug strategies.

Table 3 presents factors for commencing different medications compared with a no prescription group among patients with CD. Specifically, variables including urban living, L3, B3, gastrointestinal surgical history, and diagnosis after 2009 yielded the most significant predictors of patients not commencing CS for initial treatment strategies. However, patients with a drug history had a higher probability of commencing CS. When compared with the no prescription group, patients of male sex, urban living, BMI ≥ 24.0 kg/m^2, B3, and gastrointestinal surgical history were less likely to be prescribed CS combined with IMS as initial treatment. In contrast, patients with L4, EIMs, drug history, and perianal surgical history were more likely to be prescribed CS combined with IMS strategy. In terms of comparison between the IFX and no prescription groups, patients who were smokers, had a BMI ≥ 24.0 kg/m^2, B2 or B3, and had a gastrointestinal surgical history had a fewer possibility to be prescribed IFX. Contrarily, patients who were students, L4, had moderate severity, and had a perianal surgical history were more likely to be prescribed IFX.

Table 4 presents the variables that determined initial therapeutic regimens in patients with UC. Particularly, patients with a drug history tended to maintain treatments after diagnosis, regardless of type (5-ASA, CS, IMS, or IFX). Variables including current smoker, severe disease activity, and diagnosis after 2009 were the most significant factors for not commencing 5-ASA, whereas variables including employed or retired and E3 were related to a higher probability of commencing 5-ASA. Likewise, patients with a BMI ≥ 24.0 kg/m^2 and diagnosed after 2009 were less likely to be prescribed CS, and those with E3 and EIMs involvement were likely to be prescribed CS. Moreover, patients with a drug history were more likely to be prescribed IFX/IMS for initial treatment.

DISCUSSION

To the best of our knowledge, no multicenter cohort study has been conducted to investigate temporal trends in long-term medication use and periodic changes in treatment paradigms in Chinese IBD patients. Our findings showed that prescriptions of IMS and IFX gradually increased in IBD over the past 20 years, paralleled by decreasing prescriptions of 5-ASA and CS for CD but not for UC. Additionally, periodic changes in treatment patterns revealed a switching profile from conventional medications to IFX in CD, while 5-ASA and CS still took irreplaceable positions in UC.

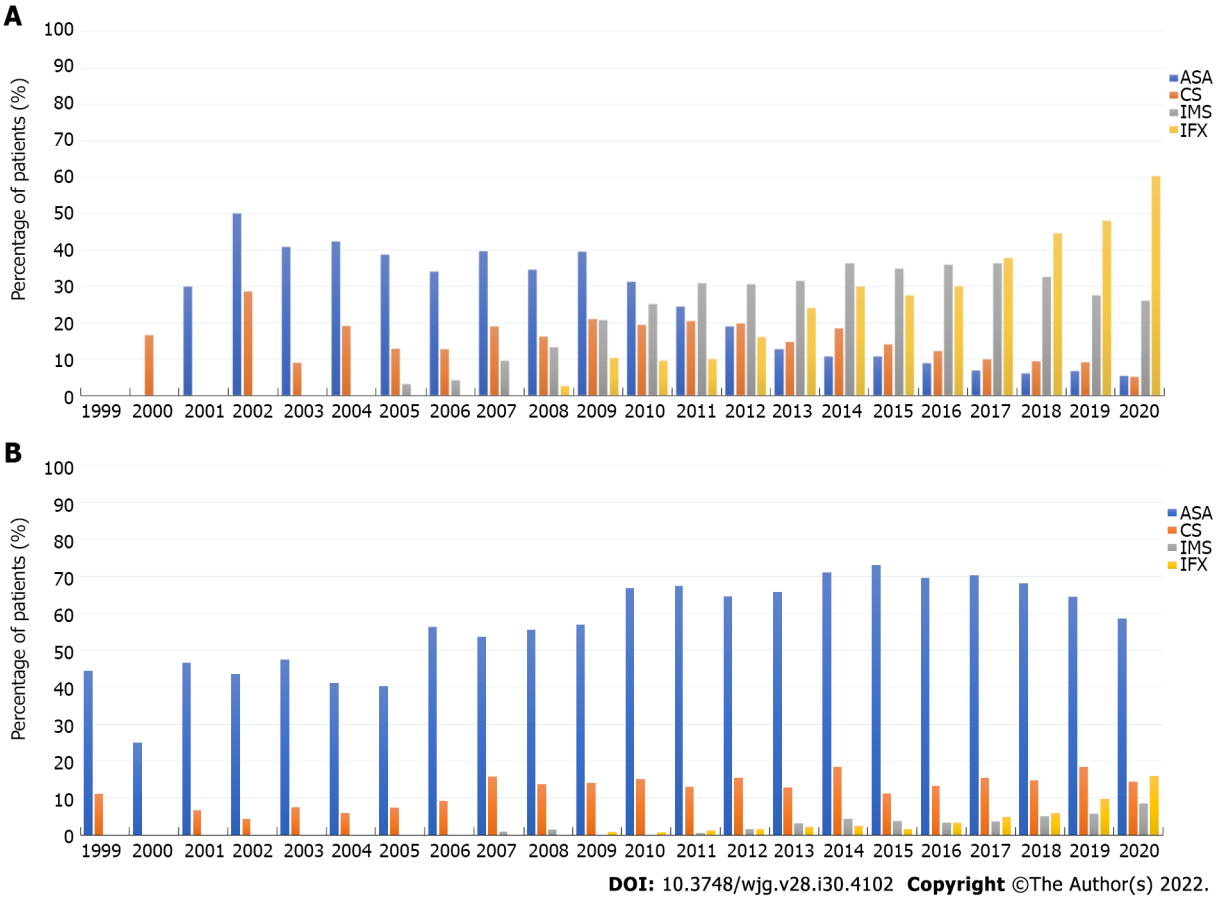
CS: Corticosteroids; IMS: Immunosuppressants; IFX: Infliximab; OR: Odd ratio; CI: Confidence interval; BMI: Body mass index; CDAI: Crohn's Disease Activity Index; IBD: Inflammatory bowel disease; NS: Non-significant.

In China, more than 1.5 million people are expected to suffer from IBD by 2025[3]. Therefore, the study population accounted for merely 0.2% of the total estimated Chinese patients with IBD. However, because there is lack of national registries covering all IBD patients, it is difficult to acquire complete data on the diagnosis, treatment, and prognosis of all Chinese patients with IBD. A well-organized national IBD registry in the near future will help facilitate larger clinical studies in China. Besides, IBD referral centers in our study are distributed across all seven administrative regions in China with diverse socioeconomic backgrounds. To some extent, the study population represents in-patients from Chinese referral centers. Moreover, we found similar patterns in demographic and clinical characteristics by further comparing IBD patients in our study with those in other large-sample Chinese studies, which also reflects the representativeness of our study to a certain extent[20,21].



In this study, the median (IQR) age of onset and diagnosis was 31.0 (23.0–45.0) years and 33.0 (25.0–48.0) years, respectively, similar to other Asian and Western populations[22,23]. The total median duration of follow-up was short. There are two possible explanations for this. On one hand, the study population mainly stems from IBD referral centers and therefore many patients will go back to grass-roots hospitals for following treatment after acquiring definite IBD diagnosis and initial treatment strategies, which may result in loss to follow-up. On the other hand, due to the observational design of this study, most information originated from medical records or databases. It would be a huge cost to follow such a large number of patients. Despite the short follow-up period, which may affect medication trend analysis, there were still more than 1000 patients who were followed for more than three years, and our analysis towards long-term changes in treatment patterns provided a credible result, which can assist in clinical drug management. We also compared baseline characteristics between CD and UC patients. Regarding demographic differences, CD patients seemed more likely to be younger at onset or diagnosis and have longer intervals from onset to diagnosis and follow-up duration. This is possibly due to more sophisticated processes in CD diagnosis and treatment. However, UC patients were more likely to be overweight compared to those with CD. UC patients who seldom implicate small intestine that would cause malabsorption of nutrients and following weight loss might explain BMI differences. In regard to clinical discrepancies, more CD patients had EIMs involvement, family history, and gastrointestinal and perianal surgical histories than UC. Patients with CD often undergo intestinal resection for perforation, ileocecal junction inflammation, or perianal surgeries before diagnosis. Contrarily, more medications were likely prescribed for UC before diagnosis, which was probably due to the fact that 5-ASA was also prescribed for patients with undetermined intestinal ulcers before definite diagnosis. Furthermore, L3 was the most frequent disease location for CD, while B1 and B2 predominated disease behaviors, sharing similar clinical patterns with other Asian cohorts[22,24].

ASA: Aminosalicylates; CS: Corticosteroids; IMS: Immunosuppressants; IFX: Infliximab.

Currently, IBD medications mainly include 5-ASA, CS, IMS, and biological agents. In our study, trend analysis for CD found a prominent decline in prescriptions of 5-ASA and CS in parallel to a significant increase in prescriptions of IMS and IFX from 1999 to 2020. A previous national study from the American database reported that 37.3% of patients with CD were prescribed 5-ASA between 2009 and 2014, despite the debatable effectiveness of 5-ASA[25]. Nevertheless, the latest ECCO guideline no longer recommends 5-ASA in patients with mild-to-moderate CD[26]. In our analysis, 5-ASA usage significantly decreased from 39.6% in 2009 to 5.5% in 2020, reflecting a positive trend in narrowing the

knowledge gap between Chinese providers and IBD consensus. We also observed an apparent reduction in CS prescription onwards, which was probably due to improved awareness of steroid-sparing, earlier treatment after diagnosis, closer surveillance for disease relapse, or more attention on adverse effect of CS[27]. Moreover, IMS emerged in 2005, and prescription rates increased strikingly afterwards, except for a slight decrease between 2018 and 2020. The effect of maintenance treatment with IMS administered to patients with CD who are steroid-dependent has been testified[28]. IFX prominently increased between 2008 and 2020. These may reflect deeper market infiltration of IFX and better treatment adherence. It is worth noting that insurance coverage of IFX was not achieved until November 28, 2019, the day IFX entered the national medical insurance. This policy will influence the decision making of Chinese IBD patients on whether to choose IFX or other IMS and may explain treatment discrepancies between Chinese patients and those from other countries. Regarding trend analysis in UC patients, 5-ASA and CS were steadily prescribed, accompanied by a modest increase in IMS and IFX, demonstrating 5-ASA as a milestone during therapeutic armamentarium extension. The American Gastroenterological Association recommends treating patients with mild-to-moderate left sided UC with mesalamine or diazo-bonded 5-ASA compounds[29]. For patients with extensive mild-to-moderate UC, ECCO recommends the addition of rectal 5-ASA to oral therapy, as combined oral and

rectal therapy delivers a greater effective dose to the affected areas of colon and leads to higher rates of remission[30]. In our study, 51.6% of CD patients and 60.1% of UC patients ceased medical treatment within 1-3 mo. We realized the contradicting results from our study with the current strategy applied worldwide. Our treatment data are mainly derived from IBD referral centers where patients may cease treatment after returning home with only one-month prescriptions. This may be explained by the following reasons which reflect the specific situation of Chinese IBD management: (1) Lack of communication between referral centers and grass-roots hospitals during the early period of IBD treatment; (2) Poor medication adherence at the patient level[31]; and (3) Knowledge gap between doctors and guidelines worldwide. Overall, we are the first to depict temporal changes in medications among a large Chinese IBD population, which has not been well elucidated before.

To further investigate long-term changes in treatment patterns, we included patients who were followed for at least three consecutive years. Our analysis showed that monotherapy or combination therapy with IFX and IMS accounted for nearly half of initial treatment strategies for CD. In fact, 12.7% were prescribed 5-ASA as the initial drug, among which nearly two-thirds ceased treatment within 1-3 mo. However, most patients switched to up-level drugs afterwards, probably reflecting the limitations of 5-ASA for disease maintenance. According to a previous study, treatment strategies for patients with moderate-to-severe CD could be listed as: (1) Conventional step-care therapy (CS and IMS are prescribed sequentially); (2) Accelerated step-care therapy (a tapering process of CS together with IMS); and (3) Top-down therapy (early combination of IMS and IFX). In our study, 7.2% of cases were prescribed CS as the initial drug, most of whom received conventional step-care therapy three months after diagnosis[32]. Another 13.1% were prescribed CS combined with IMS as the initial strategy, most of whom followed an accelerated step-care regimen. Moreover, top-down therapy was the first choice for almost half of the population. Despite short-term interruption, most patients recovered with IMS, IFX, or a minority of CS or 5-ASA. We noted that conventional medications were the main initial strategies in Cohort I, comprising mostly of two step-care therapies. By contrast, the initial approach in Cohort II was predominated by top-down therapies. Regarding therapeutic patterns in UC patients, initial treatments mainly included 5-ASA and CS. As the principal therapy in initial strategies, 5-ASA was highly effective for UC[33]. Similar to CD patterns, patients with UC who stopped treatment within 1-3 mo were re-prescribed different levels of medications afterwards, reflecting better adherence and more standardized treatment. Additionally, 5-ASA and CS were only initial strategies in Cohort I, complying with clinical settings in the early period of IBD management. In general, our analysis provides a unique insight into long-term therapeutic paradigms in Chinese population.

Since initial treatments were crucial for long-term therapeutic paradigms, we next investigated potential predictors for initial drugs. In CD patients, L3 congruously reduced the possibility of commencing CS, whereas L4 increased the possibility of commencing CS combined with IMS or commencing IFX. This is likely due to the fact that patients with upper gastrointestinal involvement are prone to behave in a more sophisticated course, requiring IMS or IFX for maintenance of remission. Intriguingly, patients with penetrating behavior and gastrointestinal surgical history appeared to have a lower likelihood of being prescribed either drug, given the intricate and drug-refractory nature, calling for short-term surgical intervention after diagnosis. We also observed an increase in CS combined with IMS or IFX in patients who underwent perianal surgeries before diagnosis. A possible explanation is that poor healing after perianal surgeries provide useful evidence for making detailed diagnosis and more appropriate selection of therapeutic strategies. Regarding factors in UC, we found an appreciable correlation between all strategies and medication history. This finding should be carefully generalized to other UC populations. Thus, future investigation elucidating detailed association between treatments before diagnosis and initial therapeutic paradigms in larger population is warranted. Interestingly, patients with E3 reflected a higher risk of 5-ASA and CS medications, possibly explained by the fact that patients with extensive colitis naturally tended to adopt medications that might relieve symptoms. Moreover, our observations indicated that patients diagnosed after 2009 were less likely to be prescribed 5-ASA or CS as initial therapies, which is mainly due to IFX insurance coverage or improved awareness of steroid-sparing medications. Generally, these results suggest that baseline characteristics probably affect initial treatment strategies to a certain extent.

There are several strengths in this study. First, patients were from IBD referral centers, which covered all the administrative regions in China. The population represented a broad spectrum of Chinese patients with IBD for over 20 years, facilitating temporal trends evaluation in medication use and drug strategies. Second, detailed baseline characteristics and prescriptions through follow-up were retrieved from consecutive medical records, which may reflect actual drug intake to some extent. Lastly, no study has analyzed periodic changes in treatment paradigms for three consecutive years and associated factors with initial drug strategies in Chinese IBD patients.

The study also has limitations. First, extrapolation of medication trends to the entire country and other Asian countries remains unproven due to lack of the national registry in China and potential differences in racial phenotypes and treatment strategies worldwide. A wholesome IBD registry system and multicenter studies among Asian populations are needed in the near future. Second, potential information and confounding bias exist due to observational design. Therefore, we assessed baseline factors thoroughly and employed multivariate logistic regression analysis to minimize bias. Moreover, outcomes, including hospitalization, surgeries, or phenotype progression were not collected, limiting

further investigation in the correlation between different drug strategies and long-term outcomes.

CONCLUSION

In conclusion, this study provides insights into temporal trends in long-term medication use and periodic changes in treatment patterns for Chinese patients with IBD. The findings suggest that prescriptions of IMS and IFX increased in parallel with steady or decreasing prescriptions of 5-ASA and CS in real-world settings. The study also shed light on periodic changes in treatment patterns, reflecting a switching profile from conventional drugs to IFX in CD. Further research into the full breadth of trends in medication use and treatment patterns should be conducted for additional compliance with guidelines for IBD management.

ARTICLE HIGHLIGHTS

Research background

Medications for inflammatory bowel disease (IBD) have changed dramatically over time, especially following market availability of infliximab (IFX). Several attempts have been made by Western and other Asian countries to provide rough medication changes.

Research motivation

No study on long-term medication profiles has been conducted in Chinese population, and minimal attention has been paid to periodic changes in IBD treatment strategies. Additionally, investigating possible predictors for initial treatment strategies may help to better understand periodic changes in therapeutic patterns in patients with IBD.

Research objectives

This study was designed to leverage the real-world evidence in Chinese referral hospitals to provide fresh insights into temporal trends in medication prescriptions among the Chinese population with IBD for over 20 years, and to investigate long-term periodic changes in treatment paradigms and identify the possible factors that influence initial drug strategies.

Research methods

A multicenter retrospective cohort study was conducted to analyze trends in medication use and therapeutic patterns. Predictors for initial drug strategies were identified using logistic regression analysis.

Research results

Of 5-aminosalicylates (5-ASA) and corticosteroids (CS) prescriptions gradually decreased, accompanied by a notable increase in immunosuppressants (IMS) and IFX prescriptions in patients with Crohn's disease (CD). Prescription rates of 5-ASA and CS were stable, whereas IMS and IFX slightly increased since 2007 in patients with ulcerative colitis (UC). Subgroup analyses showed the switch from conventional medications to IFX in patients with CD, while 5-ASA and CS were still steadily prescribed in patients with UC. Logistic regression analyses revealed that surgical history, disease behavior, and disease location were associated with initial therapeutic strategies in patients with CD. However, medications before diagnosis, disease location, and diagnostic year might affect initial strategies in patients with UC.

Research conclusions

Parallel to increasing IMS and IFX use in IBD over the past two decades, a significant decrease in 5-ASA and CS use were observed for CD but not for UC. Long-term treatment strategies analyses provided a unique insight in switching from conventional drugs to IFX in Chinese patients with CD.

Research perspectives

The study was based on IBD referral centers, therefore the study population only accounted for limited proportion of total Chinese patients with IBD. A well-organized national registry system in the near future will help facilitate larger clinical studies in China. In addition, clinical outcomes, including hospitalization, surgeries, or phenotype progression were not collected. Further investigation in the correlation between different drug strategies and long-term outcomes are needed in future studies.

Abstract

BACKGROUND

As one of the most common tumors, gastric cancer (GC) has a high mortality rate, since current examination approaches cannot achieve early diagnosis. *Fusobacterium nucleatum* (Fn) primarily colonized in the oral cavity, has been reported to be involved in the development of gastrointestinal tumor. Until now, little is known about the relationship between salivary Fn and GC.

AIM

To determine whether salivary Fn could be a biomarker to diagnose GC and explore the influence of Fn on GC cells.

METHODS

The abundance of Fn in saliva was quantified by droplet digital polymerase chain reaction in 120 GC patients, 31 atrophic gastritis (AG) patients, 35 non-AG (NAG) patients, 26 gastric polyp (GP) patients, and 20 normal controls (NC) from Qilu Hospital of Shandong University from January 2019 to December 2020. Receiver operating characteristic (ROC) curve analysis was performed to evaluate the diagnostic value of Fn as well as traditional serum tumor markers, including carcinoembryonic antigen (CEA), carbohydrate antigen (CA) 19-9, and CA72-4. Transwell assay and wound-healing assay were conducted to assess the influence of Fn infection on GC cells. The expression of epithelial-mesenchymal transition (EMT) markers was detected using western blot assay.

RESULTS

We found that the level of salivary Fn in GC patients was significantly increased compared with those in AG, NAG, and GP patients and NC ($P < 0.001$). ROC curve analysis showed a favorable capability of Fn (73.33% sensitivity; 82.14% specificity; area under the curve: 0.813) in GC diagnosis, which was superior to that of CEA, CA19-9, CA72-4, ferritin, and sialic acid. The Fn level in saliva of GC

patients was increased as the TNM stage increased. GC patients with lymph node metastasis had higher Fn levels than those without metastasis. Both transwell and wound-healing assays indicated that Fn infection promoted the migration and invasion of GC cells. Western blot analysis showed that Fn infection decreased the expression of E-cadherin and increased the expressions of N-cadherin, vimentin, and snail.

CONCLUSION

Fn abundance in saliva could be used as a promising biomarker to diagnose GC, and Fn infection could promote GC metastasis by accelerating the EMT process.

Key Words: Gastric cancer; *Fusobacterium nucleatum*; Saliva; Prognosis; Metastasis; Epithelial-mesenchymal transition

Core Tip: *Fusobacterium nucleatum* (Fn), known as a periodontal pathogen, is frequently detected in tissues of gastrointestinal tumor. Here, we found that the level of salivary Fn was increased in gastric cancer (GC) patients, which could be used as a potential biomarker for GC diagnosis, and its diagnostic capability was superior to that of traditional serum tumor markers. We also showed that salivary Fn level was positively associated with the GC TNM stage and lymph node metastasis. Further, experiments *in vitro* revealed that Fn could promote the migration and invasion of GC cells by promoting the epithelial-mesenchymal transition process. Our findings suggest that salivary Fn is a potential biomarker in diagnosis of GC.

INTRODUCTION

Gastric cancer (GC) is one of the most common malignant tumors, with morbidity and mortality ranking fifth and third in the world, respectively, posing a great threat to global human health[1]. Although the 5-year survival rate of GC is enhanced with the combination of chemotherapy and surgery, its mortality remains high due to the diagnosis at an advanced stage with a limited therapeutic scheme to choose from. Therefore, effective early diagnosis for GC is especially important.

The microorganisms in the human body are complex and they play important roles in each part of our body. Over 700 bacterial species have been detected in the human oral cavity, and they interact with each other as well as with the host[2]. The stomach was considered a sterile organ until the discovery of *Helicobacter pylori* (*H. pylori*) in 1984[3]. Subsequently, other microorganisms were found in the gastric mucosa[4]. Although the gut microbiota ecosystem is different from that of the oral cavity, there is also a partial similarity between them, since most of the bacteria in the oral cavity enter the stomach when swallowing food and saliva.

Human saliva is a unique biofluid resource with huge clinical diagnostic and risk assessment capacity. Moreover, it is easy to acquire in non-invasive and painless approaches. Most importantly, individual oral environment basically maintains a long-term relatively stable state except for little fluctuation caused by diet, infections, or other factors, and the dominant oral floras in different individuals are host specific[5]. *Fusobacterium nucleatum* (Fn) is a Gram-negative anaerobic bacterium, which is a normal composition of the oral microenvironment[6,7]. In recent years, due to its increased detection rate in oral infectious diseases, it has been identified as an opportunistic pathogen[8]. Chronic periodontitis is caused by the ecological imbalance of the subgingival plaque biofilm communities, leading to the growth of dominant species, which destroys the host immune response and leads to inflammation[9]. Fn has been proved to be one of the pathogens that grow abnormally before periodontal disease, leading to an imbalance in the composition of oral symbiotic bacteria, which leads to the occurrence of periodontitis[10]. It forms a bridge between the early symbiotic colonizers and the late pathogenic colonizers[11]. In recent years, Fn has also been found to be associated with extra-oral infections, including adverse pregnancy outcomes, rheumatoid arthritis, respiratory tract infections, and gastrointestinal neoplasm[12-14]. Accumulating evidence has shown that Fn is associated with the occurrence, development, and metastasis of colorectal cancer (CRC). However, the information for GC is

limited. In the present study, we aimed to detect the Fn abundance in saliva using digital droplet polymerase chain reaction (ddPCR), and establish a new simple and effective diagnostic approach to improve the early diagnosis of GC.

MATERIALS AND METHODS

Study population and sample collection

Subjects with GC (n = 120), atrophic gastritis (AG) (n = 31), non-AG (NAG) (n = 35), and gastric polyps (GP) (n = 26) and normal controls (NC) (n = 20) undergoing gastroscopy examination at Qilu Hospital of Shandong University from January 2019 to December 2020 were enrolled in this study. The selection of NC mainly depended on the normal results of gastroscopy examination, biochemical indexes, and tumor marker detection. GC, AG, NAG, and GP were further confirmed based on histopathological analyses. The pathological stage of GC was assessed by the 8th edition TNM staging system. The exclusion criteria were as follows: (1) Subjects who used any antibiotics within the last 4 wk; (2) Subjects with oral inflammation; and (3) Subjects without detailed general clinical data. Whole saliva specimens were collected with Salivette® tube before brushing teeth and eating breakfast in the morning. After collection, samples were immediately transferred to the laboratory with ice gauges and centrifuged at 3000 r/min for 10 min at 4 °C. All saliva samples were stored at -80 °C until further analysis. All study participants provided informed written consent prior to study enrollment. This study was approved by the Ethics Committee of the Qilu Hospital of Shandong University (Approval No. KYLL-2019-2-013).

DNA isolation

Total genomic DNA was extracted from 200 μL saliva using the QIAamp Blood Mini Kit (cat. 51106, Qiagen, Hilden, Germany), and purified DNA was finally dissolved in 80 μL AE buffer. The concentration of DNA was determined with a Qubit 3 Fluorometer using an Equalbit 1 × dsDNA HS Assay Kit (cat. EQ121-01, Thermo Fisher Scientific, United States) according to the manufacturer's instructions.

ddPCR

ddPCR was performed on the bio-digital PCR platform (Turtle Tech Ltd., Shanghai, China) in a 35 μL reaction system consisting of 5 μL genomic DNA, 3.5 μL 10 × dPCR buffer, 1 μL dPCR enzyme, 1 μM primers, and 0.5 μM probe of Fn (forward primer: 5'-TGGTGTCATTCTTCCAAAAATATCA-3'; reverse primer: 5'-AGATCAAGAAGGACAAGTTGCTGAA-3'; probe: 5'-ACTTTAACTCTACCATGTTCA-3'). After the automatic sample loading process was completed, the chips with samples added were transferred into a nucleic acid amplification instrument (Turtle Tech Ltd., Shanghai, China). Briefly, after an initial enzyme activation step at 50 °C for 10 min and then at 90 °C for 10 min, amplification (45 cycles) of Fn DNA was carried out. After amplification, the chips were transferred to the commercial digital PCR platform (BioDigital dPCR System, Turtle Tech. Ltd., Shanghai, China) to detect fluorescence amplitude signals.

Cell culture

The GC cell lines AGS and MKN-28 were purchased from Shanghai Zhongqiao Xinzhou Biotechnology Co., Ltd. (Shanghai, China) and maintained in appropriate medium (Hyclone, United States) supplanted with 10% fetal bovine serum (Hyclone, United States) under the standard conditions (50 mL/L CO_2, 37 °C).

Bacterial strains and growth conditions

Two strains of Fn (ATCC49256 and ATCC25586) used in our assays were purchased from American Type Culture Collection. The strains were first inoculated and cultured on Columbia Blood Agar under the anaerobic condition at 37 °C for 48 h. Then a single colony was transferred to a fluid thioglycolate medium, followed by incubation at 37 °C under anaerobic conditions (90 mL/L N_2, 50 mL/L CO_2, and 50 mL/L H_2) to reach an optical density (OD_{600}) of 0.2 for each bacterial strain.

Coculture

AGS and MKN-28 cells (2 × 10^5/per well) were seeded in six-well plates with 2 mL complete RPMI-1640 medium and cultured overnight. The plates were then incubated under an anaerobic condition mentioned above for 24 h. On the next day, the cultured Fn was centrifuged (4400 × g for 5 min at room temperature), and the bottom bacteria were sedimented and then re-suspended with fresh RPMI-1640 medium after the supernatant was discarded. After the OD_{600} was determined, the resuspended Fn was added to AGS and MKN-28 cells for co-culture. Cell treated with phosphate buffer solution served as a control group. The plates were centrifuged at 250 × g for 5 min and placed back in an anaerobic incubator for 24 h. For all the experiments in this study, Fn bacteria were added to the cells at an multiplicity of infection (MOI) of 100 based on the preliminary experiments, and this value was common in the published articles.

Transwell assay

After 24 h of infection, the cells were washed and seeded into the upper chamber of an 8-μm transwell insert (Costar, Corning, New York, United States). Transwell chambers used for invasion assay were pre-coated with Matrigel (Corning), while the chambers used for migration assay were not treated. The upper chamber of the transwell contained 2×10^4 cells in a volume of 200 μL serum-free medium, and 700 μL of medium containing 10% serum was added into the lower chamber. After being cultured for 24 h, the cells in the upper chamber were wiped with the cotton tip, and the adherent cells in the lower chamber were fixed with 40 g/L formaldehyde for 10 min and stained with 0.5% crystal violet for 30 min. The images were captured with an inverted microscope (Olympus, Tokyo, Japan).

Wound-healing assay

AGS and MKN-28 cells (5×10^5 cells/ per well) were seeded in six-well plates, and the later infection process was the same as the transwell assay above-mentioned. After 24 h of Fn infection, the cells were washed with RPMI-1640 medium (by this time, the cells were grown to 100% confluence, if not, cultured continually). A 200 μL pipette tip was used to make a straight scratch, simulating a wound. Subsequently, the medium and floating cells were removed and replaced with a serum-free culture medium, and the imagines were captured (0 h). After 48 h of cell culture, images were captured again. The cell migration rate was evaluated by comparing the healing degree between 0 h and 48 h.

Western blot analysis

The AGS and MKN-28 cells with or without Fn infection were lysed in radioimmune precipitation assay buffer for 30 min on ice. Then the cell lysates were centrifuged at 12000 r/min for 10 min at 4 °C, and the supernatant was collected. The bicinchoninic acid protein assay kit (Pierce, Rockford, United States) was used to quantify protein concentrations. Subsequently, equal amounts of proteins (30 μg) were subjected to sodium dodecyl sulphate-polyacrylamide gel electrophoresis, and then electrophoretically transferred onto polyvinylidene fluoride membranes. The blots were blocked with 5% skim milk in Tris-buffered saline with tween (TBST) (BD Biosciences, San Jose, CA, United States) containing 0.1% tween-20 (Bio-Rad, Richmond, CA, United States) at room temperature for 1 h. The membranes were then incubated overnight at 4 °C with the primary antibodies against E-cadherin (1:1000, Cell Signaling, #3195S, Danvers, MA, United States), N-cadherin (1:1000, Cell Signaling, #13116T), vimentin (1:1000, Cell Signaling, #5741S, Danvers, MA, United States), Snail (1:1000, Cell Signaling, #3879S), and GAPDH (1:1000, Cell Signaling, #5174S). The membranes were washed three times with 1 × TBST buffer, followed by incubation with anti-rabbit HRP-conjugated secondary antibody (1:5000; Huaan, Hangzhou, China) at room temperature for 1.5 h. The immunoreactive bands were visualized using an Amersham Imager 680 (GE, Boston, United States). GAPDH served as a loading control.

Statistical analysis

Statistical analyses were conducted using SPSS software (SPSS Inc., Chicago, IL, United States) and graphs were prepared using GraphPad Prism 8.0 (La Jolla, CA). Statistical review was performed by a biomedical statistician. Fn abundance in different groups is expressed as the median and interquartile range. A χ^2 test was used for the comparison of categorical variables. A Kruskal-Wallis test was performed for the global comparison of multiple groups and post-hoc multiple comparisons were performed using the Mann-Whitney *U* test. Receiver operating characteristic (ROC) curve analysis was conducted *via* MedCalc15.2.2 to evaluate the diagnostic value of Fn as well as other serum tumor markers, and the best cut-off values were calculated by the Youden index. All statistical tests were two-tailed, and $P < 0.05$ was considered statistically significant.

RESULTS

Abundance of Fn in the saliva of GC patients

Our ddPCR results showed a significant difference in salivary Fn among the patients with GC, AG, NAG, and GP, and NC. And the Fn level was significantly increased in GC patients compared with patients with AG, NAG, and GP and NC while there was no difference among AG, NAG, and GP patients and NC (Figure 1A). Moreover, the Fn level was increased as the TNM stage increased (Figure 1B). Further clinical characteristic analysis showed that GC patients with lymph node metastasis had higher Fn levels than those without (Table 1). However, the Fn level in GC was not significantly associated with age, gender, tumor size, pathological differentiation, or invasion depth.

Diagnostic performance of salivary Fn in GC patients

ROC analysis indicated some diagnostic power with a fitted area under the curve (AUC) of 0.813 (95% confidence interval: 0.756-0.861) (Figure 2A). When the Youden index was used to calculate the optimal cut-off value of the Fn copy number as 67.58 copies/μL, the sensitivity and specificity were 73.33% and 82.14%, respectively. To better evaluate the diagnostic value of Fn in saliva for GC, the routine clinical

Table 1 Association of *Fusobacterium nucleatum* levels in saliva with clinicopathologic features

Feature	Number of cases	*Fusobacterium nucleatum* level	*P* value
Age (yr)			0.780
< 61	56	153.00 (39.20-542.00)

N3	30	478.00 (96.09-1054.00)	

test records of traditional serum tumor markers, including CEA, CA19-9, CA72-4, ferritin, and sialic acid were assessed. The upper cut-off values of these markers were determined according to the manufacturer's directions. Table 2 shows that the Fn level was significantly higher in GC patients compared with AG, NAG, and GP patients and NC, while CEA, CA19-9, CA72-4, and ferritin did not significantly different between GC patients and the other four groups. Although sialic acid was also significantly different among the five groups, its diagnostic value was still lower than that of Fn, according to the ROC curves.

The ROC curves presented that the AUC of CEA, CA19-9, CA72-4, ferritin, and sialic acid was 0.620, 0.570, 0.541, 0.648, and 0.693, respectively (Figures 2B-F). In addition, the sensitivity of Fn was higher compared with the other traditional serum markers. As for the specificity, the value of Fn was higher than those of CEA, CA72-4, ferritin, and sialic acid, but lower than that of CA19-9. Of note, although the specificity of CA19-9 was high, its sensitivity was relatively low (Table 3). These results indicated that the diagnostic capability of Fn was superior to that of CEA, CA19-9, CA72-4, ferritin, and sialic acid.

Role of Fn in GC metastasis

To evaluate the effect of Fn infection *in vitro*, we infected AGS and MKN-28 cells with Fn. The transwell assay indicated that Fn infection significantly enhanced the invasive and migratory capacities of AGS and MKN-28 cells (Figure 3). Consistent with these results, the wound-healing assay showed that Fn infection promoted the migration of these cells (Figure 4). Since epithelial-mesenchymal transition (EMT) is an important process of metastasis, we examined the effect of Fn infection on the expression of proteins involved in the EMT process. The western blot analysis revealed that Fn infection decreased the expression of epithelial markers, such as E-cadherin, but increased the expression of mesenchymal phenotype-associated molecules, such as N-cadherin, vimentin, and snail (Figure 5).

DISCUSSION

In the present study, we reported the relationship between the Fn level in saliva and GC development for the first time. First, a more sensitive ddPCR approach was used to determine the amount of Fn DNA in saliva, and the results showed that a higher number of Fn existed in the saliva of GC patients compared with NC and patients with benign disease. Importantly, salivary Fn had good diagnostic value for GC, which was superior to traditional serum tumor markers, such as CEA, CA19-9, CA72-4, ferritin, and sialic acid, providing a new direction for the diagnosis of GC. We also found that the Fn level was positively associated with TNM stage and lymph node metastasis. Furthermore, transwell and wound-healing assays verified the role of Fn in promoting the invasion and migration of GC cells. Subsequently, we indicated that Fn infection promoted GC metastasis by accelerating the EMT process.

It is essential to diagnose GC at an early stage. Currently, gastroscopy in combination with biopsy is considered the most accurate method to diagnose GC. However, early asymptomatic patients have poor compliance with gastroscopy due to its invasiveness, which directly reduces the rate of early diagnosis of GC. Serum tumor markers are another approach to screen GC. For example, CEA, CA19-9, and CA72-4 are widely used in clinical practice. However, serum tumor markers are not recommended for routine clinical screening due to the lack of specificity and sensitivity[15]. In a cohort consisting of 587 early GC patients, the positive rate of CA19-9, CA125, and CEA was 4.8%, 1.9%, and 4.3%, respectively[16]. For Fn in saliva, it is not only easy to obtain, but also shows a better diagnostic capacity for GC. Moreover, salivary Fn has a pleasurable tissue specificity as a diagnostic marker for GC.

H. pylori is a well-known risk factor for GC. However, other bacterial genera are also detected in the gastric mucosa, such as *Prevotella, Rothia, Fusobacterium,* and *Klebsiella*[17,18]. Fn, a resident colony of

bacteria in the oral cavity, is detected significantly higher in the GC tissue compared with the para-cancerous tissue[19]. There is a microbial succession hypothesis to explain the decrease of *H. pylori* and elevation of the non-dominant flora in GC[18]. The hypothesis proposes that *H. pylori* can produce urease through the mucus layer, enhancing pH value to modify the microenvironment and triggering a strong inflammatory response. In such a process, gastric mucosal integrity is destroyed, and other secondary bacteria invade the mucus layer, causing more aggressive tumor occurrence. Therefore, Fn in the oral cavity can easily reach the stomach and colonize through the gastric mucosa barrier as the swallowing of saliva, forming an invasion focus. Thus, we think that Fn cooperates with *H. pylori* to promote GC development. Hsieh *et al*[20] have shown that Fn colonization leads to worse prognosis in GC patients with *H. pylori* positivity.

Figure 3 *Fusobacterium nucleatum* promotes the invasion of gastric cancer cells. Transwell assay of AGS and MKN-28 cells was performed 48 h after coculture with *Fusobacterium nucleatum*. The cells in the control group were treated with phosphate buffer solution. Fn: *Fusobacterium nucleatum*.

As a high-frequency periodontal pathogen, Fn has been confirmed to promote the initiation, proliferation, invasion, and chemoresistance of CRC in recent years. There are several suggested mechanisms, such as enhancing adhesion and evasion ability, modulating host immune evasion, and improving autophagy to cause chemoresistance[21-23]. It is worth noting that Fn is considered to play a more important role in promoting the formation of tumor, rather than its development[24]. Consistent with these findings, Fn has been confirmed to have key pathogenic characteristics, such as virulence factor FadA and characteristic adhesion protein Fap2[25-27]. In addition to promoting the occurrence and development of CRC, accumulating evidence has shown that Fn also plays an important role in promoting CRC metastasis[28,29]. In our present study, a high level of Fn was found in GC patients with lymph node metastasis. Although its impact in promoting tumor metastasis has been recognized, the role of Fn in such a process and its potential mechanism remain largely unclear. Chen *et al*[30] have detected Fn colonization in metastatic lung lesions of nude mice, and they further verified that Fn infection up-regulates KRT7 (type II cytokeratin, which plays a role in maintaining the structural integrity of the cells as well as promoting motile activities) to promote CRC metastasis. Besides, Chen *et al*[31] have identified that Fn activates autophagy to promote CRC metastasis. It is worth mentioning that EMT is the most well-validated method by which Fn promotes CRC metastasis, and it has been discovered that the effect is enhanced when the MOI is increased[32-34]. EMT is a classical pathway promoting metastasis. It is a special program that enables settled epithelial cells to gain the ability to migrate as single cells, which can enhance mobility, invasion, and resistance to apoptosis, conferring metastatic properties of cancer cells[35]. The examinations conducted in CRC both *in vivo* and *in vitro* have verified that Fn can promote the EMT process[28]. We supplemented the evidence that Fn promoted the EMT process in GC cells. Moreover, Fn infection significantly decreased the expression of

Figure 4 *Fusobacterium nucleatum* promotes the migration of gastric cancer cells. Wound-healing assay of AGS and MKN-28 cells was performed 48 h after coculture with *Fusobacterium nucleatum*. The cells in the control group were treated with phosphate buffer solution. Fn: *Fusobacterium nucleatum*.

cell adhesion molecules and increased the expression of mesenchymal phenotype-associated molecules, eventually resulting in GC metastasis. Taken together, we identified that Fn promoted GC metastasis by facilitating the EMT process.

Targeting Fn may reduce the progression of related cancers to ascertain the origin of Fn in cancers, and determining the route by which it reaches the tumor is of therapeutic significance. It has been found for a long time that part of Fn detected in CRC tissue is originated from the oral cavity, while how Fn in the oral cavity is transported to other body sites is also a hot topic. Initially, Fn strains with similar sequences were found in human primary CRC tissues and paired liver metastases, suggesting that these bacteria can migrate to distant sites with CRC cells[29]. Therefore, some scholars believe that Fn enters tumor tissue *via* blood circulation. The existing data have shown that Fn is detected at higher loads in GC tissue[19], and our data suggested that Fn abundance was increased in the saliva of GC patients. Could this indicate that Fn could directly enter the gastrointestinal tract, and then colonize epithelial cells? For Fn can produce a variety of adhesion factors as well as invasive factors, it is easy to adhere to the gastrointestinal mucosa, and form an inflammatory microenvironment, which is conducive to the formation of tumor. However, some evidence has also shown that Fn in the blood is more successful in CRC colonization than being gavaged, indicating that Fn the in blood (from a bleeding wound in the gum or some other way) plays a more important role in forming colonization than the ones in the digestive tract, even if there is a disadvantage in quantity[36]. Which type of Fn transmission is dominant in tumor formation (or the two work together) remains to be further studied.

There are also some limitations in our study. First, the small sample size caused by high cost led to selection bias. In follow-up studies, larger, multicenter studies are required to consolidate the findings. Second, the flora in the oral cavity is diverse. Whether other floras have an impact on the occurrence and development of GC, or whether they have interacted with Fn needs to be further explored.

CONCLUSION

Collectively, Fn in saliva exhibits a good predictive ability and represents a promising diagnostic marker for GC. Given the tumorigenicity and metastasis-promoting properties of Fn, we suggest that the elimination of Fn could reduce the incidence of GC and improve the treatment outcomes, which is similar to triple or quadruple anti-*H. pylori* therapy.

ARTICLE HIGHLIGHTS

Research background

Gastric cancer (GC) is a common malignant tumor in the digestive tract. Although the 5-year survival rate of GC is enhanced with the combination of chemotherapy and surgery, its mortality remains high due to the diagnosis at an advanced stage. It is essential to develop a new method to diagnose GC at an early stage.

Research motivation

Fusobacterium nucleatum (Fn) primarily colonized in the oral cavity, has been detected in tissues of GC in recent years. We wondered whether there is a correlation between salivary Fn and GC.

Research objectives

The research purpose was to find a new simple and effective biomarker to diagnose GC.

Research methods

The abundance of Fn in saliva was quantified by droplet digital polymerase chain reaction in 120 GC patients, 31 atrophic gastritis (AG) patients, 35 non-AG (NAG) patients, 26 gastric polyp patients, and 20 normal controls (NC). The diagnostic value of Fn was evaluated and compared with traditional serum tumor markers, including carcinoembryonic antigen (CEA), carbohydrate antigen (CA)19-9, CA72-4, ferritin, and sialic acid. Transwell and wound-healing assays were conducted to assess the influence of Fn infection on GC cells. Western blot analysis was performed to detect the expression of epithelial-mesenchymal transition (EMT) markers.

Research results

Fn had favorable diagnostic value in classifying GC from NC and benign diseases, which was superior to those traditional serum tumor markers, such as CEA, CA19-9, CA72-4, ferritin, and sialic acid. Salivary Fn level was positively associated with the GC TNM stage and lymph node metastasis. Further, *in vitro* experiments revealed that Fn could promote the migration and invasion of GC cells. Western blot analysis indicated that Fn infection decreased the expression of epithelial marker such as E-cadherin, and increased the expression of mesenchymal markers such as N-cadherin, vimentin, and

snail.

Research conclusions

Fn in saliva could be used as a promising biomarker to diagnose GC, and Fn infection could promote GC metastasis by accelerating the EMT process.

Research perspectives

Human saliva is a unique bio-fluid resource with huge clinical diagnostic and risk assessment capacity. Salivary Fn has promising value for diagnosing GC.

Abstract

BACKGROUND

Acute kidney injury (AKI) is a common and severe complication in patients with cirrhosis, and is associated with poor prognosis. Therefore, identifying cirrhotic patients with AKI who are at high risk of mortality is very important and may be helpful for providing timely medical interventions to improve the prognosis of these patients. However, studies focused on investigating the risk factors for the mortality of cirrhotic patients with AKI were scarce.

AIM

To identify risk factors for mortality and establish a nomogram for predicting the prognosis of these patients.

METHODS

Two hundred fifty consecutive patients with cirrhosis and AKI were recruited and randomly divided into training cohort (n = 173) and validation cohort (n = 77). In the training cohort, potential risk factors for death were identified by performing a Cox regression analysis, and a nomogram was established. The predictive performance of the nomogram was internally and externally validated by calculating the area under the receiver operating characteristic curve (AUROC), constructing a calibration curve and performing decision curve analysis.

RESULTS

The serum sodium level, international normalized ratio, peak serum creatinine level > 1.5 mg/dL, the presence of hepatic encephalopathy and diabetes were potential risk factors for mortality of cirrhotic patients with AKI in the training dataset. A prognostic nomogram incorporating these variables was established for

predicting the overall survival of these patients. Compared with Child-Turcotte-Pugh, the model for end-stage liver disease (MELD) and the MELD-Na scores, the nomogram in predicting 90- and 180-d mortality exhibited better discriminatory power with AUROCs of 0.792 and 0.801 for the training dataset and 0.817 and 0.862 for the validation dataset, respectively. With a nomogram score of 98, patients were divided into low- and high-risk groups, and high-risk patients had a higher mortality rate.

CONCLUSION

A prognostic nomogram displayed good performance for predicting the overall survival of cirrhotic patients with AKI, and will assist clinicians in evaluating the prognosis of these patients.

Key Words: Acute kidney injury; Cirrhosis; Nomogram; Prognosis

Core Tip: We investigated the potential risk factors for death in cirrhotic patients with acute kidney injury (AKI). A nomogram incorporating these risk factors was developed and evaluated by calculating the area under the receiver operating characteristic curve, constructing a calibration curve and performing decision curve analysis. Compared with Child-Turcotte-Pugh, the model for end-stage liver disease (MELD) and MELD-Na score, the nomogram has a better discriminative ability in predicting the overall survival of cirrhotic patients with AKI. Moreover, the nomogram was used to select patients with a high risk of death and assist clinicians in making clinical decisions.

INTRODUCTION

Acute kidney injury (AKI) is a common and severe complication occurring in patients with cirrhosis, manifesting as an abrupt increase in serum creatinine (SCr) levels and an acute significant reduction in urine output (UO) in a short period[1,2]. Many diagnostic criteria and classifications of AKI have been developed to identify AKI and improve prognosis over the last two decades, such as the Risk, Injury, Failure, Loss of kidney function, and End-stage kidney disease (RIFLE) classification in 2004[3], the Acute Kidney Injury Network (AKIN) classification in 2007[4], and the Kidney Disease: Improving Global Outcomes (KDIGO) classification in 2012[5]. However, the concept of AKI in patients with cirrhosis was debated for many years until the International Club of Ascites (ICA) proposed a new classification of AKI in 2015[1]. These classifications are based on SCr levels and/or UO. One of the main differences between the ICA classification and other classifications is the abandonment of the UO criteria[1]. Although these criteria have been established, a single criterion that comprehensively evaluates and diagnoses AKI is still unavailable.

The incidence and mortality of AKI in patients with cirrhosis varies substantially among studies[2,6,7]. In some studies, the incidence of AKI ranges from 20%-50% in patients with cirrhosis[2,8]. Moreover, studies have reported that the mortality rate of AKI was also unacceptably high in patients with cirrhosis, reaching up to 80%[6,9]. Therefore, identifying cirrhotic patients with AKI who are at high risk of mortality is very important and may be helpful for providing timely medical interventions to improve the prognosis of these patients. Currently, many studies have investigated risk factors for mortality in patients with cirrhosis[10] and other complications, such as gastroesophageal variceal bleeding[11,12], ascites[13], bacterial infections[14] and metabolic acidosis[15]. Moreover, a number of studies have focused on identifying the risk factors for the development of AKI in patients with cirrhosis[16-19] and other conditions[20-22]. Furthermore, numerous studies have also evaluated the effect of AKI on the mortality of patients with cirrhosis[16,23-25]. A systematic review reported that the risk of death from AKI was increased more than 6-fold in patients with cirrhosis[24]. However, few studies have focused on analyzing the risk factors for mortality in patients with cirrhosis who are diagnosed with AKI. Additionally, based on clinician demand, a quantitative predictive model for determining the prognosis of cirrhotic patients with AKI also must be developed to predict the risk of mortality and distinguish patients with a high risk of mortality.

Therefore, the purpose of the present study was to investigate the risk factors for mortality of cirrhotic patients with AKI and establish a nomogram for predicting the overall survival of these patients to identify high-risk patients and guide timely treatments to improve the prognosis of these patients.

MATERIALS AND METHODS

Patients

We conducted a retrospective study at the Department of Gastroenterology and Hepatology and the Department of Infectious Diseases, The First Affiliated Hospital of Nanchang University, a tertiary care referral hospital in China, between January 2015 and December 2016. The inclusion criteria were as follows: (1) Patients who were diagnosed with cirrhosis; and (2) Patients who met the criteria for at least one of the RIFLE, AKIN, KDIGO and ICA classifications. These patients were hospitalized. The exclusion criteria were as follows: (1) Patients aged less than 18 and more than 80 years; (2) Patients with a previously history renal dysfunction or chronic kidney disease; (3) Patients who underwent liver or renal transplantation; (4) Patients who received renal replacement therapy (including hemodialysis and peritoneal dialysis) before admission; (5) Patients with malignancy or severe cardiopulmonary disease; (6) Patients who were discharged or died < 48 h after admission; (7) Pregnant patients; and (8) Patients without complete data.

According to the inclusion and exclusion criteria, 382 consecutive patients with cirrhosis who were diagnosed with AKI were screened, and 250 eligible patients were recruited and randomly divided into the training cohort (n = 173) and the validation cohort (n = 77) using the built-in random packet function of SPSS 23.0 software according at a ratio of 1:2. The flow chart for inclusion and exclusion is shown in Figure 1.

The study was approved by the Ethics Committee of The First Affiliated Hospital of Nanchang University (No. AF-SG-04-2.0).

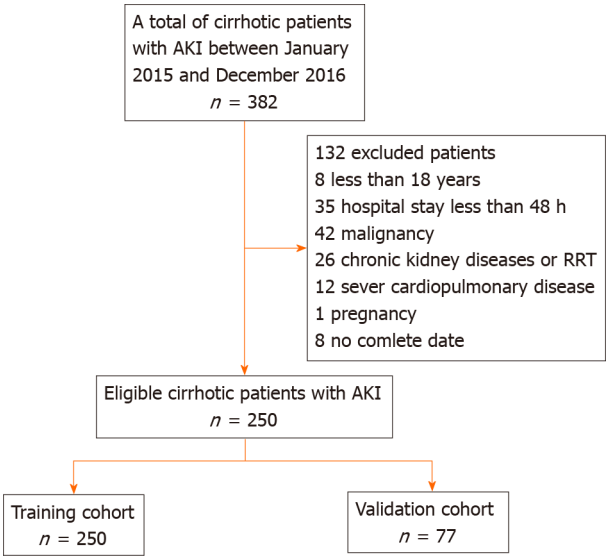
Data collection

Demographics and clinical variables, namely, demographic data (age, sex and body weight), mean arterial pressure (MAP), underlying liver disease, cirrhosis-related complications, diabetes, biochemical analysis (routine blood tests, serum biochemical tests, coagulation function tests, *etc*.), days of the hospital stay, and comorbidities were recorded and collected from every cirrhotic patient with AKI. UO was recorded for all patients during hospitalization. The Child-Turcotte-Pugh (CTP), model for end-stage liver disease (MELD) and MELD-Na scores at admission were calculated accordingly.

Definitions

Cirrhosis was diagnosed based on the medical history, physical signs and symptoms, endoscopic signs of portal hypertension, radiological evidence of liver nodularity, and liver biopsy[26].

According to the consensus of the Asian Pacific Association for the Study of the Liver[27], acute-on-chronic liver failure (ACLF) was defined as acute hepatic insult manifesting as jaundice and coagulopathy complicated within 4 wk by ascites and/or encephalopathy in patients with previously diagnosed or undiagnosed chronic liver disease associated with high mortality.



AKI was defined and classified using the RIFLE, AKIN, KDIGO or ICA classifications (Supplementary Table 1). The peak AKI stage based on the SCr level or UO criterion during hospitalization was used. For the RIFLE, KDIGO and ICA classifications, the last SCr level recorded within the previous 3 mo before admission was used as the baseline SCr level, but the SCr level at admission was used as the baseline SCr level for patients without a previous SCr measurement[1]. The SCr level at admission was also considered the baseline SCr level for the AKIN classification. The glomerular filtration rate (GFR) was used for the RIFLE classification, and the eGFR was calculated using the revised Schwartz method[28]. UO was used in the RIFLE, AKIN and KDIGO classifications.

Calculations of the CTP, MELD and MELD-Na scores

The CTP score was calculated as described in previous reports and classified as grade A (5-6 points), grade B (7-9 points), and grade C (10-15 points)[29]. The computed formula for the MELD score was 3.8 × ln (bilirubin, mg/dL) + 11.2 × ln (international normalized ratio) + 9.6 × ln (creatinine, mg/dL) + 6.4 (constant for liver disease etiology)[30,31]. The computed formula for the MELD-Na score was MELD + 1.59 × [135 – (Na, mmol/L)], and sodium ion concentrations ranged from 125 to 140 mmol/L[32].

Management of patients

A comprehensive medical intervention was administered to every patient, including supportive therapy, prevention and treatment of complications, and reduction or withdrawal of all unnecessary nephrotoxic medications. Patients also received albumin, vasoconstrictors (norepinephrine and terlipressin), intravenous antibiotics, diuretics, proton pump inhibitors or continuous renal replacement

Figure 1 Flow chart of patient inclusion and exclusion. AKI: Acute kidney injury; RRT: Renal replacement therapy.

therapy if required. Twenty-six patients (10.4%) received continuous replacement therapy.

Follow-up and outcomes

After the diagnosis of AKI, regular follow-up was performed for all cirrhotic patients with AKI by telephone and electronic medical records. Patients were followed for a maximum of 180 d or until death, liver or renal transplantation, or the end of the study period. Follow-up data on the prognosis were collected and evaluated. The primary endpoint of the study was the mortality rate.

Statistical analysis

All continuous variables were tested for a normal distribution using the Kolmogorov–Smirnov test. Variables that met the normal distribution are presented as the mean ± SD and were analyzed using Student's *t* test, while nonnormally distributed variables are summarized as medians and interquartile ranges and were analyzed using the Mann–Whitney *U* test. Categorical variables are presented as numbers and percentages and were analyzed using the χ^2 test or Fisher's exact test. Cumulative survival was evaluated using the Kaplan–Meier method and compared between groups using the log-rank test. The univariate analysis of risk factors of death in cirrhotic patients with AKI was performed using Cox regression analysis, and multivariate Cox analysis with the forward Wald method was subsequently performed for all variables with *P* values less than 0.2.

A nomogram was developed based on the weighted sum of each independent variable, with weights equal to the hazard ratios from the multivariate Cox model to predict the prognosis of cirrhotic patients with AKI. The area under the receiver operating characteristic curve (AUROC), calibration curve and decision curve analysis (DCA) were used to evaluate its predictive performance. All tests were two-tailed, and *P* values less than 0.05 were considered indicative of statistical significance. Data were analyzed using SPSS software, version 23.0 (SPSS Inc., Chicago, IL, Untied States) and R software, version 3.5.3.

RESULTS

Baseline characteristics of the study patients

The characteristics of the patients in the training and validation cohorts are summarized in Table 1. Among the 250 patients, the mean age was 53.6 ± 13.3 years, and most of the patients were male (190/250, 76.0%). Notably, 25.6% (64/250) of the patients presented AKI at the time of admission, and 74.4% (186/250) developed AKI during hospital stay. Only 7 (2.8%) of these patients had compensated cirrhosis, and 243 (97.2%) patients had decompensated cirrhosis. The main etiology of these patients in both datasets was hepatitis B, accounting for 69.6% (174/250) of the entire cohort. Most of the patients (239/250, 95.6%) had ascites, and 60.8% (152/250) of the patients had ACLF. The main causes of AKI were hypovolemia (136/250, 54.4%), followed by infections (54/250, 21.6%), nephrotoxicity (21/250, 8.4%) and other factors (39/250, 15.6%). In the comparison of the training cohort and validation cohort, although the MAP, albumin level and serum sodium level were significantly different (all $P < 0.05$), a significant difference in mortality was not observed between the training (75.1%) and validation (79.2%)

Table 1 Demographic and baseline clinical characteristics of cirrhotic patients with acute kidney injury

Variables	Total (*n* = 250)	Training cohort (*n* = 173)	Validation cohort (*n* = 77)	*P* value
Age (yr), mean ± SD	53.6 ± 13.3	53.3 ± 13.1	54.4 ± 13.7	0.554
Male, *n* (%)	190 (76.0)	127 (73.4)	63 (81.8)	0.199

Admission SCr (mg/dL), (IQR)	1.17 (0.8-1.8)	1.17 (0.80-1.75)	1.26 (0.77-1.79)	0.897
Peak SCr > 1.5 mg/dL during hospitalization, *n* (%)	211 (84.4)	148 (85.5)	63 (81.8)	0.283
HDL (mmol/L), mean ± SD	0.34 ± 0.33	0.36 ± 0.33	0.37 ± 0.31	0.857
LDL (mmol/L), mean ± SD	1.2 ± 1.0	1.2 ± 0.9	1.1 ± 1.1	0.783
CTP score, mean ± SD	10.6 ± 1.8	10.7 ± 1.8	10.4 ± 1.9	0.396
MELD, mean ± SD	23.6 ± 8.8	24.0 ± 8.2	22.7 ± 9.9	0.304
MELD-Na, mean ± SD	29.0 ± 13.0	30.1 ± 12.7	26.5 ± 13.3	0.044
Mortality within 180 d, *n* (%)	191.0 (76.4)	130 (75.1)	61 (79.2)	0.298
Period of follow up (d), median (IQR)	35.0 (17.0-143.0)	38.0 (18.0-151.0)	32.0 (15.0-119.0)	0.512

MAP: Mean arterial pressure; IQR: Interquartile range; bpm: Beat per minute; SCr: Serum creatinine; HE: Hepatic encephalopathy; INR: International normalized ratio; ACLF: Acute on chronic liver failure; WBC: White blood cell; UO: Urine output; HDL: High-density lipoprotein; LDL: Low-density lipoprotein; CTP: Child-Turcotte-Pugh; MELD: The model for end-stage liver disease; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase.

datasets (P = 0.298). Based on RIFLE, AKIN, KDIGO and ICA classifications, 234, 221, 241 and 211 of all 250 patients were diagnosed with AKI, respectively. No patients who underwent liver transplantation.

Mortality of cirrhotic patients with AKI

The median period of follow-up for all 250 patients after the diagnosis of AKI was 35.0 (17.0-143.0) d. The overall 30-d mortality, 90-d mortality and 180-d mortality rates were 46.4% (116/250), 68.8% (172/250) and 76.4% (191/250), respectively. Among these patients who died, the most common cause of mortality was hepatic failure (74/191, 38.7%), followed by infections (41/191, 21.5%), renal failure (34/191, 17.8%), variceal bleeding (24/191, 12.6%), and other causes (19/191, 9.9%). The median follow-up periods in the training and validation cohorts were 38.0 (18.0-151.0) and 32.0 (15.0-119.0) d, respectively. The mortality rates of the training cohort were 45.1%, 68.2% and 75.1% at 30 d, 90 d and 180 d, respectively. The mortality rates at 30 d, 90 d and 180 d were 49.4%, 70.1% and 79.2% in the validation cohort, respectively. No significant difference in mortality was observed during follow-up in either dataset (P = 0.511; Figure 2).

Potential risk factors for mortality in the training cohort

During the follow-up period, 130 cirrhotic patients with AKI in the training cohort died. We performed a Cox regression analysis to identify risk factors of death from cirrhotic patients with AKI (Table 2). The univariate Cox regression analysis showed that a heart rate > 100 bpm, UO, presence of diabetes, total bilirubin level, international normalized ratio (INR), serum sodium level, high-density lipoprotein level, admission SCr level, peak SCr level > 1.5 mg/dL, overt hepatic encephalopathy (HE) or ACLF, and CTP, MELD and MELD-Na scores were potential risk factors of mortality. Multicollinearity between CTP, MELD and MELD-Na scores and other predictors was avoided by excluding these predictive models from the multivariate analysis. Subsequently, the multivariate Cox regression analysis revealed that the presence of diabetes [Hazard ratio (HR) = 1.795; 95% confidence interval (CI): 1.048-3.076; P = 0.001], HE (HR = 1.986; 95%CI: 1.381-2.856; P < 0.001), INR (HR = 1.390; 95%CI: 1.081-1.787; P = 0.010), serum sodium level (HR = 0.964; 95%CI: 0.937-0.992; P = 0.011) and peak SCr level > 1.5 mg/dL (HR = 2.026; 95%CI: 1.109-3.702; P = 0.022) were potential risk factors for mortality in cirrhotic patients with AKI.

Establishment of a prediction nomogram in the training cohort

A nomogram incorporating these potential risk factors recorded after the diagnosis of AKI during hospitalization was constructed to predict the probability of death within 180 d for cirrhotic patients with AKI (Figure 3). Each predictor had a number with weights equal to the HR of the multivariate Cox regression model, and the estimated probability of death for cirrhotic patients with AKI was calculated by adding the scores of each predictor.

Validation of the prediction nomogram

In the training cohort, the AUROC of the nomogram in predicting mortality at 30, 90 and 180 d were 0.757 (95%CI: 0.685-0.830), 0.792 (95%CI: 0.726-0.859) and 0.801 (95%CI: 0.726-0.870), respectively, which exhibited good discrimination for the prognosis of cirrhotic patients with AKI (Figure 4A). The calibration plots of 30-, 90- and 180-d survival showed satisfactory agreement between the predicted prognosis and actual prognosis probability in the training cohort (Figure 4B-D). In the validation cohort, the nomogram also displayed good discrimination with AUROCs of 0.763 (95%CI: 0.656-0.869), 0.817 (95%CI: 0.716-0.917) and 0.862 (95%CI: 0.765-0.958) in predicting mortality at 30, 90 and 180 d, respectively (Figure 5A). The calibration plots also showed good agreement between the predicted and actual prognosis probabilities in the validation cohort (Figure 5B-D). Based on the results, the nomogram had good discrimination and calibration in predicting the prognosis of cirrhotic patients with AKI.

Performance of the nomogram in predicting mortality

We compared the performance of the nomogram with CTP, MELD and MELD-Na scores in predicting the overall survival of cirrhotic patients with AKI, and the results are shown in Table 3. There were no significant differences between the nomogram and the CTP, MELD and MELD-Na scores in predicting 30-d mortality for either the training or validation cohort (all P > 0.05; Figure 6A and B). However, the AUROC of the nomogram in predicting mortality at 90 d was significantly higher than that of the CTP, MELD and MELD-Na scores in both the training and validation cohort (all P < 0.05; Figure 6C and D). Moreover, the AUROC of the nomogram in predicting mortality at 180 d was also larger than that of the CTP, MELD and MELD-Na scores in both the training and validation cohort (all P < 0.05; Figure 6E and F). With regard to clinical usefulness, DCA of the nomogram was depicted and compared with the CTP, MELD and MELD-Na scores. Compared with the CTP, MELD and MELD-Na scores, medical intervention guided by the nomogram increased the net benefit for 90- and 180-d overall survival but nor 30-d overall survival in the training dataset (Figure 7A-C). In the validation dataset, the similar result was obtained: The nomogram showed the best net benefit for 90- and 180-d overall survival but not 30-d overall survival (Figure 7D-F). Taken together, these results showed that the nomogram better predicted the overall survival of cirrhotic patients with AKI than the CTP, MELD and MELD-Na scores.

According to the nomogram, the score of each patient was calculated and utilized for a stratified analysis. Based on the Youden index, the optimal cutoff value of the nomogram score in predicting mortality within 180 d in the training cohort was 98, with a sensitivity of 56.1% and a specificity of 90.7%. Based on the threshold of 98, patients in the training cohort were divided into two subgroups, with high risk (> 98 points, n = 77) and low risk (≤ 98 points, n = 96) of mortality. The high-risk group had a significantly higher mortality rate within 180 d than the low-risk group (94.8% *vs* 59.4%, P < 0.001; Figure 8A). In the validation cohort, the same cutoff value was used, and the sensitivity and specificity of the nomogram were 55.6% and 92.9%, respectively. Patients from the validation cohort were also stratified into a high-risk group (n = 36) and a low-risk group (n = 41), and the mortality rate was significantly different between both risk groups (97.2% *vs* 68.3%, P < 0.001; Figure 8B).

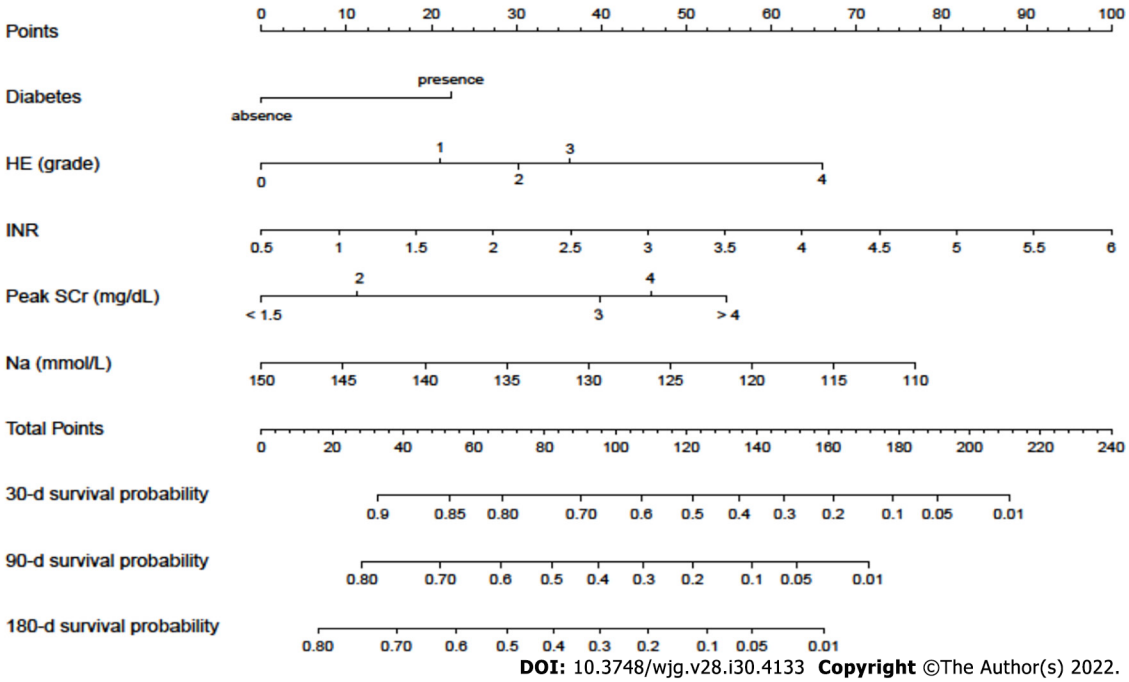
DISCUSSION



In this study, we conducted a Cox regression analysis to identify the risk factors for mortality within 180 d in cirrhotic patients with AKI, and these predictors included the presence of diabetes, HE, INR, serum sodium level and peak SCr levels. A nomogram incorporating these predictors was developed and showed good predictive discrimination and calibration for the mortality of these patients. Moreover, compared with the CTP, MELD and MELD-Na scores, the nomogram showed better performance for predicting the overall survival of cirrhotic patients with AKI. To our knowledge, this is the first to establish a quantitative nomogram based on these risk factors for the overall survival of cirrhotic patients with AKI.

AKI is a very common and life-threatening complication in patients with cirrhosis and has an unacceptably high mortality rate[33]. Therefore, many AKI criteria and classifications have been developed over the past two decades to comprehensively evaluate and diagnose AKI as early as possible and improve the prognosis. Currently, four main classifications are used: The RIFLE[3], AKIN [4], KIDGO[5] and ICA[1] criteria. SCr level and UO, which are established markers of kidney function, were the basis for the development of these AKI classifications. The use of the SCr level alone to diagnose with AKI may not be appropriate. First, SCr levels are influenced by various factors, such as age, race, sex, body weight, tubular creatinine secretion and the effect of bilirubin on creatinine assays [34,35]. Second, in patients with advanced cirrhosis in particular, the diagnostic value of SCr levels was diminished because of the reduced hepatic production of creatinine from creatine and muscle wasting[7, 36]. Finally, a greater number of AKI cases could be detected earlier using UO in combination with the

SCr level[37-39]. Notably, UO is also affected by many factors, such as the body fluid volume of the patients and the use of diuretics, which may decrease the diagnostic and predictive value of the UO criteria for AKI[37]. As a result, any single criterion for AKI may not be able to comprehensively identify and evaluate these patients. Therefore, in the present study, patients who met the criteria for at least one of the RIFLE, AKIN, KDIGO and ICA classifications were recruited as comprehensively as possible, to analyze the clinical characteristics of cirrhotic patients with AKI and identify risk factors for mortality.

The mortality rate of cirrhotic patients with AKI displays substantial heterogeneity among studies. Xiong *et al*[9] reported that the mortality rates were 76.1% and 86.7% in-hospital and at 6 mo, respectively, for patients with cirrhosis who were diagnosed with AKI upon admission to the intensive care unit (ICU), which was consistent with the results of previous studies[7,40]. The results were significantly higher than the values reported in our present study (52.4% in-hospital mortality and 76.4% 180-d mortality). Another study conducted by Kumar *et al*[41] showed that the mortality rate at 30 d was 46.7% for cirrhotic patients with AKI, which was consistent with our result of 46.4%. A meta-analysis conducted by Tariq *et al*[42] revealed that the overall in-hospital mortality, 30-d mortality, and 90-d mortality rates of patients with liver cirrhosis were 34.6%, 42.4%, and 47.1%, respectively, which was lower than the results from our study (52.4% in-hospital mortality, 46.4% 30-d mortality, and 68.8% 90-d mortality). The heterogeneity of the mortality rate may be mainly affected by the difference in the

severity of the patient's condition. Moreover, some serious complications of patients with cirrhosis may also contribute to the high mortality rate. For instance, in the present investigation, 60.8% (152/250) of patients had cirrhosis combined with ACLF, resulting in an increase in the AKI mortality rate, which was supported by previous studies by Zang *et al*[43] and Shi *et al*[44]. Furthermore, the literature has indicated that the mortality of AKI in patients with cirrhosis who were admitted to the ICU was significantly higher than that of patients admitted to regular wards[7,42]. In addition, the use of different AKI criteria to identify patients among studies also resulted in different the mortality rate[6,7]. Notably, the types of AKI may also affect the prognosis of these patients. AKI is usually divided into three subtypes: Prerenal AKI, acute tubular necrosis (ATN) and hepatorenal syndrome (HRS)[9]. AKI is closely associated with the prognosis of patients with cirrhosis. A retrospective study showed that compared with non-AKI patients, patients with prerenal AKI had a 2.37-fold higher risk of in-hospital death, patients with ATN had a 6.878-fold higher risk, and patients with HRS had a 12.98-fold higher risk[9]. The result seems to indicate that cirrhotic patients with HRS have a higher risk of death than those with ATN and prerenal AKI. Moreover, patients with HRS-AKI have a worse prognosis than those with non-HRS-AKI[2]. Taken together, the varying mortality of AKI in patients with cirrhosis may be influenced by the severity of the liver disease, the diversity of AKI classifications, survey populations, complications of cirrhosis, and the subtypes of AKI, making the evaluation of AKI difficult and in many cases impossible.

Considering the high mortality rate of AKI in patients with cirrhosis, the identification of risk factors for mortality in these patients is meaningful. However, few studies conducted to date have focused on investigating the risk factors for death in cirrhotic patients with AKI. A study conducted by Kumar *et al*[41] showed that the presence of jaundice, HE, SCr level > 1.5 mg/dL at admission, CTP score, and MELD score were independent predictors of mortality for cirrhotic patients with AKI. Another study by Pan *et al*[40] found that MAP, total bilirubin levels, acute respiratory failure and sepsis were closely associated with the prognosis of cirrhotic patients with AKI who were admitted to the ICU. In the present study, the serum sodium level, INR, peak SCr level > 1.5 mg/dL, the presence of diabetes and HE were considered potential risk factors for death in cirrhotic patients with AKI. Notably, the CTP, MELD and MELD-Na scores were excluded from the multivariate Cox regression analysis because of the increased probability of multicollinearity. An increase in INR is one of the manifestations of

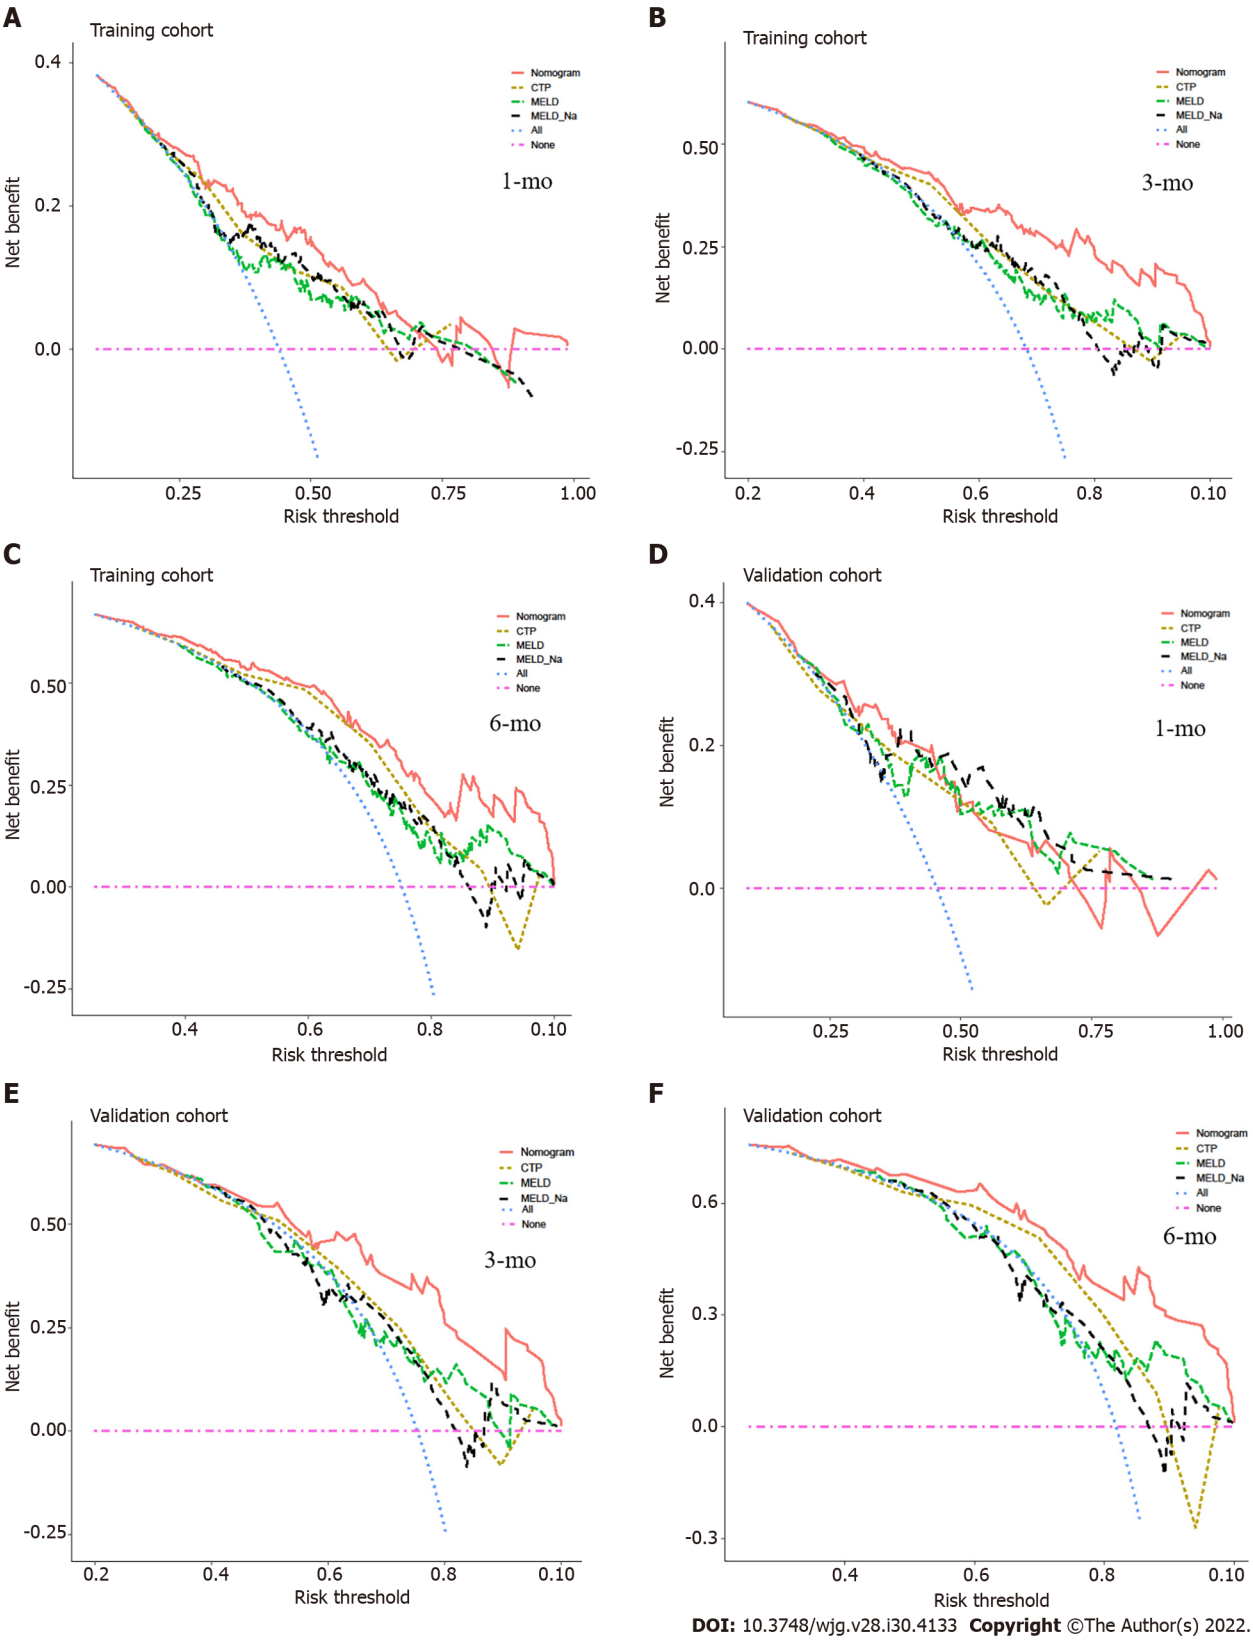
synthesis dysfunction in the liver. Similarly, HE is also an important feature of liver failure. Once HE occurs in patients with chronic liver disease, the prognosis is very poor, with a 1-year survival rate of less than 50% and a 3-year survival rate of less than 25%[46]. Studies have shown that INR is associated with the death of patients with cirrhosis[46,47]. Moreover, a serum sodium imbalance is very common in cirrhotic patients with AKI and affect the prognosis of these patients[48-50]. Furthermore, the SCr level represents the status of renal function. Patients with a peak SCr > 1.5 mg/dL had a higher short-term mortality rate than those with a peak SCr ≤ 1.5 mg/dL[51,52]. A study showed that a SCr > 1.5 mg/dL was an independent predictor of mortality in cirrhotic patients with AKI[41]. In addition, diabetes was also considered an independent risk factor for mortality in cirrhotic patients with AKI in this study. Although the mechanisms underlying the relationship between diabetes and mortality in cirrhotic patients with AKI remain unclear, several studies have documented that the presence of diabetes and poorly controlled blood glucose levels are associated with the prognosis of patients with cirrhosis[53-55]. Diabetes is an independent risk factor for the development of AKI or acute kidney disease[56,57]. Consequently, we postulate that the presence of diabetes is associated with the prognosis of cirrhotic patients with AKI. Overall, the recovery of liver and kidney function, correction of electrolyte imbalances, and monitoring and control of blood glucose levels in patients with diabetes may improve the poor prognosis of cirrhotic patients with AKI.



Currently, many studies have investigated the risk factors for the development of AKI in patients with numerous acute and chronic diseases, or have established a model for the development of AKI[20,58-60]. However, studies focused on predicting the prognosis of cirrhotic patients with AKI are scarce. According to Kumar *et al*[41], the AUROCs of CTP and MELD scores were 0.82 and 0.84, respectively, for predicting 30-d mortality in cirrhotic patients with AKI who met the ICA classification. Fang *et al*[45] reported that CTP and MELD scores had AUROCs of 0.61 and 0.757, respectively, for predicting in-hospital mortality of cirrhotic patients with AKI. Moreover, another prospective study conducted by Pan *et al*[40] indicated that CTP and MELD scores had AUROCs of 0.622 and 0.776, respectively, for predicting the in-hospital mortality of cirrhotic patients with AKI who met the RIFLE classification. In the present study, the AUROCs of CTP and MELD scores were 0.694 and 0.669, respectively, for predicting 30-d mortality of cirrhotic patients with AKI in the training cohort, respectively. The discrim-

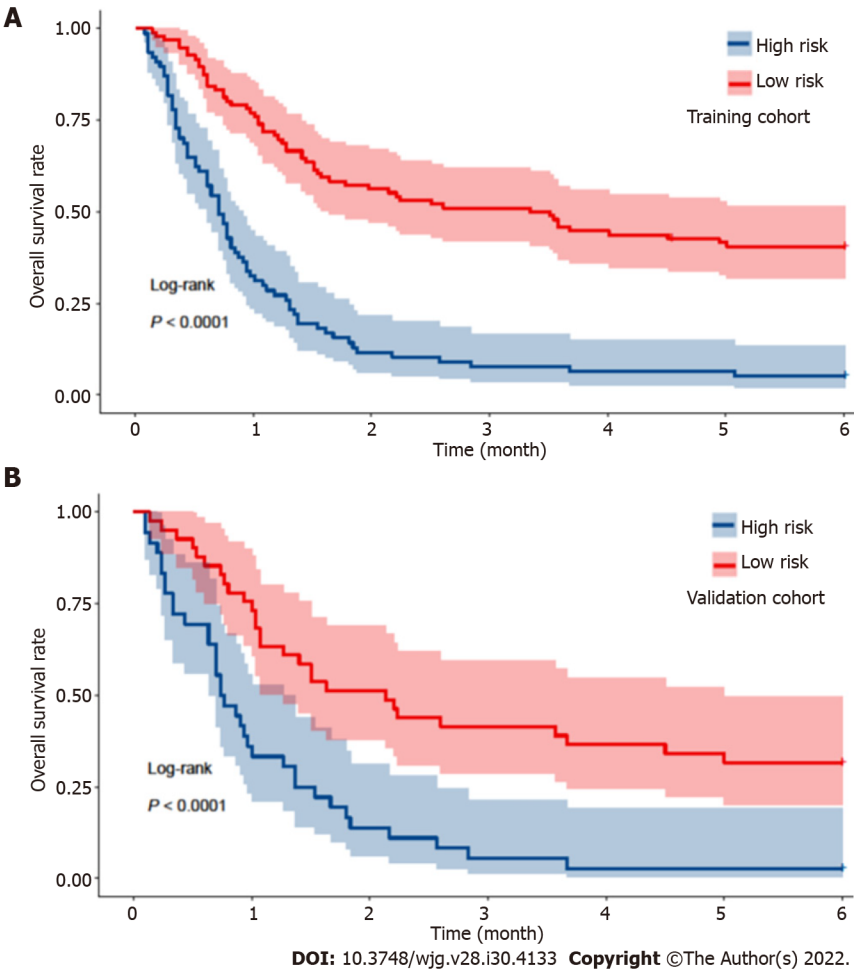

Figure 6 Comparison of the performance of the nomogram and the other scores in predicting mortality of cirrhotic patients with acute kidney injury. A: The area under the receiver operating characteristic curve (AUROC) of the nomogram and the Child-Turcotte-Pugh (CTP), model for end-stage liver disease (MELD) and MELD-Na scores in predicting 30-d mortality in the training cohort; B: The AUROCs of the nomogram and the CTP, MELD and MELD-Na scores in predicting 30-d mortality in the validation cohort; C: The AUROCs of the nomogram and the CTP, MELD and MELD-Na scores in predicting 90-d mortality in the training cohort; D: The AUROCs of the nomogram and the CTP, MELD and MELD-Na scores in predicting 90-d mortality in the validation cohort; E: The AUROCs of the nomogram and the CTP, MELD and MELD-Na scores in predicting 180-d mortality in the training cohort; F: The AUROCs of the nomogram and the CTP, MELD and MELD-Na scores in predicting 180-d mortality in the validation cohort. CTP: Child-Turcotte-Pugh; MELD: Model for end-stage liver disease.

inative ability of CTP and MELD scores differed among studies, which may be explained by the analysis of different patients. Patients with cirrhosis who were diagnosed with AKI in the study by Kumar *et al* [41] only met the ICA criteria, and those patients in the studies by Fang *et al*[45] and Pan *et al*[40] only met the RIFLE criteria, while the study population in our cohort met the criteria for at least one of the main four classifications. In addition, Fang *et al*[45] developed an MBRS (MAP + bilirubin + respiratory failure + sepsis) score (AUROC = 0.898) (including MAP, serum bilirubin level and presence of acute respiratory failure and sepsis) in 2008, a predictive model for cirrhotic patients with AKI, that had better discriminative ability than the CTP and MELD scores. Another prospective study by their team published in 2012 further validated the discrimination and calibration of the MBRS score[40]. The AUROCs and goodness-of-fit of the MBRS were 0.863 and 1.160, respectively, which were superior to the CTP and MELD scores in terms of discriminative ability[40]. Notably, the development of the MBRS score was based on patients admitted to the ICU who may suffer from multiple organ failures and comorbidities, but the authors did not clearly determine whether the MBRS score was applicable to

Figure 8 Kaplan–Meier analysis of the cirrhotic patients with acute kidney injury stratified into high-risk and low-risk mortality groups according to the nomogram score, with cutoff of 98. A: Overall survival rates were compared between patients with a high and low risk of mortality in the training cohort; B: Overall survival rates were compared between patients with a high and low risk of mortality in the validation cohort.

patients admitted to regular wards, which requires further validation in the future. Moreover, some clinical data incorporated in the MBRS score, such as the fraction of inspired oxygen, are difficult to obtain in the regular ward and have a complex calculation, which may result in the score not being widely used in clinical practice.

In the present study, we developed a quantitative and visual nomogram for predicting the overall survival of cirrhotic patients with AKI based on these potential risk factors of mortality. The nomogram could be used to calculate the scores corresponding to each potential risk factor, and the predicted probability corresponding to the sum of the scores represented the risk of death for patients with cirrhosis and AKI. For example, patients with cirrhosis presenting AKI and diabetes had SCr level of 2 mg/dL, INR 2, grade 1 HE and blood sodium level of 130 mmol/L. The total score of the patient was approximately 118 points (SCr level of 2 mg/dL, approximately 11 points; INR 2, approximately 26 points; grade 1 HE, approximately 21 points; diabetes, approximately 22.5 points; and blood sodium level of 130 mmol/L, approximately 37.5 points.), and the probability of the overall survival at 30, 90 and 180 d was approximately 53%, 23% and 15%, respectively. Compared with the CTP, MELD and MELD-Na scores, the nomogram had better discriminative power for mortality at 90 and 180 d in both the training and validation datasets (all $P < 0.05$). Moreover, with regard to clinical decisions, the DCA curve indicated that the nomogram had more net benefits than the CTP, MELD and MELD-Na scores for predicting mortality at 90 and 180 d in both the training and validation datasets. However, the AUROC and DCA curves were not significantly different between the nomogram and the CTP, MELD and MELD-Na scores for predicting mortality at 30 d in both the training and validation datasets. Overall, the nomogram was also superior to the CTP, MELD and MELD-Na scores in predicting the prognosis of cirrhotic patients with AKI, especially 90- and 180-d mortality. Furthermore, a score for each patient was calculated based on the nomogram and utilized for stratifing patients into two risk groups for mortality. The high-risk group had a significantly higher mortality rate within 180 d than the low-risk group (all $P < 0.001$) in both the training and validation cohorts. The mortality rates of high-risk patients were as high as 94.8% in the training cohort and 97.2% in the validation cohort. As a result, the nomogram might select patients with a high-risk mortality to allow treatments to be provided as soon as

possible, which may improve the prognosis of cirrhotic patients with AKI. In addition, compared with the MBRS score, the five variables included in the nomogram were all convenient and easily accessible in clinical practice. Since the use of nomograms for evaluation in clinical practice can be time-consuming and complicated, our next step will be to develop software that can be embedded in electronic medical systems to guide clinicians in the timely treatment of these patients and reduce patient mortality without increasing the working time and burden of clinicians.

Several limitations of the present study should also be considered. First, this study analyzed a small sample and employed a retrospective design in which selection biases were unavoidable. Second, this investigation was performed at one academic tertiary-care medical center; the results may not be extrapolated to other centers. In addition, a prospective, large-scale and multicenter study will be needed to validate the reliability of the nomogram.

CONCLUSION

In conclusion, the presence of HE and diabetes, serum sodium level, INR and peak SCr level > 1.5 mg/dL were considered potential risk factors for mortality. A nomogram based on these risk factors was established, and compared with the CTP, MELD and MELD-Na scores, the nomogram exhibited better predictive performance for the overall survival of cirrhotic patients with AKI. According to the score obtained from the nomogram, patients with a high risk of mortality could be selected for suitable individualized treatments, which may improve the prognosis of cirrhotic patients with AKI.

ARTICLE HIGHLIGHTS

Research background

Acute kidney injury (AKI) is a life-threatening complication in cirrhotic patients and is closely associated with the prognosis of these patients. The mortality of AKI in patients with cirrhosis was as high as 80%. Therefore, the identification of patients with AKI at high risk of death is necessary to improve their prognosis.

Research motivation

The majority of studies have focused on investigating the risk factors for the development of AKI or establishing a risk score model for predicting the development of AKI. However, studies focused on identifying the potential risk factors for cirrhotic patients with AKI are scarce.

Research objectives

This study aimed to identify risk factors of mortality and establish a nomogram for predicting overall survival in cirrhotic patients with AKI.

Research methods

We included 250 eligible cirrhotic patients with AKI in this study. These patients were randomly divided into a training cohort and a validation cohort at a ratio of 2:1. Potential risk factors for death were investigated by performing a Cox regression analysis of the training cohort. A prognostic nomogram was developed and evaluated by calculating the area under the curve of the receiver operating characteristic curve, constructing a calibration curve and performing decision curve analysis.

Research results

The serum sodium level, international normalized ratio, peak serum creatinine level > 1.5 mg/dL, the presence of hepatic encephalopathy and diabetes were considered potential risk factors for death in cirrhotic patients with AKI. The nomogram based on these risk factors has a good performance in predicting the short-term prognosis of cirrhotic patients with AKI. The cutoff value of 98 for the nomogram score was used to stratify patients; patients were divided into low- and high-risk groups, and high-risk patients had a higher mortality rate.

Research conclusions

The nomogram was a practical tool to predict the short-term prognosis of patients with cirrhosis who were diagnosed with AKI, and assist clinicians in making clinical decisions.

Research perspectives

The reliability and practicability of nomogram must be validated by conducting prospective, large-scale and multicenter studies. Application programs or software that can be embedded in electronic medical systems will be developed to guide clinicians in the timely evaluation and treatment of these patients.

FOOTNOTES

Author contributions: Wan YP, Wang AJ and Zhang W equally contributed to this work; Wang AJ and Zhu X contributed to the concept; Wan YP, Wang AJ and Zhang W designed this study; Wan YP performed the manuscript writing; Zhang W performed data analysis; Zhang H and Peng GH contributed to samples collection and data collection and validation; Zhu X were clinical experts and performed the manuscript revision; all authors read and approved the final version of the manuscript.

Supported by the National Natural Science Foundation of China, No. 81960120 and No. 82160115.

Institutional review board statement: This study was reviewed and approved by the Ethics Committee of The First Affiliated Hospital of Nanchang University (No. AF-SG-04-2.0).

Informed consent statement: Patients were not required to give informed consent to the study because the analysis used anonymous clinical data that were obtained after each patient agreed to treatment by written consent. For full disclosure, the details of the study are published on the home page of The First Affiliated Hospital of Nanchang University.

Conflict-of-interest statement: We have no financial relationships to disclose.

Data sharing statement: No additional data are available.

Open-Access: This article is an open-access article that was selected by an in-house editor and fully peer-reviewed by external reviewers. It is distributed in accordance with the Creative Commons Attribution NonCommercial (CC BY-NC 4.0) license, which permits others to distribute, remix, adapt, build upon this work non-commercially, and license their derivative works on different terms, provided the original work is properly cited and the use is non-commercial. Abstract

BACKGROUND

The emergence of restorative total proctocolectomy has significantly reduced the lifetime colorectal cancer risk associated with familial adenomatous polyposis (FAP). However, adenomas may develop in the ileal pouch over time and may even progress to carcinoma. We evaluated the cumulative incidence, time to development, and risk factors associated with ileal pouch adenoma.

AIM

To evaluate the cumulative incidence, time to development, and risk factors associated with pouch adenoma.

METHODS

In this retrospective, observational study conducted at a tertiary center, 95 patients with FAP who underwent restorative proctocolectomy at our center between 1989 and 2018 were consecutively included. The mean follow-up period was 88 mo.

RESULTS

Pouch adenomas were found in 24 (25.3%) patients, with a median time of 52 mo to their first formation. Tubular adenomas were detected in most patients (95.9%). There were no high-grade dysplasia or malignancies. Of the 24 patients with pouch adenomas, 13 had all detected adenomas removed. Among the 13 patients who underwent complete adenoma removal, four (38.5%) developed recurrence. Among 11 (45.8%) patients with numerous polyps within the pouch, seven
