ABOUT COVER

Editorial Board Member of *World Journal of Gastroenterology*, Hideyuki Chiba, MD, PhD, Director, Department of Gastroenterology, Omori Red Cross Hospital, 4-30-1, Chuo, Ota-Ku, Tokyo 143-8527, Japan. h.chiba04@gmail.com

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 edition of Journal Citation Reports® cites the 2021 impact factor (IF) for *WJG* as 5.374; IF without journal self cites: 5.187; 5-year IF: 5.715; Journal Citation Indicator: 0.84; Ranking: 31 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2021 is 8.1 and Scopus CiteScore rank 2021: Gastroenterology is 18/149.

Abstract

Dysregulated interactions between host inflammation and gut microbiota over the course of life increase the risk of colorectal cancer (CRC). While environmental factors and socio-economic realities of race remain predominant contributors to CRC disparities in African-Americans (AAs), this review focuses on the biological mediators of CRC disparity, namely the under-appreciated influence of inherited ancestral genetic regulation on mucosal innate immunity and its interaction with the microbiome. There remains a poor understanding of mechanisms linking immune-related genetic polymorphisms and microbiome diversity that could influence chronic inflammation and exacerbate CRC disparities in AAs. A better understanding of the relationship between host genetics, bacteria, and CRC pathogenesis will improve the prediction of cancer risk across race/ethnicity groups overall.

Key Words: Inflammation; African-American; Population-specific genome wide association studies; Minorities health; Microbiome; Colorectal cancer

Core Tip: Studies largely examine either variations in microbiome composition or host immunity polymorphisms, often using genome-wide association studies comprised of populations mainly of European ancestry. There is, thus, a pressing need for studies that include, recruit, and account for more widely diverse cohorts. Identification of population-associated polymorphisms driving host/microbiome interactions linked to colorectal cancer (CRC) disparity may reveal genes or pathways that could be targeted for patient-specific CRC interception strategies.

INTRODUCTION

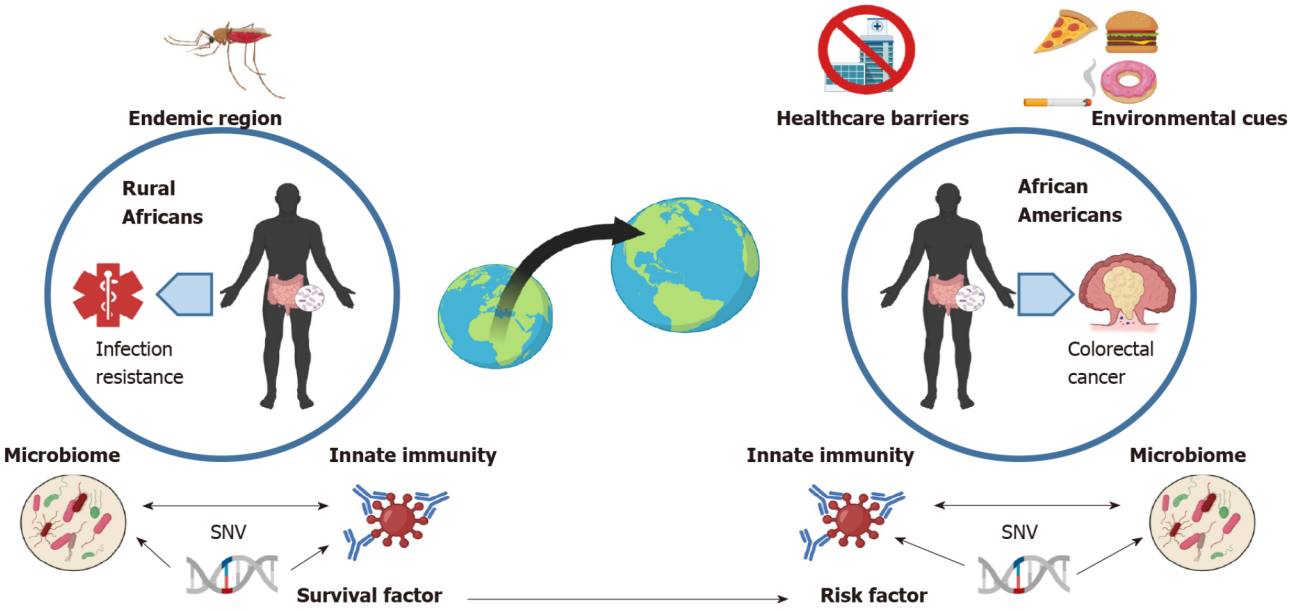
Colorectal cancer (CRC) is the second leading cause of death amongst cancer patients, an estimated 53000 of whom will die in the United States from CRC in 2021[1]. Strikingly, although total CRC mortality has decreased over the last two decades, particularly in older individuals (age 64 +), CRC incidence has increased in individuals under 50[1]. Recent studies showed early-onset CRC patients were more likely to be African-Americans (AAs), who bear the highest CRC incidence rate between 20-year-old and 44-year-old (7.9/100000) as compared to Caucasian Americans (CAs) (6.7/100000) and Asian-Pacific Islanders (6.3/100000)[2]. AAs commonly display more aggressive types of CRC as well, and are generally diagnosed at more advanced stages of the disease, exhibiting survival rates 7% below those of CAs (58% *vs* 65% 5-year survival)[3]. Such statistics must be interpreted cautiously, since the noted increase of early-onset CRC may result from recently recommended and adopted early colonoscopy (40-45 years old) screening campaigns. Nevertheless, there are multiple proposed influences on CRC disparities in AAs, including differences in health care and treatment access, comorbidities and tumor characteristics[4-8]. Socioeconomic status (SES) also weighs heavily on the late diagnoses and prevention campaign efficacy observed in AA populations[2,6,9]. Undoubtedly the source of CRC disparity is multifactorial, and a layered perspective is imperative to address the alarming rise of early onset CRC, an otherwise preventable disease when detected early.

Herein, we aim to elucidate novel biological factors that may also contribute to the AA disparities in CRC mortality. Specifically, in addition to the genetic influence on CRC pathogenesis, an accumulating body of evidence connects CRC to dysregulated interactions between mucosal innate immunity and the microbiome[10]. Indeed, sustained inflammation promoted by chronic colorectal dysbiosis is an established driver of CRC pathogenesis[11]. Related to this notion is a recent gut microbiome profiling study that found that, in addition to diminished overall species diversity, pro-inflammatory *Fusobacterium nucleatum (F. nucleatum)* and *Enterobacter* species were significantly more abundant in AA CRC patients as compared to a CA cohort[12]. The presence of *F. nucleatum* has also been linked to inflammation-associated microsatellite alterations found more prevalently in AA rectal tumors, a finding linked to worsened CRC prognosis[13-15]. Furthermore, genetic landscape and microbiome composition have been shown to influence the occurrence of proximal colorectal tumors[16], which are more difficult to detect and are diagnosed nearly four times more often in AA than in CA CRC patients[17]. Nearly 80% of sessile serrated polyps are found in the proximal colon, a phenomenon associated with microbial biofilms and *Fusobacteria*, plus the frequency of *BRAF* mutations, CpG island hypermethylation phenotype, and microsatellite instability that increases from the distal to the proximal region[16,18-22]. Altogether, there is emerging research on the genetically tuned relationships between mucosal innate immunity, the microbiome, and disparate CRC development, but a functional understanding of how said relationships impact CRC pathology remains incomplete[23]. Additionally, despite the evidence that mucosal innate immunity and the microbiome are intimately connected, this review highlights how minority health research currently evaluates their contribution to CRC risk in a largely separate fashion [24].

Accordingly, we propose an integrated concept whereby a differential mucosal inflammatory response to gut microbiota, influenced by host genetic ancestry, represents an underappreciated factor affecting population susceptibility to CRC. In support of this concept, a recent study found that the most differentially expressed genes (DEGs) between AA and CA CRC tumors were related to the regulation of inflammatory immunity[25]. More broadly, transcriptional regulation of inflammation was determined the most distinguishing DNA variation between African and European genetic ancestries[26]. Another study demonstrated that African genetic ancestry and level of African admixture (mixture with ancestral African genetic lineage) predicted a stronger inflammatory transcriptional response in macrophages infected with bacterial pathogens[27]. From this framework, one could theorize that in a CRC setting, the same bacterium or a community of bacteria may induce a differentially deleterious

inflammatory response based on a patient's immune-related genetic background. Positive ancestral selection of anti-pathogenic immunity providing survival benefit in endemic areas may, in a modern "westernized life style" context, exacerbate localized inflammation in the tumor micro-environment and, when compounded by SES and environmental factors, accelerate CRC progression into the more aggressive form seen in AA patients, whose self-reported race/ethnicity correlates with an elevated African admixture[28,29] (Figure 1).

Given that SES and a variety of environmental factors associated with CRC pathogenesis and disparities are commonly discussed elsewhere[2,9], we are limiting the scope of the present review to the nascent literature associating CRC first to genetic polymorphisms related to innate immunity, second to those related to the microbiome, and finally explore how they may conjointly contribute to CRC disparities in the AA population. We also emphasize that, by considering admixture and genetic ancestry rather than self-reported race, population-specific risk studies including microbiome genome-wide association studies (GWAS) can more accurately capture human genetic diversity, thereby increasing the likelihood of identifying clinically relevant CRC risk factors associated with African ancestry[30-34]. Furthermore, polymorphisms related to innate immunity as well as the microbiome and contributing to links between CRC risk and African ancestry may have been left undiscovered by the longstanding genetic homogeneity of genomic research cohorts, a problem we discuss in our closing remark. Although technically challenging, expanding GWAS to more diverse "multi-ancestry" cohorts will reveal novel linkages between the microbiome, inflammation, and CRC risk that can build predictive polygenic risk scores adaptable to an equally diverse patient base[35,36]. Crucially, functional evaluation of CRC risk variants associated with African ancestry may offer insights into the trend of aggressive, earlier onset CRC in AA patients, paving the way towards personalized prevention and precision medicine.



MUCOSAL INFLAMMATION, MICROBIOME, AND CRC

To better appreciate how host genetics may impact CRC risk between populations of different ancestral origins by modulating innate immunity or the microbiome, we will first highlight how mucosal inflammation and the gut microbiome interact to affect CRC pathogenesis. The human gut contains up to 10^{13} bacteria that play critical roles in immune, metabolic, cardiovascular, and neurological development [37]. The composition and functions of this bacterial community (microbiota) and its associated genome (microbiome) are highly dynamic and influenced by both environmental factors and host genetic background to maintain immunological and metabolic functionality[38]. Meanwhile, a tightly regulated physical separation between the immune system and commensal bacteria is necessary to limit a chronic inflammatory response to the microbiota[39,40]. The integrity of the intestinal barrier and its epithelium are therefore essential elements of healthy host-microbiota mutualism[40]. To establish a "demilitarized zone" and keep microbes at bay, the epithelium uses different mechanisms including tight junctions between epithelial cells, protective mucus production, and the expression of a complex arsenal of innate receptors that trigger bactericidal mediator secretion[41]. Nevertheless, a permissible level of contact or bacterial penetrance is necessary to facilitate metabolic exchanges and immunity maturation for homeostatic equilibrium between dense microbial flora and the host[39,40].

In the case of a high-fat diet, the cumulative alteration of bacterial metabolites can disrupt this equilibrium, thereby promoting carcinogenic dysbiosis and mucosal inflammation[42]. Diet is, thus, a critical environmental factor when connecting inflammation and the microbiome to CRC risk, especially when considering CRC disparities in AAs compared to Native Africans[43-45]. However, CRC as impacted by the genetic origins of host inflammatory response remains understudied. Inflammatory bowel disease (IBD), a model of perturbed micro-immune crosstalk and a known influencing factor of CRC etiology, can be a useful departure point for this line of inquiry[46]. In fact, multiple GWAS have linked higher risk of IBD, CRC[47-50], and microbiotic dysbiosis to host genetic variations, but surprisingly little is known about how CRC disparities may be compounded by the genetic regulation of host inflammatory response to gut bacteria[51].

There are, however, documented relationships between the genetic regulation of innate inflammatory immunity, the microbiome, and colon carcinogenesis. For example, adenomatous polyposis coli (Apc) $^{Min/+}$ mice knockout for toll-like receptor (TLR) 4 or its signaling adaptor partner myeloid differentiation primary response 88 demonstrated a decreased number of intestinal polyps[52]. Nucleotide-binding oligomerization domain leucine-rich repeat and pyrin domain containing 6 and nucleotide binding oligomerization domain containing protein 2 (NOD2) knockout mice were shown to develop colon tumors following colitis, and fecal microbiota transplantation from these mice into wild type recipients triggered similar tumorigenesis, which interestingly attributed carcinogenic causality to the microbiota [53,54]. In the case of lipocaline-2 knockout mice, *Alistipes spp.* commensals thrived and drove proximal colon tumorigenesis[55]. The nature of host genetic events can therefore drive different microbiome shifts impacting CRC and its anatomical pathogenesis (*i.e.*, distal *vs* proximal).

If inflammation is a mechanism connecting the microbiome and colorectal carcinogenesis, host genetic background, including immune-related single-nucleotide polymorphisms (irSNPs), could differ-

DOI: 10.3748/wjg.v28.i25.2782 **Copyright** ©The Author(s) 2022.

Figure 1 Immune-related variant may promote survival to pathogens in ancestral African environment but precipitate cancer in descendent African-Americans. Pathogens associated with endemic African regions (*e.g.*, malaria) are thought to pressure selection for specific immune-related genetic variants associated with pathogen resistance and survival of Native Africans (left). In the context of westernized diet and lifestyle, this genetic predisposition (represented herein by a single nucleotide variant), when associated with inflammatory regulation and inherited from African ancestors, may lead to altered interactions with bacteria or communities of bacteria of the gut microbiome, thereby precipitating the colon adenoma-carcinoma sequence in African-Americans (right). Higher inflammation associated with lack of exercise, high fat diet, and socio-economic status are thought to be predominant factors driving early colorectal cancer onset in African-Americans *via* their impact on shaping the gut microbiome and its interactions with the host genetic background. SNV: Single nucleotide variant. Created with Biorender.com.

entially regulate such associations based on ancestry. In humans, pattern recognition receptor polymorphisms are associated with both IBD and CRC risk[48]. GWAS have linked genetic loci to increased IBD risk and a variety of risk alleles affect immune response[56], including NOD2 or autophagy-related 16 like 1[57,58]. Such polymorphisms have been associated with microbial dysbiosis and an excessive inflammatory response[59,60]. Namely, Knights *et al*[59] found that among 474 individuals, NOD2 variants were associated with *Enterobacteriaceae* family enrichment, including *Escherichia coli*, a species notably enriched in IBD individuals. Also, Lavoie *et al*[60] described an increase of interleukin (IL)-17-producing CD4$^+$ T (*i.e.*, Th17) cells in the lamina propria of mice engineered to express the polymorphism T300A (rs2241880) in the *Atg16 L1* gene. Although Th17-based colitis was associated with an increase of *Bacteroides ovatus*, T300A did not directly induce the increase of *Bacteroides ovatus* but rather induced the increase of IL23p19, an important cytokine for maintaining the Th17 lineage[61]. Th17 cells and their canonical cytokine IL-17 are critical pro-inflammatory contributors to epithelial homeostasis and mucosal immunity by orchestrating anti-bacterial defense and epithelial repair and regeneration as well as regulating barrier permeability by controlling the expression of occludin proteins[62,63]. When dysregulated in a chronic setting, sustained IL-17 production may promote colon tumorigenesis[64,65]. Several studies have now identified IL-23/Th17 pathway-associated polymorphisms linked to IBD susceptibility and the gut microbiome profile[66-68]. Presumably, genetic regulation of Th17-driven inflammation may impact IBD and ensuing CRC risk *via* the extent or nature of colonic dysbiosis. In sum, these GWAS suggest that by influencing the extent or nature of colonic dysbiosis, genetic regulation of inflammation represents a risk factors for both IBD and CRC. Next, we review how genetic ancestry contributes to this phenomenon, and how it may exacerbate CRC disparity in AAs.

GEOGRAPHIC AND POPULATION-RELATED INNATE IMMUNITY DISPARITIES THAT MODULATE CRC RISK

The flow of genetic information across time and geography may contribute to current disparities in cancer incidence and progression[69]. Cancer is known to result from an accumulation of somatic genetic and epigenetic alterations that dysregulate the cell cycle but also depends on genetic background and polymorphisms that impact patient risk and predisposition[70,71]. Yet, few GWAS have implicated ancestral genetic variants in cancer predisposition amongst self-identified racial/ethnic

groups[72,73]. Many such polymorphisms regulate gene expression *via* epigenetic or post-translational modification mechanisms, which affect noncoding sequences like microRNA (miRNA) binding sites[74,75]. Yet, the biological and clinical significance of most polymorphisms associated with cancer disparities remains unknown[72]. Mechanistic associations between chronic inflammation and carcinogenesis could link ancestral genetic diversity to cancer, whereby immune-related genetic regulatory variants have the potential to differentially modulate CRC across populations[27].

In fact, a large fraction of population-associated polymorphisms impact gene expression related to inflammation and innate immunity, which, being likely essential for surviving life-threatening infections, evolved under stronger selection pressures than other traits[76,77]. For instance, human genome diversification *via* archaic human genome introgression (*i.e.*, admixture with Neanderthal genome) is a proposed adaptation of ancestral humans to infectious environments following "out of Africa" migration[77,78]. In non-African populations, Neanderthal-introgressed haplotypes reintroduced a splice variant (rs10774671) of the 2'-5'-oligoadenylate synthetase (*OAS*) *1* gene[79]. The *OAS* locus on chromosome 12 encodes three genes, *OAS1*, *OAS2* and *OAS3* that play an important role in virus defense. The elevated frequency of the Neanderthal-derived allele at the *OAS* locus was proposed to be the result of a positive selection in European and East Asian populations. This allele selection has a functional significance since it is associated with the production of a protein variant (OAS1 p46) characterized by higher enzymatic activity and improved resistance to West Nile virus and hepatitis virus C[80]. Therefore, the allele haplotype may provide a survival advantage to infectious agents in the non-African environment and represents an example of variety in baseline inflammation levels that may influence susceptibility to diseases like IBD and CRC in patients with insignificant African ancestry. Selection of genetic variants providing health and survival benefit in endemic areas may represent another means of adaptation and human genome diversification. In a cohort of 158 healthy individuals (distributed as European, Sub-Saharan African, and East-Asian), Barreiro *et al*[81] found that nucleotide diversity of the TLR family was shown to vary between African populations, suggesting pathogen-specific selection pressures. Specifically, the *TLR10/TLR1/TLR6* locus showed signs of recent positive selection amongst non-African populations. Furthermore, of all SNPs in this region, a high frequency *TLR1* single nucleotide variant (SNV) (non-synonymous T1805G variant) found in Europeans was the most significant population differentiator and was associated with a decrease in agonist-mediated nuclear factor-kappa B activation[81]. Although it is unclear if decreased TLR1-mediated immune response confers a selective advantage, it could potentially modulate otherwise harmful inflammatory responses to pathogens[82,83]. This finding suggested that a finely tuned balance between optimal defenses to pathogens and excessive inflammation may have been critical for evolutionary survival[78].

To investigate how ancestral immunity would impact pathogen response, Nédélec *et al*[27] studied interactions between macrophages and live bacteria (*Listeria* and *Salmonella*). Amongst the macrophages, they found that many of the DEGs; (30% of the 11914 genes analyzed) between AAs (n = 77) and CAs (n = 91) were involved in the regulation of the innate immunity. These results built off their previous findings that 9% of macrophage DEGs varied according to ancestry-associated regulation and that increased African ancestry could predict a stronger inflammatory response to infection[27]. Performing quantitative trait locus (QTL) analysis, the authors identified SNVs in 14% of DEGs or using alternative splicing between CA and AA individual-derived macrophages (either non-infected or infected with *Listeria* or *Salmonella*). A large fraction of DEGs were associated with expression QTL only in infected macrophages. In other words, SNVs in a significant fraction of inflammation-related genes were expressed in infected macrophages according to the level of African ancestry. Interestingly, the same authors also found that these DEGs included susceptibility genes previously reported by GWAS for rheumatoid arthritis, systemic sclerosis, or ulcerative colitis, all related to chronic inflammation and conditions with known AA disparity[78]. The interest of such a study, although performed on macrophages *in vitro*, is its illustration of the link between African genetic ancestry and inflammatory response to bacteria, one that could accelerate CRC by aggravating interactions between gut microbiota and the mucosal immune system. Reinforcing this concept is another GWAS that revealed that some of the most differentiating irSNPs between African and European populations were associated with genes regulating nuclear factor-kappa B or chemokine gene clusters[78]. Selected genetic variants may offer protection against infection in endemic regions for native/rural Africans but favor cancer development in descendants bearing the same variants in a western environment, a concept exemplifying the crossroad between host genetics and environmental factors that shapes cancer risk (Figure 1).

Regarding the possibility of a role of associations between irSNP and CRC risk into AA disparity, a recent study by Sanabria-Salas *et al*[33] studied links between pro-inflammatory *IL1B* haplotypes and CRC risk in patients from six Colombian cities. The authors associated the *IL1B* CGTC haplotype with CRC risk exclusively in patients from the coastal regions of Colombia who possessed the highest proportion of admixed African ancestry[33]. The same group has associated *IL1B* irSNPs (four SNPs -3737C/-1464G/-511T/-31C) with African ancestry and elevated cancer risk. The CGTC haplotype was most frequently found and highly expressed in AAs, establishing a functional link between *IL1B* irSNP and CRC risk[84]. Further studies, validating the connection between AA CRC patients and *IL1B* polymorphisms, will be required to confirm the *IL1B* SNP haplotype as a population-associated CRC risk marker; these findings nevertheless showcase a prime example of an exploitable connection

between ancestry-related inflammation and cancer risk disparity.

Next, a cancer genomic meta-analysis using 48 GWAS within the National Cancer Institute GAME-ON Network (64591 cancer and 74467 control patients) across five common cancer sites (ovarian, lung, breast, colorectal, and prostate) found that genetic variants associated with inflammation and innate immune response were relevant to CRC risk, including SH2B adapter protein 3 (*SH2B3*) (rs3184504, $P = 3.32 \times 10^{-5}$), a negative regulator of growth factors and cytokine-induced signaling (Table 1). Unfortunately, irSNP associations with race/ethnicity and geographic distributions were not evaluated[85]. In contrast, Wang *et al*[47] demonstrated the merit of accounting for population diversity in their analysis of associations between innate immunity pathways and CRC risk. In two large studies (discovery and validation cohorts) across five distinct ethnic groups (AA, CA, Japanese-American, Latino, and Native Hawaiian), they found that among more than 600 common variants associated with 37 innate immunity-related genes, a SNV in the second intron of peroxisome proliferator-activated receptor gamma (*PPARG*) (rs9858822) showed a statistically significant association with CRC in the AA population (Table 1). This variant, rare in other non-AA populations, was not previously reported. Importantly, a frequently reported *PPARG* variant rs1801282, inconsistently associated with CRC in other studies[86-88], was not detected in association with CRC in Wang *et al*[47]'s study that carefully controlled for population diversity, supporting the value of multi-ancestry SNP association studies. In another meta-analysis of 308 SNPs performed by Montazeri *et al*[89], 14 SNPs showed credible association with CRC including rs3802842, whose expression was associated with immune infiltration. Curiously, the *PPARG* rs9858822 polymorphism detected by Wang *et al*[47] failed as a positive SNP in this meta-analysis, a finding that warrants additional verification. However, such discrepancies between the multi-ethnic study of Wang *et al*[47] and European study of Montazeri *et al*[89] may highlight the issue of the underrepresented diversity when seeking genetic cancer risk. Population-associated risk may be missed, and alternatively discovered cancer risk may not be relevant for minorities.

Lastly, functional variants in the 3′-untranslated region (UTR) of inflammatory gene miRNA binding sites (miRSNPs) have been associated with CRC risk[75]. Four miRSNPs in the mannose binding lectin 2 (*MBL2*) gene 3′-UTR have been associated with increased CRC risk in the AA population. *MBL2* codes for mannose binding lactose protein, a pattern recognition receptor that binds a wide range of pathogen-expressed sugars, leading to their phagocytosis. Although not assessed in this study, the modulation of the interactions between the mucosal inflammation and the microbiome, *via* MBL2 expression, could be a mechanistic link between African ancestry and higher CRC risk[74]. irSNPs associated with CRC risk are summarized in Table 1.

Ultimately, linking chronic inflammation risk loci to positive selection *via* resistance to past infectious agents and population displacement should be done with caution, as the merits are still debated[78]. Physiological interfacing of the immune system with other biological systems (reproduction and organ development) may also explain positive selection in a manner distinct from past pathogen resistance [78]. Yet, considering the evidence of host innate immunity regulation by population-enriched irSNPS [27], it is reasonable to speculate that the mucosal inflammation associated with commensalism is differentially tuned according to the level of African ancestry and could therefore influence CRC disparities. This view is supported by disparity research in other cancers, such as the finding that *IL10* promoter SNPs enriched in AAs are also potential risk factors for prostate cancer development and progression [90]. Interestingly, one such *IL10* polymorphism (rs1800871) was associated with Proteobacteria load in the gut microbiome (Table 2), but a connection between rs1800871, proteobacteria, and prostate cancer remains to be established[90]. In breast cancer, Jenkins *et al*[91] demonstrated how the ancestral selection of immune variants in the African continent can predispose AA women to ancestry-related differences in tumor immunogenicity. Specifically, the status of a "Duffy-null" polymorphism-regulated atypical chemokine receptor 1 (*ACKR1*) allele linked West African genetic ancestry to tumor immune infiltration. Thus, for breast cancer, duffy antigen receptor for chemokines/ACKR1 polymorphism may serve as a biomarker for precision medicine and immunotherapy in patients bearing significant West African ancestry[91]. This result highlights the potential that ancestry-associated irSNPS have for cancer screening and clinical care when paired with functional analyses and elevating the importance of similar studies for CRC.

HOST GENETICS AND MICROBIOME INTERACTIONS' CONTRIBUTION TO CRC DISPARITY

While host genetics may impact mucosal inflammation and CRC risk, other factors, including environmental factors such as diet, lifestyle, and antibiotic exposure, undoubtedly influence CRC susceptibility and treatment response by shaping gut microbiome composition[51,92,93]. Notwithstanding such findings, we propose that the predominant reliance of the microbiome on environmental cues in healthy individuals may conceal host genetic contributions (including genetic ancestry and somatic mutations) in disease contexts (*e.g.*, CRC), driving the microbiome response to environmental fluctuations and defining, at least in part, differential susceptibility to cancer in AAs[94-96]. The numerous immune-related genetic variants that delineate chronic disease susceptibility between AAs and CAs (previously

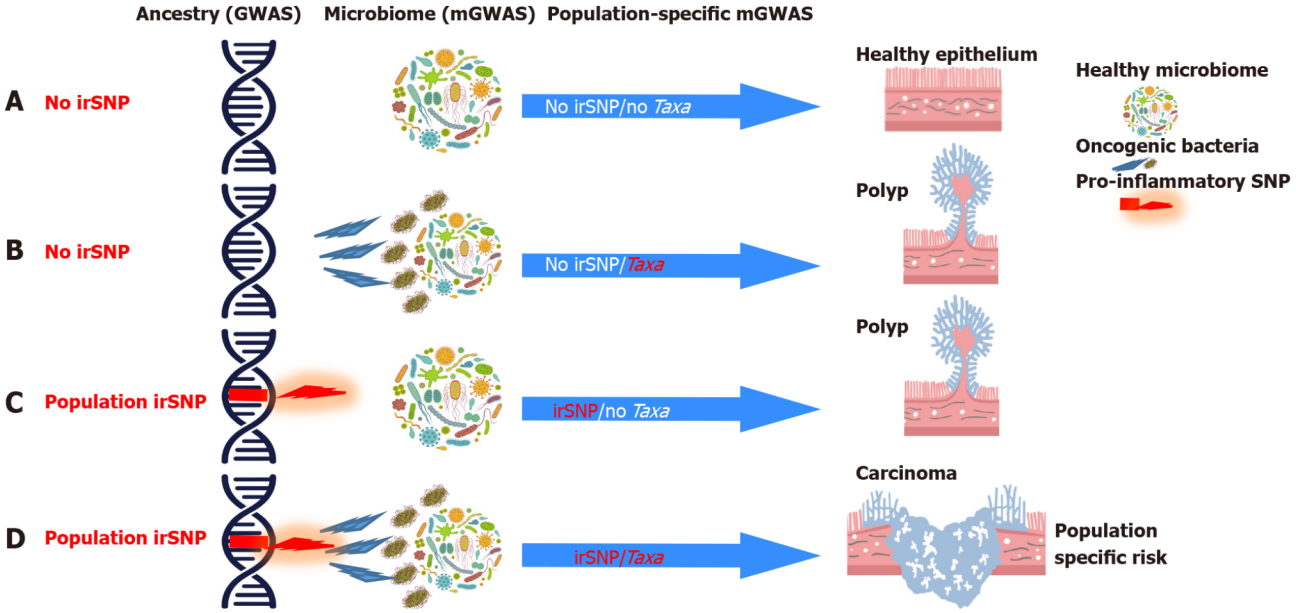
discussed) may then contribute to differential inflammatory responses to the microbiome dysbiosis and compound existing CRC disparities (Figure 2).

From this perspective, multiple metagenomic studies of fecal and mucosal samples have already found compositional and metabolomic differences between CRC and healthy patient microbiome[97-100]. Novel meta-analysis approaches combined these metagenome shotgun datasets across heterogeneous populations to explore relationships between the microbiome and CRC; associations were identified at both bacterial strain and gene levels[101-103]. A common core of 29 bacterial species was enriched in CRC cases, and choline metabolism was established as a reproducible biomarker of the CRC-associated microbiome[101,102]. While such findings are correlative and do not suggest causative links, several smaller studies have highlighted the role of specific bacteria[104-106] and microbial dysbiosis in triggering colorectal carcinogenesis in animal models[107]. However, microbiome GWAS (mGWAS) have not yet identified consistent associations between such carcinogenic bacteria and CRC risk[108]. Unfortunately, because population diversity was systematically underrepresented or not annotated in the metagenome datasets, it remains unknown how these results could translate into CRC risk factors or diagnostic biomarkers for specific racial/ethnic groups.

Meanwhile, several taxonomic and metagenomic studies have revealed an intriguing diversity in microbiome composition across racial/ethnic groups, but mechanistic understandings of associations between bacteria or groups of bacteria and race/ethnicity are sparse[34,109-113]. In particular, diversity of the microbiome is highly diet-driven. A study by O'Keefe *et al*[44] showed that a 2-wk food swap between AAs (received high fiber, low fat diet) and rural Africans (received low fiber, high fat diet) produced dramatic changes in mucosal biomarkers and a metabolome switch, illustrated by an increase in saccharolytic fermentation and anti-inflammatory butyrogenesis as well as suppression of secondary bile acid synthesis in AAs. In light of these results, it is critical that mGWAS take diet into consideration as a confounding factor, as its impact will inevitably interfere with the genetic/epigenetic influence on CRC risk[114]. Interestingly though, differences between CAs and AAs with respect to the mean alternate Healthy Eating Index (a measure of diet quality[115]) faded when adjusting for SES, implying that diet cannot entirely account for CRC disparities[116]. Multiple other factors besides diet are known to impact the composition and function of the microbiome, including smoking, alcohol consumption, as well as antibiotic exposure or metabolic condition such as diabetes or obesity, which are coincidentally also risk factors for CRC[117-119]. While these aspects of the microbiome biology have been extensively reviewed[120], we are paying much of our attention herein on the role of the host genetics and the ancestral genetic origin on the microbiome diversity and consequently CRC risk between ethnicities.



Interestingly, using the Healthy Life in an Urban Setting cohort and fecal 16S ribosomal RNA gene sequencing of over 2000 individuals, Deschasaux *et al*[110] found that microbiome diversity between racial/ethnic groups living in the same city was independent of metabolic health and only partially explained by SES, lifestyle, and diet factors. Yet, this finding was not always reproduced in other studies [45,111,121]. Overall, however, there is sufficient evidence to justify additional efforts to clarify if host genetics and population origins are taking part in shaping the microbiome[51,94]. The role of host genetic background has been suggested by mGWAS, which showed that SNPs such as rs4988235,

Figure 2 Interactions between host genetics and microbiome delineate colorectal cancer risk factors. Immune-related risk factors of colorectal cancer (CRC) may combine host genetics [including immune-related single-nucleotide polymorphisms (irSNPs)] and microbiome cues. The genetic regulation (irSNP) of bacteria (*Taxa*) recognition by the mucosal immunity may mediate the heterogeneity of CRC risk factors between populations which vary by the representation of irSNPs. A: Absence of irSNPs and pathogenic bacteria (no irSNPs/no *Taxa*) maintain healthy mucosal inflammation and gut barrier; B: Absence of irSNPs with enrichment of pathogenic bacteria (no irSNPs/*Taxa*) may lead to chronic inflammation that slowly promotes polyp formation; C: Presence of irSNP in absence of pathogenic bacteria may also lead to chronic inflammation that slowly promotes polyp formation; D: Combination of irSNP and pathogenic bacteria (dysbiosis) may trigger a smoldering chronic inflammatory response precipitating early progression of the adenoma-carcinoma sequence. Genome-wide association studies (GWAS) (irSNP as CRC risk) and microbiome GWAS (mGWAS) (bacteria as CRC risk) are poised to miss the association of the irSNP with CRC because of the necessity of a combined occurrence of irSNP and specific bacteria enrichment in the microbiota to increase the CRC risk. However, if the irSNP is linked to the genetic ancestry, population-specific microbiome GWAS will likely detect the association of irSNP and the bacteria as a CRC risk in the population carrying this genetic ancestry. CRC: Colorectal cancer; irSNPs: Immune-related single-nucleotide polymorphisms; GWAS: Genome-wide association studies; mGWAS: Microbiome genome-wide association studies.

associated with lactase persistence gene, contributed to microbiome composition[45,68,122,123]. A study performed with 416 twin pairs in the United Kingdom identified 26 "heritable" taxa, also suggesting that specific host genetic variants may participate in microbiome composition (Table 2)[124]. Notably, host genetic variants associated with microbiome composition were found to be enriched in immunity-related pathways[122]. Studies showing associations between metabolic and immune-related polymorphisms and microbiome composition are summarized in Table 2.

Finally, associations between the microbiome and somatic mutations in CRC have been described by Burns *et al*[95], who suggested that genetic determinants of the host and colon tumor mutations alter microbiome structure. The CRC mutanome could therefore help predict the composition and function of CRC-associated microbiomes and the clinical outcome or the response to therapies. To this end, of intrigue is the recent description by Ashktorab *et al*[125] and Brim *et al*[126] of genetic variation in tumor suppressor genes (*APC*), DNA mismatch repair genes, and other driver mutations (*KRAS* and *PIK3C*) in AAs with CRC, some of which were novel and not previously described in other populations. Loss of function mutations in *APC* were correlated with changes in 25 different microbial taxa, including an abundance of *Finegolia* or *Christensenellaceae*. Mutations in the zinc finger protein 717-coding gene were associated with an abundance of *Akkermansia* and *Verrucomicrobiaceae*, both colitis-associated species. Additionally, the same authors have isolated a novel *Streptococcus spp*. VT_162 from colon adenoma and CRC lesions in AAs[126]. Fecal *Streptococcus spp*. VT_162 was also confirmed in an advanced adenoma and CRC Chinese/Hong-Kong cohort[126]. An assessment of this bacterium's relative prevalence in CAs compared to AAs will be necessary. Whether CA genetic background is more restrictive, while AA genetic background is more permissive to this species is not yet established. It may be postulated that, as seen in IBD patients, host genetic background drives the nature of the microbiome and alters the CRC risk posed by procarcinogenic "driver" bacteria[48,51].

Although there is a lack of direct causative links between such bacteria and colon carcinogenesis or growth promotion, this evidence at least signals that CRC disparities in AAs may be related to differential host inflammatory responses to similar bacterial communities (inflammation-driven disparities) and/or the contribution of ancestry-related factors in shaping microbiome diversity (bacteria-driven disparities). The molecular pathological epidemiology (MPE) that aims at uncovering an interactive relationship between environmental features and disease subtypes to understand disease incidence and

Figure 3 Population-specific colorectal cancer microbiome genome-wide association studies to understand colorectal cancer disparities. Systemic underrepresentation of minorities in microbiome genome-wide association studies (mGWAS) may compromise the identification of microbiome-associated colorectal cancer (CRC) risks in African-Americans (AAs). Left: Associations between AA-enriched immune-related single-nucleotide polymorphisms (irSNPs) (pop-irSNPs) and gut bacteria (*Taxa*) may remain undetected in the global population if pop-irSNP and *Taxa* have too low frequency in the AA population and AAs are underrepresented. Right: If pop-irSNP and pathogenic bacteria are CRC risk factors in AA, they will be enriched in AA CRC patients compared to the general AA population (left), and mGWAS will detect the association between pop-irSNP and *Taxa* in AA CRC cohort. These features justify population-specific CRC mGWAS to detect additional CRC risk resulting from the interaction between ancestral irSNP and bacteria in minorities. CRC: Colorectal cancer; irSNPs: Immune-related single-nucleotide polymorphisms; mGWAS: Microbiome genome-wide association studies; AA: African-American; CA: Caucasian-American.

mortality will provide etiologic and pathogenic insights in CRC disparities[127,128]. However, discoveries made in healthy donors often remain inconsistent from one study to another, perhaps due to multiple confounding environmental factors between heterogeneous cohorts[45,129]. More likely culprits for the inconsistency seen in GWAS that seek to identify the impact of host genetics on microbiome diversity are the homogeneity in sampled cohorts and differences in experimental approaches including stool *vs* mucosa sampling, sequencing approaches, and annotations. Future GWAS must address such issues in order to identify associations between genetic background and the microbiome that can reliably be applied to the question of disparities.

CONCLUSION

CRC disparity is far from an exclusively biological phenomenon but rather involves a complex interplay of SES, environmental and genetic components that collectively impact CRC risk and prognostics. Although there is a growing understanding of this complexity, studies examining the influence on CRC pathogenesis from ancestry-specific interactions between host genetics and the commensal microbiome are lacking. Such work is nevertheless urgently needed to appropriately mitigate CRC on a population basis and especially to help address alarming new trends, such as early-onset CRC amongst AAs. To facilitate this line of investigation, we reviewed irSNPs identified in CRC mGWAS and proposed that some of such variants (and others yet to be discovered) may alter microbiome composition and/or differential inflammatory responses to bacteria, thereby impacting CRC risk in a manner associated with genetic ancestry. However, testing the functional significance of such variants will require systematic studies that can incorporate the microbiome, mucosal immunity, and host genetics. A recent investigation by DeStefano Shields *et al*[130], although not related to cancer disparity, offers a potential experimental blueprint. Researchers introduced the *BRAF*^{V600E} mutation to a Min$^{Apc\Delta716/+}$ murine model of distal colon polyposis, then colonized *BRAF* mutant and Min$^{Apc\Delta716/+}$ mice with *Enterotoxigenic Bacteroides fragilis*. Distal colon tumorigenesis was observed in Min$^{Apc\Delta716/+}$ mice following colonization, whereas *BRAF*^{V600E} Min$^{Apc\Delta716/+}$ mice developed proximal colon tumors associated with immune signature and microbiome alterations plus sensitivity to anti-programmed death ligand 1[130]. These results suggested that host gene/bacteria interactions may drive CRC risk and pathogenesis, and demonstrate how such interactions can be disentangled mechanistically using experimental models with clinical implications. In the nascent field of precision medicine and multidisciplinary big data integration, the rapidly

evolving MPE represents a successful model of integration of pathology, genomics, microbiome, immunology, epidemiology, and social science[127,128]. MPE will considerably improve precision medicine and prevention allowing, among other things, identifying SNPs that may impact microbiome and inflammation and serve as predictive markers. Genetic ancestry, however, remains to be integrated to this model to precisely address CRC disparities at the molecular level. Elucidating the mechanisms by which ancestry-associated variants impact CRC pathogenesis will be much more challenging, but models such as the one described by Lavoie *et al*[60], who used mice engineered to express the polymorphism T300A (rs2241880) in the *Atg16 L1* gene known to increase IBD risk in humans, represent a promising approach to identifying mechanisms that can lead to personalized interventions applicable to minorities.

Yet, without addressing biases in genomics science, the ability of GWAS to detect variants of significance for AAs (or other minorities in general) will remain stunted[131]. To date, cancer GWAS have examined cohorts predominantly composed of Caucasian individuals, an homogeneity that limits the appreciation of how genetic ancestry impacts cancer risk[101,102]. Critically, the lack of diverse representation in sampling cohorts results in the increased likelihood that, even if identified, cancer-associated variants may be of limited clinical significance for non-Caucasian populations. While commenting on this issue, Davis[131] recently argued that the current state of genomic medicine is inadequately equipped to confront current oncological trends of disparate incidence and mortality in inclusive fashion and advocated for a persistent push towards the prioritization of patient diversity. Such an agenda is not only more harmonious with the principles of ethical human subjects research but is also scientifically meritable, as studies that account for diversity have already revealed novel genomic data that may improve our understanding of cancer etiology[132]. Therefore, for powered GWAS to detect and discern associations between population-enriched irSNPs, the microbiome, and CRC, proper accounting of population diversity and sufficient cohort size (estimated at > 4000 individuals)[45], or even population-specific CRC studies will be essential (illustrated in Figure 3). Encouragingly, recent methodological frameworks for multi-ancestry cohort GWAS have already yielded ancestry-related cancer variant risk factors[133,134]. Moreover, the recent initiative of the National Cancer Institute: Genetic Association and Mechanism in Oncology (GAME-ON; https://epi.grants.cancer.gov), which regrouped genomic data from more than 33 GWAS across five different cancers (CRC, lung, breast, ovary, and oral), is an example of the benefit of data sharing that will help identifying through meta-analysis data cancer risk loci in understudied populations, especially since 40% of the samples are from African, Asian, and Hispanic backgrounds. However, our integrated concept for CRC genomic research proposes that to represent accurately and capture the contribution of irSNP/microbiome interactions to CRC disparities, such diversified host genomic data must be paired with microbiome data.

In sum, population-related irSNP that regulate mucosal inflammation may modify the microbiota and its interaction with colon epithelium. Alternatively, a population-related SNP not involved in immune regulation may also alter the microbiome and trigger procarcinogenic chronic inflammation. Finally, a combination of two SNPs impacting inflammation and the microbiome with minor effects on CRC pathogenesis may trigger a strong procarcinogenic bacteria/inflammation interaction when combined in an at-risk population (Figure 2). By hunting for and characterizing such genetic factors using the emerging genetic admixture and ancestry paradigms, we believe scientists and clinicians will have a precision tool that enables a clearer understanding of the association between CRC with AA populations and the increasing trend of early onset CRC, ultimately to better mitigate CRC outcome disparities.

Abstract

The severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection leads to a severe respiratory illness and alters the gut microbiota, which dynamically interacts with the human immune system. Microbiota alterations include decreased levels of beneficial bacteria and augmentation of opportunistic pathogens. Here, we describe critical factors affecting the microbiota in coronavirus disease 2019 (COVID-19) patients. These include, such as gut microbiota imbalance and gastrointestinal symptoms, the pattern of altered gut microbiota composition in COVID-19 patients, and crosstalk between the microbiome and the gut-lung axis/gut-brain-lung axis. Moreover, we have illustrated the hypoxia state in COVID-19 associated gut microbiota alteration. The role of ACE2 in the digestive system, and control of its expression using the gut microbiota is discussed, highlighting the interactions between the lungs, the gut, and the brain during COVID-19 infection. Similarly, we address the gut microbiota in elderly or co-morbid patients as well as gut microbiota dysbiosis of in severe COVID-19. Several clinical trials to understand the role of probiotics in COVID-19 patients are listed in this review. Augmented inflammation is one of the major driving forces for COVID-19 symptoms and gut microbiome disruption and is associated with disease severity. However, understanding the role of the gut microbiota in immune modulation during SARS-CoV-2 infection may help improve therapeutic strategies for COVID-19 treatment.

Key Words: COVID-19; Inflammation; Gut microbiota; Therapeutic

Core Tip: The gut microbiota of coronavirus disease 2019 (COVID-19) patients is altered compared to that of healthy individuals, with a reduction in the count of beneficial bacteria and an increase in the count of opportunistic fungi. In this review, we elucidate the components governing immune modulation. Additionally, we explore the effect of changes in the microbial ecosystem in COVID-19 patients, with an aim to help develop precise therapeutics and expand our knowledge regarding the pattern of changes in the gut microbiota of COVID-19 patients.

INTRODUCTION

The coronavirus disease 2019 (COVID-19) pandemic has stimulated research on several medical conditions and on individual patient variations during severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection to unfold underlying disease mechanisms. Scientists have determined the inflammatory response and cellular injury mediated by acute SARS-CoV-2 infection. Moreover, several studies have revealed the involvement of the gastrointestinal (GI) tract and its associated gut microbiome during COVID-19, motivating research in this field. Increasing evidence has surfaced confirming the association of the GI tract and COVID-19, including[1,2] a severe state of gut dysbiosis in COVID-19 patients[3,4]. Similarly, GI symptoms such as vomiting, abdominal pain, and diarrhea have been noted in many COVID-19 patients[5-7]. Moreover, high expression of ACE2 receptor was reported in epithelial cells of the GI tract[8]. SARS-CoV-2 RNA has been identified in rectal and anal swabs, as well as stool specimens[7,9,10]. Finally, liver damage, loss of appetite, and irritable inflammatory diseases have been reported as post-COVID-19 illnesses[11]. These all data strongly indicate a correlation between the GI including the gut microbiome, and COVID-19.

The gut microbiota plays an important role in controlling gut health and acts as a health modulator (Figure 1)[12] aidings in different metabolic activities and extensively impacting health and disease[13,14]. Ongoing research aims to better understand the gut microbiota and provide insights into the mechanistic conditions required to implement normal health functions. The gut microbiota controls specific functions in the host, such as drug and xenobiotic metabolism and nutrient metabolism[15]. Simultaneously, it helps maintain the structural integrity of the gut mucosal barrier, protects against pathogens, and regulates immunomodulation, as well as health and disease conditions[16,17]. Several other studies suggest a possible link between COVID-19 and gut microbiota composition[18,19]. Additionally, an association has been shown between altered gut microbial composition and increased risk factors in COVID-19 patients (Figure 1)[20,21].

Inflammation is a major risk factor in COVID-19 patients[22-24]. During uncontrolled inflammation, abnormal levels of cytokines such as interleukin-1 beta (IL-1β), IL-6, IL-8, IL-10, IL-12, granulocyte-macrophage colony-stimulating factor (GM-CSF), tumor necrosis factor-alpha (TNF-α), and interferon-gamma (IFN-γ) are found in the patients[23,25-27]. Certain abnormal levels of cytokines are substantial related to the severity of COVID-19 and are probably responsible for the "cytokine storm" syndrome manifested during the disease[28-30]. Research has correlated the inflammation during COVID-19 with GI and hepatic manifestations of the disease[31].

Interactions between the gut microbiota and the lungs, known as the gut-lung axis, have sparked interest for gastroenterology studies focusing on COVID-19 as these interactions affect disease severity. Changes in the gut microbiome certainly affect homeostasis and may lead to increased infections[32,33]. Similarly, in addition to the gut, COVID-19 can also have a detrimental effect on the central nervous system (CNS) and the blood-brain barrier (BBB) and disrupt the gut-brain-lung axis. Studies have explored therapeutic options (nicotinic cholinergic agonists and vagus nerve stimulation) to minimize the damage caused to this axis[34].

Research is necessary to understand how the gut microbiome is altered during COVID-19 infection and the factors that influence the microbiome during mild to moderate and severe disease. Studies have been conducted to understand the GI symptoms during COVID-19 and to detect viral shedding using the fecal matter of SARS-CoV-2 patients. The gut microbiota of COVID-19 patients has been mapped to obtain evidence regarding inflammation, disease severity, and therapeutic development.

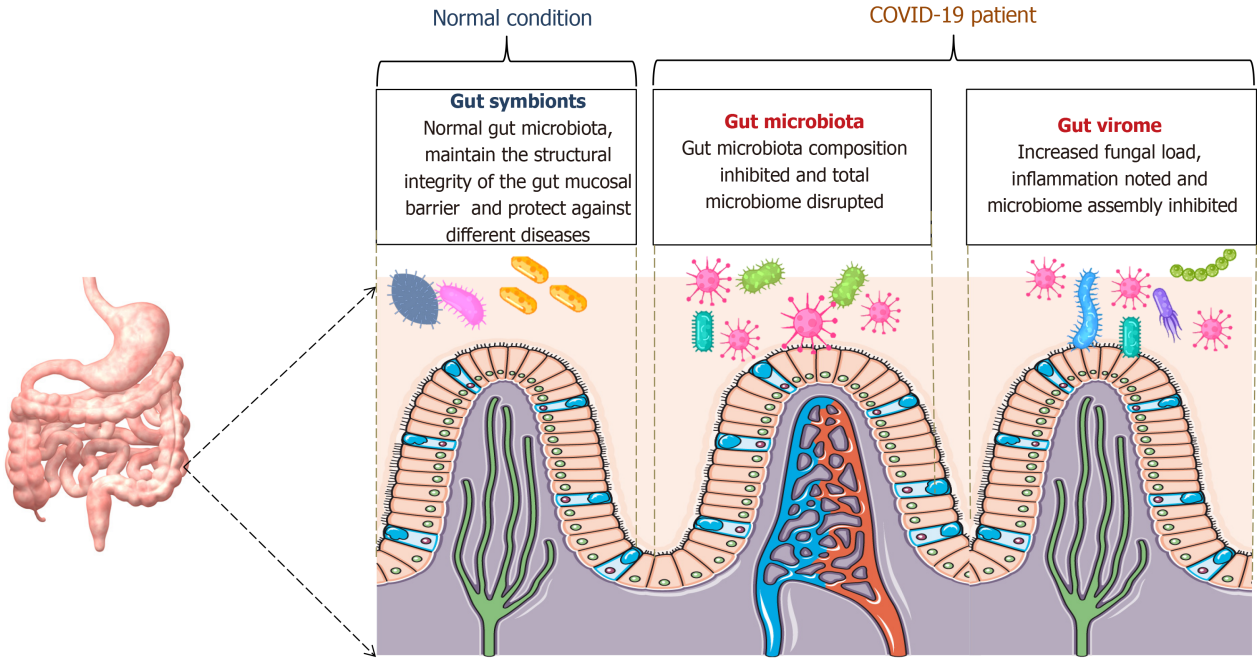

Figure 1 The schematic diagram shows normal healthy gut and the incidence in gut microbiota and gut virome in coronavirus disease 2019 patients. COVID-19: Coronavirus disease 2019.

Using these studies, we explore the following critical factors: (1) The gut microbiota imbalance and GI symptoms in COVID-19 patients; (2) fecal viral shedding in COVID-19 patients and restoration of the gut microbiota; (3) the pattern of altered gut microbiota composition in COVID-19 patients; (4) alterations in gut biosynthesis during COVID-19 infection; (5) the role of ACE2 in the digestive system and the gut microbiome; (6) crosstalk between the microbiome and the gut-lung axis during COVID-19 infection; (7) crosstalk between the microbiome and the gut-brain-lung axis during COVID-19 infection; and (8) hypoxia during COVID-19 associated with altered gut microbiota. We also discuss how immune responses and inflammation due to COVID-19 drive the changes in the microbial ecosystem and summarize therapeutic options currently in development.

GI SYMPTOMS IN COVID-19 PATIENTS

Along with respiratory symptoms and fever, GI symptoms have also been observed in COVID-19 patients (Table 1). A study by Redd *et al*[35] reported abdominal pain (14.5%), nausea (26.4%), diarrhea (33.7%), and vomiting (15.4%) in patients from the United States. Three hundred and eighteen hospitalized COVID-19 patients were evaluated to understand their symptoms. In another study with 204 COVID-19 patients, 50.5% (103 patients) exhibited GI symptoms. Among these 103 patients, 78.6% showed a lack of appetite, 34% had diarrhea, 3.9% vomited, and 1.9% complained of abdominal pain. The authors correlated patients describing GI symptoms with other measurements such as prothrombin time, monocyte count, and liver enzyme levels. Patients with GI symptoms had elevated mean liver enzyme levels, extended prothrombin times, and lower monocyte counts[36]. In a much larger cohort study involving 1099 COVID-19 patients from 552 different hospitals spread to over 30 provinces, only 3.8% of patients experienced diarrhea. The authors concluded that fever and cough are common symptoms, unlike diarrhea, among the COVID-19 patient population[37].

These findings suggest that the virus might be present for a period in the GI tract, which may cause a GI infection (Figure 2). Importantly, fecal viral shedding was noted after clearing SARS-CoV-2 from the respiratory tract, suggesting that the virus can persist for a long time in the GI tract, especially in patients who manifest GI symptoms. During COVID-19 infection, gut microbiota composition is altered, possibly explaining the GI imbalance and manifestations of the different GI symptoms such as abdominal pain, nausea, vomiting, and diarrhea, as described above. This change in the gut microbiota includes reduced levels of commensals microbes and is observed in patient samples even after 30 d of disease remission[38-40]. Additional studies addressed the imbalance of the gut microbiota and its association with different GI-related aspects of COVID-19[41]. The gut microbiota population in COVID-19 patients with low to moderate GI symptoms should also be analyzed. Evaluating these diverse patient populations will enable a thorough description of this phenomenon.

Table 1 Different gastrointestinal symptoms in coronavirus disease 2019 patients

Sl. No.	Total number of human subjects involved in study	Demographics of the study populations	Vomiting	Diarrhea	Nausea	Remarks/study summary	Ref.
1	191	Adults (46-67 years) hospitalised, Chinese peoples, 91 patients having comorbidity	7 (3.7%)	9 (4.7%)	7 (3.7%)	Identification of several risk factors and a detailed clinical course of illness for mortality of COVID-19 patients	[121]
2	171	Minor aged (1 d-15 years, hospitalised, Chinese children, no such comorbidity	11 (6.4%)	15 (8.8%)	NA	Report of a spectrum of illness from children infected with SARS-CoV-2 virus	[122]
3	1099	Median age group (35-58 years), hospitalised, Chinese patients without any comorbidity	55 (5.0%)	42 (3.8%)	55 (5.0%)	Identification and definition of clinical characteristics and disease severity of hospitalized COVID-19 patients	[37]
4	140	Adults (25-87 year), hospitalised Chinese patients with high comorbidity	7 (5.0%)	18 (12.9%)	24 (17.3%)	Report on hospitalized patients having COVID-19 with abnormal clinical manifestations (fever, fatigue, gastrointestinal symptoms, allergy)	[123]
5	73	Adults hospitalised Chinese patients, comorbidity reported	NA	26 (35.6%)	NA	Clinical significance of SARS-CoV-2 by examining viral RNA in feces of COVID-19 patients during hospitalizations	[124]
6	52	Adults (mean age 59.7 year), critically ill ICU- admitted Chinese patients, comorbidity reported	2 (3.8%)	NA	NA	Retrospective, single-centered, observational study on critically ill, ICU-admitted adult COVID-19 patients	[125]
7	138	Adult (median age 56 years), hospitalised Chinese patients with comorbidities	5 (3.6%)	14 (10.1%)	14 (10.1%)	Clinical characteristics of COVID-19 patients in hospitalized conditions	[126]
8	41	Middle age group (41-58 years) hospitalised Chinese patients with comorbidities	NA	1 (2.6%)	NA	Epidemiological, laboratory, clinical, and radiological features and treatment with clinical outcomes of hospitalized COVID-19 patients	[46]
9	62	Studied patients (median age 41 years) were hospitalised, Chinese ethnicity and comorbidity reported	NA	3 (4.8%)	NA	Most common symptoms at onset of illness with clinical data in confirmed COVID-19 patients	[127]
10	137	Studied patients (mean age 57-55) ware Chinese and hospitalised, comorbidity was also noted	NA	11 (8%)	NA	Investigation of epidemiological history, clinical characteristics, treatment, and prognosis of COVID-19 patients	[128]
11	81	Chinese patients (mean age was 49.5 years), hospitalised with high comorbidities	4 (4.9%)	3 (3.7%)	NA	Report of confirmed COVID-19 patients with chest computer tomography imaging anomalies	[129]
12	99	Hospitalised, Chinese patients (average age of the patients was 55.5 years), comorbidity was reported	1 (1%)	2 (2.0%)	1 (1%)	Inclusive exploration of epidemiology and clinical features of COVID-19 patients	[130]

NA: Not available; ICU: Intensive care unit; COVID-19: Coronavirus disease 2019; SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2.

FECAL VIRAL SHEDDING IN COVID-19 PATIENTS

Table 2 lists various cohort studies reporting fecal viral shedding by COVID-19 patients and detecting SARS-CoV-2 RNA in the fecal matter[42,43]. SARS-CoV-2 RNA-positive fecal matter was detected in 66.67% of COVID-19 patients (42 patients) in China[43]. Researchers attempted to evaluate the viral shedding period in stool samples, and noted viral shedding in asymptomatic patients. For example, SARS-CoV-2 RNA was detected from a stool sample of an asymptomatic child 17 d after viral exposure [9].

Certain studies have reported that virus separation from stool samples is difficult. For example, Wölfel *et al*[44] detected viral RNA in stool samples but attempts to isolate the virus were unsuccessful, most likely due to the mild nature of the infection. A viral load below 10^6 copies per milliliter often hampers viral isolation[36]. The viral load also varies widely from one sample to another, including stool, serum, and respiratory samples[44-46]. However, understanding the correlation between the altered gut microbiota and the viral load in patient samples is essential for advancing therapeutic strategies centered around restoring the microbiota.

Additionally, efforts should focus on determining the possible correlation between fecal viral shedding and altered gut microbiota composition at different stages the infection, *i.e.*, mild to moderate

Table 2 Fecal viral shedding in coronavirus disease 2019 patients

Sl. No.	Total number of human subjects in study	Demographics of the study populations	Gastrointestinal symptoms	Confirmed cases of fecal shedding	Remarks/study summary	Ref.
1	205	Patients (mean age of 44 years) were hospitalised, Chinese without any comorbidities	No symptoms	44	Evidence-based study for gastrointestinal infection of SARS-CoV-2 virus and its possible fecal-oral transmission route in humans	[131]
2	73	Different age group (10 mo to 78 years old), hospitalised Chinese patients without report any comorbidities	Gastrointestinal bleeding, diarrhea	39	Description of epidemiological and clinical characteristics of COVID-19 patients	[124]
3	10	Chinese patients have aged 19-40 years, hospitalised and no such comorbidity was reported	Hemoptysis, diarrhea, cough	8	Report of median aged COVID-19 confirmed patients in ICU	[127]
4	14	Patients (18-87 years) were hospitalized, Chinese individuals without any comorbidities	No symptoms	5	Retrospective analysis of laboratory-confirmed COVID-19 cases in hospitalized conditions	[132]
5	66	Chinese patients (median age of 44 years) were hospitalised, comorbidity was not reported	No symptoms	11	Viral RNA detection was performed from throat swabs, stool, urine, and serum samples in different clinical conditions in COVID-19 patients	[133]
6	18	Adults patients (median age, 47 years) from Singapore were hospitalised and comorbidities was noted	No symptoms	4	COVID-19 patient case series using clinical, laboratory, and radiological data	[134]
7	74	Studied paients belonged from China and were hospitalised with comorbidities	No symptoms	41	Analysis of respiratory and fecal samples to determine clinical symptoms and medical treatments of COVID-19 patients	[135]
8	9	Adults Chinese patients were hospitalised without any comorbidities	Diarrhea and urinary irritation	2	Detection of SARS-CoV-2 RNA in urine and blood samples, and anal, oropharyngeal swabs of confirmed COVID-19 patients	[136]

ICU: Intensive care unit; COVID-19: Coronavirus disease 2019; SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2.

or severe COVID-19.

ALTERED GUT MICROBIOTA COMPOSITION IN COVID-19 PATIENTS

SARS-CoV-2 infections have led to changes in the ecology of the gut microbiota in patients (compared to that seen in controls). These changes are influenced by the immune responses elicited during COVID-19 (Table 3). Different studies have revealed the growth of unusual microorganisms and depletion of common gut microbes (bacterial, viral, and fungal populations) in COVID-19 patients (Figure 3).

To understand the severity of disease in COVID-19 patients, the gut microbiota composition of 100 COVID-19 patients was analyzed in two hospital cohorts. Stool samples were collected from 27 of the 100 patients. The gut microbiome compositions were characterized using total DNA extracted from stool samples. The authors demonstrated that the number of gut commensals and Bifidobacteria was low and correlated with several factors of disease severity, such as high concentrations of inflammatory cytokines and C-reactive protein (CRP). These data suggests that the composition of the microbiota is associated with disease severity[38]. Another study carried out RNA and DNA profiling by sequencing of the virome using fecal matter from COVID-19 patients. The fecal matter of 98 COVID-19 patients was analyzed to understand COVID-19 severity and its association with the gut virome. The study showed that COVID-19 severity is inversely correlated with gut viruses, and older patients are more prone to severe COVID-19 outcomes[47]. Alterations in fungal microbiomes during COVID-19 have also been investigated. Analysis of the fecal mycobiome using the deep shotgun method showed heterogeneous microbial profiles, with enrichment of fungal genera such as Aspergillus and Candida. Two species of *Aspergillus* (*Aspergillus flavus* and *Aspergillus niger*) were identified in fecal samples after clearance of SARS-CoV-2 from nasopharyngeal samples[48]. Additionally, there is evidence of abundant symbionts among COVID-19 patients including *Clostridium ramosum*, *Coprobacillus*, and *Clostridium hathewayi*,

Table 3 Analysis of gut microbiota in coronavirus disease 2019 patients in different cohorts

Sl. No.	Cohort composition	No of Patients	Demographics of the study populations	Country	Significant gut microbiota found	Study conclusion	Reference
1	A pilot study with 15 healthy individuals (controls) and 15 patients with COVID-19	15	Study performed with hospitalised patients (median age 55 years), Chinese ethnicity and comorbidities were reported	Hong Kong	Abundance of *Clostridium hathewayi, Clostridium ramosum, Coprobacillus,* which are correlated with COVID-19 severity	Change in the fecal microbiome of COVID-19 patients during hospitalization, compared to healthy individuals (controls)	[48]
2	The two-hospitals cohort, serial stool samples collected from 27 COVID-19 patients among 100	27	Adults hospitalised Chinese patients, comorbidities were noted	Hong Kong	*Faecalibacterium prausnitzii, Eubacteriumrectale* and bifidobacteria	Gut microbiome involved in COVID-19 severity	[38]
3	United States cohort (majority African American)	50	Studied patients (mean age 62.3 years) were hospitalised with comorbidities, American ethnicity	United States	Some of the significant genera (*Corynebacterium Peptoniphilus, Campylobacter, etc.*)	No significant associations found between the composition microbiome and disease severity from COVID-19 patient gut microbiota	[50]
4	The study used 53 COVID-19 patients and 76 healthy individuals. 81 fecal samples collected during hospitalization	53	Adults Chinase hospitalised patients, no such comorbidities were noted	China	Elevated gut microbes such as *Rothia mucilaginosa, Granulicatella* spp, *etc.*	COVID-19 infection linked with change of the microbiome in COVID-19 patients	[137]
5	15 patients Cohort	15	Study performed adults hospitalised patients with comorbidities, Chinese ethnicity	Hong Kong	Elevated bacterial species *Collinsella tanakaei, Collinsella aerofaciens, Morganella morganii, Streptococcus infantis*	The study found fecal viral (SARS-CoV-2) activity	[54]
6	Two-hospital cohort with a total of 100 patients. Stool samples collected from 27 patients	27	Hospitalised adults patients were from China, comorbidities were noted	Hong Kong	Several gut microbiota such as *Faecalibacterium prausnitzii, Eubacterium rectale,* and bifidobacteria	Gut microbiota associated disease severity and inflammation in COVID-19 patients	[38]
7	98 COVID-19 patients (3 asymptomatic, 34 moderate, 53 mild, 3 critical, 5 severe), serial fecal samples collected from 37 COVID-19 patients	37	Adults (mean age 37 years) patients, hospitalised condition from Chinese ethnicity, comorbidities were reported	Hong Kong	A total of 10 virus species in fecal matter (9 DNA virus species and 1 RNA virus, pepper chlorotic spot virus)	Analysis of gut virome (RNA and DNA virome) in COVID-19 patients	[47]
8	Study of fecal samples from 30 COVID-19 patients	30	Patients (mean age 46 years) were hospitalised from Chinese groups, comorbidities were noted	Hong Kong	Increased proportions of fungal pathogens (*Candida albicans, Candida auris, Aspergillus flavus, Aspergillus niger*) in fecal samples	Analysis of fecal fungal microbiome of COVID-19 patients	[48]

COVID-19: Coronavirus disease 2019.

which directly correlated with disease severity. Conversely, *Faecalibacterium prausnitzii,* which was also abundant among the patients, was inversely correlated with disease severity[49].

Similarly, in a study by Yeoh *et al*[38], stool samples from 27 patients were correlated with blood markers and inflammatory cytokines. The study concluded that the scale of COVID-19 severity might be associated with the gut microbiome and linked it to COVID-19 inflammation[46]. In another study containing a greater number of African Americans, enriched genera (*Campylobacter, Corynebacterium,* and *Peptoniphilus)* were mapped in the COVID-19 patient population, the gut microbial composition was markedly different between positive and negative samples. However, the study did not identify any considerable association between COVID-19 severity and microbiome composition[50].

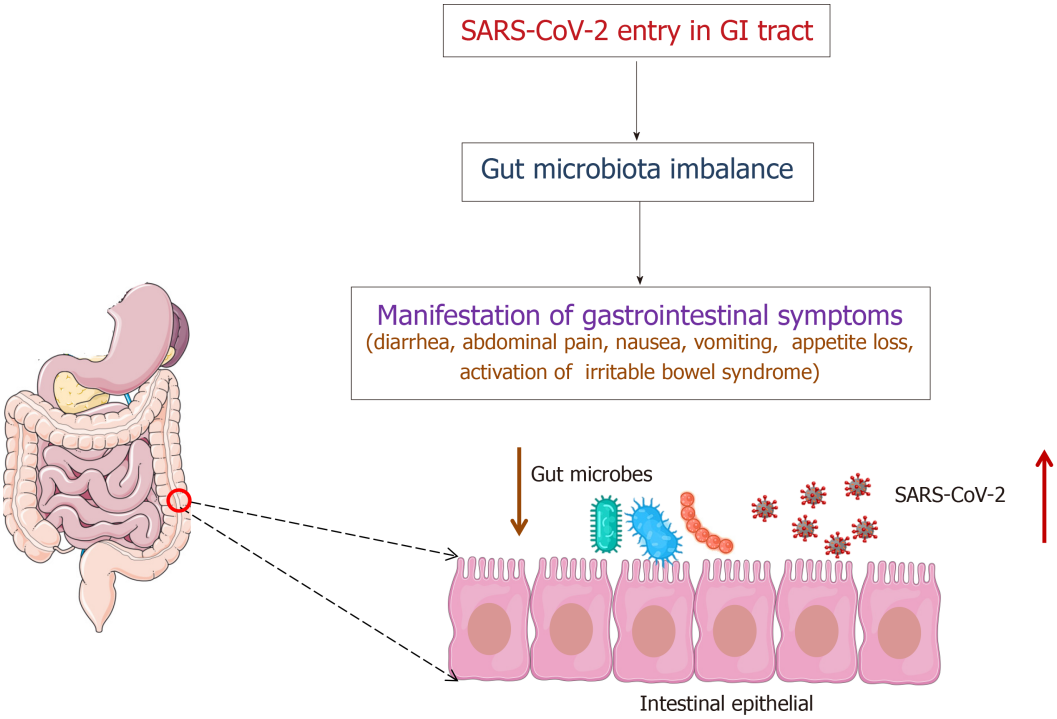

Figure 2 The schematic diagram illustrates the severe acute respiratory syndrome coronavirus 2 entry in the body, causes of gut microbiota imbalance which assists in manifesting the gastrointestinal symptoms in coronavirus disease 2019 patients. GI: Gastrointestinal; SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2.

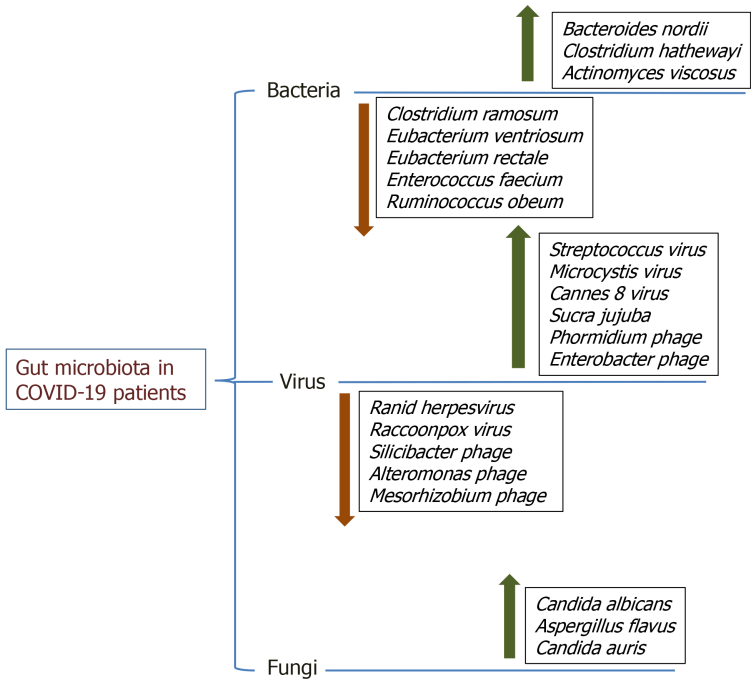

Figure 3 The diagram illustrates increased or decreased gut microbiota in coronavirus disease 2019 patients, including bacterial, viral, and fungal populations. COVID-19: Coronavirus disease 2019.

Certain studies even noted a reduction in fiber-utilizing bacteria such as *Prevotella*, *Bacteroides plebius*, and *Faecalibacterium prausnitzii* (*F. prausnitzii*), and a low Firmicute/Bacteroidetes ratio[51]. Poor outcomes were noted in special populations, such as hypertensive, diabetic, and elderly patients[52,53]. Research is still underway to ascertain the different types of gut microbial populations (pro-inflammatory, opportunistic, beneficial, or anti-inflammatory) present depending on COVID-19 severity (Figure 4).

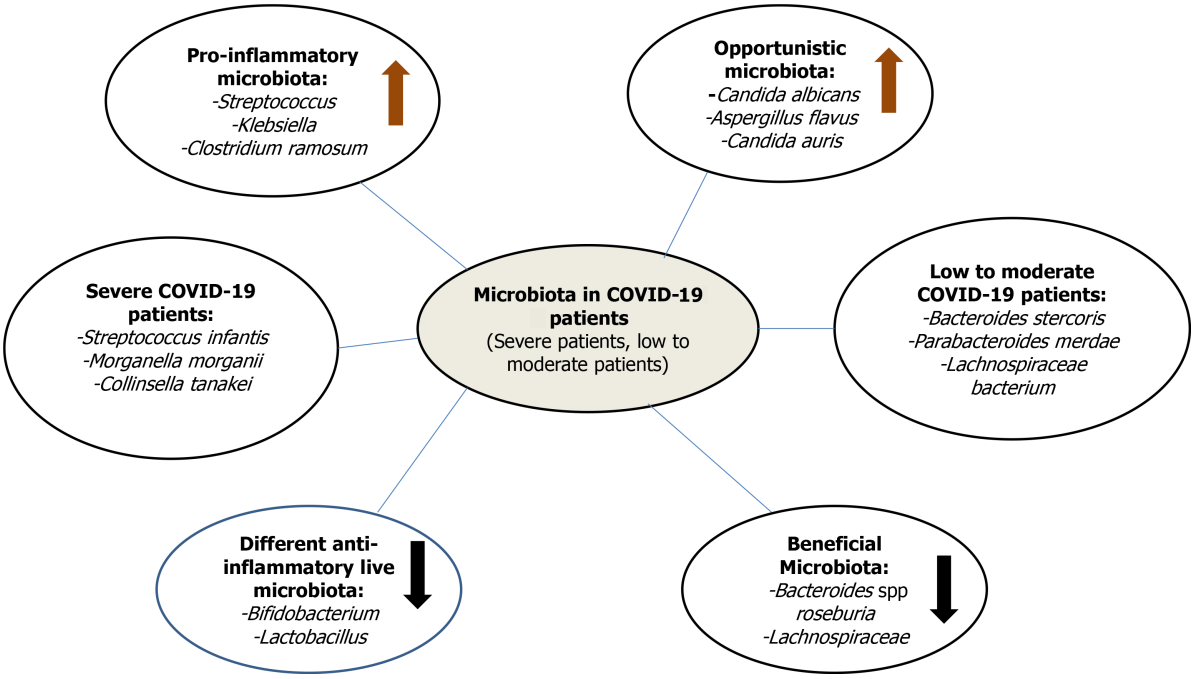

Figure 4 The diagram illustrates different types of mapped gut microbiota in coronavirus disease 2019 patients. Pro-inflammatory microbiota, opportunistic microbiota, the microbiome in severe coronavirus disease 2019 (COVID-19) patients, and the microbiome in low to moderate COVID-19 patients, anti-inflammatory microbiota, and beneficial microbiota. COVID-19: Coronavirus disease 2019.

These studies help us understand how gut microbiota composition affects patients with moderate to severe COVID-19 and how gut microbiota diversity might alter immunity in COVID-19 patients.

ALTERATIONS IN THE BIOSYNTHESIS OF BIOLOGICAL COMPOUNDS IN THE GUT DURING COVID-19 INFECTION

Other than compositional changes in gut microbiota, functional changes during SARS-CoV-2 infection were observed in some patients. The gut microbiota aids in different biosynthetic pathways, such as amino acid biosynthesis, carbohydrate metabolism, nucleotide de novo biosynthesis, and glycolysis. This might be due to the abundance of bacterial components such as *Collinsella tanakaei, Streptococcus infantis, Morganella morganii,* and *Collinsella aerofaciens*, *etc.* Apart from these microbes, many short-chain fatty acid (SCFA) synthesis bacteria, such as *Lachnospiraceae bacteria*, *Bacteroides stercoris*, *Alistipes onderdonkii,* and *Parabacteroides merdae* were present in COVID-19 samples with mild symptoms and in non-COVID-19 samples[54]. In a study using non-human primate models, β diversity analysis and 16S rRNA gene profiling were carried out to understand the gut microbiota composition during SARS-CoV-2 infection. The study revealed substantial changes in the gut microbiota composition and metabolism and a reduction in the concentration of SCFAs as well as a difference in the concentrations of bile acids. The study also found alterations in tryptophan metabolites during SARS-CoV-2 infection in the animal models[55].

Shotgun metagenomic sequencing using fecal samples has also been performed to profile the gut microbiome in SARS-CoV-2 infected patients. Researchers observed prolonged impairment of L-isoleucine biosynthesis and SCFAs due to alterations in the gut microbiome of patients with COVID-19 [56].

ROLE OF ACE2 IN THE DIGESTIVE SYSTEM AND THE GUT MICROBIOME

The ACE2 (angiotensin-converting enzyme 2) receptor acts as a binding site by which SARS-CoV-2 enters host cells[57,58]. A higher expression of ACE2 in the cell favors SARS-CoV-2 infection. Despite this, ACE2 deficiency can play a vital role in SARS-CoV-2 infection[59]. Increased ACE2 expression is found in the epithelial cells of the respiratory tract (nasal mucosa, nasopharynx, and lungs), in different parts of the intestine, and in different types of epithelial cells, including nasal, corneal, and intestinal epithelial cells in humans[60]. In addition, this protein is expressed in different parts of the digestive system, such as the small intestine, stomach, colon, and liver[61]. However, ACE2 expression is

controlled by distinct microbial communities in several body tissues. Mouse model studies suggest an association between certain microbial communities and overexpression of ACE2. This overexpression may prevent detrimental changes in hypoxia-induced gut pathophysiology and pulmonary pathophysiology[62]. ACE2 expression is controlled in the GI and respiratory tract[63]. Additionally, it can also be controlled by some bacterial species from important phyla. Downregulation of ACE2 expression was associated with the Bacteroidetes phylum. Among all species of this phylum, *Bacteroides dorei* has been shown to inhibit ACE2 expression in the colon, whereas the Firmicutes phylum plays a variable role in its modulation[20,49,64]. These findings are supported by other studies describing the modulation of ACE2 expression in the gut by the microbiota[65,66].

GUT-LUNG AXIS CROSSTALK DURING COVID-19 INFECTION

Several reports indicate that manipulation of the gut microbiota may be used to treat pulmonary diseases[67]. Therefore, the gut-lung axis crosstalk can help to elucidate these respiratory and digestive system interactions (Figure 5). Dysbiosis occurs when there are detrimental changes in the microbial composition of the gut or respiratory tract. It often leads to altered immune responses and the development of diseases, such as COVID-19. Nonetheless, of gut dysbiosis can be manipulated for treatment purposes[32,67-69]. Studies suggest that SARS-CoV-2 from the lungs travels to the gut *via* the lymphatic system leading to disrupted gut permeability[70,71]. Furthermore, the extent of dysbiosis is associated with COVID-19 severity[4,72]. Therefore, understanding the crosstalk between the microbiome and the gut-lung axis during COVID-19 infection may provide therapeutic approaches.

GUT-BRAIN-LUNG AXIS CROSSTALK DURING COVID-19 INFECTION

Like the gut-lung axis, crosstalk between the microbiome and the gut-brain axis has been recognized and remains the topic[73-75]. Several studies have illustrated the role of the microbiome-gut-brain axis in different neurological disorders[76,77].

The interaction between the brain and the gut (also called the gut-brain axis) is bidirectional, with several pathways involved, including bacterial metabolites, neuroanatomical communications, neurotransmitters, and hormones[78]. The vagus nerve is primarily involved in such communication, and these molecules (neurotransmitters/hormones) are produced in the GI tract. During communication between neurotransmitters and hormones, they might interact with the receptors on the vagus nerve, relaying information to the brain[78-81]. Many hormones can cross the BBB and affect the CNS directly. Additionally, neuroendocrine pathways which operate *via* the hypothalamic-pituitary-adrenal (HPA) axis associated with stress also affect the BBB. The stress-HPA axis is associated with the release of glucocorticoids such as cortisol from the adrenal cortex. Cortisol, is associated with augmented intestinal permeability and GI motility, affecting the gut microbiota[78,82-84]. The stress-HPA axis may also lead to inflammation and bacteria-derived impaired metabolite production, especially SCFAs[78,84]. Therefore, a thorough understanding of the gut-brain axis can help the development of therapeutic approaches *via* modulation of the gut microbial composition.

The gut microbiota might play a distinct role in controlling the host immune system, and research is underway to uncover more in this field[85,86]. The involvement of the lungs (gut-brain-lung axis) occurs when inflammation and neurodegeneration in the brain stem due to COVID-19 prevent cranial nerve signaling, disrupting anti-inflammatory pathways and normal respiratory and GI functions. Recently, the lungs have been associated in the crosstalk among the microbiota-gut-brain axis components, and this axis was also noted during COVID-19 (Figure 6)[34,78]. Moreover, in COVID-19 patients, alterations in the gut microbiota have been shown to reduce live microbes (Bifidobacterium and Lactobacillus) during intestinal microbial dysbiosis[87].

The microbial translocation to the gut and its subsequent damage may play a vital role in inferior clinical outcomes for the disease. The gut-brain-lung axis during COVID-19 infection can also offer clues indicate viable directions for therapeutic development[34].

HYPOXIA IN COVID-19 AND GUT MICROBIOTA

Abnormal cytokine release (cytokine storms) and inflammatory responses may be associated with hypoxia during severe COVID-19. Viral replication in the lungs leads to a cytokine storm, destroying normal lung function and causing hypoxemia, *i.e.*, low oxygen levels in the blood. Hypoxia-inducible factor-1α (HIF-1α) is a transcription factor that regulates cellular functions such as cell proliferation and angiogenesis. In hypoxic conditions, HIF-1α binds to the hypoxemic response element and induces the production of cytokines such as IL-6 and TNF-α, leading to hypoxia[88]. There are other collective causes of hypoxia, including pulmonary infiltration and thrombosis. The COVID-19 virus induces

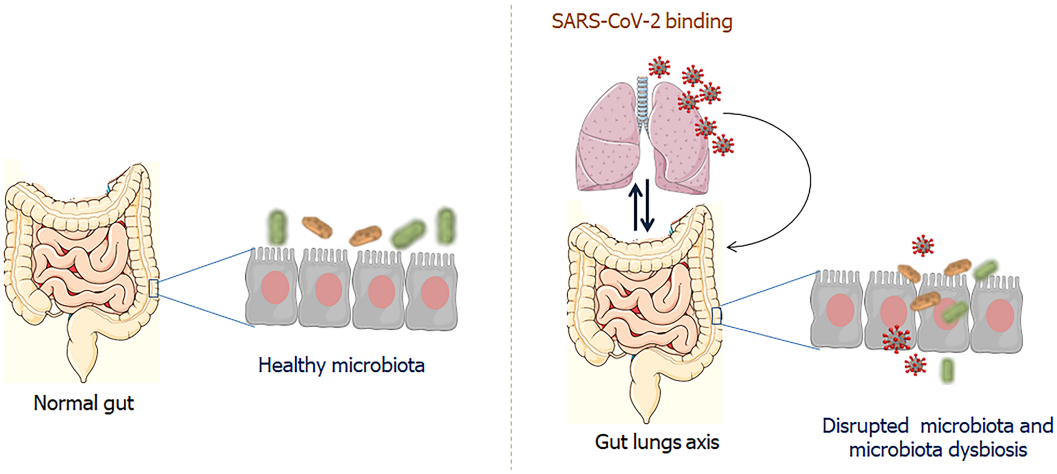

Figure 5 The diagram points out the normal gut and its microbial association. The figure also illustrates the crosstalk between the microbiome and gut-lung axis. SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2.

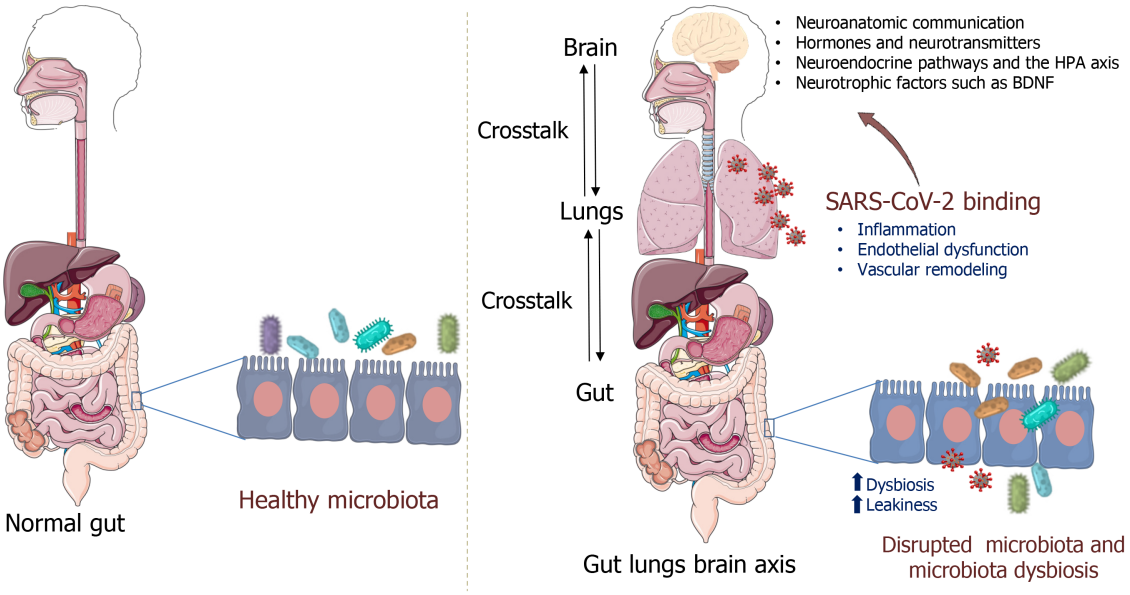

Figure 6 The diagram describes the normal gut and its microbial association. The figure also illustrates the crosstalk between the microbiome and gut-brain-lung axis. BDNF: Brain-derived neurotrophic factor; HPA: Hypothalamic-pituitary-adrenal; SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2.

pneumonia that causes atelectasis (collapsing of air sacs), leading to low oxygen levels in the body[89]. Additionally, COVID-19 leads to mitochondrial damage, production of reactive oxygen species, and subsequently HIF-1α, further promoting viral infections and inflammation[90].

As part of its normal metabolic functions, the gut microbiota produces neurotropic metabolites, neurotransmitters, peptides, and SCFA, whose levels are disrupted due to COVID-19. SCFA such as butyrate confer neuroprotection. Modulation of gut microbes (responsible for such metabolite production) by SARS-CoV-2 alters hypoxia-sensing, negatively impacting the CNS[91]. Therefore, an association between gut microbiota and hypoxia in COVID-19 patients can be speculated, and may be linked to the CNS (Figure 7).

ALTERATION OF GUT MICROBIOTA IN COVID-19: EVIDENCE FOR INFLAMMATION OR DIEASE, SEVERITY?

Under normal conditions, colonization of the normal microbiota in the gut causes resistance to pathogen [92,93]. Much of the normal gut microbiota belongs to Clostridia., which produces butyric acid. This SCFA is produced during dietary fiber fermentation along with acetic acid and propionic acid, which

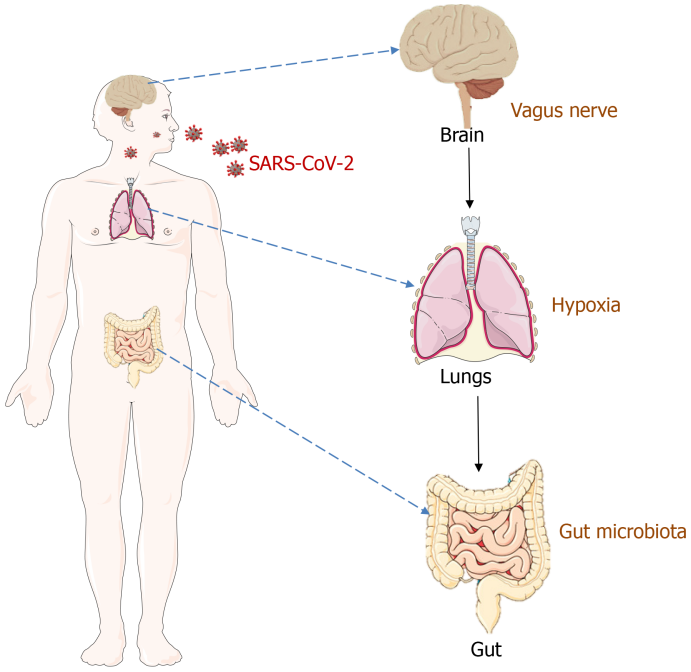

Figure 7 The figure illustrates an association between gut microbiota and hypoxia in coronavirus disease 2019 patients, and it is connected with central nervous system. SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2.

play a critical role in gut health (Figure 8A)[94,95]. Butyric acid helps in maintain the integrity of the gut barrier by providing a vital energy resource for colonocytes. This SCFA also hinders histone deacetylase activity and inhibits the activation of the nuclear factor (NF)-κB signaling pathway activation. This phenomenon may activate the G protein-coupled receptor pair (GPR41 /GPR43). These events help exert an anti-inflammatory response in normal gut health and stimulate regulatory T cells (Treg cells) [96-100]. Treg cells play a central role in suppressing inflammatory responses[97,101]. However, in COVID-19 patients, typical microbiota dysbiosis causes an imbalance in all these events.

There is a distinct connection between dysbiosis of the gut microbiota and hyper-inflammatory responses, especially cytokine release, in some COVID-19 patients[102] (Figure 8). Researchers noted that gut microbiota composition is related to the COVID-19 severity of and observed an association between altered cytokine levels and gut microbiota composition[38]. Cytokines/inflammatory factors, such as IL-1β, IL-6, and TNF-α, are usually associated with inflammation during disease[103]. In the case of severe COVID-19, the levels of certain cytokines, such as IL-6, IL-10, TNF-α, and IFN-are raised abnormally, and in some cases, cytokine storms are observed (Figure 8B)[23]. In pilot study, the quality of gut microbial composition was associated with the severity COVID-19 in 15 patients at the time of hospitalization in Hong Kong. The study showed an abundance of microbes such as *Clostridium hathewayi*, *Clostridium ramosum*, and *Coprobacillus* in COVID-19 patients. Moreover, an anti-inflammatory bacteria, *Faecalibacterium prausnitzii*, was be inversely correlated with disease severity[49].

Nonetheless, more detailed studies are needed to understand the impaired gut health during COVID-19, especially in extreme forms of the disease. Another study confirmed microbiota dysbiosis in COVID-19 patients. This study found differential bacterial populations with a decrease in *F. prausnitzii* and *Clostridium* spp and an association of IL-21 in mild to severe COVID-19 patients[51].

A gut microbiota richness analysis in COVID-19 patients was conducted over through a six-month evaluation using 16S rDNA sequencing. This study showed that, patients with decreased post-convalescence richness in bacterial microbiota had high disease severity with increased CRP. Additionally, the authors observed increased incidence of intensive care unit admissions with worse pulmonary functions in these patients[104]. The study suggested an association between the hyper-inflammatory response in COVID-19 and gut dysbiosis. However, a greater number of studies testing patients well after recovery are required to fully illustrate gut dysbiosis, associated factors, and the hyper-inflammatory response during COVID-19.

GUT MICROBIOTA IN ELDERLY OR CO-MORBID COVID-19 PATIENTS

Researchers have attempted to understand the role of the gut microbiota in elderly or co-morbid COVID-19 patients. A recent study evaluated the association of the gut microbiota and its modulation in COVID-19 patients. In this study, the cohort comprised approximately 200 severe COVID-19 patients

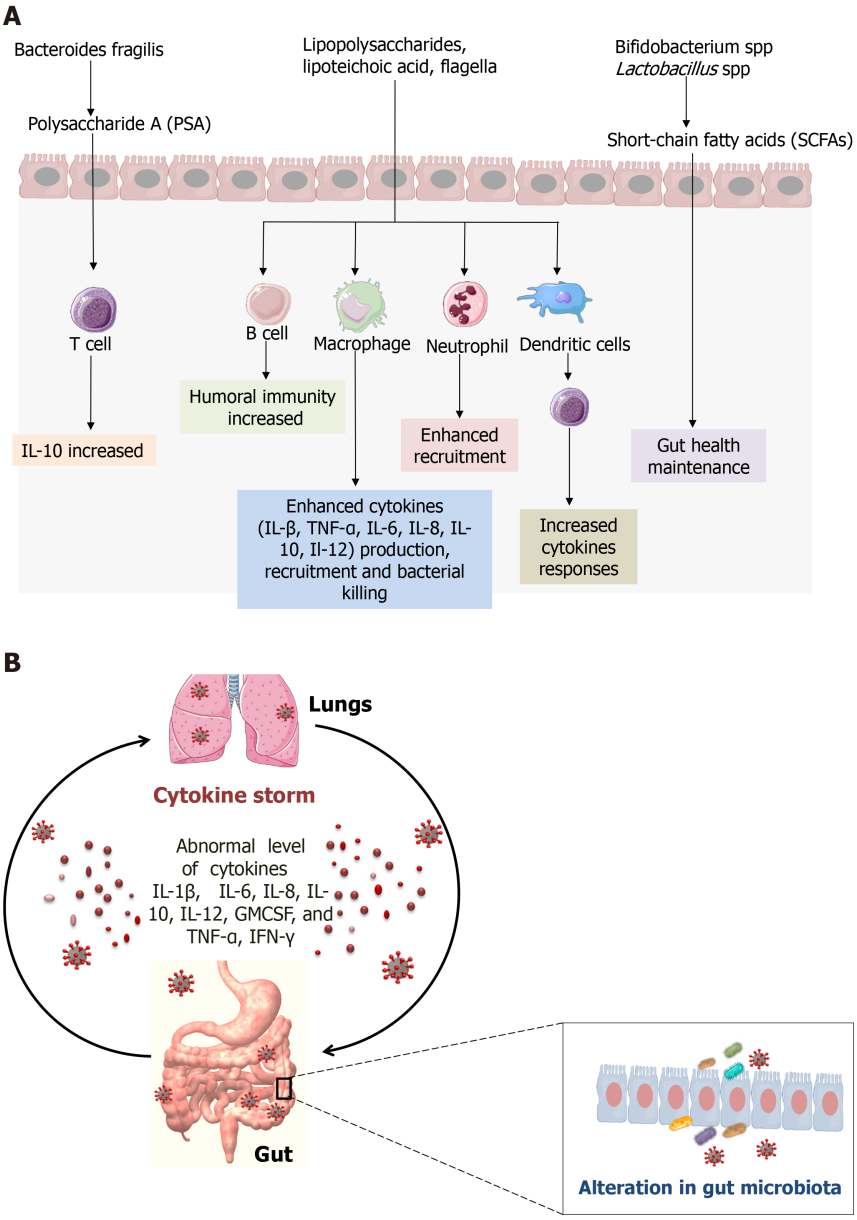

Figure 8 The figure illustrates normal gut microbiota and immunological consequences, and coronavirus disease 2019 related altered gut microbiota associated inflammation. A: Normal gut microbiota and immunological consequences for healthy gut; B: Coronavirus disease 2019 (COVID-19) related altered gut microbiota associated inflammation. The inflammatory condition in COVID-19 patients causes the abnormal release of different cytokines, such as interleukin-1 beta (IL-1β), IL-6, IL-8, IL-10, IL-12, granulocyte-macrophage colony-stimulating factor, tumor necrosis factor-alpha, and interferon-gamma. PSA: Polysaccharide A; SCFA: Short-chain fatty acid; IL-1β: Interleukin-1 beta; IL-6: Interleukin-6; GMCSF: Granulocyte-macrophage colony-stimulating factor; TNF-α: Tumor necrosis factor-alpha; IFN-γ: Interferon-gamma.

hospitalized with pneumonia. Researchers considered elderly patients (age 62 years to 64 years) and their comorbidity. Patients in this study received two types of treatments: one group was treated with only the best available therapy (BAT), and the other group was treated with oral bacteriotherapy and BAT. Researchers found a decline in mortality and decreased progress in severe disease. Finally, researchers concluded that oral bacteriotherapy might be helpful in the management of hospitalized COVID-19 patients[105]. Similarly, Rao *et al*[106] noted that people with the comorbidities are more prone to COVID-19-related complications. In this case, immune system deregulation and deaths were also noted. However, researchers used-glucan to enhance the immune system in COVID-19 patients. This glucan was used to augment the activity of macrophages, natural killer cells, and IL-8, implicating that it might enhance the defense mechanisms to combat the virus[106].

Recently, Liu *et al*[1] evaluated the role of the gut microbiota composition and its association with the post-acute COVID-19 syndrome (PACS). In this study, researchers considered the comorbidities and dietary patterns during patient selection compare gut microbiota compositions. However, no considerable differences were observed in age, comorbidities, gender, antibiotics, or antiviral drug use between patients with PACS or without PACS[1].

Therefore, in cases of elderly or co-morbid COVID-19 patients, the gut microbiota might play an important role in immune system deregulation, although further studies are required to validate the findings.

GUT MICROBIOTA BASED ON ANTIBIOTIC USAGE IN COVID-19 PATIENTS

In COVID-19 patients, the use of antibiotics is relatively common. The frequently used antibiotics in COVID-19 patients are Azithromycin, Amoxicillin Clavulanate, Cephalosporin, Tetracycline[49,107], *etc*. The composition of the gut microbiota is hampered in COVID-19 patients due to the usage of antibiotics, occasionally causing antibiotic-associated diarrhea (AAD)[108]. Antibiotics usages in COVID-19 patients were increased the number of opportunistic pathogens compared with that detected in an untreated control group. Zuo *et al*[49] reported that the gut of COVID-19 patients, using antibiotics contains opportunistic bacterial pathogens such as *Bacteroides nordii*, *Actinomyces viscosus*, and *Clostridium hathewayi*. Additional studies also reported this phenomenon[22,109]. An increase of opportunistic bacterial pathogens causes dysbiosis of the gut. Rafiqul Islam *et al*[110] also noted that the abundance of opportunistic pathogens in COVID-19 patients in Bangladesh could cause dysbiosis, with 46 genera of opportunistic bacteria being identified patient GI samples. However, a study demonstrated that particular strains of probiotics may be useful for AAD[111]. Scientists have shown that the administration of oral probiotics can recover gut health and have antiviral effects[112,53]. For probiotic strain identification, Mak *et al*[113] highlight the need for effective research to easily recognize the probiotic strains of therapeutic use. In this case, the probiotics should be specific for COVID-19, and help reduce the susceptibility to COVID-19 preventing severe COVID-19 disease.

GUT MICROBIOTA DYSBIOSIS DURING COVID-19 AND USE OF PROBIOTICS

Scientists identified an association between the gut microbiota dysbiosis and the severity of COVID-19. Magalhães *et al*[52] noted that gut microbiota dysbiosis causes poor outcomes in elderly COVID-19 patients with hypertension and diabetes. Additionally, co-morbid elderly COVID-19 patients were prone to increased inflammatory situations due to the dysbiosis. The elevated amount of bacterial products in the gut might translocate into the blood due to the increased permeability across the intestinal epithelium. Bacterial toxin products, such as lipopolysaccharides (LPS), may accumulate in blood, aggravating TLR4 and subsequent downstream signaling. This could contribute to the "cytokine storm", and result in complications in elderly COVID-19 patients[54]. Researchers also found a different route of activation of toll-like receptor (TLR4/TLR5) in COVID-19 patients[114-116]. Hung *et al*[53] also reported that gut microbiota dysbiosis increases COVID-19 severity in the elderly. However, the use of probiotics is a novel way to reduce COVID-19 severity in elderly populations.

THERAPEUTIC IMPLICATIONS AND CLINICAL TRIALS TO UNDERSTAND THE ROLE OF THE GUT MICROBIOTA DURING COVID-19

A careful analysis of the microbiome-gut-lung axis during COVID-19 infection can direct research towards therapeutic options for restoring gut health. As an altered gut microbiota is strongly associated with COVID-19 and its severity, supplementation of bacterial metabolites or commensals and prebiotics to enrich the microbial ecosystem is a path toward effective therapeutic options.

However, very few studies have explored this. A randomized clinical trial with 300 registered participants assessed the effectiveness of combination therapy using *Lactobacillus plantarum* (*L. plantarum*) CECT 7484, *L. plantarum* CECT 30292, *Pediococcus acidilactici* (*P. acidilactici*) CECT 7483, and *L. plantarum* CECT 7485, in adult COVID-19 patients (ClinicalTrials.gov; Clinical trial no. NCT04517422). Nonetheless, a deficiency of well-established data calls for more studies of this nature[41]. An open-label, randomized clinical trial with 350 participants conducted by Kaleido Biosciences sought to determine the effectiveness of a novel glycan molecule (KB109) in patients with mild to moderate COVID-19 (ClinicalTrials.gov; Clinical trial no. NCT04414124)[117]. The synthetic glycan molecule reduced the number of acute care visits by COVID-19 patients. Additionally, disease resolution in patients with comorbidities was improved, compared to that in patients relying solely on supportive self-care.

A similar study attempted to evaluate the glycan molecule's effectiveness (KB109) associated with gut microbiota function in COVID-19 patients. The same organization conducted the clinical study, an open-label, randomized clinical trial in 49 participants in the United States (ClinicalTrials.gov; Clinical trial no. NCT04486482)[118]. There were no conclusive results; however, more studies are likely to be conducted in this sense. A complete list of the clinical trials initiated to understand the role of the gut microbiota in COVID-19 and its therapeutic implications are shown in Table 4.

Table 4 List of clinical trials initiated to understand the role of gut microbiota in coronavirus disease 2019 and its therapeutic implications

Sl. No.	Objective of clinical trials	Clinical trials No.	Description of clinical trials	Remarks
1	Evaluate the combination of probiotics (*P. acidilactici* and *L. plantarum*) to reduce the viral load of moderate or severe COVID-19 patients	NCT04517422	It was a randomized controlled trial, 300 participants, treatment by dietary supplement (probiotics)	Observational study of adult and older adult, trial completed
2	To explore the natural history of mild-to-moderate COVID-19 illness and safety of a novel glycan (KB109) and self-supportive care	NCT04414124	It was a randomized, prospective, open-label, parallel-group controlled clinical study of 350 participants	Observational study of adults (both male and female), trial completed
3	Investigate the physiologic effects of the novel glycan (KB109) on patients with COVID-19 illness on gut microbiota structure and function in the outpatient	NCT04486482	It was a randomized, open-label clinical study of 49 participants	Observational study of adults patients with mild-to-moderate COVID-19 infections, trial completed
4	Evaluate the clinical contribution of the gut microbiota and its diversity on the COVID-19 disease severity and the viral load	NCT05107245	It was case-control, diagnostic study of 143 participants	Observational study on the diagnostic evaluation of the human intestinal microbiota, trial completed
5	Studied the effects of *Lactobacillus coryniformis* K8 intake on the prevalence and severity of COVID-19 in health professional	NCT04366180	A randomized, interventional study of 314 participants	Investigation of probiotic effects to healthcare personnel exposed to COVID-19 infection
6	Investigate to exploring the role of nutritional support by probiotics to COVID-19 outpatients (adult)	NCT04907877	Randomized, evidence based study of 300 participants	Used of probiotics as dietary supplement that enhance specific immune response of patients having COVID-19 respiratory infection
7	Use of dietary supplement (Omni-Biotic® 10 AAD) can decrease the intestinal inflammation and improves dysbiosis for COVID-19 patients	NCT04420676	It was a randomized Interventional study of 30 participants	This study performed as double blind, placebo-controlled study
8	Evaluate the probiotics efficacy to decrease the COVID-19 infection symptoms and duration of COVID-19 positive patients	NCT04621071	The double-blind, randomized, controlled trial of 17 participants	This study performed to explored the effects of dietary supplement: Probiotics (2 strains 10×10^9 UFC), trial completed
9	Impact analysis of probiotic strain *L. reuteri* DSM 17938 for specific Abs response against SARS-CoV-2 infection	NCT04734886	It was control, randomized trial of 161 participants	To assess the upon and after COVID-19 infection in healthy adults, trial completed
10	To evaluate the primary efficacy of live microbials (probiotics) for boosting up the immunity of SARS-CoV-2 infected persons (unvaccinated)	NCT04847349	It was double-blind, randomized, controlled trial of 54 participants	Efficacy analysis of dietary supplement (combination of live microbials) as anti COVID-19 infection, trial completed
11	Evaluate the follow -up of Symprove (probiotic) to COVID-19 positive patients	NCT04877704	The randomized clinical trial was performed with 60 patients	Observational study to supervision of hospitalized COVID-19 patients
12	Study was performed to evaluate the possible effect of a probiotic mixtures in the improvement of COVID-19 infection symptoms	NCT04390477	It was randomized case control, clinical trial of 41 participants	Observational study of dietary supplement: Probiotic to COVID-19 patients
13	The probiotic (Omni-Biotic Pro Vi 5) use for investigate the side effect of post-COVID syndrome	NCT04813718	It was a randomized trial of 20 participants	It was a therapeutic target study of probiotic for treatment of acute COVID-19 and prevention of post COVID infections
14	To evaluate the effect of a probiotic strain on the occurrence and severity of COVID-19 in hospitalised elderly population	NCT04756466	Randomized control trial of 201 participants	It was observational study, probiotic sued for improve the immune response of elderly patients
15	This study assesses the beneficial effects of the nutritional supplementation (ABBC1) to individuals taken the COVID-10 vaccine	NCT04798677	It was a double-blinded, placebo-controlled, randomized clinical study of 90 participants	Used as knowing the microbiome modulating properties, observational study
16	To investigate the consequence of *Ligilactobacillus salivarius* MP101 to hospitalised elderly individuals	NCT04922918	Non-randomised study of 25 participants	Observational study of aged patients having highly affected by COVID-19
17	Study was performed to explored the effect of the probiotic *Lactobacillus rhamnosus* GG	NCT04399252	It was a randomized double-blind, placebo-controlled trail of 182 participants	Observational study of individuals microbiome of household contacts exposed to COVID-19
18	Treatment approaches by probiotics to human gut microbiome and growing the anti-inflammatory response for COVID-19 infected patients	NCT04854941	It was a randomized controlled open-label study of 200 participants	The optimizing treatment approaches based observational study, trial completed
19	To evaluate the capability of the novel	NCT04666116	Randomized, single blind clinical	Used of dietary supplementation with

	nutritional supplement (probiotics and other vitamins) to COVID-19 infected and hospitalised patients		trial of 96 participants	probiotics aims to reduce the viral load
20	Using of probiotics for COVID 19 transmission reduction to health care professionals	NCT04462627	It was a non-randomized trial of 500 participants	Analysis and reduction of COVID-19 viral load to health care professionals

P. acidilactici: *Pediococcus acidilactici*; *L. plantarum*: *Lactobacillus plantarum*; COVID-19: Coronavirus disease 2019; SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2.

As the pandemic persists, it is critical to assess the effect of next-generation probiotics, prebiotics, synbiotics, and increased fiber intake on changes in gut microbiota composition in patients with mild to moderate and severe COVID-19.

FUTURE PERSPECTIVE

In several cases, complex pathophysiological and immunological responses are reported in the host due to SARS-CoV-2 infection. However, very little is known regarding the changes in gut virome in the COVID-19 patients, and this should be explored in future studies should explore it further. Moreover, the possible role of the gut microbiota in COVID-19 should be explored in future research. Likewise, population-based cohorts should be generated to illustrate the function of the altered gut microbiota during COVID-19 in different populations. This will enable the design of diagnostics and therapeutics for COVID-19 in different population types. Simultaneously, population-specific changes need to be described as this can help resolve severe conditions in COVID-19 patients. In the future, researchers should attempt to understand population-specific gut microbiota alteration during COVID-19 to design therapeutic interventions as required. Moreover, research could focus on the population specific changes in the immune response generated against the two altered gut microbiota during COVID-19.

CONCLUSION

Presently, abundant research has described the marked changes in the gut microbiomes of COVID-19 patients. Therefore, an apparent association exsists between the overall health of the gut microbiome and the progression of COVID-19[119]. Furthermore, the altered gut microbiota has been shown to persist in patients even after several days of recovery from COVID-19.

However, poor outcome were observed in elderly or co-morbid patients[97,120]. Recently, several studies discussed the factors associated with the modified gut microbiota in COVID-19 patients manifesting GI symptoms. According to some reports, increased inflammation may lead to a leaky gut, which enables the translocation of bacterial metabolites and toxins into the systemic circulation[97,120]. This might cause further complications to the severe COVID-19 patients.

In this review, we have illustrated various GI aspects of COVID-19 patients including the gut microbiota imbalance and GI symptoms, the patterns of altered gut microbiota composition, the crosstalk between the microbiome and the gut-lung axis, the crosstalk between the microbiome and the gut-brain-lung axis, as well as hypoxia associated with altered gut microbiota. We also highlighted the association between the gut microbiota and elderly or co-morbid COVID-19 patients, as well as that of gut microbiota dysbiosis and COVID-19 severity. Additionally, we explored the correlation between, probiotics usage and the gut microbiota based on antibiotic usage in COVID-19 patients. Therefore, our review will provide a distinct outline for researchers working in the field. Also, it will provide valuable insight into the role of gut microbiomes in COVID-19 patients.

Currently, therapeutics are in development to combat COVID-19. In addition to antiviral therapeutics, probiotics might be effective for improving gut health through the gut-lung axis. Recently, several clinical trials have been initiated to understand the role of probiotics in COVID-19 patients. The ongoing clinical trials will elucidate the role of probiotic therapeutics or for COVID-19 patients, and offer new alternatives in COVID-19 treatment.

REVIEW

Long noncoding RNAs in hepatitis B virus replication and oncogenesis

Hui-Chun Li, Chee-Hing Yang, Shih-Yen Lo

Specialty type: Gastroenterology and hepatology

Provenance and peer review: Invited article; Externally peer reviewed.

Peer-review model: Single blind

Peer-review report's scientific quality classification

Grade A (Excellent): 0
Grade B (Very good): B, B
Grade C (Good): 0
Grade D (Fair): 0
Grade E (Poor): 0

Abstract

Several diverse long noncoding RNAs (lncRNAs) have been identified to be involved in hepatitis B virus (HBV) replication and oncogenesis, especially those dysregulated in HBV-related hepatocellular carcinoma (HCC). Most of these dysregulated lncRNAs are modulated by the HBV X protein. The regulatory mechanisms of some lncRNAs in HBV replication and oncogenesis have been characterized. Genetic polymorphisms of several lncRNAs affecting HBV replication or oncogenesis have also been studied. The prognosis of HCC remains poor. It is important to identify novel tumor markers for early diagnosis and find more therapeutic targets for effective treatments of HCC. Some dysregulated lncRNAs in HBV-related HCC may become biomarkers for early diagnosis and/or the therapeutic targets of HCC. This mini-review summarizes these findings briefly, focusing on recent developments.

Core Tip: The prognosis of hepatocellular carcinoma (HCC) remains poor. It is important to identify novel tumor markers for early diagnosis and find more therapeutic targets for effective treatments of HCC. Several diverse long noncoding RNAs (lncRNAs) have been identified to be involved in hepatitis B virus (HBV)-related HCC. A better understanding of the molecular mechanisms underlying lncRNA-mediated hepatocarcinogenesis may help for their use in early diagnosis and to identify appropriate targets for the prevention and treatment of HBV-related HCC.

INTRODUCTION

Majority of the human genome (70%–90%) is actively transcribed. Only approximately 2% of these transcribed RNAs translate into proteins, while more than 90% of them are noncoding RNAs (ncRNAs). Based on size, ncRNAs are classified into small ncRNAs [less than 200 nucleotides (nt)] and long noncoding RNAs (lncRNAs, more than 200 nt). Several kinds of small ncRNAs have been characterized, including transfer-, ribo-, small nucleolar-, piwi -and miRNAs. It is well known that miRNAs (generally 22–25 nt) can regulate gene expression by suppressing protein translation or by mRNA degradation through interacting with their target mRNA sequences, usually at the 3′-untranslated regions (3′UTR). Various miRNAs have been found to be dysregulated and play important roles in hepatitis B virus (HBV) infection and hepatocellular carcinoma (HCC) progression[1].

LncRNAs are mostly transcribed by RNA polymerase II, sometimes polyadenylated and located in nuclear and/or cytosolic fractions. LncRNAs are divided into intergenic, intronic, bidirectional, sense, and antisense lncRNAs based on their genomic location and strand orientation. These lncRNAs may function as signals, decoys, guides, or scaffolds to regulate the expression of their target genes through interacting with their partner molecules[2]. In this way, lncRNAs can modulate gene expression at different levels, including epigenetic silencing, transcriptional control, post-transcriptional regulation, and protein stability modulation[2]. Thus, they are involved in many biological processes such as cell proliferation, invasion and metastasis, autophagy, and apoptosis. Indeed, dysregulation of lncRNAs has now been implicated in numerous human diseases, especially cancers, *e.g.*, HCC[2].

Liver cancer was the sixth most common cancer and the third leading cause of cancer death in the world in 2020 (https://gco.iarc.fr/today/home). HCC represents approximately 90% of all cases of primary liver cancer. The leading cause of HCC is persistent HBV infection, which occurs in more than half of the HCC cases[3]. The management of HBV-related HCC has improved in the past decade. However, the outcome of HCC is still poor. Understanding more regarding the underlying mechanism of HBV-related HCC is required for improving the prevention, diagnosis, and treatment of HCC. The roles of lncRNAs in HBV-related HCC have received much more attention lately.

In this mini-review, we briefly outline the involvement of lncRNAs in HBV replication. We summarize the findings of dysregulated lncRNAs in HBV-related diseases, especially HCC, and discuss their roles and the potential clinical applications as diagnostic or therapeutic targets for HCC.

LNCRNAS IN HBV REPLICATION

HBV, belonging to the *Hepadnaviridae* family, is a small enveloped DNA virus. Ten HBV genotypes (A–J), which are based on eight percent or more sequence divergence across the viral genome, have been identified[4]. Even with the genotype differences, HBVs share the same pattern of replication cycle in the cells[5]. HBV infection begins with the attachment of virions to the surface proteoglycans on hepatocytes, followed by high affinity binding with more specific receptors (*e.g.*, sodium taurocholate cotransporting polypeptide; NTCP)[6]. After entry into the cell, the viral compact, partially double-stranded genome (*i.e.*, relaxed circular DNA) will form the stable covalently closed circular DNA (cccDNA) by viral and host factors[7]. Then, the viral RNAs [including sub-genomic mRNAs and pre-genomic RNA (pgRNA)] are transcribed from cccDNA using the cellular transcriptional machinery. The pgRNAs and the viral polymerase proteins (HBpAg) will be encapsidated by HBV core antigen (HBcAg) proteins. The newly formed nucleocapsids containing partially double-stranded HBV DNA made from pgRNA by HBpAg then either re-enter the nucleus to produce more cccDNA or release as mature virions following the assembly with HBV surface proteins (HBsAg)[5].

The 3.2 kilobases (kb) HBV genome contains four open reading frames (ORFs): Surface (S), precore (pre-C)/core (C), polymerase (P), and X. The S ORF encodes three viral envelope proteins initiated from different start codons: Large, middle, and small surface antigens (HBsAg). HBV e antigen and core antigen (HBcAg) are encoded in the pre-C/C ORF[5]. The P ORF encodes viral polymerase (HBpAg) possessing reverse transcriptase, RNase H, and DNA polymerase activities. HBV X protein (HBxAg, HBx) derived from X ORF can transactivate the expression of both cellular and viral genes required for viral replication[5].

Nearly 257 million people worldwide have been infected with HBV, resulting in 887000 people dying of liver cirrhosis or HCC annually. Therefore, identification of new therapeutic targets against HBV is urgently needed. LncRNAs could be potential targets as a growing number of them have been found to play a role in HBV replication[8] (Figure 1).

LncRNAs facilitating HBV replication

LncRNA deleted in lymphocytic leukemia 2 (DLEU2): HBx was found to bind the DLEU2 promoter to enhance its transcription. Nuclear DLEU2 could directly bind to HBx or the histone methyltransferase enhancer of zeste homolog 2 (EZH2). The interaction of HBx and DLEU2 on the viral cccDNA displaces EZH2 from the viral chromatin to boost viral transcription and replication[9].

HOX transcript antisense RNA (HOTAIR): HOTAIR was significantly upregulated in HBV-infected cells. HOTAIR promoted HBV transcription and replication by elevating the activities of HBV promoters *via* modulation of the levels of cccDNA-bound SP1[10].

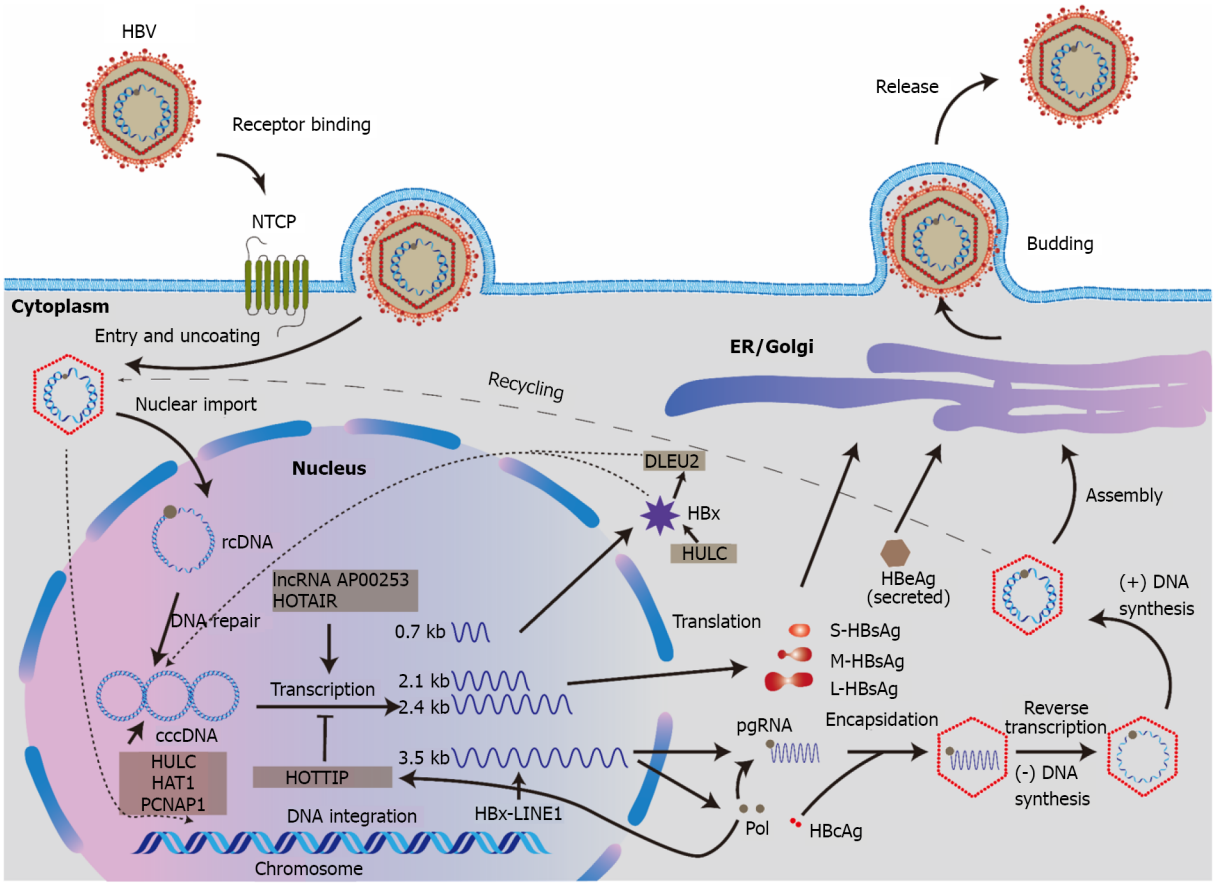
LncRNA proliferating cell nuclear antigen (PCNA) pseudogene 1 (PCNAP1): The expression levels of PCNAP1 and PCNA were significantly elevated in the livers of HBV cccDNA-positive HCC patients. PCNA could interact with HBV cccDNA in a HBc-dependent manner. PCNAP1 enhanced PCNA through sponging miR-154, which targets the 3'UTR of PCNA mRNA. Moreover, PCNAP1 or PCNA enhanced HBV replication significantly both *in vitro* and *in vivo*. Thus, lncRNA PCNAP1 enhances HBV replication through the miR-154/PCNA/HBV cccDNA axis[11].

LncRNA highly upregulated in liver cancer (HULC): The HULC gene is located on chromosome 6p24.3 and contains two exons and one intron. HULC is an lncRNA of around 500 nt mainly localized in the cytoplasm. HULC was found to elevate HBx, which coactivated STAT3 to stimulate the miR-539 promoter. Elevated miR-539, which targets the 3'UTR of APOBEC3B mRNA, downregulated APOBEC3B and promoted HBV replication. Thus, HULC activates HBV through the HBx/STAT3/miR-539/APOBEC3B axis[12]. Another study demonstrated that lncRNA HULC enhanced HBV replication through the HAT1/HULC/HBc complex responsible for the accumulation on cccDNA minichromosome[13]. Moreover, the HULC genetic variant rs7763881 is associated with HBV infection[14].

LncRNA zinc ribbon domain containing 1-antisense RNA 1 (ZNRD1-AS1): A ZNRD1, cloned from the human leukocyte antigen region, should play an important role in immune response against HBV infection. ZNRD1-AS1 is an important regulator of ZNRD1. The variant allele of ZNRD1-AS1 (rs3757328) was reported to be associated with HBV clearance[15].

LncRNA HBx-long interspersed nuclear element 1 (HBx-LINE1): HBx-LINE1 suppresses miR-122 [16], a miRNA that has been demonstrated to inhibit HBV replication by directly targeting the HBV pgRNA sequence[17]. Thus, by depleting miR-122, HBx-LINE1 enhances HBV replication.

LncRNA AP000253: AP000253 was found to promote HBV transcription and replication in hepatoma cells[18]. However, the AP000253 expression in liver tissues and the molecular mechanism of its involvement in HBV infection are not clear yet.



LncRNAs suppressing HBV replication

LncRNA HOXA transcript at the distal tip (HOTTIP): HOTTIP is a 3764 nt transcript mapped to the HOXA locus. HOTTIP was found to be induced by HBV in vitro. Further studies demonstrated that HBpAg could bind to and stabilize cAMP-responsive element-binding protein 1 (CREB1) mRNA to facilitate its translation. Then, the CREB1 protein would bind to the regulatory element of HOTTIP to promote its expression. HOTTIP significantly suppresses HBV replication through its downstream factor HOXA13, which was found to bind to HBV Enh I/Xp to reduce the production of pgRNA as well as HBV replication. Thus, HBpAg attenuates HBV replication *via* activation of the CREB1/HOTTIP/HOXA13 axis. In this way, lncRNA HOTTIP could restrain HBV replication and contribute to viral persistent infection[19].

Other lncRNAs involved in HBV replication

H11, a novel inhibitor of La protein, suppressed HBV replication by blocking the interaction between La protein and HBV RNA. Further studies have shown that 61 lncRNAs were upregulated and 74 lncRNAs were downregulated in an H11 treatment group when compared with the control group[20]. These lncRNAs should affect HBV replication though further verification is required.

The importance of lncRNAs in HBV replication has started to emerge. However, many unidentified lncRNAs critical for HBV replication should exist, such as those regulated by HBx (mentioned in the following sections). HBx is required for transcription from the viral cccDNA minichromosome. Thus, HBx modulates HBV replication. The lncRNAs affected by HBx may modulate HBV replication. The

Figure 1 Long noncoding RNAs involved in the lifecycle of the hepatitis B virus. Highly upregulated in liver cancer, HAT1, PCNAP1, and DLEU2 could enhance hepatitis B virus (HBV) replication[9,11,13]. LncRNA AP00253[18] and HOX transcript antisense RNA[10] promote, while HOXA transcript at the distal tip[19] inhibits, HBV transcription. HBV X protein-long interspersed nuclear elements 1 promotes HBV replication by suppressing miR-122, a miRNA directly targeting the HBV pgRNA sequence[16]. HULC: Highly upregulated in liver cancer; HBV: Hepatitis B virus; HBx: HBV X protein; LINE: Long interspersed nuclear elements; HOTTIP: HOXA transcript at the distal tip; HOTAIR: HOX transcript antisense RNA.

roles of these lncRNAs in HBV replication require further investigation.

LNCRNAS IN HBV-RELATED IMMUNE RESPONSES

The roles of lncRNAs in the host immune system during HBV infection have just started to emerge. LncRNA ENST00000519726 (lncRNA-HEIM) was highly expressed in monocytes and was further upregulated upon HBV infection. Elevated lncRNA-HEIM expression was remarkably correlated with the TGF- signaling pathway. Furthermore, altering the endogenous lncRNA-HEIM amount in monocytes significantly affected TGF- production[21].

LncRNA FTX downregulates the expression of tumor necrosis factor-α (TNF-α), interleukin (IL)-6, IL-1β, and nuclear factor kB (NF-kB) but upregulates the expression of Tim-3. This result demonstrated the effect of FTX on the expression of inflammatory cytokines through FTX-miR-545-TIM3 axis[22].

High lncRNA-CD160 expression level can inhibit interferon (IFN)-γ and TNF-α secretion in CD8+ T cells and decrease the immune response of CD8+ T cells. LncRNA-CD160 can interact with histone-modification enzyme gene histone deacetylase 11 (HDAC-11) to form a complex on the promoters of IFN-γ and TNF-α to inhibit their expression. Thus, lncRNA-CD160 acts as an immune suppressor. Indeed, knockdown of lncRNA-CD160 can block HBV infection[23].

Lnc-DC is a specific group of lncRNAs in dendritic cells. Lnc-DC could be activated by HBV infection. In addition, lnc-DC is important in regulating the growth, apoptosis, and immune response of dendritic cells mediated by TLR9/STAT3 signaling. Moreover, the regulation of lnc-DC controlled the immune response by reduction in secreted TNF-α, IL-6, IL-12, and IFN-γ, while increasing the IL-1β concentration in dendritic cells[24].

LncRNA#32 could positively regulate IFN-stimulated gene expression by interacting with activating transcription factor 2. Indeed, depletion of lncRNA#32 resulted in a significant increase in the replication of several viruses, including HBV. Thus, lncRNA#32 plays a role in host antiviral responses

[25].

The role of lncRNAs in the HBV-related immune responses remains unclear. There should be many unidentified lncRNAs important for HBV-related immune responses, such as those involved in HBV-related HCC.

LNCRNAS IN HBV-RELATED CHRONIC DISEASES

Progression of liver disease from chronic HBV infection to HCC may include several stages[26], such as fibrosis and cirrhosis (Figure 2). The roles of lncRNAs in these HBV-related chronic diseases are largely unknown.

Transforming growth factor-β (TGF-β) plays an important role in various pathogenic processes, from inflammation, fibrosis, and cirrhosis to cancer. LncRNA-ATB, which is activated by TGF-β, is a key regulator of the TGF-β signaling pathway. The plasma levels of lncRNA-ATB in HBV-related cirrhosis patients were significantly higher than those in healthy controls[27].

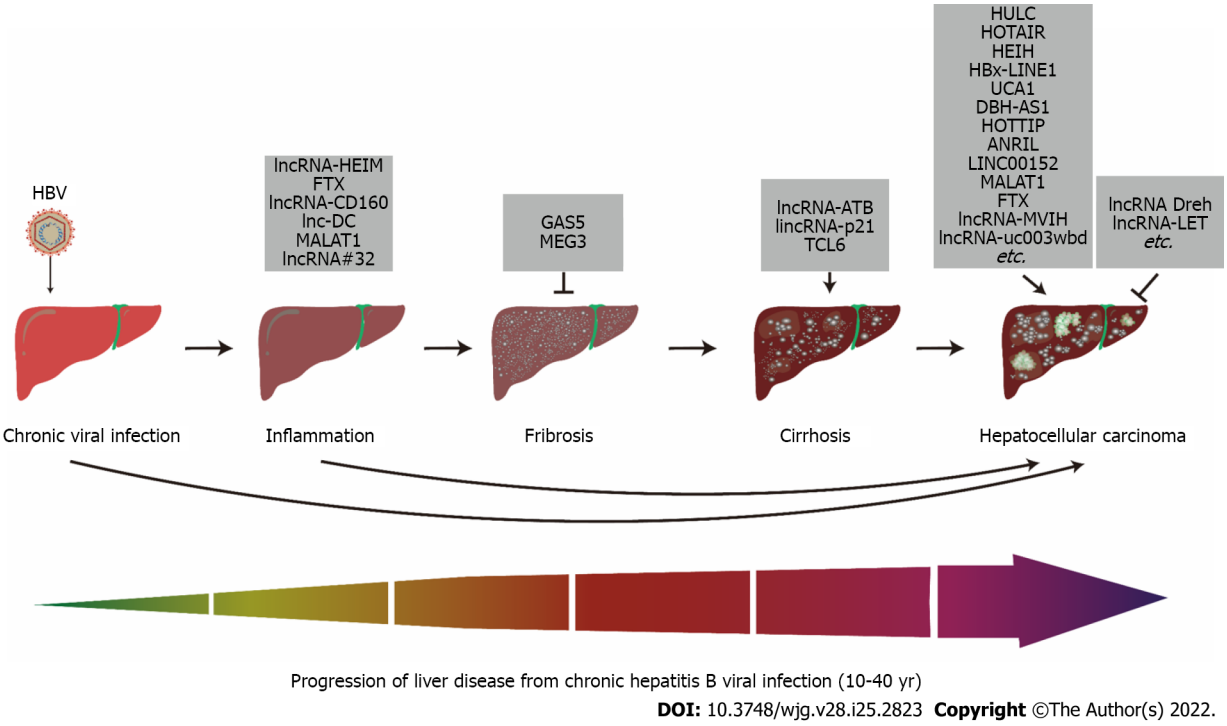
Serum lincRNA-p21 levels in CHB patients, those with hepatitis B cirrhosis, and HBV-related HCC, were higher than those in the control subjects. LincRNA-p21 level was negatively correlated with levels of HBV DNA, alanine aminotransferase, and aspartate aminotransferase in patients with liver diseases. Thus, serum lincRNA-p21 may serve as a potential biomarker for liver cell damage in patients with hepatitis virus infection, hepatitis B cirrhosis, and HBV-related HCC[28].

Compared with that in healthy controls, HBV carriers, and CHB patients, the expression of lnc-TCL6 was obviously upregulated in Child–Pugh A patients with liver cirrhosis. Thus, lnc-TCL6 was identified as a sensitive biomarker for early diagnosis of liver cirrhosis (Child–Pugh A)[29].

LncRNA metastasis associated in lung adenocarcinoma transcript 1 (MALAT1) expression in CHB group was significantly upregulated compared to the control group. Moreover, the thioredoxin interacting protein (TXNIP) was also significantly upregulated in the CHB group. Further studies indicate that the MALAT1/hsa-miR-20b-5p/TXNIP axis may mediate CHB-induced inflammatory damage in chronic HBV infection complicated with non-alcoholic fatty liver disease[30].

LncRNA-maternally expressed gene-3 (MEG3) was reported to be significantly downregulated in human HCC cell lines possibly due to the MEG3 promoter being hyper-methylated. Further studies indicated that the serum level of lncRNA-MEG3 was lower in CHB patients, which is negatively correlated to the liver fibrotic degree. In vitro experiments verified those results. Thus, lncRNA-MEG3 may serve as a diagnostic biomarker for CHB[31].

LncRNA growth arrest specific transcript 5 (GAS5) is significantly downregulated in CHB patients due to its promoter methylation. Compared with the sera of healthy controls, lower GAS5 levels were detected in the sera of CHB patients. Thus, lncRNA GAS5 is also reported as a biomarker for liver fibrosis in CHB patients[32].



CHB patients might progress to acute-on-chronic liver failure (ACLF) with a high fatality rate. Four lncRNAs (RP11-25K21.6, THRB, RAB27A, and GNPTAB) were found to be differentially expressed between the ACLF and the control groups. Aberrant lncRNAs might be used to develop novel diagnostic biomarkers and/or therapeutic targets for ACLF[33].

The role of lncRNAs in the HBV-related chronic diseases is not clear yet. Those lncRNAs involved in HBV-related HCC (mentioned in the following section) may also play roles in HBV-related chronic diseases. This requires further investigation.

LNCRNAS DYSREGULATED IN HBV-RELATED HCC

HCC was the sixth most common cancer in world in 2020. Risk factors of HCC include external stimuli such as HBV or hepatitis C virus infection, intake of aflatoxin B1, alcohol consumption, smoking, and host factors such as age, gender, genetics, and comorbidities. Globally, approximately 2 billion people have been infected with HBV. Among them, more than 350 million people are chronic HBV carriers. Chronic HBV infection has been implicated in HCC development. In fact, persistent HBV infection occurs in more than half of HCC, particularly in developing countries. Comparing with other solid malignancies, HCC is characterized by its highly invasive and metastatic potential. Indeed, HCC is the third leading cause of cancer death in world. This is in part due to the fact that patients may not exhibit symptoms at early stages of HCC[34]. Therefore, comprehensive approaches are warranted to identify novel tumor markers and find more effective therapeutic targets to improve the diagnosis and treatment of HCC[8]. In recent years the idea has emerged that regulatory ncRNAs, such as miRNAs and lncRNAs, should play regulatory roles in cancers such as HCC[1]. Specifically, various lncRNAs were reported to regulate the expression of tumor suppressor genes or oncogenes involved in cancer development[2].

HCC caused by HBV infection is related to different HBV genotypes, the mutation status of viral genomes, integration of viral DNAs, and the dysregulation of signaling pathways affected by HBV. However, the detailed mechanisms of HBV-related HCC remain to be determined. The development of

Figure 2 Various long noncoding RNAs are involved in the progression of liver diseases caused by the hepatitis B virus[26]. HULC: Highly upregulated in liver cancer; HBV: Hepatitis B virus; HBx: HBV X protein; LINE: Long interspersed nuclear elements; HOTTIP: HOXA transcript at the distal tip; HOTAIR: HOX transcript antisense RNA; GAS5: Growth arrest specific transcript 5; MEG3: Maternally expressed gene-3; MALAT1: Metastasis associated in lung adenocarcinoma transcript 1.

the majority of HBV-related HCCs is associated with: (1) Chronic inflammation; (2) Insertion of viral sequences into the cellular chromosomes; (3) Transactivation of growth regulatory genes by HBx; and (4) Altered versions of the preS/S envelope proteins[35]. If the host immune system fails to clear HBV, the infection will become chronic. Then, HBV DNA may integrate into the cellular chromosome. Indeed, integrated viral DNA is found in 85%–90% of HBV-related HCCs. Insertion of the HBV DNA occurs preferentially at certain sites in the host genome, including repetitive elements such as LINEs and Alu repeats[36]. The HBx gene is the smallest ORF encoding a 154-amino acid regulatory protein. HBx is reported to contribute to the pathogenesis of HCC by trans-modulating many growth regulatory genes and activating various signaling pathways, including p53, NF-kB, and Wnt signaling. Diverse lncRNAs involved in the events of viral immune responses, viral integration, and HBx regulatory activities should play roles in HBV-related HCC[37]. Studies on lncRNAs which are differentially expressed in HBV-HCC tissue samples may elucidate oncogenic pathways and identify novel diagnostic and therapeutic targets[8]. When compared to normal and/or non-HBV HCC samples, hundreds of dysregulated lncRNAs in HBV-related HCC tissues have been detected[38-40]. It is also reported that HBx could alter the expression of 2002 lncRNA[41]. In this mini-review, the better characterized lncRNAs in HBV-related HCC will be discussed.

UPREGULATED LNCRNAS IN HBV-RELATED HCC

HULC

HULC was the first lncRNA reported to be specifically upregulated in HCC through microarray analysis and quantitative reverse transcriptase polymerase chain reaction (qRT-PCR). By interacting with CREB, HBx up-regulates the HULC expression in hepatoma cell lines and HBV-related HCC tissues. HULC downregulates the expression of p18, a tumor suppressor gene close to HULC, and thus promotes the proliferation of hepatoma cells[42]. Moreover, HULC can act as a molecular sponge for miR-107. By sponging miR-107, HULC upregulates E2F1 and then activates SPHK1 transcription in hepatoma cell lines and HBV-related HCC tissues. Thus, HULC promotes tumor angiogenesis through miR-107/E2F1/SPHK1 signaling[43]. Altogether, these studies indicate that HULC serves as an oncogene important for HBV-related HCC. HULC is also demonstrated to act as an endogenous 'sponge' for various other miRNAs (*e.g.*, miR-372, miR-186, miR-488, miR-200a-5p, miR-6825-5p, miR-6845-5p, and miR-6886-3p) in hepatoma cell lines and HCC tissues[44]. Those findings provide new insights into the mechanism of HULC in the HCC development (Table 1).

Table 1 Long noncoding RNAs up-regulated in hepatitis B virus-related hepatocellular carcinoma

LncRNA name	Regulatory mechanism	Biological function
HULC[43]	Sequesters microRNAs and decreases p18 expression	Promotes proliferation of hepatoma cells and tumor angiogenesis *in vitro* and *in vivo*
HOTAIR[45,47]	Suppresses miRNA-218 expression and inactivation of P14 and P16 signaling	Promotes migration and invasion of HCC cells
HEIH[48]	Binds to EZH2 and represses EZH2 targets	Promotes cell proliferation and tumor growth, modulates cell cycle
HBx-LINE1[16,49]	Sequesters miR-122 and activates Wnt signaling pathway	Promotes cell motility through EMT
UCA1[53,54]	Through the HBx/UCA1/EZH2/p27 axis in nucleus; sequesters miR-216b and miR-203 in cytoplasm	Promotes growth, metastasis, and EMT of HCC cell lines
DBH-AS1[56]	Activates the ERK/p38/JNK MAPK signaling pathway	Inhibits serum starvation-induced apoptosis of HCC cells, promotes tumor growth, proliferation, and cell-cycle progression of HCC cells
HOTTIP[57]	Upregulates the expression of HOXA genes (*e.g.*, HOXA 10, 11, and 13)	Inhibits proliferation and migration of HCC cells *in vitro* and reduces tumorigenesis and pulmonary metastasis *in vivo*
ANRIL[59,60]	Represses the KLF2 transcription through binding to PRC2; serves as a molecular sponge for miR-122-5p	Inhibits apoptosis of HCC cells *in vitro* and promotes proliferation, invasion, and migration of HCC cells *in vitro*
LINC00152[61]	Inhibits the expression of E-cadherin; activates the mTOR pathway	Promotes the proliferation and EMT of HCC cell lines and tumorigenesis
MALAT1[63,66]	Upregulates LTBP3 transcription	Promotes migration and invasion of HCC cells *in vitro* and tumor growth *in vivo*
Ftx[22]	Production of miR-545/374a	Promotes tumorigenesis and tumor progression
MVIH[68]	Activates angiogenesis through reducing the secretion of PGK1	Promotes tumor growth and metastasis
Unigene56159[69]	Sequesters miR-140-5p	Promotes EMT, migration, and invasion of hepatoma cells
LINC01232[70]	Downregulation of miR-708-5p	Promotes tumor progression *in vitro*
SAMD12-AS1[71]	Inhibition of p53	Promotes cell proliferation and inhibits apoptosis
lnc-HUR1[72]	Inhibition of p53	Promotes cell proliferation and tumorigenesis
n335586[73]	n335586/miR-924/CKMT1A axis	Contributes to cell migration and invasion
XIST[74]	XIST/miR-192/TRIM25 axis	Enhances the proliferation and migration of HCC cells
SNHG5[81]	SNHG5/miR-26a-5p/GSK3β signaling pathway	Promotes HCC progression
WEE2-AS1[76]	HBx/WEE2-AS1/FERMT3 pathway	Promotes HCC proliferation and invasion
MAFG-AS1[77]	HBx/ MAFG-AS1/MAFG	Promotes HCC proliferation and migration
lncRNA-ATB[78]	Induces autophagy	Promotes cell invasion and migration
TRERNA1[79]	TRERNA1/miR-22-3p/NRAS axis	Promotes cell proliferation in HCC
lncRNA IHS[80]	Regulates the ERK- and AKT/GSK-3β signaling pathways	Promotes tumor proliferation and metastasis in HCC
SNHG20[81]	Negatively regulated PTEN protein level	Facilitates the proliferation of HCC cells
AX800134[82]	Not known	Antiapoptosis

LncRNAs: Long noncoding RNAs; HCC: Hepatocellular carcinoma; EMT: Epithelial-to-mesenchymal transition; HULC: Highly upregulated in liver cancer; HBV: Hepatitis B virus; HBx: HBV X protein; LINE: Long interspersed nuclear elements; HOTTIP: HOXA transcript at the distal tip; HOTAIR: HOX transcript antisense RNA; GAS5: Growth arrest specific transcript 5; MEG3: Maternally expressed gene-3; MALAT1: Metastasis associated in lung adenocarcinoma transcript 1; PGK1: Phosphoglycerate kinase 1.

HOTAIR

The *HOTAIR* gene is on chromosome 12. LncRNA HOTAIR is a 2158 nt transcript derived from the *HOTAIR* gene. HOTAIR is involved in the occurrence of HBV-related HCC. HBV replication and, in particular, HBx production, stimulates expression of HOTAIR and Plk1. The combination of Plk1 and HOTAIR are involved in epigenetic reprogramming associated with oncogenic transformation[45]. *In vitro* studies have demonstrated that HOTAIR has sequence-specific effects and interacts with various chromatin modifying proteins, *e.g.*, Polycomb repressive complex 2 (PRC2)[46]. Another study showed

that HOTAIR might mediate hepatocarcinogenesis by down-regulating miR-218 and in-activating P14 and P16 signaling[47]. These findings suggest that lncRNA HOTAIR should play an important role in hepatocarcinogenesis (Table 1).

High expression in HCC

The *high expression in HCC* (*HEIH*) gene is on chromosome 5. LncRNA HEIH is a polyadenylated, approximately 1600 nt in length, lncRNA, whose expression is strongly linked to HBV-associated HCC. It is located both in the nucleus and cytoplasm. HEIH could promote cell proliferation by upregulating PCNA and decreasing the expression of p16, p21, and p27 in cells. Moreover, HEIH could promote tumor growth in nude mice. Mechanistically, HEIH is physiologically associated with EZH2, the catalytic subunit of the PRC2. The association of HEIH with EZH2 is needed to repress the EZH2 target genes[48]. These studies demonstrate that HEIH contributes to HBV-related HCC through the participation of epigenetic silencing (Table 1).

HBx-LINE1

Almost all HBV-related HCC tumors (85%–90%) have at least one HBV insertion site in the host genome. Thus, integration of HBV DNA should be important for the HCC development. LINEs appear to be a favored site for HBV DNA integration. To investigate the effect of HBV integration on genome disruption, HBx-LINE1, a viral-human chimeric fusion transcript derived from viral sequences containing HBx and cellular LINEs, was found functioning as an lncRNA. HBx-LINE1 was detected in 23.3% of HBV-related HCC patients[49,50]. HBx-LINE1, on chromosome 8p11.21, was transcribed from the HBx promoter. HBx-LINE1 contains six miR-122-binding sites and serves as a molecular sponge to sequester cellular miR-122. By downregulating miR-122, HBx-LINE1 activates the β-catenin signaling pathway, and in turn enhances HCC cell proliferation, invasion, and migration[16]. However, these findings were not consistent with those from other studies[51]. More studies with a larger sample size should help further clarify the role of HBx-LINE1 in the HBV-related HCC (Table 1).

Urothelial carcinoma associated 1

The *urothelial carcinoma associated 1* (*UCA1*) gene is approximately 7.3 kb in length on chromosome 19p13.12 and contains three exons. It has three transcriptional isoforms. UCA1, around 1400 nt in length, is the most abundant isoform of the *UCA1* gene[52]. UCA1 was originally identified in the bladder cancer cell line and also played an important role in HBV-related HCC. HBx could upregulate UCA1 expression[37,53]. UCA1, an lncRNA detected in both the cytoplasm and nucleus[53], has diverse functions. In nucleus, UCA1 recruits EZH2 to the p27 promoter, reduces the p27 expression, and enhances CDK2. Thus, UCA1 could promote the growth of hepatic and hepatoma cells through the HBx/UCA1/EZH2/p27 axis[53]. In cytoplasm, UCA1 serves as a molecular sponge for miR-216b and miR-203. Through sequestering miR-216b, UCA1 could promote the growth and metastasis of HCC cell lines by up-regulating the expression of fibroblast growth factor receptor 1 and activating the extracellular signal-regulated kinase signaling pathway[54]. In addition, sequestering miR-203 facilitates epithelial-to-mesenchymal transition (EMT) in HCC cells through Snail2 upregulation[55]. Thus, UCA1 could promote cell cycle progression, enhance cell proliferation, and decrease cell apoptosis in HBx-related HCC[37] (Table 1).

DBH-AS1

DBH-AS1 is an lncRNA of approximate 2 kb located on chromosome 9q34. HBx can upregulate the expression of DBH-AS1, which promotes HCC cell proliferation[37]. DBH-AS1 activates the ERK/p38/JNK MAPK signaling pathway. Once activated, ERK/p38/JNK MAPK can upregulate cyclin-dependent kinase 6 (CDK6), CCND1, and CCNE1 (members of cyclins) and downregulate p16, p21, and p27 (inhibitors of CDK). Thus, DBH-AS1 could induce the G1/S and G2/M transitions and promote cell proliferation. DBH-AS1 was also shown to protect HCC cells from serum starvation-induced apoptosis. These results suggested that DBH-AS1 acts as an oncogene[56]. However, a recent study showed contradicting results regarding the expression pattern of DBH-AS1[57]. To elucidate the exact role of DBH-AS1 in HBV-related HCC, more research is required (Table 1).

HOTTIP

LncRNA HOTTIP, a 3764 nt transcript, is located on chromosome 7p15.2 and encodes from a genomic region in the 5′tip of the HOXA locus. LncRNA-HOTTIP was significantly overexpressed in tumor tissues compared to adjacent non-tumor tissues of the HCC patients. Patients with high HOTTIP expression were associated with increased metastasis formation and decreased overall survival. HOTTIP has also been detected to be upregulated significantly in HBV-related HCC patients[57]. Elevated HOTTIP expression could enhance cell proliferation and migration and contribute to metastasis of HCC partly by upregulating its neighboring *HOXA* genes (*e.g.*, HOXA 10, 11 and 13), which are associated with various cancer types. These findings suggest that HOTTIP acts as an oncogene in HBV-related HCC (Table 1).

Antisense ncRNA in the INK4 locus

Antisense ncRNA in the INK4 locus (ANRIL), a 3800 nt lncRNA, is in the *INK4BARF-INK4A* gene cluster[58]. ANRIL is upregulated in several cancers including HBV-related HCC[57]. The ANRIL expression was associated with tumor size, histological grade, and overall survival in HCC patients[59]. These findings indicate that ANRIL plays a role in the HCC development, particularly HBV-related HCC. Knockdown of ANRIL expression in HCC cells *in vitro* could induce apoptosis and reduce the proliferation, invasion, and migration of these HCC cells[60]. Furthermore, inhibition of ANRIL led to slower tumor growth *in vivo*[59,60]. ANRIL represses the KLF2 transcription through binding with PRC2[59]. ANRIL also serves as a molecular sponge for miR-122-5p, whose overexpression significantly repressed the proliferation, migration, and invasion of HCC cells[60]. These findings indicate that ANRIL is also an oncogene in HBV-related HCC (Table 1).

LINC00152

LINC00152, an lncRNA of 828 nt, is mapped to chromosome 2p11.2 and contains four exons. It is mainly localized in the nucleus of HCC cells. The LINC00152 expression is associated with tumor size, HBV infection, and HBx amount[61]. Elevated LINC00152 expression also results in decreased overall survival[61]. LINC00152 is up-regulated by HBx protein and enhances proliferation and EMT of HCC cell lines *in vitro* and tumorigenesis *in vivo*[61]. LINC00152 has been shown to activate the mTOR pathway, which is a classic dysregulated pathway involved in the pathogenesis of HCC. In addition, LINC00152 promotes EMT by reducing the binding of EZH2 to the E-cadherin promoter and suppressing E-cadherin expression in HCC cell lines[61]. Ablation of E-cadherin will lose cell–cell contacts, resulting in EMT. These studies suggest that LINC00152 contributes to HBV-related HCC (Table 1).

Metastasis-associated lung adenocarcinoma transcript 1

Metastasis-associated lung adenocarcinoma transcript 1 (MALAT1) (also known as nuclear-enriched abundant transcript 2), an lncRNA of approximate 8000 nt in length, is mainly localized in the nucleus [62]. MALAT1 expression is elevated by HBx in HCC tissues and cell lines[63]. Sp1 and Sp3, also found upregulated, would bind to the proximal promoter region and enhance the transcription of MALAT1 [64]. MALAT1 affects alternative splicing and gene expression[62,65]. MALAT1 could promote tumor growth and metastasis by upregulating latent-transforming growth factor beta-binding protein 3 (LTBP3) expression. These results suggest that MALAT1 mediates the oncogenic effect of HBx through enhancing the LTBP3 expression, which promotes early metastatic events[63]. Moreover, a higher MALAT1 expression correlates to HCC recurrence after liver transplantation[66]. Additionally, knockdown of MALAT1 has been shown to reduce cell viability, motility, and invasiveness and increase sensitivity to apoptosis in HepG2 cells[66]. Therefore, MALAT1 is also an oncogene contributing to the risk of HBV-related HCC (Table 1).

Ftx

LncRNA Ftx is transcribed within the X-inactivation center[67]. Ftx encodes four miRNA clusters in its introns, among them, miR-545/374a located in intron b of Ftx has been implicated in HBV-associated HCC[22]. Expression of miR-374a and miR-545 was significantly higher in tumor tissues of HBV-related HCC. Further investigations suggested that miR-545/374a may contribute to poor prognosis by enhancing tumor invasion. This was supported by the observation that the proliferation of malignant cells was significantly suppressed in the presence of miR-545/374a inhibitors. On the other hand, overexpression of the miRNAs resulted in increased proliferation. miR-545/374a also enhanced migration and invasion abilities of HCC cells. Moreover, clinical samples positive for HBV DNA showed an increase in miR-545/374a. The upregulation of miR545 was also found to be HBx-dependent. Three targets for miR-545/374a were identified: Estrogen-related receptor alpha, estrogen-related receptor gamma (ESRRG), and arginine and glutamate rich. Experimental evidence demonstrated that miR-545 could downregulate ESRRG expression. Additionally, miR-374a had been shown to activate Wnt signaling pathway. In conclusion, lncRNA Ftx involves HBV-related HCC by serving as miRNAs precursor (Table 1).

Microvascular invasion in HCC

Microvascular invasion in HCC (MVIH) is situated within the intron of the *ribosomal protein S24* gene. The MVIH expression was significantly upregulated in HBV-related HCC. Highly expressed MVIH was associated with frequent microvascular invasion and decreased overall survival[68]. Further investigations found that MVIH could promote tumor growth and metastasis by enhancing angiogenesis through reducing the secretion of phosphoglycerate kinase 1 suppressing angiogenesis[68] (Table 1).

Unigene56159

Unigene56159, an lncRNA of 2653 nt, is in the second intron of ROBO1. Unigene56159 was elevated in HBV-related HCC and HBV-producing cell line. Further investigations have found that Unigene56159, induced by HBV, could promote the EMT, migration, and invasion of hepatoma cells through seques-

tering miR-140-5p and up-regulating the Slug expression[69].

In addition to the abovementioned lncRNAs, the expression of LINC01232[70], SAMD12-AS1[71], lncHUR1[72], n335586[73], XIST[74], and SNHG5[75] was found to be increased in HBV-related HCC. Moreover, the expression of WEE2-AS1[76], MAFG-AS1[77], lncRNA-ATB[78], TRERNA1[79], lncRNA-IHS[80], SNHG20[81], and AX800134[82] was upregulated by HBx.

Those upregulated lncRNAs by HBV and/or HBx may be involved in HCC progress through diverse mechanisms to enhance HCC cell proliferation, invasion, and metastasis, and/or prevent the death of HCC cells (*e.g.*, apoptosis)[83] (Table 1).

DOWNREGULATED LNCRNAS IN HBV RELATED HCC

Downregulated expression by HBx

Downregulated expression by HBx (Dreh), an lncRNA of approximate 700 nt in length, is mapped to chromosome 5. The Dreh expression was downregulated by HBx in HCC cell lines. Dreh is also significantly downregulated in HBV-related HCC tissues. Suppression of DREH facilitates proliferation of hepatoma cells *in vitro* and also tumor growth *in vivo*[84]. Lower Dreh expression is associated with the recurrence-free survival and overall survival of HCC patients[84]. Playing as a tumor suppressor in the development of HBV-related HCC, Dreh suppressed cell proliferation and cell migration *in vitro* and *in vivo*. By binding to the intermediate filament protein vimentin, lncRNA Dreh inhibits its expression and alters its filament structure to repress tumor cell migration. Therefore, HBx inhibits Dreh expression and in turn facilitates HCC (Table 2).

Low expression in tumor

LncRNA-low expression in tumor (LET) is an lncRNA identified to be decreased in HBV-related HCC. LncRNA-LET and nuclear factor 90 (NF90) are associated with each other. LncRNA-LET could downregulate NF90. NF90 has been implicated in the stabilization of many factors [*e.g.*, hypoxia induced factor 1-α (HIF-1α)] related to tumor growth and metastasis[85,86]. The LET/NF90/HIF-1α axis may be critical for HCC invasion in hypoxic environments. Under hypoxia conditions, induced HDAC-3 suppressed LET expression, which increased the expression of NF90 and HIF-1α, and, hence, enhanced the invasiveness of HCC and contributed to HCC progression[85].

In addition to the abovementioned lncRNAs, the expression of uc.306[87], UPAT[88], SEMA6A-AS1 [89], BANCR[90], and miR143HG[91] was found to be decreased in HBV-related HCC. Moreover, the expression of lncRNA-6195[92], LINC01352[93], and F11-AS1[94] was suppressed by HBx. These downregulated lncRNAs by HBV and/or HBx serve as tumor repressors and suppress HCC cell proliferation (Table 2).

OTHER LNCRNAS IN HBV-RELATED HCC

H19

The *H19* gene is located adjacent to the *insulin-like growth factor 2* gene on chromosome 11p15.5. This gene produces a 2.3 kb lncRNA, which is exclusively expressed from the maternal allele. Reports of H19 expression in HCC are controversial. Recently, lncRNA H19 was found to be upregulated in CHB patients[95]. On the other hand, lncRNA H19 could suppress the growth of hepatoblastoma cells by promoting their apoptosis[96].

Most of these dysregulated lncRNAs are modulated by HBx, it would help to know whether altered versions of the preS/S envelope proteins would modulate the expression of lncRNAs or not. The progress of research on the role of lncRNAs in HBV-related HCC is impressive. However, the functions of a large proportion of lncRNAs dysregulated in HBV-related HCC remain elusive. Future investigation on the function of lncRNAs in HBV-related HCC will shed the light on understanding the detailed mechanisms regarding the development of HBV-induced HCC. Understanding more regarding the molecular mechanisms underlying lncRNA-mediated oncogenesis should help for their use in diagnosis and to identify appropriate targets for prevention and treatment of HBV-related HCC.

GENETIC POLYMORPHISMS OF LNCRNAS IN HBV REPLICATION AND ONCOGENESIS

A number of dysregulated lncRNAs have been identified in HBV replication and oncogenesis[2,37]. Genetic polymorphisms affecting the expression (changes in the enhancer/promoter region) or activity (differences in the coding region) of these lncRNAs may also affect HBV replication and oncogenesis. Association studies are used to identify genetic variations of lncRNAs involved in HBV replication and oncogenesis[2].

Table 2 Long noncoding RNAs downregulated in hepatitis B virus-related hepatocellular carcinoma

LncRNA name	Regulatory mechanism	Biological function
Dreh[84]	Inhibits the vimentin expression and alters its structure	Inhibits proliferation of HCC cells *in vitro* and tumor growth *in vivo*
LET[85]	LET/NF90/HIF1-α axis	Inhibits HCC invasion
uc.306[87]	May participate in the Wnt pathway	Not known
UPAT[88]	Promotes ZEB1 degradation	Suppresses cellular migration, invasion, and EMT processes
SEMA6A-AS1[89]	Not known	Not known
BANCR[90]	Not known	Not known
miR143HG[91]	Suppresses the MAPK and Wnt signaling pathways	Inhibits tumor multiplication and metastasis
LncRNA-6195[92]	Represses the enzymatic activity of ENO1	Represses the growth of HCC
LINC01352[93]	LINC01352/miR-135b/APC axis	Facilitates HCC progression
F11-AS1[94]	lncRNA F11-AS1/miR-211-5p/NR1l3 axis	Inhibits HCC growth and metastasis

LncRNAs: Long noncoding RNAs; HCC: Hepatocellular carcinoma; EMT: Epithelial-to-mesenchymal transition; HIF-1α: Hypoxia induced factor 1-α.

GENETIC POLYMORPHISMS IN THE ENHANCER/PROMOTER OF LNCRNAS

The intronic enhancer of HOTAIR had significantly higher HOTAIR levels in the rs920778 TT genotype than in the CC genotype. By upregulating HOTAIR, the rs920778 TT genotype promotes the development of HBVrelated HCC and increases proliferation of HCC cells[97].

LncRNA GAS5 (growth arrest special 5) has been found to be downregulated in HCC patients[98]. A five-base-pair Ins/Del polymorphism (rs145204276) in the promoter region of GAS5 could affect the GAS5 expression. The deletion allele of rs145204276 increases the risk of HBV-related HCC significantly, though the detailed mechanism is unclear[99].

The sequence of RERT-lncRNA overlaps with those of the Ras-related GTP-binding protein 4b and prolyl hydroxylase 1 (EGLN2). An Ins/Del polymorphism (rs10680577) in the distal promoter of RERT-lncRNA may alter the structure of RERT-lncRNA and regulate the expression of RERT-lncRNA and EGLN2. A 4-bp deletion allele of rs10680577 in RERT-lncRNA increases expression of RERT-lncRNA and EGLN2 and promotes the occurrence of HBV-related HCC[100].

GENETIC POLYMORPHISMS IN THE CODING REGION OF LNCRNAS

A polymorphism in the coding region of KCNQ1-overlapping transcript 1 (KCNQ1OT1), *i.e.* rs35622507, may alter the structure of KCNQ1OT1 and modulate the expression of KCNQ1OT1 and cyclin-dependent kinase inhibitor 1C (CDKN1C). The homozygous 10-10 genotype with significantly lower expression of KCNQ1OT1 and higher expression of CDKN1C was shown to increase the risk of HBV-related HCC[101].

LINC01149 variant rs2844512 was identified to facilitate HBV spontaneous recovery but increase the risk of HCC. Further studies indicated this variant created a binding site for miR-128-3p and upregulated MICA expression by serving as a miRNA sponge[102].

OTHER GENETIC POLYMORPHISMS IN LNCRNAS

The variant allele of ZNRD1-AS1 (*i.e.*, rs3757328) is reported to associate with HBV clearance[15].

The SNPs in glutamate-ammonia ligase overlapping with LINC00272 were associated with increased risk of HBV-related HCC[103].

Caspase recruitment domain family, member 8 (CARD8) can coordinate innate and adaptive immune responses and may participate in HBV-related HCC. Several SNPs (rs7248320) within a new identified lncRNA AC008392.1, which is located in the upstream region of CARD8 in the long arm of the 9-chromosome, affect the CARD8 expression and may serve as a susceptibility marker for HBV-related HCC[104].

Three regulatory SNPs (rs3757328, rs6940552 and rs9261204) in the ZNRD1-AS1 and the HBV genotype significantly affected HCC susceptibility. The results indicate that ZNRD1-AS1 accompanied by HBV genotypes may influence HCC risk[15].

Tumor necrosis factor receptor superfamily member 10 (TNFRSF10) including TNFRSF10A and TNFRSF10B is a death domain-containing receptor for the apoptotic ligand TNFSF10. In the upstream region of TNFRSF10A and downstream region of TNFRSF10B, lncRNAs RP11-1149O23.3 and RP11-459E5.1 were identified, respectively. The two lncRNAs are possibly involved in the regulation of TNFRSF10A and TNFRSF10B. Several SNPs (*i.e.*, rs79037040-T and rs2055822-A) in RP11-1149O23.3 and RP11-459E5.1 may affect the expression of TNFRSF10A and TNFRSF10B and may be susceptibility markers for HCC and chronic HBV infection[105].

Paired-box family member PAX8 encodes a transcription factor that may participate in the prognosis of HCC. Several SNPs (rs4848320 and rs1110839) within AC016683.6 lncRNA may affect the PAX8 expression and affect the prognosis of HBV-related HCC[106].

The association of lnc-RP11-150O12.3 variants (rs2275959, rs1008547, and rs11776545) with HBV-related HCC risk and progression has been reported[107].

LncRNAs HULC and MALAT1 have been upregulated in HBV-related HCC. Genetic variants of lncRNA HULC (rs7763881) and lncRNA MALAT1 (rs619586) are associated with the decreased susceptibility to HCC[108].

These studies suggest that genetic polymorphisms in lncRNAs should affect the development and outcome of HBV-related HCC. This may help to identify appropriate targets for prevention and treatment of HCC in the age of personalized medicine.

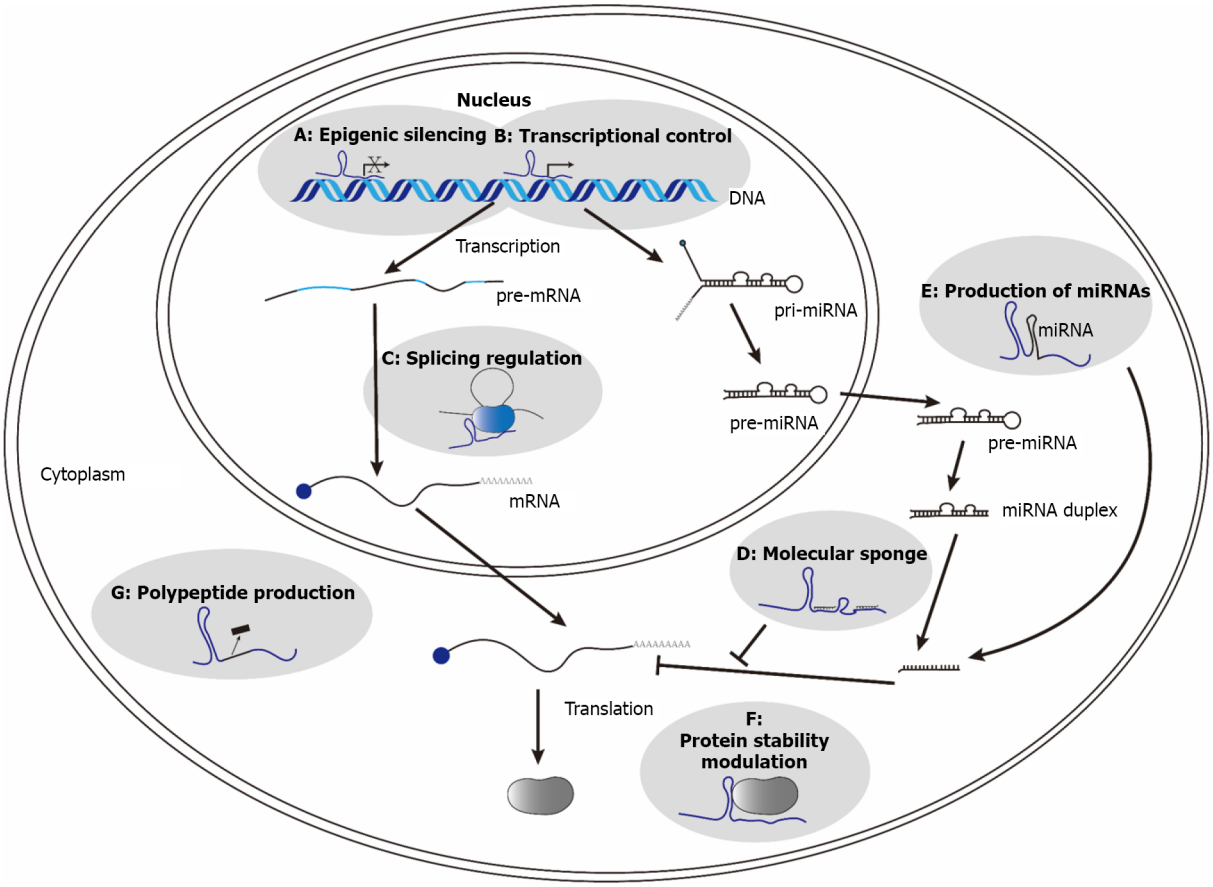
REGULATORY MECHANISMS OF LNCRNAS IN HBV REPLICATION AND ONCOGENESIS

LncRNAs can function as signals, decoys, guides, or scaffolds through interacting with their partner molecules and regulate gene expression at different levels. Up to now, at least seven mechanisms have been found to affect HBV replication and oncogenesis by dysregulated lncRNAs: Epigenetic silencing, transcriptional control, splicing regulation, molecular sponge, production of miRNAs, protein stability modulation, and production of a small polypeptide (Figure 3)[2,109,110].

Epigenetic silencing: Polycomb group (PcG) proteins are epigenetic regulators of transcription. Through multiprotein complexes PRCs, PcGs could modify histones (and other proteins) and silence target genes. LncRNAs may decrease the expression of their target genes through epigenetic silencing either by altering the expression level of PcGs or by interacting with PcGs directly and then silencing their target genes. HOTAIR enhances the degradation of suppressor of Zeste 12 homolog, a key subunit of PRC2, through Plk1[45]. Several lncRNAs interact with EZH2, a component of PRC2 to modulate (repress in most cases) the expression of their target genes, *e.g.*, HEIH[48], UCA1[53], HOTAIR[47], LINC00152[61], and PVT1[111]. ANRIL can interact with PRC2[112].

Transcriptional control: LncRNAs can activate the transcription of their target genes in cis or in trans. HOTTIP could promote the expression of its neighboring homeobox A genes (*HOAX* genes) in HCC [57]. LINC00152 binds to the promoters of epithelial cell adhesion molecule and IL-23 to activate their transcription in HCC patients[113]. MALAT1 could up-regulate the expression of LTBP3[63].

Splicing regulation: LncRNAs could affect the expression of their target genes through alternative splicing regulation. MALAT1, a nuclear lncRNA, could interact with the SR proteins (serine/arginine-rich family of nuclear phosphoproteins) and change the cellular levels of the phosphorylated forms of SR proteins to modulate alternative splicing in HCC[62].



Molecular sponge: LncRNAs could exert their effects by acting as molecular sponges for miRNAs, *i.e.*, competitive endogenous RNA (ceRNA)[114]. Through molecular sponges, lncRNAs sequester miRNAs and then de-repress the expression of the miRNA target genes. Several lncRNAs, such as Unigene56159 [69], HULC[115], HBx-LINE1[16], UCA1[55], ANRIL[60], LINC01149 variant[102], LINC01352[93], F11-AS1[94], LINC01232[70], n335586[73], XIST[74], SNHG5[75], SSTR5-AS1[116], and TRERNA1[79] are involved in the development of HBV-related HCC by sequestering miRNAs.

Production of miRNAs: LncRNAs could produce miRNAs to regulate their target genes by serving as precursors of miRNAs. The Ftx transcript encodes two clusters of miRNAs (*i.e.*, miR-374a and miR-545) in its introns in HBV-related HCC[117].

Protein stability modulation: LncRNAs could stabilize their protein targets by direct interactions. LncRNA-Dreh could bind vimentin, a type III intermediate filament, and stabilize its filament structure [84]. LncRNAs could also stabilize their protein targets by reduced degradation of these proteins indirectly. By enhancing ubiquitin-specific peptidase 22, HULC suppresses ubiquitin-mediated degradation of cyclooxygenase-2 and silent information regulator 1 in HCC[118].

Production of a small polypeptide: A putative lncRNA HBVPTPAP could encode a small polypeptide to induce the apoptosis of HCC cells[110].

Through these different mechanisms, lncRNAs can regulate gene expression. As more lncRNAs are identified, more novel mechanisms will be revealed.

Figure 3 Regulatory mechanisms of various long noncoding RNAs in hepatitis B virus replication and oncogenesis[2]. A: HOX transcript antisense RNA (HOTAIR), high expression in hepatocellular carcinoma, urothelial carcinoma associated 1 (UCA1), HOTAIR, LINC00152, PVT1, and antisense noncoding RNA in the INK4 locus (ANRIL) could regulate gene expression through epigenetic silencing; B: HOXA transcript at the distal tip, LINC00152, and metastasis associated in lung adenocarcinoma transcript 1 (MALAT1) could increase the expression of their target genes through transcriptional control; C: MALAT1 could modulate alternative splicing; D: Unigene56159, highly upregulated in liver cancer (HULC), hepatitis B virus (HBV) X protein-long interspersed nuclear elements 1, UCA1, ANRIL, LINC01149 variant, LINC01352, F11-AS1, LINC01232, n335586, XIST, SNHG5, SSTR5-AS1, and TRERNA1 regulate the gene expression through molecular sponging to sequester miRNAs; E: Long noncoding RNAs (lncRNAs) Ftx could produce miRNAs to regulate their target genes; F: LncRNA-Dreh and HULC could modulate protein stability; G: LncRNA HBVPTPAP could encode a small polypeptide to exert its function.

LNCRNAS AS POTENTIAL BIOMARKERS FOR DIAGNOSIS AND THERAPY OF HBV-RELATED HCC

It is suggested that HOTAIR may potentially be a novel HBV diagnostic biomarker based on its ability to facilitate HBV transcription and replication. This may not be practical because the commercially available diagnostic kits for HBV infection already have high specificities and sensitivities. On the other hand, the specificity and sensitivity of currently available tumor markers for HBV-related HCC (*e.g.*, α-fetoprotein) are not sufficient. This results in the poor prognosis of HBV-related HCC. This has encouraged researchers to search for novel potential biomarkers of HCC. Various miRNAs have been accepted to be biomarkers for diagnosis and therapy for HCC[119]. As an increasing number of lncRNAs, as well as the genetic polymorphisms in lncRNAs, have been found to contribute in the development of HBV-related HCC, researchers have tried to study whether these lncRNAs could be used as novel biomarkers for HBV-related HCC[120]. To be tumor markers, lncRNAs have the advantage over proteins because they can be amplified easily, *e.g.*, by RT-PCR. A number of lncRNAs dysregulated in HBV-related HCC have been suggested to be potential markers for HCCs. If these lncRNAs can be secreted to biological fluids, *e.g.*, blood, they can be easily detected. Therefore, those secreted lncRNAs are suggested to be potential markers for HBV-related HCC, such as HULC[121], IGF2AS[122], Linc00152[121], lncRNA-uc003wbd[123], lncRNA-AF085935[123], uc001ncr[124], AX800134[124], and UCA1[53-55]. However, most of these circulating lncRNAs aberrantly expressed in HBV-related HCC are also dysregulated in other tumors. It is better to identify a circulating lncRNA specific for HBV-related HCC diagnosis[125]. Alternatively, detection of several lncRNAs together could be an option[126-130].

Gene therapies such as RNA interference may become a common treatment for HCC in the future. In this way, lncRNAs can be the new therapeutic targets for HBV-related HCC. It is reported that metformin can suppress the HULC expression and block the progression of HBV-related HCC[131]. Thus, HULC could be a potential therapeutic target for RNA interference in HBV-related HCC treatment. Other lncRNAs upregulated in HBV-related HCC are also reported to be potential therapeutic targets[8] , such as MVIH[68] and HBx-LINE1[16]. On the other hand, an effective way to deliver lncRNA MEG3 RNA using MS2 virus-like-particles to inhibit HCC cells has been developed [132]. Other lncRNAs downregulated in HBV-related HCC could use a similar approach to treat HBV-related HCC, such as DREH[84] and LET[85]. Other advances in gene and epigenetic editing will enable correcting the aberrations caused by the dysregulated lncRNAs in HBV-related HCC in the future.

CONCLUSION

The important roles of lncRNAs in HBV replication and oncogenesis have started to emerge in recent years. Growing evidence indicates that some lncRNAs are dysregulated in HBV-infected cells and/or HBV-related HCC. Functional characterization of these lncRNAs has led to a more comprehensive understanding of HBV replication and oncogenesis. These lncRNAs have diverse functions, which are now beginning to be revealed. Although the progress regarding the role of lncRNAs in HBV-related HCC has been impressive, their roles in HBV replication, host immune responses, and HBV-related chronic diseases need further characterization. Even in HBV-related HCC, only a small part of lncRNAs has been well characterized, and a large portion of lncRNAs remains to be further explored. Thus, more efforts are required to understand the detailed mechanisms of these lncRNAs in the progression of HCC. The growing studies on the roles of lncRNAs in hepatocarcinogenesis could result in designing LncRNAs as potential biomarkers for diagnosis and therapy of HBV-related HCC.

Several technologies such as chromatin immunoprecipitation (ChIP), RNA sequencing, ChIP sequencing, tiled RNA expression arrays, cap analysis of gene expression, and serial analysis of gene expression have been used to detect lncRNAs. Only recently, different types of post-transcriptional chemical modifications of RNAs have been detected and characterized through sequencing-based, transcriptome-wide studies, *e.g.*, pseudouridine (Ψ), N6–methyladenosine and 5-methylcytosine. These modifications have been shown to affect the fate of RNA, including lncRNAs[133]. Further details about the roles of these chemical modifications of lncRNAs in HBV replication and oncogenesis are expected in the near future.

Abstract

Patients with inflammatory bowel disease (IBD) are more likely to have concurrent immune-mediated inflammatory diseases (IMIDs) than those without IBD. IMIDs have been observed to alter the phenotype and outcomes of IBD in recent studies. Several studies have found that IBD patients with concurrent IMIDs may have more extensive or severe disease phenotypes, and are considered to be at increased risk of requiring biologics and IBD-related surgeries, suggesting that having multiple IMIDs is a poor prognostic factor for IBD. Furthermore, IBD patients with primary sclerosing cholangitis and Takayasu arteritis are reported to have unique endoscopic phenotypes, suggesting concurrent IMIDs can influence IBD phenotype with specific intestinal inflammatory distributions. In this review, we discuss the pathogenesis, disease phenotypes, and clinical outcomes in IBD patients with concomitant IMIDs.

Key Words: Inflammatory bowel disease; Phenotypes; Outcomes; Concurrent immune-mediated inflammatory diseases

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Patients with inflammatory bowel disease (IBD) are more likely to acquire other immune-mediated inflammatory diseases (IMIDs). IBD patients with concurrent IMIDs were more likely to require biologics and IBD-related surgeries than non-IBD patients due to extensive disease phenotypes according to recent studies. As a result, when treating IBD patients, we must be aware of the concurrence of other IMIDs and understand its pathogenesis to select biologic and small molecule therapies that treat multiple concomitant diseases.

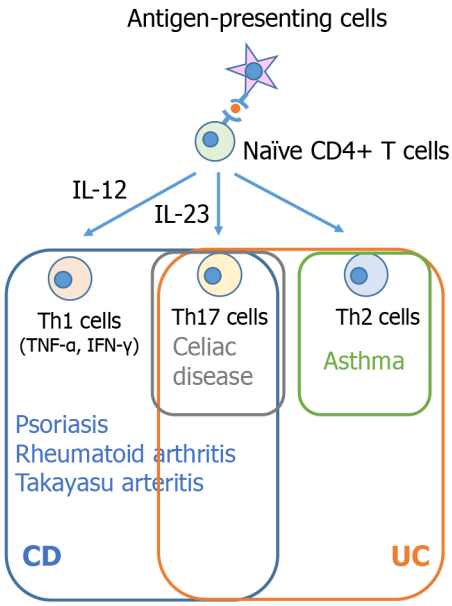
INTRODUCTION

Inflammatory bowel disease (IBD), which includes ulcerative colitis (UC) and Crohn's disease (CD), is a chronic relapsing intestinal inflammatory disorder[1]. IBD is a complex disease that is linked to both hereditary and environmental variables, although the etiology is unknown[2-4]. Previous genome-wide association studies (GWASs) identified 99 loci associated with UC and revealed a minimum of 28 shared associations between UC and CD[5]. GWASs have revealed 71 unique loci related to CD and significant genetic overlap with loci related to other immune-mediated inflammatory diseases (IMIDs)[6].



In the pathophysiology of intestinal inflammation in IBD, antigen-presenting cells (APCs) and effector T cells, such as T helper (Th) 1, Th2, and Th17 cells play a pathogenic role[4]. T-cell-mediated immune responses are triggered and modulated by APCs, such as dendritic cells and macrophages. Interleukin (IL)-12 activates Th1 cells that produce interferon-γ, tumor necrosis factor (TNF)-α, and IL-12 [7] (Figure 1). TNF-α is released from activated macrophages in response to interferon, leading to the differentiation of stromal cells into myofibroblasts and the synthesis of matrix metalloproteinases that destroy tissue[8]. While aberrant Th1 responses are thought to involve in CD intestinal inflammation, Th2 cell-mediated inflammation is suggested to be fundamental to the pathogenesis of UC[8]. Th17 cells are characterized by a distinct subset of $CD4^+$ T cells promoting the expression of IL-17 and maintained by IL-23[9,10] (Figure 1). Th17 cells and their cytokines play important roles in the inflammatory pathways of both UC and CD[11]. Innate lymphoid cells (ILCs), which do not exhibit antigen receptors to distinguish T cells from B cells, contribute to the pathogenesis in IBD as well, particularly in CD[12]. ILCs are divided into three groups based on the cytokine profiles of helper T-cell subsets, with ILC1, ILC2, and ILC3 serving as the counterparts of Th1, Th2, and Th17 cells, respectively[12].

Given that IBD patients are more likely to have additional IMIDs than nonIBD patients in various studies[13-15], multiple immune pathways may be shared between IBD and other IMIDs. Among recent cross-sectional research of members of a Northern California managed care organization, 17% of IBD patients had at least one IMID diagnosis, whereas the proportion of concurrent IMIDs was 10% in nonIBD individuals[13]. While another study found no significant differences in CD phenotype between individuals with and without IMID, UC patients with another IMID were more likely to have a pancolitis phenotype than those who did not. Furthermore, IBD patients with another IMID had a higher percentage of patients who needed TNF inhibitors or surgery than those without[14]. Of note, previous research found that IBD patients with primary sclerosing cholangitis (PSC) or Takayasu arteritis (TAK) have distinct endoscopic IBD phenotypes[16,17]. IBD can affect the phenotypes and disease courses of concurrent IMIDs as well, according to a recent meta-analysis[18]. All these studies reveal that the presence of other IMIDs in IBD patients can influence disease phenotypes and outcomes and vice versa.

We evaluate the pathogenesis, disease phenotypes, and clinical outcomes in IBD patients with concurrent IMIDs in this review, which includes IMIDs with a high prevalence among patients with IBD and IMIDs that alter IBD phenotypes and outcomes.

IMIDS WITH HIGH PREVALENCE AMONG IBD

Asthma, psoriasis, and rheumatoid arthritis (RA) were the most common IMIDs among IBD patients, according to the data from Northern California managed care organizations[13]. Another study based on prospective registry data found that 21% of IBD patients also had another IMID. Asthma (9.9%), psoriasis (6.1%), and RA (2.0%) were consistently reported to coexist with IBD[14].

Figure 1 The potential common immunological mechanisms shared between inflammatory bowel diseases and other immune-mediated inflammatory diseases. IFN-γ: Interferon-γ; TNF-α: Tumor necrosis factor-α; IL: Interleukin; Th17 cells: IL-17 producing T helper cells; Th1 cells: T helper 1 cells; Th2 cells: T helper 2 cells; CD: Crohn's disease; UC: Ulcerative colitis.

Asthma and IBD

Asthma is a prevalent chronic airway disease characterized by respiratory symptoms such as coughing and shortness of breath[19]. Asthma is a Th2 cell-mediated disease. Dendritic cells capture inhaled allergens and present them to naïve $CD4^+$ T cells, resulting in the polarization of Th2 cells. These cells produce IL-4, IL-5, and IL-13, promoting eosinophil migration to the airway, bronchial hyperresponsiveness, mucus overproduction, and immunoglobulin E synthesis[19]. ILC2 also plays a role in the pathogenesis of asthma. ILC2 is activated by IL-25 and IL-33 and can produce Th2 cell-associated cytokines, causing airway hypersensitivity and tissue remodeling[19]. Th2 cell-mediated inflammatory pathways are also implicated in IBD patients, particularly UC patients (Figure 1 and Table 1). Macrophages or dendritic cells acquire luminal antigens in the intestine and present them to naïve $CD4^+$ T cells, boosting their differentiation into Th2 cells in the immunological pathways involved in UC[20]. Given the high transcript levels of IL-17A that are detected in both of CD and UC, Th17 cells are also linked to the development of UC[11]. Although ILC1 and ILC3 are considered to be involved in the pathogenesis of CD, it is unclear if ILC2 contributes to the development of UC[12,21].

Psoriasis and IBD

Psoriasis is an immune-mediated skin disorder that affects the skin and/or joints[22] resulting in pruritic and painful skin plaques. Psoriasis is caused by the activation of plasmacytoid dendritic cells, which release various proinflammatory cytokines including TNF, interferon-γ, IL-12, and IL-23. IL-12 aids in the development of Th1 cells from naïve T cells, while IL-23 aids in the maintenance of IL-17-producing Th17 cells. Th17 cells generate IL-17A, IL-17F, and IL-22, while activated Th1 cells release interferon-γ and TNF-α, causing keratinocyte hyperproliferation and other psoriasis clinical features [23]. Similarly, Th1 and Th17 cells are involved in the major immunological mechanism of IBD, particularly CD[24]. ILC3, the counterpart of Th17 cells, is an important source of IL-17 in both psoriasis and CD[21]. Indeed, a systematic review and meta-analysis found that psoriasis patients had an increased risk of IBD, particularly CD[25]. A multicenter retrospective study found that 61% of IBD patients who started ustekinumab, an antagonist of the p40 subunit of IL-12 and IL-23, for concomitant active psoriasis achieved clinical remission of IBD[26]. Although TNF inhibitors are effective in the treatment of both psoriasis and IBD, they can also cause psoriasis[27]. TNF-α inhibition is speculated to cause uncontrolled production of interferon-γ by plasmacytoid dendritic cells, resulting in the recruitment of Th1 or Th17 cells into the dermis, which produces proinflammatory cytokines, such as IL-12 and IL-23 [28]. Thus, these data support the notion that the immune mechanism involving Th1 cells, Th17 cells, and ILC3 may be the common pathway between psoriasis and IBD (Figure 1 and Table 1).

RA and IBD

RA is a chronic inflammatory disease that affects the cartilage and bone[29] resulting in painful and disfiguring joint deformities. Dendritic cells or macrophages uptake antigens and present them to T cells in the pathogenesis of RA, resulting in Th1 or Th17 cell-mediated diseases in the synovial tissue.

Table 1 Characteristic and clinical outcomes in inflammatory bowel disease patients with concurrent immune-mediated inflammatory diseases

IMIDs with high prevalence among patients with IBD	Possible shared immune cells contributing to pathogenesis	IBD phenotypes	IBD outcomes	Possible shared therapies
Asthma	Th2 cells	Indefinite	Indefinite	Indefinite
Psoriasis	Th1 cells, Th17 cells, and ILC3	Indefinite	Indefinite	Ustekinumab; TNF inhibitors
Rheumatoid arthritis	Th1 cells, Th17 cells, ILC1, and ILC3	Indefinite	Indefinite	Tofacitinib; TNF inhibitors
IMIDs affecting phenotypes or outcomes of IBD				
PSC	Indefinite (leaky gut theory)	Severe right-sided colitis, rectal sparing, and backwash ileitis	PSC-IBD patients have fewer or no symptoms, and are less likely to require immunosuppressants, hospitalization, and surgery than IBD patients alone	Indefinite
Celiac disease	Th17 cells	CD patients with celiac disease are less likely to have ileocolonic involvement than CD patients alone	CD patients with celiac disease are less likely to require TNF inhibitors or azathioprine than CD patients alone. UC patients with celiac disease have an increased risk of colectomy	Indefinite
Takayasu arteritis	Th1 cells and Th17 cells	Discontinuous aphthous erosions/ulcers or focal mucosal inflammation	Indefinite	Tofacitinib; Ustekinumab; TNF inhibitors

IBD: Inflammatory bowel disease; PSC: Primary sclerosing cholangitis; IMIDs: Immune-mediated inflammatory diseases; TNF: Tumor necrosis factor; Th17 cells: Interleukin-17 producing T helper cells; Th1 cells: T helper 1 cells; Th2 cells: T helper 2 cells; CD: Crohn's disease; UC: Ulcerative colitis; ILC: Innate lymphoid cell.

Subsequently, the stimulated T cells activate macrophages, B cells, fibroblasts, and osteoclasts. TNF, IL-1, and IL-6 are secreted by the activated macrophages. Inflammatory mediators including matrix metalloproteinases are then produced by fibroblast-like synoviocytes, resulting in cartilage destruction. The activation of osteoclasts induces bone erosions as well[30]. A lymph node activation in RA patients is associated with an imbalance of ILCs, and ILC1 and ILC3 within the lymph node microenvironment can cause inflammation[21]. As a result, RA may have similar immune mechanisms with a CD rather than UC (Figure 1 and Table 1).

Ustekinumab was found to be ineffective in clinical trials of RA patients, whereas TNF, IL-6, and Janus kinase (JAK) inhibitors such as tofacitinib significantly improved RA disease activity when compared to placebo[31]. As a result, among medications approved for RA and IBD, TNF and JAK inhibitors may be effective for both IMIDs. Given that JAKs bind to cytokine receptors and transmit various extracellular cytokine signals such as IL-6, IL-12, IL-23, and interferons, JAK inhibitors are therefore expected to be effective for various IMIDs[28,32] (Table 1).

IMIDS AFFECTING IBD PHENOTYPES AND OUTCOMES

Several recent population-based studies and meta-analyses have shown that the presence of IMIDs may influence the disease course of IBD. According to a nationwide study of the Danish population, 22.5% of IBD patients had at least one concurrent IMID. This study found that risk factors such as older age and methotrexate use were associated with an increased risk of concurrent IMIDs, whereas male gender, a high socioeconomic status, and infliximab use were associated with a reduced risk of concurrent IMIDs. The impact of at least one concurrent IMID on the disease course of IBD was also investigated in this study. The occurrence of IMIDs increased the risk of surgery in CD patients but not in UC patients in the subgroup who developed IMIDs after the onset of IBD. Both UC and CD patients who had concurrent IMIDs were more likely to require biologics than those who did not[33]. IBD patients with concurrent IMIDs had an increased risk of extensive colitis/pancolitis and IBD-related surgeries compared with those without IMIDs, according to a recent systematic review and meta-analysis involving 16064 IBD patients with concurrent IMIDs and 3451414 IBD patients without IMIDs. Furthermore, those with concurrent IMIDs were at an increased risk of requiring immunomodulators and biologics[34]. Overall, these findings suggest that the coexistence of IMIDs is associated with severe IBD phenotypes.

Another recent systematic review and meta-analysis found that CD patients with concurrent IMIDs were more likely to have upper gastrointestinal involvement and nonstricturing and nonpenetrating phenotypes than those without IMIDs. Given that this meta-analysis suggests that CD patients with concurrent IMIDs may have a milder disease course, which contradicts the findings of the previous meta-analysis, more research is needed to better understand CD patients' behaviors if they develop other IMIDs and require medication[35].

While it is unclear how different IMIDs affect IBD phenotypes and outcomes, previous research has consistently suggested that IMIDs such as PSC or TAK can influence the endoscopic findings of IBD to specific phenotypes[16,17,36,37]. On the other hand, recent studies have shown that there is an association between celiac disease and IBD and that IBD patients with celiac disease can have distinct phenotypic characteristics and outcomes[38,39].

PSC and IBD

PSC is a chronic and progressive cholestatic disease that affects the intrahepatic and extrahepatic bile ducts[40]. PSC was found to be present in 2.2% of IBD patients. In one study, PSC was found to be present in 2.5% of UC patients and 0.96% of CD patients, respectively[41]. Patients with "extensive UC" had a higher prevalence of PSC than those with left-sided colitis. PSC was more common in CD patients with ileocolonic or colonic involvement than in those with ileal involvement[35,41]. PSC-IBD patients have a predilection for more severe right-sided colitis according to several studies[42,43]. Furthermore, patients with IBD who have PSC frequently develop a distinct IBD phenotype characterized by "rectal sparing" and "backwash ileitis"[16]. According to a systematic review of 11406 PSC-IBD patients, the pooled rate of rectal sparing and backwash ileitis was 9.9% and 12.3%, respectively[36]. Based on this systematic review, a meta-analysis found that the pooled event rate of pancolitis and rectal sparing was significantly higher in PSC-IBD patients than in IBD patients without PSC, but the rate of backwash ileitis was not statistically significant between the two groups[43].

Although PSC-IBD patients frequently develop pancolonic involvement with significant right-sided colitis, several studies have shown that their disease course was mild[43]. Previous studies found that PSC-IBD patients had fewer or no symptoms[44] and were less likely to require immunosuppressants such as steroids, thiopurines, hospitalization[45], and surgery than IBD patients without PSC[46]. In addition, patients with PSC-CD had a higher risk of nonstricturing and nonpenetrating behavior than those without PSC, as well as being less likely to undergo CD-related surgeries, according to a recent meta-analysis[35]. All of these findings suggest that PSC-IBD patients may have better IBD outcomes, suggesting that PSC-IBD is a distinct disease phenotype from IBD phenotypes in patients with other IMIDs (Table 1).

The cause of the disparity between endoscopic disease activity and clinical outcomes in patients with PSC-IBD is unknown. In a retrospective study, immunosuppressant use and colonic or ileal surgical resection were found to be less common in PSC-IBD patients than in IBD patients without PSC. However, this study discovered that a higher percentage of PSC-IBD patients used 5-aminosalicylates, suggesting that PSC-IBD patients are more likely to use 5-aminosalicylates to lower their risk of colorectal cancer or dysplasia and that their use can be associated with mild disease activity[46-48]. Meanwhile, a case-controlled study found that PSC-UC patients had a milder disease course than those with UC alone, even though the number of patients taking 5-aminosalicylates or sulfasalazine was the same[49]. Hence, more research is needed to understand if differences in the pathogenesis or medical therapies between PSC-IBD patients and patients with IBD alone can explain the unique disease phenotype of PSC-IBD.

Many studies have been carried out to better understand the mechanisms of PSC-IBD, and it has been discovered that there is less genetic overlap between PSC and IBD[50]. Thus, environmental factors such as the gut microbiome have been highlighted. According to the "leaky gut" theory, IBD-related mucosal injury allows the colonic bacteria to cross the gut barrier and into the liver, resulting in the development of PSC[43]. Although the exact mechanism is unknown, PSC-IBD patients were more likely to develop colorectal cancer than IBD patients without PSC[43], so UC guidelines recommend colorectal cancer screening at the time of PSC diagnosis[51].

Celiac disease and IBD

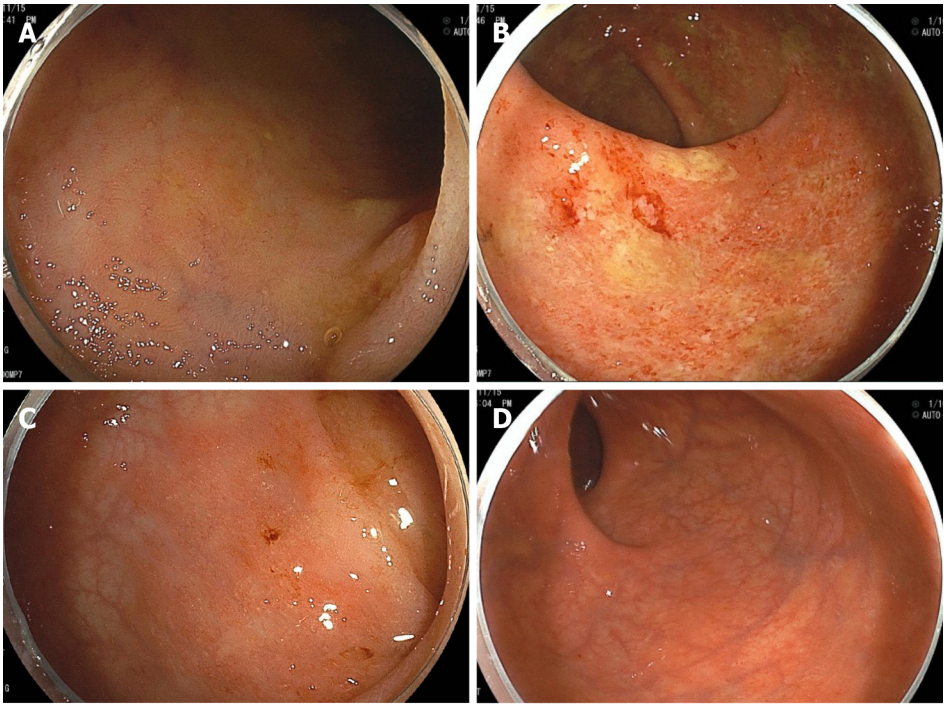
Celiac disease is a gluten-induced disease that frequently coexists in patients with IMIDs[52]. Patients with IBD have a higher risk of celiac disease compared to controls according to a systematic review and meta-analysis (risk ratio 3.96; 95% confidence interval: 2.23-7.02). Patients with celiac disease have a significantly increased risk of IBD compared to controls (risk ratio 9.88; 95% confidence interval: 4.03-24.2), suggesting the shared pathogenesis between both diseases[38]. A case–control study based on a national registry of pediatric IBD patients found that CD patients with celiac disease were less likely to have ileocolonic involvement and require medical therapies such as TNF inhibitors or azathioprine than CD patients alone. While disease distribution and medical treatments were not significantly different between UC patients with and without celiac disease, UC patients with celiac disease had a higher risk of colectomy[39], suggesting that CD patients with celiac disease may have better outcomes, whereas the concurrence of celiac disease can potentially worsen UC outcomes (Table 1).

Some genetic, environmental, and immunological factors are shared by celiac disease and IBD. GWASs revealed that celiac disease and CD share genetic risk loci including PTPN2, IL18RAP, TAGAP, and PUS10[53]. Both diseases have been linked to microbial factors[54,55]. Celiac disease is a $CD4^+$ T-cell-dependent disease associated with chronic intestinal inflammation, according to the immunological mechanism[56]. APCs present gliadin peptide to $CD4^+$ T cells, which then produce proinflammatory cytokines such as interferon-γ and IL-21, increasing intraepithelial lymphocytes (IELs)[56]. The IELs such as $CD8^+$ T cells carrying αβ T-cell receptor (TCR) or $CD4^-CD8^-$ γδ TCR^+ T cells cause cytolysis or apoptosis in intestinal epithelial cells[57,58]. Patients with celiac disease have mucosal Th17 cells, and an increased level of IL-17A expression is associated with villous atrophy, a hallmark pathologic feature of celiac disease[59,60]. Th17 cells produce IL-17, interferon-γ, and IL-21, which play a role in celiac disease pathogenesis[61]. In terms of ILCs, it remains unclear how these cells are associated with the disease initiation and progression[62]. These findings support that Th17 cells may be involved in both IBD and celiac disease (Figure 1 and Table 1).

TAK and IBD

TAK is a type of chronic large-vessel vasculitis that primarily affects the aorta, and its major branches, as well as pulmonary arteries[63]. The prevalence of UC and CD among TAK patients was reported to be 6.4% (30/470) and 9.0% (4/44), respectively[64,65]. Endoscopic features of IBD in TAK patients were found to be atypical for UC or CD in a previous retrospective study[17]. This study, which included 142 Japanese TAK patients, identified 13 TAK-IBD patients (9.2%), and their endoscopic findings at the initial time of IBD diagnosis were assessed. As a result, 7/8 (87.5%) of TAK patients had "discontinuous aphthous erosions/ulcers or focal mucosal inflammation" with only one patient having continuous inflammation typical of UC[17], suggesting that TAK-IBD patients have a distinct endoscopic IBD phenotype. This study also discovered that patients with TAK-IBD were more likely to have the HLA haplotype, which has a susceptible effect on UC, when compared with TAK patients without IBD, implying that TAK-IBD may have a similar immune mechanism to UC. A recent case study describing the evolution of colonic inflammation in a TAK-IBD patient during 10-year observation found that colonic inflammation was initially discontinuous and more severe in the proximal colon than in the remaining colon[37], supporting the presence of a distinct IBD phenotype in TAK-IBD patients (Table 1).

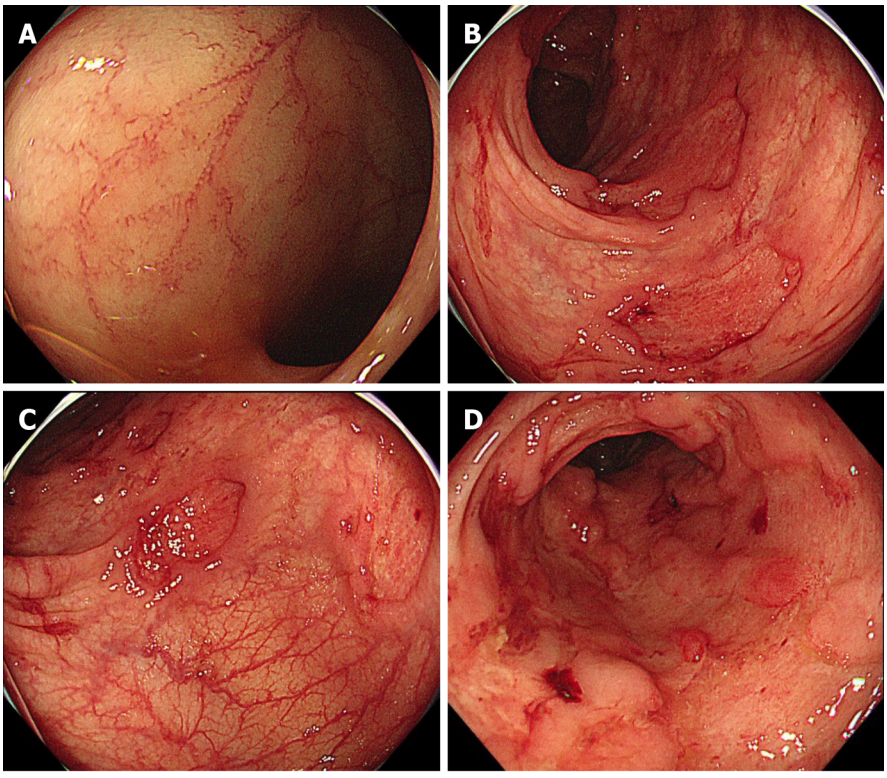
Th1 and Th17 cells are predominant in the pathophysiology of TAK just as they are in the pathogenesis of CD[66] (Figure 1 and Table 1). TAK patients' aorta expresses higher levels of IL-6, IL-12, IL-17, and interferon-γ[67], and a single nucleotide polymorphism encoding a common component of IL-12 and IL-23 is associated with the development of TAK[64]. In a previous study, ustekinumab was shown to reduce inflammatory markers and the dose of steroid needed in the treatment of TAK patients [68]. Many case studies have described TAK-IBD patients' therapeutic approaches to date. Tofacitinib, a JAK inhibitor that was recently approved for UC[69], was found to be effective for both inflammatory conditions[70,71], implying that it can inhibit multiple inflammatory signals involved in TAK and IBD, suggesting that JAK pathways could be a promising therapeutic target. To better understand the prognosis of IBD in such patients with TAK, further studies are needed.



Figures 2 and 3 show representative endoscopic findings of PSC-IBD and TAK-IBD, respectively.

CONCLUSION

Recent research has revealed that IBD and other IMIDs share overlapping genetic and immunological etiologies. Indeed, IBD patients frequently develop concurrent IMIDs, and these patients have a higher risk of severe IBD phenotypes, implying that the presence of IMIDs is a poor prognostic factor for IBD. As a result, when treating IBD patients, we should be aware of the presence of other IMIDs, as biologics and small molecule therapies may be able to treat multiple disease states simultaneously. Multidisciplinary care with rheumatologists or dermatologists is also important when deciding the therapeutic strategy for IBD patients with concurrent IMIDs.



Furthermore, patients with IMIDs such as PSC or TAK can have distinct endoscopic phenotypes of IBD, suggesting that the immune mechanisms of these IMIDs may affect how intestinal inflammation is distributed. Even though IBD patients with concurrent IMIDs are more likely to require biologics or surgery, the disease course of PSC-IBD patients is not often associated with poor IBD outcomes, although these patients are more likely to develop pancolonic inflammation. Further research involving various concurrent IMIDs is needed in light of these findings to better understand how each IMID and its medication may affect the phenotype and natural history of IBD.

In the future, clinicians and researchers will face a challenge in identifying therapeutic targets to improve patient outcomes. Previous studies have shown that Th1 and Th17 cells (rather than Th2 cells) are more likely to be involved in the concurrence of other IMIDs in IBD patients, implying that these effector T cells and their cytokines could be promising therapeutic targets. Future research is needed to gain further insights into the shared immune mechanisms involved in the pathophysiology of IBD and other IMIDs to develop appropriate therapeutic targets to treat both diseases.

Abstract

Hepatocellular carcinoma (HCC) represents the primary carcinoma of the liver and the fourth leading cause of cancer-related deaths. The World Health Organization estimates an increase in cases in the coming years. The risk factors of HCC are multiple, and the incidence in different countries is closely related to the different risk factors to which the population is exposed. The molecular mechanisms that drive HCC tumorigenesis are extremely complex, but understanding this multistep process is essential for the identification of diagnostic, prognostic, and therapeutic markers. The development of multigenic next-generation sequencing panels through the parallel analysis of multiple markers can provide a landscape of the genomic status of the tumor. Considering the literature and our preliminary data based on 36 HCCs, the most frequently altered genes in HCCs are *TERT*, *CTNNB1*, and *TP53*. Over the years, many groups have attempted to classify HCCs on a molecular basis, but a univocal classification has never been achieved. Nevertheless, statistically significant correlations have been found in HCCs between the molecular signature and morphologic features, and this leads us to think that it would be desirable to integrate the approach between anatomic pathology and molecular laboratories.

Key Words: Hepatocarcinoma; Mutation; Next-generation sequencing; Review; *TP53*; *CTNNB1*; *TERT*

Core Tip: The molecular mechanisms that drive hepatocellular carcinoma tumorigenesis are extremely complex, and a univocal classification based on molecular features has not been defined. In the age of precision medicine, the study of hepatocellular carcinoma mutations is still a field worth investigating. Based on this, we wanted to analyze the possible correlations between molecular alterations and pathological features. Considering both the literature data and our personal experience, about 80% of hepatocellular carcinomas harbor mutations in at least one of the following genes, *TERT*, *TP53*, or *CTNNB1*, with different biological and clinical implications.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the world-leading cancers, representing approximately 80% of the primary carcinomas of the liver[1] and the fourth most common cause of cancer-related deaths. The World Health Organization (WHO) estimated more than 905500 new HCC cases in 2020 worldwide [2], and based on its projection an increase of 58% is evaluated by 2040 with a total of 1400000 new cases and 1000000 deaths in 2030[2].

The etiological factors for HCC development are: (1) Infections, including hepatitis B virus (HBV) and hepatitis C virus (HCV), with or without coinfection of hepatitis delta virus; (2) Lifestyle risk factors and behaviors, such as alcohol addiction and smoking; (3) Environment, such as dietary toxins (*e.g.*, aflatoxins, or aristolochic acid); (4) Underlying diseases, such as obesity, type 2 diabetes, nonalcoholic liver steatohepatitis/nonalcoholic fatty liver disease; and (5) Genetics, some single nucleotide polymorphisms are identified to be associated with HCC risk at different stages, from predisposition to risk factors to the severity of the chronic liver disease and its evolution to cirrhosis or to the malignant transformation and tumor progression[3,4]. For example, a single nucleotide polymorphism correlated with higher infection risk (MDM2 Promoter SNP309, MDM2 G-309T, rs2279744) has been associated with HCC patients with chronic hepatitis C[5].

The incidence of HCC in different countries varies considering the different risk factors mentioned above. In Eastern Asian countries and most African countries, the incidence of HCC is mostly due to aflatoxin exposure and HBV infection, except for Northern Africa where HCV infection is prevalent[6, 7]. In traditional Chinese herbal medicines, practiced particularly in China, Vietnam, and Southeast Asia, plants containing aristolochic acid are commonly used. In this area, next-generation sequencing studies underlined that a fraction of HCCs harbored high rates of mutations matching a distinctive mutational signature of aristolochic acid exposure[8-10]. Moving to Western countries, the incidence of HCC is usually associated with HCV infection, dietary habits, and related metabolic diseases, such as nonalcoholic liver steatohepatitis and nonalcoholic fatty liver disease. In this area, the low incidence of HCC due to HBV/HCV infections can be explained considering the use of the vaccine for HBV and anti-viral treatments against HCV in contrast with the increased incidence of metabolic syndrome[11].

All the aforementioned risk factors lead to liver disease (cirrhosis or chronic inflammation) that causes an accumulation of genomic alterations driving HCC. In general, HCC arises during the progression of pre-existing chronic hepatitis, and in the vast majority (80%) of patients, HCC occurs in the setting of cirrhosis[12]. The development of HCC is a process characterized by a specific sequence of lesions, from regenerative nodules in cirrhosis, low-grade dysplastic nodules and high-grade dysplastic nodules to early and progressed HCC[13,14].

The molecular mechanisms driving HCC tumorigenesis are extremely complex. Understanding this multistep process, with underlying genetic alteration, is essential for prevention, diagnostic, prognostic, and therapeutic purposes. Considering the future perspective, a better knowledge of molecular mechanisms involved in HCC tumorigenesis would help for a correct classification of HCC, for improving patient outcomes, and to develop new therapeutic targets. The advent of NGS technologies may help in the comprehensive study of genetic alteration and the different pathways involved in the initiation and progression of HCC. In fact, the development of NGS multi-gene panels allows the parallel analysis of multiple markers giving a broad view of the genomic situation[15,16]. To date, this

molecular landscape is crucial for therapeutic decision-making in other solid tumors[15]. The Cancer Genome Atlas Research Network investigated a total of 559 cases of HCC[17]. This study found that *TERT, TP53*, and *CTNNB1* are the most frequently altered genes in HCCs; 77% of HCCs showed a mutation in at least one of these three genes[17]. Correlation data between HCC molecular signatures and etiological agents are shown in Table 1.

Bearing in mind all this evidence, the present review will discuss the main molecular mutations in HCC, with particular emphasis on the influence that these alterations have on HCC morphology and biological aggressiveness.

MOLECULAR ALTERATIONS IN HCC

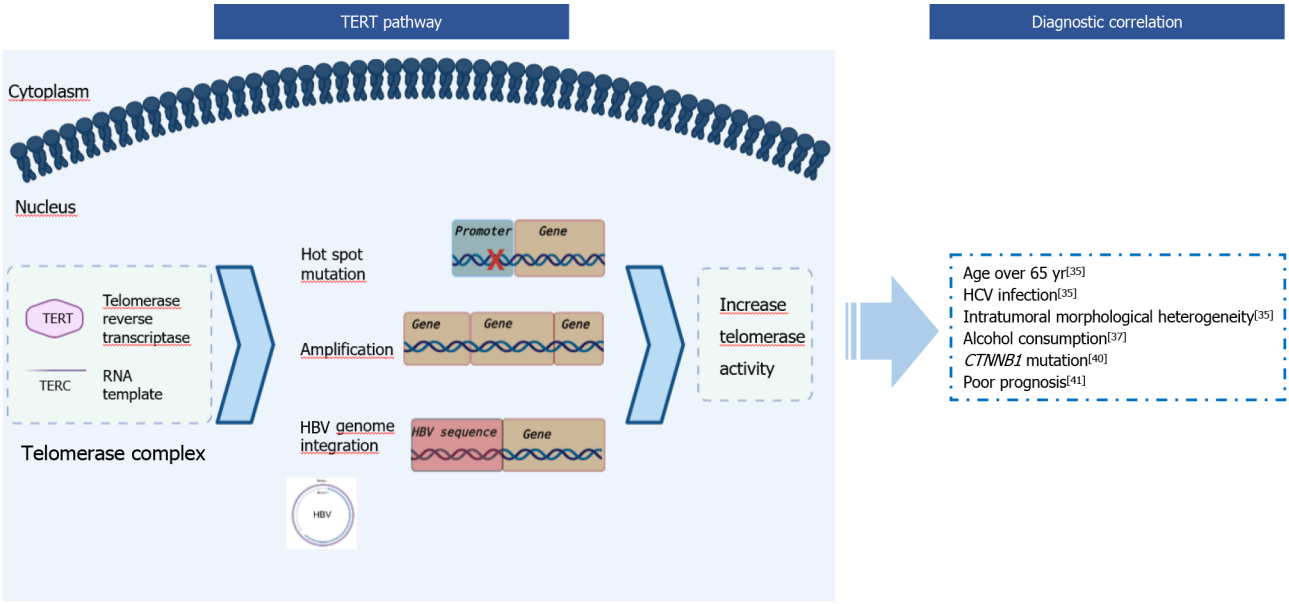
TERT

During cycles of genomic replication, the linear organization of chromosomes brings with it the problem of erosion of the 5'-terminus due to non-reproduction of the RNA primer binding site. Indeed, this erosion does not happen thanks to telomerase, constituted by telomerase reverse transcriptase (encoded by the *TERT* gene) and RNA template (encoded by the *TERC* gene). The telomerase complex adds nucleotides onto telomeres, preventing them from shortening. Telomeres are short tandem repeats of DNA (TTAGGG) coated by a protein complex known as Shelterin to protect the end of the chromosome where telomeres are located. Telomere synthesis is a controlled process activated in stem cells but deactivated in most somatic cells due to epigenetic silencing during the differentiation process. In the mature hepatocytes, the telomerase is not expressed[18,19]. The shortening of the telomeres exposes chromosomes to damage resulting in cellular senescence and is thought to be responsible for a sequence of events that drive to cancer[20].

Reactivation of *TERT* expression has been observed in several cancers (*e.g.*, melanomas, gliomas, poorly differentiated bladder cancer, anaplastic thyroid carcinomas, basal cell, squamous cell carcinomas) leading to a restoration of the telomerase activity[19] (Figure 1). This event avoids cellular senescence and leads cancer cells to acquire replicative immortality, a crucial feature in the progression of the neoplasm rather than in the transformation of the cells into malignant ones[21-24]. This upregulation of *TERT* in cancer can occur through several mechanisms, which are generally mutually exclusive: (1) Gene amplification, found in ovarian cancer, adrenocortical carcinoma, lung adenocarcinoma, and esophageal carcinoma[25]; (2) Gene rearrangements, found in high-risk neuroblastoma[26]; and (3) Gene mutations in hot-spot regions of the promoter region, found in melanomas, thyroid tumors, gliomas[19].

Alterations in the gene promoter region are the most common and most frequently detected, in particular C>T transition at chr5:1295228 (−124 or C228T) or chr5:1295250 (−146 or C250T). The C228T and C250T TERT mutations separately create an identical 11-base sequence that acts as a novel E-twenty-sis transcription factor binding site, causing *TERT* overexpression[21].

***TERT* and HCC:** Telomere length and telomere expression play a key role in the pathogenesis of HCC. Several studies have found telomere shortening in cirrhotic tissue, independently of the etiology of the liver disease (*e.g.*, alcohol abuse or viral hepatitis), suggesting that this event might represent a hallmark of liver senescence and chronic hepatitis[27-29]. In contrast to cirrhotic tissue, in 44%-59% of the HCC a reactivation of the *TERT* gene is observed[30]. Cellular senescence found in cirrhotic tissue followed by *TERT* reactivation is one of the mechanisms that may explain the development and progression of HCC in cirrhosis. In particular, with the accumulation of gene alterations senescence can induce neoplastic transformation, whereas subsequent telomerase activation can lead to a neoplastic progression (Figure 1).



Reactivation of TERT can also be caused by HBV infection (Figure 1). HBV is an enveloped virus with partially double-stranded DNA with the capacity to integrate its own genome into that of the host, leading to the deregulation of the gene involved. *TERT* promoter is the most frequent site of integration (38.5%) in HBV-related cancers, and the viral integration leads to *TERT* overexpression[31,32]. Intriguingly, *TERT* mutations have never been described in hepatocellular adenoma (HCA) in contrast to *CTNNB1* (see "*CTNNB1* and HCC" paragraph)[13,32-34].

TERT mutations in HCC have been statistically correlated with: (1) Age over 65 years (P = 0.018), HCV infection more than HBV (P = 0.048), and intratumoral morphological heterogeneity (P = 0.0001) [35,36]. In a study performed on 97 HCCs by Kwa *et al*[35], the histological patterns in the tumor areas were classified into four groups: early, well, moderate, and poor. In particular, regarding the morphological aspect in *TERT* mutated HCC they observed two or more histological patterns as opposed to *TERT* wild-type HCCs, which showed only a single dominant pattern[35]; (2) Alcohol consumption[32, 37]. Schulze *et al*[32] performed a study on 243 surgically resected HCCs, and 60% of the alcohol-related HCCs had a mutation in the *TERT* gene promoter; (3) *CTNNB1* mutations. Several studies have shown the association between *CTNNB1* and *TERT*[38-40]. This correlation was demonstrated for the first time in a mice model in which it was observed that β-catenin binds the *TERT* promoter and participates in the control of its expression[40]; and (4) Poor prognosis, (P = 0.041). A study by Oh *et al*[41] on telomere length in HCC showed that telomere elongation was a poor prognostic factor, as it decreased overall

Table 1 Recurrent gene mutations in hepatocellular carcinoma related to risk factors

Frequency mutation		Etiological factor		
		HBV	HCV	Non-viral
Driver gene	*TERT*	50%	61%	65%
	CTNNB1	15%	30%	39%
	TP53	10%-65 %	24%	16%

survival (P = 0.044). Moreover, in the case of high telomerase activity the prognosis was unfavorable (P = 0.009)[41] (Figure 1).

CTNNB1

The *CTNNB1* gene encodes β-catenin, a protein that performs several cellular functions. When interacting with the cadherin protein complex, β-catenin is important for the stabilization of the cytoskeleton and intracellular adhesions, but it also plays a role as a transcription factor in the canonical Wnt/β-catenin pathway. This pathway is involved in embryonic development, cellular homeostasis, and several diseases[42]. The cytoplasmic concentration of β-catenin is tightly controlled through its ubiquitination and proteasomal degradation. The phosphorylation required for this degradation mechanism is performed by glycogen synthase kinase 3 alpha and beta through the action of axin and the protein adenomatous polyposis coli (APC)[43,44]. In the cytoplasmic membrane, there are receptors for the Wnt molecules, called frizzled. The ligand-receptor complex triggers a cascade of cytoplasmic reactions, leading to the activation of the disheveled protein. This protein binds axin, preventing the bond between axin and glycogen synthase kinase 3[45]. This mechanism inhibits the proteasomal degradation of β-catenin. Given that *CTNNB1* continues to be transcribed, the β-catenin cytoplasmic concentration increases.

Once all the β-catenin cytoplasmic binding sites are saturated, β-catenin protein is translocated into the nucleus. Here β-catenin interacts with many transcriptional factors, in particular with T-cell factor/lymphoid enhancing factor to promote the transcription of target genes, such as *c-Myc*, *CyclinD-1*, and *Jun* (Figure 2). Most of these gene targets encode for oncoproteins, leading to the activation of oncogenic mechanisms (*e.g.*, uncontrolled growth or escape from apoptosis)[46]. For this reason, β-catenin is a molecule that may be involved in carcinogenesis and tumor progression of several cancers: HCC, lung cancer, brain and cerebellum cancer, breast cancer, colon cancer, leukemia, and others[47-49].

Figure 2 Main cellular pathways and clinical implications of *CTNNB1* mutations in hepatocellular carcinoma. Created with BioRender.com. APC: Adenomatous polyposis coli; DSH: Disheveled; GSK: Glycogen synthase kinase; HCV: Hepatitis C virus; LEF: Lymphoid enhancing factor; TCF: T-cell factor.

The Wnt pathway can also be activated by transforming growth factor-β. Dysregulation of its signaling pathway is associated with an invasive phenotype and plays a central role in inflammation, fibrogenesis, and immunomodulation in the HCC microenvironment[50,51].

Activating mutations found in the *CTNNB1* gene are generally substitutions or in-frame deletions in hotspot regions that encode for the part of the protein that acts as a domain for the *APC/AXIN1/* glycogen synthase kinase 3B complex. Thus, β-catenin is not degraded by the proteosome and then uncontrollably activates the transcription of oncogenes[52].

CTNNB1 and HCC: In HCCs, *CTNNB1* mutations are among the most encountered genetic alterations, with a frequency of 20%-40%[32]. Regarding therapy, *CTNNB1* mutations induce resistance to immune checkpoint inhibitors (anti-PD-1/PD-L1 inhibitors and anti-CTLA4)[53]. Another important aspect concerns HCA. According to the literature, 5%-10% of HCA are subject to malignant transformation, but the most recent WHO guidelines considered CTNNB1-mutated HCAs as a specific subtype, with a higher risk for malignant transformation that could lead to the development of HCC. In HCA *CTNNB1* mutations are identified in 11%-43%[54-56].

CTNNB1 mutations are not the only alterations found in HCCs, regarding Wnt/β-catenin pathway. In fact, mutations in Axin and APC in HCCs have been detected in 6%-15% and 2%-4%, respectively[57]. Generally, mutations in *CTNNB1*, Axin, and *APC* are mutually exclusive[57].

HCCs with mutated *CTNNB1* are statistically correlated to: (1) HCV infection[36]. For example, in a study on 22 HCV-related HCCs, an association between HCV infection and activation of the Wnt signaling pathway caused by the β-catenin mutation was found in 41% of cases[36], while according to the WHO, 30% of HCCs caused by HCV harbors a mutation in the *CTNNB1* gene; (2) Alcohol consumption. Schulze *et al*[37] studied 243 surgically resected HCCs, and 37% of the alcohol-related HCCs harbored a mutation in the *CTNNB1* gene; (3) *TERT* mutation[38,39]. Correlations between *CTNNB1* and *TERT* have been described in the "*TERT* and HCC" paragraph; and (4) *ARID1A* mutations (P = 0.05) and *NFE2L2* mutation (P = 0.015) associations with *CTNNB1* were demonstrated in a study performed on 125 HCCs[57] (Figure 2).

TP53

The *TP53* gene encodes for the p53 protein, which owes its name to its molecular mass (53 kDa). p53 is called "the guardian of the genome" because it is an oncosuppressor that regulates the cell cycle, apoptosis, and genomic stability by preventing genomic mutations. The p53 pathway is crucial in cellular mechanisms as it interacts with other signal transduction pathways (*e.g.*, retinoblastoma pathway, Wnt-β-catenin, cyclin-cdk). Plenty of positive and negative autoregulatory feedback mechanisms act on p53 functions[58,59]. The activation of p53 occurs in response to many different stressors, both intrinsic and extrinsic to the cell (*e.g.*, gamma or UV radiation, oxidative stress, osmotic shock) that put faithful duplication of genetic material at risk[60]. The key event for p53 activation is the phosphorylation of the N-terminal domain by protein kinases. This event leads to the accumulation of p53 in the stressed cells through an increase in the half-life of the protein and an increase in efficiency as a transcription factor. After this activation, p53 initiates a program that blocks the cell cycle, leads the

cell to senescence, and then to apoptosis[61] (Figure 3).

In unstressed cells, cytoplasmic levels of p53 are kept in check through its degradation. The Mdm2 protein binds p53, transports it from the nucleus to the cytosol, and acts as a ubiquitin ligase so that ubiquitin binds to p53 leading to proteasome degradation[62]. If the *TP53* gene is altered, the p53 protein cannot function properly, driving tumorigenesis and tumor progression. As early as 1990, *TP53* was defined as the most frequently mutated gene in human cancers. *TP53* mutations remain among the most frequent and most significant in more common human cancers, although the frequency of mutations is highly variable depending on the type of cancer: from 90% in the ovary, 50%-80% in the lung up to less than 5% in the cervix[63]. Individuals affected by Li Fraumeni syndrome carry a mutated allele of *TP53*, and this syndrome predisposes to the development of several types of cancers[64].

***TP53* and HCC:** Approximately 15%-40% of HCCs carry mutations in the *TP53* gene, with a higher frequency in advanced tumors[65]. Intriguingly, a specific *TP53* mutation is significantly associated with dietary intake of aflatoxin B1, a mycotoxin produced by *Aspergillus* fungi. Exposure to aflatoxin B1 induces the transversion G → T at the *TP53* codon 249, leading to the p.R249S (c.747G>T) substitution. This mutation could then be considered a mutational signature of exposure to aflatoxin B1 in HCC[66-68].

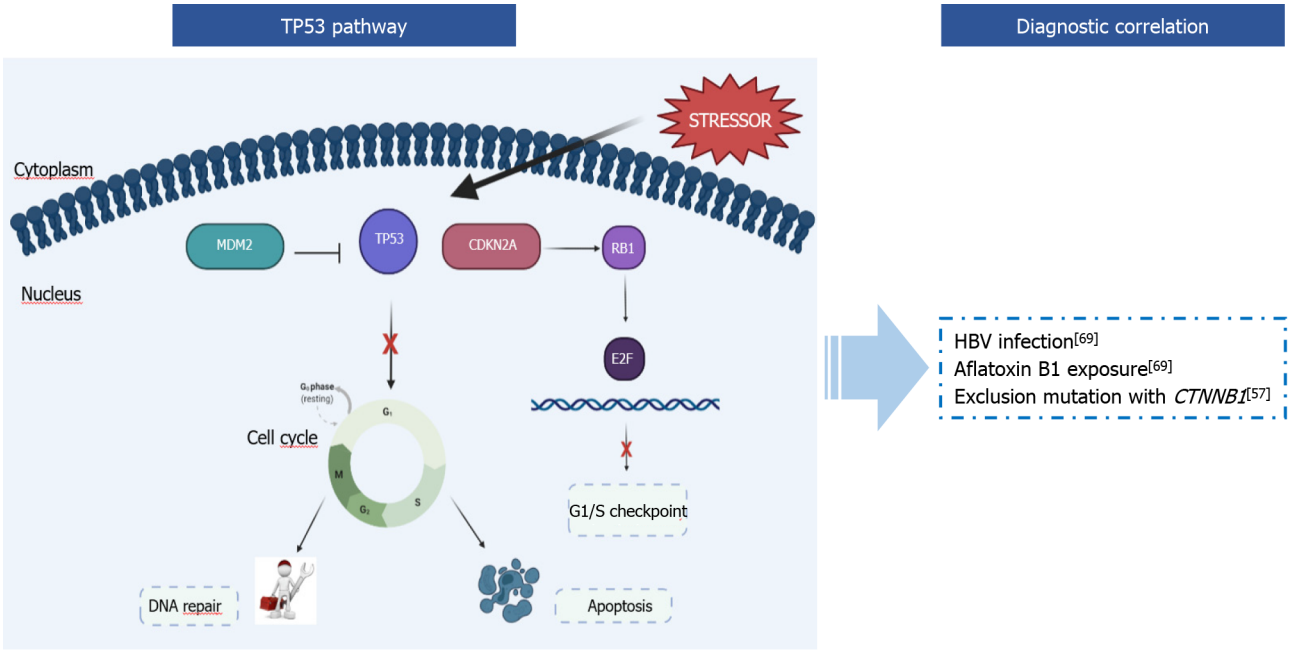
HCCs with mutated *TP53* are statistically correlated to: (1) HBV infection and aflatoxin B1 exposure [68,69]. Lunn *et al*[69] conducted a population-based study on 110 HCCs. The relative risk (RR) that they obtained for HBV infection (RR=17.0), aflatoxin B1 exposure (RR=17.4), and the two risk agents together (RR=67.7) confirmed the correlation between these agents and HCC development. Exposure to aflatoxin B1 induces the p.R249S substitution in the *TP53* gene, and HBV infection causes integration of the viral genome into that of the host, promoting mutations in genes crucial for cellular regulation, such as *TP53*. For these reasons HBV infection and aflatoxin B1 promote a high rate of mutagenesis in HCC[68,69]; and (2) *TP53* alterations were usually exclusive from *CTNNB1* mutations (P = 0.0001) but not from *AXIN1* and *APC*[57] (Figure 3).

MOLECULAR HCC SUBTYPE CLASSIFICATION

Over the years, many groups have tried to classify HCCs according to a molecular basis, but a univocal classification has been never reached.

Kabashima *et al*[70] grouped different classifications, starting from that of Shimada *et al*[71], and grouped HCCs into three molecular subtypes (MS1, MS2, MS3). The groups identified by the different studies are only fairly overlapping with each other. These classifications were based on clinical, molecular, and immunological features[70,71].

Regarding gene alterations, some correlations were found between *TP53* and *CTNNB1*. *TP53*-mutated HCCs were classified into the MS1 group, which correlated with unfavorable prognosis, viral infection, high serum alpha-fetoprotein levels, vascular invasion and proliferation, extensive mitotic activity resulting in chromosomal instability, and stem cell-like properties.



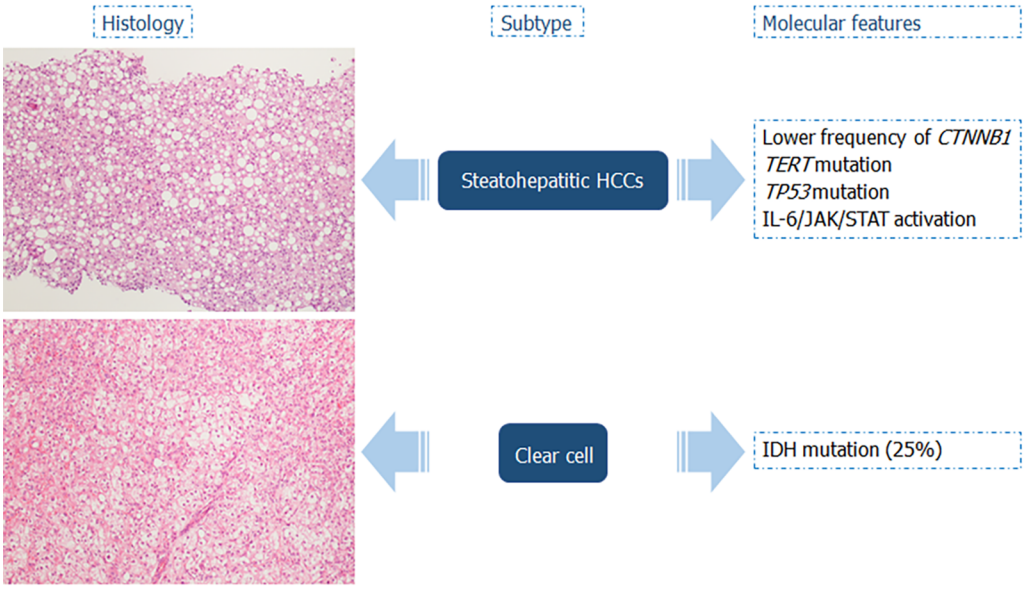
CTNNB1-mutated HCCs were placed into the MS2 group, correlating with aberrant activation of Wnt/ β-Catenin pathway, which could explain the high rate of methylation in CpG islands present in this group, as the constitutively active β-catenin protein recruits a DNMT1 methyltransferase. Another feature associated with the MS2 group is the immunosuppressive phenotype. Moreover, this class is considered non-proliferative/less progressive than others.

The MS3 group is not associated with molecular signatures, but only with metabolic disease-associated tumors[51,72-74].

The *TERT* gene is rarely found in these classifications. However, it should be considered that the most frequent mutations in *TERT* fall in a promoter region usually not covered by the exome sequencing studies. The Cancer Genome Atlas 2017 classification detected *TERT* mutations in HCC and included HCC-TERT samples in iCluster2 and iCluster3[17]. In 2019, further classification was drafted by Yang *et al*[75] that divides HCCs into 3 groups (C1, C2, C3), overlapping with a previous study performed by Hoshida *et al*[51]: C1→S3, C2→S1, C3→S2.

MOLECULAR HCC SUBTYPES AND PATHOLOGICAL FEATURES

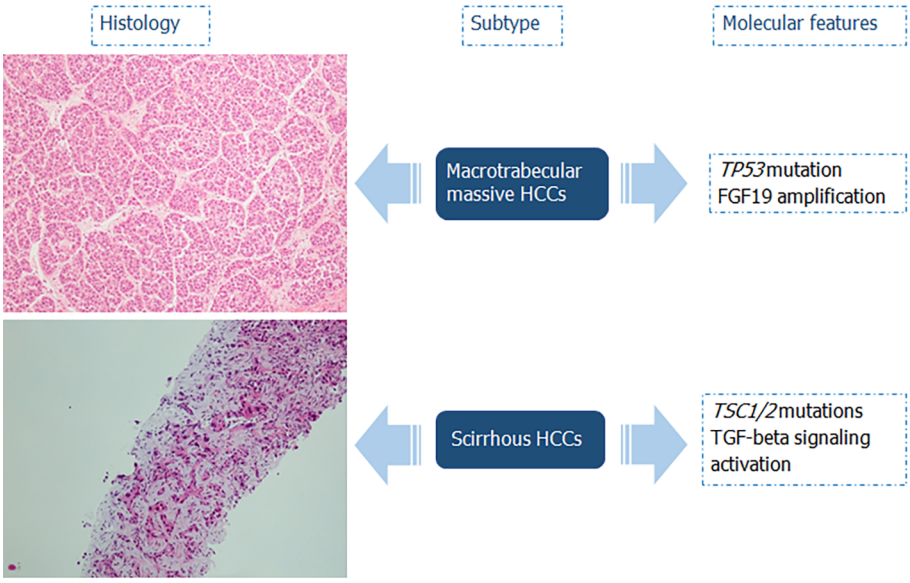
In 2017, Calderaro *et al*[76] discriminated HCCs based on the presence of *TP53* or *CTNNB1* mutations, considering that these are two genes that mutate in a mutually exclusive manner and together comprise 57% of HCCs. In this study, CTNNB1-mutated HCCs were described as larger than the CTNNB1-wildtype HCCs but characterized by a lower tumor grade, with microtrabecular and pseudoglandular patterns of growth, without inflammatory infiltrates and with the presence of cholestasis[76]. Conversely, TP53-mutated HCCs were described as poorly differentiated tumors, with large multinucleated and pleomorphic cells, solid pattern of growth, frequent vascular invasion, and angiogenesis[76].



DOI: 10.3748/wjg.v28.i25.2854 **Copyright** ©The Author(s) 2022.

Figure 3 Main cellular pathways and clinical implications of *TP53* mutations in hepatocellular carcinoma. Created with BioRender.com. HBV: Hepatitis B virus.

Selected subtypes of HCCs recognized by the most recent WHO Classification of Tumors were described to have specific molecular alterations (Figures 4 and 5)[14]: (1) Up to 63% of steatohepatitic HCCs were associated with nonalcoholic fatty liver disease. This type of HCC is characterized by the following histologic features: macrovesicular steatosis, Mallory-Denk bodies, ballooning of tumoral hepatocytes, inflammation, and trabecular or pericellular fibrosis. With regard to key molecular features, steatohepatitic HCCs were significantly associated with a lower frequency of *CTNNB1* mutations, higher rate of mutations in *TERT* and *TP53*, IL-6/JAK/STAT activation, high level of C-reactive protein, and serum amyloid A positive at immunohistochemistry[14,77-80]; (2) Clear cell HCCs are considered a well-differentiated type, characterized by a cytoplasmic clearing, due to accumulation of glycogen, lipopolysaccharides, mucopolysaccharides, or cytoplasmic vesicles. *IDH* mutations were identified in 25% of clear cell HCCs, and these alterations were significantly associated with a worse prognosis. Moreover, *IDH* mutations are also found in intrahepatic cholangiocarcinoma, a tumor with a significantly worse prognosis than HCC[14,80-83]; (3) Macrotrabecular massive HCCs are frequently larger than 50 mm with vascular invasion, correlated high alpha-fetoprotein serum levels, high expression of angiopoietin 2, and vascular endothelial growth factor A. At the histological level, this subgroup is characterized by massive trabeculae surrounded by vascular spaces and coated by immature endothelial cells. On the molecular side, *TP53* mutations and *FGF19* amplifications have been detected. Macrotrabecular massive HCC is an aggressive phenotype associated with a worse prognosis [14,80,84,85]; and (5) Scirrhous HCCs develop in the non-cirrhotic liver, and they are characterized by hyaline stroma, intratumoral fibrosis with thin trabecular pattern growth (due to this characteristic is easily confusable radiologically to cholangiocarcinoma), or the lymphoepithelioma-like subtype, consisting of dense intratumor lymphocytic infiltration. Scirrhous HCCs may exhibit *TSC1*/*TSC2* mutations and transforming growth factor-β signaling activation. Regarding prognosis, scirrhous HCCs are an aggressive subgroup, often with invasion of the portal vein, but as far as long-term follow-up is concerned, the prognosis is similar or sometimes better to conventional HCCs[76,86,87].



EXPERIENCE FROM OUR CENTER

Our preliminary results focused on 36 prospectively enrolled patients, all resected for HCC and selected for NGS by means of a laboratory-developed multi-gene panel Gene-Studio S5 sequencer, which comprises specific target regions including *TERT*[15]. We detected single mutations in the *TERT* promoter in 7 (19.4%) cases, in *TP53* in 4 (11.1%) cases, and in *CTNNB1* in 2 (5.6%) cases. *TERT* and *CTNNB1* coexistent mutations were observed in 8 (22.2%) cases, while *TERT* and *TP53* were in 8 (22.2%) cases. In 7 (19.4%) cases no mutations in these three genes were detected (Figure 6).

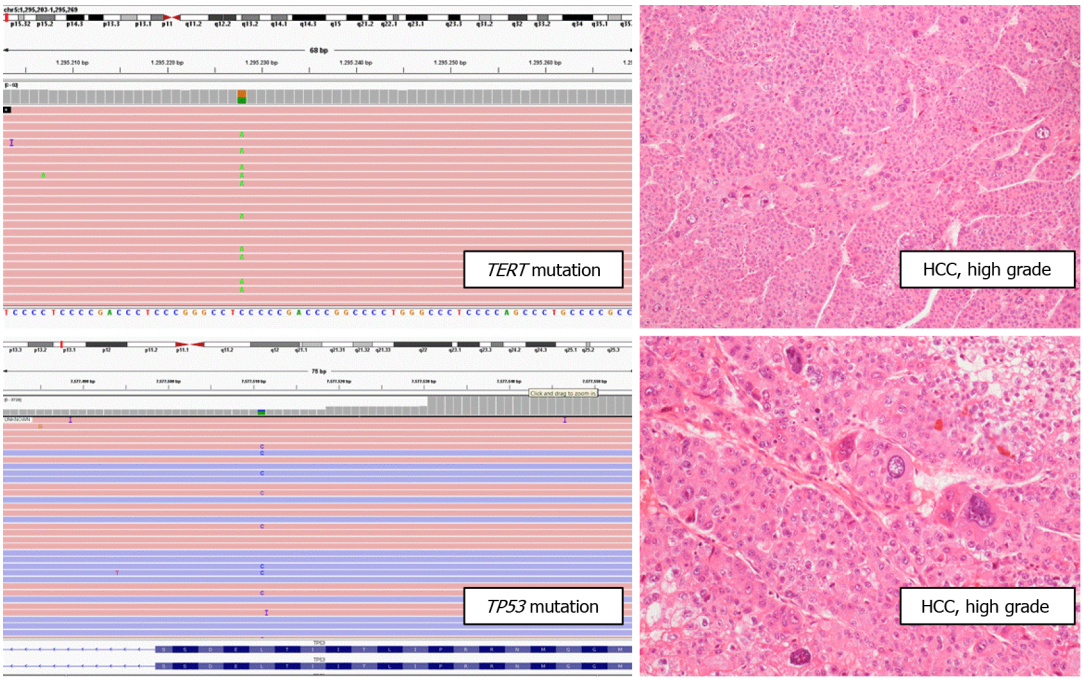
Figure 5 Macrotrabecular massive hepatocellular carcinomas and scirrhous hepatocellular carcinoma and their molecular features. Hematoxylin-eosin stain (10 magnification). HCC: Hepatocellular carcinoma; TGF: Transforming growth factor.

In line with a previous study by Calderaro *et al*[76], we observed a trend of *TERT*-mutated HCC towards a macrotrabecular or solid architecture. Moreover, the presence of *TERT* promoter mutations in combination with *TP53* mutation correlated with high-grade HCC ($P = 0.011$; Figure 7).



Interestingly, no correlations were found between mutations and tumor dimensions. This evidence leads us to hypothesize that the presence of *TERT* promoter mutations, alone or in combination with *TP53* alteration, correlates with a morphological progression in HCC, in terms of a higher tumor grade and an architecture more related to aggressive behavior (solid, macrotrabecular) but not of a dimensional evolution.

Most of the HCC in non-cirrhotic livers of our series showed no mutations or harbored only a *CTNNB1* mutation ($P = 0.031$), as a countercheck of the correlation between tumor progression and mutations. The validation of these results on a larger series as well as with post-surgical follow-up might indicate that small HCC may have an aggressive behavior from a molecular and morphological point of view, despite their dimensions.

CONCLUSION

The molecular signature of a tumor is becoming increasingly important in the approach of patients with different types of cancers, on diagnostic, prognostic, and predictive grounds. In the age of precision medicine, the study of HCC mutations is still a field that is worth investigating. Considering both the literature data and our personal experience, about 80% of HCCs harbor mutations in at least one gene among *TERT*, *TP53*, or *CTNNB1*, with different biological and clinical implications.

In the near future, a deeper analysis of these three genes is surely desirable since a molecular characterization of HCC would open up the possibility of personalized therapies, as has happened for other cancers (*e.g.*, lung adenocarcinomas, melanomas, gastrointestinal stromal tumors, colorectal adenocarcinomas). Moreover, the evidence of a tight correlation between the mutational profile and the HCC morphology is likely to imply an increasing integrative approach between anatomic pathology and

molecular laboratories.

Abstract

Despite the significant progress in cancer therapy, colorectal cancer (CRC) remains one of the most fatal malignancies worldwide. Chemotherapy is currently the mainstay therapeutic modality adopted for CRC treatment. However, the long-term effectiveness of chemotherapeutic drugs has been hampered by their low bioavailability, non-selective tumor targeting mechanisms, non-specific biodistribution associated with low drug concentrations at the tumor site and undesirable side effects. Over the last decade, there has been increasing interest in using nanotechnology-based drug delivery systems to circumvent these limitations. Various nanoparticles have been developed for delivering chemotherapeutic drugs among which polymeric micelles are attractive candidates. Polymeric micelles are biocompatible nanocarriers that can bypass the biological barriers and preferentially accumulate in tumors *via* the enhanced permeability and retention effect. They can be easily engineered with stimuli-responsive and tumor targeting moieties to further ensure their selective uptake by cancer cells and controlled drug release at the desirable tumor site. They have been shown to effectively improve the pharmacokinetic properties of chemotherapeutic drugs and enhance their safety profile and anticancer efficacy in different types of cancer. Given that combination therapy is the new strategy implemented in cancer therapy, polymeric micelles are suitable for multidrug delivery and allow drugs to act concurrently at the action site to achieve synergistic therapeutic outcomes. They also allow the delivery of anticancer genetic material along with chemotherapy drugs offering a novel approach for CRC therapy. Here, we highlight the properties of polymeric micelles that make them promising drug delivery systems for CRC treatment. We also review their application in CRC chemotherapy and gene therapy as well as in combination cancer chemotherapy.

Key Words: Polymeric micelles; Drug delivery; Colorectal cancer; Chemotherapy; Gene

therapy; Combination cancer therapy

Core Tip: Polymeric micelle-based drug delivery has demonstrated promising therapeutic outcomes against colorectal cancer. These safe nanocarriers exhibit high encapsulation efficiency of chemotherapeutic drugs, improve their water solubility and enhance the stability of nucleic acid-based therapeutics. They also accumulate preferentially at colorectal cancer sites, increase the anticancer effect of the delivered therapeutics and reduce their side effects. Incorporating stimuli-responsive and tumor targeting moieties to their structure further enhances their targeting and therapeutic efficacy. This platform also provides an opportunity to simultaneously deliver different chemotherapeutic drugs or nucleic acid-based therapeutics with chemotherapeutic drugs to the colorectal tumor to achieve an enhanced anticancer response.

INTRODUCTION

Colorectal cancer (CRC) is the third most prevalent cancer and the second leading cause of cancer-related deaths in men and women globally with an estimated 1.9 million new cases and 0.9 million deaths in 2020[1]. These numbers are predicted to reach 3.1 million and 1.6 million, respectively, within the next two decades[2]. The majority of CRC patients present with localized tumors, and nearly 20%-30% of CRC patients have unresectable metastasis[3]. While the 5-year survival rate for localized CRCs is nearly 90%, it is reduced to about 12% for distant metastatic CRCs[4].

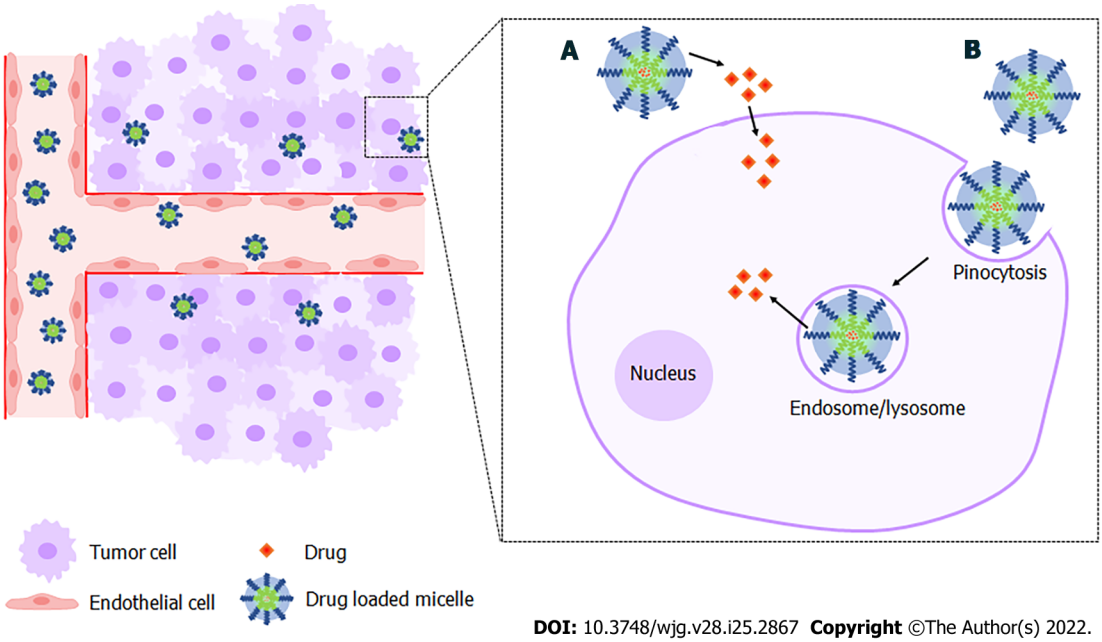
Surgery is the primary treatment for patients in early stages of CRC, whereas preoperative or postoperative radiotherapy and chemotherapy are added for patients in advanced stages[5]. Numerous chemotherapeutic drugs, approved by the Food and Drug Administration, have been used for CRC treatment including 5-fluorouracil (5-FU), irinotecan (IRI), oxaliplatin (OXA) and capecitabine[3]. However, their clinical efficacy has been constrained by the adverse side effects and drug resistance that causes cancer relapse and treatment failure[6-8]. To address these drawbacks, combination therapy has been used as an alternative therapeutic approach to cancer monotherapy. Combining therapeutic agents with different modes of action demonstrated great potential in achieving synergistic therapeutic outcomes with reduced side effects in addition to overcoming drug resistance[9]. Several combination chemotherapeutic regimens such as FOLFIRI (folinic acid, 5-FU and IRI), XELOX/CAPOX (OXA and capecitabine) and FOLFOX (folinic acid, 5-FU and OXA) are widely used in clinical treatment for CRC [10]. However, and despite the continued efforts devoted to advance CRC chemotherapy, the prognosis of this disease is still unsatisfactory, particularly for metastatic CRC patients[11].

The main concerns limiting the success of single agent or combination chemotherapy are poor solubility, short half-life, rapid metabolism of the anticancer drugs, lack of selectivity for the tumor sites, non-specific biodistribution and subsequent failure to achieve effective therapeutic concentrations at the action sites[12,13]. Over the past decades, nanotechnology-based drug delivery systems have emerged as a modern approach to overcome these limitations and improve drug performance. They enhance the pharmacokinetic proprieties of the drugs, ensure their delivery to the tumor, prevent toxicity to healthy tissues, increase drug concentration at the tumor site and therefore potentiate their anticancer activity while mitigating their associated side effects[14]. In combination therapy, they can effectively carry several drugs with dissimilar pharmacokinetic profiles and maintain the optimized synergistic drug ratio until they reach the target cancer cells[15]. Additionally, nanosized drug delivery systems opened up new opportunities for the delivery of novel therapeutics along with chemotherapeutic agents, such as genetic anticancer agents, which are considered to be innovative approaches in CRC management [15].

Among the broad range of nanocarriers, polymeric micelles have received particular attention for therapeutic applications in cancer. Many anticancer agents are polycyclic compounds with poor aqueous solubility[16], and polymeric micelles have proven to be powerful vehicles for loading and delivering hydrophobic drugs[17]. Besides being biocompatible and biodegradable, polymeric micelles provide distinct advantages including small size, low-cost, ease of preparation, high drug encapsulation capacity and structural stability[18-20]. They can be easily functionalized with stimuli-responsive and tumor targeting moieties to achieve site-specific delivery and controlled drug release[21]. They also allow the integration of multiple functions other than drug delivery including gene delivery and

imaging[21]. To date, two polymeric micelles, Genexol-PM loading paclitaxel (PTX) and Nanoxel loading docetaxel (DTX), have been approved in Korea and India, respectively, for the treatment of different types of cancer including breast and non-small cell lung cancers[22]. As these nanocarriers have shown therapeutic potential for these solid tumors, they could serve as drug delivery platforms to alleviate the current limitations of CRC chemotherapy and promote the introduction of gene therapy in the management of this disease. Here, we review the composition and characteristics of polymeric micelles in addition to the achievements in micelle-based drug delivery for CRC chemotherapy and gene therapy. Published studies included in this minireview were identified through searching PubMed and Google scholar using different permutations of these keywords "colorectal cancer" or "colon cancer," "chemotherapy" or "gene therapy," "combination" and "micelle." Clinical trials were identified through searching https://clinicaltrials.gov using two keywords "micelle" and "cancer".

COMPOSITION AND CHARACTERISTICS OF POLYMERIC MICELLES



Polymeric micelles are formed by self-assembly of amphiphilic di-block, tri-block or grafted copolymers in aqueous solutions[23]. Micelles have a two-phase structure including an inner core composed of hydrophobic blocks surrounded by a corona of hydrophilic blocks[24,25]. The widely used core-forming polymers include polyesters, polyethers or polyamino acids, while the most used hydrophilic corona-forming polymer is polyethylene glycol (PEG)[26]. Alternatively, other hydrophilic polymers could be used including chitosan, dextran and hyaluronic acid (HA)[27]. The hydrophilic corona confers steric stability to the micelle, decreases its interactions with serum components and prevents its recognition and early elimination by the reticuloendothelial system, thus enhancing its retention in the systemic circulation[28,29]. The hydrophobic core forms a loading site for lipophilic drugs. It was reported that encapsulating drugs in micelles enhanced their water solubility by 10- to 500-fold[30]. Non-polar drugs can be loaded in micelles by physical entrapment or chemical conjugation[30]. Polymeric micelles used in gene delivery are known as micelleplexes and have cationic properties, which allow the association of nucleic acids *via* electrostatic interactions. The hydrophilic blocks of these micelles are usually composed of polycations including polyethyleneimine (PEI), poly (2-dimethylaminoethyl methacrylate) and polyamino acids[31].

The concentration of copolymers that is needed to form micelles is known as the critical micelle concentration. The critical micelle concentration should be low enough to prevent the dissociation of the micelles upon dilution in the bloodstream[32]. The size of polymeric micelles typically ranges from 10 to 100 nm[33]. Given that nanoparticles that are less than 10 nm can easily undergo renal clearance and those larger than 100 nm can be rapidly eliminated by the liver and spleen, the suitable size of micelles limits their rapid clearance from the circulation[34]. In addition, the nanosize of micelles allows them to passively accumulate in tumor tissues by the enhanced permeability and retention effect[27]. This passive targeting is due to the aberrant and leaky vascular architecture coupled with defective lymphatic drainage that uniquely characterize solid tumors[35]. Being unable to pass through the normal blood vessel walls, the micelles extravasate through the leaky tumor blood vessels, accumulate preferentially at the tumor site and consequently promote the retention of the delivered drug at the tumor tissue[36].

The polymeric micelles deliver the drug payload to the cancer cells by two mechanisms. The therapeutic agents can enter the cancer cell as free drugs after their release from the micelles or be internalized as drugs encapsulated within the micelles to be released within the cell[37]. Chemically conjugated drugs are released by bulk degradation or surface erosion of the micelles, while the physically entrapped drugs are mainly released by diffusion[38]. Intact drug-loaded micelles are internalized *via* cell- dependent pinocytosis, which includes macropinocytosis, clathrin-mediated endocytosis, caveolae-mediated endocytosis and clathrin- and caveolae-independent endocytosis[39-42] Internalized micelles have been shown to localize in acidic organelles, namely endosomes or lysosomes[40,43]. The loaded drugs were suggested to be released from the micelles in these organelles[40,43] and to subsequently exert their therapeutic effect at the action site[40] (Figure 1).

Active targeting can be used to complement passive targeting for enhanced tumor selectivity, improved cellular uptake and reduced off-target effects[21,23]. The surface of the micelles can be modified with ligands that can specifically recognize and bind to receptors or proteins overexpressed on the tumor cells but that are less expressed on normal cells[44]. Different types of ligands have been conjugated to micelles to ensure their active targeting to cancer cells including antibodies and antibody fragments, proteins including transferrin, peptides such as iRGD, nucleic acid-based ligands such as the AS1411 aptamer and small molecules including folic acid (FA) and HA[45].

Another interesting approach for active targeting is to achieve adequate drug release at the tumor site by designing stimuli-responsive micelles taking advantage of the unique features of the tumor microenvironment. The tumor tissues are characterized by a low pH, upregulation of specific enzymes and elevated levels of glutathione compared with the normal tissues[34]. Stimuli-sensitive polymeric micelles are developed by introducing pH-sensitive linkers in their structures, such as hydrazone bonds or pH-sensitive ionizable functional groups, enzyme-sensitive moieties or redox-sensitive linkers

Figure 1 Schematic illustration of the passive targeting of drug formulated micelles to the tumor tissue by enhanced permeability and retention effect and the proposed mechanisms of drug release in the cancer cell. A: The drug can enter the cancer cell in its free form after its release from the micelle; B: The drug can be internalized within the micelle after which it is released in the cancer cell.

including disulfide bonds[34]. When the micelles reach the tumor, the linker degrades in response to the internal stimulus leading to the disassembly of micelles and subsequent drug release[34]. In addition to internal stimuli, polymeric micelles responsive to external stimuli such as magnetic fields, ultrasound and light are designed to achieve a temporal and spatial controlled release of the drug in the desired tumor tissue[34]. After releasing the drug, micelles can dissociate into monomers that are excreted by the kidneys, therefore avoiding any long-term adverse effects[46]. All these properties make polymeric micelles an attractive platform for drug delivery against CRC.

APPLICATION OF POLYMERIC MICELLES IN CRC TREATMENT

The properties and the cellular and molecular mechanisms of action of polymeric micelles used for drug delivery in CRC treatment are presented in Table 1.

Chemotherapy

Numerous studies have demonstrated the potential of polymeric micelles to ensure the targeted delivery of chemotherapeutic drugs to colorectal tumor sites and enhance their therapeutic effectiveness.

IRI is a topoisomerase I inhibitor that is converted by enzymatic activation in the liver and tumors to 7-ethyl-10-hydroxy-camptothecin (SN-38). The latter is about 100-1000 times more potent than IRI against cancer cells[47]. However, only 2%-5% of the administered dose of IRI is converted to SN-38 in the clinic[48]. Although SN-38 demonstrated effective anticancer activity, its direct use as a free drug in the clinic was limited by its hydrophobicity[49]. To circumvent this problem, Koizumi *et al*[50] conjugated SN-38 to PEG-poly(glutamic acid) copolymer with a phenyl ester bond to develop SN-38-loaded polymeric micelles (NK012). The micelle formulation of SN-38 demonstrated extended blood circulation compared with free IRI in mice bearing CRC xenografts. It also prolonged and improved the distribution of SN-38 in the tumor and produced stronger antitumor activities compared to free IRI. To test the correlation between the efficacy of micellar drugs and tumor hypervascularity and hyperpermeability, the effect of NK012 and free IRI was tested in a vascular endothelial growth factor (VEGF)–secreting tumor model namely SBC-3/VEGF. Interestingly, NK012 was found to improve the accumulation and the antitumor activity of SN-38 in SBC-3/VEGF tumors compared to SBC-3/Neo tumors. This was due to the high vascular density and permeability induced by VEGF. However, treatment with free IRI neither significantly increased SN-38 concentration in SBC-3/VEGF tumors nor effectively suppressed tumor growth[50].

Doxorubicin (Dox) is an anthracycline antibiotic that is commonly used to treat several types of solid cancer. However, its clinical use is hampered by dose-dependent cardiotoxicity due to its nonspecific biodistribution[51]. Recently, Brunato *et al*[52] developed methoxyPEG (mPEG)-polyamino acid based

Table 1 Overview of micelles used for drug delivery in colorectal cancer treatment, their characteristics and cellular and molecular mechanisms of action

Block copolymer	CMC	Size in nm	Zeta potential in mV	Entrapment efficiency in %	Therapeutic agent	Cell line or animal model	Cellular and molecular mechanisms of action of micelles loaded with the therapeutic agents	Ref.
PEG-poly (glutamic acid)	N/A	20	N/A	N/A	SN-38	WiDR, SW480, Lovo and HT-29 human colon cancer cells; Female BALB/c nude mice subcutaneously injected with HT-29 cells		Koizumi *et al* [50]
mPEG5kDa-b-[(Dox-hydGlu)$_6$-r-Leu$_{10}$]	4.6 ± 0.2 μmol/L	29.2 ± 1.1	3.61 ± 0.28	N/A	Doxorubucin	CT26 murine colorectal cancer cells; BALB/c mice subcutaneously injected with CT26 cells	(1) Do not cause hemolysis; (2) Do not induce a significant increase of the levels of blood markers for organ toxicity AST, BUN and CPK; and (3) Induce a slight increase of ALT and LDH	Brunato *et al* [52]
PEG-poly (L-lactate-co-hexamethylene-co-adipate) (PEG-PLLHA) and FA-PEG-poly (hexamethylene adipate-co-hexamethylene 2-hydroxyl succinate)	3.65 μg/mL	215.6 ± 3.1	−2.4 ± 0.2	82.1 ± 0.6	Docetaxel	CT-26 cells; Female BALB/c mice subcutaneously injected with CT-26 cells	(1) Induce a more severe tumor necrosis compared to their non-targeted counterparts; (2) Do not cause hemolysis or erythrocyte agglutination; (3) Do not induce histological damage to the major organs of the treated mice; (4) Induce a slight increase of BUN levels; and (5) Do not affect the concentrations of ALT, AST, ALP, and CRE	Su *et al*[54]
PEG-poly (D,L lactate-co-hexamethylene-co-adipate) (PEG-PDLLHA) and FA-PEG-poly (hexamethylene adipate-co-hexamethylene 2-hydroxyl succinate)	3.50 μg/mL	245.5 ± 4.3	−2.8 ± 0.1	79.9 ± 1.0				
D-α-tocopherol succinate (TOS)-conjugated-hyaluronic acid	N/A	95.5 ± 13.7	N/A	90	Paclitaxel	CT26 mouse colon carcinoma cells; NIH-3T3 mouse embryo fibroblasts; HT29 and Lovo human colorectal adenocarcinoma cells; BALB/c mouse subcutaneously injected with CT26 cells	(1) Induce early and late apoptosis in HT29 and Lovo cancer cells *in vitro*; and (2) Induce apoptosis and decrease tumor cell proliferation *in vivo*	Zhu *et al*[58]
mPEG-PCL and DOTAP	N/A	144.8	46.4	N/A	Bcl-xl siRNA and Mcl1 siRNA	C26 cells; BALB/c mice inoculated with C26 cells		Lu *et al*[59]
mPEG-PCL and DOTAP	N/A	46.4 ± 3.7	44.1 ± 1.5	N/A	Plasmid pVAX1-mIL22BP expressing murine IL-22BP	C26 *Mus musculus* colon carcinoma cells; 293t human embryonic kidney cells; BALB/c mice intraperitoneally injected with C26 cells	(1) Induce apoptosis *in vitro*; (2) Decrease the microvessel density characterized by CD31 positive staining; and (3) Induce lymphocyte infiltration in tumor microenvironment as indicated by the detection of CD8+	Men *et al*[60]

							and CD4+ cells in the tumor tissues	
mPEG-PCL and DOTAP	N/A	46 ± 5.6	41.8 ± 0.5	N/A	Plasmid pcDNA-Survivin-T34A expressing Survivin-T34A	C-26 murine colon adenocarcinoma cells; BALB/c mice intraperitoneally injected with C-26 cells		Duan *et al*[61]
PEI-deoxycholic acid	N/A	88.4 ± 16	N/A	N/A	XIAP siRNA and paclitaxel	HCT-116 human colorectal cancer cells; Male BALB/c nu/nu mice subcutaneously injected with HCT-116 cells		Jang *et al*[63]
PEI-poly (DL-lactic acid)	0.1167 mg/mL	235 ± 25	−22	100	Survivin shRNA and camptothecin	C26 and CHO cells; Female BALB/c mice subcutaneously inoculated with C26 cells	(1) Induce a more pronounced apoptosis *in vitro* compared with their non-targeted counterparts; and (2) Have a lower accumulation in vital organs *in vivo* compared with their non-targeted counterparts	Sanati *et al*[64]
PDMA-b-PCL and mPEG-PCL	N/A	222.1	21.1	N/A	SN-38, USPIO and VEGF siRNA	LS174T human colon adenocarcinoma cells; Female BALB/c athymic nu+/nu+ mice subcutaneously injected with LS174T cells		Lee *et al*[66]
PEI-poly (D,L lactide) and 1,2-distearoyl-sn-glycero-3-phosphoethanolamine-N-mPEG	N/A	171.25 ± 4.70	15.12 ± 0.36	81.25 ± 3.12	miRNA-34a and irinotecan	CT-26 murine colon adenocarcinoma cells; Female BALB/c mice injected with CT-26 cells	(1) Upregulate miR-34a and reduce the expression of Bcl-2 and the phosphorylation level of mTOR; (2) Negligible hemolytic activity; and (3) Do not significantly alter the levels of ALP, ALT, ALB, AST, CK, LDH, BUN and CRE	Li *et al*[67]

micelles for the delivery and controlled release of Dox in CRC. The hydrophobic block of the copolymer included six glutamic acid-γ-hydrazide and ten leucines. Dox was conjugated to glutamic acid through pH-sensitive hydrazone bond to trigger its release in the acidic lysosomal microenvironment. The release of Dox was faster at pH 5.5, which mimics the lysosomal environment. In addition, the intracellular delivery of Dox by the micelles and its trafficking through the lysosomal compartment of CRC cells, where the acidic environment can induce the cleavage of the hydrazone bond, were confirmed by confocal microscopy. Therefore, encapsulating Dox in the formulated micelles may prevent its undesired release in the bloodstream. Interestingly, Dox-loaded micelles had good tolerability, produced a higher antitumor effect compared to the free drug and had limited toxicity in CRC bearing mice[52].

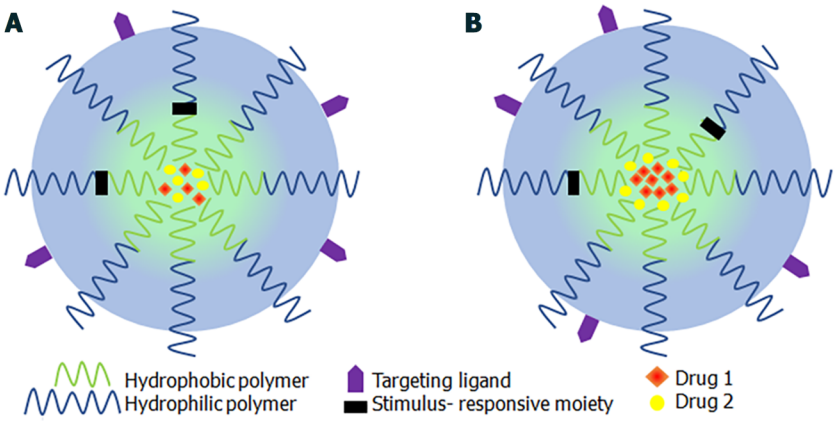
DTX is a microtubule inhibitor that is approved to treat numerous types of cancer. Due to its low water solubility, a mixture of Tween 80 and ethanol is required to solubilize DTX. Yet, Tween 80 used in the available marketed formulation of DTX Taxotere® was associated with adverse effects[53]. Recently, FA-targeted PEG-polyester micelles were formulated for the targeted delivery of DTX against colon cancer. The targeted formulation resulted in an accelerated internalization of the micelles by FA receptor-positive colon cancer cells *in vitro* and in a higher and preferential accumulation of the micelles in colon tumors *in vivo* compared to the non-targeted formulation. Besides being biocompatible and safe, the FA-targeted DTX-loaded micelles exhibited a remarkable 97% tumor-inhibiting efficiency, which was higher than that of non-targeted DTX-loaded micelles (85%) and free DTX (31%) in mice bearing colon tumor xenografts[54].

PTX is a microtubule stabilizing agent commonly used against a variety of cancers including CRC [55]. Because of its low aqueous solubility, Taxol®, the commercial formulation of PTX, uses a nonionic surfactant namely Cremophor® EL[56]. However, Cremophor® EL has been associated with serious side effects such as hypersensitivity, nephrotoxicity and neurotoxicity[57]. Zhu *et al*[58] developed smart micelles for the targeted delivery and controlled release of PTX in colon cancer. Micelles are made from the self-assembly of D-α-tocopherol succinate (TOS) conjugated to HA *via* a redox responsive disulfide bond. Their findings demonstrated that these micelles could specifically accumulate in orthotopic colon tumors and metastatic tumor cells rather than in normal intestinal tissue through binding of HA to CD44 receptors overexpressed on primary and metastatic colon tumor cells. They could also selectively release PTX in orthotopic colon tumors and metastatic tumor cells where the high levels of glutathione break disulfide bonds thus causing drug release. PTX-encapsulated micelles induced the highest survival rate (100%) in mice bearing orthotopic colon tumors compared to untreated group (60%) and free PTX (Taxol) treated group (40%). They also suppressed primary colon tumors and metastatic sites in the intestine and decreased metastasis to other organs and to the peritoneum[58].

Gene therapy

Polymeric micelles were also reported to successfully deliver anticancer genetic material to CRC. Cationic hybrid micelles composed of amphiphilic cationic lipid N-[1-(2,3-dioleoyloxy) propyl]-N, N, N-trimethylammonium methyl sulfate (DOTAP) and mPEG-poly (ε-caprolactone) (PCL) have been used to deliver genes or small interfering RNA (siRNA) for the treatment of colon cancer in preclinical studies. The cationic hydrophilic head of DOTAP ensures the adsorption of the anionic nucleic acid onto the surface of the micelles *via* electrostatic interaction. These hybrid micelles demonstrated an effective and safe delivery of siRNA targeting colon cancer cells. The micelle-based delivery of siRNA caused inhibition of the two anti-apoptotic genes *Bcl-xl* and *Mcl1*, which consequently induced apoptosis in colon cancer cells *in vitro* and suppressed the growth of colon tumors *in vivo*[59]. In another report, these hybrid micelles were used for the delivery of interleukin-22 binding protein (*IL-22BP*) gene, which is known to play a role in blocking the IL-22/IL-22R1 signal axis involved in tumor growth and

metastasis. The micelle-delivered *IL-22BP* gene was efficiently expressed in colon tumors *in vivo* leading to the inhibition of the growth of abdominal cavity metastases. Its anticancer mechanism involved blockage of IL-22, induction of apoptosis and anticancer immune response in addition to inhibition of angiogenesis[60]. In a study conducted by Duan *et al*[61], these hybrid micelles were found to efficiently deliver the classic suicide gene survivin-T34A that acts as a competitor in the survivin pathway involved in apoptosis inhibition[62]. The survivin-T34A gene-loaded micelles inhibited the proliferation of colon cancer cells *in vitro* and the growth of abdominal metastatic colon cancer and malignant ascites *in vivo* by inducing apoptosis[61]. Importantly, in all these studies, this micellar carrier did not induce any pathological changes in the vital organs of the mice with colon cancer.



Combination of chemotherapy with gene therapy

The micellar dual delivery of chemotherapeutic drugs with agents targeted against specific genes have been shown to produce synergistic therapeutic responses against CRC. Cationic micelles based on PEI-deoxycholic acid conjugates have been used for the co-delivery of PTX and siRNA targeting the X-linked inhibitor of apoptosis gene to CRC. The micellar co-delivery of siRNA targeting X-linked inhibitor of apoptosis gene and PTX effectively decreased the expression of X-linked inhibitor of apoptosis at the mRNA and protein levels *in vitro* and *in vivo*. In addition, it was more potent than PTX-loaded micelles as it caused a greater reduction in cell viability of CRC cells and inhibited the growth of colorectal tumors *in vivo*[63]. In another study, Sanati *et al*[64] synthesized cationic micelles for the targeted dual delivery of camptothecin (CPN), a topoisomerase inhibitor, and short hairpin RNA targeting survivin to colon cancer. These micelles containing PEI-poly (D,L-lactic acid) copolymers were coated with polycarboxylic acid dextran and were subsequently modified with AS1411 aptamer that has high affinity for the nucleolin receptors expressed on the surface of colon cancer cells. Cell surface nucleolin expression is known to be more elevated in cancer cells than in normal cells[65]. The conjugation of AS1411 aptamer on the micelles improved their cellular internalization through nucleolin-mediated endocytosis *in vitro* and enhanced their accumulation in colon tumors *in vivo* in comparison with their non-targeted counterparts. While the non-targeted micellar formulation of each of CPN and short hairpin RNA targeting survivin exhibited 3% and 5% tumor inhibitory effect *in vivo*, the targeted and non-targeted formulations of the combination of CPN and short hairpin RNA targeting survivin exerted 93% and 87% tumor inhibitory effects, respectively. It is important to note that the free CPN did not have any anticancer effects *in vivo,* and its micellar formulation prevented the development of its associated systemic toxicity[64]. Moreover, Lee *et al*[66] designed theranostic micelles from cationic PDMA-b-PCL and mPEG-PCL polymers for the combined delivery of SN-38, siRNA targeting human VEGF in addition to a magnetic resonance imaging contrast agent namely ultra-small superparamagnetic iron oxide nanoparticles. The SN-38/ultra-small superparamagnetic iron oxide nanoparticles/siRNA-loaded mixed micelles were targeted passively to colorectal tumor regions *in vivo.* They induced a synergistic tumor growth suppression and allowed the tracking of anticancer effects by magnetic resonance imaging during the treatment[66]. Additionally, hybrid micelles co-self-assembled from PEI-poly (D,L lactide), and 1,2-distearoyl-sn-glycero-3-phosphoethanolamine-N-mPEG were used to deliver IRI and tumor suppressive microRNA-34a (miR-34a) to colon cancer. The micellar co-delivery of the two therapeutic agents showed higher efficacy in inducing apoptosis and inhibiting migration of colon cancer cells *in vitro* compared with free IRI and the single agent formulation. The micellar IRI and miR-34a combination also accumulated in colon tumors *in vivo* and showed superior tumor growth inhibition with low acute systemic toxicity compared with free IRI and the micellar formulation of individual agents[67].

Combination cancer chemotherapy

For dual combination therapy, the encapsulation of drugs in a micellar system could be performed in two ways (Figure 2). In the first method, both drugs are physically loaded in the micelles by hydrophobic interactions. Alternatively, one hydrophobic drug is conjugated to the amphiphilic copolymer, which self-assembles and forms prodrug micelles to subsequently encapsulate the second hydrophobic drug in its core[68].

The chemotherapeutic drug Dox and the tyrosine kinase inhibitor dasatinib were effectively co-encapsulated in the inner hydrophobic core of micelles formed by PEG-peptidic conjugate namely PEG-lysyl-(α-fluorenylmethyloxycarbonyl-ε-Cbz-lysine)$_2$. The dual drug-loaded micelles exhibited greater inhibition of colon cancer cell proliferation compared with the micellar formulation or the free form of individual drugs[69]. In another study, Dox was co-delivered with the tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) in cationic micelles to CRC. The micelles were prepared with poly {(*N*-methyldietheneamine sebacate)-*co*-[(cholesteryl oxocarbonylamido ethyl) methyl bis(ethylene) ammonium bromide] sebacate. Dox was encapsulated in the micelles, whereas TRAIL was complexed onto their surface. The internalization of these micelles by CRC cells was mediated by the death receptors expressed on the cell surface. Compared to the formulation of single agents, Dox and TRAIL-loaded micelles enhanced the inhibition of CRC cell viability, the increase of sub-G1 population and the reduction of long-term survival and clonogenicity of cancer cells after the treatment. Interestingly, these remarkable anticancer effects were reported in both TRAIL sensitive and resistant CRC cells. In addition, the cytotoxic effect of the co-loaded micelles was selectively higher against cancer cells than

Figure 2 Polymeric micelles for dual drug delivery. A: Both drugs are physically loaded in the core of the micelle; B: One hydrophobic drug is conjugated to the amphiphilic copolymer forming the micelle and the second is encapsulated in its core.

normal cells. This was suggested to be due to the relative disparities in expression levels of decoy and death receptors between normal and cancer cells[70]. A third study reported the combined delivery of Dox and the proapoptotic cationic peptide KLA using DNA micelles. These micelles were made using cholesteryl-modified single strand DNA and its complementary sequence to which the KLA peptide was conjugated. The cationic peptides enhanced the stability of the micelles by protecting them from digestion by nucleases. Since oligonucleotides cannot cross cell membranes, DNA micelles were conjugated to a mucine1 aptamer to target mucine1 receptors overexpressed on the surface of cancer cells. These micelles were found to specifically bind to the mucine1 receptors overexpressing cells and to accumulate within them. The co-delivery of KLA and Dox using the targeted micelles potentiated the inhibition of colon tumor growth *in vivo* compared to free Dox in addition to attenuating its toxic effects [71]. A recent study reported the formulation of a folate receptor-targeted and redox-responsive micellar system for the co-delivery of PTX and adjudin (ADD), a mitochondrial inhibitor, to reverse multidrug resistance in colon cancer. In this drug delivery system, PTX was conjugated to dextran *via* a disulfide bond to form the PTX prodrug, and FA was conjugated to the side chain of dextran-PTX. The resulting PTX prodrug micelles were further used to encapsulate ADD in its hydrophobic core. *In vitro* studies showed that conjugation of FA to the surface of these micelles enhanced their internalization by PTX resistant CRC cells overexpressing the FA receptor. They also demonstrated that ADD inhibited PTX efflux, which consequently improved intracellular accumulation of PTX and therefore its cytotoxic activity. In addition, PTX and ADD-loaded micelles exhibited a prolonged circulation in the blood compared with free PTX *in vivo*. They also increased the concentrations of drugs in resistant colon tumors compared to their non-targeted counterparts and free PTX. Importantly, they demonstrated a strong tumor growth inhibition owing to the active tumor-targeting, the co-delivery of two therapeutic drugs and glutathione-responsive drug release[72]. In another study, micelles engineered with poly-lactic-co-glycolic acid grafted branched PEI were used to co-deliver 5-FU and methotrexate (MTX), which is an antagonist of FA and is known to have anticancer effects against different types of neoplasm. MTX was conjugated to the copolymer forming the prodrug micelles, which was further used to encapsulate 5-FU. In addition to its therapeutic potential, MTX has structural similarity with FA and can therefore act as an FA receptor targeting agent. The conjugation of MTX to the micelles improved their internalization by colon cancer cells compared to the non-conjugated micelles. The combined drug-loaded micelles were more effective in attenuating the viability of colon cancer cells compared to free 5-FU or the micellar MTX[73]. Doxifluridine, a prodrug of 5-FU, has been commonly used in cancer treatment to circumvent the toxicity of 5-FU. Doxifluridine is converted into toxic 5-FU by endogenous thymidine phosphorylase in cancer cells[74]. In a study conducted by Wang *et al*[75], doxifluridine was conjugated to PCL to form a hydrophobic segment that was grafted with hydrophilic chitosan. The produced polymeric prodrugs self-assembled into micelles used for SN-38 encapsulation. The dually loaded micelles were found to reduce the viability of colon cancer cells *in vitro* to a greater extent than doxifluridine-loaded micelles. In another study, doxifluridine-PCL hydrophobic segment was grafted with mPEG to form prodrug micelles serving as carriers to further encapsulate Dox or SN-38. The micellar co-delivery of doxifluridine with Dox or SN-38 exhibited superior inhibition of CRC cell viability with respect to doxifluridine-loaded micelles[74].

Polymeric micelles in clinical trials

Despite their promising potential in preclinical studies against colon cancer, few polymeric micelles have reached the clinical setting. A phase I clinical trial of NK012 was conducted in Japan with a total of 24 patients with solid tumors including 12 patients with CRC. NK012 was found to be well tolerated at

doses up to 28 mg/m^2 when administered every 3 wk. None of the CRC patients had a partial response. However, 5 CRC patients with a history of treatment with OXA and IRI had stable disease; 4 of them received the NK012 regimen for six cycles of treatment or more[76]. Subsequently, the efficacy and safety of NK012 was evaluated in a phase II clinical trial at an initial dose of 28 mg/m^2 in 58 Japanese patients with unresectable metastatic CRC who had been treated with OXA-based chemotherapy. Administration of NK012 resulted in a response rate similar to that of free IRI. In addition, febrile neutropenia and grade ≥ 3 neutropenia were reported in these patients suggesting that an initial dose of 28 mg/m^2 of NK012 may be too high. Further studies should be conducted to determine the optimal dose of NK012 and improve its efficacy and safety[77]. In another study, a phase I clinical trial of NK105, PTX-loaded micelles, was conducted with 19 patients with advanced solid tumors including 1 patient with colon cancer. NK105 was well tolerated, and the recommended phase II dose was determined to be 150 mg/m^2 every 3 wk. The colon cancer patient was reported to have a stable disease for longer than 4 weeks at the time of the completion of the study[78]. Two additional clinical trials on polymeric micelles in CRC were launched but their results have not been reported yet. The first is a phase I clinical trial that aims to determine the maximum tolerated dose/recommended phase II dose of the combination of NK012 with 5-FU and leucovorin in patients with CRC (NCT01238939)[79]. The second is a phase II clinical trial that aims to investigate the safety and the diagnostic performance of ONM-100, a polymer micelle covalently conjugated to an intraoperative fluorescence imaging agent indocyanine green, for the detection of cancer in patients with solid tumors including CRC patients undergoing routine surgery (NCT03735680)[80].

CONCLUSION

Polymeric micelles are potential candidates for delivery of chemotherapeutic drugs and therapeutic genetic material in single or combination treatment against CRC. Polymeric micelles exhibit a safe profile, help in solubilizing hydrophobic chemotherapeutic drugs and achieve prolonged and stabilized drug circulation in the blood. They also promote the passive accumulation of drugs at CRC sites, potentiate their anticancer activity and reduce their unwanted side effects. Conjugating polymeric micelles with stimuli-responsive and tumor targeting moieties further increases their internalization by cancer cells, thus achieving selective drug release at colorectal tumor sites and enhancing drug anticancer effects. In addition, polymeric micelles ensure an effective and safe delivery of genetic material to modulate the expression of apoptotic players in CRC. Co-delivering genetic anticancer agents with chemotherapeutic drugs using micellar systems is known to augment the therapeutic outcome of the latter and therefore represent a promising combination strategy for combating CRC.

This nanocarrier system also allows the incorporation of imaging agents with therapeutics and offers great potential to achieve tumor diagnosis, in addition to tracking the delivery and release of the therapeutic agent and evaluating its therapeutic performance. Although most of the studies evaluating polymeric micelle-mediated combination chemotherapy in CRC were performed *in vitro*, they yielded interesting results. The delivery of drug combinations using polymeric micelles could further intensify their inhibitory effects against CRC and help overcome drug resistance. However, further pharmacokinetic and pharmacodynamic studies are needed prior to the clinical translation of drug-loaded polymeric micelles. Few polymeric micelles have been used in the clinical setting for CRC treatment and diagnosis with promising outcomes, thus their application merits further investigation.

Abstract

Incretin-based therapies like glucagon-like peptide-1 receptor agonists and dipeptidyl peptidase-4 inhibitors help maintain the glycaemic control in patients with type 2 diabetes mellitus with additional systemic benefits and little risk of hypoglycaemia. These medications are associated with low-grade chronic pancreatitis in animal models inconsistently. The incidence of acute pancreatitis was also reported in some human studies. This inflammation provides fertile ground for developing pancreatic carcinoma (PC). Although the data from clinical trials and population-based studies have established safety regarding PC, the pathophysiological possibility that low-grade chronic pancreatitis leads to PC remains. We review the existing literature and describe the relationship between incretin-based therapies and PC.

Key Words: Diabetes mellitus; Dipeptidyl peptidase-4 inhibitor; Glucagon-like peptide-1 receptor agonist; Incretin; Pancreatitis; Pancreatic Cancer

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Incretin-based therapies are increasingly being used to treat patients with type 2 diabetes mellitus . The early literature regarding pancreatic safety of incretin-based therapies was discordant. However, the follow-up data of various randomised trials have consistently shown that these medications are safe.

INTRODUCTION

Incretin-based therapies such as glucagon-like peptide-1 (GLP-1) receptor agonists (RAs) and dipeptidyl peptidase-4 inhibitors (DPP-4Is) are being increasingly used to treat patients with type 2 diabetes mellitus (T2DM). GLP-1 RAs mimic the action of endogenous GLP-1, whereas DPP-4Is prevent the degradation of GLP-1. These medications can control blood glucose levels without an increased risk of hypoglycemic episodes or weight gain. The initial clinical trials for GLP-1 RA and DPP-4I were conducted in 2003 and 2004, respectively[1,2]. The United States Food and Drug Administration (FDA) issued an alert regarding the potential risk of acute pancreatitis in 2007[3]. DPP-4Is have been widely used owing to the oral administration and low risk of hypoglycemia. However, the use of GLP-1 RA was limited until 2015. But the data from cardiovascular outcome trials (CVOTs) of GLP-1 RAs changed the scenario. The significant reduction in cardiovascular deaths with GLP-1 RAs such as liraglutide and semaglutide tilted the benefit-risk relationship. These therapies have become the next treatment choice after metformin in patients with or at high risk of atherosclerotic vascular disease[4]. Newer generation incretin-based therapies [coagonists of GLP-1 with gastric inhibitory peptide (GIP) or glucagon] are in the pipeline. They are presumed to have higher efficacy than GLP-1 RAs and DPP-4Is. Various incretin-based medications categorised according to their mechanism of action are shown in Table 1.

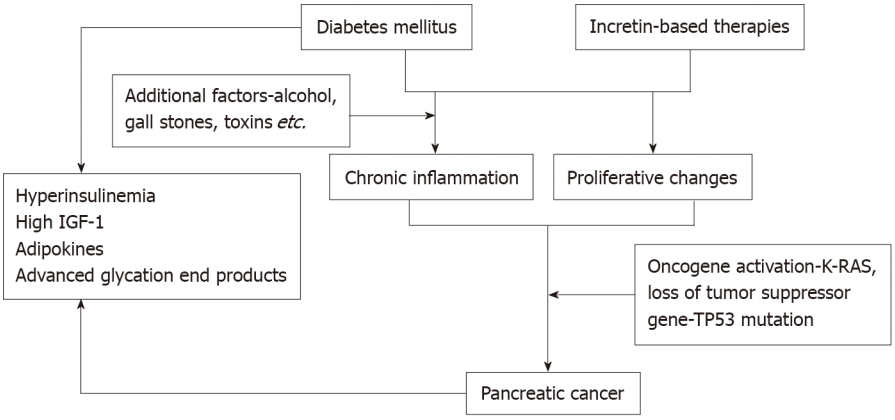
Incretin-based therapies are speculated to induce overstimulation of the GLP-1 receptor, leading to pancreatitis and pancreatic carcinoma (PC). However, the risk of both PC and pancreatitis is increased in DM compared to non-diabetic counterparts[5]. For PC, inflammation is relevant both as a risk factor and an effect of cancer. Patients with chronic pancreatitis carry a higher risk of developing PC. The initial postmarketing surveillance studies for incretin-based therapies revealed an increase in pancreatic adverse events[6]. Further observational studies of pancreatic adverse events showed conflicting results. Post hoc analyses of pertinent randomized controlled trials (RCTs) failed to distinguish pancreatic adverse events between controls and patients on incretin-based therapies[7]. However, the theoretical plausibility of PC in patients receiving incretin-based therapies still remains valid. It is worth reviewing the status of the incretin-based therapies now as an increasing number of therapies based on incretin are becoming available. The treating clinician must be aware of the benefit-risk ratio (RR) when prescribing incretin-based therapy.

SEARCH STRATEGY

Two authors (VS, AR) conducted the initial search in PubMed and Reference Citation Analysis (https://www.referencecitationanalysis.com/) database for relevant articles. The references of these articles were searched for additional relevant studies. The keywords used in the search were: 'Incretin'; 'pancreatic cancer'; glucagon-like peptide-1 receptor agonist'; 'dipeptidyl peptidase-4 inhibitor'; incretin and pancreatic cancer; 'GLP1-RA and pancreatic cancer'; 'DPP-4I and pancreatic cancer'. Only English language publications were included. SK, DN, and JS selected the appropriate articles to be included.

PATHOPHYSIOLOGY

The critical pathophysiologic mechanisms for developing PC in patients using incretin-based therapies are chronic low-grade inflammation and proliferative changes. A flowchart outlining the pathophysiology of pancreatic cancer is shown in Figure 1.



Role of inflammation

Even without any therapy, both PC and pancreatitis incidence is increased in T2DM[8,9]. Long term treatment of T2DM patients with DPP-4Is/GLP-1 RAs may exacerbate the pre-existing chronic inflammation. Any additional mutations in the background of inflammation can tilt the balance toward the

Table 1 Various incretin-based therapies

Class of drugs	Medications
GLP-1RA (oral/subcutaneous)	Subcutaneous-Exenatide, Albiglutide, Lixisenatide, Liraglutide, Semaglutide. Oral-Semaglutide
DPP-4I (oral)	Saxagliptin, Vildaglipitn, Sitagliptin, Aloglipitn, Linagliptin, Teneligliptin
Newer drugs/drugs in development	Tirzepatide (GLP1 + GIP co-agnoist)
	Cotadutide (GLP1 + glucagon co-agonist)
	Teduglutide (GLP-2 RA)
	Triple agnoists (GLP1 + Glucagon + GIP agnoists)

GLP-1RA: Glucagon like peptide receptor-1 receptor agonist; DPP-4I: Dipeptidyl peptidase-4 inhibitor; GIP: Gastric inhibitory peptide; GLP-2RA: Glucagon like peptide receptor-2 receptor agonist.

Figure 1 Flowchart explaining the mechanism of development of pancreatic cancer. IGF-1: Insulin-like growth factor-1; K-RAS: Kirsten rat sarcoma virus gene.

progression of neoplasia. Various researchers conducted animal studies to substantiate this hypothesis using rodents with mutant Kirsten rat sarcoma virus gene (K-RAS), leading to constitutive activation. The K-RAS gene is mutated in > 90% of human PC cases[10]. KC mice model has a single activating mutation (G12D) in the K-RAS gene. Prenatal expression of mutant K-RAS in all exocrine lineages of KC mice resulted in histological changes suggestive of pancreatitis, implying a cooperative relationship between K-RAS activation and inflammation. Treatment of KC mice with the pancreatitis-inducing agent caerulein (a cholecystokinin analog) dramatically accelerates the progression to pancreatic ductal adenocarcinoma (PDAC) within a few weeks[11]. Further animal experiments have shown that K-RAS mutation alone cannot reach the expected theoretical levels of activity required for the progression of carcinogenesis. Nevertheless, agents which cause inflammation can hyperstimulate K-RAS by modulating its activity above the putative threshold necessary for carcinogenesis. The constitutive activation of nuclear factor kappa B pathway in addition to K-RAS in acinar cells significantly accelerates carcinogenesis, whereas cyclooxygenase inhibition is associated with a reduced risk of PDAC. These findings highlight the importance of inflammation in the progression of PDAC[12].

Incretin-based medications induced pancreatitis in animal experiments[13-15]. However, most PDAC cases develop without clinically apparent acute or chronic pancreatitis[16]. This observation can be explained by low-grade subclinical inflammation being sufficient to promote carcinogenesis in the presence of additional drivers of carcinogenesis. On the other hand, it can also be a consequence of the earliest events in carcinogenesis.

Role of proliferative changes

In addition to low-grade asymptomatic chronic pancreatitis, incretin-based medications induce proliferative changes in the islets. Premalignant changes that precede the onset of PDAC are known as pancreatic intraepithelial neoplasia (PanIN) lesions. They herald the start of PDAC. PanINs can be found in up to 50% of the middle-aged population. However, only a few progress to PDAC[17]. As progression of PanINs to PDAC occurs *via* the accumulation of additional somatic mutations, any factor that increases cellular replication in PanINs is likely to increase the likelihood of PDAC. Both PanINs and PDAC express the human GLP-1 receptor. Acinar and duct cells proliferate in response to incretin-

based medications in the normal pancreas with an increase in pancreatic weight[18]. In the setting of chronic pancreatitis, as shown in animal models treated with incretin-based therapies, this proliferation may be sufficient to initiate carcinogenesis event sequences. Treatment with exenatide in KC mice resulted in the formation and growth of dysplastic PanIN lesions in addition to pancreatitis.

Histological changes following incretin-based therapies

The controversy about pancreatic adverse events due to incretin-based therapies was amplified by a publication by Butler *et al*[19]. The authors examined age-matched organ donor samples obtained from the Network for Pancreatic Organ Donation (nPOD). They included a total of 34 subjects with T2DM treated with incretin-based therapies (n = 8) or non-incretin-based therapies (n = 12) and nondiabetic control subjects (n = 14). The incretin group had an increase in pancreatic mass by 40% with increased exocrine cell proliferation and dysplasia. The authors also noticed alpha and beta-cell hyperplasia along with glucagon-expressing microadenomas in incretin-treated subjects. Islet cell costaining for insulin and glucagon was higher in DM subjects than non-DM control subjects and increased further with incretin therapy. The authors concluded that incretin therapy in humans results in the expansion of both exocrine and endocrine pancreatic compartments and that there is a potential for evolution into neuroendocrine tumors. However, this study was met with sharp criticism owing to methodological flaws. Harja *et al*[20], in a more detailed analysis of the nPOD database, found that the baseline characteristics were not comparable between the incretin group and the other two groups. Pancreatic weight data were missing for half of the subjects. The increase in PanINs can be explained by the nearly 20-year age difference between the incretin group and the other two groups. Bonner-Weir *et al*[21] and Kahn[22] also re-analyzed the data from nPOD and reached similar conclusions.

Despite the flaws in the study methodology, this study caught the attention of the FDA and the European Medicines Agency (EMA). Both agencies reviewed all available animal and human data for incretin-based therapies. Microscopic examinations from animal studies did not reveal pancreatic lesions or pancreatitis. Even at doses greater than human clinical exposure to incretin-based therapies, there were no tumours in rodents for up to 2 years (lifespan of rodents). The FDA studied the effect of exenatide in Zucker diabetic fatty rat, a chemical-induced pancreatitis model, and C57 black 6 (C57BL/6) high-fat diet mouse model. There was no identifiable pancreatic pathology in the pancreatitis mouse model and Zucker diabetic fatty rat model. After three months of exenatide in the C57BL/6 high-fat diet mouse, a minimal-to-moderate worsening of background findings was noted. Based on the available data, they could not draw any conclusions about the risk of pancreatic adverse events in patients using incretin-based therapies[23].

Ueberberg *et al*[24] conducted a study on cadaveric pancreata, similar to Butler *et al*[19]. They obtained pancreatic tissue during surgery from 13 diabetic patients (7 in the incretin group and 6 in the non-incretin group), 11 non-diabetic controls, and nine brain-dead organ donors. There were no differences between groups in the alpha cell area, beta and alpha cell replication, acinar, and ductal cell replication. Coexpression of insulin and glucagon has not been demonstrated. PanIN lesions were more common in the diabetic group, although the prevalence was low. Considering the small sample size and large interindividual variability, the authors advised caution on coming to any conclusion from such studies.

Chadwick *et al*[25] attempted to determine the background incidence of spontaneous pancreatic lesions in different rat strains fed a standard or high-fat diet over four months. They found that the pancreatic lesions previously thought to be due to incretins are common baseline findings. These lesions can be seen without any drug treatment. These lesions were independent of diet or glycaemic status. The authors concluded that we need to be cautious when interpreting patients' pancreatic findings on incretin-based therapies. Aston-Mourney *et al*[26] tried to characterize the amyloidogenic potential of sitagliptin in rodents. Human islet amyloid polypeptide transgenic mice, untreated nontransgenic mice, and those on treatment with sitagliptin, metformin, or the combination were followed up for one year. There was no increase in amyloid formation or ductal proliferation. However, there was an improvement in β-cell secretion, suggesting endocrine protective effects without associated toxicity to the exocrine compartment of the pancreas.

Effect of incretin-based therapies on cancer cells

The effect of incretin-based therapies on PC cells has also been studied *in vitro*. Lu *et al*[27] found that liraglutide in combination with metformin has synergistic anti-tumor effects *in vitro*. Yan *et al*[28] examined the effect of exendin-4 on a xenograft tumor model. Exendin-4 suppressed the PC cell proliferation by attenuating the function of pancreatic stellate cells (PSC) and suppressing extracellular matrix deposition. Zhao *et al*[29] examined the effect of liraglutide on PC cell line (PANC-1) cocultured with and without PSCs and found that liraglutide significantly reduced the migration and invasion of the PANC-1 cells. The authors hypothesized that the effect is probably mediated by calcium and calcium-binding proteins. In another study, Zhao *et al*[30] examined the effects of liraglutide on the chemosensitivity of PC cells to gemcitabine in PANC-1 and gemcitabine resistant cell lines (PANC-GR). Liraglutide inhibited proliferation and promoted apoptosis of the PANC-GR cells in a dose-dependent manner. It also increased GLP-1 receptor and protein kinase-A expression in the PANC-GR cells. In rodent studies, liraglutide treatment was observed to increase the chemosensitivity of PC cells to

gemcitabine.

DPP4 and cancer

DPP-4 cleaves many other polypeptides, such as chemokines, neuropeptides in addition to GLP-1. DPP-4, also known as cluster differentiation marker 26, plays a vital role in inflammation by modulating the inactivation of cytokines and chemokines. DPP-4 is expressed in various malignancies. The overexpression of DPP-4 exerts an antitumour effect predominantly through immunomodulation[31]. DPP-4 inhibition has been shown to improve antitumor immune response by preserving the function of a chemokine C-X-C motif ligand and through interleukin 33 (IL-33) mediated tumour control[32,33]. The effects of DPP-4 on cancer cells appear to be heterogeneous, depending on tumor types, stages, microenvironment, and host condition. In breast cancer and small cell lung cancers, decreased expression of DPP-4 is associated with more aggressiveness of the tumour. However, increased DPP-4 expression levels have been associated with poor prognosis in patients with PC[31].

INCRETIN-BASED THERAPIES AND PC-HUMAN STUDIES

Data from observational studies

Early case reports of pancreatitis following exenatide and sitagliptin led to the issue of FDA alert in 2007. These reports led to many database analyses to look for the prevalence of pancreas-related adverse events. Elashoff *et al*[6] raised concern regarding PDAC by studying the FDA adverse events reporting system (FDA AERS) during 2004-09. This study resulted in widespread coverage in media regarding the risk of PC. Elashoff *et al*[6] examined FDA AERS database for adverse events associated with exenatide and sitagliptin in this study. The odds ratio for reported pancreatitis was 6-fold higher for sitagliptin or exenatide users than other therapies. PC was also more frequent (approximately 3-fold) among patients who took sitagliptin or exenatide. However, we must understand that this was a retrospective, record-based study. The likelihood of reporting events is higher with new drugs than with the patients on older drugs. A series of observational studies followed this study and showed discordant results. Most of the observational studies were retrospective and record-based. Both the FDA and the EMA reviewed their clinical safety databases, and the pooled data did not reveal any compelling evidence of an increased risk of pancreatitis or PC.

The latest observational study from Montvida *et al*[34] used Centricity Electronic Medical Records from the United States. The authors assessed the time to pancreatic events for incretin-based and nonincretin therapies (sulfonylurea, thiazolidinedione, and insulin). This study surprisingly found that the group treated with insulin had higher pancreatitis events with a short time to event as compared to incretin-based therapies. For PC, the time to event rate was not significantly different between the groups. Among the older studies, few studies showed an increased risk of pancreatitis and PC, but most studies could not find any association between pancreatic adverse events and incretin-based therapies [34-38]. Although the sample size was adequate for these studies, we must keep in mind the unaccounted confounders. The baseline characteristics and the comparator drugs varied among different studies. A summary of these studies is compiled in Table 2.

Data from randomised controlled trials

Data from RCTs have conventionally been considered superior to data from observational studies. There have been many follow-up studies of the patients recruited for CVOT of the incretin-based therapies. Among the individual CVOT data, there was a non-significant trend for or against the development of PC for different incretin-based therapies. Many researchers also assessed the PC risk with incretin-based therapies using meta-analyses and systematic reviews. Alves *et al*[39] evaluated the association of liraglutide or exenatide with PC in a meta-analysis that included 25 longitudinal studies in 2012. Neither GLP-1 RAs nor DPP-4Is were associated with increased risk for PC.

The first meta-analysis evaluating PC association with all types of incretin-based therapies was published by Chen *et al*[40] in 2016. This meta-analysis included 24 RCTs enrolling 47904 patients. This meta-analysis also could not identify any increased risk of PC either as monotherapy (RR = 0.62, 95%CI: 0.38–1.01) or combination therapy (RR = 0.92, 95%CI: 0.45–1.90). This result was followed by a series of meta-analyses with a similar conclusion[41-43]. The latest meta-analysis is from Abd El Aziz *et al*[43], which evaluated 11 CVOTs studying 55921 patients. In the individual study data, lixisenatide and semaglutide were associated with nominally reduced RR, whereas liraglutide was associated with a slightly elevated RR. However, none of these RRs were statistically significant. In this meta-analysis, neither GLP-1 RAs nor DPP-4Is were associated with a significant increase or decrease in risk of PC [RR for PC- for GLP-1 RA 0.99 (95%CI: 0.9-1.08); DPP-4I 0.92 (95%CI: 0.83-1.01)]. The summary of the data from various meta-analyses is compiled in Table 3.

Newer incretin-based therapies

Tirzepatide is a dual agonist at GLP-1 and GIP receptors. It was formulated as a fatty acid-modified

Table 2 Important observational studies which evaluated the relationship between incretin-based therapies and pancreatic carcinoma

Ref.	Study design	Population	Findings
Elashoff *et al* [6], 2011	Retrospective study (Control drugs-rosiglitazone, glinides, glipizide), 2004-09	Database-FDA AERS. Patients of T2DM on exenatide and sitagliptin. *n* = 1541 events (exenatide). *n* = 322 (sitagliptin). *n* = 691 (controls)	PC was more common among patients who took sitagliptin (2.7-fold) or exenatide (2.9-fold) as compared with other therapies
Montvida *et al*[34], 2019	Retrospective record-based study. 2005 onwards. Follow-up duration 2.27-4.3 yr	Centricity electronic medical record, United States. DPP-4i *n* = 50095. GLP-1 RA *n* = 12654. SU *n* = 110747. TZD *n* = 17597. Insulin *n* = 34805	Compared with DPP-4i, the GLP-1 RA group developed PC 3 yr later (95%CI: 0.84-5.16). No other significant differences were observed between groups
Nagel *et al* [35], 2016	Retrospective study (Control drugs-rosiglitazone, glinides, glipizide), 1968-2013	Database-FDA AERS. Patients of T2DM on sitagliptin, saxagliptin, linagliptin, and alogliptin. *n* = 156 PC patients	EB05 was 10.3 for sitagliptin, 7.1 for saxagliptin, 4.9 for linagliptin, and 1.4 for alogliptin, compared with all other agents
Azoulay *et al* [36], 2016	Nested case control analysis (control drug- sulfonylureas), 2007-2014. Follow-up 1.3-2.8 yr	Database-CNODES (Canada, United States, United Kingdom). *n* = 972384	Compared with SUs, incretin-based drugs were not associated with an increased risk of PC-pooled aHR 1.02 (95%CI: 0.84-1.23)
Tseng *et al* [37], 2017	Retrospective population-based cohort study, 1997-2010. Follow up-till occurrence of adverse pancreatic event	Database-The Taiwan National Health Insurance Research Database. *n* = 13171 incretin. *n* = 13171 non-incretins	PC occurred in 6 (0.05%) and 10 (0.08%) patients in the incretin and non- incretin cohort, respectively
Boniol *et al* [38], 2018	Retrospective cohort study, 2008-2013. Follow-up 1.8-2.3 yr	Public health insurance databases of Belgium, Lombardy (Italy). *n* = 33292 incretin. *n* = 525733 control	The aHR for PC was 2.14 (95%CI: 1.71–2.67) for incretin group compared with control

FDA AERS: Food and drug administration adverse event reporting system; T2DM: Type 2 diabetes mellitus; PC: Pancreatic carcinoma; EB05: Empirical Bayesian fifty centile; aHR: Adjusted hazard ratio; CI: Confidence interval; CNODES: Canadian network for observational drug effect studies; SU: Sulfonylurea; OHA: Oral hypoglycemic agent; RR: Risk ratio; TZD: Thiazolidinedione.

Table 3 Important systematic reviews and meta-analyses which evaluated the relationship between incretin-based therapies and pancreatic cancer

Ref.	Description	Findings
Alves *et al* [39], 2012	All studies (25 RCT/longitudinal observational) assessing the estimate of pancreatitis/PC in patients with T2DM using exenatide or liraglutide	For PC risk, the OR of exenatide was 0.86 (95%CI: 0.29-2.60) and liraglutide was 1.35 (95%CI: 0.70-2.59)
Chen *et al* [40], 2016	All RCTs reporting PC with use of incretin-based therapies compared with placebo or non-incretin anti-diabetic drugs in patients with T2DM	Overall, no increased risk of PC was detected in association with incretin-based treatment (RR = 0.7, 95%CI: 0.37–1.05). The incidence of PC was even lower among incretin-based groups than controls (RR = 0.50, 95%CI: 0.29–0.87) in trials with duration more than 104 wk
Zhang *et al* [41], 2017	6 prospective randomized controlled trials (EXAMINE, SAVOR-TIMI 53, TECOS, ELIXA, LEADER and SUSTAIN-6)-3 trials for DPP-4is and 3 trials for GLP-1 RAs	Incretin-based agents did not significantly affect PC-OR: 0.71 (95%CI: 0.45–1.11)
Pinto *et al* [42], 2019	12 RCTs with GLP-1 RAs as an intervention, from database inception till 2017	GLP-1 RAs did not increase the risk for pancreatic cancer when compared to other treatments-OR: 1.06 (95%CI: 0.67-1.67)
Abd El Aziz *et al* [43], 2020	Meta-analysis of cases of acute pancreatitis and PC as well as any malignant neoplasm reported in 11 CVOTs with GLP-1 RAs and DPP-4i	Neither GLP-1 RAs nor DPP-4is were associated with a significantly elevated or reduced risk of PC. For GLP-1 RA OR was 1.14 (95%CI: 0.77-1.7) and for DPP4i OR was 0.94 (95%CI: 0.52-1.68)

PC: Pancreatic cancer; RCT: Randomised controlled trial; T2DM: Type 2 diabetes mellitus; OR: Odds ratio; RR: Risk ratio; CVOT: Cardiovascular outcome trial; GLP-1 RA: Glucagon like peptide-1 receptor agonists; DPP-4i: Dipeptidyl Peptidase-4 inhibitors; OHA: Oral hypoglycemic agent.

peptide based on the native GIP sequence. Tirzepatide demonstrated a more significant reduction in glycosylated hemoglobin, superior weight loss, and comparable adverse effects compared to semaglutide in a phase 3 trial. Pancreatitis was observed in four patients in the tirzepatide arm and three patients in the semaglutide arm during the study duration[44]. Cotadutide is a balanced GLP-1 and glucagon receptor dual agonist. Phase 2 clinical trials for cotadutide were published recently. The efficacy of cotadutide also appears to be better than that of semaglutide, although no head-to-head comparison is available. No case of pancreatitis has been reported in the phase 2a study of cotadutide, although the frequency of nausea and vomiting was increased in the cotadutide arm[45]. We must therefore wait until we have sufficient data on these new drugs. It is premature to make comment on the pancreatic safety of these drugs at present.

CONCLUSION

We have collected extensive data on the safety of incretin-based therapies over the past two decades. It seems that incretin-based therapies do not increase the risk for PC. Instead, new pre-clinical experimental data have shown beneficial effects on cancer cell lines that require further evaluation. The uncertain risks of PC appear to be smaller compared to the beneficial pleiotropic effects of incretin-based therapies. However, with newer incretin-based therapies, we should keep the theoretical possibility of PC in mind and be cautious until we obtain sufficient data.

Abstract

Non-alcoholic fatty liver disease (NAFLD) is the most common chronic liver disease worldwide and is strongly associated with metabolic deregulation. More recently, a significant impact of parental NAFLD in the offspring was demonstrated and has been widely discussed. However, pathogenetic pathways implicated in the inheritance by the offspring and relatives are still under debate. Probably, multiple mechanisms are involved as well as in NAFLD pathogenesis itself. Among the multifactorial involved mechanisms, genetic, epigenetic and environmental backgrounds are strongly related to NAFLD development in the offspring. Thus, based on recent evidence from the available literature concerning genetic, epigenetic and environmental disease modifiers, this review aimed to discuss the relationship between parental NAFLD and its impact on the offspring.

Key Words: Steatosis; Genetic; Epigenetic; Environmental; Offspring; Non-alcoholic fatty liver disease

Core Tip: Non-alcoholic fatty liver disease (NAFLD) is a multifactorial disease and familial clustering has been described, although there is still some debate about this association. Among the factors that contribute to the disease in the offspring of NAFLD patients, genetic, epigenetic and environmental factors are the most plausible ones. In this review we describe the main genetic, environmental and epigenetic factors linked to NAFLD and the studies investigating the relation of NAFLD in parents and its offspring. Although there are many experimental studies in animals, there is still much to be elucidated regarding studies and interventions in human beings.

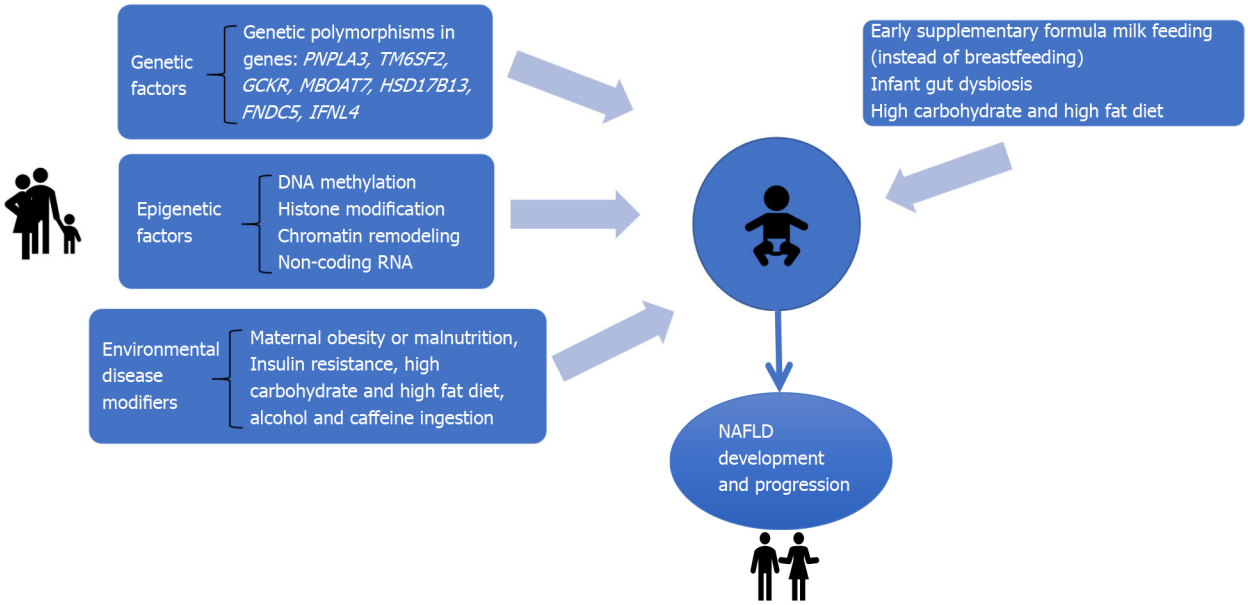
INTRODUCTION



Although non-alcoholic fatty liver disease (NAFLD) is being replaced by metabolic dysfunction-associated fatty liver disease[1], studies concerning genetic and epigenetic factors in this new scenario are still scarce. This way, we will still adopt the nomenclature NAFLD when discussing the studies in this review.

NAFLD affects about 25% to 45% of the world's western population[2]. The spectrum of the disease includes simple steatosis, steatohepatitis with or without fibrosis, leading to cirrhosis, hepatic decompensation and hepatocellular carcinoma (HCC)[3]. NAFLD is currently the third indication for liver transplantation worldwide, and it will potentially be the leading indication in 2030[4].

Many cofactors have been recognized and related to NAFLD's high prevalence and severity. Metabolic syndrome, obesity and type 2 diabetes mellitus (T2DM) are the most relevant factors associated with progression from non-alcoholic fatty liver (NAFL) to non-alcoholic steatohepatitis (NASH) and fibrosis. Patients with T2DM have a higher prevalence of NAFLD, with a high prevalence of NASH and advanced fibrosis[5]. In a bidirectional relation, NAFLD also increases up to 5.5 times the risk of future development of T2DM and could be considered an early predictor of the disease[6]. Ethnicity also influences NAFLD prevalence, with Hispanics presenting a higher prevalence than Caucasians and African Americans, independently of metabolic factors. The genetic and environmental basis could be responsible for these findings in diverse ethnic groups[7]. Accordingly, the observation of NASH and cirrhosis familial clusters suggests a substantial hereditary influence on NAFLD progression [8]. Data from diverse epidemiological, familial aggregation and twin-cohorts studies, with a well-designed methodology, suggest that hepatic steatosis is highly heritable[9-12]. Some of these studies used magnetic resonance elastography to assess liver fibrosis or serum aminotransferase levels to infer hepatic steatosis. They demonstrated a high prevalence of NAFLD in family members of children with NAFLD, monozygotic and dizygotic twins, and first-degree family members of T2DM patients[11,13]. So far, the risk of hepatic steatosis and more severe disease in family members and children of patients with NAFLD is not fully understood, as well as the pathogenetic pathways involved in this process.

Genome-wide association studies have demonstrated the association of single nucleotide polymorphisms (SNP) with NAFLD. Patatin-like phospholipase-domain-containing 3 (rs738409 C>G encoding for PNPLA3 I148M), also known as adiponutrin gene, is located at chromosome 22 and was the first SNP described[14]. Although this is the most robust variant linked to NAFLD, additional genetic variants have been identified subsequently: Transmembrane 6 superfamily member 2 (TM6SF2) [15], glucokinase regulator (GCKR)[16], membrane-bound O-acyltransferase domain-containing 7 (MBOAT7)[17] and hydroxysteroid 17 β-dehydrogenase (HSD17B13)[18], among others. These variants have been associated with multiple pleiotropic effects, including a protective effect for NAFLD as seems to occur with the HSD17B13 polymorphism[18]. The different phenotypes resulting from these genes might partially explain the heritable component and metabolic profile of NAFLD patients and their offspring[9].

Although our understanding of genetic influence has exponentially increased in the past few years, it cannot thoroughly explain the high prevalence of NAFLD in family members of patients with the disease. Experimental studies have investigated different pathways related to NAFLD development in the offspring[9,19,20]. In this context, environmental and epigenetic mechanisms play an essential role in the occurrence and progression of NAFLD. Epigenetic factors involve mechanisms that affect and regulate gene expression without changes in DNA sequences[21]. Therefore, gene expression and cell phenotype related to NAFLD might depend on the genetic information encoded by DNA sequences and epigenetic factors[22]. Figure 1 shows the multifactorial mechanisms implicated in the offspring's NAFLD development. This review aims to discuss the impact of genetic, epigenetic and environment-related variables associated with NAFLD in the offspring.

HERITAGE AND GENETIC FACTORS

Studies in familial clusters and twin cohorts

Several studies have shown a solid familial clustering of NAFLD, particularly in coexisting metabolic traits[23-25]. Familial combined hyperlipidemia is the most frequent genetic dyslipidemia with a high risk of premature atherothrombotic cardiovascular disease. To assess whether liver steatosis is involved in the pathogenetic pathway of familial combined hyperlipidemia, Brouwers *et al*[23] studied family members with steatosis and twenty spouses. Fatty liver diagnosed by ultrasound was significantly more prevalent in familial combined hyperlipidemia probands (40%) and relatives (35%) compared with their spouses[23]. Moreover, the authors evaluated the correlations between indicators of fatty liver with plasma lipid levels. Liver steatosis and alanine aminotransferase levels correlated with triglyceride levels in all familial combined hyperlipidemia family members[23].

In the multigenerational Framingham Heart Study, a community-based study, individuals with at least one parent presenting hepatic steatosis had two-fold increased odds of having liver steatosis themselves than those without a parental history. More participants without metabolic diseases had liver steatosis if they had at least one parent with liver steatosis than those without any parent with steatosis. On the other hand, there was no difference in the prevalence of steatosis in patients with high cardiometabolic risk among participants with or without a parental history of liver steatosis. Based on these findings, this study suggested that a family history of liver steatosis was a significant risk factor for liver steatosis, but only in metabolically healthy participants[26]. This study goes against the previous one, which showed a higher prevalence of steatosis in those with familial hyperlipidemia. There was no investigation if the genetic aspects of those patients with familial hyperlipidemia could have influenced the higher prevalence of steatosis.

Schwimmer *et al*[11] evaluated 33 overweight children with biopsy-proven NAFLD and 11 overweight children without; NAFLD was significantly more observed in siblings and parents of the NAFLD children group. The correlation of liver fat fraction to body mass index (BMI) was more substantial in overweight children with NAFLD than without NAFLD, showing that there is likely an interaction between BMI and genetic factors on steatosis severity in families of children with NAFLD [11].

Similar to steatosis, hepatic fibrosis in NAFLD is also a heritable trait. Familial aggregation studies revealed a marked coexistence of advanced fibrosis or NAFLD cirrhosis among index patients and their first-degree relatives[24,25]. A cross-sectional analysis demonstrated that first-degree relatives of probands with NAFLD cirrhosis present a 12 times higher risk of advanced fibrosis compared with the relatives of non-NAFLD controls[25]. Interestingly, in another recent cross-sectional study of a prospective cohort comprising 156 twins and their families, the same authors identified a metabolite (3-4-hydroxyphenyl lactate) related to the abundance of several gut microbiota species in individuals with advanced fibrosis. Then, in their conclusions, they propose a link between genetics and microbiota composition concerning NAFLD heritability[27].

The potential genetic link of NAFLD regarding steatosis and fibrosis inheritance triggered the development of studies in twins to evaluate if both steatosis and fibrosis had a significant shared gene. The first study on twins regarding NAFLD inheritance included 60 monozygotic and dizygotic twins [13]. Both liver steatosis and fibrosis were non-invasively quantified by magnetic resonance imaging. The presence of hepatic steatosis by proton-density fat fraction magnetic resonance imaging (MRI) and fibrosis by magnetic resonance elastography correlated between monozygotic twins but not between dizygotic twins, providing evidence that both hepatic steatosis and fibrosis might be heritable traits as well[13].

Following the same rationale, Cui *et al*[10] investigated a prospective cohort of community-dwelling monozygotic and dizygotic twin pairs living in Southern California, using non-invasive proton-density fat fraction MRI and magnetic resonance elastography to assess steatosis and fibrosis. They investigated if individuals prone to genetic susceptibilities to steatosis and fibrosis also had genetic susceptibilities to metabolic variables such as arterial hypertension, dyslipidemia, insulin resistance and diabetes mellitus. The authors have shown that hepatic steatosis and fibrosis have statistically and clinically significant shared genetic determination and metabolic traits such as high-density lipoprotein, triglycerides, insulin resistance, and glycosylated hemoglobin[10]. In another study, the same cohort of twins was evaluated regarding the metabolites of the gut microbiome and its effect on steatosis and liver fibrosis compared to a biopsy-proven NAFLD cohort. This proof of concept study provided a link between the gut-microbiome and 3-lactate that shared gene-effect with hepatic steatosis and fibrosis[27]. Hence, the heritage of NAFLD might relate to multiple factors like a genetic inheritance that could directly affect steatosis and fibrosis and heritable traits of the gut microbiome inherited, or even be influenced by a shared lifestyle in the probands and its parents.

Genetic polymorphisms

Genetic polymorphisms are involved in NAFLD expression regarding its relation with liver steatosis, advanced stages of fibrosis, and even a possible protective effect for disease progression[9,18,28]. However, studies evaluating their impact on the offspring of patients with NAFLD are scarce.

As previously described, PNPLA3 rs738409 C>G variant is associated with hepatic steatosis and severity of NAFLD, progression to cirrhosis and HCC, resulting in a worse prognosis[14]. PNPLA3 encodes a triacylglycerol lipase, and this variant promotes hepatic triglyceride accumulation by restricting substrate access to the catalytic dyad, thus inhibiting triglyceride hydrolysis in the cell[14].

TM6SF2 function is related to regulating cholesterol synthesis and secretion of lipoproteins. Individuals who carry the SNP rs58542926 C>T, which encodes the E167K amino acidic substitution, have a higher risk of NAFLD and histological disease severity. However, there is still a strong debate if it has a protective effect on coronary artery disease. A large study with 60801 patients with coronary artery disease compared to 123504 healthy individuals described a protective effect of the T variant of TM6SF2 on this disease and found an equivalent, although modest effect for the G variant of PNPLA3, that was more intense in the recessive model (genotype GG). At last, an exome study including more than 300000 individuals showed that both TM6SF2 and PNPLA3 polymorphisms induce a protective effect on coronary artery disease and an increased risk of NAFLD[29]. So far, there is no study regarding the evaluation of the impact of TM6SF2 in the offspring of NAFLD patients.

In young adolescents, the rs1260326 C>T variant in GCKR was significantly associated with de novo lipogenesis in those with TT genotype. Another variant in GCKR, the rs780094 A>G, was also associated with NAFLD in a meta-analysis involving 2091 cases and 3003 controls[30].

MBOAT7 was first studied in alcohol abusers and was related to a higher risk of cirrhosis. It encodes a protein involved in the re-acylation of phospholipids as a component of the phospholipid-remodeling pathway, known as the land cycle. Subsequently, the rs641738 C>T variant in this gene was associated with increased hepatic fat, more severe liver damage and fibrosis in NAFLD individuals of European descent; moreover, it has been demonstrated that the T allele may predispose to HCC in patients without cirrhosis[31].

Recently, three polymorphisms have been identified as protective against advanced stages of NAFLD. Results from exome-sequence data from 46455 individuals have shown an association of rs72613567:TA in HSD17B13, a variant with an adenine insertion, with lower levels of aminotransferases and reduced risk of chronic liver disease, including NASH[18]. Pirola *et al*[32] demonstrated the effect of this variant on a Hispanic population submitted to liver biopsy, investigating its association with histological parameters of NAFLD. They identified a lower risk of ballooning degeneration, lobular inflammation and liver fibrosis, mediated by reduced enzyme activity in converting retinol to retinoic acid, suggesting a protective effect in inflammation and fibrosis[32]. Di Sessa *et al*[33] evaluated 685 obese children (mean age 10.56 ± 2.94 years) and demonstrated that carriers of the HSD17B13 A allele had a lower percentage of liver steatosis on ultrasound imaging and lower serum aminotransferases levels[33].

Petta *et al*[34] evaluated the role of irisin, a myokine encoded by the fibronectin type III domain-containing protein 5 gene (FNDC5), in NAFLD patients. The variant rs3480 A>G was not associated with the severity of steatosis and NASH but was correlated with a lower prevalence of clinically significant fibrosis (F2-F4), showing a protective effect against fibrosis. They also found that irisin is expressed in human activated hepatic stellate cells, promoting profibrogenic actions and collagen

synthesis. Thus, the FNDC5 genotype might affect hepatic fibrogenesis by modulating irisin secretion [34].

The genetic polymorphisms associated with NAFLD, their functions and effects are summarized in Table 1.

Concerning NAFLD and family inheritance, the PNPLA3 polymorphism was the only one studied. Overweight and obese children with NAFLD confirmed by histology were evaluated regarding the role of lifetime exposures in association with a genetic predisposition, parental obesity, economic income, programming during fetal life, being breastfed or not, and later biomarkers of dietary habits and lifestyle, correlating with fibrosis. In this study, 75% of the children had fibrosis, independently associated with PNPLA3-GG genotype, parental obesity, not being breastfed, vitamin D levels (< 20 mg/dL) and fructose consumption. Notably, a high socioeconomic maternal occupation was related to less severe fibrosis[35]. These findings reinforce the multifactorial impact of NAFLD inheritance. Recently, Jain *et al*[36] studied 51 patients with NAFLD and their parents compared to 50 individuals without NAFLD and their parents as a control group. They observed that parents of the NAFLD group had a higher frequency of GG genotype when compared to parents of those without NAFLD (15% *vs* 5%)[36]. In this study, no other factors except for PNPLA3 polymorphism were evaluated.

ENVIRONMENTAL AND EPIGENETIC FACTORS: EVIDENCE IN EXPERIMENTAL AND CLINICAL STUDIES

In addition to the genetic information encoded by DNA sequences, epigenetic modifications increase or inhibit the expression of specific genes and affect chromatin structure without modifying nucleotide sequence. Epigenetics implies inheritable changes in the expression of genes, but they can also be acquired and may occur in response to environmental factors, such as nutrition, contributing to disease risk and severity[37]. These alterations can be transferred to the next generation and, in this way, may modify metabolic and NAFLD risk in the offspring. As epigenetic changes can be inheritable and modulated by environmental stimuli, they are considered reversible and could offer new individualized prevention and therapy[37]. So far, the impact of maternal and/or paternal risk factors on the clinical phenotypes of the offspring and the underlying epigenetic mechanisms has not been fully elucidated [37].

Epigenetic phenomena include four regulatory mechanisms: Modification in DNA methylation, covalent histone modification, chromatin remodeling, and RNA-based mechanisms, such as non-coding RNA. DNA methylation is the most studied[22,38].

Experimental studies

Some experimental studies, most of them in mice, tried to elucidate the mechanisms involved in the inheritance of NAFLD and the external factors that could modulate NAFLD development in the offspring through epigenetic factors. It has been shown that many factors during pregnancy may activate lipogenic and inflammatory pathways leading to NAFLD in the progeny[19]. Many authors have studied the impact of breastfeeding, maternal obesity and diet before or during pregnancy in animal models.

Oben *et al*[19] demonstrated that maternal obesity before and throughout pregnancy and lactation could be linked to dysmetabolism in the offspring of female mice. Offspring of obese dams showed a dysmetabolic pattern related to insulin resistance and NAFLD phenotype. Moreover, the offspring of lean dams fed by obese dams presented increased body weight and higher insulin levels and cytokines such as leptin, interleukin-6 and tumor necrosis factor-alpha. Raised levels of leptin were also observed in the breast milk of obese mice compared to lean ones. They proposed that a modified pathway over hypothalamic appetite nuclei signaling by maternal breast milk and neonatal adipose tissue-derived leptin in the early postnatal period was the mechanism behind these findings.

Considering the hypothesis that diet during and after pregnancy might also be involved in NAFLD in the post-weaning period, Pruis *et al*[39] observed that a maternal western-type diet during pregnancy could stimulate metabolic programming or phenotype induction, leading to NAFLD development.

Another study[40] suggested that modifying the diet during pregnancy could benefit the offspring by preventing a disrupted liver lipid profile[61]. When pregnant mice were fed either with a high fat-slow digestive diet or a rapid digestive diet, the offspring of the high fat-rapid digestive diet showed an abnormal liver lipid profile. However, it was not observed in their counterparts born from high fat-slow digestive diet fed-mice.

The relationship between obesity in pregnancy and circadian cycle deregulation might affect metabolic pathways related to NAFLD in adults. Mouralidarane *et al*[20] suggested that, in addition to an obesogenic post-weaning diet, obesity in the mother might lead to NAFLD by disrupting the liver's canonical metabolic rhythmicity gene expression. It implicates the role of abnormal circadian rhythm in the genesis of NAFLD, and alterations in this system during critical developmental periods might be responsible for the onset of the disease later in adulthood.

Table 1 Genetic polymorphisms involved in non-alcoholic fatty liver disease occurrence and related phenotypes

Gene	Variant (s)	Function	Phenotype
PNPLA3	rs738409 C>G	Triglyceride hydrolysis	↑ NAFLD, NASH, fibrosis, HCC
TM6SF2	rs58542926 C>T	Lipoproteins secretion	↑ NAFLD, NASH, fibrosis
GCKR	rs1260326 C>Trs780094 A>G	De novo lipogenesis regulation	↑ NAFLD, NASH, fibrosis
MBOAT7	rs641738 C>T	Phospholipid metabolism	↑ NAFLD and fibrosis
HSD17B13	rs72613567:TA	Conversion of retinol to retinoic acid	↓ NASH and fibrosis
FNDC5	rs3480 A>G	Hepatic fibrogenesis	↓ fibrosis

rs: Reference SNP; NAFLD: Non-alcoholic fatty liver disease; NASH: Non-alcoholic steatohepatitis; HCC: Hepatocellular carcinoma.

Another issue that might be considered regarding further development of NAFLD after birth is ethanol exposure[41]. Shen *et al*[41] developed a rat model of intrauterine growth retardation by prenatal ethanol exposure. These models were fed with normal and high-fat diets. Enhanced liver expression of the insulin growth factor-1 pathway, gluconeogenesis, lipid synthesis and diminished expression of lipid output were accompanied in prenatal ethanol exposure female offspring fed with a high-fat diet.

Oliveira *et al*[42] studied Wistar rats fed with a standard diet and a high-fat diet. Rats born from mice fed with a standard diet were not affected by changes in liver morphology, as did the offspring of high-fat-fed rats. Therefore, the study concluded that fructose intake during adolescence hastens NAFLD onset and reveals a differentiated hepatic response to metabolic insult, depending on the maternal diet. Notwithstanding, Nicolás-Toledo *et al*[43] showed that sucrose intake in adulthood increases fat content only in female rat offspring of dams fed with a low-protein diet during pregnancy, reinforcing the influence of maternal diet in the offspring[43]. Of note, regarding specific epigenetic mechanisms, Suter *et al*[44] have described that epigenetic changes to histones may act as a molecular memory of intrauterine exposure, rendering the risk of adult disease. The genome-wide epigenetic modifications in the fetal liver of susceptible offspring were analyzed, concluding that a maternal high-fat diet is associated with functional alterations to fetal hepatic histones, some of which may persist up to five weeks of age[44].

Another study by Wei *et al*[45] connected NAFLD with epigenetic methylation of specific genes in fathers that can be transmitted from gametes to embryos across generations. They have shown that even paternal diet patterns and prediabetes increase the risk of diabetes in the offspring through gametic epigenetic alterations such as different methylation of genes in the sperm of prediabetic fathers.

All these experimental studies in animal models have revealed that maternal obesity and parental diet during pregnancy or lactation may significantly influence NAFLD and lipid dysmetabolism in the offspring, either by environmental factors or through epigenetic factors, some yet to be better specified, mainly concerning environmental factors. Hence, cofactors as alcohol and fructose intake, among others not yet identified, may activate lipogenic and inflammatory pathways that can lead to NAFLD in the offspring.

Clinical studies

Studies in mothers and newborns: Animal studies confirmed that disruptions during early development could lead to increased susceptibility to metabolic dysfunctions later in life. Likewise, human data support that metabolic dysfunction and its contribution to NAFLD can be closely related to genetic and environmental predisposing factors. However, the precise mechanisms that link changes in pre and postnatal environments with NAFLD development risk in adolescence and adulthood remain poorly understood. These mechanisms involve shifts in lipid metabolism, mitochondrial dysfunction, altered gut microbiota, macrophage programming and activation of epigenetic changes.

In prior studies, it was demonstrated that low birth weight babies exhibit an altered postnatal metabolism after developing an adaptative response to a suboptimal fetal environment[46,47]. Although the mechanism is not entirely understood, exposure to excessive and deficient nutrition during the prenatal period may induce a nutritional mismatch between metabolic efficiency and energy expenditure, increasing the risk of future cardiometabolic diseases. If confirmed, an early and straightforward nutritional intervention might prevent the further development of metabolic diseases in adulthood.

Modi *et al*[48] evaluated 105 healthy mother-neonate pairs. They measured neonatal adipose tissue content by whole-body MRI and intrahepatic lipid content by a proton magnetic resonance spectroscopy. They have demonstrated that infant adiposity, particularly abdominal adipose tissue and intra hepatocellular lipid correlated with increased maternal BMI. Recently, Bedogni *et al*[49] studied the prevalence and risk factors associated with bright liver in 391 1-year-old toddlers born from healthy

mothers. The PNPLA3 I148M variant and maternal weight gain during pregnancy were related to the presence of bright liver in the ultrasonography[49]. Thus, interestingly, the authors suggested a potential gene-environment interchange between PNPLA3 and maternal environmental factors contributing to the risk of fatty liver disease at this earlier age, reinforcing the multifactorial inheritance of NAFLD.

In a large study, Ayonrinde *et al*[50] investigated the relation of maternal factors and infant nutrition with the future development of NAFLD in adolescents aged 17 years. They concluded that average pre-gestational BMI, breastfeeding for at least six months and avoiding early supplementary formula milk feeding reduce the risk of NAFLD diagnosis by liver ultrasound[50]. Additionally, more extended maintenance of breastfeeding resulted in multiple benefits on maternal metabolism and a lower risk of NAFLD in mid-life[51-53].

The Healthy Start study examined a cohort of 951 mothers from different ethnicities[54]. Similar to others, they found that maternal BMI was correlated to increased neonatal adiposity. It has also been demonstrated that increased maternal insulin resistance and fasting glucose levels contribute to this association. Excessive insulin resistance during pregnancy activates placental inflammatory pathways and affects the fetus indirectly by increasing placental nutrient transfer capacity[55].

Still regarding insulin-glucose metabolism, elevated blood glucose and insulin concentrations exacerbate de novo lipogenesis, resulting in increased intrahepatic lipids. Additionally, reduced glucose and pyruvate consumption in parallel with increased triglyceride concentrations and excess fatty acids incompletely oxidized can impair mitochondrial function and gene expression, limiting mitochondrial biogenesis and leading to NAFLD[55].

Peroxisome proliferator-activated receptor γcoactivator 1 (PGC1) gene is a transcriptional coactivator that participates in mitochondrial biogenesis and function and hypermethylation PGC1 promoter was associated with decreased mitochondrial DNA content and insulin resistance in NAFLD patients[56]. In a cross-sectional analysis, Gemma *et al*[57] noticed a positive correlation between maternal BMI and methylation of the PGC1 gene in the umbilical cord of their babies[57]. Based on their findings, the authors speculated that PGC1 might be a promising candidate gene involved in metabolic programming by epigenetic regulation[57]. DNA methylation in regulatory regions of different genes participates in NAFLD development and progression. Other epigenetic mechanisms affecting NAFLD pathogenesis include histone modification and microRNA (miRNA)-mediated processes. Notably, circulating miRNAs have been associated with the presence and heritability of NAFLD in a population study in 40 pairs of twins. Serum miR-331-3p and miR-30c were identified among the 21 miRs that differed between NAFLD and non-NAFLD individuals. These miRNAs are highly inheritable and correlate with each other suggesting a common pathway related to NAFLD[58].

Although shreds of evidence support that high pre-pregnancy BMI in the mothers may lead to significant modifications in the infant gut microbiome[59], few studies link maternal obesity and infant dysbiosis with NAFLD risk in later life. The neonatal gut microbiome can be essential for later homeostasis, and disruption of this early process may increase the risk of future metabolic diseases[60]. Emerging data provides evidence that the gut-liver axis is a fundamental element in the onset and progression of NAFLD. Gut microbiota dysbiosis may contribute to NAFLD by increasing concentrations of bacteria-derived endotoxins, pro-inflammatory cytokines, amino-acid metabolites, short-chain fatty acids and bile acids, all of which might exert effects that promote macrophage programming and activation, favoring liver injury[61].

CONCLUSION

The interplay among multiple genetic, epigenetic and environmental factors determine an individual's susceptibility to NAFLD. Current evidence points to genetic polymorphisms as pleiotropic tools that lead to diverse traits and phenotypes, including typical metabolic profiles in parents and their offspring. Importantly, epigenetic markers can also be transferred to successors by transgenerational epigenetic inheritance. Current studies in mothers and their offspring, although still small, show a direct effect of these factors and their related outcome, NAFLD. Future studies may clarify what interventions are essential for preventing this complex disease in the perinatal or postnatal period to reach the better liver and metabolic-related outcomes in the upcoming adult population.

Abstract

Gastric cancer (GC) is the fourth leading cause of cancer-related death. The occurrence and development of GC is a complex process involving multiple biological mechanisms. Although traditional regulation modulates molecular functions related to the occurrence and development of GC, the comprehensive mechanisms remain unclear. Ultraconserved region (UCR) refers to a genome sequence that is completely conserved in the homologous regions of the human, rat and mouse genomes, with 100% identity, without any insertions or deletions, and often located in fragile sites and tumour-related genes. The transcribed UCR (T-UCR) is transcribed from the UCR and is a new type of long noncoding RNA. Recent studies have found that the expression level of T-UCRs changes during the occurrence and development of GC, revealing a new mechanism underlying GC. Therefore, this article aims to review the relevant research on T-UCRs in GC, as well as the function of T-UCRs and their regulatory role in the occurrence and development of GC, to provide new strategies for GC diagnosis and treatment.

Key Words: Transcribed ultraconserved region; Gastric cancer; Development; Function; Therapeutic perspectives

Core Tip: Transcribed ultraconserved region (T-UCR) is abnormally expressed in gastric cancer (GC) cells and tumors. It has been found that a variety of T-UCR affects downstream genes and related pathways, and plays a regulatory role in the proliferation, migration and invasion of GC. However, there are few relevant reviews, and this paper aims to review the related studies of T-UCR in GC. And the function of T-UCR and its regulatory role in the occurrence and development of GC, thus providing a new strategy for the diagnosis and treatment of GC.

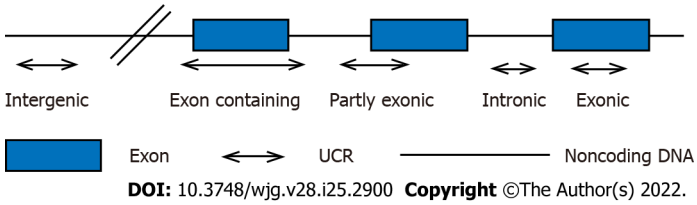
INTRODUCTION

Gastric cancer (GC) is one of the most common malignant tumours in the world. Although the incidence of GC has decreased, GC ranks fourth in cancer-related deaths due to its high lethality[1,2]. Due to the limited specific biomarkers of GC, patients usually have advanced GC when they are diagnosed. The tumourigenesis and development of GC is a multistep process involving countless signal transduction pathways and gene regulation. Among them, oncogenic and tumour suppressor factors, such as the transcribed ultraconserved region (T-UCR), play a key role[3,4].



In the human genome, 93% of genes can be transcribed to produce RNA, but only 2% are translated to protein. This type of RNA that lacks the potential for translation into protein is called noncoding RNA[5-9]. According to the number of bases it contains, noncoding RNA is divided into long noncoding RNAs (lncRNAs, > 200 bp) and small noncoding RNAs (< 200 bp, including rRNA, miRNA, snRNA, snoRNA, siRNA and pi-RNA)[10-13]. T-UCRs are lncRNAs, transcribed from UCRs. Recent studies have found that the expression level of T-UCRs is altered and abnormally expressed in human GC[14-17], which reveals a new mechanism for the occurrence and development of GC. Therefore, this article aims to review the relevant research on T-UCRs in GC, to further understand the specific mechanism of T-UCRs in GC cells, which will facilitate preventive measures against GC, early diagnoses, and new treatments.

ULTRACONSERVED REGION AND T-UCR

In 2004, Bejerano *et al*[18] compared the genomes of humans, mice, and rats. They found highly conserved DNA sequences, which were subsequently renamed ultraconserved regions (UCRs)[19]. These regions were absolutely conserved in the three species (100% identical, no insertions or deletions) and were often located in fragile sites and genomic regions of tumour-related genes. UCRs are highly conserved in the evolutionary process, due to the long-distance enhancers and ultraconserved exons that originated from the short interspersed repetitive element retroposon family 400 million years ago. At present, such extreme conservation is still active in the Indonesian "coelacanth"[20].

UCRs represent a small part of the human genome, forming a subset of conserved sequences in intragenic and intergenic regions. UCRs are functional but do not encode proteins[21]. The length of UCRs is between 200 and 799 bp. To date, humans have found at least 481 UCR regions[18,22]. It is known that a large part of these regions can actively transcribe RNA, some of them overlap with known protein-coding sequences, and more than half are predicted to not contain any protein-coding sequences [23]. Based on their overlap with known protein-coding genes, these 481 ultraconserved elements were initially divided into three categories: Nonexons, exons and possibly exons[18,19]. However, based on the positional relationship between UCRs and genes, Mestdagh *et al*[24] reclassified them into 5 categories: Exon containing (4.2%), exonic (5%), partly exonic (5%), intergenic (38.7%) and intronic (42.6%) (Figure 1). The sense/antisense strand of each region produces two transcripts, resulting in a total of 962 possible transcripts: One corresponding to the sense genome sequence (named "+") and the other corresponding to the antisense sequence (named "+ A")[25].

T-UCRs are the transcripts of UCRs[26]. Due to their high degree of conservation, T-UCRs may have fundamental functional importance for the ontogeny and phylogeny of mammals and other vertebrates. Recent studies have shown that a T-UCR acts as a regulator in a variety of pathways (such as pri-miRNA processing, transcription regulation, translation and chromatin modification)[27-29]. It is speculated that T-UCRs may be candidate genes for cancer susceptibility because the transcription level of some UCRs is dysregulated in cancer[30,31].

T-UCRS AND CANCER

Although transcribed T-UCRs are a type of lncRNA, transcribed by UCRs, they are completely different from lncRNA. T-UCRs are absolutely conserved, while lncRNAs are the least conserved among noncoding RNA[32]. The amazing evolutionary retention of T-UCRs strongly suggests their profound biological role in various physiological responses. As a type of evolutionarily conserved ncRNA, T-UCRs are regarded as essential for life by acting as an antisense transcription inhibitors for nearby protein coding RNA and other ncRNA. T-UCRs are thought to be involved in RNA processing or transcriptional regulation[18]. It has previously been demonstrated that T-UCRs act as regulators of gene expression[20,33]. In recent decades, increasing evidence has shown that T-UCRs are involved in carcinogenesis[23,30,31,34]. Recent studies have identified changes in T-UCR expression patterns associated with specific tumour phenotypes, such as hepatocellular carcinoma[35-37], pancreatic cancer [38,39], bladder cancer[40,41], colorectal cancer[22,26,42,43], prostate cancer[16,25,44,45], cervical cancer [46], neuroblastoma[24], breast cancer[47], lung cancer[22,48-50] and leukaemia[51], indicating a mechanism by which T-UCRs are involved in cancer development. Related studies in GC have also described changes in the expression pattern of T-UCRs[3,4,14-16], indicating that T-UCRs also play a regulatory role in the occurrence and development of GC.

T-UCRS IN GC

Uc.160+ is transcribed from the UCR on the 5q14.1 chromosome band. Honma *et al*[15] used real-time fluorescent quantitative polymerase chain reaction and in situ hybridization to detect Uc.160+. Compared with nontumour tissues, Uc.160+ expression is downregulated in GC and adenoma tissues. To further understand the biological mechanism of Uc.160+ in GC, the Uc.160+ overexpression vector was used to transfect GC cell lines MKN-1 and MKN-45, and then Western blotting was performed to detect the involvement of mitogens. Compared with the control group, the expression of phosphorylated-Akt and phosphorylated-ERK in the cell line transfected with the Uc.160+ overexpression vector decreased, while the expression of PTEN increased. These results suggest that Uc.160+ exclusively repressed the phosphorylation of Akt by regulating PTEN expression. In addition, Pang *et al* [17] found through a series of phenotypic experiments that the proliferation and activity of GC cells were inhibited after Uc.160 was overexpressed, and cell apoptosis was enhanced, which further proved the inhibitory effect of Uc.160 on GC. In conclusion, UC.160 plays an inhibitory role in the occurrence and development of GC.

Sakamoto *et al*[14] analysed the expression and distribution of Uc.63+ by using qRT-PCR and in situ hybridization, and they found that all GC tissues showed high Uc.63+ expression compared with normal tissues. The expression of Uc.63+ was also elevated in GC cell lines. After overexpression of Uc.63+ was induced by transfection of Uc.63+ expression vector, GC cell proliferation was significantly enhanced. After the expression of Uc.63+ was inhibited by siRNA, the proliferation of GC cells was inhibited. These results supported the possibility that Uc.63+ had a carcinogenic effect in GC. Additionally, they found that Uc.63+ had no effect on the survival rate of cancer patients, but Uc.63+ overexpression was associated with advanced cancer and GC classification. Uc.63+ was preferentially overexpressed in diffuse GC, but not in intestinal GC. In conclusion, Uc.63+ plays a key role in the classification and progression of GC.

Goto *et al*[16] found that UC.416+A is overexpressed in GC compared with normal tissues by in situ hybridization. The growth of GC cells was significantly inhibited after Uc.416+A was downregulated by siRNA. These results suggest that UC.416+A, as an oncogene, plays an important role in promoting the proliferation of GC cells. Global genetic analysis using Affymetrix GeneChips showed that the most upregulated gene was IGFBP1 (insulin-like growth factor binding protein 1) when Uc.416+A was overexpressed. Compared with the corresponding nontumour gastric mucosa, IGFBP6 was significantly downregulated in GC tissue, indicating that Uc.416+A might promote the proliferation of GC cells by inhibiting IGFBP6.

Table 1 Transcribed ultraconserved region in gastric cancer

T-UCR name	Location	Orientation	Expression in gastric cancer	Biological or molecular functions in gastric cancer	Ref.
Uc.63+	Chr.2	Sense	Downregulated	Associated with the classification and progression of gastric cancer	[14]
Uc.118	Chr.3	Antisense	Downregulated	-	[16]
Uc.158	Chr.5	Antisense	Downregulated	-	[16]
uc.160	Chr.5	Sense	Downregulated	Inhibits cell proliferation and promotes apoptosis in AGS and SGC-7901 cell lines, promoting gastric cancer tumourigenesis	[15, 17]

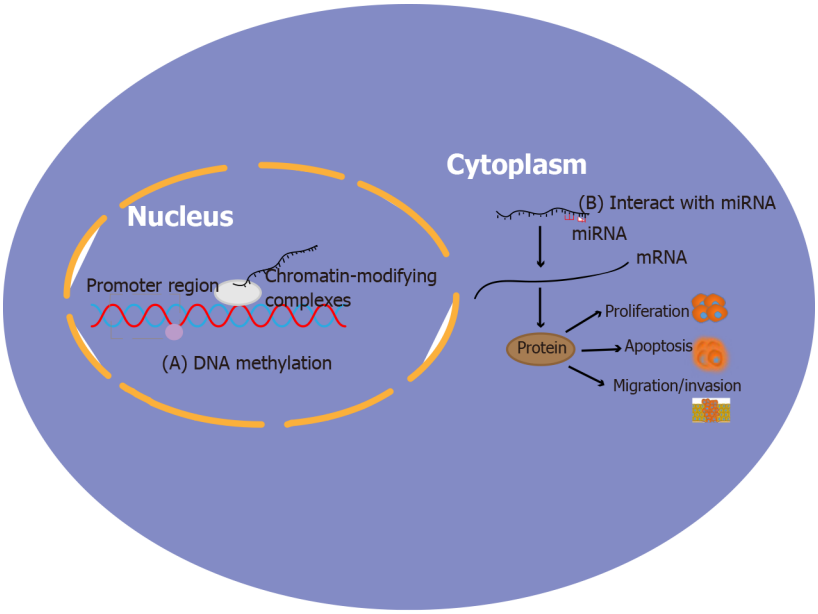
Uc.416	-	Antisense	Upregulated	Promotes proliferation in MKN-74 cell line, promoting gastric cancer tumourigenesis	[16]

T-UCR: Transcribed ultraconserved region.



In addition, the expression levels of Uc.118, Uc.158, Uc.241 and Uc.346 were found to be significantly downregulated in GC; Uc.244, Uc.249, Uc.252, Uc.261, Uc.282, Uc.283 and Uc.359 Levels were undetermined (Table 1).

REGULATORY MECHANISM OF T-UCRS IN GC

The regulatory mechanism of T-UCRs in tumourigenesis and the development of cancer is largely unclear, but current studies have found that T-UCR are involved in three different regulatory mechanisms in tumours: CpG island methylation[52], interaction with miRNAs[53-55] and direct binding to the target mRNAs[27,43]. In GC related research, it was only found that T-UCRs participate in the occurrence and development of GC through the first two pathways (Figure 2).

CpG island methylation

The field of epigenetics describes the transmission of information through heritable changes in phenotypes that do not involve changes in DNA sequences during cell division[56]. CpG island methylation, histone modification and chromatin delivery structure are the potential mechanisms of epigenetic transmission, and CpG island methylation is a key component of the changes in gene expression associated with human cancer, especially the expression of GC related genes[57-60]. GC is the most susceptible of all cancers to epigenetic changes without any changes in DNA[59,61-63]. CpG islands are DNA fragments of at least 0.5 kb, that are rich in G:C and CpG content, and are present in approximately 70% of human gene promoters. In other words, CpG islands are tandem repeats of cytosine (C) and guanidine (G), where p is the phosphoric acid between C and G. In brief, the methylation of CpG occurs under the action of methylase whereby the hydrogen on the cytosine (C) 5 carbon atom is replaced by methyl (CH3)[60,64-66]. Demethylation is the opposite process. It has been found that more than 50% of human genes are regulated by promoters including CpG islands[67]. In normal cells, except for genes with inactive X chromosomes or genes related to imprinted genes, promoter CpG islands are usually unmethylated[68]. Although the aetiology is still unclear, promoter CpG island methylation may be related to cancer development and ageing[69]. It is a common feature of

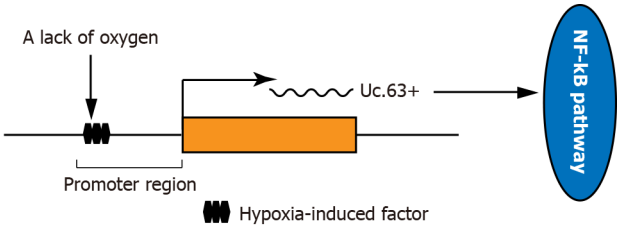
Figure 2 The mechanism by which transcribed ultraconserved region affects gastric cancer. A: DNA methylation; B: Interaction with miRNAs.



human cancers that low expression of tumour-suppressive ncRNA causes CpG island methylation and then affects epigenetic silencing. Promoter CpG island methylation has been found in almost all human cancer tissue types, and it is an important mechanism for the inactivation of tumour suppressor genes and tumour-related genes[70]. GC is the most common human cancer caused by methylation of the promoter CpG island. Interestingly, T-UCRs undergo DNA methylation-related silencing in cancer cells, and promoter CpG island methylation is now considered to be important for inactivating tumour suppressor genes or tumour-related genes. Previous studies have shown that T-UCR regulation in the occurrence and development of GC is closely related to the methylation of CpG islands of the host gene promoter[16].

Goto *et al*[16] discovered that there are CpG islands approximately 500bp upstream of the Uc.158+A transcription gene. Bisulfite genomic sequencing of GC cell lines and GC tissue samples showed specific DNA methylation of GC, which contained UCRs. The luciferase vector of the CpG island upstream of the Uc.158+A transcription gene proved that when the upstream sequence of the Uc.158+A transcription gene was methylated, reporter activity was significantly inhibited. Thus, this suggests that Uc.158+A expression is silenced by DNA methylation in the promoter region upstream of its transcription gene.

Interaction with miRNAs

Previous studies have shown that miRNAs affect the regulation of gene expression at both the transcriptional and posttranscriptional levels[71-73]. MiRNAs are also almost completely conserved[74,75]. Do T-UCRs interact with miRNAs to regulate the occurrence and development of cancer? In 2007, Calin and his collaborators demonstrated for the first time that certain T-UCRs are altered due to the direct regulation of high-level miRNAs in chronic lymphocytic leukaemia, and the expression of each T-UCR is negatively correlated with the corresponding microRNA level[19]. Recent studies have found that a T-UCR interacts with miR-596 and synergistically promotes the development of bladder cancer[28]. Terreri *et al*[55] found that the formation of T-UCR::miRNA pairs may have different effects, either targeting T-UCR or forming sponges that capture miRNAs. They also reported that the interaction between miRNAs and T-UCRs can act as a network to regulate the availability of certain lncRNAs in bladder urothelial carcinoma cells. These results indicated that miRNAs are involved in the process of T-UCR-mediated tumour regulation. In GC, we found that T-UCRs represent the possible targets of miRNAs[14-16], and these interactions may have biological and prognostic significance for cancer patients.

Goto *et al*[16] determined that the expression of miR-153 in GC cell lines with higher expression of Uc.416+A was significantly reduced, suggesting an inverse correlation between Uc.416+A and miR-153. The direct interaction between Uc.416+A and miR-153 was confirmed by a luciferase activity assay. This result showed that the overexpression of Uc.416+A is related to the downregulation of miR-153 in GC. Overexpression of UC.416+A caused changes in downstream related genes. The expression of insulin-like growth factor binding protein 6 (IGFBP6) was upregulated, and alcohol dehydrogenase 1C (ADH1C), homeobox B5 (HOXB5) and homeobox B6 (HOXB6) levels were downregulated. The expression of IGFBP6, HOXB5 and HOXB6 in GC and adjacent tissues showed statistically significant differences, indicating that the overexpression of UC.416+A is regulated by miR-153, which then affects

DOI: 10.3748/wjg.v28.i25.2900 **Copyright** ©The Author(s) 2022.

Figure 3 The mechanism of Uc.63 + in gastric cancer.

the gene changes of downstream coding proteins and plays a promoting role in the growth of GC.

CpG island methylation and miRNAs play a role together

Honma *et al*[15] found that the low expression of Uc.160+ in GC was caused by methylation of its upstream promoter region, and the low expression of Uc.160+ caused a decrease in PTEN expression, an increase in phosphatase activity and activation of the MAPK pathway. In addition, Pang *et al*[17]'s study found that UC.160 was also regulated by miR-155, which then regulated PTEN and affected the MAPK pathway. In other words, the low expression of UC.160 in GC is regulated by miR-155 and affected by methylation in the upstream promoter region of its transcriptional genes.

Other factors affecting T-UCR transcription

Sakamoto *et al*[14] found that the expression of UC.63+ is regulated by hypoxia. The promoter region located upstream of the Uc.63+ transcription gene is considered to have hypoxia-induced binding sites. Hypoxia induces overexpression of UC.63+, and the overexpression of UC.63+ upregulates its downstream target P65 and activates the NF-KB signalling pathway to promote the occurrence of GC (Figure 3).

CONCLUSION

In GC, T-UCRs change at the transcriptional level, and the abnormal expression of T-UCRs can lead to the occurrence and development of GC. Compared with normal cells, T-UCRs in GC cells have a unique expression profile, which indicates that changes in T-UCRs are involved in this malignant process. This study may provide new ideas and directions for GC diagnosis and prognosis. Compared with coding RNA, T-UCRs have incomparable advantages. Because T-UCRs do not code for proteins, they are relatively less regulated and more accurate. In addition, some T-UCR expression levels are completely different in different stages of cancer, and can also be used as one of the criteria for judging prognosis.

Despite the fact that this new type of dysregulated molecule seems to be useful in future clinical applications, further research is needed before it can be used as a valuable clinical biomarker for GC. First, although approximately 98% of the entire genome contains nonprotein coding genes, the proportion of T-UCRs is currently unclear. Second, current screening methods for T-UCRs (RT-qPCR, T-UCR chip) are useful, but simpler and more practical techniques will help in the identification and screening of disease-related T-UCRs. Third, it has been proven that T-UCRs are involved in the occurrence and development of GC, but their biological mechanism has not been fully elucidated. In addition, more powerful strategies are needed to clarify the regulatory role of T-UCR by constructing an interaction network, or to evaluate its function in typical signalling pathways. Since the knowledge of T-UCR is still in its infancy-especially when compared to other ncRNAs, further research is needed to convincingly incorporate these ncRNAs into the growing field of cancer therapeutics.

At present, there are few studies on T-UCR therapy, so there is still much room to explore treatment measures aimed at T-UCRs. Perhaps we can achieve a treatment purpose by changing the expression of T-UCRs. In the reference cell experiment, restoring the downregulated levels of T-UCRs or suppressing the overexpressed levels of T-UCRs *via* overexpression vectors or small interfering RNA methods can reverse the tumour phenotype. In clinical treatment, we can use the negative regulation between T-UCRs and miRNAs to inhibit the expression of T-UCRs, and methylation inhibitors can be used to restore the expression of T-UCRs with downregulated levels in tumours, thereby delaying or even reversing tumour progression.

Although these hypotheses have not been confirmed, we believe that as research on T-UCRs continues, the insight gained will definitely provide a novel strategy for the diagnosis, prognosis and treatment of tumours.

Abstract

Cholinergic nerves are widely distributed throughout the human body and participate in various physiological activities, including sensory, motor, and visceral activities, through cholinergic signaling. Cholinergic signaling plays an important role in pancreatic exocrine secretion. A large number of studies have found that cholinergic signaling overstimulates pancreatic acinar cells through muscarinic receptors, participates in the onset of pancreatic diseases such as acute pancreatitis and chronic pancreatitis, and can also inhibit the progression of pancreatic cancer. However, cholinergic signaling plays a role in reducing pain and inflammation through nicotinic receptors, but enhances the proliferation and invasion of pancreatic tumor cells. This review focuses on the progression of cholinergic signaling and pancreatic diseases in recent years and reveals the role of cholinergic signaling in pancreatic diseases.

Key Words: Acetylcholine; Muscarinic receptors; Nicotinic receptors; Pancreatic exocrine; Pancreatitis; Pancreatic cancer

Core Tip: The pancreas is a nerve-rich organ that lies behind the peritoneum and is surrounded by many nerve plexuses. Studies have found that cholinergic signaling is involved in the physiological function of the pancreas and the pathological process of pancreatic diseases due to its action on different receptors. Perhaps starting with cholinergic receptors could uncover potential therapeutic targets for pancreatic diseases.

INTRODUCTION

Acetylcholine is a neurotransmitter released by all cholinergic neurons that plays an important role in the peripheral and central nervous systems. The vagus nerve is the longest nerve in the human body and provides innervation to most organs, especially the organs of the digestive system. Cholinergic signaling released by vagus nerve activation mainly acts on cholinergic receptors. According to pharmacological properties, cholinergic receptors are divided into muscarinic receptors (M receptors) and nicotinic receptors (N receptors). Among them, M receptors are widely distributed in smooth muscles and glands and participate in the secretion of glands. M receptors are divided into 5 subtypes of M1-M5, among which M1, M3, and M5 receptors are coupled to Gq protein and M2 and M4 receptors are coupled to Gi protein[1,2]. Each of these five subtypes of M receptors has a unique distribution pattern and is expressed in many areas of the central nervous system and peripheral tissues[1,3-5]. N receptors are ligand-gated ion channels, a pentamer made up of 5 identical homologous subunits (including α1-10, β1-β5, γ, δ, and ε) and retain the potential to be activated by the appropriate agonist[6-8].

The pancreas is an important digestive organ of the human body and plays an important role in the digestion and absorption of food. Pancreatic diseases include acute pancreatitis (AP), chronic pancreatitis (CP), and pancreatic cancer (PCa). Recently, the incidence of pancreatic disease has been increasing year by year, posing a serious threat to human life and health[9-11]. Recent studies have found that cholinergic neuromodulation is involved in the occurrence and development of pancreatic diseases[12-14]. This article reviews the relationship between the three main types of pancreatic diseases (AP, CP, PCa) and cholinergic signaling.

CHOLINERGIC SIGNALING AND PANCREATIC EXOCRINE FUNCTION

The exocrine system of the pancreas includes three different stages, namely, the cephalic stage, the stomach stage, and the intestinal stage[15]. The total amount of daily exocrine activity of the human pancreas is 1-2 L, and approximately 20% occurs in the cephalic stage, which is under the control of the vagus nerve[16-18]. Studies on humans and animals have shown that the cholinergic system regulates pancreatic exocrine secretion through the vagus nerve reflex. These reflexes originate in the dorsal motor nucleus of the vagus nerve in the medulla oblongata. The cranial preganglionic nerve fibers exit the vagus nerve and terminate at the intrapancreatic ganglia to form synapses through cholinergic preganglionic fibers[19,20].

The intrapancreatic ganglion are the integration center of pancreatic exocrine secretion, and terminal axons from these ganglia innervate approximately every acinar artery. Although preganglionic neurotransmission is mediated by acetylcholine through nicotinic and muscarinic receptors, postpancreatic innervation can be mediated by a variety of neurotransmitters, including acetylcholine, which acts on muscarinic receptors in pancreatic acinar cells[21,22]. Cholinergic agonists produce a pancreatic secretory response similar to that of cephalic stimulation, whereas cholinergic antagonists or resection of the vagus nerve can block the cephalic response. These results show that the acetylcholine released by the efferents of the vagus nerve is the primary mechanism by which sensory input leads to the regulation of pancreatic exocrine secretion[23-26]. The cholinergic system also plays an important role in the gastric and intestinal stages of pancreatic secretion regulation[27,28], which are regulated by nerves and bodily fluids. In the intestinal phase, exocrine secretion of the pancreas is mainly regulated by cholecystokinin (CCK) and other gastrointestinal hormones. However, the cholinergic system also plays a role in the secretion of human pancreatic enzymes stimulated by CCK[21,29]. The postprandial physiological dose of CCK mainly acts on the afferent pathway of the vagus nerve in the gastric and duodenal mucosa and stimulates pancreatic exocrine secretion through the cholinergic efferent nerve [19].

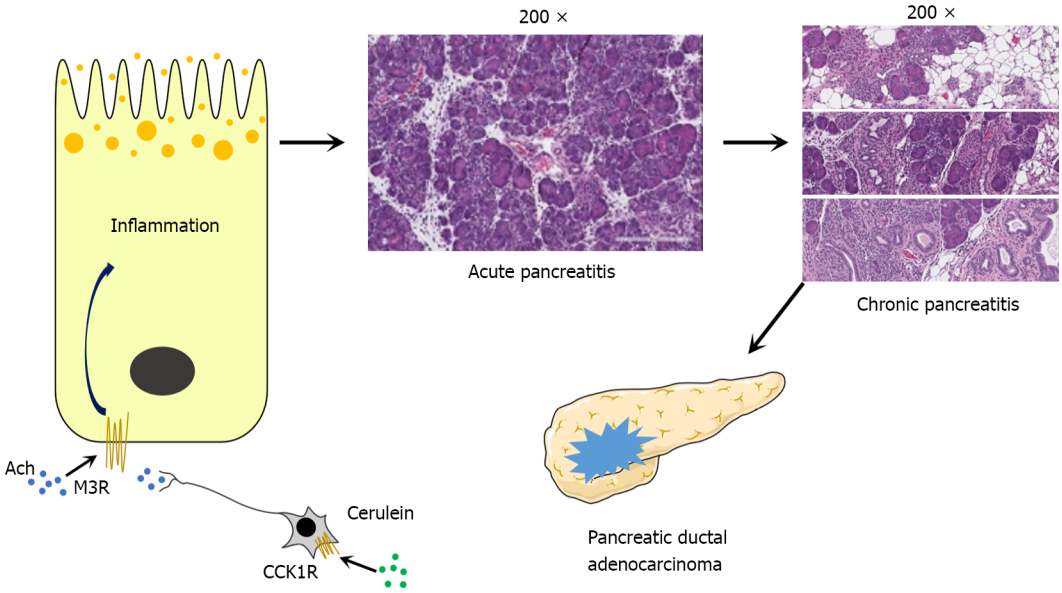
Studies have found that human pancreatic acinar cells preferentially express the M3 receptor[30] and are highly expressed in acinar cells[31]. Acetylcholine acts on the M3 receptor and couples to the Gq protein to activate phospholipase C and promote the release of intracellular calcium ions by initiating the phosphatidyl C-inositol triphosphate cascade and promoting the secretion of pancreatic acinar cells [2,32,33]. According to drug blocking studies, the M3 receptor is a muscarinic receptor that stimulates exocrine secretion form the pancreas[34-36]. However, some studies have shown that the M1 receptor can also control pancreatic exocrine secretion[37,38]. The inhibitory effect of drugs blocking the M1 receptor on the secretion of amylase in isolated pancreatic acinar cells was significantly greater than that of drugs blocking the M3 receptor[39]. Carbachol-induced amylase secretion was significantly impaired in the isolated acinars with M1 and M3 muscarinic receptor single knockout (KO) mice, and amylase secretion was eliminated in the acinar preparation of M1 and M3 muscarinic receptor double KO mice. Therefore, it is proposed that cholinergic signaling stimulates the secretion of pancreatic amylase and is mediated by the combination of M1 and M3 receptors[40].

CHOLINERGIC SIGNALING AND AP

AP is a common pancreatic disease in clinical practice. AP has a rapid onset and progress, and high morbidity and mortality worldwide[11]. There are many causes of AP, such as biliary, hypertriglyceridemia, and chronic alcohol consumption, among which biliary is the most common factor[41]. However, the specific mechanism underlying the cause of pancreatitis is not clear. When the human body is exposed to cholinergic agonists, such as scorpion stings or organophosphorus pesticide poisoning, some patients will develop AP. This is direct evidence that cholinergic signaling stimulation is associated with the occurrence of human AP[42-45]. Organophosphorus pesticides can inhibit cholinesterase activity and cause a large amount of acetylcholine to accumulate in nerve endings. Similarly, scorpion toxin is a neurotoxic protein that can cause AP by activating the nerve pathway that releases acetylcholine[46,47].

Pancreatic duct ligation in the rat model is often used to simulate clinical AP caused by gallstone obstruction[48], but the severity of experimental pancreatitis is low except when used in the possum model. However, some researchers have found in a pancreatic duct ligation rat model that cholinergic signaling stimulation can aggravate AP inflammation, suggesting that cholinergic signaling may be involved in the pathogenesis of AP caused by cholangiopancreatic duct obstruction[49]. This may be due to an increase in M3 receptor expression induced by rat pancreatic duct ligation, which amplifies the overstimulation of cholinergic signaling on acinar cells and aggravates the intracellular stress response[50]. Before the first clinical onset of acute alcoholic pancreatitis, patients usually have a history of alcohol abuse for many years. Chronic alcohol intake can affect the exocrine regulation of the pancreas by interfering with the cholinergic and trypsin pathways[51]. Long-term use of ethanol feeding can significantly reduce pancreatic acetylcholinesterase activity in rats, while the expression level of pancreatic cholinergic M receptors has not changed, which increases the level and duration of acetylcholine in the pancreas and leads to excessive cholinergic signaling stimulation and damage to pancreatic acinar cells[52,53]. Ethanol-treated pancreatic acinar cells can aggravate the pancreatic injury response caused by the cholinergic agonist carbachol, and its effect may be mediated by protein kinase C downstream signaling of cholinergic receptors[54]. The cholinergic receptor antagonist atropine can improve pancreatitis induced by the combination of alcohol and cerulein suggesting that the cholinergic signaling pathway is involved in the pathogenesis of pancreatitis[52]. Therefore, acetylcholine may play a key role in the pathogenesis of acute alcoholic pancreatitis[12].

The M3 receptor is highly expressed in human pancreatic acinar cells[31]. Wan *et al*[55] used chemical genetic technology, in which designer receptors are exclusively activated by designer drugs, to express mutant M3 receptors in mouse acinar cells, causing them to lose their response to acetylcholine but can be activated by the specific drug clozapine-N-oxide (CNO). CNO can induce AP in mutant M3 receptor mice and cause more extensive acinar cell necrosis and inflammation. In addition, the use of M3 receptor antagonists can improve the severity of AP induced by cerulein in wild-type mice (Figure 1)[55].



These results indicate that the activation of the M3 receptor by cholinergic nerve terminals releasing acetylcholine may be one of the pathogeneses of AP. Muscarinic receptor agonists stimulate the activation of trypsinogen and nuclear factor-kappaB, which are two key signaling pathways in the pathogenesis of pancreatitis[56]. Reducing inflammation has always been a major goal in the treatment of AP, and many anti-inflammatory drugs have shown beneficial responses in experimental pancreatitis[57]. However, due to the lack of an in-depth understanding of its pathogenesis, there is currently no effective prevention and treatment strategy[58]. Through in-depth research on the cholinergic signaling pathway, it may be possible to block cholinergic signaling early to treat AP, especially in the prevention of pancreatitis after endoscopic retrograde cholangiopancreatography.

CHOLINERGIC SIGNALING AND CP

CP is characterized by chronic inflammation and fibrosis of the pancreas caused by multiple factors. The incidence and prevalence of CP are increasing each year, but there is no current specific treatment[10]. The most common causes of CP are excessive drinking, smoking or genetic mutations[59]. Alcohol is considered to be one of the main risk factors for CP. A total of 40%-70% of CP patients become sick due to excessive alcohol consumption[10]. At the same time, excessive alcohol consumption increases the risk of PCa in individuals[60].

Recurrent episodes of AP have been associated with the progression of CP, which is more common in patients with alcoholism. It has been reported that a certain extent of chronic pancreatic damage was already present at the time of AP episodes[41]. The dose-response relationship between alcohol consumption for AP and CP is linear in males[61]. Alcohol-induced pancreatitis may be caused by the alcohol-induced increased viscosity of pancreatic secretions, which blocks the pancreatic duct, and by premature activation of trypsinogen in acinar cells[62].

The hypertonicity of intrapancreatic cholinergic neurons caused by chronic alcoholism may be involved in the pathogenesis of CP[13]. In CP patients, ethanol can cause excessive sensitivity of the

Figure 1 M3 receptor activation on pancreatic acinar cells causes acute and chronic pancreatitis. Ach: Acetylcholine; CCK: Cholecystokinin.

pancreatic parasympathetic nerve pathways after a meal[63]. This may be due to chronic alcoholism interrupting the autonomic nerve suppression reflex, leading to the decentralization of the intermediate autonomic nerve (located in the gastric antrum and duodenum) and the intrapancreatic ganglia. Due to an increase in the activity of these autonomic nerves, cholinergic signaling in the pancreas increases, resulting in excessive protein secretion and obstruction of pancreatic juice flow[64,65]. Histopathological analysis of pancreatic tissue samples from patients with CP (including alcoholic pancreatitis) demonstrated that the density of cholinergic fibers in the pancreas of patients with CP was slightly increased compared with normal pancreatic tissue samples[66]. Therefore, the impaired interaction between cholinergic signaling and their receptors on pancreatic acinar cells may be a mechanism of the pathogenesis of alcoholic pancreatitis.

Compared with AP, few CP models use injury mechanisms that may be related to the pathogenesis of human diseases, and the clinical relevance of the pathogenesis of most CP models is unclear[48]. However, Wan *et al*[55] used a mutant M3 receptor mouse-induced CP model and observed typical CP features, such as extensive chronic inflammation, fibrosis, adipose tissue infiltration, and pancreatic atrophy (Figure 1)[55]. The use of this M3 receptor model may increase our understanding of the pathophysiological process of human CP and identify specific treatments.

Long-term and recurrent pain is a common characteristic of CP[10,67]. A large number of studies have shown that cholinergic nerves have a significant analgesic effect on chronic neuropathic pain, inflammatory pain, and visceral pain[68-70]. Choline transporter (CHT1) is considered to be the rate-limiting step of neuronal acetylcholine synthesis and is essential for the effective recovery of acetylcholine[71,72]. CHT1 is upregulated in CP-induced pain models. CHT1 specific inhibitor, hemicholinium-3, can significantly enhance CP-induced hyperalgesia and reduce the amount of acetylcholine in the dorsal root ganglia of the pancreas in a dose-dependent manner[73]. Further research found that acetylcholine reduces pain and inflammation through α7 nicotinic acetylcholine receptors (α7 nAChRs)[70,74-77]. The activation of α7 nAChRs enhances the autophagic flux of acinar cells mediated by the transcription factor EB pathway and promotes lysosomal degradation to inhibit acinar cell damage, thereby protecting experimental pancreatitis. It has been suggested that cholinergic signaling activation of endogenous α7 nAChRs in the pancreas may be an endogenous protective mechanism in the process of pancreatitis[78]. Therefore, the use of α7 nAChRs to develop analgesic and anti-inflammatory drugs will be a promising target, especially for the treatment of CP.

CHOLINERGIC SIGNALING AND PCa

PCa is a gastrointestinal tumor with a poor prognosis, and more than 90% of PCa are pancreatic ductal adenocarcinoma (PDAC). According to reports, the 5-year survival rate for PCa patients in the United States from 2009 to 2015 was only 9%[79]. With the continuous increase in morbidity and mortality, PCa is expected to become the second leading cause of cancer-related deaths by 2030[80].

CP has been identified as a risk factor for PCa[81,82]. A meta-analysis found that CP increases the risk of PCa, and five years after the diagnosis of CP the risk of PCa increased nearly eightfold[83]. Pain is a characteristic feature of CP and PCa. Studies have found that increased nerve fiber density and hypertrophy are typical features of CP and PCa, and this pathological change appears to enhance and produce pancreatic neuropathic pain[84]. In vitro, myenteric plexus and dorsal root ganglia neurons were isolated from neonatal rats with CP and PCa, and they exhibited strong neurite outgrowth, more complex branching patterns, and somatic hypertrophy. They findings suggest that the intrapancreatic microenvironment in CP and PCa appears to be a key factor in the generation of pancreatic neuropathy and neural plasticity[85].

In-depth research on the tumor microenvironment found that perineural invasion is an important feature of PCa, which can lead to local tumor recurrence and poor prognosis[86]. As the degree of invasion increases, the survival rate of PCa patients is significantly reduced[87]. However, cholinergic signaling appears to play a tumor-suppressing role in PCa[14,88]. Regarding the relationship between heart rate variability (HRV) as an indicator of vagus nerve activity and the overall survival of patients with advanced PCa, it was found that higher vagus nerve activity represented by a higher initial HRV was significantly associated with a lower risk of death from PCa and was not affected by confounding factors such as age and cancer treatment[89]. The activation of M receptors by cholinergic signals can inhibit the progression of pancreatic tumors. Inhibition of the downstream EGFR/MAPK and PI3K/AKT signaling pathways of PCa cells through the M1 receptor signaling pathway inhibits tumor stem cells, $CD11b^+$ cells, tumor necrosis factor-α levels, and liver metastasis[14].

However, M3 receptor expression seems to be a biomarker for the poor prognosis of PDAC. Compared with patients with low M3 expression, patients with high M3 expression have a worse prognosis and shorter survival time, but the study did not find a statistically significant relationship between M3 receptor expression and peripheral nerve infiltration in PCa[90]. The presence of nonneuronal acetylcholine secreted by fibroblasts and pancreatic stellate cells in the microenvironment of pancreatic tumors activates the M3 receptor, leading to further tumor progression[91].

Oxidative stress and inflammatory signaling contribute to the development of pancreatitis. Español *et al*[92] reported that long-term inflammatory stimulation by LPS plus interferon-γ (IFN-γ) could induce muscarinic receptor expression which mainly involved the M3 and M5 receptors. It could also upregulate the expression of NOS and COX-2 to enhance the effect of carbachol on NO and PGE_2 production[92]. Transgenic overexpression of COX-2 in the pancreas induces CP and the formation of preinvasive ductal tumors[93,94]. Muscarinic receptors could serve as promising therapeutic targets for pancreatic inflammation and could prevent the transformation of CP to PCa.

The increase in acetylcholine levels by nAChRs can inhibit histone deacetylase 1-mediated CCL5 chemokines. This could weaken the ability of PDAC cells to recruit $CD8^+$ T cells and directly inhibit the production of IFN-γ by $CD8^+$ T cells. This effect is conducive to Th2 differentiation and could thereby promot tumor growth[86]. Smoking is one of the main causes of PCa[95], and approximately 21% of PCa deaths are attributed to smoking[96]. Studies have shown that nicotine (nAChR agonist) can increase the proliferation activity and self-renewal ability of PCa stem cells by activating the sonic hedgehog signaling pathway[97]. α7 nAChRs have also been shown to upregulate mucin-4 by coactivating the JAK2/STAT3 downstream signaling cascade *via* the MEK/ERK1/2 pathway, thereby increasing the migration and invasion capabilities of PCa cells[98]. Because the pancreas is widely innervated by many different neurons, the relationship between PCa and the nervous system is complicated[99]. Cholinergic signaling produces different effects based on the different receptor mechanisms involved and may become a potential therapeutic target for PCa in the future.

CONCLUSION

Cholinergic signaling participates in the physiological function of the pancreas and the pathological process of pancreatic diseases. Although the mechanism by which cholinergic signaling regulates pancreatic diseases is still unclear, an increasing number of studies have shown that cholinergic signaling plays a key role in the occurrence and development of pancreatic diseases. There are many animal models of pancreatitis that can be used to help us study the pathogenesis and pathophysiological process of pancreatitis. Among them, rodent models are most commonly used to study acute and CP, but experimental pancreatitis is not necessarily the most relevant to human diseases[48]. Due to the lack of an in-depth understanding of its pathogenesis, there is no effective prevention and treatment strategy at present. Activation of the M3 receptor may be one of the causes of pancreatitis since muscarinic receptors are widely expressed in various glands and smooth muscles throughout the body. The mutant M3 receptor model provides an alternative method for the study of pancreatitis[55]. The pancreas is an organ rich in nervous tissue and lies behind the peritoneum and is surrounded by many nerve plexus. Cholinergic signaling has different effects due to its action on different receptors, which leads to a complicated pathogenesis of pancreatic diseases such as AP, CP, and pancreatic tumors (Table 1). Reducing or enhancing the signal downstream of the receptor may provide a potential therapeutic target in the future.

Table 1 Role of different cholinergic receptors in pancreatic diseases

Pancreatic diseases	Receptor type	Relevant mechanism	Effect	Ref.
Acute pancreatitis	M3	Receptor overexpression	Acinar cell hypersecretion	[49,50,52,55]
Chronic pancreatitis	M3	Cholinergic signaling increases	Acinar cell hypersecretion	[13,64-66]
	M3/M5	Receptor overexpression	Induce fibroblast proliferation	[92]
	α7	Enhances the autophagic flux of acinar cells	Inhibit acinar cell damage	[70,74-77]
Pancreatic cancer	M1	Inhibition of the EGFR/MAPK and PI3K/AKT signaling pathways	Inhibit the progression of pancreatic tumors	[14]
	M3	Receptor overexpression	Induction of preinvasive ductal tumor formation	[90,92-94]
	α7	Activating the JAK2/STAT3 signaling pathway	Increasing the migration and invasion capabilities of tumor cells	[86,97,98]

Abstract

BACKGROUND

Colorectal cancer (CRC) is one of the most common malignancies worldwide. Given its insidious onset, the condition often already progresses to advanced stage when symptoms occur. Thus, early diagnosis is of great significance for timely clinical intervention, efficacy enhancement, and prognostic improvement. Featuring high throughput, fastness, and rich information, next generation sequencing (NGS) can greatly shorten the detection time, which is a widely used detection technique at present.

AIM

To screen specific genes or gene combinations in fecal DNA that are suitable for diagnosis and prognostic prediction of CRC, and to establish a technological

platform for CRC screening, diagnosis, and efficacy monitoring through fecal DNA detection.

METHODS

NGS was used to sequence the stool DNA of patients with CRC, which were then compared with the genetic testing results of the stool samples of normal controls and patients with benign intestinal disease, as well as the tumor tissues of CRC patients. Specific genes or gene combinations in fecal DNA suitable for diagnosis and prognostic prediction of CRC were screened, and their significances in diagnosing CRC and predicting patients' prognosis were comprehensively evaluated.

RESULTS

High mutation frequencies of *TP53*, *APC,* and *KRAS* were detected in the stools and tumor tissues of CRC patients prior to surgery. Contrastively, no pathogenic mutations of the above three genes were noted in the postoperative stools, the normal controls, or the benign intestinal disease group. This indicates that tumor-specific DNA was detectable in the preoperative stools of CRC patients. The preoperative fecal expression of tumor-associated genes can reflect the gene mutations in tumor tissues to some extent. Compared to the postoperative stools and the stools in the two control groups, the pathogenic mutation frequencies of *TP53* and *KRAS* were significantly higher for the preoperative stools ($\chi^2 = 7.328$, $P < 0.05$; $\chi^2 = 4.219$, $P < 0.05$), suggesting that fecal *TP53* and *KRAS* genes can be used for CRC screening, diagnosis, and prognostic prediction. No significant difference in the pathogenic mutation frequency of the *APC* gene was found from the postoperative stools or the two control groups ($\chi^2 = 0.878$, $P > 0.05$), so further analysis with larger sample size is required. Among CRC patients, the pathogenic mutation sites of *TP53* occurred in 16 of 27 preoperative stools, with a true positive rate of 59.26%, while the pathogenic mutation sites of *KRAS* occurred in 10 stools, with a true positive rate of 37.04%. The sensitivity and negative predictive values of the combined genetic testing of *TP53* and *KRAS* were 66.67% (18/27) and 68.97%, respectively, both of which were higher than those of *TP53* or *KRAS* mutation detection alone, suggesting that the combined genetic testing can improve the CRC detection rate. The mutation sites *TP53* exon 4 A84G and *EGFR* exon 20 I821T (mutation start and stop positions were both 7579436 for the former, while 55249164 for the latter) were found in the preoperative stools and tumor tissues. These "undetected" mutation sites may be new types of mutations occurring during the CRC carcinogenesis and progression, which needs to be confirmed through further research. Some mutations of "unknown clinical significance" were found in such genes as *TP53*, *PTEN*, *KRAS*, *BRAF*, *AKT1*, and *PIK3CA*, whose clinical values is worthy of further exploration.

CONCLUSION

NGS-based fecal genetic testing can be used as a complementary technique for the CRC diagnosis. Fecal *TP53* and *KRAS* can be used as specific genes for the screening, diagnosis, prognostic prediction, and recurrence monitoring of CRC. Moreover, the combined testing of *TP53* and *KRAS* genes can improve the CRC detection rate.

Key Words: Colorectal cancer; Feces; Next generation sequencing; Diagnosis; Gene

Core Tip: Colorectal cancer (CRC) is characterized by high morbidity and mortality, as well as low early diagnosis rate. The development of current gold standard for clinical diagnosis of CRC is restricted due to its invasiveness. The purpose of this study is to explore the potential value of fecal gene detection based on next generation sequencing in the diagnosis of CRC, to screen specific genes or gene combinations suitable for CRC diagnosis and prognosis prediction in fecal DNA, and to establish a technical platform for fecal DNA detection for CRC screening, diagnosis, and efficacy monitoring.

INTRODUCTION

Colorectal cancer (CRC), as a health issue of great concern worldwide, poses a serious threat to human health. According to the latest data released by the International Agency for Research on Cancer, there were approximately 19.3 million new cancer cases and nearly 10 million cancer deaths globally in 2020. Among them, new CRC cases amounted to about 1.93 million (10%), ranking third, while CRC deaths amounted to about 0.94 million (9.4%), ranking second. For female patients, there were approximately 860000 new cases of CRC (9.4%), second only to breast cancer, and nearly 870000 CRC deaths (9.5%), ranking third. As for male population, the numbers of new cases and deaths both ranked third for CRC, which were 930000 (10.6%) and 50000 (9.3%), respectively[1].

In recent years, the morbidity and mortality of CRC have been on the rise in China, and the onset age of patients has gradually become younger. Early detection of CRC is difficult due to the insidious onset, long progressive course, and unobvious symptoms and signs of patients at the onset stage. As the tumor grows and gradually compresses the intestinal cavity, such symptoms as altered bowel habit and abnormal stool color or traits may occur. At this time, the condition often already progresses to advanced stage. Studies have shown that the 5-year survival of patients with early CRC can reach 90%, while is only about 12.5% for advanced stage patients[2]. Thus, early diagnosis is conducive to early intervention and treatment of CRC, which is of great significance for improving the efficacy and prognosis[3,4]. In response, the American Cancer Society recommended the CRC screening since the age of 45 for adults in 2018, which is 5 years earlier than the previously recommended age[5].

The occurrence and progression are a multi-factor, multi-stage complex process[6-8]. It is generally believed that CRC is caused by the mutations and malignant proliferation of colorectal mucosal epithelial cells. Other studies have shown that CRC can develop from inflammatory bowel disease (IBD). IBD is mainly characterized by intestinal mucosal barrier dysfunction, because the changes of cytokines aggravate tissue damage and eventually lead to tumorigenesis. It is reported that patients with ulcerative colitis have a higher risk of developing CRC than the general population[9]. In addition, microRNA and tumor microenvironment also have potential pathogenic effects on CRC[10,11]. Currently, the clinically recognized gold standard for CRC detection remains endoscopy combined with histopathological analysis. Given the heterogeneity of tumor tissues and the invasiveness of endoscopy, the same patient cannot be sampled multiple times, so that the genetic testing results cannot fully display the mutation spectrum of oncogenic genes[12]. According to the Chinese *Expert Consensus on Early Diagnosis and Screening Strategies for Colorectal Tumors* published in October 2018, fecal detection is a promising method for early diagnosis[13]. Its theoretical basis is that the tumor cells in the intestinal cavity of CRC patients adhere less to the base and can be continuously exfoliated from the colorectal mucosa. Studies have shown that tumor-associated DNA can stably exist in the stools, which has high specificity for the detection of CRC and is the most suitable biomarker in fecal detection[14-16]. By extracting the DNA of shed tumor cells in stools and analyzing their mutations, the traits of intestinal tumor cells can be reflected. Fecal DNA detection, as an emerging, noninvasive technique for screening CRC, has attracted great attention in recent years, which has the advantages of noninvasiveness, convenient access to materials, good patient compliance, and continuous dynamic monitoring. It is in line with the concept and conforms to the trend of "precision medicine", which is an exceptionally promising detection method.

With the continuous development of molecular biotechnology, next generation sequencing (NGS) has emerged to gradually become a hot research topic worldwide. It is also known as high-throughput sequencing, which operates on the following principles: Four different deoxynucleotide triphosphates (dNTPs) are labeled with different fluorescent colors. Conforming to the complementary base pairing rule, the bound base releases the corresponding fluorescence by the action of DNA polymerase every time a dNTP is added. Finally, the base is identified according to the fluorescent signal. Compared to the first-generation Sanger sequencing, NGS is a set of technologies that completely change the standard concept of nucleic acid sequencing. Capable of detecting millions of DNA molecules simultaneously, it achieves concurrent synthesis and sequencing, which can greatly shorten the detection time, and has the advantages of high throughput, high efficiency, and rich information[17,18]. NGS can more comprehensively display the full spectrum of tumor-associated genes, which can reflect the changes in tumor-specific genes, expand the understanding of tumor-specific genes, and improve the predictability of targeted therapy, suggesting its significance in achieving personalized tumor treatment and developing new therapeutic strategies[19-21]. Currently, NGS has been widely applied in the research of various solid tumors, including CRC. Kraus and his colleagues performed NGS analysis on the tissue paraffin sections and blood samples of 152 CRC patients based on 18 CRC-related genes. Their results showed that NGS had a high detection rate and could effectively identify the high-risk patients with hereditary CRC[22]. In a study by Li *et al*[23], the NGS (Ion Torrent PGM platform) technology was applied to analyze 22 tumor-associated mutation hotspots in 526 CRC patients, finding that *TP53* and *KRAS* mutations were the most common in tumor tissues, and confirming that NGS was a highly sensitive detection technique.

This study performed NGS-based genetic testing of 50 tumor-associated mutation hotspots in the stools of CRC patients, and compared them with the genetic testing results of corresponding tumor tissues, with an aim to find the fecal genes or gene combinations with high specificity and sensitivity,

and to establish a technological platform for CRC screening, diagnosis, and efficacy monitoring through fecal DNA detection. The findings herein will provide support and basis for personalized diagnosis and treatment of CRC.

MATERIALS AND METHODS

Subjects

Fifty tumor tissues, 27 preoperative stools, and 19 postoperative stools (stools formed over 7 d postoperatively) collected from patients with CRC were included in an experimental group. Twenty stool samples collected from healthy subjects were included in a normal control group. Seventeen stool samples of patients with benign intestinal polyps confirmed by digestive endoscopy were collected, as well as three stool samples from patients with ulcerative colitis, totaling 20 samples, were included in a benign control group. Postoperative pathological reports of polyp patients revealed inflammatory or adenomatous polyps, none of which had progressed to the CRC stage.

This study was approved by the Ethics Committee of Taizhou People's Hospital in Jiangsu, and the patients provided signed informed consent for sample collection.

Main reagents

Fecal DNA sample preservation tubes, tissue nucleic acid preservation tubes, fecal DNA extraction kit (immunomagnetic bead method), universal columnar genomic nucleic acid extraction kit, fast DNA library preparation kit were provided by Cowin Bio., Jiangsu, while high-throughput kit (MGISEQ-2000RS) was provided by MGI, Shenzhen.

Samples sources

The subjects of this project are patients who were diagnosed with CRC for the first time and underwent surgery at Taizhou People's Hospital from January 2019 to January 2021. A total of 54 tumor tissue samples, 45 preoperative stool samples, and 41 postoperative stool samples were collected. The normal control group consisted of healthy physical examination takers without malignancies (including CRC), intestinal polyps, or IBD, from whom 20 stool samples were collected. The benign control group comprised 20 patients who were diagnosed with intestinal polyps or IBD by digestive endoscopy, and admitted to the Department of Gastroenterology, Taizhou People's Hospital for polypectomy or anti-inflammatory treatment. Twenty formed stool samples were collected from patients who had not taken laxatives preoperatively or from patients before receiving anti-inflammatory therapies. The above samples were tested by NGS, unreliable results were filtered during analysis of genetic testing results based on biological information, and poor quality samples were eliminated (heterogeneous tumor tissues, atypical fecal specimens, and little or degraded DNA in stools). Finally, effectively detected samples included 50 tumor tissues, 27 preoperative stools, 19 postoperative stools, 20 stools in the normal control group, and 20 stools in the benign control group.

Sample collection and processing

Stool samples: Patients were instructed to use the fecal DNA preservation tube correctly (tubes contained protective solution to prevent the degradation of nucleic acid, while steel beads played a mixing role). They were asked to take samples immediately after natural defecation. Using sampling spoon located on the tube cap, typical formed stool about the size of soybean was excavated while avoiding spillover of protective solution and steel beads in the tube. After tightening the tube cap, the patients were asked to shake the tubes for approximately 30 s for uniform mixing. The samples were stored in a -80 °C refrigerator for subsequent testing.

Tissue samples: The freshly isolated tumor tissues were quickly cut into pieces (< 0.5 cm in thickness) using sterile tissue scissors, and then the tissue pieces were soaked in the protective solution of preservation tubes (if the volume was excessively large, the protective solution would not easily penetrate the tissues, which could not protect the nucleic acid from degradation). After tightening the tube caps, the samples were stored in a 4–8 °C refrigerator for subsequent testing.

DNA extraction from stool samples

The DNA in stool samples should be extracted strictly in accordance with the kit instructions (immunomagnetic bead method). Initially, the samples were homogenized, and then the precipitates (fecal particles) were removed, and the supernatants were retained for subsequent use. Different reagents were added to the corresponding wells of deep 96-well plates as *per* the instruction procedures, and then the deep well plates and magnetic sleeves containing the reagents were placed at the corresponding positions of nucleic acid extractor, followed by running of the stool extraction program. Under high salinity condition, DNA can bind to the surfaces of silica-coated Magbeads. After rinsing, high-purity DNA was eluted and stored in Buffer GE. The DNA-containing Buffer GE was transferred to an EP tube and stored under refrigeration for subsequent testing.

Table 1 details the reaction system. Relevant reagents were added to the corresponding wells of deep 96-well plates (wells 1–6 corresponded to one sample, wells 7–12 corresponded to another sample, and so forth).

The deep 96-well plates and corresponding magnetic sleeves were placed into the corresponding positions of an automatic nucleic acid extractor, and then the fecal DNA extraction program was initiated. After running for about 20 min, the program was paused, and each 220 μL of pre-prepared mixture (Magbeads PN 20 μL, isopropanol 200 μL) was added to the first well of each sample, followed by continuation of the program. The product in the last well of each sample was transferred to the centrifuge tube and stored at low temperature for subsequent testing.

DNA extraction from tissue samples

DNA was extracted from tissue samples strictly following the instructions of universal columnar genomic nucleic acid extraction kit. Initially, fresh tumor tissues were ground to small pieces and added with lysis buffer and proteinase K for complete digestion and lysis. Then, RNase was added to remove RNA. Since DNA was insoluble in absolute ethanol, the samples added with absolute ethanol were centrifuged to adsorb the DNA on the column. The residual impurities dissolved in absolute ethanol were discarded along with the liquid waste in the collection tube. Next, the collection tube was replaced with a new one, and the centrifugation was repeated several times. The DNA-containing adsorption column was placed at room temperature, and let stand to dry the absolute ethanol. The elution buffer was suspended, added to the adsorption column with a new collection tube, and centrifuged, and then the DNA-containing eluate in the collection tube was collected and refrigerated for subsequent testing.

The nucleic acid extraction was carried out in Cowin Bio., Jiangsu.

Library construction and NGS detection

In accordance with the instructions of fast DNA library preparation kit, the hotspot mutation panels of 50 tumor-associated genes designed for specific genomic regions or targets were added initially based on the multiplex polymerase chain reaction (PCR) library construction technology, and then multiplex PCR enrichment was performed on specific gene region fragments. Next, the obtained target gene fragments were subjected to end repair, barcode adapter ligation, and PCR amplification (Eastwin Scientific Equipment, Suzhou) to prepare a library. Afterwards, the library was quantified with Qubit 3.0 fluorescence quantifier (Thermo Fisher Scientific, Shanghai), and the fragment size of the library was analyzed with the Bioptic Qsep 100 automatic nucleic acid analyzer (Bioptic Inc., Jiangsu) to evaluate the library quality. Finally, a high-throughput sequencer (MGI, Shenzhen) was used for sequencing, and the data splitting, denoising, and comparison were accomplished in the Linux system to obtain the gene mutation results of various samples.

The library construction and NGS were carried out in Cowin Bio., Jiangsu.

Statistical analysis

Data were analyzed using SPSS 26.0 software. The gene mutation frequencies are expressed as the numbers of cases or percentages. Inter-group differences were examined by χ^2 and Fisher exact tests. $P < 0.05$ was considered statistically significant.

RESULTS

Clinical data analysis of CRC patients

Among the CRC patients corresponding to 50 tumor tissue samples, 24 were female (48.00%) and 26 were male (52.00%). The age span was large (35–84 years), and the median age was 59.5 years. According to the histopathological results of tumor tissues, there were 29 cases of rectal cancer (58.00%), 11 cases of left colon cancer + sigmoid colon cancer (22.00%), and 10 cases of right colon cancer (20.00%). Twelve cases (24.00%) were well-differentiated + well-to-moderately differentiated, 25 (50.00%) were moderately differentiated, and 12 (24.00%) were moderately-to-poorly differentiated + poorly differentiated (the degree of differentiation was not determined in 1 of 50 colorectal cancer tumor tissues). Among 19 cases (38.00%) of lymph node metastasis, only 1 had distant metastasis (metastasis to the liver). Regarding pathological staging (according to eighth edition of AJCC TNM staging system), 33 cases (66.00%) were at stages I + II, and 17 (34.00%) were at stages III + IV (Table 2).

Gene mutations in various samples

As is clear from the NGS testing results of CRC specimens in Table 3, genes like *TP53*, *APC*, *KRAS*, *PTEN*, *MET*, *HRAS*, and *PDGFRA* had high incidences of mutations in tumor tissues and preoperative stools, while in postoperative stools, the mutation frequencies of *TP53*, *HRAS*, and *PDGFRA* were high. Despite high mutation frequencies of *HRAS* and *PDGFRA* in the three groups of samples, their mutations were mostly same sense mutations, meaning that there were only base mutations, without changes in amino acids, which had no clinical significance.

Table 1 The reaction system

Position	Reagent
Wells 1 and 7	Proteinase K: 20 μL
	Lysate: 200 μL
Wells 2 and 8	Buffer KCL: 750 μL
Wells 3 and 9	Buffer GW1: 750 μL
Wells 4 and 10	Buffer GW2: 750 μL
Wells 5 and 11	Buffer MW3: 750 μL
Wells 6 and 12	Buffer GE: 100 μL

Table 2 Clinical data analysis of colorectal cancer patients

Clinical feature	Stratification	Number of people (%)
Age (years old)	≥ 60	30 (60.00)
	< 60	20 (40.00)
Sex	Male	26 (52.00)
	Female	24 (48.00)
Tumor location	Sigmoid colon + left hemicolon	11 (22.00)
	Right hemicolon	10 (20.00)
	Rectum	29 (58.00)
Tumor size (cm)	≥ 6	12 (24.00)
	< 6	38 (76.00)
Degree of tumor differentiation	High + medium high	12 (24.00)
	Moderately	25 (50.00)
	Low medium + low	12 (24.00)
TNM classification	I + II	33 (66.00)
	III + IV	17 (34.00)

As shown in Table 4, the *PDGFRA*, *HRAS*, and *KIT* mutations occurred in only 3 of 20 stool samples in the normal control group. In the benign control group, only 4 stool samples had *PDGFRA*, *HRAS*, *KIT*, or *STK11* mutations.

Since every gene has numerous mutation sites, different site mutations have different meanings. We classified and summarized the results of gene sequencing, and queried them online (https://www.ncbi.nlm.nih.gov/clinvar/). After combining the start and stop positions of each gene mutation site, various gene mutation sites were classified into four types depending on their pathogenicity: "Pathogenic", "benign", "unknown clinical significance", and "undetected in the system" (hereinafter referred to as "undetected"). "Benign" gene mutation sites imply a large number of mutations that can occur multiple times in the normal population, albeit less than 1% incidences. Mutation sites of "unknown clinical significance" indicate that such mutations are neither pathogenic nor benign, on whom the experimental conclusions in the literature reports are inconsistent. There is insufficient evidence to clearly classify them, and further exploration is required. "Undetected" mutation sites are identified by comprehensively checking multiple items such as the exons, the types of amino acid mutations, and the start and end positions of mutations. In the case of non-conformity of any item, the corresponding mutation site is regarded as "undetected". In Table 3, the mutations of the *PTEN* gene in tumor tissues were quite frequent, all of which were mutation sites of "unknown clinical significance". Among the 27 cases of preoperative stools, 1 had pathogenic mutation. Given the small case number, the possible cause of tumor heterogeneity was not ruled out. The *MET* gene exhibited high mutation frequencies in both tumor tissues and preoperative stools, all of which were "benign" mutations upon query. The four *MET* mutations in the postoperative stools were all "undetected" mutations. In Table 4, the mutation sites of *KIT* and *STK11* in the benign control group were benign mutation sites, while the rest were all same sense mutations and had no clinical significance.

Table 3 Summary of gene mutations in colorectal cancer patients

Gene	Tumor tissue		Preoperative feces		Postoperative stools	
	Total number of mutations	Mutation frequency	Total number of mutations	Mutation frequency	Total number of mutations	Mutation frequency
TP53	40	62.00% (31/50)	27	59.26% (16/27)	7	31.58% (6/19)
APC	15	24.00% (12/50)	3	11.11% (3/27)	0	0
KRAS	30	58.00% (29/50)	11	37.04% (10/27)	0	0
PIK3CA	13	22.00% (11/50)	1	3.70% (1/27)	2	10.53% (2/19)

Total number of mutations: The overall number of mutations of any gene in various samples. Mutation frequency: The number of people with mutations in various samples/total number of people.

This study focused on analyzing the pathogenic mutation sites of various genes.

Comparison between preoperative stool and tumor tissue results in CRC patients

As shown in Table 5, the *TP53*, *APC*, and *KRAS* genes had high incidences of pathogenic mutations in tumor tissues and preoperative stools among CRC patients. Despite high mutation frequency of *PIK3CA* in tumor tissues, its pathogenic mutation frequency in preoperative stools was only 3.70% (1/27). The possible causes of tumor heterogeneity or individual disparity could not be ruled out. Although other genes had pathogenic mutations, their mutation frequencies were rather low.

Comparison between preoperative/postoperative stool results of CRC patients and control stool results

For CRC patients, the pathogenic mutation incidences of *APC*, *TP53*, and *KRAS* in the preoperative stools were 11.11% (3/27), 37.04% (10/27), and 25.93% (7/27), respectively. There were mutations of *PIK3CA*, *BRAF*, and *MPL* genes in the postoperative stools. Although they were pathogenic, only one

Positive rate of pathogenic gene mutation site: The number of people with mutations corresponding to the pathogenic mutation sites of any gene/total number of samples.

case was found for each gene. The possible cause of tumor heterogeneity could not be ruled out. No pathogenic gene mutation sites were detected in stool samples from the normal and benign control groups (Tables 6–8).

According to a combination of Tables 5–8, the *TP53*, *APC*, and *KRAS* genes all had high mutation frequencies in the preoperative stools and tumor tissues of CRC patients, while exhibiting no pathogenic mutations in the postoperative stools, or in the stool samples of the normal or benign control group. This indicates that tumor-specific DNA can be detected in the preoperative stools of CRC patients, and that the preoperative fecal expression of tumor-associated genes can reflect the gene mutations in tumor tissue to some extent. Compared to the postoperative stools and the stool samples of the two control groups, the pathogenic mutation frequencies of *TP53* and *KRAS* were significantly higher in the preoperative stools ($P < 0.05$), suggesting that fecal *TP53* and *KRAS* genes can be used for the screening, diagnosis, and prognostic prediction of CRC. Contrastively, the pathogenic mutation frequency of the *APC* gene in the preoperative stools differed insignificantly from that in the postoperative stool or the two control groups ($P > 0.05$), which was probably associated with the excessively small sample size.

Table 6 Comparison of pathogenic mutation sites in preoperative stools *vs* normal control stools

Gene	Positive rate of pathogenic gene mutation sites		χ^2	*P* value

Positive rate of pathogenic gene mutation site: The number of people with mutations corresponding to the pathogenic mutation sites of any gene/total number of samples.

Mutation site analysis for TP53, KRAS, and APC genes

As shown in Table 9, *TP53* mutations occurred in 31 of 50 tumor tissues, and the total mutation frequency was 40 times, of which pathogenic mutation sites accounted for 60.00% (24/40), with exon 5 R175H, exon 7 R248Q/W, and exon 8 R273H/C being the most common. The proportion of pathogenic mutation sites in 29 tumor tissues with *KRAS* mutations was 90.00% (27/30), most of which were located in exon 2, with G12D/V/S being predominant, followed by G13D/C. Additionally, there was 1 case of exon 3 Q61H mutation. As for the *APC* gene, all its pathogenic mutation sites were located in exon 17.

The 12 of 27 *TP53* mutations in preoperative stools were pathogenic mutations, which were mostly exon 7 R248Q and exon 8 R273H/C. The pathogenic mutation sites of the *KRAS* gene were primarily exon 2 G12D/V. As for the *APC* gene, all its pathogenic mutation sites were located in exon 17 (Table 10).

As are clear from Tables 9 and 10, the aforementioned pathogenic mutation sites occurred in both preoperative stools and tumor tissues, suggesting the possible correlation between preoperative stool and tumor tissue in CRC patients.

Combined TP53–KRAS detection

Among the 27 preoperative stools of CRC patients, 16 had pathogenic mutations of the *TP53* gene, with a true positive rate of 59.26%, and 10 had pathogenic mutations of the *KRAS* gene, with a true positive rate of 37.04%. Pathogenic mutations of *TP53* or *KRAS* occurred in 18 preoperative stools, showing a true positive rate of 66.67% (18/27). According to Table 11, the sensitivity and negative predictive value of the combined TP53–KRAS detection were 66.67% and 68.97%, respectively, which were higher than that those of *TP53* or *KRAS* mutation detection alone. This suggests that the combined testing of *TP53* and *KRAS* genes can improve the detection rate.

Distribution of mutation sites of "unknown clinical significance"

Mutation sites of "unknown clinical significance" occurred for such genes as TP53, *PTEN*, *KRAS*, *BRAF*, and *AKT1* in the tumor tissues of CRC patients. The five mutation sites of "unknown clinical significance" for *TP53* were respectively exon 5 A159V/V172G/G154D/P153S and exon 7 S241T. In the case of *PTEN*, 9 of 11 mutations were of "unknown clinical significance", all of which were exon 6 V133I. For the *KRAS* gene, the mutation sites of "unknown clinical significance" accounted for 10.00% (3/30), all of which were exon 4 A146T. In preoperative stools, the mutation sites of "unknown clinical significance" were scattered in *TP53*, *KRAS*, *AKT1*, and *STK11*. In the case of *TP53*, such mutation sites were exon 5 V172G and exon 7 I251T/S241T, which were identical to the mutation locations in tumor tissues. For the *KRAS* gene, the mutation site of "unknown clinical significance" was exon 4 A146T. As for *AKT1* and *STK11*, such mutation sites were located separately in exon 3 E17K and exon 4 E199K.

Distribution of "undetected" mutation sites

As shown in Table 12, genes like *TP53*, *APC*, *EGFR*, *FBXW7*, and *NOTCH1* in tumor tissues all had "undetected" mutation sites, among which exon 4 A84G of *TP53* occurred more frequently (4/40). For the *APC* gene, "undetected" mutation sites were all found in exon 17. The pathogenic mutation sites of *APC* in Tables 9 and 10 were also located in exon 17, suggesting that the "undetected" mutation sites of

Positive rate of pathogenic gene mutation site: The number of people with mutations corresponding to the pathogenic mutation sites of any gene/total number of sample.

APC in Table 12 may be unreported new sites. They are probably associated with the carcinogenesis and progression of CRC, which require further exploration. Table 13 shows that 6 of 27 *TP53* mutation sites in the preoperative stools were "undetected" sites. They were distributed in exon 4, exon 5, exon 7, and exon 8, among which there were three exon 7 N247D (mutation start and stop positions were both 7577542). Additionally, genes like *CDKN2A*, *HRAS*, *EGFR*, *IDH1*, and *PDGFRA* also had "undetected" mutations sites.

DISCUSSION

Studies have shown that the genetic factors coupled with prolonged unfavorable external factors induce the disturbance of homeostasis, which leads to a series of changes including angiogenesis, cell hyperproliferation, apoptosis evasion, and enhanced invasion capacity, ultimately resulting in the occurrence of malignancies. It is generally believed that CRC often develops slowly from adenomas, during which multiple steps are involved, including the activation of proto-oncogenes and the

inactivation of tumor suppressor genes. The mutation statuses of genes like *TP53*, *APC*, and *KRAS* have been reported to be closely associated with the carcinogenesis and progression of CRC[24,25]. With the introduction of the concept of "precision medicine", molecular targeted therapy has become a hot research topic in recent years. This NGS-based study investigated the value of fecal genetic testing in the CRC diagnosis.

As a tumor suppressor gene, *TP53* regulates downstream genes when cells are under stress, which induces apoptosis and cell cycle arrest *via* a series of processes, thereby preventing the growth of tumor cells[26,27]. Its mutation is a key step in facilitating the adenoma–adenocarcinoma transition. In malignancies, the p53 protein encoded by *TP53* is mutant. The mutant p53 protein can lose its tumor suppressor effect and acquire new oncogenic functions to promote the invasion and metastasis of tumor cells[28]. In this study, *TP53* had 60.00% (24/40) and 59.26% (16/27) of mutations in the tumor tissues and preoperative stools of CRC patients, respectively, among which pathogenic mutation sites accounted for 60.00% (24/40) and 40.74% (11/27) of total mutation sites. Such pathogenic mutation sites as exon 5 C176Y, exon 6 R196*, exon 7 R248Q, exon 7 G245C/S, and exon 8 R273H/C existed in both types of samples, showing consistency. Such mutation hotspots as *R273H*, *R248Q*, and *R282W* have been reported as typical "hotspots" in the DNA binding domain. Over 95% of missense *TP53* mutations occur in the DNA binding domain, which can affect the ability of proteins to bind to their target DNA sequences[29-31]. Lo *et al*[32] screened a patient with CRC lymphatic metastasis for tumor infiltrating lymphocytes. Since some tumor patients had TP53 R175H mutations during genetic testing, and HLA-A *0201 could limit the recognition of mutant TP53 R175H, they identified the T cell receptors capable of recognizing the TP53 R175H mutation hotspots, thereby finding patients with different tumor types who shared the same mutation hotspots. In their opinion, the mutant *TP53* could serve as an ideal common antigen target, and these specific hotspot mutations had potential as valuable therapeutic targets for a variety of tumor cells. A study by Olszewski *et al*[33] suggested that changes in the

oncogenic activity of TP53 led to acquisition of new functions for the mutated tumor suppressor p53 protein, and that the overexpression of such mutation hotspots as codons 175, 248, or 273 might be associated with the chemotherapeutic resistance or invasive changes. Their analysis of *TP53* mutation database in human somatic cells revealed that patients carrying TP53 R248Q allele had earlier tumor onsets, but lower frequencies of metastasis.

The 21 kDa protein encoded by *KRAS*, a member of the ras proto-oncogene family, can participate in the G protein signaling pathway and regulate the proliferation and differentiation of cells. *KRAS* mutations can continuously activate the RAS-RAF-MAPK pathway, causing uncontrolled cellular proliferation and differentiation, thereby inducing CRC[14]. Research has demonstrated that the patients' resistance to EGFR-targeted drugs was closely associated with the activation of the *KRAS* gene[34]. In the present study, the incidences of *KRAS* mutations in tumor tissue and preoperative stools of CRC patients were 58.00% (29/50) and 37.04% (10/27), respectively. Among them, pathogenic mutation sites existed in 27 tissues and 7 preoperative stools, with the most common ones being G12D/V and G13D located in exon 2. Armengol *et al*[35] explored the gene mutations in stool samples of 52 CRC patients. They found 12 cases of *KRAS* gene mutations, of which 58.3% (7/12) were located in codons 12 and 13 of exon 2. Knight argued that when there was a KRAS G12D carcinogenic mutation in the body, the formation or growth of intestinal adenomas was not inhibited by rapamycin[36]. Compared to KRAS G12D, patients with KRAS A146T mutation could have stronger resistance to EGFR tolerance, and better survival rates[37]. Mulla *et al*[38] analyzed the RAS mutations in 51 CRC patients, finding that 43% of them had RAS mutations, 91% of which were *KRAS* mutations. The majority of *KRAS* mutations were located in G12D, followed by G13D. They also found that the incidence of *KRAS* mutations was slightly higher among individuals under 50 years of age than that of the elderly (> 50 years). Ottaiano *et al*[39] reported that mutant *KRAS* was a negative influencing factor of prognosis in CRC patients. Among these patients, those with G12C/S mutation showed the shortest survival and the worst prognosis.

Varshavi *et al*[40] investigated how *KRAS* mutations in different codons affected the metabolic pathways. According to their findings, metabolic differences existed between various *KRAS* mutation sites, which might be one of the reasons for the varying efficacies of anti-cancer therapies across patients. Hence, more effective, individualized molecular targeted drugs can be searched based on such metabolic differences.

Mutations of *APC* were linked to familial adenomatous polyposis, and its inactivation and the activation of Wnt signaling pathway also played pivotal roles in the occurrence of CRC, which could affect the adhesion between tumor cells to accelerate the cellular migration[41,42]. It has been reported that in sporadic CRC, most of the *APC* mutations occurred around the mutation cluster region, especially between codons 1286 and 1513[43]. In this study, the incidences of *APC* mutations in tumor tissues and preoperative stools were 24.00% (12/50) and 11.11% (3/27), respectively. As shown in Tables 5 and 6, the pathogenic mutation frequency of the *APC* gene in preoperative stools differed insignificantly from that in control stools (P = 0.370), which thus cannot serve as a specific gene for CRC screening and diagnosis. This may be attributed to the small sample size of this study, which remains further exploration. We found that all the pathogenic mutation sites of *APC* were located in exon 17, most of which used the mutations of certain amino acids as stop codons, thus allowing premature termination of mRNA translation (Tables 8 and 9). Luo's team performed NGS-based gene sequencing

on the blood and tissue samples of 22 CRC patients and 21 patients with intestinal polyps, in order to understand gene mutations. Through screening, they found that the *APC* mutations were most common in both types of samples, which were mostly pathogenic mutation sites. These pathogenic mutation sites of the *APC* gene accounted for 77.3% (17/22) of the total pathogenic mutation sites in all samples[44].

In addition to the pathogenic mutation sites of various samples, this study also found multiple mutation sites of "unknown clinical significance", which were scattered in such genes as *TP53*, *PTEN*, *KRAS*, *BRAF*, *AKT1*, and *PIK3CA*. There were also some gene mutation sites that had not been found in the Clinvar database. *TP53* exon4 A84G and *EGFR* exon20 I821T were present in both the preoperative stools and tumor tissues of CRC patients. The mutation start and stop positions were both 7579436 for the former, while 55249164 for the latter.

CONCLUSION

Conclusively, NGS-based fecal DNA detection can be used as a complementary technique for the CRC diagnosis. Fecal *TP53* and *KRAS* can serve as a specific gene combination for the screening, diagnosis, prognostic prediction, and recurrence monitoring of CRC. Moreover, the combined TP53–KRAS testing can improve the CRC detection rate, which provides a molecular reference for developing personalized treatment programs. The mutation sites of "unknown clinical significance" and the "undetected" mutation sites may be unreported new mutation sites associated with CRC. Whether these genes are linked to the CRC diagnosis and prognosis remains to be further explored and researched.

ARTICLE HIGHLIGHTS

Research background

Colorectal cancer (CRC) is currently a health problem of global concern. In recent years, the incidence of CRC presents a trend of gradual increase. Most patients have unobvious early symptoms, and they are commonly in mid and advanced stages when the symptoms become evident, with rather high mortalities. Featuring high throughput, fastness, and rich information, next generation sequencing (NGS) can greatly shorten the detection time, which is a research hotspot at home and abroad at present.

Research motivation

As we all know, histopathological examination is the gold standard of diagnosis, but its invasiveness limits its development. Therefore, it is imperative to explore the screening, diagnosis, and prognosis of CRC by strong specificity, high sensitivity, and non-invasive methods.

Research objectives

In this study, NGS technology was used to conduct genetic testing on stool samples of CRC patients, and the results were compared with the corresponding tumor tissue genetic testing results. The aim was to find genes or gene combinations with high specificity and sensitivity in the stool and establish a technical platform for CRC screening and diagnosis and curative effect monitoring through fecal DNA detection, providing a strong basis and support for personalized diagnosis and treatment of CRC.

Research methods

NGS was used to sequence the DNA in stools of patients with CRC, which were then compared with the genetic testing results of the stool samples of normal control and benign intestinal disease groups, as well as the tumor tissues of CRC patients. Specific genes or gene combinations in fecal DNA suitable for diagnosis and prognostic prediction of CRC were screened, and their significance in diagnosing CRC and predicting patients' prognosis was comprehensively evaluated.

Research results

High mutation frequencies of *TP53*, *APC,* and *KRAS* were detected in the stools and tumor tissues of CRC patients prior to surgery. Contrastively, no pathogenic mutations of the above three genes were noted in the postoperative stools, or two control groups. This indicates that the tumor-specific DNA was detectable in the preoperative stools of CRC patients. Compared to the postoperative stools and the stools in the two control groups, the pathogenic mutation frequencies of *TP53* and *KRAS* were significantly higher for the preoperative stools ($P < 0.05$), suggesting that fecal *TP53* and *KRAS* genes can be used for CRC screening, diagnosis, and prognostic prediction. No significant difference in the pathogenic mutation frequency of the *APC* gene was found from the postoperative stools or the two control groups ($P > 0.05$), so further analysis with larger sample size is required. In 27 preoperative stools of CRC patients, the sensitivity and negative predictive value of *TP53*- *KRAS* gene combination detection were higher than those of *TP53* mutation or *KRAS* mutation alone, suggesting that *TP53*-*KRAS*

gene combination detection can improve the detection rate of CRC. The "undetected" mutation sites found in preoperative stools and tumor tissues may be new mutation types in the occurrence and development of CRC, which need to be further studied. In addition, some mutations of "unknown clinical significance" were found, and their clinical value is worth further study.

Research conclusions

NGS-based fecal genetic testing can be used as a complementary technique for the CRC diagnosis. Fecal *TP53* and *KRAS* can be used as specific genes for the screening, diagnosis, prognostic prediction, and recurrence monitoring of CRC. Moreover, the combined testing of *TP53* and *KRAS* genes can improve the CRC detection rate.

Research perspectives

Fecal genetic detection is a new method for CRC diagnosis, which has the advantages of non-invasiveness, convenient sampling, and dynamic monitoring. Although the sensitivity of fecal genetic test in CRC screening is low, it is certain that it has great potential and broad prospects in the diagnosis and prognosis assessment of CRC. In addition, the "undetected" mutation sites in preoperative stools of CRC patients and the "unknown clinical significance" mutation sites are related to the occurrence and development of CRC, which requires further research and exploration.

Abstract

BACKGROUND

The lack of effective pharmacotherapies for nonalcoholic fatty liver disease (NAFLD) is mainly attributed to insufficient research on its pathogenesis. The

pathogenesis of TM6SF2-efficient NAFLD remains unclear, resulting in a lack of therapeutic strategies for TM6SF2-deficient patients.

AIM

To investigate the role of TM6SF2 in fatty acid metabolism in the context of fatty liver and propose possible therapeutic strategies for NAFLD caused by TM6SF2 deficiency.

METHODS

Liver samples collected from both NAFLD mouse models and human participants (80 cases) were used to evaluate the expression of TM6SF2 by using western blotting, immunohistochemistry, and quantitative polymerase chain reaction. RNA-seq data retrieved from the Gene Expression Omnibus database were used to confirm the over-expression of TM6SF2. Knockdown and overexpression of TM6SF2 were performed to clarify the mechanistic basis of hepatic lipid accumulation in NAFLD. MK-4074 administration was used as a therapeutic intervention to evaluate its effect on NAFLD caused by TM6SF2 deficiency.

RESULTS

Hepatic TM6SF2 levels were elevated in patients with NAFLD and NAFLD mouse models. TM6SF2 overexpression can reduce hepatic lipid accumulation, suggesting a protective role for TM6SF2 in a high-fat diet (HFD). Downregulation of TM6SF2, simulating the TM6SF2 E167K mutation condition, increases intracellular lipid deposition due to dysregulated fatty acid metabolism and is characterized by enhanced fatty acid uptake and synthesis, accompanied by impaired fatty acid oxidation. Owing to the potential effect of TM6SF2 deficiency on lipid metabolism, the application of an acetyl-CoA carboxylase inhibitor (MK-4074) could reverse the NAFLD phenotypes caused by TM6SF2 deficiency.

CONCLUSION

TM6SF2 plays a protective role in the HFD condition; its deficiency enhanced hepatic lipid accumulation through dysregulated fatty acid metabolism, and MK-4074 treatment could alleviate the NAFLD phenotypes caused by TM6SF2 deficiency.

Key Words: TM6SF2; Nonalcoholic fatty liver disease; Fatty acid metabolism; Treatment; MK-4074

Core Tip: In this study, we observed TM6SF2 overexpression in nonalcoholic fatty liver disease (NAFLD) cases. TM6SF2 overexpression can reduce hepatic lipid accumulation, suggesting a protective role for TM6SF2 in a high-fat diet. Meanwhile, there is an imbalance in the processes of uptake, synthesis, and intracellular expense of fatty acids in TM6SF2-deficient mouse models. Therefore, we propose possible therapeutic strategies for NAFLD caused by TM6SF2 deficiency.

INTRODUCTION

The prevalence of nonalcoholic fatty liver disease (NAFLD) is rapidly increasing and is now more than one-quarter of the global population[1]. Approximately 6%–30% of patients with NAFLD evolve from simple steatosis (SS) to steatohepatitis, characterized by excessive hepatic lipid accumulation, inflammation, and hepatocyte damage[2,3]. Long-term steatohepatitis can cause liver fibrosis, and its adverse outcome may include liver dysfunction and hepatocellular carcinoma[4,5]. The prognosis of NAFLD and its related complications varies among individuals, given that genetic variants affect the occurrence and progression of NAFLD[6]. The development of genome-wide association studies and high-throughput technologies has allowed for in-depth analysis of genetic risk factors for NAFLD[7,8]. Identification of genes with high-risk single nucleotide polymorphisms (SNPs) has allowed the screening of individuals with a genetic predisposition to NAFLD[9], and several studies have reported some potential SNP loci (*e.g.*, PNPLA3 rs738409, MBOAT7 rs641738, and PPARGC1A rs2290602)

associated with the susceptibility and progression of fatty liver[10-12]. To further elucidate the mechanistic basis of the link between potential SNPs and susceptibility to NAFLD, the functions of many candidate genes have been thoroughly investigated, including *TM6SF2*.

TM6SF2 is a multi-transmembrane protein expressed predominantly in the intestine and liver, implying a metabolism-related function[13]. Our previous study and others have demonstrated that the rs58542926 locus of TM6SF2 confers susceptibility to NAFLD[14-16]. The nonsynonymous variant of TM6SF2, rs58542926 (E167K), leads to protein misfolding, acceleration of protein degradation, and, therefore, a reduction in TM6SF2 protein levels and gene function[15]. Recently, several studies have focused on the influence of TM6SF2 deficiency or its E167K mutant on cholesterol metabolism and its association with reduced very low-density lipoproteins (VLDL) content that causes a decrease in hepatic triglyceride (TG) output[17-19]. Considering that the liver is the central hub for lipid metabolism, there is a balance among the processes of uptake, synthesis, and intracellular expense of fatty acids under normal circumstances. Hepatic lipid accumulation may occur when this balance is disrupted[20]. However, the regulatory role of TM6SF2 in fatty acid metabolism in the context of NAFLD remains largely unknown. Therefore, our study aimed to elucidate the influence of TM6SF2 on fatty acid metabolism in experimental NAFLD models.

The present study revealed that hepatic TM6SF2 expression was elevated in patients with NAFLD and mouse models. Our results suggest that TM6SF2 elevation is a compensatory response to NAFLD. Physiologically, the reactive overexpression of TM6SF2 can protect the liver and reduce hepatic lipid accumulation under the condition of a high-fat diet (HFD). Loss of TM6SF2 exacerbates hepatic lipid accumulation. Further investigation revealed that the enhanced processes of uptake and synthesis of fatty acids and impaired oxidation processes were observed in hepatic TM6SF2 deficiency, suggesting that TM6SF2 deficiency caused a pathogenic link between the metabolic dysfunction of fatty acids and hepatic steatosis in NAFLD. The elucidation of metabolic alterations suggested the way of therapeutic intervention, and our results showed that liver-specific acetyl-CoA carboxylase (ACC) inhibitor (MK-4074) would block the enhanced synthesis of fatty acid, improve fatty acid β-oxidation, and then reverse the NAFLD phenotypes caused by TM6SF2 deficiency. Collectively, this study suggested a protective role of TM6SF2 in HFD conditions, revealed a pivotal role of TM6SF2 in fatty acid metabolism, and suggested a therapeutic intervention for TM6SF2-deficient exacerbated NAFLD.

MATERIALS AND METHODS

Cell culture

Knockdown of the *TM6SF2* gene was mediated by the lentiviral vectors pLenti6.3-MCS-TM6SF2-EGFP (sh-TM6SF2) or pLenti6.3-MCS-EGFP (sh-Ctrl). Target sequence for sh-TM6SF2: TGACCTGGCCCT-TGTCATATA. After two or three generations of antibiotic screening, the expression of TM6SF2 was evaluated by immunoblotting. All cells were cultured in DMEM containing 10% fetal bovine serum (FBS) and 1% penicillin-streptomycin (Cat. No. C125C5, NCM Biotech, Suzhou, China) at 37 ℃ and 5% CO_2. The cells were cultured under 1% O_2 and 5% CO_2 for 24 h to simulate hypoxic conditions. For starvation, cells were cultured in DMEM containing 0.1% FBS for 24 h.

Western blot

Cells in a 6-cm dish at 80% confluence were lysed with 250 μL of RIPA lysis buffer and centrifuged at 13000 rpm. The quantification of the supernatant collected was assessed using the BCA method (Beyotime, Jiangsu, China). Proteins were transferred to a 0.45 μm PVDF membrane according to the standard immunoblotting protocol after electrophoresis. The membrane was blocked in 5% fat-free milk and then maintained in primary antibodies for 12 h at 4 ℃. After washing, the membrane was incubated with HRP-labeled goat anti-rabbit (mouse) antibody at 25 ℃ for 60 min and visualized using an ECL reagent (Millipore, MA, United States). Supplementary Table 1 lists the antibodies used in this study.

Clinical specimens

Liver specimens were collected from the Shanghai General Hospital. Parts of the specimens were snap frozen in liquid nitrogen and then transferred to a -80℃ refrigerator to detect mRNA levels, and some were stored in formaldehyde solution for later pathological examination. When ≥ 5% of hepatocytes had steatosis, NAFLD diagnosis was confirmed. The diagnosis of the tissue sections was independently reviewed by two pathologists. This study was approved by the Ethics Committee of the Shanghai General Hospital and was performed strictly in accordance with the Declaration of Helsinki. All patients or their family members were fully informed of the study and signed written consent forms.

Immunohistochemistry

Paraffin-embedded liver tissues were deparaffinized using standard protocols and rehydrated. After antigen retrieval, the tissue was blocked and incubated with an anti-TM6SF2 (1:200) antibody overnight at 4 ℃. Then the slides were washed and incubated with biotin-labeled goat anti-mouse IgG (H + L) at

37 ℃ for 15 min and developed with a DAB work solution. Images were obtained using a microscope (Leica, Germany).

Real-time polymerase chain reaction assay

A total of 50 mg of liver samples from mice or humans was lysed with RNAiso Plus reagent (Takara Biotechnology, Otsu, Japan), and total RNA was extracted according to the standard protocol. Reverse transcription of 500ng of RNA was performed using the RNA polymerase chain reaction (PCR) Kit (Takara Biotechnology), and the resulting cDNA was used as the PCR template. Quantification of target gene expression was performed using a LightCycler® 96 (Roche, Switzerland) and a Hieff® quantitative PCR SYBR Green Master Mix (No Rox) kit (Yeasen Biotechnology Co., Ltd, China). The mRNA level of *β-actin* was used as the endogenous control. We chose the TM6SF2 level of one patient as the reference, and the TM6SF2 levels of all other patients were presented several times of this reference. The primers used are listed in Supplementary Table 1.

Experimental animals

The AAV system (type 8) expressing TM6SF2 short hairpin RNA (shRNA) (AAV-shTm6sf2) or overexpressing human TM6SF2 (AAV8-TM6SF2) was used to regulate the levels of TM6SF2 in C57BL/6 mice. The corresponding controls were AAV-shNC and AAV8-vector, respectively. All mice were fed a normal chow diet (NCD) for three days, and then 100 μL of AAV8 virus (2×10^{11}) was injected into the tail vein. Transfection efficiency was determined by immunoblotting. Male mice weighing 19–22 g (aged 4–6 wk) were housed in a 23 ± 2°C environment with a 12 h light/dark cycle. All mice were allowed water ad libitum and were continuously fed an HFD or NCD for 16 wk. For MK-4074 treatment, the mice were primarily fed an 8-wk HFD to induce NAFLD phenotypes and then administered MK4074 (10 mg/kg/day) or placebo (normal saline) for an additional eight weeks on the same diets.

Evaluation of serum parameters and hepatic lipid content

The concentrations of cytokines, metabolites, and hepatic enzymes in serum were determined using commercial kits [ab208348 for tumor necrosis factor (TNF), ab197742 for interleukin (IL)-1β, ab222503 for IL-6, JLC049 for CCL2, JLC5800 for CXCL10, ab180875 for acetoacetate, ab180876 for β-hydroxybutyrate (β-OH), C010-2-1 for aspartate transaminase (AST), and C009-2-1 for alanine aminotransferase (ALT)] according to the manufacturer's instructions. The hepatic lipid content and malonyl-CoA levels were also measured using commercial kits [A110-1-1 for TG, A111-1-1 for total cholesterol (TC), A042-2-1 for non-esterified fatty acids (NEFA), and JL47416 for malonyl-CoA], and normalized by the total protein. The details of all the commercial kits used are listed in Supplementary Table 1.

Microarrays

After palmitic acid (PA, 150 μmol/L) stimulation for 24 h, total RNA was extracted from both TM6SF2-knockdown L02 cells and the corresponding controls using RNAiso Plus (Takara Biotechnology). Microarray gene expression analysis was performed by Illumina sequencing. We analyzed differentially expressed genes (DEGs) between sh-Ctrl and sh-TM6SF2 cells by using the "edgeR" package based on the R platform[21]. Fold change > 1.2 and adjusted *P*-value < 0.05 were set as the screening cutoffs for the upregulated DEGs. These DEGs were further analyzed *via* DAVID 6.8 (https://david.ncifcrf.gov/) for Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway analyses. The "ggplot2" package in R is used for result visualization.

Preparation of fatty acid solution

A 5 mmol/L stock solution of PA (Sigma-Aldrich) was obtained by dissolving PA in 3% of bovine serum albumin (BSA, Sigma-Aldrich) medium by continuous stirring for approximately 4 h in a 60 °C water bath. The stock solution was then diluted in DMEM to achieve the designated concentration, and 3% of BSA was used as a control. The concentrations of free fatty acids range from 0.1 to 0.7 mmol/L[22-24].

Glucose and insulin tolerance test

Glucose tolerance test (GTT) and insulin tolerance test (ITT) were performed as previously described [25]. After the above steps were completed, the glucose concentrations of the blood collected from the tail vein at the indicated points were analyzed immediately using a glucose meter (Yuwell, China).

Nile red staining

After sh-ctrl and sh-TM6SF2 L02 cells were constructed, they were incubated in DMEM containing 150 μmol/L of PA for 24 h to generate a steatosis cell model. Cells were then fixed with 4% paraformaldehyde and incubated with 0.1 μg/mL Nile Red for 15 min. After washing with PBS, the cells were incubated with DAPI (Solarbio) for 5 min. Images were taken with a Leica microscope (Leica, Germany) and quantified using the ImageJ software.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) imaging was performed using a 7.0 T Bruker BioSpec MRI scanner (Bruker, United States). Before imaging, the mice were fasted overnight to avoid disturbance of stomach contents during liver imaging. The mice were first anesthetized with oxygen containing 2%–3% isoflurane and then placed in a prone position with their heads facing inward. Throughout the imaging process, the mice were continuously provided with oxygen mixed with 1%-3% isoflurane through the nosecone to maintain the respiratory rate at 50-70 breaths/minute. All mice underwent abdominal MRI to determine the maximum cross-sectional area of the liver. The region of interest was analyzed using ImageJ software, and the size of the cross-sectional area was represented by the number of pixels.

Histological analysis

Liver sections were embedded in paraffin and stained with hematoxylin and eosin (H&E), and frozen liver sections were stained with Oil Red O (O8010-5g; Solarbio) for lipid visualization. Images were obtained using a light microscope (Leica). Oil Red O- stained sections were quantified using ImageJ software.

FAO measurement

A total of 6000 cells were seeded in an XF96 cell culture microplate, and each group was assayed in five or six replicate wells. After cell adherence (about 8 h), the growth medium was changed to a substrate-limited growth medium (0.5 mmol/L of glucose, 1 mmol/L of GlutaMAX, 0.5 mmol/L of XF L-carnitine, 1% FBS, pH 7.4) for overnight incubation. Before the Seahorse Bioscience XF96 instrument (Agilent, United States) was started, the medium was changed to a PA measurement medium. Different inhibitors (oligomycin 2 μmol/L, FCCP 2 μmol/L, and R/A 1.2 μmol/L) were added to each chamber when the instrument began to measure the oxygen change rate. The difference in each group's oxygen consumption rate (OCR) revealed the level of fatty acid oxidation (FAO) based on palmitate substrates. The basal respiration, maximal respiration, spare respiratory capacity, and ATP production were calculated.

Cell viability assay

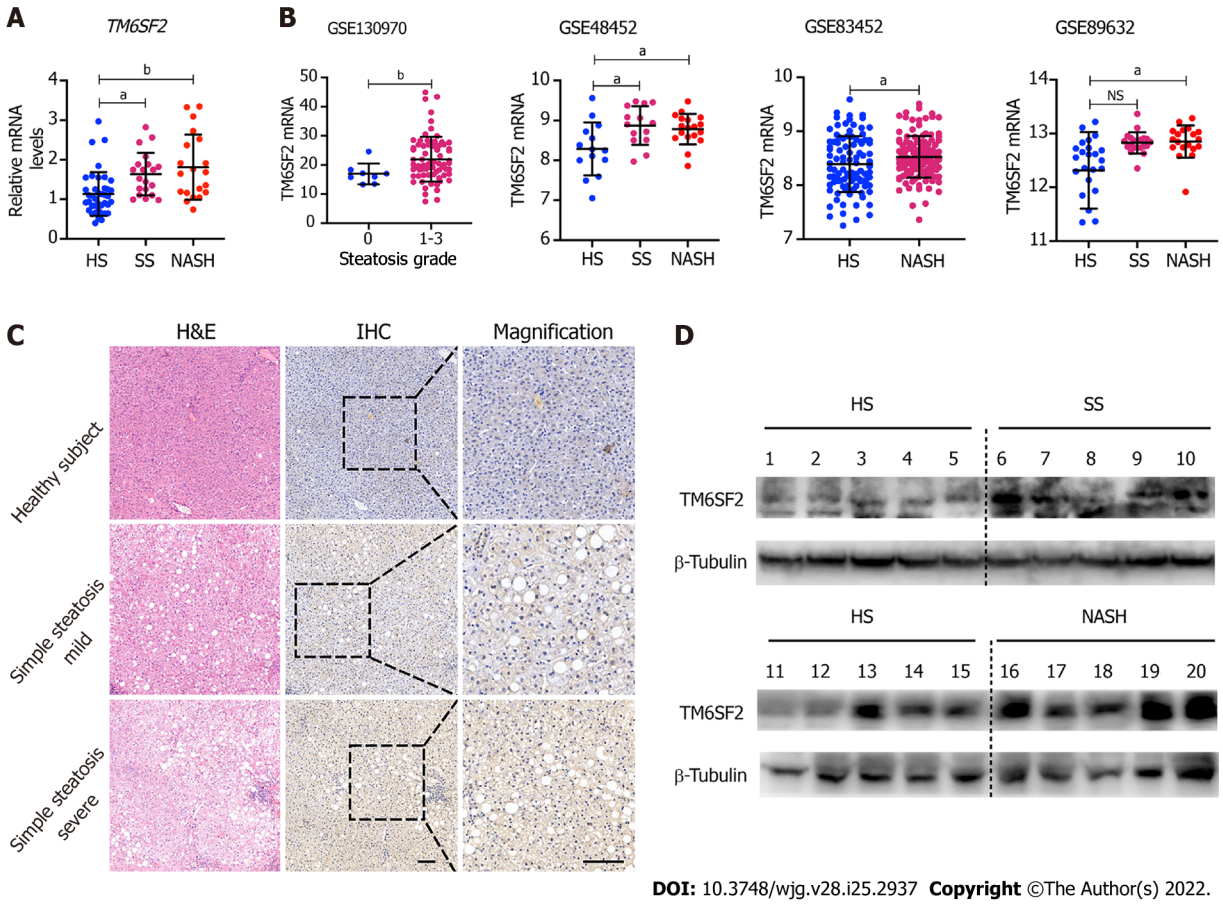
Cell viability was assessed using the CCK-8 assay (NCM Biotech, China). Sh-ctrl and sh-TM6SF2 cells were seeded in a 96-well plate at a density of 5000 cells *per* well, and a cell viability assay was performed after PA or fatty acid-free BSA treatment for 24 h. Absorbance (450 nm) was measured using a microplate reader (BioTek, United States). Each sample was assayed in five replicate wells, and the experiment was independently performed three times.

Quantitation of intracellular TG levels in cell lines

After PA or BSA treatment for 24 h, cells were lysed on ice with RIPA buffer (Beyotime, Beijing, China) for 20 min and centrifuged at 13000 rpm for 20 min at 4 °C. Then the supernatant was transferred to a new tube. TG levels were evaluated using a TG detection kit (Nanjing Jiancheng, Jiangsu, China) and normalized to the total protein level. The experiment was independently performed three times.

Bioinformatic analyses

Expression profiles of TM6SF2 in NAFLD cases were retrieved from the Gene Expression Omnibus (GEO; www.ncbi.nlm.nih.gov/geo) database. The accession numbers are GSE130970, GSE48452, GSE83452, and GSE89632. The details of the cohorts are presented in Supplementary Table 2.



Statistical analysis

All data are presented as the mean ± SD. Student's t-test was used to evaluate the differences between the two groups. Differences between more than two groups were compared using one-way analysis of variance followed by Tukey's multiple comparisons test. *In vitro* studies, all experiments were independently performed three times in vitro. The SPSS software (version 25.0) was used for all statistical analyses. $P < 0.05$ was considered statistically significant and denoted as $^{a}P < 0.05$, $^{b}P < 0.01$, and $^{c}P < 0.001$; NS: Not significant.

RESULTS

Hepatic TM6SF2 expression is upregulated in patients with NAFLD and HFD-induced mice models

The mRNA levels of TM6SF2 were examined in 80 liver samples of patients with NAFLD and healthy subjects ($n = 40$), which showed that the transcriptional levels of TM6SF2 were both elevated in patients with SS or nonalcoholic steatohepatitis (NASH) (Figure 1A, SS: $n = 20$; NASH: $n = 20$). Additionally, we retrospectively analyzed another four transcriptomic datasets retrieved from the GEO database (GSE13970, GSE48452, GSE83452, and GSE89632, Figure 1B), which contained transcriptional profiles of both healthy participants and patients with NAFLD. Patients with SS or NASH displayed higher hepatic

Figure 1 Hepatic TM6SF2 expression is upregulated in nonalcoholic fatty liver disease patients. A: Hepatic mRNA levels of TM6SF2 in liver specimens, including healthy subjects (HS, *n* = 40) and patients with simple steatosis (SS, *n* = 20) or nonalcoholic steatohepatitis (NASH, *n* = 20); B: Hepatic mRNA levels of TM6SF2 in individuals with or without nonalcoholic fatty liver disease (NAFLD) from four expression microarray series retracted from Gene Expression Omnibus database; C: Immunohistochemical staining with TM6SF2 was performed on individuals with or without NAFLD. Representative images of normal liver tissues *vs* tissues of SS were shown. Scale bars: 50 μm; D: Immunoblot analysis of TM6SF2 expression in liver specimens. HS (*n* = 10), SS (*n* = 5) and NASH (*n* = 5). $^{a}P < 0.05$; $^{b}P < 0.01$, NS: Not significant; HS: Healthy subjects; SS: Simple steatosis; NASH: Nonalcoholic steatohepatitis; IHC: Immunohistochemistry; H&E: Hematoxylin and eosin.

TM6SF2 mRNA levels than healthy participants. Immunohistochemistry staining indicated that TM6SF2 tended to upregulate TM6SF2 expression from normal liver to severe SS (Figure 1C). We also noted upregulation of TM6SF2 protein in the liver samples of patients with SS or NASH (Figure 1D). To further confirm TM6SF2 overexpression under overnutrition, we evaluated the changes in TM6SF2 expression in and *in vitro* NAFLD cell model and stimulated two cell lines, L02 and HepG2, with PA, as it was reported that this *in vitro* model mimics steatosis *in vivo*[22-24]. The results showed that PA stimulation increased the protein levels of TM6SF2 in a time- and dose-dependent manner (Supplementary Figure 1A). Further, whether in protein or mRNA levels, the augmented TM6SF2 expression was also demonstrated in HFD-fed mice for 12 wk (Supplementary Figure 1B). These results revealed that hepatic TM6SF2 levels were upregulated in patients with NAFLD and HFD-induced mouse models.

TM6SF2 overexpression mitigates hepatic lipid accumulation in HFD-induced mice models

As we had found that the levels of TM6SF2 were increased in participants with NAFLD and HFD-induced models, we wanted to determine the physiological significance of TM6SF2 elevation when NAFLD phenotypes occur. To this end, we used the AAV8 vector to deliver human TM6SF2 (AAV8-TM6SF2) in the livers of mice (AAV8-vector was used as a control) and fed them HFD for 16 wk (Figure 2A and B). The results showed that TM6SF2 overexpression in the liver significantly reduced the liver/body weight ratio, and its impact on body weight was limited (Figure 2C and D). Hepatic TM6SF2 overexpression in mice resulted in lower levels of hepatic lipid content as well as lower serum ALT and AST levels (Figure 2E and F). TM6SF2-overexpression groups relative to controls displayed equal body size (Figure 2G) but demonstrated a minor fatty liver and a smaller cross-sectional area of the fatty liver (Figure 2H). Hepatic lipid accumulation was also ameliorated in AAV8-TM6SF2 mice, as indicated by the pathological examination (Figure 2I). We also observed that TM6SF2 knocked-down cells reconstituted with wild-type TM6SF2 exhibited decreased intracellular lipid accumulation and

improved PA-induced cell death (Supplementary Figure 2). This evidence suggests that the elevation of TM6SF2 is a potential reaction to antagonize NAFLD phenotypes and serves a protective role during NAFLD.

Knockdown of TM6SF2 promotes hepatic lipid accumulation and inflammation in the HFD-induced mice model

Pathologically, there exists a genetic E167K mutation in the TM6SF2 protein in humans, and those with the TM6SF2 E167K mutation are associated with an increased risk of NAFLD[26]. Ehrhardt *et al*[27] reported that the E167K mutation causes downregulation of TM6SF2 at the protein level. To simulate the E167K condition and explore the influence of TM6SF2 on lipid accumulation, we generated TM6SF2-knockdown cells in both the L02 and HepG2 cell lines (Figure 3A), which were incubated with PA (150 μmol/L) or BSA (fatty acid free) for 24 h. We found that TM6SF2-knockdown cells demonstrated higher levels of intracellular TG (Figure 3B) and more severe lipid accumulation (Figure 3C). Lipid overload

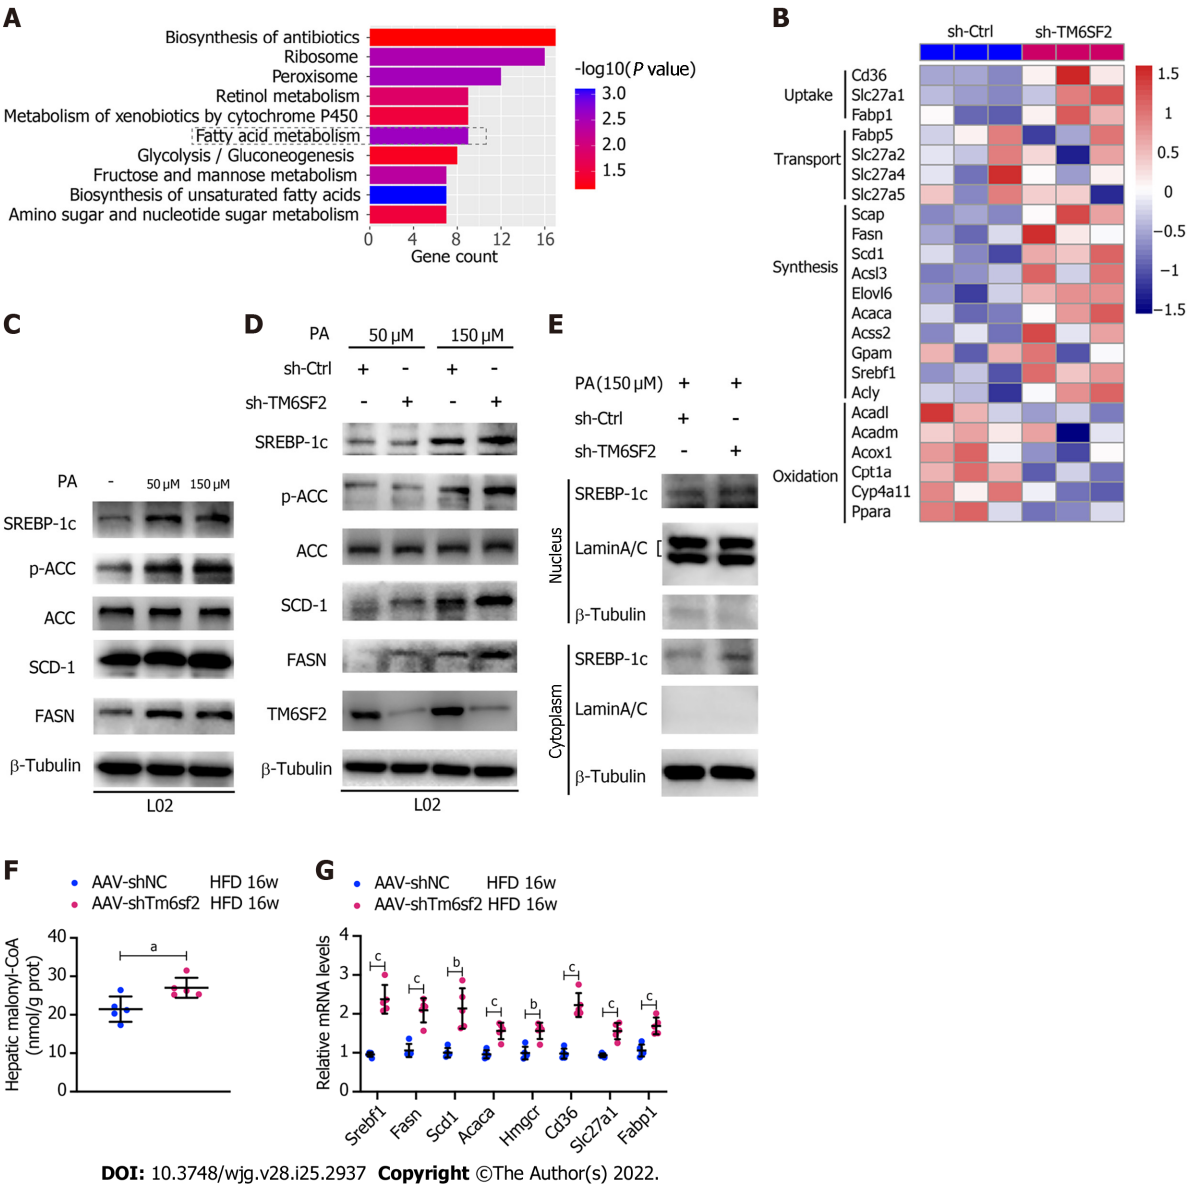
induces endoplasmic reticulum stress (ERS) and causes cell death[28,29]. The cell viability assay results proved that TM6SF2 knockdown markedly exacerbated PA-induced cell death (Figure 3D), which reflected the increase in lipid content in the TM6SF2-knockdown group. To determine whether TM6SF2 deficiency exacerbated hepatic steatosis *in vivo*, we generated hepatic TM6SF2-knockdown (hereafter referred to as AAV-shTm6sf2, AAV-shNC was used as a control) mice by injecting AAV vectors carrying TM6SF2-targeting shRNA, and mice were fed an HFD or NCD for 16 wk (Figure 4A and B). Compared to the control mice, the HFD-fed AAV-shTm6sf2 mice displayed severe hepatocellular ballooning degeneration and lipid accumulation, as shown by H&E and Oil Red O staining (Figure 4C); these mice had higher levels of hepatic TG, TC, and NEFA (Figure 4D). Similarly, AAV-shTm6sf2 mice had a higher liver/body weight ratio (Figure 4E) but exhibited a slightly higher body weight (Figure 4F) only at the initiation of feeding. In addition, hepatic TM6SF2-knockdown mice relative to controls displayed a modest increase in size (Figure 4G) but a significantly enlarged liver and a larger maximal cross-sectional area of the liver (Figure 4H). However, these parameters did not differ between the two groups when placed in a NCD environment (Figures 4D–F).

It is noteworthy that hepatic steatosis is often accompanied by inflammation, and the boundary between the two phases (SS and NASH) of NAFLD is blurred[30]. The hepatic TM6SF2-knockdown group displayed higher serum levels of inflammatory cytokines, such as TNF, IL-6, IL-1β, CCL2, and CXCL10 than control mice after 16 wk of HFD feeding (Supplementary Figure 3A). Consistently, hepatic expression of inflammation-related genes was also augmented in the AAV-shTm6sf2 group (Supplementary Figure 3B). Meanwhile, the AAV-shTm6sf2 group showed higher serum levels of ALT and AST (Supplementary Figure 3C) and more infiltrated neutrophils and macrophages than the AAV-shNC group (Supplementary Figure 3D). These results show that TM6SF2 knockdown promotes hepatic lipid accumulation and inflammation in an HFD-induced mouse model.

Hepatic knockdown of TM6SF2 enhances de novo lipogenesis



Triplicate samples of PA-treated TM6SF2-knockdown L02 cells and their controls were used for transcriptome analysis to explore the changes in biological processes in TM6SF2 knockdown and identify upregulated DEGs. KEGG pathway enrichment analysis was applied to explore the function of these DEGs, which highlighted that fatty acid metabolism was the key process that changed in TM6SF2-knockdown cells (Figure 5A), and genes associated with fatty acid synthesis were found to be upregulated (Figure 5B). To confirm this, *in vitro* NAFLD models were used to verify our findings. PA is a potent agonist of fatty acid synthesis[31]. PA administration activated fatty acid synthesis *in vitro*, as indicated by increased protein levels of p-ACC, FASN, SCD-1, and sterol regulatory element-binding protein 1c (SREBP-1c) (Figure 5C). When comparing the levels of these proteins between TM6SF2-

knockdown cells and the corresponding controls, the results showed that these proteins were upregulated in TM6SF2-knockdown cells, suggesting that PA-induced fatty acid synthesis was enhanced by the knockdown of TM6SF2 (Figure 5D). *De novo* lipogenesis is mainly mediated by SREBP-1c on the transcriptional regulation of ACC and fatty acid synthase. The mature form of SREBP-1c translocates to the nucleus and activates its target genes, such as *Acaca* and *Fasn*[32]. This translocation-to-nucleus phenomenon was also enhanced in the TM6SF2-knockdown cells (Figure 5E). In addition, TM6SF2 knockdown increased hepatic malonyl-CoA, a metabolite of ACC[33], in HFD-fed AAV-shTm6sf2 mice (Figure 5F), which indicated that ACC activity was enhanced due to TM6SF2 deficiency. It is noteworthy that the transcriptional activity of hepatic SREBP-1c is also influenced by circulating

insulin status. We evaluated the mice's blood glucose and insulin levels and found no differences between the two groups with or without HFD feeding (Supplementary Figure 4A). In addition, no obvious differences were noted in the GTT and ITT (Supplementary Figure 4B). These results suggest that the enhanced steatosis in hepatic TM6SF2-knockdown mice is unlikely to be induced by altering insulin sensitivity. Moreover, we also noted that TM6SF2 knockdown did not affect the fatty acid transport process but caused an increase in the mRNA levels of molecules involved in fatty acid uptake (*e.g.*, CD36 and FABP1) (Figure 5B). This increase was augmented when the TM6SF2-knockdown cells were under starvation or hypoxic conditions (Supplementary Figure 4C), as hypoxia and starvation have been reported to enhance lipid uptake[34-36]. In parallel, the levels of fatty acid synthesis- and uptake-related genes were elevated in the livers of AAV-shTm6sf2 mice compared to control mice (Figure 5G). This evidence suggests that the unfavorable fatty liver in hepatic TM6SF2-knowndown mice may be associated with enhanced *de novo* lipogenesis and lipid uptake.

TM6SF2 deficiency could lead to impaired FAO

It was previously reported that NAFLD caused by TM6SF2 deficiency was partially due to impaired VLDL secretion, which is detrimental to the liver, as VLDL secretion is considered a significant pathway of lipid export in the liver[18]. FAO, another method of energy expenditure[37], has rarely been

Figure 6 TM6SF2 deficiency caused the downregulation of fatty acid oxidation in liver. A: Protein levels of PPARα, CPT1A and ACOX1 was analyzed in TM6SF2-knockdown cells after palmitic acid (PA) stimulation and their response to GW7647 (10 μmol/L) treatment; B: Serum levels of β-hydroxybutyrate and acetoacetate in normal chow diet- or high-fat diet-fed AAV-shNC or AAV-shTm6sf2 mice (n = 5 mice *per* group); C and D: PA-dependent oxygen consumption rate in sh-Ctrl and sh-TM6SF2 L02 cells with or without etomoxir (ETO, 40 μmol/L) administration (C, n = 6). The basal respiration, maximal respiration, spare respiratory capacity, and ATP production were calculated (D); E: Protein levels of PPARα, CPT1A and ACOX1 were determined in TM6SF2-knockdown cells with or without ETO treatment under PA (150 μmol/L) stimulation; F: The hepatic mRNA levels of fatty acid oxidation-related genes in the indicated mice. $^{a}P < 0.05$; $^{b}P < 0.01$; $^{c}P < 0.001$. PA: Palmitic acid; NS: Not significant; NCD: Normal chow diet; HFD: High-fat diet; OCR: Oxygen consumption rate; μM: μmol/L.

reported in the absence of the TM6SF2 protein. Therefore, we evaluated and compared the expression of the key molecules involved in FAO. The results showed that TM6SF2-knockdown cells exhibited decreased levels of FAO-related proteins[38], including PPARα, CPT1A, and ACOX1, with or without PA stimulation (Figure 6A), which is consistent with the results of transcriptomic data (Figure 5B). Furthermore, PPARα signaling has been reported to function as a key factor in regulating FAO[39], and we found that the downregulated levels of FAO-related proteins in TM6SF2-knockdown cells could be reversed by PPARα activation through PPARα agonist (GW7647) stimulation (Figure 6A). We next tested hepatic FAO *in vivo* by evaluating the levels of serum ketone bodies, β-OH, and acetoacetate in both AAV-shTm6sf2 mice and control groups after a 16 h fast. The results showed that the levels of ketone bodies were significantly lower in the TM6SF2-knockdown group (Figure 6B), suggesting that TM6SF2 deficiency reduces FAO. In addition, compared to the control group, TM6SF2-knockdown L02 cells had a lower OCR with PA as the only substrate (Figures 6C and D). Meanwhile, the CPT1A inhibitor etomoxir inhibited the FAO process and diminished the difference in both groups, as well as the FAO-related proteins (Figure 6C-E). AAV-shTm6sf2 mice also showed a lower expression of FAO-related genes in the liver (Figure 6F). Together, these data indicate that TM6SF2 deficiency impairs cellular FAO.

MK4074 is effective in treating NAFLD exacerbated by TM6SF2 deficiency

These results showed that TM6SF2 deficiency could lead to abnormal fatty acid metabolism within cells,

DOI: 10.3748/wjg.v28.i25.2937 **Copyright** ©The Author(s) 2022.

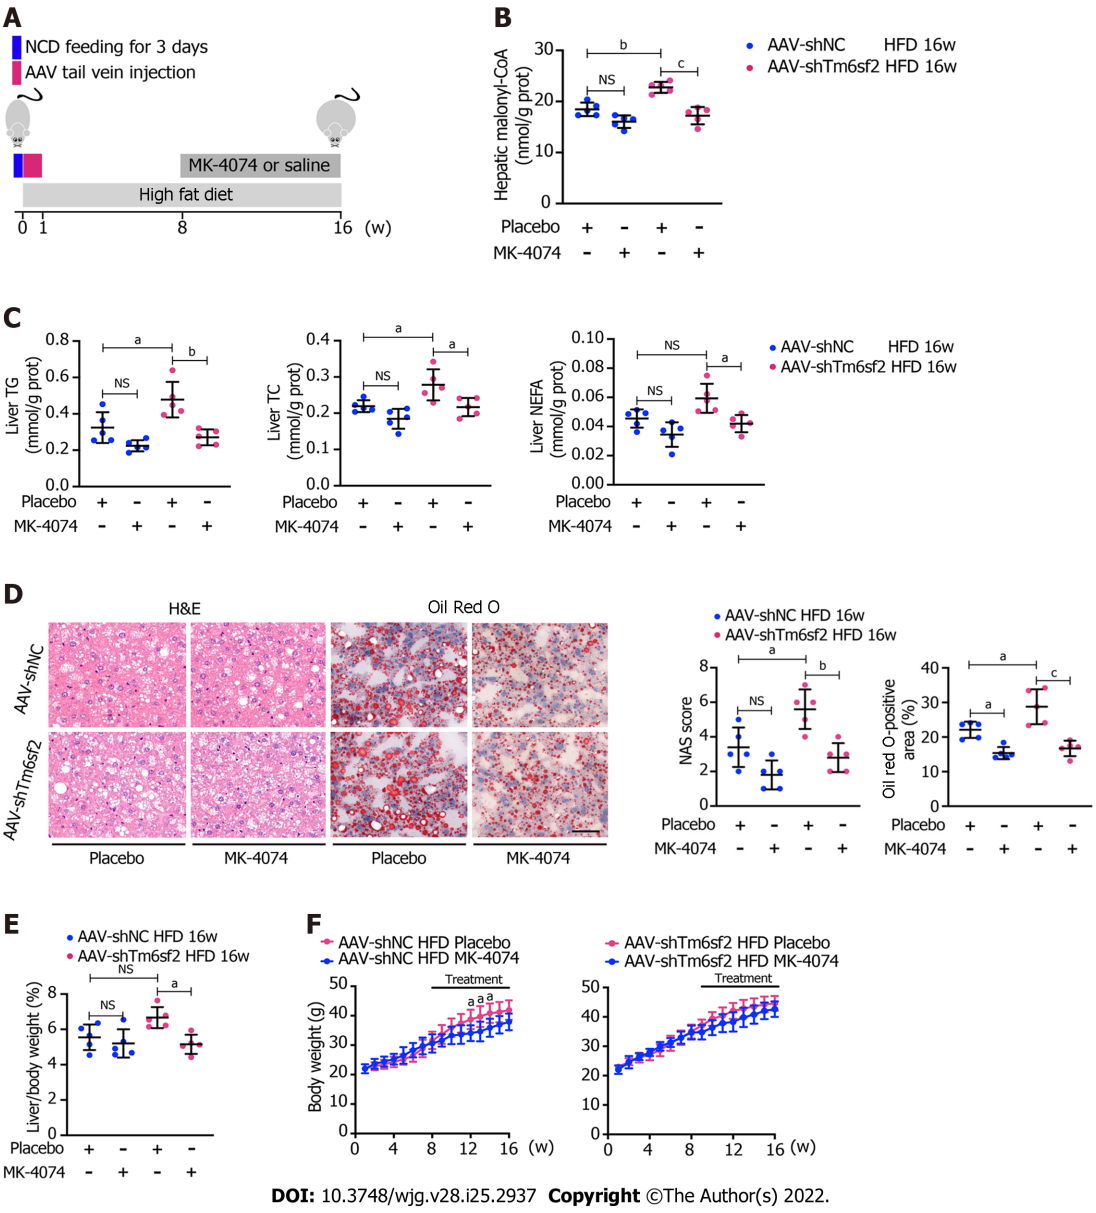

Figure 7 Schematic diagram of MK-4074 blocking acetyl-CoA carboxylase pathway and alleviating nonalcoholic fatty liver disease in TM6SF2-deficient mice. ACC: Acetyl-CoA carboxylase; NAFLD: Nonalcoholic fatty liver disease.

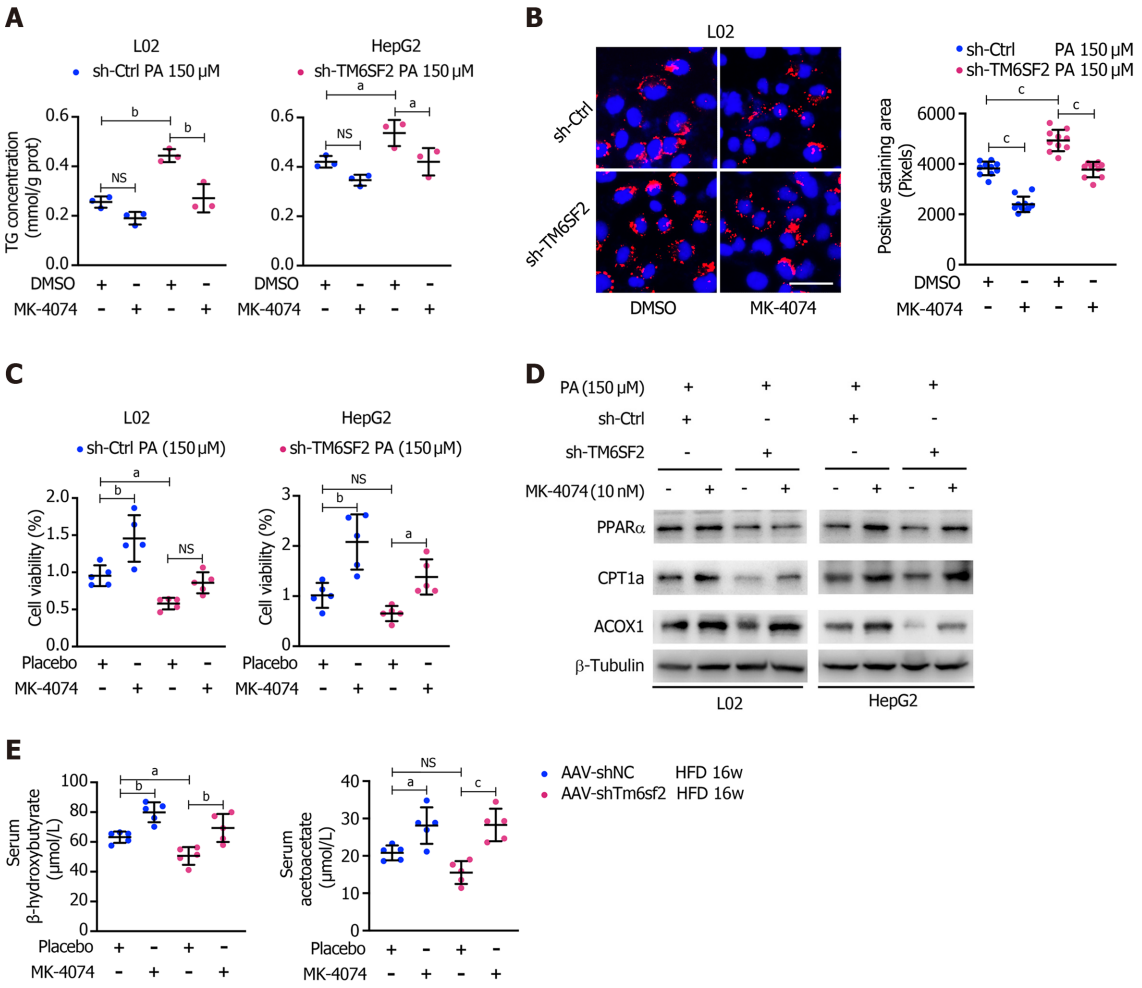
characterized by enhanced lipogenesis and uptake, accompanied by impaired fatty acid β-oxidation (Figure 7). It is worth noting that the suppressed β-oxidation process may be associated with the increased malonyl-CoA content due to the enhanced activity of ACC in this situation. Malonyl-CoA is a natural CPT1A inhibitor, which causes a decrease in β-oxidation in mitochondria[40]. Therefore, inhibiting the activity of ACC may be a promising method to alleviate fatty liver disease in mice with hepatic TM6SF2 deficiency. To test this idea and rectify this metabolic abnormality, we thought of a way of inhibiting ACC, this rate-limiting enzyme, by using a previously reported ACC inhibitor, MK-4074, which could simultaneously limit the *de novo* lipid synthesis pathway and increase the level of intracellular lipid oxidation, to explore whether the drug has therapeutic effect on TM6SF2-deficient cases. To this end, both AAV-shTm6sf2 and control mice were first subjected to 8-wk HFD feeding to induce NAFLD phenotypes, and then two groups of mice received MK-4074 (MK-4074, 10 mg/kg/day) or placebo (normal saline) treatment and were fed with HFD for an additional eight weeks (Figure 8A). The results showed that MK-4074 treatment could diminish the increase in the levels of malonyl-CoA (Figure 8B), as well as hepatic TG, TC, and NEFA caused by TM6SF2 deficiency (Figure 8C), suggesting the success of blocking the SPREBP-1c/ACC pathway. Compared to placebo treatment, the HFD-fed AAV sh-Tm6sf2- mice under MK-4074 treatment exhibited mild hepatic ballooning degeneration and steatosis (Figure 8D). At the same time, MK-4074 treatment improved the liver/body weight ratio (Figure 8E), although the body weight improvement was rather limited (Figure 8F). In addition, the beneficial effect is also manifested *in vitro* experiments that MK-4074 could reduce lipid accumulation (Figure 9A and B) and improve PA-induced cell death in TM6SF2 knocked-down groups (Figure 9C). Meanwhile, MK-4074 inhibited malonyl-CoA production (Figure 8B) and improved the decrease in FAO caused by TM6SF2 deficiency, as evidenced by the increased FAO-related protein and ketone body levels in the TM6SF2-knockdown group (Figure 9D and E), which renders MK-4074 the prime option for treating this condition.

DISCUSSION

The present study revealed that hepatic TM6SF2 expression was upregulated in both NAFLD mouse models and patients. TM6SF2 overexpression alleviated NAFLD phenotypes in HFD-induced models, suggesting a protective role for reactive TM6SF2 elevation under NAFLD conditions. Simulating the situation in patients with the E167K mutation, TM6SF2 knockdown exacerbated hepatic steatosis and inflammation. We noted a dysregulated fatty acid metabolism process under TM6SF2 deficiency, characterized by enhanced fatty acid uptake and fatty acid synthesis, accompanied by an impaired FAO process and insufficient ketone body production. Given the potential impact of TM6SF2 on fatty acid metabolism in NAFLD, exploring the effects of targeted NAFLD therapeutics on fatty liver is of the utmost importance, inspiring us to consider the impact of genetic variation on fatty liver. We used a previously reported liver-specific ACC inhibitor, MK-4074, which could reduce hepatic lipogenesis while increasing FAO, to explore the therapeutic effect on fatty liver caused by TM6SF2 deficiency (Figure 7). Our results show that MK-4074 has an encouraging effect on treating TM6SF2 knockdown-induced NAFLD, as indicated by the reduced hepatic lipid content, lower liver/body ratio, and alleviated PA-induced cell death suggesting the effectiveness of MK-4074 in treating this condition.



Previous studies have considered TM6SF2 as a pivotal molecule in hepatic lipid output in the form of VLDL-TG, and a majority of studies have focused on the association between the export of accumulated

lipids and the TM6SF2 E167K mutant[15,18,41]. The TM6SF2 E167K mutant may result in a misfolded protein easily degraded within the cells, resulting in decreased TM6SF2 levels[42]. The liver is a pivotal hub for lipid metabolism, and its dysregulation could be a significant cause of NAFLD[43]. Therefore, we investigated the cause of TM6SF2 deficiency-induced NAFLD from another perspective, dysregulated fatty acid metabolism. Our results revealed that TM6SF2 knockdown significantly increased the expression of SREBP-1c and its target genes both *in vivo* and *in vitro*, suggesting abnormally enhanced *de novo* lipogenesis (DNL). Meanwhile, the results showed that the levels of OCR were decreased in the TM6SF2-knockdown groups, indicating that the FAO process was impaired under these circumstances. We further tested the transcriptional levels of FAO-related genes in hepatic TM6SF2-knockdown mice fed an HFD and showed lower levels of genes involving FAO than the control mice on the same diet for 16 wk. Previous studies showed that elevated levels of malonyl-CoA would suppress FAO by inhibiting CPT1A activity[44]. In our study, the malonyl-CoA content was higher in AAV-shTm6sf2 mice than in the control mice, which implies that the decreased FAO process is related to the enhanced DNL due to TM6SF2 knockdown.

Figure 9 MK-4074 can improve intracellular lipid accumulation, lipid overload-induced cell death, and fatty acids β-oxidation. A: Intracellular triglyceride levels (n = 3) in TM6SF2-knockdown cells with palmitic acid (PA) (150 μmol/L) stimulation were examined after MK-4074 (10 nM) treatment for 24 h; B: Representative nile red staining images (left) and lipid droplet quantification (right) of sh-Ctrl or sh-TM6SF2 L02 cells after PA stimulation in response to MK-4074 (10 nM) treatment (10 fields of each sample were examined). Scale bars: 50 μm; C: The cellular viability was examined in TM6SF2-knockdown cells with or without MK-4074 treatment in response to PA-induced cell death (n = 5); D: The sh-Ctrl and sh-TM6SF2 cells were cultured with PA (150 μmol/L) for 24 h. Cells were then treated with MK-4074 (10 nM) for 12 h. The expression of fatty acid oxidation-related proteins was determined; E: Serum levels of β-hydroxybutyrate and acetoacetate in the indicated mice with or without MK-4074 treatment. $^{a}P < 0.05$; $^{b}P < 0.01$; $^{c}P < 0.001$. NS: Not significant; HFD: High-fat diet; TG: Triglyceride; PA: Palmitic acid; μM: μmol/L.

Currently, genetic technologies have already allowed for the identification of a subgroup of people with an increased risk of NAFLD or NAFLD-related complications associated with specific pathophysiological characteristics[45]. Unfortunately, there is no precise treatment for metabolic diseases with specific congenital genetic variations in NAFLD. However, much effort has been made to elucidate the mechanism of NAFLD caused by genetic mutations and implement precision medicine. For example, human genetics of NAFLD offers the opportunity to apply targeted therapy with the PNPLA3 I148M variant. This locus is the strongest genetic factor that increases susceptibility to NAFLD[10]. Recently, researchers used mice with the PNPLA3 variant knock-in and tried to improve NAFLD phenotypes through antisense oligonucleotides to downregulate the PNPLA3 mutant protein[46]. Although the mechanisms are not fully understood, accumulating evidence reveals that PNPLA3 I148M impairs lipid droplet remodeling in hepatocytes due to the loss of lipase activity[47]. Inhibition of PNPLA3 148M expression reduced liver fat content in these engineered mice and, specifically, had a beneficial effect in mitigating inflammation and fibrosis. If these applications are translated into humans, after safety and reliability examinations, downregulation of PNPLA3 148M may be the first case of human genetics-based targeted therapy. The importance of this method is to treat not only the phenotype of the disease but also the cause.

As described in the PNPLA3 mutant protein case, this evidence proved the possibility of targeted therapy to eliminate the cause of fatty liver in patients carrying a specific risk allele. However, there have been no reports of attempts to treat fatty liver caused by TM6SF2 deficiency or its E167K mutant. Based on our data, mice with TM6SF2 deficiency show enhanced DNL. Among the TM6SF2/SREBP-1c/ACC axis, ACC acts as the rate-limiting enzyme for converting acetyl-CoA to malonyl-CoA[48]. The

product, malonyl-CoA, was further catalyzed by FASN to form palmitate. TGs are one of the many lipid species that are integrated with DNL-derived palmitate. ACC inhibitors have the potential to mitigate hepatic steatosis in NAFLD, given that ACC is essential and pivotal in hepatic fatty acid metabolism. Independent studies have revealed that blocking DNL by ACC inhibition has a beneficial effect in reducing liver fat, steatosis, and inflammation in NAFLD models[44,49]. Among ACC inhibitors, MK-4074 has recently been tested for NAFLD treatment, and its effects have been encouraging. MK-4074 treatment decreased DNL and enhanced FAO in participants under overnutrition. Based on its function, we hypothesized that it could be used to treat fatty liver caused by the reduction of TM6SF2, and *in vivo* and *in vitro* experiments confirmed this hypothesis. ACC inhibitors have recently been shown to effectively mitigate liver fibrosis in NASH patients[49,50]. The accumulating evidence has shown that TM6SF2 E167K is also associated with NASH and fibrosis[18,51]. Whether ACC inhibitors can be applied to mitigate liver fibrosis in NASH models with TM6SF2 deficiency or the E167K mutant is unknown. This indicates the direction of our future work.

CONCLUSION

This study showed that dysregulated fatty acid metabolism occurs in the context of TM6SF2 deficiency under overnutrition. Therapeutics aimed at abnormal fatty acid metabolism may be a promising strategy for improving the hepatic lipid profile of patients with the TM6SF2 E167K variant in the clinical setting. Furthermore, our study suggests that MK-4074 could be a potential drug to lower hepatic lipid content in a TM6SF2-knockdown NAFLD mouse model. Further investigations are required to test whether this approach would lower hepatic lipid levels in NAFLD patients with the E167K mutation.

ARTICLE HIGHLIGHTS

Research background

Previously, we found that the TM6SF2 E167K mutation was associated with susceptibility to nonalcoholic fatty liver disease (NAFLD) in a Chinese cohort, but the underlying mechanism is poorly understood.

Research motivation

Because existing evidence has shown that *TM6SF2* gene mutation would reduce its expression at the protein level, we used NAFLD mouse models to explore the causes of NAFLD caused by TM6SF2 deficiency in the context of high-fat feeding and test possible treatment strategies. This would benefit our understanding of the mechanisms underlying NAFLD in humans.

Research objectives

Mechanism and therapeutic strategy of hepatic TM6SF2-deficient NAFLD *via in vivo* and *in vitro* experiments.

Research methods

This study mainly involved the knockdown and overexpression of the hepatic *TM6SF2* gene in NAFLD mice and cell models to explore its effects on pathological changes in the liver. In addition, RNA-seq, oxygen consumption rate technology, western blotting, and pathological examination were performed to investigate the underlying mechanisms of NALFD caused by TM6SF2 deficiency.

Research results

Hepatic TM6SF2 expression was upregulated in patients with NAFLD and high-fat diet (HFD)-fed mice. Overexpression of TM6SF2 mitigated hepatic lipid accumulation in HFD-fed mouse models. Knockdown of TM6SF2 promoted hepatic lipid accumulation and inflammation. TM6SF2 deficiency promotes hepatic lipid accumulation through the dysregulation of fatty acid metabolism. MK-4074 administration may serve as a potential drug to improve NAFLD caused by TM6SF2 deficiency.

Research conclusions

In this study, we found that the reactive overexpression of TM6SF2 under HFD conditions could alleviate hepatic lipid accumulation, the loss of which accelerated the NALFD phenotypes under HFD feeding. We also found that dysregulated fatty acid metabolism occurs in the context of TM6SF2 deficiency under overnutrition conditions. Therapeutics aimed at abnormal fatty acid metabolism may be a promising strategy for improving the hepatic lipid profile of patients with the TM6SF2 E167K variant in the clinical setting. Our study suggests that MK-4074 could be a potential drug for lowering hepatic lipid content in a TM6SF2-knockdown NAFLD mouse model.

Research perspectives

TM6SF2 plays a protective role in the HFD condition; its deficiency enhanced hepatic lipid accumulation through dysregulated fatty acid metabolism, and MK-4074 treatment could alleviate the NAFLD phenotypes caused by TM6SF2 deficiency. The next step was to investigate whether MK-4074 has a therapeutic effect in patients with NAFLD harboring the TM6SF2 E167K mutation.

Abstract

BACKGROUND

Post-infectious irritable bowel syndrome (PI-IBS) is generally regarded as a functional disease. Several recent studies have reported the involvement of low-grade inflammation and immunological dysfunction in PI-IBS. T helper 17 (Th17) polarization occurs in IBS. Adenosine and its receptors participate in intestinal inflammation and immune regulation.

AIM

To investigate the role of Th17 polarization of CD4+ T cells regulated by adenosine 2A receptor (A2AR) in PI-IBS.

METHODS

A PI-IBS model was established by infecting mice with *Trichinella spiralis*. The intestinal A2AR and CD4+ T lymphocytes were detected by immunohistochemistry, and the inflammatory cytokines were detected by enzyme-linked immunoassay. CD4+ T lymphocytes present in the animal's spleen were separated and cultured with or without A2AR agonist and antagonist. Western blotting and real-time quantitative polymerase chain reaction were performed to determine the effect of A2AR on the cells and intestinal tissue. Cytokine production was determined. The protein and mRNA levels of A2AR associated signaling pathway molecules were also evaluated. Furthermore, A2AR agonist and antagonist were injected into the mouse model and the clinical features were observed.

RESULTS

The PI-IBS mouse model showed increased expression of ATP and A2AR ($P < 0.05$), and inhibition of A2AR improved the clinical features in PI-IBS, including the abdominal withdrawal reflex and colon transportation test ($P < 0.05$). The number of intestinal CD4+ T cells and interleukin-17 (IL-17) protein levels increased during PI-IBS, which was reversed by administration of the A2AR antagonist ($P < 0.05$). CD4+ T cells expressed A2AR and produced IL-17 *in vitro*, which was regulated by the A2AR agonist and antagonist. The A2AR antagonist increased the production of IL-17 by CD4+ T cells *via* the Janus kinase-signal transducer and activator of transcription-receptor-related orphan receptor γ signaling pathway.

CONCLUSION

The results of the present study suggested that the upregulation of A2AR increases PI-IBS by promoting the Th17 polarization of CD4+ T cells.

Key Words: Adenosine 2A receptor; CD4+ T cells; T helper 17 polarization; Post-infectious irritable bowel syndrome; Regulation

Core Tip: T helper 17 (Th17) polarization occurs during the development of irritable bowel syndrome (IBS). Adenosine and its receptors participate in the development of intestinal inflammation and immune regulation. Here, we found that the intestinal levels of ATP, adenosine 2A receptor (A2AR), and interleukin-17 (IL-17) and the number of CD4+ T cells increased in post-infectious IBS (PI-IBS) mice. In addition, A2AR promoted CD4+ T cells' IL-17 production. Upregulated A2AR accelerated PI-IBS by promoting CD4+ T cells' Th17 polarization, which was reversed by the A2AR antagonist. Thus, our results prove that the regulation of CD4+ T cells' Th17 polarization by A2AR plays a pathogenetic role in the development of PI-IBS.

INTRODUCTION

The predominant clinical features of irritable bowel syndrome (IBS) include abdominal pain, abnormal bowel habit, and stool changes. IBS occurs predominantly in developed countries. The incidence rate is about 10%-60%. During the past three decades, the incidence of IBS has rapidly increased in underdeveloped countries[1]. IBS can occur after an acute gastrointestinal infection, which is defined as post-infectious IBS (PI-IBS)[2]. The patients suffer from refractory discomfort, live with problems, and have to undergo high medical costs for their treatment. The laboratory reports of these patients do not show morphological findings, which leads to a shortage of time in targeting treatment[3]. Low-grade inflammation and immune activation in the colonic mucosa are observed during IBS[4]. PI-IBS might be alleviated due to regulation of the inflammatory response[5]. Upregulated ephrin type-A receptor 2 and activated nuclear factor kappa-light-chain-enhancer of activated B cells signaling pathway can alleviate PI-IBS[6]. Moreover, non-coding RNAs such as microRNA can modulate inflammation and immune response by targeting peroxiredoxin-1 in PI-IBS[7].

Recently, interleukin-17 (IL-17) raised concerns in PI-IBS. For instance, rifaximin protects mice against PI-IBS by suppressing the production of IL-17[8]. Our previous studies reported that heat shock protein 70 alleviated PI-IBS by upregulating T helper 17 (Th17) response in γδ T cells[9,10].

Adenosine originates from ATP in the local tissue during inflammation and regulates tissue blood flow[11]. As an endogenous molecule, adenosine exhibits anti-inflammatory and immunosuppressive effects by binding to the adenosine receptors (ARs), which are located on some immune and tissue cells and function as a G-protein coupled receptor[12-14]. ARs consist of the following four subtypes: A1R, adenosine A2a receptor, adenosine A2b receptor, and A3R, which are expressed at various locations in the intestine[15]. Different receptors induce different pathophysiological roles. A2BR inhibits the release of inflammatory cytokines, tumor necrosis factor-α, IL-6, and IL-12[16-18]. We previously reported that ARs contribute to the modulation of immune response by γ δ T cells[19,20]. In the intestine, adenosine

and its receptors regulate the enteric nervous system and visceral hypersensitivity. Endogenous adenosine affects the secretion of hydrocarbon by duodenum, whereas extracellular ATP induces the apoptosis of intestinal epithelial cells[21,22]. Adenosine inhibits inflammatory damage in the intestine, protects the intestine against ischemia, and reduces lesions in chronic septic mice by A1AR, A2AR, and A2BR[23,24]. A3R regulates distal colonic neuro-muscle function in rats with colitis[25]. Adenosine receptors also contribute to the inhibition of visceral pain by electroacupuncture in IBS[26]. The role of ARs in intestinal functions shows that they can be a potential target for intestinal inflammatory diseases. However, ARs are not widely studied in IBS, especially in PI-IBS. A2AR is reported to protect the enteric Glia barrier function against intestinal injury induced by hypoxia[27].

The relationship between A2AR, CD4+ T cells, and IL-17 is unknown. Whether A2AR is expressed in CD4+ T cells is not known. Whether A2AR affects IL-17 production directly or through other indirect pathways is unknown. Furthermore, the relationship between A2AR, IL-17, and CD4+ T cells in PI-IBS is unknown. Therefore, we investigated the role of Th17 polarization of CD4+ T cells regulated by A2AR in PI-IBS.

MATERIALS AND METHODS

Animal grouping

57BL/6 mice (female, mean age: 56 d, average weight: 15 g) were provided by the Hainan Provincial Experimental Animal Center and fed in pathogen-free, room temperature conditions under a normal 12-h light/dark diurnal rhythm. The animals were provided with a standard diet and water *ad libitum*. Four groups of mice were formed: Control, PI-IBS, PI-IBS+Sch58261, and PI-IBS+CGS21680 (n = 24 in each group). Twelve mice were processed for the measurement of A2AR, cytokines, and signaling molecules protein and mRNA levels. Six mice were sacrificed in order to isolate, purify, and culture their CD4+ T cells. Visceral hypersensitivity and intestinal motility were evaluated in the remaining 6 animals.

PI-IBS modeling

Infection with *Trichinella spiralis* (Lanzhou Veterinary Research Institute, Lanzhou, China) was performed to establish the PI-IBS model[28]. After 60 d of infection, the parasite larvae were digested from Sprague–Dawley rats with 1.5% gastric pepsin (Invitrogen, Carlsbad, CA, United States) and suspended in 0.2 mL of saline. The mice were fed the larvae (300 larvae/mouse).

Histopathological examination

On the 56th day after infection, the animals' ileum was fixed in 10% formalin and embedded in paraffin wax. The tissues were mounted on slides after creating 5-μm-thick sections, followed by dewaxing and dehydration. The slides were stained with hematoxylin-eosin and used for further evaluation of the inflammatory score following previous scoring standards[29].

Abdominal withdrawal reflex

Visceral hypersensitivity was evaluated with the abdominal withdrawal reflex (AWR)[30]. A gasbag was inserted into the anesthetized animal's anus, which was distended in volume from 0.25 mL to 0.65 mL for 15 min, thrice, followed by a recording of the animal's behavior. The AWR score was found to be in accordance with the standard from 0 to 4 points, as described previously[30]. The AWR scoring standard: when stimulated, the animals are in stable mood, 0 point; if the animals are in unstable mood, twisting their heads once in a while, 1 point; slightly contracting their abdominal and back muscles, 2 points; intensively contracting their abdominal muscles and uplifting the abdomen from the ground, 3 points; intensively contracting abdominal muscles, bowing the abdomen and uplifting the abdomen and perineum, 4 points.

Colon transportation test

Intestinal motility was evaluated with the colon transportation test (CTT); 0.4 mL of activated carbon was placed in the animal's stomach, and the animal's initial time to black stool elimination was recorded. After 8 h, the Bristol stool scoring system was used to assess the total stool's characteristics [31]. Normal shaped stool, 1 point; soft or deformed stool, 2 points; water-like stool, 3 points.

Cellular immunohistochemistry

Cellular immunohistochemistry was performed as reported elsewhere[32]. The suspended cells were fixed in 4% paraformaldehyde and uniformly placed onto slides. The sections were then incubated with primary antibody rabbit anti-mouse A2AR monoclonal antibody and a secondary antibody goat anti-rabbit HRP antibody (ab60032 and ab6721; Abcam, Cambridge, United Kingdom). DAB reagent sets (Beijing Sequoia Jinqiao, Beijing, China) were used to determine the reactivity. The quantitative expression of A2AR in the cellular membrane was calculated using a semi-quantitative integral method.

The staining intensity was scored on a scale of 0-3. The percentage area of positively stained cells was classified as 0-4 corresponding to the values of < 5% to > 75%. The evaluation with a score of ≥ 6 was expressed as a positive expression. The stain was analyzed by Nikon DR-Si2 cell count software and digital image analysis; two senior pathologists verified the results.

Western blotting

Western blotting (Wuhan Boster Corporation, Wuhan, China) was performed to evaluate the protein level. RIPA (R0278; Sigma-Aldrich, Saint Louis, MO, United States) buffer was used to extract the protein from the ground ileum tissue samples. The Bradford assay was performed to determine the protein concentration. After separation on SDS-PAGE gel electrophoresis, 40 μg of the sample was transferred onto a polyvinylidene fluoride membrane. The following transmembrane conditions were set during the assay: (1) β-actin and A2AR: running at 200 mA for 90 min; (2) Janus kinase (JAK) and p-JAK: running at 200 mA for 120 min, followed by running at 300 mA for 30 min; (3) Signal transducer and activator of transcription (STAT3) and p-STAT3: running at 200 mA for 20 min, followed by running at 300 mA for 15 min; and (4) Receptor-related orphan receptor-γt (RORγt): running at 200 mA for 120 min.

The dilution rate of the primary antibodies rabbit anti-mouse multiple-clone antibodies is shown in Table 1.

Blotted in TBST for 60 min, the membrane was incubated with rabbit anti-mouse protein antibodies (ab2787; Abcam, United States) as the primary antibodies and with goat anti-rabbit antibodies as the secondary antibodies (ab8226; Abcam) at 4 °C for 12 h. ECL chemiluminescent assay was performed to autograph the membrane. The detected gray-scale ratio of protein/β-actin represented the relative protein level.

Real-time quantitative PCR

Total RNA in the ileum tissues was extracted with the Trizol reagent set (Invitrogen). The primers were designed by Invitrogen (Table 2). β-actin served as an internal control.

RT-PCR was performed under the following protocol conditions: The samples were run by a pre-denaturation program (5 min at 94 °C), followed by a denaturation program (1 min at 94 °C). The amplification and qualification program was repeated for 30 cycles (50 s at 57 °C, 20 s at 60 °C), followed by an extension program (7 min at 72 °C).

The relative expression was expressed as the ratio of the target gene to the control.

Determination of ATP

The ileum tissue sample was treated ultrasonically and centrifuged at 4 °C for 15 min, followed by the addition of double-distilled water (1:9). The 10% homogenate was heated in a boiling water bath for 10 min and then centrifuged at 3000 rpm for 10 min. The supernatant was collected for enumeration.

The concentration of ATP was measured by a colorimetric method. Briefly, the OD of the tube was measured at the wavelength of 636 nm. The ATP concentration in the sample μmol/gprot) = (measured OD - Control OD)/(Standard OD - OD) × standard concentration (1000 μmol/mL)/sample concentration (gprot/L).

Isolation and purification of CD4+ T cells

CD4+ T cells were isolated from the animals' spleen[33]. Briefly, the animals were sacrificed and their spleens were collected and washed with PBS. The red blood cells were rinsed with red blood cell lysis buffer. The lymphocytes liquid overflowing from the cleaned spleen was repeatedly washed with PBS, centrifuged at 1960 rpm, and incubated with CD4 (FITC) 0.25 μg/test; the CD4+ T cells were selected by fluorescence-activated cell sorting (FACS).

Evaluation of CD4+ T cells' function

The effect of A2AR on CD4 T cell function, including proliferation, apoptosis, ATP production, and Th17 polarization response was evaluated by the CCK8 assay, Annexin V staining assay, and ELISA. Furthermore, the intra-cellular signaling pathway was investigated by Western blotting and RT-PCR.

Proliferation

The CCK8 assay was performed to determine proliferation of the isolated CD4+ T cells. The cell density was set to 5×10^5/mL. The cells were added to a 96 well culture plate at the concentration of 100 μL (5×10^4 cells), followed by treatment with 100 nmol/L of CGS-21680 and 1 μmol/L Sch58261, cultured for 0.5 h at 37°C under 5% CO_2 atmosphere. Then, 20 μL/well of CCK8 was added into the system and continuously cultured for 2 h at 37°C under 5% CO_2 atmosphere. The OD_{450} of the cultured cells was measured with an enzyme-labeled instrument.

Apoptosis

The rate of apoptosis of CD4+ T cells was measured by Annexin V staining assay. Briefly, the collected CD4+ T cells were incubated in a 6-well plate (5×10^5 cells/well), to which 100 nmol/L of CGS-21680

Table 1 The dilution rate of primary antibodies

Primary antibodies	Dilution rate
β-actin	1:1000

	Reverse	5′-GCCCTTCGCCCTCATACCCGTCAC-3′	

and 1 μmol/L of Sch58261 were added and cultured at 37°C under 5% CO_2 for 0.5 h. Then, 5 μL of Annexin V-APC and 5 μL of 7-AAD staining liquid were added to the wells. FACS was performed to detect the rate of apoptosis.

Th17 polarization

ELISA was performed to determine the concentration of cytokines in the supernatant of CD4+ T cells. A high-sensitivity (sensitivity range: 0.25-16 pg/mL) ELISA kit (R&D Systems, Minneapolis, MI, United States) was used to analyze the IL-17 and IFNγ protein concentrations according to the manufacturer's protocol.

Signaling pathway

The protein and mRNA of the signaling-associated molecules were determined by Western blotting and RT-qPCR, as described previously.

Statistical analysis

The Kolmogorov–Smirnov test was performed using SPSS 22.0 software to indicate normal distribution of the data. Data were expressed as the mean ±standard error of the mean. The differences between the two groups were analyzed by the Student's *t*-test. Values in the same row with different superscripts indicate significance ($P < 0.05$), otherwise no significance ($P > 0.05$).

Ethical considerations

The experimental protocol was approved by the Animal Care and Use Committee of Hainan Province and conducted in accordance with the Chinese guidelines for animal welfare.

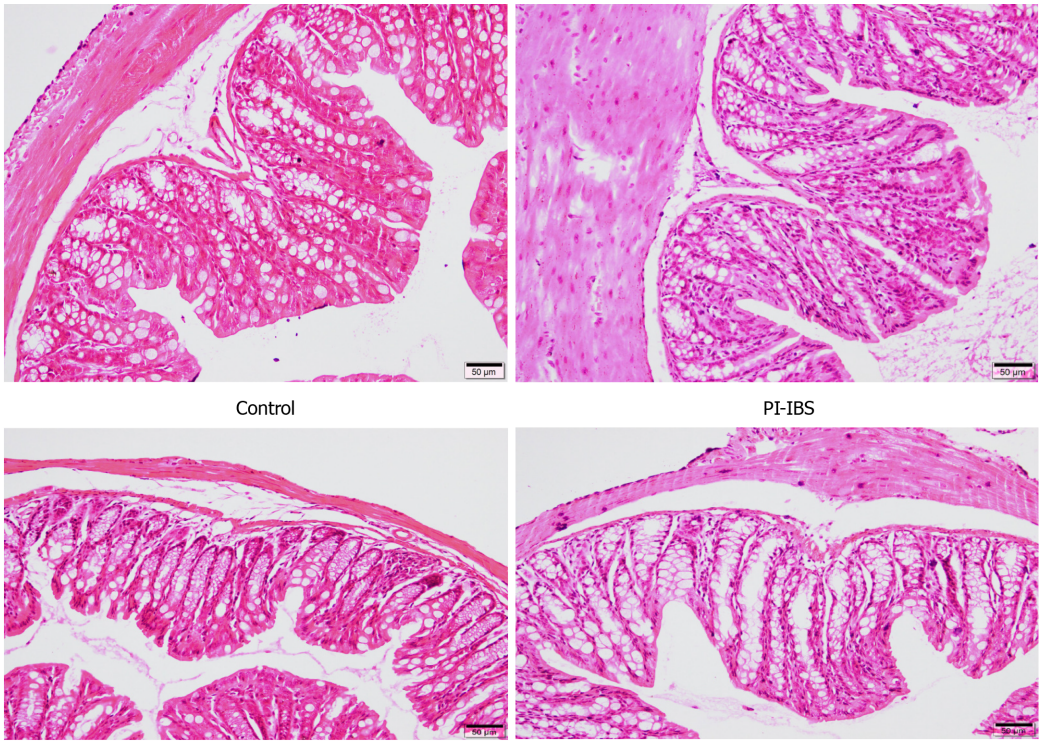
RESULTS

PI-IBS mouse model and the effect of A2AR on the clinical features of PI-IBS

On the 56th day of infection with *T. spiralis*, the experimental mice showed no significant colonic inflammation (Figure 1), accompanied by a higher AWR score, longer CTT, and higher Bristol stool grade (Tables 3 and 4), suggesting that the PI-IBS mouse model was successfully established. Injection of the A2AR agonist CGS21680 significantly increased the clinical features and slightly accelerated intestinal inflammation. On the other hand, the A2AR antagonist Sch58261 markedly improved the model animal's clinical manifestations. These results confirm the important role of A2AR in the development of PI-IBS. However, the underlying mechanism behind this role warrants further investigation.

Changes in intestinal ATP and A2AR in the PI-IBS mouse

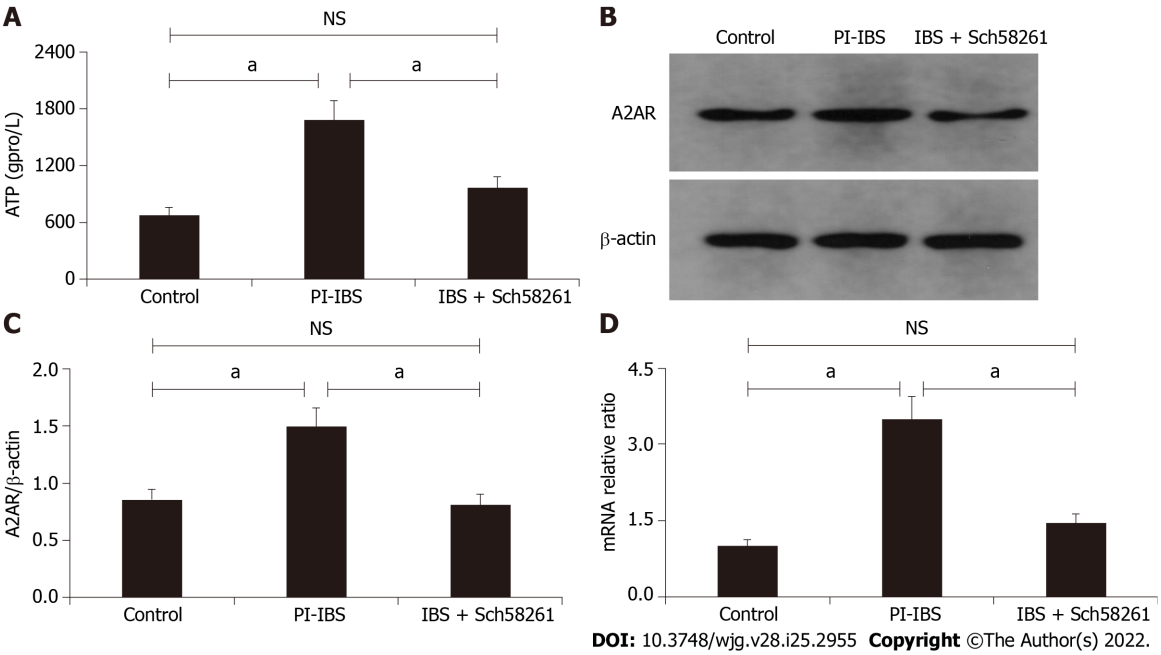
When compared with the control group, intestinal ATP significantly increased in the PI-IBS mouse (P < 0.05; Figure 2) along with an increase in A2AR protein expression (P < 0.05; Figure 3A and B). The A2AR antagonist Sch58261 significantly decreased intestinal ATP and A2AR protein levels, while the A2AR antagonist CGS21680 significantly increased these protein levels (P < 0.05; Figure 2, Figure 3A and B). These results suggest that adenosine and A2AR are involved in the development of PI-IBS.



CD4+ T cells' isolation and A2AR expression

CD4+ T cells were isolated and purified from PI-IBS mice spleens by FACS (Figure 3A) for further functional evaluation *in vitro*. Cellular immunohistochemistry results revealed that the CD4+ T cells from PI-IBS mice obviously increased their A2AR protein and mRNA expression, which could have been regulated by the A2AR antagonist and agonist, respectively (P < 0.05; Figure 3C-E). These results suggest that CD4+ T cells could express A2AR, and their expression was regulated by A2AR.

CD4+ T cells from PI-IBS mice showed obvious proliferation, decreased apoptosis, and increased ATP and IL-17 production, which could have been regulated by the A2AR antagonist and agonist, respectively (P < 0.05; Figure 4A-D). These results suggest that CD4+ T cell function, especially Th17 polarization was regulated by A2AR.



CD4+ T cells signaling pathway

The JAK/p-JAK protein and mRNA expression in CD4+ T cells from PI-IBS mice were detected by Western blotting and RT-PCR. The A2AR antagonist Sch58261 decreased JAK/p-JAK protein and mRNA expression, while the A2AR agonist CGS21680 increased JAK/p-JAK protein and mRNA

Figure 1 The effect of adenosine 2A receptor on the histopathological changes in the post-infectious irritable bowel syndrome mouse. On the 56th day of infection with *T. spiralis*, colon tissues from the infected mice were collected, fixed, sectioned, stained with hematoxylin-eosin, and evaluated by light microscopy. Compared with the control mouse, the post-infectious irritable bowel syndrome (PI-IBS) mouse model showed no significant inflammatory changes in colon tissues. CGS21680, an agonist of adenosine 2A receptor, induced subtle inflammatory changes in the colon tissues of the PI-IBS model mouse, such as slight infiltration of inflammatory cells. IBS: Irritable bowel syndrome.

Figure 3 Adenosine 2A receptor expression level in CD4+ T cells isolated and purified from the post-infectious irritable bowel syndrome mouse. A: Fluorescence-activated cell sorting results showed that CD4+ T cells (P3) were successfully isolated and purified; B-C: Immunohistochemistry staining of adenosine 2A receptor (A2AR) in CD4+ T cells; D: Western blot assay evaluated A2AR expression levels in CD4+ T cells isolated from different groups; E: Relative A2AR mRNA levels in the three groups. $^{a}P < 0.05$. A2AR: Adenosine 2A receptor; PI-IBS: Post-infectious irritable bowel syndrome; NS: Not significant.

expression. These results suggest that, during PI-IBS, the JAK pathway participates in CD4+ T cell A2AR-associated biological behavior (Figure 5A and B).

The STAT3/P-STAT3 protein and mRNA expression in CD4+ T cells from PI-IBS mice were detected by Western blotting and RT-PCR. The A2AR antagonist Sch58261 decreased STAT3/P-STAT3 protein and mRNA expression, while the A2AR agonist CGS21680 increased STAT3/P-STAT3 protein and mRNA expression. These results suggest that, during PI-IBS, the STAT3 pathway participated in CD4+ T-cell A2AR-associated biological behavior (Figure 5A and B).

The RORγt protein and mRNA expression in CD4+ T cells from PI-IBS mice were detected by Western blotting and RT-PCR. The A2AR antagonist Sch58261 decreased RORγt protein and mRNA expression, while the A2AR agonist CGS21680 increased RORγt protein and mRNA expression. These results suggest that, during PI-IBS, the RORγt pathway participated in CD4+ T cell A2AR-associated biological behavior (Figure 5A and B).

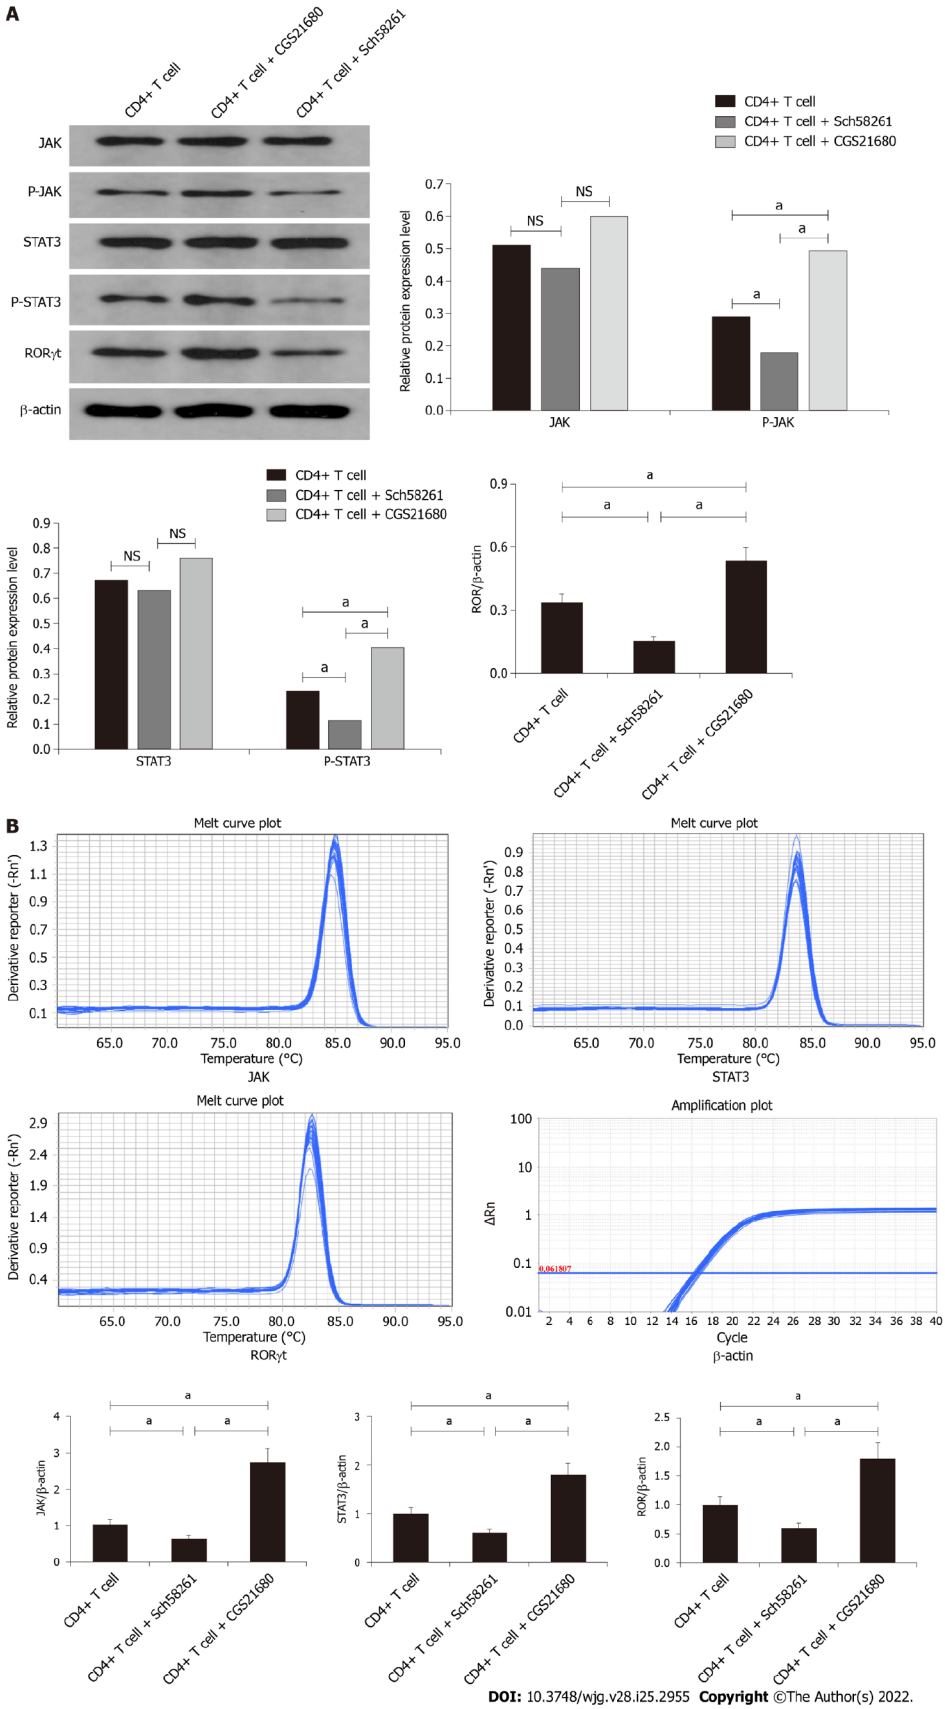
DISCUSSION



Lasting low level inflammation occurs in the intestine in IBS and especially in PI-IBS due to complex immune abnormalities. Therefore, patients show continuous clinical symptoms and not distinct biochemical and pathological changes. However, the precise mechanism underlying immune regulation in PI-IBS is unclear. Therefore, the relationship between ARs and IL-17 response in the inflammation and immune response in PI-IBS should be investigated.

Our results showed that increasing intestinal ATP level in PI-IBS was accompanied by increasing intestinal A2AR level, which suggested that ATP and A2AR could participate in the pathogenesis of PI-IBS. The quantitative changes that lead to the development of PI-IBS, resulted from PI-IBS, or increased PI-IBS is not known. The animal's intestinal tissue remained unchanged following injection of the A2AR antagonist, but the clinical symptoms improved. This result was contradictory to the previous hypotheses which state that adenosine and its receptors play a protective role in inflammation. During the inflammatory process, adenosine and its receptors could trigger another unknown pathway to maintain the balance of inflammation and the immune response, otherwise, a prolonged presence of increased concentrations of adenosine can be harmful and can induce an immunosuppressed environment that is ideal for the onset and development of neoplasia[34]. Our study reports the complex condition in PI-IBS.

We elucidated the mechanism underlying the role of A2AR in PI-IBS. CD4+ T cells act as an important regulator in inflammation and immune response. Th17 polarization is one of the most important pathways of the immune event associated with CD4+ T cells. We first found that the number of CD4+ T cells distinctly increased, accompanied by an increase in the expression of A2AR on these cells. We then found that the agonist of A2AR increased the number of CD4+ T cells accompanied by an increase in the expression of A2AR on these cells. The A2AR agonist increased the proliferation of CD4+ T cells and inhibited their apoptosis. On the contrary, the A2AR antagonist decreased the number of CD4+ T cells and inhibited their function. These results suggested that CD4+ T cells participate in A2AR-induced intestinal inflammation.

Th17 polarization was associated with A2AR. IL-17 plays a dual role in inflammation and the immune response. IL-17 can improve inflammation in some conditions. For instance, HSP70 induces γ δ T cells to produce IL-17 that protects mice against PI-IBS[10]. IL-17 protects mice against colitis induced by adherent-invasive *Escherichia coli*[35]. In other conditions, IL-17 can increase inflammation. For instance, Th17 cells and IL-17 promotes skin and lung inflammation and fibrosis in the bleomycin-induced murine model of systemic sclerosis[36].

Unfortunately, the studies involving animal models have not determined the efficacy of anti-IL-17 antibodies in improving intestinal inflammation[37]. Our results showed that the increase in A2AR expression and chronic inflammation is associated with the Th17 polarization of CD4+ T cells, which

Figure 5 Signaling pathway analysis by Western blot assay. A: Western blot results indicate that the expression level of p-JAK, p-STAT3, and receptor-related orphan receptor (ROR) were significantly increased in the CD4+ T cell + CGS21680 group and decreased in CD4+ T cell + Sch58261 group; B: The mRNA expression level of p-JAK, p-STAT3, and ROR between the different groups. [a]*P* < 0.05. A2AR: Adenosine 2A receptor; PI-IBS: Post-infectious irritable bowel syndrome; NS: Not significant.

suggested that the A2AR-CD4+ T cells-IL-17 polarization pathway is present in PI-IBS.

We investigated the intracellular signaling pathway of the Th17 polarization of CD4+ T cells induced by A2AR. We found that JAK and STAT3 protein and their phosphorylated products were significantly increased in CD4+ T cells from the PI-IBS mouse model. The A2AR antagonist reduced the protein and mRNA level of JAK and STAT3, which was increased by the A2AR agonist. Our results suggested that the JAK-STAT3 pathway is an important intracellular signaling pathway in the A2AR-induced Th17 polarization of CD4+ T cells in PI-IBS.

The present study has some limitations. The type of visceral hypersensitivity in the PI-IBS mouse model was not investigated. The water content in the Bristol stool grade was not analyzed. The direct isolation of CD4+ T cells from the intestine is difficult. Therefore, we used CD4+ T cells isolated from the spleen, which might have resulted in some variation compared with CD4+ T cells from the intestine.

CONCLUSION

In the present study, we established a mouse model of PI-IBS and the mice were administered an A2AR agonist and antagonist. Interestingly, we found that A2AR increased in PI-IBS accompanied by CD4+ T cell activation, proliferation and production of IL-17. A2AR antagonist improved the clinical symptoms and the cellular and molecular events during PI-IBS. This study showed that the upregulation of A2AR increases PI-IBS by promoting the Th17 polarization of CD4+ T cells.

ARTICLE HIGHLIGHTS

Research background

It has been proved that low-grade inflammation and immunological dysfunction are involved in post-infectious irritable bowel syndrome (PI-IBS). T helper 17 (Th17) polarization occurs in IBS. Adenosine and its receptors participate in intestinal inflammation and immune regulation.

Research motivation

To elucidate the pathogenesis of PI-IBS and identify a potential target for the treatment of this disease.

Research objectives

This study aims to explore the role of adenosine 2A receptor (A2AR) in PI-IBS and its underlying mechanism, especially the relationship between A2AR and Th17 response.

Research methods

A PI-IBS model was established by infecting mice with *Trichinella spiralis*. The expression and function of A2AR and CD4+ T lymphocytes were examined. Furthermore, the effect of A2AR on CD4+ T lymphocyte Th17 polarization was observed and the clinical features of PI-IBS were evaluated.

Research results

The main results can be summarized as follow: (1) expression of ATP and A2AR and inhibition of A2AR improved the clinical features in PI-IBS; (2) CD4+ T cells expressed A2AR and produced IL-17 *in vitro*, which was regulated by the A2AR agonist and antagonist; and (3) The A2AR antagonist increased the production of IL-17 by CD4+ T cells *via* the Janus kinase-signal transducer and activator of transcription-receptor-related orphan receptor γ signaling pathway.

Research conclusions

The upregulation of A2AR increases PI-IBS by promoting the Th17 polarization of CD4+ T cells.

Research perspectives

The present study could provide a new pathway to elucidate the pathogenesis of PI-IBS and identify a novel therapy target for this disease.

Abstract

BACKGROUND

Laparoscopic liver resection (LLR) has become a safe surgical procedure that needs additional summarization.

AIM

To review 4 years of total LLR surgeries, exceeding 1000 cases, which were performed at a single center.

METHODS

Patients who underwent LLR at West China Hospital of Sichuan University between January 2015 and December 2018 were identified. Surgical details, including the interventional year, category of liver disease, and malignant liver tumors prognosis, were evaluated. The learning curve for LLR was evaluated using the cumulative sum method. The Kaplan-Meier method was used to perform survival analysis.

RESULTS

Ultimately, 1098 patients were identified. Hepatocellular carcinoma (HCC) was the most common disease that led to the need for LLR at the center (n = 462, 42.08%). The average operation time was 216.94 ± 98.51 min. The conversion rate was 1.82% (20/1098). The complication rate was 9.20% (from grade II to V). The 1-year and 3-year overall survival rates of HCC patients were 89.7% and 81.9%, respectively. The learning curve was grouped into two phases for local resection (cases 1-106 and 107-373), three phases for anatomical segmentectomy (cases 1-44, 45-74 and 75-120), and three phases for hemihepatectomy (cases 1-17, 18-48 and

49-88).

CONCLUSION
LLR may be considered a first-line surgical intervention for liver resection that can be performed safely for a variety of primary, secondary, and recurrent liver tumors and for benign diseases once technical competence is proficiently attained.

Key Words: Laparoscopic liver resection; Single-center experience; Learning curve; Liver

Core Tip: West China Hospital of Sichuan University is the biggest and most advanced one in the western region of China. About 1500-2500 cases of liver resection have been performed in our center every year. Since the first laparoscopic liver resection (LLR) was performed in 2015, we have accumulated more than 1000 cases rapidly, including hemi-hepatectomy, mesohepatectomy, anatomical segmentectomy from segment I to VIII and even the first case of laparoscopic donor hepatectomy in Mainland China. In this study, we want to share our experiences and introduce technical innovation of LLR.

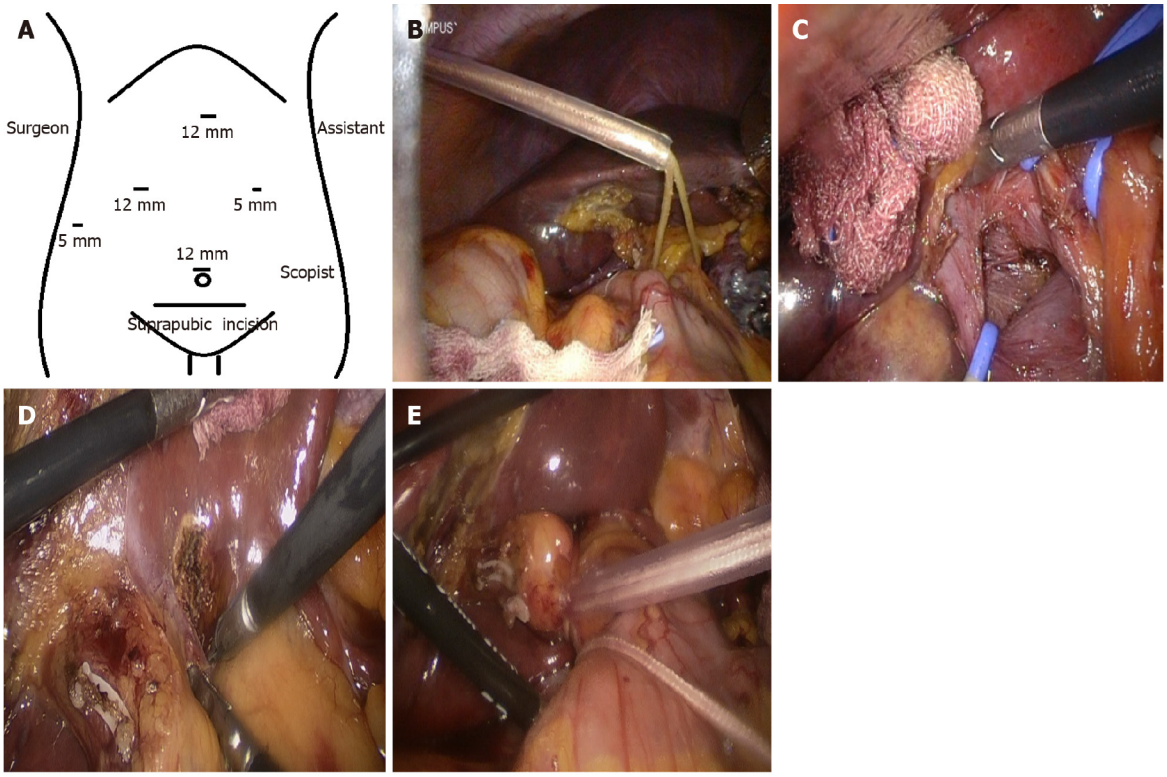
INTRODUCTION

Laparoscopic liver resection (LLR) has become a safe approach for liver resection, following advances in surgical techniques, anesthesiology, and perioperative care. Since its first use was reported in 1996 by Azagra *et al*[1], LLR has evolved to become a primary choice of intervention for many patients with liver tumors[2-6]. Experience with laparoscopic procedures has allowed for the development of complex liver resection techniques using laparoscopy, including mesohepatectomy, caudate lobectomy, and even combined resection of several hepatic segments[7-9].



Total LLR has been performed since 2015 at the West China Hospital of Sichuan University. Although total LLR has been performed for a shorter period of time at the West China Hospital of Sichuan University compared to other centers, a large number of clinical patients in the western region of China have been treated with LLR at the West China Hospital of Sichuan University, conveying a rich experience in performing open liver resection to surgeons at the center. Over the past 4 years, LLR, including hemihepatectomy, mesohepatectomy, anatomical segmentectomy from segment I to VIII, and even the first case of laparoscopic donor hepatectomy in mainland China, has been performed successfully at the center[10]. The present study reviews the single center's 4-year experience with LLR in more than 1000 patients and discusses its safety and feasibility, the learning curve for performing laparoscopic surgery, LLR technical innovations, and patient outcomes.

MATERIALS AND METHODS

Patient characteristics

Patients who underwent LLR between January 2015 and December 2018 at the West China Hospital of Sichuan University were studied retrospectively. Inclusion criteria were as follows: patients who had undergone LLR due to liver disease; patients with hemangioma who met the following criteria: (1) Symptomatic hemangioma; (2) Increasing tumor size; (3) Heavy psychological burden and anxiety symptoms that affect daily life and require surgical treatment; (4) Tumor located in special segments (*e.g.*, the caudate lobe or the porta hepatis) that are difficult to treat as tumor size increases; and (5) Unclear diagnosis in which the possibility of a malignant tumor cannot be completely ruled out; and patients with hepatocellular carcinoma (HCC) who met the following criteria: Barcelona Clinic Liver Cancer 0-B stage HCC[11]; A3 stage with normal liver function after conservative treatment; and A4 or B stage with a tumor located in the same hemiliver. Exclusion criteria were as follows: patients who only received laparoscopic surgery without hepatectomy.

Patient data (age, sex, liver function before and after the operation, complications, hospital stay after the operation, operation time, hemorrhage, ascites, and perioperative mortality) were collected. All

patients provided written informed consent for surgery, and this study was approved by the Ethical Review Board of West China Hospital of Sichuan University.

Surgical technique

Surgical procedures were described in our previous study[12]. A five-trocar approach was used at the tumor location (Figure 1A). Two hepatic inflow occlusion methods were adopted at the center[12]. Intermittent pringle (IP): During the operation, hepatic inflow was blocked for 15 min and released for 5 min (Figure 1B) and continuous hemihepatic vascular inflow occlusion (CHVIO) (Figure 1C-E).

Histopathology

Liver capsule invasion and tumor location: Liver capsule invasion was determined by the histopathological report. In this study, "central tumor" was defined as a tumor within the main hepatic body, located in segments I/IV/V/VIII; otherwise, the tumor was considered a "marginal tumor". If the tumor spanned across regions I/IV/V/VIII and another region, it was considered a "central tumor".

Diagnosis of cirrhosis: Liver cirrhosis was diagnosed by histological examination of hepatic tissues by two experienced pathologists. The histopathology diagnostic standard used to diagnose chronic hepatitis was previously described by Desmet *et al*[13]. G0-4/S1-3 was not considered liver cirrhosis, whereas G0-4/S4 was diagnosed as liver cirrhosis.

HCC differentiation: HCC differentiation was classified according to the World Health Organization Classification of Tumors of the Digestive System[14], with grade 1 being well differentiated, grade 2 moderately differentiated, and grade 3 poorly differentiated. At the center, pathological reports sometimes describe grade 1-2 or grade 2-3 HCC in a single patient. Patients with grades 1, 2 and 1-2 were allocated to the "well-to-moderately differentiated" group, and patients with grades 2-3 and 3 were allocated to the "poorly differentiated" group in this study.

Classification of complications: The Clavien–Dindo classification of surgical complications was adopted[15]. Grade I was regarded as the absence of complications, while Grades II-V were regarded as the presence of complications.

The learning curve

The learning curve of LLR was evaluated using the cumulative sum (CUSUM) method. The CUSUM procedure is a well-established method that detects data changes and monitors surgical performance. In

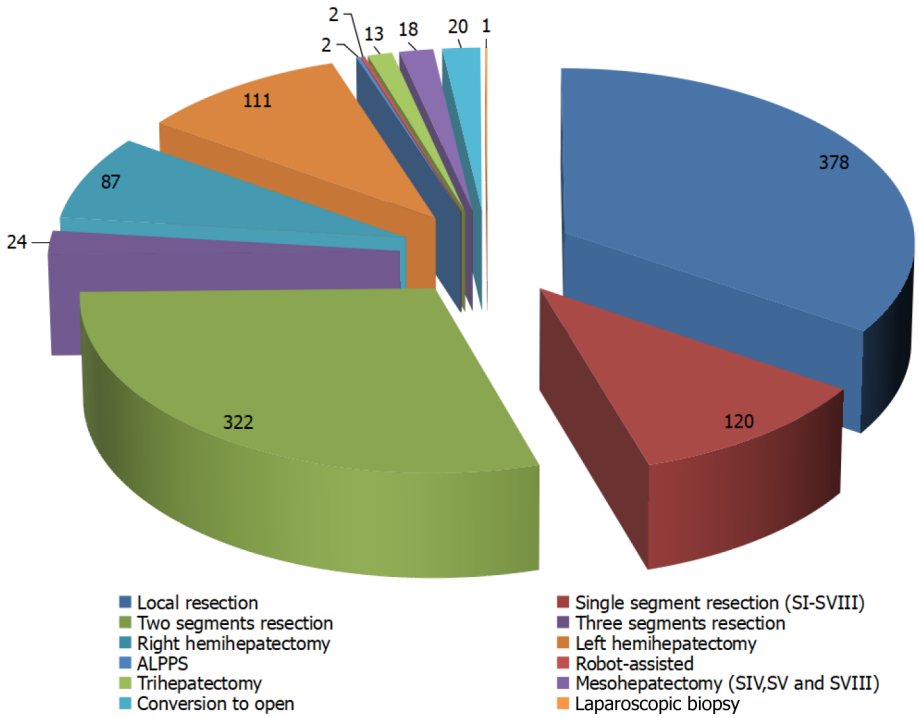
this study, the operation time of each case was ordered chronologically (date of surgery). The formulation of the CUSUM was defined as: Where was an individual operation time, and was the mean of the overall operation time[16]. The learning curve is presented as a broken line graph according to the above formulation.

Follow-up

Patients were followed up 1, 3, 6, 12, 24 and 36 mo postoperatively and assessed by computerized tomography or magnetic resonance imaging, liver function testing, and serum tumor marker measurement. All patients were followed until confirmation of death. If a patient lost contact during follow-up, the survival time was divided into the former interval of follow-up and was included in the censored data.



Statistical analysis

Measurement data between 2 comparative intervals were evaluated by independent-samples *t* test. Pearson's chi-square test and Fisher's exact test (when expected cell frequencies were less than 5) were used to determine significant differences in categorical parameters. The Kaplan-Meier method was used to perform survival analysis. Multiple regression analysis was used to assess risk factors determining the patient's disease prognosis. A P value < 0.05 was considered to represent a statistically significant difference.

RESULTS

Demographic data

A total of 1148 consecutive patients who received laparoscopic surgery (except laparoscopic cholecystectomy) between January 2015 and December 2018 were identified. Fifty patients did not meet the inclusion criteria. The remaining 1098 patients underwent LLR, and their demographic data were collected (Table 1).

Figure 2 The details of different types of liver resection at the center. ALPPS: Associating liver partition and portal vein ligation for staged hepatectomy.

The average operation time was 216.95 ± 98.51 min (range, 31-650 min). The longest operation time was observed in LLR in which resection of a tumor in segments I, IV, V and VIII was combined with resection in the caudate lobe invading the middle hepatic vein[9]. The average blood loss was 242.51 ± 143.23 mL (range, 5-4000 mL). The greatest blood loss, 4000 mL was observed in a patient who had liver paragonimiasis and that underwent conversion to open left hemihepatectomy with a splenectomy. A total of 22 patients (2.00%) underwent blood transfusion. The rate of conversion to open surgery was 1.82% (20/1098). With regard to methods of hepatic inflow occlusion, the IP maneuver was employed in 77.14% of patients (847/1098), and CHVIO was used in 21.58% of patients (237/1098). Local resection, 2 segmental resections and anatomical hepatectomy of a single segment represented the top 3 categories of LLR at the center (Figure 2).

Compared with preoperative data, alanine transaminase and aspartate aminotransferase levels peaked at postoperative day (POD) 1 and then gradually decreased ($P < 0.01$, Figure 3A and B). However, the average total bilirubin level tended to increase postoperatively and peaked at POD 5 ($P < 0.01$, Figure 3C). Albumin (ALB) levels and drainage decreased quickly following operation, and ALB levels were maintained at a lower level for a longer period of time ($P < 0.01$, Figure 3D and E).

The progression of surgical outcomes each year

Since the first LLR case in 2015, surgical procedures at the center have been continuously improved according to accumulated experiences. For example, the method of hepatic inflow occlusion was changed from CHVIO to IP, as the latter resulted in less blood loss and a clearer view of the operation site[12].

To further examine technique progression, surgical outcomes, including intraoperative data, mortality on POD 90, and surgical complications, were analyzed by year (Table 2). The inpatient time, postoperative inpatient time, operative time, postoperative liver function, mortality, complications, and drainage significantly decreased from year to year. Although some data (hospitalization expenses and blood loss) did not change significantly, the data trended toward decreasing over time. These results imply that surgeons at the center conquered the LLR learning curve, resulting in the LLR technique advancements.

The learning curves for different types of LLR

Considering that the surgical difficulty of different types of LLR is distinct, 3 representative LLR techniques were selected for investigation of their learning curves: local resection, anatomical resection, and right hemihepatectomy.

For local resection, there was one peak point observed in the 106th case. Therefore, 2 phases were initially differentiated on the graph: Phase I, cases 1-106, and phase II, cases 107-373 (Figure 4A). For anatomical resection, 2 peak points were observed at the 44th and 74th cases. Therefore, 3 phases were

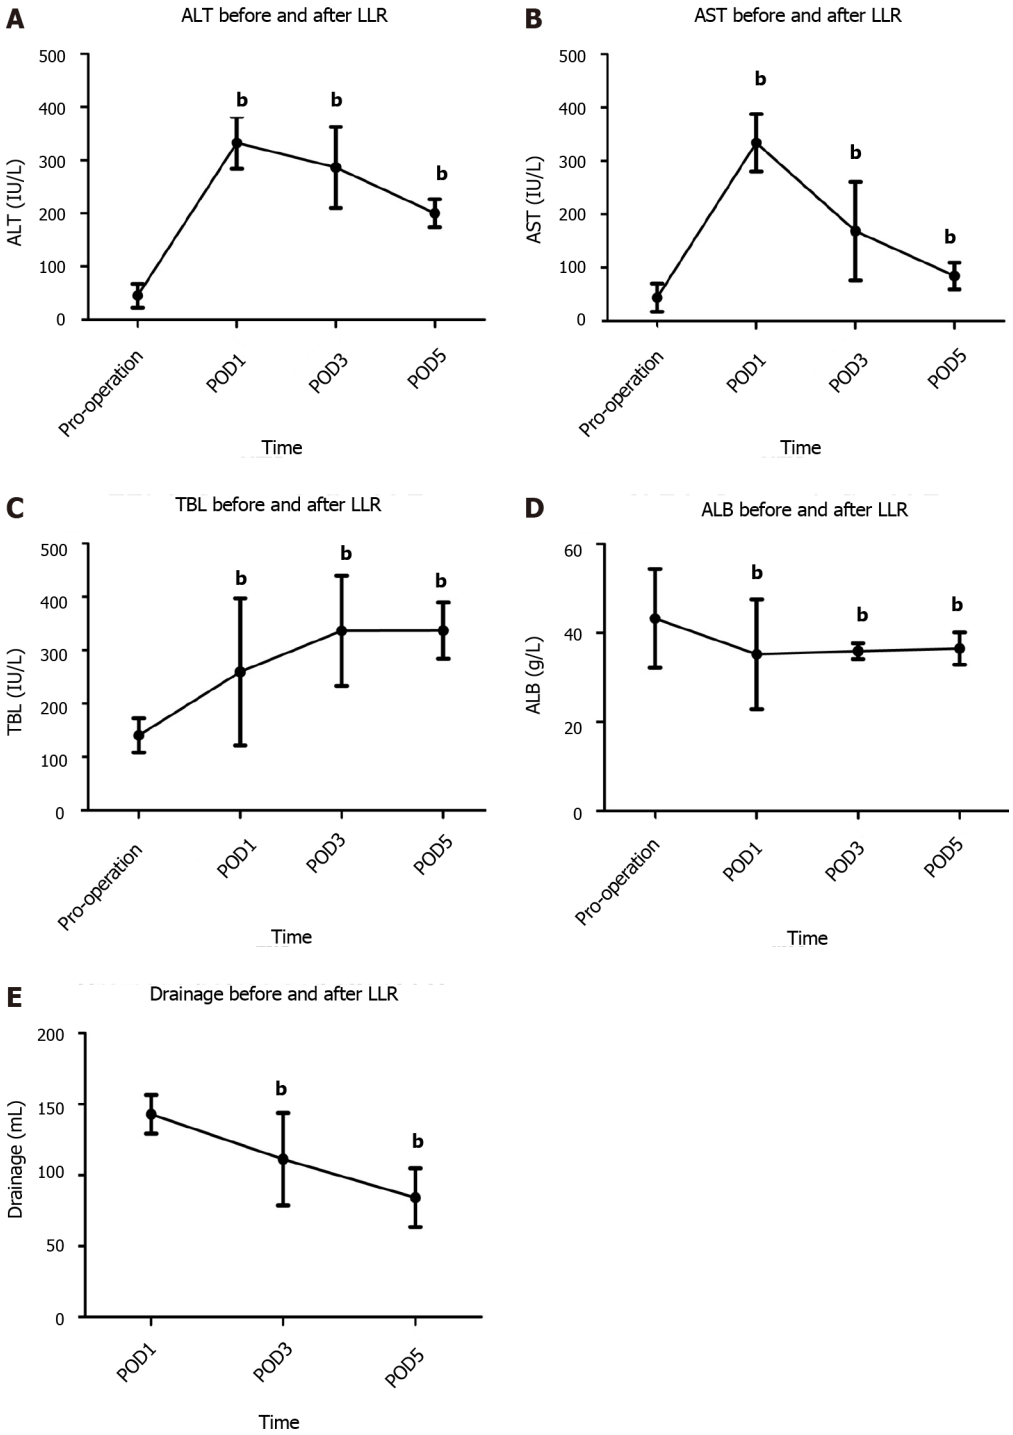
[b]$P < 0.01$.
ALT: Alanine transaminase; LLR: Laparoscopic liver resection; TBL: Total bilirubin.

initially differentiated on the graph: Phase I, cases 1-44; phase II, cases 45-74; and phase III, cases 75-120 (Figure 4B). For right hemihepatectomy, there were 2 peak points observed at the 17th and 48th cases. Therefore, 3 phases were initially differentiated on the graph: Phase I, cases 1-17; phase II, cases 18-48; and phase III, cases 49-88 (Figure 4C).

These results indicate that the learning processes of anatomical resection and right hemihepatectomy were more complicated than the learning process of local resection and involved an initial period, increased competence in LLR, and then mastery and the challenging period.

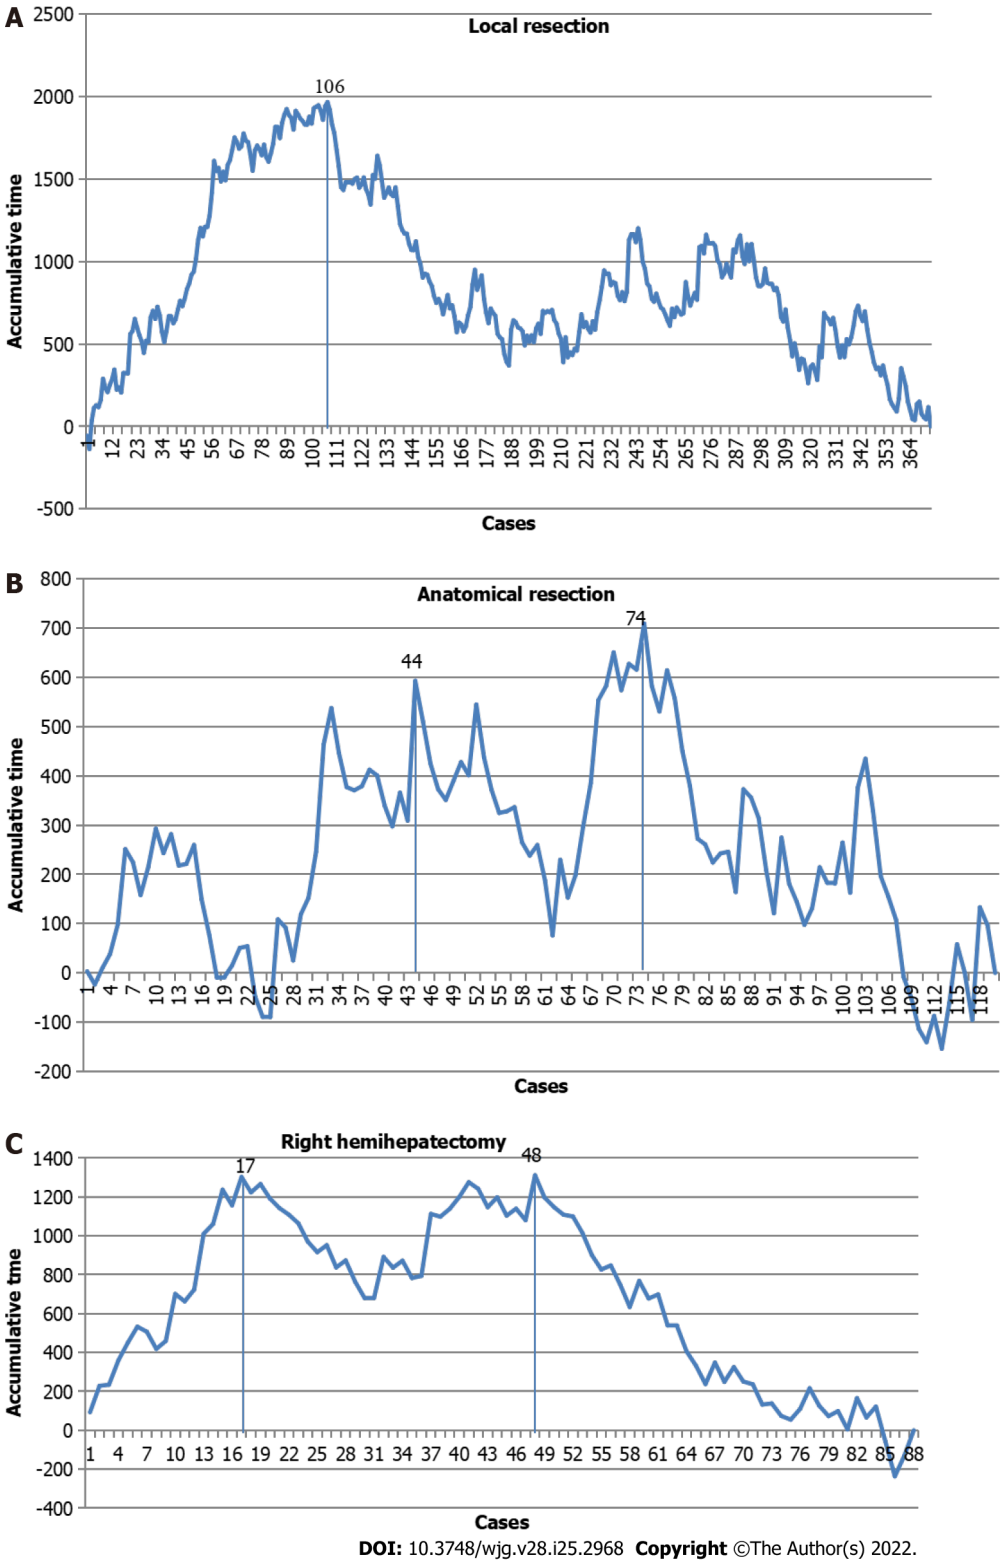


HCC patient characteristics and disease prognosis

Among the 1098 patients enrolled in the study, 462 patients suffered from HCC, and 5 patients suffered from mixed carcinoma (Table 1). The details of all 467 patients with HCC-related disease are shown in Table 3.

Follow-up data were obtained for 438 patients, and disease-free survival (DFS) and overall survival (OS) were assessed. The 3-year DFS and OS rates were 69.4% and 81.9%, respectively. The 1-year DFS and OS rates were 76.3% and 89.7%, respectively (Figure 5).

DISCUSSION



The present study shows that LLR is a safe and efficient treatment for a variety of primary, secondary, and recurrent liver tumors and for benign diseases. LLR has several advantages, including minimal damage to the abdominal wall, faster postoperative recovery, and fewer patient complaints[17,18]. Currently, LLR is widely performed in many liver surgery centers. The College of Medicine, Zhejiang University, was one of the first medical centers to perform LLR in China. They reported a 14-year, single-center experience with 365 cases and claimed that LLR has several advantages: lower economic burden, time saving, less blood loss, minimal harm, and improved safety[19]. Researchers also found that surgeons who use LLR must have extensive experience in performing open hepatectomy and that

these surgeons will experience a learning curve when performing LLR. The need for a stepwise progression through the learning curve to minimize morbidity and mortality has been highlighted by many centers[20-22]. Furthermore, using laparoscopic surgery for major liver resections and liver resections for lesions adjacent to major vessels has been confirmed to be both feasible and safe[23-25]. Previous researchers have claimed that the use of LLR for major liver resection has similar morbidity and mortality rates as open surgery. Moreover, tumor recurrence rates following LLR for lesions adjacent to major vessels was not increased[24]. Recent studies support the consensus that LLR is feasible, safe, and minimally invasive. Once surgeons progress through the learning curve, this procedure can offer benefits to patients. Halls *et al*[26] and Ban *et al*[27] established a difficulty score

Figure 4 The learning curves for different types of laparoscopic liver resection. A: The learning curve for local resection; B: The learning curve for anatomical resection; C: The learning curve for right hemihepatectomy.

model to predict intraoperative complications during LLR. Patient characteristics such as neoadjuvant chemotherapy, lesion type and size, classification of resection, and previous open liver resection were associated with a higher risk of surgery-related complications after LLR when compared to surgery-related complications after open liver resection. These findings may provide insight for surgeons when making treatment decisions to obtain better patient outcomes following LLR.

The large Chinese population, especially in Sichuan Province, allowed the center in the present study to accumulate over 1000 LLR cases in a 4-year period. These cases involved all types of LLR, including laparoscopic living donor resection. As reported, the increase in the volume of LLRs performed in 2009-

BCLC: Barcelona Clinic Liver Cancer; TNM: Tumor-node-metastasis.

2012 *vs* 2000-2008 may be partially attributed to the Louisville 2009 Consensus[28]. Therefore, approximately 22 out of the total of 160 cases were necessary to overcome the learning curve[22,29,30]. A decrease in blood loss during LLR was observed after a minimum of performing 50 cases[29]; and at least 25 cases were needed to master laparoscopic living donor resection[31]. At the center, 106 cases were needed to optimize local resection *via* LLR. However, for complex LLR, 2 peak points were observed in the learning curve. Repetitive training (an initial period, increased competence in LLR, and then mastery and the challenging period) was necessary for surgeons to master hemihepatectomy and anatomical resection *via* LLR. Furthermore, an increase in the conversion rate in 2016/2017 was noted. This time period corresponded to the second and third years of performing LLR at the center when surgeons were overcoming the second peak of the LLR learning curve and at which time there was a huge increase in the number of LLR cases requiring more complex surgeries. After the LLR technology was mastered, the conversion rate at the center decreased significantly in 2018.

Some studies have claimed that continuous hemi-hepatic vascular inflow occlusion is associated with similar outcomes as IP[32,33]. However, at the center in the present study, the IP method was adopted instead of hemihepatic vascular inflow occlusion once the LLR learning curve was overcome, as the IP

Figure 5 Survival rates of patients with hepatocellular carcinoma. A: Overall survival rates; B: Disease-free survival rates. LLR: Laparoscopic liver resection.

method resulted in less blood loss than the hemihepatic vascular inflow occlusion method[12]. Additionally, the intrahepatic Glissonian approach was adopted to replace the extra-Glissonian approach.

The morbidity and mortality rates at the center are similar to those in other centers. One study reviewed 2804 patients who received LLR and found a cumulative mortality rate of 0.3% and a morbidity rate of 10.5%. Liver-specific complications included bile leaks (1.5%), transient liver ascites (1%), and abscesses (2%)[34]. At the center in the present study, in addition to observing these common complications, 4 patients who underwent right anterior lobectomy suffered from right posterior branch injury. One of these 4 patients suffered from liver failure and ultimately died. Due to this complication the LLR technique was improved so that a longer right anterior pedicle is now exposed prior to transection. Similarly, for patients who undergo right hemihepatectomy, the right anterior and posterior pedicle must be transected to prevent left pedicle injury. For patients who undergo left hemihepatectomy, the presence of ischemia in the right lobe following ligation of the left Glissonian sheath must be determined. The cause of death in the other 2 patients was refractory hypernatremia and ascites with liver failure. The most common postoperative complications at the center were pneumonia, hypohepatia, ascites, and bile leakage. Postoperative bleeding requiring a second operation was rare in these cases. Once the LLR learning curve was conquered and the LLR technique advanced and was optimized, postoperative complications significantly decreased from year to year.

CONCLUSION

In conclusion, LLR may be performed safely for a variety of primary, secondary and recurrent liver tumors and for benign diseases. Once the learning curve is overcome, LLR can offer short-term benefits for patients.

ARTICLE HIGHLIGHTS

Research background

Laparoscopic liver resection (LLR) has become a safe approach but still need to be further summarized.

Research motivation
The present study reviews the 4-year experience of total LLR in a single center, which exceeded 1000 cases.

Research objectives
Summarize the past, in order to obtain better progress in this technology in the future.

Research methods
Patients who underwent LLR at West China Hospital of Sichuan University between January 2015 and December 2018 were identified. Surgical details in different years, categories of liver disease and prognosis of malignant liver tumors were evaluated. The learning curve for LLR was evaluated using the cumulative sum method. The Kaplan-Meier method was used to perform survival analysis.

Research results
Ultimately, 1098 patients were identified. Hepatocellular carcinoma (HCC) was the most common disease that led to the need for LLR in our center (n = 462, 42.08%). The average operation time was 216.94 min ± 98.51 min. The conversion rate was 1.82% (20/1098). The complication rate was 9.20% (from grade II to V). The 1-year and 3-year overall survival rates of HCC patients were 89.7% and 81.9%, respectively. The learning curve was grouped into two phases for local resection (cases 1-106 and 107-373), three phases for anatomical segmentectomy (cases 1-44, 45-74 and 75-120) and three phases for hemi-hepatectomy (cases 1-17, 18-48 and 49-88).

Research conclusions
LLR may be considered a first-line surgical intervention for liver resection that can be performed safely for a variety of primary, secondary, and recurrent liver tumors and for benign diseases once technical competence is proficiently attained.

Research perspectives
It is a very promising surgical procedure that can give patients a faster recovery time.

ACKNOWLEDGEMENTS

We thank Dr. Chen YF (Department of Liver Surgery & Liver Transplantation Center, West China Hospital of Sichuan University) for the assistance of data collection.

Abstract

BACKGROUND

Nutrition is a significant modifiable element that influences the composition of the gastrointestinal microbiota, implying the possibility of therapeutic diet

methods that manipulate the composition and diversity of the microbial.

AIM
To overview research papers on nutrition and gut microbiota and determines the hotspots in this field at the global level.

METHODS
Scopus and Reference Citation Analysis were used to construct a bibliometric technique. It was decided to create bibliometric indicators and mapping as in most previous studies. 2012 through 2021 served as the study's timeframe.

RESULTS
A total of 5378 documents from the Scopus database were selected for analysis. Of all retrieved studies, 78.52% were research papers (n = 4223), followed by reviews (n = 820; 15.25%). China ranked first with a total number of articles of 1634 (30.38%), followed by the United States in second place with a total number of articles of 1307 (24.3%). In the last decade, emerging hotspots for gut microbiota and nutrition research included "gut microbiota metabolism and interaction with dietary components", "connection between the gut microbiota and weight gain", and "the influence of high-fat diet and gut microbiota on metabolic disorders".

CONCLUSION
This is the first thorough bibliometric analysis of nutrition and gut microbiota publications conducted on a global level. Investigation of the association between nutrition/diet and the gut microbiota is still in its infancy and will be expanded in the future. However, according to recent trends, the “effect of gut microbiota and high-fat diet on metabolic disorders" will be an increasing concern in the future.

Key Words: Gut microbiota; Microbiome; Nutrition; Diet; Bibliometric; Scopus; VOSviewer

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: The number of publications on the gut microbiota has progressively expanded as the potential clinical implications of the gut microbiota have become better known, and this has become an emerging research subject. Therefore, this comprehensive bibliometric study intends to provide an overview of the current state of worldwide nutrition and gut microbiota research and to stay ahead of emerging trends and important turns in the field's evolution. Investigation on the association between nutrition/diet and the gut microbiota is still in its infancy and will be expanded in the future. However, according to recent trends, the “effect of gut microbiota and high-fat diet on metabolic disorders" will be a bigger worry in the future.

INTRODUCTION

The microbiome is a term that refers to the collective genomes of microorganisms living in a certain habitat, and the gut microbiota is a complex collection of microorganisms that includes archaea, bacteria, fungus, viruses, and protozoa, among others[1]. These communities interact with each other and their host, with the majority of them being bacteria that reside mainly in the colon of the gastrointestinal tract and interact with them. The human genome has thousands of genes; however, the microbiome contains millions of genes that produce a large number of metabolites that alter host activities, resulting in a substantial impact on the host at the physiological level[2]. Different levels of evidence show that functional or compositional changes in the microbiota present in the human gut contribute to human disease and health, including metabolic, immunological and neuro-behavioral traits that support the role of the microbiota in human health[3,4].

The composition of the gut microbiota varies greatly between individuals. Several studies have found that dietary variations between people are one of the external variables that influence and define the gut microbiota structure[5-8]. Studies in recent years have shown that diet or food as the main source of

energy for gut microbes can greatly affect the diversity and components of the gut microbiota, which affects host health[9-12]. In addition to diet, the gut microbiota is affected by different external variables, such as lifestyle and medication (*e.g.*, antibiotics), which mainly affect the microbiota. There are also intrinsic factors that can affect the gut microbiota, such as host genetics, immune and metabolic regulations[13]. Dietary modifications can account for more than 50% of the changes in the gut microbiota changes; however, host genes account for only 10%[14].

Research showed that disturbances in the interaction between nutrients in food and the microbiome affect its structure, which has been shown to be linked to the development of a variety of diseases[15, 16]. Long-term or, to a lesser extent, short-term dietary intake modifications could determine each human's stable microbiota profile. For example, regardless of the stage of life, the intake of protein, fat, fermentable or non-fermentable carbs, probiotic, and polyphenol effectively modulates the host's gut microbiota, metabolic, and immunological parameters. Compared to high animal protein consumption and low carbohydrate intake, high consumption increases the risk of various health conditions, such as diabetes, cancer, cardiovascular disease, and irritable bowel syndrome[7,10]. Another evidence on the diversity of bacterial content in the gastrointestinal tract of humans revealed that lower bacterial diversity has been found in individuals with various diseases such as arthritis, inflammatory bowel disease, type 1 and type 2 diabetes, eczema, and obesity than in healthy individuals who support the role of the microbiota in human health and diseases[17-21]. Accordingly, diversity appears as a positive indicator of a healthy gastrointestinal tract[22,23].

The results have been applied to numerous domains connected to the gut microbiota over the last years[24-28]. However, there are no bibliometric analyses of nutrition/diet and gut microbiota publications. As a result, the objective of the present study was to carefully review publications related to nutrition and gut microbiota to assess the current state and hotspots in this field. Therefore, this comprehensive bibliometric study intends to provide an overview of the current state of worldwide nutrition and gut microbiota research and to stay ahead of emerging trends and important turns in the field's evolution.

Data sources

We performed this bibliometric analysis using the Scopus bibliographic database, which Elsevier B.V. owns. In bibliometric research, only one database is used because bibliometric indicators and literature mapping are difficult to execute on documents acquired from several databases. Furthermore, the grey literature cannot be included in the data retrieved[29,30]. The current analysis was conducted using the SciVerse Scopus database for numerous reasons. First, Scopus has a much larger number and diversity of indexed publications compared to other databases like PubMed or Web of Science. Scopus has nearly the same number of journals indexed as PubMed and Web of Science combined[31]. Second, because all articles listed in PubMed are simultaneously indexed in Scopus, PubMed is completely comprehensive in Scopus. As a result, Scopus is considered to be comprehensive, as it includes papers from both PubMed and Web of Science[29,30]. Third, Scopus publishes publications in a wide range of disciplines, including science, technology, medicine, social science, and the arts and humanities. Fourth, Scopus enables academics to create sophisticated and extensive search queries by combining various Boolean operators. Finally, Scopus enables the researcher to export and examine the data that have been retrieved. This comprises mapping and statistical analysis. Due to the rapid update of the database, the literature retrieval was carried out on a single day (January 7, 2022). Therefore, it was decided that the publication period for this study would be between 2012 and 2021.

Goal definition

The primary goal of this study is to assess the current state and hotspots in the field of nutrition and gut microbiota by examining the scientific production data set related to nutrition and gut microbiota with the goal of characterisation and understanding it in terms of scientometric indices. Based on bibliometric and/or scientometric indicators, the mapping and analysis of scientific knowledge allow the identification of the dynamics and/or expansion of a specific field of study and the support of strategic decisions related to various research institutions[32].

Search strategy

We used the key terms "microbiome or microbiota" and "nutrition or diet" and its synonyms because we are interested in nutrition and gut microbiota *per se* as a novel concept in scientific research rather than related subjects. The current study focuses on research papers containing "nutrt* or nutrient* or diet* or eat* or feeding" and "microbiome or microbiota or *flora" to recognize items based on their search in the fields topic and the time was ten years between 2012 and 2021. The asterisk (*) was used in search query to retrieve documents with keywords such as diet or dietary.

Validation of the search strategy

The search query was repeatedly fine-tuned in the current study until the top 100 cited publications in the retrieved literature were free of false-positive results. Furthermore, the search query was checked for missing data (false-negative) using a previously published method that depends on the association between the retrieved research output and the actual research output in this field[29,30]. Instead of a title/abstract search, keywords were used in the title search. As a result, the title search will produce the fewest false positive documents, making it a reliable method[29,33-35]. However, a title/abstract search will show many false positives in which the main focus is not on nutrition and the microbiota *per se*.

Bibliometric analysis

The Scopus advanced search tool was used to implement the method. Using the "analyze" function, the retrieved documents were examined. The abstained findings were saved as.csv files in Microsoft Excel. Annual growth, document types, journal names with impact factor (IF), funding agencies, country names, institution names, and document citations were all included in the exported findings. This data was displayed as a linear graph of the annual growth of publication and tables for the core of (top 10 active) journals, funding agencies, countries, institutions, and cited documents in the results section.

The *Impact Index Per Article* for the top 10 high-cited papers collected from Reference Citation Analysis (RCA) is presented. RCA is an open multidisciplinary citation analysis database owned by Baishideng Publishing Group Inc. (Pleasanton, CA 94566, United States)[36].

Visualized analysis

Data on terms in titles and abstracts and cross-country collaboration were visualized using the free Web tool VOSviewer 1.6.17 to determine a worldwide scientific cooperation network across countries/regions and examine hotspots and research trends. Nodes in VOSviewer maps are colored and sized differently. The size is related to the number of times it occurs. The node's color shows its relationship to other nodes with similar colors[37].

RESULTS

Number of publications and evolution over time

A total of 5378 documents from the Scopus database were selected for analysis. The documents retrieved were of 11 types, mainly research articles (n = 4223; 78.52%), followed by reviews (n = 820; 15.25%). Our findings revealed that the scientific advancement of articles on nutrition and gut microbiota has grown in the past ten years. For example, we found 1295 documents in 2021, compared to only 120 documents in 2012 (Figure 1). Of the 5378 documents retrieved, 89 were clinical trials. Fifteen publications on nutrition and gut microbiota were case reports or case series.

Contributions of countries to global publications

Table 1 Lists the contributions of the top 10 countries in publications related to nutrition and gut microbiota from 2012 to 2021. Topping the list was China, with 1634 items (30.38% of the total), followed by the United States, with 1307 items (second place) (24.3%). Italy (n = 346, 6.43%) and Spain (n = 313, 5.82%) ranked third and fourth positions, respectively. An examination of countries with more than 20 publications on nutrition and gut microbiota was conducted. Using data from 44 eligible nations, five VOSviewer clusters were used to examine their centrality and connections to other countries (Figure 2). The United States and China had the highest number of publications in the clusters (green cluster). There is a direct correlation between the number and width of the lines on this map with the degree of interaction and strength between countries.

Analysis of affiliations

As shown in Table 2, the top ten affiliations with the highest number of publications relevant to nutritional science and the gut microbiota were identified. The country with the highest number of affiliations was China. The *Chinese Academy of Sciences* had the highest number of publications (n = 138; 2.57%), followed by the *China Agricultural University* (n = 111; 2.06%), the *Chinese Academy of Agricultural Sciences* (n = 95; 1.77%), and the *University College Cork* (n = 81; 1.51%).

Analysis of funding agencies

Of the documents retrieved 3271 (60.82%) were publications that were part of funded projects. Again, *Chinese funding agencies* were the most active in this field, the *National Natural Science Foundation of China* (n = 711; 13.22%) being the most active, followed by the *National Institutes of Health* (n = 327; 6.08%), and the *National Institute of Diabetes and Digestive and Kidney Diseases* (n = 190; 3.53%) (Table 3).

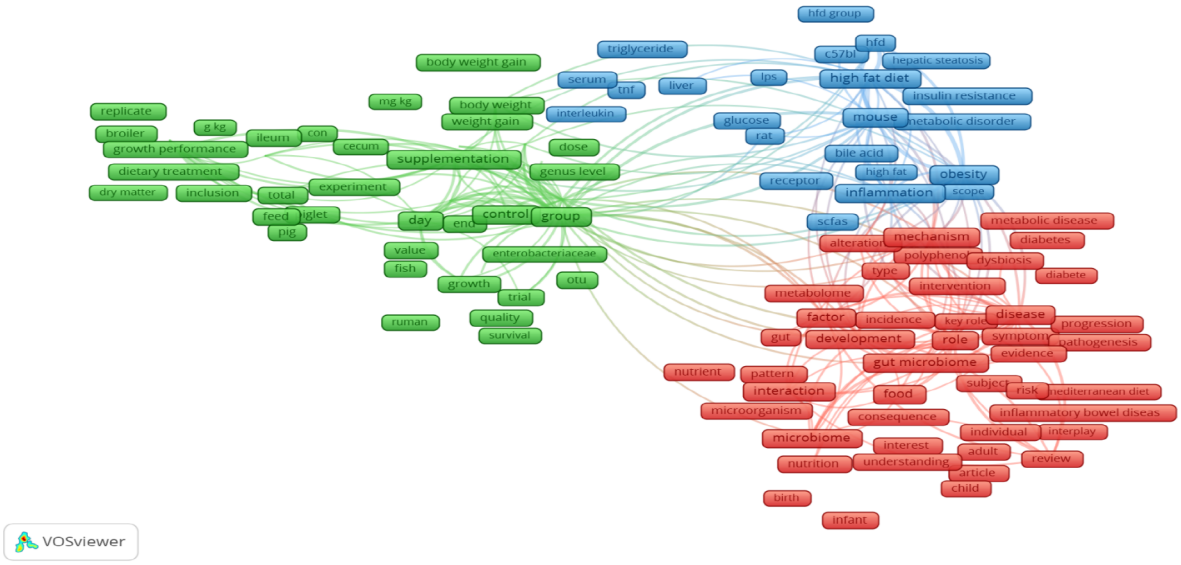
imately 22.3% of the publications.



Analysis of research hotspots

To detect trends and topics in most articles on nutrition and gut microbiota, we used VOSviewer software to look at the distribution of cooccurrence terms in the titles and abstracts of 5378 papers. By mapping terms in titles and abstracts with a minimum frequency of 100 occurrences, three major clusters emerged, highlighting three remarkable research themes. For example, in Figure 3, of the 85327 terms, 293 terms appeared at least 100 times, distributed in three clusters. Cluster 1, indicated by red frames, includes those terms commonly seen in publications related to interaction of the gut microbiota with dietary components; Cluster 2, shown by green frames, contains terms commonly seen in publications related tothe correlation between weight gain and the gut microbiota; and Cluster 3, marked by green frames, includes terms commonly observed in studies related to the effect of the gut microbiota and a high-fat diet and on metabolic syndromes. Figure 4 illustrates an overlay visualization in which the VOSviewer was used to color the terms based on their publication year. The blue and green colors indicate that the terminology appeared first, while the yellow colors indicate that they appeared later. Most studies before 2019 focused on the "connection between the gut microbiota and weight gain" and the "interaction of the gut microbiota with dietary components". However, according to recent trends, the "effect of high-fat diet and the gut microbiota on metabolic syndromes" will be a bigger concern in the future.

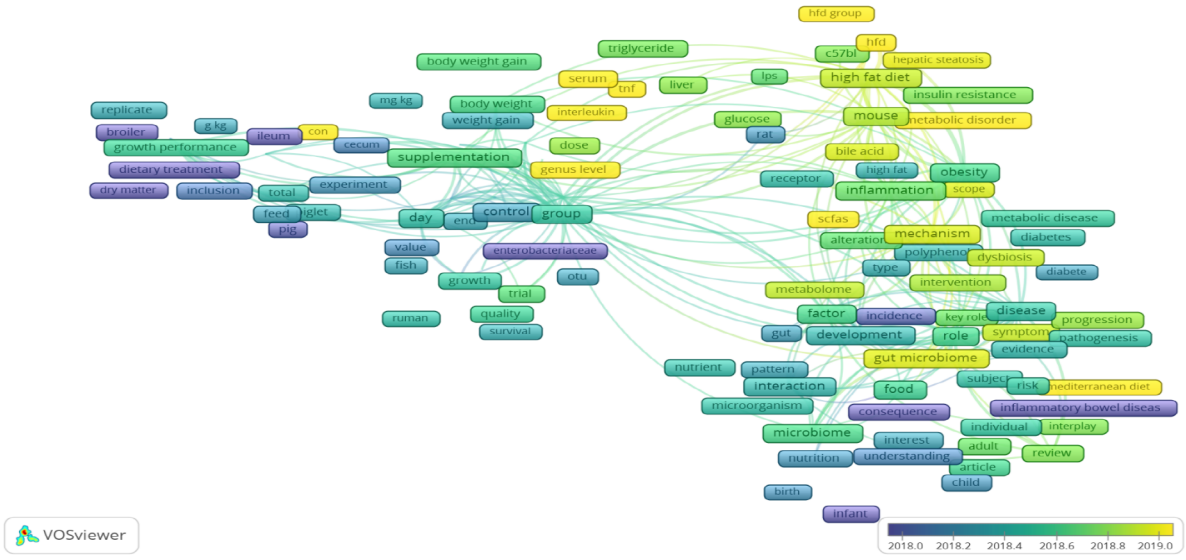
Figure 2 A network visualization map depicting international collaboration in nutrition and gut microbiota research during 2012-2021. This visualized map of collaborations was created after each country had at least 20 publications. Of 154 countries active in this field, 44 countries meet this threshold. The node's size indicates the number of publications for that country.

DOI: 10.3748/wjg.v28.i25.2981 **Copyright** ©The Author(s) 2022.

Figure 3 Network visualization map of terms in the title/abstract fields of publications relevant to nutrition and gut microbiota research from 2012 to 2021. When the minimum-term occurrences were put 100 times, this graphical map of terms was created. Of the 85327 terms in this field, 293 achieve this threshold, which were grouped into three clusters and colored differently. The size of the frame shows the number of publications that contain that term.



Analysis of citations

According to citation analysis, the retrieved articles garnered 146101 citations, averaging 27.17 *per* document, and an h-index of 154. Citations ranged from 0 to 4588. Two thousand four hundred forty-two items were indexed with ten or more citations, while 852 were indexed without citations. Table 5 lists the top ten articles with the highest number of articles on research related to nutrition and gut microbiota from 2012 to 2021. The 10 highest citations ranged from 4588 to 796. The impact index *per* article of the 10 most cited articles ranged from 96.3 to 506.2 (Table 5).

DISCUSSION

This study has developed research techniques to thoroughly analyze the current status and direction of development of studies related to nutrition and the gut microbiota from 2012 to 2021 using a bibliometric and visualization analysis. The number of publications on the gut microbiota has progressively expanded as the potential clinical implications of the gut microbiota have become better known, and this has become an emerging research subject. Our review of research on global nutrition and gut microbiota found that relevant publications have expanded in the last ten years. A possible explanation for this finding might be that our understanding of the role of the gut microbiota has advanced significantly due to the advancement of scientific tools.

The examination of collaboration networks can provide rich data for evaluating research collaborations and characterizing essential collaborators. China and the United States had a clear advantage in this field, possibly due to their superior economics and investment in the scientific field; for example, in 2013, a notable research project from the United States was launched on the intestinal microbiota-brain

axis[38], which resulted in a positive impact on the quality and productivity. In addition, Chinese scientists have made significant advances in the field of gut microbiota[39]. Fecal microbiota transplantation (FMT) has attracted remarkable interest in the treatment of extraintestinal health problems. China registered 84 (24%) of the 367 clinical investigations employing FMT[40]. This is a significant contribution by Chinese researchers to this field and the clinical transformation of studies on the gut microbiota. In addition to FMT research, Chinese researchers are also interested in the development and clinical application of probiotics[41]. Furthermore, one possible reason for the increase in Chinese publication numbers, the *National Natural Science Foundation of China* launched a fund for the role and mechanism of the 'Gut-Liver Axis' in gastrointestinal diseases (H03)[42]. This research should focus on the gut microbiota and metabolites, nutrition, neurotransmitters, gastrointestinal hormones, and bile acid, particularly their interactions with the gastrointestinal tract or liver-localized immune cells/factors to mediate a variety of functional roles. Expand on the "gut-liver axis" and its role in the mechanisms of gastrointestinal disease mechanisms to develop novel diagnostic and therapeutic strategies[42].

Furthermore, the increase in publications on the microbiota and nutrition can be attributed to the fact that numerous hot topics were published during this period of time, exposing new theories and establishing new research fields such as the "interaction of the gut microbiota with dietary components", "connection between the gut microbiota and weight gain", and "the impact of a high-fat diet and the gut microbiota on metabolic syndrome". The effect of diet on the gut microbiota and, consequently, on human health suggests new therapeutic and diagnostic concepts and guides to develop probiotic and prebiotic strategies and functional nutrition[43-47].

The 'effect of a high-fat diet and the gut microbiota on metabolic syndromes' as a theme was among the main hot topics in the current study. Most publications on nutrition and gut microbiota before 2019 used words such as "connection between the gut microbiota and weight gain" and "interaction of the gut microbiota with dietary components". This was in the early stages of this research area. The "effect of a high-fat diet and gut microbiota on metabolic syndrome" as a theme was one of the main hot topics in this work and was considered the current trend after 2019. As a result, the evidence that emerges proposes that the gut microbiota may play a role in maintaining body weight and energy balance. It is assumed to be fueled, at least in part, by changes in gut microbiota composition caused by high-fat diets (HFDs); HFDs have been correlated with changes in gut microbial profile as well as decreased diversity [48,49]. Furthermore, metabolic syndrome and its associated disorders have been linked to increasing evidence suggesting that the gut microbiota in the digestive tract plays a significant role. Numerous studies in animals and humans have shown that high-fat and high-sugar (fructose) diets are responsible for the three hallmarks of metabolic syndrome: Obesity, dyslipidemia, and insulin resistance by altering the composition and diversity of the gut microbiota[50-53]. Furthermore, there is evidence that HFD is associated with cardiovascular disease[54] because the intestinal microbiota converts dietary choline to trimethylamine, which is absorbed in the gut and converted to trimethylamine N-oxygen. This metabolite causes atherosclerosis in the liver[55].

Strengths and limitations

This is the first thorough bibliometric analysis of nutrition and gut microbiota research conducted on a global level. Research on the relationship between nutrition/diet and gut microbiota is still in its infancy and will expand in the future. The aforementioned growing hotspots serve as a foundation and guide for the development of new projects by scientific researchers, physicians, and medical educators.

Our study has several limitations. First, although Scopus is indeed the largest database available, the search for studies was carried out only from the Scopus database, which could have limited the generalizability of the findings due to the loss of certain documents published in unindexed journals. Second, the accuracy and comprehensiveness of the keywords have a significant impact on the reliability of the data retrieved in our study. As a result, some important and influential articles may be omitted from a representative list due to the use of other terms in their titles. Third, the current study only looked for terms such as "nutrition", "gut microbiota" and other related terms in the title search only. Papers with these terms in the abstract or text may have been missed in this study. Furthermore, while most publications were published and indexed in 2021, the amount of scientific research productivity this year could be higher because new journal issues are still being published and indexed.

CONCLUSION

To our knowledge, this is the first bibliometric study of trends in publications on microbiota and nutrition. We are entering an era in which we can more easily alter our health through diet and track results using our microbiota or their metabolites. Over the last decade, there has been an increase in the number of publications on the microbiota and nutrition. The top three contributors to microbiota and nutrition research were China, the United States, and Italy. China is the leading country in this area of study, achieving some significant research findings and playing a key role in the progress of the field. "Connection between the gut microbiota and weight gain', 'interaction with dietary components" and

"the effect of a high-fat diet and the gut microbiota on metabolic syndromes' were hotspots for gut microbiota and nutrition research in the last 10 years. As a result, our timely examination and analysis of hotspots and research trends may aid in the growth of this discipline. Furthermore, these findings offer a fresh perspective on the study of the microbiota and nutrition/diet, which could help with future etiological research, diagnosis, and treatment of metabolic syndromes.

ARTICLE HIGHLIGHTS

Research background

Dietary composition is crucial in regulating the gut microbiota and, as a result, in the prevention, management, and treatment of diseases including diabetes and cancer.

Research motivation

According to a growing body of evidence, the gut microbiota appears to considerably impact human health. Intestinal homeostasis, physiology, gut microbiome, immune system, and host metabolic pathways are all affected by changes in the gut microbiota. However, there are no bibliometric analyses of nutrition/diet and gut microbiota publications.

Research objectives

The current study gives an overview of research publications on nutrition and gut microbiota and identifies global hotspots on this topic.

Research methods

A comprehensive, validated search query was used to find relevant publications on nutrition and gut microbiota. SciVerse Scopus was the database used.

Research results

This is the first bibliometric analysis of trends in microbiota and nutrition publications. The number of publications on microbiota and nutrition has increased over the last decade. China, the United States, and Italy were the top three contributors to microbiota and nutrition research.

Research conclusions

In conclusion with our timely examination and analysis of hotspots and research trends, we believe that this discipline will grow. Furthermore, these findings shed new light on the study of the microbiota and nutrition/diet, which could aid in future etiological research, diagnosis, and treatment of metabolic syndromes.

Research perspectives

This comprehensive bibliometric study aims to provide an overview of the current state of global nutrition and gut microbiota research and stay ahead of emerging trends and critical turns in the field's evolution.

FOOTNOTES

Author contributions: Zyoud SH designed the study, collected the data, analyzed the data, made major contributions to the manuscript's existing literature search and interpretation, and drafted the manuscript; Shakhshir M, Abushanab AS, Al-Jabi SW, Jairoun AA, Shahwan M, Koni A and Abu Taha A were involved in the interpretation of the data, and made revisions to the initial draft; all authors provided a critical review and approved the final manuscript before submission.

Conflict-of-interest statement: All the authors report no relevant conflicts of interest for this article.

PRISMA 2009 Checklist statement: The authors have read the PRISMA 2009 Checklist, and the manuscript was prepared and revised according to the PRISMA 2009 Checklist.

Abstract

BACKGROUND

Submucosal tumor (SMT)-like gastric cancer is rare, and almost all cases undergo curative surgical treatment because the submucosal layer is usually deeply invaded by tumor cells or because histopathologic types of SMT-like gastric cancer are undifferentiated or poorly differentiated. No report has been issued on an SMT-like gastric cancer cured by endoscopic resection alone or on changes in the endoscopic features of this type of tumor over several years.

CASE SUMMARY

We describe an exceptional case of a 53-year-old male with a 1.5 cm-sized SMT-like lesion covered by normal-appearing mucosa discovered by esophagogastroduodenoscopy (EGD) at the gastric antrum. Endoscopic ultrasound (EUS) visualized a homogeneous, well-circumscribed hypoechogenic lesion arising from the second sonographic layer with associated subtle obliteration of the third sonographic layer. Initial endoscopic biopsy was negative for neoplasm. The patient refused to undergo an invasive procedure and was subsequently lost to follow-up. Three years after initial detection, EGD revealed the lesion had become markedly erythematous, and at 4 years after initial EGD it had increased in size to 1.8 cm and developed a central ulcer and a heterogeneous EUS echo. Finally, endoscopic submucosal dissection (ESD) was performed, and histopathologic examination revealed a moderately differentiated adenocarcinoma had minutely invaded the submucosal layer (invasion depth 169 μm) but without lymphovascular invasion and with negative resection margins. Fortunately, no additional surgical treatment was required. He has been followed for 4 years after ESD without any evidence of local or distant recurrence.

CONCLUSION

This report describes an extremely rare case of early gastric cancer presenting as SMT that was cured by ESD after a treatment delay of 4 years and the endoscopic changes that occurred during this period. The report highlights the importance of

considering the possibility of gastric cancer when SMT is encountered in clinical practice.

Key Words: Subepithelial lesion; Submucosal tumor; Early gastric cancer; Adenocarcinoma; Endoscopic mucosal dissection; Case report

Core Tip: We experienced an exceptionally rare case of early gastric cancer presenting as submucosal tumor (SMT) that was successfully treated by endoscopic submucosal dissection (ESD) alone, although the procedure was performed four years after first detection due to patient refusal and follow-up loss. The present case cautions that SMT-like gastric cancer should be included in the differential diagnosis when a hypoechogenic mass is detected in the 2nd or 3rd layer by endoscopic ultrasound, regardless of size and the absence of findings suggesting malignancy. When diagnosis is uncertain, invasive techniques such as diagnostic endoscopic mucosal resection or ESD, which can potentially be used for therapeutic purposes, should be considered and close follow-up is recommended.

INTRODUCTION

Gastric carcinoma is an epithelial tumor exposed to the mucosal surface that occurs in lamina propria with variable gross findings. However, cases of gastric carcinoma with features of submucosal tumor (SMT) are rarely encountered in routine clinical settings and reportedly account for only 0.2% to 0.62% of all resected gastric cancers[1]. The majority of patients with gastric adenocarcinoma resembling SMT are not indicated for endoscopic resection or offered non-curative resection after endoscopic resection. Submucosal layer is deeply invaded by tumor cells, even in cases of early gastric cancer (EGC)[2], and histopathologically, most adenocarcinomas presenting as SMTs are undifferentiated or poorly differentiated[3,4], and as a result, almost all undergo curative surgical treatment. Accordingly, no case has been reported on SMT-like gastric cancer cured by endoscopic resection alone. In addition, no report has been issued on changes in the endoscopic features of this type of tumor over several years. Here, we report an exceptionally rare case of EGC presenting as SMT that was cured by endoscopic submucosal dissection (ESD) and describe changes in the endoscopic features of this tumor over a period of 4 years.

CASE PRESENTATION

Chief complaints

A 53-year-old male Korean patient was referred to our institution for further evaluation and treatment of a gastric SMT discovered by esophagogastroduodenoscopy (EGD) during a routine medical check-up.

History of present illness

The patient had no abdominal pain or related discomfort.

History of past illness

He had a history of abdominal surgery due to duodenal ulcer perforation 30 years previously.

Personal and family history

The patient had diabetes that was being treated with oral hypoglycemic agents. He was a smoker (30 pack-years) and social-alcohol drinker and had no significant family history.

Physical examination

Physical examination was unremarkable, and his abdomen was soft, nontender, and nondistended with no palpable mass.

Laboratory examinations

Laboratory tests, which included tests for common serum tumor markers such as CEA and CA 19-9, revealed no abnormalities.

Imaging examinations

At initial EGD, an SMT-like elevated lesion of diameter 15-mm was observed at the great curvature side of the proximal part of the gastric antrum (Figure 1A). The lesion was covered with normal-appearing mucosa without any erosion, ulcer, or mucosal erythema. Mild-atrophic gastritis, confined to antrum, was observed in background mucosa. Endoscopic ultrasound (EUS; GF-UM2000, Olympus, Tokyo, Japan) demonstrated a 15 mm × 7 mm homogeneous, well-circumscribed hypoechogenic lesion arising from the second sonographic layer with associated subtle obliteration of the third sonographic layer (Figure 2A). The EUS appearance of the lesion was suggestive of a gastric neuroendocrine tumor (NET) or ectopic pancreas. Initial biopsy specimens were negative for neoplasm. Computed tomography (CT) of the abdomen showed a 15 mm protruding intraluminal mass at the gastric antrum and no evidence of lymph node enlargement or distant metastasis (Figure 3). After this initial work-up, endoscopic resection of the lesion was planned for definitive histopathologic examination and treatment. However, the patient declined any invasive procedure and was subsequently lost to follow-up.

Further diagnostic work-up

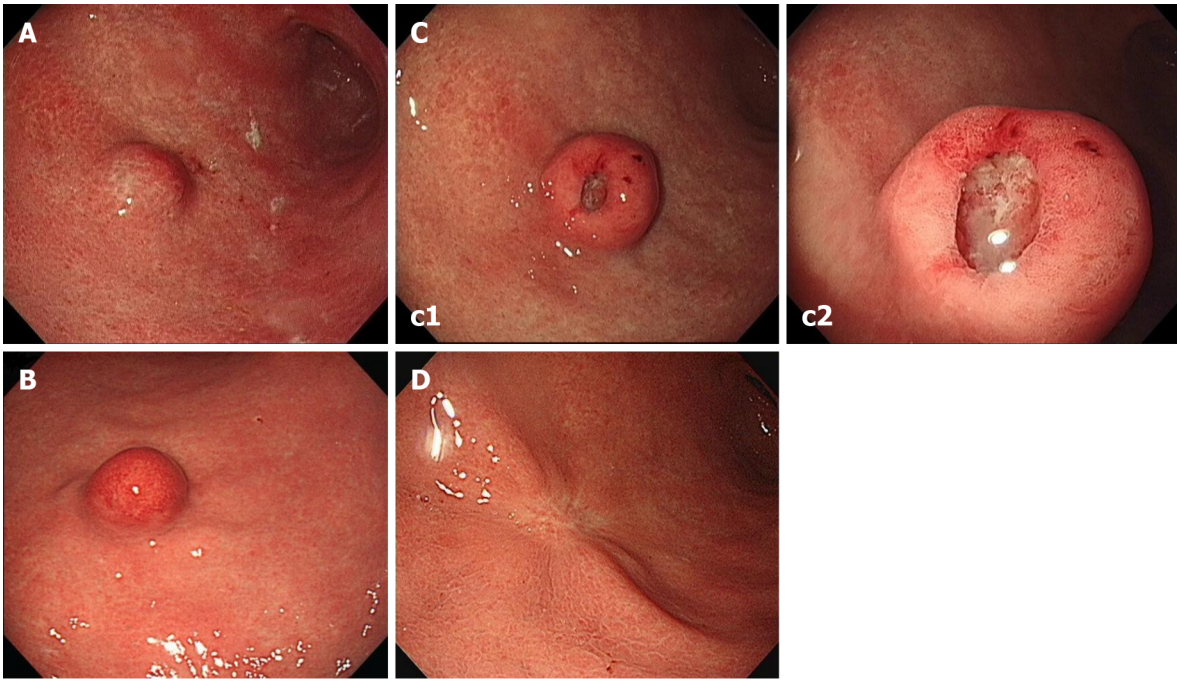
About 3 years after initial EGD, he underwent a national health screening examination at our hospital, and the previously noted gastric SMT was detected again by EGD. The lesion showed no change in size as compared with its size 3 years previously, but marked erythema of overlying mucosa was observed (Figure 1B). Endoscopic biopsy was performed, but specimens were negative for neoplasm. During consultation regarding his health examination results, he was recommended for further evaluation and treatment at the gastroenterology department but again refused and was lost to follow-up.

About a year later, he revisited our hospital with mild indigestion. Follow-up EGD then revealed the SMT-like lesion had enlarged (to a greatest diameter of approximately 18 mm) and that a 5 mm central ulcer had developed on the top of the lesion (Figure 1C). EUS also demonstrated an 18 mm × 9 mm homogeneous, well-circumscribed hypoechogenic mass arising from the second sonographic layer with associated subtle obliteration of the third sonographic layer (Figure 2B). Echogenicity at this time was slightly more heterogeneous than that observed by initial EUS. CT of the abdomen showed no evidence of lymph node enlargement or distant metastasis, and endoscopic biopsy specimens taken from the lesion revealed tubular adenoma with high-grade dysplasia.

FINAL DIAGNOSIS

The patient was then admitted for further endoscopic treatment. A serum anti-*Helicobacter pylori* (*H. pylori*) IgG assay was negative on the day of endoscopic examination. ESD of the lesion was performed, and histopathologic examination of the resected specimen revealed moderately differentiated adenocarcinoma that invaded the submucosal layer (depth of invasion 169 μm) with no lymphovascular invasion (Figure 4).

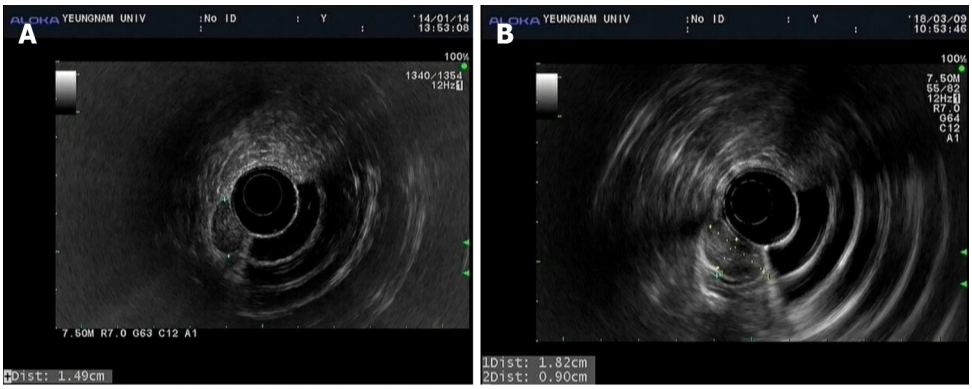
TREATMENT



Furthermore, resection margins were all negative for cancer. Also, rapid urease test and Giemsa staining were negative for *H. pylori* infection.

OUTCOME AND FOLLOW-UP

His post-ESD course was uneventful, and he has since been followed up at our outpatient department for 4 years without any evidence of local or distant recurrence. The latest follow-up EGD performed (approximately 3.5 years after ESD) showed only post-ESD scarring (Figure 1D).



DISCUSSION

This case report is meaningful for the following reasons. First, to the best of our knowledge, this is the first case report of SMT-like gastric cancer cured by ESD alone, and this result was obtained even though ESD was performed four years after initial detection. Second, this case report describes the natural course of SMT-like gastric cancer and the endoscopic changes that occurred after a treatment

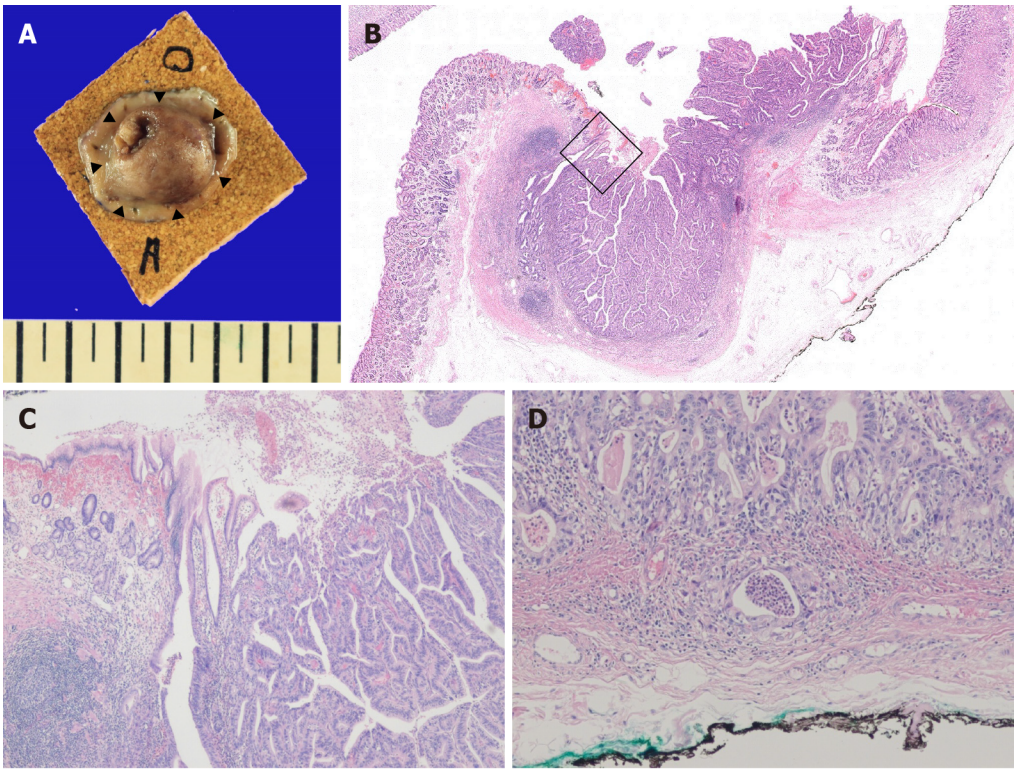
Figure 2 Endoscopic ultrasound images. A: Initial endoscopic ultrasound (EUS) image showing a well-circumscribed homogeneous and hypoechogenic mass measuring about 15 mm × 7 mm originating from the second sonographic layer with associated subtle obliteration of the third sonographic layer; B: EUS image obtained 4 years after the initial examination showing a well-circumscribed, hypoechogenic mass of greater size (18 mm × 9 mm) with slightly more heterogeneous echogenicity, and that the mass originated from the second sonographic layer with associated subtle obliteration of the third sonographic layer.

delay of 4 years. Furthermore, unlike previous reports, mucosa overlying the SMT appeared completely normal when the tumor was first detected.



Gastric cancer usually derives from the lamina propria layer and has macroscopic appearances ranging from well-defined protuberant to diffuse infiltrating. Approximately 95% of gastric cancers are adenocarcinomas[5] but only rarely appear in the form of SMT. According to the literature[2], fewer than 0.5% of gastric cancer cases present as SMT. However, when an SMT-like lesion is encountered in clinical practice, the possibility of gastric cancer should be carefully considered and the lesion differentiated from other submucosal lesions, such as gastric NET[6], leiomyoma, lymphoma, gastrointestinal stromal tumor (GIST), lipoma, ectopic pancreas, and other unusual manifestations, such as metastatic carcinoma[7] and gastric glomus tumor[8], which require completely different treatment strategies.

Pathologic diagnoses of reported cases of gastric cancer presenting as SMT include gastric adenocarcinoma[9], gastric mucinous adenocarcinoma[10,11], and gastric lymphoepithelioma-like carcinoma

Figure 4 Pathology of the endoscopically resected lesion. A: Gross appearance of the resected lesion, which had negative lateral margins. The black triangles indicate the border of the cancerous region; B: Hematoxylin & eosin stained section showing gastric wall mucosal layer elevation by the adenocarcinoma, central erosion, and exposed tumor cells (original magnification × 10); C: Microscopic finding of the boxed area in Figure B showing the periphery of the tumor mass, which demonstrated moderately differentiated adenocarcinoma (original magnification × 40); D: Microscopic finding of the vertical resection margin showing penetration of the muscularis mucosa and minute invasion of submucosa (depth of invasion 169 μm) by tumor cells (original magnification × 100).

[12]. The most common histopathologic type is undifferentiated to poorly differentiated adenocarcinoma, which constitutes 68.8% to 71.4% of these cancers[3,4]. The mechanism of SMT-like gastric cancer development is obscure, but several pathologic mechanisms have been suggested. These mechanisms include the biologic tendencies of poorly differentiated adenocarcinomas to exhibit invasion of a deeper layer at an early stage, marked lymphocyte infiltration around tumors[1], the production of large amounts of mucin by mucinous adenocarcinoma[10,11], substantial amounts of surrounding fibrosis due to repetitive inflammation, abundant edematous fibrosis[13], and adenocarcinomas arising from a submucosal heterotopic gastric gland[9,14], which have been recognized as aberrant lamina propria components associated with repeated erosion and regeneration. These factors may facilitate a predominance of submucosal growth and penetration of muscularis mucosa during the early stage of carcinogenesis and contribute to a macroscopic appearance indistinguishable from SMT.

However, the tumor in our case had a moderately differentiated histology, which was not in line with any of these mechanisms.

Although the diagnosis of SMT-like gastric cancer is usually difficult due to a deep tumor location and non-specific and overlapping imaging features, some EGD characteristics of SMT-like gastric cancer have been reported. In particular, SMT with central ulceration or depression has been described as common for SMT-like gastric cancer[10,14-16]. Erythematous surface change is another reported characteristic[14,15]. Fujiyoshi *et al*[16] concluded that a small SMT (3-5 cm) with a central ulcer or irregular erythematous change should raise suspicion of malignancy. However, since our case originally appeared as SMT with completely normal overlying mucosa, we suspected SMT originating from the second or third layer rather than cancer. However, EGD at 3 and 4 years after initial detection of the SMT-like lesion, showed erythematous change and central ulceration. Interestingly, definite changes were observed in the endoscopic features of the tumor 4 years after initial detection, but it was not possible to determine when these morphologic changes occurred precisely due to follow-up loss.

Histological diagnosis of gastric SMT by endoscopic biopsy is often difficult and detailed imaging usually fails to provide sufficient evidence to differentiate benign and malignant tumors. Furthermore, endoscopic biopsy specimens, even those taken from a central ulcer, may be unhelpful[17], and when a tumor is completely covered with normal mucosa, it is extremely difficult to obtain an adequate sample of the underlying lesion. In the present case, negative results for neoplasm were reported for biopsies performed during EGD on overlying normal mucosa at initial presentation and on overlying erythematous mucosa 3 years later.

EUS is useful for evaluating gastric SMT. Findings that suggest malignant SMT include[18] a size > 3 cm or > 5 cm, rapid growth, heterogeneous echogenicity, and irregular margins, whereas GIST or leiomyoma may present as a homogeneous, well-demarcated, submucosal mass with smooth margins. However, these imaging characteristics are non-specific, and EUS images alone are insufficient for accurate diagnosis. More invasive techniques such as EUS-guided fine-needle aspiration or biopsy and endoscopic mucosal resection may aid differential diagnoses[18]. In our patient, initial EUS depicted a 15 mm-sized well-circumscribed homogeneous mass, which did not suggest malignant SMT. However, EUS performed 4 years later showed the mass had increased in size to 18 mm and had slightly more heterogeneous echogenicity.

Gastric cancers resembling SMT are characterized by a predominance of submucosal or sometimes deeper invasion into the gastric wall[2], which suggests they are likely to be more advanced and pose a greater risk of metastasis than ordinary gastric cancers of similar size[13]. Furthermore, most adenocarcinomas presenting as SMTs are of the undifferentiated or poorly differentiated histopathologic types[3,4], and thus, in almost all case reports, SMT-like gastric cancer, even when small, has been treated in the same way as advanced gastric cancer. Although ESD can potentially be used for therapeutic purposes, the pathologic results of most specimens resected by ESD indicate non-curative resection, and thus, additional gastrectomy with lymphadenectomy is required[19]. To date, no case report of cure by endoscopic resection has been published in the English literature. However, in the present case, ESD was performed to provide a definitive histopathologic diagnosis and a treatment strategy, and additional surgery was not needed, based on a final pathologic report that the tumor was not poorly differentiated, did not invade deep submucosa, and had negative lateral and deep margins.

CONCLUSION

The present case emphasizes that although SMT-like gastric cancer is rare, it should be included in the differential diagnosis when a hypoechogenic mass is visualized in the 2nd or 3rd layer by EUS, regardless of lesion size and the absence of findings suggesting malignancy. In addition, if diagnosis is uncertain, the use of techniques more aggressive than EUS alone, such as diagnostic endoscopic mucosal resection or ESD, which can potentially be used for therapeutic purposes, should be considered and close follow-up is recommended.

Abstract

Crohn's disease (CD) is a kind of intestinal inflammatory disease that can affect any part of the gastrointestinal tract and the incidence rate of CD is gradually increasing worldwide. Acupuncture and moxibustion have unique curative effects on gastrointestinal diseases and can be new options for the treatment of CD.

Key Words: Crohn's disease; Acupuncture; Moxibustion; Treatment; Review

TO THE EDITOR

Crohn's disease (CD) can affect any part of the gastrointestinal tract, especially the terminal ileum and the ascending colon, and is collectively known as inflammatory bowel disease (IBD) with ulcerative colitis. The main symptoms include abdominal pain, diarrhea, fistula, intestinal obstruction, fever, emaciation, and nutritional disorders. In the past three decades, the incidence rate of CD has gradually increased worldwide at an annual growth rate between 4%-15%, which warrants our attention[1]. Currently, biological therapy is the preferred treatment for CD, and the commonly used biological agents such as infliximab and adalimumab have brought significant benefits to the patients. With multiple biological agents at their disposal, clinicians can, according to different symptoms, choose drugs with different anti-inflammatory mechanisms. However, despite the undisputed efficacy of these agents, a significant proportion of patients fail to receive effective treatments. For example, many patients do not respond to induction therapy or lose the response after initial improvements. As traditional Chinese medicine therapies, acupuncture and moxibustion have a long history in treating gastrointestinal diseases and significant advantages against symptoms such as abdominal pain, diarrhea, fatigue, and anorexia. Therefore, we summarize articles about clinical acupuncture and moxibustion treatment for CD to explore their unique advantages.

Using keywords such as acupuncture, CD, and clinical trials, we searched PubMed for clinical trials of acupuncture and moxibustion in the treatment of CD up to February 28, 2020, and found four articles that met the criteria. The four articles that we found and retrieved showed that acupuncture and moxibustion had curative effects on CD. Joos *et al*'s randomized controlled trial confirmed that after 4 wk of treatment, the CD activity index (CDAI) of the acupuncture group showed a significantly larger ($P = 0.003$) decrease (from 250 ± 51 to 163 ± 56) than that of the groups without acupuncture (from 220 ± 42 to 181 ± 46)[2]. Bao *et al*'s 12-wk trial with the treatment group undergoing herb-partitioned moxibustion combined with acupuncture (HMA) and the control group receiving wheat bran partitioned moxibustion combined with superficial acupuncture showed a significantly higher ($P = 0.000$) total treatment efficacy of the treatment group at 83.72% compared to 40.48% of the control group and a significantly lower ($P = 0.000$) CDAI in the treatment group than that of the control group[3]. Both clinical trials demonstrated that acupuncture combined with moxibustion significantly reduced the CDAI in the patients and significantly improved their quality of life. Shang *et al*[4] conducted a clinical trial with one group receiving HMA and the other group treated with mesalazine (MESA). After 12 wk of treatment, the expression of *ZO-1* mRNA in the HMA group was significantly improved compared with the MESA group (2378.17 ± 308.77 *vs* 2200.56 ± 281.88; $P = 0.023$), confirming that HMA can repair the intestinal epithelial barrier by up-regulating the expression of tight junction protein and its mRNA, thus reducing the intestinal inflammatory response in CD patients. Horta *et al*[5] investigated whether electroacupuncture (EAc) therapy could relieve fatigue in patients with IBD by allocating 52 patients into the EAc, sham EAc (ShEAc), and waitlist (WL) groups. Evaluation with the IBD-validated Functional Assessment of Chronic Illness Therapy-Fatigue Scale showed reduced fatigue scores in patients of the EAc and ShEAc groups after 8 wk of treatment and significantly better curative effects in the two groups than that in the WL group.

According to these four clinical trials, acupuncture treatment tends to attenuate symptoms such as abdominal pain, diarrhea, and fatigue in patients with CD. Therefore, acupuncture and moxibustion therapy may potentially improve the physical and mental health of CD patients. Unfortunately, clinical trials of acupuncture for CD with relatively long-term observation and a large sample are still lacking. Except those conducted by Chinese researchers, there are few studies on treating CD with acupuncture, and more evidence is required to support the application of acupuncture and moxibustion therapies in treating CD and verify their potential benefits.

ABOUT COVER

Editorial Board Member of *World Journal of Gastroenterology*, Koichi Suda, MD, PhD, FACS, Professor and Head, Divisions of GI and HPB Surgery, Department of Surgery, Fujita Health University, Rm C908, 1-98 Dengakugakubo, Kutsukake, Toyoake, Aichi 470-1192, Japan. ko-suda@fujita-hu.ac.jp

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 edition of Journal Citation Reports® cites the 2021 impact factor (IF) for *WJG* as 5.374; IF without journal self cites: 5.187; 5-year IF: 5.715; Journal Citation Indicator: 0.84; Ranking: 31 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2021 is 8.1 and Scopus CiteScore rank 2021: Gastroenterology is 18/149.

Abstract

Gastroenteropancreatic neuroendocrine neoplasms comprise a heterogeneous group of tumors that differ in their pathogenesis, hormonal syndromes produced, biological behavior and consequently, in their requirement for and/or response to specific chemotherapeutic agents and molecular targeted therapies. Various imaging techniques are available for functional and morphological evaluation of these neoplasms and the selection of investigations performed in each patient should be customized to the clinical question. Also, with the increased availability of cross sectional imaging, these neoplasms are increasingly being detected incidentally in routine radiology practice. This article is a review of the various imaging modalities currently used in the evaluation of neuroendocrine neoplasms, along with a discussion of the role of advanced imaging techniques and a glimpse into the newer imaging horizons, mostly in the research stage.

Key Words: Neuroendocrine tumor; Gastroenteropancreatic; Intravoxel incoherent motion; Diffusion weighted imaging; Perfusion imaging; Dual energy computed tomography

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: The prognosis of gastroenteropancreatic neuroendocrine neoplasms (GEPNENs) depends on the stage of the disease and tumor grade. Traditional imaging techniques like multiphase contrast-enhanced computed tomography perform well at disease staging. For tumor grading, histopathological examination, with determination of number of mitoses and Ki-67 index is considered optimal. Advances in imaging techniques have enabled detection of smaller neuroendocrine neoplasms (< 2 cm). By analysing functional information like diffusion, perfusion and tumor heterogeneity, quantitative imaging is currently focused on noninvasive prediction of the grade of GEPNENs preoperatively.

INTRODUCTION

Gastroenteropancreatic neuroendocrine neoplasms (GEPNENs) are a rare and heterogeneous group of tumors that originate from the gastrointestinal and pancreatic neuroendocrine cells[1,2]. They may be benign or malignant and may or may not secrete hormones. Use of the previous terminology - carcinoid tumor - is no longer encouraged. The gastrointestinal tract (GIT), having the highest density of neuroendocrine cells in the body, is the most common site of involvement of neuroendocrine neoplasms (NENs), comprising nearly 60% of all NENs[3]. Pancreatic NENs (PNENs) account for about 7% of all GEPNENs [4]. Most PNENs are sporadic. However, association with four familial syndromes (in up to 25%) is well described: multiple endocrine neoplasia type I, von Hippel Lindau syndrome, neurofibromatosis type I and tuberous sclerosis[5,6].

Classification based on histological differentiation and grade is desirable as it provides insight into tumor biology, clinical course and helps in planning management. In 2019, the 5th edition of the World Health Organization (WHO) classification of tumors series published the latest NEN classification (Table 1)[7]. The latest WHO classification recognizes that well-differentiated NENs may be high grade, but they are distinct from the poorly differentiated neuroendocrine carcinomas (NECs). Most GEPNENs are well-differentiated and slowly growing. Grade 3 NENs are most common in the pancreas, but can occur throughout the GIT[7]. Given the differences in prognosis, tumor grade is the most important factor determining the treatment of GEPNENs. The treatment of GEPNENs depends on grade, differentiation, site of origin, and stage of tumor, and the opinion about the best treatment strategy is evolving. Surgical resection remains the cornerstone and is the only curative treatment. For patients with small (< 2 cm), low-grade NENs, decisions on surgery *vs* active surveillance need to be individualized based on tumor size, morphology (homogeneous, well circumscribed tumor < 1 cm correlate with low malignant potential) and patient characteristics like age and presence of comorbidities[8].

The commonly used imaging modalities include ultrasonography (US), computed tomography (CT), magnetic resonance imaging (MRI) and positron emission tomography (PET)-CT. Imaging is primarily aimed at accurate detection, characterization and staging of these neoplasms and also at assessment of response to treatment. Sensitivity of common imaging modalities used in the evaluation of GEPNENs are summarized in Table 2.

Improvements and advances in the imaging techniques have mainly focused on the noninvasive prediction of the grade of the NENs. The European Neuroendocrine Tumor Society (ENETS) has also recommended that preoperative assessment of the grade of the NENs is essential for prognosis prediction and management planning[9]. In addition, with the improvements in the imaging technologies, the detection rates of small NENs have significantly improved, with many often being detected incidentally.

US

Transabdominal ultrasonography (USG) often is the commonest initial modality used for patients with gastrointestinal symptoms. It has value in the detection of liver metastases (sensitivity reaching 85%-90%). PNENs in general appear as hypoechoic masses with a hyperechoic halo on USG[10].

However, transabdominal USG has limitations. It has a poor sensitivity (13%-27%) for the detection of GEPNENs[11]. The technique is dependent on the experience of the operator. Presence of bowel gas and increased subcutaneous fat can obscure adequate visualization.

The advent of harmonic imaging, pulse inversion sequence, low mechanical index techniques and ultrasound contrast agents (UCAs) has enabled routine application of contrast-enhanced ultrasound (CEUS) to overcome the limitations of conventional B mode USG. The inherent advantage of CEUS is its ability to assess tumor-enhancement patterns in real time during transabdominal USG[12]. The enhancement patterns are described during arterial, portal venous and late phases. UCAs are gas microbubbles stabilized by a shell, the composition of which varies depending on the type of contrast agent. UCAs are blood pool agents and increase the back scatter of US, enhancing the echogenicity of flowing blood[12]. Harmonic imaging detects harmonic signals from the microbubbles and CEUS specific US modes filter signals from the background tissue, thereby showing even very slow blood flow without Doppler related artifacts. UCAs, unlike CT and MRI contrast agents, are excreted by the lungs and hence can be used safely in patients with deranged renal function.

Table 1 World Health Organization Classification and grading criteria for neuroendocrine neoplasms of the gastrointestinal tract and hepatopancreatobiliary organs (7)

Terminology	Differentiation	Grade	Mitoses/2 mm^2	Ki-67 index
NEN grade 1	Well differentiated	Low	< 2	< 3%
NEN grade 2		Intermediate	2-20	3%-20%
NEN grade 3		High	> 20	> 20%
SCNEC	Poorly differentiated	High[1]	> 20	> 20%
LCNEC			> 20	> 20%
MiNEN	Well or poorly differentiated	Variable	Variable	Variable

[1]Poorly differentiated neuroendocrine carcinomas are not formally graded, but are considered high-grade by definition.
LCNEC: Large cell neuroendocrine carcinoma; MiNEN: Mixed neuroendocrine non-neuroendocrine neoplasm; NEN: Neuroendocrine neoplasm; SCNEC: Small-cell neuroendocrine carcinoma.

Table 2 Sensitivity of common imaging modalities used in the evaluation of gastroenteropancreatic neuroendocrine neoplasms

Imaging modality	Sensitivity
Transabdominal USG	13%-27% for GEPNEN
Contrast enhanced ultrasound	99% in detecting liver metastases
Endoscopic ultrasonography	82%-93% for PNEN
CECT	63%-82% for PNEN
CE MRI	79% for PNEN
DWI	83% for liver metastases

USG: Ultrasonography; GEPNEN: Gastroenteropancreatic neuroendocrine neoplasms; CECT: Contrast enhanced computed tomography; CE MRI: Contrast-enhanced magnetic resonance imaging; DWI: Diffusion-weighted imaging.

The differential perfusion on CEUS has been shown to identify and diagnose pancreatic tumors. Pancreatic adenocarcinomas are in general hypovascular, while NENs are hypervascular. Takeda *et al* [13] found three patterns of hyperenhancement of PNENs and found that CEUS was useful in the differentiation of PNENs from pancreatic adenocarcinomas. Malagò *et al*[14] also showed that the enhancement patterns of nonfunctioning PNENs on CEUS (hyper-, iso- or hypovascular) correlated well with Ki-67 index and CEUS improved the detection of hepatic metastases. Hypervascular lesions had lower Ki-67 index. Another study showed that the enhancement patterns of NENs on CEUS correlated significantly with CT enhancement pattern and histological Ki-67 index and CEUS was a good predictor of response of tumors to somatostatin analogues[15].

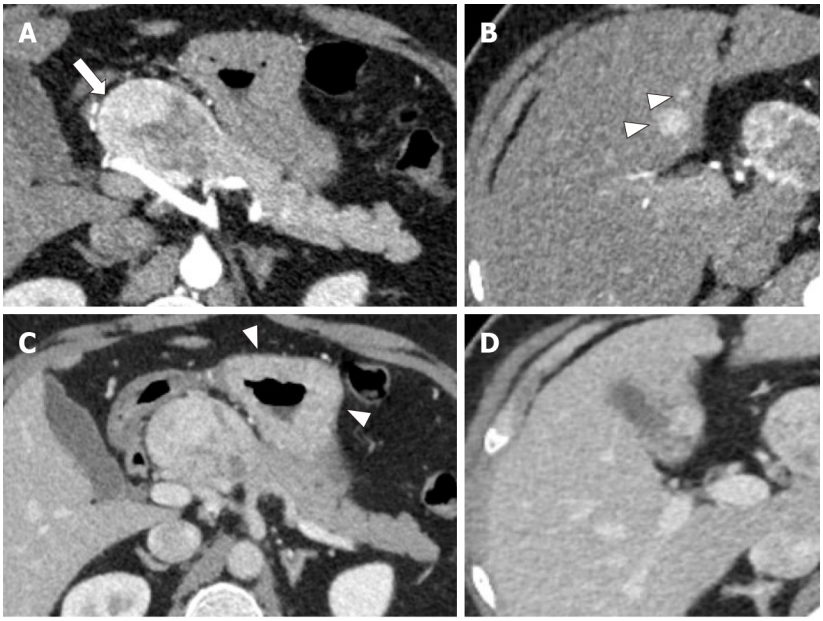
Elastography

Elastography is an advancement in USG that enables real-time measurement of tissue stiffness along with display in colors superimposed on the grey scale images[16]. In general, elastography helps with the differentiation of benign and malignant lesions based on stiffness, as malignant lesions are usually hard. Only a few studies have reported the usefulness of transabdominal shear wave elastography (SWE) in the evaluation of pancreatic tumors. Park *et al*[17] showed that elastography can differentiate benign and malignant solid pancreatic lesions based on the difference in the shear wave velocity values (relative stiffness) between the tumor and the normal parenchyma. An early study by Uchida *et al*[18] found that NENs were homogeneous and soft on elastography, comparable to the normal pancreas. They also reported that a combination of elastography and B mode USG, improved the diagnostic accuracy to 90%, from 70%-80 % when B mode USG was used alone. However, if the visualization on the baseline B mode USG is suboptimal, the results of CEUS and elastography are also often unsatisfactory. These limitations have been overcome by the use of endoscopic ultrasound (EUS).

EUS

EUS is considered the most accurate test for the diagnosis of pancreatic masses[19]. EUS uses higher frequency (7.5-12 MHz) probes, placed in proximity to the area of interest and hence performs better at detection of tumors < 2 cm for which CT and MRI have poor sensitivity[20]. Overall, EUS has a sensitivity of 82%-93% and a specificity of 92%-95% for localizing PNENs. EUS is particularly useful in the detection of benign insulinomas that lack somatostatin receptors and consequently are not detected on somatostatin receptor scintigraphy/single photon emission computed tomography (SPECT)/PET [21]. EUS also plays an important role in the detection of functional pancreatic and extrapancreatic (duodenal) gastrinomas[22]; both of which generally have a small size (average 1 cm) at diagnosis. The additional benefit of EUS is its ability to guide accurate tissue sampling *via* fine needle aspiration and core biopsy[23]. CEUS can also be performed through EUS with the use of second generation UCAs (*e.g*, Sonovue), which produce harmonic signals at low acoustic powers. A recent study showed that the time intensity curve analysis during CEUS showed high diagnostic accuracy in grading PNENs, and could differentiate grade 1/2 tumors from grade 3 tumors/carcinomas[24].

EUS elastography



EUS elastography of the pancreas has been shown to be a promising imaging technique in several studies[25-27]. However, a prospective study by Hirche *et al*[28] including 70 patients with undifferentiated pancreatic masses showed an overall lower sensitivity (41%), specificity (53%) and accuracy (45%) for the detection of malignancy. One of the early studies evaluating conventional strain elastography for pancreatic lesions showed significant strain difference between benign and malignant masses[29]. The major utility of EUS elastography is in increasing the yield of sampling by aiding better tumor targeting, especially in the background of pancreatic parenchymal fibrosis[30]. SWE EUS is a recent development and studies evaluating its utility in the pancreas are just emerging[31,32]. A recent comparative study suggested that conventional strain elastography was superior to SWE in the characterization of pancreatic lesions[33].

CT

CT is the cornerstone and the most commonly performed imaging modality for the diagnosis and preoperative staging of GEPNEN. Standard CT scan has low sensitivity (~60%) for the detection of GIT NENs[34]. Dynamic dual-phase protocol, which includes the arterial and portal venous phases, is recommended in patients with suspected NEN[35,36] (Figure 1). For PNEN, the late arterial phase acquired at 40-45 s (pancreatic phase) suits best. For detection of small bowel NENs, CT enterography (oral administration of neutral contrast agent like mannitol for bowel distension) or CT enteroclysis (administration of neutral contrast *via* nasojejunal tube) is required. CT enteroclysis combines the advantages of enteroclysis with imaging capabilities of multidetector computed tomography (MDCT). Study by Kamaoui *et al*[37] showed that CT enteroclysis had 100% sensitivity and 96.2% specificity for the detection of small bowel NEN. A comparative study from Mayo Clinic found that CT enterography was better than capsule endoscopy in detecting small bowel tumors, with a sensitivity of up to 93%[38]. This ability of CT enterography to detect small bowel tumors remains high (sensitivity of 88%) even in the presence of gastrointestinal bleeding[39].

The characteristic imaging feature on CT scan suggesting the diagnosis of NENs is their intense enhancement in the late arterial phase, owing to the hypervascular nature of the tumor. The arterial phase also helps in outlining the relationship of the tumor with the adjacent arteries. Using the maximum intensity projection technique, virtual angiographic images can be obtained. Volume rendering techniques applied to the arterial phase provide easily explainable images to the surgeon. Portal venous phase helps to draw the relationship of the tumor with major veins, especially the splenic vein and the superior mesenteric vein for PNENs. Dual-phase imaging is also crucial for the evaluation of hepatic metastases. The classic liver metastases from NEN, being hypervascular, are most evident on the arterial phase images. About 6%-15% of NEN liver metastases are appreciated only in the arterial phase[40,41]. However up to 16% are hypovascular and show delayed enhancement[40].

One of the early studies suggested that the size of the tumor is an important prognostic factor, with tumors < 1 cm showing lesser incidence of liver metastasis (20%–30%) compared to those with > 1 cm (> 40% risk)[42]. Studies have shown that up to 42% of PNENs may not show arterial phase hyperenhancement[43,44]. Such arterial phase hypoenhancing tumors were associated with a significantly lower 5-year survival (54%) compared to the lesions which were isoenhancing (89%) or hyperenhancing (93%) [45]. Rodallec *et al*[46] found that tumor enhancement on CT scan correlated with microvascular density (MVD) evaluated on histology and that hypoenhancing PNENs correlated with poorly differentiated tumors and a decrease in overall survival rate. These studies showed that the CT enhancement characteristics of NENs have a prognostic value. Gallotti *et al*[6] found that incidentally detected PNENs, size > 3 cm, complex enhancement pattern and, presence of calcification, vascular invasion, main pancreatic duct dilatation, and peripancreatic lymph nodes were associated with nonbenign tumors and required

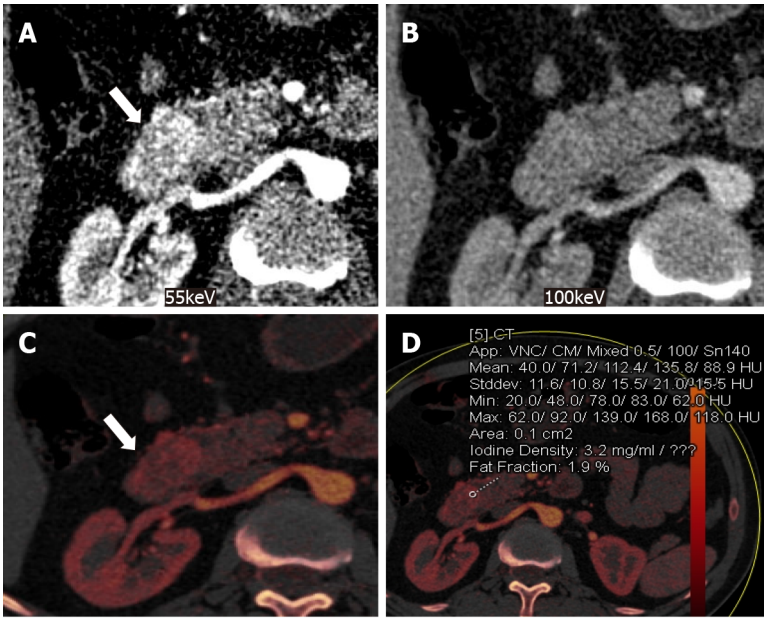
Figure 1 49-year-old man with epigastric pain and raised serum gastrin levels. A and B: Axial contrast enhanced pancreatic phase computed tomography (CT) images show a well-defined hyperenhancing mass (arrow in A) in the head and neck of pancreas, abutting the proper hepatic artery along with two hyperenhancing focal lesions in the liver (arrowheads in B), indicating hepatic metastases; C and D: Axial portal venous phase CT images show retention of contrast in the lesions in both locations. Thickened gastric mucosal folds is also noted (arrowheads in C).

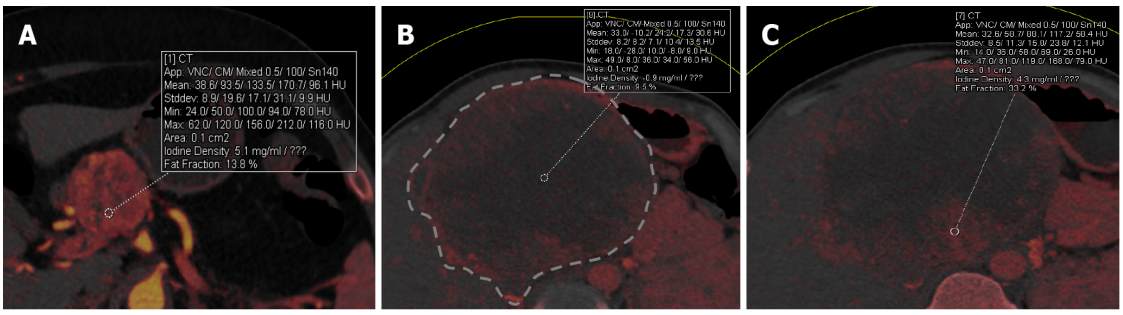
more aggressive course of management.



The role of various CT quantitative parameters based on enhancement of the NEN in the arterial or pancreatic and the venous phases has been evaluated in the prediction of tumor grade. Kim *et al*[47] found that portal enhancement ratio (HU value of the tumor divided by the HU value of pancreatic parenchyma on portal phase images) had the best odds ratio (49.6) and a cutoff value of < 1.1 had a sensitivity of 92% and specificity of 81% in differentiating grade 3 PNENs from grade 1 and 2. This high sensitivity and specificity of portal enhancement ratio in differentiating neuroendocrine carcinomas from well-differentiated NENs was also confirmed by another study[48]. Yamada *et al*[49] showed that corrected true enhancement values in the pancreatic phase had a sensitivity of 92%, specificity of 84% and area under the curve of 0.897 in the differentiation of grade 1 from grade 2 PNENs. D'Onofrio *et al*[50] showed that various tumor enhancement parameters (tumor permeability ratios, tumor parenchyma ratios, tumor arterial ratio and tumor venous ratio) were significantly different between grade 1 and grade 3 and between grade 2 and grade 3 PNENs. However, these values could not differentiate grade 1 from grade 2 tumors.

Dual-energy CT

Dual-energy CT (DECT) is an advancement in CT, which allows acquisition of images at two energy levels, with lower energy being 80-100 kVp and higher being 140 kVp. Using DECT, material decomposition of images and generation of iodine maps, virtual noncontrast images, and monochromatic images at different energy levels is possible (Figures 2 and 3). Monoenergetic images at low keV (55 keV) in the pancreatic phase of DECT show improved image contrast for evaluation of pancreatic masses[51]. Monochromatic spectral images improve the sensitivity of detection of NENs like insulinomas, particularly the hypovascular and isoattenuating tumors and the sensitivity is comparable to MRI[52]. One study showed that iodine uptake obtained from DECT is useful in the differentiation of hepatocellular carcinoma from liver metastases arising from NENs, with the former showing significantly higher iodine uptake (3.8 ± 1.2 *vs* 2.3 ± 0.6)[53]. This iodine uptake parameter on DECT may also be used in assessing the response to treatment of NENs.



Perfusion CT

Perfusion CT is a technique that measures the dynamic changes in the attenuation of the tissues after contrast administration. It allows quantitative measurement of tissue perfusion, thereby assisting in the assessment of tumor viability and biological behavior[54]. The commonly used quantitative parameters of perfusion CT in oncoimaging are blood flow, blood volume, vascular permeability-surface area product and mean transit time (Figures 4 and 5). These parameters serve as imaging biomarkers of tumor angiogenesis, which is ideally assessed histologically by calculating the MVD[55]. NENs are among the tumors with significant angiogenesis. Unlike majority of the cancers, where increased tumor

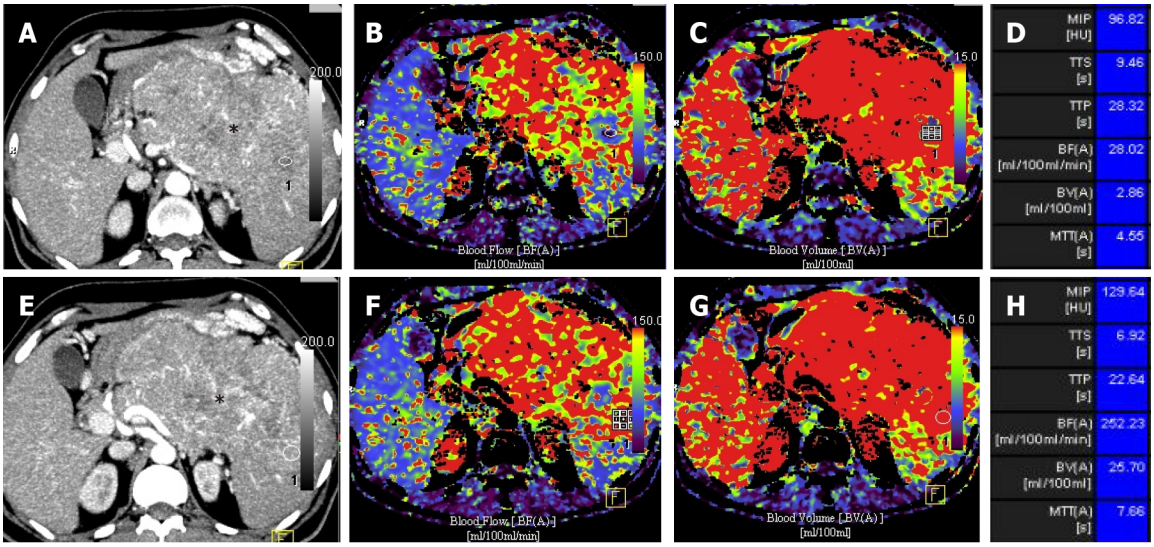
Figure 3 Dual-energy computed tomography in grading the pancreatic neuroendocrine neoplasms. A: Iodine overlay dual-energy computed tomography (CT) map of a 40-year-old woman with low-grade (grade 2) pancreatic neuroendocrine neoplasms (PNEN) in head of pancreas shows hyperenhancement of the tumor with an iodine concentration of 5.1 mg/mL; B and C: Iodine overlay dual energy CT maps of a 29-year-old man with grade 3 PNEN (outlined in B) shows large hypoenhancing areas with low iodine concentration (0.9 mg/mL) and peripheral bright areas with iodine concentration of 4.3 mg/mL (C). Measuring iodine concentration helps in objectively assessing the grade of the tumor.



vascularity is associated with aggressive behavior, higher microvascular density in NENs is associated with a low tumor grade[54]. Low MVD was found to be an unfavorable prognostic factor for PNENs in several studies despite the presence of other favorable conventional histoprognostic factors, and call for a more aggressive treatment approach[56-58]. A study by d'Assignies *et al*[59] on 36 patients with PNENs found a significant correlation between MVD and blood flow assessed by using perfusion CT. In their study, the authors found that tumors that are small (< 2 cm), benign (grade 1), with a proliferation index of ≤ 2%, and without histological signs of microvascular involvement had a significantly higher blood flow. Volume perfusion CT has been shown to improve the detection of pancreatic insulinomas, particularly the ones which have transient hyperenhancement (comprising 30% cases)[60,61]. A recent study demonstrated that addition of low dose perfusion CT to contrast enhanced CT improved the detection rate of PNENs from 83.6% to 89.1% and found that blood flow parameters were significantly different between grade 1 and grade 2 tumors[62].

Perfusion CT has also been shown to have a role in monitoring response to treatment with antiangiogenic drugs. Few studies have shown that the perfusion parameters of PNENs and liver metastases decrease as early as 48 h after treatment with anti-angiogenic drugs and perfusion CT offers a significant role in an early noninvasive assessment[63,64]. A major limitation of perfusion CT is the higher radiation dose, resulting in an additional dose of approximately 7 mSv[65].

Figure 5 Volume perfusion computed tomography images of a 67-year-old man with a large grade 3 neuroendocrine neoplasm involving body and tail of pancreas. A and B: Axial arterial phase computed tomography images with circular regions of interest placed at two different locations in the lesion (*); C-H: Parametric maps for blood flow (C and D) and blood volume (E and F) with mean value of each perfusion parameter (G and H) are shown. Lower values of mean blood flow, mean blood volume and mean transit time are features of high grade neuroendocrine neoplasm.

MRI

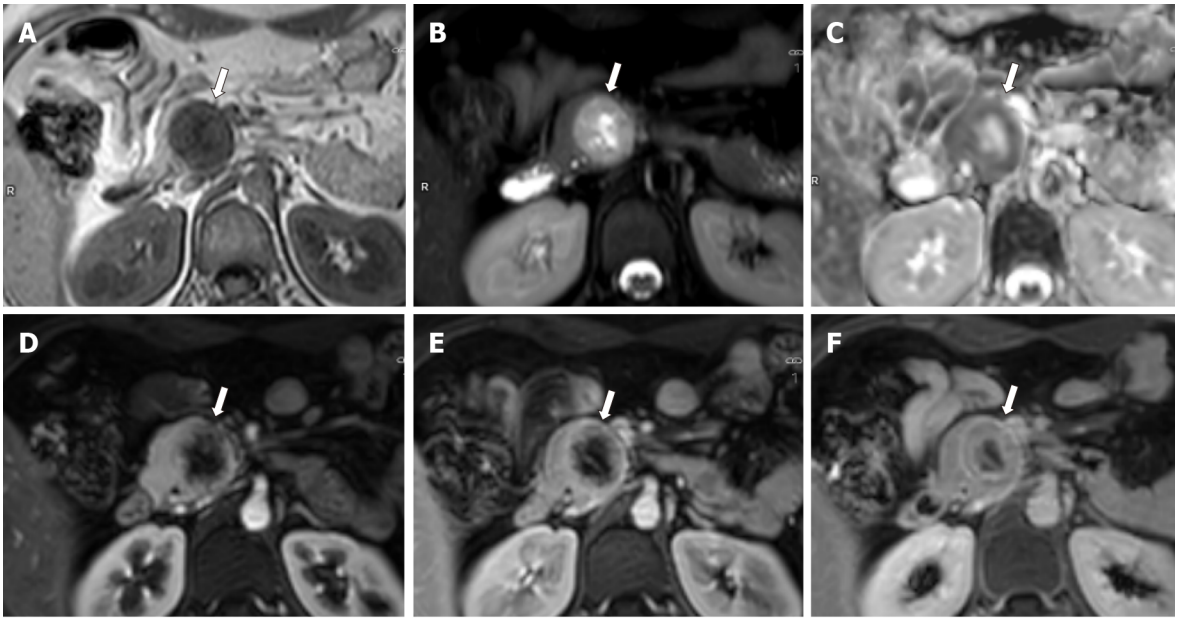
MRI is best performed as a problem-solving tool when CT scan findings are equivocal or negative, and is aimed at acquiring images of the lesion and organ with better soft tissue contrast. For instance, MRI has shown better sensitivity for the detection of liver metastases compared to CT and somatostatin receptor scintigraphy[66]. The absence of exposure to ionizing radiation makes MRI the apt modality for screening young individuals suspected of having NEN and those with syndromic association who require multiple follow up imaging[67]. Most NENs are hypointense on T1-weighted and hyperintense on T2-weighted images[10]. Contrast enhancement pattern and morphologic appearances are similar to

that seen in CT scan (Figure 6). For the detection of PNENs, the sensitivity of MRI ranges from 85% to 100% and specificity from 75% to 100%[68].

Diffusion-weighted imaging

Diffusion-weighted imaging (DWI) is a widely used technique in clinical imaging as it reflects the microscopic environment of the neoplasm including tumor cellularity and extracellular matrix. The application of DWI in oncology is mainly in tumor detection and assessing response to chemotherapy and radiotherapy. Wang *et al*[69] demonstrated that the apparent diffusion coefficient (ADC) values of PNEN correlated well with Ki-67 labelling index, thus indicating that DWI has a prognostic value (Figure 6). Another study showed that the ADC values were significantly different between benign and non-benign PNENs (1.48×10^{-3} mm^2/s *vs* 1.04×10^{-3} mm^2/s, respectively)[70]. Lotfalizadeh *et al*[71] showed that DWI has the additional value in identification of high grade tumors (grade 3) and can accurately differentiate grade 3 from grade 1/2 tumors (AUROC-0.96). The ADC values showed an inverse relation with the grade of the tumor.

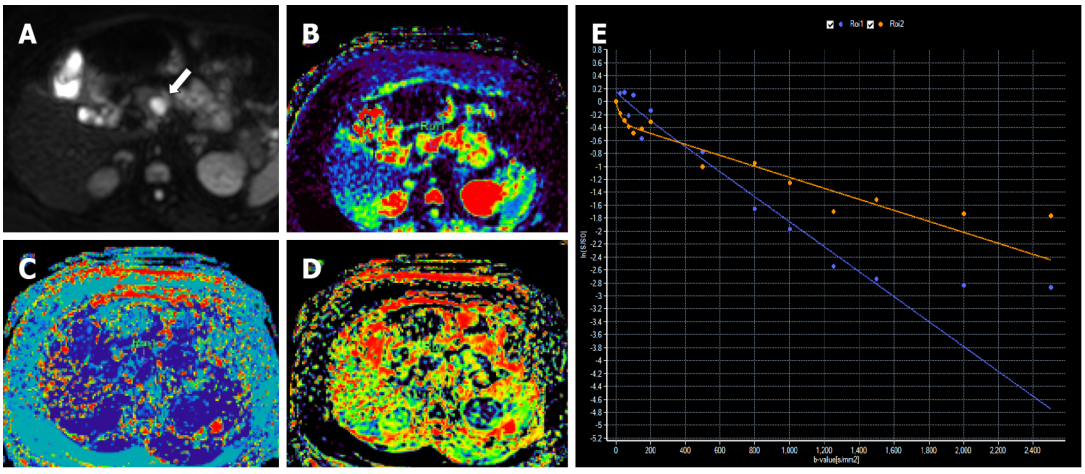
Another major utility of DWI is in the detection and characterization of liver metastases. Several studies have shown that DWI is more sensitive for the detection of liver metastases than T2-weighted and multiphase gadolinium-enhanced MRI, especially for smaller lesions[72-74]. Besa *et al*[75] showed that the ADC of liver metastases from NEN weakly and significantly correlated negatively with tumor grade and Ki-67 and that the mean ADC and the minimum ADC values were significantly different between the three grades (1.6, 1.35 and 0.9×10^3 mm^2/s and 0.84, 0.5 and 0.27×10^3 mm^2/s for grades 1, 2 and 3, respectively). DWI is hence recommended in routine MRI abdomen protocol for the detection of liver metastases from NEN.



Histogram analysis of the ADC of the whole tumor has also been shown to predict tumor grade and aggressiveness. Pereira *et al*[76] found that whole tumor histogram analysis of the ADC, including the skewness and kurtosis can reliably differentiate grade 1 from grade 2/3 tumors. Another study also showed that this histogram analysis of ADC was useful in predicting tumor grade, vascular invasion and metastasis (node, liver) in PNENs and that $ADC_{entropy}$ and $ADC_{kurtosis}$ were the best markers in identifying tumor aggressiveness[77].

DWI is also useful in predicting and assessing response to various medical treatments for NENs. A recent study by Le Bihan *et al*[78] showed that the change in the ADC values of liver metastases from NENs after transarterial radioembolization was significantly different between the partial response and progressive disease groups, thus concluding that ADC can be used as an additional marker for treatment response evaluation.

While DWI investigates diffusion of water molecules in tissues, it does not detect perfusion of blood. Intravoxel incoherent motion (IVIM) DWI detects translational motion of water molecules in a voxel and can simultaneously quantify their diffusion and microcirculation in tissue capillary network[79]. IVIM images are quantified by ADC, which integrates the effects of both diffusion and perfusion. IVIM therefore enables evaluation of tissue perfusion without the requirement of a contrast agent. The quantitative parameters in IVIM include the pure diffusion coefficient (D_{slow}), which reflects the diffusion of water molecules, the pseudodiffusion coefficient (D_{fast}), which reflects the diffusion movement of capillary microcirculation perfusion, and the perfusion fraction (f), which represents the volume ratio between the perfusion effect of local microcirculation and the overall molecular diffusion (Figures 7 and 8). IVIM-DWI is a useful method to assess true tumor cellularity of PNEN, represented by tissue diffusion, as increased microcirculation of hypervascular PNENs may cause the pseudodiffusion effect and thus leads to the overestimation of ADC values[79]. Hwang *et al*[80] observed that IVIM DWI can differentiate grade 1 from grade 2 or 3 PNENs. They found that pure diffusion coefficient is a better marker of tumor cellularity than ADC, and was significantly higher in grade 1 PNENs, thereby enabling prediction of tumor grade on imaging. A recent study showed that D_{slow} and D_{fast} parameters help in the differentiation of high grade PNENs from pancreatic adenocarcinoma with high diagnostic accuracy (0.460 *vs* 0.579×10^3 mm^2/s and 13.361 *vs* 4.985×10^3 mm^2/s, respectively)[81].



Diffusion kurtosis imaging

Diffusion kurtosis imaging (DKI) is a new rapidly advancing MRI technique based on the concept that water molecules in biological environment have non Gaussian properties. This is in contrast to standard DWI that calculates ADC using monoexponential analysis, assuming that diffusion of water in tissues follows Gaussian behavior[82]. At higher b values (> 1000 s/mm^2), due to the barriers encountered by water molecules in tissues, there is deviation from Gaussian distribution. The deviation when quantified, in fact represents the tissue microenvironment. Two quantitative parameters, diffusion coefficient (D) and kurtosis (K), representing deviation from Gaussian distribution, can be extracted from DKI. DKI thus provides a more accurate model of diffusion and quantifies tissue heterogeneity, and irregularity of cellular microstructure by capturing non Gaussian diffusion parameters (Figure 9)[82,83]. A drawback which hampers its use in routine practice is the long acquisition time due to scan acquisition at multiple b values. There are studies showing application of DKI for the assessment of the pancreas[84,85]. Shi *et al*[83] found that the radiomics model of DKI and T2 weighted imaging could improve the diagnostic accuracy for PNENs.

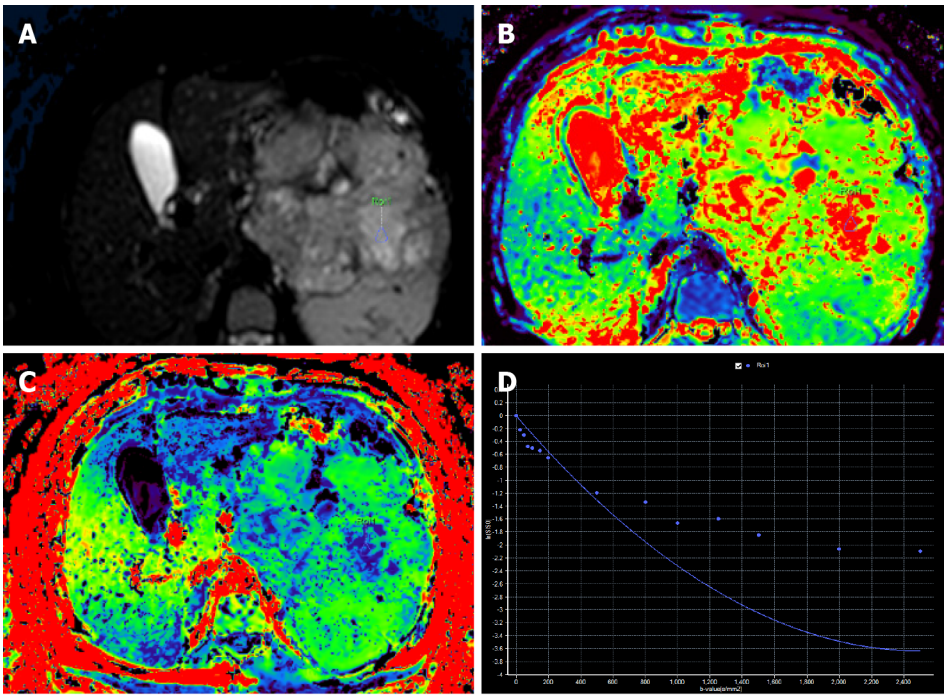
Figure 7 Intravoxel incoherent motion diffusion-weighted imaging in a 46-year-old woman with proven grade 1 pancreatic neuroendocrine neoplasm. A: Axial diffusion weighted image (b = 800 s/mm^2) shows a small pancreatic lesion with diffusion restriction (arrow); B: Color-coded diffusion map shows true diffusion coefficient, D = 2.33 × 10^3 mm^2/s; C: Color-coded perfusion map shows pseudodiffusion coefficient, D* = 5.37 × 10^3 mm^2/s); D: Color-coded perfusion fraction map shows a value, f = 3.2%; E: Signal decay curve of the tumor (purple) shows fall in signal at lower b values with plateau at higher b values. In comparison, normal pancreas (orange) shows lesser diffusion restriction than the tumor.



MR elastography

MR elastography (MRE) is a phase-contrast-based MRI technique for the evaluation of mechanical tissue properties noninvasively, *e.g.,* tissue stiffness. MRE of pancreas is at an early stage. Recent studies have used MRE to differentiate healthy from pathological pancreatic tissue[86]. The normal pancreatic stiffness in adults measured by MRE is 1.1–1.21 kPa[86]. Shi *et al*[87] used MRE for the characterization of solid pancreatic masses. They found that malignant masses had significantly higher stiffness (3.27 kPa) than benign masses (1.96 kPa). PNENs had a median stiffness of 2.32 kPa. They also suggested that stiffness ratio (ratio of stiffness of mass to normal parenchyma) may perform better in the differentiation of benign from malignant pancreatic masses.

MRI perfusion

MRI perfusion techniques for the assessment of tumor perfusion have the major advantage that they lack adverse effects of radiation compared to the radiation-intensive CT perfusion. T1-weighted dynamic contrast enhanced (DCE) MRI is the technique applied in the evaluation of tumors in the abdomen[88]. This provides both semiquantitative and quantitative information on the microvascular perfusion of the tissue. The semiquantitative analysis is based on the time-signal intensity curve and the quantitative analysis is based on the Tofts two-compartment pharmacokinetic model (intravascular and extravascular-extracellular compartments) with the parameters evaluated being Ktrans (volume transfer constant, wash in), Kep (reverse efflux rate constant, wash out) and Ve (extravascular extracellular space volume fraction)[89]. This technique has shown promising results in the evaluation of PNENs. A study by Donati *et al*[90] showed that Ktrans and Kep values were higher in NENs (2.709 ± 0.110/min; 5.957 ±

0.371/min) compared to other focal lesions and healthy pancreatic parenchyma. This in fact reflects the wash in (Ktrans) and wash out (Kep) of the contrast agent from the hypervascular NENs. Also, well differentiated and poorly differentiated NENs showed different perfusion characteristics. In the study by Kim *et al*[91], Ktrans value of NENs were significantly higher than that of neuroendocrine carcinomas (0.339 ± 0.187/min *vs* 0.077 ± 0.036/min). Ductal adenocarcinomas being hypovascular, show significantly lower average values of Ktrans and Kep[90-92]. The role of DCE MRI in the evaluation of response to systemic chemotherapy and targeted molecular therapy by assessing the changes in the values of MRI perfusion parameters reflecting good or poor response to treatment is a direction for future studies.

PET CT AND PET MRI

Hybrid anatomical and functional imaging using PET/CT is a valuable tool in the current practice of grading and management of NENs. In general, in dual tracer PET/CT (somatostatin receptor imaging with Ga^{68} DOTATATE/TOC/NOC PET/CT and glucose metabolism with FDG PET/CT), low-grade tumors, which express somatostatin receptors, bind to somatostatin analog, but not to FDG[93]. In contrast, poorly differentiated GEPNENs with high Ki-67 index would be negative on somatostatin PET/CT but FDG avid[94]. Zhang *et al*[95] suggested that dual tracer PET /CT may be used as an alternative to tissue sampling, as it reflects both cellular somatostatin receptor expression and glucose metabolism. The authors also found a positive correlation between SUVmax (standardized uptake value) and Ki-67 index with respect to FDG PET/CT and negative correlation with respect to Ga^{68} DOTATATE PET/CT. However, low-grade insulinomas show low expression of somatostatin receptors in contrast to other secreting and nonsecreting NENs and are frequently not detected on Ga^{68} DOTATATE PET/CT[96]. Since virtually all benign insulinomas express glucagon-like peptide 1 (GLP-1) receptors (incretin receptors), these receptors can be targeted by PET/CT for preoperative localization of occult benign insulinomas. GLP-1R PET/CT had higher sensitivity than MRI and SPECT/CT for localization of benign insulinomas in a study by Antwi *et al*[97]. Glucose dependent insulinotropic polypeptide receptor (GIPR) is another incretin receptor overexpressed in GEPNENs. It is a potential target for imaging the small percentage (~10%) of GEPNENs which do not express SSTR and GLP1R, as confirmed by studies in animal models[98].

With technical advances, simultaneous PET and MRI acquisition in an integrated scanner is now possible. The first study in 2013 by Beiderwellen *et al*[99] showed that every lesion detected on PET/CT was identified on PET/MRI. Hope *et al*[100] evaluated hepatic lesions in patients with NENs using Ga^{68} DOTATOC PET/CT and PET/MRI and found that there was a strong correlation between SUVmax obtained in PET/CT and PET/MRI. However, due to the high cost, the routine use of PET/MRI is limited.

RADIOMICS, TEXTURE ANALYSIS AND MACHINE LEARNING

Radiomics is the process of conversion of digital biomedical images to mineable data and the subsequent analysis of this data[101]. Texture analysis is an imaging technique under the wider arena of radiomics, that extracts, analyzes and interprets quantitative imaging features, and enables objective assessment of tumor heterogeneity beyond what is possible to human eyes[102]. In statistical-based model of texture analysis, from each voxel in a region of interest, various first order (*e.g.*, first-order entropy, kurtosis, skewness, standard deviation, mean intensity) and second order (*e.g.*, contrast, uniformity, second order entropy, *etc.*), or higher order features are extracted and analyzed using post processing software. As mentioned previously, tumor grade is an important prognostic factor of NENs and their prediction noninvasively is valuable.

CT radiomics is increasingly finding its place in the grading of NENs. Canellas *et al*[103], evaluating PNENs on CT scan, found that tumors with high entropy (a texture parameter reflecting tissue heterogeneity) values had 3.7 times higher odds of being aggressive (grades 2 and 3). In this study, entropy was a better predictor of tumor grade than the size of the lesion. Choi *et al*[104] found that lower kurtosis, lower sphericity and higher skewness correlated to grade 2 or 3 PNENs. A study on 3D texture analysis of PNENs in 100 patients showed that kurtosis was significantly different between all the three grades and entropy could differentiate grade 1 from grade 3 and grade 2 from grade 3, but not grade 1 from grade 2 tumors[50]. These results of CT texture analysis were confirmed in other recent studies [105,106] thus emphasizing its role in the prediction of tumor grade.

MRI radiomics also help in characterizing PNENs. MRI texture analysis was found to be useful in differentiating nonfunctioning PNEN from solid pseudopapillary neoplasm in a study by Li *et al*[107]. Nonlinear discriminant analysis was found to have the lowest misclassification rate of all the types of analyses performed in their study. Shindo *et al*[108] studied ADC histogram for differentiation of pancreatic adenocarcinoma from PNENs. In their study, ADC entropy had the highest area under the curve (AUC) for differentiating adenocarcinoma from NEN. De Robertis *et al*[77] found that ADC

Table 3 Summary of important research studies on imaging of gastroenteropancreatic neuroendocrine neoplasms

	Ref.	Number (*n*)	Modality	Results	Conclusion
Ultrasonography	Takada *et al* [25], 2019	30	Contrast-enhanced harmonic EUS	Three parameters in TIC showed high diagnostic accuracy: Echo intensity change - 87%; Rate of enhancement - 87%; Enhancement ratio for node/pancreatic parenchyma - 88.5%	Contrast-enhanced EUS and TIC analysis show high diagnostic accuracy for grading of PNEN
CT	Worhunsky *et al*[45], 2014	118	APCT	5-year overall survival: Hypoenhancing - 54%; Isoenhancing - 89%; Hyperenhancin - 93%. On multivariate analysis only hypoenhancement (HR 2.32, P = 0.02) was independently associated with survival	Hypoenhancement of PNEN on APCT (22% of well-differentiated PNEN) was an independent predictor of poor outcome
	Rodallec *et al*[46], 2006	37	Dual-phase contrast-enhanced CT	Poorly differentiated NEC: Hypoattenuating - 71%; Isoattenuating or weakly hyperattenuating - 29%; Well-differentiated NECmoderately or strongly hyperattenuating - 53%. Poor enhancement at pancreatic phase and less vascularized tumors were associated with decreased survival rate	Enhancement of PNEN at CT correlated with microscopic tumor vascularity. Low-enhancing PNEN correlated with poor differentiation and lower overall survival
	Park *et al* [48], 2020	69	Dynamic CT	NEC (compared to well-differentiated NEN): Significantly higher frequencies of main pancreatic ductal dilatation, bile duct dilatation, vascular invasion; Significantly lower conspicuity of interface between tumor and parenchyma, AER and PER. PER < 0.8 showed 94.1% sensitivity, 88.5% specificity for differentiation of NEC from well-differentiated NEN. On combining 3 significant CT features, the sensitivity and specificity for diagnosing NEC were 88.2% and 88.5% respectively	Tumor parenchyma enhancement ratio in portal phase is useful to distinguish NECs from well differentiated NENs. Combining qualitative and quantitative CT features aid in achieving good diagnostic accuracy in differentiation between NEC and well-differentiated NEN
	d'Assignies *et al*[59], 2009	36	MDCT perfusion	Tumor blood flow and intratumoral MVD showed high correlation (r = 0.620, P < 0.001). Blood flow was significantly higher in: Grade 1 than grade 2/3 tumors; Tumors with proliferation index ≤ 2% (P = 0.005); Tumors without histological signs of microscopic vascular involvement (P = 0.008). Mean transit time was longer in tumors with lymph node (P = 0.02) or liver (P = 0.05) metastasis	Perfusion CT is feasible in patients with pancreatic NENs and reflects MVD. Perfusion CT measurements correlated with histoprognostic factors, such as proliferation index and WHO grading
MRI	Canellas *et al*[103], 2018	80	MRI	MRI features associated with aggressive tumors: Size > 2 cm (OR = 4.8); T2 non-bright lesions (OR = 4.6); Presence of pancreatic ductal dilatation (OR = 4.9); Diffusion restriction (OR = 4.9)	MRI can assess aggressiveness of PNEN and identify patients at risk for early disease progression after surgical resection
	d'Assignies *et al*[74], 2013	59	MRI	DWI (71%-71.6%) was more sensitive than T2 weighted images (55.6%) and dynamic CEMRI (47.5%-48.1%). Combination of these sequences improved detection of liver metastases. Specificity of each sequence was comparable (89%-100%)	DWI is more sensitive for detection and characterization of liver metastases from NENs than T2-weighted and dynamic gadolinium-enhanced MRI
Radiomics, texture analysis and machine learning	Canellas *et al*[103], 2018	101	CECT with texture analysis	CT features predictive of a more aggressive tumor: Size > 2 cm (OR = 3.3); Vascular involvement (OR = 25.2); Pancreatic ductal dilatation (OR = 6); Lymphadenopathy (OR = 6.8); Entropy (OR = 3.7); Differences (P < 0.05) in progression free survival were found for: Grade 1 *vs* grade 2 *vs* grade 3 tumors; PNEN with vascular involvement; Tumors with entropy values > 4.65	CT texture analysis and CT features are predictive of aggressiveness and can be used to identify patients at risk of early disease progression after surgical resection
	De Robertis *et al*[77], 2018	42	MRI and histogram analysis	ADC entropy is significantly higher in grade 2/3 tumors (sensitivity: 83.3%, specificity: 61.1%). ADC kurtosis is higher in PNENs with vascular involvement, nodal and hepatic metastases (sensitivity: 85.7%, specificity: 74.3%)	Whole tumor ADC histogram analysis can predict aggressiveness in PNENs. ADC entropy and ADC kurtosis are the most accurate parameters for identification of PNEN with malignant behavior
	Luo *et al* [112], 2020	93	CECT with application of a CNN based DL algorithm	AUC = 0.81 of arterial phase in validation set was significantly higher than those of venous (AUC = 0.57, P = 0.03) and arterial/venous phase (AUC = 0.70, P = 0.03) in predicting the pathological grading of PNENs. The AUC and accuracy of DL algorithm for diagnosing grade 3 PNEN were 0.80% and 79.1%. There was significant difference in OS and PFS between the predicted G1/2 and G3 groups	The CNN-based DL method showed a relatively robust performance in predicting pathological grading of PNENs from CECT images
	Gao *et al*	96	CEMRI with	The average accuracy of the five trained CNNs	With the help of GAN, the CNN

	[114], 2019	application of deep learning algorithm on images	ranged between 79.08% and 82.35%, and the range of micro- average AUC was between 0.8825 and 0.8932. The average accuracy and micro-average AUC of the averaged CNN were 81.05% and 0.8847 respectively	showed the potential to predict the grades of PNENs on CEMRI

EUS: Enhanced ultrasonography; TIC: Time-signal intensity curve; APCT: Arterial phase computed tomography; ADC: Apparent diffusion coefficient; CECT: Contrast enhanced computed tomography; CEMRI: Contrast enhanced magnetic resonance imaging; CNN: Convolutional neural network; DWI: Diffusion weighted imaging; NEC: Neuroendocrine carcinoma; NEN: Neuroendocrine neoplasm; AER: Annual equivalent ratio; PER: Portal enhancement ratio; MVD: Microvascular density; WHO: World Health Organization; MDCT: Multidetector row computed tomography; OS: Overall survival; PFS: Progression free survival; AUC: Area under the curve; PNEN: Pancreatic neuroendocrine neoplasm; GAN: Generative Adversarial Network.

histogram analysis of DWI, using radiomics, could predict aggressiveness of PNENs. They found high ADC kurtosis values in tumors with vascular invasion (AUC of 0.763 for a cut off value of 4.13) and distant metastases (AUC of 0.820 for a cut off of 3.642)[77]. The future prospects of radiomics are in the direction of development of a robust predictive model combining qualitative and quantitative imaging parameters.

Machine learning is increasingly being used in medicine and has various applications including detection of disease, classification of images, identifying treatment and monitoring adherence to therapy [109,110]. The standard radiomics analysis on CT or MRI requires marking of the tumor margins for analysis. However, deep learning using convolutional neural network (CNN) performs analysis automatically and provides better results[111]. A few recent preliminary studies have shown the promising role of deep learning using CNN in the prediction of grade of PNEN and survival using contrast enhanced CT[112-114]. Clinical trials for translation of these imaging techniques into clinical practice and validation for routine use are ongoing.

In short, the quantitative parameters derived from imaging, relevant for prognostication of GEPNENs include tumor size, enhancement ratios derived from HU values, iodine uptake on DECT, entropy on CT texture analysis, tumor blood flow, tumor blood volume, and mean transit time on perfusion CT, ADC and ADC histogram analysis of DWI, true and pseudodiffusion coefficients and perfusion fraction on IVIM DWI, Ktrans and Kep on perfusion MRI and SUVmax on dual tracer PET/CT. A combination of qualitative features and quantitative factors with the newer functional imaging techniques enables better tumor classification based on their prognosis. A summary of important studies on advanced imaging in GEPNENs is shown in Table 3.

CONCLUSION

With the recent advances in CT, MRI, USG and hybrid imaging techniques like PET/CT and PET/MRI using dual tracers, smaller pancreatic and bowel NENs are now being increasingly detected and staged. In addition to tumor detection and staging, their non-invasive grading, prognostication and monitoring response to treatment are shown to be feasible and reliable with the emerging studies using quantitative imaging techniques like CT and MR perfusion studies, DWI, IVIM and texture analysis with radiomics. Standardization of these techniques with more large scale studies would be an important future prospect. These advances in imaging will help in making the right treatment choice, contributing to an overall improvement in patient outcome.

REVIEW

Tumor microenvironment involvement in colorectal cancer progression *via* Wnt/β-catenin pathway: Providing understanding of the complex mechanisms of chemoresistance

María Belén Novoa Díaz, María Julia Martín, Claudia Gentili

Specialty type: Gastroenterology and hepatology

Provenance and peer review: Invited article; Externally peer reviewed.

Peer-review model: Single blind

Peer-review report's scientific quality classification

Grade A (Excellent): 0
Grade B (Very good): B, B, B, B
Grade C (Good): C
Grade D (Fair): 0
Grade E (Poor): 0

P-Reviewer: Koustas E, Greece; Pan JS, China; Rahimi-Movaghar E, Iran; Scurtu RR, Romania; Ying HQ, China

Received: December 21, 2021
Peer-review started: December 21, 2021
First decision: March 10, 2022
Revised: April 29, 2022
Accepted: June 20, 2022
Article in press: June 20, 2022

Abstract

Colorectal cancer (CRC) continues to be one of the main causes of death from cancer because patients progress unfavorably due to resistance to current therapies. Dysregulation of the Wnt/β-catenin pathway plays a fundamental role in the genesis and progression of several types of cancer, including CRC. In many subtypes of CRC, hyperactivation of the β-catenin pathway is associated with mutations of the *adenomatous polyposis coli* gene. However, it can also be associated with other causes. In recent years, studies of the tumor microenvironment (TME) have demonstrated its importance in the development and progression of CRC. In this tumor nest, several cell types, structures, and biomolecules interact with neoplastic cells to pave the way for the spread of the disease. Cross-communications between tumor cells and the TME are then established primarily through paracrine factors, which trigger the activation of numerous signaling pathways. Crucial advances in the field of oncology have been made in the last decade. This Minireview aims to actualize what is known about the central role of the Wnt/β-catenin pathway in CRC chemoresistance and aggressiveness, focusing on cross-communication between CRC cells and the TME. Through this analysis, our main objective was to increase the understanding of this complex disease considering a more global context. Since many treatments for advanced CRC fail due to mechanisms involving chemoresistance, the data here exposed and analyzed are of great interest for the development of novel and effective therapies.

Key Words: Colorectal cancer; β-catenin pathway; Tumor stroma; Tumor microenvironment factors; Cancer progression; Drug resistance

Core Tip: Currently, there is a high probability of failure in treatments for the advanced stages of colorectal cancer (CRC). For this reason, it is necessary to obtain a better understanding of CRC biology in a more global context for the future design of novel therapeutic approaches. The effects of the Wnt/β-catenin signaling pathway and the tumor microenvironment (TME) on the progression and chemoresistance of this disease were separately described in several review articles. Therefore, herein we comprehensively analyze the complex mechanisms of CRC chemoresistance triggered by TME factors that impact Wnt/β-catenin signaling.

INTRODUCTION

Colorectal cancer (CRC) is the third most frequent malignant disease worldwide in both men and women[1,2]. Data provided by the World Cancer Research Fund International indicate that CRC incidence is growing, and the prevalence of this pathology is expected to increase by 60% in the next 15 years[3]. Among all cancer-induced deaths, the ones associated with CRC reach values of 8%-9%[4,5]. These statistics rely mainly on the fact that 20% of patients show metastasis (stage IV) at the time of diagnosis and the overall survival in these patients is low due to failure in the treatments[5,6]. To improve the response of these patients to therapy, it is necessary to expand the knowledge about the mechanisms that play a critical role in the development, progression and chemoresistance of CRC.

In 2015, Guinney *et al*[7] proposed a classification of colorectal tumors based on four consensus molecular subtypes (CMSs). Groups were defined according to certain parameters such as clinical, genetic and molecular characteristics (Figure 1): The CMS1 group, also designated microsatellite instability immune, is characterized by high microsatellite instability and immune response. The canonical subtype (CMS2) represents 37% of cases and presents hyperactivation of the Wnt and Myc signaling pathways. The CMS3 (metabolic subtype) is characterized by a marked dysregulation of metabolic pathways. Finally, the CMS4 (mesenchymal subtype) group exhibits hyperactivation of the transforming growth factor-β (TGF-β) pathway and a marked switch from the epithelial to mesenchymal transition (EMT)[7,8]. Remarkably, 90% of CRC cases present with aberrant activation of the canonical Wnt/β-catenin signaling pathway[9-11]. This pathway is strictly regulated in physiological conditions and modulates fetal development and homeostasis in adult tissues[11]. Briefly, in the absence of Wnt ligand, β-catenin is continuously phosphorylated in the cytoplasm by a destruction complex comprised of adenomatous polyposis coli (APC), axis inhibition protein (Axin), glycogen synthase kinase 3 (GSK3), and casein kinase 1. Once phosphorylated, β-catenin is ubiquitinated and degraded by the proteasome. When Wnt ligand binds to its receptor, the destruction of β-catenin stops, so this protein accumulates in the cytosol and then translocates to the nucleus. Finally, β-catenin binds to transcription factors from the T-cell factor/lymphoid enhancer factor (TCF/LEF) family and promotes the transcription of several genes[12]. There are several published research as well as review articles on the involvement of the Wnt/β-catenin pathway in CRC development, progression, and chemoresistance[10,13,14]. Furthermore, this pathway became an unquestionable target for novel therapies for CRC. Despite this, to date, there are no approved treatments or clinical trials for CRC based on targeting the Wnt/β-catenin pathway[15].

As extensively described in the open literature, hyperactivation of the Wnt/β-catenin pathway in CRC is directly associated with intrinsic causes such as mutations in the *APC* gene. This results in the nuclear accumulation of β-catenin and the induction of Wnt target genes that promote tumor progression[16]. In this contribution, we intend to analyze how Wnt/β-catenin aberrant activation can be induced or exacerbated by external causes.

In the last decade, the tumor microenvironment (TME) or tumor stroma has become relevant in the progression of CRC[17]. The TME is a niche composed of the extracellular matrix (ECM), a great variety of modified stromal cells and aberrant vasculature[9]. Intercellular communications between the tumor cells and the TME are mainly established through paracrine signaling[9,18]. These communications and factors are extrinsic and may directly affect CRC progression through the Wnt/β-catenin pathway. In this way, a wide range of novel therapeutic targets appears, expanding the possibilities of achieving effective treatments for CRC.

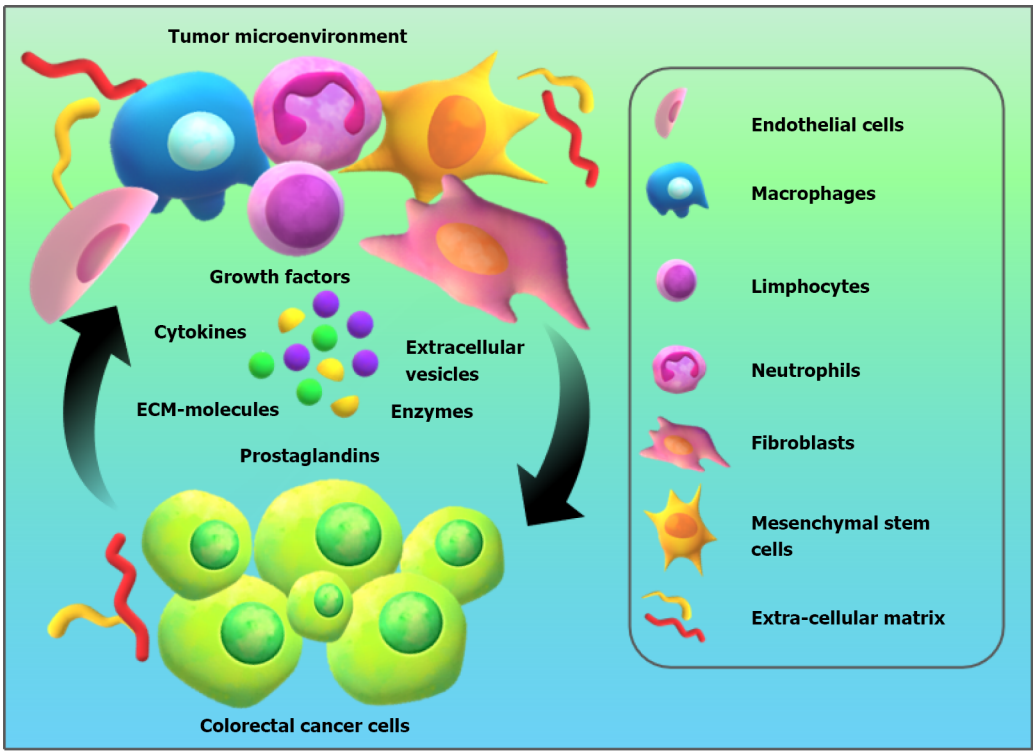
This work analyzed the available literature regarding the biomolecules associated with the TME that can modulate the Wnt/β-catenin signaling pathway in CRC cells, which allows a better understanding of the biological causes of the high morbidity and mortality of this pathology in a global context. Although antecedents of this particular analysis are registered in 2008[19], the enormous amount of information collected in recent years results in the emergence of new biomolecules, structures, and even processes related to the TME and the CRC cells that were previously unknown or unrelated. The comprehension of this information enables countless new possibilities for the development of new therapies for CRC.

DYNAMICS ESTABLISHED BETWEEN THE TME AND CRC CELLS

During CRC genesis, the TME and its associated signaling play a key role in tumor fate, since they facilitate the proliferation, invasion, metastasis, and chemoresistance processes. Specifically, the TME is composed of ECM proteins, mesenchymal stem cells, fibroblasts, cancer-associated fibroblasts (CAFs), endothelial cells (ECs), and tumor-infiltrating immune cells, with the last group comprising tumor-associated macrophages (TAMs), tumor-associated neutrophils, natural killer (NK) cells, regulatory T cells, myeloid-derived suppressor cells, and cytotoxic T lymphocytes (also known as CD8+ T cells), among others[5,20].



The TME cells and neoplastic cells continuously secrete and internalize factors that modulate the CRC development and contribute to the maintenance of the tumor ecosystem. These extracellular signals are schematized in Figure 2 and involve soluble proteins, insoluble proteins from the ECM, or compounds of variable nature loaded in vesicles[21]. Table 1 compiles the biomolecules well described in the literature that can be secreted by the TME cells and that allow communication with CRC cells. Some of these factors can travel freely through the tumor stroma space, whereas others are transported through membrane-bound vesicles known as extracellular vesicles (EVs)[22,23]. The EVs structure includes a lipid bilayer composed mainly of ceramide, cholesterol, sphingomyelin, phosphoglycerides, glycosphingolipids, phosphatidyl serine, phosphatidylethanolamine, mannose, N-linked glycans, polylactosamine, and sialic acid[22]. In recent years, EVs have acquired relevance as biological mediators in the communication between the TME and tumor cells. Concerning EVs related to CRC, their loads are considered prognostic factors or indicative of response to therapies. Recent studies have shown that EVs can carry large amounts of biomolecules from the TME cells to cancer cells and vice versa. Usual cargoes include cytokines/chemokines, angiogenic factors, ECM remodeling factors, and nucleic acids such as microRNAs (miRs), long non-coding RNAs (lncRNAs), and circular RNAs (cRNAs)[24-27]. Fluids from CRC patients such as plasma, saliva, and urine contain large amounts of secreted EVs. These molecules can stimulate or inhibit the expression of oncogenes and oncoproteins, thus affecting the phenotype of the neoplastic cells or altering the secretory profile of the TME cells[22,25,28]. Unlike cytokines and growth factors that act in the nearby cells, the EVs can influence both the primary colorectal tumor and

Table 1 Factors secreted by the tumor microenvironment and their role in colorectal cancer progression

Released/secreted components	Source, TME cell	Known effects in CRC	Ref.
Growth factors			
TGF-β	CAFs; TIICs[1]; MSCs[1]	Proliferation on tumor and stromal cells in late stages of tumorigenesis. EMT program and CSC-like traits. Metastasis, vasculogenesis and angiogenesis	[5,21,136]
BMPs	CAFs	Anti-tumor activity. Or pro-tumor activity, induce CSCs phenotype, EMT program and chemoresistance. Differentiation of colon CSCs	[5,137,138]
HGF	CAFs; TIICs; MSCs[1]	Invasion, metastasis and stemness	[21,54,139,140]
VEGF	ECs; CAFs; TIICs	Angiogenesis, invasiveness, metastasis	[104,140,141]
FGF	CAFs; MSCs	CAFs profiles. Tumor growth and metastasis	[142,143]
PDGF	CAFs	Tumor growth and metastasis	[144]
TNF-α	TIICs	Proliferation. Growth arrest and cancer cell death, angiogenesis and metastasis	[141,145]
Cytokines			
IL-1	TIICs	Angiogenesis and metastasis	[141,146]
IL-2	TIICs	Anti-tumor activity	[1,147]
IL-6	TIICs; MSCs; CAFs	Proliferation, angiogenesis and metastasis	[1,141]
IL-8	TIICs; MSCs	Tumor growth, angiogenesis and chemoresistance	[1,148]
IL-17	CAFs; TIICs	Anti-tumor or pro-tumor activity. Invasion and self-renewal of CSCs	[1,104,149]
IL-18	TIICs	Anti-tumor activity	[150]
IL-22	TIICs	Proliferation, invasion and stemness	[1,104]
IL-33	ECs; TIICs	Anti-tumor activity Suppresses tumorigenesis. Or pro-tumor activity. Angiogenesis and metastasis. Tumor growth through immunosuppressive microenvironment favoring	[1,104,151]
CCL2	TIICs; MCS	Tumor progression	[152]
CCL5	TIICs	Tumor progression. Acts on tumor cells and TAMs	[153]
CCL7	CAFs	Proliferation, invasion, and migration	[154]
CXCL12	CAFs; MSCs	Proliferation and invasion	[142,155]
PTHrP	Undefined TME cells	Proliferation, invasion, angiogenesis, migration and chemoresistance	[34,35,66,156,157]
Osteopontin	TIICs	Metastasis, stemness and chemoresistance	[85]
Prostaglandins			
PGs (like PGE2)	CAFs; TIICs; MSCs	Resistance to apoptosis, increased proliferation, angiogenesis and metastasis	[21,32]
Signaling pathways ligands			
NOTCH ligands (Jagged-1; Jagged-2; DLL4)	ECs	CSCs phenotype, EMT program and metastasis	[104,158]
WNT ligands (Wnt2, Wnt5)	CAFs	Invasion, metastasis and angiogenesis	[44,45,54]
Enzymes			
Serine proteinases (like MMPs)	TAMs; TANs	Invasion and angiogenesis	[140,145]
Immunosuppressive enzymes (like iNOS)	TIICs	Tumor progression. Inhibitory effect on the immune system, apoptosis of immune cells	[39]
Receptors			
TLRs	CAFs, ECs	Inflammatory-mediated tumorigenesis	[41,43]
RNA molecules			

miR-92a-3p	CAFs	CSCs phenotype, EMT program and chemoresistance	[24]
lncRNA H19	CAFs	Stemness and chemoresistance	[25]
miR-155	MSCs[1]	Migration	[21,159]
miR-375	MSCs[1]	Chemoresistance	[21,160]
cRNA	CAFs	Tumor progression or anti-tumor activity	[26,27]

[1]Factor's actions demonstrated for colorectal cancer (CRC). Their source from the tumor microenvironment (TME) has been identified for other types of cancer, but not for CRC. BMP: Bone morphogenetic CAFs: Cancer-associated fibroblasts; CCL: C-C motif chemokine ligand; cRNA: Circular RNA; CSCs: Cancer stem cells; CXCL: C-X-C motif chemokine ligand; ECs: Endothelial cells; EMT: Epithelial to mesenchymal transition; FGF: Fibroblast growth factor; HGF: Hepatocyte growth factor; IL: Interleukin; iNOS: Inducible nitric oxide synthase; lncRNA: Long non-coding RNA; miR: MicroRNA; MMPs: Matrix metalloproteinases; MSCs: Mesenchymal stem cells; PDGF: Platelet-derived growth factor; PGs: Prostaglandins; PTHrP: Parathyroid Hormone-related Peptide; TAMs: Tumor-associated macrophages; TANs: Tumor-associated neutrophils; TGF-β: Transforming growth factor-β; TIICs: Tumor-infiltrating immune cells; TLRs: Toll-like receptors; TNF-α: Tumor necrosis factor-α; VEGF: Vascular endothelial growth factor.

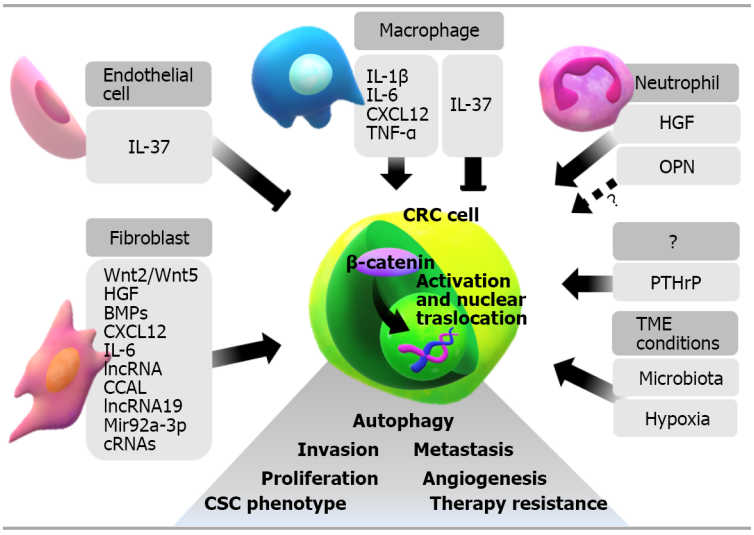
Figure 2 Extracellular signal molecules secreted by the tumor microenvironment and neoplastic cells. The traffic of soluble and insoluble factors allows crosstalk between tumor cells and their environment modulating colorectal cancer development and progression.

metastatic niche remotely[22,29]. For instance, analysis of the plasma from CRC patients revealed that EVs are directly linked to the establishment of liver proinflammatory phenotype and liver metastasis, with this effect mediated by the modulation of macrophages by EVs[30]. The correlation between CD8+ T cell activation and high EVs concentrations in plasma has also been demonstrated, thus showing the role of EVs in the modulation of the immune response in CRC[31]. In conclusion, EVs have become a new source of therapeutic targets for CRC[22].

On the other hand, the soluble molecules that are directly secreted to the biological fluids exert their actions locally and participate in the communication between the tumor and the microenvironment. These factors are prostaglandins, cytokines, and other paracrine factors, which have distinctive modes of action. Prostaglandins and cytokines act especially as immunomodulators, by promoting or inhibiting the progression of CRC[1,32,33]. Growth factors such as TGF-β, vascular endothelial growth factor (VEGF), and EGF promote the transformation and development of neoplastic cells by inducing proliferation, invasion, and migration responses and also by affecting the TME[21]. In previous works *in vitro* using two CRC cell lines with different grades of aggressiveness, we demonstrated that parathyroid hormone-related peptide (PTHrP) acts as a paracrine factor by inducing the survival, proliferation, migration, cell cycle progression, angiogenesis, and EMT program. Moreover, our *in vivo* studies in CRC

tumor xenografts revealed that the intratumor administration of PTHrP modulates the expression of several tumorigenic markers, which are involved in the same cell responses observed *in vitro*[5,34-37].

Other proteins with different functions were studied in relation to CRC and the TME. In recent years, it has been reported that both neoplastic cells and TME cells can synthesize and secrete enzymes that participate in tumorigenesis. Muñoz-Galván *et al*[38] demonstrated that phospholipase D2 (PLD2) enzyme is overexpressed and secreted by CRC cells. PLD2 in the extracellular space modulates the phenotype and secretory profile of CAFs, thus contributing to promote stemness in tumor cells[38]. Other enzymes such as nitric oxide synthase are capable of inducing immunomodulatory effects[39]. Moreover, enzymes present in the TME, such as metalloproteases, enable the invasion and migration of cancer cells[39]. These enzymes act mainly by altering the structure and function of the ECM, thus allowing the activation of other factors that amplify the pro-tumor signals[40]. Receptor proteins such as Toll-like receptors (TLRs) play a fundamental role in maintaining epithelial barrier homeostasis in the gut and mediating inflammatory and immune responses[41]. TLRs are also expressed in fibroblasts and ECs in the TME and in CRC cells. The dysregulation in TLR pathways is associated with inflammation-driven carcinogenesis[42]. In response to this evidence, currently, there are clinical trials that include TLRs agonists for the treatment of CRC (www.clinicaltrials.gov)[41,43].



The abovementioned factors generally exert their effects by modulating several signaling pathways in the tumor[1,44-46]. In accordance with the focus of this contribution, in the next sections, we further discuss which of these biomolecules participate in aberrant activation of the β-catenin signaling pathway in CRC, and how these findings have provided new opportunities for the development of more efficient therapies.

TME FACTORS AND CONDITIONS THAT MODULATE THE WNT/β-CATENIN PATHWAY IN CRC

It is clear that the signaling triggered by factors that mediate the communication between TME and CRC cells is of great importance. Since Wnt/β-catenin is involved in most of the processes related to CRC genesis and progression[8,47], in this section we focus on the factors from the TME able to modulate this pathway. Figure 3 schematizes the complex interrelationships between the TME and CRC cells that lead to the activation of β-catenin and the consequent effects on disease progression.

Other β-catenin regulation, independently of the destruction complex actions described in the introduction section, involves phosphorylation by other kinases in different amino acids, such as Ser-552 and Ser-675, resulting in the stabilization and nuclear accumulation of this protein[48]. Mutations in the gene that encodes the β-catenin protein (*CTNNB1* gene) will produce structural alterations and its consequent hyperactivation and nuclear accumulation, events directly associated with CRC genesis and progression[7,49]. Voorneveld and collaborators[50] demonstrated that nuclear β-catenin is found predominantly in cells at the invasive front of CRC tumors. Other investigations have proven that the signals that exacerbate aberrant β-catenin function independently of others than those produced by the tumor can come from the TME[44,51].

Activation of the Wnt pathway by TME factors was initially studied a decade ago. Vermeulen and colleagues showed that CAF-derived hepatocyte growth factor (HGF) activates Wnt/β-catenin signaling and subsequently the clonogenicity in cancer stem cells (CSCs) isolated from CRC patients that were transiently transfected with TCF/LEF luciferase reporter vector. Moreover, HGF restored the CSC phenotype in more differentiated tumor cells both *in vitro* and *in vivo*[52]. Essex and collaborators recently replicated these studies, emphasizing the relevance of this pathway and the interaction of tumor cells with their stroma, and in the promotion and development of CRC[53]. As stated in Table 1, various Wnt ligands are secreted mostly by CAFs[44,45,54,55]. A recent study confirmed that Wnt2 acts in an autocrine manner, generating morphogenetic changes in fibroblasts and contributing to the invasive and metastatic capacity of CRC-derived cells[44]. *In vitro* experiments revealed that the treatment of DLD1 and HCT116 cells (both derived from CRC) with conditioned medium obtained from CAFs transfected with small interfering RNA targeting Wnt2, significantly decreased cell invasion and migration[45]. It is of clinical relevance that these ligands are overexpressed in the tumor stroma of CRC patients[45,53]. Moreover, the aberrant expression of Wnt ligand is correlated with a worse prognosis [44]. EVs play a key role in activating Wnt signaling in CRC. On the one hand, EVs can transport mutant β-catenin and activate the Wnt signaling pathway in the recipient cells, thus promoting CRC progression[56]. Regarding the effects of EVs on TME cells, Hu and colleagues demonstrated *in vitro* that fibroblast-derived exosomes (one type of EVs) promote the tumor growth of CSCs upon treatment with 5-fluorouracil (5-FU) or oxaliplatin (OXA)[57]. Further investigations of the same group in subcutaneous xenografts achieved through HT-29 CRC-derived cells and fibroblast co-implantation demonstrated that stromal fibroblasts can secrete exosomes loaded with Wnt ligands. Once these exosomes interact with differentiated CRC cells, Wnt ligands induce the phenotypic reversion of CRC cells to CSCs, which includes features such as the expression of CSCs markers and elevated Wnt activity [57].

Figure 3 Influence of tumor microenvironment-derived factors in the activation of β-catenin pathways. Several cytokines, growth factors, and small nuclei acid molecules secreted by stromal cells induce aberrantly activation of β-catenin and its nuclear translocation in colorectal cancer (CRC) cells promoting events associated with an aggressive phenotype of the tumor cells. Il-37 represses the expression of β-catenin and its transcriptional activity. Osteopontin is statistically associated with the expression of β-catenin in CRC and is known to induce its activation in other types of cancer. More studies are necessary to confirm positive feedback between the secretion of this tumor microenvironment (TME) factor and β-catenin signaling pathways in CRC. In addition to these factors, the microbiota and the hypoxia in the TME, also participate in the modulation of β-catenin activation. This figure is original for this work. BMP: Bone morphogenic protein; CCAL: Colorectal cancer-associated lncRNA; cRNA: Circular RNA; CXCL: C-X-C motif chemokine ligand; HGF: Hepatocyte growth factor; IL: Interleukin; lncRNA: Long non-coding RNA; OPN: Osteopontin; PTHrP: Parathyroid Hormone-related Peptide; TNF-α: Tumor necrosis factor-α; Wnt: Wingless protein.

Hypoxia is a prevalent condition in the solid tumor TME, which involves oxygen pressures of less than 5-10 mmHg. The hypoxic TME can deeply influence CRC, and these effects may be mediated by β-catenin. For instance, it was found *in vitro* that Wnt/β-catenin signaling is responsible for the hypoxia-induced self-renewal of colorectal stem cells[58]. Furthermore, Huang and collaborators observed that hypoxic CRC cells can secrete exosomes enriched with Wnt4 Ligands. These exosomes can activate β-catenin signaling in normoxic CRC cells and stimulate prometastatic behaviors such as cell migration and invasion[59]. In another work, the authors demonstrated that Wnt4-loaded exosomes secreted by the tumor cells promoted angiogenesis through the proliferation and migration of ECs. These effects were induced in conditions of hypoxia and mediated by the activation of Wnt/β-catenin signaling[60].

Autophagy is a physiological process through which normal cells degrade intracellular components to maintain cellular homeostasis. It is postulated as an alternative to cell death when the apoptotic machinery fails and is associated with both CRC and the TME, with controversial findings[61-63]. TME hypoxia induces autophagy and also activates several tumor escape mechanisms[62]. Some of the molecular mechanisms involved in the modulation of autophagy are phosphoinositide 3-kinases (PI3K)/protein kinase B (also known as Akt)/mammalian target of rapamycin, TGF-β, Notch, and Wnt/β-catenin signaling[63]. According to evidence, autophagy induced in the early stages of tumor development prevents the infiltration of immune cells as well as tumor cell death. Autophagy can also promote tumor progression in the advanced stages of the disease[63]. On the other hand, it has been reported that the relationship between autophagy and increased lymphocytic infiltration in the TME is mediated by the autophagy-related protein Vps34 in CRC. The modulation of this autophagy-related protein would improve the efficacy of immunotherapies[64]. However, it is still necessary to conduct additional studies on the interrelationship between the Wnt/β-catenin signaling pathway and autophagy, and which TME factors can mediate these events in CRC.

Because about 90% of patients with CRC present with mutations in genes associated with the Wnt pathway[65], more efforts have been made to identify other molecules with the ability to regulate β-catenin. In line with this evidence, our research group also reported interesting results regarding the participation of PTHrP in the activation of signaling pathways associated with β-catenin. Our published data showed that the exposition of cells derived from colorectal adenocarcinoma, to exogenous PTHrP increases β-catenin expression and upregulates cyclin D1 and c-Myc oncogenes with the concomitant cell proliferation induction[66]. Regarding the role of this cytokine in the TME, we demonstrated *in vitro* that tumor conditioned media from PTHrP-exposed CRC cells promotes pro-angiogenic characteristics in the stromal EC line HMEC-1 through VEGF modulation[35]. In addition, we recently found that PTHrP modulates the protein expression and secretion from the HMEC-1 cells of secreted protein acidic and cysteine-rich, a TME factor involved in the EMT program. This event promotes molecular and morphological changes associated with EMT in cells derived from CRC[36]. In this context, we believe that cross-communication may be initially established through overexpression and secretion of PTHrP

by the tumor, which in turn affects the behavior of neoplastic cells and TME cells inducing the subsequent release from them of this cytokine and other factors. More studies are needed to elucidate which stromal cells can secrete PTHrP and participate in the modulation of the β-catenin pathway. Several authors have also described the relationship between PTHrP and activation of the β-catenin signaling pathway in other types of cancer. In prostate cancer-derived cells, PTHrP downregulates the Wnt inhibitor, DKK1, promoting aberrant activation of this pathway[67]. Other research has shown that PTHrP modulates activation of the canonical Wnt/β-catenin signaling in the mammary mesenchyme [68]. Moreover, Johnson and collaborators reported that Wnt activation promotes PTHrP expression in breast and lung tumor cells[69].

Tumor small and long non-coding RNAs are other factors transported by EVs, which are also involved in the modulation of β-catenin signaling. Colorectal cancer-associated lncRNA (CCAL) and H19 (lncRNA19) expressed by CAFs are capable of stimulating aberrant activation of β-catenin in tumor cells[9,25]. Besides, the overexpression of miR-103 and miR-107 has been detected in the plasma and tumor tissue of patients with CRC[70]. In HCT116 and HT29 cell lines, miR-103/107 overexpression enhanced β-catenin activity and its nuclear translocation. These molecules act by inhibiting Axin2, a negative regulator of the Wnt/β-catenin pathway, and in this way, β-catenin is stabilized and its activation is prolonged[70]. Another study showed that miR-92a-3p secreted by CAFs, induces β-catenin nuclear translocation and the expression of target genes related to stemness, the EMT program, and chemoresistance in the human CRC cell lines SW480, SW620, and LOVO. Moreover, the high expression of exosomal miR-92a-3p in serum predicts metastasis and chemotherapy resistance in CRC patients[24]. The overexpression of miR-100, miR-125b, miR-27a, miR-135, and MIR100HG in CRC tumors modulates the canonical Wnt pathway, promoting events such as proliferation and invasion[71,72].

In the last decade, research on small non-coding RNA molecules has focused on cRNAs. Increasing studies have shown that these molecules intervene in the development and progression of various types of tumors including CRC[73]. Results obtained by Zhang *et al*[73] show that circAGFG1 activates the Wnt/β-catenin pathway in SW480 and HCT116 cells promoting the transcription of the CTNNB1 gene. Two years earlier, Fang and his group revealed that circ_100290 promotes CRC progression through activation of the Wnt/β-catenin pathway[74]. Other cRNAs involved in the activation of this signaling pathway in CRC are Hsa_circ_0005075[75], circMTO1[76] and Circ-PRKDC[72]. On the other hand, cRNAs such as circPRKDC and cirITCH act by inhibiting the activity of the β-catenin pathway[77,78]. The action of most of these molecules is mediated by miRNAs[26,79].

HGF and its receptor RTK Met are associated with β-catenin-related pathways in CRC cells, promoting a CSC phenotype, metastasis, and drug resistance[46,51,80,81]. Other factors including tumor necrosis factor-α (TNF-α) also stimulate the main regulatory mechanism of β-catenin activation in CRC cells. Wei and colleagues demonstrated that under TNF-α action, the CSCs derived from the HT29 cell line increase the survival rate and their invasive capacity *via* the Wnt pathway. These actions are mediated by the modulation of β-catenin related proteins expression, such as c-Myc, cyclin D1, E-cadherin, and vimentin, which are cell cycle regulators associated with the stimulation of cell proliferation and/or the progress of the EMT program[82]. Molecules released from tumor cells including PLD2, modify the secretome of CAFs by promoting the release of the following factors: Macrophage migration inhibitory factor (MIF), HGF, and CCL2. The results shown in this article confirm that the treatment of CRC-derived cells (HCT116 and LS180) with these three factors induces the activation of the Wnt/β-catenin signaling pathway. The authors of this work observed a reduction of β-catenin phosphorylation together with an increase in its total expression after treatment with CCL2, HGF, and MIF, as well as a decrease and an increase in the expression of Axin1 and c-Myc, respectively, consistent with Wnt activation. This research also demonstrated that gene transcription induced by the Wnt signaling pathway correlates with high expression of PLD2 and CAFs-derived factors in CRC patients [38].

Osteopontin (OPN) is another factor that plays an important role in the regulatory mechanism of β-catenin. It is a glycoprotein synthesized by a great variety of cells and is overexpressed in CRC. This protein is capable of activating β-catenin *via* Akt and subsequently GSK3β, or by recruiting and activating mitogen-activated protein kinase (MAPK)[83,84]. Youssef and Osman analyzed tumor samples and found an association between the expression of nuclear OPN/β-catenin and markers related to poor prognosis in CRC[85]. In the last decade, an association has also been established between OPN expression and the activation and nuclear translocation of β-catenin in other types of cancer[83,84]. Recent research has shown that this protein is a target gene of the Wnt pathway[86] and in these cases, positive feedback from the system can be generated. Based on the evidence analyzed in the previous lines, positive feedback is highly probable between OPN secretion and the modulation of the Wnt/β-catenin pathway in CRC.

Other cytokines and growth factors released by the TME cells promote activation of the canonical Wnt pathway in cells derived from human CRC[87]. Bone morphogenetic proteins (BMPs) are cytokines closely linked to angiogenesis, EMT program, and induction of CSCs[88]. Voorneveld and colleagues transfected HCT116, HT29, LS174T, RKO, and SW480 cells with the BMPR2 plasmid, increasing BMP signaling. Hyperactivation of this pathway only downregulated Wnt signaling in HCT116 and LS174T cells, both were SMAD4-positive and had wild type p53. In the remaining cell lines, the Wnt pathway was activated by BMP signaling. This work demonstrated that modulation of Wnt/β-catenin signaling

by the BMP pathway is dependent on SMAD4 and p53 status[5,50]. Regarding the role of interleukins (ILs), neoplastic cells promote the release of IL-1β, mainly from TME macrophages. In HCT116 cells, this cytokine induces β-catenin activation and consequently the expression of target genes, through nuclear factor kappa B (NF-KB)/Akt signaling pathway[87,89]. IL-6 secreted by TME cells induces activation of the Wnt/β-catenin pathway through the signal transducer and activator of transcription 3/extracellular signal-related kinase (ERK) pathway favoring the promotion of the aggressive phenotype of SW48 cells [90]. Chemokines such as C-X-C Motif Chemokine Ligand 12 (CXCL12) are overexpressed in CRC. Song *et al*[91] showed that the increased expression of this cytokine and its receptor (CXCR4) in tumor cells induces activation of the canonical Wnt pathway, possibly mediating the processes of proliferation, survival, and invasion[91]. However, not all cytokines act by promoting aberrant activation of the Wnt pathway. IL-37 mainly expressed by TAMs[92] has been observed to inhibit the proliferation, migration, and CSC phenotype by directly repressing the expression of β-catenin and consequently its translocation to the nucleus[49].

Bacteria, fungi, and viruses constitute the microbiota residing within the gastrointestinal tract. However, the gut microbiota and their metabolites can be altered in the TME and directly influence CRC progression[93,94]. Various bacteria have been implicated in these processes by modulating the β-catenin pathway. *Fusobacterium nucleatum* is a CRC inductor and suppressor of NK cell activity[93,95] Recently, it was reported that *F. nucleatum* can stimulate annexin A1 protein, specifically expressed in CRC cells. Then annexin A1 can induce β-catenin nuclear accumulation and finally the exacerbation of CRC cell proliferation[96]. On the opposite side, as extensively analyzed by Li *et al*[93] in their review article, other bacteria could be beneficial for CRC treatment or its prevention. For example, *Lactobacillus* and *Clostridium butyricum* are probiotics that have inhibitory effects on CRC progression *via* modulation of the β-catenin pathway[93]. This background shows that the complex interrelations between tumor cells and their microenvironment (including the microbiota) involve the participation of one of the most outstanding signaling pathways in the promotion and development of CRC, the β-catenin pathway. Therefore, it is important to consider these phenomena in the development of new treatments that focus on inhibiting or silencing the activators/exacerbators of this pathway.

ROLE OF β-CATENIN AND THE TME IN THE CHEMORESISTANCE OF CRC

Among the most used chemotherapeutic drugs, approved as first- and second-line adjuvants in CRC, are 5-FU, irinotecan (CPT-11), OXA, capecitabine, and leucovorin[97,98]. Depending on the CRC subtype, these drugs are also used in combination with monoclonal antibodies, such as bevacizumab or cetuximab[5]. On certain occasions, signs of a poor prognosis appear. Therefore, neoadjuvant or adjuvant chemotherapy must be implemented[99]. Despite this, patients with advanced grades of metastatic disease continue to lag far behind in successful treatment. One of the main causes of failure in treatment is the chemoresistance observed in about half of patients with CRC[99,100]. In this regard, the cell responses that mediate drug resistance are associated with hypoxic conditions, autophagy, induction of the CSC phenotype, and the EMT program[101,102]. At the molecular level, the development of drug-resistant tumors involves alterations of Wnt/β-catenin among other important signaling pathways such as Hedgehog and Notch. It also includes disturbances in the expression of anti-apoptotic proteins, the overexpression of drug transporters of the ATP-binding cassette (ABC) family, increased aldehyde dehydrogenase 1 enzyme activity and also the release of factors from the TME[99, 103]. Regarding the Wnt pathway, its aberrant activation involves induction of the CSC phenotype, the EMT program, the expression of proteins from the ABC family and factors from the TME, all of these events being related to drug resistance[99]. Furthermore, various biological mediators released by stromal cells are capable of inducing chemoresistance through the Wnt/β-catenin pathway in tumor cells[9,25,104]. In this regard, *in vitro* studies made by Hu and colleagues revealed that miR-92a-3p secreted from CAFs activates the Wnt/β-catenin signaling, decreasing the sensitivity to the combination of 5-FU/OXA in SW480, SW620, and Lovo CRC-derived cells[24]. Moreover, *in vivo* studies have demonstrated that exosomes secreted by fibroblasts can load Wnt ligands, thus promoting CSC features and resistance to 5-FU or OXA. On the contrary, the inhibition of Wnt release reverted the observed effects[57]. CAFs are capable of inducing drug resistance by transferring small nucleic acid molecules such as H19 or CCAL lncRNA and activating β-catenin in neighboring cells[25]. H19 lncRNA can also trigger autophagy *via* SIRT1 and consequently induce resistance to 5-FU in CRC cells[105]. Other miRNAs such as miR-27[106], miR-103, and miR-107 decrease the sensitivity of HCT116 cells to 5-FU and OXA, through hyperactivation of the β-catenin pathway[9]. Zhou and colleagues reported that the inhibition of the Wnt/β-catenin signaling pathway by the overexpression of miR-506 decreases the chemoresistance response of HCT116 cells to OXA. The mechanism that explains this effect is that the gene and protein expression of the transporter of the ABC family and multidrug resistance protein 1/P-glycoprotein are blocked[107]. Several cRNAs are also involved in the acquisition of drug resistance by CRC cells through modulation of the β-catenin axis. For instance, circ-PRKDC participates in the development of chemoresistance to 5-FU in SW620 and SW480 cell lines by regulation of miR-375 and the Wnt/β-catenin pathway[77]. These molecules constitute a novel target for the development of

alternative therapies for CRC, given their role in the communication between tumor cells and the TME and their participation in the regulation of Wnt/β-catenin[26,108].

Macrophages also play a crucial role in the development of resistance to drugs. IL-1β released by TAMs activates the canonical Wnt pathway through NF-κB/Akt and subsequently induces the expression of genes associated with chemoresistance. This has been observed in several cell lines derived from CRC such as HCT116, Hke-3, SW480, and RKO[109,110].

In our laboratory, we previously reported that PTHrP, acting as a cytokine, induces chemoresistance to CPT-11 through ERK MAPK and Akt pathways in the CRC cell lines Caco-2 and HCT116[34]. Moreover, as described in previous sections, we also registered nuclear β-catenin nuclear-increased expression after PTHrP treatment in CRC cells[37]. In view of these data, we hypothesize that this protein also participates in the resistance to CPT-11. This is our current research focus.

Growth factors are also involved in the therapy resistance mediated by β-catenin. Activation of the c-MET pathway through HGF signaling is related to drug resistance in many types of tumors[111]. Several works have already shown that HGF is associated with both Met and β-catenin pathways[52,54]. Studies published by Woo and collaborators showed that this factor is related to resistance to CPT-11 in CRC cells[112]. Since the HGF/Met axis plays an important role in CRC, molecules such as inhibitors, neutralizing antibodies, and antagonists of this pathway have been designed. To date, preclinical trials have failed and demonstrated poor efficacy[111,113]. One of the possible causes of the resistance of CRC cells to HGF pathway inhibitors is the activation of the Wnt/β-catenin signaling pathway[113]. All of these data highlight the need for consideration of the mitogenic pathways and paracrine factors released by both the tumor and the TME as targets to revert the chemoresistance.

Li *et al*[114] made a relevant contribution in the field of basic sciences related to CRC therapy and TME cells. They observed that the pharmacological treatment of CAFs inhibits their recruitment and increases the sensitivity of tumor cells to OXA[114]. Chemotherapy combined with treatments that inhibit CAFs recruitment and/or their activity may represent a novel method for the improvement of tumor response to chemotherapy[114]. This area of research is practically vacant and needs to be further explored since other unknown factors derived from TME may be able to stimulate the nuclear translocation of β-catenin and modulate the events related to the chemoresistance of CRC cells.

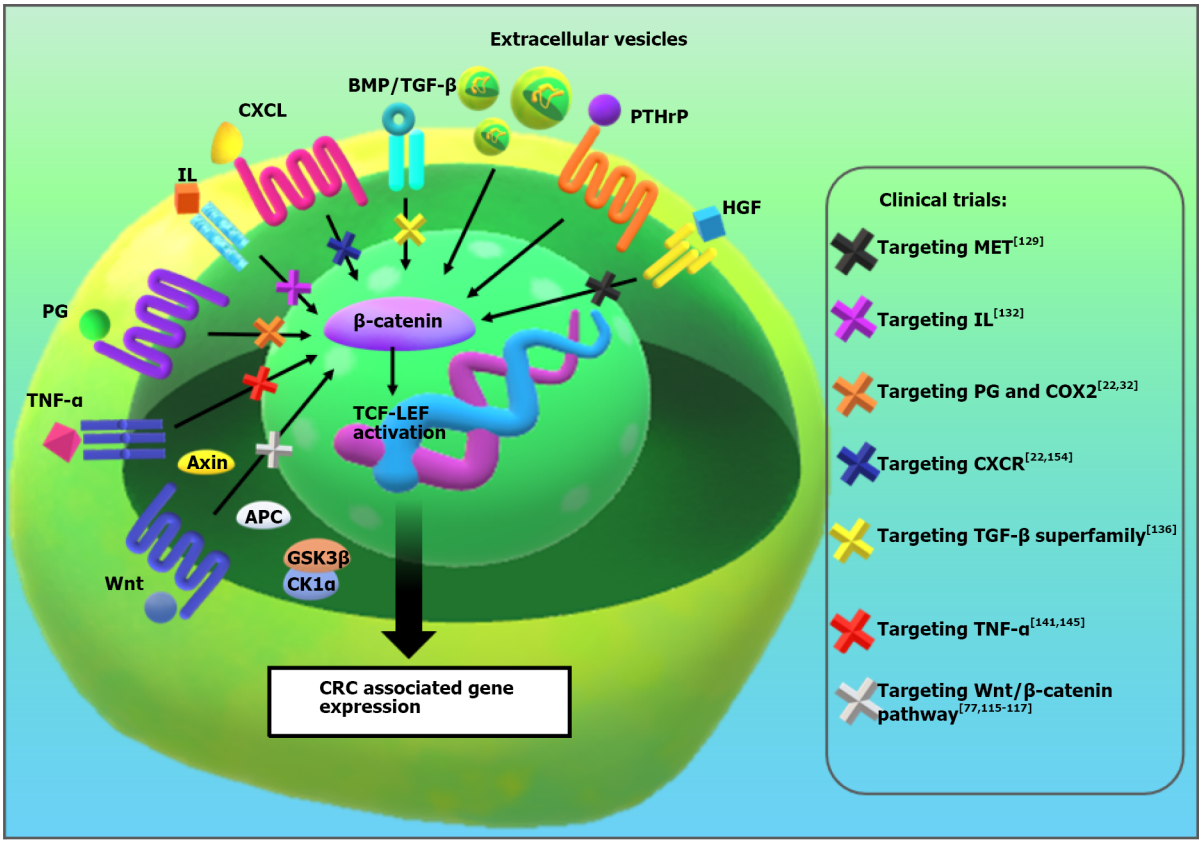
THE TME AND β-CATENIN PATHWAY: FUTURE PERSPECTIVES FOR CRC MANAGEMENT

In the last decade, therapeutic inhibition of the β-catenin pathway has been considered an invaluable tool for developing new therapy regimens for patients with CRC[115-117]. Despite this, as previously stated, there are still no approved drugs for the treatment of CRC or clinical trials based on the targeting of this signaling pathway[15,117]. For these reasons, comprehension of the regulatory mechanisms of the Wnt/β-catenin signaling pathway will not only expand the knowledge about the pathogenesis and evolution of CRC but also improve the treatment with the implementation of new targeted therapies. Many small molecules with β-catenin inhibitory effects have been developed such as tankyrase inhibitors (TNKSi), R-spondin inhibitors, and porcupine enzyme inhibitors. tankyrases (TNKSs) favor Wnt signaling by inducing Axin degradation. Therefore, TNKSi including XAV939 (XAV), JW55, NVP-TNKS656, and GOO7-LK are effective approaches for inhibiting this pathway in the preclinical stage of validation[118,119]. Moon and collaborators recently discovered that β-catenin expression influences the response of CRC-derived cells to MEK inhibitors, and that TNKSi allows the resistance to this treatment to be exceeded in CRC cell lines with mutant KRAS and PI3K. These results demonstrate the possible efficacy of combined treatments with inhibitors of MEK and β-catenin signaling pathways. However, this kind of therapeutic strategy is not yet in the clinical trial phase[118], and there is even controversy on the implementation of this type of scheme[116]. Drugs that disable enzymes related to Wnt secretion are another possibility to inhibit the Wnt/β-catenin. These compounds are denominated IWP-2, LGK974, or ETC-159 and inhibit porcupine enzyme actions. Some R-spondin inhibitors, such as OMP-131R10 (rosmantuzumab), are also currently under investigation for the treatment of CRC. When this ligand binds to the receptor leucine rich repeat containing G protein-coupled receptor 4 (LGR4) or LGR5, it enhances Wnt signaling, so blocking this point would consequently decrease the transcriptional activity of β-catenin[119].

One of the therapeutic targets that is being studied for CRC treatment is the use of antibodies or small molecules for the inhibition of Wnt ligands, like OMP-54F28, OMP-18R5, and OTSA101[116]; the disruption of the transcriptional activity of β-catenin using small molecules that prevent the binding of this protein with the nuclear transcription factors TCF and LEF, such as LF3 and 2,4-diaminoquinazoline; or pharmacological drugs that stimulate β-catenin proteasomal degradation as MSAB[119,120].

In addition to the hyper-activating mutations affecting the β-catenin pathway in CRC, as previously mentioned, cross-communication through paracrine signals between tumor cells and TME cells amplify these effects. The Wnt/β-catenin pathway is key for immune cells differentiation and functioning[120], the aberrant activation of this signaling alters the activation and downregulation of the immune

response, especially related to dendritic cells (DCs) and T cells[119]. In the TME, the β-catenin pathway-dependent production of cytokines, such as IL-10, by DCs has been shown to induce immune tolerance through CD4+ and CD8+ T cells[121]. Moreover, it was reported that β-catenin signaling is activated in tumors with an inflammatory microenvironment, immune evasion and poor infiltration of CD8+ T cells [119,122,123]. In CRC, this immune response is favored by the activation of β-catenin, Myc, and RAS[7, 124,125]. Currently known mechanisms that mediate immune exclusion and evasion through the Wnt/β -catenin pathway are: Modulating the production and release of cytokines from DCs and consequently diminishing CD8+ T cells infiltration; stimulating the production and release of soluble factors like Snail and IL-1β from tumor cells and TAMs, respectively; and increasing regulatory T cells survival, which are also effective inhibitors of CD8+ T cells[120,126]. To date, there are some inhibitors related to the immune response that are approved for clinical use, one of them is programmed death-1[127]. However, although immunomodulation can be effective in the treatment of CRC, resistance often occurs. Given that several of these drugs target CD8+ T cells, one of the explanations for the failure of these therapies may be the hyperactivation of the β-catenin pathway in the TME[128]. From this point of view, the current research focuses on the importance of the development of anticancer therapies that target the Wnt/β-catenin pathway as a checkpoint to improve the efficacy of immunotherapies, mainly by restoring T-cell infiltration[119,120,122].



In previous sections, we described the role of several TME-derived factors that activates the β-catenin signaling pathway. Currently, clinical research is aimed at blocking or inhibiting the effects of these molecules on CRC. In our laboratory, we have found that the selective inhibition of the HGF receptor, the RTK Met, suppresses β-catenin phosphorylation at domains that favor its nuclear translocation induced by PTHrP. Concerning this, Rimassa and his research group[129] explored in a clinical phase II study the effect of an oral selective Met inhibitor (tivantinib) and found that, in combination with another drug, at least 10% of patients with CRC respond better to the therapy. This drug is a possible emerging treatment that is already in phase III study in other types of tumors[130]. Another drug that inhibits the activity of the Met receptor by inducing the degradation of β-catenin is celecoxib[116]. However, recent evidence indicates that the combined treatment of celecoxib with the usual chemotherapy did not improve overall survival or progression-free time in patients with CRC[131].

On the other hand, a large number of clinical trials have been developed using cytokine-based immunotherapy for CRC. Different drugs targeting IL, prostaglandins, CXCL, TNF-α and TGF-β superfamily factors are in clinical trials. Although it has not yet been proven that they generate an effect as monotherapy or in combined treatments with commonly used drugs, future expectations are very optimistic[132,133].

Employing non-coding RNA such as miRNAs or cRNAs is a promising solution to overcome CRC drug resistance. It has been seen that miR505, miR199a/b and miR320 decreased sensitivity to cisplatin and OXA by modulating the activity of the Wnt/β-catenin pathway. Others, such as miR30-5p, favor chemosensitivity in CRC cells[134]. In this work, we have also described the role of TME-derived cRNAs in activating the β-catenin signaling pathway and its influence on CRC development and progression. Nevertheless, there is still a lot to explore about its potential role in future therapies for CRC. In this regard, recent research indicates that knockdown circ-PRKDC decreases the resistance of CRC-derived cells to 5-FU by modulating the Wnt/β-catenin pathway[77]. These results could postulate a new strategy to deal with multidrug resistance in CRC. Additionally, Viralippurath and collaborators propose that gene therapy could be aimed at silencing these oncogenic cRNAs or increasing the effects of those molecules that act as tumor suppressors[26]. Despite these findings, to date, there are no available therapies that use these small molecules to evade the strategies of tumor cells against chemotherapeutic drugs. More studies are needed regarding the role of non-coding RNAs in CRC chemoresistance as well as for the development of delivery strategies for these molecules in new targeted therapies. Figure 4 schematizes current studies related to the disruption of the interrelationships between TME and CRC cells that trigger β-catenin activation and are involved in treatment failure.

As previously mentioned, autophagy is a mechanism associated with chemoresistance in CRC[105]. Recent investigations aim to find drugs that help reverse the autophagy process and overcome chemoresistance in CRC[135]. According to Pérez-Plasencia *et al*[62], the involvement of Wnt/β-catenin signaling in the regulation of autophagy was demonstrated in several types of cancer, such as leukemia, hepatocarcinoma, squamous cell carcinoma, lung cancer and prostate cancer[62]. However, it is just a matter of time before the relationship between these two pathways in CRC will be considered crucial for future pharmacological treatments. In their work, the authors postulate several therapeutic approaches based on drugs that are capable of simultaneously disrupting components of β-catenin and autophagy pathways[61].

From what we have analyzed in this work, it is important to highlight that concerning CRC, the achievement of successful future therapies will involve the use of combined pharmacological compounds that inhibit not only the canonical β-catenin signaling pathway but also the TME- derived signaling.

Figure 4 Pharmacological targeting of the tumor microenvironment factors involved in the activation of β-catenin signaling in colorectal cancer. Several therapeutic strategies to block or inhibit the induction of the β-catenin pathway by tumor microenvironment factors in colorectal cancer (CRC) are currently under clinical study. This figure is original for this work. APC: Adenomatous polyposis coli; BMP: Bone morphogenic protein; CK1α: Casein kinase 1 alpha; CXCL: C-X-C motif chemokine ligand; GSK3β: Glycogen Synthase Kinase 3 Beta; HGF: Hepatocyte growth factor; IL: Interleukin; PTHrP: Parathyroid Hormone-related Peptide; PG: prostaglandin; TCF/LEF: T-cell factor/lymphoid enhancer factor; TGF-β: Transforming growth factor-beta; TNF-α: Tumor necrosis factor-α; Wnt: Wingless protein.

CONCLUSION

The cells of the TME are mainly responsible for triggering the mechanisms that determine a worse prognosis of cancer disease. These cells and the biological mediators released in the neoplastic context regulate the expression of ligands and modulate the activity of pro-tumor signaling pathways. TME cells control the fate of the tumor cells through permanent bidirectional communication. It is known that a considerable proportion of CRC patients evolve unfavorably due to chemoresistance. To improve CRC therapies, it is necessary to expand the knowledge about the mechanisms that play a critical role in the development, progression and chemoresistance of CRC.

Given that the factors associated with the TME activate the β-catenin signaling pathway, it will be possible in the future to improve the response of CRC patients to treatment. This goal could be achieved through new therapeutic interventions based on interrupting the crosstalk between the stroma and the tumor that control the β-catenin pathway activation. From the exhaustive search of the bibliography made by the authors of this work, it is concluded that there are multiple vacant areas in the research related to chemoresistance induced by cells from the tumor environment. Even to date, new types of biomarkers are continuously identified and related to a worse prognosis and aggressiveness of CRC. For this reason, it is imperative to strengthen *in vitro* and preclinical studies to support clinical trials in order to achieve novel therapeutic approaches considering the background of each patient and personalized medicine.

ACKNOWLEDGEMENTS

The authors would like to thank Antonela Rossi Bertone for her helpful advice. Being a teacher of English graduated from Instituto Superior Juan XXIII (from Bahia Blanca city, Argentina) and currently working at San Cayetano school (in the same city), she revised the paper and made useful comments as

regards the spelling, grammar and punctuation of this manuscript. MBND and MJM thanks CONICET for the fellowships.

Abstract

Baicalin is a natural bioactive compound derived from *Scutellaria baicalensis*, which is extensively used in traditional Chinese medicine. A literature survey demonstrated the broad spectrum of health benefits of baicalin such as antioxidant, anticancer, anti-inflammatory, antimicrobial, cardio-protective, hepatoprotective, renal protective, and neuroprotective properties. Baicalin is hydrolyzed to its metabolite baicalein by the action of gut microbiota, which is further reconverted to baicalin *via* phase 2 metabolism in the liver. Many studies have suggested that baicalin exhibits therapeutic potential against several types of hepatic disorders including hepatic fibrosis, xenobiotic-induced liver injury, fatty liver disease, viral hepatitis, cholestasis, ulcerative colitis, hepatocellular and colorectal cancer. During *in vitro* and *in vivo* examinations, it has been observed that baicalin showed a protective role against liver and gut-associated abnormalities by modifying several signaling pathways such as nuclear factor-kappa B, transforming growth factor beta 1/SMAD3, sirtuin 1, p38/mitogen-activated protein kinase/Janus kinase, and calcium/calmodulin-dependent protein kinase kinaseβ/adenosine monophosphate-activated protein kinase/acetyl-coenzyme A carboxylase pathways. Furthermore, baicalin also regulates the expression of fibrotic genes such as smooth muscle actin, connective tissue growth factor, β-catenin, and inflammatory cytokines such as interferon gamma, interleukin-6 (IL-6), tumor necrosis factor-alpha, and IL-1β, and attenuates the production of apoptotic proteins such as caspase-3, caspase-9 and B-cell lymphoma 2. However, due to its low solubility and poor bioavailability, widespread therapeutic applications of baicalin still remain a challenge. This review summarized the hepatic and gastrointestinal protective attributes of baicalin with an emphasis on the molecular mechanisms that regulate the interaction of baicalin with the gut microbiota.

Key Words: Baicalin; Biotransformation; Gut microbiota; Hepatobiliary and gastrointestinal disorders; Signaling pathways

Core Tip: Baicalin possesses therapeutic efficacy against hepatic and gastrointestinal diseases including hepatic fibrosis, xenobiotic-induced liver injury, fatty liver disease, viral hepatitis, cholestasis, ulcerative colitis, hepatocellular and colorectal cancer. The drug action is mediated through its interaction with the gut microbiota, modulation of several signaling pathways, and inflammatory factors. The limitations of low solubility, permeability, and bioavailability pose challenges in the therapeutic applications. The different modes of drug delivery used in the transport of baicalin for ready absorption have paved the way for its use as a pharmacological agent against hepato-intestinal disorders.

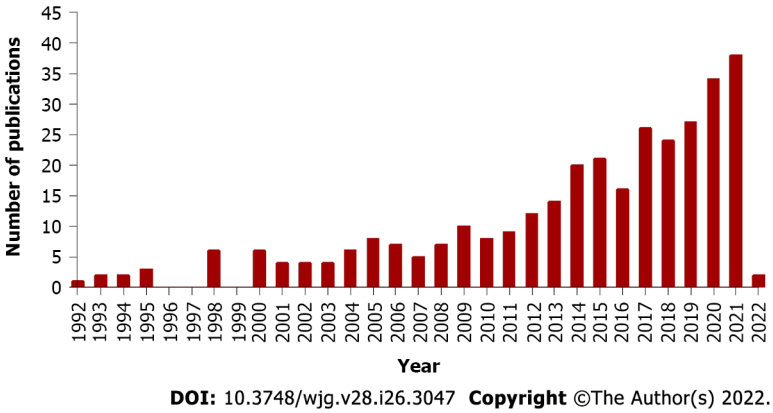
INTRODUCTION



The liver is the largest and central digestive organ in the body, which plays a vital role in several physiological processes including growth, nutrition, immunity, and metabolism of xenobiotics[1-3]. The hepatobiliary system mainly consists of the liver, and intra-hepatic and extra-hepatic bile ducts including the gall bladder. The liver in association with the intestine plays an essential role in digestion with the help of digestive enzymes, which facilitate the breakdown of larger biomolecules into simpler forms such as monosaccharides, amino acids, fatty acids, and glycerol. The intestinal microbiota also interacts with bile and other digestive juices, aiding the process of digestion. The complex network of molecular pathways and signal molecules that are involved in the functioning of the hepatobiliary system are also part of the immune cascade[4-6]. Therefore, any disruption in the gastrointestinal (GI) tract or gut microbiota results in the generation of an inflammatory response. Hepatic disorders such as fibrosis, viral hepatitis, non-alcoholic fatty liver, cirrhosis, cholestasis, and hepatocellular carcinoma (HCC) can be identified by alteration in the levels of inflammatory cytokines such as tumor necrosis factor-alpha (TNF-α), interleukin-6 (IL-6), IL-1β, and nuclear factor-kappa B (NF-κB)[7,8]. Researchers in the past two decades have found numerous natural compounds, which have the ability to interact with the gut microbiome and aid in the treatment of diseases of the hepatobiliary system[9,10]. Natural products and their derivatives form a group of compounds known as secondary metabolites produced by the plants. Several such metabolites such as silymarin, ellagic acid, phyllanthin, rutin, and glycyrrhizin have been used to treat hepatic fibrosis, viral hepatitis, fatty liver disease, and cirrhosis[11, 12].

Baicalin (5, 6-dihydroxy-7-O-glucuronide) is a flavonoid isolated predominantly from the roots of *Scutellaria baicalensis* (*S. baicalensis*), a Chinese medicinal herb that belongs to the family Lamiaceae and is widely known as Chinese skullcap[13]. The roots of *S. baicalensis* also contain several other significant bioactive molecules such as baicalein and wogonin[14]. Numerous *in vitro* and *in vivo* studies have indicated different pharmacological properties of baicalin, which include anti-oxidative, antiviral, anti-inflammatory, cardioprotective, hepatoprotective, neuroprotective, and pro-apoptotic properties. These biological activities can be attributed to the ability of baicalin to target multiple pathways and bind with several signaling molecules[15-18]. In addition, baicalin possesses anti-obese, antidyslipidemia, and pro-apoptotic effects, which help to improve hepatic function after injury, alleviate liver diseases due to alcohol abuse, and promote apoptosis of proliferating hepatocytes[19].

In the last two decades, there has been growing interest and research on the hepatoprotective and anticancer properties of baicalin indicated by the increasing number of publications on PubMed. In recent years (2017 to present), there has been a remarkable rise in the number of research and review articles on the biological potential of baicalin as shown in Figure 1. This review gives an account of the therapeutic effects of baicalin exerted on the hepatobiliary system and the mitigation of GI and liver-associated disorders. The use of baicalin alone or in combination with drugs in several *in vitro* and *in vivo* experiments in the last two decades, impact of baicalin on the gut microbiota, its interaction with molecules and receptors at different molecular pathways, and the range of doses at which baicalin has shown maximum activity have also been discussed.

SOURCES OF BAICALIN

Baicalin is the most abundant and important bioactive ingredient obtained from the roots of the

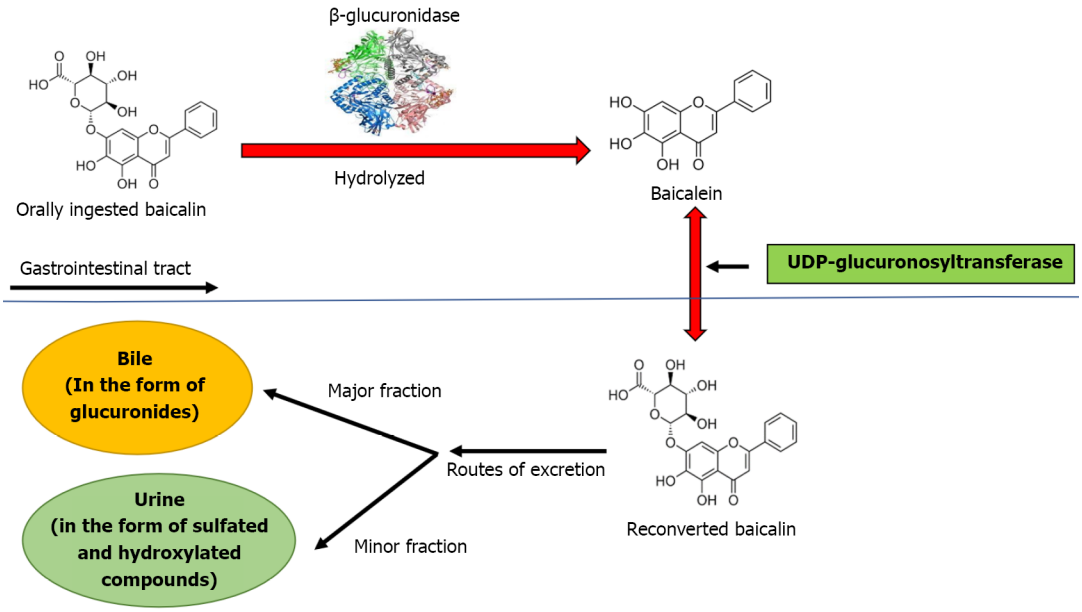
Figure 1 Increasing trend of publications on "hepatoprotective and anticancer properties of baicalin" indexed by PubMed.

medicinal plant *S. baicalensis*[20]. The roots of *S. baicalensis* possess baicalin in the range of 8% to 15%. Baicalin is also the main component of other species of *Scutellaria* such as *S. rivularia*, *S. galericulata*, and *S. lateriflora*[21,22]. Baicalin, chrysin, and its glucoside derivatives have also been obtained from various other parts of the popular Asian medicinal plant *Oroxylum indicum*, belonging to the family Bignoniaceae[23]. Baicalin, and its aglycone baicalein, are gaining increasing importance in the pharmaceutical, food, and cosmetics industries due to their remarkable biological properties. Baicalin and baicalein, in particular, have shown anti-inflammatory effects and the potential to ameliorate mitochondrial dysfunction[24], and combination strategies with baicalin or baicalein as chemotherapy adjuncts have been shown to be effective in various cancers and associated signaling pathways[25]. Due to growing interest in the properties of baicalin as a potential therapeutic agent, many studies in last few years have focused on developing appropriate techniques for the identification and quantification of baicalin in raw drug formulations including simple thin layer chromatography, and different modifications of the sophisticated technique of high-performance liquid chromatography[26,27].



CHEMISTRY AND BIOAVAILABILITY

Baicalin is a flavone glycoside (molecular mass = 446.4 g/moL; melting point = 202-205 °C), which is hydrolyzed to its aglycone baicalein in the stomach after ingestion. Baicalin is hydrolyzed to baicalein immediately after administration with the help of β-glucuronidase from gut bacteria. Baicalein is reconverted to baicalin in the systemic circulation by uridine 5'-diphospho(UDP)-glucuronosyltransferase-glucuronosyl transferase *via* phase 2 metabolism[21]. It is noteworthy that the circulating baicalin in the system is not the parent molecule but the conjugated metabolite of baicalein. Circulating baicalin returns to the GI system primarily by bile excretion in the form of glucuronides. The bile excretion of baicalin is mainly mediated by the multidrug resistance (MDR) protein 2 transporter. When baicalin and baicalein are given orally, the conjugated metabolites actually contribute to the *in vivo* effect because the glucuronide/sulfate of baicalin circulates predominantly in plasma[25]. Baicalin is moderately absorbed in the stomach and poorly absorbed in the small and large intestines (Figure 2).

PHARMACOKINETICS OF BAICALIN IN THE GI SYSTEM

The pharmacokinetic profile of baicalin in the GI system involves hydrolysis, enterohepatic recycling, carrier-mediated transport, and complex routes of metabolism with the interaction of gut microbiota. Baicalin administration is safe and endurable, and no evidence of liver or kidney toxicity has been recorded. The main obstacles to the clinical use of baicalin are its low water solubility (approximately 67.0 μg/mL) and bioavailability. Several nano-techniques such as solid nanocrystals, nanoemulsions, and lipid-based solid nanoparticles have been used to improve baicalin lysis, thus improving bioavailability[28-30]. Incomplete absorption in the GI system has emerged as the main barrier to bioavailability [31]. MDR protein 2 is the most important transporter of baicalin, which mediates bile outflow to hepatocytes[32]. In fact, biliary excretion of baicalin in rats with MDR protein 2 deficiency is significantly reduced with a significant increase in plasma baicalin levels[33]. Baicalin is also capable of crossing the blood-brain barrier and may be protective against a variety of neurodegenerative diseases [34,35].

β-glucuronidase and UDP-glucuronosyltransferase are important metabolic enzymes involved in the *in vivo* transformation of baicalin. In fact, five bile metabolites have been identified in rat liver after

DOI: 10.3748/wjg.v28.i26.3047 **Copyright** ©The Author(s) 2022.

Figure 2 Biotransformation of baicalin after oral ingestion. Orally administered baicalin is hydrolyzed to baicalein by β-glucuronidase. Further, baicalein is reconverted to baicalin by uridine 5'-diphospho-glucuronosyltransferase in intestine. The major part of baicalin excretion takes place *via* the biliary route in the form of glucuronides, and a small fraction of baicalin is excreted *via* urine in the form of sulfated and hydroxylated compounds. UDP: Uridine 5'-diphospho.

baicalin administration. The main metabolites include baicalein 6,7diβ-glucopyranuloside and 6oβ-glucopyranuronosyl baicalein-7 sulfate. These conjugated metabolites are hydrolyzed to baicalein in the GI tract by β-glucuronidase/sulfatase. Thirty-two baicalin metabolites have been reported in plasma, urine, and other rat tissues using more efficient approaches[36,37]. In terms of tissue distribution, liver and kidney contain most of the metabolites, indicating that these are the major sites of baicalin metabolism. Baicalin undergoes multiple chemical transformations *in vivo* including hydrolysis, methylation, hydroxylation, methoxylation, glucuronide conjugates, sulfate conjugates, and their combined reactions[37]. The pharmacokinetics of baicalin may help to understand its therapeutic implications in the liver. As a result of enterohepatic circulation, baicalin remains particularly concentrated in the liver and is thus beneficial in the treatment of hepatic anomalies. Baicalein also plays a crucial role in the treatment of hepatic diseases, indicating that the mechanism of baicalin's emphasis on liver-associated disorders may include the ameliorative effects of the metabolites as well. The major part of baicalin excretion takes place *via* the biliary route in the form of glucuronides, and a small fraction of baicalin is excreted *via* urine in the form of sulfated and hydroxylated compounds[38,39].

AMELIORATING EFFECTS OF BAICALIN AGAINST HEPATIC AND COLORECTAL DISEASES

Fatty liver syndrome

Fatty liver syndrome (FLS) occurs due to excess accumulation of non-esterified fatty acids in the hepatocytes. FLS accounts for approximately one-fourth of all liver-related anomalies in the world[40]. FLS causes several hepatic anomalies such as non-alcoholic fatty liver disease, non-alcoholic steatohepatitis (NASH), and advanced FLS may also lead to cirrhosis and ultimately hepatic failure[17,41]. Due to its antioxidant and hepatoprotective potential, baicalin is effective against FLS and associated diseases. Baicalin improves lipid metabolism and suppresses hepatic lipid production by inhibiting the calcium/calmodulin-dependent protein kinase kinase-β/adenosine monophosphate-activated protein kinase (AMPK)/acetyl-coenzyme A (CoA) carboxylase pathway[42,43]. Additionally, baicalin binds directly to carnitine palmitoyl-transferase-1α (CPT-1α) and promotes the influx of lipid into mitochondria, where it is oxidized[44]. Baicalin also downregulates lipid-producing genes such as fatty acid synthase (FASN), peroxisome proliferator-activated receptor-α (PPAR-α), and sterol regulatory element-binding protein-1c (SREBP-1c) to inhibit lipid accumulation in the liver[42,45]. Baicalin (200 mg/kg) has been found to reduce the expression of TNF-α, monocyte chemoattractant protein (MCP-1) and IL-1β, downregulate caspase-3 to alleviate NASH induced by a methionine- and choline-deficient (MCD) diet. In addition, treatment with baicalin can partially lessen the accumulation of lipids induced by the MCD diet in the liver by modulating the expression of SREBP-1c, FASN, PPAR-α, and CPT-1α

[46]. Moreover, baicalin (50 mg/kg) also reduces the synthesis of inflammatory cytokines including TNF-α, IL-6, and IL-1β, and suppresses the Toll-like receptor 4 (TLR-4) signaling pathways in MCD diet fed mice to inhibit fat accumulation in liver. Thus, baicalin also acts as an anti-inflammatory compound in the attenuation of non-alcoholic FLS[47]. In a study of high-fat diet induced FLS, it was found that baicalin (25-100 mg/kg) exerted a substantial ameliorating effect on FLS by activating the expression of hepatic PPAR-γ receptors[48]. In addition, baicalin (5 g/kg) also alleviates FLS by reducing the levels of serum hepatic enzymes such as aspartate aminotransferase (AST) and alanine aminotransferase (ALT), and inflammatory mediators such as TNF-α and MCP-1. Moreover, baicalin also inhibited the phosphorylation of Janus kinase (JNK), and suppressed the production of inflammatory enzyme cyclooxygenase-2 and pro-oxidative enzyme CYP-2E1 in the liver of a mouse model[49]. In another study of orotic acid-induced FLS, baicalin (12.5-50 mg/kg) downregulated SREBP-1c and upregulated AMPK to reduce the toxic effects of free fatty acids, subsequently inhibiting fat accumulation in the liver [45]. In an *in vitro* study of palmitic acid-induced FLS in AML-12 hepatocytes, baicalin (6.25-25 μM) alleviated FLS by reducing endoplasmic reticulum stress and suppression of the thioredoxin-interacting protein/Nod-like receptor protein 3 pathway[50].

Liver injury

The liver is the most important organ for the metabolism and elimination of toxins from the human body. Normal liver function can be deterred with excessive hepatic injuries, which occur due to a variety of factors including alcohol intake, chemical contaminants, hepatocellular ischemia, and drug damage[50,51]. Liver damage is a complex process that can manifest extensive hepatocellular apoptosis [52]. Baicalin (120 mg/kg) has been shown to alleviate alcohol-induced liver injury in a rat model *via* the reduced expression of inflammatory cytokines such as TNF-α, IL-6 and IL-1β and enhances the activity of antioxidant enzymes such as superoxide dismutase (SOD) and glutathione peroxidase (GSH-Px), which is further regulated by blocking the sonic-hedgehog signaling pathway[19]. Similarly, baicalin (30 mg/kg) has been shown to produce anti-inflammatory effects by downregulating the expression of IL-17 in a rat model with acetaminophen-induced liver injury[53]. Baicalin (80 and 200 mg/kg) activates heme oxygenase-1 *via* the nuclear respiratory factor (NRF)-2 antioxidant pathway and inhibits the activity of reactive oxygen species (ROS) generating enzymes in a liver injury model. Baicalin plays an important role in blocking the combination of NRF-2 and Kelch-like ECH-associated protein 1 (Keap-1) that causes phosphorylation of NRF-2, thus reversing liver damage[54,55]. Furthermore, baicalin (60 mg/kg) also downregulates extracellular signal-regulated kinase (ERK) in acetaminophen-induced liver injury[56]. In addition, baicalin (100 mg/kg) downregulates caspase-3 and caspase-9 and also increases the expression of the anti-apoptotic protein B-cell lymphoma 2 (Bcl-2). This helps to significantly reduce NG-nitro-L-arginine methyl ester-induced liver injury in rats[57].

The therapeutic effect of baicalin on reducing liver damage *via* the apoptotic pathway has also been demonstrated *via in vitro* experiments (Table 1). Baicalin at 100 μmol/L regulates apoptotic proteins such as caspase-3, caspase-9, and Bcl-2 associated X (Bax), and has a considerable therapeutic impact on the hypoxic model of L02 human hepatocytes[58]. Another *in vitro* study with L02 hepatocytes and acetaldehyde-treated HepG2 cells were used to identify the adverse effects of baicalin (20-100 mmol/L) on progression of the epithelial-mesenchymal transition (EMT) in the liver, which is an indicator of liver fibrosis and inflammation. This study demonstrated that baicalin considerably suppressed the progression of EMT by downregulating the transforming growth factor-β (TGF-β)/Smad signaling pathway, thus ameliorating liver damage[59]. Studies have shown that baicalin (60 μM) can repair liver injury in nanosecond pulse electric field (ns-PEF)-induced damage to L02 hepatocytes by stabilizing mitochondrial transmembrane potential and prevent excess ROS production[60]. Furthermore, baicalin (5 and 25 μM) can suppress the oxidation and nitrification of the hemin/nitrite/hydrogen peroxide system and protect HepG2 cells by inhibiting lipid peroxidation and GSH depletion[61]. Another study emphasized that baicalin administration (74 mg/kg) can restore the metabolism of amino acids to normal, improve the tricarboxylic acid cycle and ameliorate acute lipopolysaccharide (LPS)-induced sepsis in mice model[62].

Liver fibrosis

Liver fibrosis occurs due to excess deposition of extracellular matrix proteins and collagen. It is characterized by hepatic tissue degeneration, inflammatory cell infiltration and hepatic cell necrosis[63,64]. It has also been confirmed that activation of hepatic stellate cells (HSCs) plays a central role in liver fibrosis[65]. In the absence of appropriate treatment, advanced liver fibrosis causes chronic hepatitis subsequently leading to liver cancer or cirrhosis[66,67]. In a recent study, it was shown that baicalin (200 mg/kg) decreased the expression of fibrotic genes such as α-smooth muscle actin (SMA) and connective tissue growth factor and inflammatory cytokines such as TNF-α, macrophage inflammatory protein-1α (MIP-1α), IL-1β, MIP-2, thereby effectively suppressing liver fibrosis induced by bile duct ligation (BDL) in mice. In addition, an *in vitro* study also showed the efficacy of baicalin in reducing the activation of HSCs and downregulating the expression of SMA, fibronectin, tissue inhibitor of metalloproteinase-1 (TIMP1) protein andcollagen-1[68]. Similarly, baicalin (150 μM) reduced microRNA (miR)-3595 expression and increased the activity of the enzyme long-chain fatty acid CoA ligase 4, significantly inhibiting the activity of HSCs leading to a reduction in fibrosis in HSCT6 hepatocyte cell lines caused

ACSL-4: Long chain fatty acid CoA ligase 4; AML: Alpha mouse liver; BDL: Bile duct ligation; EMT: Epithelial-mesenchymal transition; ER: Endoplasmic reticulum; GSH: Reduced glutathione; HCC: Hepatocellular carcinoma; HSCs: Hepatic stellate cells; LPS: Lipopolysaccharide; MAPK: Mitogen-activated protein kinase; MTP: Mitochondrial transmembrane potential; NLRP-3: Nod-like receptor protein 3; nsPEF: Nanosecond-pulse electric field; PBMCs: Peripheral blood mononuclear cells; PDGF-BB: Platelet-derived growth factor BB; PPAR-γ: Peroxisome proliferator-activated receptor-γ; ROS: Reactive oxygen species; THLE: Transformed human liver epithelial; TUG-1: Taurine upregulated-1; TXNIP: Thioredoxin-interacting protein.

by platelet-derived growth factor BB[69]. Moreover, baicalin (67.5-270 μM) helps in the reduction of BDL-induced activity of HSCs by inhibiting PPAR-γ *via* Wnt signaling, leading to alleviation of liver fibrosis[70]. Baicalin (100 mg/kg) attenuated carbon tetrachloride-induced hepatic fibrosis in mice by regulating the rise in TGF-β1, hydroxyproline, type III collagen, and hyaluronic acid laminin (Table 2). In addition, baicalin also attenuates liver fibrosis by suppressing the activity of antioxidant enzymes SOD and GSH-Px[71]. Similarly, baicalin (25-100 mg/kg) evidently reduces the level of PPAR-γ, suppresses the activity of HSCs, and downregulates the expression of TGF-β1, causing inhibition of hepatic fibrosis[72].

Cholestasis

Cholestasis is a condition that occurs due to the obstruction or complete blockage of bile secretion through the intrahepatic or extrahepatic bile ducts[73]. Consequently, there is excess accumulation of conjugated bilirubin, bile salts, and cholesterol in the liver, which leads to hepatic injury and damage to the human body[74]. Baicalin plays an important role at several stages to mitigate cholestasis and related hepatic damage. Baicalin specifically targets nuclear factor-erythroid factor 2-related factor 2 (NRF-2) in reversing cholestasis. Recent studies in a mouse model indicate that the interaction of baicalin (50 mg/kg) with NRF-2, inflammatory cytokines, and oxidative stress regulatory elements forms the central pathway of reducing cholestasis induced hepatic damage. Baicalin is capable of activating SMA, TIMP1, and collagen, resulting in amelioration of liver fibrosis due to BDL-induced cholestasis[68]. Another pharmacokinetic study in a rat model indicated that administration of baicalin (50-200 mg/kg) has therapeutic potential for cholestasis. It significantly increases bile excretion rates, which lead to a decline in serum levels of total bile acids as well as hepatic enzymes such as AST, ALT, and alkaline phosphatase in 17α-ethinyl estradiol-induced cholestasis[75,76]. In estrogen-induced cholestasis, it has been shown that baicalin targets NF-κB and inhibits the expression of inflammatory markers such as TNF-α, IL-6, and IL-1β, thereby increasing the activity of hepatic bile acid-metabolizing enzymes. Reports have also shown that baicalin alleviates 17α-ethinyl estradiol-induced cholestasis in mice by suppressing the expression of multidrug resistance protein 2 and bile salt export pump genes *via* the sirtuin 1/nuclear hepatic receptor 1α (HNF-1α)/farnesoid X receptor (FXR) pathway[77].

Hepatitis

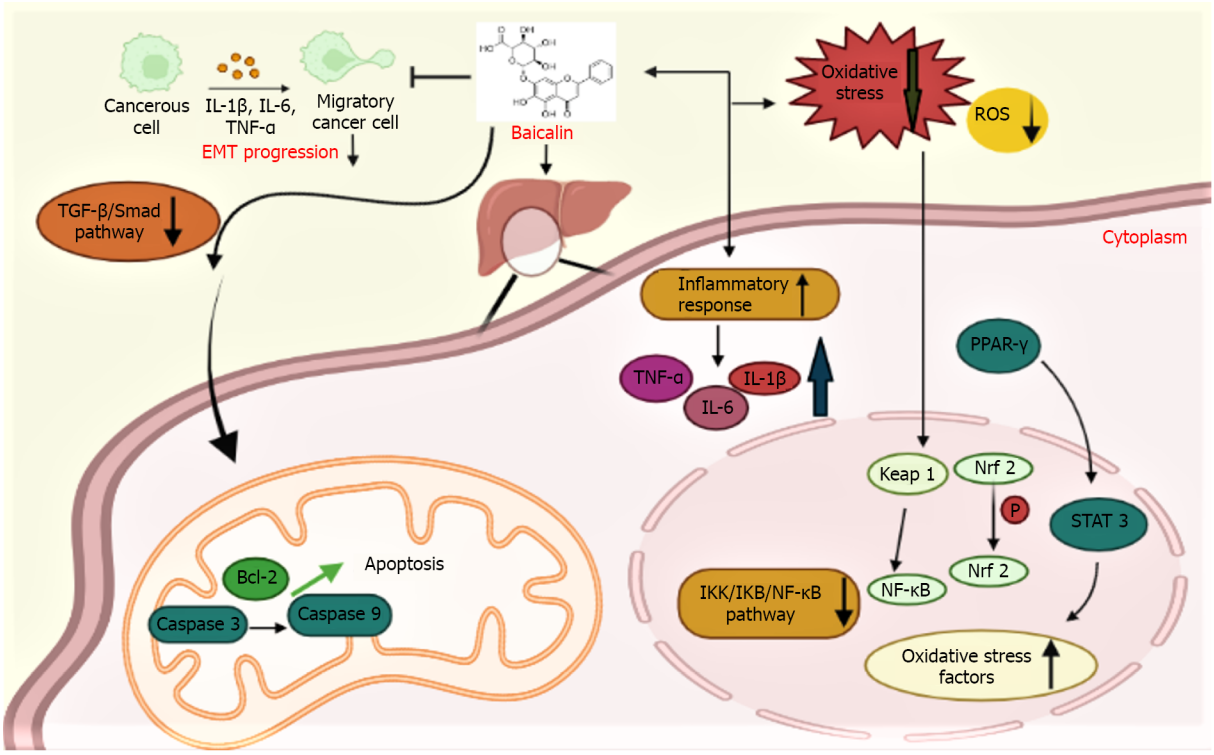
Hepatitis caused by hepatitis A virus (HAV), hepatitis B virus (HBV), and other viral hepatitis are prevalent infectious diseases worldwide[78,79]. Liver-specific proteins and immune complex hypersensitivity have multiple roles in hepatitis[80]. Subsequent studies have proven that baicalin plays a key role in the attenuation of hepatitis by lowering the levels of hepatitis B surface antigen (HBsAg), viral antigen protein hepatitis B e-antigen (HBeAg), and hepatitis B virus (HBV)-DNA, and regulating oxidative stress, inflammation, and apoptosis in hepatic cells[80,81]. It has been found that baicalin (25-100 μM) significantly increases *taurine upregulated 1* gene expression to suppress inflammation and apoptosis by downregulating the p38-mitogen activated protein kinase (MAPK) and JNK signaling pathways in L20 and transformed human liver epithelial cell lines to thwart LPS-induced hepatitis[82]. Another recent study showed that baicalin (75 μg/mL) significantly suppressed HBV replication and inflammation by downregulating the NF-κB signaling pathway in HepG2 and HuH7 cells[83]. Furthermore, it has also been confirmed that baicalin (10 μM) strongly suppresses the transcription of HBV by downregulating the liver-specific HNF-4α/HNF-1α axis in pHBV1.2 HepG2 cells[84]. In another experiment, baicalin (10 μg/kg) significantly reduced HBsAg and HBeAg levels in HepG2 cells, wild-type HBV cells, and young duck models infected with HBV by downregulating the HNF-4α/HNF-1α axis[85]. In addition, baicalin pre-treatment (100-200 mg/kg) attenuated elevated levels of plasma cytokines such as TNF-α, IL-6, and interferon-γ (IFN-γ) in male BALB/c mouse models, resulting in alleviation of hepatocyte necrosis and apoptosis[86]. Similarly in an *in vivo* study, pre-treatment with baicalin (0.5-5.0 mg/kg) considerably reduced serum levels of ALT and AST and lowered hepatic oxidative stress in a male Sprague-Dawley rat model[86]. Another study demonstrated the pro-oxidant properties of baicalin (50-200 mg/mL) by upregulating the mitochondrial signaling pathway in human peripheral blood mononuclear cells, thereby inducing the activation of caspase-3 and apoptosis[87]. Furthermore, baicalin has often been co-administered with other bioactive flavonoids in combination studies, to yield better results at prevention of hepatitis. For instance, combination of the alkaloid oxymatrine (1 g/L) with baicalin showed more efficacy against HBV than oxymatrine alone[88]. Below 31.50 μg/mL, the baicalin-phospholipid complex exhibits direct anti-duck HAV-1 activity by preventing the adsorption, replication, and release of duck HAV-1 and indirectly by promoting immunity in ducklings[89]. Baicalin (20 μg/mL) regulates the immunomodulatory effects and anti-HAV-1 reproduction by reducing the adsorption and release of HAV-1 in duck-suppressed embryonic hepatocytes[90].

HCC

HCC ranks sixth amongst the most common malignant tumors worldwide, and is the fourth highest cause of mortality due to malignancies[91]. The present modes of treatment for HCC include radiation therapy, local resection therapy, surgery, and liver transplantation. However, these treatments typically cause several side effects and have adverse consequences[91,92]. Several studies have reported that baicalin can effectively ameliorate HCC by indirectly inducing autophagy in liver tumor cells. Studies have revealed that baicalin (50 mg/kg) promotes the polarization of tumor-related macrophages into M1-like macrophages, subsequently increasing autophagy in cancerous cells to make them non-proliferating. Additionally, baicalin mediated anti-cancer effects may also be closely associated with activation of the RelB/p52 signaling pathway[93]. Similarly, baicalin (100 μmol/L) promotes apoptosis in HepG2-HCC cells by activating the ER-mediated TF-6 signaling cascade combined with S-2P protein [94]. Moreover, baicalin (160 μM) suppresses cluster of differentiation 47 and activates apoptosis and autophagy in SMMC7721-HCC cells[95]. Although nsPEFs have been developed as a new mode of treatment for cancer, they also result in the elimination of normal hepatocytes. Therefore, a study was designed combining nsPEF and baicalin for the treatment of HCC, which revealed that baicalin suppresses the proliferation of HCC cells, and protects normal liver cells by increasing mitochondrial membrane potential and reducing ROS production[59]. In recent times, cancer immunotherapy has emerged as a significant line of treatment for HCC. Baicalin (40 μM) is capable of reducing the activity of signal transducer and activator of transcription 3 protein and IFN-γ, thereby blocking the programmed death-ligand 1/programmed cell death protein 1 pathway. This increases the sensitivity of the immune system to hepatic cancerous cells and thus further activates T cells against hepatic cancer cells[96,97]. Based on several *in vitro* and *in vivo* studies, the protective effect of baicalin on many hepatic disorders is summarized in Tables 1 and 2.

Colorectal cancer

Colorectal cancer (CRC) is also a common malignant tumor worldwide, and is primarily due to genetic inheritance, colon polyps, and ulcerative colitis (UC)[98,99]. Baicalin, due to its pro-apoptotic properties, results in the killing of CRC cells. Researchers have used the human colon cancer cell line (HCT-166)



and transplanted colon tumors into mice to conduct simultaneous *in vivo* and *in vitro* experiments to examine the antitumor mechanism of baicalin (100 and 200 mg/kg). Baicalin induces apoptosis in colon tumors by inhibiting the cells at the G1 stage and arresting EMT protein expression by blocking the TGF-β/Smad pathway[100]. Baicalin (40 mmol/L) promotes Dickkopf protein expression, suppresses the expression of proteins β-catenin and c-Myc, and inhibits miR-217 expression, thereby leading to the apoptosis of HCT-166 cancer cells by inhibition of the Wnt signaling pathway[101]. Another similar study demonstrated that apoptosis of HT-29 colon cancer cells was induced by baicalin (50-200 μM) *via* inhibition of c-Myc expression and regulation of the miR-10a, miR-23a, miR-31, miR-151a, and miR-205 mechanism[14]. Similarly, it has been reported that the antioxidant properties of baicalin (40 μM) increase progesterone expression in the intestine and leads to the apoptosis of HCT-116 colon cancer cells by activating the Ras/Raf/MEK/ERK pathways[102]. Reports have also shown that the antitumor activity of baicalin can be further enhanced by glycosidase pre-treatment[103]. Several studies have revealed that the development of CRC is closely associated with genetic mutations. In a study on colon cancer cells SW-480, baicalin (50-400 μg/mL) inhibited the expression of the transcription factor SP-1, leading to the apoptosis of cancer cells[104].

Inflammatory bowel disease

Inflammatory bowel disease (IBD) is a collective term that refers to the chronic inflammation of GI tract. The two major types of IBD are Crohn's disease (CD) and UC. CD and UC are nonspecific chronic IBDs that cause inflammation and ulcers on the inner lining of the large intestine[105-107]. Baicalin plays an important role in the treatment of IBD, as it is capable of suppressing oxidative stress, immune regulation, and its anti-inflammatory properties. In addition, baicalin is capable of regulating NF-κB activation, which modulates both autophagic and inflammatory processes in intestinal epithelial cells, subsequently leading to enhancement in paracellular permeability. Baicalin alleviates dextran sulfate sodium (DSS)-induced UC by modulating the polarization of M1 macrophages to the M2 phenotype [107]. Dose-dependent administration of baicalin (30-90 mg/kg) has been found to largely downregulate the inflammatory cytokines IL-1β and TNF-α, and apoptotic genes Bcl-2 and caspase-9 in the colon tissue of rats affected by 2,4,6-trinitrobenzenesulfonic acid (TNBS)-induced UC. In addition, baicalin also inhibits the inhibitory κB (IKB) kinase (IKK)/IKB/NF-κB signaling pathway, leading to the alleviation of IBD[107,108]. Likewise, in another study, rats with TNBS-induced UC were given baicalin (5-20 mg) which resulted in the downregulation of inflammatory factors TNF-α, IL-6 and IL-1β in rat intestine and inhibition of the TLR4/NF-κB signaling pathway, leading to alleviation of UC[109]. Furthermore, baicalin (30-120 mg/kg) has also been effective in the treatment of TNBS-induced UC by promoting antioxidant enzymes such as catalase, SOD and GSH-PX, and reducing malondialdehyde (MDA). Baicalin also suppresses the regulation of apoptosis by upregulating Bcl-2 and downregulating TGF-β and Bax[110]. In a UC model generated by high temperature and humid environment, baicalin (100 mg/kg) significantly reduced the serum levels of IL-6, IL-1β, and IL-17, and inhibited SOD, GSH-PX, and MDA. That study attributed the anti-inflammatory effect of baicalin to suppression of the NF-κB and MAPK pathways[111]. In an *in vivo* study, baicalin (50-150 mg/kg) reduced myeloperoxidase activity, nitric oxide content, and elevated IL-1β, TNF-α and IL-6 levels in the colon of DSS-induced UC rats[112]. Another study revealed that baicalin (100 mg/kg) attenuated DSS-induced UC by blocking the TLR-4/NF-κB-p65/IL-6 signaling pathway and suppressing TNF-α, IL-6, and IL-13 mRNA expression [113]. Furthermore, baicalin (10 mg/kg) downregulated the expression of macrophage migration inhibitory factor, MCP-1 and MIP-3a in the colon tissue of TNBS-induced UC rat model[114]. Several reports have suggested the association of T helper 16 cell (Th17)/regulatory T cell (Treg) equilibrium with UC. Baicalin (20-100 mg/kg) regulates the Th17/Treg balance by inhibiting the rise in ROS and MDA, whereas simultaneously reducing GSH and SOD levels and regulating the expression of Th17-related factors IL-6 and IL-17 in TNBS-induced UC rats[115,116]. In a clinical study of UC patients, baicalin promoted the production of immune cells like CD4+ and CD29+ and induced immunomodulation to alleviate UC[117] (Figure 3).

INTERACTION OF BAICALIN WITH THE INTESTINAL MICROBIOTA

In the past decade, the intestinal microbiota has become an emerging aspect of research for the evaluation of several diseases. Besides playing an important role in the metabolism and breakdown of biomolecules into simpler molecules like fatty acids, amino acids, vitamins and bile salts, the gut microbiota is also capable of interacting with the host and affect the functioning of various organs including the liver and kidney to regulate homeostasis and disease development[5,118]. Baicalin, a flavonoid, exerts many therapeutic effects by modulating gut microbiota homeostasis. Intake of high fat diet causes imbalance of the gut microbiota, leading to several metabolic syndromes. Baicalin administered (200 mg/kg/d) to mice with high fat diet induced metabolic syndrome led to an increase in short-chain fatty acid (SCFA)-producing gut bacteria, thereby effectively reducing the metabolic syndrome in mice[119]. Baicalin also reduces damage to the intestinal barrier caused due to hypertension. A study reported that baicalin (100 mg/kg) significantly increased the number of SCFA-

Figure 3 Mechanism of baicalin action against hepatobiliary diseases. Baicalin downregulated peroxisome proliferator-activated receptor-α and activated the nuclear respiratory factor-2 antioxidant pathway to reduce oxidative stress in the hepatocytes. Baicalin suppressed epithelial-mesenchymal transition progression by downregulating the transforming growth factor-β/Smad pathway, inhibited the inhibitory κB (IKB) kinase/IKB/nuclear factor-kappa B pathway, reduced the elevated levels of inflammatory factors such as tumor necrosis factor-α, interleukin-6 (IL-6) and IL-1β, and attenuated the apoptotic proteins caspase-3, caspase-9, B-cell lymphoma 2, which led to the alleviation of liver diseases. ROS: Reactive oxygen species; STAT: Signal transducer and activator of transcription; PPAR-γ: Peroxisome proliferator-activated receptor-γ; IL: Interleukin; Nrf2: Nuclear respiratory factor-2; TGF-β: Transforming growth factor-β; NF-κB: Nuclear factor-kappa B; TNF-α: Tumor necrosis factor-alpha; Bcl-2: B-cell lymphoma 2; EMT: Epithelial-mesenchymal transition; IKK: Inhibitory κB kinase; IKB: Inhibitory κB.

producing bacteria and altered the intestinal microflora, leading to a reduction in damage of the intestinal barrier in rats caused by hypertension[120]. Another study revealed that baicalin (25-100 mg/kg) helped increase SCFA-producing bacteria such as *Eubacterium* spp, *Subdoligranulum* spp, and *Butyricimonas* spp, thereby ameliorating TNBS-induced UC[114]. In some cases, the gut microbiome can also downregulate the therapeutic efficacy of baicalin[121]. The gut microbiota regulates hepatobiliary homeostasis *via* the gut-hepatic axis, and although it can regulate baicalin activity, baicalin can also modulate the gut microbiota[122]. Consequently, baicalin has the potential to exert a therapeutic role in liver and gut diseases by modulating FXR and TGR5-mediated crosstalk involving bile acids associated with the gut microbiome.

DRUG DELIVERY, CLINICAL TRIAL, AND FUTURE PROSPECTS

The clinical application of baicalin in pharmacology has been challenging, due to its low solubility and bioavailability. In the last decade, many researchers have designed novel delivery strategies for baicalin that include phospholipid complex, liposomes, solid baicalin nanocrystals, and micelle formation[123]. The dissolution and solubility of baicalin is considerably enhanced when administered in combination with other molecules in complex form. For instance, baicalin has exhibited improved oral bioavailability, distribution, targeting, and therapeutic efficacy when combined with polyethylene glycol and folic acid in the form of liposomes. β-Cyclodextrin complex has also been used as an effective formulation to facilitate the effective delivery of baicalin with wide range of therapeutic outcomes[123, 124]. Moreover, baicalin is commonly used as adjuvant therapy for hepatitis. In a clinical study, single dose baicalin (500 mg/kg) in combination with cyclosporin A was found to be safe and well tolerated in adult human subjects without any severe adverse effects[125]. However, the co-administration of baicalin with other herbal formulations or drugs might impede baicalin's *in vivo* actions and consequently its efficacy. Therefore, it is important to thoroughly study the clinically approved doses of baicalin which can be administered in combination with other compounds that help to improve the absorption and effectiveness of baicalin.

CONCLUSION

GI disorders have emerged as the leading cause of mortality in the recent years across the world. Baicalin, a major flavone obtained from *S. baicalensis*, exerts protective effect against hepatobiliary and colorectal disorders by modulating signaling pathways. Further, novel delivery strategies that are used in the transport of baicalin for ready absorption including phospholipid complex, liposomes, solid baicalin nanocrystals, and β-cyclodextrin complex have paved way for its widespread use as a pharmacological alternative in hepatic and GI disorders.

Abstract

Crohn's disease (CD) is driven by the loss of tolerance to intestinal microbiota and excessive production of pro-inflammatory cytokines. These pro-inflammatory cytokines are produced by macrophages and dendritic cells (DCs) upon sensing the intestinal microbiota by the pattern recognition receptors (PRRs). Impaired activation of PRR-mediated signaling pathways is associated with chronic gastrointestinal inflammation, as shown by the fact that loss-of-function mutations in the nucleotide-binding oligomerization domain 2 gene increase the risk of CD development. Autophagy is an intracellular degradation process, during which cytoplasmic nutrients and intracellular pathogens are digested. Given that impaired reaction to intestinal microbiota alters signaling pathways mediated by PRRs, it is likely that dysfunction of the autophagic machinery is involved in the development of CD. Indeed, the loss-of-function mutation T300A in the autophagy related 16 like 1 (ATG16L1) protein, a critical regulator of autophagy, increases susceptibility to CD. Recent studies have provided evidence that ATG16L1 is involved not only in autophagy, but also in PRR-mediated signaling pathways. ATG16L1 negatively regulates pro-inflammatory cytokine responses of macrophages and DCs after these cells sense the intestinal microbiota by PRRs. Here, we discuss the molecular mechanisms underlying the development of CD in the T300A *ATG16L1* mutation by focusing on PRR-mediated signaling pathways.

Key Words: ATG16L1; Crohn's disease; Autophagy; Innate immunity; Cytokine; Pattern recognition receptors

Core Tip: The loss-of-function mutation T300A in autophagy related 16 like 1 (*ATG16L1*) increases the risk of Crohn's disease (CD). ATG16L1 is a multifunctional protein involved in autophagy and innate immunity. The CD-associated *ATG16L1* mutation T300A leads to overgrowth of intestinal microbiota and enhanced pro-inflammatory cytokine responses, which disrupt intestinal immune homeostasis. In this minireview article, we have summarized the immunopathogenesis of CD in the presence of *ATG16L1* mutation.

INTRODUCTION

Pro-inflammatory cytokines, such as tumor necrosis factor (TNF)-α, interleukin (IL)-6, IL-12, and IL-23, underlie the immunopathogenesis of Crohn's disease (CD), as evidenced by the clinical efficacy of targeting these cytokines for the treatment of patients[1,2]. These colitogenic cytokines are produced by macrophages and dendritic cells (DCs) upon sensing the intestinal microbiota by the pattern recognition receptors (PRRs), which are classified into Toll-like receptors (TLRs), nucleotide-binding oligomerization domain (NOD)-like receptors (NLRs), and retinoic acid-inducible gene I (RIG-I)-like receptors (RLRs)[3-6]. Thus, excessive pro-inflammatory cytokine responses caused by PRR activation play critical roles in the development of CD. This notion is fully supported by the identification of loss-of-function mutations in *NOD2* as one of the strongest risk factors for CD. NOD2 is an intracellular PRR that senses muramyl dipeptide (MDP) derived from bacterial cell wall components and negatively regulates TLR-mediated pro-inflammatory cytokine responses[5,6].

Autophagy refers to the process during which cytoplasmic components and intracellular pathogens are delivered to the lysosome for degradation in the form of double-membrane-bound autophagosomes [7]. The autophagy related 16 like 1 (ATG16L1) protein plays an indispensable role in the initiation and completion of the autophagic process. In addition to its role in autophagy, ATG16L1 has been shown to be involved in PRR-mediated innate immunity. ATG16L1 negatively regulates pro-inflammatory and type I interferon (IFN-I) responses mediated by TLRs, NLRs, and RLRs[8]. More importantly, the loss-of-function mutation T300A in *ATG16L1* has been identified as a risk factor for CD in parallel with mutations in *NOD2*[6]. In this minireview article, we summarize the molecular mechanisms by which the T300A mutation in *ATG16L1* predisposes the host to CD development by focusing on the regulatory role of ATG16L1 in PRR-mediated signaling pathways.

INDUCTION OF AUTOPHAGY BY ATG16L1

ATG16L1 is an indispensable molecule for autophagic responses (Table 1). The autophagy process includes vesicle nucleation, vesicle elongation, vesicle completion, fusion with lysosome, degradation, and recycling[9]. Autophagy dysfunction is associated with neurodegenerative diseases, microbial infections, and aging[7]. Although autophagy has been identified as the primary cell response to the lack of nutrients, recent studies have highlighted the importance of autophagy in microbial infection and immune responses[9]. The autophagy process is negatively regulated by growth factors, which activate the mechanistic target of rapamycin (mTOR) and the phosphoinositide 3-kinase (PI3K)-AKT pathways[7,9]. On the contrary, nutrient starvation or rapamycin treatment promotes the autophagic process through the inhibition of mTOR. Thus, the PI3K–AKT–mTOR pathway negatively regulates autophagic process. On the molecular level, mTOR activation controls the initiation of autophagy by suppressing the activation of the primary initiation complex of autophagy, called Unc-51 Like autophagy activating kinase 1 (ULK1) complex, composed of ULK1/2, ATG101, ATG13, and RB1CC1/FIP200[9]. The formed ULK1 complex translocates to the site of the second complex, called the PI3K complex[9]. The latter PI3K complex recruits a number of ATG proteins to promote elongation and expansion of the autophagosome.

Two ubiquitin-like conjugation systems, the ATG5–ATG12–ATG16L1 conjugation system and the microtubule-associated protein 1 Light chain 3 (LC3) conjugation system, play important roles in the elongation and expansion of the autophagosome[7,9]. The conjugation of the membrane lipid phosphatidylethanolamine with the soluble form of LC3 and formation of the ATG5–ATG12–ATG16L1 complex is necessary for the maturation of autophagosomes[7,9,10]. Matured autophagosomes are fused with lysosomes for the degradation of cellular materials. Vesicles containing ATG16L1 are necessary for

Table 1 Physiological functions of autophagy related 16 like 1

Function	Cell type	Ref.

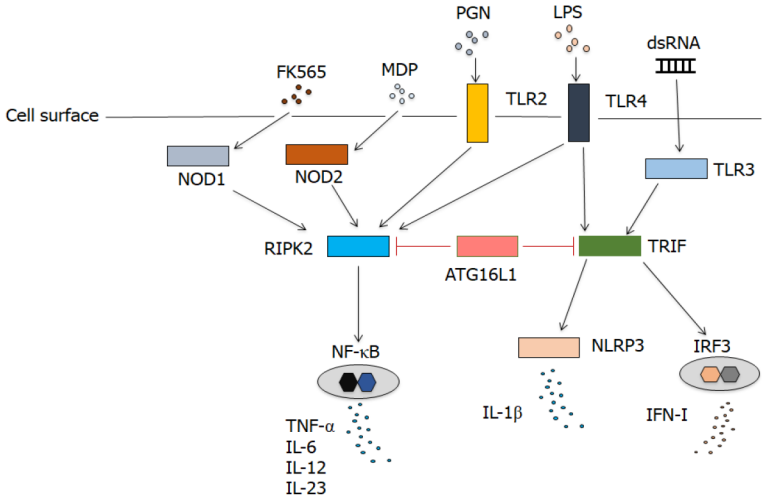
IL-1β production by TLR4	Macrophages	[16,17,19]
IL-6 and IL-12 production by TLR2	DCs	[27]



EC: Epithelial cell; DC: Dendritic cell; IFN-I: Type I interferon; RLR: Retinoic acid-inducible gene I-like receptors; MEF: Mouse embryonic fibroblast; TLR: Toll-like receptor; IL: Interleukin.

membrane trafficking and autophagosome formation[7,9,10]. Thus, ATG16L1 is an essential protein for the induction and completion of autophagic responses.

ATG16L1 AND INNATE IMMUNITY

ATG16L1 has been shown to attenuate proinflammatory cytokine responses in innate immunity (Table 1)[8]. RLRs, including RIG-I and melanoma differentiation-associated gene 5 (MDA5), are sensors for RNA viruses[3]. IFN-I, which is produced after viral RNA is sensed by RLRs, plays a protective role in host defense[3]. Mouse embryonic fibroblasts deficient in ATG5 displayed enhanced production of IFN-I after exposure to vesicular stomatitis virus due to enhanced activation of IFN regulatory factor 3 [11]. Enhanced production of IFN-I is associated with reduced viral load[11]. ATG16L1 is involved in the regulation of IFN-I mediated by RLRs. Two mitochondrial proteins, NLRX1 and its binding partner, Tu translation elongation factor, interact with ATG5, ATG12, and ATG16L1, and suppress RLR-induced IFN-I production and thereby promoting autophagy[12]. In addition, ATG16L1 has been shown to regulate IFN-I production by interacting with TLR3 and TLR4[13]. Samie *et al*[13] have provided evidence that macrophages deficient in ATG16L1 produced large amounts of IFN-I after stimulation with TLR3 and TLR4 Ligands (Figure 1). Mechanistically, the loss of ATG16L1 resulted in the accumulation of the toll-IL-1 receptor domain-containing adaptor inducing IFN-β protein (TRIF), leading to the excessive activation of TLR3- and TLR4-mediated signaling pathways. Interestingly, macrophages isolated from individuals bearing the CD-associated ATG16L1 T300A variant also exhibited enhanced IFN-I production upon stimulation with TLR3 and TLR4 Ligands[13]. Thus, ATG16L1 functions as a negative regulator of IFN-I production induced by TLR activation. Excessive activation of IFN-I signaling caused by ATG16L1 deficiency may protect against microbial infection. In fact, ATG16L1 hypomorphic mice displayed enhanced IFN-I signaling upon challenge with *Citrobacter rodentium*, which conferred protection from enteric pathogen infection[14]. This protection was mediated by mitochondrial antiviral signaling (MAVS) and stimulator of interferon genes (STING) proteins, because mice with hypomorphic ATG16L1 expression and deficient in MAVS or STING were not protected from the *C. rodentium* infection. Similarly, the clearance of *Salmonella typhimurium* from the intestine was augmented in mice with myeloid cell-specific ATG16L1 deficiency in an IFN-I-dependent manner[13]. IL-22 is a barrier protective cytokine that stimulates antimicrobial responses in the intestine[15]. IL-22 induces STING-dependent IFN-I signaling, which is augmented in the absence of ATG16L1[15]. Such enhanced IFN-I signaling promotes TNF-α production, leading to ileal inflammation, suggesting that ATG16L1 deficiency mediates pro-inflammatory TNF-α responses through cooperative interaction between IL-22 and IFN-I[15]. Taken together, these studies suggest that ATG16L1 dampens IFN-I production mediated by RLRs and TLRs. In turn, the lack of negative regulation of IFN-I signaling owing to the absence of ATG16L1 or the presence of ATG16L1 T300A variant mediates protection from microbial infection in the gastrointestinal tract in an IFN-I-dependent manner.

In addition to attenuating IFN-I production, ATG16L1 also suppresses IL-1β production by macrophages[16,17]. Macrophages expressing ATG16L1 that lacks the coiled-coil domain produced large amounts of IL-1β upon stimulation with lipopolysaccharide (LPS) (Figure 1)[17]. Pro-IL-1β is processed into the mature form of IL-1β by caspase-1[18]. Accumulation of TRIF is involved in enhanced IFN-I production in the absence of *ATG16L1* or presence of the *ATG16L1* T300A mutation[13]. Similarly, TRIF-dependent activation of caspase-1 leads to increased production of IL-1β in macrophages lacking ATG16L1[17]. In a murine model of urinary tract infection, ATG16L1 deficiency promoted clearance of

Figure 1 Negative effect of autophagy related 16 like 1 on pattern recognition receptor signaling pathways. Autophagy related 16 like 1 (ATG16L1) negatively regulates pro-inflammatory and type I interferon (IFN-I) responses by toll-like receptors (TLRs) and nucleotide-binding oligomerization domain (NOD)-like receptors (NLRs). Production of pro-inflammatory cytokines such as tumor necrosis factor (TNF)-α, interleukin (IL)-6, IL-12, and IL-23 mediated by TLRs is suppressed by ATG16L1 through the inhibition of activation of receptor-interacting serine/threonine-protein kinase 2 and nuclear factor-kB. Production of IL-1β and IFN-I mediated by TLRs is suppressed by ATG16L1 through the inhibition of toll-IL-1 receptor domain-containing adaptor inducing IFN-β, NOD-, LRR-, and pyrin domain-containing protein 3, and interferon regulatory factor 3. MDP: Muramyl dipeptide; PGN: Peptidoglycan; TLR: Toll-like receptor; LPS: Lipopolysaccharide; NOD: Nucleotide-binding oligomerization domain; RIPK2: Receptor-interacting serine/threonine-protein kinase 2; ATG16L1: Autophagy related 16 like 1; IL: Interleukin; IFN: Interferon; TRIF: Toll-IL-1 receptor domain-containing adaptor inducing IFN-β protein; NF-κB: Nuclear factor-κB; NLRP3: NOD-, LRR-, and pyrin domain-containing protein 3; IRF3: Interferon regulatory factor 3; TNF: Tumor necrosis factor.

uropathogenic *Escherichia coli* through excessive production of IL-1β[19]. Thus, ATG16L1 negatively regulates pro-inflammatory pathways mediated not only by IFN-I, but also by IL-1β.

Regulatory T cells (Tregs) expressing forkhead box P3 (FOXP3) are a specialized T cell population that is indispensable for the establishment and maintenance of immunological self-tolerance[20]. Impaired activation of Tregs leads to the development of autoimmune disorders. *Bacteroides fragilis* (*B. fragilis*) has been considered to stimulate beneficial immunoregulatory functions through induction of Tregs[21]. Chu *et al*[22] provided evidence that ATG16L1 expressed in DCs was required for the induction of Tregs expressing FOXP3 upon exposure to outer membrane vesicles (OMVs) of *B. fragilis*. Oral administration of OMVs from *B. fragilis* protected wild-type mice from experimental colitis[22], and this effect was accompanied by increased proportions of Tregs expressing FOXP3 and IL-10. Such protective effect of oral administration of OMVs was not seen in mice with DC-specific ATG16L1 deficiency. Thus, ATG16L1 is involved in the maintenance of immune homeostasis through induction of Tregs expressing FOXP3.

Mutations in *NOD2* are the strongest risk factor for the development of CD[5,6]. MDP, a bacterial component derived from intestinal bacteria, is a prototypical NOD2 ligand[23,24]. Activation of NOD2 by MDP induces autophagy in macrophages, DCs, and fibroblasts, but not in cells harboring CD-associated *NOD2* mutations[25]. Physical interaction between NOD2 and ATG16L1 is induced by the stimulation with MDP[25,26]. Thus, MDP activation of NOD2 mediates bactericidal effects in an ATG16L1-dependent manner, and the presence of CD-associated *NOD2* mutations promotes overgrowth of intestinal bacteria, leading to excessive production of pro-inflammatory cytokines.

Receptor-interacting serine/threonine-protein kinase 2 (RIPK2) is a signaling molecule downstream of NOD2 and TLRs[23,24]. It remains unclear whether ATG16L1 binds to RIPK2 after activation of NOD2. In this regard, we confirmed that ATG16L1 binds to the kinase domain of RIPK2 in overexpression studies[26,27]. In human DCs, ATG16L1 interacted with RIPK2 after the stimulation with MDP and this interaction suppressed NF-κB-dependent proinflammatory responses mediated by TLRs[26,27]. Transfection of intact *ATG16L1*, but not of *ATG16L1* with the T300A mutation, reduced TLR2-mediated NF-κB activation in human embryonic kidney cells. In the physiological setting, NF-κB activation, as assessed by the degradation of IκBα and expression of phospho-IκBα, was markedly suppressed in human DCs stimulated with TLR2 and NOD2 ligands as compared to the effect of stimulation with a TLR2 ligand alone[26,27]. Furthermore, knockdown of *ATG16L1* by its specific siRNA increased IL-6 and IL-12p40 production by human DCs upon exposure to TLR2 and NOD2 ligands as compared to the levels of those cytokines in cells transfected with control siRNA[26,27]. These studies strongly suggest that ATG16L1 functions as a negative regulator of TLR2-mediated pro-inflammatory cytokine responses (Figure 1).

NF-κB activation mediated by TLRs and NOD2 is tightly regulated by Lys (K63)- linked polyubiquitination of RIPK2[23,24,27,28]. As for the molecular mechanisms accounting for the suppression of TLR2-mediated NF-κB activation and pro-inflammatory cytokine production, ATG16L1 has been shown to inhibit polyubiquitination of RIPK2[26,28]. NOD2 activation by MDP also inhibited polyubiquitination of RIPK2 through the induction of interferon regulatory factor 4 (IRF4)[23,24]. Overexpression studies revealed that ATG16L1 and IRF4 act cooperatively to suppress K63-linked polyubiquitination of RIPK2 [27]. Given that physical interaction between RIPK2 and IRF4 or ATG16L1 is induced after NOD2 activation by MDP, it is likely that NOD2 downregulates TLR-mediated proinflammatory cytokine responses through binding of ATG16L1 and IRF4 to RIPK2. This idea is fully supported by the fact that RIPK2 expression level is markedly elevated in the colonic mucosa of patients with CD and ulcerative colitis (UC), and it corelates with the levels of pro-inflammatory cytokines, such as TNF-α and IL-6[29]. Furthermore, the percentages of lamina propria DCs expressing ATG16L1 and IRF4 in the colon inversely correlate with the expression levels of TNF-α and IL-6[27]. Collectively, these studies support the idea that ATG16L1 acts in concert with NOD2 to suppress excessive pro-inflammatory cytokine responses mediated by TLRs and thereby maintains intestinal homeostasis.

ATG16L1 AND CD

The polymorphism Thr300Ala (or T300A) in the coding region of the *ATG16L1* gene confers increased risk for the development of CD[6,10,16]. This polymorphism is a loss-of-function mutation, which affects the induction of autophagy against invading bacteria and is associated with gut bacterial overgrowth and pro-inflammatory cytokine responses[6,10,16]. Recent studies have successfully elucidated some of the molecular mechanisms accounting for the development of CD in the presence of the ATG16L1 T300A variant. Given that ATG16L1 is constitutively expressed in epithelial cells, especially Paneth cells and myeloid cells, these studies have highlighted the importance of ATG16L1-mediated signaling pathways in innate immune cells for the immunopathogenesis of CD[17,25,28,30,31].

Paneth cells are localized at the base of the crypts in the ileum, and they contribute to the maintenance of intestinal homeostasis through the secretion of antimicrobial peptides (AMPs) and inhibition of intestinal bacterial overgrowth[32]. Mice with hypomorphic expression of ATG16L1 and ATG16L1 T300A-knockin (KI) mice exhibit increased proportions of Paneth cells with abnormal phenotypes, as assessed by lysozyme localization and granule morphology[30-32]. Moreover, Paneth cells from patients with CD carrying ATG16L1 T300A have unusual granule morphology and accumulation of AMPs, with both having been observed also in mice deficient in ATG16L1 or expressing ATG16L1 T300A[32]. Furthermore, defective function of Paneth cells in the absence of ATG16L1 or the presence of the *ATG16L1* T300A mutation led to higher susceptibility to TNF-α-mediated necroptosis and accumulation of the endoplasmic reticulum stress sensor IRE1a, indicating that necroptosis and endoplasmic reticulum stress are involved in the pathogenesis of CD[33]. Thus, the ileal mucosa of patients and mice bearing ATG16L1 T300A is characterized by the defective function of Paneth cells, which results in the overgrowth of intestinal bacteria. This notion is supported by the fact that CD patients bearing the *ATG16L1* T300A mutation display impaired clearance of pathogenic bacteria in the ileal mucosa[34]. It is well established that CD occurs as a result of the interplay between genetic susceptibility and environmental factors. Cigarette smoking is a risk factor for developing CD[35]. Interestingly, cigarette smoking has been suggested to amplify effects of the *ATG16L1* T300A mutation, triggering Paneth cell defects, thereby causing chronic intestinal inflammation[31].

Pro-inflammatory cytokine responses play an important role in the development of CD[1]. The *ATG16L1* T300A mutation has been shown to enhance pro-inflammatory cytokine responses in the intestine. Mice lacking ATG16L1 in hematopoietic cells were susceptible to dextran sodium sulfate (DSS)-induced colitis[17]. Aggravated DSS-induced colitis in mice lacking ATG16L1 was alleviated by blocking IL-1β-mediated signaling pathways[17]. Furthermore, macrophages lacking ATG16L1 produced more IL-1β upon stimulation with LPS[17]. As for the molecular mechanisms accounting for enhanced production of IL-1β in the absence of ATG16L1, Saitoh *et al*[17] showed that ATG16L1 deficiency resulted in increased production of this cytokine through the TRIF-dependent activation of caspase-1. Thus, ATG16L1 deficiency predisposed mice to DSS-induced colitis by activating IL-1β-mediated signaling pathways. In line with these data obtained in mice lacking ATG16L1 in hematopoietic cells, ATG16L1 T300A-KI mice displayed enhanced production of IL-1β upon exposure to LPS[16]. These studies, which utilized ATG16L1-deficient and ATG16L1 T300A-KI mice, support the idea that intact ATG16L1-medaited signaling pathways limit pro-inflammatory cytokine responses triggered by activation of TLRs. In this regard, we and others have reported that ATG16L1 negatively regulates pro-inflammatory cytokine responses mediated by RIPK2, a downstream signaling molecule of TLRs and NLRs[27,28]. Binding of ATG16L1 to the kinase domain of RIPK2 inhibits polyubiquitination of RIPK2, followed by suppression of NF-κB activation[27,28]. These studies strongly suggest that ATG16L1 activation maintains intestinal homeostasis and attenuates reactions against microbiota by inhibiting TLR-mediated pro-inflammatory cytokine responses in macrophages and DCs. Strong support for this idea also comes from the observations that colonic pro-inflammatory cytokine

expression inversely correlates with the percentage of $CD11c^+$ DCs expressing ATG16L1 in patients with CD and that induction of remission is accompanied by accumulation of $CD11c^+$ DCs expressing ATG16L1 in the gastrointestinal tract of patients with CD[27].

ATG16L1 negatively regulates IFN-I responses mediated by RLRs and TLRs[11-14]. Isolated macrophages from patients with CD bearing the *ATG16L1* T300A mutation produced more IFN-I upon stimulation with TLR3 and TLR4 ligands than macrophages from patients with intact ATG16L1[13,36]. Excessive production of IFN-I is involved in the immunopathogenesis of CD and UC. Expression levels of the IFN-stimulated genes was shown to be higher in the inflamed colonic mucosa of patients with CD or UC than in healthy controls[13]. Moreover, expression levels of IFN-stimulated genes rapidly declined in response to infliximab treatment. Although the presence of the *ATG16L1* T300A variant is associated with colitogenic IFN-I responses, the enhanced production of IFN-I may improve survival of patients with colorectal cancer[36].

Similar to the molecular mechanisms of chronic inflammation in the presence of CD-associated mutations in *NOD2*, the *ATG16L1* T300A mutation promotes the development of CD by causing impaired production of AMPs in Paneth cells and excessive secretion of TLR-mediated pro-inflammatory cytokines by macrophages and DCs. MDP activation of NOD2 induces robust production of AMPs from Paneth cells, thereby preventing bacterial overgrowth in the intestine[5]. Paneth cells deficient in NOD2 or bearing CD-associated *NOD2* mutations fail to produce AMPs[5]. With regard to the pro-inflammatory cytokine responses, activation of intact NOD2 by MDP negatively regulates the production of TLR-mediated pro-inflammatory cytokines through the induction of IRF4[23,24]. In the absence of intact *NOD2* or the presence of CD-associated *NOD2* mutations, pro-inflammatory cytokine responses by DCs are markedly enhanced upon exposure to TLR ligands derived from the intestinal microbiota[5]. Thus, impaired function of Paneth cells and excessive pro-inflammatory cytokine responses by TLRs underlie the immunopathogenesis of CD in the presence of *ATG16L1* and *NOD2* mutations.

CONCLUSION

The autophagic protein ATG16L1 plays an indispensable role in the maintenance of intestinal homeostasis. The *ATG16L1* T300A mutation confers an increased risk for the development of CD as it is associated with increased bacterial burden and excessive pro-inflammatory cytokine responses in the gastrointestinal tract. Elucidation of the molecular mechanisms by which the *ATG16L1* T300A variant leads to the development of CD has provided new insights into the immunopathogenesis of CD induced by impaired induction of autophagy.

Abstract

Anabolic androgenic steroids (AASs) are a group of molecules including endogenous testosterone and synthetic derivatives that have both androgenic and anabolic effects. These properties make them therapeutically beneficial in medical conditions such as hypogonadism. However, they are commonly bought illegally and misused for their anabolic, skeletal muscle building, and performance-enhancing effects. Supraphysiologic and long-term use of AASs affects all organs, leading to cardiovascular, neurological, endocrine, gastrointestinal, renal, and hematologic disorders. Hepatotoxicity is one of the major concerns regarding

AASs treatment and abuse. Testosterone and its derivatives have been most often shown to induce a specific form of cholestasis, peliosis hepatis, and hepatic benign and malignant tumors. It is currently believed that mechanisms of pathogenesis of these disorders include disturbance of antioxidative factors, upregulation of bile acid synthesis, and induction of hepatocyte hyperplasia. Most toxicity cases are treated with supportive measures and liver function normalizes with discontinuation of AAS. However, some long-term consequences are irreversible. AAS-induced liver injury should be taken in consideration in patients with liver disorders, especially with the increasing unintentional ingestion of supplements containing AAS. In this paper, we review the most current knowledge about AAS-associated adverse effects on the liver, and their clinical presentations, prevalence, and pathophysiological mechanisms.

Key Words: Androgens; Steroids; Cholestasis; Fibrosis; Liver; Chemical and drug induced liver injury

Core Tip: There is a great deal of literature on the prevalence, pathophysiology, and therapeutic options for anabolic androgenic steroid (AAS)-associated adverse effects. However, AAS-induced liver injury is perhaps still underreported and poorly understood. In this paper, we review the latest knowledge obtained about molecular mechanisms of AAS-associated liver injury from most recent *in vitro* and animal studies, as well as the latest case reports regarding adverse effects of AASs in dietary supplements.

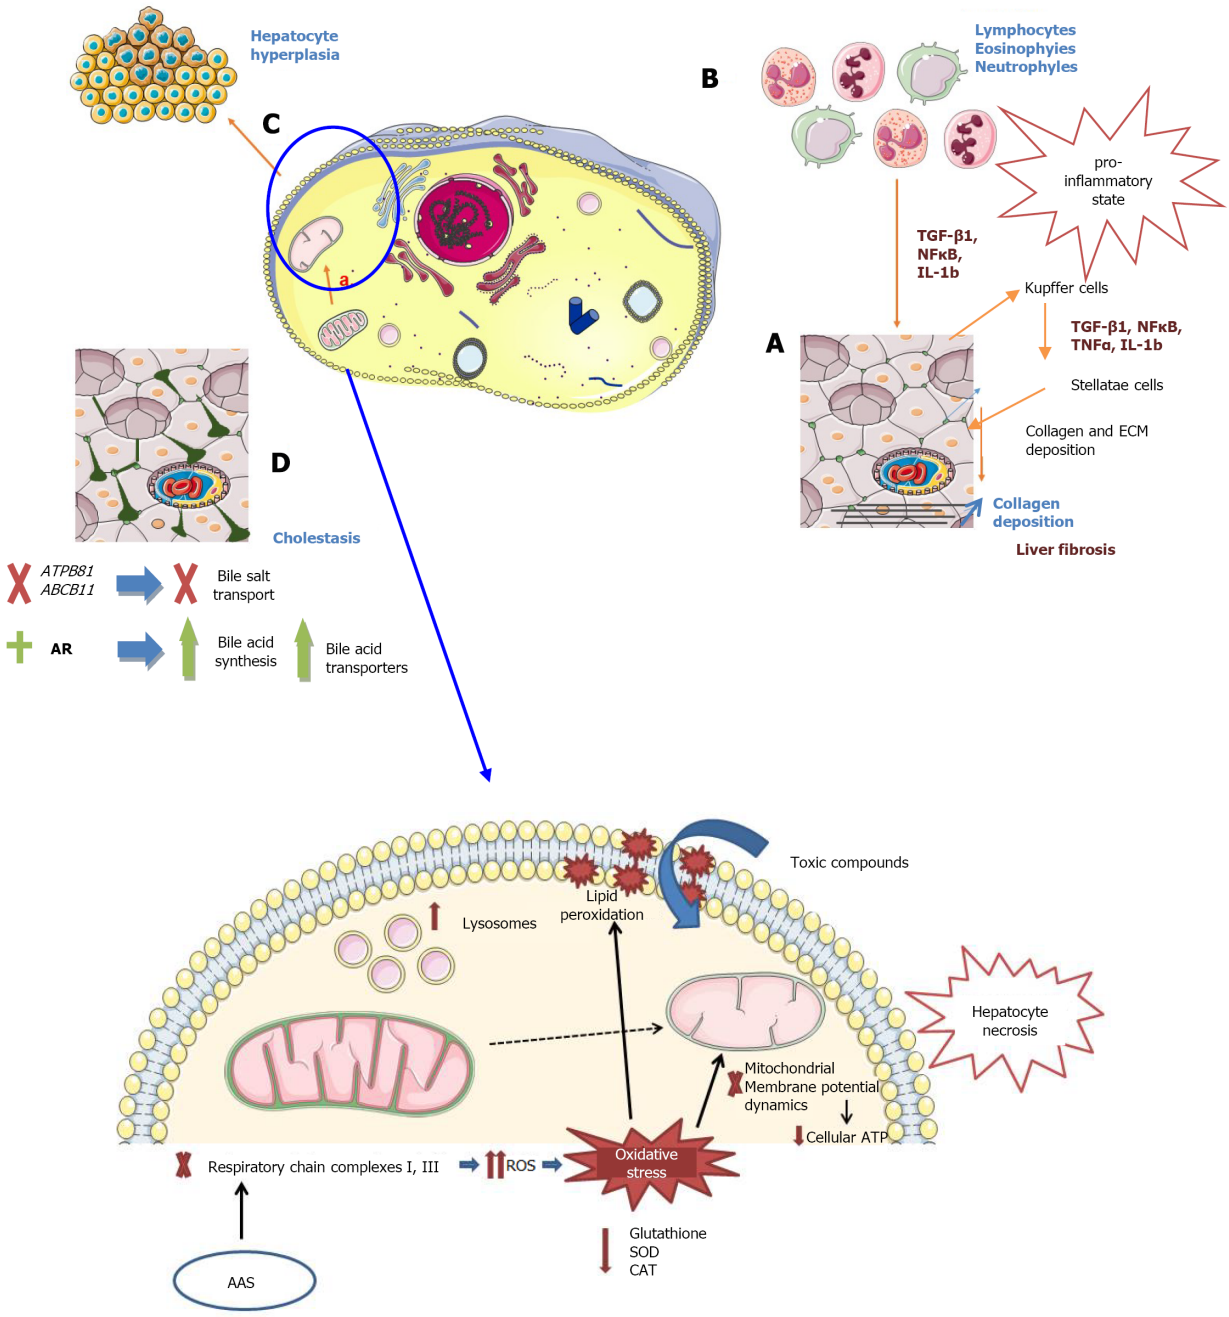
INTRODUCTION

Anabolic androgenic steroids (AASs) are group of compounds that include endogenous androgens, most importantly testosterone, and their synthetic derivatives[1]. Testosterone and synthetic AASs have been commonly used for their androgenic masculinizing effects resulting in male secondary characteristics, as well as anabolic skeletal muscle building effects due to enhanced protein utilization and synthesis mechanisms[2,3]. AASs are medically indicated in conditions such as male primary and secondary hypogonadism, aplastic anemia, muscle wasting in human immunodeficiency virus-infected patients, osteoporosis, libido dysfunction, chronic kidney disease, and breast cancer[4]. However, they are often misused because of their performance-enhancing and anabolic effects resulting in increased fat-free mass and improved muscle fiber size and strength. Abuse of AASs for aesthetic purposes and athletic performance improvement has surged as a public health problem in the past few decades among both professional and recreational athletes and bodybuilders[5,6]. Unmodified testosterone is rapidly metabolized when administered orally or parenterally and exerts a similar proportion of anabolic and androgenic effects. Chemical modifications of testosterone allow prolonged effective blood concentrations and changes to its pharmacodynamic properties, therefore enhancing desired anabolic or androgenic effects. In its synthetic derivatives used for aestethic and performance-enhancing purposes, testosterone is altered mainly through alkylation and esterification to enhance bioavailability by reducing hepatic metabolism, prolong duration of action, and maximize anabolic properties, though all of the synthetic compounds still exert significant androgenic effects. Supraphysiologic doses and prolonged unsupervised use of AASs have major impacts on users, affecting all organs and causing cardiovascular, neuroendocrine, neuropsychiatric, renal, gastrointestinal, musculoskeletal, dermatologic, immune, and hematologic disorders. Testosterone has a major impact on homeostasis of electrolytes, macromolecules, and micromolecules, including alterations in systemic iron balance and erythropoiesis. It has been established that AAS-induced erythropoiesis is mediated by erythropoietin [7]. Most recent studies also imply suppression of hepcidin (a negative regulator of the iron transporter ferroportin) as a mechanism of androgen-induced enhanced iron absorbtion and incorporation into red blood cells[8]. Some of the most common adverse effects related to AASs are dyslipidemia, hypertension, hypogonadism and infertility, aggression and mood disorders, addiction, and liver and kidney injury[9-11]. This has led to stricter laws regarding availability of AASs, mainly in professional sports organizations which ban anabolic steroid use, and test competitors for the presence of illegal steroids not only because of the unfair advantage in performance, but also because of their potentially dangerous side effects. In legal terms, AASs are classified in the United States as schedule 3 drugs by the



Drug Enforcement Agency, meaning that they can be legally obtained as prescription-only drugs. However, they are illegally sold among teammates, trainers, and fitness centers, through black market or counterfeit prescriptions. Furthermore, many AASs are legally bought and consumed unknowingly in over-the-counter dietary supplements advertised as energy, virility, and muscle strength enhancers [12-14]. Although the precise number of AAS users is difficult to determine, it is estimated that the prevalence across the world is 1%-5%[15]. A study in 2013 found that the prevalence of AAS use among male elite college students in the United States during their lifetime is about 20%[16]. In Norway high school population, a prevalence of 4% was found[17]. While it is difficult to establish a true prevalence of AAS use due to underreporting of this socially undesirable behavior, all the surveys nevertheless found significantly higher AAS use in male compared to female persons and the majority of AAS users are or were professional or near professional athletes[15]. With the liver being the main site of steroid clearance, hepatotoxicity is one of the major adverse effects of chronic AAS use. The aim of this paper is to focus on the most recent studies and knowledge obtained regarding AAS-induced liver injury.

HEPATOTOXICITY

Since the 1950s, a significant number of studies and case reports have raised concerns regarding hepatotoxic effects including cholestasis, hepatic neoplasms, hepatocyte toxicity, and peliosis hepatis related to use of AASs[11,18]. Correlation between steroids and these effects has been attributed to the role of the liver as the primary clearance site for AASs. As mentioned before, synthetic steroids are usually modified to prevent first-pass hepatic metabolism, preventing their clearance by the liver and, therefore, elevating their risk of hepatotoxicity[19]. Most studies of long-term use have not identified exact dosages and concentrations, administration paths, and types of steroid compounds often used simultaneously. Prospective studies with supraphysiologic doses are difficult to gain institutional review board (IRB) approval due to ethical and legal considerations[20], therefore randomized controlled trials are lacking and in this minireview we discuss data from case reports, *in vitro* studies, and studies on animal models.

Proposed mechanisms of liver injury include anabolic steroid-induced infiltration of inflammatory cells in the hepatic tissue, and Kupffer cell activation resulting in production of inflammatory cytokines and collagen deposition, increased oxidative stress and reactive oxygen species with subsequent mitochondrial degeneration in liver cells, and stimulation of intracellular androgenic steroid receptors inducing unregulated growth of hepatocytes. An *in vitro* study in 2021 reported that disruption of mitochondrial respiratory chain reactions occurs early in the pathogenesis of liver injury caused by supraphysiologic doses of nandrolone, a synthetic AAS commonly used for performance enhancement. It specifically inhibits respiratory chain complexes I and III, which causes accumulation of reactive oxygen species and oxidative stress[21]. Indeed, earlier animal studies detected a reduced amount of glutathione and enzymes that serve as free radical scavengers (superoxide dismutase and catalase) as well as increasing thiobarbituric acid-reactive substances indicating impaired redox homeostasis[22,23]. Furthermore, oxidative stress interfered with mitochondrial membrane potential dynamics[24] and altogether resulted in reduced cell energy supply leading to malfunction and necrosis of hepatocytes. Apart from disturbance in cellular function, distortion in mitochondrial morphology and increased number of lysosomes in hepatocytes were observed by electron microscopy[25]. Another process observed after prolonged administration of nandrolone in animal studies was excess collagen deposition in liver parenchyma. It is known that AASs induce infiltration of the liver with inflammatory cells, which together with activated Kupffer cells, favor a pro-inflammatory state by releasing nuclear factor-κB (NF-κB) and inflammatory cytokines transforming growth factor beta1 (TGF-β1), tumor necrosis factor alpha (TNFα), and interleukin-1B (IL-1B). Such conditions also lead to activation of liver stellate cells, resulting in excessive collagen synthesis and deposition[26]. Interestingly, AASs can also promote collagen synthesis by activating their intracellular receptor and activation of transcription factors involved in collagen synthesis[27]. A recent study also gave convincing evidence for a role of testosterone in the pathophysiology of liver diseases with higher occurrences in males than in females. It demonstrated that the susceptibility of the mouse liver to injury was correlated with excessive inflammatory response mediated by androgen receptors (ARs) and testosterone-induced NOD-like receptor family pyrin domain containing 3 (NLRP3) inflammasome activation associated with a variety of chronic diseases[28]. Hepatotoxicity of AASs may also vary due to individual susceptibility, pre-existing liver conditions, and genetic factors. Most frequently reported liver disorders related to AASs are cholestasis, peliosis hepatis, and development of liver tumors[11,29-32]. Figure 1 shows an overview of proposed mechanisms of hepatotoxicity caused by AAS.

AAS drug-induced liver injury (AAS DILI) has also been frequently reported to cause serum liver enzyme elevations in AAS users. Elevated aspartate aminotransferase (AST), alanine aminotransferase (ALT), and lactate dehydrogenase (LDH) activities are, in general, regarded as indicators of hepatocellular damage. Transient elevation of AST and ALT in plasma has been largely reported in AAS users [33], but liver damage may not be the cause of the elevations because of the possible contribution of heavy and intense workouts with consequent muscle damage and rhabdomyolysis. Thus, liver enzymes

Figure 1 Proposed mechanisms of anabolic androgen steroid-induced liver injury. A: Oxidative stress in the mitochondria. Anabolic androgenic steroids (AASs) impair mitochondrial respiratory function, which leads to reactive oxygen species (ROS) accumulation. Cell membrane is damaged due to lipid peroxidation and intracellular ATP depletion occurs due to mitochondrial impairment. This results in cellular dysfunction at many levels (*e.g.*, toxic compounds can enter the cell). Mitochondrial morphology is also changed, with reduced cristae and swelling. In addition, there is an increase in lysosome number. Lack of energy supply eventually leads to hepatocyte necrosis; B: Immune cell infiltration of liver parenchyma. Long-term treatment with AASs like nandrolone is associated with immune cell infiltration which maintains proinflammatory state in liver tissue. Under such conditions, Kupffer cells release transforming growth factor beta1 (TGF-β1), tumor necrosis factor alpha (TNFα), and interleukin-1B (IL-1B) which mediate hepatic stellate cell activation: Extracellular matrix and collagen deposition leading to liver fibrosis; C: Hepatocyte hyperplasia causes formation of hepatic tumors. In rats treated with high-dose nandrolone, it was observed that it supported the viability of hepatic stem cells, which are potential reservoir of cancer stem cells. Nodular hepatocyte hyperplasia causes parenchyma distortion and mechanical blockage of vasculature which forms cystic lesions filled with blood, known as peliosis hepatic; D: "Bland cholestasis". Activation of androgen receptors (ARs) by AASs interferes with bile transporters, mediates intrahepatic microfilament damage, and increases expression of genes for acid bile and bile transporter synthesis, and these changes result in bile acid accumulation, cholestasis, and cholestatic jaundice. SOD: Superoxide dismutase; CAT: Catalase; AR: Androgene receptor; AAS: Anabolic androgenic steroid; AR: Androgen receptor. Figure created with Servier Medical Art, https://smart.servier.com/.

can be elevated independent of androgenic steroid use. Studies showing elevations of creatine kinase (CK) and AST, with no ALT and gamma glutamyl transferase (GGT) elevations, support this concept and suggest that hepatotoxicity related to AASs may be over-estimated if serum ALT, AST, and GGT concentrations are the sole criteria used[34]. Furthermore, a recent multi-center prospective study regarding the incidence of liver injury in transgender patients treated with hormone therapy including AASs showed no significant ALT, AST, alkaline phosphatase (ALP), or GGT elevations[35]. Most of the hepatotoxic effects, cholestasis, peliosis, and liver tumors are associated with orally administered AASs such as testosterone cypionate, enanthate, propionate, methyltestosterone, oxymetholone, danazol, stanozolol, formebolone, and methandienone[36,37], but intramuscular preparations were also linked to hepatotoxic effects[38]. Patil *et al*[38] reported three cases of AAS-induced hepatotoxicity which all manifested differently. The first case was a 31-year-old man who developed cholestatic liver injury after 2 mo of oxymetholone use, the second case was a 24-year-old man who developed well-differentiated hepatocellular carcinomas (HCC) and multiple hepatic adenomas after 3 years of intramuscular testosterone decanoate and daily oral stanozolol use, and the third case was a 36-year-old man with steatohepatitis after 2 mo of intramuscular nandrolone decanoate use[38]. The exact incidence of AAS DILI is difficult to establish due to both underreporting and lack of awareness. On the other hand, even when a history of AAS use is known, it may be difficult to establish the causality, particularly when multiple agents are used concomitantly or if there is an underlying liver condition. However, there has been a trend of increased AAS DILI reporting in recent years which may lead to new insights into pathophysiology and disease course. According to currently available data, AAS DILI has a good prognosis as the majority of cases recover completely and only a very small number of cases develop hepatic failure or die[39].

CHOLESTASIS

Although cholestasis is unlikely in patients treated with parenterally administered unmodified testosterone, 17α-alkyl-substituted steroids, which are designed to decrease hepatic metabolism, directly contribute to a highly characteristic form of acute cholestasis, ranging from very mild to severe. Some characteristic clinical manifestations are nausea, pruritus, fatigue, jaundice, and dark urine with elevated bilirubin and ALP, but without significant elevations of AST, ALT, and GGT. Such characteristics are indicative of cholestasis with minimal inflammation of the liver or bile duct. Resolution usually occurs upon discontinuation of anabolic steroids, although some case reports indicate benefits of hydrocortisone and ursodeoxycholic acid treatment[13,39-42].

Some animal model studies have suggested AAS-induced disruption of intrahepatic microfilaments and interference with bile transporter proteins as a pathophysiological mechanism of this syndrome rather than inflammation and injury to the liver and bile duct[29,43]. El-Sherrif *et al*[13] reported two cases of cholestatic DILI caused by the short-term use of AAS-containing dietary supplement Mass-Drol. The authors found that inhibition of expression of genes *ATPB81* and *ABCB11* by AAS may play a crucial role as the underlying mechanism of cholestatic injury. This leads to impaired bile salt transport and also reduced excretion of different hepatic ectoenzymes. Indeed, both patients presented with cholestasis with marked hyperbilirubinemia, but lack of GGT rise. The authors postulated that individuals who are carriers of c.2093G >A mutation in *ABCB11* may be specifically susceptible to cholestatic hepatic injury caused by AASs due to this mechanism[13]. Additionally, the role of multidrug-related proteins (MRP2, MRP3, and MRP4) is important in bile acid transfer as a complimentary mechanism. It was shown that testosterone metabolites are substrates of MRP2 protein, which has reduced activity in Dubin-Johnson syndrome (DJS). The effect of AAS in DJS has not been investigated to our knowledge, whereas it was found that pregnancy and oral contraceptives increase bilirubin levels in women with DJS[44]. Different underlying mechanism was proposed by Petrov *et al*[45], who used an *in vitro* model to demonstrate that AR activation may upregulate the expression of bile acid synthesis genes as well as bile acid transporters. Most recent studies have reported that the patterns of "bland" cholestasis in AAS users are so specific that this picture can be virtually sufficient to make a diagnosis of AAS-induced cholestasis[46]. Many reports refer to these phenomena as AAS DILI[39,47].

PELIOSIS HEPATIS

Peliosis hepatis is a rare condition characterized by hypervascular liver parenchyma and blood-filled cysts that is known to be associated with use of AASs and several other drugs like estrogens, corticosteroids, and azathioprine. So far, disruption of hepatic extracellular matrix and direct endothelial cell injury have been suggested as generating mechanisms for liver peliosis. It has also been proposed that steroid-induced hepatocyte hyperplasia results in mechanical obstruction of hepatic vascular system, causing dilatation and loss of endothelial barrier function[11,30,48]. Molecular mechanisms in pathophysiology of peliosis remain poorly understood; however, an important role of vascular

endothelial growth factor (VEGF) has been suggested in recent studies. VEGF induces angiogenesis, capillary permeability, and proliferation of endothelial cells in liver and other tissues. Tzirogiannis *et al* [49] found a major protective effect of VEGF which almost totally reversed the extent of peliosis in a model of cadmium-induced toxic liver injury and peliosis, implying that it preserves endothelial cell function. However, a study of peliosis hepatis in a patient with follicular lymphoma found elevated VEGF and suggested that lesions could be caused by elevation of VEGF and its angiogenic effects[50]. An animal model study of peliosis hepatis associated with melanoma supports a concept that a tumor-derived factor such as VEGF could induce development of peliosis due to its endothelial cell proliferation effect[51]. These conclusions indicate a need for further research of pathophysiology in peliosis hepatis as well as AASs and their impact on growth factors. Peliosis hepatis is commonly asymptomatic, but case reports described presentation characterized by sharp abdominal pain and hemoperitoneum in cases of cyst rupture[52]. Peliosis is usually treated with supportive care and the condition has shown to regress with discontinuation of AASs[53,54]. The condition has been reported not only in use of 17-alpha-alkylated steroids, but also in patients treated with unmodified testosterone[19]. Given its benign nature, most cases of peliosis hepatis are incidentally found and the most appropriate diagnostic modalities are magnetic resonance imaging[55] and histological examination. Once diagnosed, the offending drug should be discontinued and the condition closely monitored to reduce the risk of rupture, especially with larger lesions.

NEOPLASMS

Hepatic tumors, ranging from benign adenomas to malignant hepatocellular carcinoma, have been reported in patients with long-term anabolic steroid therapy[56-58]. Studies have suggested a higher hepatic cancer prevalence in males than in females. Higher endogenous concentrations of androgens may be a major factor in the development of liver carcinomas. Having both the estrogen and ARs, the liver is a hormone sensitive organ. The use of AASs is highly associated with hepatocyte proliferation and liver tumors[59]. An i*n vitro* study on HepG2 cells showed that a supraphysiologic dose of nandrolone changed their phenotype to be stem-like, but the mechanism of this transformation remains to be elucidated. In the same study, nandrolone administered *in vivo* in a mouse model promoted "stemness" in healthy organs, primarily ones naturally rich in stem cells such as the liver. Cell "stemness" phenotype is a metabolically latent state in which there is a lower oxygen consumption in the mitochondria. Expression of *Nanog*, *Lin28*, *Myc*, and *Klf4* genes and CD133 membrane protein is also considered to be markers of cell stemness. This led to a hypothesis that long-term supraphysiologic doses of nandrolone in young healthy individuals possibly increase the risk of malignancy in stem-cell rich organs by increasing the reservoir of stem cells which over a period of time under additional toxic stimuli may turn into cancer stem cells[21]. Studies to date indicate that most of AAS-induced tumors occur with use of agents containing a 17-alpha-alkyl group, but it has also been reported in patients treated with unmodified testosterone[56,60,61]. Histologically, these tumors are most commonly hepatic adenomas or HCC, but cholangiocarcinomas and angiosarcomas have also been reported with long-term AAS use[20]. Given the possibility of malignant transformation of hepatic adenoma, which occurs 10 times more commonly in men than in women, it is recommended that surgical resection be the most appropriate approach in men. In women, estrogen-containing oral contraceptives are a common cause, so their cessation, together with periodic surveillance, is an acceptable approach[62,63]. Solimini *et al*[11] reviewed case reports regarding liver tumors as well as cholestatic hepatitis associated with AASs and reported that several different AAS agents were associated with such liver pathology. Notably, chronic AAS use of several years is linked to development of HCC, while benign neoplasms were mostly linked to short-term use of AAS[11].

ADDITIONAL CONCERNS REGARDING AASS AND THE LIVER

Other hepatic disorders associated with AASs include toxicant-associated fatty liver disease (TAFLD), and possible increased risk of hepatitis B and C infections due to unsafe administration of AASs[64]. In addition, a negative effect on lipoproteins with reduced HDL-cholesterol and increased LDL-cholesterol concentrations has been reported mostly in long-term steroid users[65,66], which contribute to increased risk of coronary disease with AAS use.

Another concerning issue is the increasing number of mislabeled over-the-counter dietary supplements sold legally and containing significant amount of AASs. This has also been associated with adverse effects, but remains underreported and poorly understood. However, new case reports have been published on DILI with jaundice, cholestasis, dyslipidemia, and elevated serum liver enzyme panels in patients directly associated with dietary supplement use. After discontinuation of supplements, liver function commonly returned to normal[67,68]. Consumers may unknowingly use AASs which can result in acute, but also chronic, health problems that are difficult to link to these products and lead to re-exposure[69-71].

CONCLUSION

AAS use is closely linked to hepatotoxicity and serious hepatic conditions such as cholestasis, peliosis hepatis, and benign and malignant hepatic tumors, as well as steatohepatitis and dyslipidemia with multiple studies supporting a causal association. Several pathophysiological mechanisms have been proposed including AR receptor-mediated inflammatory response, disturbance of hepatic antioxidant factors, promotion of hepatocyte hyperplasia, and upregulation of bile acid synthesis. Most of these conditions have been reported with 17-alpha-alkylated steroids. Liver function usually returns to normal with discontinuation of use, but a higher HCC prevalence with AASs is concerning. Another important fact is the increasing number of case reports presenting patients with dietary supplements-associated liver conditions that are still underreported. Given all of the above, screening for liver pathology in known AAS users should be considered in order to possibly reverse the condition. Also, if certain liver pathology is diagnosed incidentally, a history of AAS as potential causal agent should be actively sought, and if found, addressed promptly.

Abstract

A relevant gradual reduction of both the incidence rate of acute hepatitis B (AHB) and prevalence of chronic hepatitis B has occurred in Italy in the last 50 years, due to substantial epidemiological changes: Improvement in socioeconomic and hygienic conditions, reduction of the family unit, accurate screening of blood donations, abolition of re-usable glass syringes, hepatitis B virus (HBV)-universal vaccination started in 1991, use of effective well tolerated nucleo(t)side analogues able to suppress HBV replication available from 1998, and educational mediatic campaigns against human immunodeficiency virus infection focusing on the prevention of sexual and parenteral transmission of infections. As an example, AHB incidence has gradually decreased from 10/100000 inhabitants in 1985 to 0.21 in 2020. Unfortunately, the coronavirus disease 2019 (COVID-19) pandemic has interrupted the trend towards HBV eradication. In fact, several HBV chronic carriers living in the countryside have become unable to access healthcare facilities for screening, diagnosis, clinical management, and nucleo(t)side analogue therapy in the COVID-19 pandemic, mainly for anxiety of becoming infected with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), movement restrictions, and reduced gains from job loss. In addition, one-third of

healthcare facilities and personnel for HBV patients have been devolved to the COVID-19 assistance.

Key Words: Hepatitis B virus; Hepatitis B virus epidemiology; Acute hepatitis B; COVID-19

Core Tip: An impressive reduction in the spread of hepatitis B virus (HBV) infection has been observed over the past 5 decades in Italy. This review article analyzes, in Italy, the effects of various events on HBV endemicity: Reduction of the impact of several risk factors, HBV-universal vaccination started in 1991, the nucleo(t)side analogue therapy started in 1996, the increased immigration flows from countries at high HBV endemicity, and the restrictions generated by the coronavirus disease 2019 (COVID-19) pandemic. Particular attention has been directed at the negative effects of the COVID-19 pandemic that threaten to interrupt the favorable trend towards HBV eradication.

INTRODUCTION

Hepatitis B virus (HBV) infection is a global health problem with 3.61% of the world population chronically infected and 890000 deaths per year for cirrhosis, liver failure, or hepatocellular carcinoma (HCC)[1,2]. Despite the availability of an effective recombinant HBV vaccine from 1991[3] and of effective well-tolerated nucleo(t)side analogues since 1998, the rate of individuals persistently infected with HBV does not decrease worldwide and, unfortunately, it is increasing in some developing countries[4]. Several factors support the level of endemicity of HBV infection: (1) Most patients with chronic infections are asymptomatic and undiagnosed for years[5]; (2) 70% of the individuals with chronic HBV infections live in developing areas where HBV vaccination does not have the character of universality, with 95.3 million in Western Pacific areas and 75.6 million in Africa, where there is a prevalence of hepatitis B surface antigen (HBsAg) chronic carriers of 5.26% and 8.83%, respectively[6]; and (3) Nucleo(t)side analogues suppress but do not eradicate chronic HBV infection. Instead, in the last 30 years, a trend to HBV eradication has been observed in northern America, western Europe, and Japan [7].

As far as Italy, HBV endemicity has progressively decreased over the last 50 years, due to universal HBV vaccination since 1991, the improvement in socioeconomic conditions correlated to better standard of hygiene, substantial reduction of the family unit, and continuous mediatic human immunodeficiency virus (HIV) campaigns organized and financed by the Italian government[8].

Italy is experiencing a continuous migratory flow, more frequently from eastern Europe and sub-Saharan Africa for 20 years and today migrants represent about 9% of the resident population. As an effect of immigration, some HBV genotypes previously rare in Italy are currently responsible for about 40% of acute hepatitis B (AHB) cases[9-12]. There is the fear that the continuous immigrant flows from countries with high or intermediated HBV endemicity will adversely affect the low endemicity level of Italy. As an example, of 882 asymptomatic undocumented migrants or refugees observed in southern Italy in 2015, 78 (9%) were HBsAg positive. This rate was 14% in 444 sub-Saharan Africa subjects, 6% in 198 eastern Europe subjects, and 2%-3% in the 240 migrants from northern Africa, Bangladesh, India, Pakistan, or Sri Lanka, percentages much higher than the 0.8% registered in the people born and living in Italy[13]. The regional office of the World Health Organization (WHO) for Europe reported that a high percentage of immigrants are not vaccinated against HBV upon their arrival in host countries[14] and therefore at risk of becoming infected even in geographic areas with a low HBV endemicity level; accordingly, in Italy one fifth of the new AHB cases are represented by the immigrant population.

Like for numerous other sectors of medicine, the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) pandemic reduced care levels also for HBV-related diseases. A recent web-based survey performed in Italy registered that a quarter of healthcare centers and personnel dedicated to liver diseases had been intended for coronavirus disease 2019 (COVID-19) and that 23% of cases with chronic hepatitis B (CHB) undergoing HBV suppression with nuclo(t)side analogues have suffered interruptions of therapeutic plans[15]. There is therefore a suggestion for the healthcare institutions of Italy not to neglect the need of patients with HBV infection throughout this long terrible COVID-19 pandemic, not to lose in short time the advantages obtained with decades of considerable efforts and economic

commitment.

EPIDEMIOLOGICAL AND CLINICAL CHANGES OF AHB IN ITALY OVER LAST FIVE DECADES

HBV is a non-cytopathic virus that induces liver cell necrosis through cytolytic action of human cytotoxic T cells made able to recognize the viral antigens expressed on the surface of infected hepatocytes from a previous pre-sensitization to HBV. The degree of immune response depends on the age of the host at the acquisition of HBV infection, being absent or low in infants and young children who often develop an asymptomatic acute hepatitis frequently progressing to an HBsAg chronic carriage, but high in young adults and adults who usually develop a self-limiting symptomatic acute hepatitis, progressing to chronicity in only 2%-5% of cases. Fulminant hepatitis occurs in only 1%-3% of cases, more frequently in adolescents and young adults, with a mortality rate of 70%, and in most cases requiring liver transplantation[16-19]. In its classic form, AHB begins with generic symptoms such as fever, malaise, headache, nausea, anorexia, vomiting, and diarrhea, followed by jaundice common in adults and rare in children. The aminotransferases serum levels are usually normal or moderately increased in children and high in adults, reflecting the extension of liver damage. High serum titers of IgM to hepatitis B core antigen identify HBV as the etiological factor, simultaneously with serum HBsAg positivity. Hepatitis B e antigen (HBeAg) and serum HBV DNA are signs of high infectivity; they can be found in the early stage of the disease and are no more detectable in the elimination phase of the virus, event accompanied by seroconversion to anti-HBe. A Cochrane's review of seven randomized controlled trials involving a total number of 597 participants found that antiviral treatment has no benefit for AHB[20], since any evolution to chronicity is strongly determined by the reactivity of the patient's immune system. Some more severe cases, however, may require supportive therapy.

All yearly AHB cases occurred in Italy in the sixties were registered by the Italian Institute of Statistic (ISTAT) under one single entry, with an incidence rate of 98 cases per 100000 inhabitants, followed by a subsequent gradual decline to 20 cases per 100000 inhabitants until 1987[8]. Reliable data on AHB incidence in Italy are reported since 1985, when the surveillance of the integrate epidemiological system of acute viral hepatitis (SEIEVA) registered 12 cases per 100000 inhabitants. This incidence gradually decreased in subsequent years, driven by two important events: (1) The beginning in 1985 of mediatic HIV educational campaigns that advised the condoms for sexual intercourses at risk and to avoid syringe sharing[21]; and (2) since 1991, the national universal HBV vaccination continued so far without interruption; currently all Italian people aged 0 to 41 have been vaccinated[22]. The AHB incidence in 1987 decreased to 10.4 cases per 100000 inhabitants, 5.4 in 1990, 0.9 in 2012, 0.6 in 2016, and 0.21 in 2020 (Table 1).

These data testify the strong contribution of the HBV vaccination to reduction of AHB incidence, but it is equally evident that this reduction had already begun before the universal HBV vaccination campaign had started in 1991. The reason for this is that other factors have contributed to the decrease of AHB incidence in Italy, such as the obligation to test blood donations for HBV markers and not to transfuse the samples testing positive, improvement of socioeconomic and hygienic conditions, and some behavioral changes that have led to the reduction of domestic contacts with a chronic HBsAg carrier and not to use non-disposable or improperly sterilized instruments for medical and surgical practice, piercings, tattoos, manicures, pedicures, acupuncture, and barber's shop[23-25]. Vertical transmission of HBV is no longer a route of HBV transmission in Italy from 1991, due to the mandatory screening for HBV infection among women in pregnancy or at delivery, and to the mandatory, in babies born of HBsAg-positive mothers, active and passive immune prophylaxis. Two routes of HBV transmission remain active, the parenteral one because of the exchange of syringes or other objects between intravenous drug users and the sexual one because of the unusual use of condom in sexual intercourses. It should also be underlined that the impact of these two risk factors on HBV endemicity has progressively lowered, due to the positive effect of universal HBV vaccination which currently covers the Italian population aged 0-41.

Analyzed by the age classes, 0-14 years, 15-24 years, and 25 years or more, the data registered by SEIEVA in 1985 showed 6 subjects with AHB per 100000 inhabitants in age class 0-14, 41 in age class 15-24, and 7 in age class 25 or more. The progressive decline was observed in subsequent years in all the three age classes: (1) In 1990: 1, 17, and 4 cases per 100000 inhabitants, respectively; (2) in 1995: 1, 6, and 3 cases, respectively; (3) in 2000: 0.1, 2, and 2 cases, respectively; (4) in 2005: 0, 5, and 1.8 cases, respectively; and (5) in 2011: 0, 0.5, and 1.2 cases per 100000 inhabitants, respectively[26] (Table 1).

Patients with acute viral hepatitis B registered by SEIEVA from 2009 to 2020 were allocated in five age classes (0-14, 15-24, 25-34, 35-54, and 55 or more), with an incidence close to zero in age classes 0-14 and 15-24 and with a continuous downtrend in older age classes up to 2020[26] (Table 1). The cases of AHB in SEIEVA in the period 1991-2019 have been also analyzed by their geographical distribution[26,27], northern + central Italy *vs* southern Italy + main islands (Sicily and Sardinia), a distribution reflecting historical events and the behaviors of the respective inhabitants (Figure 1).

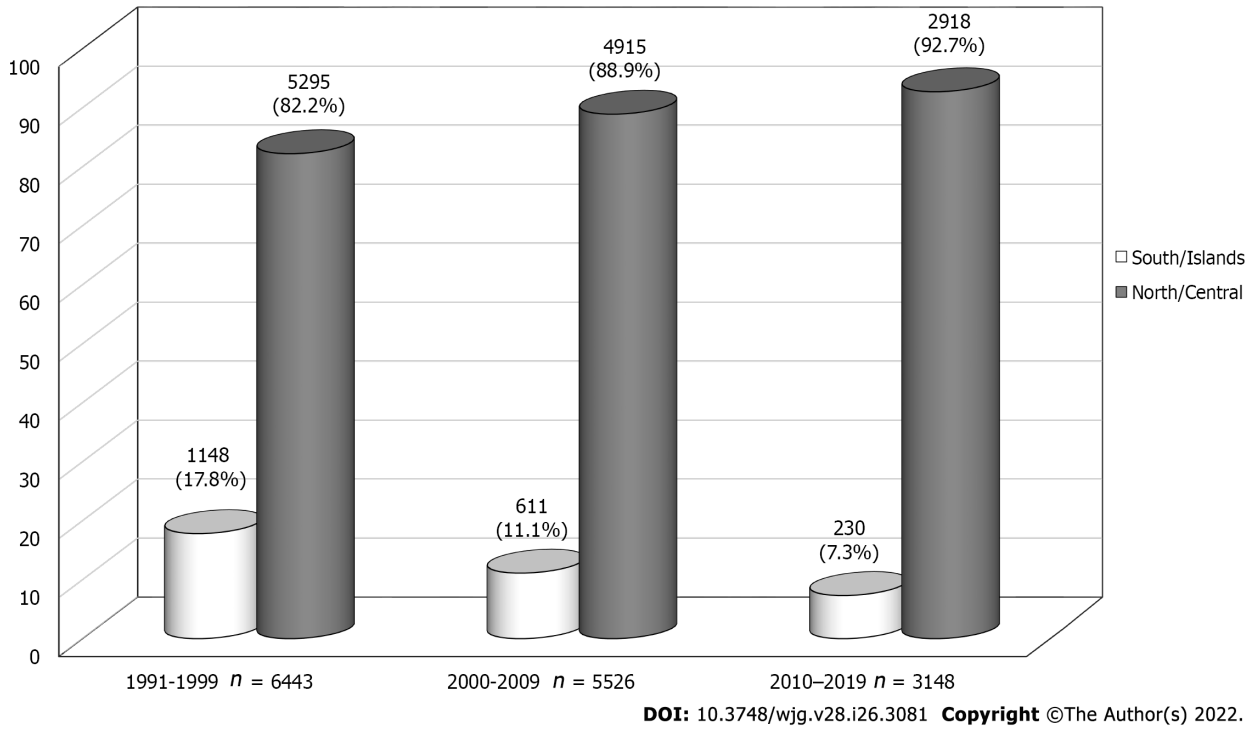

Figure 1 shows a clear trend towards an overtime reduction of the total number of cases in Italy, and moderate changes in cases distribution, increased in northern and central regions and decreased in southern and island areas[26,27].

In Italy, the uninterrupted flux of migrants over the last 20 years brought that about 9% of resident population are composed of immigrants, more frequently from eastern Europe and sub-Saharan Africa. Out of the 4981 AHB cases reported to SEIEVA from 2004 to 2019 by 10 of the 20 Italian regions, 849 (17.0%) occurred in immigrants, of whom 53.4% had come from eastern Europe, 14.6% from Asia, 21.6% from Africa, 8.9% from central/southern America, 0.1% from North America, and 0.1% from Oceania. The comparison between the AHB incidence rates among people born in Italy and foreigners, reported by the "Strong Migratory Pressure Countries", report among foreigners values up to 4 times higher until 2008, a difference progressively decreased from 2009 to 2019, when the standardized rates were 0.4 per 100000 for Italians, and 0.6 for foreigners[26,27].

In Italy, the uninterrupted flux of migrants modified the AHB molecular evolution, where, for decades, genotype D was observed in 95% of patients. Coppola *et al*[28] showed that in 123 AHB-patients, a significant increase in HBV genotypes non-D, from 11% in 1999-2003 to 41.1% in 2004-2008, associated with unsafe sexual habits. In good agreement, Ferraro *et al*[10] showed a high rate of cases with acute hepatitis B due to HBV genotypes non-D in Sicily in 2012 (44% genotype A, 3% genotype E), infected mainly through unsafe sexual intercourses.

In 2015, Zuccaro *et al*[11] reported that HBV genotypes non-D were responsible of nearly half of 103 consecutive cases of acute hepatitis B, mainly HBV genotypes A and F, associated with unsafe sexual exposure. In addition, mutations of antiviral resistance or viral mutants in the antigenic determinant "a" of HBsAg have been reported in AHB-patients[28].

Even clinical presentation and outcome of AHB have changed over time in Italy since, in abolishing the circulation of the virus in subjects aged 0-41, the universal HBV vaccination has confined acute hepatitis B to older ages when the disease is more severe[28,29].

Figure 1 Geographic distribution of 15117 new cases of acute hepatitis B registered in the surveillance of the integrate epidemiological system of acute viral hepatitis (SEIEVA) system from 1991 to 2019, according to the time of occurrence.

EPIDEMIOLOGICAL AND CLINICAL CHANGES OF CHB IN ITALY IN THE LAST 50 YEARS

The worldwide prevalence of subjects with chronic HBV infection is estimated at around 5%, with wide differences from a geographic area to another, 0.1%-2.0% in northern America and northwestern Europe, 1.0%-8.0% Japan and African countries overlooking the Mediterranean sea, and 8.0%-20.0% in Southeast Asia/sub-Saharan regions[16,17]. HBV genotype A prevails in northern America and northwestern Europe, HBV genotypes B and C in Asia, genotype D in southern Europe, northern Africa, India, and Middle East, HBV genotype E in western Africa, HBV genotype F in southern/central America, HBV genotype G in the USA and France, and genotype H in Mexico and some countries of South America[30]. CHB, defined as the persistence of HBsAg in serum for more than 6 mo, is a dynamic process which develops through five main phases: (1) "Immune tolerant" phase with mild/absent necroinflammation with normal/low aminotransferase levels, high HBV DNA levels, and HBeAg positivity, with no/slow evolution to fibrosis; (2) "immune reactive phase" characterized by liver necroinflammation, increased or fluctuating aminotransferase serum values, low or intermediate HBV-DNA level, HBeAg positivity, and progression to liver fibrosis or cirrhosis; (3) "inactive HBV carrier state" with low/absent necroinflammation, low/normal aminotransferase serum levels and with very low or undetectable serum HBV DNA, commonly, seroconversion to anti-HBe; (4) "HBeAg-negative CHB" characterized by mild to severe necroinflammation, fluctuating serum levels of aminotransferases and HBV-DNA, linked to e-minus HBV variant unable to express HBeAg[31]; and (5) "occult HBV infection" with HBsAg negativity and low HBV replication with detection of HBV DNA in the liver cells and also in serum (some cases) which clinical impact needs further investigation[32,33].

A complete clinical history should always be the first approach to patients with chronic hepatitis B, including family history, alcohol consumption analysis, metabolic risk assessment, and vaccinations performed. Physical examination should be complete and especially directed at identifying signs indicative of cirrhosis[1]. The laboratory tests useful to define the degree of viral replication and the stage of chronic hepatitis include the search for HBeAg/anti-HBe in serum, HBV DNA load, the blood count, the detection of aminotransferases, total bilirubin, and alkaline phosphatase serum values, and any other tests eventually necessary for the patient under examination[1].

For untreated adult patients, the 5-year cumulative incidence of developing cirrhosis varies between 8% to 20% across studies, and the risk of HCC from 2% to 5%[1]. Among the instrumental investigations, liver biopsy is needed to evaluate the degree of inflammation and fibrosis, a technique, however, sometimes burdened by serious complications, while transient elastography is considered sufficient for the evaluation of fibrosis alone; hepatic ultrasound is of great use for monitoring the clinical course of liver cirrhosis and, in particular, for the early identification of intrahepatic nodules of HCC. Better definition of HCC can be obtained with computed tomography and magnetic resonance imaging.

Drugs recommended and most frequently used to treat CHB are nucleus(t)side analogues tenofovir disoproxil fumarate or tenofovir alafenamide and entecavir, chosen in relation to their high genetic barrier, antiviral potency, and excellent profiles of resistance, tolerability, and safety[1,34]. The duration of treatment remains indefinite because these drugs suppress HBV replication but do not eradicate viral infection and reactivation of both viral replication and chronic disease occurs frequently upon treatment suspension, sometimes with a serious clinical impact[1,34].

At the end of 1970s, the HBV endemicity was considered intermediate, with a prevalence of HBsAg chronic carriers nearly 3%[35,36] and with an increasing gradient from North to South of Italy, where 5% of people were HBsAg positive[37,38]. At that time, the main routes of transmission were vertical transmission at delivery, intravenous drug use (IVDU), and living with an HBsAg chronic carrier, mainly between siblings.

As a result of the reduced HBV circulation, the percentage of HBsAg chronic carriers has decreased overtime in Italy. An impressive decline in HBsAg prevalence in children and teenagers has been observed even before the universal HBV vaccination had been introduced. As an example, the rate of HBsAg positivity decreased from 2.2% in 1980 to 0.8% in 1988 in schoolchildren aged 7-12 years in the city of Naples[39]. This decline has been confirmed in subsequent studies in pregnant women tested at the delivery[40], and in young adults at their enrolment in the army[41].

The rate of HBsAg positivity in patients with chronic hepatitis of all etiologies, either inpatients or outpatients of numerous Italian liver units, was: 61% in 1975[42], 44% in 1980, 34% in 1989[43], and 12.2% in 2001[43-45]. At present, only 0.8% of subjects born in Italy are HBsAg positive, also thanks to the universal HBV vaccination. Additional evidence of efficacy of HBV vaccination in Italy was the increase in the mean age of patients with CHB, from 30.8 years in 1980-1989[42] to 57.3 years in 2019[46].

The positive effects of HBV vaccination to reduce levels of HBV endemicity were also observed in countries with a high level of endemicity. About that, it seems interesting to evaluate the data reported by some authors from China, a nation that like Italy has achieved a remarkable socio-economic improvement in the last decades, where an extensive vaccination campaign against HBV infection has been conducted. A national cross-sectional epidemiological study performed in China in 1992 reported a 9.8% rate of HBsAg chronic carriers[47]. A reduction of this prevalence to 7.2%, due also to a series of measures implemented by the Chinese government, has been reported by Tedder *et al*[48] in 2006. A tendency to a further decline has been shown by a meta-analysis by Wang *et al*[49] who, analyzing the data published in 27 studies from January 2013 to December 2017, estimated a 6.89 HBsAg prevalence in the Chinese population, with more than 90% of HBV infected subjects aging more than 20 years[49]. The data reported by the above-mentioned studies indicate that even starting from very high level of endemicity, the correct application of general and special prophylactic measures, including a wide vaccination campaign against HBV, can yield significant results.

Italy, as mentioned above, has now a country of migration from geographical areas with high or intermediate HBV endemicity in the last two decades. Currently, nearly 9% of the 60 million of inhabitants are immigrants, of whom the major part has not received HBV vaccination and 250000 are estimated to be HBsAg chronic carriers with a 30% rate of HBeAg positivity[50]. The integration of immigrants is proceeding slowly, and it is unlikely that their continuous flow could not impair the favorable results obtained in Italy in the last five decades. El-Hamad *et al*[23] observed 3.728 migrants, mainly undocumented, 12.4% from northern Africa, 21.4% from sub-Saharan Africa, 16.8% from Asia, 44% from eastern Europe, and 5.4% from Central/South America, have come to Italy from 2006 to 2010. The mean rate of HBsAg positivity was 6%, different in the various geographic groups as well as the prevailing HBV genotype, both reflecting those of the country of origin. Coppola *et al*[13] studied 882 undocumented migrants/refugees who lived in the South Italy (period of study January 2012-June 2013), of whom 9% were HBsAg positive. This percentage was 14% in 444 individuals from sub-Saharan Africa, 6% in 198 individuals from Eastern Europe, and 2%-3% in the remaining 240 migrants from other geographic areas[13]. Zermiani *et al*[51] found a 3.5% HBsAg positive rate in migrant female sex workers. A cross-sectional Italy study[50] carried out in 3760 HBV chronic carriers from February to July 2008, reported that 37.1% (932 cases) were migrants from Far East, 35.4% from eastern Europe, 17.5% from sub-Saharan Africa, 5.5% from northern Africa, and 4.5% from other sites. HBV genotype D was detected in 40% of migrants and in 87% of subjects born in Italy. Migrants more frequently than subjects born in Italy were HBV-inactive carriers and less frequently showed CHB, cirrhosis, and HCC.

Sagnelli *et al*[52] evaluated 53 HBsAg chronic carriers with genotype E, immigrated in Southern Italy, of whom 47 (88.7%) were from sub-Saharan Africa, 4 (7.5%) from eastern Europe, and 1 (1.9%) from Asia. The molecular epidemiology study disclosed four statistically supported clusters and traced the genetic evolution and phylogenesis. In addition, phylogenetic analysis on a time scale considering the year of arrival in Italy showed that 52 immigrants had contracted genotype E infection in their country of origin before they arrived in Italy[52].

CONCLUSION

In Italy, the level of HBV endemicity has progressively decreased over the last 50 years. The main

contribution to the downward trend of AHB incidence and of the prevalence of their chronic sequelae is mainly attributable to improvement in socioeconomic and hygienic conditions, the effective educational HIV infection campaigns, and the HBV vaccination since 1991 continued without interruptions until now[43]. There was a consequent strong reduction in the impact of major risk factors for HBV infection acquisition. Vertical transmission from HBsAg positive mother to their newborn babies is just a memory, due to mandatory determination of serum HBsAg in pregnant women, and to passive and active immunization of babies born of HBsAg positive mothers. Besides, the impressive reduction in size of families, particularly in the South Italy regions and islands, has strongly impaired HBV transmission through household contacts with HBsAg-positive chronic carriers. A strong contribution to the significant reduction of HBV endemicity in Italy has been also given by the mandatory screening of blood donations for HBV markers and by the remarkable reduction or abolition of improperly sterilized instruments for medical, surgical, and cosmetic procedures. Also, the role of IVDU has progressively reduced by extension of vaccination to persons aged up to 41. Currently, sexual transmission plays the major role in HBV transmission in Italy, due to infrequent use of condom in unsafe sexual activity[53].

As a consequence of the reduced impact of risk factors for HBV infection acquisition, the prevalence of HBV chronic carriers in the general population has undergone an impressive continuous decrease and to date is 0.8%; similarly, the current AHB incidence B has been reduced to 0.21 per 100000 inhabitants, higher in males than in females, most of cases occurring in Italian citizens with unsafe sexual habits aged over 41 and in unvaccinated migrants[27]. In this regard, most immigrants who come to Italy are not vaccinated against hepatitis B and are three times more likely to acquire HBV infection than Italian citizens[13,26,52,53]. The WHO Regional Office for Europe strongly motivated the national health authorities of the host countries to set up national hepatitis B vaccination protocols for all unvaccinated migrants and instruct local health authorities how to apply them[14]. It should be also emphasized that HBsAg positive migrants should be entrusted to local healthcare facilities for further diagnostic information and clinical therapeutic follow-up.

Like for numerous other sectors of medicine, SARS-CoV2 pandemic has reduced care level also for HBV related diseases. In this period, nearly half people worldwide have not been able to enter clinical center for HBV prevention, diagnosis, and treatment due to breakdowns or other restrictions on the movement imposed by individual governments, absence, or reduction of earnings due to loss of work activities and for the subject' fear to acquire SARS-CoV-2 infection in clinical environments[54]. Furthermore, the activity of clinical structures dedicated to HBsAg positive patients has been greatly reduced, with a sharp contraction in the number of beds for hospitalization, day hospital facilities and healthcare personnel, devolved to assistance for SARS-CoV-2 patients. In Italy, recent web-based survey performed by the Italian Association for the Study of the Liver (AISF) registered that a quarter of hepatology centers have been transformed into divisions for the management of COVID-19 patients and also a quarter of other health services for liver outpatients have been suspended[15]. A continuous clinical/therapeutic follow up has been provided only to 32.5% of patients with decompensated cirrhosis and to 18% of those with HCC; in addition, 23% of CHB patients treated with nuclo(t)side analogues have undergone temporary interruptions of therapy[15]. In this regard international guidelines give clear indications on how to apply therapy with entecavir or tenofovir for an effective long-term suppression of viral replication in CHB patients: Start therapy at first diagnosis, and then continue without interruption to avoid serious and sometimes life-threatening virus reactivations[55,56].

The percentage of subjects vaccinated against COVID-19 in developing countries is decidedly low. In addition, many children have not yet been vaccinated and a minority of adults has refused vaccination in countries with a high socioeconomic level. All this has favored the development of viral variants more and more infectious that is leading the pandemic to its fifth wave. Nevertheless, by reducing SARS-CoV-2 circulation, COVID-19 vaccination is exerting a favorable effect on CHB management, whose consistency, however, is not yet fully assessable because liver units and transplant centers are still suffering severe limitations. Furthermore, most of the damages produced by COVID-19 to patients with liver diseases will come both from the delays in screening, diagnosis and start of treatment and from the interruptions of clinical activities for outpatients, damages not yet calculable. However, the consequences of the first 3 waves of the COVID-19 pandemic have been analysed by Tapper *et al*[57] who reported that all screening procedures were significantly delayed and that this has resulted in a substantial increase in early diagnoses in the advanced stages of liver diseases or at the onset of complications. Analysing the events following the pandemic waves, these Authors identified three phases: The first one taking place in lockdown and other social distances, characterized by high priority for the needs of COVID-19 patients and a strong delay for elective and routine activities regarding other pathologies; the second one following abolition of physical distancing, with a rapid increase in morbidity and decompensation of non-COVID-19 diseases and by a crowding of health facilities forced to solve old and new problems; a long third stage heavily burdened by consequences of delays in diagnosis and start of treatment and by the interruptions of clinical-therapeutic follow-up[57]. More tuned with the problems of HBsAg positive subjects, Mandel *et al*[58] analysed the effect of three waves of COVID-19 pandemic on HBV testing volume in Ontario, a state of Canada with a high socioeconomic level. Test volume for HBV DNA decreased by 37% during the first pandemic wave, by 27% in second one and by 20% in the third one, reflecting reduction in HBsAg testing, 33%, 18% and 15%, respectively. These reductions are most likely due to both an adaptation of citizens to subsequent pandemic waves,

and a favorable effect of an overtime increase in COVID-19 vaccination coverage.

In numerous developing countries, the COVID-19 pandemic is also severely damaging the programs of the HBV-vaccination, as demonstrated by an analysis by the Institute for Health Metrics and Evaluation which showed in 2020 a dropped of vaccination activity to 1990s levels[59].

In clinical practice, telemedicine was increased over the past 20 years[60], with a sharp increase in 2020 and 2021 due to social distancing measures mandatory to curb COVID-19. Consent to the use of telemedicine was expressed by American Association for the Study of Liver Diseases and EASL-ESCMID experts who recommended it in COVID-19 emergency for the care of chronic hepatitis patients, those on waiting for liver transplantation, and those already transplanted[61,62]. On the strength of the experiences gained in waves of COVID-19, telemedicine can usefully be introduced in programs of prevention and screening, diagnosis, clinical, and therapeutic follow-up of HBV patients, with particular advantage for those living in rural areas and for those who have serious trouble getting to a liver unit.

The COVID-19 has caused quickly significant damage to hepatitis B setting that has lost some of the beneficial impact of several scientific research on clinical practice and on technological application, and huge economic investments. Local health authorities should monitor the damages inflicted to HBV patients by COVID-19 pandemic and work to reduce and, when possible, abolish them. Also, a greater spread of telemedicine could reduce the impact of COVID-19 pandemic.

To prevent onset of new SARS-CoV-2 variants highly infectious, nations with high economic levels should contribute to increase the coverage of COVID-19 vaccination in low- or moderate-income nations; the development of new low-cost vaccines suitable for countries with limited health resources will be of help in solving this problem. As far HBV infection, the HBV-universal vaccination must continue worldwide without interruption and health authorities should extend their HBV vaccination protocols to all unvaccinated migrants.

Abstract

The rapid progress of research into inflammatory bowel disease (IBD) has resulted in increasingly more treatment options. Different options have different advantages and disadvantages, and the preferences of patients may also differ. If patients can be invited to the formulation of medical decision-making, their compliance and satisfaction would be improved, thus possibly achieving better therapeutic results. The present review aims to summarize the current literature on shared decision-making (SDM) in the management of IBD, with the goal of promoting the application of SDM.

Key Words: Inflammatory bowel diseases; Decision making; Shared; Therapeutics

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: It is often challenging to make therapeutic decisions for patients with inflammatory bowel disease (IBD), given the uncertainty of therapeutic options and diverse patient values. Shared decision-making (SDM) is a process to formulate treatment with patients, trying to clarify and take account of the preferences of patients, increasing their compliance and satisfaction. We summarize current evidence and illustrate the necessity of applying SDM in IBD management.

INTRODUCTION

Inflammatory bowel disease (IBD) refers to a group of chronic inflammatory diseases of the gastrointestinal tract, mainly including Crohn's disease (CD) and ulcerative colitis (UC), which are lifelong diseases that tend to affect individuals aged 20–40 years[1,2]. IBD affects nearly all aspects of living, including patients' private, occupational and social lives. In total, 50%–80% of UC patients and about 67% of CD patients suffer from relapses and remissions, which is a clinical feature of IBD. Around 15%–30% of UC patients fail to achieve sustained remission, while only 13% of CD patients have a relapse-free course[3,4]. Therefore, IBD has a large socioeconomic burden, and direct and indirect costs caused by UC reach 0.81–1.49 billion dollars per year in the United States[5].

Previous research on the mechanism of IBD suggests that genetic susceptibility, intestinal microbiota, environmental factors (such as diet and stress), and the association between proinflammatory and anti-inflammatory cells and factors are involved in the occurrence and development of IBD[6,7]. An increasing number of therapeutic agents have been investigated, including the tumor necrosis factor (TNF)-α antagonist infliximab, and the effectiveness of these agents has been confirmed[8]. Although the large number of treatment options available for IBD is a positive aspect, it complicates the choice of optimal treatment for individual patients.

TRADITIONAL THERAPEUTIC STRATEGIES

The primary therapeutic aim for IBD is to induce and maintain remission[9], of which mucosal healing is the most important target[10]. Besides clinical remission, the most important objective is to achieve mucosal healing under endoscopy[1,2,9,11], which is associated with reduction in recurrence, surgical interventions, intestinal damage and steroid dependence[12,13]. The current treatment regimens for UC and CD are stratified according to severity. A step-up strategy is usually used to treat mild-to-moderate IBD[1,2,14]. For example, mild-to-moderate UC would be first subjected to 5-aminosalicylic acid (5-ASA). When efficacy is unsatisfactory, treatments are escalated to glucocorticoid and/or immunosuppressants, while biologicals are usually used as the final resort. By contrast, for severe IBD or steroid-refractory IBD, immunosuppressants or biologicals may be considered in the earlier stage.

Although the majority of patients with mild-to-moderate UC who receive 5-ASA achieved symptomatic relief within 8 wk, 41% of patients who achieve induced remission eventually experience relapse[15,16]. Thus, daily medication over a longer period of time is necessary to maintain remission. In addition, multiple daily doses of 5-ASA are required in the stage of induced remission, which may impair compliance, particularly for outpatients without regular medication reminders. Additionally, when 5-ASA administration is reduced to once daily during the induction or maintenance of remission stage[16,17], patient compliance may drop to 40%[18]. Poor compliance is a key obstacle for the induction and maintenance of remission[19].

Glucocorticoids constitute an important treatment for the induction of remission in active disease, particularly in CD. However, about 16% of CD patients do not respond to glucocorticoids after treatment for 30 d[20]. In addition, glucocorticoid therapy is often accompanied by a variety of side effects, including diabetes, hypertension, opportunistic infections, and osteoporosis[21,22]. More than 28% of patients with CD develop steroid dependence[20]. Glucocorticoids are not effective in maintaining remission, and the risks associated with long-term use are marked; thus, the dose of glucocorticoids needs to be tapered at the onset of clinical remission[9,16]. When mucosal remission is not achieved, complications such as fistula and stenosis can easily occur[23,24].

Contrary to traditional step-up therapy, the TOP-DOWN trial[25] confirmed that early combination of immunosuppressants led to a higher remission rate than standard step-up therapy in patients without steroids. Evidence has confirmed that the early use of biologicals may benefit certain patients with mild-to-moderate IBD[26]. The CHARM[27], SONIC[24], PRECISE 2[28] and GEMINI 2[29] trials demonstrated the advantages of early biological treatment over step-up therapy in patients with CD, involving anti-TNFα (infliximab and certolizumab) and anti-integrins (vedolizumab). Without sufficient evidence in patients with UC, previous studies showed lower remission rates in patients who had a shorter course of the disease[30], while other studies suggested that early use of vedolizumab increased remission in patients with UC[31].

However, no consensus has formed regarding the early use of biologicals for patients with mild-to-moderate IBD. The Pharmaceutical Benefits Scheme (PBS) of Australia specifies that biologicals should be considered only when the disease remains clinically active after 6 wk of steroids and 3 mo of immunosuppressants[9]. Despite current evidence supporting early use of biologicals, particularly for patients with CD, clinical decision-making needs to involve patients when treatment is economically demanding. It would be improper for clinicians to use biologicals at an early stage solely relying on the personal opinion of the physician, as it could generate conflicts between physicians and patients.

Refractory IBD patients with severe complications (uncontrolled hemorrhage, perforation, abscesses or malignancy) are candidates for surgery[1,2]. However, a previous study showed that gastroenterologists might differ from IBD patients in the willingness to surgery. Patients were more willing than

gastroenterologists to take risks to undergo surgery, and surgeons agreed with patients in the majority of cases[32]. The differences in perceptions among physicians and surgeons have a marked impact on patients, including the timing of referral for surgery.

Due to the convenience of wide access to information, patients may have their own ideas about treatment. Ignoring patients' values or preferences may lead to patient dissatisfaction, poor compliance, and eventually reduced treatment efficacy. Therefore, it is advisable to involve patients in decision-making and to discuss patients' preference after they have been fully informed about the treatment options, which can share the risks and improve patients' compliance. This is called shared decision-making (SDM).

SDM

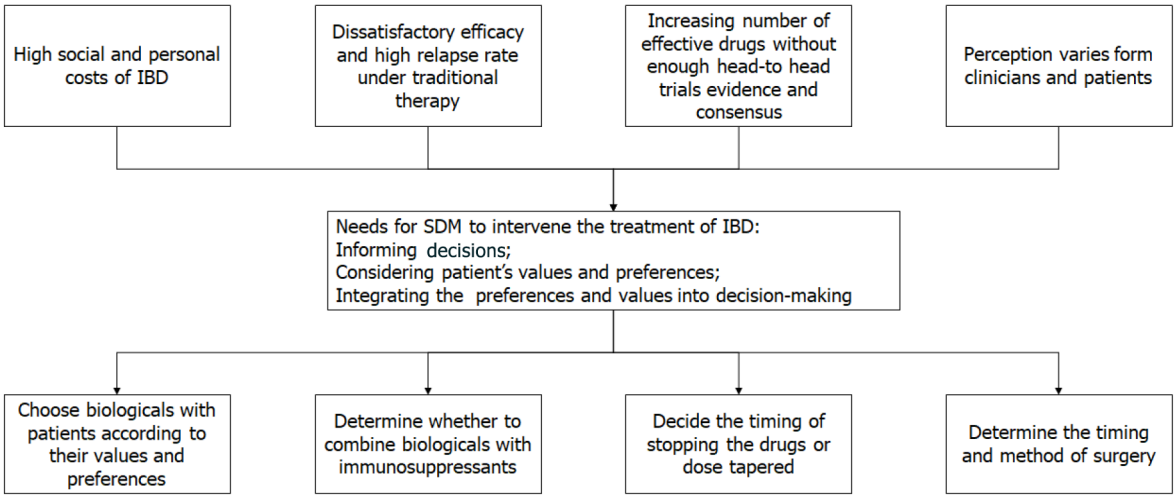
SDM is an approach where clinicians and patients share the best available evidence when faced with decision-making, and that patients are supported to consider options to achieve informed preferences [33]. Different from traditional diagnosis and treatment procedures, SDM requires that clinicians provide alternative choices of examinations and treatments, and describe the associated risks and benefits, while patients express their preferences and values, and both sides ultimately make decisions that are appropriate and are consistent with patients' best interests[34].

SDM consists of three key steps: (1) Clinicians inform patients of alternative decisions and provide relevant, high-quality, accessible information; (2) Clinicians consider the patients' values and preferences, particularly the most desired therapeutic targets; and (3) Physicians integrate the patients' preferences and values into the decisions to be made[34-36]. The three-talk model is practical to distribute the aforementioned three steps into three conversations, including team talk, option talk and decision talk[37,38]. In the team talk, physicians first actively promote patient participation, inform patients of the current options available for consideration, help patients realize that this is a bidirectional treatment requiring their own participation, and allow patients to think about the primary therapeutic target. In the options talk, physicians introduce each choice to the patients in detail, including the associated advantages and disadvantages, so that patients can compare each option based on their values. For example, for patients with CD, it is necessary to discuss treatment options, such as medical, surgical, and endoscopic therapy, and evidence-based information should be used to explain the remission rate, risks, and costs of each option, so as to objectively demonstrate the advantages and disadvantages of each choice to allow the patients to balance the pros and cons of each approach according to their own preferences and values. In the decision talk, physicians should elicit the patients' preferences and values; thus, the physicians need to understand what is most important to the patients, and make the appropriate decision together with the patients based on the patients' preferences and values. It should be emphasized that it is a course of patients' deliberation, from the stage of being aware of the options to that of understanding those options and having sufficient time to think about what is most important to them with the support of the physicians.

Decision aids can be used for patient education during SDM[39,40]. Decision aids are tools based on evidence-driven medical information. For example, patients can be intuitively told of the clinical remission rate of CD under infliximab monotherapy, and the approximate increased infection rate as well. These tools can be accessed online, on paper, or in video form[34,41,42], and aim to help patients to make deliberate choices among various treatment alternatives[43]. These tools can help patients to obtain relevant clinical evidence, include patients' preferences when medical decision-making dilemmas occur, allow patients to understand the possible long- and short-term results, and promote high-quality decision-making. In terms of decision aids for biological agents, Almario *et al*[44] designed the online decision aid tool IBD and me, which covers the commonly used cetuzumab, viduzumab, adalimumab, infliximab, galimumab and eutecumab; and introduces the timing and frequency of biological use, route of administration, side effects (mainly infectious and oncogenic risks), and common adverse effects of hormones and immunosuppressants. A personalized decision preference report can be obtained after finishing the questionnaire online.

SDM IN IBD

Surveys have shown that the majority of IBD patients agree to be involved in decision-making, and want to be informed about alternative treatments[45-48]. The majority of patients who participate in SDM experience improved clinical satisfaction, higher trust in doctors, and better compliance[49-51]. However, SDM is not suitable for all cases. Medical decisions include effective decisions and preference-sensitive decisions[52]. For effective decisions, it has been demonstrated that the benefits outweigh the risks, so the decisions are undoubtedly the best strategy. For example, coloproctectomy is required in UC patients with complicated colorectal cancer. However, for preference-sensitive decisions, there is no sufficient evidence to demonstrate which treatment is the best, as there may be multiple reasonable treatment options (even including follow-up observation); thus, the judgement of the benefit/risk ratio



falls upon patients, such as whether the treatment target they value has been achieved, or whether the side effects they are concerned about have occurred in the past. Of the two decision types, SDM only fits in the preference-sensitive decisions, which is often present in the management of IBD. IBD is a complex disease with large individual variation, and each treatment has particular advantages and disadvantages. Therefore, SDM is suitable for the management of IBD.

In addition to the aforementioned selection of step up therapy or top-down early intervention treatment strategy, SDM can be used for choosing biologicals. A number of biologicals are currently available for the treatment of IBD, including infliximab, adalimumab, certolizumab, golimumab, natalizumab, vedolizumab and ustekinumab, with differences in the mechanism, route of administration, and side effects[53]. However, it was not until 2019 that the first head-to-head VARSITY trial[54] compared the efficacy and safety of intravenous vedolizumab to subcutaneous adalimumab. Other head-to-head trials of different biologicals are still awaited[55]. Clinicians' selection of biologicals especially for CD patients is varied, because the majority of real-world data on CD show no significant differences in clinical remission rate[56]. Under these circumstances, it is a preference-sensitive decision to choose biologicals. For example, infliximab is administered intravenously, while adalimumab is administered subcutaneously, thus the length of hospital stay varies. While infliximab is administered at intervals of 0, 2 and 6 wk to induce remission, and then administered every 8 wk, adalimumab is administered every 2 wk. In such a case, some patients may be more concerned with the frequency or route of administration due to the distance to the hospital, and therefore may choose infliximab treatment at longer intervals, whereas other patients may give priority to side effects. In a study involving 640 patients with IBD[44], factors that influenced the choice of biologicals for patients with UC were in the following order: long-term remission rate, route/frequency of administration, and risk of lymphoma. For patients with CD, these factors were short-term remission rate, risk of lymphoma, and route/frequency of administration. Of note, a small percentage of patients (3.6%) cited the mechanism of action as the primary factor for their selection of a given biological. At the same time, physicians' assumption of patients' acceptance of biologicals and their preferred route of administration differs from the patients' opinion[57]. If doctors impose on their patients what they think is universally applicable instead of incorporating the patients' preference into the decision-making process, patients may be forced to agree to a treatment plan against their own values. Patients who do not trust their doctors may develop a self-protective mechanism of rejection, thus leading to poor compliance. This awkward situation can be avoided to a large extent by involving patients in the decision-making process.

For the past 20 years, it has been discussed whether biologicals alone or in combination with immunosuppressants should be used for the treatment of IBD. The results of the SONIC study showed the advantages of the combination treatment[58]. Infliximab combined with immunosuppressants achieved higher rates of clinical remission and mucosal healing compared with infliximab or azathioprine alone in corticosteroid-free patients with CD. This may be associated with the fact that immunosuppressants reduce the generation of antidrug antibodies and increase the blood concentration of biological agents[58,59]. Although there is increasing evidence that combination treatment is superior to single-drug treatment[59-61], and the early use of infliximab with azathioprine or methotrexate for ≥ 1 year has been recommended[62], to date, not all the studies support the use of combination treatment, particularly in the case of biologicals other than infliximab[63-67]. In terms of safety, previous studies have shown that biologicals combined with immunosuppressants can increase the incidence of infection and malignancy[68-72]. Therefore, the benefit/risk ratio remains unclear regarding the combination of biological agents with immunosuppressants; thus, clinicians need to explain the benefits and risks to patients. More importantly, the preferences of the patients need to be considered to determine whether the patients would be willing to accept the risk of increased infection and tumor incidence to achieve an increase in remission rate. By involving patients in the decision-making process, the risk of increased side effects can be shared by both doctors and patients.

IBD patients have a risk of relapse after reduction or withdrawal of 5-ASA, glucocorticoids, immunosuppressants, biologicals, or combination therapy. Approximately 30% of patients with CD or UC who stop immunosuppressant monotherapy relapse within 2 years, while 50%–75% relapse within 5 years. By contrast, the risk of relapse after stopping anti-TNF therapy is 30%–40% at 1 year and > 50% at 2 years[73]. The therapeutic cost associated with the long-term use of aforementioned drugs is high, and some side effects may be related to the duration of use, such as the risk of cancer after the use of biologicals. Therefore, whether the treatment should be stopped or the dose tapered needs to be weighed with regard to the possible benefits, costs and risks, and decisions must be made individually. Given the high recurrence rate of IBD and the uncertainty about the optimal timing for clinical, biochemical and endoscopic follow-up, follow-up plans after drug withdrawal or dose reduction should also be made together with patients, taking their preferences into account[73].

As mentioned above, in addition to requiring informed consent, whether patients with IBD should undergo surgery also requires SDM. Controversies exist regarding the choice of surgery[74]. Ileal pouch–anal anastomosis (IPAA) has become the standard surgical option offered to patients with UC, with endoanal mucosal resection being the second choice. IPAA preserves the anal transition zone, which improves fecal continence. However, the elimination of colonic mucosa is the goal of surgical intervention; thus, what IPAA preserves will put the patient at risk of developing dysplasia and

Figure 1 The reasons and fields of application for shared decision making in inflammatory bowel disease treatments. IBD: Inflammatory bowel disease; SDM: Shared decision making.

residual disease in the remaining anal canal epithelium, while mucosectomy can decrease dysplasia risk. Therefore, doctors and patients should balance the benefits against potential relapse and malignant change in the retained mucosa.

DISCUSSION

In multiple aspects of IBD management, SDM has shown potential. We believe that SDM can and should be used in IBD therapy (Figure 1). As mentioned, the treatment of IBD is a preference-sensitive choice; the advantages and disadvantages of which need to be weighed by the patients. Clinicians need to invite patients to the decision-making process, even though not all situations are suitable for SDM. For example, when perforation occurs in a UC patient with toxic megacolon, there is no doubt about the choice of treatment, but patients still need to be aware of the need to undergo surgery. Therefore, clinicians must determine whether it is a preference-sensitive decision and whether SDM is required. If patients decline to participate in the SDM even after multiple invitations by doctors, clinicians may not have to continue spending their time on persuading patients.

SDM is a type of informed consent based on evidence-based medicine, putting forward certain requirements for doctors and patients. Challenges inevitably exist in the implementation of SDM. From the aspect of clinicians, as mentioned above, it is important to consider whether doctors are fully aware of the pros and cons of the drugs they choose as new treatments emerge and research advances rapidly. Although it can be resolved with the help of decision aids tools, the tools also should be updated continually. In addition, clinicians should have the awareness and techniques of SDM, and need to receive professional education. With the SDM skills, physicians' willingness to impart relevant knowledge to patients should be emphasized. In addition, different perceptions of IBD between physicians and surgeons may influence patients' perceptions. However, it is worth mentioning that diagnosis and treatment after discussion with a multidisciplinary team is a model that will help bridge the cognitive gap between physicians and surgeons. IBD patients' preferences and disease patterns vary [44], meaning that no SDM plan fits all patients once and for all. Doctors need to be flexible, and patients need to have unlimited access to information and they should be actively invited to the decision-making process. The implementation of SDM undoubtedly needs policy support. For example, biologicals obtained in a first-tier city may not be available in other less-developed cities, which is a restriction for SDM. Unfortunately, SDM is not adequately addressed in current medical education, leading to less awareness of what it is and how to implement it. Therefore, we can't emphasize it too much that the healthcare providers should be trained in their early stage of career to increase the benefits of implementing of SDM. And the early stage training hopefully will cultivate physicians' habit unconsciously to take advantage of SDM in the medical practice.

These challenges need to be carefully considered before SDM can be implemented. Although SDM is theoretically suitable for patients with IBD, studies comparing SDM with traditional decision-making methods remain sparse and are eagerly awaited in the future. We hope that this review will promote the use of SDM in the management of IBD.

CONCLUSION

The investigations delineated in the present article revealed the dilemma of choosing individualized treatments for patients with IBD. We also discussed the advantages of SDM and the aspects in which SDM can be used. Current evidence showed the limitations of conventional step-up therapy for IBD. However, lack of head-to-head clinical trials and diverse treatment preferences of patients lead to difficulty of individualized decision-making. We demonstrate the latest advance of SDM with the support of clinical data, hoping that SDM will be better used by physicians caring for IBD patients.

Abstract

Liver is the most common site of metastases of colorectal cancer, and liver metastases present with distinct histopathological growth patterns (HGPs), including desmoplastic, pushing and replacement HGPs and two rare HGPs. HGP is a miniature of tumor-host reaction and reflects tumor biology and pathological features as well as host immune dynamics. Many studies have revealed the association of HGPs with carcinogenesis, angiogenesis, and clinical outcomes and indicates HGP functions as bond between microscopic characteristics and clinical implications. These findings make HGP a candidate marker in risk stratification and guiding treatment decision-making, and a target of imaging observation for patient screening. Of note, it is crucial to determine the underlying mechanism shaping HGP, for instance, immune infiltration and extracellular matrix remodeling in desmoplastic HGP, and aggressive characteristics and special vascularization in replacement HGP (rHGP). We highlight the importance of aggressive features, vascularization, host immune and organ structure in formation of HGP, hence propose a novel "advance under camouflage" hypothesis to explain the formation of rHGP.

Key Words: Colorectal cancer liver metastases; Histopathological growth pattern; Desmoplastic histopathological growth pattern; Replacement histopathological growth pattern; Prognostic value; Vessel co-option

Core Tip: Histopathological growth pattern (HGP) reflects tumor–host interaction, vascularization, aggressiveness and immune infiltration. Remarkable performance on predicting survival and recurrence and distinct response to therapies makes HGP a promising prognostic biomarker and stratification parameter in pretreatment decision-making. Exploiting on mechanism of HGP would provide potential therapeutic targets. In this context, we propose one novel "advance under camouflage" hypothesis to interpret formation of replacement HGP.

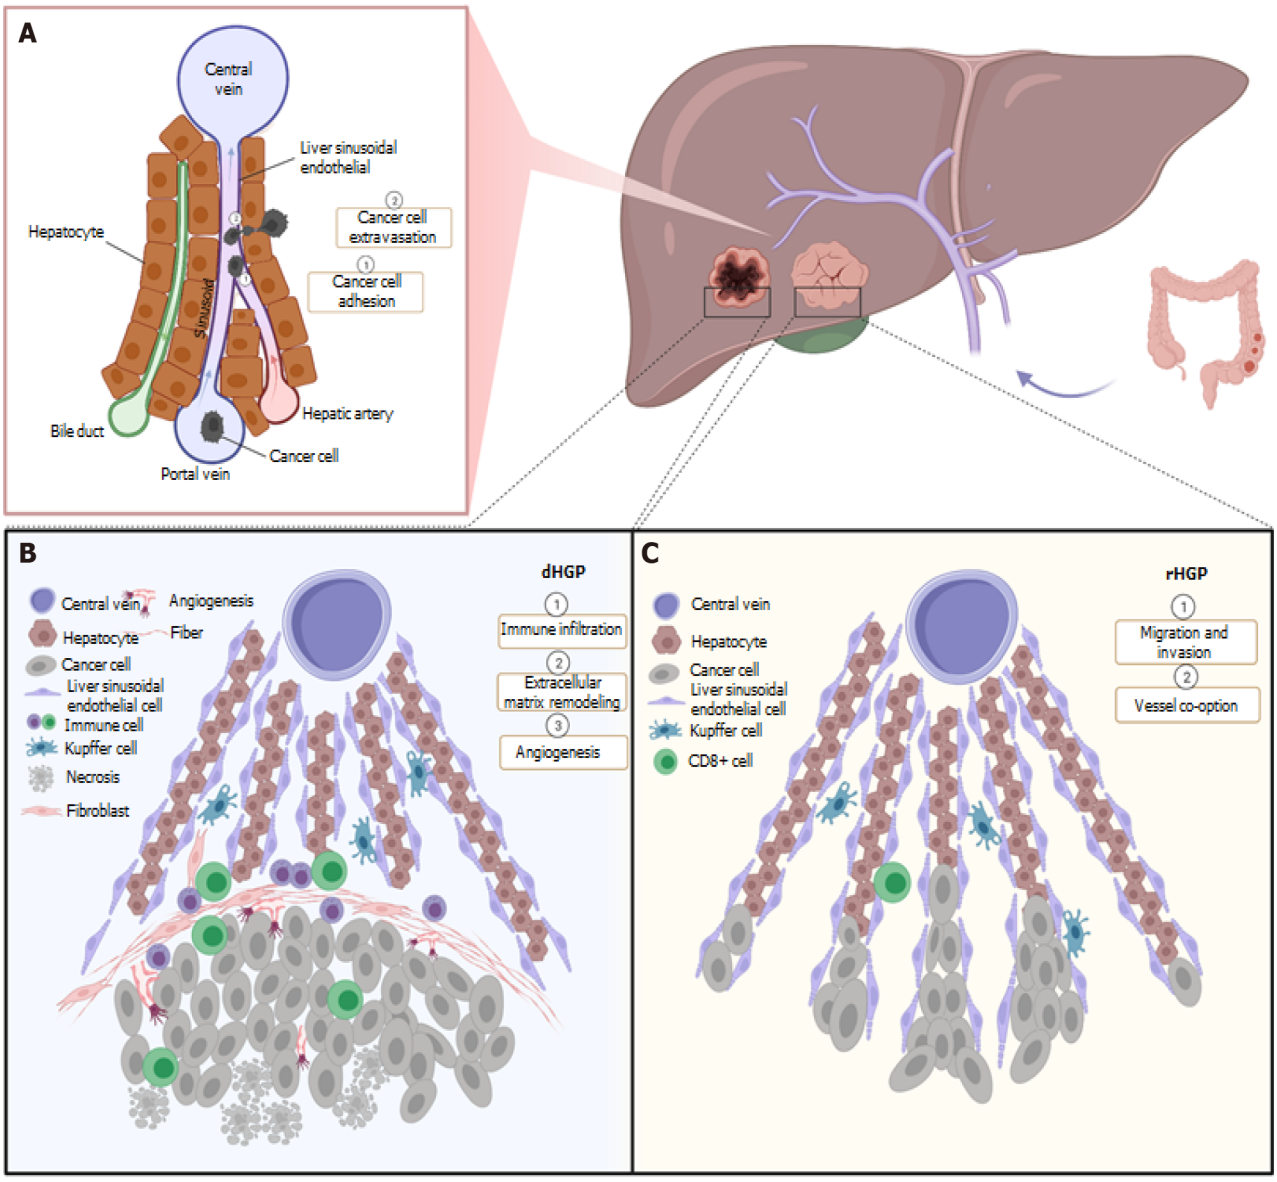
INTRODUCTION



Colorectal cancer (CRC) is the third most frequent tumor worldwide and the second most common in Europe. In diagnosed CRC, 20%–25% of patients are classified as stage IV and 15%–25% of those develop liver metastases[1]. For these whose metastases are confined to the liver, the only opportunity to cure is radical surgical resection. However, not all patients are fit for surgery and there is still a high rate of intrahepatic recurrence after curative resection. Therefore, the attempt on seeking for more comprehensive prognostic and stratification markers is of utmost importance. Deriving from this aim, the invasive margin as one pathological variable was selected to construct a prognostic system for rectal cancer patients[2]. There, tumor margin was classified into expanding type (pushing or well circumscribed) and infiltrating type. Based on these studies, the histopathological growth pattern (HGP) initially came into shape.

In 2016, international consensus guidelines[3] for scoring HGPs of liver metastasis were produced. Three common HGPs, *i.e.*, desmoplastic HGP (dHGP), pushing HGP (pHGP) and replacement HGP (rHGP), and two rare HGPs, *i.e.*, sinusoidal HGP and portal HGP are described in these consensus guidelines. In principle, HGPs could be distinguished according to the character of the invasive margin and morphology of the tumor, which is usually observed in light microscopy on standard hematoxylin and eosin (H&E)-stained tissue sections. Distinct biological and invasive patterns are presented in different HGPs. The key histopathological characteristic of dHGP is that there is a broad desmoplastic rim at the tumor periphery, which separates tumor cells from normal liver tissue. rHGP tumor cells mimic the liver architecture and replace the hepatocytes within liver plates, and the tumor displays an infiltrative border and irregular contours. pHGP tumor expands in a pushing way and the adjacent liver is compressed. Its interface is as sharp as that of dHGP but without a desmoplastic rim[3]. Figurative knowledge of dHGP and rHGP is presented in Figure 1.

PROGNOSTIC VALUE OF HGPS

Frequently, HGP predicts overall survival and recurrence in patients resected for CRC liver metastasis (CRCLM). HGPs have been extensively characterized not only in liver metastases but also in the primary cancer and metastases in lung, brain and skin; therefore, there are different categorization about HGPs in different tissues. They are ordinarily classified into dHGP and non-dHGP or expanding and infiltrative HGP[2] when used as prognostic biomarkers. In this fashion, dHGP refers to pure dHGP with a 100% desmoplastic interface on every section, while non-dHGP actually includes pushing, replacement and a mixed (pushing-replacement) pattern. As the major form in most cases, rHGP represents non-dHGPs and infiltrative HGP. One of the most important findings from studies on predictive value of HGP is that CRCLM patients with dHGP, especially pure dHGP, are prone to longer overall survival. dHGP is verified as an independent factor for superior overall survival (OS) and progression-free survival (PFS)[4-8], while non-dHGPs are strong prognostic indicators of worse survival[8-14]. More than in CRCLM, a similar trend has been observed in liver metastases from cutaneous melanoma[15], which implies that the prognostic value of HGP is generally applied in various liver metastases.

For CRCLM patients who have undergone hepatectomy, high recurrence rate may cause repeat resection and impair their survival. Non-dHGP might be responsible for this damage from intrahepatic as well as overall recurrences[12]. Compared with dHGP, rHGP and pHGP more frequently experience multiorgan recurrence, while dHGP has more liver-limited disease recurrence[16-18]. Evidence supports that dHGP predicts good outcomes, but the infiltrative pattern or rHGP indicates poorer outcomes and higher recurrence. In this context, we provide an overview of studies focusing on prognostic and strati-

Figure 1 Formation and mechanism of desmoplastic histopathological growth pattern and replacement histopathological growth pattern.
A: Cancer cells originating from colorectal cancer arrive in the liver *via* portal vein, adhere to lumen of liver sinusoid and migrate with extravasation through fenestrae on liver sinusoidal endothelial cells (LSECs); B: There is a desmoplastic rim in interface of tumor with desmoplastic histopathological growth pattern, with tumor cells destroying liver plate, causing immune infiltration and extracellular matrix remodeling induced by activated fibroblasts and deposited fiber. Both angiogenesis and necrosis are presented in the tumor; C: In replacement histopathological growth pattern, tumor cells with highly migration and invasion replace hepatocytes and co-opt LSECs but without disturbing the liver structure and extensive immune infiltration. dHGP: Desmoplastic histopathological growth pattern; rHGP: Replacement histopathological growth pattern.

fication value of HGPs in Table 1.

Apart from predicting survival, the growth pattern of primary CRC was also found to predict the HGP of liver metastases. The primary CRCs with expanding growth pattern significantly tend to form dHGP liver metastasis, while CRC patients presenting with infiltrating growth pattern are more likely to have rHGP liver metastasis[19]. It seems that some invasive characteristics are inherited from primary tumor to secondary metastases. However, there are few reports about this. Wu *et al*[19] found several specific gene mutations, among which representative gene mutation *PIK3CA* appearing in 40% of primary CRC patients with dHGP liver metastasis was speculated to mediate vascular development and angiogenesis through the vascular endothelial growth factor (VEGF) signaling pathway, further supporting dHGP. Nevertheless, these findings have not revealed the genomic correlation between growth pattern in primary CRC and HGP in liver metastases.

Some relevant factors such as surgical margin, immunoscore[20] and glucose uptake[21,22] were also widely investigated as predictor in outcomes of CRC. The combination of HGP with resection margin, parameters of immune status, genes and metabolism also paves the way for creating comprehensive and accurate predictive models. Surgical margin in tumorectomy is a critical but controversial issue as

Table 1 Studies on stratification value of histopathological growth pattern in colorectal cancer liver metastasis

Year	Factors	Prediction	Distribution of HGPs	Ref.
Survival stratification				
2018-2019	dHGP and rHGP (based on radiomics)	dHGP *vs* rHGP and mixed HGP: longer PFS (no detail)	119 patients: dHGP (206 lesions), rHGP (140 lesions)	Wei *et al* [43]
2004-2019	Pushing GP and infiltrative GP	Infiltrative GP *vs* pushing GP: Worse OS (50.2 mo *vs* 92 mo) and DFS (10.5 mo *vs* 21.5 mo), higher intrahepatic recurrence (75% *vs* 20%)	266 patients: Infiltrative (n = 182, 68.4%) and pushing (n = 84, 31.6%)	Jayme *et al* [16]
2005-2017	dHGP and non-dHGP group; metabolic-clinical risk score	dHGP *vs* non-dHGP: Longer 5 yr OS (83.3% *vs* 34.3%) and 10 yr OS (62.5% *vs* 22.8%) and DFS (14.4 mo *vs* 8.3 mo)	108 patients: dHGP (26, 20%), non-dHGP (38, 35%)	Bohlok *et al* [23]
2000-2015	dHGP and non-dHGP; positive resection margins (R1) and negative resection margins(R0)	Non-dHGP *vs* dHGP: worse OS (50 mo *vs* 80 mo), higher risk of positive resection margins (76.6% *vs* 23.4%)	1302 patients: dHGP (305, 23%) and non-dHGP (997, 77%); R1 (170, 13%) and R0 (1132, 87%)	Nierop *et al* [9]
2004-2017	dHGP and non-dHGP, clinical risk score, the immunoscore	dHGP *vs* non-dHGP: Higher immunoscore (51.9% *vs* 33%), longer relapse free survival (32 mo *vs* 12 mo) and OS (not reached *vs* 40 mo)	166 patients: dHGP (54, 32.5%), non-dHGP (112, 67.5%)	Liang *et al* [4]
2012-2017	Expanding GP, infiltrating GP; low tumor budding score, and Crohn's disease-like response	Expanding GP in primary CRC: dHGP liver metastasis and better OS (no detail); infiltrating GP in primary carcinoma: rHGP liver metastasis and worse OS (no detail)	29 patients; primary CRC: expanding GP (11, 37.9%) and infiltrating GP (18, 62.1%); liver metastasis: dHGP (15, 51.7%) and rHGP (14, 48.2%)	Wu *et al*[19]
2000-2015	dHGP and non-dHGP	dHGP *vs* non-dHGP: More liver-limited disease recurrence (43% *vs* 31%); less frequently experience multi-organ recurrence (19% *vs* 34%)	690 patients: dHGP (173, 25%) and non-dHGP (517, 75%)	Nierop *et al* [17]
2000-2009	Infiltrative and pushing tumor margin	Infiltrative margin *vs* pushing margin: poorer 5 yr DFS (20.2% *vs* 40.5%)	91 patients: infiltrative margin (54, 59.3%) and pushing margin (37, 40.7%)	Pinheiro *et al*[12]
2007-2011	dHGP, rHGP, pHGP, mixed HGP	rHGP *vs* dHGP, pHGP and mixed HGP: Poorer OS (22.8 mo *vs* > 60 mo, 44.2 mo and 40.3 mo)	217 patients: pHGP(33%), dHGP(32%), rHGP(11%) and mixed HGP(24%)	Nielsen *et al* [8]
1997-2005	dHGP, rHGP, pHGP, mixed HGP	pHGP *vs* dHGP, rHGP and mixed HGP: Poorer 2 yr OS (43.8% *vs* 72.5%, 70.2%, and 54.3%)	205 patients: pHGP (15.6%), dHGP (34.6%), rHGP (27.8%) and mixed HGP (17.6 %)	Van den Eynden *et al* [13]
Therapy response stratification				
2000-2016	dHGP and non-dHGP	Non-dHGP: Superior response to adjuvant systemic chemotherapy on improving OS and DFS but only in patients that were not treated with chemotherapy	1236 patients; 580 not pretreated patients (46.9%): dHGP (91, 15.6%) and non-dHGP (489, 84.4%); 656 pretreated patients (53.1%), dHGP (189, 28.8%) and non-dHGP (467, 71.2%). biologic factors driving margin-based differences may lead to the need for larger surgical margins, which indicate less chance of residual tumor cells and recurrence. Nierop *et al*[9] found that patients with non-dHGP are at higher risk of positive resection margins. It seems to be necessary to enlarge resection margin size when tumors present more aggressive borders or worse HGPs. Partly answering this question, Jayme *et al*[16] found that those with infiltrative-type borders indeed presented with worse overall and disease-free survival, and had a 2.32 higher risk of hepatic recurrence than patients with pushing borders. However, a larger resection margin (> 10 mm) in patients with infiltrative borders did not affect the prognosis. It could be pointed out that what really counts is tumor biology rather than tumor size. In parallel with HGPs, high preoperative glucose uptake representing high metabolism rate is associated with poor prognosis in CRCLM[21,22]. When integrating preoperative metabolic parameters with HGPs, the postoperative prognostic value could be improved[23]. As

expected, similar results appeared in studies on correlation between HGPs and immunophenotype and genomic mutation[19,24].

HGPS AND THERAPIES

HGP is also a useful tool to stratify patients for their response to therapy. For both resectable and unresectable patients, additional chemotherapy and angiogenesis inhibitors (AIs) are regarded as essential adjuvant therapy, however, their timing of administration and effect remains a matter of debate. Previous studies showed perioperative chemotherapy was not that beneficial as expected[25,26]. Retrospective analysis on long-term outcomes of 236 resectable CRCLMs suggested that there were no measurable differences between groups receiving adjuvant and perioperative chemotherapy[26]. Whereas an interesting phenomenon is that the effectiveness of adjuvant therapies varies with different HGP subgroups. For patients who were not pretreated with chemotherapy, non-dHGP subgroup have longer OS and disease-free survival (DFS) after adjuvant chemotherapy[27]. dHGP and pHGP are more sensitive to triplets + cetuximab and triplets + bevacizumab, respectively, while rHGP has poor response to the both therapies[28]. In other words, HGPs may determine the sensitivity to chemotherapy and AIs. Besides, chemotherapy somehow changes the component of HGPs. One study found more than half (55%) of chemonaive resected CRCLMs showed rHGP, while patients with neoadjuvant therapy presented the opposite phenomenon, in which dHGP comprised the major proportion (66%)[6]. Chemotherapy as an independent relevant factor induced an HGP phenotypic change with an increase of dHGP. A similar trend was shown in another study in which Nierop *et al*[29] evaluated the effect of preoperative systemic chemotherapy on the HGPs of CRCLM, and obtained multiple verification in three independent cohorts. Conclusively, HGP could be a stratification factor when considering the effectiveness of adjuvant chemotherapy after resection.

The remarkable results with AIs in preclinical studies brought hope to patients; however, with passing decades, AIs have failed to demonstrate a survival advantage. Increasing findings strongly imply that rHGP is insensitive to AIs and increasing proportion of rHGP furtherly drives reactive resistance after AIs therapy, all of which is mainly due to vessel co-option being as predominant vascularization. Serial clinical studies in patients with liver metastases verified that rHGP is prevalent in post-treatment patients and rHGP subgroup poorly responds to AI therapy[30]. Whereas, supplementary inhibition of rHGP through suppressing cancer cell motility and migration facilitated effectiveness of AIs *in vivo*. Other direct evidence supporting vessel co-option (rHGP) as a mechanism of acquiring resistance to AI therapy was obtained from an orthotopic human hepatocellular carcinoma (HCC) model[31]. The researchers paid more attention to vascularization within the tumor instead of the interface between the tumor and liver, and found the number of co-option vessels was elevated from 23.3% in untreated controls to 75% in resistant tumors, along with a shift from angiogenesis (dHGP) to vessel co-option (rHGP)[31]. These observations make it clear that rHGP induces resistance to AI therapy in *in vivo* and *in vitro*.

Collectively, HGPs determine the sensitivity to therapy, and both chemotherapy and AIs somehow change the components of HGPs. Chemotherapy tends to the change with increase of dHGP, while AIs make a shift from angiogenesis (dHGP) to vessel co-option (rHGP). Considering prognostic significance and drug response of HGP in liver metastases, HGP could be used to guide treatment for CRCLM patients, select out ideal subgroup, design precision therapy for individual patient, even develop approaches to transform HGP of drug-resistant group to one sensitive type so that they can benefit from current therapy.

HGPS AND VASCULARIZATION

Tumors adopt various forms of vascularization, among which, angiogenesis occupies a dominant position. Yet, increasing evidence shows that vessel co-option is a crucially alternative nonangiogenic strategy by which tumor cells hijack the pre-existing vessels instead of creating new vessels and gain access to nutrients to support tumor survival, growth and metastasis. Different HGPs correspond with distinct vascularization patterns, which also vary with metastatic organs. In CRCLM, rHGP and dHGP obtain blood supply *via* different routes, *i.e.*, the former is vessel co-option while the latter is sprouting angiogenesis. This difference of vascularization contributes to distinct therapy response.

For a long time, dHGP has been known to represent an angiogenic growth pattern. Different from rHGP, tumors with dHGP completely destroy liver architecture and form neovascularization. Chemotherapy and antiangiogenic agents caused 100% necrosis and few surviving carcinoma cells left under the desmoplastic rim[32]. It is believed that leakiness of immature vascular allows cytotoxic agents sufficient interaction with malignant cells contributing to more efficient of chemotherapy on dHGP. In the process of sprouting angiogenesis, with extracellular matrix (ECM) and basement membrane degrading, endothelial cells and pericytes proliferate, migrate and eventually form immature vasculature[33,34]. Like a double-edged sword, abnormal basement and loose pericytes of new vessels

lead to leakiness and heavily impair blood supply to the whole tumor which causes hypoxia and acidosis[35]. This leakiness may affect drug delivery and only after normalizing the abnormal tumor vasculature can chemotherapy as well as oxygen efficiently penetrate throughout tumor[35]. AIs has been verified with the ability to prune proliferating vessels, render tumor vasculature normalized and enhance the delivery and efficacy of cytotoxic agents[36,37]. Collectively, sprouting angiogenic vascularization contributes to favorable effect of chemotherapy on dHGP.

In contrast, rHGP tumors expand in a "conventional way" by replacing liver cells, attaching liver sinusoidal endothelial cells (LSECs) and co-opting liver vessels with liver structure preserved. The data from Frentzas and colleagues[30] provide direct evidence supporting cancer cells utilizing pre-existing sinusoidal blood vessels in rHGP liver tumors. They found invading tumor cells followed the "RR" rule that tumor cells replaced hepatocytes in the liver parenchyma but respected the sinusoidal blood vessels, leaving the sinusoidal space complete. Sinusoidal vessels with one end embedded in the tumors were frequently observed, with the other end originating from normal liver. Different from dHGP, there were more mature vessels in continuity with the sinusoidal network in rHGP. rHGP lesions preserve more viable carcinoma cells, more microvascular density (MVD) and showed no necrosis after chemotherapy and antiangiogenic agents[32].

These vascularization characteristics could partly explain why rHGP tumors initiate less response to chemotherapy and antiangiogenic therapy than dHGP tumors do, and even resistance to antiangiogenic therapy. Tumor with rHGP lacks proliferating vasculature, while the co-opted liver sinusoidal capillary network as a mature and endogenous vascular network does not respond to AIs. Current studies on vascularization of HGPs extensively pay attention to tumor periphery other than central region, and particularly co-option vessels were only observed in interface. In this case, what the vascularization in central region of rHGP tumor requires further investigation.

IDENTIFYING HGPS IN NONINVASIVE METHODS

In spite of strong prognostic and stratification value, HGP has not been put into clinical decision-making, which is mainly because of its limitation of requiring histopathological assessment of surgical resection specimens. Thus, a noninvasive method identifying HGP is urgently needed, especially when selecting optimal therapies for patients with untreated and unresectable liver metastasis and predicting their survival for long-term healthcare. Rim enhancement as a hotspot topic has attracted much attention. Radiomics stands out with a remarkable performance in identifying HGPs and predicting outcomes and several novel predictive models combining morphological score or not have superior ability to conventional response evaluation criteria.

Over the years, several noninvasive approaches, such as computed tomography (CT), magnetic resonance imaging (MRI) and ultrasound, were used to identify HGP and explore their correlation with response to therapy and even survival forecasting. There are some common imaging features of HGPs, *e.g.*, a significantly enhanced rim and clear tumor–liver interface in dHGP, compared with an indefinite margin and no rim enhancement in rHGP. Earlier studies on the correlation between radiology images and morphological features concentrated on rim enhancement since knowledge on HGP was insufficient. In the 1990s, scientists studied the enhancing rim through comparing radiology images with histopathological slides, attributed this phenomenon to blood flow and perfusion and believed that the morphological substrate of rim enhancement of colorectal metastases seen by CT was compressed liver parenchyma[38]. The compressed liver parenchyma lacked a portal blood supply but was compensated by an increase in the arterial blood supply, and the rim enhancement of metastases could only be seen during hepatic arteriography. Similarly, Terayama *et al*[39] found two-way blood flow between the tumor and the adjacent liver tissues contributed to peritumoral enhancement. This abnormal blood circulation and occlusion in the tumoral–peritumoral area caused sinusoidal congestion, the thickness of which reflected thickness the perilesional hyperintense rim[40]. The findings from Semelka *et al*[41] implied that the level of compression of hepatic parenchyma was not positively correlated with the degree of perilesional enhancement. The concomitant reactions such as peritumoral desmoplastic reaction, vascular proliferation and peritumoral inflammation contributed a lot to the increase in rim enhancement. Above all, these findings on the mechanism of rim enhancement focusing on inflammatory infiltration and reactive vascularization step forward to comprehensive knowledge on HGP.

Nevertheless, in some cases, it is difficult to recognize some minor differences in rim enhancement because distinct vascularization for HGPs cannot be exactly and quantitatively identified visually. Current studies have focused on the correlation between HGPs and radiomics. Radiomics is a promising tool to predict HGPs but still faces great challenges. Radiomics containing pre- and post-contrast (arterial and portal venous phase) multidetector CT images were demonstrated to improve distinguishing accuracy on HGPs in the training cohort[42]. Importantly, the performance predicting HGPs of radiomics models alone did not differ from combining clinical and qualitative imaging factors[42]. Given the diagnostic performance of this model with area under the curve > 0.9, another study verified its potential for predicting survival[43]. In unresected patients additionally treated with bevacizumab-

containing chemotherapy, the dHGP subgroup had > 1-year PFS, which was in line with HGP prediction on resected specimens[43].

CT criteria based on morphological forecast outcomes superior to Response Evaluation Criteria In Solid Tumors (RECIST) based on tumor size and number[44,45]. A radiomics model based on tumor-liver interface exhibited better predictive value compared with a model based on tumor zone; nevertheless, combination of the two models was superior to any single one, even clinical model[46]. Some evaluative and predictive models, *e.g.*, SPECTRA-score[47] based on a radiomic nomogram, displayed superior sensitivity and accuracy to standard evaluation with RECIST 1.1. Even though CT, MRI and positron emission tomography/CT have comparative diagnostic value in detecting CRCLM, gadoxetate-disodium-enhanced MRI was found to have greater accuracy in a systemic review[48]. These imply that the combined prediction model of morphological characteristics and imaging studies perform better than the mono-model.

UNDERLYING MECHANISM OF HGPS

dHGP: Immune infiltration and ECM remodeling

Immune infiltration: The tumor microenvironment not only carries out major tumor-relevant activities including antitumor response and stromal remodeling but also involves in formation of distinct pathological phenotypes. The immunoscore of patients with dHGP remains high, which implies that dHGP is an abundant immune status. As unique marker of dHGP tumor, the desmoplastic rim usually indicates active antitumor response meanwhile rim itself is a product of matrix deposition and immune infiltration. Here, adaptive lymphocytes participate in both cytotoxic and immunosuppressive effects. In dHGP, there was an increase of $CD3^+$ T cells, $CD8^+$ T cells, $CD20^+$ B cells and CD8/CD4 ratio; all of which enhance antitumor immunity, while decrease of $CD4^+$ T cells[4,5]. That this phenomenon appeared in peritumoral and intratumoral regions and even distant tumor-free liver but not peripheral blood suggested local immune situation instead of systemic immunity drove and determined the HGP phenotype. In dHGP, Eefsen *et al*[49] observed macrophages accumulating at the tumor border in patients given neoadjuvant chemotherapy and higher level of urokinase-type plasminogen activation receptor in chemonaive patients. As part of the plasminogen activation system, urokinase-type plasminogen activation receptor is mainly expressed in macrophages and myofibroblasts and some cancer cells[50], and induces changes in the macrophages during tumor invasion. Therefore, higher urokinase-type plasminogen activation receptor expression in desmoplastic metastases may be a secondary reaction of the tumor cells to the desmoplasia.

ECM remodeling: Desmoplasia is also a host-specific reaction to protect against malignant cells invasion of adjacent parenchyma and plays a protective role in tumor progression. On formation of desmoplasia, cancer-associated fibroblasts (CAFs) play a pivotal role through producing collagen and fiber, coupled with the role of self-produced cytokines and growth factors, thereby remodeling the ECM [51]. When stromal content automatically decreases within tumor microenvironment or inducing stromal depletion with medication, *e.g.*, type I collagen, the tumor will become more aggressive, with lower tissue stiffness and rapid growth, leading to poorer overall survival of the host[52]. This desmoplastic capsule mainly consists of collagen fibers originating from activated myofibroblasts. Capsule formation typically occurs when there is a high level of infiltration by $CD4^+$, $CD45RO^+$ and $CD8^+$ T cells in the near stromal region[53]. However, the distant stromal area with low density of immune cells hardly ever forms a capsule. The desmoplastic rim may be a complicated collection of several components, *e.g.*, fibers, blood vessels, fibroblasts and immune cells. This rim originates from the antitumor response, and functions as a barrier separating malignant cells from normal tissues.

rHGP: Aggressive characteristics and special vascularization

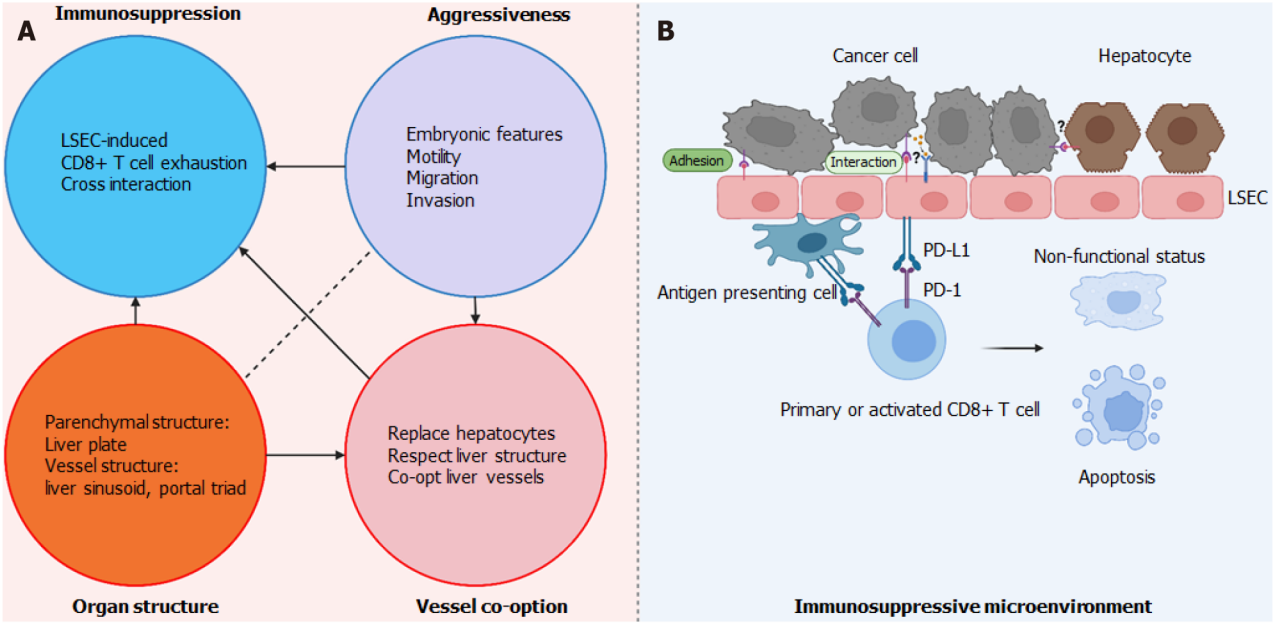
Metastatic capability: Cell motility, invasion and migration: To our knowledge, rHGP was initially described as infiltrating growth pattern[2] other than replacement growth pattern, implying that this type of tumor has aggressive biology and is prone to adopt an infiltrative growth patten. Tumor cells with rHGP present a highly motile, invasive and adhesive phenotype, which accelerates infiltration of the adjacent liver and utilizes the pre-existing vasculature.

For molecules involved in cancer cell motility supporting rHGP, the actin-related protein 2/3 (ARP2/3) complex is indispensable. It has been demonstrated ARP2/3 mediates the nucleation of actin filaments at the frontier cells to drive cell movement and facilitate the motility and invasion of breast and colorectal cancer cells[54]. ARP2/3 subunit ARPC3 is highly expressed in rHGP human CRCLM specimens, and its knockdown results in a significant decrease of rHGP in animal models[30]. *In vitro* data have shown that ARPC3 silencing suppresses migration other than proliferation of CRC cells. Apart from ARP2/3, Runt-related transcription factor (RUNX)1 also regulates motility and epithelial–mesenchymal transition (EMT) in cancer cells. As a key upstream transcriptional regulator of ARP2/3, RUNX1 is overexpressed in rHGP CRCLM lesions[55], and its inhibition could suppress tumor cell motility and EMT. Downstream proteins ARP2/3 and thrombospondin 1 are also reported to

facilitate cancer cell motility; however, whether RUNX1 support of rHGP is ARP2/3 dependent needs more investigation.

Tumor with strong adhesion to hepatocytes has potential to develop rHGP. Claudins as critical components of tight-junctional complexes that modulate carcinogenesis and metastasis[56]. Claudin-2 acts as an essential determinant in the formation of rHGP liver metastases from either CRC or breast cancer[57]. During tumor metastasis to the liver, there is functional shift in claudin-2 from tight-junctional complex to adhesion molecule between cancer cells and hepatocytes[58,59]. Claudin-2 promotes tumor cell adhesion to hepatocytes and is specifically expressed at high levels in rHGP; at the same time, claudin-8 is specifically expressed at high levels in dHGP[57].

Co-opting vessels: Different HGPs are associated with different types of tumor vascularization. In rHGP, tumor cells replace hepatocytes to spread and co-opt liver vessels to obtain blood. Since rHGP corresponds with vessel co-option, those regulating vascular factors should be paid attention. Angiopoietin (Ang)1 and Ang2 are vascular growth factors that act as agonists to active their ligand Tie2, which then together induce endothelial cell (EC) formation, survival, proliferation and migration. Ang1 has a distinct vascular-relevant effect, protects against EC apoptosis, and mediates vessel maturation by enhancing pericyte recruitment. Ang2 has a proangiogenic function through mediating pericyte detachment and blood vessel destabilization[60]. In human resected CRCLM specimens with rHGP, Ang1 supporting vessel co-option displays higher expression in the liver adjacent to tumor[61]. To demonstrate the critical role of Ang1, an animal model of Ang1 knockout was established and showed a change from rHGP to dHGP along with a decrease of liver metastases[61]. This verified that high expression of Ang1 in the host liver supported rHGP. Additionally, some inflammatory molecules partly participated in rHGP. RNA sequencing showed that two genes, *CXCL6* and *LOXL4*, were significantly upregulated in rHGP tumors *vs* dHGP tumors, and were involved in cell migration and wound healing[62]. Neutrophils expressing *LOXL4* concentrated at the tumor–liver interface and in areas of inflammation in rHGP lesions, and circulating neutrophil expression of LOXL4 protein is increased in CRCLM patients. It indicates that the chemoattraction and subsequent activation of neutrophils may be vital in promoting rHGP in CRCLM[62].



Hypothesis for HGPs

Liver injury hypothesis: When coping with exogenous or endogenous injuries, the liver has both the potential for healthy regeneration following acute injury and the potential for repair toward fibrosis under persistent damage[63]. Given malignant cells proliferate within the liver, causing injury and activating host reactions, van Dam *et al*[64] proposed the hypothesis that HGPs represent the response patterns of the liver to injury.

Development of liver metastases has similar pathological changes to those in liver injury. In liver fibrosis, portal fibroblasts and hepatic stellate cells transform to activated myofibroblasts, binding with components of ECM (crosslinking collagen), and together induce fibrogenic activation and support fibrogenic units based on activation and reorganization of cholangiocytes, accounting for fibrotic progression[65]. For dHGP, the peripheral desmoplastic rim shares one common ECM remodeling and ductular reaction with liver fibrosis, among which the activated cholangiocytes proliferate and form small nonfunctional bile ducts. Differently, rHGP adopts an analogous pattern with liver regeneration where the process of new cells replacing older hepatocytes takes place. In the context of vascularization, in liver regeneration, regenerating liver cells co-opt pre-existing sinusoidal capillaries instead of sprouting angiogenesis which is akin to rHGP. Even though it is far from reaching a certain conclusion that dHGP and rHGP exemplify liver fibrosis and regeneration, but there is still similarity between formation of liver metastasis and liver development and regeneration; knowledge of which would enable us to determine the underlying mechanism of HGPs.

Advance under camouflage hypothesis: Researchers have detailed knowledge of the mechanism of dHGP, but there is little ideal explanation for the formation of rHGP. Except for some tumoral phenotypic and molecular drivers observed in rHGP, there is still no systematic model to support the explanation. We put forward a hypothesis that malignant cells benumb and educate the immune system, and advance by an unknown path under camouflage (Figure 2).

The tumor cells with an infiltrative pattern paralyze or tame the local immune system *via* interaction with LSECs and induce immune tolerance. LSECs are a major group of hepatic cells that specialize in detection and capture of pathogens from the blood. However, in some cases, this group also downregulates T-cell response through crosstalk with immune cell subsets, leading to immune escape[64,66]. Through programmed death (PD) ligand 1 on T cells binding to PD-1 on LSECs, $CD8^+$ T cells are activated to a dynamic but nonlicensed type, which fails to produce effector cytokines (*e.g.*, interferon-γ) and have decreased cellular cytotoxicity[67]. Similar suppressive immune activity takes place with mediation of another specific surface protein LSECtin, through which LSECs directly identify activated T cells and inhibit immune-response-mediated T cells[68]. These strongly imply that LSECs are important players in immune tolerance, which enhances invasive and metastatic potential of tumor cells. Taking advantage of this point, tumor cells obtain sufficient interaction with LSECs and hepatocytes, so that tumor cells educate these normal liver cells and remodel the immune microenvir-

Figure 2 "Advance under camouflage" hypothesis for replacement histopathological growth pattern. A: "Advance under camouflage" hypothesis of replacement histopathological growth pattern (rHGP) includes four elements. Embryonic features, motility, migration and adhesion contributes to aggressiveness of tumor, which drives tumor progression as an intrinsic factor. Tumor cells interact with liver sinusoidal endothelial cells (LSECs) and hepatocytes, so that tumor cells educate these normal liver cells and remodel the immune microenvironment into a tolerance state *via* CD8+ T cells. In this manner, under camouflage of LSECs, tumor cells are able to survive and slowly progress. Co-opting LSECs enable the tumor to obtain sufficient blood supply and less chance of exposure to immune system. With its unique parenchymal and vessel structure, organ architecture of liver supports the whole advance process; B: Immunosuppressive microenvironment in tumor with rHGP. Under cross interaction of cancer cells and LSECs and other immune cells (unknown mechanism), programmed death (PD) ligand 1 on LSECs and antigen presenting cells binds to PD-1 on T cells making CD8+ T cells activated to a dynamic but nonfunctional type which fails to produce effector cytokines and has decreased cellular cytotoxicity, or is apoptostic. LSEC: Liver sinusoidal endothelial cell; PD: Programmed death.

onment into a state of tolerance. In this manner, under camouflage of LSECs, tumor cells are able to survive and slowly advance. To expand further, the leading cells at the tumor border also initiate adaptive changes, *e.g.*, enhanced metastatic capacity including cell motility, adhesion and migration. Many of them are driven by some embryonic features that are relevant to co-option-type metastases[69,70]. As a whole, embryonic characteristics, interaction between tumor and normal liver cells, and immunological inertia allows efficient and safe advance of tumor cells. Two other factors must be paid attention: (1) Co-opting normal hepatic vasculature reduces the chance of direct exposure of the tumor to the immune system and achieves normalization of the blood supply. In this case, the intratumoral microvessel keep their normal structure and evenly perfuse the whole nodule, which reduces hypoxia and necrosis and is conducive to overall development of the tumor; and (2) Organ structure is another essential aspect. In an organ with a clear and distinct architecture such as the lungs and liver, the metastatic foci can often expand and develop along with its structure[71,72], which implies that organ architecture sometimes directs how tumor cells expand. We propose a complex axis that 'embryonic characteristics playing a primitive driving role - tumor hepatic sinusoidal endothelial cell interaction as the mediator - organ structure as the support' and advance under camouflage hypothesis to explain the underlying mechanism of rHGP.

CONCLUSION

We proposed a novel hypothesis to explain the mechanism of rHGP formation. We denoted four elements, *i.e.*, intrinsic features of cancer cells, tumor vascularization, immunosuppressive microenvironment and host organ structure in the HGP formation. Vascularization and tumor microenvironment have been emphasized in previous studies while the pivotal role of organ structure is addressed for the first time in this review. Common features in angiogenic HGP, for instance, desmoplastic reaction, immune infiltration and sprouting angiogenesis, have been shown. Organ specific morphology was only observed in non-angiogenic HGP, exhibiting angio-tropism and structure-dependent properties. It was observed that non-angiogenic HGP metastases in brain[73] and skin[74] adopted pericytic mimicry and extravascular migratory behavior to get access to the blood. Similarly, metastatic cells remained the mesenchymal structure (pulmonary alveoli and hepatic plate) and presented with alveolar HGP, interstitial HGP and perivascular cuffing HGP in the lung[75], as well as rHGP in the liver. Thus, it

Table 2 Characteristics of desmoplastic histopathological growth pattern and replacement histopathological growth pattern in colorectal cancer liver metastasis

Aspects	dHGP	rHGP
Morphology	Sharp desmoplastic rim separating tumor cells from adjacent liver	Ill-defined border; Tumor cells replace normal hepatocytes along with the architecture of liver plate
Invasion pattern	Expanding and mild	Infiltrative and aggressive
Immune phenotype	Abundant	Desert
Vascularization	Angiogenesis	Non-angiogenesis (vessel co-option)
Organ-specific	No, widely appears in brain, lung and liver	Yes, only appears in liver
Therapy response	Superior response	Inferior response and drug resistance
Clinical outcome	Longer OS, DFS and PFS	Poorer survival and high recurrence

dHGP: Desmoplastic histopathological growth pattern; rHGP: Replacement histopathological growth pattern; OS: Overall survival; DFS: Disease-free survival; PFS: Progression-free survival.

could be hypothesized that the organ architecture provides metastatic tumor cells with attachment and support for their growth. We also highlight the specific interaction of tumor cells with LSECs in rHGP which might indirectly contribute to tumor progress. However, it is still a pure conceptual idea and it remains to be verified.

Clinical implications of HGP are as follows: (1) The association of HGP with clinical outcomes suggests that HGP can be used to stratify patients by survival risk. Early risk stratification helps provide individualized care and guide long-term follow-up; (2) Patients with dHGP are more likely to benefit from systematic therapy, those with rHGP are prone to acquire resistance to AIs and those with non-dHGP are at high risk of positive surgical margin, indicating that HGP can serve as a biomarker for therapy. Based on pre-treatment prediction of HGP, stratification of patients may help clinicians in treatment decision-making and surgical planning for CRCLM patients. The patients with non-dHGP tumor are at higher risk of hepatic recurrence, therefore radical surgery may be of utmost importance. Furthermore, combination therapy would be an inevitable choice for the subgroup with rHGP. Nevertheless, the above benefit from HGP is on the premise of identifying HGP by a non-interventional method. In this regard, radiomics aiming to distinguish HGP in combination with other markers may be a powerful tool in classification of patients; and (3) Studies of mechanism of HGP favor development of therapeutic approaches, and it is encouraging that there have been relevant preliminary trails. For instance, vessel co-option was found to be inhibited through suppressing cancer cell motility and migration in rHGP tumor, and inhibitors targeting both angiogenesis and vessel co-option were more effective *in vivo*[30]. Considering the enrichment of fibrotic and angiogenic reaction of dHGP tumors, anti-angiogenic and anti-fibrotic therapies may be effective for these tumors. However, even though both anti-fibrotic[76,77] and anti-VEGF[78] treatment could restore the immune response, these treatments should be used with caution due to the unsatisfying results shown in trials[79].

In addition, we put forward our perspectives on some hot topics. HGP is a miniature of tumor-host reaction and reflects tumor biology and pathological features as well as host immune dynamics. In this sense, HGP builds a bridge between microscopic characteristics and clinical implications. Is HGP plastic? With existence of spatial and temporal heterogeneity, tumors utilize different vascularization at different stages, and their HGP also changes with development of tumor, but knowledge about this is still lacking. What is the key motivation shaping HGP? In addition to motility, invasion and migration giving rise to formation of HGP, the association between HGP and other biological characteristics such as embryonic features, stemness, and spontaneous mutation should be explored. In summary, HGP is a paradox involving several dimensions: malignant and normal cells, central and peripheral sites, angiogenesis and non-angiogenesis, and aggressive and mild characteristics (the summary on characteristics of dHGP and rHGP is listed out in Table 2). Combination of AIs with immune checkpoint inhibitors and AIs with vessel co-option inhibitors showed better effects, suggesting that complex targeted treatment would be a direction for the precision therapy in the future.

Abstract

Locoregional treatments, as alternatives to surgery, play a key role in the management of hepatocellular carcinoma (HCC). Liver magnetic resonance imaging (MRI) enables a multiparametric assessment, going beyond the traditional dynamic computed tomography approach. Moreover, the use of hepatobiliary agents can improve diagnostic accuracy and are becoming important in the diagnosis and follow-up of HCC. However, the main challenge is to quickly identify classical responses to loco-regional treatments in order to determine the most suitable management strategy for each patient. The aim of this review is to provide a summary of the most common and uncommon liver MRI findings in patients who underwent loco-regional treatments for HCC, with a special focus on ablative therapies (radiofrequency, microwaves and cryoablation), trans-arterial chemoembolization, trans-arterial radio-embolization and stereotactic ablative radiotherapy techniques, considering the usefulness of gadoxetate

disodium (Gd-EOB-DTPA) contrast agent.

Key Words: Carcinoma; Hepatocellular; Magnetic resonance imaging; Gd-EOB-DTPA; Radiofrequency ablation; Catheter ablation; Ablation techniques

Core Tip: Ablation techniques are useful tools in the treatment of patients with hepatocellular carcinoma, both in case with a small lesion and as a bridging option prior to surgical resection or liver transplantation and in addition to palliative treatment in advanced disease. In clinical practice it is of utmost importance to acquire a specific skill to identify classical magnetic resonance imaging appearance of the treated lesion and for early detection of tumor recurrence, to guarantee the best possible management for each patient.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the most common primary liver cancer and represents a major public health issue worldwide[1]. Treatment of patients with HCC is closely related to Barcelona Clinic Liver Cancer (BCLC) stage. Locoregional treatments, as alternatives to surgery, play a key role in the management of HCC. Percutaneous thermoablation strategies are considered as an alternative to surgery in patients with BCLC 0-A, transcatheter embolization therapies are essential in patients with more advanced disease (*i.e.*, BCLC B) and both together with Stereotactic Body Radiation Therapy (SBRT) are useful in patients who are not a surgical candidate[2].

The evaluation of both short- and long-term treatment outcomes is crucial for patient management. According to the guidelines, this evaluation should be performed using either dynamic computed tomography (CT) or magnetic resonance imaging (MRI)[2].

Liver MRI enables a multiparametric assessment, going beyond the vascularity assessment provided by traditional dynamic CT[3,4]. In recent years, liver MRI has made significant advances in the evaluation of HCC thanks to the introduction of new sequences for non-contrast evaluation (*e.g.*, diffusion-weighted sequences), the high temporal resolution sequences for optimal contrast enhancement assessment[5,6] and finally, the use of hepatobiliary contrast agents (gadoxetate disodium: Gd-EOB-DTPA, Eovist/Primovist; gadobenate disodium: Gd-BOPTA, Multihance). Gd-EOB–DTPA combines the properties of an extracellular agent, allowing for conventional contrast-enhanced multiphasic imaging, and a hepatocyte agent, allowing for hepatocyte uptake and biliary excretion evaluation, with the added benefit of tumor assessment in the transitional phase (TP) and delayed hepatobiliary phase (HBP) (20-min)[4,7,8]. This contrast agent improves the diagnostic accuracy and is becoming increasingly important in the detection of HCC[9].

The use of liver MRI with hepatobiliary contrast agents has become critical in patients with HCC. Therefore, understanding the typical and atypical features of treatment outcomes and recurrences is of paramount importance for proper treatment strategy.

The purpose of this review is to provide a comprehensive overview of locoregional therapies and to describe how to assess treatment outcomes using contrast-enhanced hepatobiliary MRI.

ABLATIVE THERAPIES

There are several ablation techniques available for the treatment of HCC as reported in a recent literature review by Makary *et al*[10], such as radiofrequency ablation (RFA), microwaves (MWA), cryoablation (CA), irreversible electroporation (IRE), laser-induced interstitial thermotherapy (LITT), and high-intensity focused ultrasound (HIFU). The process of choosing among alternative techniques is principally based on institutional expertise and should be fitted to each patient. The main target for the abovementioned treatment methods is an early-stage HCC with a maximum axial diameter of 3 cm with BCLC class 0 or A. Moreover, this approach may lead to better clinical outcomes in patients with larger HCC lesions (axial diameter of 3 cm to 5 cm), when combined with trans-arterial chemoembolization

(TACE)[10].

Even though the ablation techniques are widely performed, they are not risk-free: it is important to underline that the treated patients can present post-ablation syndrome, loco-regional bleeding, and adjacent organs injuries. The ablative therapy shows similar outcomes to surgical resection in the treatment of HCC with a maximum diameter of 3 cm, with a remarkable advantage of no pre-and post-surgical complications[10].

Most published studies on electronic medical databases including PubMed and Web of Science are strictly linked to RFA and MWA, while CA, IRE, LITT, and HIFU are not deeply evaluated and consequently data regarding response to therapy are lacking. On this basis, we'll present the most common MR imaging findings regarding RFA, MWA and CA therapies.

RFA

RFA technique relies on the destruction of tumoral tissue by producing frictional heat using rapidly alternating electrical current thanks to the application of at least one electrode inside the region of treatment. The ablation zone includes a wider region than the tumor itself, of at least 5 mm to 10 mm[8]. The use of RFA results in hyperthermia-induced coagulation necrosis and represents a heterogeneous low or mixed signal intensity on T1-weighted (T1w) and homogeneously low signal intensity on T2-weighted (T2w) images.

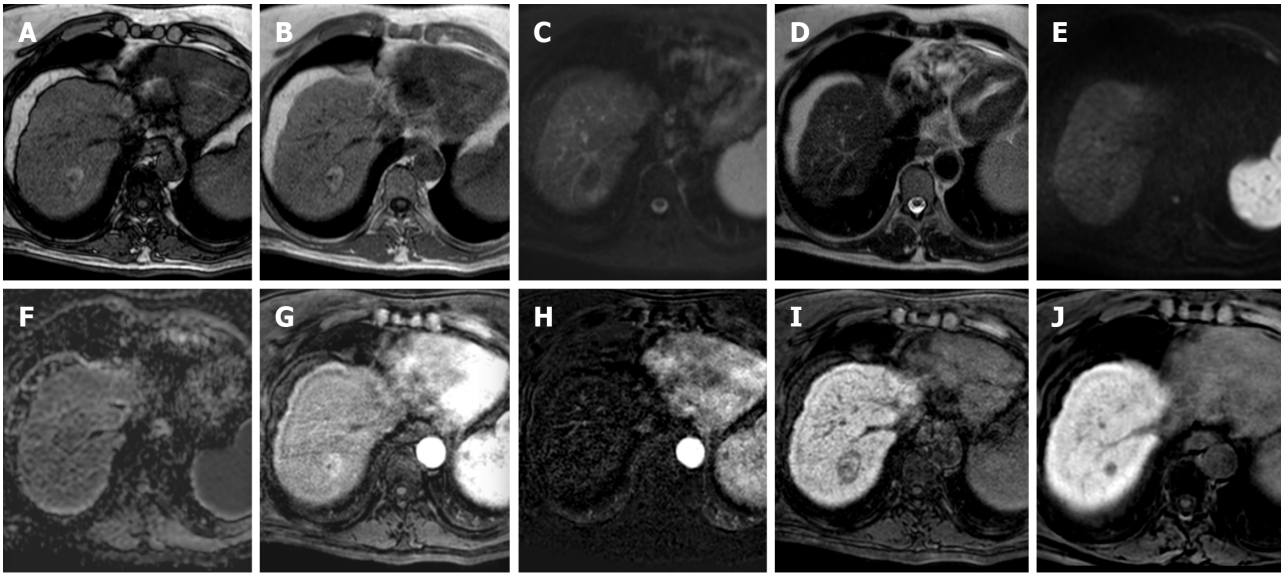
After contrast media administration (extracellular or hepatobiliary agents), the RFA zone manifests as a well-demarcated hypointense area with the absence of contrast enhancement[8]. The presence of slight rim signal intensity on T2w images and contrast enhancement especially in the equilibrium phase should be considered as a physiological response to thermal injury, mainly during early follow-up[11]. The typical appearance of HCC recurrence is the hypervascularity on arterial phase [arterial phase hyperenhancement (APHE)], hypointensity on portal-venous and HBPs. However, in clinical practice, the discrimination between hyperemia and residual HCC might be difficult. This aspect was demonstrated by Mikami *et al*[12], who reported a typical enhancement pattern in only 17.5% of recurrent HCCs, while 40.6% with APHE without washout in the portal venous phase and 11.9% with portal venous phase washout without APHE.

In this setting, the use of Gd-EOB-DTPA can help to distinguish vascular pseudolesions from hypervascular tumors including recurrent HCC[13]. Since 2013, it has been reported[14] the efficacy of EOB-MRI in the decision-making of curative treatment for HCC: it was demonstrated that the HBP improves the diagnostic accuracy and treatment decision making in the early-stage HCC and these results can perfectly fit candidates to RFA. Imai *et al*[15], by enrolling 97 patients who underwent RFA, revealed that EOB-MRI had higher diagnostic accuracy and sensitivity for detection of recurrent hypervascular HCC (44 *vs* 24, $P < 0.001$) in comparison to CT. They also reported a good inter-observer agreement between the 2 readers, underlying the effectiveness of EOB-MRI.

As known, the main advantage of EOB-MRI is the HBP, where the radiologist can face a hypointense nodule without significant hypervascular appearance. On this basis, it is important to determine the risk of non-hypervascular HCC recurrence after loco-regional treatment. The systematic review and meta-analysis by Kim *et al*[16] demonstrated the post-ablation recurrence of HCC: they showed that hypointense nodules in the HBP represent a high-risk factor for recurrence (hazard ratio = 1.74-3.07), underlying the importance of EOB-MRI in the detection of HCC recurrence post-RFA.

More recently, a retrospective study by Bae *et al*[17] on 183 patients who underwent different treatments including RFA, showed that satellite nodules and peritumoral hypointensity on HBP images were associated with poor disease-free survival and overall survival ($P = 0.018$ and $P = 0.016$, respectively).

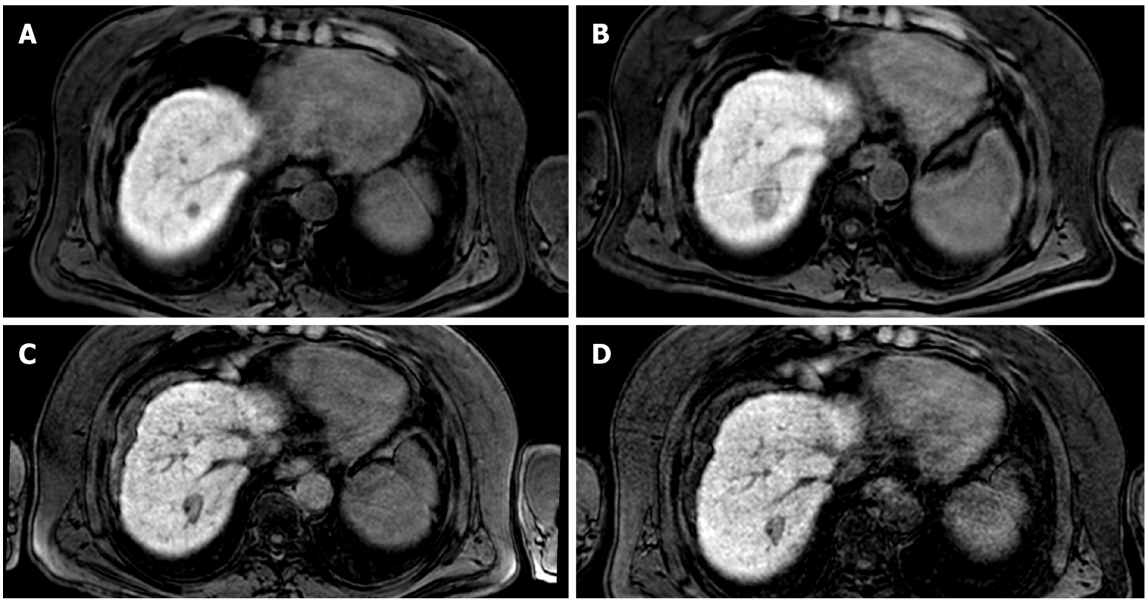
On the other hand, the study by Rimola *et al*[18], on 49 patients who underwent locoregional treatment, determined that MRI with extracellular agents has a similar specificity in detecting viable HCC in comparison to EOB-MRI (84% *vs* 85%, respectively), with a higher AUROC (0.80 *vs* 0.72, respectively). These findings are not in line with most studies, however, should be carefully considered due to the small sample size and the remarkable risk of bias, since different ablation techniques were evaluated.



Finally, EOB-MRI was found efficient not only in the evaluation of treatment response but also in the feasibility of ablative margin grading before RFA. Koda *et al*[19] by enrolling 124 HCCs, showed that EOB-MRI enables an early assessment of RFA effectiveness in the majority of HCC nodules with the tumor size as an independent predictor factor for local tumor progression.

To conclude, EOB-MRI can be considered as a useful tool in the detection of HCC recurrence after RFA treatment, however, large prospective studies are needed to determine a more accurate evaluation of diagnostic performance.

Figure 1 depicts a liver MRI after RF treatment with no evidence of disease persistence or relapse, and Figure 2 depicts its evolution. Figure 3 depicts a case of HCC recurrence after RF treatment.



Microwave ablation

MWA technique is based on analogous physical principles of RFA, however, it employs an antenna that produces electromagnetic waves which can interact with water molecules and, consequently, raises the temperature[20].

DOI: 10.3748/wjg.v28.i26.3116 **Copyright** ©The Author(s) 2022.

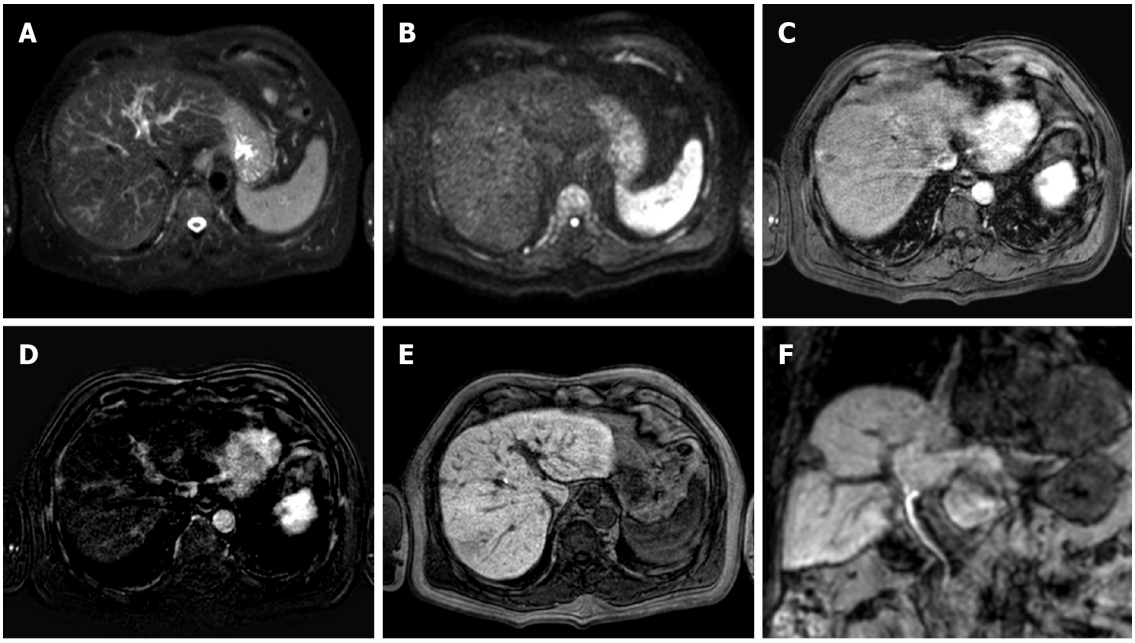


Figure 1 hree-month follow-up liver magnetic resonance imaging of a 69-yr-old male post radiofrequency ablation of right hepatic lobe hepatocellular carcinoma (segment VII). A: Out-phase T1-weighted image; B: In-phase T1-weighted image; C: T2-spectral attenuated inversion recovery; D: T2-weighted image; E: High b-value diffusion weighted imaging; F: Apparent diffusion coefficient map; G: Arterial phase magnetic resonance imaging (MRI); H: Arterial phase MRI with image subtraction technique; I and J: Hepatobiliary phase MRI. Follow-up MRI (A-I) after 3 mo post treatment revealed a good outcome characterized by inhomogeneous high signal hyperintensity in T1 sequences due to the presence of coagulative necrosis with associated signal hypointensity in T2 weighted sequences and the absence signal hyperintensity in diffusion weighted imaging. Dynamic study showed no enhancement in arterial phase with inhomogeneous hypointensity during hepatobiliary excretion. Findings are suggestive of complete tumor ablation also when compared to the similar pre-treatment sequences (J).

Figure 2 The evolution of the ablation zone shown in Figure 1. A: Hepatobiliary phase (HBP) phase magnetic resonance imaging (MRI) prior to radiofrequency ablation (RFA); B: HBP MRI 3 mo after RFA; C: HBP MRI 9 mo after RFA; D: HBP MRI 19 mo after RFA. Liver MRIs demonstrate a progressive reduction of ablation zone together with fibrotic changes.

MR findings after MWA are like those reported for RFA. On unenhanced T1w images, the ablated lesion shows a target-like appearance: linear hypointensity in the center of the ablation zone surrounded by hyperintense region due to coagulative necrosis, and outer hypointense areas of signal intensity corresponding to a slight to high signal intensity on T2w images due to inflammation[21]. After injection of contrast media, no APHE should be seen to consider a complete response. However, only a few studies evaluated the usefulness of EOB-MRI in the detection of HCC recurrence after MWA. Imai *et al*[15] reported that the diagnostic value of EOB-MRI is better than CT to evaluate HCC after

DOI: 10.3748/wjg.v28.i26.3116 **Copyright** ©The Author(s) 2022.

Figure 3 Two-years liver magnetic resonance imaging follow-up of a 71-yr-old male with liver cirrhosis and previous subcapsular hepatocellular carcinoma in segment VIII underwent radiofrequency ablation. A: T2-spectral attenuated inversion recovery; B: High b-value diffusion weighted imaging; C: Arterial phase magnetic resonance imaging (MRI); D: Arterial phase MRI with image subtraction technique; E and F: Hepatobiliary phase MRI. Liver MRI showed recurrent hepatocellular carcinoma (8 mm) located infero-lateral to the radiofrequency scar, characterized by moderate to high signal hyperintensity in T2, hyperintensity in high b-value diffusion sequences, with arterial "wash in" and hypointensity in hepatobiliary excretion phase.

treatment by image-guided tumor procedures, including patients who underwent both ablation and chemoembolization.

CA

As reported by Song[22], CA should be included in the family of thermal ablation in HCC patients. The physical bases are like RFA and MWA, however, the employed temperature is not hot but cold, thanks to chemical agents such as liquid nitrogen. According to a recent meta-analysis[23], the effects of MWA and CA appeared to be similar to those of RFA, but there were lower rates of local tumor progression and higher rates of complete thermal ablation in large tumors compared to RFA ($P < 0.05$). MR imaging findings after the CA procedure are similar to RFA and MWA, as reported above: the ablation zone at 24h appears hypointense and heterogeneously hyperintense on T1w and T2w images, respectively[24]. Foci of inhomogeneous signal intensities on T1w and T2w images should be principally due to blood products and can be present in further follow-up examinations[24]. The peripheral zone shows a slight to hyper- signal intensity on T2w images, due to inflammation and granulation tissue formation. The residual tumor presents analogous imaging features to the treated lesion, while the recurrence can be seen as an area of APHE with consequent hypointensity on portal-venous and HBP. Even if not fully reported in the literature, a focal hypointense area of HBP images without APHE might be referred to a suspected recurrence.

TACE AND TRANS-ARTERIAL RADIOEMBOLIZATION

Treatment options for HCC depend on tumor burden and extent, patient's performance status, liver function, extra-hepatic disease, and co-morbidities, according to the BCLC system[10]. Intra-arterial therapies, including TACE and trans-arterial radio-embolization (TARE), come into play to improve survival and quality of life where curative treatments like ablation, liver resection, or liver transplantation are not applicable[10,25]. TACE and TARE are regarded as a standard of care for a patient with intermediate-stage HCC (BCLC class B, Child-Pugh A-B) not eligible for surgical resection or transplantation and without portal vein thrombosis or extrahepatic spread. Moreover, the application of these techniques range from curative-intent for small tumors, to downstaging or bridging to resection and transplantation for early and intermediate disease, and locoregional control and palliation for advanced disease[26].

The main contraindications to TACE and TARE are decompensated liver cirrhosis, bilobar liver involvement, and technical infeasibility; absolute contraindication specific to TARE is the presence of

hepato-pulmonary shunt or hepato-enteric shunts[10].

In the case of portal vein thrombosis, in clinical practice, TACE is contraindicated, even if Patidar *et al* [27] described a good outcome of patients with segmental-branch or first-border branch portal vein thrombosis treated with TACE. On the contrary, TARE may have applications even if there is portal vein thrombosis because of the reduced embolic effect of the technique[10].

TACE

TACE is performed by cannulation of the arteries that feed the HCC through a catheter or a microcatheter and releasing both the chemotherapeutic agent and embolic particles. The treatment may be performed in two ways, conventional TACE that uses lipiodol, an oily radiopaque material mixed with one or more chemotherapeutics agents, followed by administration of an embolic agent and drug-eluting beads TACE (DEB-TACE) with slowing releasing of chemotherapy by particles[26].

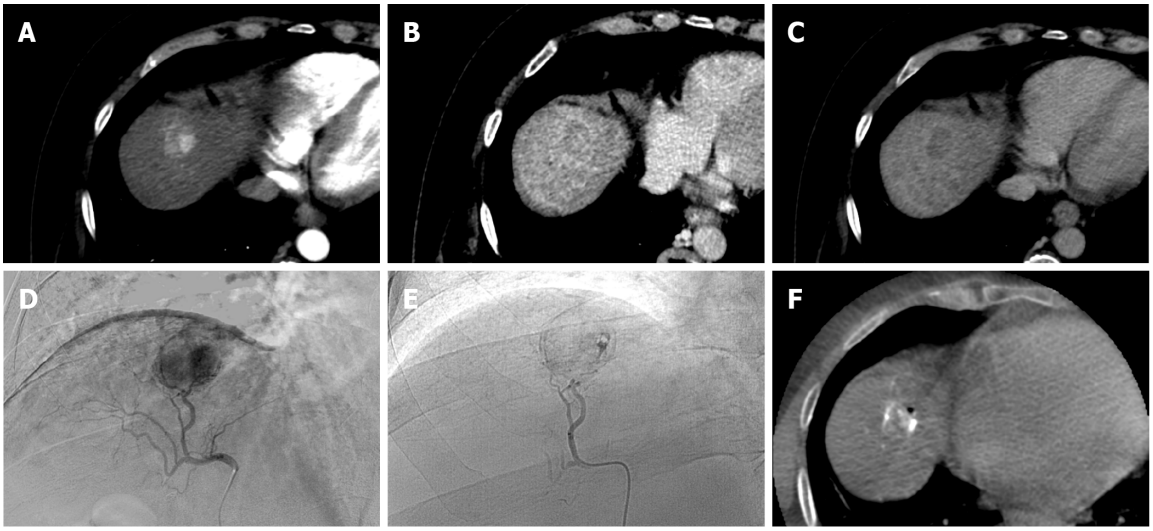
Multiphasic MRI is performed to evaluate the response to treatment and to detect new HCCs from 1 mo to 3 mo after treatment for the first imaging study, followed by every 3 mo for 2 years[28]. As previously mentioned, MRI may use gadolinium-based extracellular contrast agents, or gadolinium-based hepatobiliary agents[28,29].

MRI imaging after TACE is related to tumor necrosis caused by ischemic injury from arterial embolization and chemotoxic injury from the administered chemotherapy[28]. Gd-EOB-DTPA allows similar dynamic acquisition of extracellular agents in arterial and portal phases, essential in detection of a viable tumor. If the treatment is successful the expected findings are: absence of APHE, associated with surrounding perfusion changes related to edema and arterial embolization, a thin APHE phase due to inflammatory, that may persist up to a year, and a volumetric reduction of the treated lesion over time[28]. The HBP contributes to the diagnosis of complete response to treatment, showing a corresponding hypointensity of the lesion if complete necrosis occurs. A thin, continuous, and smooth APHE rim associated with a corresponding isointense area in the HBP defines a benign finding[30].

After treatment, the damage of the liver parenchyma around the treated lesion may cause geographic perfusion changes and corresponding hypointensity on the HBP, a feature that needs careful evaluation and examination of additional sequences to avoid diagnostic mistakes of infiltrative disease[31]. If pseudolesions related to treatment occur (arterial-venous shunt and portal vein obstruction), they usually don't show hypointensity on the HBP, an element that helps in the diagnosis of benignity, although hypointense pseudolesions on the HBP mimicking malignancy have been described by Motosugi *et al*[32].

The sign of residual and/or recurrent disease is represented by the presence of thick, peripheral, irregular, eccentric, nodular APHE with or without washout within the treated lesion, or enhancement similar to pre-treatment tumor. Aslam *et al*[30] showed findings suggestive of the presence of viable tumor after thermoablation, applicable for TACE too: the presence of thick, nodular and eccentric hypointense signal on HBP or a discontinuous hypointense rim. Considering these findings on the HBP-like viable tumor is much more important when there is equivocal APHE, consisting of viable isoenhance or hypoenhance tumor in arterial phase[33].

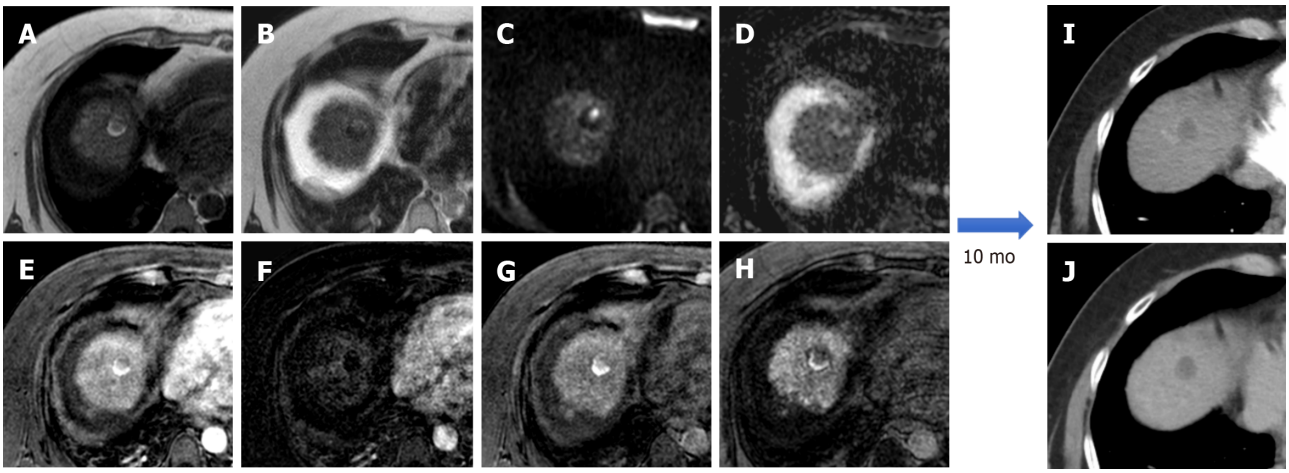
Figure 4 depicts a pre-treatment CT images and subsequent TACE treatment of an HCC nodule, the results of which are illustrated in Figure 5.



TARE

TARE is a trans-arterial catheter treatment based on delivering microspheres (glass or resin) coated with ^{90}Y. ^{90}Y is an unstable isotope that releases a beta particle during its decay into a stable element, zirconium 90, inducing destruction of the target tumor with a limited depth of penetration to minimize radiation exposure of surrounding parenchyma[33].

^{90}Y microspheres have a main radiant effect and a small microembolic effect due to the little diameter of microspheres; therefore, tumor necrosis related to TARE is mostly radiation-induced and the arterial flow to adjacent parenchyma is largely conserved, which is an important advantage in the case of portal venous thrombosis (*i.e.*, contraindication for TACE)[33].



Multiphasic MRI after TARE is performed at 3-mo intervals even for the first examination, because imaging performed earlier may show exuberant arterial phase involving the treated lesion and the surrounding parenchyma with consequently difficult interpretation[29]. MRI imaging findings in TACE and TARE are not similar because of the different mechanisms of action: TARE induces modifications that evolve because of the impact of radiation on the liver parenchyma surrounding the lesion[28,30].

The expected Gd-EOB-DTPA imaging findings of TARE-treated HCC are persistent APHE or portal washout that can persist for at least one year, geographic peri-tumoral APHE, complete loss of APHE, thin rim of peripheral APHE, transitory growth in the size of the tumor due to edema, and cytostatic effect of radiation, a delay in tumor decreasing size. In TARE, in the immediate post-treatment setting, the penetration of beta particles in the surrounding liver parenchyma causing inflammation, edema, hemorrhage, leads to a heterogeneous enhancement, more accentuated than TACE. Even in this case, Gd-EOB-DTPA may show a related hypointensity on the HBP, an important element to be assessed since it can be misdiagnosed with an infiltrative disease. This finding may usually resolve after 6 mo, so in the early phase is very important to consider other sequences to make the differential diagnosis, especially T2w and DWI images. The changes in the lesion diameter should be characterized with

Figure 5 Post-trans-arterial chemoembolization follow-up magnetic resonance imaging with hepatospecific contrast agent in the same patient described in Figure 4. A: In-phase T1-weighted image; B: T2-weighted image C: High b-value diffusion weighted imaging (DWI); D: Apparent diffusion coefficient map; E: Arterial phase magnetic resonance imaging (MRI); F: Arterial phase MRI with image subtraction technique; G: Portal venous phase MRI; H: Hepatobiliary phase MRI; I: Ten-month computed tomography (CT) follow-up: arterial phase; J: Ten-month CT follow-up: delayed phase. Liver MRI shows an inhomogeneously hyperintense nodule in T1WI in its right posterior portion, coexisting with a more hyperintense area in T2WI with high signal intensity in high b-value DWI in the left anterior portion. Dynamic study showed no arterial enhancement confirmed with the subtraction technique image, absence of vascularization in the portal phase and inhomogeneous hypointensity in the hepatobiliary phase. The findings are suggestive of good treatment outcome with presence of both coagulative and colliquative necrosis and no residual disease and CT scans control after 10 mo confirmed the outcome.

caution based on the persistent APHE and typical washout of the lesion after TARE. Viable tumor manifests itself with an increase in the size of the treated nodule with new or growing nodular enhancement within or beyond the margin of the post-radiation zone with hypointense signal on the HBP[28,30].

For both TARE and TACE techniques the use of Gd-EOB-DTPA implies knowledge of some technical concerns. An optimal arterial phase may be more difficult to obtain compared to extracellular-contrast agents because of acute transient severe motion artifacts affecting EOB-MRI. Several approaches have been applied to reduce motion artifacts: (1) Lowering thecontrast injection rate; (2) Using multiple arterial phasetechnique; (3) Shortening the scanning time; and (4) Using a modified breathing command, and dilutingcontrast medium[5,34]. Moreover, "washout" evaluation of the nodule has to be assessed in the portal phase because hypointensity during the TP could be related to true washout or

pseudo-washout resulting from the hyperintensity of the surrounding parenchyma[34]. Another element to be considered is the adequacy of the HBP, strictly linked to the assessment of the degree of contrast uptake in the liver parenchyma relative to the hepatic vessels and of the presence of contrast excretion into the biliary system. A signal intensity ratio of 1.8 between liver and vein, with the maximal enhancement of liver parenchyma and hypointensity of the veins, is the best predictor of the ideal phase. In a functional liver, this ideal condition is achieved at 15-20 min after contrast injection[35]. In this setting, the main limitation of Gd-EOB-DTPA is the necessity of a functional liver for an optimal HBP; the cirrhotic liver may have diminished or delayed parenchymal enhancement leading to failure of the mechanism of contrast uptake and excretion. Therefore, in a situation with deeply compromised liver function (Child-Pugh B-C) acquisition of delayed HBP beyond the 20 min is necessary.

At present, the treatment response algorithms used in the clinical practice, such as Modified Response Evaluation Criteria in Solid Tumors (mRECIST), European Association for the Study of the Liver Disease Criteria, and Liver Imaging and Reporting Data System Treatment Response Algorithm are enhancement-based classification systems that don't include transitional or HBP obtained by Gd-EOB-DTPA[28-30]. However, many authors have analyzed the contribution of EOB-MRI in follow-up after TACE and TARE with promising results. To the best of our knowledge the actual studies published in the literature, have analyzed the impact of Gd-EOB-DTPA in the follow-up of loco-regional therapy group (for example both ablation and TACE) without examination of the single procedure, therefore next considerations are almost effective for both TACE and TARE.

In a recent study, Kim *et al*[33] showed an increased sensitivity in the detection of viable tumor considering all ancillary features (HBP hypointensity, restricted diffusion, and intermediate signal on T2w) with growing sensitivity into the LI-RADS-TR viable category of 57%-87% *vs* 39%-65% without changing in specificity. Park *et al*[36] obtained similar results for TACE and ablation, with increased sensitivity of 84% *vs* 76%.

Kim *et al*[37] first, in a recent retrospective study, analyzed the impact of the incorporation of the individual ancillary feature instead of multiple ancillary features on the diagnostic performance of the LI-RADS-TR for viable tumor. They found that hypointense signal during the transition and/or HBP can improve the sensitivity than contrast dynamic assessment alone.

Conversely, Rimola *et al*[18] show a small contribution of HBP in the evaluation of tumor response after loco-regional therapy, with greater accuracy, sensitivity, and inter-reader agreement using extracellular agents in comparison with Gd-EOB-DTPA[37]. These results may depend on better conspicuity of the APHE with extracellular agents and to the misdiagnosis of viable tumor for hypointense areas on the HBP related to damaged liver parenchyma, an avoidable mistake considering additional sequences[18,30].

Another important fact is that EOB-MRI in follow-up after TACE and TARE significantly contributes not only to determination of viable tumors on the treated cavity but also for detection of new HCC lesions, that may be disguised by the post-treatment changes of the surrounding hepatic parenchyma [30].

The use of EOB-MRI after TACE and TARE is widespread in the clinical practice and its contribution with transitional and HBP to identify the viable tumor, necrotic cavity, damaged liver tissue, and new HCC has been shown in the literature, although it still has not been included in treatment response algorithms.

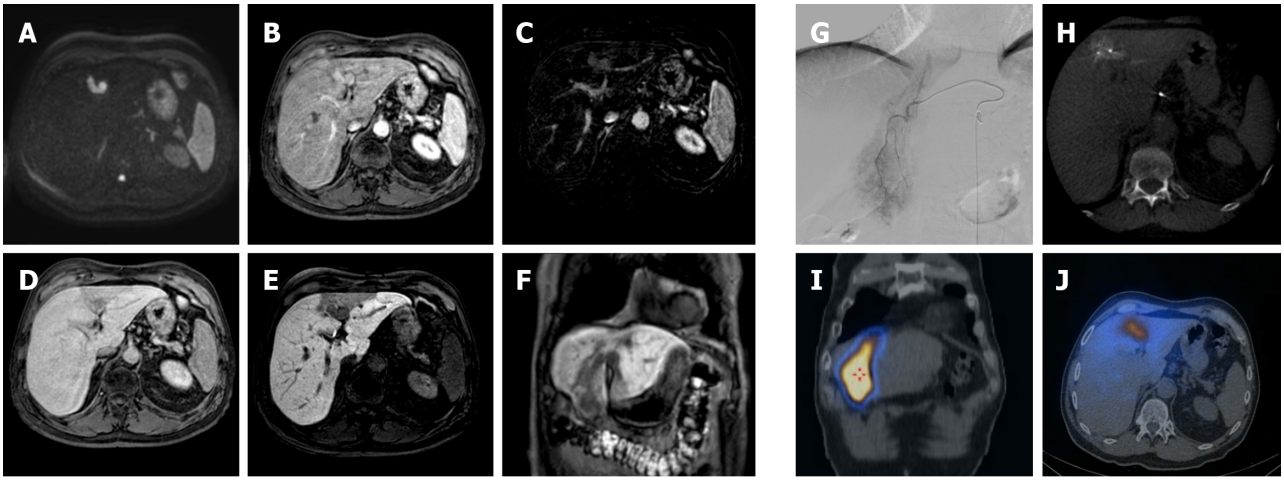

Figure 6 depicts the pre-treatment liver MRI and preoperative planning for TARE of a patient with voluminous infiltrating HCC. Figure 7 illustrates the outcome of treatment.

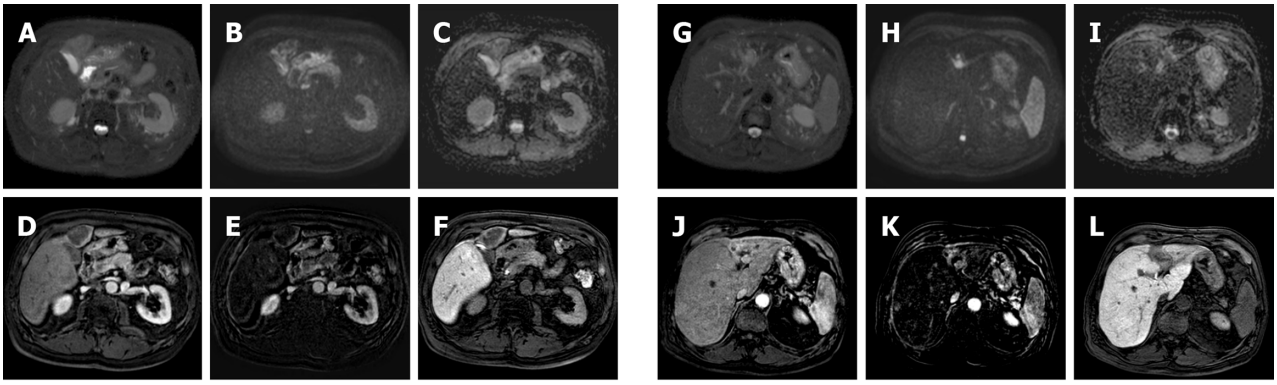
STEREOTACTIC ABLATIVE RADIOTHERAPY

Recent improvements in image guidance and conformal radiation techniques have made it possible to administer high doses of radiation to liver tumors with minimal damage to adjacent parenchymal tissue [38]. Although SBRT is not part of the current BCLC system, it is included as a treatment option in the most recent version of the National Comprehensive Cancer Network (NCCN) for primary liver cancer for unresectable disease or medically inoperable patients[38,39].



Indications for SBRT are applicable in the following cases: (1) Early-stage HCC, not eligible for surgical resection, liver transplantation, or local ablation; (2) Intermediate or advance stage HCC not eligible or not responsive to TACE; (3) Palliative purpose for symptomatic end-stage HCC; and (4) Bridging or downstaging therapy for liver transplantation in patients not eligible for other locoregional therapies[40].

Factors that generally hinder percutaneous ablative therapies, such as proximity of the tumor to vascular structures, bile ducts or the diaphragmatic surface are not contraindication to treatment[41]. SBRT is most appropriate in patients with cirrhotic disease in Child-Pugh class A. Treatment is available for patients up to Child-Pugh B7, for whom close clinical monitoring and dose reduction are recommended due to the increased risk of radiation-induced liver disease (RILD). From a technical point of view, the number of target lesions, together with their intraparenchymal location, are potential limitations during treatment planning and dose delivery.

Figure 6 A 62-yr-old patient with infiltrative hepatocellular carcinoma with associated neoplastic portal vein thrombosis. A: High-b-value diffusion-weighted image; B: Arterial phase magnetic resonance imaging (MRI); C: Arterial phase MRI with image subtraction technique; D: Portal venous phase MRI; E and F: Hepatobiliary phase MRI; G: Pre-treatment arteriography; H: Pre-treatment cone beam computed tomography (CT); I and J: Post trans-arterial radio-embolization single photon emission computed tomography (SPECT) images. Left panel shows pre-treatment liver MRI, illustrating the cranial portion of the lesion with portal branch infiltration; whereas the right panel shows pre-treatment arteriography, the cone beam CT of the cranial portion of the lesion with the portal vein infiltration, and preoperative planning with SPECT images post administration of Tc-99m-labeled albumin macroaggregates with hyperfixation at both lesion site and portal thrombosis.

DOI: 10.3748/wjg.v28.i26.3116 **Copyright** ©The Author(s) 2022.

Figure 7 Post-trans-arterial radio-embolization images in the patient mentioned in Figure 6. A: T2-spectral attenuated inversion recovery; B: High b-value diffusion weighted imaging; C: Apparent diffusion coefficient (ADC) map; D: Arterial phase magnetic resonance imaging (MRI); E: Arterial phase MRI with image subtraction technique; F: Hepatobiliary phase (HBP) MRI; G: T2-spectral attenuated inversion recovery; H: High b-value diffusion weighted imaging; I: ADC map; J: Arterial phase MRI; K: Arterial phase MRI with image subtraction technique; L: HBP MRI. The liver MRIs reveal almost no signal restriction in DWI and no enhancement in dynamic study in the caudal portion of the lesion (left panel) which are suggestive of a good outcome. Whereas in the cranial infiltrating part of the lesion (right panel) at portal branch level, the high signal in DWI with arterial enhancement is suspected for residual disease.

Ionizing radiations directly impairs the DNA replication process by causing breaks and thus preventing cancer cells from replicating, most powerfully on tissues with a high cell turnover. After radiotherapy, centrilobular hepatocytes die by a hypoxic process secondary to vascular congestion, which does not recover until several months later[42]. Furthermore, proinflammatory mechanisms will be set on the treated region. These histological changes initially lead to an acute reduction in cellular vascular supply, with peripheral hypervascularization induced by the proinflammatory mechanisms, while over time, fibrosis leads to a reduction of tumor size and vascular supply[43]. Damage also occurs in the surrounding liver parenchyma with the evolution of the chronic inflammatory context, characterized initially by edema and subsequently by fibrosis, leading to capsular retraction[42].

Acute, subacute and chronic stages can be distinguished by assessing the evolution of histological changes. In the acute stage (1-3 mo) typical peripheral hyperarterialization, defined as a ring-like enhancement during the arterial and portal venous phases, can be observed. In the subacute stage (3-6 mo), the involved parenchyma shows relative hypointensity before and after contrast media injection especially on the portal-venous phase, with progressive enhancement in the late phases, concerning the occlusion of the centrilobular veins and to the reduced clearance of intravenous contrast. In the chronic

stage (> 6 mo), imaging will reveal changes caused by radio-induced fibrosis. The subcapsular location of the target lesions also correlates with the progressive occurrence of capsular retraction. This reaction typically appears as a band-like finding, a typical appearance that can help the differential diagnosis with residual or recurrent tumor[44]. Finally, the classic RILD generally occurs within 4 mo of total or subtotal hepatic irradiation, and manifests with hepatomegaly, ascites, and increased alkaline phosphatase levels, without a radiological intrahepatic progression disease. Nowadays, this complication is effectively prevented by sparing a sufficient portion of the parenchyma during therapy.

Patients with pre-existing chronic liver disease undergoing this type of treatment tend to experience a different spectrum of toxicity than with classic RILD, including a general decline in liver function, a marked increase in transaminases or jaundice within 3 mo of the end of therapy, collectively referred as "non-classic" RILD[44].

The radiological findings of SBRT treated lesions differ from the imaging of other locoregional therapies. Indeed, while the latter results in immediate tumor devascularization, SBRT leads to gradual histological changes in the lesion and surrounding parenchyma over time, which may lead to the incorrect assumption of a lack of efficacy.

As previously mentioned, different algorithms are employed to determine the response evaluation, such as mRECIST, applied to CT and MRI[45]. The intensity of arterial enhancement may appear quite early (15-45 d after SBRT) and may persist over time. Therefore, lesions dimensionally stable over time with a reduced arterial hypervascularization should be considered as a responder. The decrease in size occurs more slowly, over 22-24 mo, due to progressive necrosis up to 12 mo after treatment, which results in a slower evolution of structural changes.

In post-SBRT MRI examinations it is common to find a hyperintense perilesional halo on T2w due to the inflammatory reaction and venous congestion induced by veno-occlusive disease or, in subsequent follow-ups, a slight signal hyperintensity on T2w in the whole irradiated field, a direct sign of parenchymal fibrosis. Moreover, the application of DWI sequences can provide information on tissue cellularity and the integrity of cell membranes. In fact, during the early phase after treatment, hepatic edema occurs due to decreased venous outflow secondary to centrilobular obstruction, and there may be mild restricted diffusion and a slight increase in apparent diffusion coefficient (ADC).

Finally, tumor response after SBRT can be challenging, as described above: tumor shrinkage may not happen in the immediate months after SBRT. Even in the absence of volumetric reduction, progressive reduction in tumor enhancement is consistent with treatment response. This is typically accompanied by a corresponding increase in ADC. An increment in ADC of 20%-25% was found to be an indicator of SBRT response in a few small retrospective studies[46,47]. Thus, in stereotactic radiotherapy, a statistically significant increase in ADC values measured in HCC undergoing radiofrequency was found to be the most important independent factor in recurrence and survival rates.

The use of hepatobiliary contrast agents allows the assessment of both lesion and the adjacent hepatocytes: The presence of a hypointense nodular lesion during HBP nearby an SBRT-treated HCC may signify either the presence of neoplastic cells or a scar. The picture is further complicated by the manifestation in such sequences of the focal hepatic reaction induced by radiotherapy. This alteration can be demarcated as a band-like area of signal hypointensity, such as hyperintensity on T2w, related to altered hepatocyte function in the irradiated field[48].

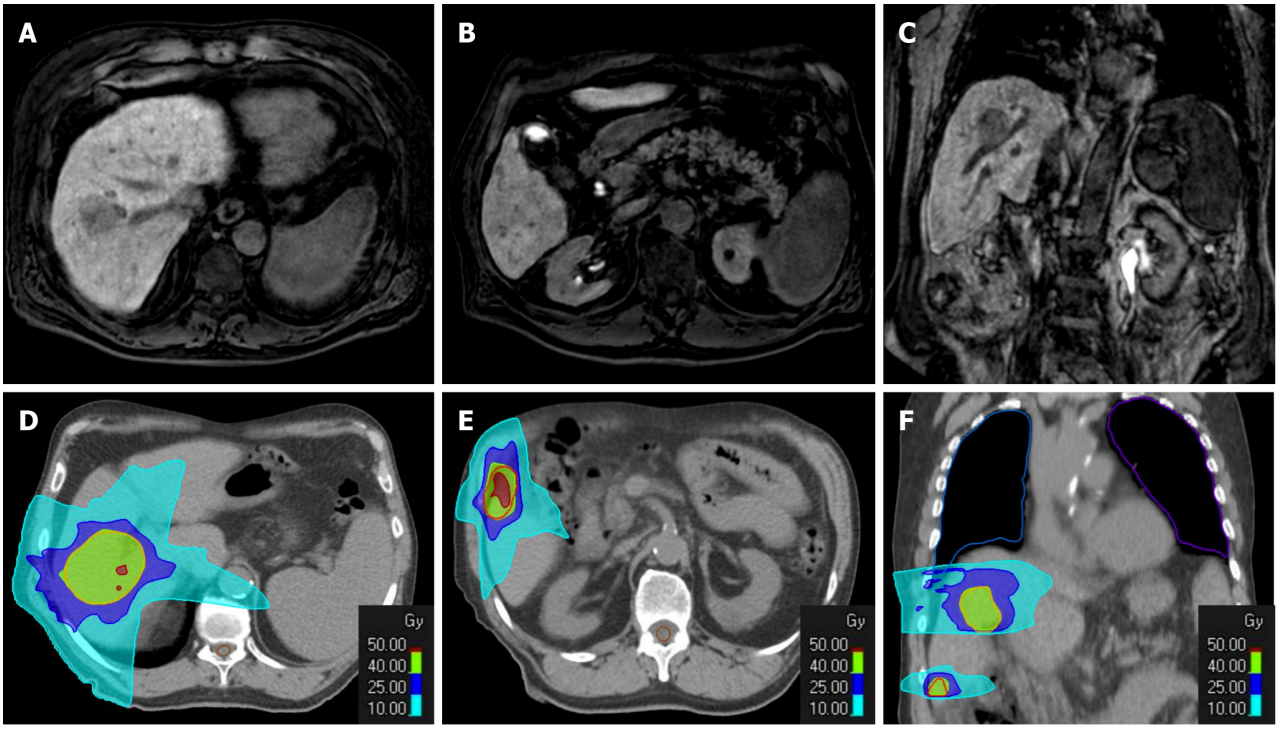

Figure 8 depicts the radiotherapy treatment plan; Figure 9 shows the SBRT treatment outcomes; Figure 10 depicts the treated zone's evolution; and Figure 11 illustrates the outcome 20 mo after treatment.

LIVER MRI ACCURACY AND LIMITATIONS

Although MRI is notably known as a highly sensitive and accurate imaging technique in detection and characterization of focal liver lesions, there is still no consensus regarding the best imaging follow-up modality for patients affected with HCC after locoregional treatments. Moreover, to date, only few studies have conducted a comparison among imaging techniques after locoregional treatments, and this raises the scientific interest in further investigations.

Kubota *et al*[49], by evaluating 84 HCCs underwent TACE treatment, showed the superiority of MRI to CT for early detection of lesion. Authors reported 76.0% sensitivity, 67.6% specificity and 72.6% accuracy for lipiodol-CT in comparison to 100% sensitivity, specificity and accuracy for dynamic MRI. Moreover, DWI and ADC values can help identify the early HCC recurrence: the presence of pathological tissues results in a higher signal intensity on DWI relative to normal liver parenchyma and a low signal on ADC maps, differentiating it from treated lesion (necrotic/edematous area) which manifests as high ADC values[50]. In these settings, the use of Gd-EOB-DTPA can maintain the highest diagnostic values, as mentioned above.

MRI was demonstrated to be useful also prior to treatment, especially by evaluating the HBP. Kim *et al*[16] found that HBP hypointense nodules without APHE are risk factors for intrahepatic distant recurrence in HCC patients treated with RFA or hepatectomy in a meta-analysis of 842 patients. In patients with HCC who have these nodules on pretreatment gadoxetic acid-enhanced MRI, stratification

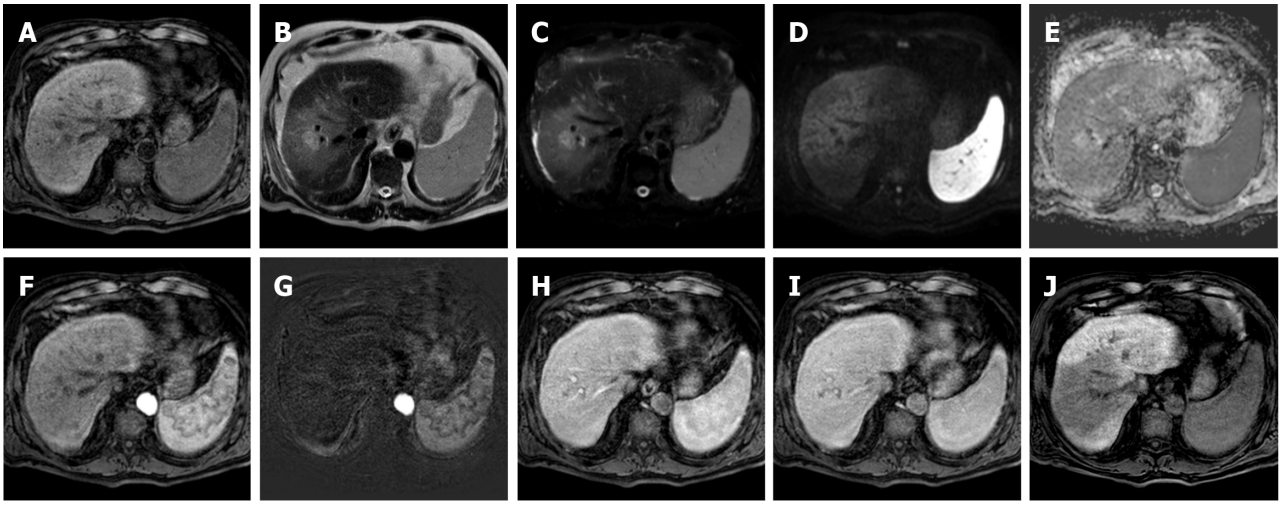
Figure 8 Radiotherapy treatment planning of a 70-yr-old male patient with two hypovascular hepatocellular carcinomas in segment VIII (4.3 cm) and segment VI (1.3 cm). A-C: Hepatobiliary phase magnetic resonance imaging (MRI); D-F: Computed tomography (CT) simulation for radiation therapy planning. In the upper panel from A to C are reported hepatobiliary phase MRI images prior to stereotactic ablative radiotherapy treatment. In the bottom panel from D to F are reported CT images from radiotherapy treatment plan with isodose curve distributions.

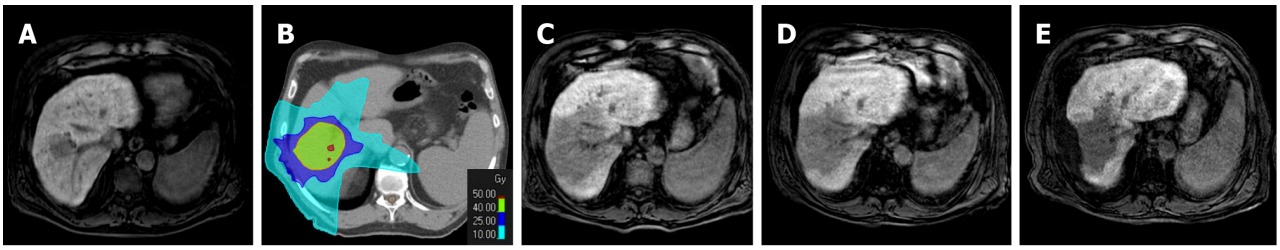
of patient management in terms of performing additional tests or treatment for these nodules, as well as modification of proper follow-up strategies, may be required.



Considering the therapeutic response to RFA, literature may not be much of a help since the two most important studies in this field were published in the early 2000s[51]. Both studies reported that MRI may have an edge over CT in the early detection of local regrowth in particular after 4 mo of treatment [51]. This aspect should be carefully considered according to readers' experience, MR image quality, and the scattered use of hepatobiliary contrast agents, which was not widely used 20 years ago.

Regarding therapeutic response to TACE, it is important to underline that beam hardening artifacts can lead to the underestimation of hyperenhancement during the CT arterial phase and thus reducing the sensitivity and accuracy dramatically[49,52]. On the other hand, the wider use of DEB-TACE can partially solve this issue due to the lack of beam hardening artifacts[53]. The abovementioned issues can be partially left out when using MR to detect recurrence. On the other hand, the use of dual-energy CT can help increase diagnostic accuracy, even if not widely available[54]. CT and MR diagnostic accuracy can be considered completely superimposable after TARE[26], although the added value of HBP imaging was not deeply evaluated.

In the recent years, perfusion techniques, both with CT and MR, were used to diagnose HCC and determine different treatment responses, especially after medical therapy: in this setting CT perfusion can be considered a reliable tool in the early detection of recurrence, as reported by Choi *et al*[55]. More recently the effectiveness of CT perfusion was evaluated by Ruff *et al*[56], demonstrating that residual tumor perfusion parameters are linked to HCC recurrence. However, both CT and MR perfusion imaging need an extra time, added costs and are not widely available to be considered convenient tool in daily clinical practice[57].

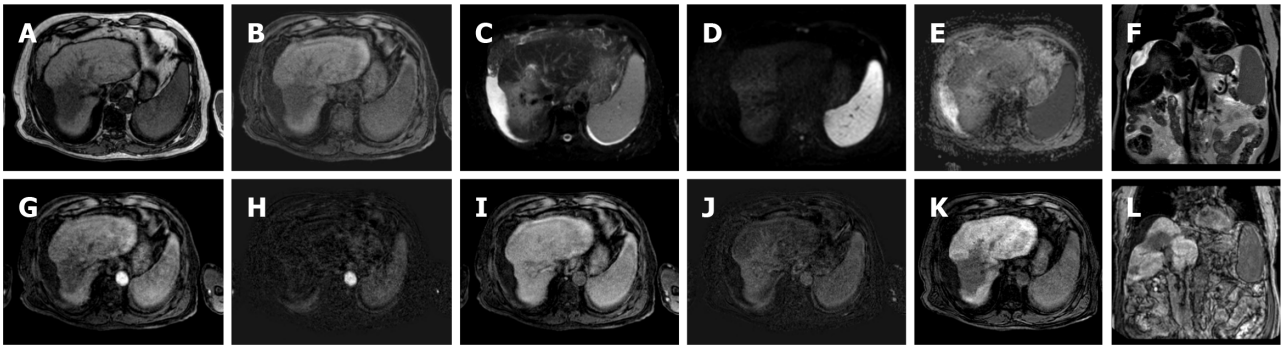


In the recent years, radiomics models based especially on texture analysis are showing promising results[58]. Zhang *et al*[59], by enrolling 132 patients who underwent locoregional therapies, demonstrated that radiomic features extracted from Gd-EOB-DTPA MR imaging associated with clinical data can predict the early tumor recurrence. Even if pioneering, radiomics analyses should be carefully evaluated, especially due to different types of software and MR techniques used which vary between centers. However, further studies should focus on these aspects to validate its potential values[60].

Overall, it is important to underline the presence of artifacts during MR acquisition, especially in the arterial phase when using Gd-EOB-DTPA studies. As previously reported and demonstrated[61], flow rate and acquisition protocol[5] can lead to the degradation of the arterial phase and should be carefully managed to avoid the leak of important data, linked to the risk of early recurrence.

DOI: 10.3748/wjg.v28.i26.3116 **Copyright** ©The Author(s) 2022.

Figure 9 Four-months follow-up post stereotactic body radiation therapy liver magnetic resonance imaging of the hepatocellular carcinoma in segment VIII shown in the Figure 8. A: Non contrast T1-weighted high resolution isotropic volume examination; B: T2-weighted image; C: T2-spectral attenuated inversion recovery; D: High b-value diffusion weighted imaging (DWI); E: Apparent diffusion coefficient (ADC) map; F: Arterial phase magnetic resonance imaging (MRI); G: Arterial phase MRI with image subtraction technique; H: Portal venous phase MRI; I: Delayed phase MRI; J: Hepatobiliary phase MRI. The liver MRI shows an ill-defined area of signal hypointensity in T1 in the treatment zone with a blurred and inhomogeneous signal hyperintensity with evidence of increased signal hyperintensity in the residual nodule. A shaded signal hyperintensity on DWI without signal hyperintensity of the previous lesion, with higher ADC values relative to the surrounding liver parenchyma. No areas of enhancement are shown, and a coarse hypointense signal in the hepatobiliary phase due to the initial fibrotic evolution of the treated zone is evident.



DOI: 10.3748/wjg.v28.i26.3116 **Copyright** ©The Author(s) 2022.

Figure 10 The evolution of the hepatocellular carcinoma stereotactic body radiation therapy treatment zone in patient shown in Figures 8 and 9. A: Hepatobiliary phase (HBP) magnetic resonance imaging (MRI) prior to stereotactic body radiation therapy (SBRT); B: SBRT plan with isodose curve distributions; C: HBP MRI 4 mo after treatment; D: HBP MRI 8 mo after treatment; E: HBP MRI 20 mo after treatment. The MRIs demonstrated the progressive fibrotic evolution of the treatment area.

Finally, the use of CT or MRI is strictly linked to each institution's flow charts: it is important to underline the low CT associated costs, the need for less patient cooperation, and its usefulness when ascites is present[62]. Also in these settings, a direct comparison with MR with HBP imaging is lacking and further studies are needed to validate the abovementioned data.

CONCLUSION

Locoregional therapy is critical in the treatment of patients with HCC. The accurate evaluation of tumor response using imaging modalities is essential for optimal management. Gadoxetic acid-enhanced liver MRI is an important radiological tool in these patients because it allows for optimal non-invasive tissue characterization using a multiparametric approach. For HCC patients to get proper therapeutic management, radiologists must know the usual post-treatment imaging findings associated with locoregional therapy, as well as a thorough comparison of imaging before and after therapy. Overall, gadoxetic acid-enhanced liver MRI is a critical modality in the assessment of results following locoregional HCC therapy, having a significant impact on patient management.

Abstract

BACKGROUND

The development of venous thromboembolism (VTE) is associated with high mortality among gastric cancer (GC) patients. Neutrophil extracellular traps (NETs) have been reported to correlate with the prothrombotic state in some diseases, but are rarely reported in GC patients.

AIM

To investigate the effect of NETs on the development of cancer-associated thrombosis in GC patients.

METHODS

The levels of NETs in blood and tissue samples of patients were analyzed by ELISA, flow cytometry, and immunofluorescence staining. NET generation and hypercoagulation of platelets and endothelial cells (ECs) *in vitro* were observed by immunofluorescence staining. NET procoagulant activity (PCA) was determined by fibrin formation and thrombin–antithrombin complex (TAT) assays. Thrombosis *in vivo* was measured in a murine model induced by flow stenosis in the inferior vena cava (IVC).

RESULTS

NETs were likely to form in blood and tissue samples of GC patients compared with healthy individuals. *In vitro* studies showed that GC cells and their conditioned medium, but not gastric mucosal epithelial cells, stimulated NET release from neutrophils. In addition, NETs induced a hypercoagulable state of platelets by upregulating the expression of phosphatidylserine and P-selectin on the cells. Furthermore, NETs stimulated the adhesion of normal platelets on glass surfaces. Similarly, NETs triggered the conversion of ECs to hypercoagulable phenotypes by downregulating the expression of their intercellular tight junctions but upregulating that of tissue factor. Treatment of normal platelets or ECs with NETs augmented the level of plasma fibrin formation and the TAT complex. In the models of IVC stenosis, tumor-bearing mice showed a stronger ability to form thrombi, and NETs abundantly accumulated in the thrombi of tumor-bearing mice compared with control mice. Notably, the combination of deoxyribonuclease I, activated protein C, and sivelestat markedly abolished the PCA of NETs.

CONCLUSION

GC-induced NETs strongly increased the risk of VTE development both *in vitro* and *in vivo*. NETs are potential therapeutic targets in the prevention and treatment of VTE in GC patients.

Key Words: Neutrophil extracellular traps; Gastric cancer; Platelet; Endothelial cells; Venous thromboembolism

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: We found that gastric cancer (GC)-induced neutrophil extracellular traps (NETs) strongly increase the risk of venous thromboembolism (VTE) development in GC patients. NETs are potential therapeutic targets in the prevention and treatment of VTE in GC patients.

INTRODUCTION

Gastric cancer (GC) is one of the most prevalent gastrointestinal tumors and the third most fatal cancer in the world[1,2]. Additionally, venous thromboembolism (VTE) is a more common complication among GC patients when compared to healthy individuals[3-5]. Notably, VTE is associated with a high mortality in GC patients[6,7]. Several factors, such as tumor stage, neoadjuvant chemotherapy, and surgery, contribute to the development of VTE in GC patients[8,9]. Cancer cells exert a procoagulant activity (PCA) in their microenvironment, which is related to activation of the coagulation system[10]. However, the molecular mechanism underlying PCA in GC patients is poorly understood. Uncovering molecular targets associated with VTE in GC patients can help in the development of appropriate therapy, which can improve the clinical outcomes of these patients.

Neutrophil extracellular traps (NETs) are web-like structures composed of filamentous DNA and histones, decorated with antimicrobial protein granules and enzymes, including neutrophil elastase (NE), myeloperoxidase (MPO), matrix metalloproteinase-9 (MMP-9), and cathepsin G (CatG)[11,12]. They result from interactions between neutrophils and bacterial or other stimulating factors[13,14]. Overall, they protect the host from pathogen-related damage. NETs were initially described as an antimicrobial reaction, but some undesirable effects of NETs have been reported in autoimmune diseases[15-17]. Citrullinated histone H3 (citH3) is proposed as a biomarker reflecting NETs formation. Recent studies have linked NETs to the development of metastasis and cancer-associated thrombosis[18,19]. In particular, NETs result in arterial and venous thrombosis, both of which are mediated by neutrophils[20]. Furthermore, using mouse models, it has been shown that thrombosis in breast cancer tissues is closely linked to the formation of NETs[21]. This finding suggests the potential relationship between NETs and cancer-associated thrombosis.

A recent study revealed that priming metastatic pancreatic cancer cells with platelets stimulates neutrophils to release NETs, which promotes thrombosis in both static and dynamic states[22]. We first reported that platelets derived from GC can stimulate neutrophils to release NETs. NETs enhance PCA in GC patients, which is positively correlated with the expression of the thrombin–antithrombin (TAT)

complex and the level of serum D-dimers[23]. Moreover, both human and animal studies suggest that enhanced thrombosis may result from increased activated platelets[24,25]. Nevertheless, little is known about the interaction between NETs and platelet activation in GC patients. Venous endothelial cell (EC) injury in cancer patients is also closely related to venous thrombosis[26,27]. Interestingly, the cytotoxicity of NETs against ECs enhances PCA in oral squamous cancer, even in patients with obstructive jaundice and inflammatory bowel disease[28-30]. Even so, the potential mechanism underlying EC injury in GC patients is poorly understood.

Our central hypothesis is that GC-induced NETs participate in VTE responses by platelet activation and endothelial injury. Therefore, we first explored the complex relationship between NET formation and platelet activation as well as EC injury. Furthermore, we showed the effect of NETs on thrombosis in an inferior vena cava (IVC) stenosis mouse model. In general, our results may indicate that NETs are potential therapeutic targets in the prevention and treatment of VTE in GC patients.

MATERIALS AND METHODS

Patients and tissue samples

Sixty-three patients newly diagnosed with primary GC and 13 healthy donors (HDs) attending the Second Affiliated Hospital of Harbin Medical University between October 2019 and April 2021 were enrolled in this study. GC diagnoses were performed based on pathological examinations. Pathological tumor-node-metastasis (TNM) staging and histological classification of GC were performed according to the 7th American Joint Committee on Cancer (AJCC) guidelines[31]. Patients who were < 18 years old or pregnant, those on antitumor or anticoagulant treatment before surgical treatment, or those with underlying complications such as endocrine, cardiovascular, hematological and other cancers or infectious disease were all excluded. The main clinical characteristics of the patients with GC and HDs are shown in Table 1. We extracted tumor and adjacent normal tissues from GC patients who consented to this study in writing. Blood samples of preoperative patients were obtained at first diagnosis before any clinical treatment, and blood samples of postoperative patients were obtained from 1 mo after surgery before adjuvant therapy to avoid errors caused by postoperative stress. The protocol for this study was approved by the Ethics Committee of the Second Affiliated Hospital of Harbin Medical University (No. KY2016-032).

Isolation of human plasma, platelets, and neutrophils

Fresh whole venous blood was collected into tubes containing 3.2% sodium citrate using 21-gauge needles. The patients underwent overnight fasting before blood collection. The blood was centrifuged at 150 *g* for 20 min at room temperature (RT) to obtain platelet-rich plasma (PRP), within 1 h of collection. Clean top PRP layer was collected in a new tube, diluted with platelet wash buffer (TBD, Tianjin, China), and centrifuged at 460 *g* for 20 min at RT to obtain clean platelets and platelet-free plasma (PFP) [32]. The platelets were resuspended in prewarmed modified Tyrode's buffer (137 mmoL/L NaCl, 2.8 mmoL/L KCl, 1.0 mmoL/L $MgCl_2$, 12 mmoL/L $NaHCO_3$, 0.4 mmoL/L Na_2HPO_4, 5.5 mmoL/L glucose, pH 7.4; Solarbio, Beijing, China). Neutrophils were isolated based on the density gradient centrifugation, using the whole blood neutrophil isolation kit (TBD). After lysing erythrocytes based on the red blood cell lysis buffer (150 mmoL/L NH_4CL, 10 mmoL/L $KHCO_3$, 0.2 mmoL/L Na_2EDTA, pH 7.4; TBD), the purity (> 96%) and viability (> 96%) of neutrophils were assessed using Wright–Giemsa staining and Trypan blue staining, respectively.

Cell lines and conditioned medium

The human metastatic GC KATO-III and MKN-45 cell lines, human primary GC AGS cell line, human gastric mucosal epithelial cell (GES-1) line, human umbilical cord endothelial cell (HUVEC) line, and mouse forestomach squamous carcinoma (MFC) cell line were purchased from PROCELL (Wuhan, China). All cell lines were characterized using short tandem repeat (STR) profiling. The GES-1, AGS, MKN-45 and MFC cells were cultured in RPMI 1640 (Gibco, USA), KATO-III cells were cultured in IMDM (Gibco), and HUVECs were cultured in DME/F12 (HyClone, Logan, UT, USA). All media were supplemented with 10% fetal bovine serum (FBS; Gibco) and 1% penicillin–streptomycin solution (Beyotime, Beijing, China). Incubation was performed at 37°C under 5% CO_2in a humidified environment. To prepare conditioned medium (CM), the cells were cultured to 90% confluence in medium supplemented with 10% FBS, washed three times using 1 × PBS, and recultured for 48 h in medium without FBS. The supernatant was centrifuged at 1500 *g* for 10 min at 4°C to remove cell debris. The CM was collected and stored at -80°C until use.

Animal models

The animal protocol was designed to minimize pain or discomfort to the animals. Wild-type male C57BL/6 mice (7–9 wk old, weighing 20–26 g) were purchased from the Animal Experimental Center of Harbin Medical University, and all procedures were approved by the Animal Care and Use Committee

Table 1 Main clinical and laboratory features of 13 healthy subjects and 63 patients diagnosed with gastric cancer

Characteristics (n = 76, DF = 4)	Control (n = 13)	Stage I (n = 14)	Stage II (n = 15)	Stage III (n = 22)	Stage IV (n = 12)

of the Second Affiliated Hospital of Harbin Medical University (No. KY2016-032). The animals were individually housed and maintained under standard conditions (12 h/12 h light/dark cycle, 22 ± 1 °C, 50% humidity) and provided with a conventional laboratory diet and an unrestricted supply of drinking water. In the subcutaneous tumor models, mice were injected with MFC cells (2 × 10^{7} cells/mL) subcutaneously into the right axilla, and the tumor volumes were measured every 3 d from 7 d after injection with MFC cells and allowed to reach 1000 mm^{3} (usually 28–35 d). The volume was calculated by measuring the length (L) and width (W) of the tumor: Tumor volume = π/6 × L × W^{2}. Thereafter, a murine model of deep vein thrombosis (DVT) was developed as previously described[33]. The mice were anesthetized by intraperitoneal injection of 2,2,2-tribromoethanol (Sigma, St . Louis, MO, USA), and the intestines were removed to expose the IVC after entering the abdominal cavity through a median abdominal incision. The IVC was carefully separated below the left renal vein plane. After 5-0 (1 mm) sutures passed through the IVC, 3-0 (2 mm) sutures were placed at the parallel part of the IVC as the blocking line. The IVC was ligated and 3-0 sutures were carefully extracted. This procedure has been shown to decrease the vascular lumen by approximately 90%. The other branches of the IVC were ligated to the level of the iliac vein. Thereafter, the abdominal incision was closed, mice were sacrificed after 6 or 48 h, and thrombi that had formed in the IVC were harvested. The IVC stenosis mice in the treatment groups were injected with DNase I (50 μg/mouse; Roche, Switzerland) intraperitoneally every 12 h until the time of death. All animals were killed for tissue collection. Blood (300 μL/mouse) was drawn from the periorbital eye plexus and stabilized with 0.5 mmoL/L EDTA. Plasma was obtained as described above. Thrombi of control and tumor-bearing mice were fixed in 4% paraformaldehyde for 24 h, embedded in Optimal Cutting Temperature (OCT) compound (SAKURA, Torrance, CA, USA), and cryosectioned at a thickness of 4 μm for immunofluorescence staining.

Quantification of plasma NETs marker

Plasma cell-free DNA (cf-DNA), MPO-DNA and citH3-DNA complexes were quantified using capture ELISA as previously described[34]. The quantification of cf-DNA was performed using the Quant-iT PicoGreen dsDNA assay kit (Invitrogen, Carlsbad, CA, USA). For detection of NET-DNA complexes, 5 μg/mL anti-MPO (ab90810; Abcam, Cambridge, UK) or anti-citH3 antibody (ab5103; Abcam) was coated onto 96-well plates overnight at 4°C. After blocking in 1% bovine serum albumin (BSA), the plasma from GC patients or healthy individuals was added per well and incubated at RT for 2 h. After washing five times with PBST, Quant-iT PicoGreen dsDNA Reagent was added. The values were then read with a fluorometer with a filter setting of 480 nm/520 nm excitation/emission wavelengths.

Fibrin formation and TAT complex assay

Fibrin formation of platelets and ECs was detected by turbidity as previously described[35]. To assess

the fibrin formation in the setting of platelet or EC monolayers, cell monolayers in 96-well plates were stimulated by NETs with or without DNase I, activated protein C (APC), and sivelestat treatment alone or together for 4 h, followed by two washes with Hank's balanced salt solution (137 mmoL/L NaCl, 5.3 mmoL/L KCl, 4.17 mmoL/L $NaHCO_3$, 0.33 mmoL/L Na_2HPO_4, 5.5 mmoL/L glucose, pH 7.4) and then 150 μL PFP from HDs was cocultured with cells at 37°C for 2 min, followed by the addition of 50 μL prewarmed 25 mmoL/L $CaCl_2$. The fibrin formation was tested using turbidity measurements and quantified as the maximum value by measuring the OD at 405 nm every 10 s for 30 min on a SpectraMax 340 PC plate reader. To assess the fibrin formation in the plasma of mice, 150 μL PFP from control, tumor-bearing mice, or DNase I infused tumor-bearing mice was cultured at 37°C for 2 min, followed by addition of 50 μL prewarmed 25 mmoL/L $CaCl_2$. To detect the level of TAT complex, a human and mouse TAT complex ELISA kit (Jingkbio, Shanghai, China) was used as previously described[36].

Flow cytometry

Circulating NETs were measured using flow cytometry. Here, whole blood from HDs and GC patients was diluted with 1 × PBS and incubated in the dark at RT for 30 min with FITC-conjugated-citH3 (eBioscience, San Diego, CA, USA) and PE-conjugated MPO (eBioscience) antibodies. For the assessment of phosphatidylserine (PS) and P-selectin expression on platelets, platelets (2×10^6 cells) isolated from the blood of HDs and GC patients were incubated with FITC-conjugated lactadherin (Haematologic, Essex Junction, VT, USA), APC-conjugated CD62P (Biolegend, San Diego, CA, USA), and PerCP-conjugated CD41 (Biolegend) antibodies.

Immunofluorescence staining of NETs

Tumor and paratumor tissues of GC patients were fixed in 4% paraformaldehyde for 24 h, embedded in OCT compound (SAKURA), and cryosectioned into slices of 4-μm thickness. The samples were cultured overnight at 4°C with primary rabbit anti-histone H3 (1:500, ab5103; Abcam) and mouse anti-MPO (1:500, ab90810; Abcam) antibodies, and washed three times with PBS before incubation for 1 h at RT with Alexa Fluor 594-conjugated goat anti-rabbit (1:200; Proteintech, China) and Alexa Fluor 488-conjugated goat anti-mouse (1:200; Proteintech) secondary antibodies. The tissues were stained for 5 min at RT in the dark with 4',6-diamidino-2-phenylindole (DAPI) and anti-fade mounting medium (Solarbio, Beijing, China). Thrombi in the IVC of tumor models or control mice were stained with primary rabbit anti-histone H3 (1:500, ab5103; Abcam) and rat anti-Ly6G (1:500, Novus, St. Charles, MO, USA), and the specimens were incubated with the Alexa Fluor 488-conjugated goat anti-rabbit (1:200; Proteintech) and Alexa Fluor 594-conjugated goat anti-rat (1:200; Proteintech) secondary antibodies as previously described[37]. The tissue images were captured using a confocal microscope (LSM 800; Zeiss, Germany).

Neutrophils (5×10^5 cells) isolated from HDs were seeded and incubated in glass-based poly-L-lysine-coated 24-well plates for 1 h at 37°C under 5% CO_2. Thereafter, cell suspensions of KATO-III, MKN-45, AGS, and GES-1 (2×10^5 cells) or CM from GC cells were cocultured with neutrophils for 4 h at 37°C under 5% CO_2. To detect and quantify NETs, the samples of the CM group were incubated with primary rabbit anti-histone H3 and mouse anti-MPO antibodies and then fluorescent secondary antibodies. For the samples of cell-cell contact groups, NETs were stained with Sytox Green (Solarbio) for 10 min in the dark at RT. All images were captured using a confocal microscope (LSM 800; Zeiss) and analyzed with ImageJ software (National Institutes of Health, Bethesda, MD, USA).

Preparation of cell-free NETs

Cell-free NETs were isolated from neutrophils of GC patients as previously described, with modifications[38]. Neutrophils (10^7 cells/mL) were cultured for 4 h at 37°C under 5% CO_2 in medium supplemented with 500 nM PMA (HY-18739; MedChemExpress, Monmouth Junction, NJ, USA). The supernatant was discarded, and ice-cold 1 × PBS was added to wash down the cell layer of neutrophils to obtain the NET medium and centrifuged at 1500 *g* for 10 min at 4°C to remove cell debris. Thereafter, 1.5 mL supernatant (sterile DNA–protein complex) was centrifuged at 15 000 *g* for 15 min at 4°C. The resultant pellets were suspended in ice-cold 1 × PBS, followed by DNA concentration measurement in the medium obtained using spectrophotometry (Biospec-nano, Japan). An adequate DNA concentration in the medium should range between 50 and 100 μg/mL. The medium containing the NETs was stored at -80°C for subsequent experiments.

Platelet activation and adhesion assays

Platelet activation and adhesion assays were performed as previously described[22]. Glass-based wells of 24-well plates were coated with cell-free NETs after overnight incubation in the corresponding medium at 4°C in a humidified chamber. For controls, 1% denatured BSA was used. Denatured BSA was prepared by heating the solution in PBS without calcium or magnesium to 80°C for 3 min and immediately placing it on ice until cool; it was then stored at 20°C until use. Platelet suspensions (10^7 cells/mL) were then seeded in the wells, cultured for 1 h at 37°C under 5% CO_2, fixed for 15 min at RT with 4% paraformaldehyde, and washed three times using 1 × PBS before 20 min permeabilization

using 0.1% Triton-X 100. The platelets were then incubated for 30 min with Alexa Fluor 594-conjugated phalloidin primary antibody (1:300; Thermo Fisher, Waltham, MA, USA). To assess PS and P-selectin expression, the platelet suspension was incubated for 1 h at 37°C under 5% CO_2, and the cells were stimulated with NETs for 1 h, followed by FITC-conjugated lactadherin (Hematologic) staining for 30 min. Platelets were washed twice with PBS before fixation for 15 min at RT with 4% paraformaldehyde, permeabilized using 0.1% Triton-X 100 for 20 min, and then stained with primary rabbit anti-P-selectin (1:200; Proteintech) and mouse anti-CD41 (1:500; Novus) antibodies. Images were captured using a confocal microscope (LSM 800; Zeiss) and analyzed with ImageJ software (National Institutes of Health).

HUVECs stimulation assay

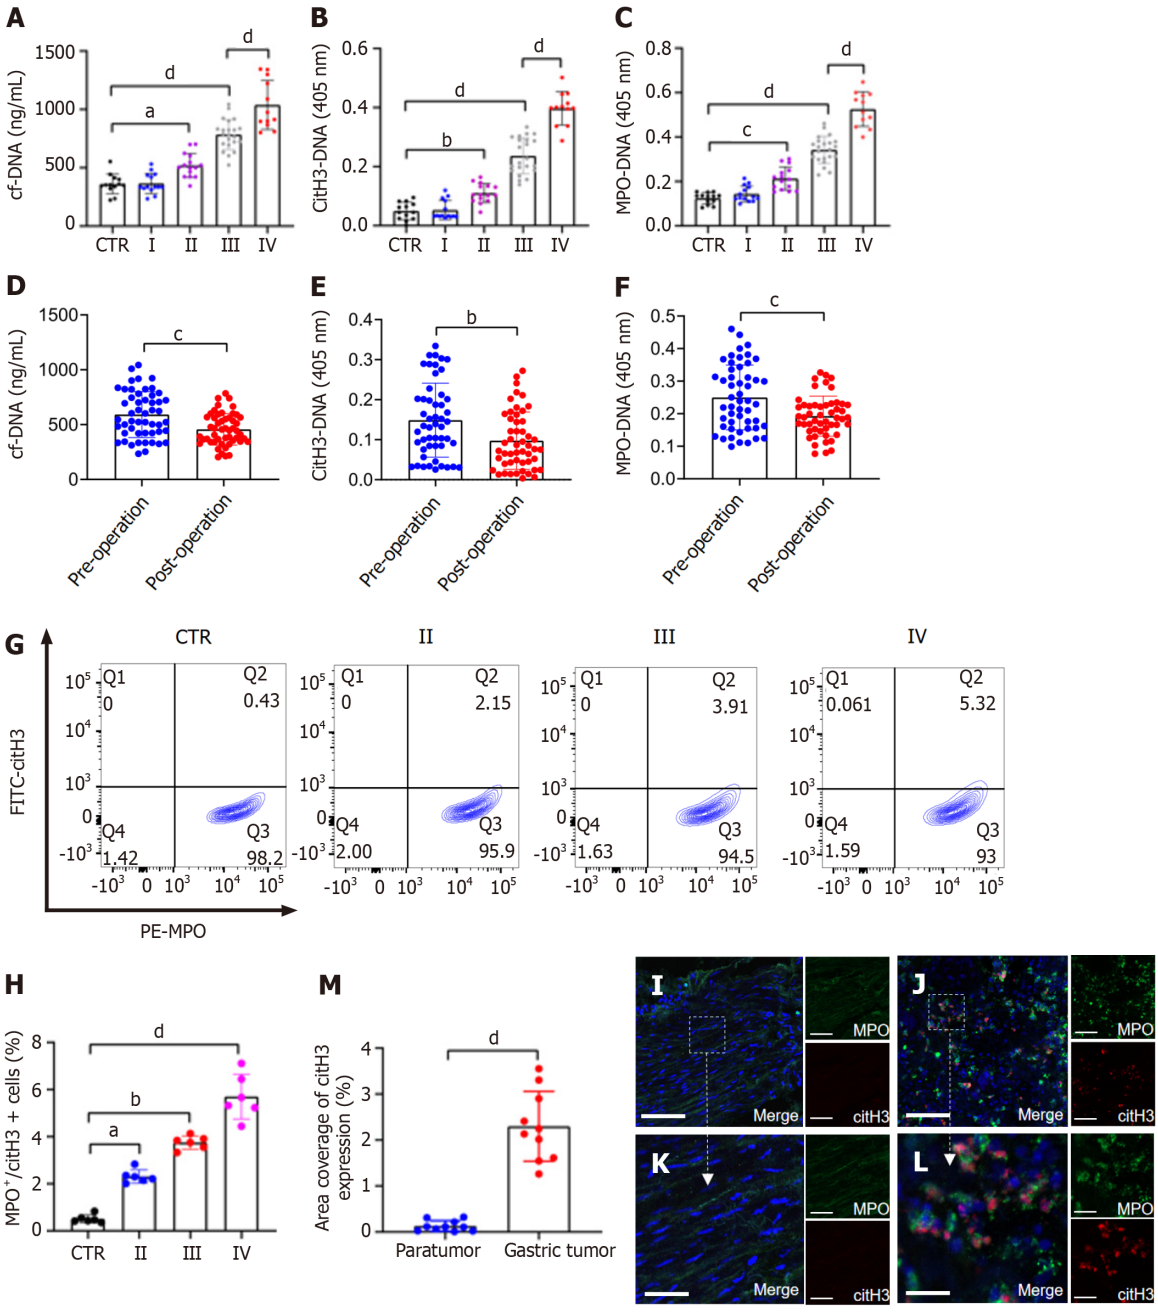
HUVECs were incubated with cell-free NETs or PBS in 24-well plates for 4 h when the cells grew to a confluent monolayer. The cells were fixed in 4% paraformaldehyde for 15 min at RT, washed three times using 1 × PBS, and blocked for 1 h using 10% goat serum with 1% BSA solution in PBS. For detection of tissue factor (TF) expression, ECs were incubated overnight at 4 °C with rabbit anti-TF (1:500, ab228968; Abcam) and mouse anti-CD31 (1:500, ab9498; Abcam) primary antibodies. The cells were washed with PBS and reincubated for 1 h at RT with Alexa Fluor 594-conjugated (Proteintech) goat anti-rabbit and Alexa Fluor 488-conjugated (Proteintech) goat anti-mouse secondary antibodies. For detection of intercellular junctions of cells, cells were incubated overnight at 4°C with rabbit anti-VE-cadherin (1:500, ab33168; Abcam) primary antibody, followed by Alexa Fluor 488-conjugated (Proteintech) goat anti-rabbit secondary antibody, and were further incubated with Alexa Fluor 594-conjugated phalloidin primary antibody (1:300; Thermo Fisher, Waltham, MA, USA). They were stained with DAPI and fixed with mounting medium (Solarbio) for 5 min at RT in the dark. The cells were observed and photographed using a confocal microscope. The photos were analyzed with ImageJ software.

Platelet and HUVEC inhibition assays

For inhibition assays, platelets and HUVECs were cocultured with cell-free NETs for 1 h at 37°C in a humidifier chamber in the presence of DNase I (100 U/mL, Roche), APC (100 nM, HY-P1918; MedChemExpress), and sivelestat (100 nM, HY-17443; MedChemExpress) alone or together. DNase I cleaves NET DNA, whereas APC and sivelestat disrupt histones and NE functions, respectively.

Statistical analysis

Data are expressed as the mean ± SD. Data were analyzed to assess distribution normality. For normally distributed data, statistical significance was analyzed using Student's *t*-tests and one-way analysis of variance. For non-normally distributed data, statistical significance was analyzed using the Mann–Whitney test and Kruskal–Wallis test. All analyses were performed using GraphPad Prism version 8.0 and SPSS 16.0 statistical software. Spearman's correlation was used to evaluate the association between two variables. $P < 0.05$ was considered statistically significant.



RESULTS

GC patients display greater NET formation

The levels of plasma cf-DNA, citH3-DNA,and MPO-DNA complexes in GC patients ($n = 63$) and HDs ($n = 13$), which reflect the concentration of NETs, were measured using capture ELISA. The levels of NET markers were significantly higher in patients with stage II/III/IV GC than in HDs (Figure 1A–C). There was also a significant difference in preoperative and postoperative plasma NET marker levels in GC patients (Figure 1D–F). The levels of NET markers positively correlated with those of serum D-dimer (cf-DNA: $r = 0.5595$, $P < 0.0001$; citH3-DNA: $r = 0.5469$, $P < 0.0001$; MPO-DNA: $r = 0.5479$, $P < 0.0001$), suggesting that NETs were associated with hypercoagulation and VTE development in GC patients. The levels of NETs ($MPO^+/citH3^+$ neutrophils) in the circulation in GC patients and HDs were measured using flow cytometry. Circulating NETs were higher in the blood of patients with either GC stage (II–IV) than in their HD counterparts (Figure 1G and H). Furthermore, based on MPO and citH3 levels, immunofluorescence staining revealed that NETs were significantly higher in the tumor microenvironment than in the paratumor tissue of the same patients (Figure 1I–M).

GC cells stimulate formation of NETs by neutrophils

To assess whether GC cells directly stimulated NET formation, we analyzed the expression of NETs in a coculture of GC cell lines and neutrophils. Immunofluorescence analysis revealed that compared with GES-1 cells, the rate of NET formation was significantly higher in GC cells (Figure 2A). However, the formation of NETs was greater in the metastatic GC cell line than in the nonmetastatic GC cell line (Figure 2B). We measured NET formation when normal neutrophils were cocultured with CM from KATO-III, MKN-45, AGS and GES-1 cells. Immunofluorescence analysis further revealed that the CM of KATO-III and MKN-45 cells exerted greater neutrophil activation for NET formation than the CM of

AGS cells. However, the CM of GES-1 cells had no effect on NET formation (Figure 2C and D). Overall, these findings demonstrate that GC cells stimulate NET formation through both intercellular contact and noncontact mechanisms.

NETs contribute to hypercoagulation of platelets

To examine the effect of NETs on platelet activation, we measured the levels of PS and P-selectin expression in these cells. Flow cytometry revealed that compared to HDs, the expression of PS and P-selectin was significantly higher on platelets of patients with GC (Figure 3). In addition, platelets

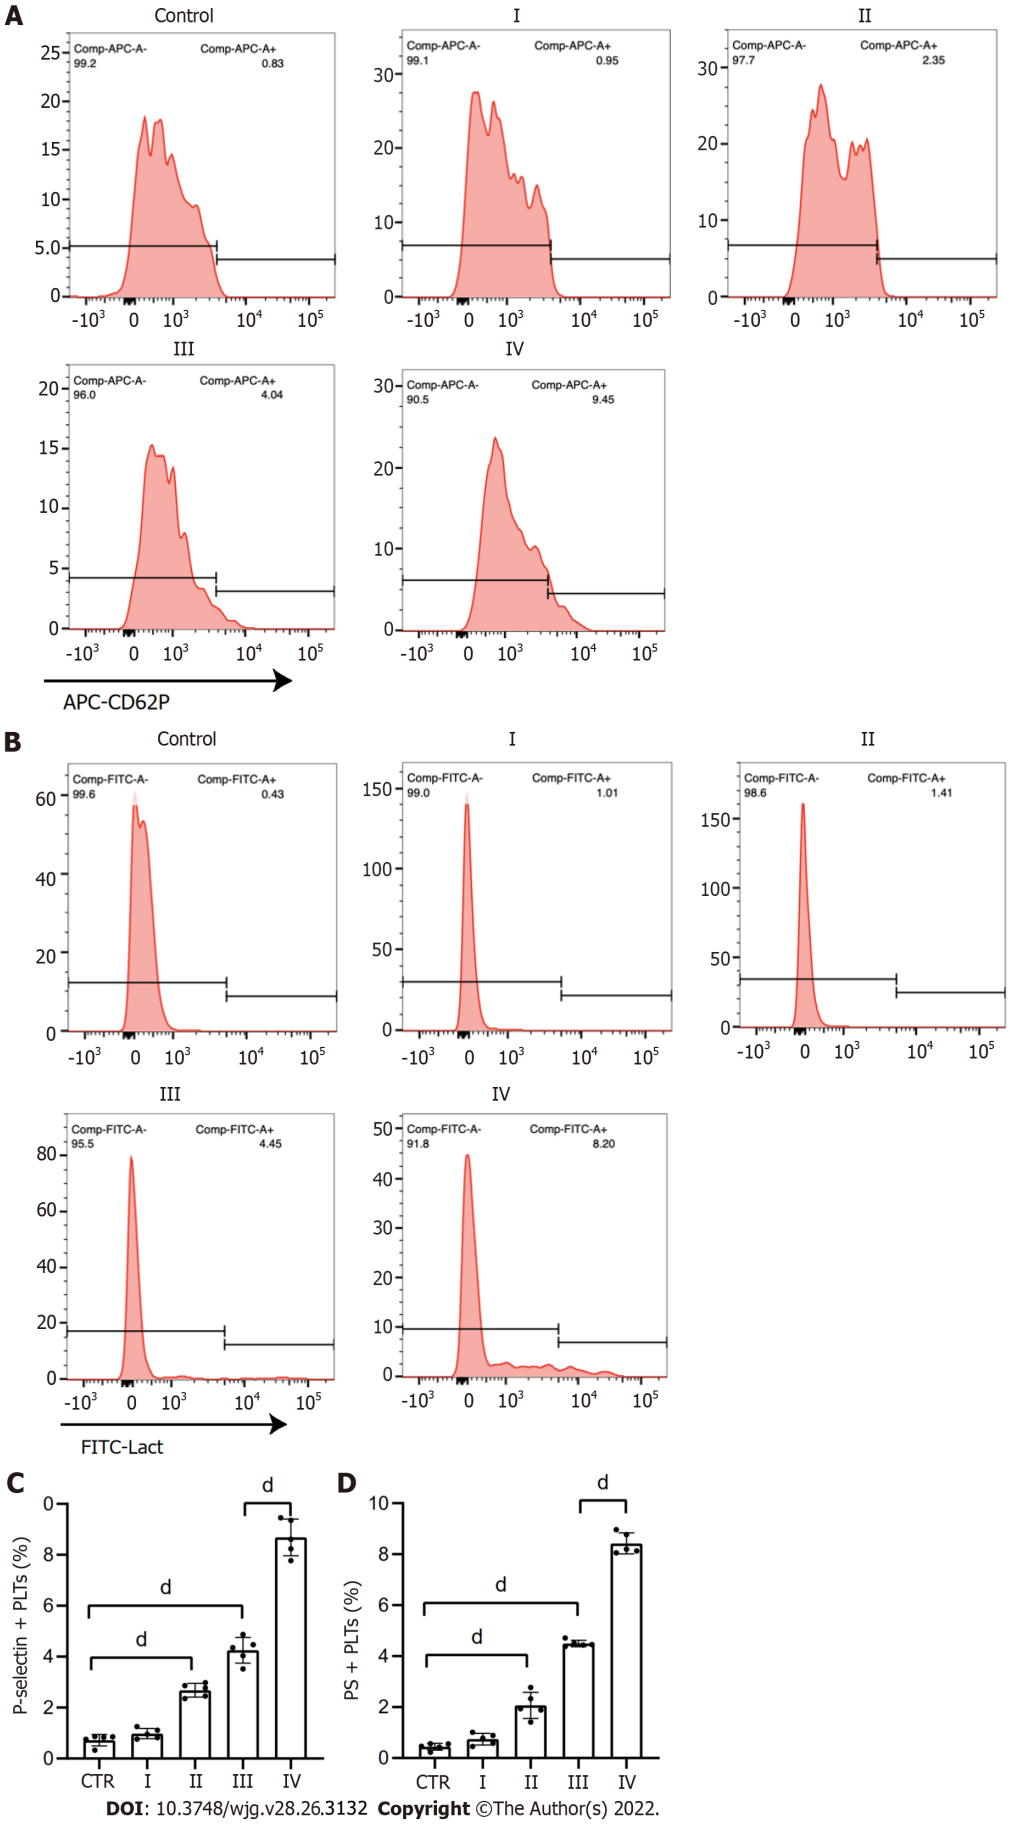
isolated from HDs were cocultured with NET medium or PBS before analyzing PS and P-selectin expression. We found that NETs stimulated PS and P-selectin expression on platelets by confocal microscopy (Figure 4A–C). Flow cytometry also demonstrated this hypercoagulable phenotype of platelets which was stimulated by NETs (Figure 4D and E). In the inhibition assay, we added DNase I, APC and sivelestat alone or together to cleave DNA, histones and NE, which were the most functional factors of NETs. At the highest concentration of NETs (0.5 μg DNA/mL), flow cytometry revealed that DNase I, APC, sivelestat, or a combination of the three inhibited 60.2%, 47.1%, 41.9% and 83.2% of PS expression, respectively (Figure 4D), and 55.2%, 47.0%, 41.0%, and 91.76% of P-selectin expression on platelets, respectively (Figure 4E).

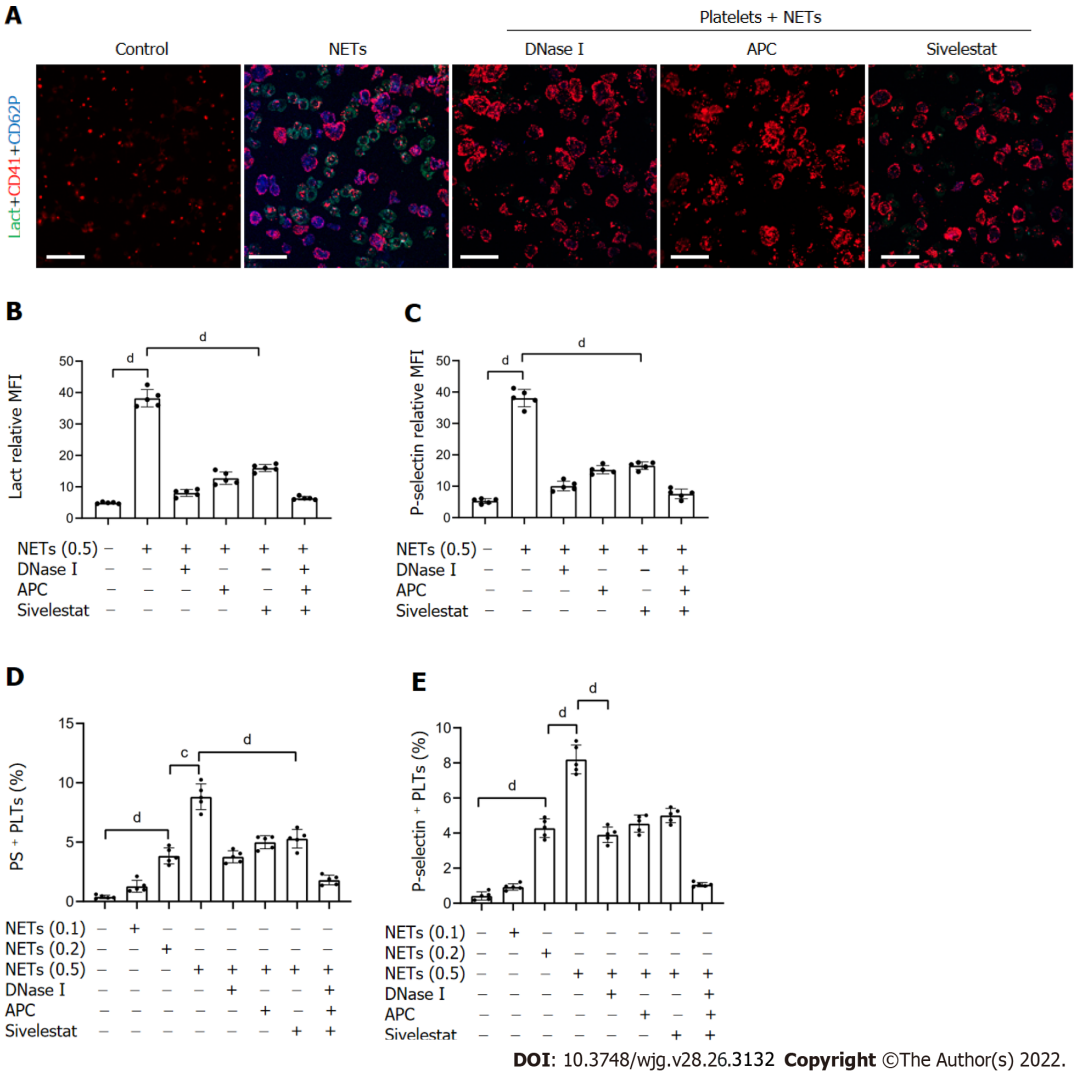


NETs promote platelet adhesion and prothrombotic state

Previous studies have shown that NETs promote thrombosis in murine late-stage breast cancer models and DVT models[19,39]. However, whether NETs derived from GC neutrophils have the ability to stimulate platelet adhesion under static conditions is unknown. To determine the effect of NETs on platelet adhesion, platelets isolated from HDs were seeded in NET-coated wells to measure the effects of NETs on the adherence of platelets to blood vessels. Confocal microscopy revealed that NETs enhanced adherence of platelets to glass slides (Figure 5A and B), indicating that NETs induce the development of thrombosis. Moreover, the results revealed that fibrin formation and TAT complex levels were increased when control plasma was cocultured with platelets activated by NETs (Figure 5C and D).

Inhibition assays revealed that digestion of NET DNA using DNase I modulated the adhesion of platelets on glass surfaces. Even so, a few platelets still adhered to the NET-coated well pretreated with DNase I (Figure 5A). This suggested that other protein components other than NET-DNA participated in the adhesion of platelets. NETs treated with DNase I, APC, sivelestat, or a combination of the three inhibited 67.1%, 56.6%, 38.9%, and 91.8% of platelet adhesion, respectively (Figure 5B). The degree of platelet adhesion in the combination group was comparable to that of the controls. We found that DNase I, APC, sivelestat, or a combination of the three reduced fibrin formation by 81.1%, 73.9%, 64.3%, and 90.7%, respectively (Figure 5C), and inhibited 78.9%, 57.4%, 51.2%, and 91.9% of TAT complex level, respectively (Figure 5D), at the highest concentration of NETs. Taken together, these findings demonstrate that NETs play a role in the development of thrombosis.

NETs drive hypercoagulation of ECs



To detect the effect of NETs on EC thrombogenicity, HUVECs were cocultured with NET medium. Confocal microscopy revealed that NETs destroyed the normal intercellular junctions between ECs

(Figure 6A and C). NET treatment upregulated expression of TF on the surface membrane of ECs (Figure 6B and D). In addition, plasma fibrin formation and TAT complex levels were significantly increased when control plasma was incubated with EC monolayers activated by NETs (Figure 6E and F). Further inhibition assays were performed to assess the effect of NETs on ECs after pretreatment with DNase I, APC, sivelestat, or a combination of the three. We found that NET treatment after incubation with DNase I, APC, sivelestat, or all three drugs returned 47.5%, 36.3%, 33.4%, and 86.5%, respectively, of VE expression on ECs (Figure 6C), whereas similar treatment inhibited 60.4%, 44.8%, 38.6%, and 95.5%, respectively, of TF expression (Figure 6D). Additionally, we found that NET treat-ment after incubation with the above inhibitors inhibited 59.7%, 54.4%, 54.0%, and 91.5% of fibrin formation level, respectively (Figure 6E), and inhibited 51.2%, 35.6%, 25.9%, and 84.3% of TAT complex level, respectively (Figure 6F). Taken together, these findings suggest that NETs promote hypercoagulation of ECs; thus, inhibiting NET function can protect against venous injury.

NETs promote formation of thrombi in tumor-bearing IVC flow restriction mice

Based on these findings *in vitro* and the pivotal role of NETs in thrombosis, we hypothesized that GC-

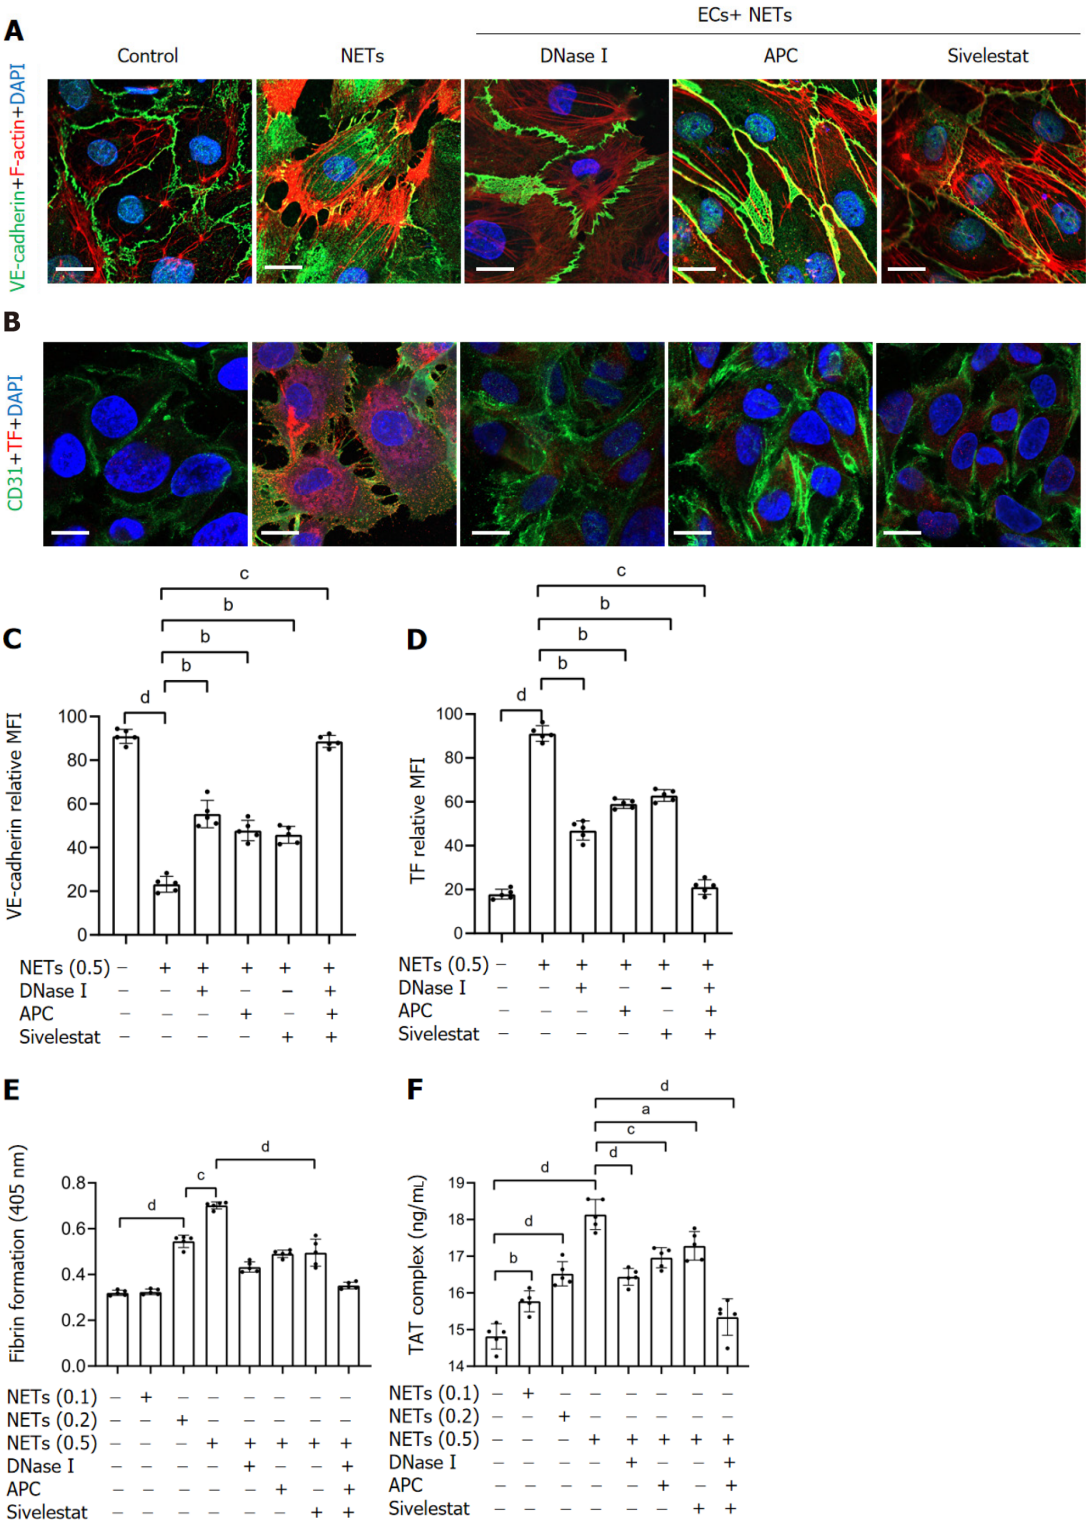

Figure 5 NETs promote platelet adhesion and prothrombotic state. A: Isolated platelets were incubated on glass slides which were coated with 1% dBSA, NETs (μg DNA/mL), or NETs pretreated with DNase I, APC, and sivelestat alone or together, followed by the F-actin components of platelets with 594-phalloidin staining. Magnification 63×; scale bars: 10 μm. Red-platelets; B: The percentage of area coverage of platelet adhesion was defined as the rate of red area in the total area and analyzed with ImageJ software; C: Isolated platelets were cocultured with different concentrations of NETs for 30 min with or without DNase I, APC and sivelestat treatment alone or together, and plasma fibrin formation was tested using turbidity measurements and monitored OD at 405 nm; D: TAT complex level of activated platelets was analyzed by ELISA. All values are the mean ± SD. $^{a}P < 0.05$; $^{b}P < 0.01$; $^{c}P < 0.001$; $^{d}P < 0.0001$. dBSA: Denatured bovine serum albumin; NETs: Neutrophil extracellular traps; DNase I: Deoxyribonuclease I; APC: Activated protein C; TAT: Thrombin–antithrombin.

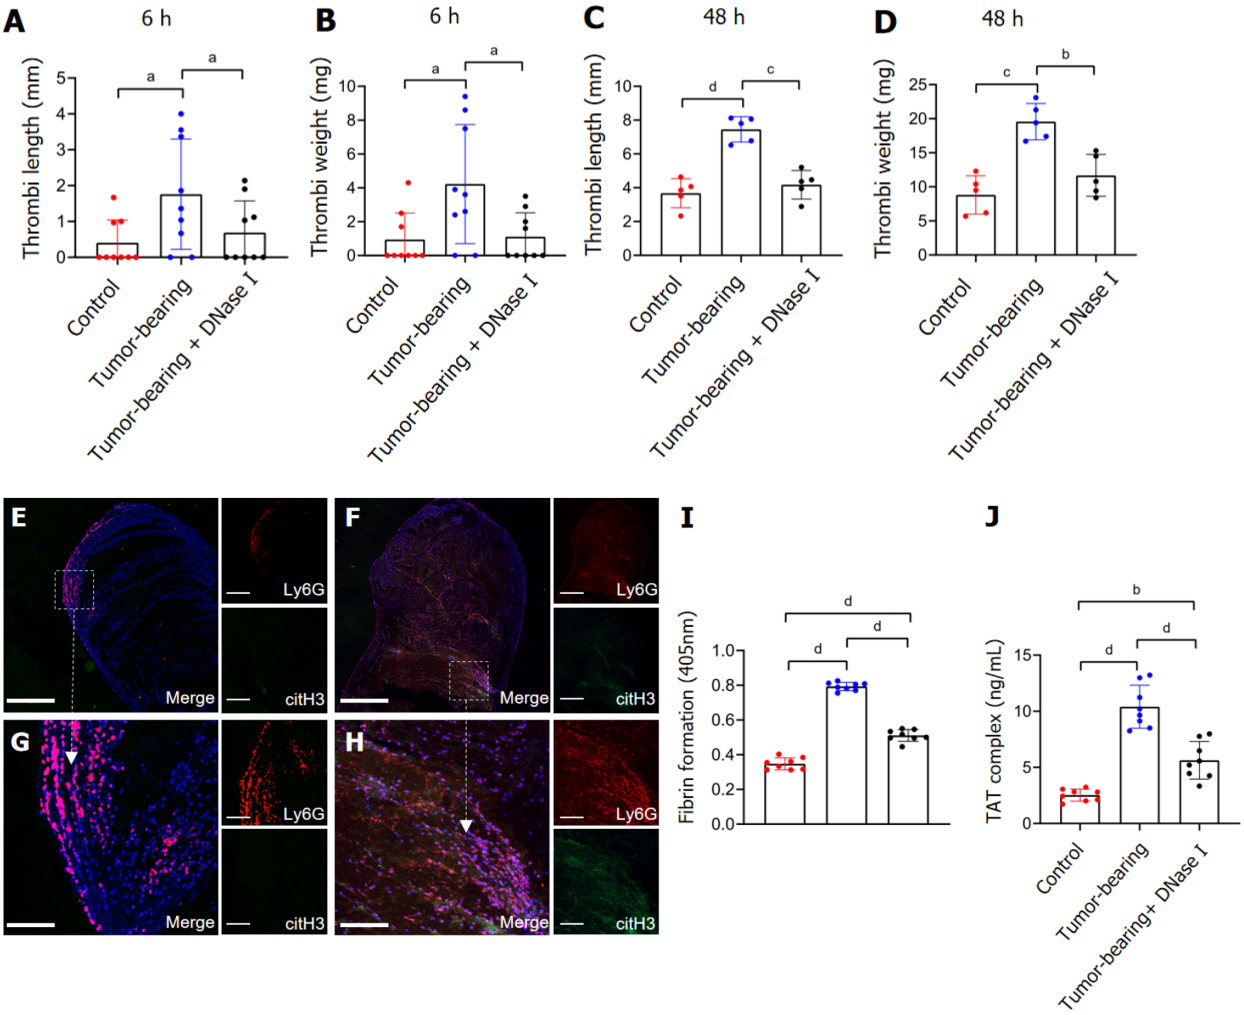
induced NETs can also promote thrombosis *in vivo*. Here, in a mouse IVC flow stenosis model, tumor-bearing mice demonstrated more capacity to form thrombi and showed heavier weight and longer length of thrombi compared to control mice (Figure 7A–D). In the 6 h models, three of nine of control mice showed thrombi, whereas seven of nine of tumor-bearing mice formed thrombi. In the 48 h models, all mice demonstrated thrombi in the IVC. In addition, confocal images of thrombi formed in the tumor-bearing mice after 48 h of IVC stenosis showed that NETs were significantly accumulated compared to control mice (Figure 7E–H). The thrombi of control mice included some neutrophils (Ly6G+) but were not activated to form NETs (Figure 7E and G). Furthermore, tumor-bearing mice showed higher fibrin formation and TAT complex levels than control mice (Figure 7I and J).

In the inhibition assay, we infused DNase I into mice immediately after IVC stenosis and examined thrombosis after 6 or 48 h of surgery. We found that treatment with DNase I significantly inhibited thrombi formation in tumor-bearing IVC stenosis mice (Figure 7A–D). Furthermore, fibrin formation and TAT complex levels in tumor-bearing mice were significantly decreased by DNase I treatment (Figure 7I and J). These data suggest that NETs play a role in thrombosis *in vivo*, which was induced by GC, and inhibiting NETs by DNase I had a protective effect on thrombosis in this mouse model.



DISCUSSION

Inflammation is one of the hallmarks of cancer. Additionally, neutrophils are among the most important immune cells implicated in promoting tumor progression[40,41]. NETs participate in cancer progression by promoting the proliferation, invasion, metastasis and angiogenesis of cancer cells as well as thrombosis in numerous tumor types[42-44]. A recent study using mouse models with Jak^{2V617F} knock-in revealed that most myeloproliferative neoplasms display NET formation and DVT[45]. Our previous studies revealed that NETs promote the migration and metastasis of GC cells both *in vitro* and *in vivo* through epithelial mesenchymal transition[46]. Intriguingly, inhibition of NETs promotes apoptosis and inhibits the invasion of GC cells by regulating the expression of Bcl-2, Bax and nuclear factor-κB proteins[47]. Our initial studies revealed that NETs released by neutrophils in GC patients promoted the conversion of thrombin and fibrin[23]. Accordingly, we hypothesized that NETs promote thrombosis in GC patients. We investigated the interactions between GC cells, neutrophils, platelets and ECs, with a keen focus on their role in cancer-associated thrombosis.

Figure 7 Tumor-bearing mice show a greater ability to form thrombi by inferior vena cava flow restriction. A and B: The values for weight and length of thrombi present in control, tumor-bearing mice, DNase I infused tumor-bearing mice at 6 h after surgery. Each group, *n* = 9; C and D: Values for weight and length of thrombi present in mice at 48 h after surgery. Each group, *n* = 5; E and F: Confocal imaging of thrombi derived from control mice and tumor-bearing mice with Ly6G and citH3 staining. Magnification 10×; scale bars: 200 μm. Red-Ly6G, Green-citH3, and Blue-DAPI; G and H: Magnified (40×) part of thrombi derived from control mice and tumor-bearing mice. Scale bars: 50 μm. Red-Ly6G, Green-citH3, and Blue-DAPI; I and J: Fibrin formation levels in the plasma of control, tumor-bearing mice, or DNase-I-infused tumor-bearing mice were detected by turbidity measurement at 405 nm, and TAT complex levels were detected by ELISA. Each group, *n* = 8. All values are the mean ± SD. $^{a}P < 0.05$; $^{b}P < 0.01$; $^{c}P < 0.001$; $^{d}P < 0.0001$. DNase I: Deoxyribonuclease I; TAT: Thrombin–antithrombin.

In this study, we found that the levels of plasma NET markers and citH3-positive neutrophils were significantly higher in GC patients than in HDs. Expression of NETs decreased significantly after resection of GC tissues. Neutrophil infiltration and NET formation were upregulated in tumor tissues, relative to adjacent paratumor tissues of the same GC patient. The levels of serum D-dimer were positively correlated with tumor TNM stage, consistent with previous findings[48]. These findings suggest that the expression of NETs promotes GC development and thrombosis in the same group of patients.

It has been reported that hepatocellular cancer and hypoxic CM stimulate the production of NETs by neutrophils[44]. However, the relationship between GC cells and neutrophils is poorly understood. Our experiments demonstrated that both metastatic and nonmetastatic GC cancer cells directly stimulated production of NETs from neutrophils, contrary to GES-1 cells. CM of GC cells, but not that of GES-1, also induced the formation of neutrophil-related NETs. This suggests that NET formation is also mediated by factors secreted by GC cells. Inflammatory cytokines, such as interleukin (IL)-1β, IL-6, IL-8, and tumor necrosis factor-, as well as damage-associated molecular patterns, all overexpressed in tumor microenvironments, stimulate neutrophils to release NETs[49,50]. Although IL-8 is the cytokine with the highest overexpression in GC patients, whether it is the main mediator of NET formation and the subsequent underlying mechanism in GC remain to be validated.

A recent study showed that NETs promote thrombosis by activating and promoting the adhesion of platelets in the venous walls of pancreatic cancer patients[22]. Activated platelets express PS on their surface membranes[51]. Additionally, P-selectin expression on the surface membrane of platelets is also

associated with thrombosis[52]. In this study, we found that compared to HDs, PS and P-selectin expression on platelets was significantly higher in GC patients, particularly those with stage III/IV GC. NET treatment upregulated PS and P-selectin expression on platelets. Additionally, NETs stimulated the adhesion of normal platelets on glass slides. However, even though DNase I treatment modulated this phenomenon, some platelets still adhered to the glass slides, suggesting that other secretory factors participated in the adhesion property.

Previous studies have shown that histones in NETs promote thrombosis in colorectal cancer patients [53]. NE is another most abundant protein that binds NETs. Although this potent protein stimulates tumor progression both *in vitro* and *in vivo*, the mechanisms underlying NE-mediated cancer-associated thrombosis remain to be clarified. A recent study on DVT using mouse models showed that NE deficiency or NE inhibition alone does not completely inhibit DVT[54]. In this study, we found that hypercoagulation of platelets was not completely mediated by NET DNA, but also by other secretory proteins in the NETs, such as histones and NE. Consequently, DNase I treatment of NETs had no complete effect on hypercoagulation of platelets. However, a combination of DNase I, APC and sivelestat treatment almost completely inhibited hypercoagulation of platelets. Although sivelestat did not show a strong antihypercoagulation effect similar to DNase I, it nonetheless modulated the activation and adhesion of platelets. This demonstrated that histones and NE also participate in the activation and adhesion of platelets.

DVT can be triggered by injury to vascular ECs. Previous studies have shown that under certain malignancies, NETs can induce dysfunction and apoptosis of ECs[35]. In patients with chronic pancreatic disease and pancreatic cancer, NETs exert their cytotoxicity against ECs *via* intercellular cell adhesion molecule-1 and vascular cell adhesion molecule-1 expression[26]. Recent studies have shown that treatment of ECs with NETs derived from patients with colorectal cancer promotes and enhances the production of fibrin and the corresponding coagulation[53]. In this study, we found that NET treatment inhibited the secretion of intercellular junctions in ECs and promoted hypercoagulation of platelets by upregulating TF expression. Moreover, NET treatment upregulated the expression of PS on ECs. ECs activated by NETs significantly increased the level of TAT complexes and fibrin generation in the plasma of HDs. Given that a combination of DNase I, APC and sivelestat treatment completely inhibited hypercoagulation, the process was regulated through numerous mechanisms. These findings strongly suggest that NETs contribute to GC-associated thrombosis.

In the late stage of murine mammary tumor models, thrombi were found in lung vessels, and NETs accumulated, indicating that cancer-induced NETs contribute to the cancer-associated thrombosis[19]. Here, we demonstrated that GC-bearing mice have a greater ability to form thrombi than control mice have and that NETs were abundantly present in the thrombi of tumor-bearing mouse IVC stenosis models. Most of this response can be blocked by DNase I treatment, which was similar to previous studies. In DVT models, flow restriction of the IVC may result in a hypoxic microenvironment to recruit neutrophils and stimulate NET release. In addition, cancer cells often secrete more inflammatory factors, which aggravate the recruitment of neutrophils to form NETs under a hypoxic conditions[50]. Therefore, neutrophils are exposed to two major triggers of NET release: A tumor hypoxic environment and IVC flow restriction, which then participate in the development of thrombi in GC.

CONCLUSION

Our findings demonstrate that GC cells can directly induce NET formation, which in turn strongly increases the risks of VTE development both *in vitro* and *in vivo*. In addition, we found that not only NET DNA but also histones and NE participate in the development of cancer-associated thrombosis. Accordingly, NETs are potential therapeutic targets against VTE in GC patients.

ARTICLE HIGHLIGHTS

Research background

The development of venous thromboembolism (VTE) is associated with high mortality among gastric cancer (GC) patients. Neutrophil extracellular traps (NETs) have been reported to correlate with the prothrombotic state in some diseases, but it was rarely reported in GC patients.

Research motivation

Cancer cells exert a procoagulant activity (PCA) in their microenvironment, which is related to activation of the coagulation system. However, the molecular mechanism underlying PCA in GC patients is poorly understood.

Research objectives

The present study aimed to investigate the effect of NETs on the development of cancer-associated thrombosis in GC patients.

Research methods

The levels of NETs in blood and tissue samples of patients were analyzed by ELISA, flow cytometry, and immunofluorescence staining. NET generation and hypercoagulation of platelets and endothelial cells (ECs) *in vitro* were observed by immunofluorescence staining. NET PCA was determined by fibrin formation and thrombin–antithrombin complex assays. Thrombosis *in vivo* was measured in a murine model induced by flow stenosis in the inferior vena cava (IVC).

Research results

NETs were likely to form in blood and tissue samples of GC patients compared with healthy individuals. *In vitro* studies showed that GC cells and their conditioned medium, but not gastric mucosal epithelial cells, can stimulate NET release from neutrophils. Furthermore, NETs induced hypercoagulable state of platelets and ECs. In a model of IVC stenosis, tumor-bearing mice showed a stronger ability to form thrombi, and NETs abundantly accumulated in the thrombi of tumor-bearing mice compared with control mice. Notably, the combination of deoxyribonuclease, activated protein C, and sivelestat markedly abolished the PCA of NETs.

Research conclusions

Our findings demonstrate that GC-induced NETs strongly increase the risk of VTE development both *in vitro* and *in vivo*. NETs are potential therapeutic targets in the prevention and treatment of VTE in GC patients.

Research perspectives

The treatment strategies can consider the combination of traditional anticoagulant drugs and NETs inhibiting drugs, so as to reduce the risk of cancer associated thrombosis in patients with GC and improve the clinical treatment effect.

Abstract

BACKGROUND

As the main component of oral contraceptives (OCs), ethinylestradiol (EE) has been widely applied as a model drug to induce murine intrahepatic cholestasis. The clinical counterpart of EE-induced cholestasis includes women who are taking OCs, sex hormone replacement therapy, and susceptible pregnant women. Taking intrahepatic cholestasis of pregnancy (ICP) as an example, ICP consumes the medical system due to its high-risk fetal burden and the impotency of ursodeoxycholic acid in reducing adverse perinatal outcomes.

AIM

To explore the mechanisms and therapeutic strategies of EE-induced cholestasis based on the liver immune microenvironment.

METHODS

Male C57BL/6J mice or invariant natural killer T (iNKT) cell deficiency (Jα18$^{-/-}$ mice) were administered with EE (10 mg/kg, subcutaneous) for 14 d.

RESULTS

Both Th1 and Th2 cytokines produced by NKT cells increased in the liver skewing toward a Th1 bias. The expression of the chemokine/chemokine receptor Cxcr6/Cxcl16, toll-like receptors, Ras/Rad, and PI3K/Bad signaling was upregulated after EE administration. EE also influenced bile acid synthase

Cyp7a1, Cyp8b1, and tight junctions ZO-1 and Occludin, which might be associated with EE-induced cholestasis. iNKT cell deficiency (Jα18$^{-/-}$ mice) robustly alleviated cholestatic liver damage and lowered the expression of the abovementioned signaling pathways.

CONCLUSION

Hepatic NKT cells play a pathogenic role in EE-induced intrahepatic cholestasis. Our research improves the understanding of intrahepatic cholestasis by revealing the hepatic immune microenvironment and also provides a potential clinical treatment by regulating iNKT cells.

Key Words: Natural killer T cell; Th1/Th2; IFN-γ; Estrogen; Cholestasis

Core Tip: In this study, we observed the production of both Th1 and Th2 cytokines by natural killer T (NKT) cells in the liver after 14 d of exposure to ethinylestradiol-induced cholestasis. The liver immune microenvironment was also skewed toward a Th1 bias mainly contributed by NKT cells. Invariant NKT cell deficiency robustly alleviated cholestatic liver damage and downregulated the associated signaling pathways, highlighting the pathogenic role and therapeutic potential of hepatic NKT cells in cholestatic liver diseases.

INTRODUCTION

Cholestasis is a mild and common phenomenon during liver diseases but also a crucial triggering element of severe hepatopathy, such as fibrosis, cirrhosis, and hepatic venous thrombosis[1]. Both estrogen and oral contraceptives (OCs) can elicit intrahepatic cholestasis (IHC), whose effects manifest as retention of toxic bile acids in the liver and circulation[2]. 17α-ethinylestradiol (EE) is used as a model drug to induce murine IHC. As the predominant component of OCs and hormone replacement therapy, the clinical counterpart of EE-induced IHC includes women who are taking OCs, postmenopausal replacement therapy and susceptible pregnant women. Sex steroids may lead to alterations in bile components and the elevation of total bile acids (TBAs), which may induce apoptosis and oxidative stress and thus have harmful effects on hepatocytes and other organs[3]. In clinical studies, administration of EE to both males and females leads to increased serum TBA levels and decreased clearance of sulfobromophthalein[4]. In murine studies, the mechanisms involve the activation of AMP-activated protein kinase[5] and estrogen receptor α[6], the inhibition of farnesoid X receptor (FXR), bile acid transporters, bile acid synthase and metabolism enzymes, and inflammatory reactions[7-9]. The first-line therapy ursodeoxycholic acid (UDCA) for cholestatic diseases is a naturally hydrophilic bile acid, although its potency is limited, as approximately 40% of patients are not responsive to UDCA treatment [10].

Among these predisposing factors, the significance of the local immune microenvironment in the liver has been emphasized because sex hormones are immunomodulators that are metabolized in the liver. In a murine model of EE-induced cholestasis, hepatic expression of TNF-α and IL-6 was greatly upregulated[8]. Proinflammatory mediators can affect nuclear receptors and transporters and then cause bile acid equilibrium disorder, increased cytokine secretion, and further exacerbated cholestasis, forming a positive regulation loop[8]. In patients with intrahepatic cholestasis of pregnancy (ICP), an increase in Th1-type cytokines and a decrease in Th2-type cytokines suggest the involvement of proinflammatory and cytotoxic Th1 biases in ICP[11]. However, the impotency of corticosteroids in the treatment of cholestasis indicates that promising therapies or active agents are in heavy demand[12].

Natural killer T (NKT) cells are one of the most abundant lymphocytes in the liver, and their role in cholestasis is noteworthy[13]. NKT cells behave similarly to conventional T cells and function as both effector and regulatory immune cells. Jα18$^{-/-}$ mice are not prone to developing cholestatic liver injury after alpha-naphthylisothiocyanate (ANIT) administration due to the invariant NKT-cell (iNKT cell) knockout-related reduction in cytokines and the restored expression of transporters and bile acid metabolism enzymes[14]. Recent work also demonstrated that IL-4 secreted by type 1 NKT cells (iNKT cells) may inhibit type 2 NKT cells and upregulate immunoregulators, affecting the expression of bile

acid nuclear receptors, transporters, and CYP450 enzymes, thus exacerbating triptolide-induced cholestatic liver damage[15]. However, Jα18$^{-/-}$ mice showed aggravation of liver damage after bile duct ligation (BDL) surgery compared with wild-type mice due to the increase in neutrophils, chemokines and cytokines[16]. Moreover, knockout of the bile acid sensor FXR gene increases liver NKT cells and aggravates liver damage, indicating that FXR can regulate the activation of liver NKT cells[17]. Certain antigens that can activate NKT cells exist in the bile of patients with chronic liver diseases[18]. Thus, the aim of the present study was to investigate the effects and mechanisms of NKT cells in a murine model of EE-induced cholestatic hepatotoxicity.

MATERIALS AND METHODS

Reagents

17α-EE (CAS:57-63-6, batch number: E0037, contents > 98.0% (T) high performance liquid chromatography) was purchased from tcichemicals (Shanghai, China). EE was dissolved in an 80% 1,2-propylene glycol solution and diluted with physiological saline to a dosing concentration of 10 mg/kg before the experiment. Anti-CD16/32 antibody (clone: 2.4G2), which was used for blocking before staining, anti-CD3e-FITC antibody (clone: 145-2C11), anti-CD49b-APC antibody (clone: DX5), leukocyte activation cocktail with BD GolgiPlug™, anti-IFN-γ-PE antibody (clone: XMG1.2), and anti-IL-4-PE antibody (clone: 11B11) were purchased from BD Pharmingen (San Diego, CA, United States).

Animals and treatment

Male C57BL/6J mice (6-8 wk of age and 18-20 g of weight) were obtained from SLAC Laboratory Animal Co., Ltd. (Shanghai, China). iNKT cell-deficient Jα18$^{-/-}$ mice on a C57BL/6 background (6 to 8 wk old) were kindly provided by Dr. Li Bai (University of Science and Technology of China). All mice were administered physiological saline or EE (10 mg/kg) subcutaneously (s.c.) for 14 continuous d. Each group contained 6 mice. All mice were maintained and bred under controlled conditions (pathogen-free, 22 ± 2 °C, 12:12-h light-dark regular photoperiod) with ad libitum mouse chow and water access. The animals were housed in the laboratory for 1 wk prior to experiments to acclimate. All procedures involved in this study were performed under the Ethical Committee of China Pharmaceutical University and the Laboratory Animal Management Committee of Jiangsu Province guidelines (Approval No.: 2021-10-003).

Nonparenchymal cell isolation and labeling

After perfusing saline solution into the heart to eliminate blood, the mouse liver was minced through a 200-gauge nylon mesh and washed with cold PBS. After centrifugation at 50 × g for 2 min in the crude solution, the separated supernatant was centrifuged for another 10 min at 800 × g. The cell pellets were resuspended in 40% Percoll for centrifugation at 1250 × g for 15 min. After nonparenchymal cell (NPC) isolation from the cell pellets by red blood cell lysis solution (0.15 M NH4Cl and 0.1 mmol/L Na2EDTA) treatment and 2 washes, NPCs were stimulated with leukocyte activation cocktail for 4-5 h (BD Pharmingen).

After stimulation, NPCs were blocked with anti-CD16/32 and then surface-labeled with FITC-conjugated anti-mouse CD3e and APC-CD49b antibodies. NPCs were permeabilized with Cytofix/Cytoperm (Becton Dickinson) following the manufacturer's instructions, and intracellular staining was performed by incubation with IFN-γ or IL-4 antibodies. After each step, unbound antibodies were excluded from the system by centrifugation. Then, the cells were analyzed using a FACSCalibur flow cytometer (Becton Dickinson, Palo Alto, CA, United States), with 50000 events recorded per tube. The results were processed using FlowJo version 10 software (FlowJo, Ashland, OR, United States). The gating strategy was as follows: first, NPCs were gated by FSC and SSC, followed by the gating of CD3e$^+$ or CD3e$^-$ cells. CD49b$^+$ IFN-γ$^+$, CD49b$^+$ IL-4$^+$ or CD49b$^-$ IFN-γ$^+$, and CD49b$^-$ IL-4$^+$ cells were then gated and analyzed.

Blood biochemical analysis

Anticoagulant-free serum was collected and then analyzed for the levels of alkaline phosphatase (ALP), total bile acid (TBA), alanine transaminase (ALT), and aspartate transaminase (AST) using the ALP, ALT, and AST quantification kit (Whitman Biotech, Nanjing, China) and TBA quantification kit (Jiancheng Bioengineering Institute, Nanjing, China).

Histopathology and immunohistochemistry

The liver lobules were fixed, paraffin embedded, sectioned, and stained with hematoxylin and eosin for histopathological examination. Slides were coded, randomized, and assessed by pathologists who, during the evaluation of the slides, were blinded to the treatment groups. Scoring for liver injury was conducted according to the following criteria: no hepatocellular necrosis, proliferation of pseudocholangiolar duct, or inflammatory cell infiltration, 0; mild, 1; moderate, 2; severe, 3. The other sections were

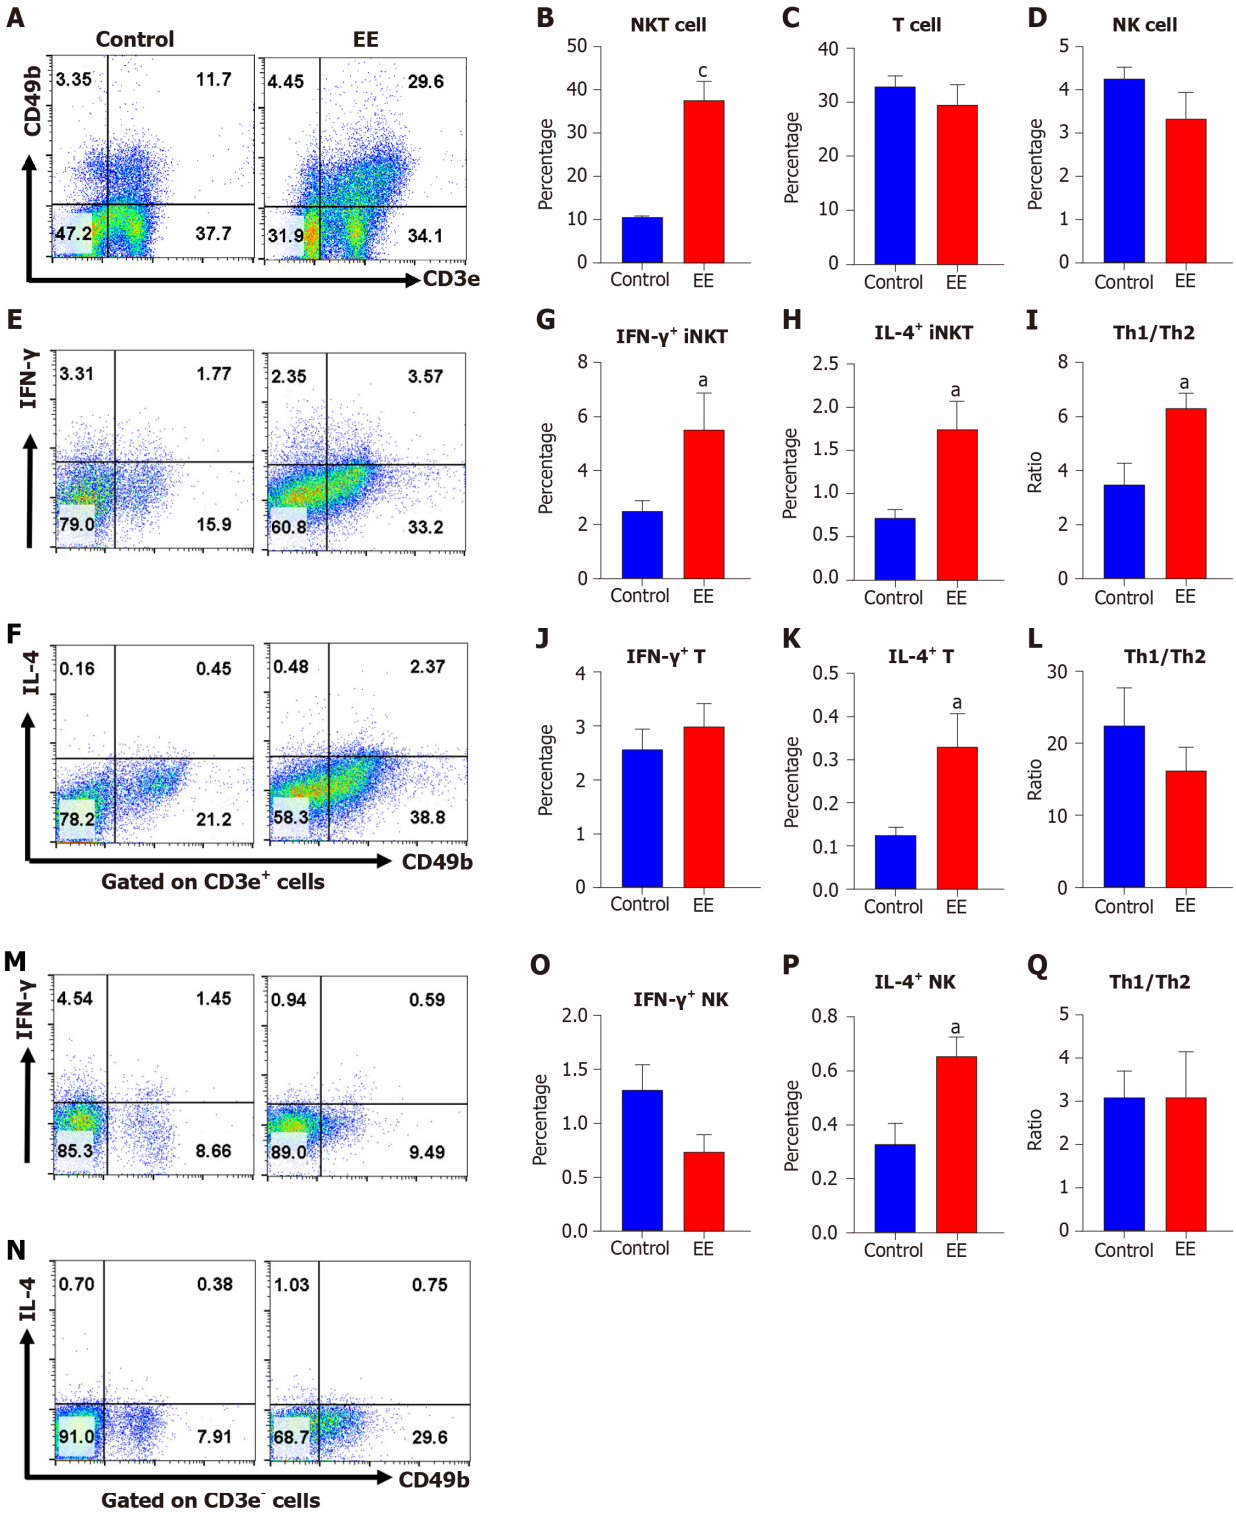
subjected to IHC for semiquantification of the expression of toll-like receptor (TLR) 9 (Novus, 26C593.2, dilution percentage: 1:200).

RNA extraction and real-time polymerase chain reaction

RNA was extracted from liver sections by TRIzol reagent (Vazyme Biotech, Nanjing, China). Isolated RNA was processed by the HiScript™ Q RT SuperMix for quantitative polymerase chain reaction (qPCR) (+ gDNA wiper) kit (Vazyme Biotech) for cDNA synthesis. A 20 μL real-time PCR system was prepared according to the manufacturer's instructions. The mRNA levels were normalized to the housekeeping gene *Gapdh*. The primer sequences used are shown in Table 1.

Statistical analysis

Values are expressed as the means ± SE. The groups were evaluated using Student's *t* test. A P value < 0.05 was considered statistically significant.

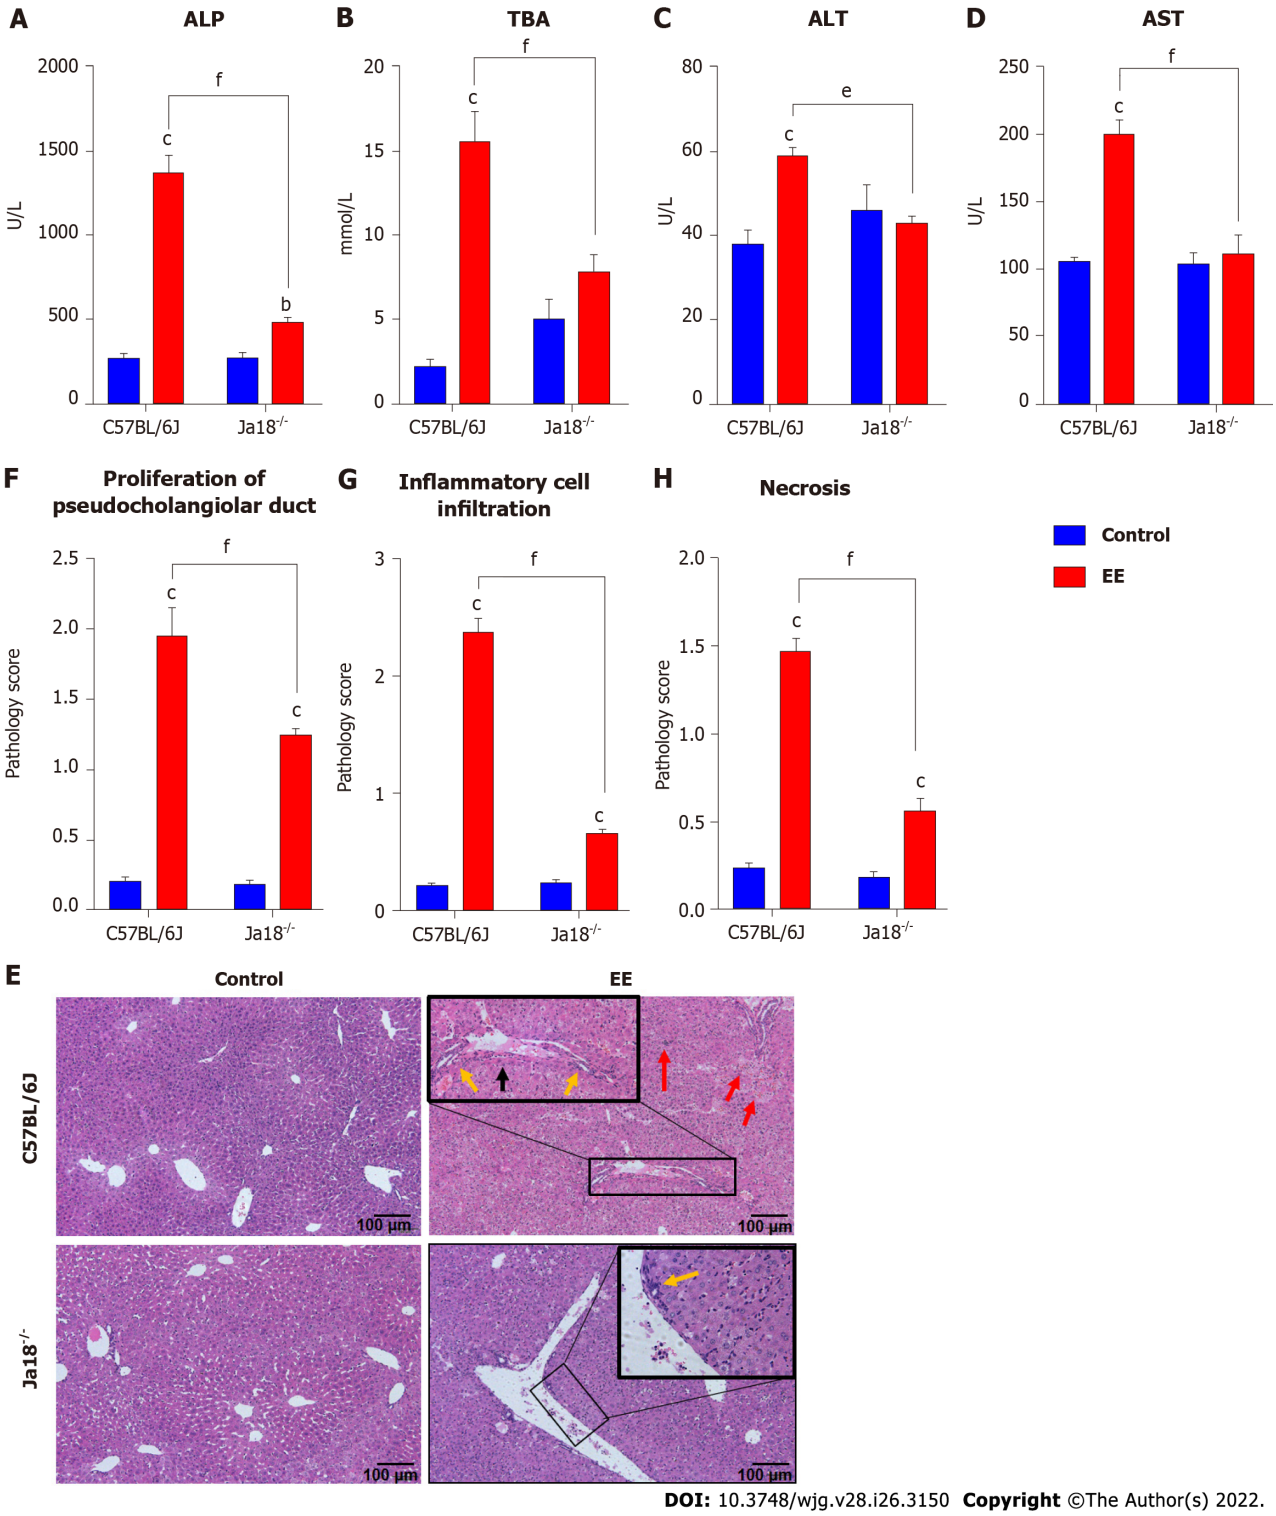


RESULTS

EE promotes hepatic NKT-cell proliferation along with biased Th1 cytokine production

Increased activation of NKT cells, T cells, or NK cells has been reported to contribute to the pathophysiology of cholestasis[15,19,20]. Here, we measured and analyzed their percentages and Th1/Th2 cytokine production to evaluate their activation. Hepatic NKT cells, $CD3^+$ T cells (excluding NKT cells) and NK cells were defined as $CD3e^+CD49b^+$ (Figure 1A upper right), $CD3e^+CD49b^-$ (Figure 1A lower right), and $CD3e^-CD49b^+$ (Figure 1A upper left), respectively. After EE administration, the percentage of hepatic NKT cells expanded more than 3-fold compared with the control group, while the frequencies of $CD3^+$ T cells and NK cells showed no significant changes (Figure 1A-D). Both IFN-γ and IL-4 secreted from NKT cells increased, which further indicated NKT-cell activation. Moreover, the upregulated Th1/Th2 ratios indicated that a skewed hepatic Th1 immune response was due to NKT cells (Figure 1E–I). Compared with the control group, IL-4 secreted by $CD3^+$ T cells and NK cells increased, and their IFN-γ secretion and Th1/Th2 ratios remained unaltered (Figure 1J–Q).

iNKT cells exacerbate EE-induced cholestatic liver damage



For further investigation of the NKT-cell effect, cholestatic liver injury was compared between iNKT cell knockout mice ($J\alpha18^{-/-}$ mice) and C57BL/6J mice after EE administration. Compared with the control group, EE induced increased levels of ALP, TBA, ALT, and AST in C57BL/6J mice. Compared with C57BL/6J mice, $J\alpha18^{-/-}$ mice demonstrated significantly lower levels of ALP, TBA, ALT, and AST (Figure 2A-D). Based on the scoring criteria[21], the histopathological and hepatic injury score results showed proliferation of pseudocholangiolar duct (yellow arrows), inflammatory cell infiltration (red arrows) and hepatocyte necrosis (black arrows) after EE treatment, whereas $J\alpha18^{-/-}$ mice exhibited reduced proliferation of the pseudocholangiolar duct, inflammatory cell infiltration, and necrosis (Figure 2E-G). These results showed that iNKT cell-deficient mice can inhibit the development of cholestatic hepatotoxicity induced by EE, indicating a pathogenic effect exerted by iNKT cells on EE-

iNKT cell deficiency lowers the hepatic expression of chemokine/chemokine receptors

CXCR6, the receptor for chemokine CXCL16, is expressed on the surface of several hepatic lymphocytes, including NKT cells. The CXCR6-dependent infiltration of NKT cells into the liver induces enhanced inflammation in a murine model of chronic hepatic damage[22]. The qPCR results showed that EE promoted the hepatic mRNA expression of Cxcr6/Cxcl16 in C57BL/6J mice. Compared with C57BL/6J mice, iNKT cell deficiency significantly suppressed the mRNA expression of Cxcr6/Cxcl16, which may be related to the absence of the need for hepatic recruitment of NKT cells (Figure 3).

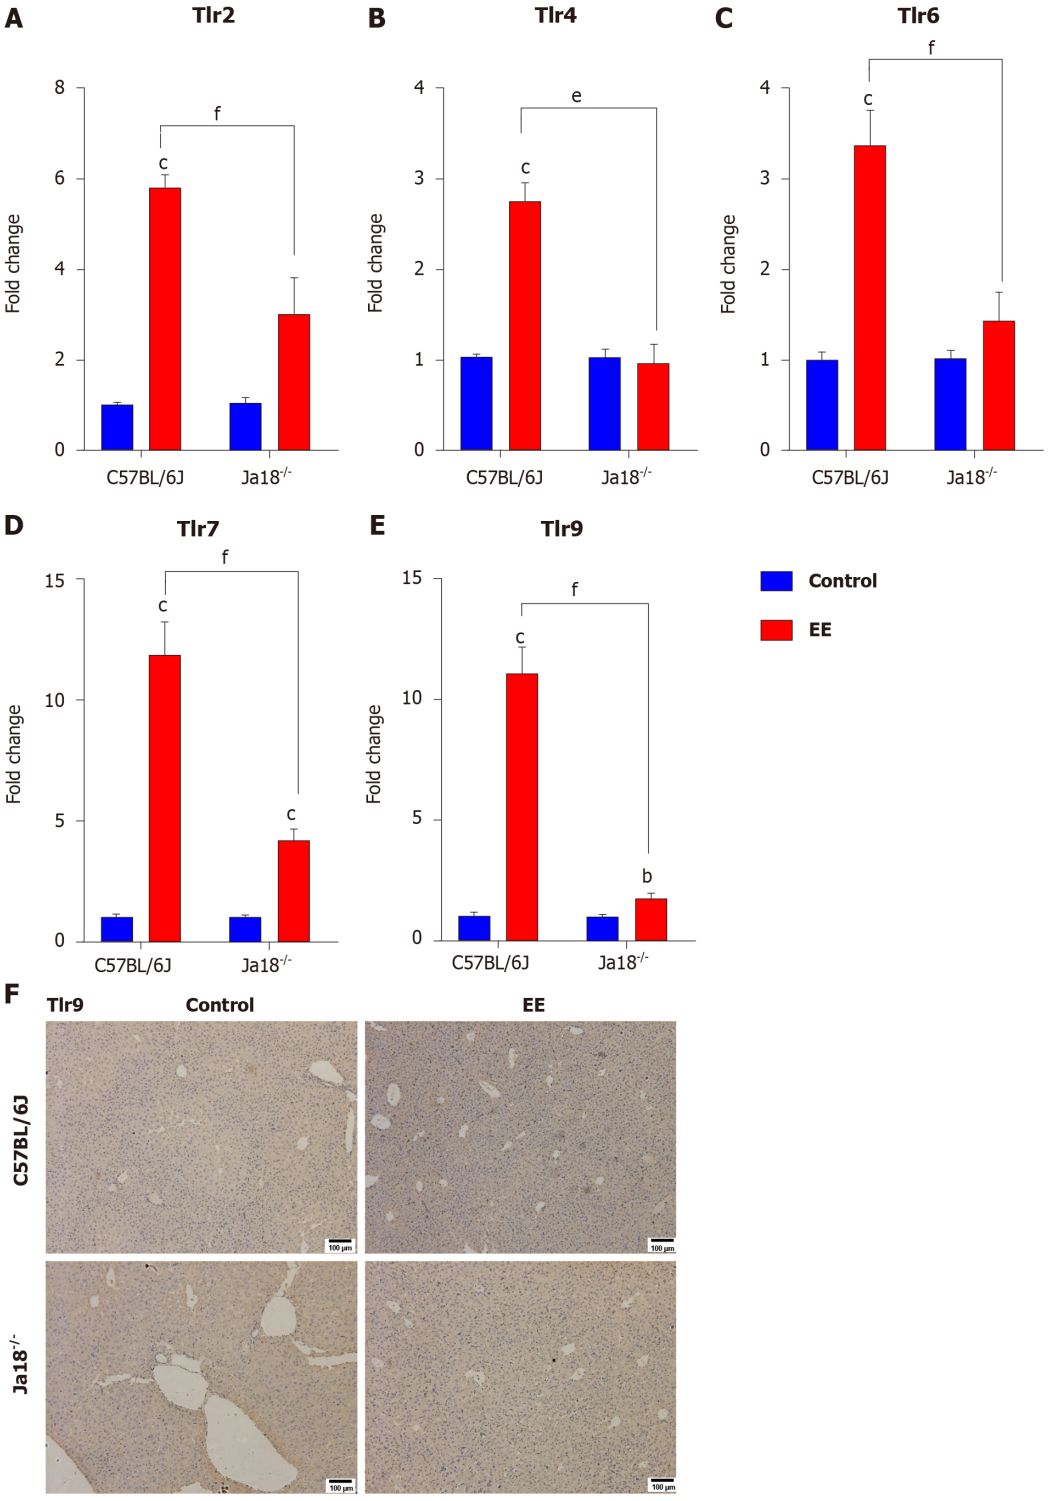
Absence of iNKT cells alters the expression of TLRs and associated signaling pathways

Accumulating evidence suggests that TLRs contribute to the development of hepatobiliary damage[23]. TLRs have also been reported to contribute to the activation and subsequent cytokine production of NKT cells[24]. Intriguingly, iNKT cells have been reported to express certain TLRs, some of which are functional[25]. In the present study, TLRs associated with NKT-cell activation or liver disease were measured and analyzed. The results showed that the mRNA expression levels of Tlr2, Tlr4, Tlr6, Tlr7, and Tlr9 were significantly upregulated after EE administration. Deficiency of iNKT cells significantly downregulated the expression of the above TLRs compared with that in C57BL/6J mice (Figure 4), which suggested that the absence of iNKT cells may influence the expression of TLRs. The hepatic immunohistochemistry results of TLR9 showed a trend similar to that of mRNA (Figure 4F).

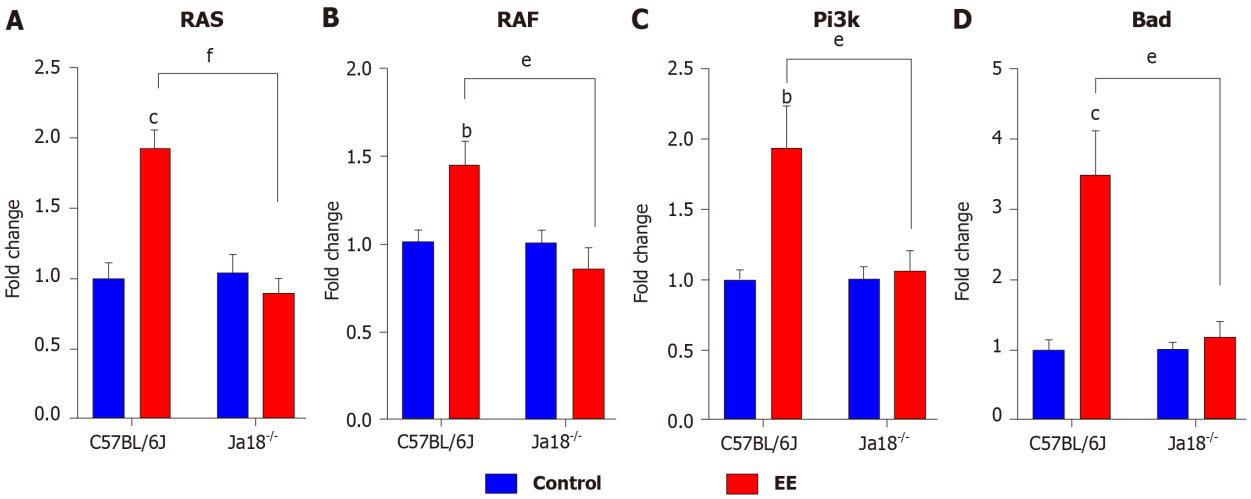


TLRs or T cell receptors (TCRs) can stimulate T cells, leading to MAPK signaling pathway activation, which is required for the effects of T cells[26]. iNKT cell activation by TCR stimulation has also been reported to be mediated by ERK and p38 MAPK[27]. In the present study, the expression of both MAPK and PI3K signaling was investigated after EE administration in C57BL/6J and Jα18$^{-/-}$ mice. The hepatic mRNA expression levels of MAPK upstream Ras and Raf as well as Pi3k and its downstream Bad, which might be associated with TLR activation, were increased in C57BL/6J mice after EE administration. The above mRNA levels were remarkably inhibited in Jα18$^{-/-}$ mice compared with C57BL/6J mice, which suggested that the absence of iNKT cells changes the expression of MAPK and PI3K signaling pathways (Figure 5).

Knockout of iNKT cells may inhibit the synthesis of bile acid and weaken the inhibition of hepatocyte polarity

Dysregulated bile acid homeostasis may be attributed to the disorder of bile acid synthesis/metabolism and/or the dysfunction of tight junctions (TJs)[28]. To investigate the possible mechanism of the alleviation of cholestatic liver injury in NKT-cell knockout mice, the levels of CYP450 synthase and TJs were detected. The mRNA levels of Cyp7a1 and Cyp8b1 were upregulated after EE administration in C57BL/6J mice, whereas a nonsignificant difference was shown in Jα18$^{-/-}$ mice. In comparison to C57BL/6J mice, the mRNA expression of Cyp7a1 and Cyp8b1 was inhibited in Jα18$^{-/-}$ mice after EE administration, indicating the relatively reduced synthesis of bile acid (Figure 6A and B). The IHC results showed that, in comparison to the control group, fewer cells positively stained for ZO-1 or Occludin after EE treatment in C57BL/6J mice, and positive cells remained unaltered between the control and EE groups in Jα18$^{-/-}$ mice (Figure 6C and D). These data suggested that knockout of iNKT cells can inhibit bile acid synthase and weaken the inhibition of hepatocyte polarity, thereby reducing cholestatic liver injury.

DISCUSSION



As the most common hepatic disorder, the principal pathogenic factors of EE-induced IHC include estrogen and toxic bile acid, both of which are correlated with immune imbalance. Increased activation

Figure 4 Absence of invariant natural killer T cells alters the expression of toll-like receptors. A-E: Hepatic mRNA levels of Tlr2 (A), Tlr4 (B), Tlr6 (C), Tlr7 (D) and Tlr9 (E) were determined and compared; F: Changes in the protein level of TLR9 were determined by immunohistochemistry. All values are the means ± SE (n = 4-6). $^{b}P < 0.01$, $^{c}P < 0.001$ *vs* control; $^{e}P < 0.01$, $^{f}P < 0.001$ *vs* C57BL/6J group.

status of NKT cells, T cells, or NK cells has been reported to contribute to the pathophysiology of cholestatic diseases[15,19,20]. Therefore, the percentages of hepatic NKT cells, $CD3^+$ T cells, and NK cells along with their Th1/Th2 cytokine secretion and bias were compared in the present study. Surprisingly, in EE-induced cholestasis, only the NKT-cell percentage and its Th1/Th2 cytokine secretion and ratio significantly increased, indicating their activation and Th1-biased immune response. The percentage of $CD3^+$ T cells and NK cells, along with their secretion of Th1 cytokines, remained unaltered. Th2 cytokines from $CD3^+$ T cells and NK cells showed a rising trend, which did not seem to affect the Th1/Th2 balance (Figure 1). Our results revealed that both Th1 and Th2 cytokines existed in the liver,

Figure 5 Absence of invariant natural killer T cells alters the expression of Ras/Raf and PI3K/Bad signaling pathways. A-D: Hepatic gene expressions of Ras (A), Raf (B), Pi3k (C) and Bad (D) were determined and compared. All values are the means ± SE (n = 4-6), $^{b}P < 0.01$, $^{c}P < 0.001$ *vs* control; $^{e}P < 0.01$, $^{f}P < 0.001$ *vs* C57BL/6J group.

consistent with previous studies[14,29], and the Th1 bias was mainly contributed by NKT cells. To further confirm the effect of NKT cells in EE-induced cholestasis, cholestatic liver damage was compared between iNKT cell-deficient mice and C57BL/6J mice after EE administration. Jα18$^{-/-}$ mice showed significantly reduced blood biochemistry parameters, including levels of ALP, TBA, ALT, and AST, and alleviated liver histopathological changes, suggesting that NKT cells have a harmful effect on EE-induced cholestasis. NKT cells have been accepted as a key connection between innate and adaptive immunity. Upon activation, NKT cells can activate and influence most innate and adaptive immune cells by rapid and abundant cytokine production[30,31]. NKT cells, whose role is noteworthy in cholestasis, are mostly abundant in the liver rather than other organs. In the PBC mouse model, NKT cells are highly activated and secrete enormous amounts of IFN-γ. In comparison to mice with PBC, cholangitis and liver inflammation are significantly alleviated in mice with NKT-cell deficiency[32]. Our previous investigations also found that iNKT cells and their cytokines aggravate ANIT- and triptolide-induced cholestasis by disrupting bile acid homeostasis[14,15]. Although NKT cells can be protective by suppressing neutrophils in an extrahepatic cholestasis model[16], our research data suggest the harmful effects of NKT cells in EE-induced cholestasis. The above studies indicate that the role of NKT cells may vary in different diseases and models.

Under physiological conditions, CXCR6/CXCL16 regulate the migration of NKT cells in hepatic sinusoids[33]. Under the early pathologic states of chronic liver damage, they specifically mediate the hepatic accumulation of NKT cells, exacerbating hepatic inflammation and promoting fibrogenesis[22]. CXCL16 can be expressed in hepatobiliary tissues of patients with hepatopathy[34] but also in mouse liver sinusoidal endothelial cells triggered by intestinal microorganism-induced bile acids, indicating that its expression is related to hepatobiliary damage[33,35]. Our results showed that the hepatic gene levels of Cxcr6 and Cxcl16 were upregulated (Figure 3). Inflammatory cytokines, such as IFN-γ, which was increased in the present model, are capable of further inducing CXCL16 expression, forming a positive regulation loop[36]. In the present study, iNKT cell deficiency inhibited the mRNA levels of Cxcr6 and Cxcl16, which may be linked to the absence of hepatic infiltration of NKT cells (Figure 3).

Activation of iNKT cells can be caused by direct interaction with TCR or indirect effects of TLR agonists and/or IL-12[37]. TLRs, which are widely expressed in the liver, can stimulate hepatic inflammation and actively participate in the initiation and development of liver damage under pathological conditions[38,39]. Lipopolysaccharide (LPS), a specific TLR4 Ligand, activates hepatic iNKT cells and leads to their secretion of IL-4 within 2 h *in vivo* or in vitro, demonstrating that TLR4 is expressed and functional in iNKT cells[40]. In alcoholic liver disease, TLR4 inhibition results in drastically reduced levels of hepatic proinflammatory mediators[41]. TLR4 deletion nearly eliminates inflammatory cell infiltration in the liver and hepatocyte injury in a murine model of ischemia reperfusion[42]. In EE-induced cholestatic liver injury, hepatic mRNA levels of Tlr2, 4, 6, 7, and 9 were markedly increased (Figure 4). CD1d knockout mice (lacking NKT cells) exhibit enhanced (> 4-fold) proinflammatory cytokine secretion and higher mRNA levels of TLR4 in the kidney of a nonalcoholic fatty liver disease model[43]. In the present study, iNKT cell deficiency significantly downregulated the expression of the above TLRs compared with C57BL/6J mice (Figure 4), suggesting the effect of iNKT cells on the expression of TLRs. NKT cells have been found to express certain functional TLRs[24]. The IHC results of TLR9 showed a similar trend as the mRNA levels (Figure 4F). In a murine autoimmune hepatitis model induced by concanavalin A, NKT cells infiltrate and are activated, promoted by TLR9

stimulation, thereby leading to aggravated hepatotoxicity[44]. The PI3K/Akt and Ras/Raf/MEK/ERK signaling pathways are considered to be activated and function following inflammation[45], which further upregulates proinflammatory mediators in cholestasis[46]. Our data demonstrated that the mRNA levels of the downstream pathways Ras/Raf and Pi3k/Bad were also upregulated, while iNKT cell deficiency suppressed their upregulation (Figure 5). These results indicated that iNKT cell deletion affected TLRs and their downstream Ras/Raf and PI3K/Bad signaling.

Growing numbers of studies have reported that hepatocyte TJs, constituting hepatocyte polarization, play a pivotal role in the maintenance of the epithelial barrier and permeability; therefore, their structural disruption can lead to the leakage of bile components into blood circulation, bile acid homeostasis disorder, and cholestatic liver injury[47]. TJ damage can be found in obstructive jaundice patients[48] and murine cholestatic models of ANIT[28], carbon tetrachloride[49], BDL[50], and EE[51]. Inflammation has been associated with structural and functional alterations of hepatic TJs[52]. In the present study, the results showed that iNKT cell-deficient mice ameliorated disorders of bile acid synthesis and TJs (Figure 6) and restored previously deteriorated bile acid homeostasis and hepatocyte barrier function, contributing to the mitigation of EE-induced cholestatic hepatotoxicity.

CONCLUSION

In EE-induced cholestatic hepatotoxicity, EE promoted hepatic NKT-cell proliferation and activation, which contributed to Th1 cytokine bias and influenced the liver immune microenvironment. EE also upregulated the expression of Cxcr6/Cxcl16, TLRs, and downstream Ras/Rad and PI3K/Bad signaling. Moreover, EE influenced the levels of the bile acid synthase Cyp7a1 and Cyp8b1 and the TJs ZO-1 and

Occludin. iNKT cell deficiency significantly alleviated cholestatic liver damage and downregulated the abovementioned signaling pathways, indicating the pathogenic effects of hepatic iNKT cells in EE-induced cholestatic liver damage. It is noteworthy that mouse and human NKT cells share similar functions, including the killing of tumor/infected cells by cytotoxicity and their crucial role in autoimmunity[53]. Therefore, regulation of NKT-cell activation may serve as a potential therapeutic strategy with clinical implications for cholestatic diseases.

ARTICLE HIGHLIGHTS

Research background

Cholestasis is mild and common during liver diseases but is also a crucial triggering element of severe hepatopathy. As the predominant component of oral contraceptives (OCs) and hormone replacement therapy, 17α-ethinylestradiol (EE) is used as a model drug to induce murine intrahepatic cholestasis (IHC). The clinical counterpart of EE-induced IHC includes women who are taking OCs, postmenopausal replacement therapy, and susceptible pregnant women.

Research motivation

The significance of the local immune microenvironment in the liver has been emphasized because estrogens are immunomodulators that are metabolized in the liver.

Research objectives

The aim of the present study was to investigate the effects and mechanisms of natural killer T (NKT) cells in a murine model of EE-induced cholestatic hepatotoxicity.

Research methods

Male C57BL/6J mice or invariant NKT (iNKT) cell deficiency (Jα18$^{-/-}$ mice) were administered with EE (10 mg/kg, subcutaneous) for 14 d.

Research results

Both Th1 and Th2 cytokines produced by NKT cells increased in the liver skewing toward a Th1 bias. The expression of the chemokine/chemokine receptor Cxcr6/Cxcl16, toll-like receptors, Ras/Rad, and PI3K/Bad signaling was upregulated after EE administration. EE also influenced bile acid synthase Cyp7a1, Cyp8b1, and tight junctions ZO-1 and Occludin, which might be associated with EE-induced cholestasis. iNKT cell deficiency (Jα18$^{-/-}$ mice) robustly alleviated cholestatic liver damage and lowered the expression of the abovementioned signaling pathways.

Research conclusions

The present study demonstrated that hepatic NKT cells play a pathogenic role in EE-induced intrahepatic cholestasis, contributing to the development of the IHC mechanisms and the potential treatment targeting NKT cells.

Research perspectives

Hepatic NKT cells and their Th1 cytokine production play a pathogenic role in a 14-d murine model of EE-induced intrahepatic cholestasis.

ACKNOWLEDGEMENTS

The authors would like to acknowledge Li Bai (University of Science and Technology of China) for kindly providing iNKT cell-deficient (Jα18$^{-/-}$ mice).

Abstract

BACKGROUND

Inflammatory bowel disease (IBD) is caused by an abnormal immune response. Programmed cell death 1 (PD-1) is an immunostimulatory molecule, which interacts with PD ligand (PD-L1) playing a prime important role among autoimmune diseases. *Bifidobacterium infantis* (*B. infantis*) can promote the differentiation of CD (cluster of differentiation) 4^+ T cells into regulatory T cells (Tregs). Tregs participate in the development of IBD and may be related to disease activity. *B. infantis* amplify the expression level of PD-1, PD-L1 and Tregs' nuclear transcription factor forkhead box protein 3 (Foxp3). But the mechanism of *B. infantis* on PD-1/PD-L1 signaling remains unclear.

AIM

To explore the mechanism of *B. infantis* regulating the immune response in IBD.

METHODS

Forty-eight-week-old BALB/c mice were randomly divided into five groups: The control group, dextran sulphate sodium (DSS) model group, DSS + *B. infantis* group, DSS + *B. infantis* + anti-PD-L1 group, and DSS + anti-PD-L1 group. The control group mice were given drinking water freely, the other four groups were given drinking water containing 5% DSS freely. The control group, DSS model group, and DSS + anti-PD-L1 group were given normal saline (NS) 400 μL daily by gastric lavage, and the DSS + *B. infantis* group and DSS + *B. infantis* + anti-PD-L1 group were given NS and 1×10^9 colony-forming unit of *B. infantis* daily by gastric lavage. The DSS + *B. infantis* + anti-PD-L1 group and DSS + anti-PD-L1 group were given 200 μg of PD-L1 blocker intraperitoneally at days 0, 3, 5, and 7; the control group, DSS + anti-PD-L1 group, and DSS + *B. infantis* group were given an intraperitoneal injection of an equal volume of phosphate buffered saline

(PBS). Changes in PD-L1, PD-1, Foxp3, interleukin (IL)-10, and transforming growth factor β (TGF-β) 1 protein and gene expression were observed. Flow cytometry was used to observe changes in $CD4^+$, $CD25^+$, $Foxp3^+$ cell numbers in the blood and spleen.

RESULTS

Compared to the control group, the expression of PD-1, Foxp3, IL-10, and TGF-β1 was significantly decreased in the intestinal tract of the DSS mice ($P < 0.05$). Compared to the control group, the proportion of $CD4^+$, $CD25^+$, $Foxp3^+$ cells in spleen and blood of DSS group was visibly katabatic ($P < 0.05$). *B. infantis* upgraded the express of PD-L1, PD-1, Foxp3, IL-10, and TGF-β1 ($P < 0.05$) and increased the proportion of $CD4^+$, $CD25^+$, $Foxp3^+$ cells both in spleen and blood ($P < 0.05$). After blocking PD-L1, the increase in Foxp3, IL-10, and TGF-β1 protein and gene by *B. infantis* was inhibited ($P < 0.05$), and the proliferation of $CD4^+$, $CD25^+$, $Foxp3^+$ cells in the spleen and blood was also inhibited ($P < 0.05$). After blocking PD-L1, the messenger ribonucleic acid and protein expression of PD-1 were invariant.

CONCLUSION

It is potential that *B. infantis* boost the proliferation of $CD4^+$, $CD25^+$, $Foxp3^+$ T cells in both spleen and blood, as well as the expression of Foxp3 in the intestinal tract by activating the PD-1/PD-L1 pathway.

Key Words: *Bifidobacterium infantis*; Enteritis; Programmed cell death ligand; T-Lymphocytes

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: *Bifidobacterium infantis* (*B. infantis*) can be used as a therapeutic agent to treat inflammatory bowel disease. It regulates the intestinal microbiota, alleviates inflammation, and regulates the immune response. We found that *B. infantis* increases the expression of forkhead box protein 3 (Foxp3) and the proliferation of $Foxp3^+$ T cells, and activates the programmed cell death 1 (PD-1)/ PD ligand 1 pathway.

INTRODUCTION

Inflammatory bowel disease (IBD) results from the aberrant immune responses or the disruption of immune tolerance to intestinal antigens. Several factors, including the immune system, infections, and genetic and environmental factors, may remarkably contribute to the development of IBD[1-4]. To maintain immune tolerance to the intestinal environment, the intestinal immune system monitors changes in the bacterial microbiota and the expression of antigens on the surface of the intestinal mucosa[5,6]. Antigen-presenting cells, including dendritic cells and intestinal epithelial cells, present intestinal antigens to $CD4^+$ T cells and induce their differentiation into regulatory T cells (Tregs), which maintain tolerance to the intestinal microbiota. Hyperactive T cell responses to the intestinal microbiota contribute to the inflammatory response observed in IBD[7].

Programmed cell death protein 1 (PD-1) and PD-ligand 1 (PD-L1), belong to the CD28/B7 super-family, which primarily functions in T cell-mediated immune responses and is closely related to several diseases and disease states, including autoimmune diseases, tumors, chronic viral infections, and chronic inflammation[8-10]. The role of the PD-1/PD-L1 signaling pathway in glomerulonephritis, systemic lupus erythematosus, rheumatoid arthritis, dilated cardiomyopathy, autoimmune diabetes, and other autoimmune diseases has been widely studied[11,12]; however, few studies have examined the role of the PD-1/PD-L1 signaling pathway in IBD[13].

Tregs are a subpopulation of T lymphocytes with immunoregulatory functions[14]. They can inhibit the activation and proliferation of autoreactive T cells by secreting cytokines such as interleukin (IL)-10 and transforming growth factor β (TGF-β), downregulating the function of auxiliary T cells, and maintaining intestinal homeostasis and immune tolerance[15,16]. Tregs are divided into two categories: Natural Tregs (nTregs) and induced Tregs (iTregs). The nTregs mature in the thymus and are positive for CD4, CD25, and Foxp3. The iTregs are induced by specific antigen stimulation of $CD4^+$ T cells in the presence of IL-2 and TGF-β1, in the intestine, spleen, and other peripheral sites[17]. Animal studies have shown that injecting T cells with no CD4 and Tregs expressing CD25 into T cell-deficient mice can

induce the development of autoimmune colitis, whereas the injection of T cells expressing CD4 with that of $CD25^+$ Tregs can inhibit colitis development. These results suggest that $CD4^+$ and $CD25^+$ Tregs are vital for the inhibition of the intestinal immune response[18]. Maul *et al*[19] found that the percentage of Tregs in the peripheral blood of patients with IBD decreased in the active phase and increased in the remission phase of the disease; however, the number of Tregs in the intestinal epithelium increased in the active phase of the disease but was still significantly lower than that observed in patients with diverticulitis. This suggests a role of Tregs in IBD development.

The adoptive transfer of immature $CD4^+$ T cells into wild-type $rag^{-/-}$ mice and PD-$L1^{-/-}rag^{-/-}$ mice significantly decreases the number of Tregs in PD-$L1^{-/-}rag^{-/-}$ mice, suggesting a dominant role of PD-L1 in Treg differentiation[20]. PD-L1 can enhance Treg function and promote the production of IL-10 by Tregs[21]. Treg differentiation depends on the PD-L1 signaling pathway. Higher levels of PD-L1 expression in hepatodendritic cells result in greater induction of Tregs which maintain the tolerance toward transplanted organs.

We have previously found that *Bifidobacterium infantis* (*B. infantis*) can alleviate intestinal epithelial injury and maintain intestinal immune tolerance in a mouse model of IBD and may have therapeutic implications for the immunological injuries observed in IBD**.** *Bifidobacterium infantis* notably increased the expression levels of PD-L1 and PD-1 in the intestine and promoted the expression of nuclear transcription factors and of anti-inflammatory factors (IL-10 and TGF-β1) in Tregs[22,23]. Therefore, this study aimed to explore the mechanism of action of *B. infantis* in the PD-1/PD-L1 signaling pathway and the differentiation and function of Tregs.

MATERIALS AND METHODS

Reagents and antibodies

Dextran sulfate sodium (DSS; molecular weight 36000-50000) was purchased from MP Biomedicals (Irvine, CA, United States). *B. infantis* freeze-dried powder, containing 1.6×10^{11} colony-forming units (CFU)/g, was provided by Shandong Kexing Biological Products Co., Ltd. (Batch No. 2017012, Shandong Province, China). Invivomab anti-mouse PD-L1 was purchased from BIOX Cell (Lebanon, NH, United States). BALB/c mice were purchased from Huafukang Biotechnology (Beijing, China). Allophycocyanin (APC) rat anti-mouse Cd4, Bb515 rat anti-mouse, P-phycoerythrin (PE) rat anti-mouse Foxp3, and a transcription factor buffer set were purchased from BD Biosciences (Franklin Lakes, NJ, United States). Antibodies against PD-L1, PD-1, and Foxp3 were purchased from Proteintech Group (Rosemont, IL, United States). Antibodies against IL-10 and TGF-β1 were purchased from Abcam (Cambridge, United Kingdom). Real-time quantitative PCR was performed using the following reagents: TRIzol (Invitrogen, Thermo Fisher, Waltham, MA, United States), Primescript™ RT Regent kit with gDNA eraser, quick response training (qRT) PCR kit SYBR® premier ex taq™ II (Tli RNaseH Plus, Takara, Japan), and the specific primers (Biotechnology Co., Ltd., China).

Animals

Forty-eight-week-old BALB/c mice, male and female, weighing 20 g ± 2 g, were raised under pathogen-free conditions in the standalone animal experimental center affiliated with the Shengjing Hospital of China Medical University. The mice were kept at 20 °C-26 °C and in an atmosphere with a relative humidity of 40%-70%, with a 12 h light/dark cycle. Sterilized water and standard feed were provided for free consumption by the animals. The experimental protocol was approved by the ethics committee of the hospital (No. 2017PS353K). The operators ensured that suitable measures were taken to reduce malaise and injury to the animals during experiments.

Experimental grouping and modeling

Forty mice were randomly divided into five groups: Control, DSS, DSS + *B. infantis*, DSS + *B. infantis* + anti-PD-L1, and DSS + anti-PD-L1. Mice in the control group were given free access drinking water for 7 d. The other four groups were administered sterilized water containing 5% DSS for 7 d. The drinking. Drinking water was changed daily. The control, DSS, and DSS + anti-PD-L1 groups were administered 400 μL normal saline (NS) *via* gavage daily, and the DSS + *B. infantis* and DSS + *B. infantis* + anti-PD-L1 groups were administered 400 μL NS *via* gavage and *B. infantis* (1×10^9 CFU) daily. The DSS + *B. infantis* + anti-PD-L1 and DSS + anti-PD-L1 groups were administered an intraperitoneal injection of PD-L1 blocker (200 μg), and the control, DSS model, and DSS + *B. infantis* groups were intraperitoneally injected with phosphate-buffered phosphate buffered saline (PBS) on days 0, 3, 5, and 7.

Specimen collection

General characteristics of the mice: During the experimental period, temperament, reactivity, activity, hair color, weight, eating, and defecation of each mouse were observed seriatim and recorded in detail daily.

Peripheral blood collection: On day 8, all animals were anesthetized *via* isoflurane inhalation, and the beards were removed. Blood was collected through retro-orbital bleeding and placed in blood collection vessels containing EDTA. The blood and EDTA were mixed and stored on ice.

Extraction of single cells from mouse spleen: After blood collection, the sacrificed mice were dissected along the midline, and the spleen was fully exposed. After blunt dissection, the spleen was removed, placed in PBS, and transported on ice. The spleen was then transferred to a glass dish containing RPMI 1640 medium and mashed with ground glass. The cells were then transferred to a centrifuge tube and centrifuged at 1200 rpm for 5 min, and the supernatant was discarded. Next, 2 mL of RBC lysate was added to each sample. PBS (3 mL) was added to dilute and stop the lysis, and the samples were centrifuged again at 400 × *g* for 5 min at 4 °C. The supernatant was discarded and 3 mL of PBS was added. The cells were filtered and centrifuged for 10 min. The supernatant was discarded, and PBS was added to obtain a single-cell suspension. All the procedures were performed at 4 °C to ensure cell viability.

Acquisition of mouse colon: After splenectomy, the colon was exposed and the colon from the blind part to the anus was removed, washed with pre-cooled NS, and divided into four parts. The samples were then transferred to a -80 °C ultra-low-temperature refrigerator in liquid nitrogen for long-term preservation.

Detection of $CD4^+$, $CD25^+$, $Foxp3^+$ T cells by flow cytometry

Spleen: Splenic $CD4^+$, $CD25^+$, and $Foxp3^+$ T cells were detected using flow cytometry. The prepared single-cell spleen suspension (100 μL) was aliquoted into labeled flow tubes. Anti-$CD4^+$ and anti-$CD25^+$ antibodies were then added to the tubes and the tubes were incubated at 4 °C in the dark for 30 min. Next, 1 mL of 1X fix/perm working solution was added to each sample and the samples were incubated at 4 °C in the dark for 40 min to permeabilize the nucleus. Anti-Foxp3 antibody was then added and the resulting solution was incubated at 4 °C in the dark for 40 min. Excess antibodies were removed, and the samples were run on a flow cytometer (FACSCalibur, BD Bioscience).

Peripheral blood: After RBC lysis, flow cytometry was performed on the peripheral blood samples using the protocol described above.

Western blotting

Total protein was extracted from the colon, and the protein concentration was determined. The samples were subjected to electrophoresis at 60 V. After marker separation, the voltage was adjusted to 80 V. After 30 min, the voltage was adjusted to 100 V. Electrophoresis was terminated when the target protein with the lowest molecular weight reached the end of the gel. A voltage of 100 V was used to transfer proteins to the membrane. Proteins with a molecular weight < 25 kDa were transferred for 25 min, and proteins weighing 26-70 kDa were transferred for 70 min. The membrane was blocked with 2.5% bovine serum albumin (BSA) at room temperature for 1.5 h. Primary antibodies against PD-L1 (1:750), PD-1 (1:500), Foxp3 (1:1000), IL-10 (1:800), TGF-β1 (1:500), and GAPDH (1:10000) were added and the membrane was incubated at 4 °C overnight. Then, goat anti-rabbit IgG secondary antibody labeled with horseradish peroxidase was added to the membrane, followed by incubation at room temperature for 1.5 h. In a dark room, a chemiluminescence imaging analysis system was used to visualize the membranes. GelPro software was used to analyze the images and to perform quantitative analysis using the following formula: Protein content = grey value of the target protein of the sample/grey value of the same sample.

Real time qPCR

The experiment consists of 5 steps: (1) Ribonucleic acid (RNA) purification: DSS can reduce the purity of RNA, so extra purification of the colon RNA was necessary. RNA purification was performed as follows: 30 μL lithium chloride (8 mol/L) + 270 μL ddH_2O was added to 10 μL RNA and placed on ice for 2 h. The samples were then centrifuged at 14000 × g for 30 min. The supernatant was then discarded, and the RNA was dissolved in 90 μL ddH_2O. Next, 10 μL sodium acetate (3 mol/L) + 200 μL anhydrous ethanol was added to the RNA and incubated at -20 °C for 30 min to precipitate the RNA. The samples were then centrifuged at 14000 × g for 30 min at 4 °C. The supernatant was then discarded, 500 μL 75% ethanol was added, and the samples were gently blown with a pipette to clean the RNA. Next, the samples were centrifuged at 800 × g for 10 min at 4 °C. The supernatant was discarded, and the RNA was dissolved with 10 μL ddH_2O. Finally, the samples were transferred to -80 °C on ice for preservation; (2) detection of RNA concentration: The ratio of A260/A280 was eligible for all of the samples, which indicates that the purity of the RNA was high and suitable for further experiments; (3) preparation of cDNA by RNA reverse transcription: The gDNA was removed, and the specimens were heated to 42 °C for 2 min. For reverse transcription, the reaction solution was prepared according to Table 1. The samples were heated at 37 °C for 15 min and 85 °C for 5 s. The reaction was then stopped and cooled down to 4 °C; (4) concentration and purity of cDNA: After zero adjustment, 1 μL of the cDNA sample to

Table 1 Preparation of reverse transcription system

RT: Real time; dd: Double distilled.

be tested was dropped onto the detection probe to determine the concentration and purity. The probe was washed with ddH2O between the evaluation of the two samples; and (5) qRT-PCR: qRT-PCR was carried out as follows: PCR amplification reaction, denaturation at 95 °C for 5 min, PCR reaction at 95 °C for 10 s, and 60 °C for 30 s for 45 cycles.

Statistical analysis

Data are presented as mean ± SD. Differences among the groups were analyzed using the analysis of variance. SPSS (version 23.0; IBM, Armonk, NY, United States) and GraphPad 7.0 (Software, CA, United States) statistical software were used to perform statistical analyses. Two-tailed *P* values were calculated, and statistical significance was set as $P < 0.05$.

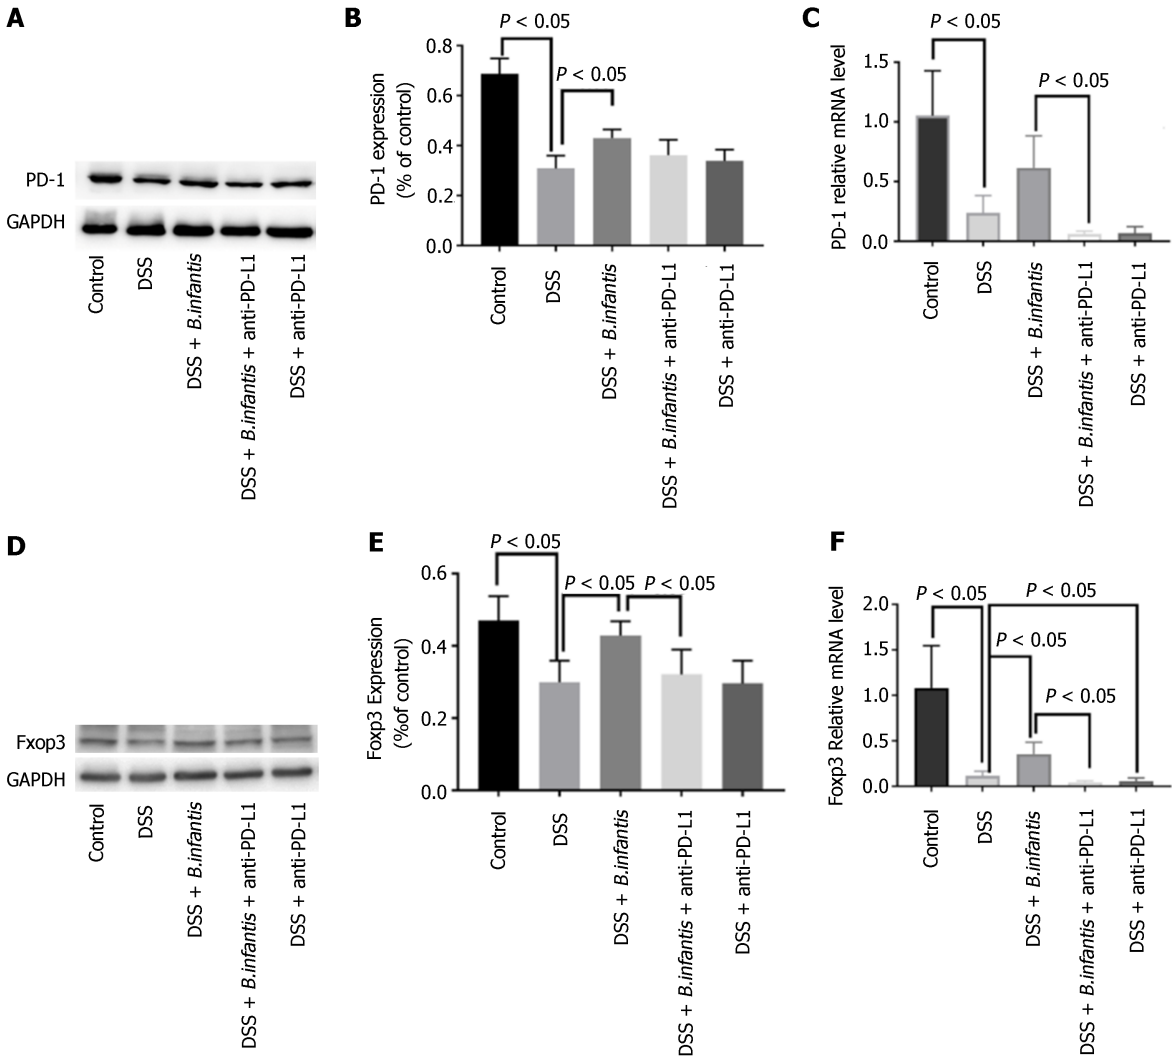
RESULTS

The effect of B. infantis on the expression of PD-1 after PD-L1 blockade

Western blot results: Compared to the DSS + *B. infantis* group, PD-1 protein in the DSS + *B. infantis* + anti-PD-L1 group decreased, but the difference was not statistically significant ($P = 0.07$). Compared to DSS model group, the expression of PD-1 was no significant distinction in DSS + anti-PD-L1 group ($P = 0.62$) (Figure 1A-C).

qRT-PCR results: In contrast to control group, PD-1 messenger ribonucleic acid (mRNA) in DSS group decreased significantly ($P < 0.05$). In constrast to DSS group, the expression of DSS + *B. infantis* group increased, but the difference was not statistically significant ($P = 0.36$). Compared to the *B. infantis* group, PD-1 RNA decreased significantly in the DSS + *B. infantis* + anti-PD-L1 group ($P < 0.05$) (Figure 1A-C).

Effect of B. infantis on Tregs and Foxp3 expression after PD-L1 blockade



Western blot results: Compared to the DSS + *B. infantis* group, Foxp3 protein decreased in DSS + *B. infantis* + anti-PD-L1 group, and the difference was statistically significant ($P < 0.05$). There was no significant difference in Foxp3 protein expression between the DSS model group and DSS + anti-PD-L1 group ($P = 0.99$) (Figure 1D-F).

RT-qPCR results: In contrast to control group, Foxp3 mRNA in DSS model group decreased significantly ($P < 0.05$); Foxp3 mRNA in DSS + *B. infantis* group was significantly higher than that in DSS model group ($P < 0.05$). Compared to the *B. infantis* group, the expression of Foxp3 mRNA decreased significantly in the DSS + *B. infantis* + anti-PD-L1 group ($P < 0.05$). In comparison with DSS model group, Foxp3 mRNA in DSS + anti-PD-L1 group was also visible distinction ($P < 0.05$) (Figure 1D -F).

Flow cytometry results

Flow cytometry of peripheral blood: Compared to control group, the proportion of peripheral $CD4^+$, $CD25^+$, $Foxp3^+$ cells decreased visibly ($P < 0.05$) of DSS group and increased visibly in the blood of the DSS + *B. infantis* group ($P < 0.05$). Compared to the DSS + *B. infantis* group, the proportion of $CD4^+$, $CD25^+$, $Foxp3^+$ cells in the peripheral blood of DSS + *B. infantis* + anti-PD-L1 group was significantly lower ($P < 0.05$). The proportion of $CD4^+$, $CD25^+$, $Foxp3^+$ cells in the blood of the DSS + anti-PD-L1 group was also distinctly lower compared to the DSS group ($P < 0.05$) (Figure 2).

Flow cytometry of splenocytes: The ratio of splenic $CD4^+$, $CD25^+$, $Foxp3^+$ cells in DSS model group was significantly lower ($P < 0.05$), comparing to control group. The ratio of $CD4^+$, $CD25^+$, $Foxp3^+$ cells in the DSS + *B. infantis* group was significantly higher than that in the DSS model group ($P < 0.05$). Compared to the DSS + *B. infantis* group, the proportion of $CD4^+$, $CD25^+$, $Foxp3^+$ cells in the DSS + *B. infantis* + anti-

PD-L1 group decreased significantly ($P < 0.05$). The proportion of $CD4^+$, $CD25^+$, $Foxp3^+$ cells in the DSS + anti-PD-L1 group also decreased significantly compared to the DSS group ($P < 0.05$) (Figure 3).

The effect of B. infantis on the expression of IL-10 and TGF-β1 after PD-L1 blockade

Western blot results: The expression of IL-10 and TGF-β1 protein in the DSS + *B. infantis* group was lower than that in DSS + *B. infantis* + anti-PD-L1 group ($P < 0.05$). Compared to the DSS model group, there was no apparent distinction in the express of IL-10 ($P = 0.99$) or TGF-β1 in the DSS + anti-PD-L1 group ($P < 0.05$) (Figure 4).

Real time PCR results: In comparison with control group, mRNA of IL-10 and TGF-β1 in the DSS model group decreased ($P < 0.05$), and mRNA of IL-10 and TGF-β1 in the DSS + *B. infantis* group increased clearly ($P < 0.05$). IL-10 and TGF-β1 mRNA expression in DSS + *B. infantis* + anti-PD-L1 group decreased clearly ($P < 0.05$) contrsating to DSS + *B. infantis* group. Compared to the DSS model group, IL-10 and TGF-β1 mRNA in DSS + anti-PD-L1 group were also statistically distinction ($P < 0.05$) (Figure 4).

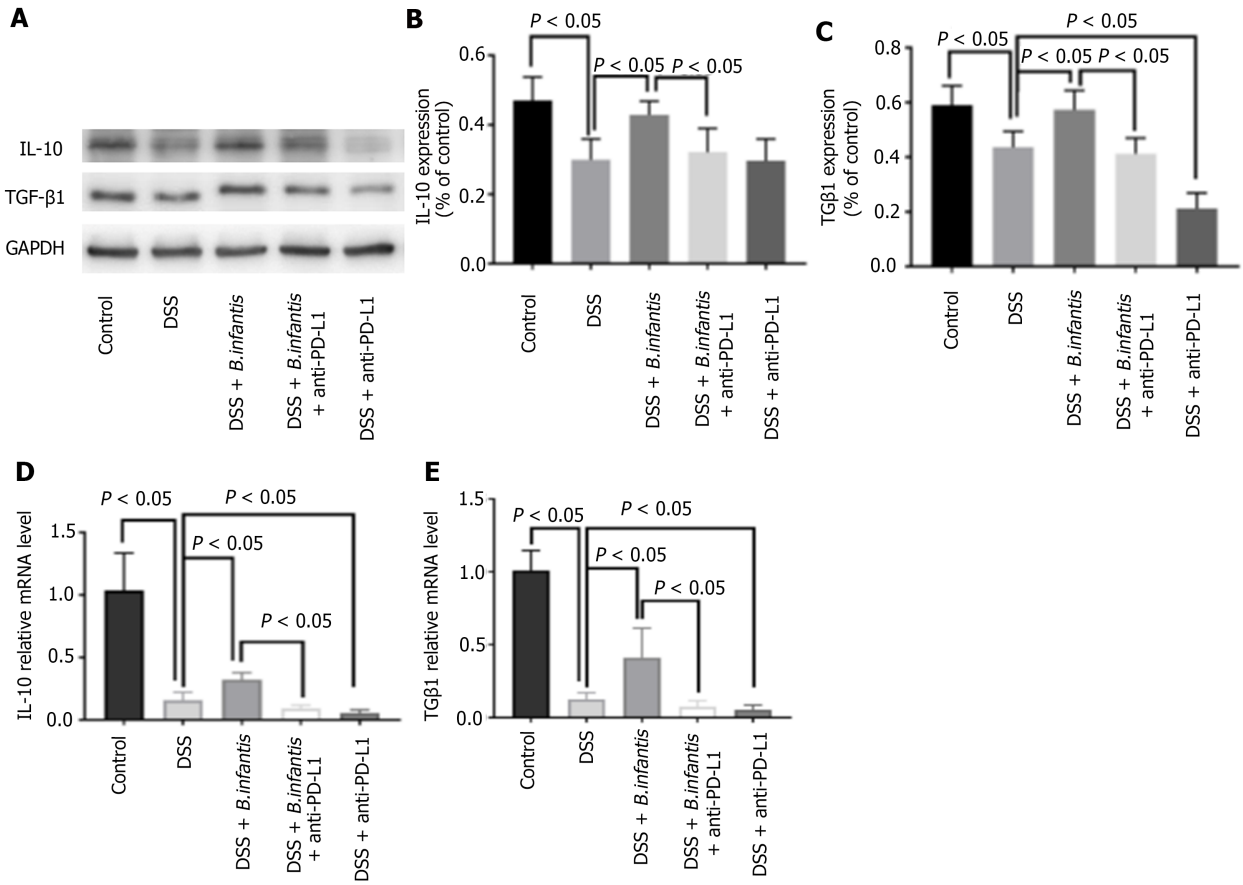
DISCUSSION

The specific pathogenesis of IBD remains unclear; however, abnormal inflammatory responses and continuous inflammatory damage to the intestine are recognized as the basic mechanisms of IBD pathogenesis[24,25]. Intestinal immunity is a complex and interactive process, involving several immune factors such as intestinal mucosal immunity, T cells, cytokines, and intestinal microecology [26]. The intestinal mucosal immune system is responsible for monitoring the intestinal microbiota and surface antigens[27], presenting antigens to CD4⁺ T cells, promoting the interaction between PD-1 and PD-L1, establishing immune tolerance, and preventing the occurrence of autoimmunity. Several inflammatory mediators including interferon γ, tumor necrosis factor α, IL-10, and other cytokines, are involved in the pathogenesis of DSS colitis, suggesting that inflammatory immune responses play a critical role in the pathogenesis of IBD[28-30].



A recently discovered immunostimulatory molecule, PD-1 interacts with its ligand PD-L1 to regulate T cell-mediated immunity and induce immune tolerance, thereby playing a critical role in autoimmune

diseases (such as IBD), tumor immunity, and the acceptance of transplanted organs. Studies have shown that PD-1 knockout results in autoimmune diseases in animal models[31-33]. Activation of the PD-1/PD-L1 signaling pathway can induce the differentiation of Tregs[34] and the release of cytokines, such as IL-10 and TGF-β1, to inhibit the activation and proliferation of reactive T cells, thus maintaining intestinal immune tolerance. Additionally, the inhibition of the PD-1/PD-L1 pathway may reduce the proportion of Tregs[35]. These findings indicate that PD-1/PD-L1 signaling plays a critical role in immune tolerance[36]. In this study, we found that PD-L1 inhibition did not alter the PD-1 protein and mRNA levels in the intestine of DSS-induced mice, suggesting that PD-L1 did not affect the transcription or translation of PD-1 in the intestine of the IBD mouse model. However, although the expression of PD-1 mRNA in the intestinal tracts of DSS mice significantly decreased, the expression of PD-1 protein did not change after *B. infantis* administration. We, therefore, speculate that PD-L1 inhibition may indirectly inhibit the *B. infantis*-induced PD-1 gene transcription, but not the post-transcriptional modification and translation of PD-1 protein. This transcriptional inhibition of PD-1 may be due to a negative feedback mechanism caused by the high PD-1 protein levels. Further studies are

needed to determine how PD-L1 inhibition suppresses the transcription and translation of PD-1 and the underlying mechanism of action of the effect of *B. infantis* on PD-1 after PD-L1 inhibition.

B. infantis can be used to treat IBD by regulating the intestinal microbiota, alleviating inflammation, and regulating the immune response. *B. infantis* can reduce the intestinal wall permeability, edema, and neutrophil infiltration in IBD mice, and alleviate intestinal inflammatory responses[37]. We have previously shown that a combined administration of *B. infantis* with *Clostridium butyricum* increases the abundance of probiotic bacteria (such as members of the genera *Bifidobacterium* and *Lactobacillus)* in the intestinal microbiota of patients with IBD, reduces the prevalence of enterococci, improves clinical symptoms, and promotes the healing of colonic mucosa[38]. *B. infantis* also plays an important role in immune regulation by promoting the proliferation of Tregs[39] and increasing the expression of IL-10 and TGF-β1. *In vivo* and *in vitro* experiments have revealed that *B. infantis* can significantly accelerate the differentiation of $CD4^+$ T cells into Tregs by inducing the maturation of resistant dendritic cells and further inhibiting the inflammatory response induced by reactive T cell activation. Furthermore, we have previously revealed that, compared to the observations in normal mice, the number of $CD4^+$, $CD25^+$, and $Foxp3^+$ T cells in the blood and spleen of DSS mice and the expression of Foxp3 mRNA in their intestines showed a decrease, suggesting that the differentiation and proliferation of Tregs may be correlated to the pathogenesis of IBD[40]. The number of Tregs in the colon was reported to be related to the intestinal microbiota. Treg populations in the colons of sterile mice are significantly low; however, feeding sterile mice with feces collected from specific pathogen-free mice significantly increases the number of Tregs in the colon[41], indicating that Treg population is dependent on the intestinal microbiota. In patients with IBD, the proportion of normal intestinal bacteria decreases, resulting in intestinal microbiota-associated disorders[42]. Therefore, improving the composition of the intestinal microbiota can help increase the number of Tregs; however, further studies are needed for the elucidation of the underlying mechanism. In the present study, we found that *B. infantis* promotes the proliferation of $CD4^+$, $CD25^+$, and $Foxp3^+$ T cells in the blood and spleen, as well as the expression of Foxp3 mRNA in the intestine. PD-L1 inhibition significantly reduced the numbers of $CD4^+$, $CD25^+$, and

Foxp3$^+$ T cells in the blood and spleen, and decreased the expression of Foxp3 protein and mRNA in the intestine. Therefore, *B. infantis* promotes Treg proliferation by activating the PD-L1/PD-1 pathway.

In addition, our results indicate that *B. infantis* promoted the mRNA expression of IL-10 and TGF-β1 in the mouse intestine. PD-L1 inhibition significantly reduced the protein and mRNA expression levels of IL-10 and TGF-β1 in the intestine. These results further indicate that *B. infantis* affected IL-10 and TGF-β1 expression through the PD-1/PD-L1 pathway. Notably, Tregs mainly secrete TGF-β1 and IL-10 to inhibit inflammatory responses. Further studies are needed to confirm the immunosuppressive effects of *B. infantis* in patients with IBD. Additionally, Francisco *et al*[20] found that PD-L1 can downregulate Protein kinase B (Akt), mammalian target of rapamycin (mTOR), and extracellular regulated protein kinases (ERK2), while upregulating phosphatase and tensin homolog deleted on chromosome ten (PTEN) expression in Tregs; however, whether *B. infantis* can accelerate the differentiation and proliferation of Tregs by activating the PD-1/PD-L1 pathway and regulating Akt, mTOR, or PTEN expression requires further investigation.

CONCLUSION

In conclusion, *B. infantis* may accelerate the proliferation of CD4$^+$, CD25$^+$, and Foxp3$^+$ T cells in the spleen and peripheral blood, and the expression of Foxp3 in the intestine by activating the PD-1/PD-L1 signaling pathway. It can also promote the expression of IL-10 and TGF-β1 to reduce the intestinal inflammatory response, which has a therapeutic effect on IBD mice. We aim to further investigate the role of the PD-1/PD-L1 pathway in IBD and the possible therapeutic effect of *B. infantis* on patients with IBD in future studies.

ARTICLE HIGHLIGHTS

Research background

The immune-inflammatory response plays an important role in the pathogenesis and development of inflammatory bowel disease (IBD). *Bifidobacterium infantis* (*B. infantis*) can repair the acute intestinal mucosal injury and maintain autoimmune tolerance in mice with IBD.

Research motivation

The specific mechanism of action of *B. infantis* in the treatment of IBD is unclear. Understanding this underlying mechanism will help in the treatment of IBD.

Research objectives

To explore if *B. infantis* can promote regulatory T cell Treg differentiation through the programmed cell death 1 (PD-1)/PD ligand (PD-L1) pathway to promote the expression of forkhead box protein 3 (Foxp3), interleukin (IL)-10 and transforming growth factor β (TGF-β) 1, and reduce the inflammatory response.

Research methods

We blocked the expression of PD-L1 in the intestine and performed western blotting and real-time qPCR to observe the effects of *B. infantis* on PD-1, Foxp3, IL-10, and TGF-β1. Flow cytometry was used to examine the changes in the differentiation of CD4$^+$, CD25$^+$, and Foxp3$^+$ cells in the blood and spleen after blocking PD-L1.

Research results

PD-L1 inhibition reduced the promoting effects of *B. infantis* on intestinal PD-1, Foxp3, IL-10, and TGF-β 1. The promoting effect of *B. infantis* on the differentiation of CD4$^+$, CD25$^+$, and Foxp3$^+$ cells was also reduced.

Research conclusions

B. infantis mediates Foxp3 expression through the PD-1/PD-L1 pathway, thereby promoting Treg differentiation and improving IL-10 and TGF-β1 expression to reduce the immune and inflammatory response in IBD. *B. infantis* may act as a therapeutic agent for IBD.

Research perspectives

To explore the mechanism of action of *B. infantis* in the treatment of IBD at the cellular level. Further experiments are essential to determine whether *B. infantis* inhibits the immune response through the PD-1/PD-L1 pathway in the patients with IBD.

Abstract

BACKGROUND

Parathyroid hormone-related peptide (PTHrP) plays a key role in the development and progression of many tumors. We found that in colorectal cancer (CRC) HCT116 cells, the binding of PTHrP to its receptor PTHR type 1 (PTHR1) activates events associated with an aggressive phenotype. In HCT116 cell xenografts, PTHrP modulates the expression of molecular markers linked to tumor progression. Empirical evidence suggests that the Met receptor is involved in the development and evolution of CRC. Based on these data, we hypothesized that the signaling pathway trigged by PTHrP could be involved in the transactivation of Met and consequently in the aggressive behavior of CRC cells.

AIM

To elucidate the relationship among PTHR1, PTHrP, and Met in CRC models.

METHODS

For *in vitro* assays, HCT116 and Caco-2 cells derived from human CRC were incubated in the absence or presence of PTHrP (1-34) (10^{-8} M). Where indicated, cells were pre-incubated with specific kinase inhibitors or dimethylsulfoxide, the vehicle of the inhibitors. The protein levels were evaluated by Western blot technique. Real-time polymerase chain reaction (RT-qPCR) was carried out to determine the changes in gene expression. Wound healing assay and morpho-

logical monitoring were performed to evaluate cell migration and changes related to the epithelial-mesenchymal transition (EMT), respectively. The number of viable HCT116 cells was counted by trypan blue dye exclusion test to evaluate the effects of irinotecan (CPT-11), oxaliplatin (OXA), or doxorubicin (DOXO) with or without PTHrP. For *in vivo* tests, HCT116 cell xenografts on 6-wk-old male N:NIH (S)_nu mice received daily intratumoral injections of PTHrP (40 μg/kg) in 100 μL phosphate-buffered saline (PBS) or the vehicle (PBS) as a control during 20 d. Humanitarian slaughter was carried out and the tumors were removed, weighed, and fixed in a 4% formaldehyde solution for subsequent treatment by immunoassays. To evaluate the expression of molecular markers in human tumor samples, we studied 23 specimens obtained from CRC patients which were treated at the Hospital Interzonal de Graves y Agudos Dr. José Penna (Bahía Blanca, Buenos Aires, Argentina) and the Hospital Provincial de Neuquén (Neuquén, Neuquén, Argentina) from January 1990 to December 2007. Seven cases with normal colorectal tissues were assigned to the control group. Tumor tissue samples and clinical histories of patients were analyzed. Paraffin-embedded blocks from primary tumors were reviewed by hematoxylin-eosin staining technique; subsequently, representative histological samples were selected from each patient. From each paraffin block, tumor sections were stained for immunohistochemical detection. The statistical significance of differences was analyzed using proper statistical analysis. The results were considered statistically significant at $P < 0.05$.

RESULTS

By Western blot analysis and using total Met antibody, we found that PTHrP regulated Met expression in HCT116 cells but not in Caco-2 cells. In HCT116 cells, Met protein levels increased at 30 min ($P < 0.01$) and at 20 h ($P < 0.01$) whereas the levels diminished at 3 min ($P < 0.05$), 10 min ($P < 0.01$), and 1 h to 5 h ($P < 0.01$) of PTHrP treatment. Using an active Met antibody, we found that where the protein levels of total Met decreased (3 min, 10 min, and 60 min of PTHrP exposure), the status of phosphorylated/activated Met increased ($P < 0.01$) at the same time, suggesting that Met undergoes proteasomal degradation after its phosphorylation/activation by PTHrP. The increment of its protein level after these decreases (at 30 min and 20 h) suggests a modulation of Met expression by PTHrP in order to improve Met levels and this idea is supported by our observation that the cytokine increased *Met* mRNA levels at least at 15 min in HCT116 cells as revealed by RT-qPCR analysis ($P < 0.05$). We then proceeded to evaluate the signaling pathways that mediate the phosphorylation/ activation of Met induced by PTHrP in HCT116 cells. By Western blot technique, we observed that PP1, a specific inhibitor of the activation of the proto-oncogene protein tyrosine kinase Src, blocked the effect of PTHrP on Met phosphorylation ($P < 0.05$). Furthermore, the selective inhibition of the ERK 1/2 mitogen-activated protein kinase (ERK 1/2 MAPK) using PD98059 and the p38 MAPK using SB203580 diminished the effect of PTHrP on Met phosphorylation/activation ($P < 0.05$). Using SU11274, the specific inhibitor of Met activation, and trypan blue dye exclusion test, Western blot, wound healing assay, and morphological analysis with a microscope, we observed the reversal of cell events induced by PTHrP such as cell proliferation ($P < 0.05$), migration ($P < 0.05$), and the EMT program ($P < 0.01$) in HCT116 cells. Also, PTHrP favored the chemoresistance to CPT-11 ($P < 0.001$), OXA ($P < 0.01$), and DOXO ($P < 0.01$) through the Met pathway. Taken together, these findings suggest that Met activated by PTHrP participates in events associated with the aggressive phenotype of CRC cells. By immunohistochemical analysis, we found that PTHrP in HCT116 cell xenografts enhanced the protein expression of Met (0.190 ± 0.014) compared to tumors from control mice (0.110 ± 0.012; $P < 0.05$) and of its own receptor (2.27 ± 0.20) compared to tumors from control mice (1.98 ± 0.14; $P < 0.01$). Finally, assuming that the changes in the expression of PTHrP and its receptor are directly correlated, we investigated the expression of both Met and PTHR1 in biopsies of CRC patients by immunohistochemical analysis. Comparing histologically differentiated tumors with respect to those less differentiated, we found that the labeling intensity for Met and PTHR1 increased and diminished in a gradual manner, respectively ($P < 0.05$).

CONCLUSION

PTHrP acts through the Met pathway in CRC cells and regulates Met expression in a CRC animal model. More basic and clinical studies are needed to further evaluate the PTHrP/Met relationship.

Key Words: PTHrP; MET receptor tyrosine kinase; Parathyroid hormone receptor type 1; Colorectal cancer; Drug resistance

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Colorectal cancer (CRC) is one of the leading causes of cancer death, and chemoresistance is common in the treatment of CRC patients. Parathyroid hormone-related peptide (PTHrP) and the receptor tyrosine kinase Met are involved in the aggressive behavior of CRC cells. However, to date it is unknown whether PTHrP and Met are related to promoting events associated with the progression and chemoresistance of CRC. Herein we showed, for the first time, a PTHrP/Met axis that could have a positive impact on the knowledge of CRC biology and on the development of new targeted therapies.

INTRODUCTION

Colorectal cancer (CRC) is one of the most frequent tumors of the digestive system and represents the third type of cancer with the highest incidence worldwide[1]. According to statistics, the development of metastasis and resistance to chemotherapeutic drugs causes 90% of deaths in patients with CRC[2]. Although treatment strategies have been improved in the past years, the mortality associated with this oncological disease is still around 50%[1,3]. In this line, the World Cancer Research Fund International indicates that CRC incidence is still increasing and that its prevalence is expected to augment by 60% in the next few years[4]. This is mainly due to the emergence of CRC patients under 50 years old and the appearance of new tumors subtypes that have a refractory response to the usual therapy[5]. Currently, two of the chemotherapeutic agents approved as first and second-line palliative drugs in CRC are oxaliplatin (OXA) and irinotecan (CPT-11)[6,7]. However, more than half of patients with stage II/III disease who underwent surgery and were treated with these drugs relapsed and died[8]. Thus, all these facts evidence an urgent need to elucidate the molecular mechanisms associated with two key aspects of therapy: Effectiveness and resistance.

Parathyroid hormone-related peptide (PTHrP) is a cytokine-like protein that is normally produced in many adult and fetal tissues[9,10]. The N-terminal 13 amino acid residues of PTHrP exhibit high structural homology with the PTH[11]. This allows the binding of both ligands to the same G-protein-coupled receptor, PTH/PTHrP type 1 (PTHR1)[12,13]. It is known that PTHrP and its receptor are expressed in the same cells or neighboring cells. This juxtaposition is directly related to its activity as an autocrine and paracrine factor[14,15].

Regarding the expression of this protein in neoplastic disease, studies in patients show its overexpression in tissues of breast, prostate, lung, and colon cancers[16,17]. Moreover, 95% of colorectal adenocarcinomas have elevated expression of this protein[18-20]. Although PTHrP was initially identified as a major contributor to hypercalcemia in paraneoplastic syndromes, it is known that this peptide also plays a key role in the development and progression of many tumors [10,16,21-23]. In this concern, in CRC-derived cells we found that PTHrP stimulated cell proliferation, survival, and migration, the epithelial-mesenchymal transition (EMT), the release of pro-angiogenic factors, and the resistance to CPT-11[13,24-26]. In xenografts of CRC cells, we have observed that PTHrP also modulates the expression of molecular markers linked to tumor progression[24-27]. Despite these contributions, relevant aspects from the action of this peptide are still unknown, specifically, whether PTHrP could promote resistance to other forms of chemotherapy and the validation of our previous observations using human samples.

Met is a receptor with tyrosine kinase (RTK) activity, and it is expressed in normal tissues and participates in various physiological processes such as embryonic development and wound repair[28]. Only hepatocyte growth factor (HGF) is known as a necessary ligand for its activation. However, cross-communications between this RTK and G-protein-coupled receptors were reported to promote its aberrant activation[29-31]. Met overexpression or its dysregulation can lead to malignant cell transformation and contributes to the development and progression of different types of cancer including colorectal tumors[28,32-35]. Moreover, Met dysregulation is also associated with drug resistance in colon cancer cells[32,35,36]. Several studies demonstrated the overexpression of this RTK in tumor tissue of CRC patients; in this regard, its inhibition is being widely investigated as a complementary treatment to usual therapies[37,38]. Despite this, the value of Met as a prognostic marker or in treatment strategies has not been established yet.

Although empirical evidence suggests that Met and PTHrP play a key role in the development and evolution of CRC, it is still unknown whether PTHrP and Met act cooperatively to promote events associated with the progression and chemoresistance in CRC. Based on our previous studies, we hypothesized that the signaling pathway trigged by PTHR1 after binding to PTHrP could be involved in

the transactivation of the RTK Met and consequently in the aggressive behavior of CRC cells. For this reason, the present work aimed to elucidate the relationship among PTHR1, PTHrP, and Met.

MATERIALS AND METHODS

Reagents and antibodies

Human PTHrP (1-34) and trypan blue dye were obtained from Sigma-Aldrich Chemical Co (St. Louis, MO, United States). Antibodies were purchased from the following sources: Anti-Met and anti-phospho Met (Tyr 1234/1235) and anti-E-cadherin were provided by Cell Signaling Technology (Beverly, MA, United States); anti-PTH/PTHrP receptor type 1, anti-GAPDH, goat anti-rabbit peroxidase conjugated secondary antibody, and goat anti-mouse peroxidase conjugated secondary antibody were from Santa Cruz Biotechnology (Santa Cruz, CA, United States). PD98059, SB203580, and PP1 were obtained from Calbiochem (San Diego, CA, United States) and SU11274 from Sigma-Aldrich Chemical Co. RNase CocktailTM Enzime Mix was from Applied Biosystems (Carlsbad, CA, United States). Protein size markers were from Amersham Biosciences (Piscataway, NJ, United States). Immobilonpolyvinylidene difluoride (PVDF) membranes and electrochemiluminescence (ECL) detection kit were from Amersham (Little Chalfont, Buckinghamshire, England). The chemotherapeutic drugs CPT-11, OXA, and doxorubicin (DOXO) were generously provided by Dr. Ariel Zwenger.

Cell culture and treatment

Human colon cancer cells Caco-2 and HCT116 (American Type Culture Collection, Manassas, VA, United States) were grown at 37 °C in an atmosphere containing 5.5% CO_2 in Dulbecco's Modified Eagle Culture Medium (DMEM) containing 10% heat-inactivated and irradiated fetal bovine serum (FBS), 1% non-essential amino acids, penicillin (100 IU/mL), streptomycin (100 mg/mL), and gentamicin (50 mg/mL). The cells were cultured until reaching 80% confluence and then they were deprived of FBS for 2 h. Treatments were performed by incubating cells with 2.5% FBS-DMEM in the absence or presence of PTHrP (1-34) (10^{-8} M) at different times. This dose was selected based on previous studies[39,40]. Where indicated, cells were pre-incubated for 30 min with PD-98059 (20 μM), an inhibitor of the mitogen-activated protein kinase (MAPK) kinases (MEKs), the upstream kinases of ERK1/2; SB203580 (20 μM), an inhibitor of p38 MAPK; PP1 (10 μM), an inhibitor of Src; or SU11274 (0.5 μM), a Met inhibitor. In previous works, we confirmed the effectiveness of the inhibitors PD98059, SB203580, and PP1[26,27], whereas SU11274 dose was chosen in accordance with the literature[41]. Controls were run by the addition of an equivalent volume of dimethylsulfoxide (DMSO), the vehicle of the inhibitors.

Western blot analysis

Cells were washed with phosphate buffered saline (PBS) with 25 mmol/L NaF and 1 mmol/L Na_3VO_4 and lysed in buffer containing 50 mmol/L Tris-HCl (pH 7.4), 150 mmol/L NaCl, 3 mmol/L KCl, 1 mmol/L ethylenediaminetetraacetic acid (EDTA), 1% Tween 20, 1% Nonidet P-40, 20 μg/mL aprotinin, 20 μg/mL leupeptin, 1 mmol/L phenylmethylsulfonyl fluoride (PMSF), 25 mmol/L NaF, and 1 mmol/L Na_3VO_4. Lysates were vortexed for 45 s, incubated on ice for 10 min, and then centrifuged at 14000 *g* and 4 °C for 15 min. The supernatant was collected and protein quantification was performed by the Bradford method[42]. The proteins present in the samples were separated (30 μg/lane) using sodium dodecyl sulfate (SDS)-polyacrylamide gels (8%-10% acrylamide) and electrotransferred to hydrophilic polyvinylidene fluoride (PVDF) membranes. The membranes were blocked with 5% skim milk in Tris buffered saline-Tween (TBS-T) buffer (50 mmol/L Tris, pH 7.2-7.4, 200 mmol/L NaCl, 0.1% Tween-20), and then incubated overnight with the appropriate dilution of primary antibody (Met #8198 1:3000, p-Met #3077 1:500, E-cadherin #3195 1:1000; GAPDH sc-32233 1:5000) in TBS-T with 2.5% bovine serum albumin. After washing, the membranes were incubated with the appropriate dilution of horseradish peroxidase conjugated secondary antibody in TBS-T with 2.5% skim milk. Finally, proteins were revealed using a commercial electrochemiluminescence kit, and the bands obtained were digitized densitometrically and quantified with Image J program.

Stripping and reprobing membranes

To remove primary and secondary antibodies, membranes were incubated in stripping buffer (62.5 mmol/LTris-HCl pH 6.8, 2% SDS, and 50 mmol/L β-mercaptoethanol) at 55 °C for 30 min in agitation, washed for 10 min in TBS-T (1% Tween-20), and then blocked, as indicated above. After this procedure, it is possible to re-test antibodies in the membranes.

RNA isolation and cDNA synthesis

HCT116 cells were incubated in serum-free DMEM for 2 h and then treated with or without PTHrP (10^{-8} mol/L, in DMEM 2.5% FBS) for 15 min. Total RNA from all samples was isolated using the High Pure RNA Isolation Kit (Roche Diagnostics, Mannheim, Germany) according to the manufacturer's instructions. Total RNA (1 g) from each sample was used for first-strand cDNA synthesis using High

Capacity cDNA Reverse Transcription Kits following the manufacturer's instructions (Applied Biosystems, United States). The cDNA product was quantified and then stored at -20 °C for real-time polymerase chain reaction (RT-qPCR).

RT-qPCR

PCR reactions were carried out on a real-time PCR system (Applied Biosystems, model 7500). The primers used are the following: 5'-GGAAACACCCATCCAGAATGTCATT-3' (forward) and 5'-TGATATCGAATGCAATGGATGATCT-3' (reverse) for *Met*; 5'-ACCACAGTCCATGCCATCA-3' (forward) and 5'-TCCACCACCCTGTTGCTGTA-3' (reverse) for *GAPDH*. The PCR reactions were prepared using SYBR green master mix (No. 4309159, Applied Biosystems). On ice, the following was added: 5 μL of 2 × SYBR green, 0.8 μL of forward primer (400 nmol/L), 0.8 μL of reverse primer (400 nmol/L), 2 μL of template cDNA (12 ng), and 1.4 μL of Milli Q sterile water. *GAPDH* cDNA was amplified in parallel for all genes to provide an appropriate internal PCR control. For each experiment, water was added as a sample without a template (negative control). Mean Ct of the gene of interest (Met) was calculated from triplicate measurements using the following equation: Ct =Ct of the gene of interest -Ct of *GAPDH*. mRNA levels were calculated by the $2^{-\Delta CT}$ method.

Wound healing assay and morphological monitoring

Once confluence was reached, a cross-shaped wound was made manually in the cell monolayer with a tip and two washes were performed with sterile 1 × PBS to remove debris from the procedure. Then, the treatments were performed in DMEM without FBS as detailed above. Finally, the wounds were visualized under an inverted microscope and each of them was photographed at 0 h, 5 h, and 24 h, where the same fields were photographed. For each condition, the closure of the wound concerning the control was analyzed using ImageJ-NIH program, which allows for quantifying the area that remains cell-free.

To evaluate morphological changes potentially associated with the EMT, cells were treated with PTHrP as detailed above and the same fields were observed with a microscope and photographed during the times when significant molecular changes were observed.

Measurements of drug effects of chemotherapeutics

CPT-11, OXA, and DOXO cytotoxicities were assessed by trypan blue dye exclusion test. HCT116 cells were seeded in a 24-well plate until 80% confluence and then treated with or without PTHrP 10^{-8} M and/or CPT-11(10 μM)/OXA (10 μM)/DOXO (5 μM) in triplicate for 24 h. The doses of these drugs were chosen according to previous works[26,43-45]. Where indicated, HCT116 cells were pre-incubated with SU11274 (0.5 μM)[41] or DMSO, the vehicle of the inhibitor. After the treatment, cells were washed with PBS and then incubated with trypsin-EDTA to separate them from the culture substrate. The cell suspension was diluted in equal volume with trypan blue stain (1:1). The number of cells per field was counted in a Neubauer chamber; cells that exclude the dye were considered viable cells. The number of viable cells was calculated according to the following formula: Total number of viable cells = average number of viable cells × dilution factor × 10^4[46].

Xenograft in nude mice

Xenografts on 6-wk old male N:NIH (S)_nu mice (body weight 20-25 g) were generated through a subcutaneous injection of 1 × 10^6 HCT116 cells in their left dorsal flanks[47]. Four days after this procedure, the animals were randomly separated into treated and control groups (n = 6/group). Mice received a daily intratumoral injection of PTHrP (40 μg/kg) in 100 μL PBS, or PBS as a control. This manner of administration was in order to keep the compound level constant in the tumor area. The dose of PTHrP was selected according to previous studies performed by us and by other investigators with PTH and/or PTHrP in rodents[27,48-50]. Throughout the experiment, animals were kept under strict sanitary barriers in insulated cabins and had access to sterilized food and water *ad libitum*. Besides, they were exposed to 12 h cycles of light and darkness (200 Lux/1 m from the floor), atmospheric pressure, 25 °C, and humidity of 40%-60%. Humanitarian slaughter was carried out after 20 d of treatment by inhalation of the chemical agent CO_2. The tumors were removed, weighed, and fixed in a 4% formaldehyde solution and included in a paraffin block for subsequent treatment in immunoassays. At the end of the trial, the average weights were 0.30 g ± 0.11 g (standard deviation) and 0.40 g ± 0.10 g for control tumors and treated tumors, respectively. Whereas the average volumes were 0.21 mm^3 ± 0.08 mm^3 (standard deviation) and 0.26 mm^3 ± 0.08 mm^3 for control tumors and treated tumors, respectively. The present animal protocol was approved by the Institutional Committee for the Care and Use of Experimental Animals from the Universidad Nacional del Sur (CICUAE-UNS, institutional endorsement updated to 2021) and it was executed in accordance with the National Institutes of Health guide for the care and use of laboratory animals (NIH 1996) in order to minimize pain or discomfort for the animals.

Patients and clinical specimens

The following research protocol (File number 8610-017183/2018, Registry of Investigations in Health (RIS) number N° 11.00.18) has the endorsement of the Advisory Commission on Biomedical Research in

Beings Human Rights (CAIBSH) and the approval of the Health Ministry of the Province of Neuquén, Argentina (provision 0088-18-1-19) and was authorized by the Ethical Committee of the Hospital Interzonal de Graves y Agudos Dr. José Penna, Buenos Aires, Argentina in accordance with article 23 of Law 11044 of the Ministry of Health and the Central Research Ethics Committee (CECI) on research with biological samples from Argentina.

We performed an analysis of specimens obtained from patients with colorectal adenocarcinoma which were admitted to the Hospital Interzonal de Graves y Agudos Dr. José Penna (Bahía Blanca, Buenos Aires, Argentina) and the Hospital Provincial de Neuquén (Neuquén, Neuquén, Argentina) from January 1990 to December 2007. Normal colorectal tissue samples were assigned to a control group. The medical record of each patient was analyzed for the information as follows: Sex; age; primary tumor location; histological grade; and initial stage (according to the TNM staging system issued by the American Joint Committee on Cancer-AJCC and International Union for Cancer Control-UICC). The exclusion criteria were: Patients under 18 years of age due to the low prevalence of this cancer in the child and youth population[51]; pregnant patients due to the fact that high levels of PTHrP have been observed in the placenta and fetal tissues[52]; lactating patients because high levels of PTHrP have been detected in breast tissue and in breast milk and correlate with serum PTHrP levels in these women[53]; patients who have previously developed other types of tumors (liver, lung, and bone) since CRC commonly metastasizes to these sites. These considerations are necessary to exclude cases where the cytokine derived from other tissues may interfere with the analysis of the results from this study. All are exclusion criteria at the time of diagnosis. The confidentiality criteria were based on the regulatory provisions referring to confidentiality in clinical investigations, including Law 11044 and Law 25326 on data protection, from Argentina, the Guide for Health Research of the National Ministry of Health, the UNESCO Declaration on the Protection of Genetic Data and the Declaration of Helsinki of the World Medical Association (version 2008), and the Council for International Organizations of Medical Sciences (CIOMS) Guidelines. This study respected the dignity and rights of the patients. All data derived from the clinical history was treated under strict confidentiality to protect and preserve the patient's identities.

Paraffin-embedded archival blocks from primary tumors were reviewed by hematoxylin-eosin staining technique; subsequently, representative histological samples of each patient were selected for immunoassays.

Immunohistochemistry

From each paraffin block, tumor sections were sliced and prepared for immunohistochemical detection using the primary monoclonal antibody anti-Met (#8198, 1:2000) or anti-PTHR1 antibody (sc-12722-3D1.1, 1:50) according to the manufacturer's protocol. The sections were deparaffinized with xylol for 15 min and subsequently rehydrated in decreasing concentrations of alcohol. Antigenic retrieval was carried out using a pressure cooker with sodium citrate buffer (10 mmol/L, pH 6) for 15 min at 1 atm. The sections were washed twice with PBS and we proceeded to block endogenous peroxidase with 30% $H_2O_2$for 10 min. After two washes with PBS, the corresponding antibody was added to each sample and incubated overnight at 4 °C. Immunohistochemical staining was carried out manually using ABCAM Detection IHC Kit (Abcam, Cambridge, MA, United States) according to the manufacturer's instructions. The images obtained under an optical microscope were analyzed using an open-source image processing package based on ImageJ-NIH program[54,55].

Statistical analysis

To obtain statistical data, three experiments were carried out independently and the results are expressed as the mean ± SD. To determine significant differences between two groups of data, Student's *t*-test (two-tailed, equal variance) was carried out. A P value < 0.05 was considered statistically significant.

For the statistical analysis of human tumor samples, the correlation coefficient between the expression of Met and PTHR1 was evaluated by the Spearman test. Then, the patients were grouped according to clinicopathological characteristics such as age, sex, TNM stage (II, III, and IV), location of the primary tumor (right colon, left colon, and rectum), and histological grade (G1, G2, and G3). The Fisher's exact test was used to evaluate the association of Met or PTHR1 expression with each variable. These statistical analyses were performed using the R programming language version 4.1.1[56]. A P value < 0.05 was considered statistically significant.

RESULTS

PTHrP modulates the expression of the RTK Met in human HCT116 cells

Met is a heterodimeric receptor that is composed of two chains, alpha and beta. Initially, this RTK is synthesized as a single-chain precursor (pro-Met), and it then undergoes posttranslational modifications to produce the mature form[57]. The binding of the HGF to the beta subunit of Met induces its dimerization and the phosphorylation of tyrosine domains in the intracellular portion of the receptor

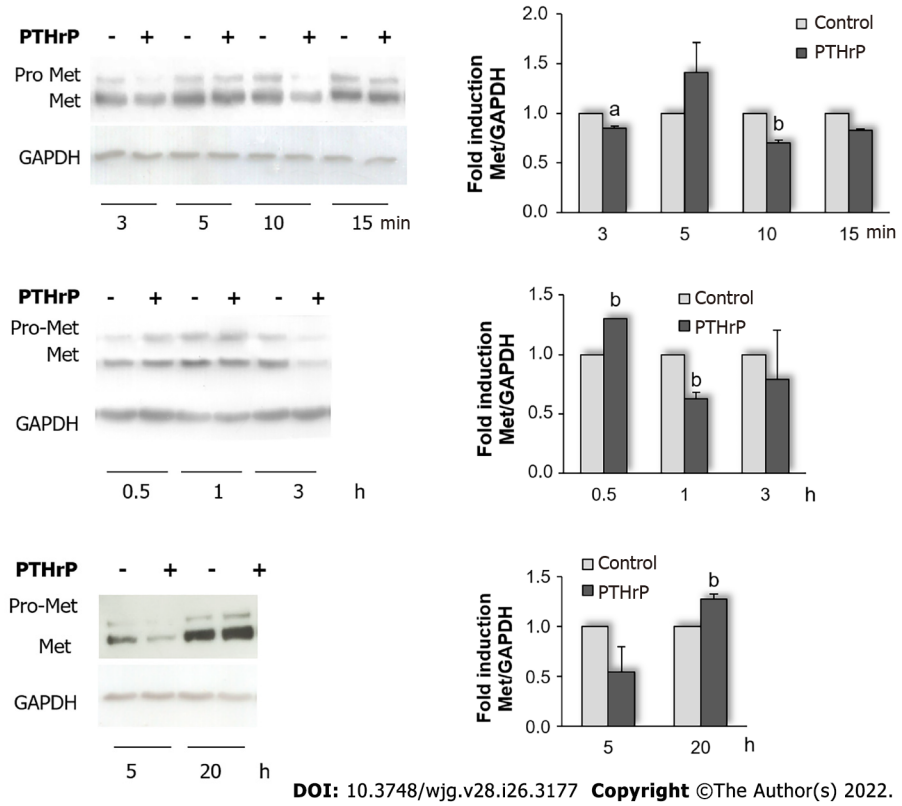
(Y1234 and Y1235). These events promote the kinase activity of Met and its autophosphorylation (Y1349 and Y1356). Then, various proteins are recruited to these phosphorylated sites, triggering different signaling pathways[33,58].

In CRC cells, Met signaling is activated by various mechanisms to promote tumor development and progression[28,59]. Gene amplification or mutations (that lead to receptor overexpression) and increased activity due to ligand-mediated stimulation induce the aberrant activation of Met[28]. As mentioned earlier, another mechanism that favors its abnormal activation involves the phosphorylation in Met activator domains and is indirectly due to the previous activation of cell-surface receptors like G-protein-coupled receptors[29,31].

In the past years, several authors have reported a correlation between the overexpression of PTHrP and tumor progression in lung, breast, and prostate cancers[16,21,60]. Our research group has shown that this cytokine also promotes the aggressive phenotype of intestinal tumor cells[13,24-26]. This pro-tumor factor exerts its action on CRC cells through several mitogenic signaling pathways[13]. In view of this background, in this work we decided to investigate whether the molecular mechanisms trigged by PTHR1 after binding of PTHrP are capable of modulating the expression of the mature form of the RTK Met and/or its activation in CRC-derived cells. To that end, we initially treated Caco-2 cells and HCT116 cells with PTHrP for different times and then the cell lysates were immunoblotted with an anti-Met antibody. We selected these cell lines from CRC with different aggressive phenotypes because both express the receptor PTHR1 and we had previously verified that their cell responses are mediated exclusively by this receptor[26,40,61]. Met did not change its protein expression when Caco-2 cells were treated with PTHrP over a wide interval of exposure times (data not shown). However, the response of the HCT116 cell line, which is more aggressive than Caco-2 cell line, was different. As seen in Figure 1 (top and middle panels), PTHrP treatment for 30 min increased Met protein levels. However, the protein expression diminished at 3 min and 10 min, and at 1 h to 3 h of exposure to the peptide. Figure 1 (lower panel) shows that at 5 h of treatment, Met protein levels continued to decrease. However, PTHrP increased Met protein expression at 20 h of treatment.

As it happens with other RTKs on the cell surface, after its phosphorylation/activation, Met is internalized with the subsequent decrease in its protein levels due to the proteasomal degradation[62,63]. In this regard, the reduction of Met protein levels observed in HCT116 cells suggested a previous activation of this receptor by PTHrP, and the increment of its protein level after these decreases (at 30 min and 20 h) suggested a modulation of Met expression by PTHrP in order to improve Met levels.

PTHrP promotes Met phosphorylation and activation through Src kinase in human HCT116 cells



Our next goal was to elucidate if the decrease in Met protein levels observed in HCT116 cell line and mediated by exogenous PTHrP could be due to its previous phosphorylation/activation. Thus, we proceeded to evaluate the status of phosphorylated Met under PTHrP action. As shown in Figure 2A, Western blot analysis using a specific antibody that recognizes active Met, revealed that PTHrP treatment for 3 min and 10 min increased the phosphorylation of Met at the residues Tyr 1234 and Tyr 1235. These phosphorylation sites constitute activating domains of the receptor. The decrease in total Met protein levels (showed in Figure 1 and pointed in Figure 2A with arrows) ruled out the possibility that an increase in phosphorylated Met levels at the same time was due to the up-regulation of Met protein expression.

Src is a cytosolic tyrosine kinase deregulated in 80% of CRC patients[64-66]. Previously, we reported the activation of Src in the HCT116 cell line induced by PTHrP at 3 min of treatment[26]. As we mentioned above and taking into account that we observed phosphorylation of Met by PTHrP on specific tyrosine residues that are needed for its activation, we decided to evaluate whether Src is involved in this process induced by the cytokine PTHrP in intestinal tumor cells. For this purpose, the cells were pre-treated with PP1, a specific inhibitor of Src activation, and then with PTHrP for 3 min. As shown in Figure 2B, we observed that PP1 decreased PTHrP-induced phosphorylation of Met at Tyr1234/1235. These findings suggested that in the HCT116 cell line, PTHrP rapidly activate the Src signaling pathway, leading to the phosphorylation and activation of Met.

PTHrP promotes the phosphorylation/activation of Met through the MAPK signaling pathway in human HCT116 cells

It has been described that MAPK signaling pathway activation is very common in CRC and is related to an aggressive phenotype of intestinal tumor cells[67]. Due to its relevance in cancer, in recent decades the possibility of employing MAPK pathway inhibitors has been studied for the treatment of this disease[68,69]. In our laboratory, we found that PTHrP induces the activation of the ERK 1/2 MAPK and p38 MAPK and that the activity of Src converges in the phosphorylation/activation of MAPK in CRC-derived cells [26,27].

Based on our previous results, we next decided to investigate in our model if ERK 1/2 MAPK and p38 MAPK are also involved in the effects of PTHrP on the Met signaling pathway. To that end, the cells were pre-incubated with PD-98059 (a selective inhibitor of MEK, the upstream kinases of ERK 1/2) or with SB-203580 (a specific p38 MAPK inhibitor) and then exposed to PTHrP for 1 h. This time point was selected because the phosphorylation/activation of ERK 1/2 MAPK and p38 MAPK significantly

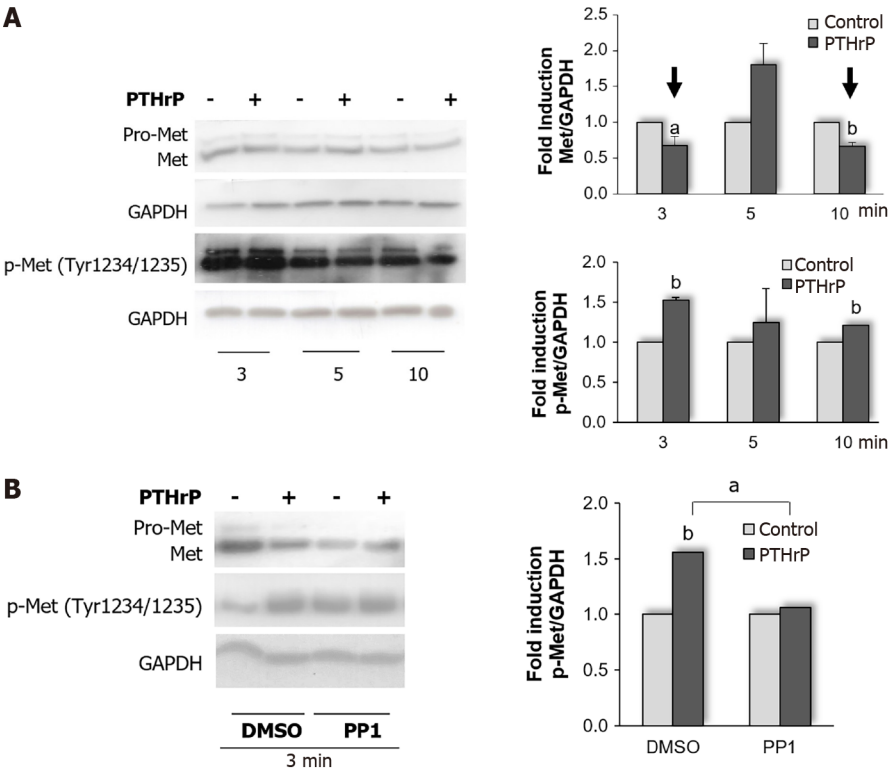
Figure 1 Parathyroid hormone-related peptide modulates the protein expression of Met receptor in HCT116 cells. Cells were treated with or without 10^{-8} mol/L parathyroid hormone-related peptide (PTHrP) for different times. The protein levels of pro-Met (Met precursor) and Met [tyrosine kinase receptor (RTK) mature form] were analyzed by Western blot to investigate whether the molecular mechanisms trigged by PTHR type 1 (PTHR1) after binding of PTHrP are capable of modulating the expression of the mature form of the RTK Met in HCT116 cells. GAPDH protein levels were determined as a control of the amount of proteins present in the membrane, since this protein is not substantially modified with the treatment by the cytokine. Graph bars represent the average of the results obtained from three independent experiments. GAPDH: Glyceraldehyde 3-phosphate dehydrogenase; Met: Receptor tyrosine kinase Met; PTHrP: Parathyroid hormone-related peptide. $^{a}P < 0.05$; $^{b}P < 0.01$.



increased at 60 min after PTHrP treatment in HCT116 cells[26,27]. Regarding the cell response when tumor cells were exposed to PTHrP for 1 h (Figure 1), Figure 3 shows an increase in the phosphorylated Met levels, suggesting that the treatment with the cytokine for 1 h also induces the phosphorylation/activation of Met with the subsequent reduction in its protein levels due to its proteasomal degradation. Moreover, Figure 3 reveals that the selective inhibition of MEK MAPK and p38 MAPK averted the effect on Met phosphorylation, suggesting that Met activation is regulated by the ERK 1/2 MAPK and p38 MAPK signaling pathways in HCT116 cells under PTHrP action.

PTHrP increases Met gene expression in human HCT116 cells

As it was commented earlier, the fact that Met, like other RTKs, undergoes proteasomal degradation after its phosphorylation/activation[62,63] explains that at the same time points of PTHrP exposure (3 min, 10 min, and 60 min), the levels of phosphorylated Met increased while the protein levels of total Met decreased. Furthermore, in this work we elucidated that Met is phosphorylated by PTHrP through the Src and MAPK signaling pathways. In view of the results shown in Figure 1, we selected a time before 30 min with the purpose to evaluate whether the increase in Met protein levels initially observed by PTHrP treatment is related to the modulation of gene expression. By real-time PCR, we analyzed the *Met* mRNA levels and found that PTHrP increased *Met* gene expression at 15 min (Figure 4). This result suggested that in HCT116 cells, PTHrP at least at this time promotes the transcription of the *Met* gene and its translation, correlating with the increase of the protein levels observed at 30 min of PTHrP exposure.

Met signaling pathway induced by PTHrP participates in cell events related to the aggressive behavior of human HCT116 cells

Our studies in CRC cell models have demonstrated that PTHrP favors several events associated with the progression of the disease, such as cell proliferation, migration, and the EMT program[13,24,26,27,39]. Based on these previous findings and since Met is modulated by PTHrP in HCT116 cells, we decided to evaluate whether the Met signaling pathway participates in events induced by the cytokine and associated with an aggressive phenotype of CRC-derived cells. For this purpose, cells were incubated

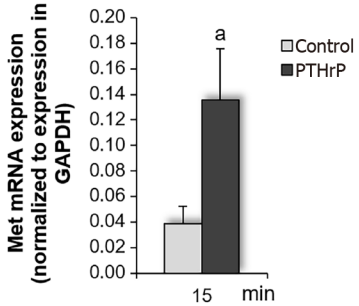
Figure 2 Parathyroid hormone-related peptide increases Met phosphorylation and activation through Src kinase in HCT116 cells. A: Cells were exposed to 10^{-8} mol/L parathyroid hormone-related peptide (PTHrP) 10^{-8} mol/L for 3 min, 5 min, and 10 min. The protein levels of Met and p-Met (phosphorylated in the residues Tyr1234 and Tyr1235) were assessed by Western blot to investigate whether PTHrP is capable of modulating Met phosphorylation and activation in HCT116 cells. Graph bars represent the average of the results obtained from three independent experiments; B: Cells were pre-treated with PP1, a selective Src inhibitor, for 30 min and then exposed to 10^{-8} mol/L PTHrP for 3 min to evaluate whether Src kinase mediates the effect of PTHrP on Met activation in HCT116 cells. Controls were run by adding an equivalent volume of DMSO, the vehicle of the inhibitor. The protein levels of p-Met and Met were evaluated by Western blot. Graph bars represent the average of the results obtained from three independent experiments. In all experiments, GAPDH protein levels were determined as a control of the amount of proteins present in the membrane, since this protein is not substantially modified with the treatment by the cytokine. DMSO: Dimethylsulfoxide; GAPDH: Glyceraldehyde 3-phosphate dehydrogenase; Met: Receptor tyrosine kinase Met; p-Me: Phospho-Met (Tyr1234/1235); PTHrP: Parathyroid hormone-related peptide. $^{a}P < 0.05$; $^{b}P < 0.01$.

with SU11274, an ATP competitive inhibitor of the catalytic activity of the Met kinase[70], followed by the treatment with or without PTHrP for different times, and then we performed different procedures as described below. The times of PTHrP exposure were selected based on our previous findings[24,26,27]. As shown in Figure 5A, PTHrP or PTHrP plus DMSO (the vehicle of the inhibitor) at 24 h increased the number of HCT116 cells. However, the treatment with the Met inhibitor significantly decreased the number of viable cells concerning the control. As the Met signaling pathway is involved in the proliferation and survival of intestinal tumor cells[41,71-73], this descent in the cell viability suggests that both cell responses are affected.



By the wound healing assay, we evaluated whether Met signaling is also involved in the migration of HCT116 cells induced by PTHrP. We observed the wound healing in the culture of confluent HCT116 cells to compare the migration between untreated cells and cells treated with PTHrP in the presence or absence of SU11274. Representative photographs, taken at time points 0 h, 5 h, and 24 h of the identical location and the quantification of the results of two separate experiments are shown in Figure 5B. A significant enhancement in wound closure was detected in cells exposed to PTHrP or PTHrP plus DMSO compared to the control at 5 h and 24 h. However, this effect was not observed in cells that had been pre-treated with the Met inhibitor.

We recently published results revealing that PTHrP is able to induce the EMT in HCT116 cells[24]. The EMT is a key program of CRC that participates in the invasion, angiogenesis, and chemoresistance associated with metastasis[74,75]. Based on this previous work, herein we analyzed if PTHrP also induces this program through the Met pathway. To that end, HCT116 cells were incubated with SU11274 and then treated with or without PTHrP. The cells were observed under an inverted microscope after treatment with PTHrP for 5 h and 24 h to analyze the morphological changes associated with the EMT. The arrows in Figure 5C point to morphological changes corresponding to the transition from a polygonal structure to spindle-like structure in cells treated for 24 h with PTHrP or PTHrP plus DMSO. These findings revealed an effective transition to the mesenchymal phenotype and are consistent with our previous work in HCT116 cells[24]. There were no changes between SU 11274

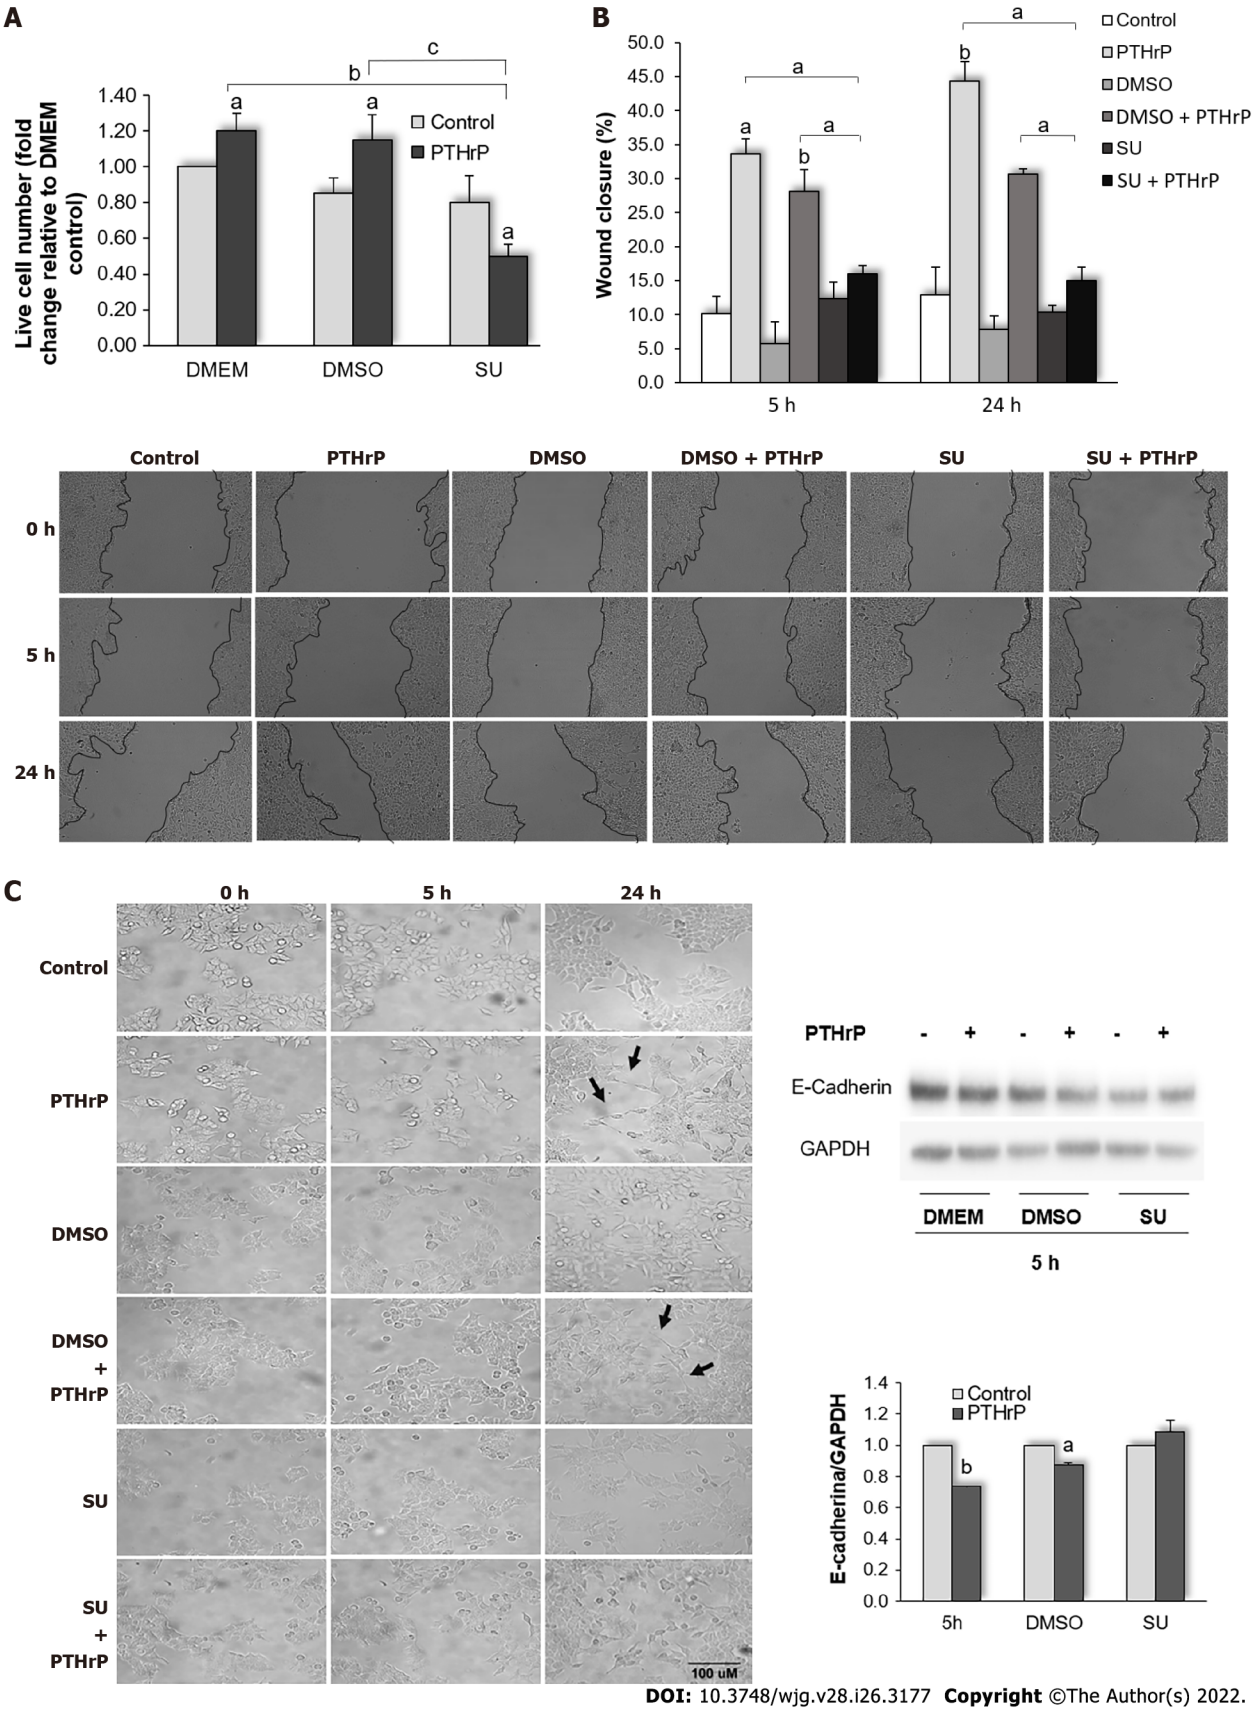
Figure 4 Parathyroid hormone-related peptide increases mRNA levels of *Met* in HCT116 cells. Colon cancer cells were exposed to parathyroid hormone-related peptide (PTHrP) for 15 min, followed by real-time polymerase chain reaction analysis to detect *Met* mRNA levels as described in Materials and Methods to evaluate whether PTHrP modulates *Met* mRNA levels in HCT116 cells. Graph bars represent the average of the results obtained from three independent experiments. GAPDH: Glyceraldehyde 3-phosphate dehydrogenase; Met: Receptor tyrosine kinase Met; PTHrP: Parathyroid hormone-related peptide. $^{a}P < 0.05$.

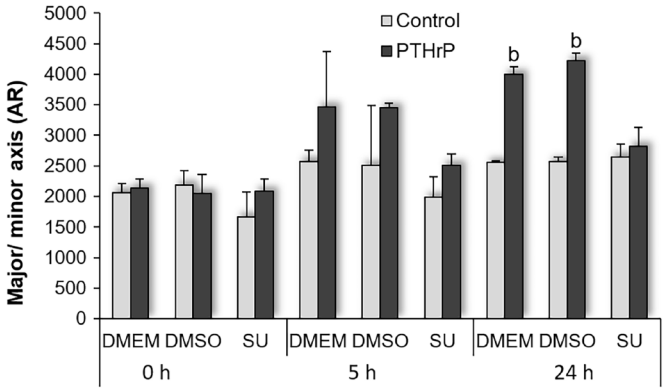


control cells and those treated with the inhibitor of Met plus PTHrP. To further evaluate the phenotype related to a mesenchymal shape, we measured the minor and major axes in the photomicrographs using the Image J-NIH program. Figure 6 reveal that under PTHrP action, the cells lost their epithelial characteristics. The increase of the relation between the major and minor axes indicated that the exposure to PTHrP for 24 h significantly increased the degree of HCT116 cell elongation, a typical feature of the mesenchymal shape. However, when the cells were pre-incubated with SU11274, the effects of the cytokine were reverted.

It has been shown that the loss of the expression of the epithelial marker E-cadherin is associated with EMT progress in CRC[76,77]. In our recent work[24], we showed that in HCT116 cells, PTHrP at 5 h modulated the expression of E-cadherin and other epithelial markers as well as certain mesenchymal markers. Based on these morphological changes related to the EMT and mediated through Met, we then explored by Western blot analysis whether Met is involved in the modulation of E-cadherin protein expression by the cytokine. As seen in Figure 5C, the effects of the cytokine on E-cadherin protein levels were reverted when the cells were pre-incubated with SU11274. Taken together, these findings suggest that PTHrP induces the EMT program in HCT116 cells through the Met signaling pathway.

In agreement with other works published[78], our findings suggest that the Met signaling pathway induced by PTHrP is involved in cell events related to tumor aggressive behavior in the HCT116 cells.

PTHrP attenuates the cytotoxic effect of CPT-11, OXA, and DOXO in human HCT116 cells through the Met signaling pathway



In CRC-derived cells, our group has previously described a role of PTHrP in the resistance to CPT-11, the most widely used chemotherapeutic drug today[26]. In the treatment of CRC, many pharmaco-

Figure 6 Analysis of the aspect ratio (major/minor axis) of HCT116 cells, obtained using the Image J-NIH program. The table shows values of parameters associated to cell morphology: Area; perimeter; round; major axis; minor axis; and aspect radio, relation between major axis and minor axis (AR). Graph bars show the AR for each condition. The increase of the degree of cell elongation at 24 h of exposure to parathyroid hormone-related peptide was significantly reversed in the presence of the Met inhibitor. DMSO: Dimethylsulfoxide; PTHrP: Parathyroid hormone-related peptide; SU: SU11274. [b]*P* < 0.01.

logical strategies have been implemented. OXA is another drug commonly employed for this purpose and it exerts its cytotoxic action through different mechanisms with respect to CPT-11. Thereby, the combination of CPT-11 and OXA is generally used to improve the effectiveness of the adjuvant therapy [79,80]. DOXO is another chemotherapeutic agent that has been effective in the treatment of advanced CRC; however, the side effects associated with its use at high doses and the development of chemores-

istance constitute a great challenge to the effective treatment[43,81,82]. Since the greatest problem in CRC treatment is the development of chemoresistance, we proceeded to evaluate if PTHrP affects the cytotoxicity promoted by these other drugs. Trypan blue dye exclusion test revealed that PTHrP not only decreased the sensitivity of intestinal tumor cells to CPT-11 but also to OXA and DOXO (Figure 7).

Studies carried out by colleagues demonstrated the correlation between overexpression and/or hyper-activation of Met in tumor tissues with a poor prognosis of cancer patients and with a chemoresistant phenotype[32,83,84]. These findings support the interest in Met inhibitors as new therapeutic strategies. Since herein we found that Met inhibition substantially reverts the effects of PTHrP on events associated with the malignant behavior such as cell proliferation, migration, and the EMT program, we set out to assess if the signaling pathway trigged by this RTK also promotes chemoresistance in our experimental system. Counting live cells by means of trypan blue dye exclusion test revealed that Met inhibition restored the sensitivity of HCT116 cells to CPT-11 (Figure 7A), OXA (Figure 7B), and DOXO (Figure 7C) even in the presence of PTHrP, suggesting that this cytokine attenuates the cytotoxic effect of these drugs in CRC cells through the Met signaling pathway.

PTHrP enhances the protein expression of Met and its receptor in HCT116 cells tumor xenografts

In a murine model, we have previously observed that the administration of PTHrP in HCT116 cell xenografts changed the protein expression of markers linked to CRC progression, such as Ki67, cyclin D1, ERK1/2 MAPK, CREB/ATF-1[26], RSK[27], VEGF[25], SPARC, and E-cadherin[24]. As Met overexpression promotes events related to tumor progression like proliferation, invasion, and migration[63,70] and taking into account our previous finding in the animal model, in this work we evaluated whether the administration of PTHrP in the same murine model (HCT116 cell xenografts in nude mice N: NIH(S)_nu) also changes the protein levels of Met in tumor tissues. To that end, 12 male mice, between 4 and 6 wk of age and with a body weight between 20 g and 25 g, were randomly divided into two groups (n = 6 each), after an acclimatization period of 4 d. Group 1 received the cytokine vehicle (100 μL PBS), while group 2 received PTHrP at a concentration of 40 μg/kg body weight in 100 μL PBS[49]. The treatment was intra-tumoral daily and until the end of the experiment to maintain the level of the compound constant in the tumor area. The mice were kept throughout the protocol in sterile conditions (see Materials and Methods). The immunohistochemical analysis with the quantification of Met immunoreactivity revealed that Met levels were elevated in tumors from mice treated with PTHrP (0.190 ± 0.014) compared to tumors from control mice (0.110 ± 0.012; $P < 0.05$) (Figure 8, top images). As the present work was aimed to elucidate the relationship between PTHR1, PTHrP, and Met, we also analyzed the immunoreactivity of PTHR1 using an anti-PTHR1 antibody in HCT116 cell xenografts from untreated nude mice (control) and mice treated with PTHrP. Interestingly, as seen in Figure 8 (lower images), PTHrP increased the protein expression of its receptor in the tumor of these animals (2.27 ± 0.20) compared to tumors from control mice (1.98 ± 0.14; $P < 0.01$). The data shown in this section together with those in the first and fourth sections of results indicate that PTHrP modulates the expression of Met both *in vitro* and *in vivo*. Perhaps the cytokine modulates the expression of its own receptor in this animal model in order to amplify its signaling within the cell and thus makes its effects more effective in CRC. More studies are necessary to confirm this hypothesis.

Evaluation of Met and PTHR1 expressions in CRC human samples

As we mentioned before, the Met receptor has the HGF as its only known ligand. However, it could be aberrantly activated by G-protein-coupled receptors[29,31]. The results reported herein in the previous sections suggest that PTHR1 activation (after its binding with PTHrP) is able to trigger the activation of the Met signaling pathway through a cross-talk between both receptors that is mediated by cytosolic kinases like Src. In this context, and taking into account the findings obtained by *in vitro* and *in vivo* assays, we decided to validate our observations and therefore our ultimate objective was to assess the expression of both receptors in CRC human tumor samples with the aim to elucidate if there is a relation between them and with the tumor characteristics. So, we analyzed 23 specimens obtained from patients with colorectal adenocarcinoma. Seven cases with normal colorectal tissues were assigned to the control group. Table 1 shows the patients' characteristics. The average age was 62 years; 48% (n = 11) were male, and 52% (n = 12) were female. Regarding the primary tumor location, 39% (n = 9) presented right-colon cancer, 30.5% (n = 7) presented left-colon cancer, while in 30.5% (n = 7) of patients the location was in the rectum; 61% (n = 14) of the tumors presented a high grade of histological differentiation, while 39% (n = 9) were moderately or poorly differentiated; 48% (n = 11) of the patients with CRC presented stage II, 39% (n = 9) stage III, and 13% (n = 3) stage IV.

The expression of Met and PTHR1 was evaluated in biopsies of patients with well (G1), moderately (G2), and poorly differentiated (G3) colon adenocarcinomas, as well as in normal colon tissue using the immunohistochemical technique. Figure 9A shows the comparison between both quantifications, Met and PTHR1, for each histological grade of differentiation. As shown in Figure 9B, in normal tissue Met receptor labeling is homogeneous throughout the cytoplasm of the epithelial cell. However, in tumor cells, we observed that the intensity of the immunostaining in the membrane increased as tumor differentiation declined. Concerning PTHR1, the intensity of the staining gradually decreased in histologically less differentiated tumors and the receptor seemed to relocate from the plasma membrane of the epithelial cell in G1 to the cytoplasm and the perinuclear zone in G3. Based on these observations, we

Table 1 Clinicopathological characteristics of the patients

decided to investigate whether there is a correlation between the expression of Met and PTHR1. No statistical significance was found between the expression of both receptors in the tumor samples. Additionally, we studied if there is a statistically significant association between the clinicopathological characteristics and the immunohistochemical staining for Met or PTHR1. For this purpose, we dichotomized the specimens into low, medium, and high expression levels of Met or PTHR1. We found that in less differentiated tumors, Met expression increased (P = 0.035), while PTHR1 expression was statistically lower (P = 0.0496). However, we did not find a statistically significant association of Met or PTHR1 with age, sex, primary tumor location, and TNM stage. These results indicate that the expression of PTHR1 is more marked in well-differentiated tumors, while Met showed a higher expression level in poorly differentiated tumors.

DISCUSSION

Resistance to chemotherapeutic drugs constitutes an obstacle in the therapy of CRC[2]. In this context, it is crucial to identify the molecular mechanisms related to the aggressive phenotype of CRC to develop more effective therapeutic strategies and find new prognostic and predictive markers.

PTHrP is expressed in various types of cancer, including CRC[16]. In fact, 95% of colorectal tumors present elevated levels of this protein[18-20,85]. Our research group found that this cytokine modulates different signaling pathways and events associated with the aggressive phenotype in CRC-derived cells [13,24-26].

Several studies have demonstrated the participation of the Met signaling pathway in the evolution of different types of cancer[28,33-35,83]. Moreover, this receptor is overexpressed and/or can be aberrantly activated by several mechanisms in CRC cells, triggering tumor development and progression[28,36,38,59]. A recent study addresses the relationship between the HGF/Met axis and cytokines such as PTHrP in bone metastasis and renal cell cancer progression[86]. In agreement with these observations, the results from this work suggest that the expression and activity of Met are regulated by signaling pathways trigged by the binding of PTHrP to PTHR1. We observed that exogenous PTHrP treatment modulates Met protein and gene expression in HCT116 cells. Despite that the cytokine regulates Met expression in HCT116 cells, our initial observations in Caco-2 cells reveal that PTHrP is not able to modulate its protein levels. In line with these findings, we previously reported that PTHrP modulates the protein levels of SPARC (an invasion marker) and E-cadherin (a marker related with EMT program) in HCT116 cells but not in Caco-2 cells[24]. The fact that the cytokine can modulate the expression of markers associated with the malignant behavior in a more aggressive cell line (HCT116) but not in a less aggressive cell line (Caco-2) may be because these CRC cells have different mutations[87,88] and

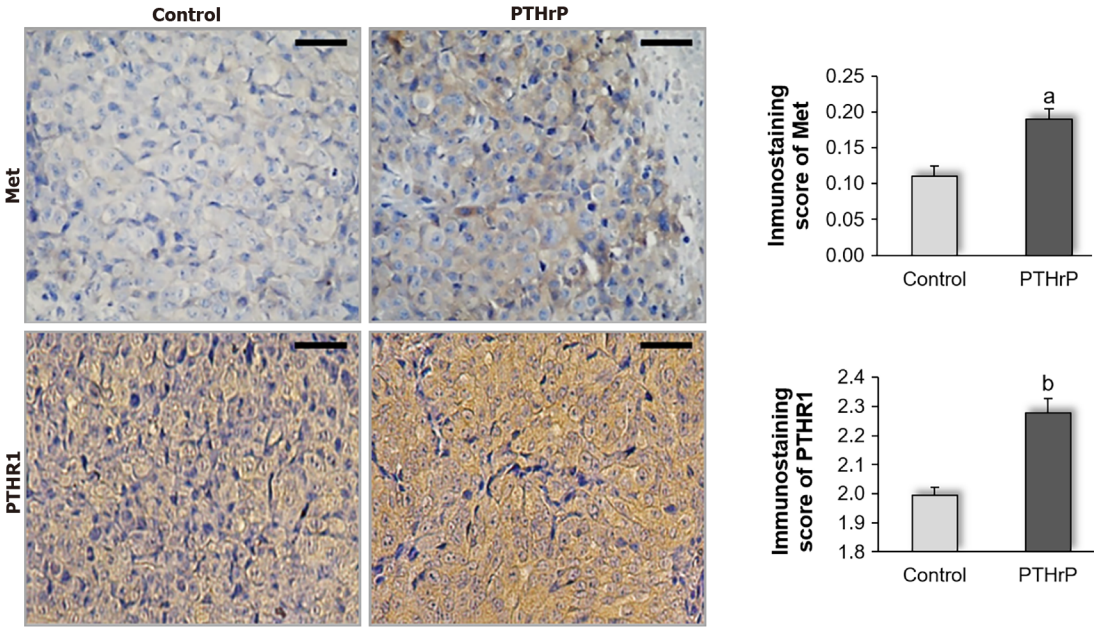
Figure 7 Parathyroid hormone-related peptide attenuates the cytotoxicity of CPT11, oxaliplatin, and doxorubicin through the Met signaling pathway. A-C: HCT116 cells were pre-incubated with SU11274, a specific Met inhibitor, and then treated with PTHrP (10^{-8} M) and/or irinotecan (CPT-11, 10 μM) (A), oxaliplatin (OXA, 10 μM) (B), or doxorubicin (DOXO, 5 μM) (C) for 24 h. The number of viable cells was quantified by Trypan blue technique. In each experiment, a control with DOXO, the vehicle of the inhibitor, was performed. Graph bars represent the average of the results obtained from two independent experiments. CPT-11: Irinotecan; DMSO: Dimethylsulfoxide; DOXO: Doxorubicin; OXA: Oxaliplatin; PTHrP: Parathyroid hormone-related peptide; SU: SU11274. $^{a}P < 0.05$; $^{b}P < 0.01$; $^{c}P < 0.001$.



perhaps several events triggered by PTHrP in these two cell lines may be dependent on these mutations explaining the different response between Caco-2 and HCT116 cells.

We found in HCT116 cells that the peptide promotes the activation of Met by phosphorylation on Tyr residues. Bradley and colleagues and later Critchley and his research group, demonstrated that, like other RTKs, Met after its activation is degraded by the proteasomal pathway[62,63]. Consistent with these data, our results suggest that Met protein levels decline after PTHrP-induced phosphorylation.

Previous studies by our research group established that PTHrP in the HCT116 cell line promotes phosphorylation and activation of Src; then this kinase acts upstream of ERK 1/2 MAPK to induce their phosphorylation/activation, though the mechanisms that lead to the phosphorylation/activation of p38 MAPK by the cytokine is still unknown[13,26]. Herein, we demonstrated that PTHrP induces the phosphorylation and activation of Met through Src. Furthermore, PTHrP modulates the phosphorylation/activation of Met through ERK 1/2 and p38 MAPK. The fact that the cytokine diminishes Met protein levels in a range of time between 1 h to 5 h suggests that Met is activated by PTHrP (with its subsequent degradation) not only by the MAPKs but also by some pathway/s that is/are effector/s of the action of these MAPKs. This idea is supported by our finding that the effects of PTHrP is mediated by these MAPKs in HCT116 cells at longer exposure times[26]. More studies are needed to confirm this hypothesis.

Given these observations, the results obtained in this work suggest that at least the Src-ERK 1/2 MAPK and p38 MAPK axis is required for the phosphorylation/activation of Met induced by PTHrP in our model. Since MAPKs are serine-threonine kinases and Met requires phosphorylation on tyrosine residues for its activation, further studies are necessary to determine the link between these molecules.

As we previously mentioned, in CRC, the Met signaling pathway is associated with tumor evolution and also with resistance to chemotherapeutic drugs[32]. Currently, the inhibition of this RTK is being widely studied as a complementary therapy to conventional CRC treatments[37,38]. SU11274 prevents Met activation because it is an ATP competitive inhibitor of Met catalytic activity[70]. We previously showed that PTHrP has several effects on CRC derived cells such as proliferation, survival, migration, and induction of EMT program, among others[13,26,39]; the fact that we found a significant reduction in the viability and migration of HCT116 cells in the presence of an Met inhibitor as well as the reversal of the mesenchymal phenotype induction, even in the presence of PTHrP, indicates that Met mainly

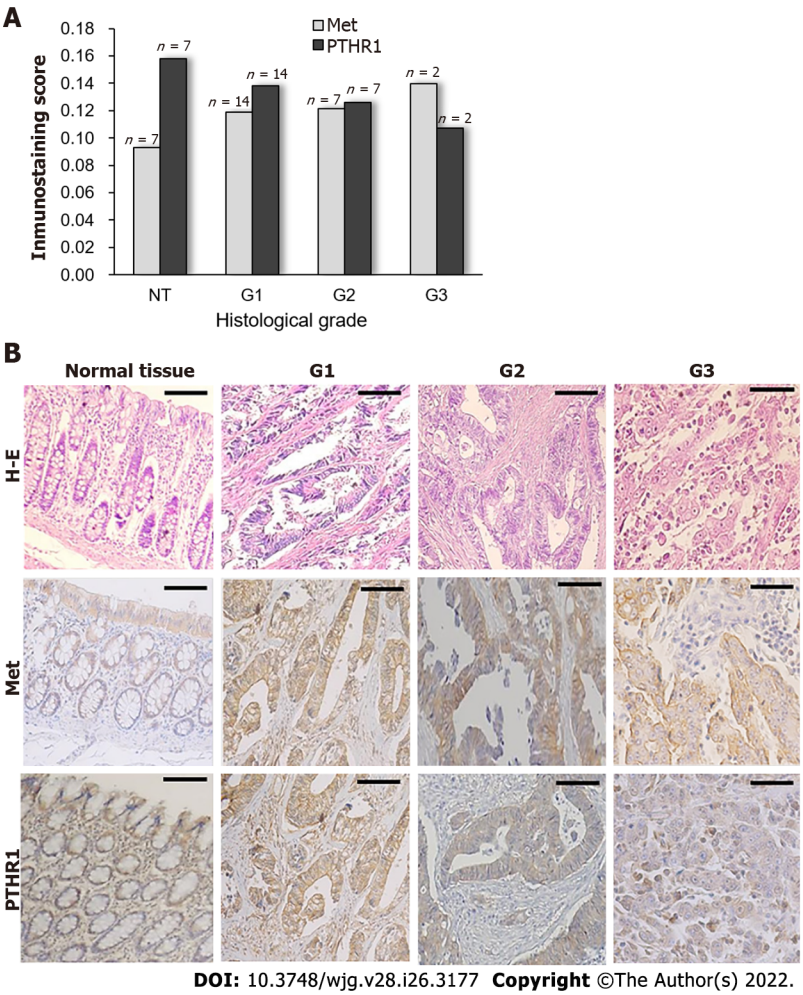
Figure 8 Parathyroid hormone-related peptide increases the protein expression of Met and parathyroid hormone receptor type 1 in tumor xenografts. Met and parathyroid hormone-related peptide receptor type 1 (PTHR1) protein levels were evaluated by the immunohistochemistry technique in the HCT116 cell tumor-bearing nude mouse model. Tumor sections were stained with an anti-Met antibody or anti-PTHR1 antibody. Images (400 ×) are from the tumor treated with saline solution (left) or with PTHrP (right). The immunostaining was quantified with the Fiji image processing package of the Image J-NIH program. Scale bar: 50 μM. Met: Receptor tyrosine kinase Met; PTHR1: Parathyroid hormone receptor type 1; PTHrP: Parathyroid hormone-related peptide. $^{a}P < 0.05$; $^{b}P < 0.01$.

participates in the molecular mechanisms that are involved in these cell responses to PTHrP action.



PTHrP favors the aggressive behavior of CRC cells, inducing other events related to the malignant phenotype such as chemoresistance to CPT-11. The tumor cell response to this drug under PTHrP action involves the ERK signaling pathway[26]. Other investigations carried out by Paillas and colleagues demonstrated that the p38 MAPK pathway also modulates the sensitivity of CRC cells to CPT-11[89]. Given the data obtained previously by us and by other researchers and taking into account the link in CRC between Met signaling and the MAPKs pathway showed in this work and by other authors[41], our next motivation was to further investigate the chemoresistance of CRC-derived cells induced by PTHrP by analyzing two key aspects: Whether the cytokine affects the sensitivity of CRC cells to other chemotherapeutic drugs and whether the Met signaling pathway participates in PTHrP-trigged chemoresistance.

Our work shows that the treatment with this cytokine also attenuates the cytotoxicity induced by OXA and DOXO. This is an interesting result as it indicates that PTHrP promotes resistance to different types of cytotoxic agents. Perhaps the mechanisms trigged by this cytokine alter specific targets or the signaling of these drugs. Tumor cells develop different strategies to avoid chemotherapeutic drug effects. To improve the efficacy of the treatment, combinations of multiple agents are usually used[90]. Given that these drugs present different modes of action, pharmacological doses, and side effects[91-93], in the future it will be necessary to continue this research by testing new drugs and combinations thereof as well as elucidating the specific targets of PTHrP for each one.

Besides, the use of SU11274 together with CPT-11, OXA, or DOXO increases the sensitivity of CRC cells to these drugs, suggesting that Met participates in the chemoresistance induced by PTHrP. The inhibitors of markers/pathways related to cancer progression are still under investigation and like all anti-cancer approaches, their applications have challenges in the therapy of the disease[78,94]. With respect to the inhibition of the Met signaling pathway, a recent publication by Du and colleagues proposes to target the HGF/Met axis as a possible strategy for patients with metastatic CRC[94].

So far, our *in vitro* observations have allowed us to suppose the existence of a mechanism based on the action of PTHrP on the regulation of *Met* gene expression and also on its activation through Src kinase and the MAPKs pathway. Once activated, Met signaling leads to molecular changes in the tumor cell to promote chemoresistance to CPT-11, OXA, and DOXO. Probably, the up-regulation of Met expression also collaborates in the induction of events associated with the aggressive behavior of CRC cells (Figure 10). Besides, our results support those studies that suggest the incorporation of Met inhibitors combined with adjuvant drugs as new therapeutic strategies in CRC treatment and establish the need to further investigate whether PTHrP is a predictive and/or prognostic marker of CRC.

In this work, we also performed *in vivo* assays with the aim to evaluate the effects of PTHrP in a different context for tumor cells. As we expected, in agreement with our *in vitro* observations, HCT116

cell tumor xenografts treated with the peptide exhibited an increase in Met protein expression concerning the control. PTHrP increases the levels of its own receptor, perhaps to amplify its signaling within the cell, and thus makes its effects more effective in CRC. Despite the limitations of the N:NIH (S)_nu model regarding the interaction of tumor cells with the stroma[13,24], these results allow us to presume a relationship between the aberrant expression of Met already observed in the tumor tissue of CRC patients[38] and PTHrP/PTHR1.

As we previously stated, although HGF is the only known ligand capable of inducing Met phosphorylation and activation, studies have shown that the cross-communication with G-coupled protein receptors transactivates this RTK. Concerning this, it was demonstrated that the prostaglandin E2 receptor EP1 can induce an aberrant activation of RTKs like Met in hepatocellular carcinoma cells [30]. Similar results had previously been obtained by Fischer and colleagues in pancreatic and hepatocellular carcinoma cells[29]. As we previously mentioned, PTHrP has intracrine, autocrine, endocrine, and mainly paracrine actions through the binding to a G-coupled protein receptor, PTHR1[9,10]. For this reason, the peptide and its receptor are expressed in the same cells or adjacent cells and changes in their expression are directly correlated[14,15]. Considering the previously described background, we evaluated Met and PTHR1 expression in normal colorectal tissues and in biopsies from patients with colon adenocarcinoma. Although Lee and colleagues did not find a statistical relevance between Met overexpression and the clinicopathological characteristics of patients with CRC, they demonstrated that it is associated with a lower overall survival and progression-free survival[38]. In contrast, Kim and his research group concluded that Met expression in patients with CRC is not a prognostic indicator for overall survival[95]. Despite these data, there was no information about the association between Met and PTHR1 expression and its impact on the evolution of CRC. As we expected, given that both receptors have a physiological role, Met and the PTHrP receptor are expressed in normal colon tissue. We found a statistically significant result when we compared the staining of tumors with high

DOI: 10.3748/wjg.v28.i26.3177 **Copyright** ©The Author(s) 2022.

Figure 10 Possible mechanism based on the action of parathyroid hormone-related peptide in the regulation of Met gene expression and its activation. The binding of parathyroid hormone-related peptide (PTHrP) to PTHR type 1 (PTHR1) in HCT116 cells promotes the up-regulation of *Met* gene expression. PTHrP also induces the activation of Met through Src kinase and the mitogen-activated protein kinases (MAPKs) pathway (Erk 1/2 MAPK and p38 MAPK). Once activated, Met signaling leads to molecular changes in the tumor cell that promote events related to the aggressive behavior of colorectal cancer cells. CRC: Colorectal cancer; Erk 1/2: Extracellular signal-regulated kinases 1/2; Met: Receptor tyrosine kinase Met; P: Activators domains phosphorylated; PTHR1: Parathyroid hormone receptor type 1; PTHrP: Parathyroid hormone-related peptide.

histological differentiation compared to those more undifferentiated with regard to the immunoreactivity for Met and PTHR1 that gradually increase and diminish, respectively.

Interestingly, García and colleagues showed that in neuroblastoma, PTHrP acts as a growth factor promoting tumor progression and high levels of its receptor are associated with less aggressive tumor characteristics; also, the intracrine and paracrine actions of the cytokine promote phenotypes with different levels of aggressiveness in their experimental models. These researchers found that PTHR1 is poorly expressed in neuroblastoma cell lines that are not well differentiated; however, in those cells with a high degree of differentiation, PTHR1 has greater expression. Furthermore, they observed that the receptor knockdown promotes a much more aggressive phenotype in more differentiated cells[96]. These data support our observations and could be related with the role of PTHrP and PTHR1 in the promotion of an aggressive phenotype of CRC.

We observed that the intensity of Met immunostaining in tumor cell plasma membrane increases as tumor differentiation declines. Concerning the location of PTHR1 in the plasma membrane, the intensity of the staining gradually decreases in histologically less differentiated tumors; also, it is located in the cytoplasm and the perinuclear region of the tumor cell, with immunoreactivity more predominant in samples with histological degree G3. This could be related to an intracrine role of the cytokine most preponderant in less differentiated CRC cells. More studies are necessary to confirm this.

Based on the above, it is presumed that in the early stages of tumor development, PTHrP would act by binding to its receptor in the tumor cell, possibly inducing Met receptor expression. The secretion of this cytokine from tumor stromal cells has also been reported[97] and we have previously demonstrated its influence on the synthesis and release of tumor microenvironment factors that favor an aggressive CRC phenotype[24,25]. Considering that in less differentiated tumors, we observed lower expression of PTHR1, we hypothesize that in this instance the tumor stromal cells adopt a leading role by secreting (perhaps in response to PTHrP) other cytokines that promote the expression and activation of molecular markers related to a worse prognosis of the disease. The high levels of Met in more advanced stages could be mediated not only by the action of PTHrP but also by other cytokines as other researchers have previously demonstrated[63,98]. It is known that the loss of cellular identity, characteristic of an advanced undifferentiated state, is evidenced by changes in the expression of surface molecules including receptors on tumor cells[99]. The high levels of PTHR1 observed in normal samples and primary neoplasms, and its decrease in undifferentiated histological grades could respond to this effect. On the other hand, high expression of Met in tumor samples is observed in association with a low degree of cellular differentiation. In this context, perhaps PTHR1 and Met could act as markers of cellular dedifferentiation. However, more studies are needed to verify this hypothesis.

CONCLUSION

Here we have demonstrated using an *in vitro* model that the PTHrP pathway promotes events that are associated with a worse evolution of CRC through Met activation. We also provide evidence for the association between PTHrP action and Met expression *in vivo*. Given all this information, it will be of great interest to ascertain the participation of Met in other molecular events related to CRC progression trigged by PTHrP and its translational relevance. More studies are needed in the areas of basic and clinical oncology to confirm this.

ARTICLE HIGHLIGHTS

Research background

Colorectal cancer (CRC) patients usually relapse and die due to the development of metastasis and resistance to chemotherapeutic drugs employed in the treatment. Parathyroid hormone-related peptide (PTHrP) is a cytokine that has a key role in the carcinogenesis and the progression of several tumors. Our research group found that the binding of PTHrP to its receptor, the parathyroid hormone receptor type 1 (PTHR1), promotes events associated with the aggressive phenotype of colorectal cancer cells. The receptor tyrosine kinase Met is associated with metastasis and chemoresistance in CRC.

Research motivation

The mechanisms that lead to an aggressive tumor behavior and a worse response to CRC treatment are still unknown. To date, it has not been studied whether there is a cross-talk between the PTHrP and Met signaling pathways to trigger molecular mechanisms associated with CRC progression.

Research objectives

To investigate the relationship between PTHR1, PTHrP, and Met in the aggressive behavior of CRC cells. These findings could have implications for the future diagnosis, prognosis, and treatment of patients with CRC.

Research methods

By RT-PCR and Western blot analysis, we studied whether PTHrP modulates the expression of Met and its activation in CRC cells. By Western blot and using specific inhibitors, we also evaluated the signaling pathways involved in Met activation induced by PTHrP. By Trypan blue technique, Wound healing assay, Western blot, and morphological analysis, we evaluated whether the Met signaling pathway mediates the effects induced by PTHrP in HCT116 cells. By the immunohistochemistry technique, we evaluated the expression of Met and the PTHrP receptor, PTHR1, in HCT116 cell xenografts of nude mice in response to the treatment with or without PTHrP. An observational analysis of human samples was performed to validate the findings obtained by *in vitro* and *in vivo* assays.

Research results

PTHrP modulated the expression of Met and promoted its activation through Src kinase and the mitogen-activated protein kinase (MAPK) signaling pathway in human HCT116 cells. The Met signaling pathway triggered by PTHrP participated in cellular events related to the aggressive behavior of human HCT116 cells such as proliferation, morphological changes associated with epithelial to mesenchymal transition, and migration and in the decrease of the sensitivity to chemotherapy drugs. PTHrP increased the protein expression of its receptor, PTHR1, and of Met in HCT116 cell tumor xenografts. PTHR1 was highly expressed in well-differentiated human CRC samples. In contrast, Met showed an expression pattern that was increased in poorly differentiated CRC tumors.

Research conclusions

PTHrP promotes events associated with a worse behavior of CRC cells through Met activation. To date, our *in vitro* observations suggest that the binding of PTHrP to its receptor, PTHR1, promotes the regulation of *Met* gene expression and also its activation through the Src kinase and the MAPKs pathway. Once activated, Met signaling leads to molecular changes in the tumor cell to promote events associated with the aggressive behavior of CRC cells. Our previous data together with the findings shown herein reveal that PTHrP *in vivo* modulates the expression of markers linked to tumor progression (including Met) and also of its own receptor. These events could favor the tumor phenotype in the CRC animal model studied in this work.

Research perspectives

In the future, it will be of great interest to evaluate whether Met mediates other molecular mechanisms and events triggered by PTHrP that are involved in CRC progression. Concerning translational

relevance, more studies are needed in the areas of basic and clinical oncology.

Abstract

BACKGROUND

Endoplasmic reticulum (ER) stress contributes to the pathogenesis of chronic liver diseases, but how hepatocytes respond to ER stress has not been clarified. Alpha-fetoprotein (AFP) is secreted by hepatoma cells and elevated levels of serum AFP are associated with development of liver malignancies.

AIM

To investigate whether and how AFP could regulate ER stress and hepatocyte injury.

METHODS

The distribution of AFP and the degrees of ER stress in liver tissues and liver injury were characterized by histology, immunohistochemistry, and Western blot in biopsied human liver specimens, two mouse models of liver injury and a cellular model. The levels of AFP in sera and the supernatants of cultured cells were quantified by chemiluminescence.

RESULTS

High levels of intracellular AFP were detected in liver tissues, particularly in the

necrotic areas, from patients with chronic liver diseases and mice after carbon tetrachloride (CCl_4) administration or induction of ER stress, but not from the controls. The induced intracellular AFP was accompanied by elevated activating transcription factor-6 (ATF6) expression and protein kinase R-like ER kinase (PERK) phosphorylation in mouse livers. ER stress induced AFP expression in LO2 cells and decreased their viability. ATF6, but not PERK, silencing mitigated the ER-stress-induced AFP expression in LO2 cells. Conversely, AFP silencing deteriorated the ER stress-mediated LO2 cell injury and CCl_4 administration-induced liver damages by increasing levels of cleaved caspase-3, the C/enhancer binding protein homologous protein expression, mixed lineage kinase domain-like pseudokinase and PERK phosphorylation, but decreasing ATF6 expression.

CONCLUSION

ER stress upregulated intra-hepatocyte AFP expression by activating ATF6 during the process of liver injury and intracellular AFP attenuated hepatocyte apoptosis and necroptosis by alleviating ER stress.

Key Words: Alpha-fetoprotein; Endoplasmic reticulum stress; Necroptosis; Apoptosis; Liver injury

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: During the process of liver injury, alpha-fetoprotein (AFP) expression was up-regulated in hepatocytes, especially in the necrotic areas, but it did not increase the serum AFP level. Endoplasmic reticulum (ER) stress induced intracellular AFP expression through activating activating transcription factor-6 and the up-regulated intracellular AFP expression attenuated hepatocyte apoptosis and necroptosis by feedback-down-regulating ER stress.

INTRODUCTION

Chronic liver diseases, such as chronic hepatitis B (CHB), affect many patients, especially in East Asia, such as China. However, the pathogenesis of chronic liver diseases remains unclear. Although human liver has powerful capacity to compensate the disease-related liver injury, how hepatocytes respond and defense against these diseases has not been clarified. Hence, it is of great significance to clarify it for the management of patients with chronic liver diseases.

Alpha-fetoprotein (AFP) is a protein with similar biological function to albumin and secreted mainly by embryonic tissue cells physiologically and malignant hepatocytes pathologically after birth. Elevated levels of serum AFP have been considered as a reliable biomarker for prediction of birth defect and diagnosis of liver cancer, teratoma, renal cell carcinoma, and pancreatic cancer[1] although moderate serum AFP levels can be temporarily detected in individuals with aberrant liver regeneration, hepatitis, and chronic liver disease. Furthermore, low levels of serum AFP have been continually observed in patients with liver cirrhosis and positively correlated with the degrees of liver inflammation and fibrosis [2,3]. The low and moderate levels of serum AFP are likely from the activation and proliferation of liver precursor cells, including oval cells, hepatic progenitor cells, in response to severe liver damages, particularly in liver failure[4-6]. While hepatocyte proliferation usually compensates for mild and moderate liver injury, liver precursor cells can differentiate into hepatocytes and bile duct cells, promoting liver regeneration. The activated liver precursor cells can secrete AFP and high levels of serum AFP have been suggested to be a biomarker of better prognosis of liver failure[7,8]. However, it is unclear whether chronic liver injury can induce AFP expression and secretion in differentiated mature hepatocytes, and how the induced AFP modulates the pathogenic process of chronic liver diseases.

It is notable that endoplasmic reticulum (ER) stress contributes to the pathogenesis of chronic liver diseases[9,10] and is regulated by inositol requiring enzyme-1 and activating transcription factor-6 (ATF6) and protein kinase R-like ER kinase (PERK)/eukaryotic translational initiation factor 2 alpha (eIF2α) signaling[11,12]. Aberrant ER stress can activate cell injury reactions, such as apoptosis and necroptosis by activating the C/enhancer binding protein (EBP)-homologous protein (CHOP) pathway,

caspase-3 cleavage and mixed lineage kinase domain-like pseudokinase (MLKL) phosphorylation[13, 14]. Our previous study has shown that ER stress inhibits the AFP secretion in hepatoma cells and the increase in the levels of intracellular AFP feedback attenuates the ER stress-related apoptosis and necroptosis in hepatoma cells[15]. However, it is unknown how ER stress can regulate AFP expression and secretion, and how intracellular AFP can modulate the ER stress-induced liver injury during the pathogenic process of chronic liver diseases.

In this research, we focus on whether intracellular AFP exists in hepatocytes during the liver injury, its regulatory relationship with ER stress, and its role in hepatocyte injury through clinical research, *in vivo* and *in vitro* experiments.

MATERIALS AND METHODS

Clinical samples

A total of 34 biopsied liver specimens were collected from CHB patients, eight surgical liver specimens were obtained from patients with hepatic trauma, and another eight surgical liver specimens were obtained from patients with hepatocellular carcinoma (HCC) in the Department of Infectious Diseases, or Hepatobiliary Surgery, the Affiliated Hospital of Zunyi Medical University since 2012. The patients with CHB were diagnosed, according to the Guidelines for Prevention and Treatment of Chronic Hepatitis B revised in 2019[16]. Individual patients were excluded if she/he had current infectious disease, autoimmune liver disease, liver malignant tumor, alcoholic liver disease, drug-induced liver disease, multiple organ dysfunction syndrome, obvious bleeding tendency, deep jaundice, obvious ascites, or another situation not suitable for liver biopsy. Their demographic and clinical data are shown in Table 1. The experimental protocol was approved by the Ethics Committee of Affiliated Hospital of Zunyi Medical University (ZYFYLS[2018] 28).

Establishment of liver injury in mice

Male BALB/c mice (25.0 g ± 3.0 g) were purchased from the Animal Center of Zunyi Medical University (Guizhou Province, China; SYXK[Qin] 2021-0004). The mice were maintained in a specific pathogen-free facility with a controlled temperature (20 °C-24 °C), a 12-h light/dark cycle and allowed free access to food and water *ad libitum*. The experimental protocol was established, according to the Animal Care and Research guidelines[17] and approved by the Animal Experiment Ethics Committee of Zunyi Medical University (LS[2020] 2-231).

To induce liver injury by carbon tetrachloride (CCl_4) administration, the mice were randomized using a random number table into the healthy control group (NC; untreated), solvent control group (olive oil, 5 mL/kg, intraperitoneally, *i.p.*) and CCl_4 group (1 mL/kg mixed with 4 mL of olive oil, *i.p.*) (n = 12 per group). The mice in the solvent and CCl_4 group were administrated with solvent or CCl_4 once or twice per week for 8 wk. Their peripheral blood samples were collected 24 h after the last dose, euthanized and their liver tissues were dissected.

To induce ER stress-related liver injury, the mice were randomized into the healthy NC (untreated), solvent control (phosphate buffer saline, PBS, 10 mL/kg) and tunicamycin (TM; an inhibitor of protein glycosylation) groups (2 mg/kg in the same volume of PBS, *i.p.*; Sigma) once (n = 12 per time point group). One or two days later, their peripheral blood samples were collected, euthanized and their liver tissues were dissected.

To test the role of AFP in the CCl_4-induced liver injury, the mice were randomized and treated intravenously with 1×10^{10} recombinant serotype 8 adeno-associated virus (rAAV8) for expression of control short hairpin RNA (shRNA) or *Afp*-specific shRNA (Table 2, Genechem, Beijing, China). Six weeks after infection, the levels of AFP expression in the livers of mice were analyzed by Western blot to confirm *Afp* silencing. The mice with control shRNA or *Afp*-specific shRNA were administrated with olive oil or CCl_4 as the control shRNA + olive oil, CCl_4 (control shRNA + CCl_4), *Afp* shRNA + olive oil, or *Afp* shRNA + CCl_4 (*Afp* shRNA + CCl_4). Their peripheral blood samples were collected, euthanized and their livers were dissected at 36 h (n = 12 per group) post CCl_4 administration, based on our preliminary studies.

Cell lines and culture

Human hepatocyte LO2 and hepatoma HepG2 cell lines were obtained from the Type Culture Collection of the Chinese Academy of Sciences (Shanghai, China) and identified by STR. The cells were cultured in RPMI-1640 containing 10% fetal bovine serum, 100 Units/mL of penicillin and 100 μg/mL of streptomycin at 37 °C in a 5% CO_2 incubator. To induce ER stress, LO2 cells were treated with, or without (NC group), solvent control group (dimethyl sulfoxide, DMSO) and 0.5 μmol/L thapsigargin (TG; an inhibitor of intracellular calcium balance) in DMSO (Sigma, TG group) for 12 h, 24 h and 48 h, respectively.

In addition, LO2 cells (1.2×10^6 cell/well) were cultured in 6-well plates overnight and transfected with plasmids for control shRNA, *PERK*-specific shRNA and *ATF6*-specific shRNA (Beijing Genechem) using lipofectamine 3000 (Fisher). Two days later, the cells were treated with vehicle DMSO or TG for 24

h. Additionally, LO2 cells were transfected with plasmid for the expression of control shRNA or *AFP*-specific shRNA (Beijing Genechem) for 48 h and treated with DMSO or TG for 36 h, respectively.

Western blot analysis

LO2, HepG2 cells, or individual liver samples were homogenized in immunoprecipitation assay lysis buffer (R0010, Solarbio, Beijing, China). After centrifugation, individual liver lysates (40 μg) were separated in sodium dodecyl sulfate polyacrylamide gel on 10% gels and transferred to polyvinylidene fluoride membranes (Millipore, Billerica, MA, United States). The membranes were blocked with 5% skim dry milk in TBST (Tris-HCl buffer salt solution + Tween 20) and probed with mouse monoclonal antibodies (mAb) against AFP (sc-130302; Santa Cruz Biotechnology, Santa Cruz, CA, United States), ATF6 (sc-166659, 1:1000, Santa Cruz Biotechnology), GAPDH (sc-166545, 1:10000, Santa Cruz Biotechnology), CHOP (GADD153, sc-71136, 1:10000, Santa Cruz Biotechnology), eIF2α (sc-133132, 1:10000, Santa Cruz Biotechnology), phosphorylated PERK (p-PERK, MA5-15033, 1:1000, Thermofisher Scientific, United States), and PERK (sc-377400, 1:10000, Santa Cruz Biotechnology), or rabbit monoclonal antibodies against cleaved caspase-3 (9664, 1:10000, Cell Signaling Technology), and phosphorylated eIF2α (p-eIF2α, 3398, 1:10000, Cell Signaling Technology), or rabbit polyclonal antibodies against phosphorylated MLKL (p-MLKL, PA5-105677, 1:2000, Thermofisher Scientific), and MLKL (PA5-34733, 1:3000, Thermofisher Scientific). After reaction with horseradish peroxidase (HRP)-conjugated anti-mouse or anti-rabbit IgG, the immunocomplexes were visualized with enhanced chemiluminescent reagents. Quantity One software (Bio-Rad, Hercules, CA, United States) was used to determine the relative levels of each targeted protein to the control (standardized as 1)[18].

Pathological analysis of liver tissue

Fresh liver tissues (5 mm × 5 mm in size from each mouse or 1 mm × 30 mm in size from one patient)

were fixed in 4% paraformaldehyde for ≥ 24 h, paraffin-embedded and cut. The liver tissue sections (5 μm) were dewaxed, rehydrated and routine-stained with hematoxylin and eosin (H&E). The sections were examined under a light microscope (OLYMPUS CX31) using CaseViewer 2.4 software (3DHISTECH, Hungary). The necrotic areas in the liver were analyzed by Image-Pro Plus 6.0 (Media Cybernetics, United States)[19]. The Histology Activity Index-Knodell scores were determined by two pathologists blindly[20].

Immunohistochemistry

The liver tissue sections were dewaxed, rehydrated and blocked with 3% of bovine serum albumin for 20 min. The sections were incubated with mAb against AFP (sc-130302, 1:250) at 4 °C overnight and the bound antibodies were detected with HRP-conjugated anti-mouse IgG, followed by visualizing with diaminobenzidine. The intensity of anti-AFP staining was evaluated by Image Pro Plus 6.0[19].

TUNEL assay

The effect of *Afp* silencing on the frequency of apoptotic hepatocytes in liver sections was determined by terminal deoxynucleotidyl transferase (TdT)-mediated deoxyribonucleotide derivative digoxigenin (dUTP) nick end labeling (TUNEL) using a specific kit (Roche, 11684817910), according to the manufacturer's instruction. Briefly, the paraffin-embedded liver sections were dehydrated, permeabilized, and incubated with a mixture of TdT and dUTP at 1:14 in a humidified chamber for 2 h at 37 °C. The labeled cells were detected with detection solution and after being washed, the sections were counterstained with 4′, 6-diamidino-2-phenylindole. The TUNEL signals were examined under a fluorescent microscope. The apoptotic cells were defined by nuclear green staining while non-apoptotic cells with blue nuclear staining. Five visual fields in each section were randomly selected and the percentages of apoptotic cells in each section were calculated using the formula of positive cells/total cells × 100%.

Analysis of AFP levels

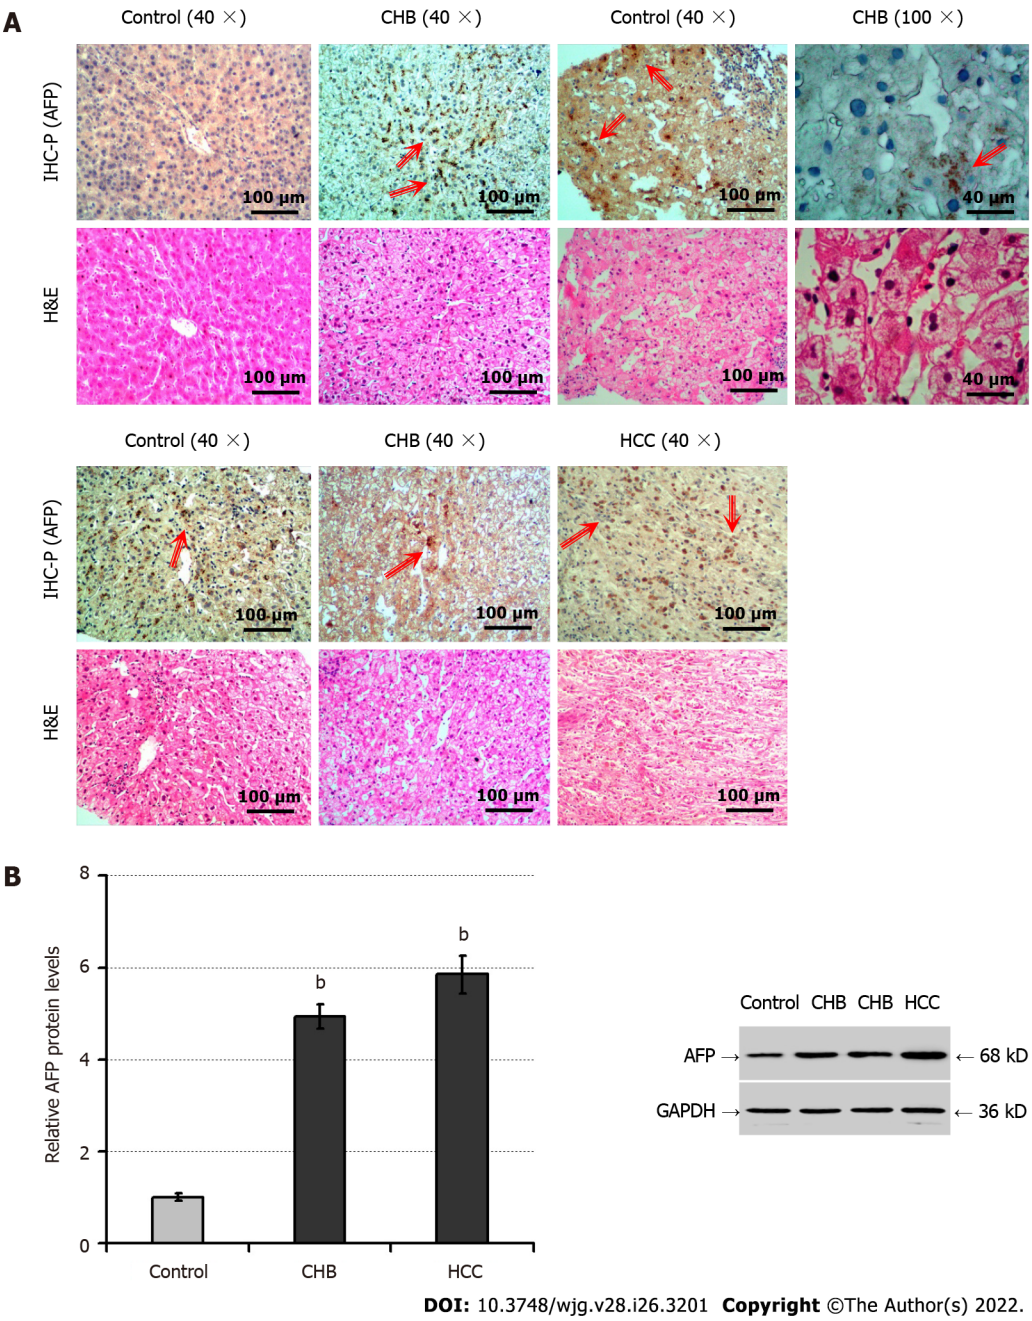
AFP levels in the supernatant of cultured cells and mouse serum samples were measured by chemiluminescence immunoassay on the Beckman Coulter Auto Analyzer (Model DX1800; 04481798190, Roche Diagnostics GmbH) as previously described[21]. Samples were centrifuged to remove the remaining cells and possible cell debris before testing the AFP concentration.

Alanine aminotransferase and total bilirubin levels

The levels of serum alanine aminotransferase (ALT), total bilirubin (TBil) were two commonly used measures of liver injury, and analyzed by an auto-analyzer (AU5800, Beckman Coulter, United States)[22].

Cell viability assay

The impact of specific gene silencing or ER stress on LO2 cell viability was determined using the cell counting kit-8 (CCK-8; Cat. No. 40203ES60; Yeasen Biotechnology, Shanghai, China), per the product instruction. Briefly, LO2 cells (5000 cells/100 μL medium/well in 96-well plates) were treated with, or without, TG for 48 h (5 replicates per sample). During the last one-hour culture, the cells were exposed to CCK-8 and the absorbance of individual wells was detected at a wavelength of 450 nm (Bio-Rad, CA, United States). The relative cell viability (%) = (OD value of the treatment group-OD value of the blank group)/(OD value of the control group-OD value of the blank group) × 100.



Statistical analysis

Data are representative images or expressed as the mean ± SD of each group from 3 separate experiments. The difference of normally distributed values among groups was analyzed by one-way ANOVA and post hoc Tukey's method. The difference between groups was analyzed by Student's *t*-test. Survival rates were estimated using the Kaplan-Meier method and analyzed by the log-rank test. A *P*-value less than 0.05 was considered statistically significant.

RESULTS

AFP expression is induced in the liver of patients with chronic liver injury

To explore the potential role of AFP in the progression of chronic hepatocyte injury, we analyzed AFP expression in liver tissues of patients with CHB (n = 34), controls (liver trauma; n = 8), and those with HCC (positive controls, n = 8). While there were healthy hepatocytes without degeneration and necrosis in the control liver tissues there were many hepatocytes undergoing degeneration and necrosis (Figure 1A). Immunohistochemistry indicated positive anti-AFP staining in the liver tissues from patients with HCC or CHB, but little in the controls. Interestingly, the positively stained anti-AFP was particularly in the regions with hepatocyte degeneration and necrosis of the liver tissues from CHB

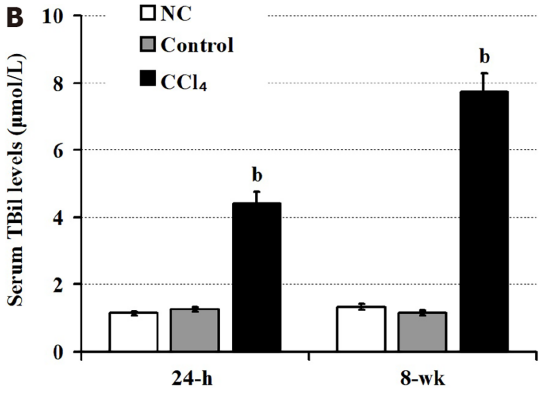

Figure 1 The intrahepatic levels of alpha-fetoprotein protein are elevated in injured livers. A: Immunohistochemistry and hematoxylin and eosin (H&E) staining analyzed alpha-fetoprotein (AFP) expression and pathological changes, respectively, in liver tissues of patients with chronic hepatitis B (CHB, n = 34), trauma (n = 8) or hepatocellular carcinoma (HCC, the positive control group, n = 8). The upper panels display immunohistochemical staining, and the lower panels exhibit H&E staining in sequential tissue sections. The positive expression of AFP was stained with brownish yellow by immunohistochemistry and indicated by the arrows; B: The relative levels of AFP protein expression were analyzed by Western blot in the liver specimens indicated. H&E: Hematoxylin and eosin; IHC-P: Immunohistochemistry-paraffin; AFP: Alpha-fetoprotein; HCC: Hepatocellular carcinoma; CHB: Chronic hepatitis B. $^{b}P < 0.01$, compared with the control group.

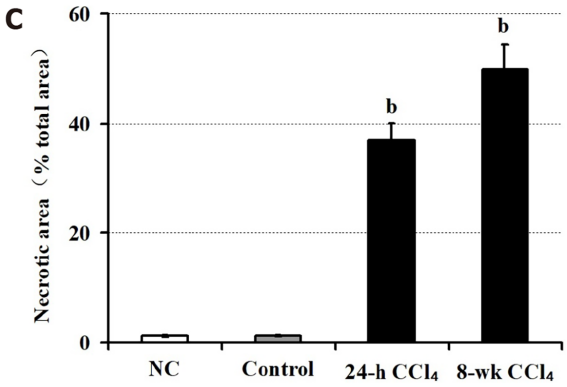

patients. Further Western blot displayed significantly increased levels of AFP expression in the livers from HCC or CHB patients, relative to that in the controls ($P < 0.01$, Figure 1B). Such data indicated that AFP expression was induced in hepatocytes, associated with hepatocyte degeneration and necrosis in humans during the process of hepatocyte injury.

Induction of liver injury enhances AFP expression and ER stress in the liver of mice following CCl_4 administration

Next, we tested whether AFP expression could be induced in the liver of mouse model of CCl_4-induced hepatocyte injury. As expected, CCl_4 administration significantly elevated serum ALT ($P < 0.05$; Figure 2A), TBil ($P < 0.05$; Figure 2B) levels, accompanied by increased areas of liver tissue necrosis in mice, relative to the NC and the control groups (olive oil) of mice ($P < 0.05$; Figure 2C), particularly in the livers of mice following administration with CCl_4 for 8 wk. There were similarly low levels of serum

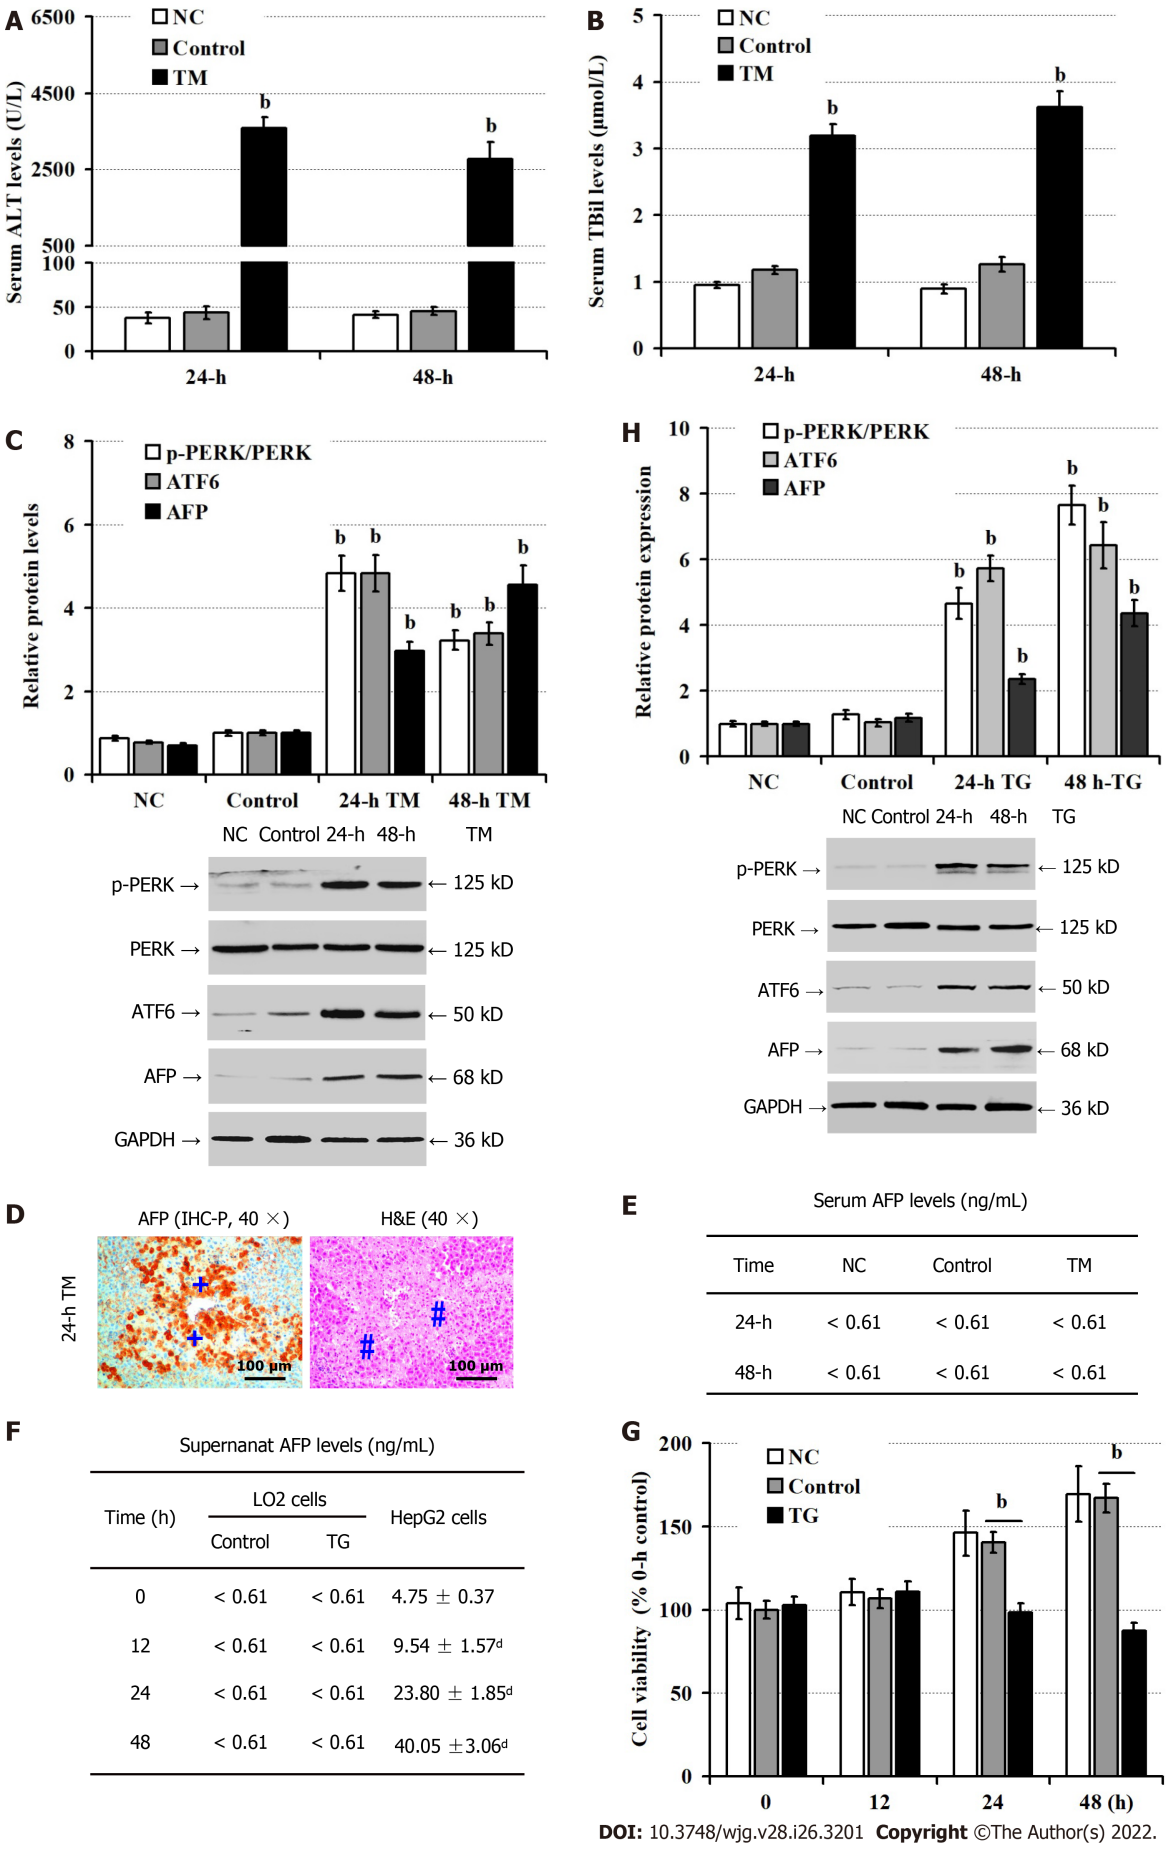
Figure 2 Administration with carbon tetrachloride induces alpha-fetoprotein expression, endoplasmic reticulum stress and liver injury in mice. Male BALB/c mice were untreated (NC), or administrated with olive oil (control) or carbon tetrachloride (CCl_4) for 24 h, or 8 wk. A: Serum alanine aminotransferase levels; B: Serum total bilirubin levels; C: Hematoxylin and eosin staining analysis of pathological changes in mouse liver tissues at 24-h and 8-wk post CCl_4; D: Chemiluminescence immunoassay of serum alpha-fetoprotein (AFP) levels; E: Western blot analysis of the relative levels of AFP expression in liver tissues of mice; F: Immunohistochemical staining of AFP expression in liver tissue of mice at 24-h post CCl_4, the positive expression of AFP was stained with brownish yellow and indicated by a plus sign; G: Western blot analysis of the relative levels of protein kinase R-like endoplasmic reticulum kinase phosphorylation and activating transcription factor-6 expression in liver tissues of mice. AFP: Alpha-fetoprotein; ALT: Alanine aminotransferase; ATF6: Activating transcription factor-6; CCl_4: Carbon tetrachloride; H&E: Hematoxylin and eosin; PERK: Protein kinase R-like endoplasmic reticulum kinase; TBil: Total bilirubin. $^bP < 0.01$ compared with the control group.



AFP detected in the different groups of mice (about 0.61 ng/mL, Figure 2D). In contrast, Western blot revealed that CCl_4 administration obviously up-regulated AFP expression in the livers of mice in a trend of time-dependence ($P < 0.05$; Figure 2E). Further immunohistochemistry exhibited that the up-regulated AFP expression was mainly accumulated in the injured liver areas (Figure 2F). Finally, CCl_4 administration significantly enhanced the relative levels of PERK phosphorylation and ATF6 expression ($P < 0.05$; Figure 2G), the hallmarks of enhancing ER stress in the livers of mice. Collectively, CCl_4 administration induced hepatocyte injury and ER stress, and up-regulated AFP expression, but not its secretion in mice.

ER stress up-regulates AFP expression in hepatocytes

Given that up-regulated AFP expression was associated with enhanced ER stress, we tested whether induction of ER stress could up-regulate AFP expression in TM-injected mice. Compared with the NC and vehicle controls, significantly elevated levels of serum ALT ($P < 0.05$; Figure 3A) and TBil ($P < 0.05$; Figure 3B) were detected in mice at 24 h and 48 h post TM injection, implicating that induction of ER stress induced liver damages in mice. Consistently, Western blot revealed that TM injection obviously up-regulated ATF6, and AFP expression and PERK phosphorylation in the livers of mice, relative to that of the controls ($P < 0.05$; Figure 3C). Interestingly, there were damaged liver areas with strong anti-AFP staining in the mice with TM injection (Figure 3D). However, there were similar levels of serum AFP in the different groups of mice (< 0.61 ng/mL, Figure 3E). Furthermore, while there was no detectable AFP in the supernatants of cultured human non-tumor hepatocyte LO2 cells, even after treatment with TG, the levels of AFP in the supernatants of cultured HepG2 cells increased in a time-dependent manner (Figure 3F). Moreover, TG treatment significantly decreased the viability of LO2 cells at 24 h and 48 h post treatment ($P < 0.05$, Figure 3G), but TG treatment significantly enhanced the relative levels of AFP and ATF6 expression and PERK phosphorylation in LO2 cells ($P < 0.05$, Figure 3H). Thus, induction of ER stress induced hepatocyte injury and AFP expression.

ATF6 silencing mitigates the TG-induced AFP expression in LO2 cells

To understand how ER stress promoted AFP expression, we transfected LO2 cells with *PERK* or *ATF6*-specific shRNA. We found that *PERK* silencing significantly reduced the viability of LO2 cells ($P < 0.05$), and deteriorated the TG-induced damages in LO2 cells ($P < 0.01$; Figure 4A). While *PERK* silencing significantly reduced the levels of PERK protein expression in both regular cultures and TG-treated LO2 cells, and mitigated the relative levels of TG-enhanced eIF2α phosphorylation in LO2 cells, *PERK* silencing failed to significantly alter AFP protein expression in LO2 cells regardless of TG treatment (Figure 4B). In contrast, *ATF6* silencing significantly reduced the viability of LO2 cells, but enhanced the TG-induced damages in LO2 cells ($P < 0.01$; Figure 4C). Moreover, transfection with *ATF6* shRNA not

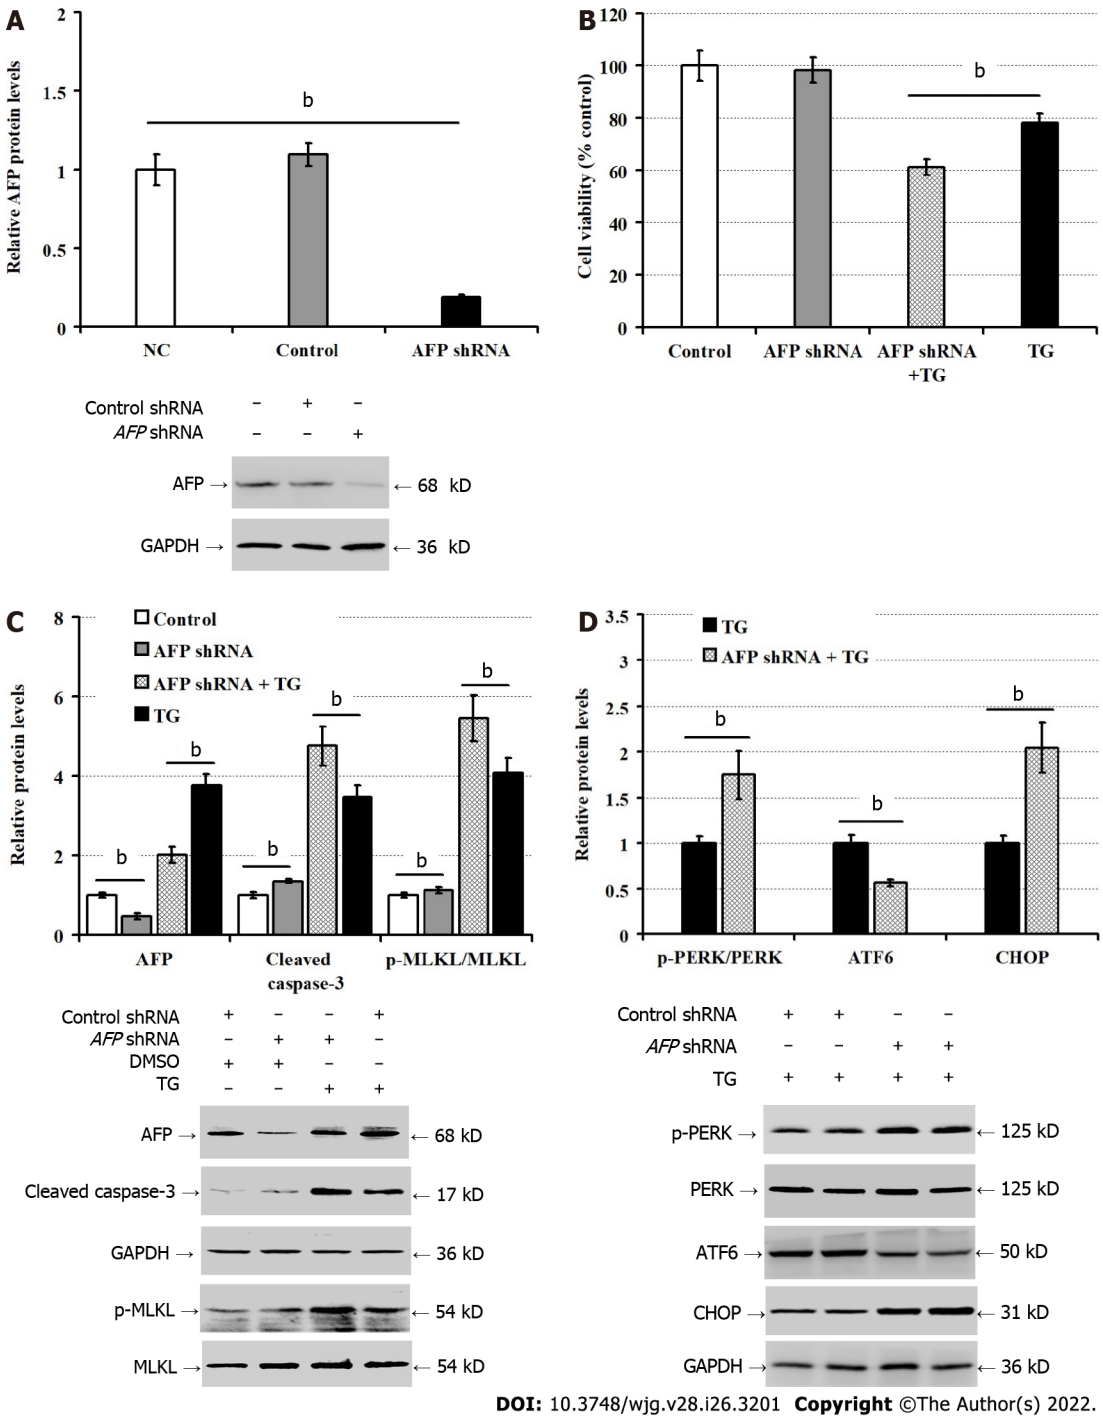
Figure 4 Activating transcription factor-6 silencing inhibits the expression of alpha-fetoprotein induced by thapsigargin *in vitro*. LO2 cells were transfected with control shRNA, *protein kinase R-like endoplasmic reticulum kinase* (*PERK*)-shRNA, or *activating transcription factor-6* (*ATF6*)-shRNA for 48 h, and treated with dimethyl sulfoxide (control) or thapsigargin for 24 h. A: Cell counting kit-8 (CCK-8) analysis of cell viability; B: Western blot analysis of p-PERK, phosphorylated eukaryotic translational initiation factor 2 alpha, and alpha-fetoprotein expression; C: CCK-8 analysis of cell viability; D: Western blot analysis of the relative levels of ATF6 and AFP protein expression. AFP: Alpha-fetoprotein; ATF6: Activating transcription factor-6; CCK-8: Cell counting kit-8; DMSO: Dimethyl sulfoxide; p-eIF2α: Phosphorylated eukaryotic translational initiation factor 2 alpha; p-PERK: Phosphorylated protein kinase R-like endoplasmic reticulum kinase; TG: Thapsigargin. $^{a}P < 0.05$, $^{b}P < 0.01$, compared with these two groups.

only significantly inhibited ATF6 expression, but also attenuated the relative levels of AFP expression in both regular cultures and TG-treated LO2 cells ($P < 0.01$; Figure 4D). Hence, *ATF6* silencing mitigated the TG-induced AFP expression in LO2 cells.

AFP silencing increases the TG-induced hepatocyte apoptosis and necroptosis in LO2 cells

To understand the importance of AFP in ER stress-induced hepatocyte injury, we further explored the impact of *AFP* silencing on the ER stress-induced hepatocyte injury *in vitro*. Compared with the control LO2 cells, transfection with *AFP*-specific shRNA, but not the control shRNA, dramatically reduced AFP expression in LO2 cells ($P < 0.01$; Figure 5A), and deteriorated the TG-induced damages ($P < 0.01$), but it did not significantly alter the viability of LO2 cells ($P > 0.05$, Figure 5B). Furthermore, the *AFP* silencing significantly increased the levels of cleaved caspase-3 and MLKL phosphorylation regardless of TG treatment ($P < 0.05$, Figure 5C). Consistently, *AFP* silencing also significantly increased CHOP expression and PERK phosphorylation, but decreased ATF6 expression in LO2 cells ($P < 0.01$, Figure 5D). These results clearly indicated that *AFP* silencing enhanced spontaneous and TG-induced ER stress, apoptosis and necroptosis in LO2 cells.

AFP silencing deteriorates the CCl_4-induced liver injury in mice

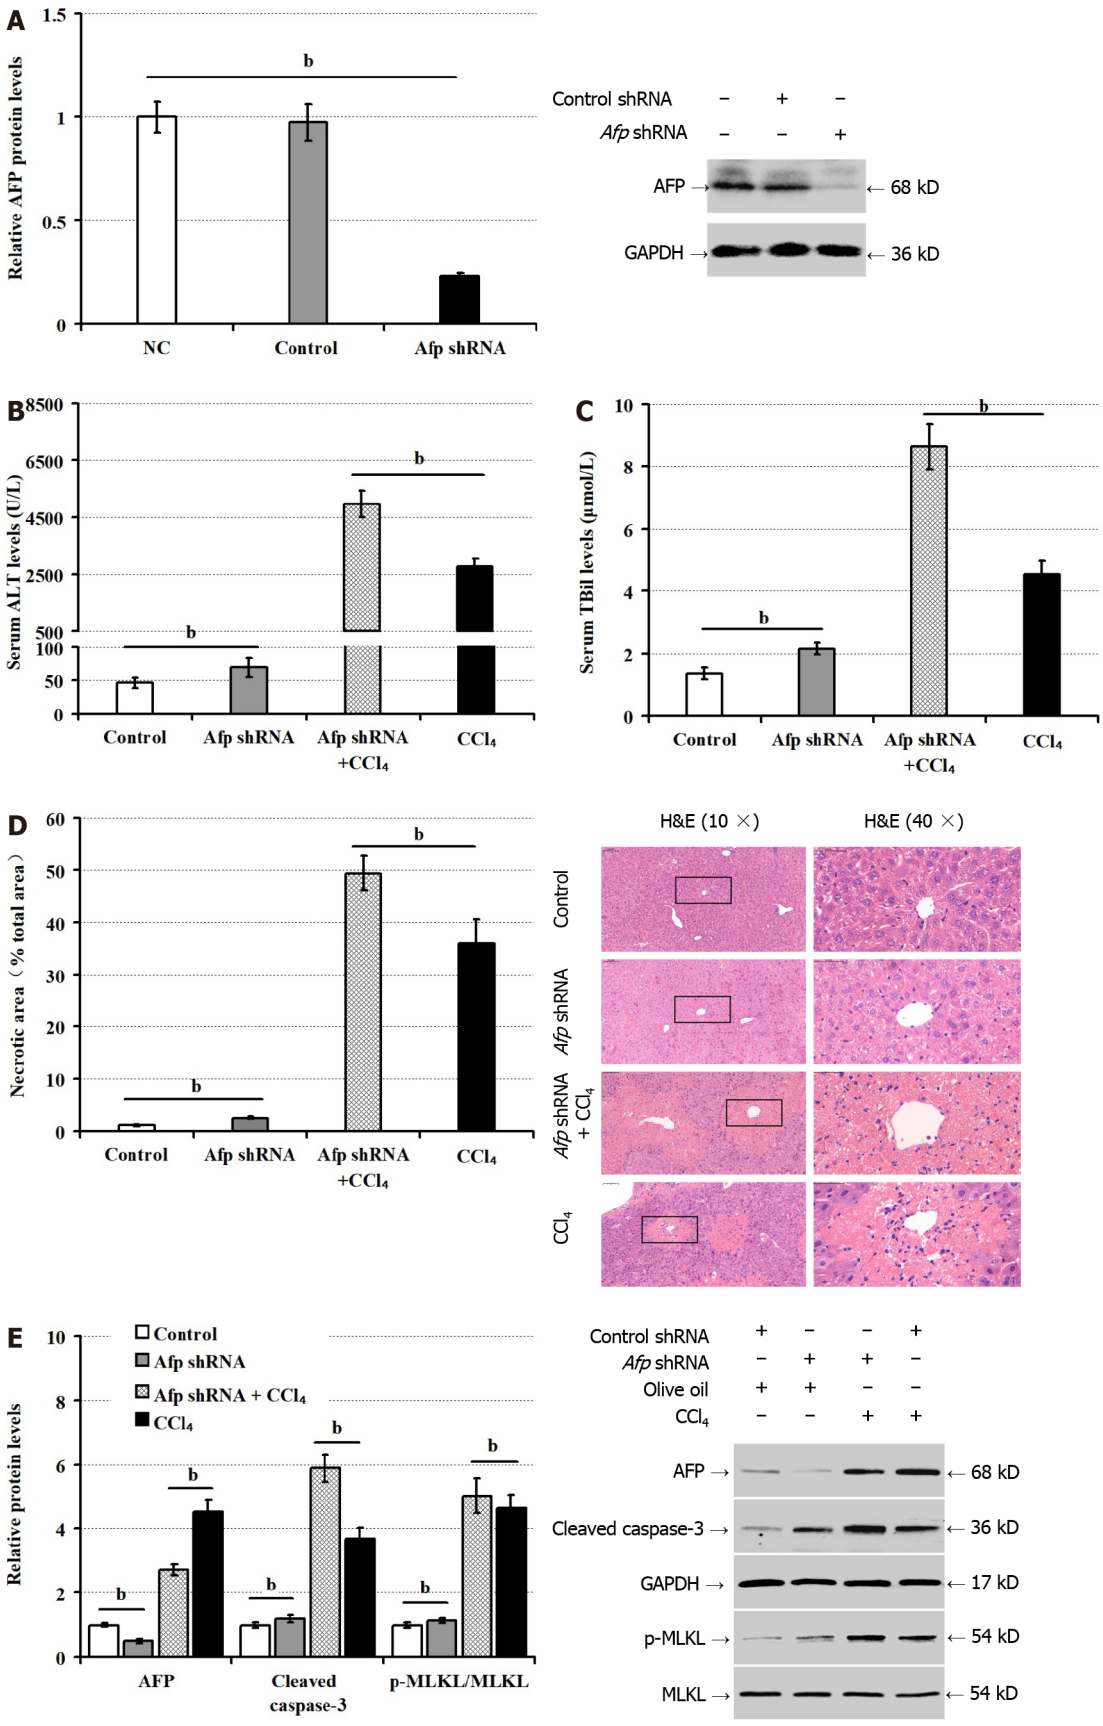


Finally, we tested whether induction of *Afp* silencing could modulate the CCl_4-induced liver injury in mice. After intravenous administration with rAAV8 virus for the expression of control or *Afp*-specific shRNA for 6 wk, the levels of AFP expression in the liver tissues were reduced dramatically, confirming the *Afp* silencing ($P < 0.01$, Figure 6A). Both groups of mice were administrated with vehicle olive oil or CCl_4 and 36 h later, we found that *Afp* silencing increased serum ALT ($P < 0.01$, Figure 6B), and TBil levels ($P < 0.01$, Figure 6C), regardless of CCl_4 administration. Compared with the control mice, *Afp* silencing increased the percentages of necrotic areas in the livers of mice ($P < 0.01$, Figure 6D). Furthermore, *Afp* silencing decreased AFP expression, but remarkably increased the relative levels of cleaved caspase-3 expression, MLKL phosphorylation ($P < 0.01$, Figure 6E) and the percentages of apoptotic hepatocytes in the livers of both vehicle and CCl_4-treated mice ($P < 0.01$, Figure 6F). Finally, *Afp* silencing significantly increased CHOP expression and PERK phosphorylation, but decreased ATF6 expression in the livers of CCl_4-treated mice ($P < 0.01$; Figure 6G). Therefore, *Afp* silencing enhanced ER stress and liver injury induced by CCl4 in mice.

DISCUSSION

In this study, we investigated AFP expression, its regulatory mechanism, and its effect on hepatocyte injury during the process of liver injury. We detected high levels of AFP expression in the livers, particularly in the areas of hepatocyte necrosis, of patients with CHB, but not in those with hepatic trauma. Similarly, high levels of AFP expression were observed in the livers of mice following CCl_4 administration and ER stress induction. The induced AFP expression was accompanied by liver injury in those patients and mice. Interestingly, there was no significant difference in the levels of serum AFP in those experimental patients and mice, compared to the controls. Moreover, induction of ER stress in human non-tumor hepatocyte LO2 cells also induced AFP expression, hepatocyte apoptosis and necroptosis, but failed to detect AFP in the supernatants of cultured cells. These indicated that during chronic liver diseases, ER stress and other inducers triggered hepatocyte apoptosis and necroptosis and stimulated AFP expression, but limited its secretion, leading to increased levels of intracellular AFP in hepatocytes. These novel data extended our previous study on hepatoma cells[15], and support the notion that AFP can be induced during the process of chronic liver diseases[7,23]. Our findings may shed light on the liver responses to ER stress in the pathogenic process of chronic liver diseases.

Low levels of serum AFP are detected in patients with chronic liver disease, and are positively correlated with the degrees of liver damages[8,24]. Although high levels of AFP expression were detected in mouse livers, we did not detect abnormally high levels of serum AFP in liver-injured mice, consistent with our observation in hepatoma cells[15]. These indicated that ER stress induced intracellular AFP expression by limiting its secretion. Given that healthy hepatocytes do not express AFP in adults it is possible that ER stress-induced hepatocyte injury may also induce compensative hepatocyte proliferation to repair liver damages in these models. However, the induced intracellular AFP is unlikely from the proliferation and differentiation of liver precursor cells. We are interested in further investigating how ER stress limits the secretion of AFP in hepatocytes during the process of chronic liver diseases.



AFP expression is regulated in a manner of tissue-specific and time-restriction[25]. Previous studies have shown that AFP expression is regulated by transcription factors, such as hepatocyte nuclear factor-1 (HNF1), ACCAAT-enhancer binding protein (C/EBP) and NF-1 and their enhancers[26-28]. Furthermore, the mutation in the AFP promoter region can increase the binding affinity of HNF1, leading to sustained increase in the levels of AFP expression[29]. Moreover, the AFP promoter activity is also regulated by the competitive modulation of these transcription factors, activators and inhibitors [30]. In this study, we explored how ER stress induced AFP expression in hepatocytes. ER stress mainly enhances eIF2α activation and regulates the expression of target molecules through ATF4, ATF6, and XBP1 to enhance cell ability to eliminate and degrade misfolded proteins[11]. We found that *ATF6*, but not *PERK*, silencing significantly mitigated the ER stress-induced AFP expression in LO2 cells. These data suggest that ATF6 may promote AFP expression in hepatocytes under an ER stress condition.

Functionally, AFP can act as a carrier to maintain plasma colloidal osmotic pressure and transport bilirubin, estrogen, fatty acids, retinoids, steroids and progesterone to regulate hormone homeostasis [31]. Second, AFP can induce immune cell apoptosis and down-regulates the gene expression of a variety of inflammatory factors, inhibiting autoimmunity and aberrant inflammation by protecting the fetus from maternal immune attack and attenuating the immune clearance of tumors[32,33]. Furthermore, AFP can enhance the malignant behavior of hepatoma cells by inhibiting their apoptosis and autophagy[34,35]. Accordingly, AFP can promote the survival and growth of a variety of tumor and non-tumor cells[36,37]. AFP can reduce the tumor necrosis factor alpha (TNF-α)-mediated damages of liver cancer cells or hepatocytes, and promotes their proliferation[38,39]. Studies have found that AFP can enhance the expression of p53, c-fos, c-jun, N-ras and hepatocyte growth factor receptor by binding

to its receptors to activate the cyclic adenosine 3′, 5′-monophosphate (cAMP)-protein kinase A (PKA) pathway and induce Ca^{2+} influx. This process increases intracellular cAMP and PKA, and promotes the proliferation, differentiation and regeneration of hepatocytes. In this study, *Afp* silencing deteriorated the ER stress-mediated apoptosis and necroptosis of LO2 cells *in vitro*. Preferable liver *Afp* silencing also aggravated the CCl_4-induced liver damages, hepatocyte apoptosis, and necroptosis in mice. The results suggest that the induced AFP expression in the liver by ER stress may enhance the resistance of hepatocytes to apoptosis and necroptosis stimulators, alleviating liver injury. Interestingly, we found that AFP silencing also exacerbated the ER stress, but lowed ATF6 expression in LO2 cells and in hepatocytes of liver tissues in mice, consistent with our previous observation[15]. These findings suggest that intracellular AFP induced by the ATF6 signaling may feedback-attenuate the ER stress-induced hepatocyte apoptosis and necroptosis, partially by up-regulating ATF6 expression. Given that AFP is not a transcription factor for the ATF6 expression the ER stress-induced AFP expression may through signal-crosstalk induce the ATF6-specific transcription factor and activator expression, indirectly inducing ATF6 expression in hepatocytes in a condition of ER stress.

We have reported that ATF6 is important for hepatocyte apoptosis and programmed necrosis[40]. It is possible that intracellular AFP may interact with intracellular proteins, transcription factors, kinases, co-activators and cell cycle regulators, such as PTEN to activate the PI3K/AKT/mTOR signaling to support the hepatocyte survival[41]. In addition, intracellular AFP may also interact with the apoptosis-related signaling to enhance apoptosis resistance by up-regulating Bcl-2 expression[35]. However, how intracellular AFP mitigates the ER stress-induced hepatocyte injury remains to be further examined.

CONCLUSION

ER stress induced intracellular AFP expression through activating ATF6 and the induced intracellular AFP feedback-attenuated the ER stress-induced hepatocyte injury. Thus, our findings may shed lights

on the molecular regulation by which hepatocytes respond to ER stress, promoting compensative liver repair following ER stress-induced liver injury.

ARTICLE HIGHLIGHTS

Research background

Endoplasmic reticulum (ER) stress plays an important role in the pathogenesis of chronic liver diseases, but how hepatocytes respond to ER stress has not been clarified. Alpha-fetoprotein (AFP) is secreted by hepatoma cells and elevated levels of serum AFP are associated with development of liver malignancies.

Research motivation

Anti-injury response is an important force for hepatocytes to resist liver injury mediated by various reasons, which has a close relationship to the progress and prognosis of liver injury. Studying the anti-injury mechanism of hepatocytes is important for the diagnosis and treatment of liver injury in the clinic.

Research objectives

To investigate whether and how AFP could regulate ER stress and hepatocyte injury.

Research methods

The distribution of AFP and the degrees of ER stress in liver tissues were characterized by histology, immunohistochemistry, and Western blot in biopsied human liver specimens, two mouse models of liver injury and a cellular model. The levels of AFP in sera and the supernatants of cultured cells were quantified by chemiluminescence.

Research results

ER stress induces liver injury and increases intracellular AFP expression in hepatocytes. ER stress up-regulates intracellular AFP expression by up-regulating activating transcription factor-6 (ATF6). Upregulated AFP feedback attenuates ER stress, forming a regulatory loop. Upregulated AFP mitigates the ER stress-induced hepatocyte apoptosis and necroptosis.

Research conclusions

ER stress upregulated intracellular AFP expression in hepatocytes by up-regulating ATF6 during the process of liver injury and intracellular AFP feedback-attenuated hepatocyte apoptosis and necroptosis by alleviating ER stress.

Research perspectives

Intracellular AFP induced by ER stress alleviates hepatocyte apoptosis and necroptosis by activating ATF6.

Abstract

BACKGROUND

Non-alcoholic steatohepatitis (NASH) cirrhosis is the second most common indication for liver transplantation (LT). The role of body mass index (BMI) on outcomes of NASH cirrhosis has been conflicting.

AIM

To compare the longitudinal trajectories of patients with lean *vs* obese NASH cirrhosis, from listing up to post-transplant, having adjusted their BMI for ascites.

METHODS

We retrospectively reviewed all adult NASH patients listed for LT in our program from 2012 to 2019. Fine-Gray Competing Risk analyses and Cox Proportional-Hazard Models were performed to examine the cumulative incidence of transplant and survival outcomes respectively.

RESULTS

Out of 265 NASH cirrhosis listed patients, 176 were included. Median age was 61.0 years; 46% were females. 111 patients underwent LT. Obese robust patients had better waitlist survival [hazard ratio (HR): 0.12; 95%CI: 0.05–0.29, $P < 0.0001$] with higher instantaneous rate of transplant (HR: 5.71; 95%CI: 1.26–25.9, $P = 0.02$). Lean NASH patients had a substantially higher risk of graft loss within 90 d post-LT (1.2% *vs* 13.8%, $P = 0.032$) and death post-LT (2.4% *vs* 17.2%, $P = 0.029$). 1-3- and 5-year graft survival was poor for lean NASH (78.6%, 77.3% and 41.7% *vs* 98.6%, 96% and 85% respectively). Overall patient survival post-LT was significantly worse in lean NASH (HR: 0.17; 95%CI: 0.03–0.86, $P = 0.0142$) with 83% lower instantaneous rate of death in obese group.

CONCLUSION

Although lean NASH is considered to be more benign than obese NASH, our study suggests a paradoxical correlation of lean NASH with waitlist outcomes, and graft and patient survival post-LT.

Key Words: Outcomes; Frailty; Waitlist; Liver transplant; Survival

Core Tip: Non-alcoholic steatohepatitis continues to rise as an indication for liver transplantation (LT). In this study, we analyzed our single-center data of adult patients listed for LT between 2012 and 2019 and reported their outcomes on the waitlist as well as post-LT based on their body mass index.

INTRODUCTION

Non-alcoholic steatohepatitis (NASH) cirrhosis is currently the second most common indication for liver transplantation (LT) and is on track to become the leading indication by 2030 in the United States[1,2]. The ability to cure hepatitis C with antivirals and the twin epidemics of diabetes and obesity have fueled the rise of NASH as an indication for LT worldwide.

NASH patients are often older at presentation and have some or all the components of metabolic syndrome such as diabetes, hypertension, dyslipidemia, and obesity. Non-alcoholic fatty liver disease (NAFLD) and NASH have also been described in the absence of obesity[3]. About 25% of all NAFLD patients exhibit this lean phenotype[4]. However, the role of body mass index (BMI) on outcomes of NASH cirrhosis has been conflicting. Several studies have disproved the perception of NAFLD being a 'milder' condition in lean individuals. In fact, lean patients with NASH have been shown to have more severe liver disease, more advanced fibrosis, shorter waitlist survival, and poorer post-transplant graft and patient survival[5-8].

However, these retrospective studies have been limited by their ability to accurately interpret BMI and the paucity of specific details regarding waitlist and post-transplant outcomes such as cardiometabolic disease, recurrent NASH, and graft fibrosis. Previous attempts to correct BMI for ascites have been shown to move at least 20% of patients to a lower BMI group[9]. Therefore, our study's objective is to compare the longitudinal trajectories of patients with lean *vs* obese NASH cirrhosis, from listing up to post-transplant, having adjusted their BMI for ascites.

MATERIALS AND METHODS

The study was approved by the Research Ethics Board of the University Health Network (Toronto, Canada).

Patients

This was a single-centre retrospective study of all NASH cirrhosis patients listed for LT between November 12, 2012, and May 31, 2019, in the Multi-Organ Transplant Program at the University Health

Network in Toronto, Canada. The study's start date was decided as November 13, 2012, as our program transitioned to the model for end stage liver disease (MELD)-Na system for listing on that day. All patients were followed until May 31, 2020, yielding a minimum follow-up of 1 year. In our program, NASH cirrhosis was diagnosed either based on findings of significant steatosis on histopathology (pre-transplant liver biopsy or explant pathology), or the presence of risk factors (diabetes, obesity, and metabolic syndrome) in the absence of significant alcohol consumption and evidence of other etiology on serology or histopathology.

We excluded candidates listed for hepatocellular carcinoma with exception points, all other candidates listed with exception points, patients with fulminant liver failure, NASH concomitant with a secondary etiology of chronic liver disease (such as alcohol, viral, autoimmune hepatitis, or cryptogenic cirrhosis), multiorgan transplants and those relisted for transplantation.

Data collected from the database on each recipient at the time of listing included age, gender, height, weight, BMI, Na MELD, Creatinine, estimated glomerular filtration rate (eGFR), biochemical parameters (bilirubin, albumin, international normalized ratio), frailty using clinical frailty scale, complications of cirrhosis including the severity of ascites and associated comorbidities were collected. The severity of ascites (mild, moderate, or severe) is graded according to what was recorded in the patient's clinical notes as determined either by physical or more often by radiological examination. Duration on the waitlist, intensive care unit (ICU) stay, sepsis, outcomes on the waitlist, reasons for delisting, and cause of death were also collected. Post-transplant data includes the type of transplant, re-hospitalization within 90 d, recurrence of NAFLD and NASH, time to recurrent NAFLD or NASH, metabolic, cardiovascular, and biliary complications, BMI at 1 and 5 years, patient, and graft survival details.

The above data was collected from the Organ Transplant Tracking Registry software, an internal transplant database linked to the electronic medical record of all patients evaluated at the University Health Network.

Our primary outcomes included patient and graft survival at 90 d, 1- 3- and 5 years.

Dry-weight BMI or adjusted BMI

The adjusted BMI was calculated by evaluating the patient's dry weight, which is estimated by post-paracentesis body weight, or weight recorded before fluid retention if available, or by subtracting a percentage of weight based upon the severity of ascites (mild 5%; moderate 10%; severe 15%) as performed in several studies. The dry-weight BMI or adjusted BMI was then calculated by dividing the patient's estimated dry weight (kg) by the square of the patient's height (m) as performed in several studies[10,11]. We categorized the variable of calculated adjusted BMI at listing into two groups: Group 1 comprising of overweight (BMI ≥ 25 and < 30 kg/m^2) or obese group (BMI ≥ 30 kg/m^2) and Group 2 comprising of underweight (< 18.5 kg/m^2) or normal (≥ 18.5 and < 25 kg/m^2) BMI group.

Adjusted BMI was determined for all the listed patients. The cohort of patients was analyzed according to their weight category.

Statistical analysis

A two-sided test with an overall sample size of 153 subjects (51 in the underweight or normal group, and 102 in the overweight or obese group) achieved 80% power at a 0.05 significance level when the estimated hazard ratio (HR) for the overall survival was 0.5 with the null hypothesis of HR = 1. To account for drop-offs, final sample size was increased to 54 and 122. These results assume that the HR was constant throughout the study and that Cox proportional hazards (PH) regression was used to analyze the data.

Descriptive statistics were performed for demographic and clinical variables. Counts and proportions were calculated for categorical variables and the differences between patients with lean *vs* obese NASH were compared using the Chi-squared test or Fisher's exact test. Mean ± SD and median (range) were calculated for continuous variables and the differences between the two groups were compared using two-sample t-tests or Wilcoxon tests, depending on the distribution of the data.

Cumulative incidence of transplant by lean *vs* obese NASH was plotted and group differences were compared using Gray k-sample test and Fine-Gray Competing risk models. Kaplan-Meier plots for waitlist survival and post-transplant survival were also plotted and differences between patients with lean and obese NASH were compared using log-rank tests and Cox PH models. Complete-case analyses were performed on observations with complete sets of data while the data for observations that has one or more missing values were removed.

Sample size was calculated using PASS (Power Analysis and Sample Size Software) 2021. (NCSS, LLC. Kaysville, Utah, United States, ncss.com/software/pass). SAS 9.4 (SAS Institute, Cary NC) was used to perform statistical analyses. Statistical significance was defined as a P value of ≤ 0.05.

RESULTS

Patient characteristics

Out of 265 patients listed for NASH cirrhosis, 176 met the eligibility criteria. The median age was 61 (32–71.4) years; 46% were females. A total of 111 patients underwent LT, 78 deceased donor LT (DDLT), and 33 living donor LT (LDLT). Table 1 describes the pre-LT clinical and laboratory variables.

Impact of ascites on BMI

Correcting for ascites volume resulted in patients moving into a lower BMI classification among all groups except the underweight group (BMI < 18 kg/m^2). The change was larger among patients in the higher BMI groups with 72.2%, 62.9%, and 78.1% of patients moved to a lower BMI group from Obesity classes 3, 2, and 1, respectively as shown in Table 2.

Waitlist parameters and outcomes

Patients in lean NASH group were elderly at time of listing (median age 61.6 years *vs* 60.3 years, P = 0.048), had worse renal functions at end of listing (median eGFR 48 mL/min/1.73 m^2 *vs* 57 mL/min/1.73 m^2, P = 0.017), carried more severe ascites (66.6% *vs* 45%, P = 0.03) and were more paracentesis dependent (72.2% *vs* 52.9%, P = 0.016). Other characteristics such as sex, clinical frailty scale, and frequency of complications were similar between the two groups.

Patients in the overweight/obese group spent a median of 139.5 d on the waitlist which was not dissimilar to the 117 d spent by their counterparts in the lean group. Waitlist events such as episodes of sepsis and ICU stay were similar in the two groups. With regards to waitlist outcomes, a similar number of patients were de-listed or transplanted in both groups. More patients belonging to the lean NASH group compared to the obese group died (31.5% *vs* 20.5%, P = 0.26); however, the difference was not significant. Time to death or delisting was similar in both obese and lean groups (HR: 0.83; 95%CI: 0.46–1.50, P = 0.53). However, when sub-grouped based on BMI and frailty, patients with obese NASH and none/mild frailty had better survival than lean NASH with moderate to severe frailty (HR: 0.12; 95%CI: 0.05–0.29, P < 0.0001) (Figure 1).

With regards to transplant data, a comparable number of patients underwent DDLT and LDLT in both obese and lean groups (DDLT: 69.5% in overweight/obese group and 72.4% in the lean group; P = 0.77). The cumulative incidence of transplant was equal in both groups (HR: 1.33; 95%CI: 0.87–2.05, P = 0.16). However, obese NASH patients with none/mild frailty had a significantly better instantaneous rate of transplant than lean NASH with moderate to severe frailty (HR: 5.71; 95%CI: 1.26–25.9, P = 0.02) (Figure 2). The Median cold ischemia time in obese patients undergoing DDLT was significantly longer than that of lean patients (465 min *vs* 330.5 min, P = 0.024).

Post-transplant outcomes

Compared to listing, the obese group had a significant reduction in BMI 1 year post-transplant (β = -2.08, SE = 0.87, P = 0.006). At 5-year post-transplant, the overweight or obese group's BMI returned to the same level as listing time (β = 1.80, SE = 1.54, P = 0.52). No change in BMI was observed in the underweight or normal group (overall P = 0.3) (Figure 3). There was no difference in post-transplant parameters such as 90-d rehospitalization, biliary complications or recurrence of NASH in lean *vs* obese groups. However, renal function was significantly better in lean NASH patients at 5 years (median creatinine 111 μmol/L *vs* 153.5 μmol/L, P = 0.019) (Table 3).

The graft loss within 90 d post-transplant (1.2% *vs* 13.8%, P = 0.032) and death following transplant (2.4% *vs* 17.2%, P = 0.029) were significantly higher in lean patients compared to obese patients. The 1- 3- and 5-year graft survivals were significantly worse for lean patients 98.6%, 96% and 85% *vs* 78.6%, 77.3% and 41.7% respectively, all P < 0.05) (Table 3). There was a trend toward worse 1- 3- and 5-year patient survival (98.7%, 96% and 90% *vs* 89.7%, 81.8% and 58.3%; P = 0.06, 0.07 and 0.07 respectively). The two groups were analysed to compare patient survival using Kaplan Meier Survival Plots and Cox PH models, which noted a statistically significant difference in overall survival between the two groups (HR: 0.17; 95%CI: 0.03–0.86, P = 0.0142). The instantaneous rate of death in the overweight/obese group was 83% lower than those in the underweight/normal weight group (Figure 4).

DISCUSSION

Our study highlights the paradoxical impact of pretransplant BMI on the survival of NASH patients post-liver transplant, with lean NASH patients demonstrating inferior 90-d, 1- 3- and 5-year graft survival, and overall patient survival.

Lean NAFLD prevalence varies from 12% to 20% depending on the population. The presence of comorbid conditions such as components of metabolic syndrome along with older age increases the morbidity and mortality of NASH cirrhotic patients. However, it is unclear if the same applies to lean NASH. The prevalence of metabolic syndrome is less common in lean NAFLD patients as compared to

obese[4,12-14]. A long-term follow-up study showed that biopsy-proven lean NAFLD patients are more likely to develop severe liver disease (F3/F4) than overweight patients[5]. Literature is scant about the outcomes of lean NASH while on the waiting list for LT. A study comprising of 1090 patients revealed shorter cumulative survival in lean NAFLD compared to non-lean NAFLD (log-rank test = 5.6; $P < 0.02$) [6] In a recent study, morbid obesity and diabetes were related to an increased risk of drop out of NASH patients from the waiting list[15].

Frailty, a common complication of cirrhosis, is seen more frequently in NASH cirrhosis patients as compared to other etiologies such as alcoholic liver disease[16]. Frailty has previously been shown to determine a patient's overall health, the number of hospitalizations, length of hospital stay, delisting, and waitlist mortality[17-21]. especially in patients older than 65 years of age[22] independent of portosystemic encephalopathy or ascites[23]. However, the impact of frailty in the NASH cohort was not assessed. In a multicentre study, frailty was associated with a 2-fold higher risk of wait-list mortality among nonobese/class 1 obese patients, while more than 3-fold higher risk of wait-list mortality among class 2 or greater obese liver transplant candidates[24]. However, NASH comprised only 17.5% of their patient population, while BMI was not corrected for ascites which was present in 37.1% of their patients. In a retrospective analysis, a higher frailty score was associated with an increased risk of delisting in NASH patients (HR: 1.46; 95%CI: 1.06–2.03, $P = 0.02$)[16]. In our study, lean NASH patients with frailty had poor survival (HR: 0.12; 95%CI: 0.05–0.29, $P < 0.0001$) with lower instantaneous rate of transplant (HR: 5.71; 95%CI: 1.26–25.9, $P = 0.02$). Therefore, the convergence of frailty with lean NASH led to significantly worse outcomes on the waitlist as well as in the early period post-transplant.

Though lean NAFLD is considered to be benign, the dysfunctional adipose tissue, in particular, visceral adiposity is related with increase cardiometabolic risk in lean NAFLD. Further, alterations in

Table 2 Percentage of patients who changed body mass index groups after ascites correction

Reduction in BMI after ascites correction					Original/uncorrected	Unchanged

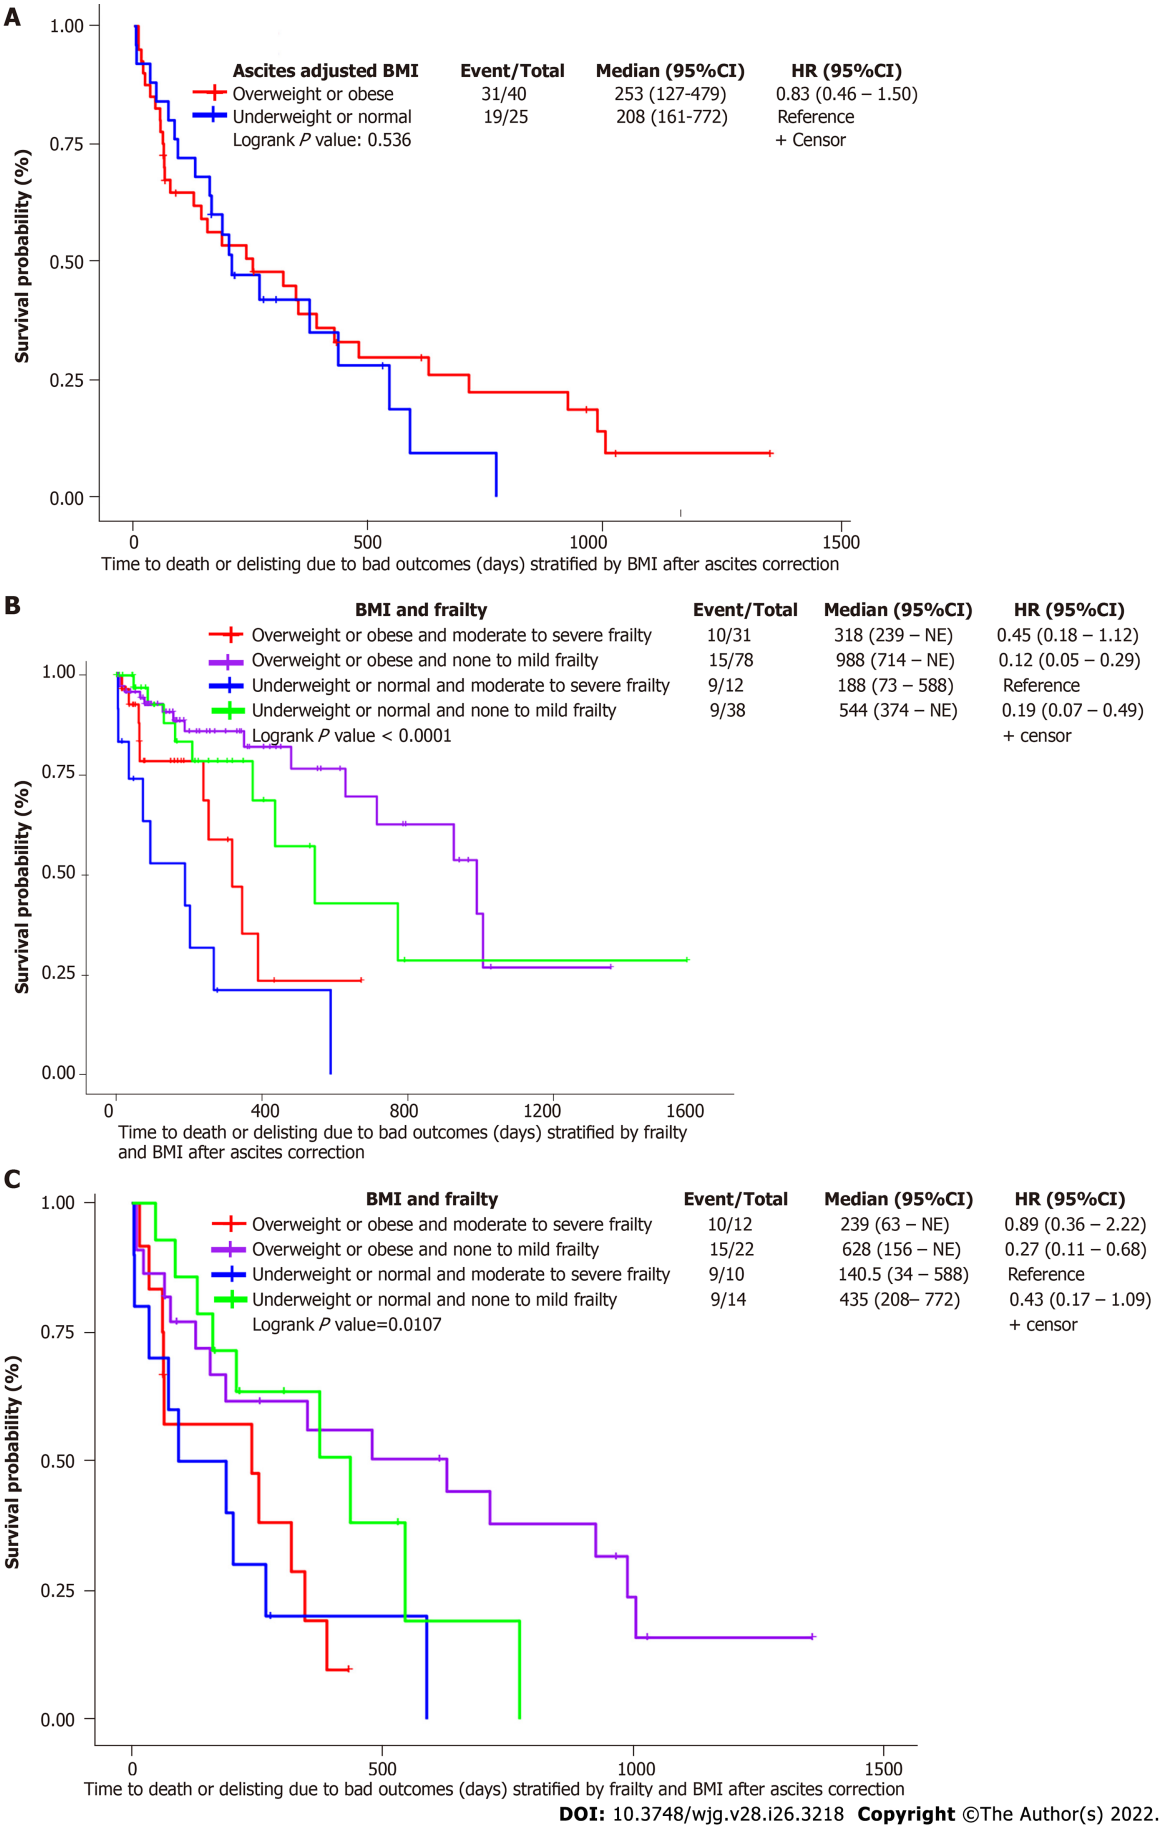
BMI: Body mass index.

TM6SF2, a gene conferring susceptibility to NASH and fibrosis, are shown to be increased in lean NAFLD than obese NAFLD patients. However, there is a paucity of data on post-transplant outcomes in lean patients specifically[25]. In the post-transplant setting, a pivotal study looking at the patients on the UNOS database revealed that both short- and long-term survivals were low in patients who were morbidly obese before transplantation, owing to adverse cardiovascular events[26]. However, none of the patients in this study belonged to the NASH group. On the contrary, obesity was noted to paradoxically favour the NASH patients compared to their non-NASH counterparts. A recent study found that lean patients have both poorer graft and patient survival than their obese counterparts[7]. However, they did not adjust the BMI for ascites, whereas elevated BMI might have reflected fluid overload instead of true obesity. There is still much that is not known or understood, and hence it is challenging to explain the underlying molecular mechanisms linking lean NASH with worse outcomes post LT. Nonetheless, our study also confirms the enigmatic effect of obesity in the NASH subset. This study also highlighted the importance of correcting BMI for ascites. Despite correcting BMI for ascites, 69% of NASH patients belong to the overweight/obese group.

NASH has been associated with metabolic syndrome-related complications such as cardiovascular disease and chronic kidney disease (CKD)[27]. Post-transplant the risk of metabolic complications increases further owing to the immunosuppressive medications. Furthermore, calcineurin inhibitors carry direct nephrotoxic effects. In general, obese NAFLD patients appear to have a higher risk of developing CKD than non-obese[28]. In post-LT patients, obesity has been identified as a risk for post-operative severe acute kidney injury[29] as well as renal disease progression needing a kidney transplant after LT[30]. We further augmented this data by showing that median creatinine in our obese patients was significantly higher than in lean patients at 5 years (153.5 μmol/L *vs* 111 μmol/L, P = 0.019). The incidence of diabetes and hypertension were numerically higher in the obese group at 1 and 5 years, however, this difference was statistically insignificant. Further, the incidence of cardiovascular events was also not significantly different among the two groups. Further expansion of follow-up to 10 years might show a statistically meaningful difference. However, this analysis was not possible in the current study. Given the selection criteria with the start of the study from November 2012, none of the patients has achieved the 10-year benchmark yet.

This study has been limited by its retrospective design, smaller sample size, and lack of a comparison group from a non-NASH subset. We also acknowledge the limitation of missing data given the retrospective design, transfer of care to other local centres post-transplant, and a limited number of patients achieving the 5-year benchmark. The results of this study should be interpreted cautiously as it does not suggest the listing of all morbidly obese NASH cirrhotic patients for liver transplant. Nonetheless, under current practice, outcomes of carefully selected NASH patients with higher BMI are better than their lean counterparts. This conundrum could have been explained by improvement in patient selection protocols, post-transplant critical care support, and immunosuppressive treatment. Future larger studies would be required to validate the generalizability of our findings. Moreover, there is need of identifying the factors such as genetic variants, and body fat distribution/visceral adiposity, which can play role in this paradox.

CONCLUSION



Lean NASH is associated with adverse outcomes on the waiting list as well as early post-transplant, in

Figure 4 Kaplan-Meier–overall survival: Time to death post liver transplant stratified by ascites adjusted body mass index groups. Lower panel shows the 1- and 5-yr survival estimates. HR: Hazard ratio; BMI: Body mass index.

ARTICLE HIGHLIGHTS

Research background

Non-alcoholic steatohepatitis (NASH) cirrhosis is the second leading indication for liver transplantation (LT). There is a conflicted role of body mass index (BMI) on outcomes of NASH cirrhosis while on waitlist and post liver transplant.

Research motivation

There are few reports on the waitlist and post liver transplant outcomes of lean *vs* obese NASH patients, and the impact of ascites adjusted BMI have not been fully clarified.

Research objectives

The objective of this study was to compare the longitudinal trajectories of patients with lean *vs* obese NASH cirrhosis, from listing up to post-transplant, having adjusted their BMI for ascites.

Research methods

A retrospective analysis of all adult NASH patients listed for LT at the University Health Network, Toronto between November 2012 and May 2019 was performed. We summarized the clinical characteristics of patients with lean and obese NASH. Competing risk analyses and Cox Proportional Hazard models were used to assess the cumulative incidence of transplant and survival outcomes.

Research results

Out of 265 patients listed for NASH cirrhosis, 176 were included. The median age was 61 (32–71.4) years; 46% were females. 111 patients underwent LT. Lean NASH patients were elderly at time of listing (median age 61.6 years *vs* 60.3 years, P = 0.048), worse renal functions at end of listing (median estimated glomerular filtration 48 mL/min/1.73 m^2 *vs* 57 mL/min/1.73 m^2, P = 0.017), carried more severe ascites (66.6% *vs* 45%, P = 0.03) and were more paracentesis dependent (72.2% *vs* 52.9%, P = 0.016). Obese robust patients had better waitlist survival [hazard ratio (HR): 0.12; 95%CI: 0.05–0.29, P < 0.0001] with higher instantaneous rate of transplant (HR: 5.71; 95%CI: 1.26–25.9, P = 0.02). Lean NASH patients had a substantially higher risk of graft loss within 90 d post-LT (1.2% *vs* 13.8%, P = 0.032) and death post-LT (2.4% *vs* 17.2%, P = 0.029). 1- 3- and 5-year graft survival was poor for lean NASH (78.6%, 77.3% and 41.7% *vs* 98.6%, 96% and 85% respectively). Overall patient survival post-LT was significantly worse in lean NASH (HR: 0.17; 95%CI: 0.03–0.86, P = 0.0142) with 83% lower instantaneous rate of death in obese group. Post-transplant renal function was significantly better in lean NASH patients at 5 years (median creatinine 111 μmol/L *vs* 153.5 μmol/L, P = 0.019).

Research conclusions

Although lean NASH was thought to be more benign than obese NASH, our study suggests a paradoxical correlation of lean NASH with waitlist outcomes, and graft and patient survival post-LT, in conjunction with often comorbid frailty.

Research perspectives

To understand the underlying molecular mechanisms linking lean NASH with worse outcomes, there is need of identifying the factors such as genetic variants, body fat distribution/visceral adiposity, which can play role in this paradox.

FOOTNOTES

Author contributions: Qazi-Arisar FA and Uchila R given their equal contribution in the manuscript; Bhat M was the guarantor and designed the study; Qazi-Arisar FA, Uchila R, Chen C, Yang C, Chen SY, Karnam RS and Azhie A participated in the acquisition, analysis, and interpretation of the data, and drafted the initial manuscript; Qazi-Arisar FA, Xu W, Galvin Z, Selzner N, Lilly L and Bhat M revised the article critically for important intellectual content.

Institutional review board statement: The study was reviewed and approved by the Research Ethics board of the University Health Network (Toronto, Canada).

Informed consent statement: Given retrospective nature of study from chart review, written informed consent was not required.

Conflict-of-interest statement: Dr. Bhat reports other from Novo Nordisk, other from Ipsen, grants from Paladin, grants from Natera, grants from Oncoustics, grants from MedoAI, grants from Lallemand, personal fees from Novartis, personal fees from Lupin, outside the submitted work.

Data sharing statement: No additional data are available.

STROBE statement: The authors have read the STROBE Statement—checklist of items, and the manuscript was prepared and revised according to the STROBE Statement—checklist of items.

Open-Access: This article is an open-access article that was selected by an in-house editor and fully peer-reviewed by external reviewers.
