Abstract

BACKGROUND

Recently, hepatic arterial infusion chemotherapy (HAIC) plus lenvatinib has been frequently used to treat unresectable hepatocellular carcinoma (uHCC) in China. In the clinic, the hepatic arteries of some patients shrink significantly during this treatment, leading to improved short-term efficacy.

AIM

To investigate the relationship between the shrinkage of hepatic arteries and the short-term effect of HAIC plus lenvatinib treatment.

METHODS

Sixty-seven participants with uHCC were enrolled in this retrospective study. The patients received HAIC every 3 wk, followed by oral lenvatinib after the first HAIC course. Hepatic artery diameters were measured on CT before treatment and after 1 and 2 mo of treatment. Meanwhile, the changes in tumor capillaries were also examined on pathological specimens before and after 1 mo of treatment. The antitumor response after 1, 3, and 6 mo of treatment was assessed using the modified Response Evaluation Criteria in Solid Tumors (mRECIST). The relationship between the changes in vessel diameters and the short-term effect of the combination treatment was evaluated by receiver-operating characteristic and

logistic regression analyses.

RESULTS

The hepatic artery diameters were all significantly decreased after 1 and 2 mo of treatment ($P < 0.001$), but there was no difference in the vessel diameters between 1 and 2 mo ($P > 0.05$). The microvessel density in the tumor lesions decreased significantly after 1 mo of combination treatment ($P < 0.001$). According to mRECIST, 46, 41, and 24 patients had complete or partial responses after 1, 3, and 6 mo of treatment, respectively, whereas 21, 21, and 32 patients had a stable or progressive disease at these times, respectively. Shrinkage of the tumor-feeding artery was significantly associated with the tumor response after 1, 3, and 6 mo of treatment ($P < 0.001$, $P = 0.004$, and $P = 0.023$, respectively); however, changes in other hepatic arteries were not significantly associated with the tumor response. Furthermore, shrinkage of the tumor-feeding artery was an independent factor for treatment efficacy ($P = 0.001$, $P = 0.001$, and $P = 0.002$ and 1, 3, and 6 mo, respectively).

CONCLUSION

The hepatic arteries shrank rapidly after treatment with HAIC plus lenvatinib, and shrinkage of the tumor-feeding artery diameter was closely related to improved short-term efficacy.

Core Tip: In this study, it was observed for the first time that the hepatic arteries shrank rapidly after hepatic arterial infusion chemotherapy plus lenvatinib therapy, and the close relationship between shrinkage of the tumor-feeding artery and improved short-term effect in patients with unresectable hepatocellular carcinoma was also confirmed. These findings would be of great significance to physicians for evaluating the effectiveness of this combination therapy earlier in the course of treatment and altering the treatment plan as needed.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common malignant tumors, with 850000 new cases reported per year worldwide[1,2]. In total, 70%-80% of patients with HCC in China are ineligible for surgical resection at the time of onset[3]. Recently, hepatic arterial infusion chemotherapy (HAIC) has been increasingly used to treat patients with unresectable HCC (uHCC) in Asian countries[4,5]. HAIC is recommended as a major treatment option in patients with intermediate and advanced HCC by current Japanese and Chinese guidelines[6].

Lenvatinib is an oral multi-target tyrosine kinase inhibitor (TKI) with antiangiogenic effects. Previous studies demonstrated the survival benefit of lenvatinib plus HAIC *vs* lenvatinib alone in patients with advanced HCC[7]. This combination therapy often requires 6-8 cycles, and early assessment of the antitumor response appears essential for both patients and physicians[8].

Recently, a clinical study demonstrated that the diameters of hepatic arteries are significantly reduced after TKI therapy[9]. Since the early imaging response is often associated with survival benefits, it should be clarified whether the changes in hepatic vessel diameters are related to the efficacy of HAIC combined with lenvatinib. As a result, we conducted a retrospective study of patients with uHCC treated with HAIC plus lenvatinib. The aim of this study was to: (1) Explore the changes in hepatic arteries after combination treatment; and (2) Determine the relationship between the hepatic artery changes and early therapeutic effects.

MATERIALS AND METHODS

Patient eligibility

This was a single-center, retrospective analysis of data from 67 patients with uHCC treated at our institution from January 2019 to October 2020. Approval for the study was obtained from the local ethics committee on human research. The HCC diagnosis was based on the findings of pathological, imaging, and clinical assessments using the European Association for the Study of the Liver criteria[10]. Eligible patients were those aged 18 years or older with uHCC (including patients with large/multifocal HCC and/or with vascular invasion and extrahepatic spread) who received HAIC plus lenvatinib as an initial treatment. Patients who underwent transcatheter arterial chemoembolization or received other TKIs before combination therapy were excluded. Enrolled patients who discontinued treatment during the follow-up period were also excluded.

Treatments

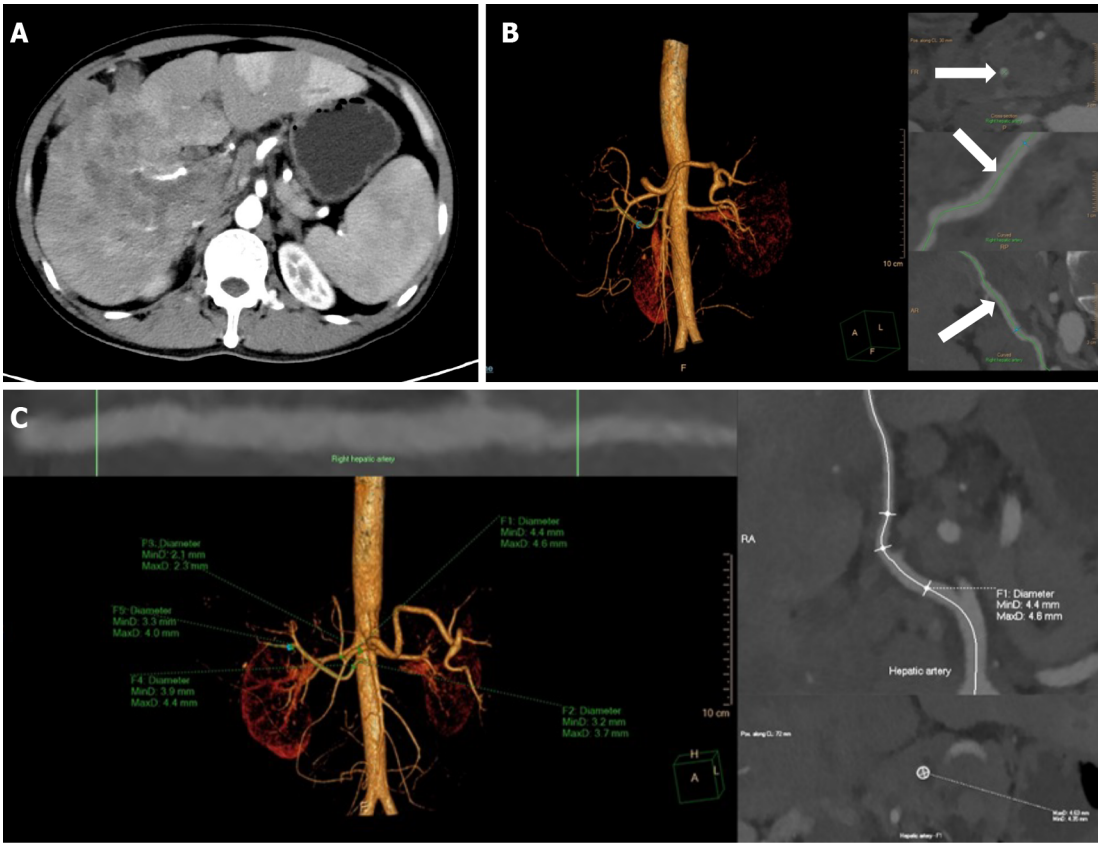
HAIC was repeated at an interval of 3 wk in enrolled patients in our hospital. A catheter was initially advanced into the celiac or superior mesenteric artery for digital subtraction angiography from the femoral artery; then, a microcatheter was left in the tumor-feeding artery (TFA) for subsequent treatment.

The patients received the following regimen for HAIC through the indwelling microcatheter connected to an artery infusion pump in the ward: oxaliplatin 85 mg/m^2 administered intraarterially for 2 h, leucovorin 400 mg/m^2 administered intraarterially for 1 h, and 5FU 400 mg/m^2 intra-arterial bolus injection on day 1, followed by 5FU 2400 mg/m^2 continuous arterial infusion for 46 h. Three days after the first HAIC course, patients began to take lenvatinib (Eisai, Tokyo, Japan) orally at the recommended doses of 12 mg/day for patients weighing ≥ 60 kg and 8 mg/day for patients weighing < 60 kg[11]. Dose adjustment or termination of lenvatinib therapy was allowed when drug-related adverse events (AEs) occurred. Discontinuation of the combination treatment was also allowed for potentially fatal AEs, clinical tumor progression, or the need for conversion therapy.

Evaluations and measurement

Therapeutic responses after 1, 3, and 6 mo of combination treatment were assessed according to the modified Response Evaluation Criteria in Solid Tumors using CT (Philips Brilliance iCT; Philips Medical Systems, Best, the Netherlands) images. Treatment responders were defined as patients with a complete response (CR) or partial response (PR). Non-responders were defined as patients with stable disease (SD) or progressive disease (PD). AEs were assessed using the Common Terminology Criteria for Adverse Events (CTCAE) version 5.0[12].

Epigastric enhanced CT Digital Imaging and Communication of Medicine (DICOM) data were collected before treatment and after 1 and 2 mo of treatment and introduced into an image post-processing workstation (Philips IntelliSpace Portal; Koninklijke Philips N.V., Eindhoven, the Netherlands) for three-dimensional reconstruction. On the image post-processing workstation, multiplanar reconstruction images centered on the contrast-enhanced hepatic arteries and the centerline (CLL) of the blood vessels were generated by the software to straighten the curved arteries. The trunk or the thickest branch of the TFA was selected as the object of measurement. The CLL was adjusted manually to measure the largest diameter of the arteries. The diameters of the opening of the common hepatic artery (CHA), proper hepatic artery (PHA), left hepatic artery (LHA), right hepatic artery (RHA), and TFA were further measured by manually drawing the region of interest (Figure 1)[13]. The change in vessel diameters was defined and calculated using the following formula: $\Delta_{artery} = (D_{post} - \Delta_{pre}) / \Delta_{pre}$ (Δ_{artery}: The rate of change in the diameter of CHA, PHA, LHA, RHA, or TFA; D_{pre}: The vessel diameter before combination treatment; D_{post}: The vessel diameter after combination treatment).



Both the measurement of artery diameters and the evaluation of therapeutic efficacy were individually conducted by two physicians with experience in gastroenterological diagnostics, and differences were resolved by a more experienced physician.

Immunohistochemistry

Tumor angiogenesis was evaluated by measuring microvessel density (MVD) after staining using an anti-CD34 antibody. Punch biopsy samples were obtained from tumor lesions before and 1 mo after the start of HAIC plus lenvatinib therapy. The tumor samples were fixed in 10% formalin and embedded in paraffin. After routine laboratory procedures, immunohistochemistry was performed to detect the expression of CD34 (endothelial cell marker) through the avidin–biotin–peroxidase complex[14,15]. MVD was measured at × 100 magnification in five regions of interest using a light microscope. All endothelial cells, including individual cells and grouped cells, were counted as a single vessel if they were separated from the surrounding tumor and other connective tissues[16].

Statistical analysis

Statistical analyses were performed using IBM SPSS Statistics 26.0. The measurement data were presented as the mean ± SD, and $P < 0.05$ indicated statistical significance. Considering the loss to

Figure 1 Reconstruction and measurement of the hepatic arteries. A: The thickest branch of tumor-feeding arteries generated from the right hepatic artery; B: Three-dimensional reconstruction of hepatic arteries in an image post-processing workstation and the adjustment of center line (arrows) on multiple layers; C: The hepatic artery diameters are measured automatically by drawing the region of interest. F1-5, the opening of the common hepatic artery, the proper hepatic artery, the left hepatic artery, the right hepatic artery and the tumor-feeding artery.

follow-up, the changes in the artery diameters were compared using the mixed linear model for repeated measured data, and follow-up pairwise comparison was conducted among the three periods. The independent-samples *t*-test was used to analyze the changes in MVD. Receiver-operating characteristic (ROC) analysis was used to evaluate the changes in the diameter of all hepatic arteries to differentiate between responders and non-responders and identify the cutoff values. The cutoff was calculated for any factors that were statistically significant in the ROC analysis, which were candidates for univariate and multivariable logistic regression analyses with baseline data.

RESULTS

Participant characteristics

During the study period, patients meeting the inclusion criteria were followed up for 6 mo after the start of the combination treatment. The study population was predominantly male (59/67, 88.1%), and most of the enrolled patients were infected with hepatitis B virus (53/67, 79.1%). In total, 45 (67.2%) patients were estimated to have Child–Pugh stage A liver function, and 22 (32.8%) patients were categorized as Child–Pugh stage B. Portal vein tumor thrombosis was diagnosed in 44 (65.7%) patients, hepatic vein tumor thrombus in 17 (25.4%) patients, and extrahepatic spread occurred in 13 (19.4%) patients. The characteristics of the patients are summarized in Table 1.

Treatment-related AEs

There were no treatment-related deaths in our study. According to CTCAE, grade 1-2 events were observed in 37 patients (55.2%) and grade 3 events in 2 (3.0%) patients, whereas no grade ≥ 4 AEs occurred. The most common grade 1-2 events were abdominal pain (17/67, 25.4%), fever (8/67, 11.9%), and transient nausea and vomiting (8/67, 11.9%). The grade 3 events were liver dysfunction and decreased leukocyte counts, both of which normalized after treatment.

Efficacy

Five patients missed the 3-mo imaging evaluation, and 11 patients missed the 6-mo evaluation because of loss to follow-up. In total, 46, 41, and 24 patients were classified as responders (CR + PR) after 1, 3, and 6 mo of treatment, respectively, whereas the numbers of non-responders (SD + PD) at these time points were 21, 21, and 32, respectively. The overall response rates (ORR) in this study at 1, 3, and 6 mo were 68.7%, 66.1%, and 42.9%, respectively. Eight patients received downstaging therapy within 1 year after treatment, of which six patients underwent hepatectomy and the other two patients underwent radiofrequency ablation.

Artery diameters

Vessel diameters were measured in all patients before treatment and after 1 mo of treatment, whereas six patients missed the 2-month measurement. After 1 and 2 mo of treatment, all vessel diameters had gradually decreased compared with the baseline ($P < 0.001$), but the difference in vessel diameters between 1 and 2 mo was not significant ($P > 0.05$, Figure 2). According to the ROC analysis, the change in the TFA diameter was significantly different between the responders and non-responders at 1, 3, and 6 mo ($P < 0.001$, $P = 0.004$, and $P = 0.023$, respectively), and the corresponding cutoff values were -0.169, -0.169, and -0.264, respectively. Meanwhile, there were no significant differences in the diameters of other hepatic arteries between the groups (Table 2). Considering the unclear clinical meaning of continuous changes in vessel diameters, the change in the TFA diameter was classified as reduced or unchanged based on the cutoff values.

The results of the univariate and multivariable logistic regression analyses of tumor response are listed in Table 3. According to the multivariable analysis, the change in the TFA diameter was an independent factor for the efficacy of HAIC plus lenvatinib after 1 [odds ratio (OR) = 0.12; 95% confidence interval (CI): 0.03-0.43; $P = 0.001$], 3 (OR = 0.06; 95%CI: 0.01-0.29; $P = 0.001$), and 6 mo (OR = 0.14; 95%CI: 0.04-0.47; $P = 0.002$) of treatment. Other independent factors included the alpha-fetoprotein level (OR = 0.17; 95%CI: 0.04-0.73; $P = 0.018$) at 1 mo and tumor size (OR = 7.65; 95%CI: 1.36-42.88; $P = 0.021$) at 3 mo.

MVD

The MVD of tumor lesions after the administration of lenvatinib was robustly smaller than that before treatment, suggesting that angiogenesis was strongly suppressed by lenvatinib ($P < 0.001$, Figure 3).

DISCUSSION

In the present study, significant shrinkage of hepatic arteries was observed in patients with uHCC after 1 mo of HAIC plus lenvatinib therapy for the first time. We also confirmed that the morphological change in the TFA was closely related to the tumor response after 1, 3, and 6 mo of combination treatment, and this change was an independent factor for improved short-term therapeutic efficacy. These findings would be of great significance to physicians for evaluating the effectiveness of this combination therapy earlier in the course of treatment and altering the treatment plan as needed.

Hepatic arteries were shown to be markedly thin following TKI treatment, and Chen *et al*[17] attributed these morphological changes to the anti-angiogenic effect of targeted drugs. Notably, lenvatinib more effectively suppresses angiogenesis and inhibits tumor growth than sorafenib by targeting both vascular endothelial growth factor (VEGF) and fibroblast growth factor[18,19]. In our study, shrinkage of hepatic vessels was observed early after the start of HAIC plus lenvatinib therapy, and the powerful antiangiogenic effect of lenvatinib was proven by the decrease in the MVD of the tumor lesions. Meanwhile, anti-VEGF therapies can reverse vessel abnormalities and improve the tumor microenvironment[20]. The decline in local tumor perfusion secondary to the decrease in tumor capillaries and the "normalization hypothesis" may be the main reasons for the conspicuous reduction of hepatic arteries with the combination regimen.

The efficiency of HAIC combined with lenvatinib for intermediate and advanced HCC has been confirmed in previous studies[21,22]. In this study, the ORR reached 68.7%, 66.1%, and 42.9% at 1, 3, and 6 mo, and conversion therapy was achieved in eight patients, which further verified the effectiveness of the combination therapy. Thus, it was necessary to explore the mechanism of action of this combination therapy. A reduction in hepatic artery diameters was observed in most patients in the present study. Kuorda *et al*[23] also reported that local tumor perfusion declined significantly after oral lenvatinib administration. These findings illustrated that lenvatinib reduces the tumor blood supply after combination therapy. Meanwhile, HAIC has the advantage of achieving high local concentrations in the tumor during arterial infusion[24]. According to the pharmacokinetic characteristics of the intra-arterial infusion[25], a decrease in tumor blood flow can increase the dose of the drug in the target organ, thus enhancing the antitumor effect of HAIC. Furthermore, the normalization and improved functionality of tumor vessels including reduced hypoxia, reduced vascular leakage, and improved vascular permeability can improve the delivery of local chemotherapeutic drugs in tumors[26,27]. The increased drug accumulation in the target organ often results in improved therapeutic efficacy. Since the combined therapy could improve the therapeutic effect, it may also expand the scope of HAIC, which is limited to patients with HCC and multinodule lesions or vascular invasion.

In clinical practice, HAIC often requires 6-8 courses. Moreover, repetitive and inefficient treatment is harmful to patients with uHCC. Therefore, early evaluation of the treatment response is of great significance. In this study, we found that the reduction in the TFA diameter after combination therapy was an independent factor for improved therapeutic efficacy within 6 mo. The morphological change in the TFA is easy to observe during HAIC, and it can help in estimating the early therapeutic effect. Since an improved short-term effect often results in a good prognosis, the observation on thinning of the TFA is significant and more practical for patients with uHCC who are receiving HAIC plus lenvatinib.

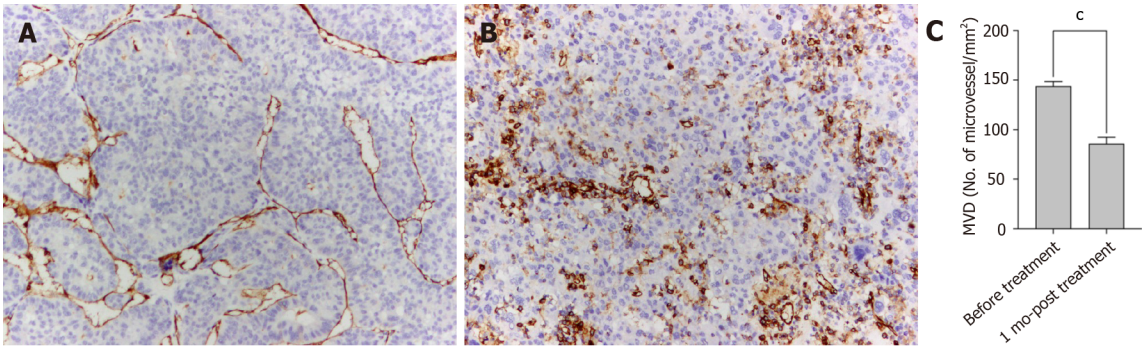
Any factors that were statistically significant at $P < 0.10$ in the univariate logistic regression analysis were candidates for entry into the multivariate logistic regression analysis. TFA: The tumor-feeding artery; ECOG PS: Eastern Cooperative Oncology Group performance status; HBsAg: Hepatitis B surface antigen; AFP: Alfa-fetoprotein; PVTT: Portal vein tumor thrombus; HVTT: Hepatic vein tumor thrombus; OR: Odds ratio; CI: Confidence interval.

The present study had some limitations. This was a single-center retrospective study, and the sample size was small.



CONCLUSION

In conclusion, lenvatinib can reduce the diameters of hepatic arteries and thus enhance the effect of HAIC. Shrinkage of the TFA after HAIC plus lenvatinib therapy was linked to improved short-term outcomes in patients with uHCC.

ARTICLE HIGHLIGHTS

Research background

Combination of hepatic arterial infusion chemotherapy (HAIC) and lenvatinib has been frequently used to treat unresectable hepatocellular carcinoma (uHCC) in China.

Research motivation

Shrinkage of hepatic arteries after the combination therapy is a common phenomenon and may early reflect the antitumor response, the relationship between which needs further exploration.

Research objectives

To investigate the relationship between hepatic artery diameters reduction and the short-term efficacy of HAIC plus lenvatinib.

Research methods

Sixty-seven patients with uHCC receiving HAIC plus lenvatinib were analyzed retrospectively. The modified Response Evaluation Criteria in Solid Tumors was used to assess the antitumor response after 1, 3, and 6 mo of treatment. The measurement of hepatic artery diameters before treatment and after 1 and 2 mo of treatment were conducted in a computed tomography image post-processing workstation. Meanwhile, the changes in tumor capillaries were also examined on pathological specimens before and after 1 mo of treatment.

Research results

All the hepatic artery diameters and the microvessel density in the tumor lesions were significantly decreased after the combination treatment (all $P < 0.001$). Shrinkage of the tumor-feeding artery (TFA) was significantly associated with the antitumor response after 1, 3, and 6 mo of treatment ($P < 0.001$, $P = 0.004$, and $P = 0.023$, respectively) and an independent factor for treatment efficacy ($P = 0.001$, $P = 0.001$, and $P = 0.002$ and 1, 3, and 6 mo, respectively).

Research conclusions

The retrospective study demonstrated that the shrinkage of the TFA diameter was closely related to improved short-term efficacy of treatment with HAIC plus lenvatinib for the first time.

Research perspectives

We believe the findings in this paper will be of interest to the researchers in uHCC. Further, prospective randomized multicenter trials are needed to confirm the relationship between the morphological change in TFA and the early therapeutic effect of uHCC treatment.

Abstract

BACKGROUND

Sodium glucose cotransporter-2 inhibitors (SGLT2-I) are the most recently approved drugs for type 2 diabetes (T2D). Recent clinical trials of these compounds reported beneficial cardiovascular (CV) and renal outcomes. A major cause of vascular dysfunction and CV disease in diabetes is hyperglycemia associated with inflammation and oxidative stress. Pre-clinical studies demonstrated that SGLT2-I reduce glucotoxicity and promote anti-inflammatory effects by lowering oxidative stress.

AIM

To investigate the effects of SGLT2-I on markers of oxidative stress, inflammation, liver steatosis, and fibrosis in patients of T2D with non-alcoholic fatty liver disease (NAFLD).

METHODS

We referred fifty-two consecutive outpatients treated with metformin monotherapy and exhibiting poor glycemic control to our centre. We introduced the outpatients to an SGLT2-I (dapagliflozin, empagliflozin, or canagliflozin; n = 26)

or a different hypoglycemic drug [other glucose-lowering drugs (OTHER), *n* = 26]. We evaluated circulating interleukins and serum hydroxynonenal (HNE)- or malondialdehyde (MDA)-protein adducts, fatty liver index (FLI), NAFLD fibrosis score, aspartate aminotransferase (AST)/alanine aminotransferase (ALT) ratio, AST-to-platelet-ratio index (APRI), and fibrosis-4 on the day before (T0) and following treatment for six months (T1). We also performed transient elastography at T0 and T1.

RESULTS

Add-on therapy resulted in improved glycemic control and reduced fasting blood glucose in both groups. Of note, following treatment for six months, a reduction of FLI and APRI, as well as of the FibroScan result, was reported in patients treated with SGLT2-I, but not in the OTHER group; furthermore, in the SGLT2-I group, we reported lower circulating levels of interleukin (IL)-1β, IL-6, tumor necrosis factor, vascular endothelial growth factor, and monocyte chemoattractant protein-1, and higher levels of IL-4 and IL-10. We did not observe any modification in circulating interleukins in the OTHER group. Finally, serum HNE- and MDA-protein adducts decreased significantly in SGLT2-I rather than OTHER patients and correlated with liver steatosis and fibrosis scores.

CONCLUSION

The present data indicate that treatment with SGLT2-I in patients with T2D and NAFLD is associated with improvement of liver steatosis and fibrosis markers and circulating pro-inflammatory and redox status, more than optimizing glycemic control.

Key Words: Sodium glucose cotransporter-2 inhibitors; Non-alcoholic fatty liver disease; Oxidative stress; Type 2 diabetes; Liver fibrosis; Inflammation

Core Tip: Non-alcoholic fatty liver disease (NAFLD) is the most common hepatic disorder, and it is often associated with type 2 diabetes mellitus (T2DM). Diabetic patients often suffer from advanced NAFLD and are keen on progressing toward severe fibrosis and end-stage liver disease. There is no approved treatment for NAFLD, but new drug classes introduced to treat T2DM can exert favorable effects beyond glucose control. This pilot study demonstrates that treatment with sodium glucose cotransporter-2 inhibitors in patients with T2DM and NAFLD is associated with improving liver steatosis and fibrosis markers and circulating pro-inflammatory and redox status.

INTRODUCTION

Patients affected by type 2 diabetes mellitus (T2DM) present with an increased risk of cardiovascular (CV) disease, which is associated with a high mortality rate and low quality of life[1,2]. T2DM is strongly associated with non-alcoholic fatty liver disease (NAFLD), whose prevalence in diabetic patients is over 60%[3,4]. NAFLD is the most common chronic liver disease, characterized by a broad spectrum of hepatic disorders, ranging from simple steatosis to steatohepatitis (non-alcoholic steatohepatitis), fibrosis, and cirrhosis[5]. The co-existence of NAFLD and T2DM pushes the progression of liver damage, increasing the risk of advanced fibrosis[6]. Besides, NAFLD is an independent risk factor of CV disease. Patients with T2DM and NAFLD present a higher CV risk than diabetic patients without NAFLD, suggesting that these conditions share common pathophysiological mechanisms, including low-grade systemic inflammation and oxidative stress[7].

Studies using new classes of antidiabetic drugs, such as sodium-glucose co-transporter-2 inhibitors (SGLT2-I) and glucagon-like peptide-1 receptor agonists (GLP1-RA), demonstrated definite CV advantage in patients with T2D[8]. Several clinical trials suggest that both classes also ameliorate liver steatosis and inflammation, potentially reversing fibrosis in NAFLD[9]. The currently approved SGLT2-I are dapagliflozin, canagliflozin, empagliflozin, and ertugliflozin, which increase urinary glucose

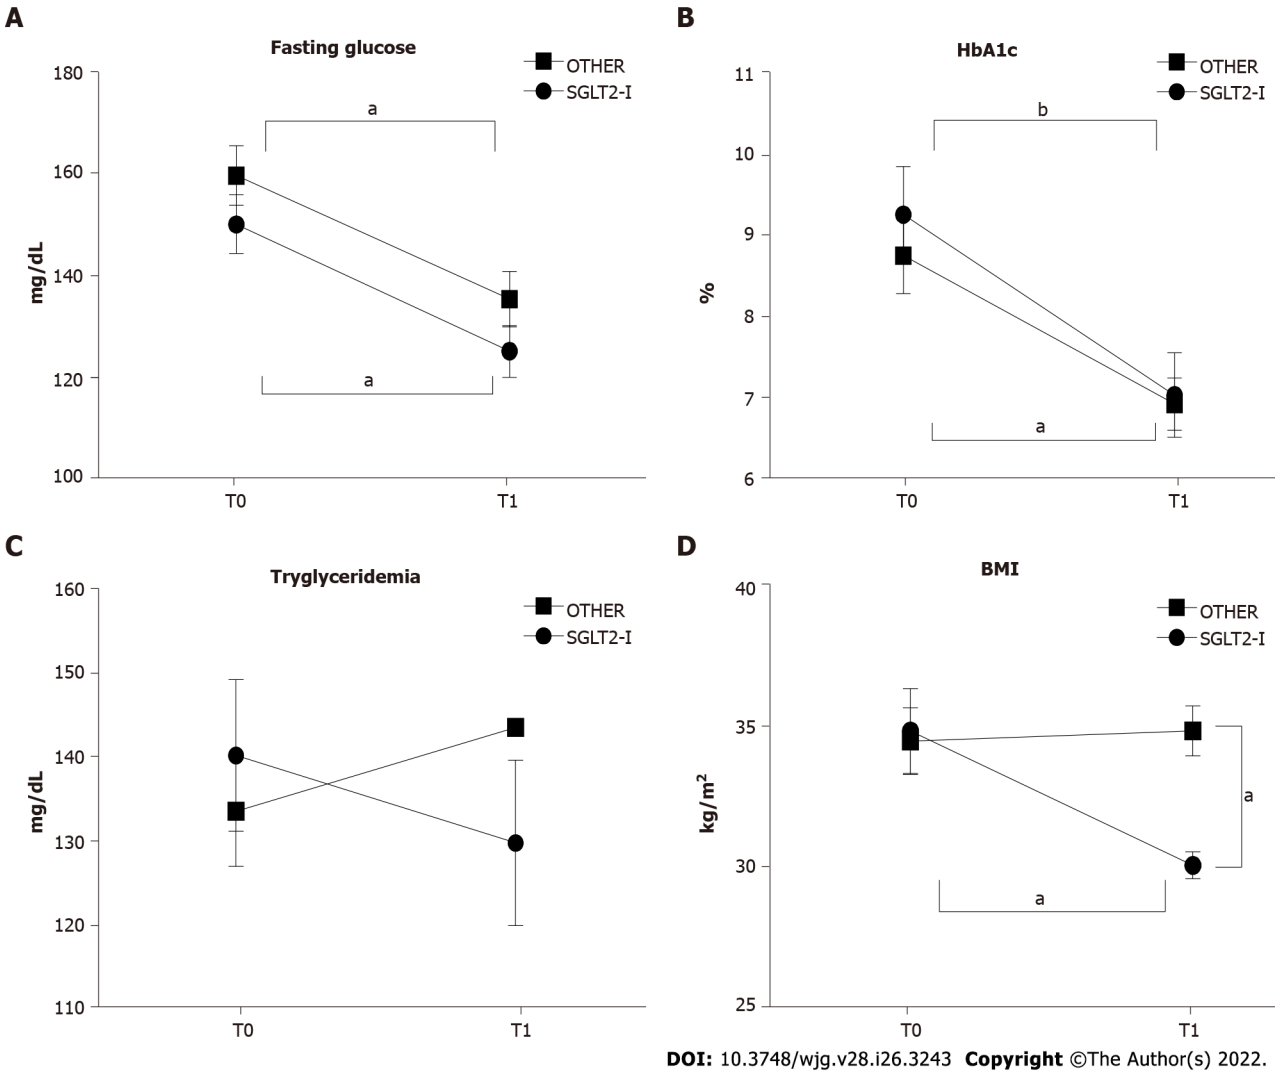
excretion and improve glycemic control independent of insulin. Furthermore, these drugs reduce body weight, visceral adiposity, blood pressure, and arterial stiffness[10]. Real-world CVD-REAL and CVD-REAL 2 studies have demonstrated that the benefits of SGLT2-I on CV outcomes observed in clinical trials may be attributed to a class effect and may be extended to a broad range of patients[11,12]. Despite clinical evidence on the efficacy of SGLT2-I in both the reduction of CV events and the improvement of hepatic damage in NAFLD, human mechanistic trials remain elusive.

Pre-clinical studies demonstrated that dapagliflozin, empagliflozin, and canagliflozin attenuate inflammation in apolipoprotein E knockout mice[13-15], reduce oxidative stress and improve mitochondrial function through direct pleiotropic and epigenetic effects[16,17]. Furthermore, these compounds may also exert antifibrotic effects in diabetic and non-diabetic cardiopathy or nephropathy [18-20]. Such results strongly encourage clinical studies to clarify the impact of SGLT2-I on systemic inflammation, oxidative stress, and liver fibrosis in diabetic patients with NAFLD. Thus, the present investigation was aimed to evaluate the effects of SGLT2-I addition to metformin on circulating markers of inflammation and oxidative protein damage in patients affected by uncontrolled T2DM and NAFLD and compare these outcomes with other glucose-lowering drugs (OTHER).

MATERIALS AND METHODS

Study design

We collected and analyzed data from 204 patients affected by T2DM who underwent outpatient consultation between June 2017 and June 2018 at the University Internal Medicine clinic of the "Policlinico Riuniti" in Foggia (Italy). We designed the investigation as an observational pilot study considering the problematic setting, the limited scale, and the multiple outcome parameters. Patients aged > 18 years old who were: (1) Diagnosed with NAFLD; and (2) Presented with glycated hemoglobin equal to or greater than 7% after at least three months of treatment with metformin monotherapy at the maximal tolerated dosage were assessed for eligibility. NAFLD was suspected on previous ultrasound imaging and/or altered liver function tests[21]. We did not consider subjects diagnosed with viral or autoimmune hepatitis, atherosclerotic CV disease, chronic inflammatory disorders, or those diagnosed with active cancer for the study. Further exclusion criteria were alcohol consumption > 20 g/d (women) or > 30 g/d (men), anemia, severe hepatic failure, glomerular filtration rate < 60 mg/min/m^2, use of drugs affecting redox balance, use of anti-inflammatory medications or corticosteroids during the observational period, use of medications associated with fatty liver (amiodarone, tamoxifen, sodium valproate, methotrexate), current smoker status, and prescription of a glucagon-like peptide-1 agonist (Supplementary Figure 1).



52 patients were finally referred to a combination therapy; of these, 26 patients were treated with an SGLT2-I, while 26 patients were treated with OTHER. The combination therapy was not randomized, and the second compound was chosen according to the standard of medical care in diabetes - 2017, considering the clinical characteristics of patients to maximize therapeutic advantages and minimize risks and side effects[22]. Compliance and adverse events were assessed by a verbal questionnaire. The frequency and distribution of the different compounds prescribed are reported in the Supplementary Table 1. For the study purposes, patients enrolled were assessed at baseline (T0) and after six months (T1). Our Institutional Review Board approved the study at the Policlinico Riuniti in Foggia (reference number 2325/2018) and performed it according to the Declaration of Helsinki. All patients gave written informed consent.

Laboratory measurements

Blood samples were obtained from a brachial vein between 8:00 and 9:00 AM, after an overnight fast, and immediately processed. Standard laboratory measurements included glycated hemoglobin A1c (HbA1c), fasting serum glucose, serum triglycerides, serum aspartate aminotransferase (AST), alanine aminotransferase (ALT) and gamma-glutamyl transpeptidase (gamma-GT) activities, platelet count, and serum albumin. The concentrations of serum cytokines and growth factors, including several interleukins (IL), such as IL-1α, IL-1β, IL-2, IL-4, IL-6, IL-8, IL-10, tumor necrosis factor (TNF), interferon-γ (IFN-γ), monocyte chemoattractant protein-1 (MCP-1), epidermal growth factor (EGF), and vascular endothelial growth factor (VEGF), were measured using the EV 3513 cytokine biochip array and competitive chemiluminescence immunoassays (Randox Laboratories Ltd, Crumlin, United Kingdom), according to the manufacturer's instructions, using the Randox Evidence Investigator[23]. As previously reported, serum fluorescent adducts formed between peroxidation-derived aldehydes [hydroxynonenal (HNE) and malondialdehyde (MDA)] and proteins were measured by spectrofluorimetry[24].

Non-invasive markers of liver steatosis and fibrosis

Patients were assessed at baseline and after six months of treatment for the following parameters: Fatty liver index (FLI), calculated according to the formula e^y / (1 + e^y) × 100, where "y" = 0.953 × ln(triglycerides, mg/dL) + 0.139 × body mass index (BMI), kg/m^2 + 0.718 × ln (gamma-GT, U/L) + 0.053 × waist circumference, cm - 15.745[25]; AST-to-platelet ratio index (APRI), calculated according to the formula

Figure 1 Glycemic control and body weight in patients enrolled in the study and included in groups treated with the sodium-glucose co-transporter-2 inhibitors or other glucose-lowering drugs before (T0) and after 1 wk of treatment (T1). A: Serum fasting glucose; B: Serum hemoglobin A1c; C: Serum triglycerides; D: Body mass index in patients observed in the study, grouped according to the assigned treatment. Data in the graphs are represented as mean ± SEM. Two-way analysis of variance and Tukey assessed statistical differences as post hoc test. $^{a}P < 0.05$, $^{b}P < 0.001$. HbA1c: Hemoglobin A1c; SGLT2-I: Sodium-glucose co-transporter-2 inhibitor; OTHER: Other glucose lowering drug; BMI: Body mass index.

AST, IU/L/AST upper limit of normal, IU/L/platelets, 10^9/L[26]; NAFLD fibrosis score, calculated according to the formula - 1.675 + 0.037 × age, years + 0.094 × BMI, kg/m^2 + 1.13 × impaired fasting glucose or diabetes (yes = 1, no = 0) + 0.99 × AST/ALT ratio - 0.013 × platelets, 10^9/L - 0.66 × albumin, g/dL[27]. The cut-off values chosen to categorize fibrosis grades F0-F2 or F3-F4 were < -1.455 and > 0.675, respectively; fibrosis-4 (FIB-4), calculated according to the formula (age, years × AST, IU/L)/(platelets, 10^9/L × rad ALT, IU/L)[28]. The cut-off values chosen to categorize fibrosis grades F0-F1 or F3-F4 were < -1.30 and > 2.67, respectively; AST/ALT ratio, whose cut-off value > 0.8 is associated with advanced disease[29].

Transient elastography

Transient elastography (TE) was performed by a Fibroscan (Echosense, Paris) on supine patients with the right arm elevated. The probe tip was put on the intercostal space at the level of the right liver lobe. The Fibroscan probe contains an ultrasound transducer and a mechanical device that provides a controlled vibrating external shot on the body surface to generate shear waves. TE measures liver stiffness (LS) in 1 cm cylindric volume (width: 25-65 mm, M probe; 35-75 mm, XL probe) below the skin surface. Criteria for a valid examination were as follows: (1) At least 10 valid measurements; (2) A success rate [(valid + invalid measurements)/total measurements] > 70%; and (3) An interquartile range < 30% of the median value. Measurements were expressed as KPa[30].

Statistical analysis

Data were expressed as count and percentages for categorical variables and as mean ± SDM for

BMI: Body mass index; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; Gamma-GT: Gamma-glutamyl transpeptidase; HbA1c: Hemoglobin A1c; eGFR: Epidermal growth factor receptor; SGLT2-I: Sodium-glucose co-transporter-2 inhibitor; OTHER: Other glucose lowering drug.

quantitative variables. Gaussian distribution of the samples was evaluated by Kolgomorov-Smirnov test. The significance of differences between the 2 treatment groups (SGLT2-I *vs* OTHER) at baseline was assessed by student's *t*-test (continuous variables) or in contingency tables by Pearson's Chi-squared test and Fisher's exact test (categorical variables). The significance of differences between the 2 treatment groups between the beginning (T0) and the end of the observational period (T1) was assessed by the two-way analysis of variance to test the main effects of time and treatment as a between-subject factor; the interaction time × treatment was studied, and a Tukey test was applied as post hoc test for multiple comparisons. The correlation analysis between changes in non-invasive markers of hepatic steatosis and fibrosis with fasting serum glucose or HbA1c, serum interleukins, or serum HNE- and MDA-protein adducts was performed using Pearson correlation test followed by linear regression. All tests were 2-sided, and $P < 0.05$ were considered statistically significant. Statistical analysis was performed with the Statistical Package for Social Sciences version 23.0 (SPSS, Inc., Chicago, IL) and Graph-Pad Prism 6.0 for Windows (GraphPad Software, Inc., San Diego, CA).

RESULTS

Baseline characteristics of the subjects included in the SGLT2-I or the OTHER group are represented in Table 1. The two groups were comparable in terms of clinical and biochemical features. No side effects in both groups were reported. After six months of treatment, a lowering effect on both fasting serum glucose (time factor: $F_{(1, 100)} = 16.04$, $P < 0.0001$) and HbA1c (time factor: $F_{(1, 100)} = 14.83$, $P < 0.0001$) was observed, with a significant reduction from T0 to T1 in both groups (Figures 1A and B). No significant variations were reported as regards serum triglycerides after 6 mo of treatment (Figure 1C). Interestingly, we observed an impact of time, treatment and interaction on body mass index (time factor: $F_{(1, 100)} = 4.146$, $P = 0.0444$; treatment factor: $F_{(1, 100)} = 4.169$, $P = 0.0438$; interaction factor: $F_{(1, 100)} = 5.650$, $P = 0.0194$), and the post hoc analysis resulted in significant differences between the two treatment groups at T1, and between T0 and T1 in the SGLT2-I group (Figure 1D). These data suggest that 6 mo of add-on treatment to metformin improves glycemic control compared to baseline; nevertheless, this improvement is not related to a particular drug class. Furthermore, a beneficial impact on weight loss is

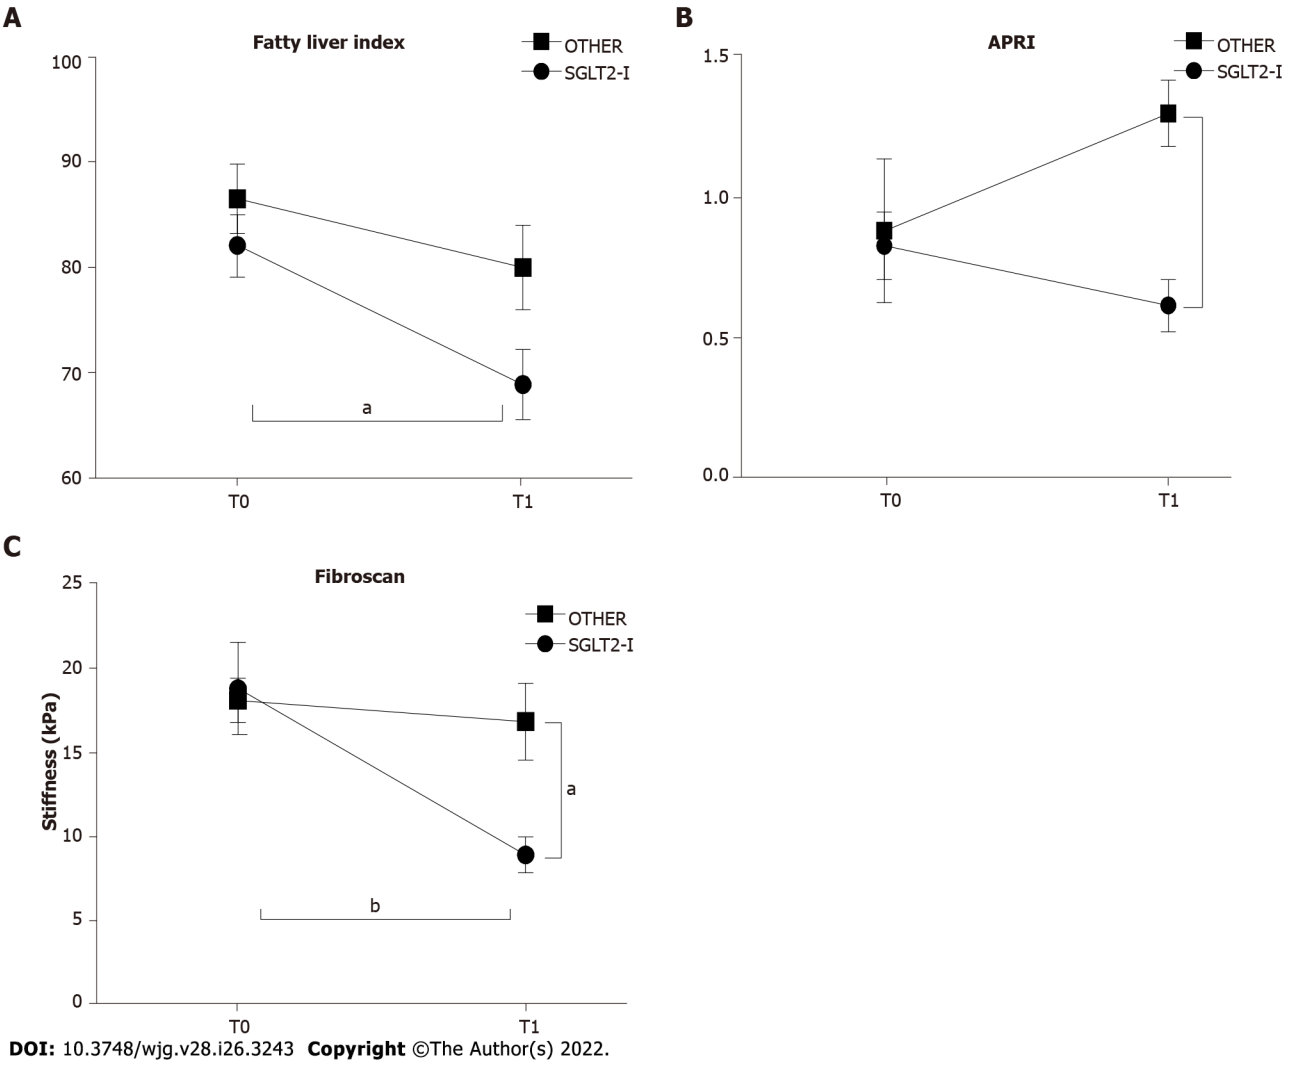
exerted by SGLT2-I but not by other glucose-lowering agents.



Effect of different add-on therapies on liver function tests and non-invasive markers of hepatic steatosis/fibrosis

We then compared the impact of combined treatment with SGLT2-I *vs* OTHER on circulating liver enzymes. The effect of treatment was significant for serum AST level ($F_{(1, 100)} = 7.703$, $P = 0.0066$), and the post hoc analysis showed lower values in SGLT2-I rather than the OTHER group at T1 (Figure 2A). No significant variations were reported for serum ALT and gamma-GT activities (Figures 2B and C). Non-invasive liver steatosis and fibrosis markers were further evaluated at baseline and after 6 mo of therapy in both groups. We observed the effect of both time and treatment on FLI (time factor: $F_{(1, 100)} = 8.279$, $P = 0.0049$ and treatment factor: $F_{(1, 100)} = 5.113$, $P = 0.0259$), but after 6 mo it decreased only in the SGLT2-I group - and not in OTHER patients - with respect to baseline (Figure 3A). A significant effect of treatment was also observed for the APRI ($F_{(1, 100)} = 5.309$, $P = 0.0233$), with a lower value in SGLT2-I rather than OTHER group at T1 (Figure 3B). The proportion of patients affected by a fibrotic form of liver disease according to NAFLD fibrosis score, FIB-4, and AST/ALT ratio reduced significantly after 6 mo of therapy in the SGLT2-I group rather than in the OTHER group (Table 2). Finally, we observed a significant effect of time ($F_{(1, 100)} = 7.996$, $P = 0.0057$) and interaction ($F_{(1, 100)} = 4.772$, $P = 0.0313$) on hepatic elastometry, and LS in patients treated with SGLT2-I for six months was lower with respect to baseline and to the OTHER group (Figure 3C).

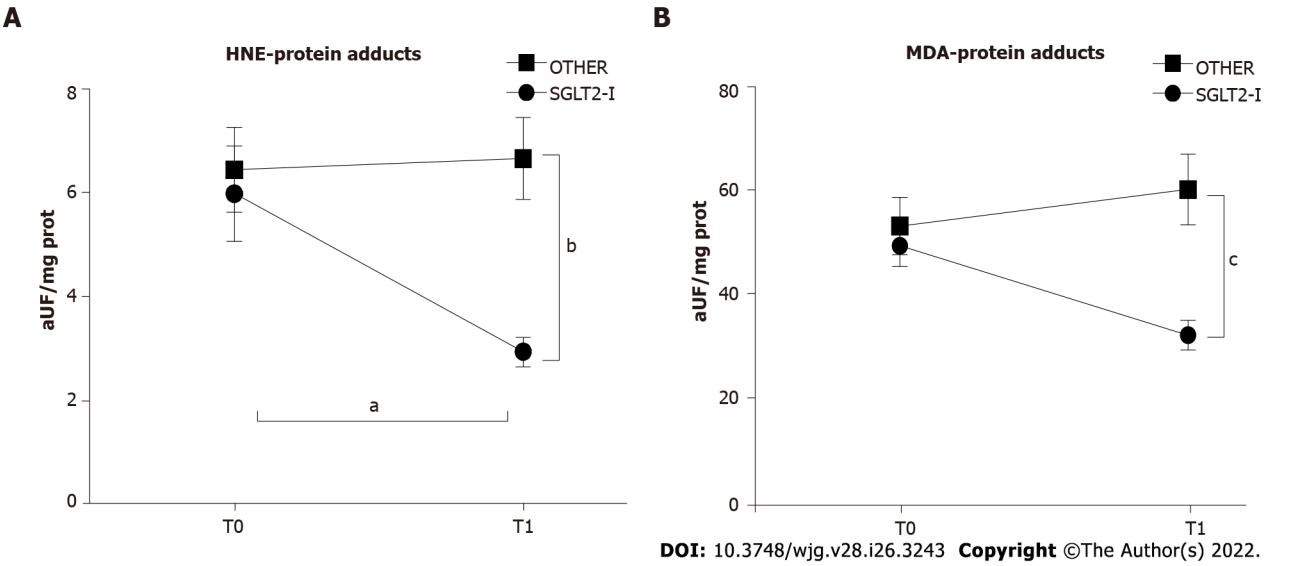
Data are expressed as mean ± SD. Statistical differences were assessed by two-way analysis of variance. VEGF: Vascular endothelial growth factor; MCP-1: Monocyte chemoattractant protein-1; EGF: Epidermal growth factor; SGLT2-I: Sodium-glucose co-transporter-2 inhibitor; OTHER: Other glucose lowering drug; IL: Interleukin; TNF: Tumor necrosis factor; IFN: Interferon.



factors evaluated at baseline (T0) and after 6 mo of therapy (T1) in both treatment groups. We could not observe any significant impact of time, treatment, or interaction on IL-1α, IL-2, IL-8, IFN-γ, and EGF. On the contrary, the time effect was observed for IL-1β, IL-4, IL-10, and TNF; the treatment effect was reported for IL-4, IL-6, IL-10, and TNF; the interaction effect was described for IL-1β, IL-6, IL-10, VEGF, and MCP-1. According to the post-hoc analysis, SGLT2-I patients at T1 showed: (1) Lower values of the pro-inflammatory cytokines IL-1β and TNF, and VEGF than T0; (2) Lower values of the pro-inflammatory cytokines IL-6 and TNF, VEGF, and MCP-1 than OTHER patients at T1; and (3) Higher values of the anti-inflammatory cytokines IL-4 and IL-10 as compared to SGLT2-I at T0 and OTHER at T1.

We evaluated systemic oxidative stress markers changes by measuring serum HNE- and MDA-protein adducts. A significant effect of treatment and interaction was observed for both HNE-protein adducts (treatment factor: $F_{(1, 100)} = 7.924$, $P = 0.0059$; interaction factor: $F_{(1, 100)} = 4.820$, $P = 0.0305$) and MDA-protein adducts (treatment factor: $F_{(1, 100)} = 10.17$, $P = 0.0019$; interaction factor: $F_{(1, 100)} = 5.844$, $P = 0.0174$). The post hoc analysis showed that, after 6 mo of therapy, circulating markers of oxidative stress were lower in the SGLT2-I group rather than OTHER patients; furthermore, HNE-protein adducts were significantly reduced from T0 to T1 in SGLT2-I patients (Figures 4A and B).

Reduction of liver steatosis and fibrosis markers is associated with decreased circulating oxidative stress in patients treated with SGLT2-I

We then focused on patients treated with SGLT2-I. We performed a Pearson's correlation analysis on non-invasive markers of hepatic steatosis and fibrosis, circulating parameters of glucose metabolism, inflammation, and oxidative stress after 6 mo of therapy. Of note, the FLI, the APRI, and LS showed: (1) A positive bivariate relationship with pro-inflammatory cytokines (IL-1β, IL6, TNF); and (2) A negative correlation with the anti-inflammatory cytokines (IL-4 and IL-10). Interestingly, all the non-invasive liver steatosis and fibrosis markers were strongly related to HNE- and MDA-protein adducts (Supplementary Table 2).

To verify whether the improvement of non-invasive markers of liver steatosis and fibrosis reported in patients treated with SGLT2-I after 6 mo of therapy was associated with the observed reduction of serum HNE- and MDA-protein adducts, a linear regression analysis on T1-T0 difference values was

performed. Further, SGLT2-I treatment related alterations in both markers of circulating oxidative stress were directly related to variations in FLI, APRI, and LS (Figures 5A-C).

DISCUSSION

The present study demonstrates that the addition of an SGLT2-I - as compared to dipeptidyl peptidase-4 inhibitors (DPP4-I) or pioglitazone - to metformin monotherapy exerts a positive impact on systemic inflammation and circulating oxidative stress in patients with T2DM and NAFLD. It is associated with favorable changes in the non-invasive hepatic steatosis and fibrosis markers. The incidence of T2DM is exponentially increasing worldwide[31]. T2DM often presents associated with NAFLD since insulin resistance accounts for the alteration of lipid homeostasis, favoring hepatic fat accumulation by induction of lipogenesis and inhibition of very-low-density lipoprotein secretion[32,33]. Furthermore, hyperglycemia in diabetic patients worsens insulin resistance through mechanisms induced by glucose toxicity[34]. In addition, the efficacy of several antidiabetic drugs is lost during the time, leading to the progression of T2DM, which could worsen NAFLD[35]. There are currently no approved therapies for the treatment for NAFLD. Several compounds tested in phase 2 and phase 3 clinical trials target metabolic stress as a critical factor for the initiation and progression of hepatic injury. Data on the effects of antidiabetic drugs in NAFLD are limited although pioglitazone and GLP1-RA have demonstrated some protective effects[36]. SGLT2-I are molecules with direct action on the kidney, reduce the reabsorption of filtered glucose and significantly decrease blood glucose levels both in fasting and post-prandial conditions, with consequent decline of glucose toxicity and improvement of insulin resistance [37]. Moreover, these drugs may interfere with several mechanisms involved in the progression of T2DM, such as dysfunction or apoptosis of pancreatic β-cells[38].

Clinical studies testing the efficacy of SGLT2-I on NAFLD demonstrated that this class of drugs reduces both hepatic steatosis, as evaluated by several imaging techniques, and serum liver enzymes [39]. Our study confirms these observations since we report that the addition of SGLT2-I to metformin reduces both the FLI and serum AST after 6 mo; this effect is not observed when pioglitazone or DPP4-I are added to metformin. Furthermore, our data show that six months of therapy with an SGLT2-I are associated with reducing hepatic fibrosis - which occurs mainly in NAFLD patients with higher fibrosis grade - as suggested by decrease in NAFLD fibrosis score, FIB-4, as well as LS measured by TE. These results are comparable to the reported outcome in a similar study, suggesting that SGLT2-I are superior to other oral hypoglycemic agents in reducing hepatic steatosis and fibrosis[40].

Among other glucose-lowering agents, pioglitazone and GLP1-RA were demonstrated to reduce hepatic steatosis, inflammation, and fibrosis[41,42]. We designed this study by excluding patients treated with GLP1-RA, even though 38.5% of patients of the OTHER group were treated with pioglitazone added to metformin. Despite this subgroup of patients in the comparison group, SGLT2-I improved non-invasive liver steatosis and fibrosis markers. A previous randomized trial compared the SGLT2-I ipragliflozin against pioglitazone, showing that both treatments were equivalent in reducing

Figure 5 Linear regression analysis between the variation of circulating oxidative stress parameters and non-invasive markers of hepatic steatosis or fibrosis in patients treated with the sodium-glucose co-transporter-2 inhibitors. Data in the graphs represent scatterplots of hydroxynonenal- or malondialdehyde-protein adducts A: Fatty liver index; B: Aspartate aminotransferase-to-platelet ratio index; C: Liver stiffness. HNE: Hydroxynonenal; AST: Aspartate aminotransferase; MDA: Malondialdehyd.

liver fat infiltration and serum aminotransferase levels, even though ipragliflozin effected a reduction in body weight and abdominal fat area[43]. However, it is worth noting that more than one-third of patients included in our study showed a high grade of steatosis and fibrosis as assessed by non-invasive markers. In contrast, previous studies using pioglitazone enrolled patients with milder hepatic injury. More than potentially explaining differences between the present results and those of different studies, our results suggest that SGLT2-I treatment would be more beneficial in T2DM patients with advanced NAFLD.

Mechanisms explaining the benefits of SGLT2-I therapy in T2DM and NAFLD are primarily undefined, but the results of this study lead to several speculations. Even though SGLT2-I significantly controls blood glucose, an improvement in glucose metabolism was described in all patients treated with additional drugs. However, other studies could not demonstrate that amelioration of NAFLD after SGLT2-I treatment was dependent on improved circulating glucose concentration[44-46]. Weight loss induced by non-pharmacological interventions such as diet, exercise, or bariatric surgery, may ameliorate liver damage in NAFLD[47]. SGLT2-I decreases body weight and fat mass, reducing hepatic steatosis and serum liver enzymes[48]. Our data show that SGLT2-I effectively promoted weight loss after 6 mo of therapy in patients with T2DM and NAFLD. However, there was no relationship between BMI reduction and the improvement of non-invasive markers of hepatic steatosis and fibrosis.

Besides, previous studies have also shown improved liver function tests, and steatosis irrespective of weight loss in patients affected by T2DM and NAFLD treated with SGLT2-I[49,50]. The evidence so far indicated that SGLT2-I would induce different beneficial mechanisms than glucose control and weight

loss in NAFLD. The present results further revealed that SGLT2-I - and not pioglitazone or DPP4-I - favorably modulate circulating cytokines, switching from pro-inflammatory to anti-inflammatory patterns, and reducing systemic markers of oxidative stress. These results are further buttressed by pre-clinical studies providing proving2-I inhibits pro-inflammatory cytokine secretion and reduces oxidative stress[16,51,52]. Our study clearly demonstrates a significant association between improving hepatic steatosis/fibrosis markers and reducing circulating oxidative stress in patients treated with SGLT2-I for 6 mo. On the other hand, we could not find any relationship between changes in circulating cytokines and reduction of liver injury markers. Reactive oxygen species (ROS) and reactive nitrogen species (RNS) represent physiological products of cellular metabolism, which are normally counteracted by endogenous antioxidants. When ROS/RNS production overwhelms the antioxidant defense, oxidative stress occurs with consequent injury of macromolecules such as nucleic acids (DNA oxidation), lipids (lipoperoxidation), and proteins, which in turn leads to an impairment of normal cellular functions[53]. Oxidative stress promotes the generation of HNE and MDA, lipid peroxidation products which are able to generate adducts with cellular and circulating proteins, which may be used as systemic markers of injury. Oxidative stress is considered one of the main determinants of NAFLD pathogenesis and progression[54]. For the first time, our study provides evidence that the reduction of circulating oxidative stress induced by SGLT2-I is related to improved markers of hepatic damage in T2DM patients with NAFLD, suggesting a potential protective mechanism by this drug class. Studies to define how SGLT2-I modulate molecular pathways that impact redox balance need to be designed.

This study suffers from the following limitations: (1) It was not designed as a randomized placebo-controlled trial since the type of combined treatment was decided according to a patient-centered approach (of note, the newest Standards of Medical Care in Diabetes were not available at the time of enrolment); (2) Patients treated with GLP-1 agonists were not included; (3) Since this study was performed at a single-center, it may have presented some bias, resulting in slightly larger intervention effects than multicenter studies; (4) Our small pilot study was not designed to determine the impact of single compounds; and (5) Liver histology was not performed to evaluate steatosis, inflammation, and fibrosis.

CONCLUSION

In conclusion, treatment with SGLT2-I in T2DM patients affected by NAFLD is associated with a rapid improvement of non-invasive markers of hepatic steatosis and fibrosis, providing insights into the mechanisms by which such class of antidiabetic drugs may reduce liver damage in humans. More extensive randomized controlled trials are encouraged to confirm these preliminary observations, and fundamental studies are needed to define the molecular mechanisms underlying the effects of SGLT2-I in NAFLD.

ARTICLE HIGHLIGHTS

Research background

Clinical trials of sodium glucose cotransporter-2 inhibitors (SGLT2-I), recently approved drugs for type 2 diabetes (T2D), reported beneficial cardiovascular (CV) and renal outcomes.

Research motivation

Inflammation and oxidative stress are major causes of vascular dysfunction and CV disease in diabetes and pre-clinical studies demonstrated that SGLT2-I promote anti-inflammatory effects by lowering oxidative stress.

Research objectives

To investigate the effects of SGLT2-I on markers of oxidative stress, inflammation, liver steatosis, and fibrosis in patients of T2D with non-alcoholic fatty liver disease (NAFLD).

Research methods

Observational prospective study enrolling 52 consecutive outpatients treated with metformin monotherapy and exhibiting poor glycemic control, which were introduced to an SGLT2-I (n = 26) or a different hypoglycemic drug (n = 26). Circulating interleukins and serum hydroxynonenal (HNE)- or malondialdehyde (MDA)-protein adducts, fatty liver index (FLI), NAFLD fibrosis score, aspartate aminotransferase (AST)/alanine aminotransferase (ALT) ratio ratio, AST-to-platelet-ratio index (APRI), and fibrosis-4, as well as transient elastography (FibroScan) on the day before (T0) and following treatment for six months (T1) were evaluated.

Research results

With respect to other hypoglycemic drugs, treatment with SGLT2-I resulted in a reduction of FLI and APRI, as well as of the FibroScan result, as well as lower circulating levels of interleukins (IL)-1β, IL-6, tumor necrosis factor, vascular endothelial growth factor, and monocyte chemoattractant protein-1, higher levels of IL-4 and IL-10, decreased serum HNE- and MDA-protein adducts. Markers of circulating oxidative stress correlated with liver steatosis and fibrosis scores.

Research conclusions

This study indicates that, more than optimizing glucose control, treatment with SGLT2-I in patients with T2D and NAFLD is associated with improvement of liver steatosis and fibrosis markers and circulating pro-inflammatory and redox status.

Research perspectives

This study encourages extensive randomized controlled trials to confirm these preliminary observations, and basic investigations to define the molecular mechanisms underlying the effects of SGLT2-I in NAFLD.

Abstract

BACKGROUND

The correct localization of the primary tumor site and a complete histological diagnosis represent the milestones for the proper management of gastro-entero-pancreatic neuroendocrine neoplasms (GEP-NENs).

AIM

To analyze current evidence on the role of endoscopy in the diagnosis/treatment of GEP-NENs.

METHODS

An extensive bibliographical search was performed in PubMed to identify guidelines and primary literature (retrospective and prospective studies, systematic reviews, case series) published in the last 15 years, using both medical subject heading (MeSH) terms and free-language keywords: gastro-entero-pancreatic neuroendocrine neoplasms; endoscopy; ultrasound endoscopy; capsule endoscopy; double-balloon enteroscopy; diagnosis; therapy; staging.

RESULTS

In the diagnostic setting, endoscopic ultrasonography (EUS) represents the diagnostic gold standard for pancreatic NENs and the technique of choice for the locoregional staging of gastric, duodenal and rectal NENs. The diagnosis of small bowel NENs (sbNENs) has been improved with the advent of video capsule endoscopy and double-balloon enteroscopy, which allow for direct visualization of the entire small bowel; however, data regarding the efficacy/safety of these techniques in the detection of sbNENs are scanty and often inconclusive. From a

therapeutic point of view, endoscopic removal is the treatment of choice for the majority of gastric NENs (type 1/2), for well-differentiated localized nonmetastatic duodenal NENs < 1 cm, confined to the submucosa layer and for < 10 mm, stage T1–T2, rectal NENs. EUS-guided pancreatic locoregional ablative treatments have been proposed in recent studies with promising results in order to control symptoms or reduce tumor burden in selected patients.

CONCLUSION

Standard axial endoscopy and EUS still play a pivotal role in several GEP-NENs. Advanced techniques for increasing the rate of R0 resection should be reserved for high-volume referral centers.

Key Words: Gastro-entero-pancreatic neuroendocrine neoplasms; Endoscopy; Ultrasound endoscopy; Capsule endoscopy; Double-balloon enteroscopy; Diagnosis; Therapy; Staging

Core tip: Standard axial endoscopy and endoscopic ultrasonography (EUS) play a pivotal role in gastro-entero-pancreatic neuroendocrine neoplasms (GEP-NENs). Upper/lower gastrointestinal endoscopy is essential for the detection of gastrointestinal NENs. EUS represents the diagnostic gold standard for pancreatic NENs and the technique of choice for the locoregional staging of gastric, duodenal and rectal NENs. The diagnosis of small bowel NENs has been improved with the advent of capsule endoscopy and double-balloon enteroscopy, however, their use is limited in clinical practice. In selected localized GEP-NENs, endoscopic therapy is appropriate with radical intent. The multidisciplinary management and the referral to high-volume tertiary centers remain fundamental.

INTRODUCTION

Gastro-entero-pancreatic neuroendocrine neoplasms (GEP-NENs) represent heterogeneous and rare tumors, whose incidence has been progressively increased in the last decades[1]. The prognosis of these neoplasms is widely variable depending on several factors including the site of the primary tumor, the grading as assessed by the specific WHO classification, and the stage as classified in a specific TNM system[2]. It is therefore clear that the correct localization of the primary tumor site, as well as a complete histologic diagnosis, represent the milestones for the proper management and the prognosis of these tumors[3-5].

In this scenario, despite advances in radiological and metabolic imaging, standard axial endoscopy and endoscopic ultrasonography (EUS) still play a pivotal role in several GEP-NENs. Upper gastrointestinal (GI) endoscopy is essential for the detection and characterization of esophageal, gastric, and duodenal NENs. Ileocolonoscopy allows the assessing and diagnosing of rectal, colonic and rarely distal ileal lesions. Small bowel NENs have proven difficult to diagnose, given their nonspecific presentation and poor accessibility of the distal small bowel to common endoscopic techniques. The diagnosis of small bowel NENs (sbNENs) has been largely improved with the advent of video capsule endoscopy (CE) in 2000 and double-balloon enteroscopy (DBE), the most promising device-assisted enteroscopy (DAE) system, in 2001, which allow for direct visualization of the entire Sb[6]. Finally, EUS is the modality of choice for both diagnosing pancreatic NENs and for the locoregional staging of several NENs, including gastric, duodenal, pancreatic and rectal NENs; of note, in the setting of pancreatic NENs (panNENs), it has demonstrated higher accuracy in tumor detection than other imaging modalities[7].

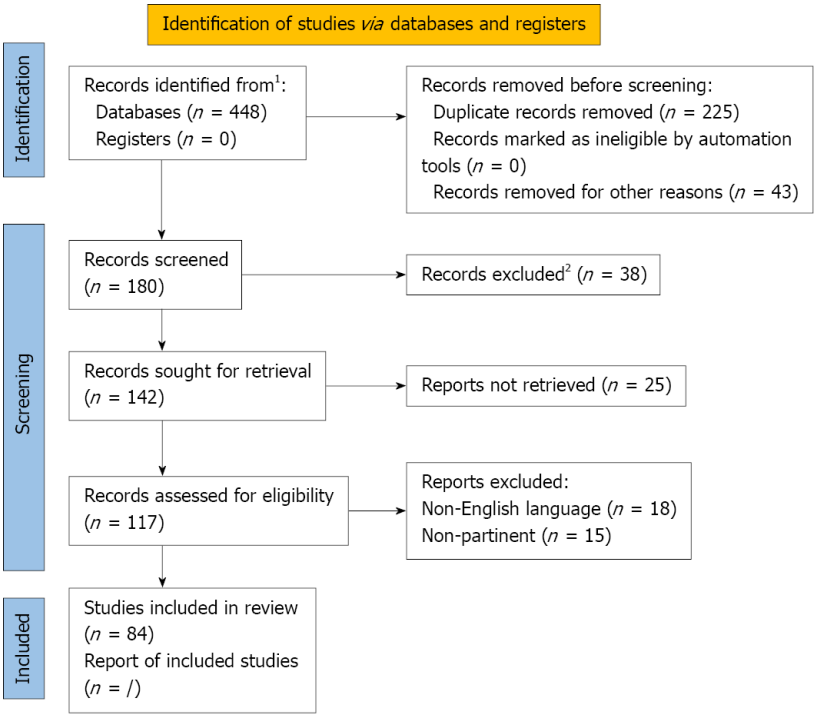
The present review is aimed at analyzing current evidence on the role of endoscopy in the management of GEP-NENs, with a specific focus on CE and DBE for sbNENs and EUS for the diagnosis and staging of panNENs and other NENs. Furthermore, we summarized available evidence on the role of endoscopy in the radical treatment of selected GEP-NENs.

MATERIALS AND METHODS

An extensive bibliographical search was performed in PubMed to identify guidelines and primary literature (retrospective and prospective studies, systematic reviews, case series) published in the last 15 years, using both medical subject heading (MeSH) terms and free-language keywords: gastro-entero-pancreatic neuroendocrine neoplasms; endoscopy; ultrasound endoscopy; capsule endoscopy; double-balloon enteroscopy; diagnosis; therapy; staging. The reference lists from the studies returned by the electronic search were manually searched to identify further relevant reports. The reference lists from all available review articles, primary studies, and proceedings of major meetings were also considered. Articles published as abstracts were included, whereas non-English language papers were excluded.

RESULTS

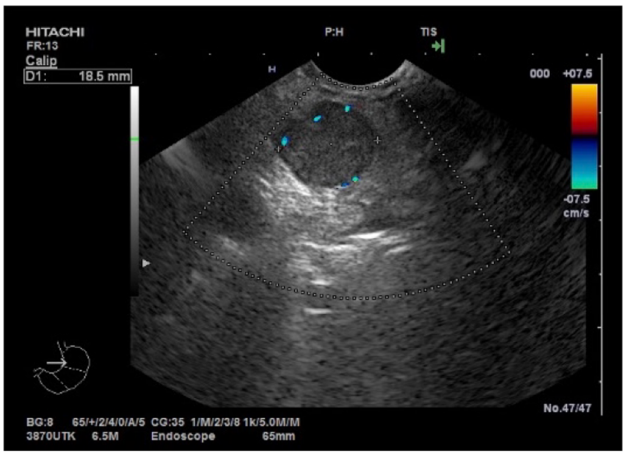
A total of 448 records were reviewed and 84 were defined as fulfilling the criteria for final consideration. Figure 1 presents the flow chart showing the process of study selection.



DIAGNOSIS

Ultrasound endoscopy (EUS)

EUS represents the diagnostic gold standard for panNENs and the technique of choice for the locoregional staging of gastric, duodenal and rectal NENs. According to the latest European Neuroendocrine Tumor Society (ENETS) Consensus guidelines, EUS proved to be the most accurate diagnostic technique in panNENs detection, leading to an up-to-94% sensitivity[8]; PanNENs usually appear rounded and homogeneously hypoechoic at EUS examination (Figure 2). EUS sensitivity in detecting panNENs is even higher than noninvasive computed tomography (CT)-scan or magnetic resonance imaging (MRI) pancreatic lesion detection rate[9]. EUS is also extremely accurate in locating the lesions, even very small ones, within the pancreatic parenchyma, and it can describe the distance between the lesion and the main pancreatic duct, which represents an independent predictor of aggressive tumor behavior and of developing pancreatic fistulas[10]. EUS overall complication rate is about 1%–2%, higher for pancreatic cysts rather than for solid masses[11].



Advanced EUS techniques allow to study specific morphological and histological details of the detected lesions that may be helpful in the differential diagnosis of panNENs and in the choice of the corresponding best-suited treatment[7]. Contrast-enhanced harmonic EUS (CH-EUS) allows real-time visualization of parenchymal perfusion and, thus, helps in distinguishing hypovascular carcinomas from hypervascular less aggressive lesions. It consists of harmonic detectors that register microbubbles produced by contrast agents administrated intravenously; this method allows the identification of microvessels even with slow blood flow[12]. As demonstrated for nonfunctioning panNENs, the CH-EUS vascular pattern of neuroendocrine lesions represents an indirect reliable surrogate predictor of their aggressiveness and, thus, of their prognosis; a statistically significant positive correlation was, in fact, proven between the inhomogeneous sonographic pattern of the lesions and their Ki67 proliferative index, which in turn represents the most reliable independent predictor of malignancy. Sonographic heterogeneity at CH-EUS, and especially hypoenhancement in the early arterial phase, corresponds to lower intratumoral microvascular density and to a greater degree of fibrosis on pathological specimens, which were demonstrated to be typical features of tumor aggressiveness on a par with tumor grading [13]. According to a Japanese retrospective study[14], hypoenhancement at CH-EUS proved to be a reliable predictor of tumor aggressiveness and poor prognosis also for G1 and G2 panNENs, with sensitivity, specificity, positive predictive value, negative predictive value and accuracy of 94.7%, 100%, 100%, 96.6% and 97.9%, respectively.

EUS-fine needle aspiration (FNA) is another diagnostic advanced EUS technique, which represents the gold standard least invasive option to obtain the histological identification of a suspected pancreatic neoplasm or peripancreatic lymph nodes, with a sensitivity ranging between 80% and 90% and a specificity of nearly 96%[15] (Figure 3). It is also the operative technique of choice to aspirate the contents of cystic lesions for serological analysis and for the tumor marker dosage, which might help in the differential diagnosis of pancreatic cystic lesions. It can be performed with different diameter needles, mainly depending on the type and site of the lesion, its consistency, and echogenicity. There are several techniques described, which make different use of the suction: some of them suggest not to apply any suction due to the high risk of contaminating the specimen with blood (especially in case of highly vascularized lesions), some others apply wet or dry negative-pressure suction to guarantee sufficient material for histological diagnosis, and others again proposed a slow-pull fanning technique to ensure at the same time a greater collection of pathological cells and a low blood contamination risk [16]; to date, even if still no consensus has been reached on the optimal strategy, overall FNA–EUS sampling adequacy rates up to 94%[17,18] and its diagnostic sensitivity proved to be significantly higher

Figure 2 Endoscopic appearance at endoscopic ultrasound of a pancreatic neuroendocrine neoplasm with marginal vascularization.

than CT and/or MRI specifically in case of solid, cystic and combined solid-cystic panNENs (84% *vs* 42%, 70% *vs* 10% and 81% *vs* 36% respectively)[19].

The Ki-67 index histological expression of the suspected pancreatic lesion plays a fundamental role in defining the aggressiveness of the tumor, together with its radiological aspect, its localization and distance from the pancreatic duct, and its CH-EUS vascular behavior. Therefore, the Ki-67 index also drives the choice of the best-suited therapeutic approach. Data about the concordance rate between EUS–FNA and surgical specimens in terms of G1, G2 or G3 panNEN and G3 pan-neuroendocrine carcinoma differentiation based on the Ki-67 index are discordant, ranging from a 78% of accordance rate (k-statistic: 0.65)[10], to a relatively significant discrepancy, especially for G2 lesions[20]. This discordance may be first attributed to the fact that endoscopic sampling of large lesions > 20 mm, often included in the studies available to date, may not be representative of the area with the highest concentration of malignant cells and, thus, that the measured Ki-67 index might be not indicative of the most proliferative area of the neoplasm. There is a strong necessity for further studies that subclassify more accurately the included lesions depending on their size.

Figure 3 Endoscopic appearance at endoscopic ultrasound of a pancreatic neuroendocrine neoplasm located at the tail of the pancreas during fine needle aspiration/biopsy procedure.

New EUS needle acquisition techniques (*i.e.*, 19/22/25- G ProCoreTM needle, Cook Endoscopy, Winston-Salem, NC, USA; 19-G fine-needle biopsy, Cook Endoscopy Inc., Limerick, Ireland; Acquire® Endoscopic Ultrasound Fine Needle Biopsy (FNB) Device 22/25-G, Boston Scientific, Natick, MA, USA; SharkCoreTM, Covidien, Dublin, Ireland) have been proposed to overcome the rare cases of EUS–FNA inadequate tissue sampling; these devices are designed to maximize tissue capture and minimize bleeding and tissue fragmentation and some of them are thought to provide both cytological and histological sampling[21]. However, further studies are needed to validate these approaches in the specific setting of NENs.

EUS real-time elastography (EUS–RTE) allows not only a qualitative but also a quantitative assessment of the elasticity of the suspected pancreatic lesion compared to the one of the normal surrounding pancreatic parenchyma. Based on the evidence of higher tissue stiffness in the case of malignant lesions when compared to the normal parenchyma[22], some authors have proposed different quantitative elastography cutoffs to stratify the risk of malignancy. Havre *et al*[23] observed a EUS–RTE sensitivity of 67% and specificity of 71% in detecting pancreatic malignant lesions with a strain ratio cutoff of 4.4. Iglesias-García *et al*[24] showed an EUS–RTE sensitivity of 100% and specificity of 88% in differentiating specifically pancreatic adenocarcinomas from panNENs with a 26.6 strain ratio cutoff value. Even if, according to the European Federation of Societies for Ultrasound in Medicine and Biology (EFSUMB) guidelines, EUS–RTE cannot yet replace the histo-cytopathological diagnosis of carcinoma[25], this technique may facilitate the differentiation from benign to malignant pancreatic lesions.

Another advanced technique in EUS that can drive in the diagnostic orientation is represented by the needle-based confocal laser endomicroscopy, which allows the real-time direct *in vivo* visualization of the histological aspect of the GI mucosa overlying pancreatic NENs, which is traditionally described as clusters of compact cells on a dark background surrounded by numerous small and irregular vessels and fibrotic areas[26]. Giovannini *et al*[27], observed a negative predictive value of 100% for the characterization of pancreatic NENs in EUS needle-based confocal laser endomicroscopy; therefore supporting the concept that it cannot be considered as an alternative to the histological diagnosis, but that it may help to rule out malignancy.

Further applications of EUS in panNENs is represented by the preoperative EUS-guided fine-needle tattooing and EUS-guided fiducial implantation, which may help surgeons find little pancreatic lesions during laparoscopic surgery, limiting the laparoscopic resection to the lesion itself, sparing the normal surrounding parenchyma, and reducing the operating time[28].

As regards GI-NENs, EUS mainly plays a diagnostic and staging role; its sensitivity in detecting GI-NENs is up to 94%[29]; they usually appear as submucosal rounded, hypoechoic, well-demarcated lesions and can be detected when smaller than 10 mm, especially rectal NENs thanks to the growing sensibility to colorectal carcinoma screening. According to the ENETS most recent guidelines, in case of the endoscopic identification of a GI lesion that is compatible with a GI-NEN, EUS is recommended in case of lesions > 10 mm in order to study the depth of the lesion, to stage the hypothetical presence of locoregional lymph nodes and, thus, to drive the choice of the most appropriate endoscopic or surgical treatment[30]. Less than 10 mm GI-NENs, in fact, have a low risk of both lymphatic invasion and distant metastases, which is reported to be 1%–2%[31]. GI-NENs measuring 10–19 mm at their first endoscopic diagnosis deserve more accurate EUS evaluation because of the reported higher incidence rate of lymph node invasion or distant metastases, leading up to 5%–15%[32]. If the GI-NEN is limited to the submucosa and does not invade the muscularis mucosae (which corresponds to a T1 lesion), regardless of its lateral spreading, a simple *en bloc* endoscopic resection treatment has proved to be effective in

guaranteeing a radical resection and a very limited recurrence rate during the follow-up[33], otherwise, a surgical approach is suggested. T2 or N+ stage lesions should be accurately studied with total body imaging such as 68-Ga-DOTATATE positron emission tomography (PET) and a CT scan in order to plan the best therapeutic approach.

Capsule Endoscopy (CE) and Double-balloon enteroscopy (DBE)

The small intestine is the most common NEN site in humans. Historically, sbNENs have proved difficult to diagnose because of both the lack of specific symptoms at presentation and the poor accessibility of the distal small bowel[34]. Conventional radiology (both CT and MRI either in the standard technique or in combination with enteroclysis) are often not accurate enough in the detection of sbNENs [35], whereas PET/CT with 68Ga-DOTA peptides remains the most sensitive modality in the detection of well-differentiated NENs, although it does not allow to get a histological diagnosis and might not be fully accurate in the anatomical location of the primary tumor being, for instance, unable to differentiate between intestinal and mesenteric localization[36]. Furthermore, in the case of metastatic disease, the detection of the primary tumor is recommended in both resectable and non resectable diseases. However, in up to 10% of the cases after the discovery of liver or lymph node metastases, the primary tumor site remains unknown despite an extensive workup[35].

With the advent of CE and DBE the diagnosis of sbNENs has improved, even if data regarding the efficacy and safety of these techniques in the detection of sbNENs are scanty and mainly based on small retrospective series, given the rarity of the disease and the still-limited use of these techniques in routine clinical practice. Most of the available studies are focused on small bowel tumors in general and only a small percentage of included patients displayed an sbNEN[37-39]. In a study comparing CT, enteroclysis, nuclear imaging, and CE of the small bowel[34], CE showed a high diagnostic yield (45%) in identifying primary tumors. Of note, in 12 of 20 patients (60%), CE showed small-intestinal lesions that were then confirmed histologically as NEN in six of seven patients who underwent surgery.

When considering the few studies specifically focused on NENs, the results came back to be inconclusive. In a retrospective study by Frilling *et al*[40], including 390 patients with metastatic NENs of whom 11 with unknown primary tumor, CE identified lesions suggestive of small bowel primary in 8/10 patients in whom it was successful, and these tumors were all histologically confirmed. In a recent prospective study[41], the diagnostic yield of CE was reported to be limited. In 24 patients with a histological diagnosis of metastatic NEN of unknown origin, CE, which was preferred to DBE as less invasive and less expensive, was requested before explorative laparotomy and its diagnostic yield was compared to the surgical exploration. CE identified a primary sbNEN in 11 subjects. However, diagnosis of sbNEN was confirmed only in five (41%) cases after surgical and ultrasound exploration were performed. The high number of false-positive results could have been related to small bowel contractions, extrinsic compression, lymph stasis, or submucosal lesion of another type.

Although CE is less invasive, DBE is necessary for determining the precise location, number of tumors, and pathological diagnosis; it can be carried out through the oral (antegrade) or the anal (retrograde) route and with a combined oral and anal approach[42]. Bellutti *et al*[43], in a study involving 12 consecutive patients with suspected sbNEN or with liver NEN metastases, who underwent DBE, found a diagnostic yield of DBE for primary tumor of 33%. In a case series by Scherubl *et al*[44], five consecutive patients with metastatic midgut carcinoids underwent DBE and an NEN of the ileum was detected in four of the five patients; the histopathological evaluation of their biopsy specimens confirmed the diagnosis revealing well-differentiated NENs. Conversely, conventional radiological imaging did not visualize any of the primary tumors.

In our recent prospective study[45], we reported sensitivity and specificity of 60% and 100%, respectively for DBE in detecting sbNEN in six patients with unknown primary, showing that DBE is a safe and effective procedure in diagnosing sbNENs. We suggested that when a sbNEN is suspected, DBE should be taken into account as an accurate diagnostic tool in order both to collect biopsies for final diagnosis and to make tattoos before surgery; of note, DBE should be preferred over CE in the presurgical setting given the high specificity. Considering the limited available data, further studies are needed to better define the actual role of CE and DBE in the diagnosis of sbNENs.

TREATMENT

Gastric NENs

Gastric NENs (gNENs) are usually subclassified into three types, according to their pathophysiology and behavior[29,46]. Type I tumors correspond to the majority of gNENs (~80%) and are associated with autoimmune atrophic gastritis. Histologically, type I gNENs are composed of enterochromaffin-like cells. The diagnosis is made by upper digestive endoscopy with biopsy. The majority of type I gNENs present as small, multiple tumors, located in the gastric body or fundus, and limited to the mucosal or submucosal layers of the stomach wall[46,47]. Since the risk of metastasis is < 5% in type I gNENs, a conservative approach based on endoscopic follow-up with lesion resection is advised for this kind of tumor. The treatment of choice for type I gNENs is endoscopic resection for lesions > 0.5 cm and

endoscopic surveillance for lesions < 0.5 cm[46,48,49]. This approach has been shown to be safe and effective in a prospective series of 33 type I gNENs, with no significant procedure-related complications, no development of metastases, and a 100% long-term survival rate[50].

The ENETS guidelines[29] suggest performing EUS in case of lesions > 1 cm. Staging EUS is frequently performed to confirm the appropriateness of endoscopic resection, which applies to lesions not infiltrating beyond the muscularis propria[7]. For lesions > 1 cm, EUS is excellent for determining the exact tumor size and for excluding infiltration of the type I gNENs into the muscularis propria (T2) or enlarged regional lymph nodes[47,51].

Type II gNENs correspond to 5%–10% of gNENs; they usually develop when multiple endocrine neoplasia type 1 is present and are often associated with Zollinger–Ellison syndrome[46,48]. Like type I gNENs, type II gNENs originate from enterochromaffin-like cells. They are small, multiple, and relatively benign tumors, even though about 10%–30% of patients present as metastatic at the diagnosis [52]. For type II gNENs local excision is recommended, preferentially by endoscopy; as well as for type I gNENs, EUS plays a pivotal role in determining the tumor size, lymph node involvement, and depth of invasion; endoscopic treatment is again reserved for lesions not infiltrating beyond the muscularis propria, without lymph node involvement[7,53].

Type III gastric NENs are usually larger sporadic tumors with an infiltrative and metastatic tendency and account for 15% of all gNENs. They are generally characterized by being single lesions, > 1 cm and with a greater likelihood of evolving to regional and systemic metastases, as more than half of patients with type III gNENs are metastatic at diagnosis, mainly to the liver[46,48]. From a therapeutic point of view, surgery is the standard treatment, *i.e.*, total or subtotal gastrectomy together with lymphadenectomy, as recommended in gastric adenocarcinoma. For patients with any surgical contraindication, endoscopic resection may be an alternative, but the risk of regional lymph node spread remains high [46]. Of note, in selected cases of small (< 1 cm) type III G1/G2 (Ki-67 < 5%) gNENs fully resected (R0) by endoscopy with no risk factors for metastatic disease, endoscopic resection might be sufficient[54]. As for other gNENs, EUS is a useful tool for locoregional staging, particularly to stage the disease by assessing the presence of regional lymph node involvement.

Conventional polypectomy with a snare for flat mucosal lesions should be avoided because complete resection is often not achieved. Early gNENs are generally removed by endoscopic mucosal resection (EMR) or endoscopic submucosal dissection (ESD)[47,54]. In EMR, snare resection is preceded by the submucosal injection of saline in order to raise the tumor and cut into the submucosa below the tumor [47]. ESD is preferred over EMR in case of suspicion of limited submucosal invasion or a tumor > 2 cm [55]. After submucosal injection of saline, the submucosa is dissected with specific knives in order to achieve endoscopic *en bloc* resection of the whole neoplasm.

The resected specimen has to be carefully evaluated regarding grade, angioinvasion, and infiltration of the deep resection margin. In case of angioinvasion, histological infiltration of the muscularis propria (T2), or grade G2/G3, radicalization with surgery with lymph node dissection is the therapy of choice in localized neuroendocrine disease[47].

Duodenal NENs

Duodenal NENs (dNENs) are rare, usually small well-differentiated tumors in most of the cases; however, according to a recent multicenter retrospective study[56], dNENs' prognosis may be highly variable as these tumors can be metastatic in up to 50% of the cases at the time of first diagnosis and can develop metastases thereafter. Upper GI endoscopy with biopsy is necessary for dNEN diagnosis and EUS should be performed to assess the local extent of tumor depth.

In view of this heterogeneous behavior, surgical resection has been suggested as the preferred treatment modality over endoscopic treatment, and surgery is generally recommended for ampullary dNENs and lesions > 2 cm in size[38]. Endoscopic resection is the treatment of choice for well-differentiated localized nonmetastatic tumors with a diameter < 1 cm and confined to the submucosa layer and the rationale for preferring the endoscopic treatment for tumors < 1 cm relies on the fact that they seem to have a low rate of nodal disease[57]. In this setting, there is no current evidence to prefer an endoscopic approach over another as prospective studies comparing the available techniques (*i.e.*, ESD *vs* EMR) are lacking.

However, there is still controversy regarding the management of tumors between 1 and 2 cm, which is mainly based on the tumor location and the presence of nodal involvement on imaging. According to some authors, > 10% of patients with dNENs < 1 cm in size develop lymph node metastases, thus suggesting the need for a radical surgical approach for all dNENs despite the size of the primary tumor [58-60]. Another issue to be taken into account is the high risk of conventional and functional imaging of understaging mainly due to the presence of nodal and distant micrometastases[60]. These results represent a sign of warning for conservative approaches including endoscopy, suggesting as a possible strategy, the inclusion of EUS in the preoperative phase, although prospective studies are necessary to draw solid conclusions.

In summary, all considered, endoscopic resection either EMR or ESD should be reserved for dNENs < 10 mm, limited to the submucosal layer without evidence of lymph node or distant metastases, whereas surgery might be advised for dNENs > 10 mm with evidence of muscular layer invasion or nodal involvement. EUS should be encouraged for all dNENs in order to plan the best therapeutic approach.

Rectal NENs

Endoscopic treatment for rectal NENs (rNENs) is indicated if there is no evidence of invasion beyond submucosa and presence of locoregional disease since it aims to achieve a complete oncological resection[61].

The ENETS guidelines[30] suggest that well-differentiated (G1/G2) rNENs that are < 10 mm in stage T1 and T2 and rNENs between 10 and 20 mm in stage T1 without lymph node metastasis should be removed endoscopically. On the contrary, surgical resection is indicated in cases of G3 rNENs, 10–19 mm with muscolaris propria invasion (stage T2) and for tumors > 20 mm and/or in presence of lymph node metastases.

Endoscopic techniques for treating rNENs include standard polypectomy, EMR, modified EMR, ESD, and endoscopic full-thickness resection (EFTR). Standard polypectomy does not offer an adequate and complete resection of the lesion; therefore, it is not indicated in rNEN treatment[62]. Of note, a large number of rNENs is still removed by an improper method, such as routine snare polypectomy, during colorectal cancer screening making management more complex and putting patients at risk of metastatic spread[63].

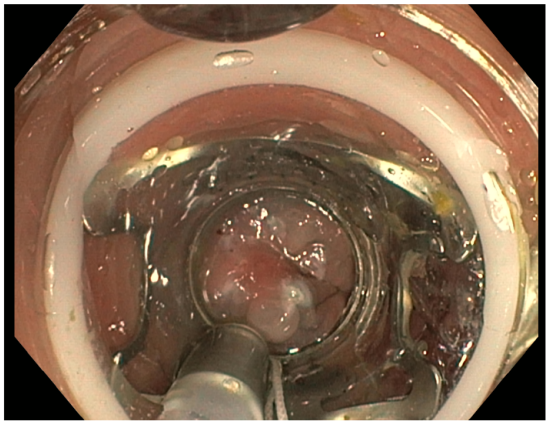
EMR is largely used in the resection of small and superficial neoplasia confined to the mucosa and submucosal layer, but its application in rNENs is still debated since modified EMR and ESD are superior in terms of *en bloc* resection rate and histological complete resection rate (defined as *en bloc* resection with no margin involved)[64,65].

Recently, Park *et al*[66] observed that when EMR is performed underwater, the histological complete resection rate of NENs < 10 mm is similar to that for ESD (86.1% *vs* 86.1%, respectively) but with a shorter procedure time (5.8 ± 2.9 *vs* 26.6 ±13.4 min, respectively).

EMR performed with a dual-channel endoscope allows deeper resection compared to conventional EMR by lifting the lesion with forceps. Lee *et al*[67] observed that dual-channel EMR reaches a complete histological resection rate similar to that of ESD for rNENs < 16 mm (86.3 *vs* 88.4 %, respectively), but with a shorter procedure time (9.75 ± 7.11 *vs* 22.38 ± 7.56 min, respectively) and fewer complications.

Modified EMR techniques include the use of special devices that allow better resection of the tumor. EMR after circumferential precutting (EMR-P) is performed by lifting the submucosal with saline injection, precutting using the tip of the snare or special endoknife and resecting the tumor with a snare. Cap-assisted EMR (EMR-C) is performed by lifting the mucosa with saline injection, suctioning the lesion with a transparent cap fitted to the scope and then removing it with a snare looped along the ridge of the cap. EMR with a ligation device (EMR-L) is conducted by lifting the lesion with saline injection, deploying an elastic band around its base, and resecting with a snare. Histological complete resection rate for EMR-P is superior to EMR and no difference was found between EMR-P and the other modified EMR techniques, even if it required a longer procedure time[68]. Park *et al*[69] demonstrated that EMR-C is a safe and effective technique for rNENs, with a histological complete resection rate even better than that of ESD (92.3% *vs* 78.4%, respectively).

EMR-L is only applicable for tumors of < 10 mm due to the short diameter of the caps fitted to colonoscopes, but it is significantly superior to EMR in terms of complete resection of rNENs (93.3% *vs* 65.5%, respectively), regardless of the tumor location[70]. Histological complete resection rate is similar between EMR-C and EMR-L. However, Lee *et al*[71] demonstrated that EMR-L might be preferable for achieving a higher rate of *en bloc* resection (100% *vs* 92.9%, respectively), but this could be due to the fact that the band thickness used in EMR-L is larger than the snare thickness of EMR-C.



ESD is an interventional procedure suitable for *en bloc* resection of slightly invasive GI lesions. After injection of the submucosal with a viscous solution, an endoknife is used to incise the mucosa surrounding the lesion and to dissect it from the submucosal layer. ESD is an effective technique to treat rectal lesions, even if it is associated with a high risk of complications and a long procedure time. As it concerns rNENs, ESD has been demonstrated to be superior to EMR in terms of histological complete resection rate, but there are no significant differences between ESD and modified EMR[70].

Niimi *et al*[72] observed that ESD is associated with a longer procedure time and hospitalization period compared with EMR-L, with a similar complete resection rate. In order to reduce procedure time, Wang *et al*[73] proposed a hybrid ESD, in which the mucosal incision is performed with a polypectomy snare instead of an endoknife. This technique showed a similar *en bloc* resection rate (99.2% *vs* 98.2) and complete resection rate (94.1% *vs* 90.9%) to ESD but with a shorter procedure time (13.2 ± 8.3 *vs* 18.1 ± 9.7 min).

EFTR is a technique mainly used in lesions that are difficult to resect and its application in rNENs has recently been proposed. A full-thickness resection device is fitted over the scope and, after placement of a modified over-the-scope-clip, allows a single step EFTR (Figure 4).

Meier *et al*[74] collected data on 40 EFTRs in rNENs and observed that resection was macroscopically and histologically complete in all cases without major events, but prospective comparative studies between different resection techniques are still missing.

To conclude, rNENs < 10 mm should be treated endoscopically, and EMR-L should be considered as the first-line treatment; ESD can be used as second-line therapy when EMR-L is not applicable. EFTR can be an effective and safe technique in lesions that are difficult to treat. Treatment of rNENs with a size of 10-19 mm should be chosen after assessing the stage and the grade of differentiation.

pancreatic NENs

In recent years there has been a great development of EUS techniques, not only used as diagnostic, but also as therapeutic tools. These methods find application in the management of panNENs, given the direct approach to the pancreas through the echoendoscope. The incidentally discovered small panNENs, mainly nonfunctional, represent a therapeutic challenge because surgery could be very complex in the face of neoplasms with indolent biological behavior, and active surveillance may represent an option for G1 or low G2 neoplasms, asymptomatic, mainly localized in the head of the pancreas, without radiological signs suspicious for malignancy[8,75]. In this setting, however, EUS-guided pancreatic locoregional ablative treatments, using either ethanol injection or radiofrequency ablation, have been proposed in recent studies with promising results in order to control symptoms or reduce tumor burden in selected patients[76]. The thermoablative techniques are the most used, mainly the radiofrequency methods. EUS-guided radiofrequency ablation (RFA) is reported to be a potentially effective and safe treatment for Pan-NENs[77].

Several RFA devices for EUS-guided applications are currently available. The Habib EUS-guided RFA probe (EndoHPB, EMcision UK, London, UK) is a 1 Fr (0.33 mm), monopolar catheter, which can be inserted through a regular 19- or 22-gauge FNA needle and connected to a standard radiofrequency generator. The other systems are needle-electrodes, and the most commonly used in literature is the one from Taewoong Medical (EUSRA, Taewoong Medical Co. Ltd., Gimpo-si, Geyonggi-do, South Korea), an 18- or 19-gauge needle with a long electrode lacking insulation over the terminal tip, connected to a dedicated RF current source, and an inner cooling system that circulates chilled saline inside the needle to avoid tissue charring. Under the EUS guide, the needle is inserted into the target lesion that is being treated by using high-frequency alternating current, and the energy release is applied when the needle tip of the electrode is within the lesion, while maintaining a distance of at least 2 mm from the pancreatic and bile ducts and vessels, to avoid injury or duct strictures. A recent systematic literature review explored the feasibility, effectiveness, and safety of EUS–RFA in the treatment of panNENs[94]: 12 articles describing 61 patients and 73 panNENs were analyzed and the overall effectiveness of EUS–RFA resulted in 96% (75%–100%) without any difference between functional and nonfunctional panNENs and without relevant side effects (mild adverse events, AEs 13.7%)[78-81].

The same conclusions were also confirmed by a further systematic review which included 14 studies with a total of 158 patients with solid pancreatic tumors[82]. However, even if the results of these studies are encouraging, especially for nonfunctioning panNENs and insulinomas < 2 cm, EUS–RFA is a recent technique and long-term data are thus lacking[82]. Larger studies with longer follow-up are needed to evaluate the long-term effectiveness of EUS–RFA. The specific setting of patients and the actual indication for the radiofrequency has not been standardized.

As concerned EUS-guided ethanol injection for small panNENs, this option has been proposed and studied for the treatment of patients with small panNENs not suitable for surgery or who refused surgical approach. Using pure ethanol or ethanol–lipiodol emulsion, the complete ablation rate has been reported to be ~50% up to 80% by performing more sessions[83].

In view of these results, a study protocol for a multicenter prospective study has been published[84] and the results will become available in due time.

Finally, possible future intriguing perspectives can be represented by the application, also in panNENs, of the novel techniques of locoregional delivery of drugs, such as LOcal Drug EluteR [LODER(TM)] which is a novel biodegradable polymeric matrix that shields drugs. panNENs may be considered as a possible future field of application of locoregional radiotherapy by using fiducial markers implantation, similarly to other pancreatic cancers.

Table 1 Available endoscopic treatment options for gastro-entero-pancreatic neuroendocrine neoplasms

Primary site	Tumor characteristics	Endoscopic management
Stomach	Type I < 5 mm	Surveillance
	Type I ≥ 5 mm	Resection (EMR, ESD)
	Type II	
	Type III	Resection (EMR, ESD)[1]
	G1-G2	
	< 10 mm	
Duodenum	< 10 mm[2]	Resection (EMR, ESD)
	G1	
	No muscularis mucosae invasion	
	No periampullary	
Pancreas	≤ 20 mm	Surveillance; EUS-guided RFA; EUS-guided ethanol injection
	G1-low G2	
	Non-functioning	
	No bile/pancreatic duct compression	
	Functioning tumors, not suitable for surgery	EUS-guided ethanol injection
	The patient refuses the surgical approach	
Rectum	< 10 mm[3]	Resection (EMR, mEMR, ESD, EFTR)
	G1-G2	
	No muscularis mucosae invasion	

[1]Endoscopic resection of type III gastric NENs can be considered curative only in case of histological complete resection.
[2]There is still controversy regarding the management of duodenal NENs between 10 and 20 mm.
[3]Treatment of rectal NENs with a size of 10–19 mm should be chosen after assessing the stage and the grade of differentiation.
G: Grading according to WHO classification; EMR: Endoscopic mucosal resection; mEMR: Modified endoscopic mucosal resection; ESD: Endoscopic submucosal dissection; EFTR: Endoscopic full-thickness resection; EUS: Endoscopic ultrasound.

DISCUSSION

The incidence of GEP-NENs has hugely increased over the last decades mainly due to better disease knowledge and to an improvement in diagnostic techniques, including endoscopy. Standard axial endoscopy and EUS still play a pivotal role in several GEP-NENs. Upper GI endoscopy is essential for the detection and characterization of esophageal, gastric and duodenal NENs. EUS represents the diagnostic gold standard for panNENs and the technique of choice for the locoregional staging of gastric, duodenal and rectal NENs. Ileocolonoscopy allows the assessing and diagnosing of rectal, colonic and rarely distal ileal lesions. However, the diagnosis of sbNENs has been largely improved with the advent of CE and DBE, although data regarding the safety and efficacy of these techniques in the neuroendocrine setting are still scanty and their use is still limited in clinical practice. In terms of treatment, in selected localized GI-NENs with the absence of features associated with lymph node metastases, endoscopic therapy is generally an appropriate treatment with radical intent. In highly selected G1 or low G2 small neoplasms without radiological signs suspicious for malignancy EUS-guided pancreatic locoregional ablative treatments, using either ethanol injection or radiofrequency ablation, have been proposed in recent studies with promising results in order to control symptoms or reduce tumor burden. Table 1 summarizes available endoscopic treatment options for GEP-NENs.

CONCLUSION

In summary, endoscopy plays a key role for diagnosis and treatment of GEP-NENs. In selected localized GEP-NENs, endoscopic therapy is appropriate with radical intent. Advanced resection techniques aimed at increasing the rate of R0 resection should be reserved to high-volume referral centers. The multidisciplinary management remains the gold standard to offer the patient the best therapeutic

approach.

ARTICLE HIGHLIGHTS

Research background

The prognosis of gastro-entero-pancreatic neuroendocrine neoplasms (GEP-NENs) is widely variable depending on several factors including the site of the primary tumor, the grading, and the stage. The correct localization of the primary tumor site, as well as a complete histologic diagnosis, represent the milestones for the proper management and the prognosis of these tumors. Standard axial endoscopy and endoscopic ultrasonography (EUS) still play a pivotal role in several GEP-NENs.

Research motivation

The incidence of GEP-NENs has hugely increased over the last decades; given the well-known heterogeneity of these tumors and the lack of large prospective studies, there is an urgent need to standardize their management.

Research objectives

To analyze current evidence on the role of endoscopy in the management of GEP-NENs (both diagnosis and potential treatment). A specific focus will be reserved to capsule endoscopy, double-balloon enteroscopy and ultrasound endoscopy.

Research methods

An extensive bibliographical search was performed in PubMed to identify guidelines and primary literature (retrospective and prospective studies, systematic reviews, case series) published in the last 15 years, using both medical subject heading (MeSH) terms and free-language keywords: gastro-entero-pancreatic neuroendocrine neoplasms; endoscopy; ultrasound endoscopy; capsule endoscopy; double-balloon enteroscopy; diagnosis; therapy; staging.

Research results

EUS represents the diagnostic gold standard for pancreatic NENs (panNENs) and the technique of choice for the locoregional staging of gastric, duodenal and rectal NENs. EUS proved to be the most accurate diagnostic technique in panNEN detection. EUS–fine needle aspiration is a diagnostic advanced EUS technique, which represents the gold standard least invasive option to obtain the histological identification of a suspected pancreatic neoplasm or peripancreatic lymph node. The diagnosis of small bowel NENs (sbNENs) has been improved with the advent of capsule endoscopy (CE) and double-balloon enteroscopy (DBE), even if data regarding the efficacy and safety of these techniques in the detection of sbNENs are scanty and mainly based on small retrospective series, given the rarity of the disease and the still-limited use of these techniques in routine clinical practice. In selected localized gastrointestinal NENs with the absence of features associated with lymph node metastases, endoscopic therapy is generally an appropriate treatment with radical intent. In highly selected G1 or low G2 small neoplasms without radiological signs suspicious for malignancy EUS-guided pancreatic locoregional ablative treatments, using either ethanol injection or radiofrequency ablation, have been proposed in recent studies with promising results in order to control symptoms or reduce tumor burden.

Research conclusions

Endoscopy plays a key role in GEP-NENs for both the diagnosis and the treatment. In selected localized GEP-NENs, endoscopic therapy is appropriate with radical intent. The multidisciplinary management and the referral to high-volume tertiary centers remain fundamental.

Research perspectives

Further studies are needed: (1) To better define the actual role of CE and DBE in the diagnosis of sbNENs; and (2) To better analyze the possible role of endoscopic confocal laser endomicroscopy in the diagnosis of panNENs and radiofrequency ablation as a potential treatment. Possible future intriguing perspectives can be represented by the application, also in panNENs, of the novel techniques of locoregional delivery of drugs.

Abstract

The recent manuscript entitled "Relationship between clinical features and intestinal microbiota in Chinese patients with ulcerative colitis" reported a difference in the intestinal microbiota of patients with ulcerative colitis according to the severity of the colitis. The influence of the intestinal microbiota on the development and progress of gastrointestinal disorders is well established. Besides the diversity in the microbiome, the presence of virulence factors and toxins by commensal bacteria may affect an extensive variety of cellular processes, contributing to the induction of a proinflammatory environment.

Core Tip: The manuscript entitled "Relationship between clinical features and intestinal microbiota in Chinese patients with ulcerative colitis" and previous investigations have identified alterations in the intestinal microbiome of patients with inflammatory bowel disease, ulcerative colitis, and colorectal cancer. The microbiota composition impacts the development of inflammatory disorders. Nevertheless, investigations should focus on identifying alterations not only on the diversity of the microbiota but the presence of the toxin-producing bacteria. Further investigations should investigate alterations in the microbiota composition and the production of toxins by commensal bacteria such as *Escherichia coli*, *Clostridium perfringens*, and *Bacteroides fragilis*.

TO THE EDITOR

We read with great interest the manuscript entitled "Relationship between clinical features and intestinal microbiota in Chinese patients with ulcerative colitis" published by He *et al*[1] in the World Journal Gastroenterology. He *et al*[1] performed an investigation on the microbiota composition on the fecal and mucosa samples from patients with ulcerative colitis. Their work reinforces the importance of the microbiota on the inflammatory process and gastrointestinal disorders. Importantly, the manuscript provided information on the composition of the gastrointestinal microbiota of patients with ulcerative colitis of various severity and patients without ulcerative colitis[1]. We would like to raise a few considerations regarding the microbiota and gastrointestinal inflammatory disorders.

The microbiota is an ecosystem in constant regulation, influenced by the diet, antibiotics, sanitary conditions, environmental stimulus, and the host's immune system[2]. The gastrointestinal tract is the largest reservoir of bacteria in the human body and shapes both the local and systemic immune responses[3-5]. The microbiome influences the maturation and development of the host's immune system[6], regulating the development of food tolerance, response to inflammation, infections, vaccination, and metabolism[7,8]. Importantly, the microbiota directly influences the development of the inflammatory process independent of dietary intake[9], and abrupt alterations in the microbiota composition can result in an inflammatory insult[10]. He *et al*[1] identified an increase in *Escherichia* and *Shigella* in patients with ulcerative colitis in comparison to patients without ulcerative colitis[1]. *Escherichia* and *Shigella* has been implicated in a reduction in the response to anticoagulation therapy and could impact the treatment of patients with gastrointestinal disorders and under anticoagulation therapy such as coronavirus disease 2019 patients[11-14].

Shiga toxin-producing *Shigella* species and *Escherichia coli* are considered pathogenic, associated with diarrhea and colitis[15]. These toxins can induce the activation of the NOD-like receptor protein 3 inflammasome, inducing the production of interleukin (IL)-1β and IL-18 and cellular death by pyroptosis[16]. The virulence of Shiga-toxin-producing *Escherichia coli* can lead to diarrheal sicknesses and death[17,18]. Shiga-toxins can be encapsulated within microvesicles and influence the inflammatory response in other organs, such as the kidneys[19]. Shiga toxin-producing *Escherichia coli* (O26:H11 strain 97-3250 and O145:H28 strain 4865/96) induces a greater production of chemokines and cytokines, such as IL-8 and IL-1β, in comparison to *Escherichia coli* (O9:H4 strain HS)[20].

The complex symbiotic interaction between the microbiota and the host is mediated by an equilibrium in the tolerance and inflammatory response to microbial products in the gut[6]. He *et al*[1] did not identify an increase in other strains in patients with ulcerative colitis. Nevertheless, in addition to the microbiota composition, certain commensal bacteria, such as *Clostridium perfringens* and *Bacteroides fragilis*, can express a wide range of toxins and metabolic compounds to induce inflammation [21-23]. *Clostridium perfringens* is a gram-positive anaerobic bacteria, commonly in the environment and is part of the resident microbiota but can become virulent by the expression of toxin genes[24,25]. *Clostridium perfringens* can produce over 20 toxins including alpha (α), beta (β), epsilon (e), enterotoxins, and hydrolytic enzymes[26-29]. These toxins can damage and kill intestinal cells, disturb the epithelial barrier, and induce proinflammatory and propathogenic milieu[26,30,31].

The alpha toxin produced by *Clostridium perfringens* is a zinc-dependent metalloenzyme, is able to rupture the plasma membrane of the host's cells[25,32], induces an immature profile in the host's innate immune response (neutrophils), and is involved in the formation of myonecrosis in animals, including humans[33,34]. The β toxin is a pore-forming toxin associated with hemorrhagic diarrhea[35]. *Clostridium perfringens* with the expression of α and β toxins is associated with necrotic enteritis in animals and humans[36-38]. The e toxin is also pore-forming and is involved in intestinal and neurological diseases in humans[39-43].

In addition, *Clostridium perfringens* is able to produce several other toxins such as enterotoxins[44-46], NetB[47,48], and TpeL[49,50], which can induce inflammatory responses, biofilm formation, and chronically disrupt the intestinal epithelium[44,47,50]. *Bacteroides fragilis,* another resident bacteria, can produce a zinc-dependent metalloprotease called fragilisyn[51]. Fragilisyn-producing *Bacteroides fragilis* are named *Enterotoxigenic Bacteroides Fragilis* (ETBF)[52]. ETBF toxin is coded by the *bft* gene and is highly correlated with diarrhea in humans[53,54]. ETBF can cleave E-cadherin in the epithelial cells, allowing bacterial translocation[55,56]. ETBF induces an IL-17-mediated immune response with the infiltration of lymphocytes and neutrophils and damages the DNA *via* the formation of microadenoma [4,53,54]. In addition, the inflammatory process may be mediated by several bacteria. For example, in the "driver-passenger" model, the colonization by one bacteria may facilitate the expansion and proinflammatory action of another microorganism[55].

A recent manuscript by Avril and DePaolo[56], identified that the co-colonization of ETBF and *Escherichia coli* strains, harboring the pks island, promotes the development of intestinal cancer. ETBF promotes the degradation of the intestinal mucus and induction of IL-17-mediated inflammation by the host's immune cells. This process enables the adherence of *Escherichia coli* to the intestinal wall, releases colibactin, and promotes cancer development[56]. Therefore, quantitative analyses are important to characterize the composition of the microbiota in several diseases and aid in the design of possible interventions to modulate the immune response of the host in microbiota-mediated inflammatory disorders[1]. Nevertheless, due to the potential pathobiont role of several resident bacteria, investigations on toxin-producing bacteria are crucial for an overall interpretation of the role of the microbiota on gastrointestinal disorders.

Abstract

In recent years, the interaction between the gut microflora and liver diseases has attracted much attention. The intestinal microflora is composed of bacteria, archaea, fungi and viruses. There are few studies on the intestinal virome, and whether it has a causal relationship with bacterial changes in the gut is still unclear. However, it is undeniable that the intestinal virome is also a very important portion of the blueprint for the development of liver diseases and the diagnosis and therapeutic modalities in the future.

Key Words: Alcoholic fatty liver disease; Nonalcoholic fatty liver disease; Fatty liver disease; Gut microbiome; Intestinal virome

Core Tip: As of the study of the gut microflora expands, the interaction between the intestinal virome and liver diseases has been gradually revealed. In this letter to the editor, we discuss the changes in the intestinal virome in patients with alcoholic liver disease and nonalcoholic liver disease, and provide suggestions for developing future diagnosis and treatment methods.

TO THE EDITOR

We have carefully studied the reviews recently written by Sharma *et al*[1], titled "Significance of gut microbiota in alcoholic and nonalcoholic fatty liver diseases". The authors elaborated the intestinal microecological changes in both alcoholic and nonalcoholic liver diseases, and the important effects of intestinal microorganisms on the development of fatty liver diseases. These findings could provide new ideas for the future diagnosis and treatment of fatty liver disease.

In addition to bacteria, archaea and a small amount of fungi, viruses are also an indispensable part of the intestinal microflora in human[2] . In 2020, a multicenter observational study on the enteroviruses from 89 patients with alcoholic hepatitis, 36 patients with alcohol use disorder and 17 patients without alcohol use disorder was concluded[3]. The results showed that in stool samples from patients with alcoholic liver disease, bacterial and fungal diversity decreased and virus diversity increased, which mainly manifested as a large increase in the number of *Myoviridae*, *Lactobacillus* phages, *Streptococcus* phages, *Podoviridae*, *Geobacillus* phages, *Escherichia* phages, and *Herpesviridae*[3]. This trend was positively correlated with the severity of the disease. The changes in the intestinal microecology of people with alcohol use disorder are mainly characterized by an increase in *Parvoviridae* and *Lactococcus* phages[3]. Another study of the intestinal virome in patients with nonalcoholic fatty liver disease (NAFLD) showed that the average relative abundance and viral diversity of phages in patients with NAFLD and severe hepatic fibrosis were significantly lower than those in patients with NAFLD and no or mild hepatic fibrosis[4]. Hence viruses also have positive implications in the diagnosis, severity classification, treatment and prognosis of alcoholic and nonalcoholic liver diseases. However, as an easily neglected part of gut microecology, the impact of viruses was not mentioned in Sharma *et al*[1]'s article.

Bacteria and fungi in the gut microflora have large individual variability and are susceptible to various factors such as age, drugs[5], environment[6], and diet[7]. Likewise, the same is true for viruses. A shotgun metagenome sequencing analysis of DNA viruses in fecal samples from cynomolgus monkeys of different ages showed that the abundance of DNA viruses was inversely proportional to age; that is, the DNA virus group in fecal samples of elderly individuals decreased significantly[8]. However, Lang *et al*[4] found that after the use of proton pump inhibitors, enteroviruses in the feces of patients with nonalcoholic liver disease were also changed. In addition, in high-fat diet-fed mice, the structural composition and β-diversity of enteroviruses were changed. There was a significant decrease in the expression of *Siphoviridae* and a significant increase in the expression of the eukaryotic viruses *Phycodnaviridae* and *Mimivirdae*, and these changes were accompanied by changes in intestinal bacteria [9]. Therefore, considering the original proposal that gut microorganisms should be included in future liver disease diagnosis and treatment, we suggest that in addition to performing a horizontal comparison and finding representative biological markers, it is indispensable to have a methodological design and vertical comparison. However, the effects of confounding factors should also be considered, and individualized diagnosis and treatment plans should be developed for different patients.

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 edition of Journal Citation Reports® cites the 2021 impact factor (IF) for *WJG* as 5.374; IF without journal self cites: 5.187; 5-year IF: 5.715; Journal Citation Indicator: 0.84; Ranking: 31 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2021 is 8.1 and Scopus CiteScore rank 2021: Gastroenterology is 18/149.

Abstract

The circadian rhythm in humans is determined by the central clock located in the hypothalamus's suprachiasmatic nucleus, and it synchronizes the peripheral clocks in other tissues. Circadian clock genes and clock-controlled genes exist in almost all cell types. They have an essential role in many physiological processes, including lipid metabolism in the liver, regulation of the immune system, and the severity of infections. In addition, circadian rhythm genes can stimulate the immune response of host cells to virus infection. Hepatitis B virus (HBV) infection is the leading cause of liver disease and liver cancer globally. HBV infection depends on the host cell, and hepatocyte circadian rhythm genes are associated with HBV replication, survival, and spread. The core circadian rhythm proteins, REV-ERB and brain and muscle ARNTL-like protein 1, have a crucial role in HBV replication in hepatocytes. In addition to influencing the virus's life cycle, the circadian rhythm also affects the pharmacokinetics and efficacy of antiviral vaccines. Therefore, it is vital to apply antiviral therapy at the appropriate time of day to reduce toxicity and improve the effectiveness of antiviral treatment. For these reasons, understanding the role of the circadian rhythm in the regulation of HBV infection and host responses to the virus provides us with a new perspective of the interplay of the circadian rhythm and anti-HBV therapy. Therefore, this review emphasizes the importance of the circadian rhythm in HBV infection and the optimization of antiviral treatment based on the circadian rhythm-dependent immune response.

Core Tip: Some studies in the literature contribute to the association of the circadian rhythm and liver pathophysiology associated with hepatitis B virus (HBV) infection. However, this is the first review to report the latest molecular mechanisms of HBV infection, including cellular circadian rhythm disorders, circadian clock-related immune response, therapeutic strategies in improving health outcomes, and the significance of personalized medicine and chronotherapy in treating chronic HBV infections.

INTRODUCTION

The circadian rhythm in humans is determined by the central clock found in the hypothalamus's suprachiasmatic nucleus (SCN) which receives light signals from the retina[1]. Endogenous functional circadian rhythms are active in peripheral tissues. For example, the circadian clock in humans, expressed in almost every cell, consists of a whole range of transcription-translation feedback loops[2]. Furthermore, all peripheral clocks in every tissue are synchronized by the central clock in the SCN[3]. Therefore, circadian clock genes and clock-controlled genes (CCG) exist in almost all cell types. Approximately 10%-40% of the genome is encoded in a circadian manner[4]. Furthermore, most physiological processes, such as lipid metabolism, immune system regulation, and infection severity, are under circadian control, and therefore circadian rhythm disorders can result in pathophysiological changes downstream[4,5].

The liver has a vital role in maintaining energy homeostasis within the body. The primary biochemical reactions within the liver are involved in the breakdown and generation of glucose, which is associated with fatty acid metabolism[6]. In addition, the metabolic functions of the liver show rhythmic fluctuations with a periodicity of 24 h[6]. Hepatitis-causing viruses depend closely on hepatocytes for replication, survival, and spread[6]. In addition, viral infection can disrupt the hepatocytes' circadian rhythm[5]. Circadian rhythm transcription factors alter liver metabolism and are linked with various conditions, including viral infection, fatty liver disease, diabetes, and hepatocellular carcinoma (HCC)[1].

What makes the hepatitis B virus (HBV) significantly different from other hepatotropic viruses is its global impact on human health[7], namely, infections caused by this virus result in liver disease, which is a growing global problem[8]. According to the World Health Organization (WHO), it is estimated that 296 million people lived with chronic hepatitis B in 2019, and that 1.5 million new infections are detected each year[9]. Furthermore, due to HBV infection in 2019, mainly from cirrhosis and HCC, about 820000 people died[10]. Hepatitis B can develop in an acute or chronic form[11]. Most infected people do not have any symptoms, which does not mean that there is no disease. Symptoms of acute infection usually occur 2 mo to 3 mo after infection and are nonspecific[12,13].

The HBV begins to multiply within the first 3 d of infection[14]. Whether and to what extent liver damage occurs depends on the infected person's immune system, the infectious dose, and the site of virus entry. Tissue compatibility antigens and interferon promote the viral antigens' [hepatitis B surface antigen (HBsAg), hepatitis B envelope antigen (HbeAg), and hepatitis B core antigen (HBcAg)] exposure to cytotoxic T lymphocytes[15]. If there is no adequate response by these cells, milder signs of the disease occur, which may progress to the development of chronic hepatitis[16]. About 10% of acute HBV infections progress to a chronic form[17]. Chronic HBV can be clinically manifested as mild conditions to severe chronic hepatitis[18], which, in untreated cases, results in 8%-20% of cases with cirrhosis and HCC[19]. Persistent hepatitis is a mild disease that occurs in 8%-10% of patients, occasionally causing elevated aminotransferases, but generally does not progress toward cirrhosis and has a favorable prognosis[20]. HBV plays a significant role in the development of HCC, which can occur many years after chronic infection[21]. Still, typically the HBV is not a cytopathogen, and cell damage is thought to be mediated by a persistently unproductive immune response[17].

Therefore, this mini-review highlights the significance of the circadian rhythm in HBV infection, and the effectiveness of therapy in relation to the circadian rhythm-dependent immune response.

HBV

The epidemiological model of the spread of HBV and human immunodeficiency virus (HIV) is the same, but HBV is 50-100 times more infectious than HIV[22]. The source of infection is people with HBV infection[23]. However, the geographical prevalence of HBV infection varies[24]. In addition, it depends

on several factors, such as different modes of transmission in the population and the age at which the infection originated, which relates to the likelihood of progression to chronic infection[25].

HBV is mainly transmitted by percutaneous or mucosal exposure to infected blood or body fluids [26]. Perinatal transmission is the primary route of infection in endemic regions[27], while the most direct route in the low-endemic regions is sexual transmission[28]. Globally, the epidemiology of HBV infection is changing, influenced by infant vaccination programs and migration between low- and high-prevalence populations[29]. On the basis of the available data, it is estimated that the prevalence of new chronic HBV cases is 70% in developing countries[30].

On the basis of the prevalence of the HBsAg, the epidemiology of HBV in certain areas of the world can be classified into one of three categories (Table 1)[31]: Low prevalence areas (< 2%), medium prevalence areas (2%-7%), and high prevalence areas (> 8% HBsAg prevalence)[32]. These categories are important for understanding the transmission and outcome of infection, and the consequences of chronic hepatitis B[25].

Biology and life cycle of HBV

HBV is a DNA virus with ten known genotypes, labeled A-J. HBV belongs to the group of hepatotropic viruses from the family Hepadnaviridae, genus Orthohepadnavirus[33]. It is a small round virus of a very complex structure, 42 nm in diameter, with a double shell (Dane particle) (Table 2)[33]. Genotypes are divided into subgenotypes due to the significant variability of the nucleotide sequences[34]. They are based on a more than 4% difference along the entire genome. In addition, HBV genotypes and subgenotypes are related by geographical distribution, and also related to the pathogenesis and outcome of HBV infection (Table 3)[35].

The HBV genome has 3.2 kb long, relaxed circular, partially double-stranded DNA (rcDNA)[36]. The minus strand is complete, while the plus strand is regularly incomplete with a stable 5′ end, but an inconsistent 3′ end. The 5′ end of the plus strand is covalently linked to the RNA with a 5′ cap formation. In addition, the viral polymerase (reverse transcriptase) is covalently bound to the 5′ end of the minus strand[36,37].

Linear DNA is the direct precursor of viral DNA that is randomly incorporated into the hepatocytes' DNA throughout infection. Incorporated DNA has no role in virus replication[37,38]. The HBV genome is highly compact, with four open reading frames (ORFs) overlapping multiple times and encoding seven proteins[39]. All ORFs are identical orientations and encoded by the negative strand of DNA[40]. Thanks to the ORFs, the coding capacity increases, and DNA is transcribed one and a half to two times because there is no stop codon[41]. In addition to ORF, there are six start codons, four promoters, and two transcription enhancers[42].

ORF C encodes the nuclear core antigen HBc and envelope E antigen (HBe)[39]. The precore protein in serum indicates active virus replication[43]. The presence of HBeAg in serum suggests prevented or decreased virus replication. HBeAg can repress the cellular immune response to HBsAg, thereby reducing perinatal transmission and promoting chronic infection[37,44]. The longest ORF is the P gene, encoding most of the virus genome (80%) and viral polymerase (reverse transcriptase)[45]. The ORF X encoding hepatitis B protein X (HBx) activates viral RNA transcription[37,38]. HBx causes the progression of the cell cycle and is essential for activating the transcription of covalently closed circular DNA (cccDNA) and pregenomic RNA (pgRNA) after infection[37]. ORF S codes three different sizes of the surface S antigen (S-small, M-medium, and L-large HBs)[46]. The M- and L-HBs have additional PreS2 and PreS1 domains[39]. The PreS1 region, present in L-HBsAg, possesses a binding domain for the sodium taurocholate co-transporting polypeptide (NTCP) receptors, essential for viral internalization[37,47]. HBsAg are embedded in the outer lipid envelope, and the inner nucleocapsid structure contains the DNA genome, HBcAg, and viral polymerase (reverse transcriptase)[48]. In addition, HbeAg is between the nucleus and the outer shell[49].

HBV replicates in hepatocytes *via* pgRNA (Figure 1)[35]. The entry of the virus into the hepatocyte is the first step in its life cycle[50]. After the virus enters the liver, S-HBsAg recognizes heparan sulfate proteoglycans (HSPG) on the hepatocytes, and binds them with low affinity[51]. A high-affinity interaction between the PreS1 region of the L-HBs protein and NTCP follows[52]. Later, the virus envelope and the hepatocytes' membrane merge, releasing the nucleocapsid into the cytoplasm[53]. After the capsid shell is removed, the viral genome is transferred to the nucleus. As a result, viral DNA enters the nucleus of the hepatocytes. The relaxed circular (rc) genome is restored, resulting in cccDNA [54]. Viral DNA can be integrated into the hepatocytes' DNA, and is a constant HBsAg source[55]. The cccDNA is a template for pgRNA production and the transcription of all viral mRNAs[37]. On this basis, cccDNA in the hepatocytes can stimulate virus replication[56]. The cccDNA is associated with cellular histones and forms a minichromosome. Each viral protein has a promoter and mRNA, except for reverse transcriptase, translated from the same pgRNA as the virus core protein[37,44]. The onset of infection is indicated by the expression of core proteins and polymerase from pgRNA. HBc is a phosphoprotein and a subunit of the viral nucleocapsid. The core proteins are constructed into nucleocapsids, icosahedral shells of 120 dimers[57]. They merge with RNA and are assembled into core particles. Viral DNA synthesis takes place in the core particles, followed by packaging of pgRNA and polymerase[37,47]. Upon completing viral DNA synthesis by reverse transcription, viral particles can exit the hepatocytes in two ways. First, while envelope protein levels are low, core particles recycle and

F		Central and South America
G		Europe, USA
H		Central and South America, California (USA)
I	I1-12	Vietnam
J		Japan

USA: United States.

enter the nucleus, resulting in the replenishment of cccDNA[37,39]. Later, the core particles gather with the envelope proteins in the endoplasmic reticulum, enter the secretory pathway, and are discharged from hepatocytes into the blood[58]. In addition to infectious virions (Dane particles), incomplete subviral particles are secreted by secretory pathways (such as spheres and filaments lacking nucleocapsid proteins and naked nucleocapsids)[59]. The virus emerges on the surface of the hepatocytes by budding, and can thus infect another cell[52]. Once created in the cell nucleus, the cccDNA minichromosome is very difficult to eliminate from infected cells, where it can survive until the death of the host cell[56].

Figure 1 Hepatitis B virus life cycle. Hepatitis B virus (HBV) enters hepatocytes *via* interaction with the heparan sulfate proteoglycan (HSPG), followed by the sodium taurocholate co-transporting polypeptide (NTCP) receptor. The virus envelope and the hepatocytes' membrane merge, releasing the nucleocapsid into the cytoplasm. The viral genome is transferred to the nucleus after the capsid is removed. The relaxed circular genome is restored in the nucleus, resulting in covalently closed circular DNA (cccDNA), and viral DNA could be integrated into the host DNA. Integrated viral DNA is a constant source of hepatitis B surface antigen (dashed line). The cccDNA is a template for pregenomic RNA (pgRNA) production and the transcription of all viral mRNAs. In addition, the cccDNA is associated with host factors and cellular histones, and forms a minichromosome. The core proteins are constructed into nucleocapsids together with pgRNA. Viral polymerase converts the pgRNA to relax circular DNA, resulting in a mature nucleocapsid. The core particles can recycle and replenish cccDNA (dashed line), or gather with the envelope proteins in the endoplasmic reticulum and Golgi, and enter the secretory pathway. Through the secretory process, virions gain surface antigens and are secreted as infectious virions-Dane particles. Also, incomplete subviral particles are secreted, such as spheres and filaments lacking nucleocapsid proteins. HSP: Heparan sulfate proteoglycan; NTCP: Sodium taurocholate co-transporting polypeptide receptor; cccDNA: Covalently closed circular DNA; pgRNA: Pregenomic RNA; HBx: Hepatitis B protein X; HBsAg: Hepatitis B surface antigen; HBe: E antigen; ER: Endoplasmatic reticulum.

CIRCADIAN RHYTHM

The molecular basis of the circadian rhythm includes transcriptional and translocation feedback loops. In addition, the circadian rhythm is driven by the circadian locomotor output cycles kaput (CLOCK), and brain and muscle ARNTL-like protein 1 (BMAL1 or ARNTL) transcription factors. In contrast, transcription repressors are period (PER) and cryptochrome (CRY) transcription factors. The central transcription factors that make up the activation and positive part of the molecular clock are BMAL1 and CLOCK. The heterodimer CLOCK-BMAL1 enters the nucleus, where it initiates transcription by binding to a specific sequence, the E-box, in promoters of the target genes. CLOCK's main downstream goals include *BMAL1* and its repressors, cryptochrome (*CRY1*, *CRY2*), and period (*PER1*, *PER2*, and *PER3*) and multiple CCG[60]. CRYs and PERs accumulate during the positive loop in the cytoplasm. They are controlled by F-box/LRR-repeat protein 3 (FBXL3) and casein kinase 1 (CK1) ε and CK1δ[4,61]. CK1ε and CK1δ phosphorylate PERs for degradation, while FBXL3 stimulates CRYs degradation. If CK1ε phosphorylates heterodimer PER-CRY, it enters the nucleus and suppresses the CLOCK-BMAL1 heterodimer. By suppressing their activator, CRYs and PERs suppress their own expression[62]. Posttranslational phosphorylation of CRYs and PERs promotes their degradation, which triggers a new circadian cycle, with increased binding of the CLOCK-BMAL1 heterodimer to the E-box of CCG[2,63].

The second regulatory loop includes the retinoic acid receptor-related orphan receptor (*ROR*) α and *RORγ*, and the *REV-ERBα* and *REV-ERBβ* genes. The CLOCK-BMAL1 heterodimer initiates their transcription by binding to the E-box elements of their promoters. RORs and REV-ERBs receptors bind to the ROR element (RORE). REV-ERBα and β inhibit transcription, while RORα and γ stimulate expression of target genes. RORs and REV-ERBs together create cyclic fluctuations in the expression of

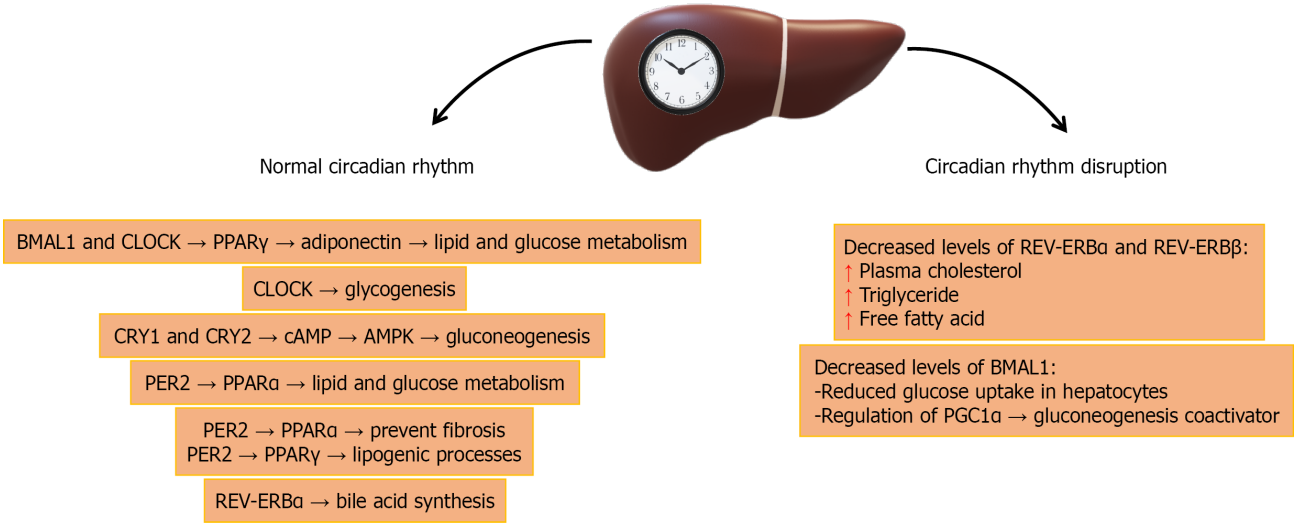
many CCG, including the regulation of *BMAL1* transcription[6,64]. REV-ERBα accumulates rapidly and prevents *BMAL1* transcription, while RORα accumulates more slowly and promotes *BMAL1* transcription. In this way, the stability and robustness of the rhythmicity of the internal clock system are enhanced[2,63].

An additional independent feedback loop includes the helix-loop-helix e40 family (DEC1 or BHLHE40) and DEC2 (BHLHE41) that prevent CLOCK-BMAL1 activity[65]. The CLOCK-BMAL1 heterodimer stimulates the expression of *DEC1* and *DEC2* by binding to the E-box of their promoters. Conversely, DECs suppress transcription of genes with E-box elements in the promoter, including transcription of itself and CRYs and PERs, due to its binding to the E-box[66]. In addition, the CLOCK-BMAL1 heterodimer affects the expression of other CCG by stimulating D-box binding protein (DBP) transcription, by binding to E-box elements on the promoter[67]. DBP rhythmically triggers genes with D-box elements in the promoter[2,4].

The transcriptional and translational feedback loop creates rhythms in the expression and levels of downstream CCG[4]. All of these connected feedback loops create a circadian rhythm. For example, CCGs containing RORE elements in promoters are transcribed during the active phase. In contrast, the genes' promoters containing E-box and D-box elements are transcribed during the resting phase[63].

The circadian rhythm is controlled at the transcriptional and posttranslational levels, including cellular pathways, transcription factors, epigenetic changes, and posttranslational modifications[68]. Many posttranslational modifications of clock elements include acetylation, phosphorylation, ubiquitylation, and sumoylation[4,63]. Epigenetic modifications, such as DNA methylation, histone modifications, and non-coding RNAs, interfere with the target genes' transcription and post-transcriptional expression, including clock genes[69]. Different patterns of histone modifications, such as histone deacetylase sirtuin 1 (SIRT1), or microRNA, can be direct and indirect modulators in maintaining different aspects of circadian rhythm function[53,70].

Liver physiology and circadian rhythm



With a lack of environmental signs, such as the alternation of light and dark, food intake affects the circadian rhythm of the liver[6]. Circadian rhythms largely control different genes, levels of proteins, and the enzymes in the liver[2]. The circadian rhythm and liver metabolism are connected through the peroxisome proliferator-activated receptors (PPARs) α and γ[6,71]. PPARα controls the transcription of genes participating in lipid and glucose metabolism, while PPARγ is involved in lipogenic processes because it binds eicosanoids from omega-3 or omega-6 fatty acids[4,72]. Both genes are rhythmically expressed, and their expression is controlled by PER2, which directly regulates *BMAL1* transcription (Figure 2). The binding of PPARα to PPAR response elements (PPRE) in the *BMAL1* promoter leads to its transcription. Also, PPARα interacts with PER2 in the liver to impact the expression of target genes [73]. In the positive feedback loop in the liver, BMAL1 and CLOCK control the circadian oscillations of *PPARα*[4], and thus the expression of enzymes participating in glucose and lipid homeostasis, and the biosynthesis of bile acids and apolipoproteins[6]. REV-ERBα is implicated in the control of bile acid synthesis[74]. Adiponectin, triggered by BMAL1 and CLOCK *via* the transcription of *PPARγ* and its coactivator 1α (PGC-1α), is involved in glucose and lipid metabolism[75].

In addition, gluconeogenesis is controlled in a circadian manner in the liver *via* CRY1 and CRY2, which prevent signaling *via* the secondary messenger cyclic adenosine monophosphate (cAMP)[76]. Moreover, AMP-activated protein kinase (AMPK) can influence circadian cycle length by phosphorylating CRYs and directing it to degradation[4]. Activation of RORα in the liver may impact lipid metabolism and control hepatic steatosis by triggering AMPK[77]. Furthermore, CLOCK controls glycogenesis in the liver by acting on glycogen synthase 2 expression[78]. Disorders of the *CLOCK* and *BMAL1* genes lead to impaired glucose homeostasis[6]. Histone deacetylase SIRT1 prevents hepatic steatosis by controlling lipid homeostasis by positive binding of PPARα and PGC1α coactivators, or by direct action on BMAL1[70].

Circadian rhythm and HBV

There is a functional association between virus replication and circadian dysfunction in the pathogenesis of liver disease[79]. HBV has been revealed to impact the liver clock genes and disrupt the internal molecular clock in order to make better use of hepatocytes for self-replication[80]. HBV is randomly incorporated into the human genome, yet there are sites where it is incorporated more frequently, such as circadian rhythm-related elements, *CLOCK*, and *BMAL1*. Those elements are one way that the circadian rhythm is associated with diseases caused by HBV infection[81]. HBV replicates in the liver where around 20% of genes exhibit a rhythmic expression pattern, implying that the virus has successfully evolved to persist in the liver[5,50]. Integrated copies of HBV, which have regulatory elements similar to circadian rhythm genes, present additional circadian rhythm motifs in the infected cell, resulting in undesirable oscillations of specific genes, or disrupted circadian rhythms of the hepatocytes, and are a risk factor for cancer[50].

The circadian rhythm impacts gene expression in the liver and thus HBV replication[50]. In patients with HBV infection, a reduction in *BMAL1* and an increase in *REV-ERBα* and *REV-ERBβ* transcription have been observed compared to healthy subjects, which indicates that circadian rhythm gene transcription is impaired in HBV infection[50]. In hepatocytes, decreased expression or deletion of *REV-*

ERBα and *REV-ERBβ* in hepatocytes increases plasma cholesterol, triglycerides, and free fatty acid levels [63]. In addition, REV-ERB binds and controls NTCP expression, and stimulation of *REV-ERB* prevents HBV from entering the hepatocytes[50]. The NTCP receptor has a circadian pattern in hepatocytes[82]. Decreased expression of *BMAL1* in hepatocytes leads to reduced glucose uptake. In addition, BMAL1 regulates the transcription of the *PGC1α* gene, a coactivator of gluconeogenesis[63]. Thus, PPARα can prevent the development of fibrosis[63], and it is known that HBV dysregulates PPARα and PPARγ[6]. Also, BMAL1 binds HBV DNA, and controls viral genome expression and new viral particle formation [50].

The impaired circadian rhythm in HCC may favor the selective survival of cancer cells and facilitate carcinogenesis[83]. An increased risk of developing HCC is linked with chronic HBV infection. The HBx protein is linked with HCC due to the disturbance of cell proliferation[19]. It is a possible cause of significantly reduced transcription levels of the *BMAL1*, *PER3*, *CRY1*, *CRY2*, and *CK1ε* genes in HCC [84]. At the same time, elevated HBx expression in HCC results in increased *CLOCK*, *PER1*, and *PER2* expression[1,85]. In addition, abnormal expression of *REV-ERBα* was observed in a cell line that stably expressed HBV[86]. The circadian rhythm acts *via* REV-ERBα in the liver on hepatocyte nuclear factor 4 alpha (HNF4α), and thus directs the action of glucocorticoid receptors on energy metabolism (Figure 3). Consequently, the interactions between CRY and glucocorticoid receptors affect carbohydrate metabolism, hence transacting *PER2*[87]. HNF4α increases the transcription of pgRNA in hepatoma cells and thus affects HBV biosynthesis[88]. In addition, P2-HNF4α inhibits the expression of *BMAL1*, leading to the localization of P1-HNF4α from the nucleus to the cytoplasm. *BMAL1* is expressed in healthy hepatocytes, but tumor growth is prevented if *BMAL1* expression is induced in HNF4α-positive tumor cells[89]. The possible reason for the inhibition of tumor growth is that BMAL1 mediates the transcription of *P53* pathway genes, a well-known tumor-suppressor gene[90]. DNA viruses rely more on host transcription for gene expression; however, *BMAL1* deficiency increases virus replication. REV-ERBα has a protective effect because it reduces the inflammatory response, thus decreasing the severity of the disease. Thus, REV-ERBα agonists inhibit HBV replication, while BMAL1 promotes virus replication. Nevertheless, as BMAL1 stimulates oscillations in genes that metabolize drugs and sensitivity to toxicity, it also promotes HBV infection in hepatocytes[91].

HBV infection leads to overexpression of *RORα* and *RORγ*[92]. *RORγ* overexpression is associated with promoter methylation and HBx protein. Furthermore, HBx-induced *RORγ* may facilitate the proliferation and migration of hepatoma cells[93], and RORα may be a possible diagnostic and prognostic biomarker for disease severity[94]. Overexpression of *RORα*, *CRY2*, and *PER1* is associated with a better survival of HCC patients, and regulating the circadian rhythm gene may help in the chronotherapy of such patients[94]. HBV infection leads to disruptions of the *CLOCK* gene and its downstream circadian genes and other CCGs[2]. All the above indicates that circadian rhythm disorders caused by a virus may contribute to the pathogenesis of cancer.

Immunopathogenesis of chronic HBV infection and circadian rhythm

Clinical manifestations of chronic hepatitis B result from a cellular and humoral immune response to the recognized target antigenic viral epitopes, HBcAg and HBsAg[21]. Integration of HBV into the

Figure 3 Relationship between circadian rhythm genes and hepatitis B virus replication. Gray dashed lines indicate normal circadian rhythm in hepatocytes. Black arrows show the association between core clock proteins and hepatitis B virus (HBV) entry into hepatocytes and its replication. Increased levels of REV-ERB protein prevent the entry of HBV into hepatocytes by impaired action on the sodium taurocholate co-transporting polypeptide (NTCP) receptor. Brain and muscle ARNTL-like protein 1 (BMAL1) protein binds HBV DNA and thus controls viral genome expression and the formation of new viral particles. In infected hepatocytes, REV-ERB through HNF4α mediator increases pregenomic RNA (pgRNA) transcription, while HNF4α inhibits BMAL1 expression, promoting HBV replication. Red arrows indicate circadian rhythm genes inhibited by hepatitis B protein X (HBx) protein (BMAL1, CRY1, CRY2, and PER3). Conversely, HBx increases *CLOCK*, *PER1*, *PER2*, and *RORγ* gene expression (indicated by blue arrows). Increased expression of *RORγ* leads to the proliferation of hepatoma cells. hepatocytes' genome serves as a constant source of HBsAg during chronic infection. It may induce dysfunctional T-cell responses, and favor harmful immunopathology and disease progression to fibrosis and cirrhosis[95]. Hepatocytes expressing HBcAg are recognized and attacked by cytotoxic $CD8^+$ lymphocytes (CTL)[96]. The increase in alanine aminotransferase is the result of hepatocyte lysis[97]. HBcAg has strong immunogenicity and can cause the antigen-specific T-cell responses necessary for controlling HBV infection. HBcAg stimulates the production of interleukin 6 (IL)-6, IL-10, IL-17A, IL-22, IL-23, and transforming growth factor β (TGFβ) by peripheral blood mononuclear cells[98]. In addition, the immunosuppressive cytokine IL-10 negatively controls the expansion of Th17 cells, which plays a part in the existence and promotion of HBV infection[46]. Persistent HBV infection is marked by a poor immune response due to the poor response of $CD4^+$ lymphocytes in the early phases of infection. This results in qualitatively and quantitatively weaker $CD8^+$ T cell responses[21].

In addition to other viral proteins, HBeAg is also important for the persistence of infection, as it suppresses the humoral and cellular immune response to HbcAg, weakens the action of CTL on HBcAg, and allows the maintenance of the infection[99]. The predominance of Th-1 over the Th-2 cytokine response, with the production of IL-2, interferon-alpha (IFN-α), and lymphotoxin-β receptor (LT-βR), is responsible for virus elimination during acute and chronic HBV infections[100]. Conversely, the predominance of Th-2 cytokine response is responsible for maintaining chronic infection, with IL-4, IL-5, and IL-10, which enhance the humoral immune response[98].

Many innate and adaptive immune system elements are under circadian regulation[1], and the adaptive immune response mediates virus removal and liver disease[95]. Cellular immune rhythms are synchronized with the central clock in the SCN[6]. Innate and adaptive immune system cells have a molecular clock that controls their rhythmic activity over 24 h[101]. Certain functions of the innate immune system rely on the hepatocytes' circadian rhythm[5,65]. Increased amounts of pro-inflammatory hormones such as growth hormone, prolactin, and melatonin and cytokines such as IL-1 and TNF-α are present during the rest period. In addition, immune rhythms are affected by hormonal

rhythms, so cortisol regulates the number of naive T cells. Epinephrine influences the number of CTL cells over 24 h[102].

Furthermore, the transcription factor CRY2 links the circadian rhythm and the innate immune system [103]. Moreover, CLOCK and BMAL1 control transcription of the pattern recognition receptor, which is involved in nucleic acid detection during viral infections[104]. RORγ regulates the differentiation of Th17 cells, which secrete IL-17, an essential regulator of pro-inflammatory signaling[93]. REV-ERBα has a protective effect in various inflammatory processes[105]. Additionally, the suppression of REV-ERB receptors elevates virus-associated mortality by promoting the inflammatory response[106]. The circadian hormone melatonin has protective and antiviral actions and a role in the inflammatory response[105]. Melatonin increased IFN-γ levels during viral infection, decreased Venezuelan equine encephalomyelitis virus (VEE) levels, and reduced mortality rates in mice infected with VEE. The protective impact of melatonin is associated with increased IL-1β production because it acts as a cytokine modulator and antioxidant[107]. This shows the positive role of the circadian rhythm in regulating antiviral immunity[91].

ANTIVIRAL THERAPY

There are two main drugs for HBV infection therapy: Nucleoside/nucleotide analogs (NAs), which interfere with viral DNA synthesis during reverse transcription, and IFN-α[108,109]. NAs effectively inhibit virus replication and may suppress the generation of new cccDNA[109]. Existing drugs can suppress virus replication, slow fibrosis progression, and decrease infectivity, but rarely remove the cccDNA responsible for HBV persistence[108]. Therefore, the development of therapy aims to achieve a "functional healing" state, *i.e.*, the removal of cccDNA from hepatocytes[110,111]. However, in the treatment of HBV infection, NAs rarely eliminate the virus, that is, they do not eradicate HBV from the liver[95]. This is because each HBV surface protein (S, M, and L) has an HBsAg determinant. Therefore, HBsAg circulates in the bloodstream of HBV patients, mainly in non-infectious subviral spheres and filaments[95].

Alternative therapeutic strategies are based on silencing viral genes using RNA interference (RNAi) [108] and antisense oligonucleotide (ASO) technology[110]. Both approaches are based on the effective suppression of HBV replication in patients with chronic HBV infection[108,110]. RNAi is a mechanism for silencing genes after transcription, and can be used in mammalian cells against viral infections[108]. ASO technology prevents HBV antigen production by targeting all HBV genome transcripts in infected hepatocytes[10,110]. It is based on NAs that act on viral polymerase but do not influence the cccDNA transcription[110]. ASO and other nucleic acid-based therapies may potentially decrease the tolerogenic outcome of the high HBsAg levels characteristic of chronic infection[63,110].

Role of circadian rhythm in antiviral therapy

One of the principles of personalized medicine is to optimize the time of day for administration of drugs whose action is affected by the circadian rhythm[5,112]. Circadian oscillations can affect vaccine responses to viral pathogens[91]. The direct impact of the circadian rhythm on the cellular and humoral immune reaction is mediated by melatonin and cortisol. Research on the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) has shown that melatonin can affect circadian clocks and modulate the immune response during viral infections and thus impact virus replication[113]. Therefore, vaccination in the morning or evening may impact the immune response to the vaccine[114]. Thus, it was observed that patients vaccinated against the SARS-CoV-2 in the morning had significantly lower C-reactive protein levels compared to patients vaccinated in the evening[115]. Making a simple effort to determine the appropriate time for administration of drugs or vaccine can improve the drug's effectiveness and reduce side effects[5]. However, studying the interaction of the circadian rhythm and virus replication may lead to a better knowledge of viral infections and the associated immune response, discovery of new antiviral targets, improvement of existing treatments, and therapy for chronic infections[5]. Chronic infection is linked with a weakened immune response, and poor T-cell responses that fail to control HBV replication[50]. The effectiveness of current antiviral therapies could be enhanced by modulating the timing of vaccine administration. For example, the engineered T cell receptor activity showed a circadian pattern upon antigen activation. However, this daily effect was attenuated in *CLOCK* mutant mice, emphasizing the importance of timing T cell therapy to maximize antiviral immunity[1].

Many studies show that the efficacy or toxicity of treatment depends on the dosing time in many diseases. Also, inter-individual variations in the circadian rhythm resulting from lifestyle differences should be considered[116]. The efficiency of the DNA virus vaccine can be enhanced by specifying the time of day for vaccination. For example, some studies have found that patients immunized in the morning produce a more significant antibody response to hepatitis A and influenza vaccines[1,117]. In addition, morning vaccination is considered to significantly increase responses to viral-specific antibodies, compared to afternoon vaccination[1]. As viruses are intracellular pathogens that replicate within host cells, given the high association of circadian rhythm transcription factors with cell

transcription, the circadian rhythm plays a vital role in determining host susceptibility to viral infections and the immune response[1].

Circadian clock-modulating small molecules may help inhibit or activate circadian rhythm proteins and enzymes in viral infections. Thus, the small molecule SRT2183 modulates the circadian clock that inhibits SARS-CoV-2 replication[118] because it modulates physiological and circadian rhythm gene expression[119]. Inhibiting *BMAL1* expression and overexpression of *REV-ERB via* circadian rhythm-modulating small molecules may prevent dengue virus, hepatitis C virus, Zika virus, and HIV1 virus replication. In addition, clock genes have antiviral abilities that can be applied to HBV[120]. One of the effective circadian clock-modulating small molecules in treating HBV infections is GSK4112, a synthetic ligand for REV-ERB, but it is not suitable for *in vivo* use due to its poor pharmacokinetic properties. In contrast, ARN5187 is a REV-ERBβ agonist with dual function, an inhibitor of REV-ERB and autophagy [121]. SR9009 is a REV-ERBα agonist based on the chemical structure of GSK4112. It has better pharmacokinetic properties than GSK4112 and affects many oncogenes. In addition, REV-ERBα is known to regulate cancer development by inhibiting proliferation[121], and hence SR9009 inhibits *BMAL1* and prevents the entry and replication of HBV into hepatocytes[50].

Challenges associated with antiviral drug development, including circadian clock-modulating small molecules, may be adverse effects or suboptimal pharmacokinetics. Therefore, for an antiviral agent to succeed, the target drug should be distributed locally to avoid unfavorable consequences on other tissues.

CONCLUSION

Interaction exists between viruses and the circadian rhythm of hepatocytes. Infection susceptibility depends on the infectivity of the inoculum, the mode of transmission, the length of exposure to the virus, and the time of the day infection occurs[1]. Understanding how HBV interacts with the circadian rhythm of hepatocytes may influence the treatment of infections[1]. Viruses are among the most critical human carcinogens[6], and pharmacotherapy and chronotherapy should be united to treat or prevent viral infections[1]. Research on the impact of viral infections on the circadian rhythm may help detect new antiviral targets and optimize the timing of immune-based therapies[1]. The main challenge in treating HBV infection is eradicating or silencing the cccDNA[50]. By acting on specific components of the circadian rhythm, such as REV-ERB and BMAL1, HBV can be prevented from entering hepatocytes and producing new virions. In addition to lifestyle changes, circadian rhythm-focused approaches may provide new therapeutic options in treating HBV infections[63].

Abstract

Pancreatic ductal adenocarcinoma is one of the most aggressive and lethal cancers. Surgical resection is the only curable treatment option, but it is available for only a small fraction of patients at the time of diagnosis. With current therapeutic regimens, the average 5-year survival rate is less than 10% in pancreatic cancer patients. Immunotherapy has emerged as one of the most promising treatment options for multiple solid tumors of advanced stage. However, its clinical efficacy is suboptimal in most clinical trials on pancreatic cancer. Current studies have suggested that the tumor microenvironment is likely the underlying barrier affecting immunotherapy drug efficacy in pancreatic cancer. In this review, we discuss the role of the tumor microenvironment in pancreatic cancer and the latest advances in immunotherapy on pancreatic cancer.

Key Words: Pancreatic ductal adenocarcinoma; Tumor microenvironment; Immunotherapy; Clinical trial; Chemotherapy; Treatment

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Despite advances in basic and translational research, pancreatic cancer remains one of the most lethal cancers. Recent breakthroughs in immunotherapy have revolutionized cancer therapy and have shown great potential to transform pancreatic cancer treatment. However, due to the barrier related to the tumor microenvironment, pancreatic cancer has shown inferior treatment outcomes toward various immunotherapy regimens. Further efforts, such as combinatory immunotherapy or molecular tumor subtyping, are warranted to overcome immunotherapy resistance in pancreatic cancer.

INTRODUCTION

Pancreatic ductal adenocarcinoma (PDAC) develops in the exocrine compartment of the pancreas and accounts for approximately 90% of pancreatic malignancies, making it the most common pancreatic neoplasm. Due to the lack of early diagnosis and limited treatment response, PDAC remains a highly aggressive and lethal malignancy and is the fourth leading cause of cancer-related death worldwide[1]. Although there has been notable progress in understanding tumor biology and the development of novel therapeutic regimens, the average 5-year survival rate is still less than 5%-10% in PDAC patients [1,2]. The clinical manifestations of pancreatic cancers are generally nonspecific, including weight loss, abdominal pain, thromboembolic disease, and type 2 diabetes[3,4]. In approximately 60%-70% of PDAC cases, the tumor arises from the head of the pancreas and could present as pancreatitis and obstructive jaundice[5]. Tumors of the pancreatic body and tail frequently have a poor prognosis due to their late presentation and associated advanced tumor stage[6].

The standard of care for resectable PDAC is surgical resection followed by adjuvant chemotherapy. Surgical resection remains the only curative therapy, but it is available for merely 10%-20% of patients at the time of diagnosis. Moreover, even with curative surgical resection, local recurrence and distal metastasis of PDAC are still quite common[7]. Advanced-stage PDAC is routinely treated with neoadjuvant chemotherapy, and the current first-line therapy regimens include gemcitabine, gemcitabine plus nab-paclitaxel, and FOLFIRINOX (the combination of oxaliplatin, leucovorin, fluorouracil, and irinotecan) [8]. Recently, the poly(adenosine diphosphate-ribose) polymerase inhibitor (PARPi) olaparib (Lynparza) has been approved for patients with germline BRCA-mutated metastatic pancreatic cancer[9]. The development of these neoadjuvant chemotherapy regimens has greatly improved patient survival and quality of life. However, a significant portion of PDAC eventually relapses despite surgical resection and/or neoadjuvant chemotherapy and leads to patient death[10,11].

The difficulties in treating pancreatic cancer lie at the cellular and genetic levels[12]. Mutational changes in pancreatic tumors lead to gene instability, tumor growth, and resistance to treatments[13]. In addition to the characteristic molecular landmarks, including oncogenic *KRAS* mutation and inactivation of the tumor suppressor genes *CDKN2A/P16*, *TP53,* and *SMAD4*, PDAC also frequently harbors mutations involving diverse cell signaling pathways[14]. The molecular heterogeneity likely accounts for its drug resistance in chemotherapy[15]. In addition, pancreatic cancer stem cells, accounting for approximately 1% of all pancreatic cancer cells, have the capacity for self-renewal and exhibit chemoresistance properties[16].

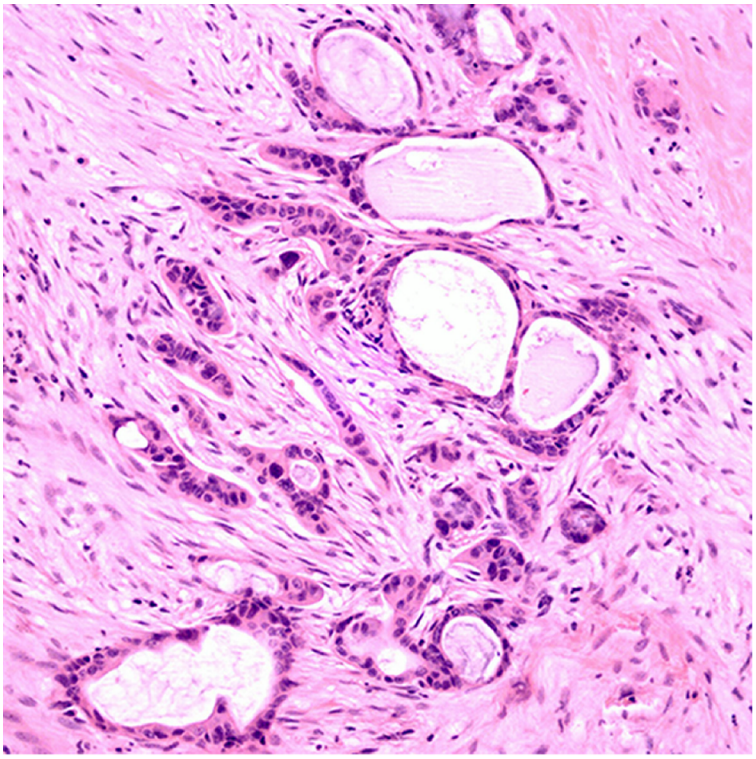
Immunotherapy has emerged as one of the most promising treatment options for advanced solid tumors, including lung, kidney, bladder, liver, and colorectal cancers[17]. Unfortunately, PDAC is notoriously resistant to immunotherapy, and thus far, most phase I/II clinical trials on PDAC have failed to demonstrate the desirable clinical efficacy of immunotherapy[18]. Of note, microsatellite instability (MSI), one of the predictive biomarkers for immune checkpoint blockade therapy, is only detected in a rare small portion of PDAC patients (less than 1%)[19,20]. On the other hand, emerging evidence has pinpointed the tumor microenvironment (TME) in PDAC as a critical component of treatment resistance toward immunotherapy[21,22].

In this review, we discuss the role of the tumor microenvironment and the latest advances in immunotherapy on pancreatic cancer through the search of peer-reviewed clinical and basic research articles related to this topic on PubMed, as well as the publicly accessible information on relevant

clinical trials through ClinicalTrials.gov.

TUMOR MICROENVIRONMENT IN PANCREATIC CANCER

PDAC is a type of stromal-rich cancer that frequently presents with a prominent desmoplastic reaction and is characterized by fibrogenic connective stromal tissue surrounding invasive carcinoma[23] (Figure 1). Desmoplastic reaction, or desmoplasia, is considered as the morphological basis of the TME. In general, the TME in PDAC demonstrates extensive desmoplasia, decreased stromal vascularization, and altered immune cell infiltration that lead to reduced drug activity and advancement of tumor progression. This process is characterized by an increase in the deposition of noncellular components, such as extracellular matrix (ECM), as well as an increase in the proliferation of cellular components, such as cancer-associated fibroblasts (CAFs) and immune cells[24,25]. Various cytokines, including interferons, interleukins, tumor necrosis factor (TNF), and transforming growth factor β (TGF-β), also play essential roles linking the TME cellular and noncellular components to regulate tumor growth, metastases, and drug resistance. Of note, the overall stroma is responsible for most of the tumor mass, but the stromal cellular components make up a relatively small fraction, approximately 10%-30%, of the tumor mass[26].



Noncellular components of the tumor microenvironment

The ECM is a significant factor in the initiation and progression of PDAC, and its deposition is associated with tumor migration, invasion, and poor prognosis[27]. The ECM is predominantly produced by cancer-associated pancreatic stellate cells (PSCs), a subtype of CAFs[28]. In PDAC, the ECM comprises most of the tumor mass and various matrix proteins, including collagen, fibronectin, proteoglycans, hyaluronan, proteolytic matrix metalloproteinases (MMPs), and tissue inhibitors of MMP [29]. Among ECM components of particular interest are hyaluronan and MMPs in tumor progression and prognosis in PDAC.

In general, ECM provides a rigid barrier leading to increased tumor pressure, decreased vascularization, and reduced drug delivery. A significant cause of drug resistance is the inability of conventional chemotherapeutic drugs such as gemcitabine to penetrate the thick stromal layer[30]. Therefore, it is rational to propose a combinatory therapeutic strategy for PDAC by targeting the tumor ECM. Hyaluronan, or hyaluronic acid (HA), is a glycosaminoglycan polymer and a major component of the ECM. Increased deposition of HA is associated with tumor metastases, drug resistance, and poor prognosis in PDAC[27,31]. Since stromal HA levels are dynamically regulated by synthases (to produce HA) and hyaluronidases (to degrade HA), hyaluronidase-based drug development has been a promising field in targeted therapy against the TME. The enzymatic depletion of hyaluronan through recombinant hyaluronidase (PEGPH20) has led to significantly increased overall survival when combined with neoadjuvant chemotherapy[32]. This is attributed mainly to improved delivery of systemic therapy through degradation of HA and remodeling of the TME. However, a recent phase IB/II randomized study (NCT01959139) of FOLFIRINOX plus pegylated recombinant PEGPH20 showed increased toxicity with this combination therapy and decreased overall survival (OS) (7.7 mo *vs* 14.4 mo) compared with FOLFIRINOX monotherapy[33]. Moreover, despite promising results of PEGPH20 in phase I-II studies, in a recent phase III randomized study (HALO 109-301), the addition of PEGPH20 to nab-paclitaxel/gemcitabine did not improve OS and progression-free survival (PFS) in patients with hyaluronan-high metastatic PDAC, and additional development of PEHPH20 in metastatic PDAC was halted[34].

MMPs are calcium-dependent metalloproteinases responsible for ECM protein degradation and are implicated in cancer initiation, growth, and metastasis. Clinical trial results with broad-spectrum MMP inhibitors were discouraging due to lack of specificity, associated toxicity, and insufficient clinical benefit[35], warranting further basic and translational studies to classify the role of individual MMPs in PDAC. Among MMP family members, the expression levels of MMP-2, MMP-7, MMP-9, and MMP-11 were significantly elevated in PDAC tumor tissues compared with normal pancreas samples[36,37]. Increased MMP-2 expression in PDAC leads to tumor invasion and progression[38-40]. MMP-7 expression is also associated with PDAC initiation and progression[41] and has been shown to be an independent prognostic factor for PDAC in a multivariate analysis. MMP-9 is significantly associated with pancreatic cancer progression and poor prognosis[37] and has emerged as a prognostic biomarker and potential therapeutic target. Highly selective and potent MMP-9 inhibitory antibodies have been developed for ulcerative colitis and colorectal cancer[42]. However, in a preclinical study, systemic ablation of MMP-9 facilitated pancreatic cancer growth and metastasis by creating a tumor-promoting TME[43]. This study has suggested a controversial role for MMP-9 in pancreatic cancer progression.

Additional studies have also demonstrated conflicting results in drugs targeting the tumor stroma. Olive *et al*[44] demonstrated that depletion of ECM in PDAC, through inhibition of the Sonic Hedgehog signaling pathway, promoted gemcitabine efficacy and improved survival. However, the involvement of the Sonic Hedgehog-dependent tumor stroma in PDAC has been controversial, as evidence shows that some components of the tumor stroma could actually act to restrain, rather than support, tumor

Figure 1 Pancreatic ductal adenocarcinoma with an associated tumor microenvironment. Please note the desmoplastic stromal reaction surrounding the tumor glands, decreased stromal vascularization, and scattered infiltrating inflammatory cells (HE stain, 200 x).

growth[45]. All these failures indicate that targeting desmoplasia alone is insufficient for treating advanced PDAC. The tumor stroma has both tumor-promoting and tumor-suppressing functions, which are probably context dependent. The stromal heterogeneity should be considered for the development of targeted therapy.

Cellular components of the tumor microenvironment

PDAC displays unique immunologic hallmarks. The TME in PDAC consists of diverse cellular components, including CAFs, regulatory and cytotoxic lymphocytes, macrophages, and endothelial cells [46]. CAFs are the major TME cellular component responsible for the production and deposition of ECM proteins. The involvement of CAFs in the progression of PDAC has been a hot and controversial topic. Similar to the observations made with tumor stroma, CAFs also play dual functions in regulating PDAC progression. On the one hand, CAFs promote cancer progression and drug resistance through the deposition of dense ECM, the release of exosomes (extracellular vesicles), and metabolic support[47-49]. On the other hand, depletion of CAFs leads to accelerated PDAC progression and reduced survival in multiple preclinical studies[50,51]. These discrepancies are likely associated with the heterogeneity of CAFs[52,53], a concept supported by recent studies demonstrating the existence of multiple distinct and mutually exclusive CAF subtypes in pancreatic cancer[54,55]. CAF subtypes with diverse biomarkers, including α-smooth muscle actin (αSMA), fibroblast activation protein (FAP), S100A4, and platelet-derived growth factor receptor-β (PDGFRβ), have been identified[56]. Specifically, FAP-positive active CAFs have been linked to tumor-promoting functions by maintaining an immunosuppressive TME[57]. FAP is a type-II transmembrane serine protease, and its expression has been detected in both the tumor stroma and cancer cells in PDAC, with the highest expression in the tumor stroma at the tumor front [58]. FAP-positive CAFs potently shape the immune landscape in the TME by secreting TGF-β, VEGF, and multiple matrix processing enzymes[59,60], recruiting circulating myeloid-derived suppressor cells (MDSCs) into the tumor stroma[57], and inhibiting natural killer cell (NK) cytotoxicity and cytokine production[61]. FAP has been suggested as an ideal target for the TME, and its specific therapeutic reagents are in development[62].

In addition to CAFs, the TME also consists of multiple types of immunosuppressive cells, including regulatory T cells (Tregs), MDSCs, and tumor-associated macrophages (TAMs)[63]. These cells correlate to provide an immunosuppressive TME and have been under extensive preclinical and clinical investigation.

Tregs, defined as CD4+/CD25+/FOXP3+ T cells, are a subtype of repressive T cells that play an essential role in maintaining immune tolerance and preventing autoimmune disorders. Tregs can be found in PDAC and premalignant lesion intraductal papillary mucinous neoplasms (IPMNs). The

prevalence of Tregs in CD4+ T lymphocytes correlates significantly with the progression and invasion of IPMNs and is associated with poor prognosis in PDAC. The immunosuppressive function of Tregs has been attributed to the secretion of suppressive cytokines, including IL-10 and TGF-β1, and the induction of CD4+ T-cell death[64,65]. Preoperative chemoradiation therapy has been shown to decrease Tregs in PDAC[66]. However, in a recent study, depletion of Tregs in a mouse model caused accelerated tumor progression due to unexpected crosstalk between Tregs and CAFs in PDAC[67]. This study has challenged the current view and posed uncertainties in developing Treg-based targeted therapy.

MDSCs and TAMs have also been suggested as potential therapeutic targets against the TME. Even though these two cell types are considered as separate entities, they have no demarcated boundaries and share many common characteristics[68]. MDSCs are a group of heterogeneous immature myeloid cells and can potently suppress T-cell function in tumors[69]. The levels of MDSCs correlate with the progression of PDAC and have been proposed as a predictive biomarker of chemotherapy failure[70,71]. TAMs are circulating monocyte-derived macrophages in the tumor stroma and represent a significant population of immune cells within the TME. TAMs can be further subclassified into the M1 and M2 subtypes, with M1 being proinflammatory (antitumorigenic) and M2 being anti-inflammatory (protumorigenic)[72]. M2-polarized TAMs are associated with an unfavorable prognosis in PDAC[73]. Liu *et al*[74] revealed progressive accumulations of MDSCs and M2-polarized TAMs accompanied by dynamic reductions in cytotoxic T cells (CTLs) and helper T cells (Ths) in PDAC progression. Gemcitabine affects the TME by inhibiting the expansion of MDSCs and the induction of Th2 cells while promoting M2-polarized TAMs[74]. M2-polarized TAMs can also be induced by other chemotherapeutic agents, such as carboplatin and cisplatin, leading to increased secretion of interleukin-6 (IL-6), IL-10, and prostaglandin E2[75]. In addition, interferon-γ upregulates the expression of programmed death-ligand 1 (PD-L1) in MDSCs, resulting in an immunosuppressive environment[76]. Further investigations and clinical trials are needed to test the efficacy of targeting MDSCs and TAMs in pancreatic cancer.

IMMUNOTHERAPY IN PANCREATIC CANCER

Current treatment options for PDAC have limited effects on patient survival. The recent development of immunotherapy has improved clinical outcomes for various types of solid tumors[17] and can revolutionize cancer treatment in PDAC. Activating the patient's T cells is the principal basis for cancer immunotherapy. This is accomplished through multiple mechanisms, such as decreased tumor-specific antigen presentation, T-cell activation, T-cell infiltration into the pancreatic tumor, and elimination of cancer cells by T cells[77]. Multiple cancer immunotherapies have been introduced, including immune checkpoint inhibitors, cancer vaccines, and adoptive cell transfer.

Immune checkpoint inhibitors

Immune checkpoint molecules are a group of surface receptors expressed on various immune cells that transduce inhibitory signals to T cells upon ligand binding. These molecules play an important role in preventing an autoimmune attack against self-antigens. Due to strong immune selective pressure, cancer cells frequently adopt the power of immune checkpoint molecules to avoid immune destruction. Initially approved for the treatment of metastatic melanoma, immune checkpoint inhibitors (ICIs) have been cleared to treat various solid tumors, including advanced or metastatic urothelial carcinoma, non-small-cell lung cancer, colorectal cancer, triple-negative breast cancer, and head and neck squamous cell carcinoma[78,79]. Currently, FDA-approved immune checkpoint inhibitors (ICIs) include anti-CTLA-4 agents (ipilimumab), anti-PD-1 agents (nivolumab, pembrolizumab, cemiplimab) and anti-PD-L1 agents (atezolizumab, avelumab, durvalumab)[79].

ICIs have emerged as a new therapeutic option for pancreatic cancer. Unfortunately, most phase I and II clinical trials on ICI treatment have failed to show the desired beneficial effect in PDAC. Two independent phase II clinical trials have demonstrated unsatisfactory clinical outcomes on monotherapy with anti-CTLA-4 mAb (Table 1). Single-agent ipilimumab, an anti-CTLA-4 mAb, was ineffective for the treatment of advanced PDAC (NCT00112580) (https://clinicaltrials.gov/ct2/show/NCT00112580)[80,81]. Monotherapy with tremelimumab, another anti-CTLA-4 mAb, also yielded poor clinical outcomes in PDAC, with 18 out of 20 patients demonstrating progressive disease and a poor median OS of 4 mo (95%CI: 2.83-5.42 mo) (NCT02527434) (https://clinicaltrials.gov/ct2/show/NCT02527434).

Combination therapy with ipilimumab and gemcitabine, on the other hand, has demonstrated promising results due to the increased immune response by enhancing naïve T-cell activation[82]. In a phase 1b clinical trial (NCT01473940) (https://clinicaltrials.gov/ct2/show/NCT01473940), initial results on combination therapy with ipilimumab and gemcitabine showed that the treatment was tolerable, with a median PFS of 2.5 mo (95%CI: 0.8-4.8 mo) and a median OS of 8.5 mo (95%CI: 2.2-10.3 mo). In this study, five out of the 11 patients had stable disease, while two had a partial response. An ongoing clinical trial (NCT01928394) (https://clinicaltrials.gov/ct2/show/NCT01928394) is comparing nivolumab (anti-PD-1 mAb) monotherapy and combination therapy with nivolumab plus ipilimumab in patients with advanced or metastatic PDAC, and the results will be released in 2023.

Table 1 Complete immune checkpoint inhibitor-based clinical trials in pancreatic ductal adenocarcinoma

Strategy	Treatment	Phase	Number	Cancer stage	Outcomes
Immune checkpoint inhibitor (target) monotherapy	Tremelimumab (CTLA-4)	II	NCT02527434	Advanced/metastatic PDAC	Tremelimumab monotherapy is ineffective for metastatic PDAC.
	Ipilimumab (CTLA-4)	II	NCT00112580	Advanced PDAC	Ipilimumab monotherapy is ineffective for advanced PDAC.
	Atezolizumab (PD-L1)	I/II	NCT03829501	Advanced PDAC	No results reported yet
Immune checkpoint inhibitor (target) + immune checkpoint inhibitor(target)	Tremelimumab (CTLA-4) + Durvalumab (PD-L1)	II	NCT02558894	Metastatic PDAC	ORR 3.1% for combination therapy. (ORR 0% for monotherapy).
	Nivolumab (PD-1) + Ipilimumab (CTLA-4)	I/II	NCT01928394	Advanced/metastatic PDAC	No results reported yet
Immune checkpoint inhibitor (target) + chemotherapy	Tremelimumab (CTLA-4) + Gemcitabine	I	NCT00556023	Advanced PDAC	Median OS 7.4 mo (95%CI: 5.8-9.4 mo)
	Ipilimumab(CTLA-4) + Gemcitabine	Ib	NCT01473940	Advanced/metastatic PDAC	Median OS 6.90 mo (95%CI: 2.63–9.57 mo)
	Pembrolizumab (PD-1) + Gemcitabine and Nab-paclitaxel	Ib/II	NCT02331251	Advanced/metastatic PDAC	Median OS 15.0 mo (95%CI: 6.8–22.6 mo)
Immune Checkpoint Inhibitor (Target) + Target therapy	Durvalumab (PD-L1) + Galunisertib	I	NCT02734160	Metastatic PDAC	Median PFS 1.9 mo (95%CI: 1.5-2.2 mo); median OS was NR (95%CI: 3.6 mo, NR)
	Durvalumab (PD-L1) + Pexidartinib	I	NCT02777710	Advanced/metastatic PDAC	No results reported yet
Immune Checkpoint Inhibitor (Target) + Radiation Therapy	Tremelimumab (CTLA-4) + Durvalumab (PD-1) + SBRT	I/II	NCT02311361	Advanced/metastatic PDAC	ORR of 9.6% including 2 patients who achieved a durable partial response lasting over 12 mo

https://clinicaltrials.gov/. PDAC: Pancreatic ductal adenocarcinoma; CTLA-4: Cytotoxic T lymphocyte-associated antigen-4; PD-1: Programmed cell death protein 1; PD-L1: Programmed cell death ligand 1; OS: Overall survival; PFS: Progression-free survival; ORR: Overall response rate; NR: Not reached.

Notably, in a phase I clinical trial (NCT00556023) (https://clinicaltrials.gov/ct2/show/NCT00556023), a tolerable and safe profile was demonstrated by combination therapy with tremelimumab plus gemcitabine, warranting further study in patients with metastatic PDAC. Thirty-four patients were enrolled in the study, and the median OS was 7.4 mo (95%CI: 5.8-9.4 mo). Two patients achieved a partial response at the end of treatment[83]. A phase Ib/II study (NCT02331251) (https://clinicaltrials.gov/ct2/show/NCT02331251) was performed to evaluate the safety and efficacy of pembrolizumab, an anti-PD-1 mAb, in combination with gemcitabine plus nab-paclitaxel chemotherapy. The median PFS and OS were 9.1 and 15.0 mo for chemotherapy naïve-treated patients, respectively, and changes in tumor cell-free DNA copy number instability were considered to be a potential prognostic factor for OS[84].

A phase I study on atezolizumab, an engineered IgG1 mAb targeting PD-L1, showed tolerability at doses up to 20 mg/kg every three weeks in a Japanese cohort[85]. In a phase II randomized clinical trial (NCT02558894) (https://clinicaltrials.gov/ct2/show/NCT02558894), evaluation of durvalumab, an anti-PD-L1 agent, with or without tremelimumab in patients with metastatic PDAC was evaluated following the failure of 5-FU and gemcitabine-based chemotherapy[86]. No patients in the study responded to durvalumab monotherapy, and the efficacy analysis demonstrated an objective response rate (ORR) of 3.1% (95%CI: 0.08-16.22) with the combination therapy of durvalumab plus tremelimumab [86].

A high tumor mutational burden (TMB) in cancer cells tends to produce more immunogenic neoantigens and may predict immunotherapy response[87]. A phase II clinical trial (NCT05093231) (https://clinicaltrials.gov/ct2/show/NCT05093231) investigating the efficacy of pembrolizumab plus olaparib in metastatic pancreatic adenocarcinoma patients exhibiting high tumor mutation burden is ongoing, and the results will be released in 2026.

Based on the results from current clinical trials, further studies need to focus on the combined approaches using ICIs with different therapeutic approaches, including chemotherapy, radiotherapy, or additional innovative platforms of immunotherapy, such as cancer vaccine and adoptive cell transfer.

Therapeutic cancer vaccines

Therapeutic cancer vaccines include whole-cell vaccines, dendritic cells, DNA, and peptide vaccines that activate cancer antigen-specific cytotoxic T lymphocytes (CTLs), eliciting immunogenic antigen presentation and leading to an anticancer response[88]. One such pancreatic cancer vaccine is GVAX,

which is generated from irradiated pancreatic cancer cells expressing granulocyte-macrophage colony-stimulating factor (GM-CSF)[89] (Table 2). Upon vaccination, GVAX secretes GM-CSF, induces subsequent activation of antigen-presenting cell and T-cell priming, and stimulates the patient's immune system against pancreatic cancer cells[90]. GVAX was tolerable even at high doses, and the vaccination-induced increased delayed-type hypersensitivity response to autologous tumor cells[91]. In a phase II clinical trial on GVAX (NCT00084383) (https://clinicaltrials.gov/ct2/show/NCT00084383), sixty patients received GVAX 8-10 wk after surgical intervention, followed by adjuvant 5-FU-based chemoradiotherapy. The median PFS was 17.3 mo (95%CI: 14.6-22.8 mo), with a median OS of 24.8 mo (95%CI: 21.2-31.6 mo), which compares favorably with published data for resected PDAC[92]. Combinatory immunotherapy has aimed to induce a much more sustained antitumor T-cell response [93]. In a phase Ib trial for locally advanced, unresectable or metastatic PDAC (NCT00836407) (https://clinicaltrials.gov/ct2/show/NCT00836407), thirty patients received either ipilimumab monotherapy or ipilimumab plus GVAX cancer vaccine, and the median OS was 3.6 mo for the ipilimumab monotherapy group, compared to 5.7 mo in the group with combination therapy[94]. Although combinatory immunotherapy has shown its potential for advanced PDAC, more studies are needed to fully explore this novel therapeutic strategy's capability.

Few human leukocyte antigen (HLA)-A(*)2402-restricted tumor-associated antigens, including the KIF20A-10-66 peptide, have been identified in PDAC[95]. A phase I/II clinical trial in Japan showed a better prognosis in patients with metastatic PDAC and HLA-A*2402-positive status who received KIF20A-10-66 peptide vaccination as second-line treatment after failure of gemcitabine chemotherapy [96]. In two separate phase II clinical trials, KIF20A-derived peptide was evaluated in combination with two antiangiogenic cancer vaccines targeting vascular endothelial growth factor receptor 1 (VEGFR1) and VEGFR2. In the HLA-A*2402-matched group, patients with peptide-specific CTL induction had improved prognosis and increased OS[97,98]. Another HLA-A24-restricted antigenic peptide, SVN-2B, also functions as an immunogenic molecule. A vaccination protocol of SVN-2B in combination with interferon-α has demonstrated effective clinical and immunological responses for advanced PDAC[99].

Algenpantucel-L is a whole-cell pancreatic cancer vaccine with two irradiated allogenic human pancreatic cell lines (HAPa-1 and HAPa-2) expressing the murine enzyme (1,3)-galactosyltransferase (α GT)[100]. Of note, the αGT enzyme is the critical barrier to xenotransplantation due to hyperacute rejection[101]. As a result, Algenpantucel-L will induce a hyperacute rejection of the allograft cells through rapid activation of antibody-dependent cell-mediated cytotoxicity (ADCC), leading to a response against the patient's pancreatic cancer cells through epitope spreading[102]. A phase II, open-label trial (NCT00569387) (https://clinicaltrials.gov/ct2/show/NCT00569387) evaluated the use of the Algenpantucel-L tumor vaccine in combination with gemcitabine plus 5-FU chemoradiotherapy in patients with resected PDAC. Seventy patients were recruited in the study, and the 12-mo disease-free survival (DFS) and OS were 63% and 86%, respectively, suggesting that the Algenpantucel-L tumor vaccine could be administered with standard chemotherapy following surgical resection of pancreatic cancer[101]. Unfortunately, in a recent phase 3, open-label, randomized clinical trial (NCT01836432) (https://clinicaltrials.gov/ct2/show/NCT01836432), Algenpantucel-L failed to improve survival on borderline resectable or locally advanced PDAC receiving neoadjuvant chemoradiation therapy[103].

Overexpression of Mucin 1 (MUC-1), a type I transmembrane protein with O-linked glycosylation, plays a crucial role in oncogenic signaling to promote metastasis, angiogenesis, and invasion[104]. MUC-1 has served as a target for cancer vaccine immunotherapy[105]. Following surgical resection, a phase I/II study of a MUC1 peptide-loaded dendritic cell vaccine was conducted in 12 pancreaticobiliary cancer patients. Four out of twelve (33.3%) patients who received this MUC-1-based tumor vaccine were alive after four years without evidence of recurrence[106]. An optimized construct with MUC-1-variable number tandem repeats has been designed with much more potent immunogenicity [107].

Dendritic cell vaccines have been introduced to enhance the antitumor immune response through the stimulation of naïve T cells[108]. In a study evaluating the effectiveness of a dendritic cell vaccine in patients with advanced PDAC (NCT01410968) (https://clinicaltrials.gov/ct2/show/NCT01410968), autologous dendritic cells were isolated in HLA-A2-positive patients, loaded with three A-2 restricted peptides, and readministered as a cellular vaccine. The results were promising with the generation of antigen-specific T cells in three patients, as well as tolerable adverse effects[109]. In a phase I study in Japan, a Wilms' tumor 1 (WT1)-pulsed dendritic cell vaccine combined with chemotherapy showed safety and potential acquisition of immunity in resected PDAC[110]. Multiple associated studies have further supported the clinical benefits of dendritic cell-based vaccines in PDAC[111-113].

Approximately 95% of PDAC patients have mutations in the *KRAS* oncogene. Despite an early study suggesting an unproven efficacy by targeting mutated KRAS in PDAC[114], multiple subsequent clinical studies have demonstrated the clinical potential for such a therapeutic approach. A phase I/II clinical trial (NCT02261714) (https://clinicaltrials.gov/ct2/show/NCT02261714) evaluated the efficacy of a synthetic mutant RAS peptide vaccine with GM-CSF in PDAC. TG01, a mixture of 7 synthetic RAS peptides representing the most common *KRAS* mutations, combined with GM-CSF and gemcitabine was well tolerated with a robust immune response and improved clinical outcome[115]. One study demonstrated a long-term immune response and improved survival in patients with resected PDAC after KRAS vaccination[116]. An alternative KRAS-based tumor vaccine is GI-4000, a recombinant heat-

Table 2 Complete vaccine immunotherapy-based clinical trials in pancreatic ductal adenocarcinoma

Treatment	Phase	Number	Cancer stage	Outcomes
GVAX, 5-FU, chemoradiation	II	NCT00084383	Resected stage I/II PDAC	Median OS 24.8 mo (95%CI: 21.2-31.6 mo)
GVAX, cyclophosphamide, CRS-207	II	NCT01417000	Metastatic PDAC	Cy/GVAX and CRS-207 extended OS for PDAC patients, with minimal toxicity
GVAX, cyclophosphamide, CRS-207	II	NCT02004262	Metastatic PDAC	Cy/GVAX and CRS-207 did not show survival benefit over chemotherapy in patients with previously treated metastatic PDAC
GVAX, Ipilimumab, FOLFIRINOX	II	NCT01896869	Metastatic PDAC	Ipilimumab + GVAX group did not show survival benefit over chemotherapy [median OS 9.38 mo (95% CI, 5.0-12.2 mo) *vs* 14.7 mo (95%CI: 11.6-20.0 mo)]
Algenpantucel-L	II	NCT00569387	Surgically resected PDAC	The addition of algenpantucel-L to standard adjuvant therapy for resected pancreatic cancer may improve survival (12-mo DFS 62%, 12-mo OS 86%)
Gemcitabine, 5FU Chemoradiation, Algenpantucel-L	III	NCT01072981	Surgically Resected PDAC	No results reported yet
Dendritic cells pulsed with MUC-1/WT-1	I/II	NCT03114631	PDAC	Dendritic cells immunotherapy provided a favorable outcome in PDAC patents (12-mo OS 78.2% *vs* 33.8%)
GI-4000 (KRAS), Gemcitabine	II	NCT00300950	Non-metastatic, Post-resection PDAC	Overall, GI-4000 group showed a similar pattern of recurrence-free survival and OS compared with the placebo group. For stratified R1 resection subgroup, there was a trend in 1 year OS (72% *vs* 56%), an improvement in OS (523.5 *vs* 443.5 d (hazard ratio: 1.06; 95%CI: 0.53–2.13, P = 0.872), and increased frequency of immune responders (40% *vs* 8%; P = 0.062) for GI-4000 *vs* placebo.
Ras-peptide vaccine, IL-2, GM-CSF	II	NCT00019331	Metastatic PDAC	No results reported yet
GV1001 (telomerase peptide vaccine), Gemcitabine, Capecitabine	III	NCT00425360	Locally Advanced or Metastatic PDAC	Adding GV1001 vaccination to chemotherapy did not improve OS.

https://clinicaltrials.gov/. PDAC: Pancreatic ductal adenocarcinoma; Cy: cyclophosphamide; DFS: Disease-free survival; OS: Overall survival.

inactivated Saccharomyces cerevisiae yeast-derived vaccine expressing mutated KRAS proteins. A phase I trial revealed a favorable safety profile and immunogenicity of the GI-4000 cancer vaccine[117]. A subsequent phase II trial (NCT00300950) (https://clinicaltrials.gov/ct2/show/NCT00300950) compared GI-4000 plus gemcitabine with placebo plus gemcitabine alone in patients with resected PDAC carrying *KRAS* mutation. GI-4000 was well tolerated. It led to a similar median OS compared with placebo. However, compared with the placebo group, the GI-4000 group had a trend of improved OS (523.5 *vs* 443.5 d) and an increased frequency of immune responders (40% *vs* 8%) in the stratified R1 resection subgroup[118].

The GV1001 tumor vaccine consists of a fragment (16 amino acids) of human telomerase reverse transcriptase (hTERT) found in a high proportion in PDAC cancer cells and has been introduced as a novel therapeutic regimen[119]. In a phase I/II clinical trial evaluating the clinical outcomes in patients with unresectable PDAC, GV1001 plus GM-CSF elicited an immune response in 63% of patients, resulting in a median OS of 7.2 mo for immune responders compared to 2.9 mo for nonimmune responders[120]. However, in a randomized phase III study of patients with locally advanced and metastatic PDAC, combination therapy consisting of GV1001, gemcitabine, and capecitabine chemotherapy showed no improvement in OS compared to chemotherapy alone [6.9 mo (95%CI: 6.4–7.6 mo) *vs* 7.9 mo (95%CI: 7.1–8.8 mo)] (NCT00425360) (https://clinicaltrials.gov/ct2/show/NCT00425360) [121]. Another GV1001-based phase III clinical trial (NCT00358566) (https://clinicaltrials.gov/ct2/show/NCT00358566) was terminated early because of a lack of survival advantage.

Adoptive cell transfer

Adoptive cell transfer, also known as cellular immunotherapy, includes chimeric antigen receptor T-cell (CAR T cell) therapy and tumor-infiltrating lymphocyte (TIL) therapy[122,123]. CAR T-cell therapy is the most common type of adoptive cell transfer. Generally, it involves harvesting the patient's T cells, genetic modification to express surface chimeric antigen receptor, *ex vivo* expansion, and then transferring the cells back to enhance tumor immunity. In forty-three patients with PDAC who underwent radical pancreatectomy, gemcitabine plus adoptive cell transfer with T cells stimulated by the MUC1-expressing human pancreatic cancer cell line demonstrated a median OS of 14.7 mo[124]. Mesothelin is a tumor antigen highly expressed in PDAC[125]. In a preclinical study, CAR T-cell therapy targeting mesothelin demonstrated promising tumor-suppressive effects[126]. Amatuximab

Table 3 Complete adoptive cell transfer-based clinical trials in pancreatic ductal adenocarcinoma

Treatment	Phase	Number	Cancer stage	Outcomes
MORAb-009, Gemcitabine	II	NCT00570713	Advanced PDAC	MORAb-009 did not show survival benefit over placebo group [median OS 6.5 mo, 95%CI: 4.5–8.10 mo *vs* 6.9 mo 95%CI: 5.4–8.8 mo]
MORAb-009	I	NCT00325494	PDAC	No results reported yet
Radiolabeled Amatuximab (MORAb-009)	I	NCT01521325	PDAC	No results reported yet
Autologous Redirected RNA Mesothelin CAR T cells	I	NCT01897415	PDAC	No results reported yet
CART-133 T cells	I/II	NCT02541370	Relapsed and/or Chemotherapy Refractory Advanced PDAC	No results reported yet

https://clinicaltrials.gov/. PDAC: Pancreatic ductal adenocarcinoma; OS: Overall survival.

(MORab-009), a chimeric mAb targeting mesothelin, also led to reduced growth of mesothelin-expressing tumors, including PDAC[127]. In a phase I trial, the efficacy of MORAb-009 was tested in seven PDAC patients, and one patient had disease control for greater than six months[128]. However, in a phase II randomized placebo-controlled clinical trial (NCT00570713) (https://clinicaltrials.gov/show/NCT00570713) evaluating the efficacy of MORAb-009 plus gemcitabine, no significantly improved clinical outcome was observed [median OS: 6.5 mo (95%CI: 4.5–8.10 mo) *vs* 6.9 mo (95%CI: 5.4–8.8 mo)]. Compared with the development of ICIs and cancer vaccines, adoptive cell transfer therapy is still in the early development phase against pancreatic cancer (Table 3); more preclinical and clinical studies are needed to further explore its full clinical potential.

IMMUNOTHERAPY AND THE TUMOR MICROENVIRONMENT

Immunotherapy has thus far failed to fulfill its promise in PDAC. The underlying mechanisms appear to be complex and multifactorial primarily due to their unique genetic signatures, metabolic features, and immunosuppressive TME. Pancreatic cancers carry unique molecular genetic backgrounds. MSI in pancreatic cancer is extremely rare (approximately 1%). Oncogenic *KRAS* mutations, the most common mutation in PDAC, have also contributed to PDAC initiation and maintenance by producing an immunosuppressive TME[129].

Furthermore, altered metabolism of glucose, amino acids, and lipids and their crosstalk with the TME play essential roles in PDAC tumor progression[130]. Multiple lines of evidence have pinpointed the TME as one of the significant barriers to developing effective immunotherapy for PDAC. It is of great clinical interest to sensitize PDAC to immunotherapy through modification of the TME.

One such effort has been focused on CAFs in the TME. As an immunosuppressive component of the TME, FAP-positive CAFs potentially account for the ineffectiveness of immunotherapy in PDAC[131]. Another subtype of CAFs, characterized by the expression of the leucine-rich repeat-containing 15 (LRRC15) protein, could only be detected in pancreatic cancer tissue and is associated with poor response to anti-PD-L1 therapy[132]. Notably, FAP-positive CAFs are the only CAF subtype that expresses CXC motif chemokine ligand 12 (CXCL12). Ablation of FAP-positive CAFs or inhibition of CXCL12 uncovers the antitumor activity of CTLA-4 and PD-L1-based immunotherapy[133]. A phase I/II clinical trial (NCT03168139) (https://clinicaltrials.gov/ct2/show/NCT03168139) was conducted to evaluate the treatment effect of pembrolizumab in patients receiving docetaxel (NOX-A12), an agent targeting CXCL12 and TME in metastatic PDAC. No results have been reported yet.

Cellular components in the TME, including MDSCs and TAMs, are also promising targets in the combinatory strategy for immunotherapy. MDSCs and TAMs induce an immunosuppressive TME, partially through colony-stimulating factor 1 receptor (CSF1R) and focal adhesion kinase (FAK)[134]. Small molecular inhibitors of CSF1R or FAK can reprogram the TME and improve T lymphocyte-mediated pancreatic cancer destruction[135,136]. Multiple clinical trials with CSF1R or FAK inhibitors combined with immunotherapy are currently ongoing (Table 4).

CONCLUSION

Despite advances in translational research, PDAC remains a highly lethal malignancy. Recent breakthroughs in immunotherapy have revolutionized cancer therapy and have shown great potential to transform future PDAC treatment. However, PDAC has shown inferior treatment outcomes toward

Table 4 Ongoing clinical trials with immunotherapy plus agents targeting the tumor microenvironment in pancreatic ductal adenocarcinoma

Strategy	Treatment	Phase	Number	Cancer stage

	Nivolumab (PD-1) + Cabiralizumab	I	NCT02526017	Advanced PDAC
	Nivolumab (PD-1) + Cabiralizumab + Gemcitabine	II	NCT03697564	Advanced PDAC (Stage IV)
Immune checkpoint inhibitor (target) + FAK targeted agent	Pembrolizumab(PD-1) + Defactinib	I/IIa	NCT02758587	Advanced PDAC
	Pembrolizumab(PD-1) + Defactinib + Gemcitabine	I	NCT02546531	Advanced PDAC
	Pembrolizumab (PD-1) + Defactinib	II	NCT03727880	Resectable PDAC

https://clinicaltrials.gov/. PDAC: Pancreatic ductal adenocarcinoma; CTLA-4: Cytotoxic T lymphocyte-associated antigen-4; PD-1: Programmed cell death protein 1; PD-L1: Programmed cell death ligand 1; CAFs: Cancer-associated fibroblasts; CXCL12: CXC motif chemokine ligand 12; CSF1R: Colony-stimulating factor 1 receptor; FAK: Focal adhesion kinase.

various immunotherapy regimens compared to other cancer types. The TME has been considered as the fundamental underlying barrier to therapy resistance. To overcome this therapeutic resistance, further investigations with innovative treatment strategies will be needed.

FOOTNOTES

Author contributions: Smith C and Yin F collected and analyzed the data, made the tables and figure, wrote and finalized the manuscript; Zheng W, Dong J, Wang Y, Lai J and Liu X critically reviewed the manuscript; and All authors have approved the final manuscript.

Conflict-of-interest statement: The authors declare no competing interests in this study.

Abstract

The prevalence of nonalcoholic fatty liver disease (NAFLD) is rising worldwide, paralleling the epidemic of obesity. The liver is a key organ for the metabolism of proteins, fats and carbohydrates. Various types of fats and carbohydrates in isocaloric diets differently influence fat accumulation in the liver parenchyma. Therefore, nutrition can manage hepatic and cardiometabolic complications of NAFLD. Even moderately reduced caloric intake, which leads to a weight loss of 5%-10% of initial body weight, is effective in improving liver steatosis and surrogate markers of liver disease status. Among dietary patterns, the Mediterranean diet mostly prevents the onset of NAFLD. Furthermore, this diet is also the most recommended for the treatment of NAFLD patients. However, clinical trials based on the dietary interventions in NAFLD patients are sparse. Since there are only a few studies examining dietary interventions in clinically advanced stages of NAFLD, such as active and fibrotic steatohepatitis, the optimal diet for patients in these stages of the disease must still be determined. In this narrative review, we aimed to critically summarize the associations between different dietary patterns, obesity and prevention/risk for NAFLD, to describe specific dietary interventions' impacts on liver steatosis in adults with NAFLD and to provide an updated overview of dietary recommendations that clinicians potentially need to apply in their daily practice.

Core Tip: In this review, we emphasize that based on the current evidence, there is no consensus on the ideal macronutrient composition of the diet for nonalcoholic fatty liver disease (NAFLD) patients. We have shown that dietary habits are the most important factor in NAFLD prevention. The Mediterranean and healthy dietary pattern, characterized by high consumption of vegetables, fruits, nuts, olive oil, low-fat dairy products and fish, were linked with a reduced NAFLD risk. The Dietary Approach to Stop Hypertension diet, intermittent fasting and ketogenic diet are other dietary regimes that have growing interest among specialists who advise patients with NAFLD. Nevertheless, new studies designed to assess the effects of these diets on liver-related outcomes and liver histology are needed. We also noted that dietary advice should be personalized in NAFLD patients.

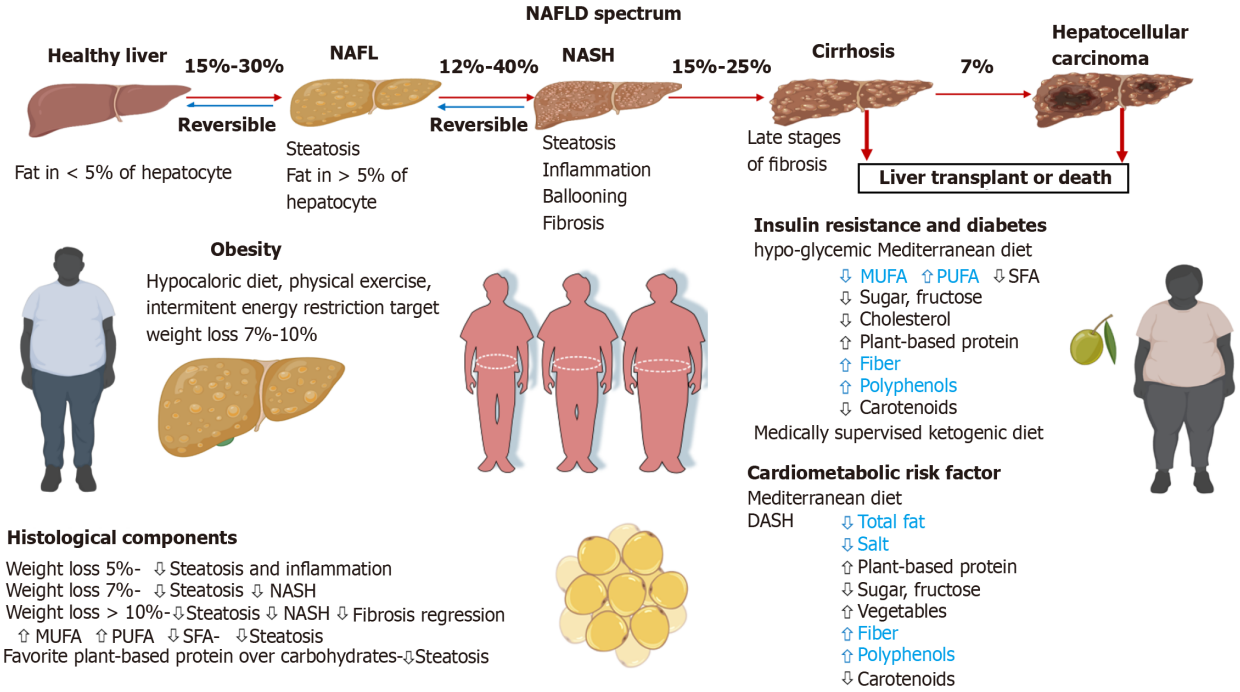
INTRODUCTION

Nonalcoholic fatty liver disease (NAFLD) is the accumulation of excess fat (more than 5%) in the liver parenchyma in people with no significant alcohol consumption or secondary causes of hepatic steatosis [1]. The prevalence of NAFLD is rising in many countries, paralleling the epidemic of obesity worldwide. The highest rates of NAFLD have been observed in North Africa (31%), the Middle East (32%) and Asia (27%)[2].



NAFLD represents a clinicopathological spectrum, ranging from benign hepatic steatosis to nonalcoholic steatohepatitis (NASH) and characterized by hepatocellular injury and inflammation, which leads to hepatic fibrosis[3,4]. Up to 20% of patients with fibrotic NASH progress to cirrhosis and associated complications[5,6]. Fibrotic NASH can lead to hepatocellular carcinoma, even at the pre-cirrhotic stage (Figure 1). Approximately 90% of the obese population, 60% of patients with diabetes type 2 and 50% of patients with dyslipidemia have NAFLD[6-8]. Moreover, NAFLD is a risk factor for severe coronavirus disease 2019, and thus nutritional prevention of coronavirus disease 2019 complications has been highlighted in a recent review[8].

Nevertheless, obesity, overnutrition, dietary components and a sedentary lifestyle are modifiable risk factors for NAFLD. Central obesity is probably the most significant modifiable risk factor for this disorder, which arises from energy imbalance[9]. The relationship between excessive caloric intake and the NAFLD development has been shown in interventional studies. Weight loss as a primary therapeutic approach produced clinically meaningful outcomes in patients with NAFLD[10,11]. However, the success of such weight loss interventions depends on the intensity of diet counseling and the frequency of visits to dietitians. Two dietary patterns that seem to promote the improvement of NAFLD with incorporated recommendations are the Mediterranean and the Dietary Approach to Stop Hypertension (DASH) diets[12].

This review critically summarizes the associations between dietary patterns, obesity and prevention/risk for NAFLD as well as the impact of specific dietary interventions on hepatic steatosis in adults with NAFLD. It also provides an updated overview of dietary recommendations that clinicians potentially need to apply in their daily practice.

LITERATURE SEARCH

This narrative review was based on PubMed electronic database search for relevant publications using the following terms ("fatty liver" OR "NAFLD" OR "non-alcoholic fatty liver disease" OR "steatosis of liver" OR "steatohepatitis" OR "steatosis") AND "obesity" AND ("diet" OR "dietary pattern" OR "dietary interventions" OR "nutrition") to identify the studies on the association between dietary patterns and NAFLD and specific clinical dietary intervention studies in adult patients with NAFLD. Also, we focused on systematic reviews with meta-analyses. Studies relevant to the topic, conducted in humans, published in English and preferably published in the last 10 years were included. All studies are checked in Reference Citation Analysis database (https://www.referencecitationanalysis.com/). The list of references was reduced because priority had been given to studies that are relevant to clinical practice. The final list of references was approved with the consent of the authors.

MECHANISMS OF LIVER INJURY IN PATIENTS WITH OBESITY

The pathophysiology of NAFLD involves multiple genetic and environmental factors. Genetic factors include specific polymorphisms and epigenetic modifications. As the most common genetic determinant of NAFLD, the I148M variant of patatin-like phospholipase domain-containing protein 3 gene has been recognized[13]. Environmental factors are related to diet and lifestyle, hormonal disturbances, insulin resistance (IR), obesity, oxidative stress, lipotoxicity, unfavorable gut microbiota and many others[9]. Despite well-established risk factors for NAFLD, the pathways leading to the disease are not elucidated, but the role of the diet is undeniable.

It is known that the liver utilizes fatty acids and sugars as primary metabolic substrates, but the overload of these substances results in the accumulation of toxic lipid products[14]. These products increase oxidative stress by overproduction of reactive oxygen species and inflammation in hepatocytes that leads to liver injury. Moreover, a higher intake of saturated fatty acids (SFAs) promotes hepatic liver accumulation and the development and progression of NAFLD[15]. On the contrary, intake of unsaturated fats has a protective role[16].

Recent studies revealed the underlying mechanism of this process, highlighting mitochondrial dysfunction as a key player (reviewed by Meex and Blank[17]). Hepatocytes are very rich in mitochondria, and intake of SFAs induces changes in their structure and function. The process starts with liver steatosis due to reduced oxidation and enhanced lipolysis of adipose tissues. Steatosis affects the efficacy of the respiratory transport chain[18]. Consequently, overproduction of reactive oxygen species and lipid peroxidation arise, eventually resulting in inflammation, apoptosis and damage of the liver. In addition, SFAs from food enter the mitochondrial membrane and alter its permeability and fluidity, contributing further to NAFLD progression[19].

Besides the diet itself, obesity is also associated with NAFLD pathophysiology. In obesity, the capacity of an expanded adipose tissue to store lipids is limited, and the excess of lipids is stored in hepatocytes. The main form of lipids stored in the liver are triglycerides (TGs). Namely, high levels of free fatty acids in circulation, derived from enhanced lipolysis or diminished absorption by subcutaneous adipose tissue, bring ectopic fat accumulation, mostly in the liver. The sources of free fatty acids that form in the liver TG are not only from the diet (around 15%) but from increased lipolysis of TGs in adipose tissue (approximately 60%) and *de novo* lipogenesis (DNL) in the liver (25%) from dietary sugars, glucose and fructose[20]. This is supported by a study using stable isotopes, which has shown that accumulated lipids in the liver of NAFLD patients are mainly attributable to DNL. This stage of fat accumulation in the liver is the beginning of NAFLD, and managing obesity at this stage is of crucial importance. The lack of successful obesity treatment leads to intrahepatic inflammation and infiltration

of immune cells, such as lymphocytes, monocytes and neutrophils, which release cytokines in the liver [21]. This process not only intensifies inflammation but also promotes intrahepatic fibrogenesis, leading to progression of NAFLD to NASH.

Another relationship between obesity and NAFLD has been established through adipokines[22]. Adipokines are hormones derived from adipose tissue, and they are commonly represented by leptin and adiponectin. While their synthesis is balanced in people with normal weight, in obesity the dysregulation of pro- and anti-inflammatory adipokines is present. The enlarged, hypertrophic adipocytes produce proinflammatory adipokines and cytokines and promote IR. Adiponectin suppresses the secretion of proinflammatory cytokines (interleukin 6, tumor necrosis factor α), promotes the release of anti-inflammatory interleukin 10 and negatively correlates with visceral adipose tissue mass[23]. On the contrary, leptin is a product of white adipose tissue, and its level in circulation depends on the fat tissue mass and adipocyte size[24]. This is a satiety hormone with pleiotropic effects, and its concentration is a marker of obesity-related complications: Neuropathy and atherosclerosis[25,26]. Hyperleptinemia is considered crucial for NAFLD progression, although the exact mechanisms are still unclear. However, new findings pinpointed that leptin mediates pyroptotic-like cell death of macrophages and hepatocytes through infiltrated CD8+ T lymphocytes[27]. These results can provide a new strategy for future treatment of NAFLD.

Among the other risk factors, metabolic syndrome (MetS) has demonstrated the strongest association with NAFLD and its advanced stage, NASH. Since MetS is characterized by several features, including waist circumference, hypertension, hyperglycemia and dyslipidemia (low high-density lipoprotein cholesterol and/or high TG level), the clearest biological link with NAFLD development and progression was found for glucose level[28]. In line with this, 75% of patients with diabetes mellitus have NAFLD as well. This relation is bidirectional: Patients with NAFLD have a higher risk of developing diabetes[29]. Although IR is involved in NAFLD pathogenesis, improving IR is often insufficient to prevent further progression of NAFLD[30].

Furthermore, increased central adiposity, an important component of MetS, is considered a more significant marker of NAFLD than total body fat. This is expected, considering the role of visceral fats in the biosynthesis of adipokines. According to a recent study, there is a cross-talk between IR, adipose tissue inflammation and NAFLD, with dipeptidyl peptidase 4 as the key factor. This enzyme, secreted by the hepatocytes, has been shown to promote IR and inflammation of visceral adipose tissue[31]. In support of that, Barchetta *et al*[32] reported that levels and activity of dipeptidyl peptidase 4 in circulation are independently associated with NAFLD presence and severity in patients with or without other metabolic diseases and with various grades of obesity. The authors proposed dipeptidyl peptidase 4 as a novel marker for NAFLD/NASH risk stratification and follow-up of NAFLD patients.

ASSOCIATIONS BETWEEN DIETARY PATTERNS AND RISK OF NAFLD

Since people do not consume nutrients in isolation, the best option to describe the relationship between nutrition and health outcomes is the analysis of dietary patterns. Dietary patterns are a combination of a variety of foods habitually consumed by an individual, which together create synergistic effects on our health[33]. Two main dietary patterns, such as a "Western dietary pattern" and "Mediterranean dietary pattern" have been significantly associated (although in the opposite direction) with NAFLD, independently of potential confounders[34]. However, there are more dietary patterns (*e.g.*, healthy, traditional) identified for these associations.

Mediterranean dietary pattern and NAFLD

Mediterranean diet (MD) is a plant-based diet containing significant amounts of fiber, antioxidants, vegetable proteins, monounsaturated fat and polyunsaturated fatty acids (PUFAs), and with an appropriate n-6/n-3 PUFA ratio. This diet is known as a high-fat diet, with a fat intake of up to 45% of total daily calories[35]. The basic source of dietary fat in this diet is olive oil[33,36], where oleic acid, a monounsaturated fatty acid (MUFA), is a major component[37]. The MD is also characterized by high amounts of PUFAs. Dietary sources of the PUFAs, especially long-chain n-3 fatty acids, which include eicosapentaenoic acid and docosahexaenoic acid, in the MD are fish and nuts[38]. The MD is therefore rich in macronutrients that have been shown to have a beneficial effect on glucose and lipidic metabolism, and consequently on NAFLD[39]. The observational studies on the association between MD and NAFLD are summarized in Table 1. A reverse association between high adherence to MD and NAFLD odds, even after adjusting for some confounders such as age, sex, diabetes, physical activity, energy intake, smoking status and supplements use was seen in two case-control studies[40,41] and one cross-sectional study[42]. It should be highlighted that higher consumption of nuts, fruits and vegetables, legumes and fish as well as lower intake of meat were reported to be protective against NAFLD[43].

However, Entezari *et al*[40] observed that the reverse relationship between adherence to MD and odds of NAFLD disappeared after controlling for the anthropometric variables (body mass index and waist-to-hip ratio), which means that the MD may improve fatty liver by body weight modification,

Table 1 Association between the Mediterranean dietary patterns and nonalcoholic fatty liver disease

Ref.	Country/Region	Assess adherence to the MD	Food groups associated with lower risk NAFLD	Study design	Number of patients and age range	Main results	Associations
Entezari *et al* [40]	Iran	MDS	↑ Intake nuts and fruits, vegetables, legumes, high MUFA/PUFA ratio, cereals and fish. ↓ EI, low-fat dairy and meats	C-C	247 (43.7% male); 18–55 yr	↑ Adherence to MD was associated with ↓ risk of NAFLD after controlling for age (OR: 0.40, 95%CI: 0.17–0.95) and sex, diabetes, PA and supplement intake (OR: 0.36, 95%CI: 0.15–0.89). This association disappeared after adjusting for BMI, WHR (OR: 0.70, 95%CI: 0.25–1.97)	↓, After controlling for anthropometrical variables ↔
Giraldi *et al* [41]	Italy	MDS	↑ Legumes consumption ↓ risk of NAFLD (OR: 0.62; 95%CI: 0.38-0.99) and ↑ fish intake ↓ risk of NAFLD (OR: 0.38; 95%CI: 0.17-0.85)	C-C	815 (371 with NAFLD); 59 ± 16 yr; 444 controls; 45 ± 14 yr	↑ Adherence to the MD was associated with ↓ risk of NAFLD (OR: 0.83; 95%CI: 0.71-0.98) after controlling for age, sex, EI, diabetes status, smoking status, BMI and PA	↓
Baratta *et al* [42]	Italy	MD questionnaire	↓ Meat intake	C-S	584 patients (61.8% males) with cardiometabolic risk factors screened for the presence of liver steatosis; 56.2 ± 12.4 yr	↑ Adherence to MD was associated with ↓ risk of NAFLD (intermediate *vs* low tertile OR: 0.12; $P < 0.05$; high *vs* low tertile OR: 0.09; $P < 0.05$)	↓
Aller[45]	Spain	14-item MD assessment tool	-	C-S	82 NAFLD patients (42.7% low and 57.3% high steatosis grade, 68.3% steatohepatitis and 51.2% liver fibrosis mean age 44 + 11 yr	↑ Adherence to MD was associated with ↓ likelihood of having steatohepatitis OR: 0.43; 95%CI: 0.29-0.64 and steatosis OR: 0.42; 95%CI: 0.26- 0.70	↓
Park *et al*[46]	United States; 5 targeted racial/ethnic groups: African American, Native Hawaiian, Japanese American, Latino and White	Alternate MDS	-	Nested C-C	2959 with NAFLD (509 with cirrhosis; 2450 without cirrhosis) and 29292 controls; mean age 44.2 + 11.3 yr	↑ Adherence to MD was not associated with lower NAFLD risk	↔
Chan *et al* [47]	Hong Kong of China	MDS	↑ Vegetables and legumes, fruits and dried fruits, vitamin C	C-S	797 (41.7% males) 27.6% had a fatty liver aged ≥ 18 yr	MDS was not associated with the prevalence of NAFLD	↔
Kontogianni *et al*[44]	Greece	MDS	-	C-S	73 overweight/obese patients with NAFLD (69% males) *vs* 58 age-sex- and BMI matched controls; mean age 45 yr	No difference in the MDS was observed between patients and controls. One unit increase in the MDS was associated with ↓ likelihood of having NASH (OR: 0.64; 95%CI: 0.45-0.92), after controlling for sex and abdominal fat	↓

BMI: Body mass index; C-C: Case-control; C-S: Cross-sectional; CI: Confidence interval; EI: Energy intake; MD: Mediterranean diet; MDS: Mediterranean Diet Score; MUFA/PUFA: Monounsaturated fatty acids/Polyunsaturated fatty acids; NAFLD: Non-alcoholic fatty liver disease; OR: Odds ratio; WHR: Waist to hip ratio; PA: Physical activity.

modulation of lipid profile and inflammatory markers. Although Kontogianni *et al*[44] did not find a significant difference between NAFLD patients and controls in terms of adherence to the MD, higher adherence to this diet was inversely associated with alcoholic steatohepatitis. Similar results were seen

in the study by Aller *et al*[45].

On the other hand, in a nested and matched case-control study[46] as well as a cross-sectional study [47] it was found that adherence to the MD in any models (crude or adjusted to some confounders) was not associated with the risk of NAFLD. It should be highlighted that the dietary indices that measure adherence to the MD vary among the included studies. Hence, the specific dietary components and/or food items included within each of these indices and the methods used to evaluate compliance should be taken into consideration when interpreting obtained results. Nevertheless, a recent meta-analysis has proven that MD reduced the risk of NAFLD by 23%[43]. Also, the European Association for the Study of the Liver, and the European Association for the Study of Diabetes-European Association for the Study of Obesity Clinical Practice Guidelines have encouraged the MD as a lifestyle choice for treating the disease[48].

Various mechanisms may be associated with the beneficial effects of the MD on metabolic health and NAFLD, but the most important for this association is an appropriate fatty acid composition due to high MUFA content and an appropriate n-6/n-3 PUFA ratio[49]. It has been proven that MUFA may prevent the development of NAFLD by improving blood lipid concentrations, lowering body fat contents and decreasing postprandial adiponectin expression[50]. MUFAs (oleic acid) from olive oil have numerous beneficial effects on NAFLD, including decreased oxidized low-density lipoprotein, low-density lipoprotein cholesterol (LDL-C) and TG concentration, without the concomitant decrease in high-density lipoprotein cholesterol (HDL-C)[51], as well as lowering blood pressure and improving insulin sensitivity[37]. Additional effects of the MD relate to its polyphenol content. For example, polyphenols present in olive oil, such as oleuropein, hydroxytyrosol and tyrosol, have important antioxidant and anti-inflammatory effects[51]. The high content of dietary fiber both in soluble and insoluble forms in the MD is associated with a decrease in serum TGs and blood glucose[40]. The beneficial effect of the MD on NAFLD progression is also linked with an absence of added sugars and fructose in this diet.

Healthy dietary patterns and risk/prevalence of NAFLD

A healthy dietary pattern is defined as an appropriate intake of fruits & vegetables, nuts, olive oil, low-fat dairy products and fish. MD is one example of a healthy dietary pattern, but there are also other specific healthy diets. In Table 2, associations between healthy dietary patterns and the risk/prevalence of NAFLD are summarized.

In nine out of ten collected studies–in two prospective studies[52,53], four case-control studies[33,54-56], and three cross-sectional studies[57-59], a healthy dietary pattern was associated with a decreased risk of NAFLD independent of several confounders added to the models. Moreover, in a study by Chung *et al*[60] "simple meal pattern" characterized by a high intake of root and yellow vegetables, fruits, dairy products, eggs and nuts also exhibited an inverse correlation with NAFLD. Kalafati *et al*[55] found that individuals in the second quartile of the unsaturated fatty acids pattern, a dietary pattern with strong antioxidant properties, had 55.7% reduced odds of developing NAFLD than those in the first quartile, after adjusting for several confounders. However, higher consumption of unsaturated fatty acids was not associated with further protection from NAFLD, which may be explained by the fact that a greater intake of this diet leads to higher energy intake. Moreover, the mentioned authors found that the score for the prudent pattern (recognized also as a healthy dietary pattern) based on oil-based cooked vegetables, legumes, potatoes, fruits, vegetables and fatty fish was negatively associated with TG and uric acid levels, mediators of the associations between obesity and the incidence of NAFLD[61]. Only one study, presented by Alferink *et al*[62], found that adherence to vegetable and fish patterns (a kind of healthy pattern) was not associated with the risk of NAFLD.

The protective effect of healthy diets on the risk of the NAFLD could be a consequence of high consumption of vegetables and moderate intake of fruits, which are sources of antioxidant vitamins, such as vitamins A, E and C (protective against oxidative stress)[43]. Moreover, fruits and vegetables are good sources of dietary fiber, which has an inverse association with IR and the risk of NAFLD progression. Fish are sources of long-chain n-3 PUFAs, which are capable of reducing TGs and have a protective role against NAFLD[38].

Western and traditional dietary patterns and risk/prevalence of NAFLD

Although definitions of Western dietary patterns vary, this diet is often characterized by high consumption of soft drinks, red and processed meat and refined cereals, with concurrently low intake of fish, fruit and vegetables as well as whole grains[63]. Therefore, this diet is characterized by a high intake of animal and trans fats, sugar and fructose and a low intake of fiber and phytochemicals[52]. It was observed that when a western diet is provided in excess, even for a short period of 1 wk, it leads to increased hepatic steatosis[33]. In Table 2, associations between Western and traditional and healthy dietary patterns and the risk/prevalence of NAFLD are summarized.

Oddy *et al*[52], in their prospective cohort study, found that a higher score of the Western dietary pattern at 14 years of age was associated with a greater risk of NAFLD at 17 years. Similar results were obtained in other observational studies[34,56]. On the other hand, some studies report significant associations of this diet with the risk of NAFLD[58,60]. In the literature, the following dietary patterns familiar to the western patterns are also present: Fast food[54,55]; animal food/high protein[53,54]; red meat and alcohol[62]; high-salt[57]; high-fat dairy and refined grains[62]; high-carbohydrate/sweet/sugar/high

Table 2 Characteristics of the observational studies on the association between different dietary patterns and nonalcoholic fatty liver disease

Ref.	Country/Region	Dietary pattern	Food items in dietary patterns	Type of study	N, age	Main results	Associations
Oddy *et al*[52]	Australia	Western	Takeaway foods, confectionery, red meat, refined grains, processed meats, chips, sauces, full-fat dairy products and soft drinks	P	995. FFQ completed at 14 yr and liver ultrasound at 17 yr	Higher western pattern score at 14 yr was associated with ↑ risk of NAFLD at 17 yr (OR: 1.59; 95%CI: 1.17–2.14; $P < 0.05$) before adjustment to BMI	↑
		Healthy	Whole grains, fruit, vegetables, legumes, fish			A healthy diet at 14 yr appeared protective against NAFLD at 17 yr in centrally obese adolescents (OR: 0.63; 95%CI 0.41-0.96; $P < 0.05$)	↓
Salehi-Sahlabadi *et al* [34]	Iran	Western	Fast foods, soft drinks, processed meat, high-fat dairy products, hydrogenated fats, mayonnaise, salty snacks, sugar sweetened desserts, organ meats and refined grains	C-C	675 (450 with NAFLD) NAFLD: 38.6 ± 8.7 yr; Controls: 37.9 ± 8.9 yr	The western pattern was associated with ↑ risk for NAFLD after adjustment for age, sex, BMI, PA, SES and EI	↑
		Healthy	Fish, skinless poultry, low-fat dairy, fresh fruits, natural juices, canned fruits, dried fruits, vegetables, nuts, olive and garlic			A healthy pattern was associated with ↓ risk for NAFLD, after controlling for mentioned variables	↓
		Traditional	Red meat, organ meats, skinless poultry, eggs, yogurt drink, tea, legumes, tomato sauce, sugar sweetened-desserts, potato, condiments, salt, pickles and broth			Lack of association between traditional pattern and risk of NAFLD adjusted for mentioned variables	↔
Chung *et al*[60]	Korea	Western and high-carbohydrate	Processed meats, bread, soft drinks, pork, noodles, beef, cakes, snacks, beef soup, sugar, coffee, chicken, processed fish and refined grains	C-S	1190 (331 with NAFLD) NAFLD: 53 ± 9 yr; Controls: 51 ± 10 yr	Lack of association between Western/high-carbohydrate pattern and risk of NAFLD after adjustment for age, sex, WC, smoking status, EI, diabetes and hypertension	↔
		Traditional	Vegetables; fermented vegetables such as kimchi and jjangajji; fish and seafood; mush-rooms; fermented, processed, natural soybeans			↑ Adherence to the traditional pattern was associated with ↑ risk of NAFLD (OR: 1.85; 95%CI: 1.11-3.08; $P < 0.05$) after controlling for mentioned variables	↑
		Simple meal	Fruits, root and yellow vegetables, eggs, dairy products and nuts			↑ Adherence to the simple meal pattern was associated with ↓ risk of NAFLD (OR: 0.59; 95%CI: 0.34-1.00; $P < 0.05$), after controlling for mentioned variables	↓
Dehghanseresht *et al*[54]	Iran	Ordinary	Sweets, oils, fruits, white meats, refined grains, tea and coffee, salt, biscuits, snacks as well as red and organ meats	C-C	244 (122 with NAFLD) aged 19–70 yr	↑ Adherence to the ordinary pattern was associated with ↑ risk of NAFLD; $P < 0.001$	↑
		Traditional	Red and organ meats, dairy products, condiments, salt, tea and coffee and low			↑ Adherence to the traditional pattern was associated with ↑ risk of	↑

			intake of fruits			NAFLD $P < 0.001$	
		Vegetables and dairy (healthy pattern)	Vegetables, whole grains, legumes and nuts and dairy products			↑ Adherence to the vegetables and dairy pattern was ↓ association with NAFLD risk (OR: 0.23; 95%CI: 0.09–0.58; $P < 0.05$)	↓
		Fast food	Sauces, pickles, fast foods, soft drinks, snacks and biscuits			No association between Fast food patterns and the risk of NAFLD	↔
Yang *et al*[57]	China	Traditional Chinese	Staple food, coarse grains, fruits, eggs, fish and shrimp, milk and tea	C-S	999 (345 with NAFLD) aged 45–60 yr	No association between traditional pattern and the risk of NAFLD	↔
		Animal food	Kelp/seaweed and mushroom, pork, beef, mutton, poultry, cooked meat, eggs, fish and shrimp, beans and grease			After controlling for potential confounders, animal food patterns had ↑ prevalence rate for NAFLD (PR: 1.35; 95%CI: 1.06–1.72; $P < 0.05$	↑
		Grains-vegetables (healthy pattern)	Coarse grains, tubers, vegetables, mushroom and kelp/seaweed, cooked meat and beans			After adjustment for BMI, a vegetable pattern had ↓ prevalence rate for NAFLD (PR: 0.78; 95%CI: 0.62–0.98, $P < 0.05$).	↓
		High-salt	Rice, pickled vegetables, processed meat, bacon, salted duck egg, salted fish and tea			No association between high salt and the risk of NAFLD	↔
Jia *et al*[65]	China	High-carbohydrate/sweet	Fruits, cakes and candied fruits	C-S	4365 (1339 with NAFLD: adults	↑ Adherence to a high-carbohydrate/sweet pattern was associated with ↑ the prevalence of NAFLD in females but not in males	↑ only in females not in males
Kalafati *et al*[55]	Greece	Fast food	Energy-dense foods rich in saturated fat and sugar and included fast foods, sweetened soft drinks, fried potatoes and savory and puff pastry snacks	C-C	351 (134 with NAFLD) Case: 50.0 ± 10.5 yr; Control 44.0 ± 11.0 yr	↑ Adherence to a fast-food pattern was associated with ↑ odds for NAFLD after adjustment for age, sex, EI, PA, pack-yr smoked, education, MS ($P < 0.01$)	↑
		Prudent (healthy pattern)	Oil-based cooked vegetables, legumes, potatoes, fruits, vegetables and fatty fish			↑ Adherence to the prudent pattern was associated with ↓ TG and uric acid levels (β: -5.96; $P < 0.05$; β: -0.15; $P < 0.05$, respectively)	↓
		High-protein	Red meat, poultry, eggs			The high protein pattern was not associated with any NAFLD-related biomarker	↔
		The unsaturated FA	Nuts, chocolate and other foods rich in unsaturated FA			Individuals in the second quartile of the unsaturated FA pattern had ↓ odds of developing NAFLD *vs* the first quartile after being adjusted for mentioned confounders ($P < 0.05$)	↓
Tutunchi *et al*[56]	Iran	Healthy	Vegetables, legumes, fruits and low-fat dairy products	C-C	210 (105 with NAFLD) Cases 46 ± 9 yr; Controls 45 ± 9 yr	A healthy pattern was associated with ↓ odds of NAFLD (OR: 0.34; 95%CI: 0.16–0.81) after controlling for sex, education, PA, BMI,	↓

						WC	
		Western	Sweet, hydrogenated fat, red and processed meat and soft drink dietary patterns			↑ Adherence to the western pattern was related to ↑ risk of NAFLD (OR: 2.68; 95%CI: 1.31–4.16), after controlling to mentioned confounders	↑
Zhang *et al*[61]	China	Sugar-rich	Strawberry, kiwi fruit, persimmon, sweets, candied fruits, Chinese cakes	P	17360 free from NAFLD at baseline; During a median follow-up of 4.2 yr, 4034 with NAFLD, aged > 18 yr	After adjusting for age, sex, BMI, smoking, alcohol, education, occupation, income, PA, EI, personal and family history of the disease, depressive symptoms, dietary supplement use, inflammation markers, WHR and each other dietary pattern score, the sugar-rich pattern was associated with ↑ risk of NAFLD (HR: 1.11; 95%CI 1.01, 1.23)	↑
		Vegetable (healthy pattern)	Cucumber, green leafy vegetables, Chinese cabbage, celery, pumpkin			After adjusting for mentioned confounders, vegetable diet was associated with ↓ risk of NAFLD (HR 0.96; 95%CI: 0.86, 1.07)	↓
		Animal food	Animal organs, animal blood, preserved eggs, instant noodles, pork skin, sausage			After adjusting for mentioned confounders, animal food diet was associated with ↑ risk of NAFLD (HR: 1.22; 95%CI: 1.10, 1.36)	↑
Alferink *et al* [62]	The Netherlands	Vegetable and fish (healthy pattern)	Vegetables, poultry, fish and fruit	P	963 (343 with NAFLD) Baseline: 71.0 yr; Follow-up: 75 yr	No associations between vegetable and fish diet and NAFLD	↔
		Red meat and alcohol	Red, refined or organ meat, salty snacks and beer or spirits and low intake of fruit and tea			No associations between red meat and alcohol pattern and NAFLD	↔
		Traditional	Vegetable oils and stanols and margarine or butter, potatoes, whole grains and sweet snacks or desserts			↑ Adherence to the Traditional pattern was associated with ↓ risk of NAFLD (OR: 0.40; 95%CI 0.15–1.00) adjustment for sex, age, baseline education level, PA, EI, alcohol intake and follow-up time, BMI, baseline type 2 diabetes mellitus and baseline hypertension	↓
		Salty snacks and sauces	Savory food groups such as nuts, legumes, salty snacks and sauces			No associations between salty snacks and sauces pattern and NAFLD	↔
		High-fat dairy and refined grain	Fruit juice, refined grains, high-fat dairy products and sweet snacks or desserts			No associations between high-fat dairy and refined grain pattern and NAFLD	↔
Fakhoury-Sayegh *et al*[64]	Lebanon	Traditional	Vegetables, chickpeas, red beans, lentils, peas, vegetable oil/olives	C-C	222 (112 with NAFLD) Cases: 40 ± 6 yr; Controls: 39 ± 13 yr	↑ Adherence to traditional pattern ↓ the odds of NAFLD (OR: 0.30; CI 95%: 0.11–0.86; $P < 0.05$) adjusted for MS, EI, education, PA, family history, smoking, place of residence and profession	↓

		High fruits	Fruits and fruit juices			↑ Adherence to high fruits pattern ↑ the odds of NAFLD (OR: 4.061; 95%CI: 1.320–12.100, $P < 0.05$, adjusted for mentioned confounders	↑
		The high meat and fast food diet: (Western-like dietary pattern)	Meat such as pork, chicken, beef meat and hotdog			↑ Adherence to Western pattern ↑ the odds of NAFLD (OR: 4.081; 95%CI: 1.36–12.28, $P < 0.05$) adjusted for mentioned confounders	↑
Nakashita *et al* [58]	Japan	Healthy	Seaweeds, vegetables, mushrooms, pulses, potatoes and starches	C-S	281 men (89 with NAFLD) NAFLD: 62 (57–67) yr; Controls: 61 (56–67) yr	A healthy pattern was correlated with the ↓ risk of NAFLD	↓
		Western	Fats and oils, meat, seasonings, spices			No correlation between western pattern and NAFLD	↔
		Snacks	Sugars and starches, beverages (tea, coffee, fruit juice, soft drinks), fruits			No correlation between snacks pattern and NAFLD	↔
Adriano *et al* [59]	Brazil	Healthy	Fruits, vegetables/legumes, white meat, olive oil, margarine, bread/toast (with significant negative loading for beef)	C-S	229 older adults (74.7% women) NAFLD: 67.0 ± 5.0 yr; Controls: 70.1 ± 7.0 yr	↑ Adherence to the healthy pattern was associated with ↓ prevalence of NAFLD (PR: 0.70; 95%CI: 0.50, 0.98, $P < 0.05$) after adjustment for sex, age, EI, BMI, smoking status, PA, family income and use of hypoglycemic drugs	↓
		Regional snacks (Northeast of Brazil)	Tea/coffee, dairy products, cassava flour/tapioca/cuscus, butter and olive oil			↑ Adherence to the regional snacks pattern was associated with the ↑ prevalence of NAFLD (PR: 1.42; 95%CI: 1.02, 1.92, $P < 0.05$) after adjustment for mentioned confounders	↑
		Energy-dense	Processed cold meats, beef, viscera, sweet products/desserts/sugar, soft drinks, tubers/spaghetti/pastries			No association between energy density pattern and NAFLD	↔
		Traditional	Rice, beans, bread/toast, tea/coffee, sweet products/desserts/sugar			No association between traditional pattern and NAFLD	↔

BMI: Body mass index; C-C: Case-control; C-S: Cross-sectional; CI: Confidence interval; EI: Energy intake; FA: Fatty acid; FFQ: Food frequency questionnaire; HR: Hazard ratio; NAFLD: Nonalcoholic fatty liver disease; MS: Metabolic syndrome; OR: Odds ratio; P: Prospective; PA: Physical activity; PR: Prevalence ratio; SES: Socioeconomic status; TG: Triglyceride; WC: Waist circumference; WHR: Waist-to-hip ratio.

fruits[53,64,65]; as well as, snacks and energy-dense dietary pattern[58,59,62]. The majority of these dietary patterns increased the risk of NAFLD. Although high-carbohydrate/sweet/sugar/high fruits dietary pattern was associated with a significantly higher risk of NAFLD, Jia *et al*[65] found that this diet was positively associated with the prevalence of NAFLD only in females but not in males. Overall, Hassani Zadeh *et al*[43], in their meta-analysis, found that Western dietary patterns increased the risk of NAFLD by 56%.

The Western dietary pattern rich in saturated and trans-fatty acids may affect the hepatic cell steatosis *via* chylomicron uptake[34]. This dietary pattern, due to high amounts of refined grains, white bread and sugar-sweetened beverages has been also strongly associated with IR, diabetes and obesity. Soft drinks, the main constituents of the Western diet, contain substantial amounts of added sugars and fructose[66]. It was indicated that a higher intake of fructose induces hepatic IR and inflammation, thereby fueling the development of NAFLD. In addition, fructose metabolism could promote hepatic lipogenesis by inhibiting the DNL pathway and regulating lipogenic gene expression in the liver[67]. It should be noted that moderate consumption of fruits due to the presence of other dietary components such as dietary fiber and antioxidant vitamins can have a protective effect against NAFLD. On the other hand, excessive fruit consumption, as was seen in a study by Fakhoury-Sayegh *et al*[64], may increase

the risk for NAFLD, due to the high content of simple sugars (especially fructose).

The traditional diet may differ depending on the region or country and encompasses the common foods eaten there. Since this pattern comprises both healthy and unhealthy food items in different proportions, in collected studies we can observe the different influences of this pattern on the risk of NAFLD. For example, in a Korean study[60] the traditional diet was characterized by high intake of vegetables, fermented vegetables, such as kimchi, fish and seafood, mushrooms and fermented, processed and natural soybeans and was associated with a higher risk of NAFLD independent of several confounders added to this model. A traditional Iranian dietary pattern characterized by intake of red and organ meats, dairy products, condiments, salt, tea and coffee and low fruits consumption was related to an increased risk of NAFLD[54]. However, in another Iranian study[34], a traditional diet, represented by a high intake of red meat organ meats, skinless poultry, eggs, yogurt drink, tea, legumes, tomato sauce, sugars sweets-desserts, potato, condiments, salt, pickles and broth, was not associated with risk of NAFLD. Similar observations were reported by Yang *et al*[57] and Adriano *et al*[59] where traditional Chinese food items (staple food, coarse grains, fruits, eggs, fish and shrimp, milk and tea) and traditional Brazilian foods (rice, beans, bread/toast, tea/coffee, and sweet products/desserts/sugar) were not associated with a risk of NAFLD. In turn, Alferink *et al*[62] found that traditional Dutch dietary patterns consisting of vegetable oils, stanols and margarine or butter, potatoes, whole grains, and sweet snacks or desserts were associated with regression of NAFLD. Similar observations revealed that the traditional Lebanon diet (characterized by high intake of vegetables, chickpeas, red beans, lentils, peas, and vegetable oil/olives) was also related to a lower risk of NAFLD [64].

DIETARY INTERVENTION STUDIES IN NAFLD PATIENTS

Lifestyle modification, including a change in diet, weight loss target and structured exercise/physical intervention is the first-line and a cornerstone therapy for the NAFLD condition. It is implemented to reduce the cardiometabolic risk factors and cardiovascular disease events and to resolve NAFLD. Table 3 displays the NAFLD diet treatment recommendations/guidelines of The European Association for the Study of the Liver[48] and the European Society for Clinical Nutrition and Metabolism[68], in addition to the American Association for the Study of Liver Diseases[69,70], the Asian Pacific Association for the Study of the Liver[71], the American Gastroenterological Association[7] and the World Gastroenterology Organization[72].

The primary dietary goal for patients with NAFLD is to implement a hypocaloric diet due to a caloric deficit. Most often, low-calorie diets lead to an energy deficit of 500-1000 calories. Ordinarily, overweight NAFLD patients are advised to have a deficit of at least 500 calories/d for weight loss[10,48,73,74]. A weight loss of 3%-5% of body weight is necessary to improve liver steatosis[10]. To improve most of the histopathological characteristics in NAFLD, hepatocyte ballooning, lobular inflammation and fibrosis, a greater loss of body weight of 7%-10% is required[75]. Meta-analysis of 8 randomized controlled trials confirm that a 7% reduction in body weight was associated with improvement of the NAFLD Activity Score[76]. But, it should be noted that 94% of patients who lost 5% of initial body weight stabilized/or improved liver fibrosis[77]. Meta-analyses of 22 randomized controlled trials with 2588 participants reported that weight-loss interventions were significantly associated with improvements in alanine aminotransferase (ALT), ultrasonography pronounced liver steatosis, NAFLD Activity Score and presence of steatohepatitis[11]. Caloric restriction alone or in combination with physical activity encourages the loss of body weight and reduces hepatic steatosis and subsequently promotes fat mobilization from the liver[70]. In adults with NAFLD, exercise alone may prevent, reduce and cured liver steatosis. However, the ability of physical activity to improve other NAFLD spectrum histological parameters remains unknown.

Based on the current evidence, there is no consensus on the ideal macronutrient composition of the diet for NAFLD patients. The best nutrition recommendation is a traceable diet, based on individual preferences, eating habits and behaviors[74]. Also, there is no solid evidence to support a particular macronutrient composition of a hypocaloric diet unique for use in NAFLD patients. Independent of weight loss, a diet low in carbohydrates and higher in protein intake is associated with improvements of metabolic parameters in NAFLD patients[73,78]. A recent meta-analysis 32 controlled isocaloric feeding studies with a constant proportion of protein in the diet and varying ratios of carbohydrate and fat indicates that diet differences are too small, which implies the importance of caloric intake in NAFLD patients[79]. Overall, more future studies on macronutrient composition in diet are needed.

As previously stated, Mediterranean dietary patterns prevent the onset of NAFLD. The MD is also the most recommended diet for the treatment of NAFLD patients[12]. It improves liver steatosis, as indicated by the results of several studies, regardless of whether there is a calorie restriction in the diet. Independent of weight loss, patients have greater reductions in intrahepatic lipid content and insulin sensitivity after following the MD compared to a low-fat/high-carbohydrate diet. Consumption of a MD with calories less than the required daily energy allowed male NAFLD patients to reduce body weight, lipid accumulation, visceral adiposity index, fatty liver index, hepatic steatosis index and IR, as well as a

Table 3 Summary of international guidelines on diet for nonalcoholic fatty liver disease patients

	EASL/EASD/EASO clinical practice guidelines for the management of NAFLD [48]	ESPEN guideline on clinical nutrition in liver disease[68]	AASLD practice guidance: The diagnosis and management of NAFLD[69,70]	APASL clinical practice guidelines for the management of MAFLD[71]	AGA clinical practice guidelines for diagnosis and management of NAFLD[7]	WGO guidance for NAFLD/NASH [72]
Target for weight loss	7%-10%	7%-10% (in obese patient); > 10% to improve fibrosis	3%-5% (to improve steatosis); 7%-10% for histological improvement	7%-10%	≥ 5% if steatosis; ≥ 7% if NASH; ≥ 10% if fibrosis	5%-10%
Macronutrient composition	Low to moderate fat and moderate to higher carbohydrate; low carbohydrate, ketogenic diets or high protein	Irrespective of macronutrient composition, MD to improve steatosis and IR	Less relevant	Low-carbohydrate, low-fat and Mediterranean-type diets	Minimize SFA, ↓ red and processed meat	Avoid trans-fats; ↑ omega 3/omega 6 PUFA
Energy restriction	Hypocaloric: Reduction of 500-1000 kcal/d target weight loss of 0.5-1.0 kg/wk	Hypocaloric diet according to obesity guidance	Hypocaloric diet reduction of 500-1000 kcal/d	Hypocaloric diet reduction of 500-1000 kcal/d	Hypocaloric: 1200-1500 kcal/d or ↓ from baseline 500-1000 kcal/d	Hypocaloric: ↓ calories intake 25%
Fructose intake	Avoid fructose-containing beverages and foods				Avoid fructose commercially produced	Avoid fructose and soft drinks
Coffee intake	No liver-related limitations	"More likely to benefit health than harm"		"More likely to benefit health than harm"		
Alcohol intake	Risk below (< 30 g men, < 20 g women)	Abstain	Not consume heavy amounts		Restrict

reduced share of SFA in the serum fatty acid profile decreased serum levels of SFAs and increased serum levels of MUFAs and n-3 PUFA[80]. The MD has well-documented metabolic benefits to reduce cardiovascular risk and thus is well valued in the medical community[81]. This observation is important because NAFLD patients have an increased risk of cardiovascular disease.

A systematic review and meta-analysis of randomized controlled trials presented that Mediterranean and hypocaloric dietary interventions favoring unsaturated fatty acids led to improved intrahepatic lipid content and transaminases levels (ALT, aspartate aminotransferase) in NAFLD patients[82]. The gamma-glutamyl transferase level does not change significantly during the Mediterranean dietary interventions[82]. Diet compositions in randomized controlled trials used in these meta-analyses can be considered comparable. Based on the calculated NAFLD fibrosis score, the composite score of age, glucose levels, platelet count, albumin and aspartate aminotransferase/ALT ratio, indicated that risk for advanced hepatic fibrosis was 11% among NAFLD patients with incidentally discovered hepatic steatosis[76]. In patients with NAFLD, gamma-glutamyl transferase levels decreased only after low glycemic index-MD intervention[83]. Hence, it is confirmed that MD without caloric restriction reduced the liver fat. Since there are only a few studies examining dietary interventions in clinically advanced stages of NAFLD (active and fibrotic NASH), the optimal dietary recommendation for nutrition intervention in NAFLD remains to be defined.

Well-discussed risk factors for hepatic steatosis are high SFA intake and overconsumption of carbohydrates, such as fructose. This type of diet leads to obesity. Intervention studies provide clear and strong evidence of a link between excessive calorie intake and NAFLD development as well as being linked to excess energy intake with increased lipolysis, induced IR and increased harmful ceramides in plasma[15,16]. Excessive intake of SFA (1000 extra kcal/d) conducted in obese patients for 3 wk increased intrahepatic TG content more than the intake of unsaturated fats (+ 55% *vs* + 15%, respectively)[16]. Also, overconsumption of simple sugars increased the intrahepatic TG content (+ 33%) by stimulating DNL (+ 98%). In a review by Stokes *et al*[84], short-term hypocaloric diets (up to 16 wk) have shown beneficial effects in reducing intrahepatic lipid content. Also, research supports that carbohydrate restriction and consumption of unsaturated fatty acids have efficacious metabolic effects in NAFLD[12,81,84]. Obesity is closely related to low levels of n-3 PUFA in plasma phospholipids[85].

Dietary modifications including n-3 PUFA supplementation are considered to be suitable therapeutic strategies for obese NAFLD patients, though further clinical trials are required.

However, among NAFLD patients, weight loss is largely unsuccessful in the real world in the ambulatory and clinical settings[86]. However, more frequent clinical encounters and controls are associated with an increased likelihood of weight loss (enhanced probability of weight reduction). Therefore, national strategies are needed for targeted success in weight loss success in high-risk populations.

Time-restricted feeding and intermittent fasting

The newest popular dietary intervention in the past few years is time-restricted feeding as a form of daily intermittent fasting (IF). This dietary approach restricts the time between the first and last food intake, without emphasizing calorie restriction. IF implies a > 60% energy restriction on > 2 d/wk. In time-restricted eating, daily food intake is limited to 8-10 h. These diets with a limited eating window appear to be safe in the NAFLD population. Patients tolerate this diet well. The key feature of this dietetic approach is the so-called "metabolic switch" that occurs 12 h after the cessation of food intake, where glycogen stores in the liver are depleted, and adipose tissue lipolysis increases[87]. This type of diet seems to be effective for weight loss, whereas many authors denied that the effect is still the result of a real calorie restriction. Patients with NAFLD follow the IF diet based on metabolic changes that are presented among overweight/obese individuals. A recent meta-analysis, involving patients with NAFLD, has shown that IF is beneficial in weight loss and liver enzyme levels[88]. However, no additional metabolic benefit has been shown compared to calorie-restricted diets[89]. In patients with NAFLD improvement in fatty liver index correlates with the number of fasting days and with the degree reduction in body mass index[90].

In a study performed by Cai *et al*[91], 271 NAFLD patients were randomized to time-restricted feeding, alternate-day fasting and control groups and were followed for 12 wk[91]. Findings from this study indicated that alternate-day fasting could be an effective diet method for weight loss and amelioration of lipid metabolism, with no direct effect in steatosis regression. In one Malaysian randomized controlled trial, 8 wk of IF with alternate-day calorie restriction resulted in the reduction of body weight and liver enzymes as well as hepatic steatosis compared to a habitual diet[92]. 8 wk of IF with limited caloric intake on alternating days led to a decrease in body weight and liver enzymes, as well as hepatic steatosis compared to the usual diet. Additional evidence for the benefit of IF to diminish hepatic steatosis and body weight compared to common lifestyle modification has been reported by 5:2 diet (intermittent calorie restriction: 600 kcal/d for men and 500 kcal/d for women for 2 non-consecutive days per week). But, the same effect was obtained in another group of participants on a low-carbohydrate high-fat diet (daily caloric intake: 1900 kcal/d for men and 1600 kcal/d for women) [89]. Data regarding IF efficacy in the steatosis/fibrosis regression are lacking. For now, it is important for medical practitioners not to advise this diet to patients with cirrhosis caused by NAFLD due to the well-known effect of starvation on the development of sarcopenia.

DASH diet

Evidence from two observational studies revealed that high adherence to the DASH-style diet is inversely associated with the risk of developing NAFLD[93,94]. It is indicated that subjects who fully adhered to the DASH diet were 30% less likely to have NAFLD. DASH is a low-glycemic index and low energy-dense diet, emphasizing low sodium intake and minimal consumption of processed foods. It is well known that the DASH diet is associated with a reduction in cardiovascular risk, as originally intended for hypertension patients. A randomized controlled trial including 60 overweight/obese adults, with ultrasonography proven NAFLD showed that the DASH diet over 8 wk led to more effective weight loss, improvement of aminotransferases and markers of IR, TG and total-C/HDL-C ratio compared to a contemporary control diet[95]. The DASH diet may be a promising dietary option for NAFLD patients, as weight loss, improved cardiometabolic factors and regression of steatosis are surrogate markers of liver disease status and the main goals of NAFLD treatment. This diet has aroused interest among specialists who care for patients with NAFLD. Further studies are essential to assess the effects of the DASH diet on liver histology and the clinical outcome of patients with NAFLD.

Ketogenic diet

Ketogenic diet (KD) is the most popular low-carbohydrate eating plan based on a strict restriction in carbohydrates (less than 20-50 g/d) consumption. The KD became a popular weight loss intervention among obese patients due to its effectiveness despite safety concerns of this diet plan if dyslipidemia is present[96]. Therefore, KD could have a positive impact on NAFLD, due to very low content of carbohydrates in the diet. However, it is not known if ketosis plays an additional role. Several mechanisms may be proposed links between ketosis and improvement of NAFLD. First, a ketogenic diet decreases insulin levels that lead to increased rate of fatty acid oxidation and decreased lipogenesis [97]. Then, restriction of carbohydrates encourages the formation of ketone bodies, which cause satiety by a still-unknown mechanism[98]. In turn, reduced calorie intake leads to weight loss.

Few studies have tested KD as a treatment strategy for NAFLD patients. Based on fat content, KD can be a normocaloric, hypocaloric or non-restricted caloric diet. Pérez-Guisado *et al*[99] conducted a pilot study on 14 overweight male patients with MetS and with ultrasonography-proven NAFLD. Patients fed unrestricted Mediterranean high-fat KD, high in unsaturated fats (*i.e.* olive oil and fish oil rich with omega-3 fatty acids). Adherence to Mediterranean high-fat KD showed a significant improvement in body weight, aminotransferases and LDL-C levels, and steatosis degree (21% of the patients had complete fatty liver regression)[99].

Mardinoglu *et al*[100] reported a 2-wk KD intervention (carbohydrate 20–30 g/d, fat 241 g/d, 3115 kcal/d) in 17 obese patients with NAFLD. Despite a slight weight loss, liver fat content (assessed by magnetic resonance spectroscopy) was reduced by 43.8% in obese patients in this study. At the same time, a concomitant decrease in *de novo* gene for liver lipogenesis was obtained[100]. Moreover, literature data indicated that normocaloric high-fat KD inhibits DNL and induces fatty acid oxidation, caused sustained weight loss and reduced hepatic fat accumulation[16,101]. Based on the above findings KD could be a potential therapeutic dietary intervention for addressing steatosis regression and weight loss. Future studies are needed on the KD effect on fibrosis regression and resolution of inflammation. Because ketosis may have beneficial effects independently of the diet composition, studies aiming to identify the specific role that ketone bodies play in the pathophysiology of NAFLD are warranted.

Added sugars

Study evidence from cross-sectional trials pronounced a directly proportional association between the intake of refined sugar (especially high fructose corn syrup) due to the consumption of sweet sugar beverages with the risk of developing NAFLD[81,102]. Patients with NAFLD consume 2-3 times more fructose. Higher fructose consumption is also related to an increased risk of having steatohepatitis and advanced fibrosis in NAFLD patients. Based on current evidence, fructose supplementation was linked with higher adiposity and enhanced visceral fat, hypertriglyceridemia and IR, occurs due to increase DNL in liver, in spite of similar weight gain when compared to glucose[103]. Increasing the frequency of the snacks with added sugar consumption led to a prominent increase in the hepatic fat content. The augmented hepatic steatosis was proportional to visceral fat accumulation and to the rise in DNL.

Fructose-rich diets, based on sugar-sweetened beverages increase hepatic synthesis of TG and are recognized as a major mediator of NAFLD[73]. It was observed that carbohydrate overfeeding in overweight persons consumed 1000 kcal/d from simple carbohydrates (sugar-sweetened soft drinks, candy, pineapple juice) for 3 wk caused a 10-times greater relative increase in fat content in the liver than in body weight (27% *vs* 2%, respectively)[104]. The recommendation to avoid sweet sugar beverages reduced the intake of extra empty calories and supported a caloric deficit for weight loss. Notably, high fructose consumption in NAFLD patients was compiled, with an increase in hepatic fructokinase and fatty acid synthase mRNA when compared to healthy persons[105]. Fructose can advance hepatic steatosis both directly *via* DNL and indirectly *via* DNL feedback inhibition of fatty acids. Overconsumption of fructose may increase the risk of developing NASH and advanced fibrosis, although the relationship may be confounded by excess energy intake or by unhealthy dietary patterns and sedentary lifestyle, which are common in NAFLD patients[106].

Current literature evidence suggests that higher fructose intake (> 20E% or 100–220 g/d) may adversely affect disease onset and progression[81]. Meta-analyses reported that moderate fructose consumption lower than 10% of energy (< 50 g/d for a 2000 kcal diet) does not induce weight gain or dyslipidemia. Sugar-sweetened beverage intake of ≥ 1 serving/d rises the risk of having NAFLD by 50% [33] and liver fibrosis by 250%[107]. It seems that artificially sweetened beverages and defined 100% fruit juices have similar effects as sugar-sweetened beverages. The results of a systematic review indicated that fructose in the diet isocalorically replaced with other carbohydrate sources for 1-10 wk did not affect NAFLD biomarkers[108]. Fructose overconsumption increases intrahepatic lipids and ALT levels. This effect results from excess energy intake rather than fructose consumption[108]. In the future, long-term prospective clinical trials are essential to understand and confirm a link between NAFLD progression and fructose consumption.

Coffee consumption

NAFLD patients who drink three to four cups of coffee per day will have more health benefits than harm, with the reduction in risk for various health outcome[109]. Nevertheless, a recent meta-analysis of 11 epidemiological studies confirmed association with regular coffee consumption and decreased risk of NAFLD[110]. Moreover in patients already diagnosed with NAFLD, coffee consumption reduced risk for the development of liver fibrosis[97,110]. A case-control study showed involvement of coffee in the fatty liver score, pronounced by ultrasound in all coffee consumers[111]. A systematic review determined that coffee consumption was inversely related to the severity of steatohepatitis in NAFLD patients[112]. Prohibitive effects on fibrosis progression were determined by the FibroTest based on fasting biochemical markers presented in a prospective study in the general population[113]. It was noted that decaffeinated coffee has the same helpful effect on NAFLD[114]. It was considered that two cups of coffee/day helped in the prevention of hepatocellular carcinoma[115], while three cups of coffee/day prevented steatohepatitis and fibrosis[109]. As observations have so far been based on epidemiological studies, future clinical studies need to confirm whether coffee consumption can be

considered a preventative factor for NAFLD. Until then, routine prescription of coffee for NAFLD prevention/treatment is not recommended.

CONCLUSION

In conclusion, the Western dietary pattern characterized by high intake of soft drinks, red and processed meat and refined cereals with coincidentally low intake of fish, fruit and vegetables as well as whole grains tended to increase the risk of NAFLD. The healthy and Mediterranean dietary patterns characterized by high consumption of vegetables, fruits, nuts, olive oil, low-fat dairy products and fish were linked with a reduced NAFLD risk. More prospective cohort studies are needed to confirm the association between dietary patterns and NAFLD risk. Macronutrient composition and excessive caloric intake are critical determinates of obesity and liver health. DASH, IF and KD have aroused interest among specialists who care for patients with NAFLD. Further well-designed studies are needed to assess the effects of these diets on liver-related outcomes and liver histology. Dietary advice should be provided by a multidisciplinary team with a specialized dietitian as an individual approach, as we already know that our genetics and gut microbiota cause differences in the effects of the diet to our metabolism. Future research in field interaction overfeeding and genomics are warranted, as are of the inter-individual difference of liver steatoses.

Abstract

The morbidity and mortality of hepatocellular carcinoma (HCC) rank 6th and 4th, respectively, among malignant tumors worldwide. Traditional diffusion-weighted imaging (DWI) uses the apparent diffusion coefficient (ADC) obtained by applying the monoexponential model to reflect water molecule diffusion in active tissue; however, the value of ADC is affected by microcirculation perfusion. Using a biexponential model, intravoxel incoherent motion (IVIM)-DWI quantitatively measures information related to pure water molecule diffusion and microcirculation perfusion, thus compensating for the shortcomings of DWI. The number of studies examining the application of IVIM-DWI in patients with HCC has gradually increased over the last few years, and many results show that IVIM-DWI has vital value for HCC differentiation, pathological grading, and predicting and evaluating the treatment response. The present study principally reviews the principle of IVIM-DWI and its research progress in HCC differentiation, pathological grading, predicting and evaluating the treatment response, predicting postoperative recurrence and predicting gene expression prediction.

Key Words: Hepatocellular carcinoma; Intravoxel incoherent motion; Differentiation; Pathological grading; Treatment response; Gene expression

Core Tip: Intravoxel incoherent motion (IVIM) diffusion-weighted imaging (DWI) quantitatively measures information related to pure water molecule diffusion and microcirculation perfusion using a biexponential model, thus compensating for the shortcomings of traditional DWI. The number of studies assessing IVIM-DWI in patients with hepatocellular carcinoma (HCC) has gradually increased over the last few years. This review, which is based on the literature, identified an imaging biomarker for HCC differentiation, pathological grading, predicting and evaluating the treatment response, predicting postoperative recurrence and predicting gene expression prediction. The results of this analysis show that IVIM-DWI has important value in the treatment and diagnosis of HCC.

INTRODUCTION

The morbidity and mortality of hepatocellular carcinoma (HCC) rank 6th and 4th, respectively, among malignant tumors worldwide[1,2]. The apparent diffusion coefficient (ADC) obtained using traditional diffusion-weighted imaging (DWI) reflects water molecule diffusion in tissue[3]. However, many studies have shown that a voxel contains other diffusion information in addition to the diffusion movement of pure water molecules, namely, the microcirculation perfusion of the capillary network in tissue[3-6]. One limitation of traditional DWI is that it is unable to distinguish water molecule diffusion and microcirculation perfusion information. Le Bihan *et al*[6,7] proposed that intravoxel incoherent motion (IVIM) quantitatively obtains information on both pure water molecule diffusion and diffusion related to microcirculation perfusion, thus compensating for the shortcoming of traditional DWI. Therefore, IVIM has become a research hotspot in recent years. The liver is suitable for IVIM research because of its relatively large blood supply. Since the first application of IVIM-DWI for the study of liver disease by Yamada *et al*[8], the number of studies assessing IVIM-DWI in patients with HCC has progressively increased, and significant progress has been achieved. This study mainly reviews IVIM-DWI research progress in the diagnosis and treatment of HCC.

THE BASIC PRINCIPLES OF IVIM-DWI

DWI is currently the only functional magnetic resonance imaging (MRI) technology that noninvasively measures water molecule diffusion in living tissue[3]. According to the theory of traditional DWI, the movement of free water molecules is considered to conform to a Gaussian distribution. However, due to the presence of complex cell structures and multiple diffusion barriers, such as cell membranes, in biological tissues, the diffusion behavior of water in biological tissues is more complicated. Therefore, the displacement of water in tissue may substantially deviate from a Gaussian distribution, challenging the validity of the monoexponential model to varying degrees. Additionally, the ADC, which reflects the water molecule diffusion, is affected simultaneously by microcirculation perfusion[3,5,7]. IVIM-DWI uses sufficient b values and biexponential models for the acquisition and analysis of images and distinguishes information regarding the pure tissue diffusion of water molecules and diffusion related to microcirculation perfusion. Among IVIM-DWI parameters, the simple diffusion coefficient, which is also referred to as the slow apparent diffusion coefficient (D), reflects the diffusion movement of pure water molecules in the tissue in a region of interest (ROI). The false diffusion coefficient, which is also called the fast apparent diffusion coefficient (D*), reflects diffusion movement related to microcirculation perfusion in the capillary network in an ROI. The fraction of the fast apparent diffusion coefficient (f) represents the volume ratio of the local microcirculation perfusion-related effect to the total diffusion effect, which may reflect the blood volume in an ROI. The formula for determining the relationship between IVIM-DWI signal attenuation and b values in tissue is as follows:

$S_b/S_0 = (1 - f) \times \exp(-bD) + f \times \exp[-b(D + D^*)]$

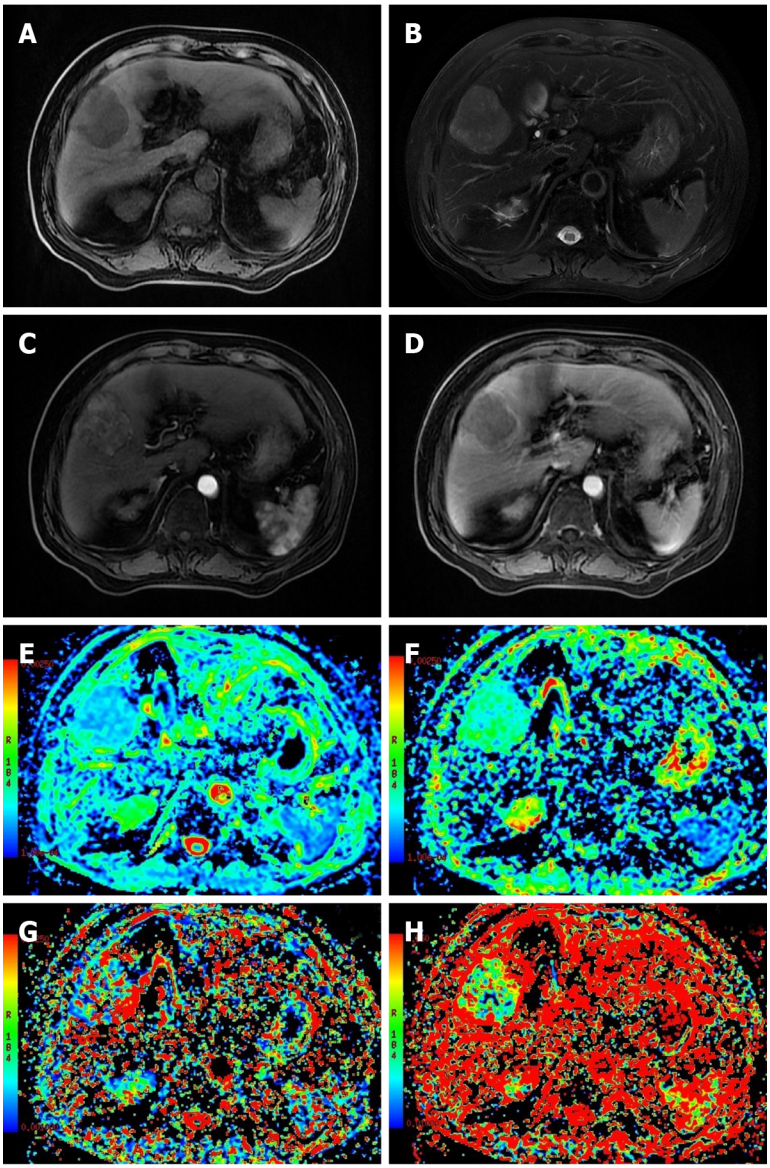
Where b is the diffusion sensitivity coefficient with units of s/mm^2, while the unit for both D and D* is mm^2/s, and S represents intravoxel signal intensity, with S_0 and S_b representing the signal intensities when b = 0 and b has other values, respectively. The b value determines the effect of microcirculation perfusion on DWI signal attenuation[6]. When the b value is low (b < 200 s/mm^2), the effect of microcir-

culation perfusion accounts for a large proportion of the total diffusion effect, whereas when the b value is high (b ≥ 200 s/mm^2), signal attenuation basically reflects only the pure water molecule diffusion in a voxel.

HCC DIFFERENTIATION

To date, many studies have shown that IVIM-DWI has important value in differentiating HCC from other liver lesions[8-22]. In theory, malignant tumors restrict the movement of water molecules to a significantly greater extent than benign tumors; thus, the ADC and D values of malignant tumors are lower than those of benign tumors[23]. Studies have confirmed that the ADC and D values of malignant liver lesions are remarkably lower than those of benign liver lesions and are useful to distinguish benign from malignant liver lesions, with the D value showing higher differentiation efficiency[8,10-15,17]. Yoon *et al*[14] conducted an IVIM study on 169 lesions in 142 patients. The values of ADC and D in malignant liver lesions [1.14 ± 0.24, 0.95 ± 0.21, (× 10^{-3} mm^2/s), respectively] were significantly lower than those in benign liver lesions (1.72 ± 0.37, 1.61 ± 0.34, (× 10^{-3} mm^2/s), respectively). The area under the receiver operating characteristic (ROC) curve (AUC) values for the ADC value and D value in differentiating liver malignancies and hypervascular malignancies were 0.933 and 0.971, respectively, and 0.919 and 0.961, respectively (all $P < 0.0005$).

However, research results for D* values and f values in differentiating benign and malignant liver nodules are inconsistent. A study by Ichikawa *et al*[16] showed that the D* value of malignant liver lesions was significantly lower than that of benign lesions, but no difference in f values was observed between benign and malignant lesions. A study by Luo *et al*[10] also revealed that the D* values of HCC were obviously lower than those of focal nodular hyperplasia, with no significant difference in the f value between the two groups. However, another study[11] by the same group showed that the f value in the malignant group was significantly lower than that in the benign group, and the D* value did not differ significantly between the two groups. The studies by Klauss *et al*[12] and Doblas *et al*[18] both showed no significant differences in the D* and f values between benign and malignant liver lesions and no significance in the values of D* and f in differentiating those two types of liver lesions. Recently, Podgórska *et al*[24] reported that the perfusion-diffusion ratio was more effective than IVIM-DWI parameters in differentiating solid benign and malignant primary liver lesions.

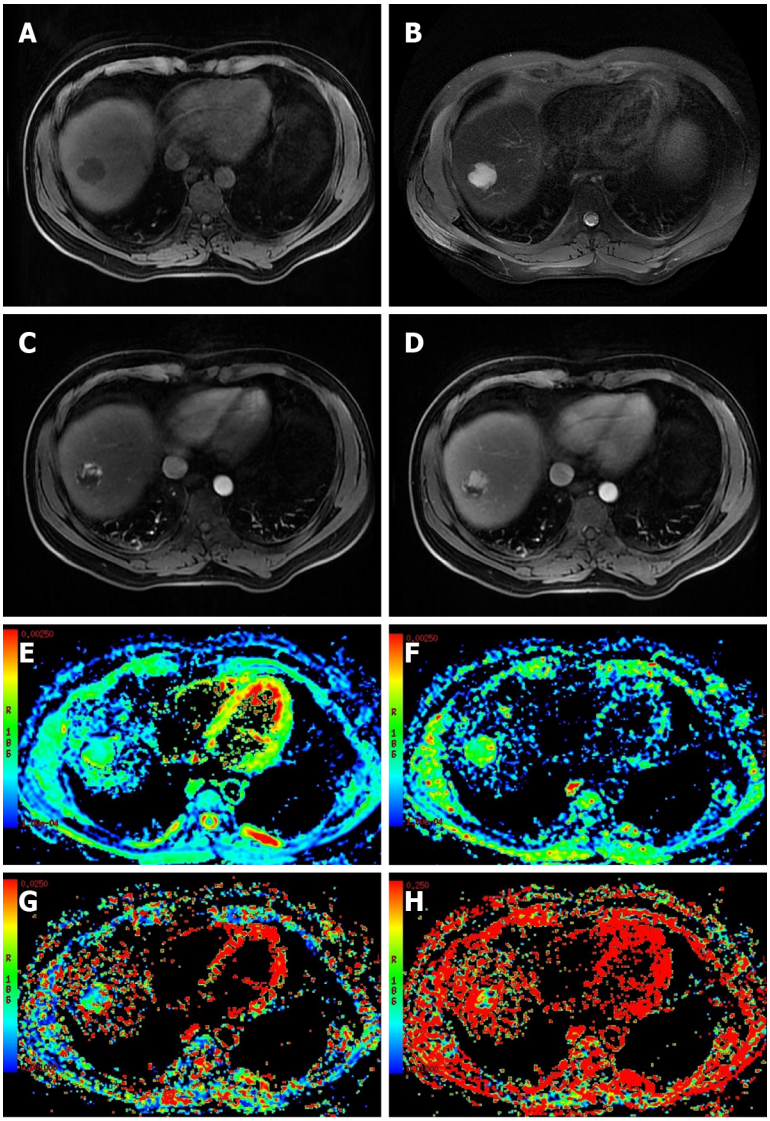


The inconsistencies in the results described above may be related to the following factors: (1) D* and f values not only reflect blood perfusion information but may also reflect other information, such as particle or gland excretion[10,15,25]; (2) the D* values of hepatic hemangioma with different blood supply types exhibit a range of fluctuation range[13]; and (3) interference from other factors, such as the b value distribution, ROI settings, and differences in tumor composition, may occur[16,23,26] (Figures 1 and 2).

Relatively few studies assessing the differentiation of malignant nodules with different pathological characteristics in the liver have been published. The few available studies have involved differentiating HCC from intrahepatic cholangiocarcinoma (ICC) and/or metastasis[9,27-29]. Our previous study[27] showed significantly lower ADC and D values for HCC than for ICC, a significantly higher D* value for HCC than for ICC, higher diagnostic efficiency for D* [AUC = 0.896], and no significant difference in f values between the two groups. According to other studies, ADC and D for HCC are obviously lower than those for ICC. However, the results for the IVIM-DWI parameters D* and f are not consistent. Choi *et al*[9] and Shao *et al*[28] reported that the f values of HCC were higher than those of ICC, while the D* values did not differ significantly between the two studied groups. Wei *et al*[29] did not document significant differences in either D* or f values between HCC and ICC groups.

The results of studies analyzing the differentiation between HCC and liver metastases differ substantially. Choi *et al*[9] found that the f value of HCC was significantly higher than that of liver metastases, but no significant differences were detected in other IVIM-DWI parameters. The study by Wu *et al*[30] indicated no obvious differences in the values of ADC, D, D*, and f for HCC from those for hepatic metastases, which may be due to changes in microcirculation and cell density caused by metastatic tumors of different origins. Dividing liver metastases into different subgroups according to different origins may be a more reasonable approach.

PREDICTION OF PATHOLOGICAL GRADING



Preoperative prediction of the pathological grade of HCC has important value in formulating guidelines for individualized treatments. Studies have shown that IVIM helps predict the pathological grade of HCC before surgery[23,26,31-44]. A meta-analysis by Yang *et al*[32] included 16 studies (1428 cases of HCC) using IVIM-DWI for pathological grading and found that ADC and D values showed high accuracy for the pathological grading of noninvasive HCC and better differentiation efficiency for D values than for ADC values. The explanation for this result may be that a higher tumor pathological

grade indicates greater cellularity, a higher nuclear-to-cytoplasmic ratio, and a smaller extracellular space, resulting in more restricted water diffusion, which ultimately leads to lower ADC and D values [23,33,35]. A potential explanation for the superiority of D values compared to ADC values may be that D values theoretically avoid the effect of microcirculation perfusion information. The results for the correlation between D* and f values and pathological grading are inconsistent. In addition to reporting results for ADC and D values and tumor tissue grading consistent with those of previous studies, Li *et al* [36] used rat models and showed that the D* and f values of higher-grade lesions were higher than those of lower-grade lesions and that D* and f values were positively correlated with the tumor tissue grade. Sokmen *et al*[26] and Granata *et al*[38] found that f values were significantly correlated with the HCC pathological grade, while a significant correlation was not identified between D* values and the pathological grade. On the other hand, multiple studies by Zhu *et al*[23,33,35] showed that neither D* values nor f values were significantly correlated with the HCC pathological grade.

PREDICTION AND EVALUATION OF TREATMENT RESPONSES

Locoregional therapy

IVIM-DWI accurately reflects microstructures and blood perfusion changes before and after tumor treatment and is particularly suitable for the prediction and evaluation of the responses to and efficacy of tumor locoregional therapy (LRT)[45]. Many researchers have investigated the value of IVIM-DWI in the prediction and evaluation of transarterial chemoembolization (TACE) efficacy in patients with HCC [46-52]. Park *et al*[50] reported that the preoperative D* value of HCC with better lipiodol deposition was markedly higher than that of HCC with poor lipiodol deposition, suggesting that the D* value may predict lipiodol deposition after TACE for patients with HCC. As shown in our previous study[46], the ADC and D values of HCC were obviously elevated four weeks after TACE treatment, the D* value was significantly reduced, and the f value did not change significantly.

Hectors *et al*[53] investigated the effect of yttrium 90 radioembolization on diffusion and perfusion in HCC. The authors performed multiparametric MRI including IVIM-DWI on 24 patients with HCC before (n = 24) and six weeks (n = 21) after radioembolization. The ADC and D values of HCC were significantly increased at six weeks after radioembolization (P < 0.0004), while the D* values were significantly reduced (P = 0.014), and no significant change was detected in f values (P = 0.765).

Server *et al*[54] administered LRT to 15 patients with HCC (11 patients underwent transarterial radioembolization, and four patients underwent TACE, and IVIM-DWI was performed before and eight

weeks after LRT). Their results indicated that the ADC and D values obtained after LRT were significantly higher than those recorded before treatment, but the f values were significantly lower than those recorded before LRT. In the responder group, the ADC and D values were significantly increased, and the f values were significantly reduced after LRT. No significant differences were detected in the nonresponder group. Based on these findings, IVIM effectively predicts and evaluates the response to and efficacy of LRT. In these studies, the potential explanation for the inconsistency in the blood perfusion parameters D* and f may be that they represent different types of perfusion in various aspects, with the former usually reflecting the blood flow rate in capillaries and the latter mainly reflecting blood volume (Table 1).

Systemic therapy

Changes in volume are often not obvious in the early stage of targeted therapy for HCC. Compared to traditional imaging methods, IVIM-DWI has more advantages in the early evaluation of the HCC response to targeted therapy[55-59]. Wagner *et al*[56] revealed that the D value of viable tumor regions in malignant liver tumors was significantly lower than that of necrotic tumor tissue but higher than that of fibrotic tumor regions. Joo *et al*[55] used IVIM-DWI to evaluate the efficacy of the vascular blocker CKD-516 against rabbit VX2 liver tumors and found that the D* and f values of the treatment group were noticeably reduced at four hours. Based on these studies, IVIM-DWI is useful to assess early responses to tumor vascular blockers[56]. Yang *et al*[57] investigated the values of IVIM-DWI in evaluating the response of 35 nude mice with HCC to sorafenib. Compared to the values recorded at baseline and in the control group, the ADC and D values of the treatment group at each time point were significantly higher, while the f value was significantly decreased at 7 d and increased at 21 d. The values of ADC, D, and f were significantly correlated with the necrotic fraction. Lewin *et al*[58] used IVIM parameters to evaluate the efficacy of sorafenib treatment in patients with advanced HCC. The f values of responder patients were obviously increased at two weeks and two months after treatment, while these values decreased in nonresponder patients. Therefore, the authors propose that the f value is useful as a reliable marker to evaluate sorafenib treatment efficacy in patients with advanced HCC. Shirota *et al*[59] used IVIM-DWI to evaluate the responses of patients with HCC undergoing sorafenib treatment and found that the D value at baseline was significantly higher in the responder group than in the nonresponder group. The sensitivity and specificity of the D value for evaluating the treatment response were 100% and 67%, respectively (Table 2).

Immunotherapy for HCC is an emerging method with promising results; it exerts an antitumor effect without affecting tumor size. Functional imaging methods will play an important role in evaluating the response to immunotherapy. Andersson *et al*[60] evaluated the response of patients with HCC to intratumoral injections of the immune primer ilixadencel using IVIM-DWI and a histogram analysis. Seventeen patients with HCC were enrolled in this study. Their results showed that the 10th percentile of D* decreased significantly after treatment to baseline, and significant correlations were identified between the 10th percentile and median D value. Chen *et al*[61] reported that both pretreatment IVIM-DWI and DCE-MRI parameters, especially ADC and slope, may predict progression-free survival and overall survival in patients with HCC receiving lenalidomide (a dual antiangiogenic and immunomodulatory agent) as second-line therapy. Recently, the application of immune checkpoint inhibitors in tumors has become a new research hotspot. Subsequently, IVIM-DWI will inevitably play a valuable role in predicting the response to and evaluating the efficacy of tumor immunotherapy.

PREDICTION OF POSTOPERATIVE RECURRENCE

Some researchers have reported the value of IVIM-DWI in predicting recurrence and prognosis after the surgical resection of HCC. Microvascular invasion (MVI) is one of the main factors affecting postoperative recurrence or survival among patients with HCC. IVIM-DWI predicts HCC MVI prior to surgery[62]. Wei *et al*[63] prospectively studied the predictive value of preoperative IVIM-DWI and conventional imaging characteristics for MVI. The results of the univariate analysis showed that the characteristics that were significantly correlated with HCC MVI were decreased ADC values, decreased D values, and irregular circumferential enhancement. In the multivariate analysis, only the D value was an independent risk factor for HCC MVI (the AUC was 0.815). Zhao *et al*[64] and Li *et al*[65] reported similar results. Zhang *et al*[66] studied 157 patients undergoing HCC resection and found that D values might serve as a marker for predicting HCC recurrence after hepatectomy and that the predictive capability would be improved if it was combined with age and the alpha-fetoprotein level.

PREDICTING GENE EXPRESSION

Recently, some studies have indicated that IVIM-DWI predicts gene expression in patients with HCC [67-69]. We recently investigated the correlations of HCC IVIM-DWI parameters with angiopoietin-2

Table 1 Summary of locoregional therapy studies

Ref.	Country	Subject number	Key findings
Juan *et al* [46], 2019	China	20	After TACE, the ADC and Dslow values of HCC increased significantly, and the value of Dfast decreased significantly; the f value did not change markedly.
Wu *et al* [47], 2019	China	55	Compared with nonresponders, the mean, median, and 25th percentile of the PF, ADC, and ADCtotal were higher in responders, while the skewness and kurtosis of PF, kurtosis of ADC and ADCtotal were lower
Lin *et al* [48], 2016	China	118	Before TACE, significant differences in ADC, Dslow and Dfast were observed between the effective and ineffective groups. After TACE, the effective group exhibited lower Dfast and higher ADC and Dslow values than the ineffective group. The tumor regression rate was negatively correlated with Dfast but positively correlated with ADC and Dslow
Park *et al* [50], 2014	Korea	44	The preoperative D* value was significantly increased in the good lipiodol uptake group compared with the poor uptake group after TACE, while the ADC, D, and f values were not significantly different between these two groups
Jia F *et al* [51], 2020	China	56	ROC curve analyses revealed that the combined model including APT SIs and D values was better able to predict the tumor response to TACE than the individual parameters
Wu L *et al* [52], 2017	China	30	The ADCtotal ratio and D ratio measured 24-48 h after TACE were independent predictors of the response to TACE of patients with HCC and showed stronger associations with PFS than mRECIST criteria
Hectors *et al*[53], 2020	United States	24	The ADC and D values of HCC were significantly increased at six weeks after radioembolization, while the D* values were significantly reduced, with no significant change in f values
Server *et al* [54], 2019	Turkey	15	The ADC and D values after LRT were significantly higher than those measured before treatment, while the f values were significantly lower than those recorded before LRT. In the responder group, the ADC and D values were significantly increased after LRT, whereas the f values were significantly reduced

TACE: Transarterial chemoembolization; ADC: Apparent diffusion coefficient; HCC: Hepatocellular carcinoma; PF: Perfusion fraction; ROC: Receiver operating characteristic; APT: Amide proton transfer; SIs: Signal intensities; PFS: Progression-free survival; LRT: Locoregional therapy.

Table 2 Summary of systemic therapy studies

Ref.	Country	Subject number	Key findings
Joo *et al*[55], 2014	Korea	21	The D* and f values of the treatment group were significantly decreased at four hours. The sizes of the decreases in f and fD* at four hours were negatively correlated with the tumor size at 7 d of follow-up
Wagner *et al* [56], 2012	France	48	The D values of viable tumor regions in malignant liver tumors were significantly lower than those of necrotic tumor tissue but higher than those of fibrotic tumor regions
Yang *et al* [57], 2017	China	35	Compared with the values at baseline and those recorded in the control group, the ADC and D values in the treatment group were significantly higher at each time point, whereas the f values decreased significantly at 7 d and increased at 21 d
Lewin *et al* [58], 2011	France	12	The f values increased significantly in responder patients at two weeks and two months after treatment but decreased in nonresponder patients. The f value was useful as a reliable marker to evaluate sorafenib treatment efficacy in patients with advanced HCC
Shirota *et al* [59], 2016	Japan	9	The D values at baseline were significantly higher in the responder group than in the nonresponder group. The sensitivity and specificity of the D values for evaluating treatment response were 100% and 67%, respectively

ADC: Apparent diffusion coefficient; HCC: Hepatocellular carcinoma.

(Ang-2) and transketolase (TKT) expression[67]. We observed significantly higher D* and f values in the high Ang-2 expression group than in the low Ang-2 expression group, and the values of D* and f were positively correlated with the Ang-2 expression levels . On the other hand, the ADC and D values of the TKT high expression group were significantly lower than those of the TKT low expression group, and the ADC and D values were negatively correlated with TKT expression. Based on this result, IVIM-DWI noninvasively predicts Ang-2 and TKT expression in HCC before surgery. Shi *et al*[68] performed IVIM-DWI of 52 patients with HCC and identified four IVIM-derived histogram metrics with the capability for differentiating Ki67 expression, with *P* values less than 0.05. By establishing a diagnostic model based on a logistic regression model, the AUC value for diagnosing high Ki67 expression was 0.861. The results of this study suggest that the histogram indicators obtained from IVIM-DWI scanning can accurately predict the Ki67 expression status.

CONCLUSION

IVIM-DWI accurately and precisely reflects tissue structures and pathophysiological changes and has important application value for HCC differentiation, pathological grading, and predicting and evaluating the treatment response. However, the factors affecting IVIM-DWI measurement results are complicated and diverse[8,20,25,70-76]. Factors including the number, distribution, and fitting methods of b values, other physiological activities (such as gland secretion and flow), ROI settings, scanning devices and field strength, imaging acquisition methods, and motion artifacts all affect data quality[23,25,34,41]. Increased standardization of data acquisition and analysis is imperative to facilitate the generation of reliable IVIM-DWI biomarker measures that are broadly applicable[74,77,78]. In addition, recent studies have shown that IVIM-DWI modeling of the perfusion component is constrained by the diffusion component, and a reduced D slow measure leads to artificially higher PF and D fast measures [75,76]. These results should also be considered in the design of future IVIM-DWI studies. We postulate that with advances in imaging technology and further in-depth research, IVIM-DWI will certainly play a more prominent role in the diagnosis and treatment of HCC.

Abstract

Liver cancer is the third leading cause of cancer-related death worldwide with primary type hepatocellular carcinoma (HCC). Factors, including carcinogens, infection of hepatitis viruses, alcohol abuse, and non-alcoholic fatty liver disease (NAFLD), can induce HCC initiation and promote HCC progression. The prevalence of NAFLD accompanying the increased incidence of obesity and type 2 diabetes becomes the most increasing factor causing HCC worldwide. However, the benefit of current therapeutic options is still limited. Intrahepatic immunity plays critically important roles in HCC initiation, development, and progression. Regulatory T cells (Tregs) and their associated factors such as metabolites and secreting cytokines mediate the immune tolerance of the tumor microenvironment in HCC. Therefore, targeting Tregs and blocking their mediated factors may prevent HCC progression. This review summarizes the functions of Tregs in HCC-inducing factors including alcoholic and NAFLD, liver fibrosis, cirrhosis, and viral infections. Overall, a better understanding of the role of Tregs in the development and progression of HCC provides treatment strategies for liver cancer treatment.

Key Words: Hepatocellular carcinoma; Regulatory T cells; Alcoholic fatty liver disease; Non-alcoholic fatty liver disease; Treatment; Clinical trials

INTRODUCTION

Liver cancer is the third leading cause of cancer-related death worldwide with 8.3% of death ratio, following lung and colorectal cancers[1]. The most common type of primary liver cancer is hepatocellular carcinoma (HCC) and the second type is cholangiocarcinoma[2]. Factors, including carcinogens (*e.g.*, aflatoxin B1), infection of hepatitis viruses, alcohol abuse, and non-alcoholic fatty liver disease (NAFLD), can induce HCC and promote HCC progression[3-5]. In addition, accompanying the increasing incidence of obesity and type 2 diabetes (T2D), NAFLD becomes an increasing factor that causes HCC worldwide[6,7].

Surgical resection is a curative treatment option for the early stage of HCC. However, most cases in HCC were found in the late stage. In addition, other minimally invasive local therapies, such as radiofrequency ablation and microwave ablation, and systemic therapy, such as tyrosine kinase inhibitors, are treatment options for patients who are not suitable for surgery[8]. Furthermore, immunotherapy by targeting checkpoint inhibitors [*e.g.*, anti-programmed cell death protein 1 (PD-1)/programmed death-ligand 1 (PD-L1) antibodies] shows benefits against advanced HCC in the clinic. A combination treatment by blocking both PD-L1 (*e.g.*, atezolizumab) and vascular endothelial growth factor (VEGF) (*e.g.*, bevacizumab) is one of the best first-line treatments for advanced HCC[9]. Other potential immunotherapy options including T cell-mediated therapy such as chimeric antigen receptor-engineered T cells[10-12], peptide-based vaccines[13-15], and micro ribonucleic acids (miRNAs)-mediated therapies[16], are undergoing investigations for HCC treatment.

Intrahepatic immunity including both innate and adaptive immune responses plays pivotal roles in the development and progression of HCC, especially for T cells[17]. Among them, the imbalance between effector CD4 and/or CD8 T cells and regulatory T cells (Tregs) induces immunotolerance and promotes HCC progression[18,19]. Factors impacting the balance of effector T cells and Tregs include gut microbiota, transforming growth factor-beta (TGF-β), and treatments such as trans-arterial chemoembolization[18-20], *etc.* The expression of cytokines such as interleukin (IL)-2, IL-5, interferon (IFN)-γ was increased with an increased ratio of cytotoxic T lymphocytes (CTLs)/Tregs with the treatment of Lenvatinib, a multiple kinase inhibitor, while the expression of T-cell immunoglobulin mucin-3 (Tim-3) and CTL-associated antigen-4 (CTLA-4) was decreased on Treg cells[21]. Therefore, modulating the Treg frequency and the expression of related cytokines are critically important for anti-tumor immunotherapy.

In this review, functions of Tregs on HCC causing factors such as alcoholic liver disease (ALD), NAFLD, liver fibrosis, and cirrhosis are discussed. In addition, molecules mediated Treg functions and therapeutic options by targeting Tregs are summarized. Moreover, clinical trials by targeting Tregs to modulate immune response were analyzed.

TREGS IN CHRONIC LIVER DISEASE

Tregs in ALD

As immunosuppressive cells, Tregs play a pivotal role in chronic liver diseases, including ALD. For example, chronic-binge alcohol exposure in C57BL/6 mice induced the reduction of Treg cells, but increased T helper 17 cells (Th17) cells and the production of IL-17[22]. Treatment with ginsenoside F2

can ameliorate ALD by increasing the frequency of Foxp3$^+$Tregs and decreasing IL-17-producing Th17 cells compared to control groups[23]. However, the molecular mechanism of how Tregs impact the progression of ALD except for modulation of liver inflammation remains unclear.

Tregs in NAFLD and nonalcoholic steatohepatitis

The balance Th17 cells/Tregs plays an essential role in metabolic diseases by regulating immune response and glucose and lipid metabolism[8]. The lower Treg (forkhead box P3$^+$/FOXP3$^+$) and higher Th17 cell (IL-17-producing cells) numbers were found in portal or periportal tract in livers of adult NAFLD patients, whereas more Tregs were shown in pediatric NAFLD patients[24]. In addition, severe liver inflammation was positively associated with intralobular expression of FOXP3 in pediatric patients but was positively associated with higher expression of IL-17 and lower expression of FOXP3 in adult patients, indicating the role of Tregs in NAFLD is age-dependent. Intrahepatic imbalance of Th17/Treg cells promotes the progression of NAFLD, accompanying higher expression of inflammatory cytokines such as IL-6, IL-17, and IL-23 in both serum and liver[25]. Feeding a high-fat diet (HFD) can impact the balance of Th17/Treg cells and Th1/Th2 cells of CD4 T cells in mesenteric lymph nodes (MLN). In addition, those CD4 T cells can potentially migrate into the liver to promote liver inflammation to result in NAFLD progression[26]. The effects of CD4 T cells in MLN on liver inflammation and fat accumulation can be ameliorated by administration of antibiotics and probiotics, indicating an important role of gut microbiota in NAFLD pathogenesis[26].

Dywicki *et al*[27] showed intrahepatic Tregs were increased in high-fat high-carbohydrate (HF-HC) diet-induced nonalcoholic steatohepatitis (NASH) in BALB/c mice. In addition, depletion of adaptive immunity aggregated HF-HC diet-induced NASH in recombination activating 1-knockout BALB/c mice. Although Tregs showed an anti-inflammation effect in ALD[23], adoptive transfer of Tregs increased steatosis and serum level of alanine aminotransferase (ALT), indicating that Tregs enhance the progression of NAFLD[27]. Another study also showed that increasing Tregs in subcutaneous adipose tissue induced by adoptive transfer of Tregs from healthy C57BL/6J mice to high-fat HFD (HFHFD)-fed mice increased hepatic steatosis during NAFLD development[28].

Mechanistically, the formation of neutrophil extracellular traps during NASH progression can induce Treg differentiation from naïve CD4 T cells, which is dependent on Toll-like receptor 4 (TLR-4) and involved in NASH-HCC progression[29].

Tregs in liver fibrosis and cirrhosis

Progression of chronic liver disease, including ALD and NAFLD, can promote the development of liver fibrosis and its advanced stage liver cirrhosis. However, there are no currently available therapies that can treat or reverse liver cirrhosis. Deng *et al*[30] reported that co-infusion with human amniotic mesenchymal stromal cells (hAMSCs) and Tregs can prevent mild liver fibrosis. Tregs play a critical role in the secretion of hepatocyte growth factor (HGF) and cell differentiation of hAMSCs.

Furthermore, an imbalance of Th17 cells/Tregs was also shown in cirrhotic patients with hepatitis B virus (HBV) infection. The frequency of Tregs was reduced in peripheral blood, while the frequency of Th17 cells was increased, resulting in a decreased Treg/Th17 ratio as a potential diagnostic marker for decompensated liver cirrhosis[31]. Another study also showed that the frequencies of both Tregs and Th17 cells were increased in the blood of patients with HBV infection and cirrhotic livers but with a higher extent in Th17 cells, resulting in an increased ratio of Th17/Treg, compared to the control group [32]. In addition, the mRNA levels of proinflammatory cytokines IL-1β, IL-6, and tumor necrosis factor (TNF)-α, as well as the protein expression of nuclear factor κB in the liver were significantly increased in HBV-infected liver and cirrhotic liver compared to healthy controls. Another study also showed that HBV infection can induce IL-8/C-X-C motif chemokine receptor 1/TGF-β signaling to provoke Treg polarization, resulting in suppression of anti-tumor immunity and enhance of HCC metastasis[33]. Moreover, the frequency of Tregs in blood and plasma levels of IL-35 were increased and positively related to viral load in HCV infected patients with cirrhosis and HCC[34].

Tregs in HCC

A meta-analysis showed that a higher infiltration of CD3 T cells, CD8 T cells, and natural killer cells was associated with better overall survival (OS), disease-free survival (DFS), and recurrence-free survival (RFS). In contrast, a higher infiltration of Tregs and neutrophils indicated lower OS and DFS[35]. Another report also showed that an increase of Tregs or a decrease of M1 macrophages (proinflammatory phenotype) were associated with a poor prognosis of HCC patients[36]. C-C chemokine receptor type 4 (CCR4)$^+$Tregs are predominant Tregs that are recruited in tumor tissue of HCC associated infection of hepatitis viruses, which is associated with HCC resistance to sorafenib treatment[37]. The frequency of CD127^{low}, CD25$^+$, CD4$^+$, Tregs was increased significantly in the peripheral venous blood of HCC patients compared to healthy controls[38]. In addition, the serum levels of TGF-β1 and IL-10 in HCC patients were positively associated with the Treg population in the blood, which were decreased post-operation and chemotherapy treatments. C-C motif chemokine ligand (CCL) 5 expression on circulating tumor cells in HCC patients can attract Tregs to induce an immunosuppressive environment, one of the mechanisms for CTC escaping immune surveillance[39].

The expression of immune checkpoint proteins in the HCC microenvironment impacts Tregs and antitumor immunity. PD-L1^{+}neutrophils, Tregs, and neutrophil to lymphocyte ratio were significantly increased in peripheral blood of patients with poorly differentiated HCC with a worse prognosis compared to that in patients with highly-moderately differentiated HCC[40]. Zhou *et al*[41] reported that tumor-associated neutrophils can induce the infiltration of the macrophages and Tregs from HCC mice or patients *via* producing CCL2 and CCL17, resulting in HCC progression and resistance to sorafenib. CTLA-4 on Tregs in HCC impacts dendritic cell function by downregulating CD80/CD86 on dendritic cells (DCs)[42]. Therefore, blockade of CTLA-4 in HCC can improve DC-mediated anti-tumor immunity.

Treatment with tivozanib, a tyrosine kinase inhibitor, can suppress Tregs by inhibiting receptor tyrosine kinase c-Kit (CD117)/stem cell factor (SCF) axis and increased CD4^{+}PD-1^{+}T cells, resulting in a significant improvement in OS of HCC patients[43]. Treatment with Lenvatinib also can inhibit IL-2 mediated Treg differentiation except for decreasing PD-L1 expression in HCC cells[44]. Overall, the balance between Tregs with other T cells plays a vital in liver diseases, including the initiation and progression of HCC (Figure 1).

Furthermore, alteration of intrahepatic immunity is associated with HCC prognosis and treatment (Figure 2). An increase of Tregs, Th2, and Th17 T cells, as well as M2 macrophages, is usually and positively associated with HCC progression in patients, whereas an abundance of CD8 T cells, Th1 T cells, and M1 macrophages is associated with HCC therapy and good prognosis for HCC patients[45]. Single-cell RNA sequencing technologies have been applied to investigate the immune landscape of HCC samples to illustrate the subtypes of immune cells in HCC and their gene expressing profiles, as well as immune cell interactions, such as DCs with Tregs or CD8 T cells[46].

IMPORTANT MOLECULES MEDIATED TREG FUNCTION AND METABOLISM

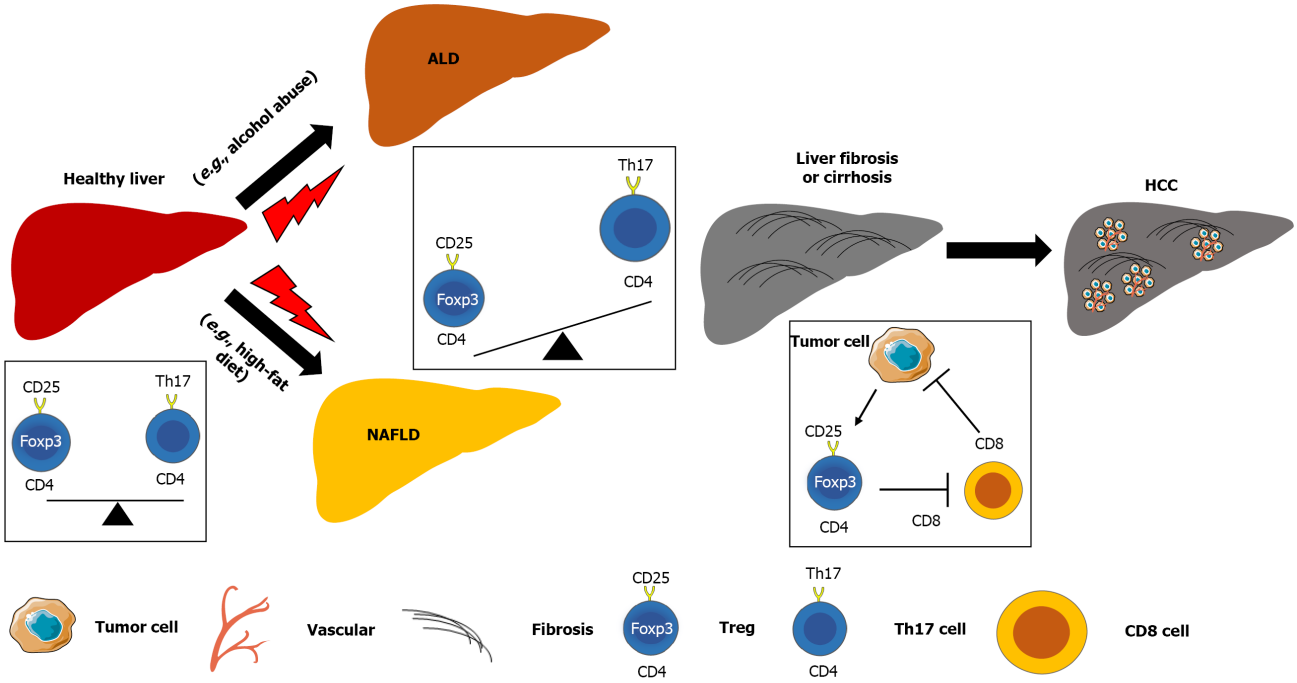
HIF-1α

Hypoxia-inducible transcription factors (HIFs) regulate cell metabolism, proliferation, and migration in low oxygen or hypoxic environment, as well as angiogenesis[47]. It has been reported that the expression of HIF-1 alpha (HIF-1α) was higher in HCC tissues compared to that in corresponding adjacent tissues. In addition, overexpression of HIF-1α was associated with poor outcomes of HCC in human patients[48]. Chronic intermittent hypoxia can promote NASH progression *via* regulating the balance of Th17/Treg by inducing the expression of HIF-1α[49].

Gal-9

Tregs can be subclassified into inflamed-tissue related memory Tregs (mTregs) and non-related resting Treg (rTregs). During HBV infection, mTregs were increased accompanying liver inflammation and liver injury evidenced by an increase of serum ALT level, but not rTregs[50]. The S-type lectin galectin-9 (Gal-9) was increased in the HBV-infected liver, contributing to T cell depletion and exhaustion by binding Tim-3[51]. For example, activation of Gal-9/Tim-3 signaling in concanavalin A-induced mouse hepatitis suppressed the induction of effector T (Teff) cells and the production of IFN-γ[52]. In addition, the Gal-9/Tim-3 signaling pathway plays an important role in the expansion of mTregs[50].

GDF15



The expression of growth differentiation factor 15 (GDF15) was positively related to the frequency of Tregs in HCC. GDF15 can promote the suppressive effect of natural Tregs *via* binding with its unrecognized receptor CD48 on T cells to inhibit the function of homology and U-box containing protein 1, which can degrade FOXP3[53]. Thus, neutralizing GDF15 by an antibody can eradicate HCC and enhance anti-tumor immunity.

microRNAs

Hepatic expression of microRNA-195 (miR-195) was reduced in NAFLD development, accompanying an increased ratio of Th17/Treg ratio in the blood, as well as the expression IL-17, CD40, and TNF-α in rat liver[54]. Overexpression of miR-195 can maintain the balance of Th17/Treg to ameliorate NAFLD and liver inflammation. Many miRNAs can regulate Th17/Treg cell balance in NAFLD such as miR-29c *via* interacting with insulin-like growth factor binding protein 1/IGFBP1)[55]. In addition, other microRNAs such as miR-155[56,57], miR-423-5p[58], and miR-1246[59] play important roles in modulating the balance of Tregs with Th17 cells and their functions in liver disease.

TLRs

Activation of TLR signaling pathway can suppress the effect of Tregs on adaptive immune response, which is in part dependent on microbial production-induced expression of IL-6[60]. TLR9-deficiency increased the frequency of Treg cells in the intestine, resulting in a decrease of IL-17 and IFN-γ producing Teff cells[61]. The imbalance of Treg/Teff cells compromised immune response to oral

DOI: 10.3748/wjg.v28.i27.3346 **Copyright** ©The Author(s) 2022.

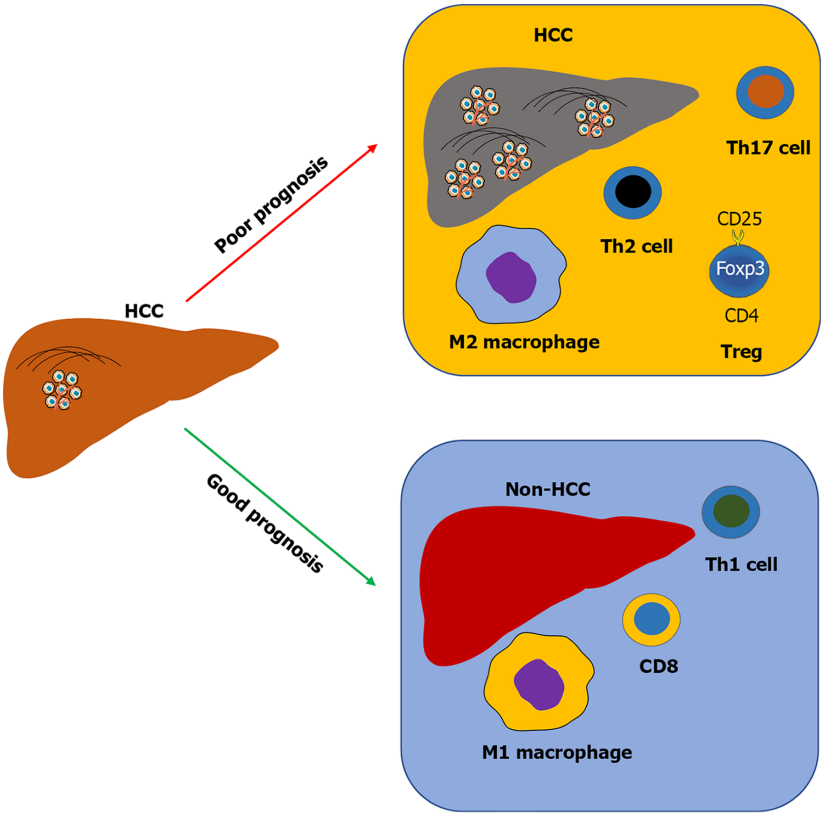
Figure 1 The imbalance of regulatory T cells and effector T cells promotes the progression of chronic liver diseases and hepatocellular carcinoma. Chronic liver diseases such as alcoholic liver disease and non-alcoholic fatty liver disease induced by factors such as alcohol abuse and high-fat diet, respectively, can induce liver fibrosis, cirrhosis, and even hepatocellular carcinoma. The imbalance of regulatory T cells with T helper 17 cells or CD8 T cells is involved in the pathogenesis of liver inflammation, fibrosis, and cancer progression. ALD: Alcoholic liver disease; HCC: Hepatocellular carcinoma; NAFLD: Non-alcoholic fatty liver disease; Treg: Regulatory T cells; Th: T helper.

infection, which can be reversed by reconstitution of gut flora deoxyribonucleic acid (DNA)[61]. In addition, the antibiotic treatment caused gut microbiota dysbiosis and recapitulated TLR9 deficiency-induced impaired immune response.

Yes-associated protein (YAP)

Yes-associated protein (YAP), a coactivator and a corepressor of the Hippo signaling pathway, plays a vital role in Tregs *in vivo* and *in vitro*[62]. Blocking YAP-mediated activation of activin can improve anti-tumor immunity *via* regulating TGF-β/mothers against decapentaplegic homolog (SMAD)[62]. Similarly, blockage of TGF-β signaling can compromise Treg function to improve anti-tumor immune response[63], which may expand the population of quiescent Tregs, $CD4^+CD25^-Foxp3^+$.

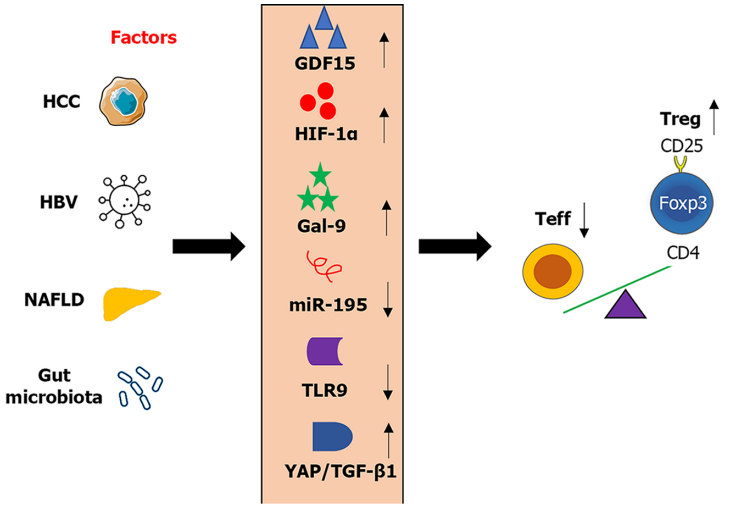
The above-mentioned molecules can modulate Treg metabolism and function as potential molecular targets for HCC treatment. In addition, modulation of these molecules can potentially recover the balance of Tregs with other tumor-infiltrating immune cells to activate anti-tumor immunity (Figure 3).



TREATMENT OPTIONS

Modulation of microRNAs

Administration of miR-26a can reduce the frequency of Tregs and the concentrations of alpha-fetoprotein, des-gamma carboxyprothrombin, and VEGF in Balb/c mice with diethylnitrosamine-induced HCC[64]. The suppressive effects of miR-26a on HCC growth and angiogenesis are mediated by targeting IL-6/signal transducer and activator of transcription 3 (Stat3) signaling[65] and HGF/HGF receptor (HGFR/c-Met) signaling[66], respectively. In addition, miR-26a inversely regulated the expression of F-box protein 11 (FBXO11), which was upregulated and played an oncogenic role in HCC [67].



Adoptive transfer of cells

Adoptive transfer of Tregs attenuated triptolide-induced liver injury, while depletion of Tregs showed the opposite effect, indicating that Tregs contribute to the progression of liver injury[68]. Another study showed that adoptive transfer of hepatic stellate cell (HSC)-stimulated Tregs can significantly decrease liver injury in mice with autoimmune hepatitis by inducing the balance of Treg/Th17 ratio[69]. In addition, the adoptive transfer of HSCs promoted the differentiation of Tregs and decreased Th17 cells,

Figure 3 Factors mediated the imbalance of regulatory T cells/effector T cells. Factor such as Hepatitis B virus, gut microbiota, and non-alcoholic fatty liver disease, as well as hepatocellular carcinoma tumor cells, can modulate several important molecules produced in the liver. Alteration of these molecules has been associated with the change of frequency and/or function of regulatory T cells in chronic liver disease, resulting in an imbalance of regulatory T cells/effector T cells. HCC: Hepatocellular carcinoma; HBV: Hepatitis B virus; NAFLD: Non-alcoholic fatty liver disease; Teff: Effector T cells; Treg: Regulatory T cells; GDF: Growth differentiation factor; HIF: Hypoxia-inducible transcription factors; Gal: Galectin; miR: micro ribonucleic acid; TLR: Toll-like receptor; YAP: Yes-associated protein; TGF-β: Transforming growth factor-beta.

resulting in amelioration of liver injury[70]. Deng *et al*[30] reported that co-infusion with hAMSCs and Tregs can prevent mild liver fibrosis. Tregs play a critical role in the secretion of HGF and cell differentiation of hAMSCs.

Table 1 Treatment options for hepatocellular carcinoma by targeting regulatory T cells and relative signaling pathways

Treatment	Targets	Functions	Ref.
CCR4 antagonist	CCR4	Administration of a CCR4 antagonist or N-CCR4-Fc, a neutralizing pseudo-receptor that can block Tregs accumulation in HCC, can enhance therapeutic efficacy to PD-1 blockade and sorafenib	Gao *et al*[37], 2022
miR-26a	IL6/Stat3 and HGF/c-Met	The suppressive effects of miR-26a on HCC growth and angiogenesis are mediated by targeting IL-6/signal transducer and activator of transcription 3 signaling and HGF/HGFR/c-Met signaling, respectively	Yang *et al*[65], 2013; Yang *et al*[66], 2014
GDF15 neutralizing antibody	GDF15/CD48	Inhibiting GDF15 function by a neutralizing antibody can effectively eradicate HCC and promote a tumoricidal immune response in mice	Wang *et al*[53], 2021
Supplementation of *Lactobacillus rhamnosus* GG or its culture supernatant	The ratio of Treg and Th17 cells	Supplementation of *Lactobacillus rhamnosus* GG or its culture supernatant can ameliorate chronic alcohol-induced liver injury by reducing hepatic inflammation, enhancing intestinal barrier integrity, and inducing balance in the ratio of Treg and Th17 cells to reduce alcoholic-induced liver injury	Chen *et al*[22], 2016; Wang *et al*[72], 2013; Wang *et al*[73], 2012
Prohep, a novel probiotic mixture	Gut microbiota and Treg differentiation	Probiotic treatment regulated T-cell differentiation in the gut by reducing Th17 polarization and increasing the differentiation of anti-inflammatory Treg cells, by increasing the abundance of beneficial bacteria, such as *Prevotella* and *Oscillibacter*	Li *et al*[74], 2016
Anti-PD-1 and anti-PD-L1 antibodies	PD-1 and PD-L1	Another study also showed that Treg-mediated inhibition of IFN-γ production and cytotoxicity of CD8 T cells can be partially reduced by anti-PD-1 and anti-PD-L1 antibodies in HCC	Langhans *et al*[76], 2019
Dual anti-PD-1/VEGFR-2 therapy	VEGFR-2 and PD-1	Dual therapies increased CD8 T cell infiltration and activation, reduced Tregs and infiltration of $CCR2^{+}$monocytes, as well as the phenotype of tumor-associated macrophages (the M1/M2 ratio) in HCC tissue	Shigeta *et al*[75], 2020
Anti-CTLA-4 monoclonal antibody	Tregs	Treg depletion-mediated by anti-CTLA-4 monoclonal antibody (clone 9H10) restored the function of tumor antigen-specific CD8 T cells, with a synergistic effect with anti-PD-1 treatment	Lee *et al*[77], 2020
Resveratrol	Tregs and immunosuppressive cytokines including TGF-β1 and IL-10	Treatment with resveratrol, a natural phenol, can inhibit H22 (a mouse HCC cell line)-induced orthotopic HCC tumor growth *via* decreasing the frequency of $CD8^{+}CD122^{+}$Tregs and M2-like macrophages in mice	Zhang *et al*[79], 2020

CCR: C-C chemokine receptor; HGF: Hepatocyte growth factor; HGFR: Hepatocyte growth factor receptor; HCC: Hepatocellular carcinoma; PD-1: Programmed cell death protein 1; miR: micro ribonucleic acid; IL: Interleukin; GDF: Growth differentiation factor; Treg: Regulatory T cells; Th: T helper; IFN: Interferon; VEGFR: Vascular endothelial growth factor receptor; CTLA: Cytotoxic T lymphocyte-associated antigen; TGF-β: Transforming growth factor-beta.

Modulation of gut microbiota

Depletion of Tregs in the intestine caused an increase in the abundance of *Firmicutes* and intestinal inflammation[71]. Supplementation of *Lactobacillus rhamnosus* GG or its culture supernatant can ameliorate chronic alcohol-induced liver injury by reducing TNF-α expression *via* inhibition of TLR4- and TLR5-mediated hepatic inflammation[72], as well as amelioration of intestinal barrier integrity and suppression of alcohol-induced endotoxemia[73]. In addition, the culture supernatant can balance the ratio of Treg and Th17 cells to reduce alcoholic-induced liver injury[22].

Treatment with Prohep, a novel probiotic mixture, significantly inhibited the HCC growth compared to the control group, resulting in an abundance of beneficial bacteria, such as *Prevotella* and *Oscillibacter* [74]. This study also showed that probiotic treatment regulated T-cell differentiation in the gut by reducing Th17 polarization and increasing the differentiation of anti-inflammatory Treg cells.

Blockade of immune checkpoints

Dual anti-PD-1/VEGF receptor-2 therapy increased CD8 T cell infiltration and activation, reduced Tregs and infiltration of $CCR2^{+}$monocytes, as well as the phenotype of tumor-associated macrophages (the M1/M2 ratio) in HCC tissue[75]. Another study also showed that Treg-mediated inhibition of IFN-γ production and cytotoxicity of CD8 T cells can be partially reduced by anti-PD-1 and anti-PD-L1 antibodies in HCC[76].

Treg depletion-mediated by anti-CTLA-4 monoclonal antibody (clone 9H10) restored the function of tumor antigen-specific CD8 T cells, with a synergetic effect with anti-PD-1 treatment[77].

Other treatments

CCR4 expression in Tregs accompanied with an increased expression IL-10 and IL-35, resulting in suppression of CD8 T cells and HCC progression. Administration of a CCR4 antagonist or N-CCR4-Fc, a

Table 2 Clinical trials by targeting regulatory T cells to modulate the immune response

Trial	Phase	Treatment	Results	Ref.
NCT02476123	I	Anti-CCR4 antibody mogamulizumab	Treg depletion induced by anti-CCR4 antibody (mogamulizumab), in combination with anti-PD-1 antibody (nivolumab) showed antitumor activity and increased $CD8^+$ T cell infiltration	Doi *et al*[78], 2019; Sánchez-Fueyo *et al*[83], 2020
NCT02166177	I	Intravenous infusion of ex vivo expanded Tregs	Treg transfer can transiently increase circulating Tregs and inhibit anti-donor T cell responses in patients with liver transplants	Fueyo *et al*[83], 2020
NCT02166177	I	Autologous Treg therapy	To defect safety and efficacy study of regulatory T cell therapy in liver transplant patients	Whitehouse *et al* [84], 2017
NCT01624077	I	Injection of Tregs	To defect safety and efficacy study of regulatory T cell therapy in liver transplant patients	Whitehouse *et al* [84], 2017
NCT03654040	I	A single dose of alloantigen-reactive Tregs (arTreg) (≥ 90 × 10^6 total cells)	It is a single-center, prospective, open-label, non-randomized clinical trial exploring cellular therapy to facilitate immunosuppression withdrawal in liver transplant recipients	Cvetkovski *et al* [85], 2021
NCT03577431		arTreg-CSB (2.5 × 10^6 cells)		
NCT02260375	I	Infusion of mesenchymal stromal cells	MSC infusion in liver transplant recipients slightly increased circulating Treg/memory Treg over baseline, without a statistically significant, but not in the control group	Casiraghi *et al* [86], 2021
NCT02027116	I	DNA vaccine GLS-6150	GLS-6150 decreases Treg cell frequency and enhances HCV-specific T cell responses without significant side effects	Han *et al*[87], 2020
NCT02174276	II	GS-4774, a yeast-based therapeutic vaccine	Treatment with GS-4774 increased T-cell functions by increasing the production of IFN-γ and TNF and reducing the cell number of Tregs	Boni *et al*[88], 2019
NCT02360592	IV	Combined therapy with interferon plus IL-1 and hepatitis B Vaccine	Combination therapy increased the level of hepatitis B surface antigen with partial restoration of Tregs and NK cells	Wu *et al*[89], 2019
NCT02072486	None	Sorafenib, a multiple kinase inhibitor	Treatment with sorafenib can significantly suppress extracellular signal-regulated $kinases^+$ FMS-like tyrosine $kinase\ 3^+$ Tregs and myeloid-derived suppressor cells to benefit the survival of HCC patients	Kalathil *et al* [90], 2019

CCR: C-C chemokine receptor; CSB: Co-stimulatory blockade; PD-1: Programmed cell death protein 1; Treg: Regulatory T cells; MSC: Mesenchymal stromal cells; DNA: Deoxyribonucleic acid; GLS: Glutaminase; IFN: Interferon; TNF: Tumor necrosis factor; IL: Interleukin; NK: Natural killer; FMS: Feline McDonough sarcoma.

neutralizing pseudo-receptor that can block Tregs accumulation in HCC, can enhance therapeutic efficacy to PD-1 blockade and sorafenib[37]. Treg depletion induced by anti-CCR4 antibody (mogamulizumab), in combination with anti-PD-1 antibody (nivolumab) showed antitumor activity and increased CD8+ T cell infiltration[78].

Treatment with resveratrol, a natural phenol, can inhibit H22 (a mouse HCC cell line)-induced orthotopic HCC tumor growth *via* decreasing the frequency of $CD8^+CD122^+$Tregs and M2-like macrophages in mice[79].

Ren *et al*[80] reported that Tregs were further increased in HCC patients compared to healthy and cirrhosis controls, as well as in HCC patients with Barcelona clinic liver cancer (BCLC) stage C compared to that in HCC patients with BCLC stage B. The authors also showed that treatment with microparticles-transarterial chemoembolization dramatically decreased Treg cell proportion at 1-2 wk post-treatment. Overall, the treatment options for HCC associated with Treg regulation were summarized in Table 1.

CLINICAL TRIALS

Tregs display multiple roles in the development and progression of HCC. The ratio of Treg/Th17 cells in peripheral blood can be applied to monitor immune tolerance as immune markers in liver transplantation[81]. The balance of Treg/Th17 cells or other effector T cells is essential for suppressing autoimmune diseases and cancers[82]. Therefore, treatments including diverse immunomodulatory therapies can regulate Tregs to enhance the antitumor immune response. In Table 2, potential therapies in clinical trials were summarized. Treatments including infusion of Tregs[83-85] and mesenchymal stromal cells (MSCs)[86], vaccines[87-89], and kinase inhibitors[90].

CONCLUSION

Tregs modulate the intestinal and intrahepatic immune response, contributing critically important roles in the gut-liver axis. Functional changes of Tregs are involved in the pathogenesis of chronic liver diseases, such as ALD and NAFLD, causing factors for HCC. Several important molecules investigated in recent studies are summarized and targeting them may potentially treat HCC by modulating Treg function and/or frequency. Clinical trials are undergoing to further explore the new treatments for HCC, which modulate the function of the frequency of Tregs. In the future, multi-omic analysis including metabolic and proteomic data for Treg metabolism and function during the progression of HCC is critical to illustrate the underlying mechanisms of Tregs in HCC pathogenesis and find out new therapeutic targets.

Abstract

Single-incision laparoscopic surgery (SILS), or laparoendoscopic single-site surgery, was launched to minimize incisional traumatic effects in the 1990s. Minor SILS, such as cholecystectomies, have been gaining in popularity over the past few decades. Its application in complicated hepatopancreatobiliary (HPB) surgeries, however, has made slow progress due to instrumental and technical limitations, costs, and safety concerns. While minimally invasive abdominal surgery is pushing the boundaries, advanced laparoscopic HPB surgeries have been shown to be comparable to open operations in terms of patient and oncologic safety, including hepatectomies, distal pancreatectomies (DP), and pancreaticoduodenectomies (PD). In contrast, advanced SILS for HPB malignancy has only been reported in a few small case series. Most of the procedures involved minor liver resections and DP; major hepatectomies were rarely described. Single-incision laparoscopic PD has not yet been reported. We herein review the published SILS for HPB cancer in the literature and our three-year experience focusing on the technical aspects.

Key Words: Hepatectomy; Hepatopancreatobiliary cancer; Laparoendoscopic single-site surgery; Pancreatectomy; Pancreaticoduodenectomy; Single-incision laparoscopic surgery

INTRODUCTION

Single-incision laparoscopic surgery (SILS), also known as laparoendoscopic single-site surgery, is an advanced minimally invasive procedure that leaves a single small incision after surgery. Since it was introduced in the 1990s, numerous studies regarding SILS for minor procedures have been published, such as for cholecystectomy[1]. In contrast, its application in advanced hepatopancreatobiliary (HPB) surgeries is rarely reported[2-8].

By minimizing the incision number, SILS has the potential advantages of less pain, fewer wound complications, faster recovery, and favorable cosmesis. Nevertheless, the existing literature regarding minor SILS fails to reach a conclusion. For example, single-incision laparoscopic cholecystectomies (SILC), the most published SILS to date, have been shown to be superior in marginal benefits such as less pain and shorter hospital stays, while incisional hernia and bile duct injury are considerable drawbacks[9-11]. Nevertheless, it is always necessary to remove a sizable specimen during advanced HPB surgeries. One of the small incisions in standard multi-incision laparoscopic surgeries (MILS) has to be enlarged to fit the specimen size as well as the only incision in SILS. Since incisional hernia has become a minor issue, patient and oncologic safety has attracted more concern in advanced single-incision laparoscopic HPB surgeries. MILS has been shown to be comparable to open operations for HPB malignancy, including hepatectomies, distal pancreatectomies (DP), and pancreaticoduodenectomies (PD), in recent years[12-24]. The fact that only a few case series of SILS for HPB cancer have been reported reflects the limitations of surgical techniques, instrumental technology, and adequate training. Although our previous study showed that practicing minor SILS helps to achieve competence in this technique for complicated diseases[25], there is still a long way to go. In this review, we conducted an updated literature search for SILS to treat malignant HPB diseases that were reported in English. Studies involving robotic technology were excluded. Meanwhile, a summary of our three-year experience focusing on the technical aspects was described.

SINGLE-INCISION LAPAROSCOPIC HEPATECTOMY (SILH) FOR MALIGNANCY

Literature review

Eight original studies[26-33] and 20 case reports[34-47] were identified with a cutoff value of 10 malignant cases. The outdated reports of sequential studies from the same groups were excluded. Nearly all the case reports involved minor liver resections [partial hepatectomies, monosegmentectomies, and left lateral sectionectomies (LLS)]. Three of the eight original articles described major hepatectomies (resection of over two segments), including nine right hemihepatectomies (RHs), 34 left hemihepatectomies, and seven right posterior sectionectomies (RPSs)[27,29,32] (Table 1). Most procedures were performed for malignant diseases. Five nonrandomized comparative studies between SILH and multi-incision laparoscopic hepatectomies (MILHs) were conducted[26-28,30,32]. Hyun *et al*[26] reported a shorter postoperative hospital stay and comparable pathologic features for minor SILH compared with minor MILH; long-term survival outcomes were absent. Mittermair *et al*[27] showed less blood loss, a lower number of patients with blood loss > 25 mL, and more blood transfusions in the major SILH group; no local tumor recurrence occurred during a median follow-up of 61 mo. Tsai *et al*[28] reported a shorter operative time and shorter postoperative hospital stays in the SILH group for LLS but not partial hepatectomies of segment 5-6; the 1-, 3-, and 5-year overall and recurrence-free survival rates for hepatocellular carcinoma were similar in both the SILH and MILH groups. Wang *et al*[30] showed shorter postoperative hospital stays for patients without cirrhosis undergoing LLS in the SILH group; the 1-year recurrence-free survival rates for hepatocellular carcinoma were similar in both the SILH and MILH groups. Han *et al*[32] reported a shorter operative time, less blood loss, and earlier

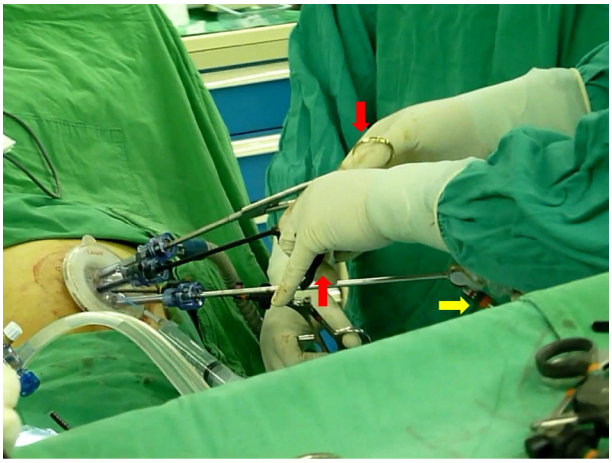
SILH: Single-incision laparoscopic hepatectomies; MILH: Multi-incision laparoscopic hepatectomies; RH: Right hemihepatectomies; LH: Left hemihepatectomies; RAS: Right anterior sectionectomies; RPS: Right posterior sectionectomies; LLS: Left lateral sectionectomies; MR: Minor resections including monosegmentectomies and partial hepatectomies.

enteral feeding in the SILH group; the safety resection margins were similar in both the SILH and MILH groups. However, long-term survival outcomes were not presented.

In summary, SILH was superior to MILH in terms of shorter postoperative hospital stays in three comparative studies of minor liver resections[26,28,30]. For major hepatectomies, the two related studies came to a different conclusion. While Mittermair C *et al*[27] declared more substantial blood loss requiring transfusion in SILH, Han *et al*[32] reported a shorter operative time, less blood loss, and earlier enteral feeding for the single port technique.

Our experience and technical review

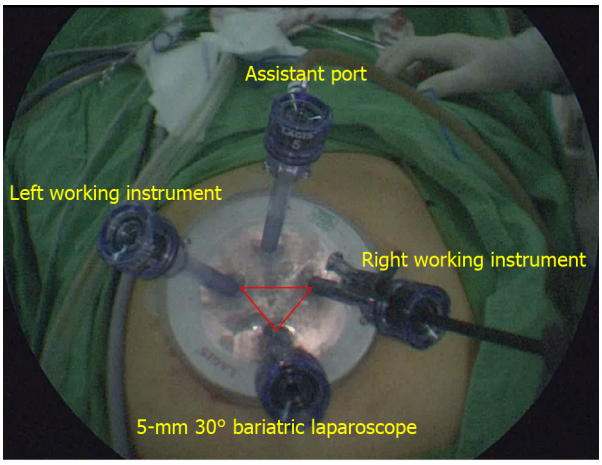
While SILC[25] and single-incision laparoscopic common bile duct exploration (SILCBD)[48] have become our standard of care for cholelithiasis over the past decade, we have developed more advanced SILS for malignant HPB diseases since 2016. The principles of standard MILS and surgical oncology were strictly followed to maintain a high standard of patient safety and prognosis. From July 2018 to July 2021, 31 SILH procedures were performed by the first author to treat malignant diseases (Table 1). Eleven (35.5%) major liver resections involved three RHs, two left hemohepatectomies (LHs), three right anterior sectionectomies (RASs), and three RPSs. The others were 20 (64.5%) minor resections. An additional port was needed in five (16.1%) procedures, and no open conversion occurred. There was one case of surgery-related 90-d mortality due to pulmonary infection.



Patient position

During formal hepatic surgery, the patient was placed in a reverse Trendelenburg position with arms abducted and legs split. The surgeon stood between the patient's legs to facilitate hepatic hilar management. The assistant held the laparoscope at the patient's left/right side (between the left/right limbs) during right/Left hepatic resections. For LLS, the operative table could be tilted toward the patient's right side. In contrast, it should be tilted toward the patient's left side during RPS. Lateral decubitus positions were not favored because of impaired access to the hepatic hilum.

Port and instrument



By using conventional laparoscopic ports and straight instruments through a 1.5-2.5 cm skin incision and multiple nearby punctures on the deep fascia, the costs can be reduced to a minimum. This single-incision multipuncture approach is only suitable for short-duration procedures such as SILC[25], SILCBDE[48], and minor SILH because of its inherent problem of air leakage. Otherwise, a 3-6 cm single skin and deep fascia incision with a homemade (surgical glove) or commercial multichannel port is recommended for major liver resections to remove a sizable specimen at the end of surgery.

We recommended 30° rigid laparoscopes and conventional straight instruments, as the latter could be manipulated more intuitively than curved or articulated instruments. A 5-mm 30° bariatric laparoscope can effectively prevent "sword fighting" between the light cable of the laparoscope and the instrument handles (Figure 1). The port configuration was arranged in a reverse triangular pattern (Figure 2). The 30° laparoscope passed through the lower port and the fulcrum to the upper part of the operative field to provide an overlooking view, and the two working instruments reached the lower part of the

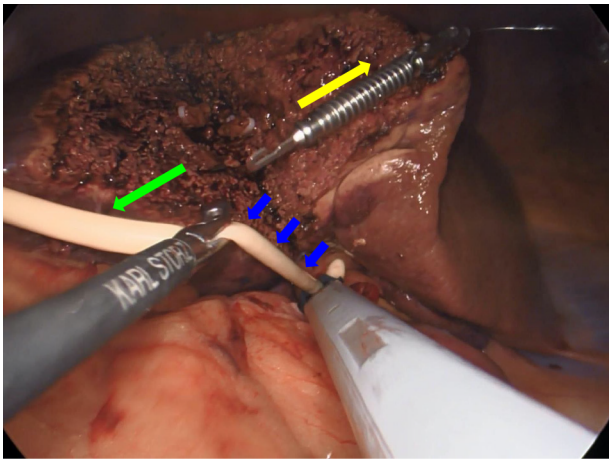
Figure 2 The port configuration was arranged in a reverse triangular pattern on a commercial multichannel port in a single-incision laparoscopic surgery. The upper port served as an assistant port for additional traction or suction/irrigation.

operative field to perform the procedure. This configuration decreased collisions between the laparoscope and the working instruments. Finally, a fourth port could be used to perform traction or suction.

Abdominal incision



Considering that upper abdominal incisions induce more pain, we avoided making incisions above the umbilical level. A praumbilical incision with downward extension is good for performing single-incision laparoscopic LH or RH. Otherwise, a transverse incision at the same level of the umbilicus is suitable to perform single-incision laparoscopic RAS or RPS. The incision should be tailored to the specimen size for its removal.

Hepatic inflow control

For temporary hepatic inflow control (Pringle maneuver), we favored the use of a 14-French Foley catheter (Figure 3), which was introduced by Huang *et al*[49] in 2018. During selective inflow control for major SILH, such as the extra Glissonian approach or individual dissection, a laparoscopic right angle dissector or a goldfinger retractor is useful. As the working instruments were kept aligned with the laparoscope in SILH, it was difficult to see the distal ends of the instruments. Laparoscopic working instruments with curved or flexible ends were easier to manipulate under limited vision.

Parenchymal transection

To avoid interinstrumental collisions, auxiliary traction devices substituted for assistant tractions. We preferred EndoGrab™ (Virtual Ports Ltd., Hod Hasharon, Israel), while gravity would provide counter-

Figure 3 The hepatoduodenal ligament was encircled by a 14-French Foley catheter (blue arrows) for temporary hepatic inflow control (Pringle maneuver) in a single-incision laparoscopic right posterior sectionectomy. An EndoGrab™ (Virtual Ports Ltd., Hod Hasharon, Israel) provided traction in the direction of the yellow arrow, while gravity created countertraction (green arrow).

traction in some instances (Figure 3). The transection line should be kept aligned with the laparoscopic view at all times.

Single-incision laparoscopic suturing technique

Suturing is the last line of defense in patient safety for not only open but also laparoscopic surgeries. It can be applied in various difficult situations to stop bleeding or biliary leakage. While performing single-incision laparoscopic suturing technique (SILST), forward-backward, vertical, and rotational movements are frequently used rather than transverse movements. The curved tip of a Maryland dissector helps to form a loop made by two instruments nearly parallel to each other (Figure 4). In addition, monofilament threads make loops more easily in SILST due to their high elasticity.

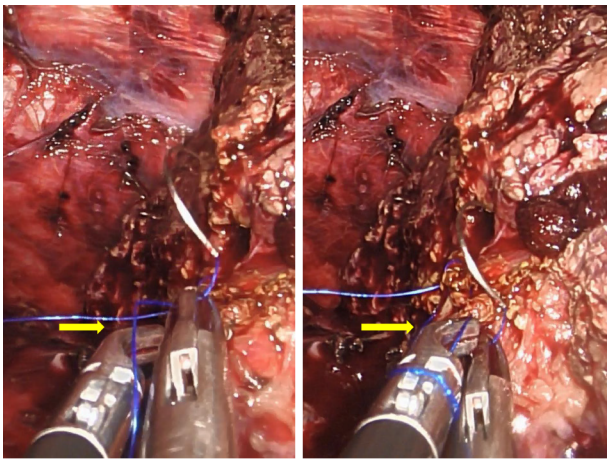
SINGLE-INCISION LAPAROSCOPIC PANCREATECTOMY FOR MALIGNANCY

Literature review

While most reported single-incision laparoscopic DP (SILDP) was used to treat benign lesions, only three original studies[50-52] (Table 2) and three case reports[53-55] of SILDP for cancer were identified with a cutoff value of 10 cases. Series containing neoplasms with uncertain behavior were excluded, as well as outdated reports of sequential studies from the same groups. All three original studies were nonrandomized comparative studies. SILDP was compared with multi-incision laparoscopic DP (MILDP) in two studies and the robotic approach in the remaining study. SILDP was associated with a longer operative time, reduced postoperative pain, and lower spleen/splenic vessel preservation rates than MILDP[50,51]. Robotic DP and splenectomies required a longer operating room time than SILDP and splenectomies, but the operative durations were similar[52]. All the patients except one undergoing DP for neoplasms had R0 resections, and six (7 ± 6.6) lymph nodes were noted according to the pathologic reports. However, long-term survival outcomes were not provided.

For PD, one of the most complicated abdominal surgeries, we could not find any report of applying a single-incision laparoscopic technique.

Our experience and technical review



We have no experience in performing SILDP for malignancy. Two patients with benign lesions (serous cystadenoma) underwent this procedure in the last two years. However, we have performed single-incision laparoscopic PD (SILPD) on three patients since May 2020. All procedures were accomplished successfully without conversion to MILS or open operations. No major complications, such as postoperative pancreatic fistula, occurred, and there was no 90-day mortality. The pathology report was distal cholangiocarcinoma in the first patient and pancreatic ductal adenocarcinoma in the other two. Routine D2 Lymph node dissections and intraoperative frozen sections for checking resection margins were carried out for oncologic safety. To the best of our knowledge, this report is the first experience of SILPD in the world and is now under submission.

SILDP: Single-incision laparoscopic distal pancreatectomies; MILDP: Multi-incision laparoscopic distal pancreatectomies; SILDPS: Single-incision laparoscopic distal pancreatectomies and splenectomies; RDPS: Robotic distal pancreatectomies and splenectomies; N/A: Not applicable.

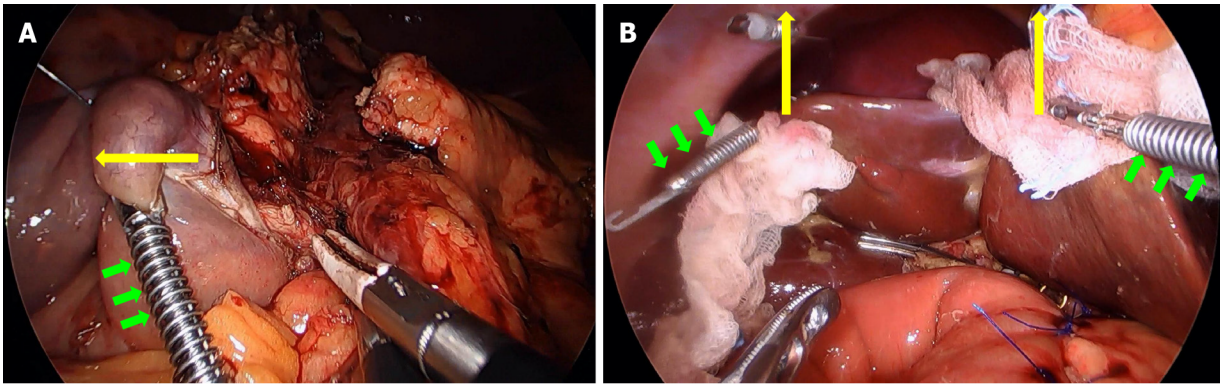
DOI: 10.3748/wjg.v28.i27.3359 **Copyright** ©The Author(s) 2022.

Figure 4 The curved tip of a Maryland dissector (yellow arrow) helped to form a loop made by two instruments nearly parallel to each other in a single-incision laparoscopic surgery. A monofilament thread was used in this case.

Patient position

During a single-incision laparoscopic pancreatectomy, the patient was placed in a reverse Trendelenburg position with the surgeon standing between their legs. The operative table could be tilted toward the patient's right side for SILDP. The assistant held the laparoscope at the patient's left side (between the left limbs) during the resection phase and hepaticojejunostomy during SILPD. In contrast, the assistant held the laparoscope at the patient's right side (between the right limbs) during SILDP and pancreaticojejunostomy/gastrojejunostomy in SILPD.

Port and instrument



Major pancreatic and hepatic resections shared the same port configuration and instrument selection. Sometimes the surgeon had to cross the instruments to achieve an adequate approaching angle (the angle between the two working instruments) or solve a handedness problem, such as suturing a left target with a right-handed instrument.

Abdominal incision

In order to achieve less pain and better cosmesis, a several centimeter praumbilical incision with downward extension is good for performing a SILDP or a SILPD. The incision should be enlarged to facilitate specimen removal in a retrieval bag at the end of surgery if necessary.

Auxiliary traction

EndoGrab™ (Virtual Ports Ltd., Hod Hasharon, Israel) could be applied on the duodenum to be resected during the uncinate process dissection in a SILPD (Figure 5A). It was very useful for liver retraction during SILDP or SILPD (Figure 5B).

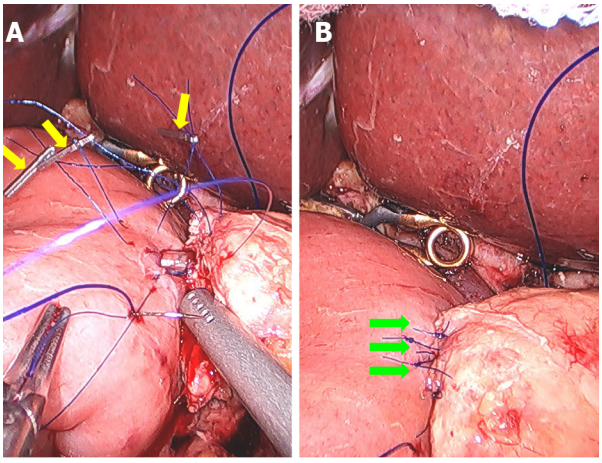
DOI: 10.3748/wjg.v28.i27.3359 **Copyright** ©The Author(s) 2022.

Figure 5 EndoGrab™ (Virtual Ports Ltd., Hod Hasharon, Israel) provided auxiliary traction during single-incision laparoscopic pancreatectomies. A: EndoGrab™ (green arrows) was applied on the duodenal 3rd portion to provide lateral traction (yellow arrow) during the uncinate process dissection in a single-incision laparoscopic pancreaticoduodenectomy (SILPD); B: Two EndoGrabs™ (green arrows) facilitated upward traction (yellow arrows) of the liver edges during the reconstruction phase in a SILPD. Two pieces of gauze served as cushions to minimize the traumatic effect of EndoGrabs™ (green arrows) on the liver.

SILST

Unlike hepatectomies, suturing constituted a major component in pancreatic resections, such as hemostasis (Video 1), closure of the pancreatic stump in a DP and creation of the three anastomoses (pancreaticojejunostomy, hepaticojejunostomy, and gastrojejunostomy) in a PD. During critical duct-to-mucosa pancreaticojejunostomy, we recommend interrupted suturing for the inner layer to prevent anastomotic stricture caused by a "purse-string effect". Holding the interrupted stitches with metallic clips before tying them helped to gain adequate space for the anastomosis. In our experience, up to three metallic clips could be used simultaneously during anastomosis without confusing the surgeon (Figure 6). While performing SILST, all the principles of suturing in open surgery and MILS should be followed on the basis of high quality. Otherwise, additional port(s) should be utilized to minimize anastomotic leakage.

Step-by-step procedures in SILPD



While the laparoscopic view was unchanged during SILPD, the procedural steps were standardized to shorten the operative time as well as the learning curve. These steps include division of the gastrocolic ligament, release of the hepatic flexure of the transverse colon, Kocher maneuver (Station 13 Lymph nodes harvest), division of Treitz's ligament, pulling of the proximal jejunum to the patient's right side, creation of the tunnel under the pancreatic neck, division of the proximal jejunum and its mesentery, division of the lesser omentum and distal stomach (Station 5 and 6 Lymph node harvest), division of the pancreatic neck, dissection of the uncinate process (Station 14 Lymph nodes harvest), Station 8 and 12 Lymph node harvest, division of the common hepatic duct, removal of the gallbladder from the liver bed, specimen extraction, pancreaticojejunostomy, hepaticojejunostomy, gastrojejunostomy, and peritoneal irrigation with drainage.

SINGLE-INCISION LAPAROSCOPIC BILE DUCT RESECTION (SILBDR) FOR MALIGNANCY

Literature review

We only found one case report of SILBDR in the literature[56]. Two patients with Bismuth–Corlette type I perihilar cholangiocarcinoma underwent the procedure, including hepatoduodenal ligament lymphadenectomy, successfully with good recovery. The resection margins of the proximal and distal bile ducts were free from tumor invasion, but long-term follow-up was pending. The authors concluded that SILBDR can be optional in strictly selected patients with Bismuth–Corlette type I perihilar cholangiocarcinoma.

As perihilar cholangiocarcinoma is relatively rare to diagnose in an early stage, more advanced procedures, such as hemihepatectomies, caudate lobectomies, or PD, are usually performed in addition to bile duct resections for a better prognosis. The feasibility of SILS for resecting advanced-stage perihilar cholangiocarcinoma, an extremely complicated, demanding, and time-consuming procedure, should be considered with caution.

DOI: 10.3748/wjg.v28.i27.3359 **Copyright** ©The Author(s) 2022.

Figure 6 Single-incision laparoscopic suturing technique was applied to a pancreatiojejunostomy. A: Three metallic clips (yellow arrows) were used at the same time during the inner duct-to-mucosa anastomosis of the pancreatiojejunostomy (PJ) in a single-incision laparoscopic pancreaticoduodenectomy; B: Completed inner duct-to-mucosa anastomosis (green arrows) of the PJ.

CONCLUSION

Minor SILH, such as LLS, monosegmentectomies, and partial liver resections, are feasible and safe to treat selected patients with cancer by experienced laparoscopic surgeons. Although the evidence level is low, minor SILH seems to be superior to minor MILH in terms of shorter postoperative hospital stay. The oncologic outcome is comparable for both procedures. Large-scale randomized controlled clinical trials are necessary to address this issue.

Major SILH might be feasible for highly selected patients by experienced laparoscopic surgeons in high-volume centers. The current evidence is limited and fails to determine its position compared with major MILH. Surgical skill refinement and technology advancement are anticipated to overcome this demanding procedure.

Although technically feasible, SILDP has been shown to be associated with longer operative time and lower spleen/splenic vessel preservation rates. Strict patient selection is mandatory for the possible accompanying splenectomy. Well-designed randomized controlled studies are needed to compare this procedure with MILDP. Robotic technology may have a positive effect on minimally invasive DP.

SILPD is just in its infancy, and this is also true for SILBDR. While developing these techniques, patient and oncologic safety should be prioritized. A low threshold to convert the procedures should always be kept in mind.

ACKNOWLEDGEMENTS

We gratefully acknowledge the work of Dr. Hsu JW in assisting with the surgical procedures and the data collection.

Abstract

Colorectal cancer (CRC) is a leading cause of human mortality worldwide. As conventional anticancer therapy not always being effective, there is growing interest in innovative "drug-free" cancer treatments or interventions that improve the efficacy of established therapy. CRC is associated with microbiome alterations, a process known as dysbiosis that involves depletion and/or enrichment of particular gut bacterial species and their metabolic functions. Supplementing patient treatment with traditional probiotics (with or without prebiotics), next-generation probiotics (NGP), or postbiotics represents a potentially effective and accessible complementary anticancer strategy by restoring gut microbiota composition and/or by signaling to the host. In this capacity, restoration of the gut microbiota in cancer patients can stabilize and enhance intestinal barrier function, as well as promote anticarcinogenic, anti-inflammatory, antimutagenic or other biologically important biochemical pathways that show high specificity towards tumor cells. Potential benefits of traditional probiotics, NGP, and postbiotics include modulating gut microbiota composition and function, as well as the host inflammatory response. Their application in CRC prevention is highlighted in this review, where we consider supportive *in vitro*, animal, and clinical studies. Based on emerging research, NGP and postbiotics hold promise in establishing innovative treatments for CRC by conferring physiological functions *via* the production of dominant natural products and metabolites that provide new host-microbiota signals to combat CRC. Although favorable results have been reported, further investigations focusing on strain and dose specificity are required to ensure the efficacy and safety of traditional probiotics, NGP, and postbiotics in CRC prevention and treatment.

Key Words: Colorectal cancer; Traditional probiotics; Next-generation probiotics; Postbiotics; Gut microbiota

Core Tip: The effects of traditional probiotics, next-generation probiotics (NGP), or postbiotics in colorectal cancer (CRC) prevention and complementary therapy can be associated independently or in mutual cooperation with several mechanisms, including suppression of inflammation, enhancing apoptosis of tumor cells, restoring intestinal barrier function, competition with pathogens and by promoting healthy gut microbiota composition and function. Traditional probiotics, NGP, or postbiotics supplementation is also a potential strategy to boost the effectiveness of chemotherapy and immunotherapy, reduce the rate of postoperative complications, and improve the quality of lives of CRC patients.

INTRODUCTION

Colorectal cancer (CRC) is the third most commonly diagnosed cancer in males and the second in females worldwide; thus a significant change in lifestyle is required to facilitate effective CRC prevention[1]. CRC is a heterogeneous disease of the intestinal epithelium, comprising the colon, rectum, and anus. It is characterized by a dysregulated immune response, accumulation of stem cell mutations, intestinal barrier disruption, and dysbiosis, which is often regarded as an unfavorable alteration in gut microbiota composition and function. Up to 90% of CRC risk is thought to be lifestyle-dependent, primarily due to dietary or environmental factors including feeding patterns that modulate consumption of fiber, red and processed meat or alcohol consumption, and low omega-3 fatty acids and vitamin D intake. Obesity, lack of physical activity, and smoking are also significant risk factors that promote CRC-associated microbiota changes[2]. CRC is linked with microbiome alterations, which include depletion and/or enrichment in particular bacterial species that are present in CRC patients (extensively reviewed by Torres-Maravilla *et al*[3], Ternes *et al*[4], Janney *et al*[2], Fong *et al*[5], and Wirbel *et al*[6]).

The human microbiota is a complex ecosystem of bacteria, viruses, eukaryotes, and archea, which can regulate a variety of host physiological functions including digestion, immune response, metabolism, disease pathogenesis, elimination of toxins, and biosynthesis of key compounds such as essential vitamins and cofactors. Microbiota can even modulate gut-brain axis function to alter, for example, anxiety and mood. Symbiotic bacteria that colonize the human gut can be classified into several phyla comprising Bacteroidetes and Firmicutes, followed by Proteobacteria, Fusobacteria, Actinobacteria, Verrucomicrobia, and Spirochaetes. Microbiome composition varies between healthy individuals, as well as in CRC patients[7]. CRC-associated bacteria that have been identified to date include enrichment of *Fusobacterium nucleatum*, *Enterococcus faecalis*, *Streptococcus gallolyticus*, entero-toxigenic *Bacteroides fragilis*, *Escherichia coli*, *Peptostreptococcus* spp., and *Ruminococcus* spp. By contrast, *Lactobacillus* spp., *Bifidobacterium* spp., *Faecalibacterium* spp., *Roseburia* spp., *Clostridium* spp., *Granulicatella* spp., *Streptococcus thermophilus*, and other species of *Lachnospiraceae* family are depleted in CRC (Table 1)[2-5]. These altered microbiota signatures can potentially be used to provide future diagnostics, and their presence/absence may contribute to the pathogenesis or prevention/treatment of CRC. However, the pathophysiological role of dysbiosis in CRC still remains unclear, since microbiota changes may reflect changes in host health status and some bacteria may even confer protection as a compensatory response to disease progression. This complexity is clearly evident by the report of specific bacteria associated with tumor initiation phase (driver bacteria) whereas other bacteria are associated with tumor development during progressive stages of CRC (passenger bacteria). Driver bacteria reportedly contribute to the formation of a tumor microenvironment that is comprised of normal epithelial cells and cancer cells. In this milieu, secreted microbial metabolites trigger damage to normal host cells, thus reprograming their metabolism to change the intestinal microenvironment and microbiome profile towards a more "CRC supportive" composition[8-10]. Potential driver bacteria include *Bacteroides fragilis*, *Escherichia coli*, *Enterococcus Faecalis*, *Bacillus*, *Bradyrhizobium*, *Methylobacterium*, *Streptomyces*, *Shigella*, *Citrobacter*, *Salmonella*, *Intrasporangiaceae*, and *Sinobacteraceae*. On the other hand, passenger bacteria occupy an existing tumor microenvironment where they are thought to either promote or inhibit CRC progression. Reported passenger bacteria include species *Fusobacterium*, *Parvimonas*, *Peptostreptococcus*, *Campylobacter*, *Streptococcus*, *Schwartzia*, *Burkholderiales*, *Caulobacteraceae*, *Delftia*, *Oxalobacteraceae*, *Faecalibacterium*, and *Sutterella*[8-11]. The host gut microbiota and immune system play important roles in CRC prevention and development. Therefore, probiotics, next-generation probiotics

Table 1 Overview of the most relevant bacteria related to colorectal cancer

Enriched bacteria	Depleted bacteria	Ref.
Fusobacterium nucleatum, Peptostreptococcus spp., *Porphyromonas asaccharolytica, Prevotella* spp., *Parvimonas micra, Bacteroides fragilis, Streptococcus gallolyticus, Escherichia coli, Campylobacter* spp., *Shigella* spp., *Enterococcus faecalis*	*Blautia* spp., *Faecalibacterium prausnitzii, Clostridium butyricum, Streptococcus thermophilus, Roseburia* spp.	[4,55-57]

(NGP), or postbiotics could be used as weapons to prevent CRC, to support the treatment and to improve the clinical outcomes in CRC patients.

This minireview summarizes recent CRC findings from clinical, animal and *in vitro* studies, and discusses the efficiency of probiotics, NGP, and postbiotics in CRC prevention and therapy.

TRADITIONAL PROBIOTICS

Probiotics are defined as "live, non-pathogenic microorganisms that, when administered in adequate amounts, may confer a health benefit on the host"[12]. Probiotics have a centuries-long history of safe use as prevention and adjuvant therapy in combating human diseases. They are also promising candidates in modulating human gut microbiota composition and function in CRC patients. Traditional widely used probiotics mainly belong to *Bifidobacterium* spp., *Lactobacillus* spp. and other lactic-acid-producing bacteria, including species belonging to *Streptococcus, Enterococcus*, and *Lactococcus*, complemented by yeasts of the genus *Saccharomyces*. The beneficial effects of probiotics, functioning in a species and/or strain-specific manner, include sustaining a healthy microbiome, reversing dysbiosis, preventing pathogenic infections and mucosal adhesion of pathogens, stabilizing and enhancing intestinal barrier function. Probiotic bacteria may achieve these beneficial functions in part by producing anti-carcinogenic, anti-inflammatory, anti-mutagenic and other biologically important compounds such as short-chain fatty acids (SCFAs), vitamin K, or B-group vitamins[5,7,13,14].

Current research builds on a foundation of work demonstrating that gut microbiota modulation through administration of probiotics and/or prebiotics plays an important role in CRC prevention and therapy. In a randomized, double-blinded, placebo-controlled trial, 60 patients underwent surgical CRC resection, of whom 29 received the probiotic powder (*Bifidobacterium animalis* subsp. *lactis* HY8002 [1 × 10^8 CFU], *Lactobacillus casei* HY2782 [5 × 10^7 CFU], and *Lactobacillus plantarum* HY7712 [5 × 10^7 CFU]) and 31 placebo, for 4 wk, starting at 1 wk preoperatively. The treatment group receiving probiotic powder showed an increase in abundance of *Bifidobacterium*, *Akkermansia*, *Parabacteroides*, *Veillonella*, *Lactobacillus*, *Erysipelatoclostridium* and a reduction in bacteria associated with CRC, such as *Prevotella*, *Alloprevotella*, *Fusobacterium*, and *Porphyromonas*. Lower serum zonulin, improved postoperative bowel function, and postoperative recovery were evident in the probiotic group compared with placebo[15]. In another randomized clinical trial, a group of 31 CRC patients received probiotic supplement *Bifidobacterium longum* BB536 (5 × 10^{10} CFU/2 g/daily) preoperatively for 7–14 d and postoperatively for 2 wk. Attenuated postoperative inflammatory responses (high-sensitivity C-Reactive protein), reduced risk of postoperative infectious complications, and accelerated health recovery after colorectal resection were evident in the treatment group. Hospital stay was significantly shortened and correlated significantly with increased Actinobacteria and decreased Firmicutes after probiotic intervention[16]. Aisu *et al*[17] administered BIO THREE® 2 mg *Enterococcus faecalis* T110, 10 mg *Clostridium butyricum* TO-A, and 10 mg *Bacillus mesentericus* TO-A to 75 CRC patients 15 d prior to the surgery. Incidence of postoperative complications and superficial incisional infections were lower, and these health effects were as shown to associate with an increased mean proportion of beneficial *Bifidobacterium*, postoperatively, even though this organism was not administered as part of the probiotic regime. The change in microbial diversity and improved integrity of the mucosal barrier were also observed by Liu *et al*[18] after *Lactobacillus plantarum* CGMCC 1258, *Lactobacillus acidophilus* LA-11, *Bifidobacterium longum* BL-88 (2.6 × 10^{14} CFU/2 g/daily) administration 6 d preoperatively and 10 d postoperatively to CRC patients. The numbers of beneficial bacteria, including *Bifidobacteria* and *Lactobacilli*, increased in the probiotic group after surgery, whereas they decreased in the placebo group. By contrast, Enterobacteriales and *Pseudomonas*, were decreased in the probiotic group whereas they increased in the placebo group. Based on a number of clinical trials, the preoperative oral intake of probiotics combined with the postoperative treatment in patients who need gastrointestinal surgery is potentially recommended. Larger rigorously controlled clinical trials are required to endorse these preliminary positive outcome studies since avoidance of probiotic use has also been recommended in patients with immunodeficiency and dysbiosis. More studies and the key outcomes are listed in Table 2.

Table 2 Efficiency of probiotics in colorectal cancer prevention and therapy-clinical trials

Probiotic strain/synbiotics	Dose/length of the study	Trial type/sample size	Microbial changes/key outcomes	Ref.
Lactobacillus rhamnosus GG, *Bifidobacterium lactis* Bb12 + inulin enriched with oligofructose	10^{10} CFU and 10 g of prebiotic, 12 wk	Human prevention study-CRC patients (*n* = 15 placebo, *n* = 19 synbiotics), polypectomized patients (*n* =19 placebo, *n* = 21 synbiotics)	↑*Bifidobacterium*, ↑*Lactobacillus*, ↓*Clostridium perfringens*; ↓proliferation rate of colorectal cells and stimulation of peripheral blood mononuclear cells (↑IFNg, ↓IL-2)	Rafter *et al*[58]
Bifidobacterium longum BB536, *Lactobacillus johnsonii* La1	2×10^7 CFU or 2×10^9 CFU, 3 d preoperatively and 3 d postoperatively	CRC patients undergoing elective colorectal resection- Randomized double blind, placebo-controlled study (*n* = 10 placebo, *n* = 21 probiotics)	*B. longum* BB536 did not adhere to colonic mucosa only La1, ↓*Enterobacteriaceae* ↓*Enterococcus*, modulation of local immunity (↑CD3+, CD4+, CD8+, activity of dendritic cells); no clinical effect	Gianotti *et al*[59]
Bifidobacterium longum, *Lactobacillus acidophilus*, *Enterococcus faecalis*	3×10^8 CFU, 3 d (from -5 to -3 d) preoperatively	Single-center prospective randomized control study (*n* = 30 placebo, *n* = 30 probiotics)	↑*Bifidobacterium* and ↓*Escherichia*; ↓endotoxins, D-lactic acid, serum IL-6 and C-reactive protein; ↑serum IgG and IgA; ↓postoperative occurrence of infectious complications of CRC	Zhang *et al*[60]
Bifidobacterium longum, *Lactobacillus acidophilus* and *Enterococcus faecalis*	1:1:1 daily 6×10^7 CFU, 5 d	Perioperative intake of probiotics in CRC patients (*n* = 11 placebo, *n* = 11 probiotics)	↑richness and diversity of mucosal microbes, ↓*Peptostreptococcus*, ↓*Comamonas*, ↓*Fusobacterium*, ↑*Enterococcus*, ↑Proteobacteria; no clinical effect	Gao *et al*[61]
LactoLevure (*Lactobacillus acidophilus* LA-5, *Lacobacillus plantarum*, *Bifidobacterium lactis* BB-12, *Saccharomyces boulardii*)	1.75×10^9 CFU, 0.5×10^9 CFU, 1.75×10^9 CFU, 1.5×10^9 CFU, respectively, 1 d preoperatively and 15 d postoperatively	CRC patients undergoing surgery- Randomized, double-blind, placebo-controlled study (*n* = 80 placebo, *n* = 84 probiotics)	Reduction of the postoperative pneumonia rate, anastomotic leakage and surgical site infections; ↑gene expression of SOCS3; ↑circulating IL-6, TNF-α	Kotzampassi *et al*[62] (NCT02313519)
Colon Dophilus™ [*Bifidobacterium breve* HA-129 (25%), *Bifidobacterium bifidum* HA-132 HA (20%), *Bifidobacterium longum* HA-135 (14.5%), *Lactobacillus rhamnosus* HA-111 (8%), *Lactobacillus acidophilus* HA-122 (8%), *Lactobacillus casei* HA-108 (8%), *Lactobacillus plantarum* HA-119 (8%), *Streptococcus thermopilus* HA-110 (6%), *Lactobacillus brevis* HA-112 (2%), *Bifidobacterium infantis* HA-116 (0.5%)]	10×10^9CFU/ daily, 12 wk	Patients with CRC, concomitantly with irinotecan chemotherapy- Randomized, placebo-controlled study (*n* = 23 placebo, *n* = 23 probiotics)	Reduction in the incidence and severity of chemotherapy induced diarrhea and incidence of enterocolitis.	Mego *et al*[63] (NCT01410955)

NGP

One potential approach to achieve CRC prevention and treatment is through NGP administration. As described above, the most frequently used probiotics belong to *Bifidobacterium* spp. and *Lactobacillus* spp. However, recent studies using metagenomic approaches have revealed the importance of further identification and characterization of commensal species, mainly anaerobic ones, residing in the gastrointestinal tract that play an important role in regulating the immune system and maintaining overall gut health. Growing evidence suggests that dysbiosis may contribute to CRC progression as well as several other diseases[19-22]. Although there is no official definition of NGP, it is generally defined as live microorganisms identified on the basis of comparative microbiota analyses between healthy and sick individuals/animals that, when administered with strain-specificity and in dose dependent manner, confer health benefits on the host[23,24]. Compared with healthy individuals, patients with CRC possess a different compositional structure and physiological activity of the gut microbiota with SCFAs-producing bacteria being depleted. This suggests that SCFAs-producing bacteria might potentially exhibit anti-inflammatory and anticarcinogenic properties, as well as being NGP candidates in CRC prevention and therapy. SCFAs, primarily acetate, propionate, and butyrate, are key physiological metabolites of the microbial fermentation of dietary fiber in the colon. Butyrate is the major energy source for colonocyte homeostasis, promoting growth stimulation and production of protective cytokines that maintain gut barrier integrity and function[14,25-27]. Furthermore, increasing levels of SCFAs in the gut helps to create a favorable microenvironment for beneficial bacteria by inhibiting the growth and adhesion of pathogens, and by enhancing vitamin bioavailability, mineral absorption and promoting mucosal integrity. Most butyrate-producing bacteria in the human colon belong to the Firmicutes phylum, clostridial clusters IV and XIVa, the most dominant species being *Faecalibacterium prausnitzii* and *Eubacterium rectale,* followed by *Eubacterium* spp. as well as *Anaerostipes* spp. and *Roseburia* spp. In addition to butyrate-producing bacteria, other NGP candidates with important regulatory effects on gut homeostasis include *Akkermansia muciniphila*, non-toxigenic *Bacteroides fragilis*, *Propionibacterium freudenreichii,* and some strains of *Bacillus* spp. and *Clostridium* spp., which belong to Generally Recognized As Safe microorganisms[7,28,29].

Chronic oral administration of *Butyricicoccus pullicaecorum* BCRC 81109 (butyrate producing bacteria) to BALB/cByJNarl male mice decreased colon tumor progression over 9 wk. This protection against CRC clinical outcomes was linked to activation of the SCFAs transporter solute carrier family 5 member 8 and/or G-protein-coupled receptor (GPR) 43[30]. Chen *et al*[25] also observed in an *in vivo* animal study that application of butyrate producing bacteria *Clostridium butyricum* ATCC 19398 (2×10^9 CFU/0.2 mL 3 times a week for 12 wk) inhibited intestinal tumor development by an increasing apoptosis of CRC cells, by modulating the Wnt/β-catenin signaling pathway. There was also a reduction in pathogenic bacteria and bile acid-biotransforming bacteria, whereas an increase in beneficial *Lactobacillus* spp. and SCFAs-producing *Rumincoccaceae* and *Eubacterium* spp. was evident. Thus, reduction in colonic secondary bile acids increased cecal SCFAs levels and activated G-protein coupled receptors, GPR43 and GPR109A, which were mechanistically implicated. Growth of CRC cell lines (HCT-116 and SW1116) was significantly inhibited by strains *Bacillus subtilis* ATCC 23857 and *Clostridium butyricum* ATCC 19398, and by their main metabolites bacitracin and butyrate. mRNA levels of important receptors and transcriptional factors related to inflammation for example, TLR4, MYD88, nuclear factor-kappa B (NF-κB), interleukin 22 (IL-22), and survivin were decreased and expression of $p21^{WAF1}$ was increased after treatment of SW1116 cells with *Bacillus subtilis* and *Clostridium butyricum* NGP[31]. Purified components produced by NGP cells were also studied and inhibition of human cancer cell proliferation by controlling the cell cycle was detected. Polysaccharide A purified from *Bacteroides fragilis* NCTC9343 (non-toxigenic) induced the production of the pro-inflammatory cytokine IL-8[32] and aspartic protease Amuc_1434 (recombinant enzyme) from *Akkermansia muciniphila* upregulated the expression of tumor protein 53, increased mitochondrial reactive oxygen species (ROS) levels and promoted apoptosis of LS174T cells[33]. Pahle *et al*[34] employed *Clostridium perfringens* enterotoxin (CPE) in CPE gene therapy to selectively target claudin-3 and claudin-4 expressing colon carcinomas *in vitro* and *in vivo* by using a translation optimized CPE expressing vector. Elevated toxicity of the optimized CPE expressing vector was evident in claudin-positive cells 48 h after the transfection, with toxicity rates of 76%–92% and rapid cytotoxic effects such as membrane disruption and necrosis. Further *in vivo* studies focused on the efficiency of NGP application in CRC are listed in Table 3 and postbiotics derived from NGP are considered below.

POSTBIOTICS

Postbiotics is an extensively researched subject that remains a largely understudied topic in CRC. Due to the phenomenal number and variety of metabolites produced by bacteria, it has been an enormous challenge to isolate and characterize the specific compound/s responsible for the therapeutic efficacy. Moreover, defining safety profiles and appropriate application doses of particular postbiotics in the preclinical and clinical settings may require regulatory guidelines and approvals[5]. The International

Table 3 Efficiency of next-generation probiotics in colorectal cancer *in vivo*

NGP strain	Application	Study/ cohort	Mechanism/effect(s)	Ref.
Akkermansia muciniphila MucT ATCC BAA-835	pasteurized culture 1.5 × 10^8 CFU/100 μL or recombinant Amuc_1100 3 μg (specific outer membrane protein)/2 wk before AOM injection until sacrifice	23-wk *in vivo* animal study, acute colitis was induced by AOM (10 mg/kg) (intraperitoneally) + 2% DSS (in water)-male C57BL/6J mice	Prevention of AOM/DSS-induced tumorigenesis by DNA damage attenuation, cell apoptosis and abnormal proliferation. Significant amelioration of acute colitis, relieved colon shortening and splenomegaly, delayed tumor formation and reduced expression of γH2AX, cleaved caspase 3 and Ki67. Blunted CAC through the expansion and activation of cytotoxic T lymphocytes, indicated by TNF-α induction and PD-1 downregulation	Wang *et al* [67]
Akkermansia muciniphila ATCC BAA-835	1 × 10^8 CFU/mouse every other day (day 7-12), gavage administration	4-wk *in vivo* animal study, CRC induced by mice colon cancer cells CT-26 (1 × 10^6) (subcutaneously)-*n* = 70, male BALB/c mice	*A. muciniphila* colonization significantly increased inhibition rate/anti-cancer effect of FOLFOX (from 48% to 76%) and significantly decreased marker of proliferation-Ki67 (% of positively stained cells)	Hou *et al*[68]
Clostridium butyricum (powder by Kexing Biopharm CO., LTD)	2 × 10^8 CFU/0.2 mL/3 times *per* week, gavage administration	78 d *in vivo* animal study, CAC induced by intraperitoneal AOM (12.5 mg/kg) + 2.5% DSS (in water)-*n* = 30, C57BL/6 mice	Inhibition of NF-κB pathway and apoptosis promotion. Change in the microbiome composition-reduction of Firmicutes to Bacteroidetes ratio. Reduction of incidence and size of CRC and increase of tumor cells apoptosis. Reduction in cytokines including TNF-α, IL-6 and level of COX-2. Decrease in phosphorylation of NF-κB and level of Bcl-2. Increase in Bax expression	Liu *et al*[69]
Clostridium butyricum ATCC 19398 or *Bacillus subtilis* ATCC 23857	2.5 × 10^8 CFU/0.3 mL/3 times *per* week for 28 wk, oral administration	28 wk *in vivo* animal study. CRC induced with DMH (20 mg/kg body weight)/weekly (intraperitoneally)-*n* = 72, male C57BL/6 mice	Inhibition of intestinal tumorigenesis and modulation of immunity and inflammation. Reduction in tumor size and incidence. After supplementation with probiotics, mice showed decreased Th2 and Th17 expression and increased CD4/CD8 expression compared to DMH-treated mice. Reduced gene expression of TLR4–MYD88–NF-κB, IL-22 and increase of $P21^{waf1}$ and Tlr3 mRNA levels in intestinal mucosa	Chen *et al* [31]

AOM: Azoxymethane; CAC: Colitis-associated cancer; CRC: Colorectal cancer; DMH: 1,2-dimethylhydrazine; DSS: Dextran sulfate sodium; FOLFOX: Oxaliplatin, fluorouracil and calcium folinate; IL: Interleukin; NF-κB: Nuclear factor-kappa B; TNF-α: Tumor necrosis factor-alpha.

Scientific Association for Probiotics and Prebiotics (ISAPP) offers expertise in microbiology, microbial physiology, gastroenterology, nutrition, food science and pediatrics. ISAPP recently provided the clear definition and scope of postbiotics to include "preparation of inanimate microorganisms and/or their components that confer a health benefit on the host"[35]. Postbiotics, which exert desired physiological effects to the host, include inactivated microbial cells or cell components (cell surface proteins, endo- or exo-polysaccharides, peptidoglycan-derived muropeptides and teichoic acids) or important metabolites secreted by gut microbiota through a fermentation process or released under certain conditions such as a change in intestinal environment or after lysis (SCFAs including acetate, propionate and butyrate; enzymes; bacteriocins; reuterin; acetoin; organic acids, *etc*)[5,35,36]. Therefore, the isolation and characterization of new postbiotics is a growing field and requires careful biochemical characterization of beneficial mechanisms. Supplementation with postbiotics, can in some cases be an effective and safer strategy to prevent and/or treat diseases, compared with ingestion of viable probiotic bacteria[5].

Microbial metabolites undoubtedly play an important role in CRC pathogenesis. Certain postbiotics exert antitumor activity, including selective cytotoxicity against tumor cells suggesting their therapeutic potential (Figure 1)[5]. For example, SCFAs are well-known inhibitors of epigenetic enzymes histone deacetylases, which play a central role in gene regulation; thus, SCFAs have the ability to induce cell cycle arrest, and/or apoptosis in many cancer cell lines[37]. Cell-free supernatants (CFS) of different *Lactobacillus* and *Bifidobacterium* strains have been shown to induce apoptosis or inhibit proliferation of CRC cell lines[38-40]. Chen *et al*[41] demonstrated that supernatants of *Lactobacillus johnsonii* BCRC17010 and *Lactobacillus reuteri* BCRC14625 strains in high concentrations were able to damage HT-29 cell membranes causing elevated lactate dehydrogenase release. A recent study has reported a potent selective cytotoxicity effect of postbiotic metabolites from *Lactobacillus plantarum* strains *via* anti-proliferative effects and induction of apoptosis in HT-29 cells whilst sparing the normal cells[42]. Cousin *et al* [43] showed that metabolites from *Propionibacterium freudenreichii* ITG-P9, namely propionate and acetate, had induced intrinsic apoptosis of CRC cells, *via* the production and release of SCFAs acting on mitochondria. Moreover, CFS or SCFAs in combination with Tumor Necrosis Factor-Related Apoptosis-Inducing Ligand (TRAIL), increased the pro-apoptotic gene expression (TRAIL-R2/DR5), decreased the anti-apoptotic gene expression of FLIP and XIAP in HT-29 cancer cells and enhanced the cytotoxicity in CRC cells compared to human healthy intestinal epithelial cells. Further control studies are required to delineate specific molecular targets in these models since enhanced toxicity to fermentation induced acidic pH shifts remains a potential protective mechanism.

As inflammation is undeniably linked to carcinogenesis, any postbiotic that inhibits inflammation is also an important candidate acting as anti-tumor agent. It was shown that *Lactobacillus rhamnosus* GG-

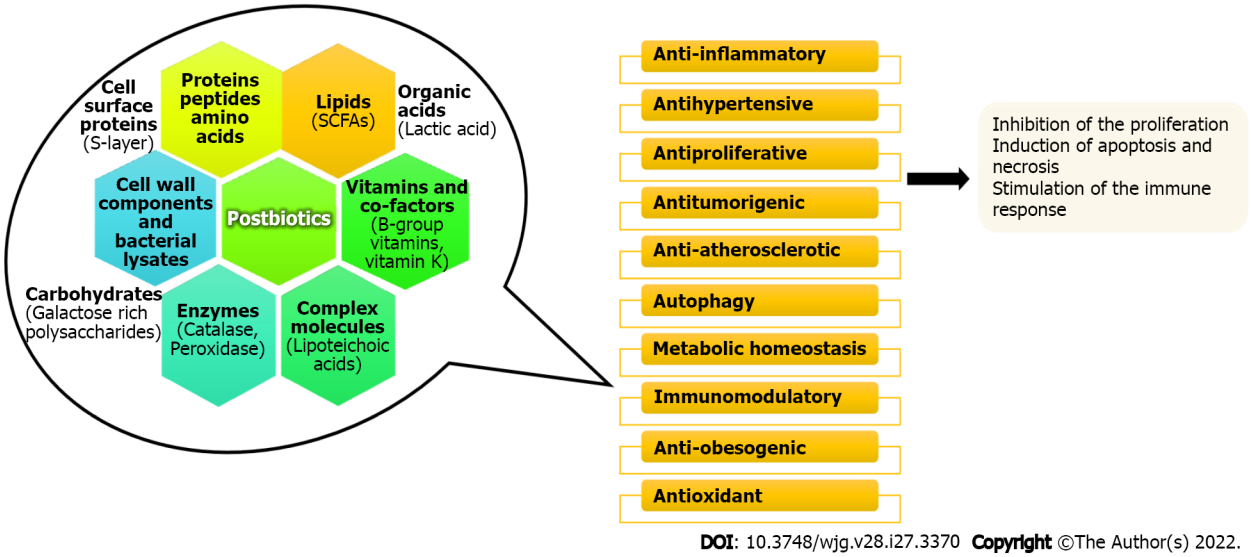

Figure 1 Examples of postbiotics and their proposed activity in patients with colorectal cancer. SCFAs: Short-chain fatty acids.

derived protein p40 can play a role in the prevention of CRC by suppressing intestinal epithelial inflammation, inhibiting epithelial cells apoptosis and by promoting IgA production[44-46]. CFS derived from several other probiotic strains, such as, *Lactobacillus acidophilus*, *Lactobacillus casei*, *Lactobacillus rhamnosus* GG and *Bifidobacterium breve*, were able to downregulate inflammation, exhibit antioxidant activity or maintained intestinal barrier integrity[47-49].

To date, only a few animal studies have been performed to evaluate the effectiveness of postbiotics in CRC prevention and therapy *in vivo*. The stage is now set to expand this work with the use of translational *in vivo* models and clinical trials, which are essential to demonstrate efficacy. Sharma and Shukla [50] observed that CFS from *Lactobacillus rhamnosus* MD 14 MH656799 containing acetamide, acetate, propionate, butyrate, thiocyanic acid and oxalic acid attenuated early colon carcinogenesis in Sprague–Dawley rats (n = 36). The protective mechanism was linked to reduced fecal procarcinogenic enzymes, oxidants, aberrant crypt foci, vis-à-vis downregulating oncogenes (β-catenin, K-ras, Cox-2, NF-κB) and upregulating tumor suppressor p53 gene leading to an almost healthy colon histology. De Moreno de LeBlanc *et al*[51] evaluated the effect of the enzyme catalase as a postbiotic from catalase-producing *Lactococcus lactis* htrA-NZ9000 on the prevention/regression of 1,2-dimethylhydrazine (DMH) induced CRC in BALB/c mice (n = 180-210). Catalase-producing *Lactococcus lactis* increased catalase activity in DMH-treated mice and reduced H_2O_2 levels compared with the control group. Using the histopathological grading scale of chemically induced CRC, mice that received catalase-producing *Lactococcus lactis* had significantly less colonic damage and inflammation (2.0 ± 0.4) compared to control animals that received non-catalase-producing *Lactococcus lactis* (4.0 ± 0.3) or placebo-treated animals (4.7 ± 0.5). Increased antioxidant activity reduced levels of H_2O_2 and ROS involved in CRC onset and progression.

There are also promising results from studies of postbiotics derived from NGP. Recently, numerous *in vitro* studies showed that supernatant from SCFAs-producing bacteria, such as *Butyricicoccus pullicaecorum* BCRC 81109[30], *Clostridium butyricum* ATCC 19398[25], *Propionibacterium freudenreichii* TL142[52], *Propionibacterium acidipropionici* CNRZ80, *Propionibacterium freudenreichii* subsp. *freudenreichii* ITG18, *Propionibacterium freudenreichii* subsp. *shermanii* SI41[53] suppressed CRC cells proliferation and induced apoptosis. The same results were documented by Zhao *et al*[54], where single strain CFS from human *Bacillus* strains BY38, BY40, BY43, BY45 exhibited inhibitory effects on the proliferation of CRC cells in a dose-dependent manner through the induction of cell apoptosis. These results suggest that NGP could represent novel and promising anti-tumor agents against CRC. Further *in vitro* studies focused on the activity of postbiotics derived from different probiotic strains in CRC cell lines are listed in Table 4.

CONCLUSION

Traditional probiotics have utility in the management of CRC as adjuvant treatment, mainly to reduce postoperative complications and to alleviate the side effects of chemotherapy. Antitumorigenic mechanisms of probiotics include the modification of intestinal microbiome, improvement of intestinal barrier integrity, immune potentiation and maintaining gut homeostasis. However, it is well known that the efficiency of probiotics is strain specific. The available clinical data indicate that CRC patients most

Table 4 Efficiency of postbiotics on cancer cells *in vitro*

Probiotic strain	Derived postbiotic	Cell line	Mechanism/effect(s)	Ref.
Lactobacilus casei ATCC334	CFS (ferrichrome)	Caco-2/bbe, SKCO-1, SW620	In CFS, ferrichrome subsequently identified as the responsible molecule that induced apoptosis *via* JNK-DDTI3 signaling axis, thus having tumor-suppressive effect and exerted minimal effect on normal intestinal epithelial cells	Konishi *et al*[70]
Lactobacillus rhamnosus MD 14 MH 656799	CFS (acetate, butyrate, propionate, acetamide, thiocyanic acid, and oxalic acid)	Caco-2, HT-29	CFS with metabolites exhibited both anti-genotoxic and cytotoxic potential against CRC cells	Sharma *et al*[71]
Bifidobacterium adolescentis SPM0212	CFS	Caco-2, HT-29, SW480	CFS significantly inhibited the proliferation of cancer cells	Kim *et al*[39]
Lactobacillus fermentum KCTC 3112	CFS	CCD18-Co, HCT-116, HT-29	Induction of cancer cells apoptosis by CFS up-regulating Caspase-3, Bax, Bak, Noxa, and Bid mRNA expressions	Lee *et al*[38]
Lactobacillus casei (ATCC 334), *Lactobacillus rhamnosus* (GG ATCC 53103)	CFS	HCT-116	Anti-metastatic effects of high molecular weight fractions	Escamilla *et al*[40]
Lactobacillus acidophilus ATCC 4356, *Lactococcus lactis* ATCC 11454, *Lactobacillus casei* ATCC 334, *Lactobacillus reuteri* ATCC 55148, *Saccharomyces boulardii* ATCC MYA-796	CFS	HT-29	Downregulation of the expression of PGE-2 and IL-8 in cancer cells by metabolites of probiotics. CFS differently modulated IL-1β, IL-6, TNF-α, and IL-10 production by human macrophages, suggesting a peculiar anti-inflammatory activity	De Marco *et al*[48]
Lactobacillus casei ATCC 393	Sonicated-cell suspension	CT26, HT-29	Inhibition of cancer cells proliferation and induction of apoptosis	Tiptiri-Kourpeti *et al* [72]
Lactobacillus reuteri PTCC 1655	Sonicated-cell suspension	HT-29-ShE	Anti-metastatic and anti-proliferative effects	Maghsood *et al*[73]
Lactococcus lactis PTCC 1336	Nisin, cell wall, cytoplasmic extract of nisin	SW480	Anti-proliferative effects, associated with the decreased expression of cyclin D1 in SW480 cell line	Hosseini *et al*[74]
Pediococcus pentosaceus FP3, *Lactobacillus salivarius* FP25/FP35, *Enterococcus faecium* FP51	SCFAs (butyrate and propionate)	Caco-2	Significant proliferation inhibition of Caco-2 cells and activation of apoptosis	Thirabunyanon and Hongwittayakorn [75]
Streptomyces levis ABRIINW111	Extracted metabolites	SW480	SW480 growth inhibition, increased Caspase-3 and reduced Ki67 expression in a concentration/time-dependent manner; subG$_1$ phase (apoptosis) increased by metabolites and cell cycle arrest in G$_1$, G$_2$/M and S phase; *p53* gene expression followed SW480 cells treatment significantly	Faramarzian Azimi Maragheh *et al*[76]
Streptomyces sp. MUM256	MUM256 extract	HT-29, Caco-2	Antioxidant properties, cytotoxicity against CRC cells by reduction in viability and induction of apoptosis (depolarization of mitochondrial membrane potential and arrest in subG$_1$ phase)	Tan *et al*[77]
Clostridium butyricum ATCC 19398	SCFAs	HCT-116, HCT-8, Caco-2	Suppression of the Wnt/b-catenin signaling pathway and modulation of the gut microbiota composition.	Chen *et al*[25]

CFS: Cell-free supernatant; CRC: Colorectal cancer; IL: Interleukin; SCFAs: Short-chain fatty acids; TNF-α: Tumor necrosis factor-alpha.

often benefit from combined administration of strains *Lactobacillus acidophilus*, *Lactobacillus casei*, *Bifidobacterium lactis*, and *Bifidobacterium longum*. Use of their combination or in combination with other species is more effective than individual supplementation. Nevertheless, consideration of each CRC patient's health status is still strictly recommended before administering viable probiotics. The gut microbiota is emerging as a contributing factor in the etiopathology of CRC. It is necessary to consider gut microbiota-drug interactions, including composition and metabolic activity of gut microbiota, which can both positively and negatively affect the outcome of CRC therapy. And even though research in this area is still in its infancy, it can be assumed that future clinical treatment and prevention of CRC will focus on supplementing the microbiome with commensal species (NGP candidates) that are predominantly anaerobic. Recent studies indicate that SCFAs-producing bacteria, especially butyrate producers, such as *Akkermansia muciniphila*, *Propionibacterium freudenreichi*, and *Butyricicoccus pullicaecorum* belong to

beneficial NGP that may have applicability in CRC therapy. Furthermore, it was discovered that strains previously defined as potential pathogens appear to possess probiotic properties when these lack key virulence factors, for example non-toxigenic *Bacteroides fragilis* NCTC9343 has positive effects on patient's health. A significant disadvantage of NGP is, above all, their safety as this has not yet been sufficiently confirmed in animal and clinical studies. Safety validation is of particular importance before administering NGP to oncology patients. Although NGP research is experimentally demanding, emerging data shows great potential. Therefore, it is necessary to continue and explore new possibilities of NGP use in the therapy or prevention of diseases, including CRC, especially through clinical trials. Supplementation with postbiotics should be favorable in CRC therapy, because postbiotics have the ability to stimulate immune responses, inhibit cancer cell proliferation, induce apoptosis and necrosis, and they can shape microbiome composition in CRC patients. The advantage of postbiotics is that they do not pose a risk of unwanted infection to the patient, although screening for product contamination will be important. Moreover, it is possible to accurately determine and verify administered doses of a particular postbiotic. However, this emerging research area currently lack *in vivo* or clinical data to assess feasibility. In conclusion, the administration of traditional probiotics, NGP or postbiotics, supported by various experimental studies, is an efficient complementary therapeutic approach to combat CRC. A protective effect of probiotics and postbiotics against CRC onset is also indicated, however, lifestyle changes are recommended as a first line of defense in CRC prevention.

Abstract

Acute pancreatitis (AP) is one of the most common gastrointestinal diseases and remains a life-threatening condition. Although AP resolves to restitutio ad integrum in approximately 80% of patients, it can progress to necrotizing pancreatitis (NP). NP is associated with superinfection in a third of patients, leading to an increase in mortality rate of up to 40%. Accurate and early diagnosis of NP and associated complications, as well as state-of-the-art therapy are essential to improve patient prognoses. The emerging role of endoscopy and recent trials on multidisciplinary management of NP established the "step-up approach". This approach starts with endoscopic interventions and can be escalated to other interventional and ultimately surgical procedures if required. Studies showed that this approach decreases the incidence of new multiple-organ failure as well as the risk of interventional complications. However, the optimal interventional sequence and timing of interventional procedures remain controversial. This review aims to summarize the indications, timing, and treatment outcomes for infected NP and to provide guidance on multidisciplinary decision-making.

Key Words: Pancreatitis; Acute necrotizing pancreatitis; Necrosis; Superinfection; Endoscopy; Surgery

Core Tip: Acute pancreatitis remains a potentially life-threatening disease. Necrotizing pancreatitis (NP) is associated with superinfection and increases the mortality rate. We summarized the current evidence and clinical recommendations of multidisciplinary approaches focusing on conservative, interventional, and surgical treatment. The interventional approach is often required as a first step in treating infected NP, while further options include minimal invasive or an escalation to open surgical treatment. Although this "step-up approach" is well-established, the exact timing, sequence, and procedure choice remain controversial; this review aims to summarize current evidence and to provide guidance for decision making in clinical practice.

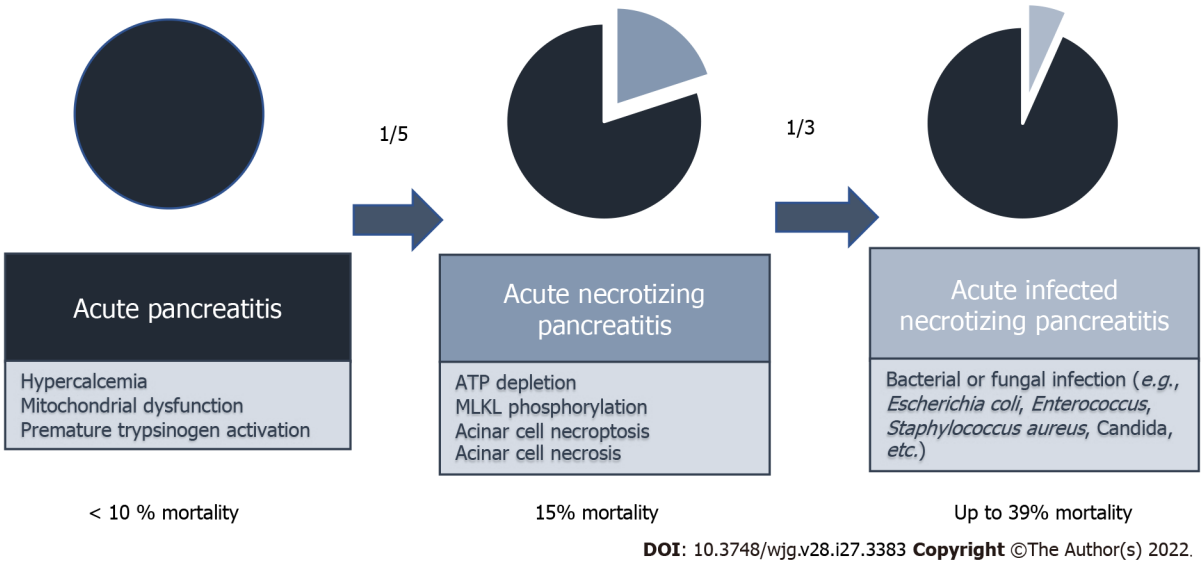
INTRODUCTION

Acute pancreatitis (AP) is one of the most common and severe gastrointestinal diseases[1]. The rate of AP-related hospitalization in the United States increased from 65.38 to 81.88 per 100000 United States adults per year from 2001 to 2014[2].



The pathophysiology of AP is characterized by acinar cell injury leading to premature intrapancreatic activation of digestive proteases. ATP depletion and mixed lineage kinase domain-like protein phosphorylation lead to acinar cell necroptosis and necrosis[3]. This results in a cascade effect leading to autodigestion of the pancreatic parenchyma. The acinar cell injury and autodigestion can be induced by different mechanisms; recent publications discuss, for example, the role of hypercalcemia and organelle dysfunction. Cholecystokinin, biliary acids, and alcohol consumption can lead to increased Ca^{2+} efflux by the endoplasmic reticulum (ER). In turn, hypercalcemia can damage the mitochondrial membrane, reducing ATP production and hence the function of the Ca^{2+} efflux mechanisms of the cell itself, which increases the intracellular Ca^{2+} levels even further. This intracellular Ca^{2+} overload ultimately leads to the release and activation of digestive enzymes, which results in premature activation of trypsin. In addition, bile acids, alcohol, and other pancreatic toxic substances can trigger the acinar cells themselves, leading to higher secretion of trypsin[4-6].

AP can be classified as either interstitial edematous or necrotizing pancreatitis (NP). While inflammation and edema of the pancreatic parenchyma and peripancreatic tissues characterize intestinal edematous pancreatitis, further pancreatic or peripancreatic necrosis is known as NP[6], which is a potentially life-threatening disease associated with a 15% mortality rate. In approximately a third of patients with NP, superinfection (fungal or bacterial infection) of necrosis occurs during the clinical course, mostly within 2 to 4 wk after disease onset. Infected NP (INP) results in an even higher mortality rate of up to 30% to 39% (Figure 1)[7-9]. The major causes of INP are obstructing gallstones (up to 50%) and alcohol abuse (20%)[10].

Several scores were introduced in order to predict the severity of AP and its mortality. A retrospective study from 2013 comparing some of these scores revealed that especially the Bedside Index for Severity in Acute Pancreatitis (BISAP) and Acute Physiology and Chronic Health Evaluation (APACHE-II) score stand out compared to scores like the computed tomography (CT) severity index, Ranson Score, body mass index, or hematocrit in terms of predicting severity, organ failure, and death. The BISAP score is a combination of the following five parameters, each worth one point: Altered mental state, blood urea nitrogen > 25.2 mg/dL or more, positive systemic inflammatory response syndrome criteria, age over 60 years, and pleural effusion on CT scan. In comparison, the APACHE-II score uses 14 different parameters, ranging from age to the Glasgow Coma Scale[11].

Another applicable score in INP is the Marshall Score, which determines the presence of organ failure, which, according to the 2012 revised Atlanta Classification of AP, is a criterion that differentiates between mild (no organ failure), moderate (organ failure after less than 48 h), and severe (organ failure after more than 48 h) pancreatitis. The Marshall Score assesses the respiratory system on a scale from 0 to 4 using PaO_2/FIO_2, the renal system using serum creatinine in mg/dL, and the cardiovascular system using the systolic blood pressure in mmHg. A score of 2 or higher for any of the systems indicates organ failure[12].

The clinical management of INP is complex and involves a multidisciplinary team of intensive care specialists, gastroenterologists, and surgeons. Recent trials have provided important insight into the disease mechanisms and have optimized the treatment strategies. However, the indications, timing, and outcomes of different interventional strategies remain controversial.

Figure 1 Mortality rates of acute pancreatitis and pathomechanisms. The mortality rate of all patients with acute pancreatitis (AP) is less than 10%. One-fifth of the patients developed necrotizing AP by ATP depletion, MLKL phosphorylation, acinar cell necroptosis, and/or acinar cell necrosis. One-third of the patients with necrotizing AP developed bacterial or fungal infection. The mortality rate of the infected necrotizing pancreatitis is up to 39%.

PHASES OF AP

According to the 2012 revised Atlanta classification of pancreatitis, two AP phases can be differentiated: the early (< 1 wk after onset) and late (> 1 wk after onset) phases. The early phase is characterized by the first clinical signs of pancreatitis: Abdominal pain, biochemical findings, and imaging findings consistent with pancreatitis. During this time, a pro-inflammatory sterile response occurs, which can lead to systemic inflammatory response syndrome (SIRS)[13]. Nevertheless, AP is self-limited in more than 80% of patients, and treatment in the early phase consists of supportive care instead of a curative intervention[14]. However, necrosis and acute necrotic collection (ANC) can occur in the late phase. ANC is considered a local complication of AP and is characterized by a collection of both fluid and necrosis without a defined wall[8]. ANC can resolve spontaneously or eventually become encapsulating, which allows the collection to become more organized within a well-defined inflammatory wall [15,16]. This process takes approximately 4-6 wk and the end-product is called a walled-off necrosis (WON)[17]. Once WON is diagnosed, whether the pancreatic or peripancreatic necrotic tissue and ANCs are sterile or infected must be determined to plan the subsequent treatment course. Superinfection of acute NP increases the mortality rate (24% *vs* 3.5%)[18,19]. In order to prevent SIRS, sepsis, and multiple (respiratory, cardiovascular, hepatic, and renal) organ failure, the treatment goal is to remove the infected non-vital tissue[13,18,20].

DIAGNOSIS OF ACUTE INP

The diagnosis of AP is mostly based on clinical symptoms; the major ones being abdominal pain, fever, nausea, and vomiting. The diagnosis is further narrowed by measuring the levels of serum amylase and/or lipase. As a diagnostic criterion for pancreatitis, these markers exceed the physiological range by approximately three times. Characteristic imaging findings, such as enlargement of the pancreas and hypodense areas within the parenchyma and/or the peripancreatic tissue, are radiological imaging criteria[8,17,21].

The primary imaging modality within the first 48 h is a transabdominal ultrasound, primarily to determine the need for cholecystectomy for biliary pancreatitis. If the diagnosis of AP remains uncertain, a CT scan can be performed. However, changes on CT are most evident approximately 72 h after AP onset[21].

To diagnose NP, contrast-enhanced CT (CECT) is the preferred imaging modality, as it can identify the presence of gas in the necrotic collection. Magnetic resonance imaging can also be used but is less sensitive than CECT[22]. The diagnosis of infected necrosis is based on clinical criteria including fever and rising serum inflammatory markers[23].

INP REQUIRES A MULTIDISCIPLINARY APPROACH

INP requires both closely monitored intensive care and interventional approaches to remove infected necrotic areas. Endoscopic interventional options involve endoscopic drainage and/or endoscopic necrosectomy. Further interventions are percutaneous transgastric drainage, minimally invasive or open necrosectomy. Using the acronym "PANCREAS", Gomes *et al*[24] summarized eight important steps in the management of severe AP: Perfusion, analgesia, nutrition, clinical and radiological assessment, endoscopy, antibiotics, and surgery.

Historically, INP patients have undergone early open debridement of necrotic tissue (median timing of the operation 21[25] to 28[26] d), mostly followed by local continuous lavage[26]. Recently, interventional strategies have shifted towards a so-called "step-up approach," which involves endoscopic or surgical interventions that comprise open and minimally invasive procedures. The approach starts with simple, less invasive interventions like endoscopic drainage, and escalates to more invasive and finally surgical procedures if these approaches fail.

CONSERVATIVE TREATMENT

INP patients require close monitoring and may need to be admitted to intensive care treatment due to the risk of sepsis and consequent organ failure[27]. The major components of conservative therapy are fluid administration, nutrition, and antibiotics.

FLUID ADMINISTRATION

Hypovolemia is a constant risk in AP patients; moreover, installing fluid infusions and closely monitoring patient circulation parameters is therefore essential. The duration of intravenous infusions as well as the total volume of fluids per day, are subject to ongoing debate[24].

A recent meta-analysis analyzed the impact of early aggressive fluid therapy (infusion rate of 3-5 mL/kg/h in the first 24 h) as compared to non-aggressive hydration. Eleven trials were included, and the authors could not detect a difference in mortality rate; however, aggressive fluid therapy increased the risk of acute kidney injury and pulmonary edema. Furthermore, there was no difference in overall outcomes such as incidence of SIRS, organ failure, or pancreatic necrosis for both therapeutic strategies [28]. Another study demonstrated that early rapid fluid therapy is associated with persistent organ failure, primarily of the respiratory system[29].

Recent studies have favored Ringer's lactate solution as the fluid of choice as opposed to saline solution, as the former reduced systemic inflammation[30]. Recent studies have concluded that the optimal AP regimen involves 3-4 L of Ringer's lactate solution every 24 h and predefined checkpoints at 6-8 h in order to tailor the fluid management to the condition of the patient. Furthermore, measuring urine output, intraabdominal pressure, and vital signs can help adjust the regimen of fluid therapy[31].

NUTRITION

While fasting was considered helpful in AP in the past, current evidence supports early oral or enteral nutrition even if patients experience AP-related complications. As patients with acute NP have increased energy requirements and sustained protein catabolism, an early start of enteral nutrition within the first 48 h of symptom onset is the current standard of care[32]. Regarding nutrition protocol, 25 kcal/kg/d up to a maximum of 30 kcal/kg/d with 1.2-1.5 g/kg of protein per day is recommended [24]. As compared to parenteral nutrition, enteral nutrition is associated with a lower rate of infectious complications and organ failure, shorter hospital stay, and reduced mortality rate[33,34].

ANTIBIOTICS AND PANCREATIC FUNGAL INFECTION

In contrast to patients with general AP, INP patients require immediate antibiotic therapy starting as soon as the diagnosis of INP is confirmed. INP should be initially treated with empirical antibiotics covering both aerobic and anaerobic Gram-negative and Gram-positive microorganisms, such as Imipenem or Ciprofloxacin[35]. A CT-guided fine-needle aspiration (FNA) can help design a more targeted treatment plan. The bacteria most frequently identified in IPN are *Escherichia coli*, *Enterococcus*, *Staphylococcus aureus*, *Staphylococcus epidermidis, Klebsiella pneumoniae, Pseudomonas spp*., and *Streptococcus spp*.[36].

Although antibiotic therapy is an essential tool in the treatment of INP patients, there is insufficient evidence to support the role of antibiotic prophylaxis after the diagnosis of sterile pancreatitis in order to prevent superinfection[36-38].

The use of prophylactic antibacterial therapy and duration of antibacterial therapy have been observed to increase the incidence of pancreatic fungal infection, which is a condition in patients with NP that is associated with increased mortality, intensive care unit admission rate, and length of stay. Its incidence was 26.6% in a study including 2151 patients with NP[39].

INVASIVE TREATMENT

Treatment planning and determining therapy concepts in INP patients should be performed within a multidisciplinary team of surgeons, interventional radiologists, and gastrointestinal endoscopists at experienced centers. Specialists should assess the feasibility of different access routes (transgastric, transduodenal, percutaneous, retroperitoneal, laparoscopic, or laparotomic) and weigh the treatment options, while considering the individual clinical condition of each patient (Table 1).

ENDOSCOPY

Endoscopy plays an emerging role in the treatment of INP[40]. Interventional approaches such as the placement of plastic or metal stents for endoscopic transluminal drainage (ETD) or direct necrosectomy are endoscopically feasible[41].

ETD AND STENT CHOICE

ETD is performed as the standard first step of endoscopic INP treatment. The aim of this procedure is to establish a temporary connection between the gastric cavity and necrotic cavity in the adjacent pancreas in order to drain necrotic collections.

ETD is performed with the assistance of endoscopic ultrasound, which helps avoid puncturing of vessels (*via* color doppler) or targets other than the necrotic collections[42]. The endoscopist then places either a plastic, double pigtail stent; a self-expandable metal stent (SEMS); or a lumen-apposing metal stent (LAMS). The metal stents are larger in diameter (15-20 mm) than the plastic stents (2.33–3.33 mm) and provide access for potential subsequent debridement (Figure 2). SEMS are not commonly used, as they have been reported to migrate into the collapsed fluid collection, posing a risk of major bleeding [43]. LAMS are designed to prevent migration and minimize the risk of leakage with their apposing features[44,45]. Another advantage of LAMS over plastic stents is the delivery system *via* a single-step platform, resulting in a shorter intervention time[46]. Retrospective studies comparing drainage with either LAMS or plastic stents found that the procedure time is significantly shorter for LAMS drainage [47,48]. One of these studies also shows that LAMS drainage results in increased clinical success, reduced need for surgery, and a lower recurrence rate[47].

A more recent randomized clinical trial, however, compared both stent types in a total of 60 patients (31 undergoing LAMS placement and 29 undergoing plastic stent placement) and found that LAMS was not superior to plastic stents. The authors detected no difference in treatment success, the number of procedures required, length of stay, adverse events (within < 3 wk of LAMS removal), readmissions, or overall treatment costs[49,50]. Moreover, the study showed significant stent-related adverse events if LAMS were left in place for more than 3 wk. Given these heterogeneous results, future studies are needed to further evaluate the outcomes of different ETD strategies. Nevertheless, the treating medical team should consider the different procedure duration, since the average time to place the LAMS is shorter compared to plastic stents (15 *vs* 40 min, $P < 0.001$)[51].

ENDOSCOPIC NECROSECTOMY

If the clinical condition of INP patients fails to improve 72 h after ETD, necrosectomy should be considered. Endoscopic transluminal necrosectomy (ETN) can be performed, using a LAMS as access route to the necrotic cavity. With help of forceps, nets, and lavage techniques with saline or hydrogen peroxide, the necrotic tissues are removed endoscopically. ETN can be performed several times if necroses cannot be removed in one procedure[52,53]. It is important to consider that multiple ETN attempts also cause an increased risk of procedure-related complications such as bleeding or perforation [42].

Table 1 Overview of possible interventions in infected necrotizing pancreatitis

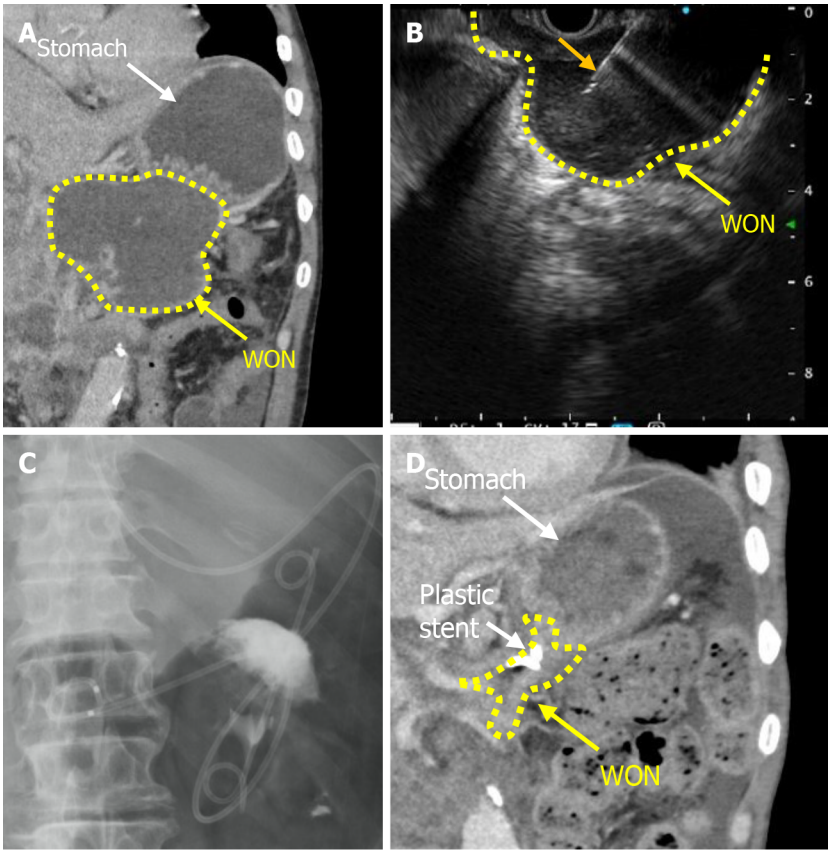
		Indications	Contraindications	Most common complications	Ref.
Interventions	Endoscopic transluminal drainage	Standard first step for INP, standard for PFC treatment	Unencapsulated collections, distance from gastroduodenal duct (> 1 cm), vascular pseudoaneuryms	Major bleedings, perforation, post-procedure infection, recurrence, migration of the stent	[37, 38, 40]
	Endoscopic necrosectomy	No improvement in clinical condition within < 72 h after ETD, follow-up treatment	Large necrotic areas, dense necrosis, disconnected duct	Bleeding, perforation, pancreatic fistula, infections	[37, 48, 50]
	Percutaneous catheter drainage	Hardly accessible ANC, ETD not feasible, as combination with ETD	Intracystic haemorrhagia, pancreatic ascites	Intestinal fistula, infection	[36, 51]
	Open surgery	Infected necrosis, suspected perforation, abdominal compartment syndrome, ischemia, intrabadominal haemorrhagia, poorly walled off necrosis, final treatment option if other interventions fail	No clear contraindications reported	Bleeding, infection, perforation, multi-organ failure	[52, 53]
	Minimally invasive surgery	Infected necrosis	Extensive or hardly accessible collections	Bleeding, infection, perforation	[44, 57, 58]

INP: Infected necrotizing pancreatitis; ANC: Acute necrotic collection; ETD: Endoscopic transluminal drainage.

If a transgastric access is not possible or WONs are located in an inaccessible lateral position, a sinus tract endoscopy (STE) may be an option. In order to perform STE, a CT-guided percutaneous drainage catheter is placed 10 d prior to the procedure. The catheter causes the tract wall to mature, so the insertion of an adult gastroscope under fluoroscopic control can be performed safely. The necrotic cavity is lavaged and necrotic tissue is removed, as is done in the ETN procedure (Figure 3)[54].

Endoscopic necrosectomy reduces the rate of surgical interventions[55]. However, these interventions are limited to small necrotic areas and can be very time consuming (60-120 min)[56].

PERCUTANEOUS CATHETER DRAINAGE



Percutaneous catheter drainage (PCD) is often used prior to endoscopic necrosectomy if the ANC is located in the flank or pelvic region and access *via* ETD is not possible. An interventional radiologist places a general-purpose pigtail drainage catheter into the necrotic collection using the Seldinger technique *via* the most direct transperitoneal route. The preferred route for PCD is through the retroperitoneum. In this case, the drain can be used to guide potential further minimally invasive retroperitoneal necrosectomy (*i.e.*, video-assisted retroperitoneal debridement or STE). A combination of endoscopic transluminal and PCD (also known as dual-modality drainage) is a further option in patients with large collections extending into the paracolic gutters or pelvic region[57]. PCD is the least invasive intervention and was the only intervention needed for patients with INP in 35% (15 out of 43) patients in the randomized PANTER trial[40].

SURGERY

Larger, more complex, and endoscopically not accessible necrotic areas may require minimally invasive or open surgical approaches[16].

OPEN SURGERY

AP can lead to severe complications, such as hemorrhage, perforation, or ischemia. These complications may require immediate open surgical treatment. Abdominal compartment syndrome is a further severe potential complication of AP that must be managed *via* laparotomy. The drainage or debridement of ANCs and contacting the omental bursa should be avoided during these surgical emergency procedures [58]. Beside emergency indications, INP itself is a well-accepted indication for surgical treatment[59].

DOI: 10.3748/wjg.v28.i27.3383 **Copyright** ©The Author(s) 2022.

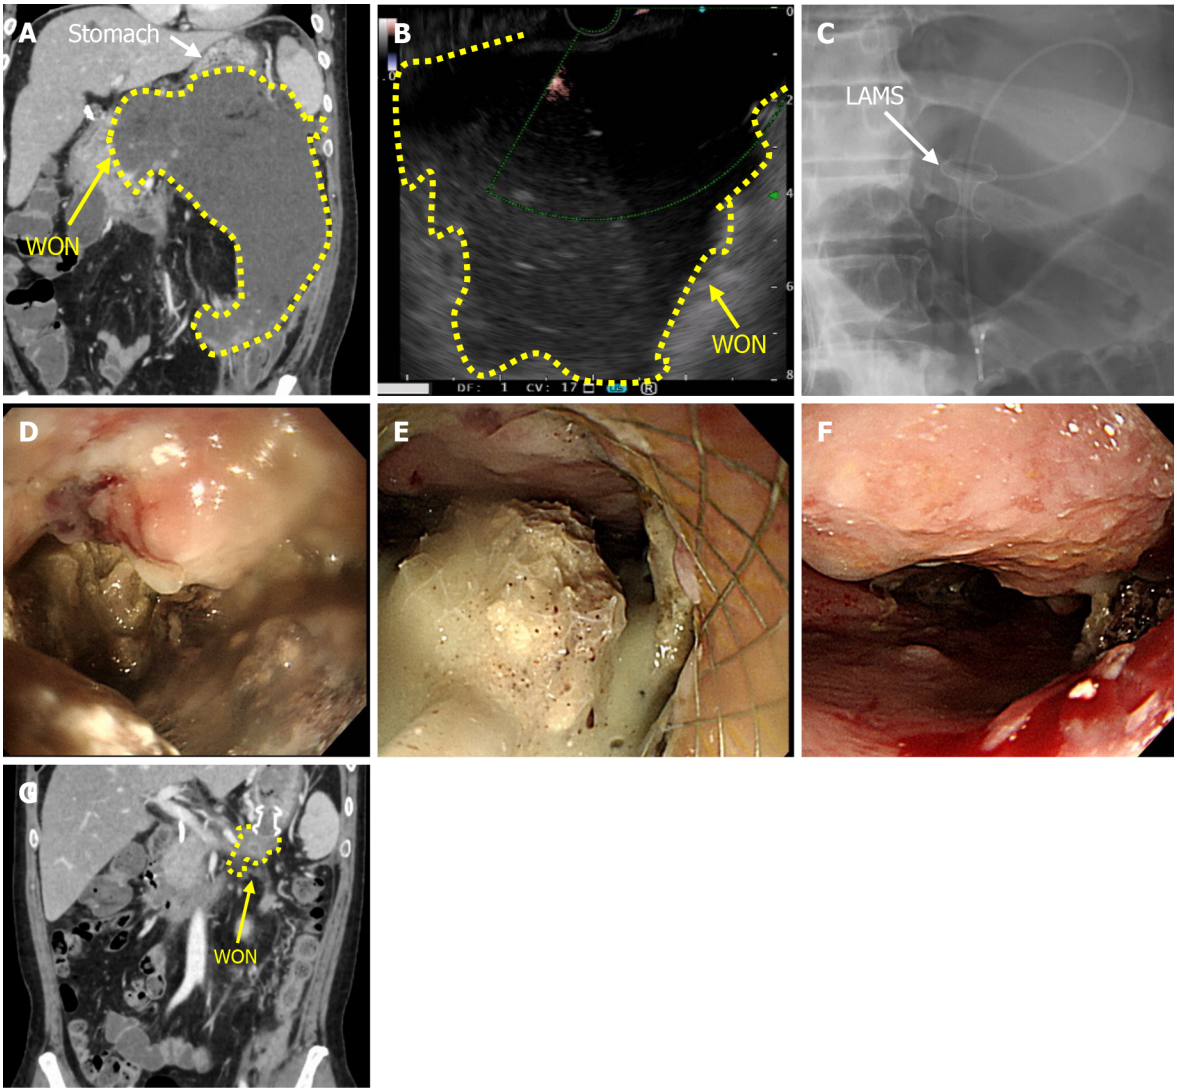


Figure 2 Endoscopic transluminal drainage with plastic stenting. A: A typical computed tomography (CT) scan with walled-off necrosis (WON) formed by necrotizing pancreatitis (white arrow shows stomach and yellow dotted line is the demarcation line of the WON); B: Endoscopic ultrasonography (EUS)-guided drainage for WON was performed (orange arrow shows the needle of 22-gauge EUS needle); C: Two plastic stents and nasobiliary drainage tube was placed into the WON; D: The size of the WON was reduced in the CT scan one month after the procedure. WON: Walled-off necrosis.

Open surgical necrosectomy follows the main principle of exposing the necrotic area and bluntly debriding necrotic tissue: Necrosectomy can be performed with: (1) Open packing; (2) Closed packing; (3) Closed continuous lavage; and (4) Planned re-laparotomies. Open packing involves packing the necrotic cavity with non-adherent dressing after surgical necrosectomy. Readmissions follow every 48 h until the abdomen can be closed after inserting drains. Closed packing is performed when multiple, large, gauze-filled Penrose drains are placed in the residual cavity after necrosectomy and the abdomen is subsequently closed. Closed continuous lavage is performed with the help of two or more double-lumen Salem sump tubes and single-lumen silicone rubber tubes, which are inserted from each flank side and have an in- and outflow of the lavage. Up to 40 L of lavage fluids are used. Planned re-laparotomies provide continuous removal of necrotic tissue over several following days. Surgeons often incorporate zippers into the abdominal wall facilitating repetitive surgical intervention[59].

The standard surgical access is performed either as a transperitoneal or retroperitoneal access. Transgastric access has been added more recently and is considered a fast single-stage option for the treatment of symptomatic WON in severely ill patients[60]. A recent study suggested choosing surgical transgastric necrosectomy whenever feasible in the case of a disconnected pancreatic duct, for dense and large necrosis, and if cholecystectomy must be performed. If the transgastric access is not possible, the authors suggested video-assisted retroperitoneal debridement (VARD) as an alternative procedure[61].

MINIMALLY INVASIVE SURGERY

The main procedures of minimal invasive management of INP are minimal access retroperitoneal pancreatic necrosectomy (MARPN) and VARD. MARPN involves the placement of a 12-French catheter under CT guidance by an interventional radiologist prior to surgery. The preformed access tract is then dilated up to 30-French during the minimal invasive procedure, so that a rigid nephroscope can be entered. The nephroscope serves as visualization instrument and working channel for necrosectomy at the same time. An irrigation drainage system for continuous lavage is installed at the end of the procedure. MARPN can be done multiple times until the patient's condition improves.

Figure 3 A case with endoscopic transluminal drainage with lumen-apposing metal stent. A: Computed tomography (CT) scan before performing the endoscopic ultrasonography (EUS)-guided drainage (White arrow shows the stomach and the yellow arrow shows the walled-off necrosis (WON); the yellow dotted line is the demarcation line of the WON); B: EUS (with color doppler) picture shows marked echoic lesion without vessels; C: Lumen-apposing metal stent (LAMS) and nasobiliary drainage tube were placed (white arrow shows LAMS: Hot AXIOS™ 15 mm × 10 mm, Boston Scientific, Marlborough, MA, United States; Boston Scientific Japan, Tokyo, Japan); D: Esophagogastroduodenoscopy was inserted into necrotic cavity through LAMS; E: Necrosectomy was performed using endoscopic retrieval net; F: Endoscopic findings of the WON one month after the multiple necrosectomy sessions (2-3 times/wk); G: CT scan shows marked reduction of WON cavity one month after multiple necrosectomy sessions. WON: Walled-off necrosis; LAMS: Lumen-apposing metal stent.

VARD consists of combined manual and laparoscopical necrosectomy. It was first reported in 2007 by van Santvoort *et al*[62], who described it as "a hybrid between pure endoscopic retroperitoneal necrosectomy and the open translumbar approach." The procedure starts with a left flank subcostal incision facilitating direct manual debridement followed by a laparoscopic deeper inspection and debridement by laparoscopic instruments. The intervention ends with a continuous lavage.

COMPARISON BETWEEN OPEN AND MINIMALLY INVASIVE SURGERY

Open surgical necrosectomy in AP was historically associated with a mortality rate of 50% or higher[63, 64]. Improved intensive care management, as well as advances in surgical techniques, including minimally invasive options, and the availability of first line endoscopic and minimally invasive procedures have improved patient outcomes over the past decades[65].

A retrospective study compared outcomes of INP patients between 1997-2008 and 2009-2013 and revealed decreased mortality (23.8% *vs* 11.2%, $P = 0.001$) and overall complication rates (73.3% *vs* 64.4%, $P = 0.80$) in the more recent cohort. Minimal invasive approaches contribute to better treatment success rates and improved outcomes in INP as compared to open surgery. MARPN also reportedly results in decreased postoperative multiorgan failure compared to open pancreatic necrosectomy (35% *vs* 20.4%, *P*

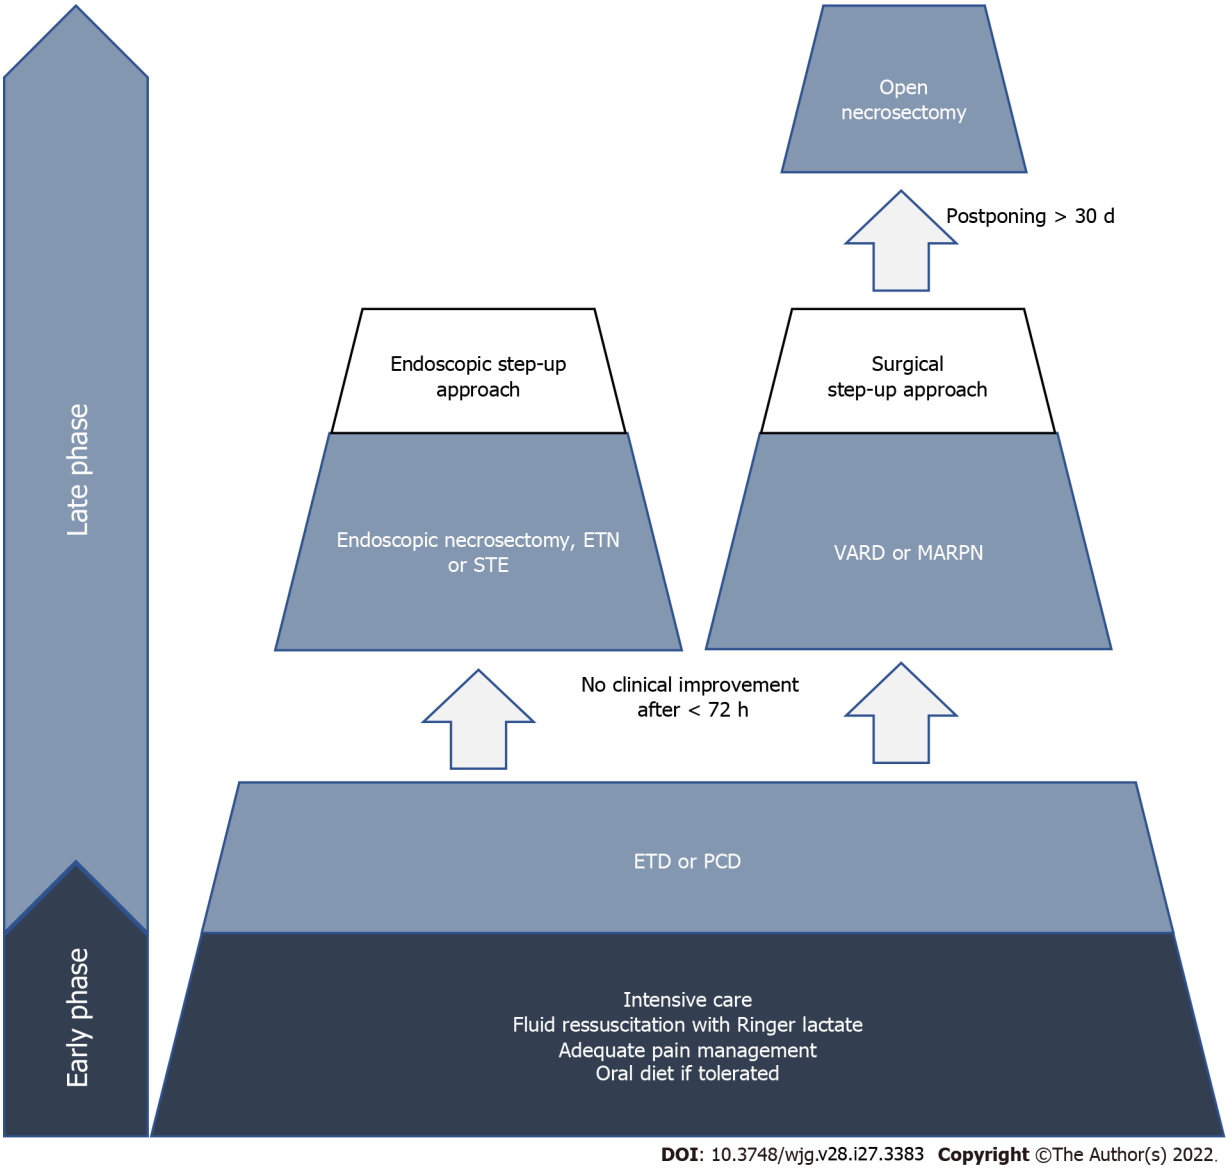
= 0.001)[66].

A recent retrospective cohort study comparing 88 patients with open surgical necrosectomy to 91 patients who were treated with minimal invasive surgery (MIS) showed that MIS results in a fivefold decrease in mortality[49]. A meta-analysis published in 2018 reported lower risk of death rates in the very high-risk group when comparing minimally invasive necrosectomy to open surgery[67].

STEP-UP APPROACH

The therapeutic approach in INP patients has shifted from open surgical treatment to a less invasive management that can be summarized by "three Ds": Delay – drain – debride. This approach leads to the introduction of the so-called "step-up approach", which was first described in 2006 by the Dutch Pancreatitis Study group in their PANTER trial[40].

Delay refers to the solidification and complete encapsulation of the pancreatic collection when WON occurs. This is presumed to optimize conditions for intervention, with a lower risk of bleeding and less reinterventions. Drain alludes to using a percutaneous or endoscopic transgastric catheter drainage to mitigate sepsis. Finally, when patients fail to show clinical improvement, debridement is required; in such cases, performing endoscopic or surgical necrosectomy is the next step[40]. A multidisciplinary team of INP experts can choose from different treatment options for each step and decides on the most suitable approach for each individual patient. Re-evaluation periods of 72 h between steps should be maintained[49]. This therapeutic management is also referred to as the "step-up approach", which comprises both an endoscopic and a surgical approach. The overall paradigm is to start with the least invasive and harmful intervention with an option to escalate to more radical approaches with continuous evaluation. The step-up approach decreased the incidence of new multiple-organ failure from 40% to 12% when compared to primary laparotomy[40]. It is the current state-of-the-art approach and has been implemented in all major guidelines (Figure 4)[23,68].



ENDOSCOPIC OR SURGICAL STEP-UP APPROACH

The step-up approach can be performed using endoscopic or surgical necrosectomy. Comparing both approaches has been subject of several randomized trials. From 2008 to 2010, the first prospective, multicentric randomized controlled trial comparing the surgical and endoscopic step-up approaches was performed in the Netherlands. The so-called PENGUIN trial compared endoscopic transgastric necrosectomy with prior retroperitoneal drainage and different techniques of surgical necrosectomy (VARD or, if not feasible, laparotomy) in 10 INP patients per group. The results demonstrated reduced inflammatory response as measured by serum interleukin 6 Levels, reduced rates of pancreatic fistulas (10% *vs* 70%, P = 0.020), and no occurrence of new-onset multiorgan failure (0% *vs* 50%, P = 0.030) in patients in the endoscopic arm[69]. The authors concluded that the endoscopic approach was associated with reduced physiological stress, while surgical access was more invasive.

The multicentric TENSION trial was conducted during 2011-2015 in the Netherlands and compared the outcomes of 51 patients following the endoscopic step-up approach to 47 following the surgical step-up approach. The findings showed no significant difference in mortality and major morbidity between both groups (43% in the endoscopic step-up approach *vs*. 45% in the surgical step-up approach, P = 0.880). However, the mean hospital stay was shorter (53 *vs* 69 d, P = 0.014), fewer pancreatic fistulas occurred (5% *vs* 32%, P = 0.001), and there was a lower overall mean cost (60228 € *vs* 73883 € in the endoscopic step-up approach group[70]).

From 2014 to 2017, the monocentric MISER trial was performed in the United States, comparing minimally invasive surgery (laparoscopic debridement or VARD) to the endoscopic step-up approach in a total of 66 patients. They included severely ill patient cohorts and excluded patients who had improved clinically with only percutaneous drainage as treatment. Consistent with the findings of the TENSION trial, MISER showed no difference in mortality rates (8.8% with the endoscopic step-up approach *vs*. 6.3% with minimally invasive surgery, P = 0.999). However, patients assigned to the endoscopic approach were less likely to develop enteral and pancreatic-cutaneous fistulas (0% *vs* 28.1%, P = 0.001), experienced a lower rate of major complications (12% *vs*. 41%, P = 0.007), and had lower rates of SIRS (20.6% *vs* 65.6 %, P < 0.001). Six months after treatment, patients in the surgical group had significantly more disease-related adverse events than did those in the endoscopic group (43.8 % *vs* 5.9 %, P < 0.001). Finally, the physical health scores for quality of life at 3 mo were better with the endoscopic approach (P = 0.039) and the mean total cost were lower ($75830) compared with the surgical approach ($117492)[49].

The currently available randomized controlled trials point to the endoscopic step-up approach as the preferred treatment for INP patients. However, if the endoscopic treatment is unfeasible, or the necrotic collection extends to the flank or pelvic region (which is difficult to access endoscopically), surgical interventions constitute the alternative when performed as a step-up approach. Each INP patient should be assessed and treated by a multidisciplinary team with sufficient experience in both approaches.

Figure 4 Overview of the step-up approaches of infected necrotizing pancreatitis patients. In the acute phase, multidisciplinary treatment for acute pancreatitis is recommended. Endoscopic necrosectomy or surgical step-up should be considered if there no clinical improvement is observed within 72 h. Open necrosectomy should be considered after video-assisted retroperitoneal debridement or minimal access retroperitoneal pancreatic necrosectomy. ETN: Endoscopic transluminal necrosectomy; STE: Sinus tract endoscopy; ETD: Endoscopic transluminal drainage; PCD: Percutaneous catheter drainage; VARD: Video-assisted retroperitoneal debridement; MARPN: Minimal access retroperitoneal pancreatic necrosectomy.

TIMING OF INTERVENTIONS

The optimal timing of interventions remains a controversial topic and is subject to ongoing debate. An international survey performed in 2016 among 87 pancreatologists revealed that 55% of experts routinely postponed invasive interventions after diagnosing infected necrosis in AP and awaited the effect of antibiotics. However, 33% of pancreatologists preferred surgical necrosectomy as early as possible in infected necrosis, while the remaining 67% would select that route only in the case of WON [71].

A 2014 prospective study including 223 patients revealed that a postponed surgical intervention after 30 d was associated with a lower mortality rate compared to that associated with surgical intervention before day 30 [10% (9/87) *vs* 21% (28/136), $P = 0.040$][72]. This study followed up on a retrospective study from 2007 that also revealed that patients receiving a postponed surgical necrosectomy exhibited lower mortality rates as compared to those receiving surgical treatment after 15-29 d and 1-14 d (8% *vs* 45% *vs* 75%, $P < 0.001$)[26].

A recent study of the Dutch Pancreatic Study Group, the POINTER trial, determined whether the outcomes in INP patients could be improved by early catheter drainage. In the study, catheter drainage was performed immediately in 55 patients, while 49 received the treatment after waiting until WON occurred. Patients were included when there was gas reported on CECT, positive gram/culture FNA,

and clinical suspicion for INP. The rate of organ failure was comparable in both groups and there was no difference in mortality rates. The total number of interventions was 4:1 in the early intervention group compared to the group with delayed intervention, and the total number of necrosectomies in the whole number of patients was 28 (51%) in the immediate as compared to 11 (22%) in the postponed drainage group. Postponing the intervention led to conservative treatment in nearly 40% of patients. This trial could not detect a benefit of immediate drainage over postponed drainage. Conversely, postponing intervention may ultimately avoid necrosectomy and its potential complications[73].

CONCLUSION

Recent advances in endoscopic and minimally invasive therapy have led to a shift in the interventional strategy for INP. Although no standardized approach suits every patient, the "step-up approach" has emerged as a paradigm to treat this severe disease. The key is to start with the least invasive procedure and potentially escalate to more invasive interventions after continuous evaluation, if necessary. This approach highlights the importance of a multidisciplinary team to guide therapeutic approaches in INP patients. The strategy should be based on the individual patient and should allow for dynamic changes in regard to the patient's clinical condition. This claim is also backed by the studies presented in this review that demonstrate lower rates of new multiorgan failure and reduction of hospitalization days, among other preferred outcomes. Even with these recent advances, INP continues to elicit a high mortality rate and further research is required to optimize strategic approaches.

ACKNOWLEDGEMENTS

We thank Hiramatsu K at Asahikawa Kosei Hospital for providing percutaneous radiological drainage pictures; We also thank Okada T, Kawamoto T, Fujinaga A, and Goto M at Asahikawa Kosei Hospital, as well as Hayashi A, the member of Division of Metabolism and Biosystemic Science, Gastroenterology and Hematology/Oncology Department of Medicine, Asahikawa Medical University for providing endoscopic drainage pictures.

Abstract

Artificial intelligence (AI) is playing an increasingly important role in medicine, especially in the field of medical imaging. It can be used to diagnose diseases and predict certain statuses and possible events that may happen. Recently, more and more studies have confirmed the value of AI based on ultrasound in the evaluation of diffuse liver diseases and focal liver lesions. It can assess the severity of liver fibrosis and nonalcoholic fatty liver, differentially diagnose benign and malignant liver lesions, distinguish primary from secondary liver cancers, predict the curative effect of liver cancer treatment and recurrence after treatment, and predict microvascular invasion in hepatocellular carcinoma. The findings from these studies have great clinical application potential in the near future. The purpose of this review is to comprehensively introduce the current status and future perspectives of AI in liver ultrasound.

Key Words: Machine learning; Deep learning; Radiomics; Diffuse liver diseases; Focal liver diseases; Ultrasound

Core Tip: Artificial intelligence (AI) is playing an increasingly important role in medicine, especially in the field of medical imaging. Currently, there is a need of a comprehensive review to introduce the application of AI based on ultrasound in diffuse and focal liver lesions. In this article, we introduce the application of AI in the assessment of liver fibrosis and nonalcoholic fatty liver and the differentiation of focal liver lesions. In addition, we discuss the performance of AI based on ultrasound in predicting curative effect, prognosis and microvascular invasion in hepatocellular carcinoma. Lastly, we illustrate the future prospect of AI in liver ultrasound.

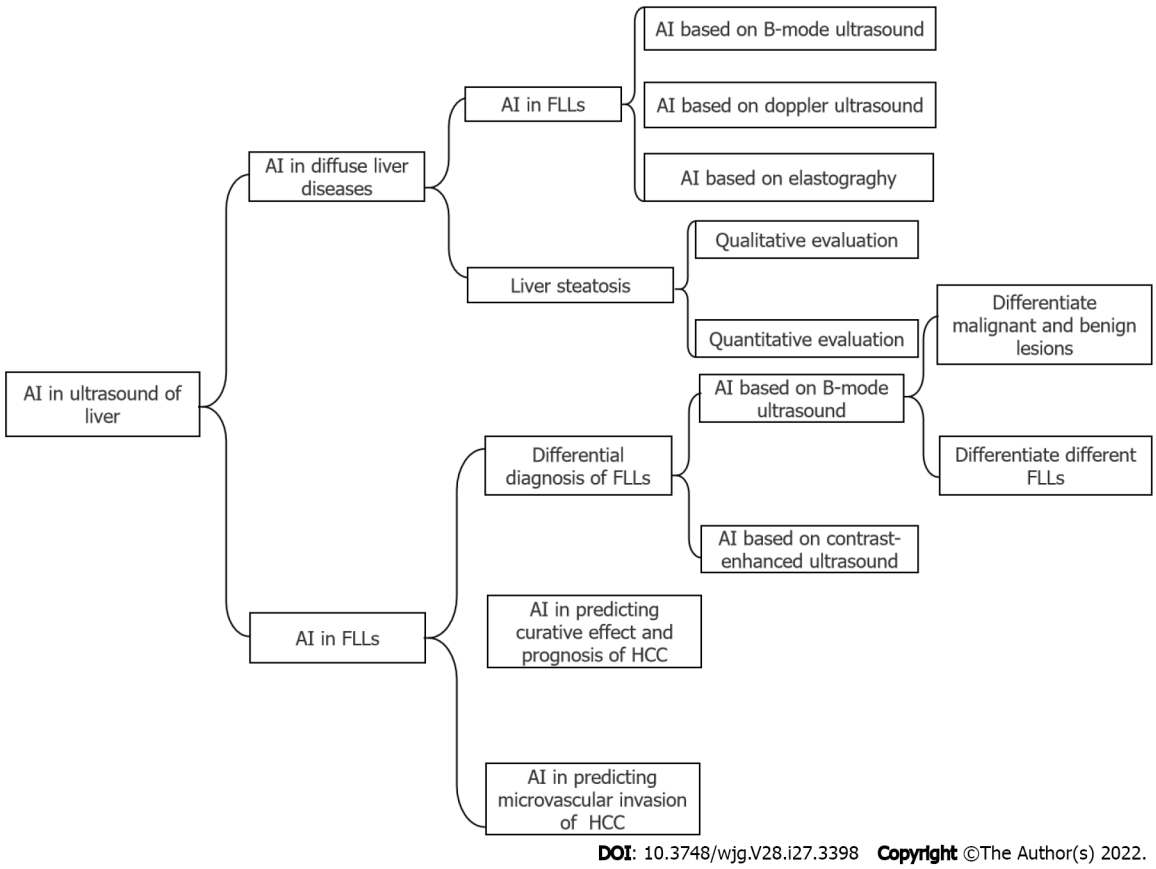
INTRODUCTION

In the past several years, liver diseases have affected millions of lives and became one of the main causes of illness and death in the world[1]. It is reported that more than one-fifth of the Chinese population are affected by liver diseases, such as liver fibrosis, liver cancer and nonalcoholic fatty liver disease (NAFLD), contributing unambiguously to health loss. Therefore, paying more attention to liver diseases is of great significance.

Artificial intelligence (AI) is defined as the research of algorithms that enable machines to have the ability of reasoning and performing functions such as solving problems, recognizing object and word, inferring world states, and making decisions[2]. AI is a precise prediction technique that automates learning and recognizes patterns in data. Apart from this, AI has been extensively applied to medical diagnosis, especially in medical image analysis. This application mainly relies on deep learning, a subfield of machine learning. Deep learning is on the frontier of AI, which is based on deep neural networks (DNNs) with more than one hidden layer. Convolutional neural networks (CNNs) are a branch of DNNs that are particularly useful for recognizing images and have stimulated a large amount of interest from industry, academia and clinicians[3].

Compared to other medical imaging techniques, ultrasound is noninvasive, portable and can provide real-time imaging. In recent years, AI-powered ultrasound has become more developed and been implemented in clinical applications in order to reduce the subjectivity and improve the efficiency of ultrasound diagnosis[4]. Many studies have confirmed the value of AI in the evaluation of thyroid nodule, breast lesion and liver lesion classification by ultrasound. In addition to these applications, other AI applications in ultrasound have also been explored and achieved great progress.

In liver medical imaging, AI can make a quantitative assessment by recognizing imaging information automatically to aid physicians in making more precise and comprehensive imaging diagnoses[5]. This technique has been extensively applied to computed tomography (CT), positron emission tomography-CT, magnetic resonance imaging and ultrasound to diagnose liver lesions. For instance, deep learning based on CT and positron emission tomography-CT can be used to detect new liver tumors and metastatic liver malignancy, and to predict the primary origin of liver metastasis[6-8].



There are also many studies that have illustrated the application of AI in liver ultrasound, while a comprehensive review of AI in this field is lacking. In this review, we will introduce the application of AI based on ultrasound in diffuse liver diseases, including liver fibrosis and steatosis, and focal liver lesions (FLLs), including their differential diagnosis, prediction of a curative effect and prognosis and microvascular invasion (MVI) of hepatocellular carcinoma (HCC). The main structure of this review was illustrated in Figure 1.

APPLICATION OF AI IN DIFFUSE LIVER DISEASE

There are a variety of diffuse liver diseases that can be asymptomatic or cause severe liver dysfunction, and many of them may lead to cirrhosis, hepatic carcinoma, and death. We will introduce the applications of AI based on ultrasound in two common diffuse liver diseases, *i.e.* liver fibrosis and steatosis.

Liver fibrosis

Liver fibrosis is the early step of cirrhosis and an important pathological basis of HCC[9]. Therefore, the early detection and prevention of liver fibrosis is essential in the clinical setting. However, although liver biopsy is the gold standard for classifying liver fibrosis using the Metavir score[10] or New Inuyama classification[11] to distribute the score ranging from F0 (no fibrosis) to F4 (cirrhosis). The use

Figure 1 Main structure of this review. AI: Artificial intelligence; FLLs: Focal liver lesions; HCC: Hepatocellular carcinoma.

of tissue examination for the assessment of liver fibrosis is controversial because liver biopsy is invasive and liver fibrosis is not equably distributed throughout the liver. There are an increasing number of credible, noninvasive and available approaches being widely applied in clinical practice. Recently, a large number of noninvasive techniques have been used to prevent adverse outcomes through the application of AI based on ultrasound.

AI based on B-mode ultrasound: As early as 20 years ago, AI was used to assist the diagnosis of liver fibrosis. Badawi *et al*[12] creatively proposed an approach that employed fuzzy reasoning techniques to identify diffuse liver diseases automatically by using digital quantitative features measured from the ultrasound images. They extracted parameters only from B-mode images, and the results revealed that this approach had higher specificity and sensitivity for the diagnosis of liver fibrosis than the statistical classification techniques, which had a certain effect but could not help much.

Apart from this, a novel deep multi-scale texture network based entirely on B-mode ultrasound images that was proposed recently seems to be more convenient[13]. The area under the receiver operating characteristic curve of this approach was 0.92 for significant fibrosis (≥ F2) and 0.89 for cirrhosis (F4) in the validation group, which outperformed the ultrasonographers and three serum biomarkers during diagnosis. Although it cannot be used for liver fibrosis staging now, it has excellent potential in the future workflow.

AI based on Doppler ultrasound: On the basis of grey-scale parameters from B-mode images, Doppler parameters of intrahepatic blood vasculature were added as essential parameters. Eventually, five ultrasonographic variables, including the liver parenchyma, thickness of the spleen, the hepatic vein waveform, hepatic artery pulsatile index and damping index, were selected as the input neurons. A data optimization procedure was used in an artificial neural network for the diagnosis of liver fibrosis, which achieved an area under the curve of 0.92[14]. Although this model proved to predict liver cirrhosis accurately, it still could not provide a specific grading.

AI based on elastography: In recent years, with the development of ultrasound, studies have proposed computer-aided techniques based on elastography that is of great importance in ultrasound images to identify and stage liver fibrosis. Real-time tissue elastography (RTE) is one of the recently developed elastography techniques. In a study, 11 image features were extracted directly from the RTE software that was installed in the ultrasound system to quantify the patterns of the RTE images[15]. Then, the data were processed and divided among four classical classifiers. The results showed that the

performance of the adopted classifiers was much better than the previous liver fibrosis index method, which predicted the stage of fibrosis using RTE images and multiple regression analyses. The good performance in this study demonstrated that machine learning had the potential to perform as powerful tools for staging liver fibrosis.

Nowadays, most applications of AI in evaluating the stage of liver fibrosis are based on shear wave elastography. An automated approach including the image quality check, region of interest (ROI) selection and CNN classification based on shear wave elastography showed a more accurate detection of ≥ F2 fibrosis levels than a previously published baseline approach, with an area under curve of 0.89 *vs* 0.74[16]. The deep learning radiomics also presented the potential diagnostic performance in chronic hepatitis B patients compared with two-dimensional shear wave elastography[17]. AI could help stage liver fibrosis more accurately with the assistance of elastography.

Liver steatosis

Hepatic steatosis, characterized by the accumulation of fat droplets in hepatocytes, can develop into nonalcoholic fibrosis, steatohepatitis, cirrhosis, and even HCC[18,19]. Early detection and treatment may halt or reverse NAFLD progression[19]. As a consequence, there is a critical need to develop noninvasive imaging methods to assess hepatic steatosis. Noninvasive liver imaging methods including CT, magnetic resonance imaging and ultrasound have been extensively investigated[20].

Ultrasound is the first-line examination for identifying liver steatosis. It shows an enlarged liver with a greater number of echoes caused by fat droplets, and the liver is brighter and more hyperechoic compared with the right kidney. The image is qualitative and relies on the subjective judgement of the operator, which definitely leads to variable results and low reproducibility[21]. To overcome the observer bias, a series of quantitative and semi-quantitative parameters, including attenuation and backscatter coefficients, the hepato-renal index (HRI) and ultrasound envelope statistic parametric imaging (known as speckle statistics), have been implemented, some of which represent excellent reproducibility and reliability[21-24]. At present, almost all the studies published have concentrated on NAFLD.

It was reported that the detection of moderate and severe steatosis based on ultrasound has an 84.8% sensitivity and a 93.6% specificity, while mild steatosis has an even lower sensitivity[25]. Recently, some researchers applied AI to improve the ultrasound detection rate of NAFLD, and the results were promising. Table 1 shows the studies using AI based on ultrasound to identify steatosis. The studies showed that AI had tremendous potential in helping diagnose liver steatosis. Some studies attempted to optimize CNN models. In the future, classifying the degree of liver steatosis with the assistance of the AI could be a trend.

Qualitative evaluation: Deep learning has been applied to qualitatively evaluate NAFLD. An approach of assessing fatty liver disease by utilizing deep learning based on CNNs with B-mode images was proposed[26]. The study recruited 135 participants with known or suspected NAFLD to investigate the function of four liver views (three views in the transverse plane, including hepatic veins at the confluence with the inferior vena cava, right portal vein and right posterior portal vein, and one view in the sagittal plane, *i.e.* the liver and kidney view) in the assessment[27]. The study assessed attention maps for liver assessment based on CNNs, which illustrated that the available image features provided by each view could assess liver fat. Unlike the previous study, magnetic resonance imaging proton density fat fraction was used as a reference standard, which was not precise enough compared with liver biopsy.

A novel framework combining transfer learning with fine-tuning was proposed[28]. Although this study revealed that the new framework outperformed CNN, this conclusion was not entirely convincing because the radiologists' qualitative scores were the reference standard. This framework was also utilized in other studies and achieved a good performance.

With the development of deep learning, Chou *et al*[29] established two-class, three-class and four-class prediction models to classify the severity of steatosis by using B-mode ultrasound images from 2070 patients. Although liver biopsy is the gold standard, the deep learning model could select eligible patients for a liver biopsy by evaluating the severity of fatty liver preliminarily, which would reduce unnecessary tests.

Different deep learning algorithms tend to have different performances. The combined deep learning algorithm based on B-mode images had an area under the receiver operating characteristic curve of 0.9999 and accuracy of 0.9864 compared with other algorithms[30]. Therefore, in future studies selecting an optimal algorithm is important.

Quantitative evaluation: AI has also been applied to quantitatively evaluate NAFLD. Radiofrequency signals may negate the loss or change of data during translation to B-mode ultrasound images. A study acquired the diagnosis and fat fraction of NAFLD by inputting the original data based on one-dimensional algorithms[31]. The investigators obtained a 97% sensitivity and 94% specificity, and the positive predictive value was up to 97%, which demonstrated that the utilization of original ultrasound radiofrequency could be applied in diagnosing NAFLD and to quantifying liver fat fraction. Similarly, in an animal experiment, a CNN model based on radiofrequency signals was shown to have a better

Table 1 Studies using artificial intelligence based on ultrasound for fatty liver disease diagnosis

Task	Reference standard	Sample size	Method	Results	Ref.
Fatty liver disease diagnosis	Liver biopsy	55 patients with severe obesity, 38 of whom had fatty liver disease	Deep learning with B-mode image ultrasound	Sensitivity: 100%; specificity: 88%; accuracy: 96%; AUC: 0.98	[26]
Fatty liver disease diagnosis	Radiologist qualitative score	157 ultrasound liver images from unknown number of participants	Deep learning with B-mode image ultrasound	Sensitivity: 95%; specificity: 85%; accuracy: 90.6%; AUC: 0.96	[28]
NAFLD assessment	MRI proton density fat fraction	204 participants, 140 of whom had NAFLD, 64 control participants	One-dimensional CNNs	Sensitivity: 97%; specificity: 94%; accuracy: 96%; AUC: 0.98	[31]
NAFLD assessment	MRI proton density fat fraction	135 adult participants with known or suspected NAFLD	Transfer learning with a pretrained CNN by four ultrasound views of liver routinely obtained	SCC: 0.81; AUC: 0.91 (PDFF ≥ 5%)	[27]
NAFLD assessment	Liver biopsy	295 subjects, 198 mild fatty liver, one moderate degree of fatty liver	DCNN-based organ segmentation with Gaussian mixture modeling for automated quantification of the HRI	ICC of two radiologists and DCNN were 0.919, 0.916, 0.734	[33]
The severity of fatty liver	Abdominal ultrasound	21855 B-mode ultrasound images, 2070 patients with different severities from none to severe fatty liver	Pretrained CNN models with B-mode ultrasound images	The areas under the receiver operating characteristic curves were 0.974 (mild steatosis *vs* others), 0.971 (moderate steatosis *vs* others), 0.981 (severe steatosis *vs* others), 0.985 (any severity *vs* normal) and 0.996 (moderate-to-severe steatosis clinically abnormal *vs* normal-to-mild steatosis clinically normal)	[29]

AUC: Area under curve; CNN: Convolutional neural network; DCNN: Deep convolutional neural network; HRI: Hepato-renal index; ICC: Intraclass correlation; MRI: Magnetic resonance image; NAFLD: Nonalcoholic fatty liver disease; PDFF: Proton density fat fraction; SCC: Spearman correlation coefficient.

performance than the traditional quantitative ultrasound when classifying steatosis[32].

An HRI model based on CNNs was also tested for NAFLD evaluation. Cha *et al*[33] reported that an automated approach had no significant difference in hepatic measurements and HRI calculations compared with experienced radiologists, which indicated that the aid of deep learning could reduce a radiologist's workload and improve the residents' diagnostic accuracy. In this study, an automated HRI calculation algorithm was used, including liver and kidney segmentation, kidney ROI extraction, liver ROI extraction, and calculation of the HRI.

APPLICATION OF AI IN FLLS

HCC is the most conventional original malignant FLL, which is the sixth most common cancer in human beings as well as the fourth cause of cancer-related deaths in the world[1]. Hence, early accurate differential diagnosis of malignant and benign FLL is important for the management and prognosis of patients[34].

Ultrasound is the first-line imaging modality to identify FLLs in the clinical workflow. The development of AI provides a new method to improve the accuracy of ultrasound in diagnosing FLLs. Compared with radiologists viewing anatomical images, AI can better reflect monolithic tumor morphology as well as capture both granular and radiological patterns in a specific task, which is difficult by normal human vision[35]. Figure 2 illustrates the flowchart of the application of deep learning and radiomics in FLLs. Studies have confirmed that the application of AI can improve the diagnostic performance of ultrasound for FLLs (Table 2).

Differential diagnosis of FLLs

AI based on B-mode ultrasound: AI has been widely used in differentiating malignant and benign FLLs based on B-mode ultrasound. Gray level co-occurrence matrix could be used in extracting features from B-mode images, which has been used in differentiating malignant and benign FLLs combined with a fuzzy support vector machine[36]. This study achieved an area under the curve of 0.984 and 0.971 in database 1 and database 2, respectively, which confirmed the feasibility of AI in this field.

Table 2 Studies using artificial intelligence based on ultrasound for focal liver lesion diagnosis

Modality and task	Approach	Target disease: number of the case	Performance	Ref.
Classifying different FLLs based on B-mode	ANN	Cyst: 29; hemangioma: 37; malignant tumor: 33	Cyst *vs* hemangioma accuracy: 99.7%; cyst *vs* malignant tumor accuracy: 98.7%; hemangioma *vs* malignant tumor accuracy: 96.1%	[40]
Differentiating benign and malignant lesions based on B-mode	CNN	Benign lesions: 300; malignant lesions: 296	All lesion accuracy: 84%; uncertain set of lesion accuracy: 79%	[37]
Classifying different FLLs based on B-mode	ANN (sparse autoencoder)	Normal liver: 16; cyst: 44; hemangioma: 18; HCC: 30	overall accuracy: 97.2%; overall sensitivity: 98%; overall specificity: 95.7%	[41]
Differentiating benign and malignant lesions based on B-mode	FSVM	training set; DS1: benign lesions: 132, malignant lesions: 68; DS2: malignant liver cancer: 50, hepatocellular adenoma: 150, hemangioma: 35, focal nodular hyperplasia: 145, lipoma: 70	DS1: accuracy: 97%, sensitivity: 100%, specificity: 95.5%, AUC: 0.984; DS2: accuracy: 95.1%, sensitivity: 92.0%, specificity: 95.5%, AUC: 0.971	[36]
Classifying different FLLs based on B-mode	CNN	Non-tumorous liver: 258, hemangioma: 17, HCC: 6, cyst: 30, focal nodular hyperplasia: 8	AUC for tumor detection: 0.935; AUC for tumor discrimination (mean): 0.916	[42]
Diagnosing HCC based on B-mode	CNN	Malignant tumor: 1786; benign tumor: 427	AUC for EV: 0.924	[38]
Differentiating benign and malignant lesions based on B-mode	CNN	HCC: 6; cyst: 6600; hemangioma: 5374; focal fatty sparing: 5110; focal fatty infiltration: 934	IV: overall sensitivity: 83.9%; overall specificity: 97.1%; HCC detection rate: 85.3%; EV: overall sensitivity: 84.9%; overall specificity: 97.1%; HCC detection rate: 78.3%	[39]
Classifying different FLLs based on CEUS	ANN	hemangioma: 16; focal fatty liver: 23; HCC: 41; metastatic tumor: 32 (hypervascular: 20 hypovascular: 12)	Accuracy: 94.5%; sensitivity: 93.2%; specificity: 89.7%	[47]
Differentiating benign and malignant lesions based on CEUS	Deep belief networks	HCC: 6; hemangioma: 10; liver abscess: 4; metastases: 3; focal fatty sparing: 3	Accuracy: 83.4%; sensitivity: 83.3%; specificity: 87.5%	[59]
Differentiating benign and malignant lesions based on CEUS	SVM	Benign tumor: 30; malignant tumor: 22	Accuracy: 90.3%; sensitivity: 93.1%; specificity: 86.9%	[45]
Differentiating benign and malignant lesions based on CEUS	SVM	Benign tumor, HCC or metastatic tumor: 98	Benign *vs* malignant accuracy: 91.8%, sensitivity: 93.1%, specificity: 86.9%; benign *vs* HCC *vs* metastatic carcinoma: accuracy: 85.7%; sensitivity: 84.4%; specificity: 87.7%	[46]
Differentiating benign and malignant lesions based on CEUS	Deep canonical correlation analysis + multiple kernel learning	Benign tumor: 46; malignant tumor: 47	Accuracy: 90.4%; sensitivity: 93.6%; specificity: 86.9%	[43]
Differentiating benign and malignant lesions based on CEUS	3D-CNN	HCC: 2110; focal nodular hyperplasia: 2310	Accuracy: 93.1%; sensitivity: 94.5%; specificity: 93.6%	[44]
Differentiating benign and malignant lesions based on CEUS	Deep neural network	Focal nodular hyperplasia: 16; HCC: 30; hemangioma: 23; hypervascular metastasis: 11; hypovascular metastasis: 11	Top accuracy: 88%	[48]
Differentiating benign and malignant lesions based on CEUS	CNN	Development set: malignant tumor: 281, benign tumor: 82; testing set: malignant tumor: 164, benign tumor: 47	Accuracy: 91.0%; sensitivity: 92.7%; specificity: 85.1%; AUC: 0.934	[49]

ANN: Artificial neural network; AUC: Area under curve; CEUS: Contrast-enhanced ultrasound; CNN: Convolutional neural network; DS1: Database 1; DS2: Database 2; EV: External validation; FLL: Focal liver lesion; FSVM: Fuzzy support vector machine; HCC: Hepatocellular carcinoma; IV: Internal validation; SVM: Support vector machine; 3D: Three-dimensional.

With the development of AI, deep learning plays a more vital role in the differential diagnosis of FLLs. A CNN with ResNet50 was utilized to recognize benign from malignant solid liver lesions through ultrasonography. The performance was comparable to that of expert radiologists[37]. However, this study did not involve other information such as clinical factors. In another (multicenter) study, after adding seven clinical factors, a higher accuracy, sensitivity and specificity was obtained, compared with those from radiologists with 15 years of experience. The area under the curve for recognizing malignant from benign lesions reached up to 0.924 in the external validation cohort[38].

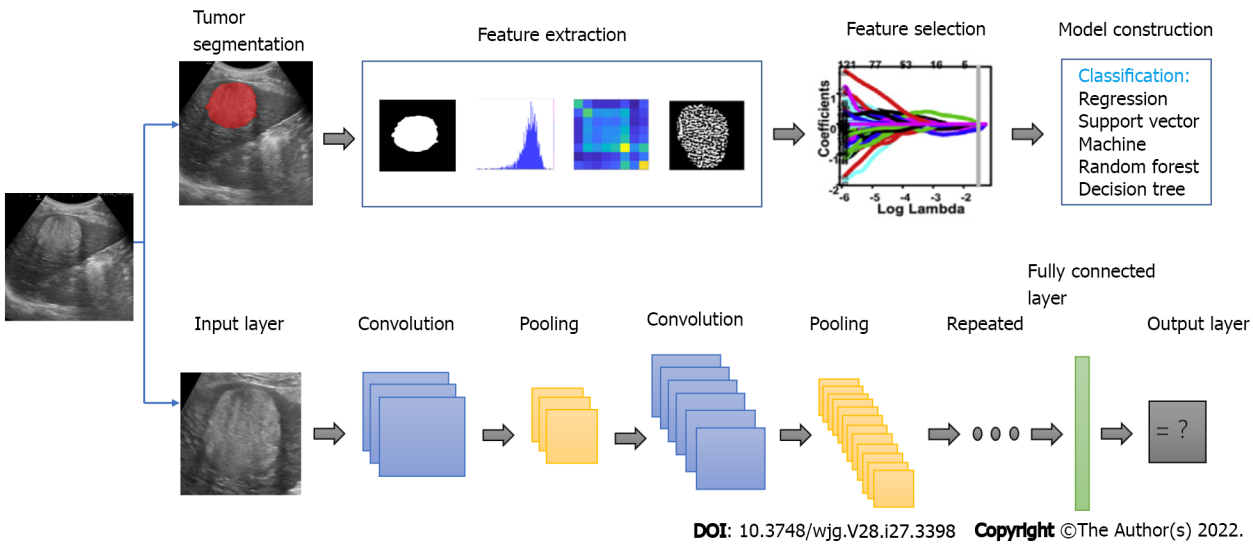

Figure 2 Illustration of the flowchart of the application of deep learning and radiomics in focal liver lesions. These two methods were based on big data, which contained image preprocessing, feature extraction and model construction.

However, the aforementioned studies only included common FLLs. Increasing the types of FLLs may confuse the diagnosis and reduce the accuracy. Similar to the previous study, a multicenter study estimating internal validation and external validation cohorts had a larger volume of training data and involved more varieties of FLLs, including cysts, HCC, hemangiomas, focal fatty infiltration and focal fatty sparing[39]. Although they obtained a lower sensitivity due to more types of diseases, the performance in the external validation cohorts was still satisfactory. In addition, they utilized videos as training materials to achieve real-time analysis in the future workflow. This novel approach would offer great convenience to radiologists in helping differentiate FLLs.

AI could also be used in the classification of FLLs. In order to optimize feature sets, a hybrid textural feature extraction system was proposed by Hwang *et al*[40]. In their preliminary study, a high accuracy was observed in classifying cysts *vs* hemangiomas and cysts *vs* malignant lesions. However, when classifying hemangiomas *vs* malignant lesions by extracting multiple ROI, the accuracy was only 80%. The proposed approach exhibited a better accuracy in all classification groups by quantifying the key features in ultrasound images, especially in classifying hemangioma *vs* malignant, with an accuracy of 96.13%.

Later, a sparse autoencoder system based on deep learning was proposed in diagnosing cysts, hemangiomas and malignant lesions, and it outperformed the three progressive techniques, including K-enarest neighbor, multi-support vector machine and naive Bayes, with an overall accuracy of 97.2% [41].

These two studies[40,41] focused on three kinds of FLLs. An algorithm that could simultaneously detect and characterize FLLs based on deep learning was proposed in diagnosing HCC, focal nodular hyperplasia, cysts, hemangiomas and metastasis, and it achieved an average area under the curve of 0.916[42]. That study yielded promising results by using a small amount of data. Larger databases would increase the accuracy of this model.

AI based on contrast-enhanced ultrasound: It is reported that contrast-enhanced ultrasound (CEUS) images had better sensitivity and specificity for differentiating between malignant and benign tumors compared with B-mode images, which indicated CEUS had a superior diagnostic performance. Combining AI with CEUS could differentiate benign and malignant FLLs and classify different kinds of malignant lesions.

AI could be used to differentiate malignant and benign FLLs based on three-phase CEUS images. A two-stage multiple view learning that represented the integration of deep canonical correlation analysis and multiple kernel learning was used to fuse the characteristics of three-phase patterns in CEUS, presenting an accuracy of 90.41%[43]. The proposed algorithm had both a low computational complex and a high predictive accuracy. For multiview CEUS images, utilizing a multimodal feature fusion algorithm is necessary.

Compared with deep canonical correlation analysis-multiple kernel learning, the use of a three-dimensioned CNN, which integrated the relationship between two temporally adjacent frames to extract features spatially and temporally, achieved a higher accuracy of 93.1%, sensitivity of 94.5% and specificity of 93.6%[44]. However, this algorithm still needs to be validated.

These two studies above[43,44] exploited heterogeneous visual morphology to describe the difference between liver masses. Apart from this method, time-intensity curve (TIC), which represents the contrast

intensity constantly and generates the fitted curve of enhanced intensity during the process, was used in many studies.

Support vector machine[45,46] and deep learning[47,48] based on TICs have presented good performances in differentiating FLLs. A support vector machine-based image analysis system was used for FLL classification and presented an area under the curve of 0.89[45]. An artificial neural network diagnostic system based on TICs was shown to have a similar accuracy and specificity in classifying five different liver tumors 10 years ago[47]. Later, deep learning became more mature, and TICs of the arterial and the portal vein phases of CEUS videos were extracted on the basis of the deep belief networks, a kind of neural network that was composed of layers of Boltzmann machines, to analyze the extracted TICs[48]. The accuracy of this deep learning method for classifying benign from malignant lesions was 83.36%. A novel evaluation procedure named 'leave-one-patient-out' and custom DNNs were creatively presented. That study involved various types of liver lesions and compared the custom DNN designs with the state-of-the-art architectures and obtained a maximal accuracy of 88% by utilizing the proposed evaluation procedure in both pretrained and trained-from-scratch models. This novel approach has a magnificent prospect for development, and it is worth further investigation.

AI based on CEUS was shown to assist in clinical settings as the reference and improve the performance of residents in the differentiation of benign and malignant FLLs[49]. In the future, it will likely play a supporting role in clinical work. However, AI based on TICs tends to complicate the calculation because generating TICs is a time-consuming process. Therefore, developing new approaches to extract features from CEUS images is important.

Application of AI in predicting curative effect and prognosis of HCC

It was reported that the Edmondson-Steiner grade is a vital preoperation predictor of tumor survival and recurrence after undergoing surgical resection[50,51]. Because preoperative pathological differentiation grade can only be obtained by an invasive biopsy[52], it is necessary to explore a noninvasive method to predict therapeutic effect, recurrence and metastasis to achieve personalized treatment.

Some studies[53-55] demonstrated the superiority of AI based on CEUS in predicting a curative effect and prognosis in HCC. Although the results revealed a better performance of AI models compared with a single clinical or ultrasound model, a better performance may be obtained by adding clinical factors in the future studies.

Predicting curative effect of HCC: Transarterial chemoembolization (TACE) is the first-line therapy in patients who are diagnosed with mid-stage HCC, and the response to the first TACE treatment is related to the subsequent curative effect and survival. Therefore, it is necessary to predict the personalized responses to the first TACE treatment. A deep learning radiomics-based CEUS model, machine learning radiomics-based B-mode image model and machine learning radiomics-based TIC of the CEUS model were established to achieve this function[53]. These models presented a better performance compared with the hepatoma arterial embolization prognostic score based on three indexes concerning liver function and tumor load, which will be of great benefit in selecting both first treatment and subsequent therapies after the first TACE treatment.

Predicting prognosis of patients with HCC: Radiofrequency ablation and surgical resection are recommended for early-stage HCC. Deep learning could also be used to predict the progression-free survival of these two therapies in HCC patients[54]. Two models based on these two kinds of therapies provided a satisfactory prediction accuracy and calibration of 2-year progression-free survival. In another study[55], a three dimensional-CNN model, which avoided missing information from CEUS images compared with extracting features from four-phase images, was used. It was observed that predicting prognosis of different treatments in advance and timely swapping of treatment would increase the 2-year progression-free survival, which could contribute to a better prognosis.

Application of AI in predicting MVI of HCC

MVI has shown to be the independent predictor of recurrence and poor outcomes of HCC. Therefore, making a noninvasive and accurate preoperative identification of MVI would be of great significance for HCC patients. The application of AI in predicting MVI achieved good performance based on gray-scale ultrasound images and CEUS.

The radiomics score based on ultrasound of HCC was established and shown to be an independent predictor of MVI[56]. The performance of the clinical nomogram improved significantly with the aid of a radiomics score, which demonstrated the important role of this technique.

Features of the peritumoral area have been shown to be more accurate recently[56]. The radiomic signatures from the gross and peritumoral region showed the best performance compared with the gross-tumoral region and the peritumoral region[57]. The area under the curves were 0.726 based on features of the gross and peritumoral region and 0.744 after the incorporation of essential clinical information.

These studies[56,57] mentioned above have confirmed the application of AI based on gray-scale ultrasound, and AI could be applied to CEUS in predicting MVI as well. Zhang *et al*[58] extracted radiomics features from the B-mode, artery phase, portal venous phase and delay phase images of

preoperative CEUS to construct four radiomics scores based on the primary dataset. Then, they used four radiomic scores and clinical factors for multivariate logistic regression analysis, which demonstrated that the portal venous phase and delay phase radiomics score, tumor size and alpha-fetoprotein level were independent risk factors in predicting MVI. The radiomics nomogram based on these four predictors indicated a better discrimination and a good calibration compared with the clinical model (based on tumor size and alpha-fetoprotein level) in both the primary dataset (area under the curve: 0.849 *vs* 0.690) and the validation dataset (area under the curve: 0.788 *vs* 0.661). This study developed a new noninvasive predictive nomogram based on CEUS that could provide useful information in predicting MVI preoperatively, thus facilitating the choice of a more appropriate surgical option.

CONCLUSION

In conclusion, AI can provide great assistance in the evaluation of diffuse liver diseases (including liver fibrosis and liver steatosis) and FLLs. First, it could be applied to identify and stage liver fibrosis on the basis of B-mode ultrasound, Doppler ultrasound, and elastography. Second, the application of deep learning could be used to make qualitative evaluation based entirely on B-mode images and quantitative evaluation based on radiofrequency signals and HRI, which would improve the ultrasound detection rate of NAFLD. Third, AI has the ability to differentiate malignant FLLs from benign FLLs as well as classify different kinds of FLLs with a better performance compared with clinical indexes. Fourth, the curative effect and prognosis of HCC treatment can be predicted, and an optimal personalized treatment can be chosen. Last, AI based on B-mode ultrasound and CEUS could predict MVI of HCC preoperatively, which could be helpful for more appropriate surgical planning. These applications had good specificity, accuracy and a comparable or even better performance compared with experts in the diagnosis and differentiation of diffuse and focal liver lesions.

There are also some limitations in the applications of AI using ultrasound. First, it is difficult to prepare a large-scale dataset, especially for medical images. Second, although deep learning is the widest used algorithm and has good performance in various studies, its interpretability and generalization is low. Third, the input data may vary from different equipment and operators, which would influence the performance of AI. Last, because a large amount of data is needed to train and validate the established algorithms, the conclusions of many single-center studies are not convincing. Therefore, researchers are expected to conduct more multicenter studies and incorporate more samples, as much as possible. At the same time, optimizing algorithms and creating standards for medical images are also necessary. Despite medical images, researchers could also build the database containing important clinical factors to establish a more comprehensive AI model for future work.

Abstract

High rates of excessive calorie intake diets and sedentary lifestyles have led to a global increase in nonalcoholic fatty liver disease (NAFLD). As a result, this condition has recently become one of the leading causes of hepatocellular carcinoma (HCC). Furthermore, the incidence of NAFLD-associated HCC (NAFLD-HCC) is expected to increase in the near future. Advanced liver fibrosis is the most common risk factor for NAFLD-HCC. However, up to 50% of NAFLD-HCC cases develop without underlying liver cirrhosis. Epidemiological studies have revealed many other risk factors for this condition; including diabetes, other metabolic traits, obesity, old age, male sex, Hispanic ethnicity, mild alcohol intake, and elevated liver enzymes. Specific gene variants, such as single-nucleotide polymorphisms of patatin-like phospholipase domain 3, transmembrane 6 superfamily member 2, and membrane-bound O-acyl-transferase domain-containing 7, are also associated with an increased risk of HCC in patients with NAFLD. This clinical and genetic information should be interpreted together for accurate risk prediction. Alpha-fetoprotein (AFP) is the only biomarker currently recommended for HCC screening. However, it is not sufficiently sensitive in addressing this diagnostic challenge. The GALAD score can be calculated based on sex, age, lectin-bound AFP, AFP, and des-carboxyprothrombin and is reported to show better diagnostic performance for HCC. In addition, emerging studies on genetic and epigenetic biomarkers have also yielded promising diagnostic potential. However, further research is needed to establish an effective surveillance program for the early diagnosis of NAFLD-HCC.

Core Tip: This review summarizes the risk factors and diagnostic biomarkers for nonalcoholic fatty liver disease (NAFLD)-associated hepatocellular carcinoma (HCC). The highlighted risk factors include liver fibrosis, diabetes, age, sex, race, alcohol intake, elevated liver enzymes, and specific genetic variants. Currently available diagnostic biomarkers include alpha-fetoprotein (AFP), des-carboxyprothrombin, and the AFP isoform L3. The combined use of these biomarkers may increase the diagnostic sensitivity of NAFLD-HCC detection. However, more discussion will be necessary on the cost-effectiveness of these approaches. This review also summarizes emerging means of discovering novel biomarkers using omics techniques. A better understanding of these risk factors and diagnostic biomarkers will facilitate the effective surveillance of NAFLD-HCC.

INTRODUCTION

Hepatocellular carcinoma (HCC) accounts for the majority of primary liver cancers[1]. It is the sixth most common form of cancer and the fourth leading cause of worldwide cancer-related deaths[2]. By contrast to the declining trends for other major cancers, mortality rates from liver cancer have increased by almost 3% *per* year[3]. Chronic liver infection from hepatitis B or C virus (HBV or HCV, respectively) and alcohol abuse are the most common causes of HCC[1,4]. However, there is a growing concern about the rapid increase in nonalcoholic fatty liver disease (NAFLD) as another cause of HCC.

NAFLD is a spectrum of chronic liver diseases characterized by excess fat accumulation in hepatocytes[5]. The prevalence of NAFLD is rapidly increasing worldwide, with recent studies reporting a global percentage of approximately 25%[6]. Unsurprisingly, the incidence of NAFLD-associated HCC (NAFLD-HCC) is also increasing in many areas of the world. In the United States, the proportion of NAFLD-HCC among all HCC patients has significantly increased from 9.3% to 13.6% over the past decade[7]. In a French cohort of patients who underwent liver resection, the prevalence of NAFLD-HCC increased from 2.6% (1995-1999) to 19.5% (2010-2014)[8]. Similar trends are also seen in Asian countries. According to a nationwide survey conducted in Japan, the proportion of nonalcoholic steatohepatitis (NASH)-related HCC has increased from 1.5% (2007 or before) to 7.2% (2014–2016)[9]. Universal HBV vaccination and widespread use of direct-acting antiviral agents for HCV are expected to decrease the number of virus-related HCC cases. Nonetheless, NAFLD-HCC is expected to continue to rise in the future[10,11].

NAFLD-HCC is often diagnosed at an advanced stage due to a lack of efficient surveillance policies [11]. In the Veteran Affairs population, only 40% of NAFLD-HCC patients underwent HCC surveillance compared to more than 80% of patients with HCV-related HCC[12]. From the perspective of cost-effectiveness, HCC screening should be considered when the annual risk of HCC exceeds 0.4–2.0%[13,14]. However, in a large-scale retrospective cohort study, out of 2382289 person-years of follow-up, only 490 patients with NAFLD were diagnosed with HCC (0.21/1000 person-years)[15]. Thus, it is necessary to more effectively identify high-risk patients who will benefit from HCC surveillance. Additionally, the diagnostic performance of the implemented examination is important for effective surveillance. Although ultrasonography with or without alpha-fetoprotein (AFP) is recommended for HCC screening [16], the sensitivity and specificity of these examinations are insufficient in patients with NAFLD. The high prevalence of obesity in patients with NAFLD impairs ultrasonography performance[17]. Therefore, many researchers have been searching for alternative NAFLD-HCC surveillance tools to increase the chances of early diagnosis. Recent advances in omics technology have enabled easier genetic and epigenetic benchmark analysis. Thus, many potential biomarkers are currently under investigation.

In this review, we discuss the current evidence for clinical and genetic HCC risk factors. We also summarize previous reports on the diagnostic biomarkers of NAFLD-HCC, including those under development. Finally, we briefly address future perspectives on HCC surveillance for NAFLD patients.

CLINICAL RISK FACTORS

Liver fibrosis

Liver fibrosis is the most important risk factor for the development of HCC in patients with NAFLD[18,

19]. In a large retrospective cohort study, the annual HCC incidence rates amongst NAFLD patients with and without cirrhosis were 10.6 and 0.08 *per* 1000 person-years, respectively[15]. This indicates that the presence of liver cirrhosis increases the risk of NAFLD-HCC by more than 10-fold (Table 1).

Liver biopsy is the gold standard for evaluating the fibrotic stage of the liver[20]. However, noninvasive examinations are more widely used in clinical practice. Available serum biomarkers for assessing fibrosis include the aspartate transaminase (AST)-to-platelet ratio index, Fibrosis-4 (FIB-4) index, and enhanced liver fibrosis score[21]. The FIB-4 index is calculated using various factors; including age, AST, alanine aminotransferase (ALT), and platelet count. Furthermore, a significant association between the FIB-4 index and HCC risk in NAFLD patients has been reported[15,22]. The Mac-2-binding protein glycosylation isomer is a novel serum biomarker that shows relatively high efficacy at assessing liver fibrosis[23]. It may also be useful in predicting the risk of hepatocarcinogenesis among NAFLD patients[24].

Additionally, elastography techniques using ultrasound or magnetic resonance imaging are useful tools for noninvasive evaluation of degree of fibrosis[21]. A retrospective study from Japan suggested that shear wave velocity measurements can be used for HCC risk assessment in NAFLD patients[25].

Diabetes mellitus and other metabolic traits

Several studies have demonstrated that (mostly type 2) diabetes mellitus is associated with an increased risk of HCC development in NAFLD patients. The hazard ratio for HCC in diabetic patients has been reported to be around 2.2–4.2[22,26,27] (Table 1). In a nationwide Japanese study, the annual incidence of HCC was only 0.11% in diabetes patients overall. However, it increased to 1.0% when they had an FIB-4 index of 3.5 or more[14]. Therefore, the degree of liver fibrosis, together with presence or absence of diabetes, should be assessed to predict the risk of NAFLD-HCC.

There have been conflicting reports regarding the association between other metabolic traits such as hypertension, dyslipidemia, with NAFLD-HCC[28]. However, a recent study showed that these conditions were also risk factors for NAFLD-HCC (Table 1). Furthermore, the hazard ratio for HCC was 5.6 in patients with diabetes, hypertension, and dyslipidemia[27,29].

Obesity

Regardless of underlying liver diseases, obesity is associated with an increased risk of HCC[30]. This relationship has also been confirmed in patients with NAFLD[29,31]. In a cohort of NAFLD-HCC patients treated with curative radiofrequency ablation, the degree of visceral fat accumulation, but not body mass index (BMI), was independently associated with an increased risk of HCC recurrence[32]. A propensity score-matched study showed that the incidence of both NASH and HCC were significantly lower in patients who underwent bariatric surgery, indicating a protective role of sustained weight loss by bariatric surgery[33].

Age, sex, and race

Old age, male sex, and Hispanic ethnicity are also known risk factors for NAFLD-HCC (Table 1); the details are described in another review article[31]. In the United States, a multicenter case-control study showed that old age (*per* year) and male sex were independently associated with a higher NAFLD-HCC risk [odds ratios (OR), 1.08 and 4.34, respectively][34]. In another study, age ≥ 65 years was associated with a 1.83 times higher NAFLD-HCC risk compared to age < 65 years[15]. Regarding ethnicity, a previous study showed that Hispanic patients had a lower NAFLD-HCC risk (OR, 0.3). By contrast, another study showed the opposite result (hazard ratio, 1.59)[15,34]. Several other studies have shown that Hispanic ethnicity is, in itself, a risk factor for NAFLD, partly because of the high prevalence of patatin-like phospholipase domain 3 (*PNPLA3*) variants among Hispanic people[35,36].

Alcohol intake and smoking

NAFLD is defined as hepatic steatosis without harmful alcohol intake (more than 30 g/day for men and 20 g/day for women). However, mild alcohol intake can also be a risk factor for NAFLD-HCC[37]. Previous studies have shown that mild drinking habits were associated with 3.6–4.8 times higher risk of HCC in NAFLD patients compared to no habits of drinking[38,39] (Table 1). No study has specifically investigated the association between smoking and NAFLD-HCC. However, smoking is associated with an increased risk of HCC. Additionally, it has been reported to be associated with advanced liver fibrosis in NAFLD patients[31,40]. Because these factors are modifiable, NAFLD patients should be informed that cessation of alcohol intake and smoking may reduce the risk of future HCC development.

Elevated liver enzymes

Patients with NASH are thought to have a higher risk of HCC than those with NAFLD[18]. However, liver biopsy is required to accurately distinguish these conditions. Therefore, elevated liver enzyme levels are often used as surrogate markers for NASH in clinical practice. Several studies have shown that elevated liver enzymes in NAFLD patients are significantly associated with an increased risk of HCC (hazard ratio, 2.07–8.20)[41-43] (Table 1). At the same time, however, normal transaminase levels do not exclude the possibility of advanced liver fibrosis[44].

Table 1 Clinical risk factors for nonalcoholic fatty liver disease-associated hepatocellular carcinoma

Risk factors	Reported evidence	Ref.
Liver fibrosis	The annual incidence rate of HCC in NAFLD patients with cirrhosis was more than 10 times higher than in those without	[15,22,24,25]
	Non-invasive fibrosis markers (*e.g.*, FIB-4 index, M2BPGi, and shear wave velocity in VTQ) also had significant associations with the risk of NAFLD-HCC	
Diabetes	Associated with increased risk of HCC in NAFLD patients (hazard ratio: 2.2–4.2)	[22,26,27]
Hypertension	May be an independent risk factor for NAFLD-HCC	[29]
Dyslipidemia	May be an independent risk factor for NAFLD-HCC	[29]
Age	Increased age was an independent risk factor for HCC in patients with NASH-related cirrhosis	[15,34]
	NAFLD patients aged ≥ 65 had 1.83 times higher risk of HCC than those aged < 65	
Male sex	Male patients with NASH-related cirrhosis had 4.34 times higher risk of HCC than female patients	[34]
Ethnicity	Hispanic ethnicity was associated with 1.59 times higher risk of HCC in NAFLD patients compared to white ethnicity (however, there have been conflicting results)	[15]
Mild alcohol intake	Associated with increased risk of HCC in NAFLD patients (hazard ratio: 3.6–4.8)	[38,39]
Elevated liver enzymes	Associated with increased risk of HCC in NAFLD patients (hazard ratio: 2.1–8.2)	[41-43]

HCC: Hepatocellular carcinoma; NAFLD: Nonalcoholic fatty liver disease; FIB-4: Fibrosis-4; M2BPGi: Mac-2-binding protein glycosylation isomer; VTQ: Virtual touch quantification; NASH: Nonalcoholic steatohepatitis.

Combined risk assessment

As we described above, many factors influence the risk of HCC in NAFLD patients. Therefore, integrating multiple factors will improve the accuracy of risk assessment. Lee *et al*[45] proposed a risk prediction model consisting of age, platelet count, and liver stiffness. This showed relatively good prediction performance in the validation cohort (*i.e.*, area under the receiver operating characteristic curve (AUROC), 0.78)[45]. Ioannou *et al*[46] reported another prediction model with a similar predictive value (AUROC, 0.75), consisting of age, sex, diabetes, BMI, platelet count, serum albumin, and AST/√ALT ratio[46].

GENETIC RISK FACTORS

Although NAFLD development and progression is largely determined by environmental factors, several genetic factors are involved in NAFLD pathogenesis. These genes included *PNPLA3*, transmembrane 6 superfamily member 2 (*TM6SF2*), glucokinase regulator (*GCKR*), membrane-bound O-acyl-transferase domain-containing 7 (*MBOAT7*), and 17-beta-hydroxysteroid dehydrogenase 13 (*HSD17B13*)[5,47]. Epigenetic factors, such as DNA methylation, histone modification, and non-coding RNAs, also play roles in the progression of NAFLD and hepatocarcinogenesis[48]. The risk of severe liver fibrosis has been reported to be 12.5-fold higher in patients with first-degree relatives with NAFLD-related cirrhosis than those without[49].

Single-nucleotide polymorphisms (SNPs) of *PNPLA3* have been the most studied for its association with HCC[50]. In a cohort of European Caucasian patients with NAFLD, the *PNPLA3* rs738409 polymorphism was significantly associated with HCC risk. GG carriers were found to evince a 5-fold increased risk compared to CC carriers[51]. This association was confirmed by subsequent studies[52,53]. The *TM6SF2* rs58542926 polymorphism has been reported to be another risk factor for HCC and advanced fibrosis/cirrhosis[54,55]. In addition, the *MBOAT7* rs641738 variant has also been reported as a risk factor for NAFLD-HCC. Furthermore, in an Italian cohort, the rs6417338 C-to-T variant was associated with a 1.65-fold increased risk of HCC[56]. Other reported SNPs associated with NAFLD-HCC risk include Toll-like receptor 5 rs5744174[57], signal transducer transcription 6 rs167769[58] activator, yes-associated protein 1 rs11225163[58], *HSD17B13* rs72613567[55], and dystrophy-associated fer-1-like protein rs17007417[59] (Table 2).

Zhang *et al*[55] reported a combined risk assessment model consisting of *PNPLA3*, *TM6SF2*, and *HSD17B13* variants[55]. In this study, patients with the highest score had a 29-fold higher risk of developing HCC. Bianco *et al*[60] reported another polygenic risk assessment model consisting of *PNPLA3*, *TM6SF2*, *GCKR*, *MBOAT7*, and *HSD17B13*[60]. The sensitivity and specificity for diagnosing HCC were 0.43 and 0.79%, respectively (AUROC, 0.65).

Table 2 Genetic risk factors for nonalcoholic fatty liver disease-associated hepatocellular carcinoma

Risk factors	Reported evidence	Ref.
PNPLA3	Carriage of rs738409 GG polymorphism is associated with 5.1–6.4-fold increased risk of HCC in NAFLD patients	[51-53,60]
	PNPLA3 G variant (GG *vs* CG *vs* CC) was not significantly associated with the risk of cardiovascular events extrahepatic cancers or overall death, but was associated with HCC (HR: 2.66) and liver-related death (HR: 2.42)	
	Used for developing polygenic risk scores	
TM6SF2	*TM6SF2* minor allele carriage (rs58542926 C>T) was associated with advanced fibrosis/cirrhosis and HCC (OR, 2.8) in NAFLD patients	[54,55,60]
	Combined assessment with *PNPLA3* and *HSD17B13* variants were useful for risk stratification of NAFLD-HCC	
	Used for developing polygenic risk scores	
MBOAT7	*MBOAT7* rs641738 C>T variants were associated with higher risk of HCC in NAFLD patients (OR, 1.65–2.10)	[56,60]
	Used for developing polygenic risk scores	
TLR5	*TLR5* rs5744174 TT genotype was a risk factor of HCC in patients with steatohepatitis-related cirrhosis (OR, 1.9)	[57]
STAT6	*STAT6* rs167769 CC genotype was inversely associated with the risk of HCC in NASH patients (OR, 0.015)	[58]
YAP1	Carriage of *YAP1* rs11225163 C allele was inversely associated with the risk of HCC in NASH patients (OR, 0.047)	[58]
HSD17B13	Combined assessment with *PNPLA3* and *TM6SF2* variants were useful for risk stratification of NAFLD-HCC	[55]
DYSF	*DYSF* rs17007417 T allele carriage was associated with increased risk of HCC in NAFLD patients (OR, 2.74)	[59]
GCKR	*GCKR* rs1260326 T allele carriage was associated with increased risk of HCC in NAFLD patients (OR, 1.38)	[59,60]
	Used for developing polygenic risk scores	

PNPLA3: Patatin-like phospholipase domain 3; HCC: Hepatocellular carcinoma; NAFLD: Nonalcoholic fatty liver disease; HR: Hazard ratio; TM6SF2: Transmembrane 6 superfamily member 2; HSD17B13: 7-beta-Hydroxysteroid dehydrogenase 13; OR: Odds ratio; MBOAT7: Membrane-bound O-acyltransferase domain-containing 7; TLR5: Toll-like receptor 5; STAT6: Signal transducer activator of transcription 6; NASH: Nonalcoholic steatohepatitis; YAP1: Yes-associated protein 1; DYSF: Dystrophy-associated fer-1-like protein; GCKR: Glucokinase regulator.

DIAGNOSTIC BIOMARKERS

Currently available biomarkers

The currently available serum biomarkers for diagnosing HCC include AFP, des-carboxyprothrombin (DCP), and AFP isoform L3 (AFP-L3) (Table 3). Only AFP is recommended for HCC surveillance as *per* the major guidelines[31]. However, patients with NAFLD-HCC tend to have lower AFP levels than those with viral HCC[12,61]. Thus, the combined use of multiple tumor markers may be considered to increase the detection rate of HCC[62]. The GALAD score is a scoring system for the diagnosis of HCC. This score can be calculated by sex, age, lectin-bound AFP, AFP, and DCP. In a German cohort of NASH patients with and without HCC, the GALAD score exhibited excellent diagnostic performance (AUROC, 0.96). This was significantly better than AFP (AUROC, 0.88), DCP (AUROC, 0.87), and AFP-L3 (AUROC, 0.86) alone[63]. However, it must be noted that that only 20% of the HCC patients included in this study were within the Milan criteria. In addition, further research is needed from the perspective of cost effectiveness to determine whether this scoring system should be recommended for routine HCC screening in patients with NAFLD.

Potential biomarkers under investigation

Many serum biomarkers are under investigation for more accurate diagnosis of NAFLD-HCC without imaging. These biomarkers include iron and transferrin saturation[64], glypican-3 and adiponectin[65], midkine[66], apoptosis inhibitor of macrophages[67,68], glycosylation patterns of glycoproteins[69], and specific types of glycopeptides[70,71] (Table 3). Recently, Kozumi *et al*[72] showed that intrahepatic and serum thrombospondin 2 (*THBS2*) expression levels are strongly associated with advanced fibrosis in patients with NASH[72]. In their study, HCC was observed only in patients with high serum levels of

Table 3 Currently available and potential diagnostic biomarkers for nonalcoholic fatty liver disease-associated hepatocellular carcinoma

Biomarkers	Reported evidence	Ref.
Currently available		
AFP	Modest diagnostic ability for HCC in NAFLD patients (AUROC, 0.71–0.88)	[63,84]
DCP	The diagnostic ability for NAFLD-HCC was similar to that of AFP	[63,84]
	Combined use with AFP improved the diagnostic performance	
	Used for calculation of GALAD score	
AFP-L3	The diagnostic ability for NAFLD-HCC was similar to that of AFP	[63]
	Used for calculation of GALAD score	
Under development		
Iron status	Elevations of serum iron levels and transferrin saturation were associated with increased risk of HCC in NAFLD patients (HR, 2.91 and 2.02, respectively)	[64]
Proteins	Midkine increased the diagnostic yield in AFP-negative HCC in NAFLD patients; 59.2% of AFP-negative NAFLD-HCC patients had elevation of serum midkine levels	[65-67,72]
	IgM-free AIM had better diagnostic performance for NASH-HCC than AFP or DCP (AUROC, 0.905–0.929)	
	Serum TSP-2 levels were significantly associated with advanced fibrosis in NASH patients. Among 164 patients with NAFLD, HCC occurred only in patients with high serum levels of TSP-2	
Glycoprotein	Glycosylation patterns of alpha-1 acid glycoprotein may serve as a diagnostic biomarker for AFP-negative HCC in NAFLD patients	[69]
Proteoglycan	Glypican-3 had modest diagnostic ability (AUROC, 0.759), similar to AFP (AUROC, 0.763). When combined with age, sex, DCP and adiponectin, the AUROC increased to 0.948	[65]
Glycopeptide	Site-specific N-glycopeptides from vitronectin may serve as diagnostic biomarkers for NASH-HCC. When used together with AFP, the AUROC were 0.834 and 0.847, compared to 0.791 of AFP alone	[70,71]
	Site-specific N-glycopeptides from serum haptoglobin showed better diagnostic accuracy for NASH-HCC than AFP	
Cytokine (adipokine)	Adiponectin had slightly better diagnostic ability (AUROC, 0.770) than AFP (AUROC, 0.763). When combined with age, sex, DCP and glypican-3, the AUROC increased to 0.948	[65]
Cell-free DNA	*TERT* promoter mutation (C228T) in serum cfDNA showed better diagnostic ability for early NAFLD-HCC than AFP and DCP	[76,78]
	Methylation biomarkers in cfDNA improved the diagnostic performance when combined with AFP	
microRNA	The expression levels of exosomal miR-182, miR-301a and miR-373 in both serum and ascetic fluid were higher in NASH-cirrhosis patients with HCC than in those without HCC	[77]

AFP: Alpha-fetoprotein; HCC: Hepatocellular carcinoma; NAFLD: Nonalcoholic fatty liver disease; AUROC: Area under receiver operating characteristic curve; DCP: Des-carboxyprothrombin; AFP-L3: AFP isoform L3; HR: Hazard ratio; IgM: Immunoglobulin M; AIM: Apoptosis inhibitor of macrophages; TSP-2: Thrombospondin-2; NASH: Nonalcoholic steatohepatitis; TERT: Telomerase reverse transcriptase; cfDNA: Cell-free DNA; miR: microRNA.

thrombospondin-2 (TSP-2). Thus, serum TSP-2 testing may also be useful for NAFLD-HCC surveillance.

Genetic and epigenetic biomarkers have attracted increasing attention in recent years (Table 3). For example, telomerase reverse transcriptase (*TERT*) promoter mutations, the most common form of HCC genetic alteration[73-75], can be analyzed using cell-free DNA (cfDNA). Akuta *et al*[76] reported that *TERT* C228T mutation could be detected in 63.9% of NAFLD-HCC patients by analyzing cfDNA[76]. Notably, it can be positive, even in patients with normal AFP and DCP levels. Another example of circulating biomarkers is non-coding RNAs, especially microRNAs. In a preliminary study, the serum expression levels of miR-182, miR-301a, and miR-373 were significantly higher in NASH-HCC patients than in NASH patients without HCC[77]. DNA methylation can also be analyzed using peripheral blood. In a recent study, methylation cfDNA biomarkers provided a modest diagnostic value for NAFLD-HCC with a sensitivity of 87.5% and specificity of 39.4%[78]. The combination of this DNA methylation panel and AFP led to a better cohort wide diagnostic performance than either of them used

alone. Although the utility of these biomarkers is yet to be validated, in the near future, advances in omics technology will surely provide better diagnostic tools for NAFLD-HCC than conventional tumor markers.

FUTURE PERSPECTIVES

A more effective surveillance approach is strongly desired to reduce the number of deaths due to NAFLD-HCC. As advanced liver fibrosis is the most common risk factor for NAFLD-HCC, current screening recommendations primarily focus on patients with cirrhosis. However, in a French study, only 37% of patients undergoing liver resection for NAFLD-HCC had bridging fibrosis or cirrhosis; with a frequency significantly lower than that of other etiologies[8]. Similar results were observed in a Japanese multicenter study; in which only 49% of patients with NAFLD-HCC had underlying cirrhosis [79]. Therefore, more than half of patients with NAFLD-HCC will lose the chance of early detection if no other risk factors are considered. As discussed above, other clinical factors and specific genetic variants have robust associations with NAFLD-HCC risk. We should make the best use of this evidence to enhance effective HCC surveillance. In addition, more accurate diagnostic biomarkers for NAFLD-HCC are needed. Among the currently available biomarkers, the GALAD score seems to be the most reliable. However, advances in omics technology will certainly provide more powerful diagnostic tools in the future. For instance, a recent study showed that fragmentomic cfDNA analysis offered excellent accuracy in detecting primary liver tumors (AUROC, 0.995), regardless of the underlying liver disease [80]. Moreover, it showed a sensitivity of over 95%, even for stage I tumors. Thus, further research on genetic and epigenetic biomarkers is very much needed.

Novel conceptional criteria for metabolic dysfunction-associated fatty liver disease (MAFLD) were proposed in 2020[81]. Although MAFLD has been reported as a more practical definition for identifying patients with fatty liver disease with high risk of disease progression[82], it remains unclear whether the evidence of risk factors and diagnostic markers for NAFLD-HCC can be extended to MAFLD-HCC. A nationwide cohort study conducted in Taiwan revealed that patients with NAFLD/MAFLD overlap had similar risk of HCC compared to those with NAFLD alone[83]. Nonetheless, further studies are warranted on this topic.

CONCLUSION

The incidence of NAFLD-HCC is increasing rapidly worldwide. Thus, an effective surveillance approach is required to reduce the number of deaths due to this condition. Although advanced fibrosis is the most important risk factor for NAFLD-HCC, other clinical risk factors such as diabetes, old age, male sex, and elevated liver enzymes should also be considered. Recent advances in omics technology have revealed that genetic factors such as the SNP of *PNPLA3* also affect the risk of hepatocarcinogenesis in patients with NAFLD. With regards to the diagnostic biomarkers for NAFLD-HCC, only AFP is recommended for surveillance as *per* major guidelines. A recent study showed that the GALAD score evinced a more effective diagnostic performance than when AFP was used alone. However, clinical implementation should be discussed from the perspective of cost-effectiveness. Specific gene mutations and DNA methylation can be detected in cfDNA and are expected to be novel biomarkers for the early NAFLD-HCC diagnosis, as well as specific proteins, glycopeptides, and adipokines.

ACKNOWLEDGEMENTS

We would like to thank Drs. Ken Takahashi, Takahiro Shimizu, Yuji Eso, Eriko Iguchi, Ken Kumagai, Masako Mishima, Mari Teramura, Shigeharu Nakano, Takahiko Ito, Haruka Amino, and Takahiro Inoue for their helpful discussions and comments on the manuscript.

Abstract

BACKGROUND

The biochemical phenomenon defined as poly adenosine diphosphate (ADP)-ribosylation (PARylation) is essential for the progression of pancreatic cancer. However, the excessive accumulation of poly ADP-ribose (PAR) induces apoptosis-inducing factor (AIF) release from mitochondria and energy deprivation resulting in the caspase-independent death of cancer cells.

AIM

To investigate whether sustained calcium supply could induce an anticancer effect on pancreatic cancer by PAR accumulation.

METHODS

Two pancreatic cancer cell lines, AsPC-1 and CFPAC-1 were used for the study. Calcium influx and mitochondrial reactive oxygen species (ROS) were observed by fluorescence staining. Changes in enzyme levels, as well as PAR accumulation and energy metabolism, were measured using assay kits. AIF-dependent cell death was investigated followed by confirming *in vivo* anticancer effects by sustained calcium administration.

RESULTS

Mitochondrial ROS levels were elevated with increasing calcium influx into pancreatic cancer cells. Then, excess PAR accumulation, decreased PAR glycohydrolase and ADP-ribosyl hydrolase 3 levels, and energy deprivation were observed. *In vitro* and *in vivo* antitumor effects were confirmed to accompany elevated AIF levels.

CONCLUSION

This study visualized the potential anticancer effects of excessive PAR accumu-

lation by sustained calcium supply on pancreatic cancer, however elucidating a clear mode of action remains a challenge, and it should be accompanied by further studies to assess its potential for clinical application.

Key Words: Pancreatic cancer; Calcium; Reactive oxygen species; Poly adenosine diphosphate-ribose; Poly adenosine diphosphate-ribosylation; Poly adenosine diphosphate-ribose polymerase; Apoptosis-inducing factor; Nicotinamide adenine dinucleotide; Anticancer effect

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Accumulation of poly adenosine diphosphate-ribose (PAR) was induced by an increase in reactive oxygen species following sustained calcium supply, which in turn led to the death of pancreatic cancer cells by energy deprivation and apoptosis-inducing factor expression. Although calcium-mediated accumulation of PAR would be a potential strategy for the treatment of pancreatic cancer, the association with the mechanical role of calcium in enabling the inactivation of PAR-degrading enzymes needs to be elucidated.

INTRODUCTION

Recent literature emphasizes that the biochemical phenomenon defined as poly adenosine diphosphate (ADP)-ribosylation (PARylation) is essential for the progression of cancer[1]. Poly ADP-ribose (PAR) is synthesized by the biochemical reaction of PAR polymerase-1 (PARP-1), which catalyzes the polymerization of ADP-ribose from the donor nicotinamide adenine dinucleotide (NAD+) to form a linear or branched PAR polymer[2]. Because PARylation is implicated in the multistep process involving various physiological maintenance factors and overcoming stress conditions for cancer cell survival, there might be connections between PARP-1 function and pancreatic cancer progression as a bridgehead linked by PARylation[1,2].

Although PARylation is essential for cancer survival, the excessive accumulation of PAR can mediate apoptosis-inducing factor (AIF) release from mitochondria and its nuclear translocation, resulting in the caspase-independent death of cancer cells[3]. The mode of action of the relationship between AIF and PAR involved in cell death has not been elucidated, but AIF translocation to the nucleus leading to chromatin condensation and large-scale DNA fragmentation is a well-established theory[3,4]. Cell death following PAR accumulation was recently defined as parthanatos, which is considered another death mechanism in a large category of apoptosis-type reactions[4]. Therefore, targeting ADP-ribosyl hydrolase 3 (ARH3), a type of PAR-degrading protein, and PAR glycohydrolase (PARG), a reversible covalent-modifier targeting PAR, might be potential methods to induce anticancer effects *via* PAR accumulation[5-7]. Although approaches to inhibit such enzymes through RNA interference or genetic manipulation have been tried, there have been few studies of the relevant mechanisms targeting pancreatic cancer[6,7].

Calcium is a key element in physiological signal transduction that enables the adjustment of energy production to cellular demand[8]; however, some reports indicated that cancer cells were affected during the influx of a high concentration of calcium resulting in excessive reactive oxygen species (ROS) produced from mitochondria[9]. Furthermore, there was an association between PARP-1 and an increase in ROS[1,10,11]. It was reported that the hyperactivation of PARP-1 was induced by an increase in ROS caused by intracellular calcium influx, the activation of PARP-1 as a response to DNA damage, or to drive an antioxidant program to protect cells from ROS[1,10,11]. This implies that excessive PAR accumulation can be induced as a result of PARP-1 hyperactivation followed by PARylation, suggesting the prospect of influencing pancreatic cancer cell survival by supplying high concentrations of calcium. The study aimed to investigate whether a sustained calcium supply induced intracellular PAR accumulation with an increase in ROS and to demonstrate the potential of this phenomenon to promote anticancer effects on pancreatic cancer.

MATERIALS AND METHODS

Cell lines and culture conditions

AsPC-1 and CFPAC-1 were obtained from the American Type Culture Collection (Manassas, VA, United States). The cells were grown in Roswell Park Memorial Institute 1640 and Iscove's Modified Dubecco's Medium supplemented with 10% fetal bovine serum (Welgene, Gyeongsan, Korea) and 1% penicillin/streptomycin (Welgene, Gyeongsan, Korea). All cells were cultured under a humidified atmosphere at 37 °C containing 5% CO_2.

Reagents

Lactate calcium salt (CaLac) and calpeptin were purchased from Sigma-Aldrich (St. Louis, MO, United States) and dissolved in distilled water. The solutions were stored at 4 °C until use.

Measurement of intracellular calcium

Calcium concentrations were measured using a confocal laser scanning microscope (Leica, Heidelberg, Germany). Cultured pancreatic cancer cells were loaded with 10 μM Fluo-3/AM (Invitrogen, Frederick, MD, United States) dissolved in dimethyl sulfoxide (Sigma-Aldrich). Then the cells were incubated for 30 min at 37 °C. Fluo-3/AM was excited at 488 nm and emitted fluorescence was measured at 515 nm.

Immunocytochemistry

Pancreatic cancer cells were fixed on bio-coated coverslips (BD bioscience, NJ, United States) using 4% paraformaldehyde, and incubated for 15 h with the primary antibody against AIF (1:200, Santa Cruz Biotechnology, Santa Cruz, CA, United States). Subsequently, the cells were incubated with an anti-rabbit secondary biotinylated anti-body (1:5000, Abcam) and visualized with streptavidin conjugated to fluorescein (Vector Laboratories, Burlingame, CA, United States). MitoSOX Red (Thermo Fisher Scientific, Waltham, MA, United States) was used to detect mitochondrial superoxide production. Fluorescence was measured using a confocal laser scanning microscope (Leica). Signal intensities were quantified and analyzed using the Xenogen Imaging System (IVIS® 100 series, Caliper Life Science, MA, United States).

Enzyme-linked immunosorbent assay

PARG, RNF-146, PAR, and AIF levels were quantified from 1×10^6 number of pancreatic cancer cells or 2 mm^3 volume of tumor tissues using each assay kit (PARG assay kit: Trevigen, Gaithersburg, MD, United States; RNF-146 ELISA kit: Abbexa, Houston, TX, United States; PAR ELISA kit: Cell Biolabs, San Diego, CA, United States; AIF ELISA kit: Abcam, Cambridge, England), according to the manufacturer's instructions.

Adenosine triphosphate assay

The cell culture medium was supplemented with CaLac, and cultures were incubated for 24 h. 1×10^6 cells were then sonicated. The cells were centrifuged at 1500 g for 20 min to remove insoluble material, and the supernatant was collected. Adenosine triphosphate (ATP) was measured by ATP colorimetric assay kit (Abcam) according to manufacturer's instructions.

NAD+ and NADH assay

The cell culture medium was supplemented with CaLac, and the cultures were incubated for 24 h. 1×10^6 cells were then sonicated. The cells were washed twice with phosphate buffer solution (PBS), and NAD+ and NADH levels were measured using the NAD/NADH quantitation kit (Sigma) according to the manufacturer's protocol.

Transferase-mediated dUTP nick end labeling assay

Pancreatic cancer cells were treated with CaLac for 24 h and then washed with cold PBS. The cells were fixed with 4% paraformaldehyde for 30 min and washed twice with PBS for 2 min. Fixed cells in permeabilization solution (0.1% Triton X-100 and 0.1% Sodium citrate) were washed. The tumors were fixed in 10% neutral buffered formalin and embedded in paraffin. Tissue sections (4 μm) were made from paraffin-embedded blocks on a microtome, and then the sections were deparaffinized and rehydrated. To detect cell death, the DeadEnd™ Fluorometric transferase-mediated dUTP nick end labeling (TUNEL) system kit (Promega, Madison, WI, United States) was used according to the manufacturer's instructions.

FACS analysis

Annexin V and propidium iodide (PI) staining was performed using an Annexin V-FITC Apoptosis Detection Kit (BD Biosciences). 2.5×10^6 of AsPC-1 and CFPAC-1 cells were exposed to CaLac for 24 h. The cells were resuspended in 100 μL of Annexin V-FITC binding buffer, and then 5 μL of Annexin V-FITC conjugate and 10 μL of PI buffer were added. Annexin V and PI were analyzed using a FACS

CaliburTM instrument (BD Biosciences).

Cell viability assay

Pancreatic cancer cells were cultured in a 96-well plate (3×10^3 cells/well) for 24 h, and then treated with CaLac for 24 h at 37 °C. Then, 10 μL of 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide was added to each well, and the cells were incubated at 37 °C for 1 h in a humidified environment containing 5% CO_2. After the media was discarded, 200 μL of dimethyl sulfoxide (Cell Signaling Technology, Danvers, MA, United States) was added to each well. The absorbance was read at 570 nm using a microplate reader (iMark Microplate Absorbance Reader, Bio-Rad, CA, United States).

Xenograft animal model

Twenty-eight male Balb/c nude mice (5 wk of age) were purchased from the Charles River Breeding Laboratories (Wilmington, MA, United States). All animals were maintained on a 12 h light/dark cycle (light on, 08:00) at 22-25 °C, with free access to food and water. To investigate the antitumor activity of CaLac *in vivo*, a therapeutic strategy was devised to investigate its effect on the heterotopic xenograft animal model. Fourteen mice were used for establishing a heterotopic xenograft model using AsPC-1 cells (5×10^6) resuspended in 100 μL of phosphate-buffered saline. The cells were injected subcutaneously into the left flank of mice. Once the tumors reached a diameter of 8 mm, 7 mice were randomly divided into the untreated group, and 7 mice were divided into the CaLac-treated group. 20 mg/kg of CaLac was subcutaneously injected daily for 21 d. Tumor growth was monitored three times per week. To harvest tumors for histological and molecular biology analysis, carbon dioxide inhalation was used for euthanasia at the end of the experiments.

Immunohistochemistry

The tumors were fixed in 10% neutral buffered formalin and embedded in paraffin. Tissue sections (4 μm) were made from paraffin-embedded blocks on a microtome, and then the sections were deparaffinized and rehydrated. Endogenous peroxidase activity was blocked by 3% H_2O_2 in distilled water for 30 min. Antigen retrieval was induced by slide heating with 10 mmol/L citrate buffer (pH 6.0) using a microwave oven. The sections were blocked using a blocking agent (Invitrogen, Frederick, MD, United States) and incubated overnight with the primary antibodies at 4 °C. The primary antibodies were as follows: Ki-67 (1:200, Santa Cruz Biotechnology) and proliferating cell nuclear antigen (PCNA, 1:200, Santa Cruz Biotechnology). The sections were then incubated with biotinylated anti-mouse antibody (1:500, Vector Laboratories, Burlingame, CA, United States) for 1 h. After a PBST wash, the sections were treated with 3,3'-diaminobenzidine substrate (Dako, Carpentaria, CA, United States) and counterstained with hematoxylin (Thermo Fisher Scientific). A Leica DM 1000 LED microscope (Leica Microsystems, Wetzlar, Germany) was used for image analysis.

Statistical analysis

Data are presented as the means ± SD. Statistical significance was analyzed using the Student's *t*-test or one-way analysis of variance, depending on the normality of the data distribution. $P < 0.05$ was considered as statistically significant. All statistical analyses were performed by Sigma Stat v3.5 (Systat Software Inc., Chicago, IL, United States).

RESULTS

Calcium influx increases mitochondrial ROS in pancreatic cancer cells

The fluorescence intensity of fluo-3 by calcium reaction was increased in cells of both types of pancreatic cancer, AsPC-1 and CFPAC-1, following CaLac treatment (Figure 1A). In a quantitative analysis of fluorescence intensity, intracellular calcium levels were significantly increased by sustained calcium supply to about 2.1- and 1.9-fold in AsPC-1 and CFPAC-1, respectively, compared with the untreated group (Figure 1B). The increase in red fluorescence level in pancreatic cancer cells indicated increased ROS generation in pancreatic cancer cells by sustained calcium supply, indicating that ROS originated from mitochondria by the simultaneous use of a mitochondrial tracer showing green fluorescence (Figure 1C). In an analysis of the mean fluorescence intensity (MFI), mitochondrial ROS levels detected by MitoSOX™ were significantly increased by sustained calcium supply to about 2.33- and 2.63-fold in ASPC-1 and CFPAC-1, respectively, compared with the untreated group (Figures 1D and E).

An increase in ROS causes the excessive accumulation of PAR and energy deprivation

In addition to the immediate association of PAR accumulation by increased ROS levels, PARG and RNF-146 were supplementally investigated to confirm a change in the enzyme levels involved in PAR accumulation. A decrease in the enzymatic activity of PARG and ARH3 following calcium supply was observed (Figures 2A and B), accompanied by the accumulation of PAR in pancreatic cancer cells (Figure 2C). Changes in coenzyme factors involved in energy metabolism following the accumulation of

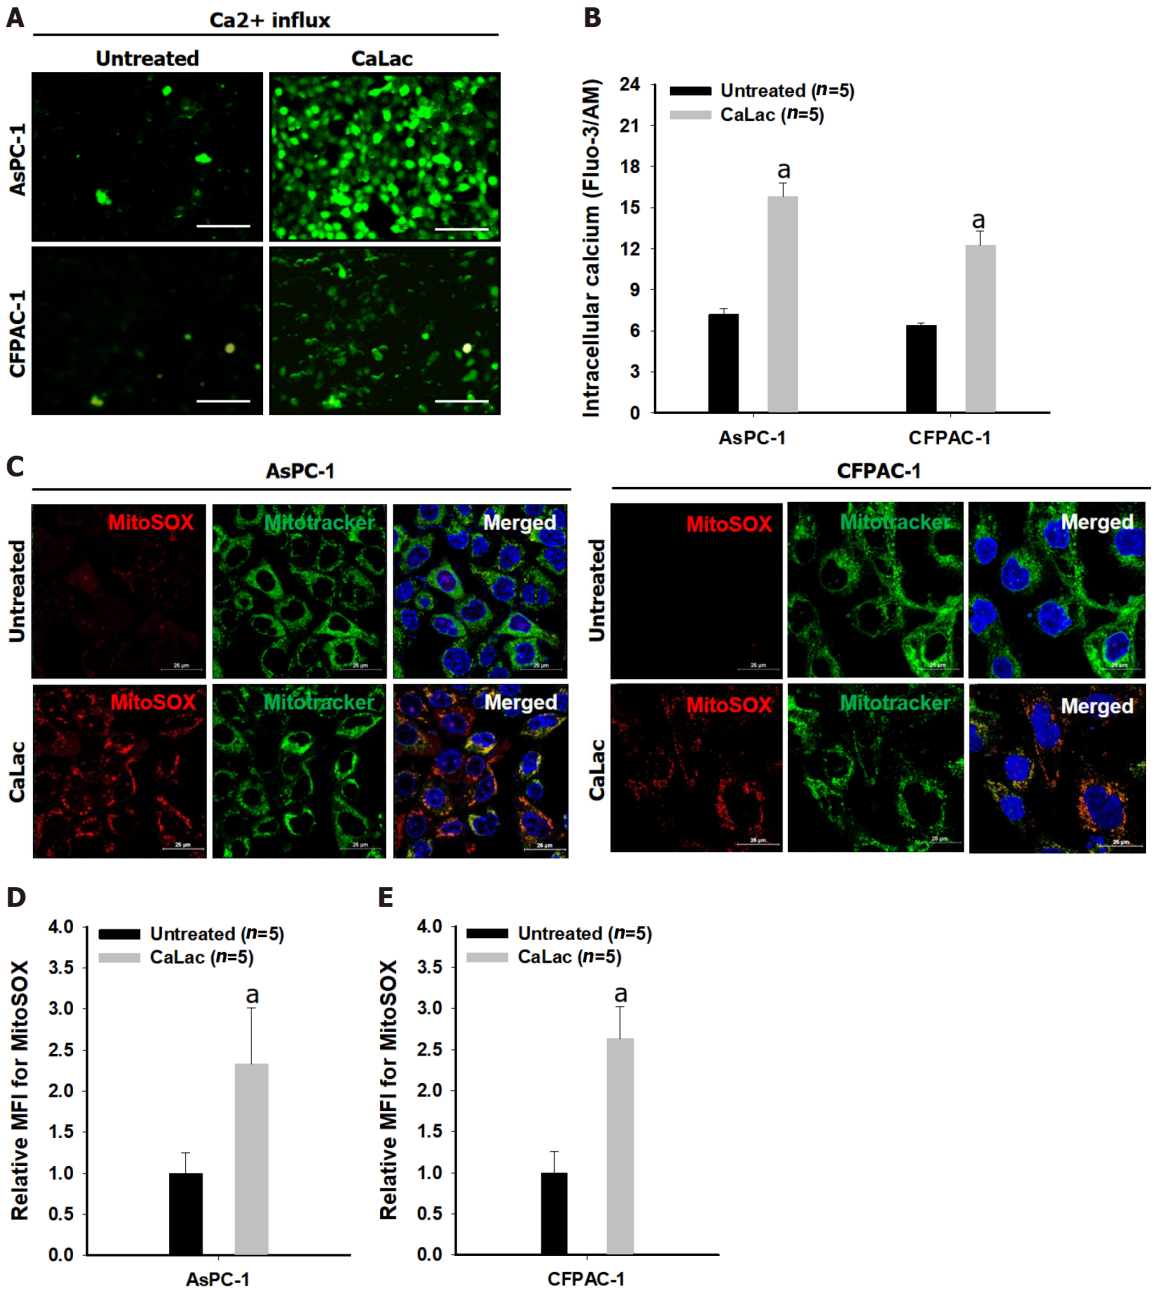

Figure 1 Confirmation of mitochondrial reactive oxygen species generation by sustained calcium supply. CaLac: Lactate calcium salt; MitoSOX: Mitochondrial superoxide indicator.

PAR were also identified (Figures 2D and E). These results indicated that the excessive synthesis of PAR resulted in reduced NAD+ levels (Figure 2D) and the increase of NADH levels (Figure 2E), which led to a depletion of ATP (Figure 2F).

An increase in AIF expression induces the death of pancreatic cancer cells

The results of immunocytochemical staining for the co-expression of AIF with the mitochondrial tracker in two types of pancreatic cancer cells indicated the calcium supply induced the translocation of AIF from the cytoplasm into the nucleus, whereas only cytoplasmic co-expression was observed in the untreated group (Figure 3A). Furthermore, it was quantitatively increased by calcium supply when the expression of AIF only was confirmed as a separate result through MFI analysis (Figures 3B and C). Then, the reaction ratio by TUNEL staining per total cells was significantly increased (Figures 3D and E), and Annexin V labeled cells increased from 6.61% to 37.61% and from 4.8% to 26.91% in AsPC-1 and CFPAC-1, respectively (Figure 3F). A decrease in cell viability by calcium supply was macroscopically

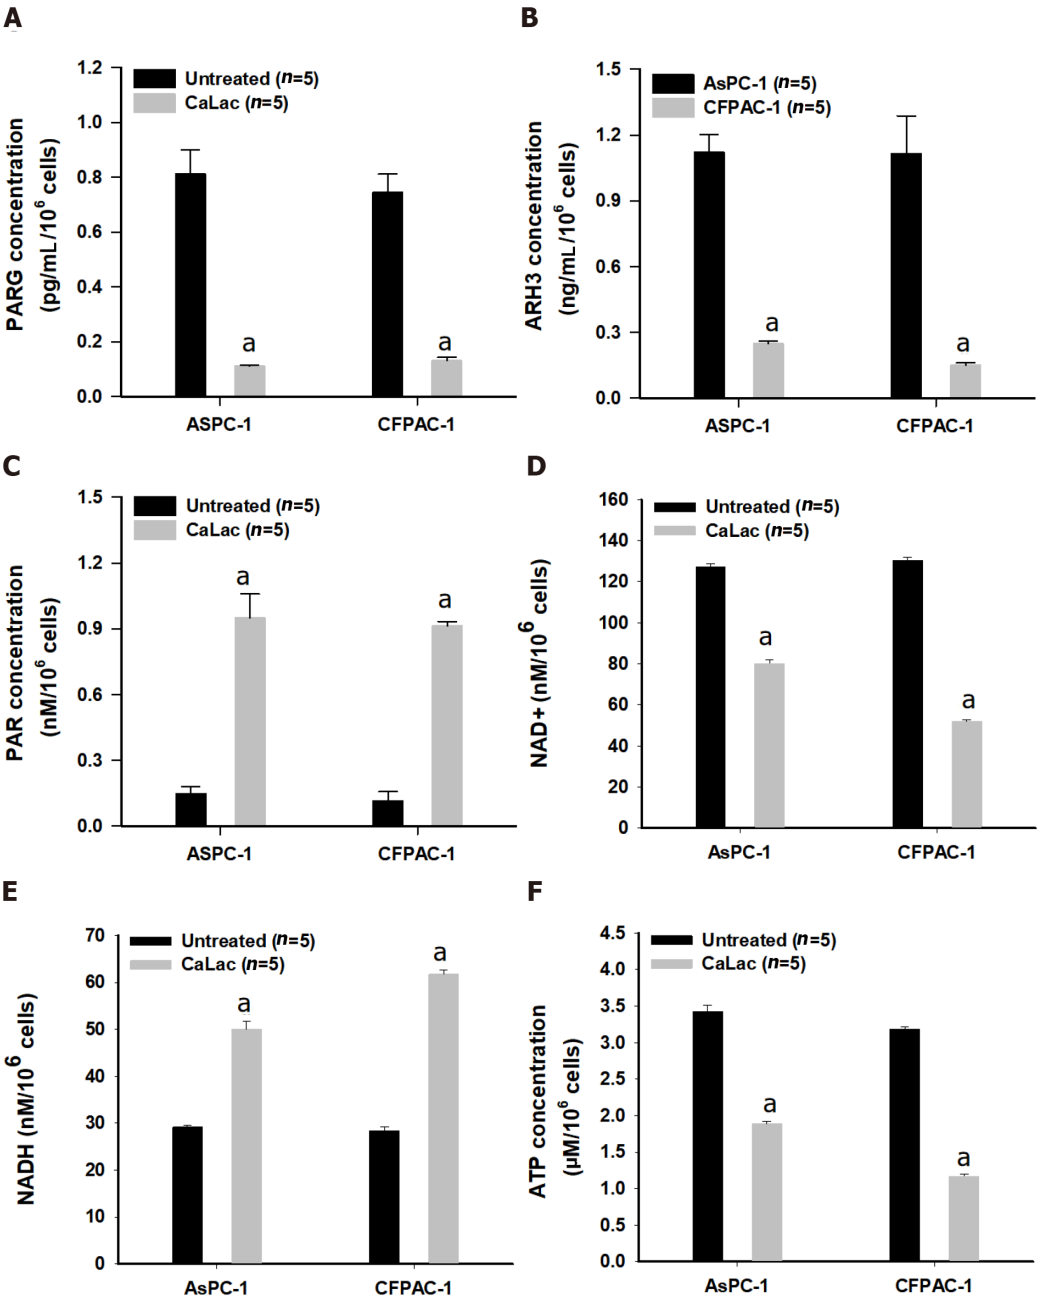

Figure 2 Confirmation of enzyme change and poly adenosine diphosphate-ribose accumulation by calcium supply resulting in energy crisis. observed by microphotographs (Figure 3G), and the CaLac group (calcium supply) showed low cell viability (mean 35.5%) when defining the total cell viability of the untreated group as 100% (Figure 3H).

An increase in PAR accumulation relates to calcium-dependent proteolytic enzyme activity in pancreatic cancer cells

To elucidate an increase in PAR accumulation by sustained calcium supply, the calpain inhibitor, calpeptin, was introduced. Changes in PARG, ARH3, PAR, and AIF were sequentially observed in pancreatic cancer cells (Figure 4). Although PARG levels were significantly decreased by sustained calcium supply, there was only a slight decrease (no significant difference) when combining calpeptin with calcium supply (Figures 4A and B). Calpeptin itself did not directly change the levels of PARG (Figures 4A and B) similar to that of ARH3 (Figures 4C and D). Furthermore, the levels of PAR and AIF

were increased by calcium supply, which was restored to a level similar to that of the untreated group under culture conditions in which calpeptin was added (Figures 4E-H).

Sustained calcium administration induces anticancer effects on pancreatic cancer

Comparative results of tumor growth in heterotopic xenograft models demonstrated the inhibition of pancreatic cancer growth by calcium administration (Figures 5Aand B, Figure 6). The tumor volume on the last day of measurement was 830.37 ± 138.36 and 431.41 ± 91.98 in the untreated and the CaLac groups, respectively. Tumor volume was reduced by about 48.1% in the CaLac group compared with the untreated group (Figure 5B). There were few viable cells capable of discriminating the staining of nuclei in tumor tissues of the CaLac group (Figure 5C), indicating an increase in PAR-dependent AIF expression following sustained calcium-induced apoptosis (Figures 5D and E). The apoptotic signal in tumor tissues was increased 5.13-fold in the CaLac group compared with the untreated group (Figures 5F and G). As a result of apoptosis, the malignancy indicators of tumors were significantly reduced (Figure 5H) and the expressions of Ki-67 and PCNA were significantly reduced by about 64% and 68%, respectively in the CaLac group (Figures 5I and J).

DISCUSSION

This study demonstrated that the accumulation of PAR was induced by an increase in ROS following sustained calcium supply, which in turn led to the death of pancreatic cancer cells by energy deprivation and AIF expression. CaLac is a small molecule generated by the reaction of lactic acid with calcium carbonate and is characterized as a weak electrolyte with a neutralized charge[12]. Such a characteristic of CaLac suggests it might readily cross cell membranes as a bound form. Therefore, the accumulation of calcium was greatly increased in pancreatic cancer cells by the sustained treatment of CaLac, which was in line with our direction of research targeting intracellular calcium accumulation. It is well known that intracellular calcium uptake can promote ROS formation in mitochondria by stimulating tricarboxylic acid cycle enzymes and electron transport chain activity[9]. The results indicated that calcium accumulation by CaLac led to an increase in the mitochondrial ROS of pancreatic cancer cells. An active calcium signal must operate within physiological levels, but when intracellular calcium levels exceed this threshold, excessive ROS production can have a detrimental effect on cell survival by disrupting mitochondrial bioenergetic regulation and cellular functions[13]. The main reason for investigating an increase in PAR synthesis among the various biological phenomena mediated by calcium-dependent excessive ROS is its key function as a protective mechanism for cancer cell survival under hostile conditions[1,10,11,14]. ROS can be spontaneously generated during the ceaseless process of the rapid growth of cancer cells, but excessive ROS can cause DNA damage by irreversible oxidative stress[15]. PAR synthesis is defined as PARylation by PARP-1 recruits or modifies several nuclear proteins during the DNA damage response against harmful oxidative stress; however, the excessive synthesis of PAR can lead to cell death[1,14]. A sustained calcium supply causes the accumulation of PAR to cope with long-lasting DNA damage along with an increase of ROS in pancreatic cancer cells. Well-established phenomena induced by PAR accumulation include energy deprivation and AIF release from mitochondria[3,4,16]. Because PAR is catalyzed for synthesis from donor NAD+, excessive PAR accumulation causes a decrease in the intracellular level of NAD+, leading to energy deprivation[8,17]. Furthermore, an increase in AIF release induces cell death by large-scale DNA fragmentation defined as parthanatos, although a clear mechanism has not been elucidated[4,16]. The results indicated that AIF migrates from the mitochondria to the cytoplasm and nucleus in response to the accumulation of PAR followed by inducing the death of pancreatic cancer cells. Therefore, excessive PAR accumulation caused by an increase in ROS by sustained calcium supply can be considered to mediate anticancer activity as the main mechanism with energy deprivation and AIF release in pancreatic cancer cells. Cancer cells activate PAR erasing enzymes PARG and ARH3 to hydrolyze ribose-ribose bonds, PAR itself, or O-acetyl-ADP-ribose resulting in the prevention of excessive PAR accumulation[6,18]. These hydrolytic reactions form a biochemical mechanism to counter the PAR-mediated death of cancer cells[4,19,20]. In this study, it was confirmed that the enzymatic activities of PARG and ARH3 were significantly decreased after sustained calcium supply; however, the activity was restored by treatment with calpeptin, a potent, cell-permeable calpain inhibitor. Calpain is a break-down molecule and a calcium-dependent cysteine protease that can also induce ROS production depending on its activation, and it may also damage ion channels, cell adhesion molecules, and cell surface receptors as well as various enzymes[21,22]. On this basis, it is anticipated that calcium-dependent calpain activation would directly induce the enzymatic inactivity of PARG and ARH according to the results of calpeptin application on pancreatic cancer cells. However, the current research outcome was unable to provide a clear mechanistic basis for the enzymatic inactivation of PARG and ARH by calpain. Because PARG and ARH3 are directly related to the accumulation of PAR in pancreatic cancer cells, we wish to investigate this further in more detail.

CONCLUSION

This study focused on the accumulation of PAR to induce energy deprivation and AIF release by sustained calcium supply to investigate its potential anticancer effect on pancreatic cancer. We demonstrated that an increase in ROS and inhibition of PAR-erasing enzymes might be the main contributors to these effects. However, the connection to the mechanistic role of calcium in enabling the inactivation of PAR-degrading enzyme needs to be elucidated, and additional studies to explore the potential of clinical application are required.

ARTICLE HIGHLIGHTS

Research background

The excessive accumulation of poly adenosine diphosphate(ADP)-ribose (PAR) induces energy deprivation and apoptosis-inducing factor (AIF) release from mitochondria resulting in the caspase-independent death of cancer cells, and an increase in PAR is closely related to an increase in reactive oxygen species (ROS).

Research motivation

Increasing ROS can be induced in cancer cells by calcium influx. Therefore, it would be possible to expect the anticancer effect targeting pancreatic cancer through calcium-dependent PAR accumulation.

Research objectives

This study focused on the accumulation of PAR to induce energy deprivation and AIF release by sustained calcium supply to investigate its potential anticancer effect on pancreatic cancer.

Research methods

Two pancreatic cancer cell lines, AsPC-1 and CFPAC-1 were used for the study. Calcium influx and mitochondrial ROS were observed by fluorescence staining. Changes in enzyme levels, as well as PAR accumulation and energy metabolism, were measured using assay kits. AIF-dependent cell death was investigated followed by confirming *in vivo* anticancer effects by sustained calcium administration.

Research results

Mitochondrial ROS levels were elevated with increasing calcium influx into pancreatic cancer cells. Then, excess PAR accumulation, decreased PAR glycohydrolase and ADP-ribosyl hydrolase 3 levels, and energy crisis were observed. *In vitro* and *in vivo* antitumor effects were confirmed to accompany elevated AIF levels.

Research conclusions

Accumulation of PAR was induced by an increase in ROS following sustained calcium supply, which in turn led to the death of pancreatic cancer cells by energy deprivation and AIF expression. Calcium-mediated accumulation of PAR would be a potential strategy for the treatment of pancreatic cancer.

Research perspectives

Although this study visualized the potential anticancer effects of excessive PAR accumulation by sustained calcium supply on pancreatic cancer, elucidating a clear mode of action remains a challenge, and it should be accompanied by further studies to assess its potential for clinical application.

Abstract

BACKGROUND

Hepatocellular carcinoma (HCC) exhibits high invasiveness and mortality rates, and the molecular mechanisms of HCC have gained increasing research interest. The abnormal DNA damage response has long been recognized as one of the important factors for tumor occurrence and development. Recent studies have shown the potential of the protein RING finger and WD repeat domain 3 (RFWD3) that positively regulates p53 stability in response to DNA damage as a therapeutic target in cancers.

AIM

To investigate the relationship between HCC and RFWD3 *in vitro* and *in vivo* and explored the underlying molecular signalling transduction pathways.

METHODS

RFWD3 gene expression was analyzed in HCC tissues and adjacent normal tissues. Lentivirus was used to stably knockdown RFWD3 expression in HCC cell lines. After verifying the silencing efficiency, Celigo/cell cycle/apoptosis and MTT assays were used to evaluate cell proliferation and apoptosis. Subsequently, cell migration and invasion were assessed by wound healing and transwell assays. In addition, transduced cells were implanted subcutaneously and injected into the tail vein of nude mice to observe tumor growth and metastasis. Next, we used lentiviral-mediated rescue of RFWD3 shRNA to verify the phenotype.

Finally, the microarray, ingenuity pathway analysis, and western blot analysis were used to analyze the regulatory network underlying HCC.

RESULTS

Compared with adjacent tissues, RFWD3 expression levels were significantly higher in clinical HCC tissues and correlated with tumor size and TNM stage ($P < 0.05$), which indicated a poor prognosis state. RFWD3 silencing in BEL-7404 and HCC-LM3 cells increased apoptosis, decreased growth, and inhibited the migration in shRNAi cells compared with those in shCtrl cells ($P < 0.05$). Furthermore, the *in vitro* results were supported by the findings of the *in vivo* experiments with the reduction of tumor cell invasion and migration. Moreover, the rescue of RFWD3 shRNAi resulted in the resumption of invasion and metastasis in HCC cell lines. Finally, gene expression profiling and subsequent experimental verification revealed that RFWD3 might influence the proliferation and metastasis of HCC *via* the Wnt/β-catenin signalling pathway.

CONCLUSION

We provide evidence for the expression and function of RFWD3 in HCC. RFWD3 affects the prognosis, proliferation, invasion, and metastasis of HCC by regulating the Wnt/β-catenin signalling pathway.

Key Words: RING finger and WD repeat domain 3; Hepatocellular carcinoma; Invasion; Proliferation; Metastasis; Wnt/β-catenin signaling pathways

Core Tip: The relationship between RING finger and WD repeat domain 3 (RFWD3) and tumorigenesis process has been reported occasionally, but the relationship between RFWD3 and hepatocellular carcinoma (HCC) is still unclear. This research reports the significant role of RFWD3 in HCC development by using bioinformatics databases, clinical samples, cell phenotypes, *in vivo* experiments, and microarray analyses. It provides evidence that RFWD3 expression might affect the tumorigenesis process of HCC by regulating the Wnt/β-catenin signalling pathways, laying a basic foundation for future relevant studies.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common malignant tumors and is highly invasive with a high mortality rate[1]. Reportedly, the incidence of HCC has increased rapidly by approximately 3%–4% *per* year in the United States[2]. Despite advances in medical research, early diagnosis of HCC remains difficult, and most patients are diagnosed with middle-or late-stage disease[3-5]. Moreover, even though some progress has been made in the clinical diagnosis and treatment of HCC, the long-term survival after treatment for patients diagnosed with early-stage HCC is low[6]. With the development of biomedicine, more basic studies have been carried out on HCC, but the underlying mechanism remains unclear, warranting promising interventions[7,8].

Multiple signal transduction pathways have been demonstrated to be involved in cellular responses to stress. For example, the ubiquitin-proteasome system (UPS) plays an important role in DNA damage repair, transcription regulation, cell cycle arrest, and apoptosis[9-11]. Several studies have focused on the role of the protein RING finger and WD repeat domain 3 (RFWD3) in the ataxia telangiectasia-mutated (ATM)/ATM-Rad3-related pathways of DNA damage response[12-16]. RFWD3 contains a RING finger domain and displays *in vitro* E3 ubiquitin ligase activity. It comprises an SQ-rich region in the N-terminus, a coiled-coil domain, and a WD40 domain in the C-terminus. In addition, sequence comparison revealed that the residues flanking serine 46 and serine 63 of RFWD3 are conserved[17]. According to the current literature, RFWD3 accumulates at stalled replication forks as part of the DNA damage response[18,19]. At these sites, RFWD3 co-localizes with replication protein A (RPA) and binds *via* its WD40 domain at the C-terminus to RPA2[20,21]. It functions in replication checkpoint signalling

upon replication stress and promotes replication fork restart after homologous recombination (HR)[22, 23]. RFWD3 is regarded as a tumor suppressor gene, and recent functional and mechanistic studies have indicated that it maintains the stability of p53[24]. Feeney *et al*[25] reported that it facilitates RPA-mediated DNA damage response[25]. Furthermore, RFWD3 is required for the proliferation of non-small-cell lung cancer, gastric carcinoma, and colorectal cancer cells and may have an important role[26-28]. However, the relationship between HCC and RFWD3 has not been explored.

In a preliminary experiment using a small number of HCC samples, our team found that RFWD3 expression was higher in HCC tissues than in adjacent non-cancerous tissues[29]. To rule out the effects of small sample numbers, the results were then verified using the open-source database. For this purpose, we chose RNA SEQ data (FPKM normalized) of liver cancer from The Cancer Genome Atlas (TCGA) database directly downloaded from the UCSC Xena database and further transformed it into log2 (TPM + 1) format. The results were concordant with our preliminary findings. Furthermore, the immunohistochemical analysis demonstrated that RFWD3 expression was associated with the clinical TNM stage (and with survival, according to the database). Therefore, in this study, we tested the hypothesis that RFWD3 plays a significant role in HCC development.

To test this hypothesis, in this study, we investigate the relationship between HCC and RFWD3 *in vitro* using human HCC cell lines and *in vivo* using HCC xenograft models in nude mice. Further, we unravel the underlying molecular signalling transduction pathways in HCC. The findings of this study provide evidence for the first time that RFWD3 plays a significant role in HCC cell proliferation and may serve as a potential therapeutic target for HCC.

MATERIALS AND METHODS

Tissue samples

Sixty tissue sample pairs (HCC and adjacent normal liver tissues) were obtained from clinical patients who underwent surgical HCC resection at the First Affiliated Hospital of Zhengzhou University (Zhengzhou, China). Before the operation, all patients were informed that the resected tissues could be used for research, and consent was obtained from each patient. After resection, the tissues were snap-frozen immediately and stored at −80 °C. All the experimental procedures were approved by the Ethics Committee of the First Affiliated Hospital of Zhengzhou University (Approval No. 10[2017]).

TCGA liver HCC cohort assessment

TCGA liver HCC cohort included 374 cancer tissues and 50 adjacent normal tissues. According to the expression level of *RFWD3* gene, we used the best cut-off value to divide the HCC patients into high and low expression groups by the Surv function of the survminer package. Then, the Kaplan-Meier method and log-rank test were used to evaluate the differences in overall survival and recurrence-free survival between the two groups. All data processing, statistical analyses, and graphical presentations (of this section) were carried out using R 4.0.5 software.

Immunohistochemical analysis of human HCC tissues

HCC tissue microarray data of 60 HCC and adjacent tissues, including some basic clinical data shown in Table 1, were obtained from BiochipTech (Zhengzhou, China). Immunohistochemistry (IHC) was performed using a 1:100 dilution of a primary antibody against *RFWD3* (Multi Sciences, Hangzhou, China), and all immunohistochemical procedures were performed according to a common standard protocol. First, the expression levels of RFWD3 between HCC and adjacent tissues were compared with a histochemical score (H-score). Then, a scoring system that combined the staining intensity (SI: 0, negative; 1, weak; 2, moderate; 3, strong) and the percentage of positive cells (PP: 0, < 5%; 1, 6%–25%; 2, 26%–50%; 3, 51%–75%; 4, > 75%) was used to compare the correlation of clinical data in patients with RFWD3 expression (SI × PP > 4 was considered high expression; SI × PP ≤ 4 was considered low expression).

Cell lines and culturing, lentivirus vector construction, and transduction

The human HCC cell lines BEL-7404 and HCC-LM3, maintained in our laboratory, were cultured (BEL-7404: 10% FBS, 90% RPMI-1640; HCC-LM3: 10% FBS, 90% DMEM; all purchased from Gibco, United States) according to the American type culture collection protocol. All cells were cultured in 50 ml/L CO_2 at 37°C in a moderately humid environment. The RFWD3 siRNA sequence (5-CAGAGAATGATG-GCAACAT-3) was synthesized and cloned into the AgeI/EcoRI sites of the lentivirus-based GV493-puromycin vector (shRNAi). The negative control lentiviral vector (5-TTCTCCGAACGTGTCACGT-3) was used as a control (shCtrl). The cells were divided into two groups (shCtrl and shRNAi), seeded in six-well plates, and allowed to grow until the logarithmic phase and less than 70% confluency. After verifying the transfection efficiency, the cells were harvested for subsequent *in vivo* and *in vitro* experiments. Additionally, the *RFWD3*-reverse mutation sequence (5-CTGAGAACGACGGAAATAT-3) was synthesized and cloned into the *BamHI*/*AgeI* sites of the lentivirus-based GV557-neomycin vector

Table 1 Clinicopathological features in hepatocellular carcinoma tissue microarrays

(KD-OE). The virus without anti-Smad served as negative controls (KD-OE-NC) for subsequent phenotypic validation. The GV493-puromycin and GV557-neomycin vectors were obtained from GeneChem (Shanghai, China).

Quantitative reverse transcription-polymerase chain reaction

Quantitative reverse transcription-polymerase chain reaction (qRT-PCR) was used to detect the mRNA expression level of RFWD3 using the following primers: Forward: 5′-AGAGTATGGAGGGGT-TGTTGAC-3′ and reverse: 5′-TAGAAGCAGAAGGTAGCAGAGG-3′. Total RNA was extracted from tissues and cells using TRIzol reagent (Thermo Fisher Scientific, United States) and reverse transcribed into cDNA using a Prime-Script RT Reagent Kit with gDNA Eraser (Takara Bio, Japan). Following a common standard protocol, qRT-PCR was performed in a total volume of 10 μL on a 7900-HT Fast Real-time PCR System (Applied Biosystems Inc., United States) to evaluate RFWD3 expression in 60 pairs of HCC tissues and determine the RFWD3 knockdown efficiency in cells transduced with shCtrl and shRNAi.

Western blot analysis

To determine the RFWD3 virus transfection efficiency in cells transduced with shCtrl, shRNAi, KD-OE, and KD-OE-NC, the levels of RFWD3 protein expression were assessed by western blot (WB). Briefly, the total protein was extracted by incubating the cells in RIPA lysis buffer (Thermo Fisher Scientific, United States) supplemented with a protease inhibitor cocktail (Thermo Fisher Scientific, United States) for 1 h on ice, followed by sonication (Shanghai Experimental Instruments, China) for three 5 s cycles on ice. After centrifugation (14000 ×*g*, 4 °C, 15 min), the supernatant was collected for protein concentration measurement using a bicinchoninic acid protein assay kit (Pierce Biotechnology, United States). Denatured protein samples (30 μg/10 μL) were separated by SDS-PAGE (Invitrogen, United States) and transferred to polyvinylidene fluoride membranes (Bio-Rad, United States). Afterward, the membranes were blocked with 5% non-fat milk (BD Biosciences, United States) dissolved in 30 mL Tris-buffered saline with Tween-20 (TBST) for 2 h at common room temperature. The membranes were then incubated overnight at 4 °C with primary antibodies against GAPDH (1:1000; Abcam, United States) and RFWD3 (1:1000; Multi Sciences, Hangzhou, China). After three 5 min washes in TBST with agitation, the membranes were incubated for 1 h at room temperature with the appropriate secondary

horseradish peroxidase-linked antibodies, including goat anti-rabbit IgG for GAPDH (1:2000; Abcam, United States) and goat anti-rabbit IgG for RFWD3 (*1:2000*; Multi Sciences, Hangzhou, China). An ECL kit (Pierce Biotechnology, United States) was used to visualize the protein bands.

Cell growth and proliferation assays

A Celigo imaging cytometer (Celigo; Nexcelom Bioscience, United States) and MTT assays were used to detect the number of cells at each time point, and the growth status of the cells was analyzed. For the Celigo assay, cells in the logarithmic phase were digested with trypsin (Sangon Biotech, Shanghai, China), seeded in 96-well plates (2000 cells/well in 100 μL medium) with three wells *per* condition, and cultured in a 37 °C incubator with 50 mL/L CO_2. From the first day to the fifth day after seeding, the plate was subjected to high-throughput screening every day. GFP fluorescence was measured in each scan to generate a five days cell proliferation curve. For the MTT assay, two groups of cells were seeded in 96-well plates (2000 cells/well) with three wells *per* condition and incubated at 37 °C for six consecutive days. Cell viability was analyzed every 24 h by washing the cells twice with PBS and adding MTT solution (5 mg/mL) to each well. After 4 h of incubation, the supernatant in each well was removed, and 100 μL DMSO was added to solubilize the formazan crystals. After 10 min, the optical density (OD) was measured at an excitation wavelength of 490 nm and an emission wavelength of 570 nm using a microplate reader (VarioskanFlash; Thermo Fisher Scientific, United States).

Cell cycle assays

Cell cycle progression was examined using propidium iodide (PI; Sigma, United States) and RNase A (Thermo Fisher, United States). Cells in the logarithmic growth phase in six-well culture plates were digested with trypsin (Sangon Biotech, Shanghai, China) and diluted with the culture medium. Three replicate tubes were analyzed for both the shCtrl and shRNAi groups (1×10^6 cells/tube). The cells were centrifuged at 1300 rpm for 5 min, and the supernatant was discarded. The cell pellet was washed with pre-cooled D-Hanks equilibrium solution (4 °C with pH = 7.2–7.4), and the harvested cells were fixed with 70% cold ethanol at 4 °C overnight. Afterward, the cells were washed twice with 4 °C D-Hanks solution and incubated with 10 mg/mL RNase at 37 °C. Cell cycle progression was monitored by staining the nuclei with PI. The fluorescence of DNA-bound PI in cells was measured using flow cytometry (FCM; FC500 flow cytometer; Cytomics, United States). Finally, ModFit LT software (Windows version 4.0; Verity Software House, United States) was used to analyze the cell populations in different phases of the cell cycle.

Cell apoptosis assays

Cell apoptosis was assayed using an Annexin V-APC/PI apoptosis detection kit (Biosciences, Thermo Fisher, United States). Cells in the logarithmic phase were digested with trypsin (Sangon Biotech, Shanghai, China) and diluted with the culture medium. Three replicate tubes each were analyzed for the shCtrl, shRNAi, KD-OE, and KD-OE-NC groups of each cell line (1×10^4 cells/tube). The cells were centrifuged at 1300 rpm for 5 min, and the supernatant was discarded. The cell pellet was washed with a pre-cooled D-Hanks equilibrium solution (4 °C with pH = 7.2–7.4). The cells were then washed with 1 × binding buffer, centrifuged at 1300 rpm for 3 min, and resuspended in 200 μL 1 × binding buffer. Next, 10 μL Annexin V-APC staining solution was added, and the samples were incubated for 10–15 min at room temperature in the dark. Finally, apoptosis was detected in the samples.

Cell invasion and migration assays

Cell migration was assayed using wound healing and transwell assays. For the wound-healing assay, cells were plated in 6-well plates and scratched with a sterile pipette tip. The cells were then imaged using a microscope (Olympus, Japan) to observe migration after 12 and 24 h. For the invasion and migration assays, the upper surfaces of transwell chambers (Costar, Cambridge, MA, United States) were uncoated (for the migration experiments) or coated with Matrigel (1:4, BD, United States) (for the invasion experiments). Cells were then added to the upper chambers containing 200 μL serum-free medium (BEL-7404: RPMI-1640; HCC-LM3: DMEM) *per* well, and 500 μL medium (with 10% FBS) was added to the lower chambers. After 48 h, the chambers were cleaned, stained with hematoxylin, transferred to glass slides after the operation, and then observed under a microscope (Olympus, Japan). Six fields *per* chamber were used to quantify the invaded cell numbers with 100 × and 200 × magnifications.

Establishment of HCC xenograft models in nude mice

All animal experimental protocols were conducted following the ARRIVE (Animal Research: Reporting In Vivo Experiments) guidelines (https://www.nc3rs.org.uk/arrive-guidelines) and performed following protocols approved by the Research Ethics Committee of the First Affiliated Hospital of Zhengzhou University (Approval No. 10[2017]). Nude mice were purchased from Shanghai B&K Universal Group Limited (certificate number: SCXK 2013-0016; Shanghai, China). For the proliferation assay, 5×10^6 HCC-LM3 cells stably transduced with the lentiviral pSC-1-GFP vector carrying shCtrl or shRNAi were suspended in PBS and injected subcutaneously into the flank region of 6-week-old male

athymic nude mice (six mice in each group). For the metastasis assay, 2×10^6 HCC-LM3 cells transduced as described above were injected into the tail vein of nude mice. The animals were acclimatized to laboratory conditions (23 °C, 12 h/12 h light/dark, 50% humidity, ad libitum access to food and water). After four weeks, the mice were euthanized by barbiturate overdose (intravenous injection, 150 mg/kg pentobarbital sodium) for tissue collection and photographed.

Microarray-based gene expression analysis

To elucidate the molecular mechanisms involved in the association between RFWD3 and HCC, we performed microarray-based gene expression analysis to compare gene expression between the shCtrl and shRNAi groups. We then used ingenuity pathway analysis (IPA) to explore the molecular signal transduction pathways involved in HCC. All procedures were performed according to a common protocol, and assistance was provided by the Shanghai Biotechnology Corporation (SBC, Shanghai, China).

Statistical Analysis

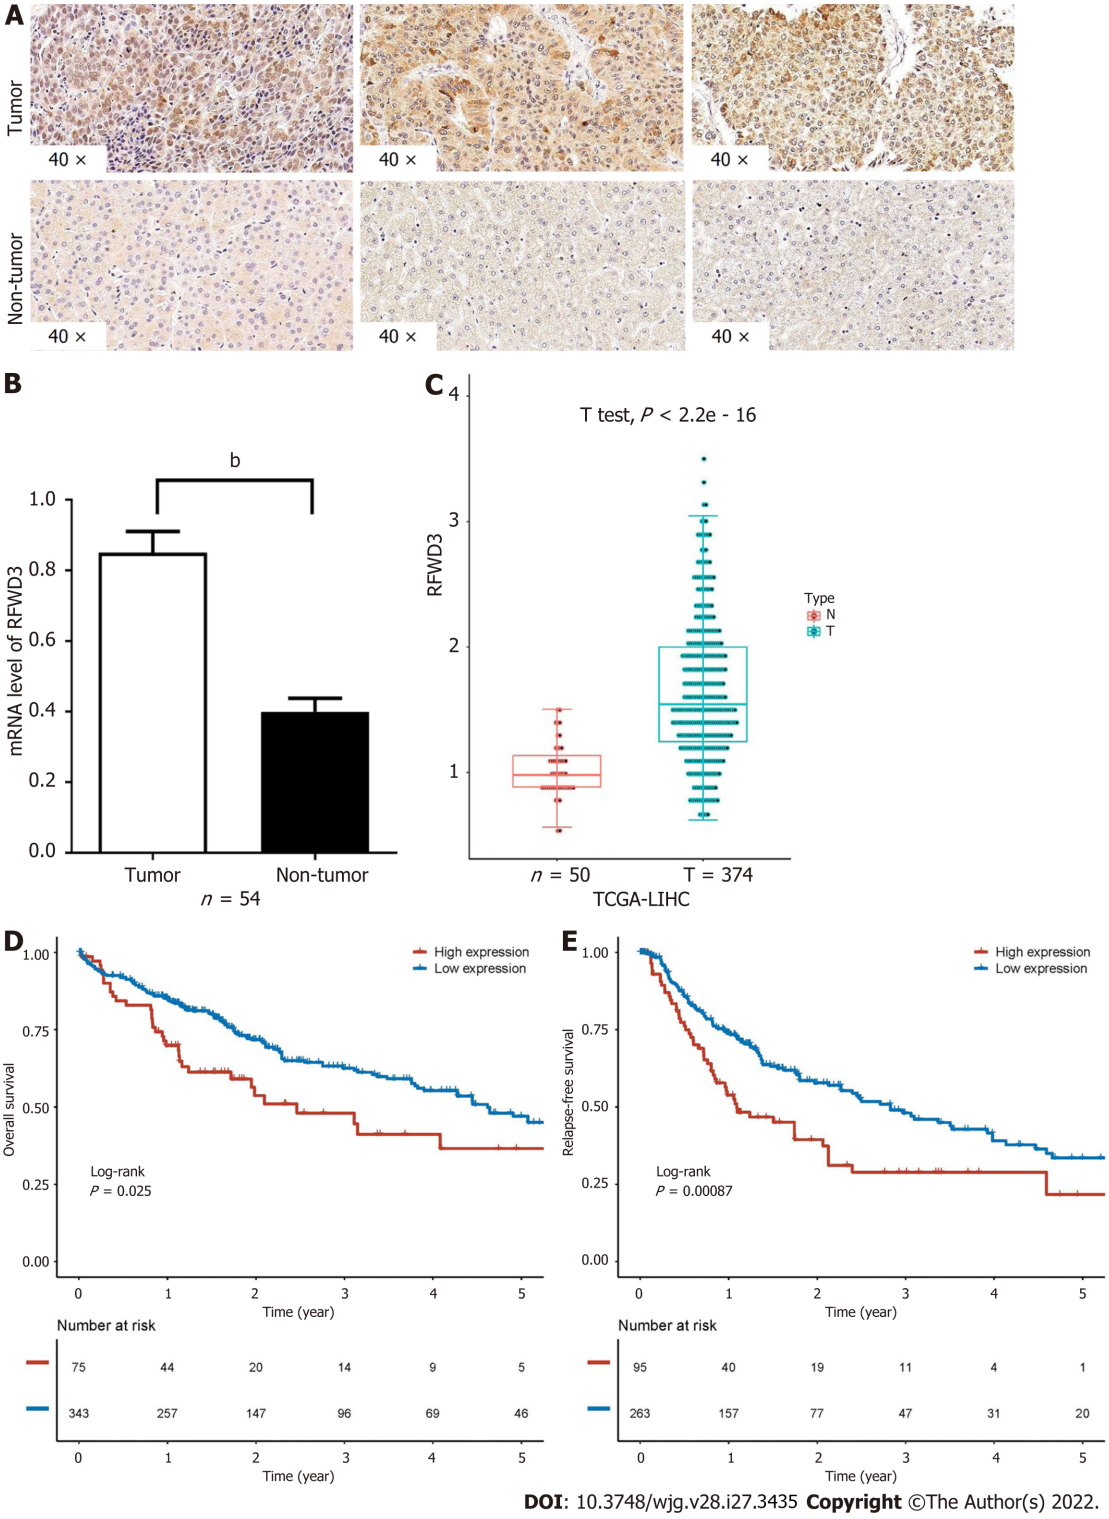
Statistical analyses and related statistical illustrations were performed using SPSS (version 21.0; IBM, Armonk, NY, United States) and GraphPad Prism software (ver. *5.0* for Windows; GraphPad Software Inc., United States). The Pearson chi-square test was used to determine the correlation between clinical characteristics and immunohistochemical staining. Other results are expressed as mean ± SD. A t-test was used to compare the two groups, and a P value of < 0.05 was considered statistically significant.

RESULTS

RFWD3 is ppregulated in HCC and correlated with worse prognosis

RFWD3 expression was examined in HCC tissues and matched adjacent normal tissues. IHC analysis of 60 tissue pairs revealed that HCC tissues exhibited a higher H-score than non-tumor tissues (Figure 1A) [30]. This result was supported by the qRT-PCR analysis of 54 tissue sample pairs (some outlier value pairs were excluded) (Figure 1B). These results were concordant with the RFWD3 expression data obtained by analyzing the bioinformatics database (Figure 1C). In addition, the bioinformatics database showed that higher RFWD3 expression represents a worse prognosis in HCC (Figure 1D and E). These data indicate that high RFWD3 expression might predict poor HCC development and prognosis (Table 1).

Validation of lentiviral-mediated knockdown efficiency in cell lines



After verifying the high expression of RFWD3 in HCC tissues, we selected HCC cell lines for further *in vitro* experiments. BEL-7404, HCC-LM3, SMMC-7721, and BEL-7402 cells were evaluated for the stable expression of RFWD3. Based on qRT-PCR and cell growth analyses, we chose BEL-7404 and HCC-LM3 cells for lentiviral-mediated knockdown of RFWD3 expression (Figure 2A). After lentiviral transduction, compared with the shCtrl group, the shRNAi group showed obvious knockdown of RFWD3 (qRT-PCR: BEL-7404: $P < 0.01$; HCC-LM3: $P < 0.01$) (Figure 2B). These results were subsequently confirmed with WB analysis and GFP fluorescence imaging (Figure 2C and D).

RFWD3 knockdown inhibits HCC growth and proliferation in vitro

A high-content screening assay (Celigo) was performed to monitor cell growth for five days. The total cell count and growth rate were lower in the shRNAi group than in the shCtrl group (Figure 3A). To further verify these results, we used an MTT assay. After five days of incubation in the same environment, consistent with the Celigo results, the OD value was significantly lower in the shRNAi group than that in the shCtrl group (Figure 3B). Taken together, these results indicate that RFWD3 knockdown significantly reduced the proliferation of HCC cells.

RFWD3 knockdown induces cell cycle arrest

To determine whether RFWD3 affects cell proliferation by regulating the cell cycle, we used PI staining to evaluate cell cycle progression. In the shCtrl and shRNAi groups, the cell cycle distributions were as follows (presented as the mean value of three replicates). For BEL-7404 shCtrl cells, 40.09% were in G0/G1 phase, 35.01% were in the S phase, and 24.9% were in the G2/M phase, while for BEL-7404 shRNAi cells, 37.82% were in G0/G1 phase, 30.03% were in S phase, and 32.15% were in G2/M phase. For HCC-LM3 shCtrl cells, 55.07% were in G0/G1 phase, 36.98% were in the S phase, and 7.95% were in the G2/M phase, while for HCC-LM3 shRNAi cells, 54.98% were in G0/G1 phase, 29.84% were in S phase, and 15.18% were in G2/M phase. Compared with shCtrl cells, shRNAi cells showed a reduced percentage of cells in G0/G1 (BEL-7404: $P < 0.01$) and S phase (BEL-7404: $P < 0.01$; HCC-LM3: $P < 0.01$), and the fraction of cells in the G2/M phase was significantly increased (BEL-7404: $P < 0.01$; HCC-LM3: $P < 0.01$). These results indicated that RFWD3 knockdown blocked cell cycle progression through the G2/M phase (Figure 3C and D).

Figure 1 Expression of RING finger and WD repeat domain 3 in hepatocellular carcinoma and its correlation with a worse prognosis. A: RING finger and WD repeat domain 3 (RFWD3) expression in hepatocellular carcinoma (HCC) tumor and non-tumor tissues detected using immunohistochemical staining; B: Expression analysis of RFWD3 in 54 tissue sample pairs (some invalid samples were removed) using quantitative reverse transcription-polymerase chain reaction ($^bP < 0.01$); C: Comparison of RFWD3 expression between tumor and non-tumor tissues in HCC patients (T = 374, *n* = 50, the data source is the Cancer Genome Atlas (TCGA) (TCGA) database); D and E: Kaplan-Meier survival curves of HCC patients with high and low expression of RFWD3 (*n* = 91, the data source is the TCGA database).

RFWD3 knockdown increased cell apoptosis

To determine whether RFWD3 affects cell proliferation by inducing apoptosis, an Annexin V-APC/PI apoptosis detection kit (AV/PI) was used to detect apoptosis in the two groups of cells by FCM. The apoptosis ratios were (presented as the mean value of three replicates) 4.47 ± 0.3748 for BEL-7404 shCtrl cells, 9.77 ± 0.1142 for BEL-7404 shRNAi cells, 2.14 ± 0.2234 for HCC-LM3 shCtrl cells, and 9.01 ± 0.2230

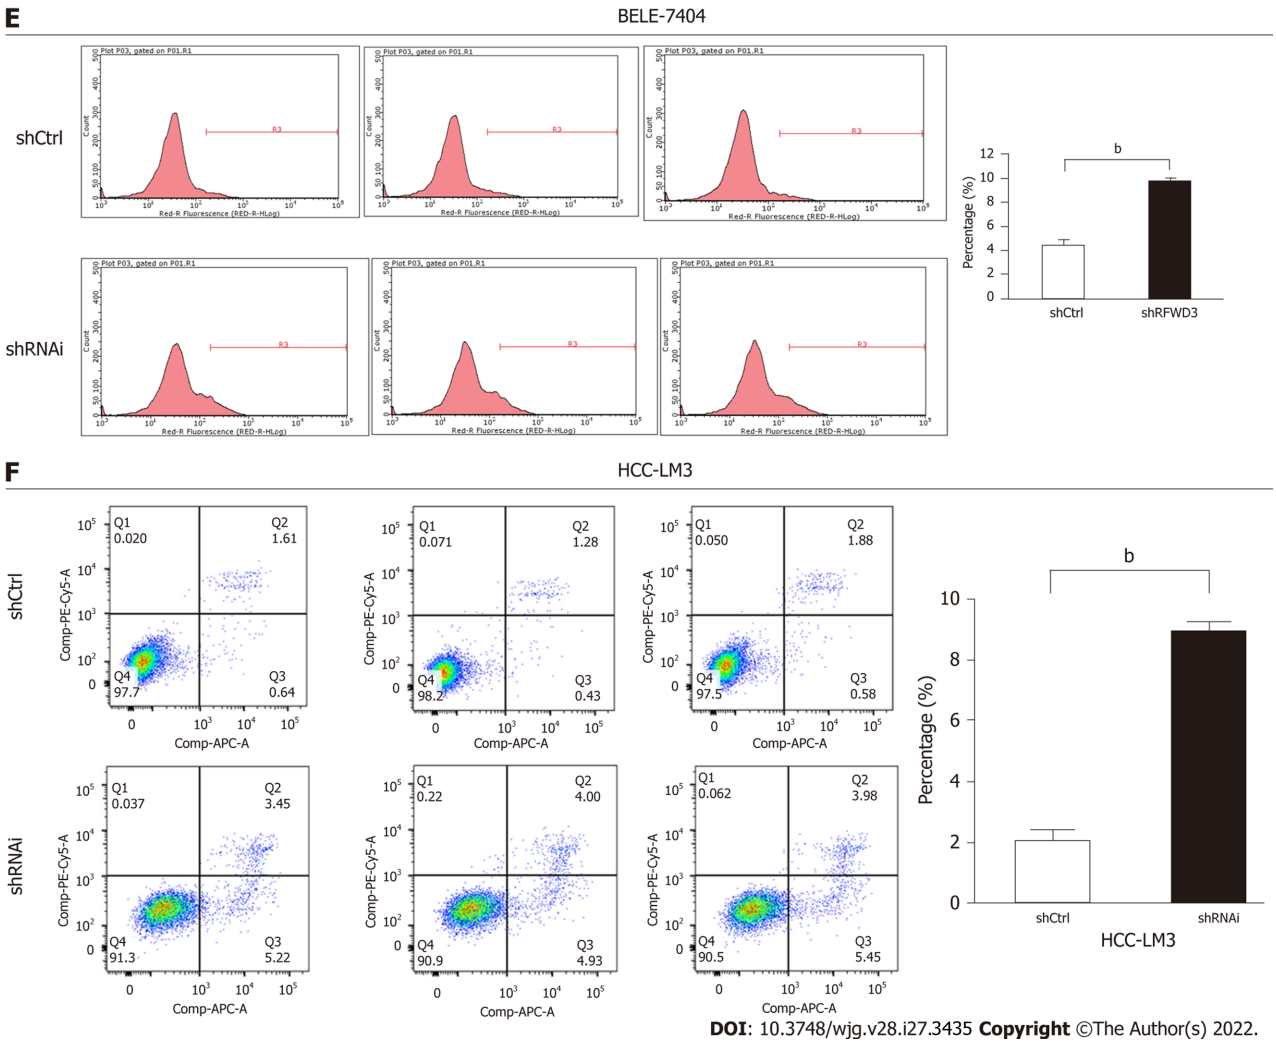
for HCC-LM3 shRNAi cells. Compared with shCtrl cells, shRNAi cells had a higher apoptosis rate (BEL-7404: $P < 0.01$; HCC-LM3: $P < 0.01$). This result demonstrated that RFWD3 knockdown increased the apoptosis ratio, thus affecting the proliferation of HCC cells (Figure 3E and F).



RFWD3 knockdown reduced HCC cell invasion and migration

Wound healing and transwell assays were used to evaluate HCC cell invasion and migration. In the wound healing assay, the shCtrl groups exhibited better healing ability ($P < 0.05$). After 12 h, the wound area was 103.40 ± 1.32 in BEL-7404 shCtrl cells, 125.90 ± 4.46 in BEL-7404 shRNAi cells, 145.40 ± 0.84 in HCC-LM3 shCtrl cells and 159.50 ± 2.21 in HCC-LM3 shRNAi cells. Over time, the difference in the size of the wound area between the two groups increased. After 24 h, the wound area was 22.97 ± 0.22 in BEL-7404 shCtrl cells, 60.94 ± 2.41 in BEL shRNAi cells, 60.22 ± 12.68 in HCC-LM3 shCtrl cells and 134.40 ± 0.84 in HCC-LM3 shRNAi cells (Figure 4A). We next examined cell migration and invasion with transwell assays. The migration of both BEL-7404 and HCC-LM3 shRNAi cells was attenuated compared with shCtrl cells ($P < 0.05$). Similar results were observed in the invasion assay (Figure 4B). These data revealed that RFWD3 knockdown reduced HCC cell invasion and migration.

RFWD3 knockdown decreased HCC cell proliferation, invasion, and metastasis in vivo

We established an HCC xenograft model in nude mice to verify the results *in vivo*. HCC-LM3 shCtrl and shRNAi cells were injected subcutaneously (Figure 5A) and into the tail vein (Figure 5B) of nude mice (six mice in each group). After four weeks, the mice were euthanized by cervical dislocation. The tumors

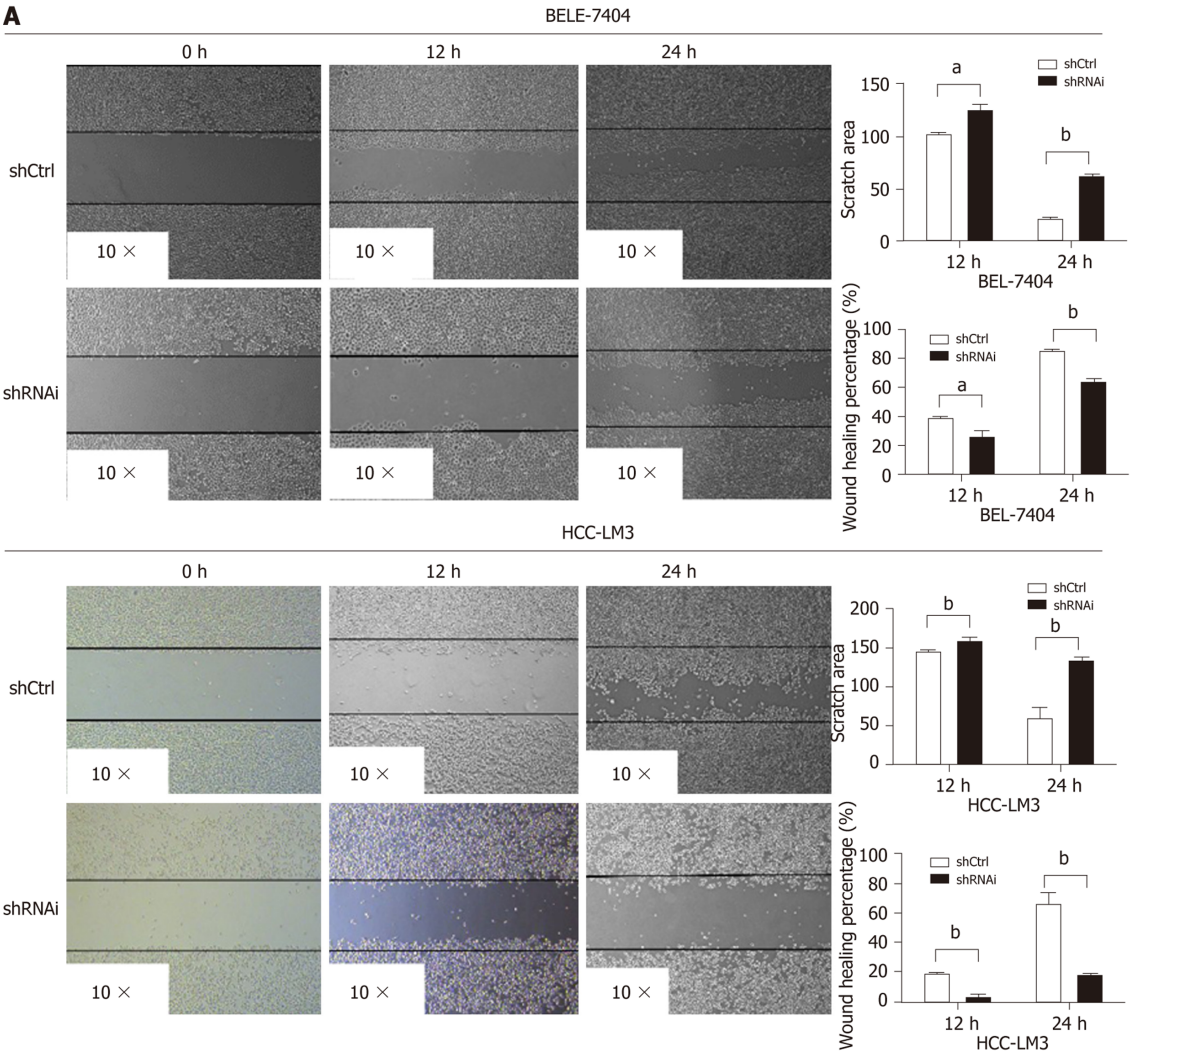
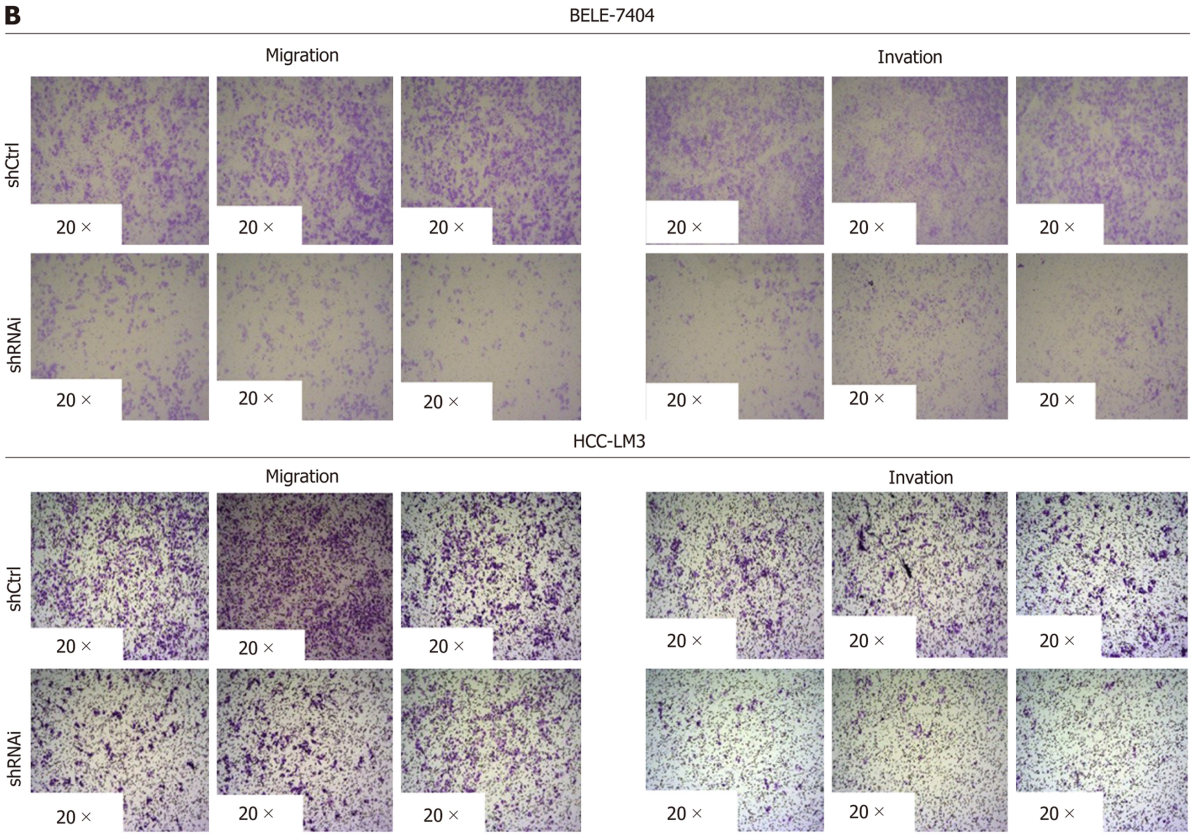
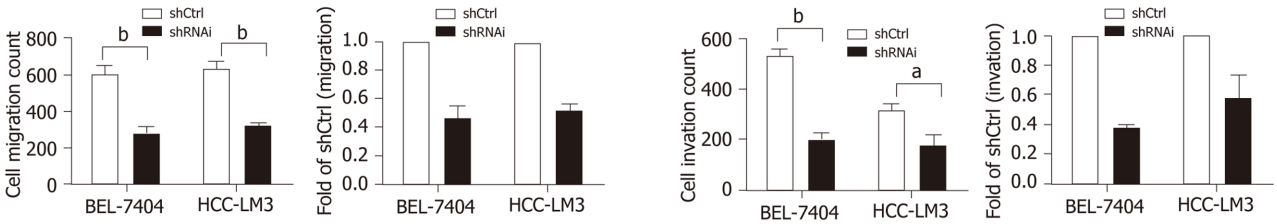
Figure 3 RING finger and WD repeat domain 3 knockdown inhibits cell growth and proliferation and induces cell cycle arrest and apoptosis. A: Cell growth and proliferation of BEL-7404, Hepatocellular carcinoma (HCC)-LM3 shRNAi, and shCtrl cells continuously monitored using a Celigo instrument for five days; B: MTT assay demonstrating that RING finger and WD repeat domain 3 siRNA significantly reduced the proliferation of HCC cells; C and D: The cell cycle progression evaluated by flow cytometry (FCM) with propidium iodide (PI) and RNase A ($^bP < 0.01$); E and F: FCM to assess the apoptosis in shRNAi and shCtrl groups of cells using Annexin V-APC/PI Apoptosis Detection Kit ($^bP < 0.01$).



(subcutaneous injection groups) and lung tissues (tail vein injection groups) were removed for imaging analysis. The growth and invasion ability of tumors was significantly lower in mice injected with shRNAi cells than in mice injected with shCtrl cells. These results show that silencing RFWD3 effectively reduced HCC tumor proliferation, invasion, and metastasis in vivo.



Validation of the efficiency of lentiviral-mediated rescue of RFWD3 shRNAi in cell lines



To rule out off-target effects and confirm the biological function of RFWD3 shRNAi, a rescue experiment was performed with RFWD3-KD-OE in HCC cells. After transfection with an LV-RFWD3 lentiviral vector, we used GFP fluorescence imaging to confirm transduction efficiency (Figure 6A). Compared with the RFWD3-KD-OE-NC group, the RFWD3-KD-OE group showed upregulation of RFWD3 in qRT-PCR (Figure 6B). WB analysis also confirmed the lentivirus transduction efficiency (Figure 6C).

RFWD3-KD-OE resume shRNAi HCC cells proliferation, invasion, and migration

In the MTT assay, the OD value of the RFWD3-KD-OE group was higher than that of the RFWD3-KD-OE-NC group. These results indicate that RFWD3-KD-OE rescued the proliferation of shRNAi BEL-7404 cells (Figure 7A). Furthermore, no difference was observed between the G1 and S phases in the two groups of cell cycle progression assays. However, in the G2/M phase, the fraction of RFWD3-KD-OE-NC cells was increased (the average value was 30.51% in RFWD3-KD-OE-NC cells, 29.74% in RFWD3-KD-OE cells, $P < 0.05$); however, the gap in data was diminished compared with previous BEL-7404 RNAi groups (24.9% in shCtrl cells, 32.15% in shRNAi cells, $P < 0.05$) (Figure 7B). In the subsequent apoptosis experiments, BEL-7404 RFWD3-KD-OE-NC cells had a higher apoptosis rate (the average

value was 20.47% in RFWD3-KD-OE-NC cells, 18.03% in RFWD3-KD-OE cells, $P < 0.01$) (Figure 7C). This result demonstrated that RFWD3-KD-OE reduced the apoptosis ratio, thus affecting the proliferation of shRNAi BEL-7404 cells. In transwell assays, the migration of BEL-7404 RFWD3-KD-OE cells was higher than that of RFWD3-KD-OE-NC cells ($P < 0.01$) (Figure 7D). Similar results were observed in the invasion assay ($P < 0.01$; Figure 7E). These data revealed that RFWD3-KD-OE rescued BEL-7404 shRNAi cell invasion and migration.

RFWD3 influence the progress of HCC via the Wnt/β-catenin signalling pathway

To further validate the results of the *in vitro* and *in vivo* experiments, we performed microarray analysis to explore the molecular mechanism underlying the differential RFWD3 expression between shCtrl and shRNAi HCC cells. A total of 454 genes (Figure 8A) exhibited differential mRNA expression between the two groups (> 2-fold, $P < 0.05$). We then analyzed the disease and function to determine the enriched gene sets. Genes involved in cell death, viability and survival, cell movement and invasion, cellular assembly and organization, DNA replication, recombination and repair, and cellular function and maintenance were significantly enriched ($P < 0.05$, Figure 8B). Classical pathway analysis revealed that, in addition to the previously reported p53 and cell cycle checkpoint control pathways, the Wnt/β-catenin signalling pathway was altered following RFWD3 silencing ($P < 0.05$, Figure 8C and D). Next, we used IPA to analyze the knowledge-based interactome associated with the regulation of these pathways (Figure 8E). Some genes involved in tumorigenesis were shown to be regulated by RFWD3, including *CREBBP*, *KREMEN-1*, *LRP6*, *JUN*, *WNT5A*, and *WNT7B*. Finally, we tested the protein expression between shCtrl and shRNAi and RFWD3-KD-OE *vs* RFWD3-KD-OE-NC groups and found that the expression of *CREBBP*, *WNT5A*, *JUN*, *WNT7B*, and *LRP6* were decreased, and the expression of *KREMEN-1* was increased in the shRNAi and RFWD3-KD-OE-NC groups than that in shCtrl and RFWD3-KD-OE groups (Figure 8F-I). These results indicate that the Wnt/β-catenin signalling pathway is involved in the RFWD3-mediated promotion of HCC tumorigenesis.

DISCUSSION

In this study, we demonstrated reduced growth and proliferation of HCC cells in the shRNAi group. Subsequent evaluation of cell cycle progression revealed disrupted cell cycle progression at the G2/M phase, whereas the FCM analysis showed a higher rate of apoptosis in the shRNAi group than in the ShCtrl group. These results confirmed that RFWD3 silencing caused both cell cycle arrest at the G2/M phase and apoptosis. Furthermore, the *in vitro* experiments revealed that shCtrl cells had better healing abilities than shRNAi cells. In the subsequent transwell experiments, we also found that the shRNAi cells had about half the metastatic capacity of the shCtrl cells. These results were validated *in vivo* using mice models, which showed that the tumor volumes in mice injected subcutaneously with shRNAi cells were significantly smaller than those in mice injected with shCtrl cells. Furthermore, the pulmonary metastasis group revealed that lung metastasis was significantly reduced in mice injected with shRNAi cells than in those injected with shCtrl cells.

To rule out off-target effects with RFWD3-shRNAi, we performed a rescue experiment. After verifying the transfection efficiency and screening of stable cell lines, we carried out phenotype verification. Compared with the control group, the cell growth state was restored in the RFWD3-KD-OE group. It also showed a higher OD value in the MTT assay, decreased fraction of G2/M phase, and diminution gap of data compared with RFWD3-KD-OE-NC group. Furthermore, in the apoptosis experiments, the RFWD3-KD-OE group had a lower apoptosis rate than the RFWD3-KD-OE-NC group. The same results were observed in the transwell assays, and the migration and invasion abilities of the RFWD3-KD-OE group were recovered. These data revealed that RFWD3-KD-OE resumed BEL-7404 shRNAi cell invasion and metastasis and proved that the previous RFWD3-shRNAi experimental results were not due to off-target effects.

Subsequently, we proved that RFWD3 silencing plays a positive role in inhibiting the proliferation, invasion, and metastasis of HCC. Previous studies have reported that the essential role of RFWD3 in HR makes it important for cell survival, as it promotes the repair of DNA damage. Therefore, the increased apoptosis could be attributed to the unrepaired DNA damage upon RFWD3 loss. On the contrary, the migration and metastasis phenotypes could be explained by decreased viability due to increased

RFWD3 function during DNA repair. In other words, this condition may be explained by a common theory: "There are more firefighters on the fire scene than ordinary people." However, the questions like whether the increased expression of RFWD3 in HCC is a compensatory mechanism to deal with increased genomic instability or whether RFWD3 is regulated by a Janus-faced regulator that plays other roles in HCC, consequently promoting the progression of HCC remained unanswered.

To answer these questions, we explored the mechanism underlying HCC and identified the molecular signalling transduction pathways using microarray-based gene expression analyses and IPA. The raw data (Supplementary materials 1) were verified with the uniformity, integrity and reliability (Supplementary materials 2). Gene expression profiling revealed that RFWD3 silencing enriched the expression of genes involved in cellular function and maintenance, cell death, viability, movement, invasion and survival, and DNA replication, recombination, and repair (Supplementary materials 3). In terms of the gene pathways involved, in addition to the p53 and cell replication cycle pathways that were previously reported in the literature, we found that the Wnt/β-catenin signalling pathway also had a significant impact. Further examination of the knowledge-based interactome associated with the regulation of Wnt/β-catenin *via* IPA analysis demonstrated that *CREMEN1, JUN, CREBBP, WNT5A, WNT7B,* and *LRP6*, which have been implicated in the proliferation and metastasis of various cancers, were differentially regulated by RFWD3 (> 2-fold, $P < 0.05$).

Reportedly, Wnt/β-catenin signalling plays an important role in embryonic liver development and regeneration and preserves liver health. An aberrant Wnt signalling activity has been implicated in several human cancers[31,32]. In normal tissues, only a small amount of β-catenin is found in the cytoplasm and is quickly degraded by the UPS. It is bound by a destruction complex containing *GSK3B, AXIN,* and *APC* and then ubiquitinated by β-transducin repeat-containing protein and subsequently degraded by the proteasome[33]. In the traditional Wnt/β-catenin pathway in tumors, the destruction complex is disassembled by the phosphorylation of *LRP6* and *GSK3β*, thereby preventing β-catenin degradation[34]. The accumulated β-catenin is transferred from the cytoplasm to the nucleus, where it competes with Groucho to form the *β-catenin-TCF/LEF* transcriptional complex. Finally, the Wnt signalling pathway is activated to regulate the transcription of target genes such as *cyclin D1*, *c-myc*, and *MMP9* under the synergistic effect of auxiliary factors, thus regulating tumor progression[35]. *KREMEN-1* is a transmembrane protein that contains a kringle domain. Studies have shown that it is a high-affinity receptor for *DKK*. *KREMEN-1, DKK*, and *LRP5/6* form a ternary complex that inhibits Wnt/β-catenin signalling, thus inducing head defects in Xenopus embryos[36,37]. Furthermore, *KREMEN-1* expression is prevalent in adult mammals but is often lacking in tumors. It has been shown that Wnt/β-catenin signalling maintains the low differentiation state of stem cells and undifferentiated cells, but *Dickkopf-KREMEN* blocks Wnt/β-catenin signalling causing cells to differentiate[38].

Collectively, the findings demonstrated that factors involved in Wnt/β-catenin signallings, such as *CREBBP, WNT5A, JUN, WNT7B,* and *LRP6*, were downregulated by RFWD3 silencing, and the expression of *KREMEN-1* was increased, indicating that RFWD3 might influence the progression of HCC *via* the Wnt/β-catenin signalling pathway. Based on these findings, it can be inferred that RFWD3 affects the Wnt/β-catenin signalling pathway and therefore affects HCC tumorigenesis. However, the detailed regulatory mechanism is still unclear and should be explored in future studies.

The intensity of the node color indicates the degree of upregulation (red) or downregulation (green) following RFWD3 silencing in hepatocellular carcinoma cells; F-I: The expression of *CREBBP, Wnt5A, JUN, Wnt7B* and *LRP6* were decreased, and the expression of *KREMEN-1* was increased in the shRNAi group using western blot analysis, in rescue experiment, the results are reversed.

CONCLUSION

In this study, we validated the expression and function of RFWD3 in HCC and demonstrated that RFWD3 expression might affect the proliferation and metastasis of HCC by regulating the Wnt/β-catenin signalling pathway. The findings suggest that RFWD3 could be a potential therapeutic target for HCC; however, it warrants further investigations to ascertain these possibilities.

ARTICLE HIGHLIGHTS

Research background

Hepatocellular carcinoma (HCC) is one of the most common malignant tumors with a high mortality rate. The molecular biology research of HCC can reveal the potential mechanism and provide direction for its comprehensive treatment.

Research motivation

The relationship between RING finger and WD repeat domain 3 (RFWD3) and the tumorigenesis process has been reported occasionally; however, the relationship between RFWD3 and HCC is still unclear.

Research objectives

We aimed to investigate the relationship between HCC and RFWD3 and explore the underlying molecular signalling transduction pathways.

Research methods

We analyzed RFWD3 expression in HCC tissues and evaluated cell phenotypes such as proliferation, apoptosis, migration, and invasion using Lentivirus mediated RFWD3 knockdown. In addition, *in vivo* experiments were performed to observe tumor growth and metastasis. Next, the phenotype was verified using the lentiviral-mediated rescue of RFWD3 shRNA. Finally, we unraveled the regulatory network underlying HCC using microarray, bioinformatics, and western blot analyses.

Research results

RFWD3 expression levels were correlated with tumor size and TNM stage in clinical samples. RFWD3 silencing increased apoptosis, decreased growth, and inhibited migration in HCC cell lines and nude mice, which were resumed with RFWD3 shRNAi rescue. Subsequent experiments revealed that RFWD3 might influence the proliferation and metastasis of HCC *via* the Wnt/β-catenin signalling pathway.

Research conclusions

This study shows that RFWD3 affects the Wnt/β-catenin signalling pathway and therefore affects HCC tumorigenesis.

Research perspectives

The findings suggest that RFWD3 could be a potential therapeutic target for HCC. However, it warrants further investigations to ascertain these inferences.

Abstract

BACKGROUND

The gut microbiota (GM) has been proven to play a role in the regulation of host lipid metabolism, which provides a new theory about the pathogenesis of dyslipidemia. However, the associations of GM with dyslipidemia based on sex differences remain unclear and warrant elucidation.

AIM

To investigate the associations of GM features with serum lipid profiles based on sex differences in a Chinese population.

METHODS

This study ultimately recruited 142 participants (73 females and 69 males) at

Honghui Hospital, Xi'an Jiaotong University. The anthropometric and blood metabolic parameters of all participants were measured. According to their serum lipid levels, female and male participants were classified into a high triglyceride (H_TG) group, a high total cholesterol (H_CHO) group, a low high-density lipoprotein cholesterol (L_HDL-C) group, and a control (CON) group with normal serum lipid levels. Fresh fecal samples were collected for 16S rRNA gene sequencing. UPARSE software, QIIME software, the RDP classifier and the FAPROTAX database were used for sequencing analyses.

RESULTS

The GM composition at the phylum level included Firmicutes and Bacteroidetes as the core GM. Different GM features were identified between females and males, and the associations between GM and serum lipid profiles were different in females and males. The GM features in different dyslipidemia subgroups changed in both female patients and male patients. Proteobacteria, Lactobacillaceae, *Lactobacillus* and *Lactobacillus_salivarius* were enriched in H_CHO females compared with CON females, while Coriobacteriia were enriched in L_HDL-C females. In the comparison among the three dyslipidemia subgroups in females, *Lactobacillus_salivarius* were enriched in H_CHO females, and Prevotellaceae were enriched in L_HDL-C females. Compared with CON or H_TG males, Prevotellaceae, *unidentified_Ruminococcaceae*, *Roseburia* and *Roseburia_inulinivorans* were decreased in L_HDL-C males (P value < 0.05), and linear discriminant analysis effect size analysis indicated an enrichment of the above GM taxa in H_TG males compared with other male subgroups. Additionally, *Roseburia_inulinivorans* abundance was positively correlated with serum TG and total cholesterol levels, and *Roseburia* were positively correlated with serum TG level. Furthermore, Proteobacteria (0.724, 95%CI: 0.567-0.849), Lactobacillaceae (0.703, 95%CI: 0.544-0.832), *Lactobacillus* (0.705, 95%CI: 0.547-0.834) and *Lactobacillus_salivarius* (0.706, 95%CI: 0.548-0.835) could distinguish H_CHO females from CON females, while Coriobacteriia (0.710, 95%CI: 0.547-0.841), Coriobacteriales (0.710, 95%CI: 0.547-0.841), Prevotellaceae (0.697, 95%CI: 0.534-0.830), *Roseburia* (0.697, 95%CI: 0.534-0.830) and *Roseburia_inulinivorans* (0.684, 95%CI: 0.520-0.820) could discriminate H_TG males from CON males. Based on the predictions of GM metabolic capabilities with the FAPROTAX database, a total of 51 functional assignments were obtained in females, while 38 were obtained in males. This functional prediction suggested that cellulolysis increased in L_HDL-C females compared with CON females, but decreased in L_HDL-C males compared with CON males.

CONCLUSION

This study indicates associations of GM with serum lipid profiles, supporting the notion that GM dysbiosis may participate in the pathogenesis of dyslipidemia, and sex differences should be considered.

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Dyslipidemia is the circulating lipid expression of metabolic syndrome, and alterations of gut microbiota (GM) are indicated to participate in the pathogenesis of dyslipidemia; however, little evidence was found in the literature on sex differences for these associations. Our results demonstrated the GM features in different dyslipidemia subgroups in females and males, suggesting a complex interaction between GM and lipid metabolism. Our observations may provide new evidence that different GM taxa may be associated with distinct lipids, and that GM may affect specific aspects of lipid metabolism. More studies are required to propose specific taxa that have the potential to ameliorate dyslipidemia.

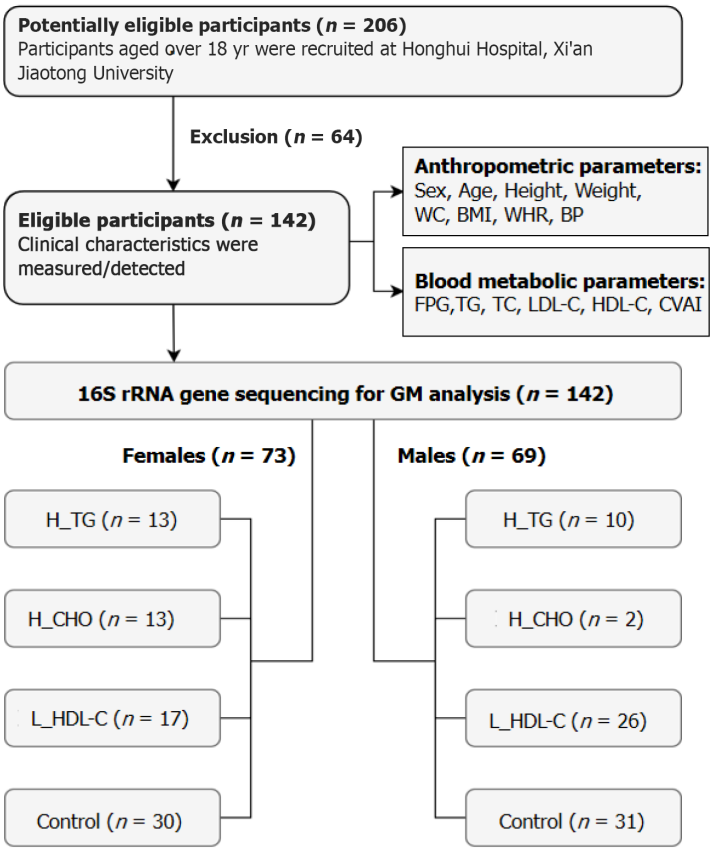
INTRODUCTION

Obesity has become a worldwide public health challenge, with its prevalence nearly tripled since 1975 [1]. Obesity is defined as a chronic accumulation of excessive lipids in tissues[2], which is related to the disruption of lipid metabolism[3]. As a defect in lipid metabolism, dyslipidemia is defined as any abnormality in blood lipid levels, and is characterized by an elevation of circulating triglyceride (TG), total cholesterol (TC), and low-density lipoprotein cholesterol (LDL-C), or a decrease in high-density lipoprotein cholesterol (HDL-C). Since observational studies have shown that 60%-70% of adults have lipid levels outside the recommended range[4,5], it is essential to reveal the underlying mechanism of dyslipidemia. Circulating lipid levels are known to have an important genetic contribution from over 500 single-nucleotide polymorphisms in more than 150 Loci, explaining approximately 40% of the total individual variation[6]. However, the unexplained 60% variation has been attributed to undiscovered elements and unquantified environmental factors, such as dietary intake and physical activity[7,8]. In recent years, considerable progress has been made in elucidating the mechanism responsible for dyslipidemia, and accumulated evidence has shown that the gut microbiota (GM) may play a potential role in obesity and related metabolic diseases, such as dyslipidemia[9-12].

The human gastrointestinal tract harbors over 100 trillion microorganisms[13], and the gut bacteria having effects on human health are the most prevalent and well-studied. In humans, GM profiles vary among different ethnicities (host genetics) and between different sexes[14,15], and are mainly shaped by early life events and stabilize in adolescence[16]. However, its composition and activity can be dynamic, and may be altered dramatically by multiple factors, such as medications, chronic dietary patterns and other environmental exposures[15,17,18]. This "microbial organ" has been recognized to perform various physiological functions[19-21], and is often called "a new virtual metabolic organ"[22,23]. The first indication of associations between GM and disorder statuses were for inflammation[24], and altered GM community (dysbiosis) has now been established in the development of cardiometabolic phenotypes[25]. These lines of evidence have raised an interest in GM as an important candidate in accounting for the unexplained variation in serum lipid levels in humans, and as a target for the therapeutic benefit of dyslipidemia[26]. Recent studies have convincingly linked GM to dyslipidemia, and GM was reported to explain substantial variation in TG and HDL-C levels independent of genetic factors in a Dutch study[26]. In addition, accumulating data from animal studies demonstrate that GM can affect host lipid metabolism through multiple direct and indirect biological mechanisms[27,28]. Nevertheless, determining associations between GM and host lipid metabolism remains a challenge in humans. Furthermore, sex is an important factor that may influence GM profiles, and sex differences can be observed in serum lipid profiles[29-31]. However, the relationship between GM and dyslipidemia based on sex differences remains unclear.

Collectively, ethnicity, geography and sex are potent factors that could influence the GM community [14,15,32]. Thus, this study focused on the associations of GM features with dyslipidemia based on sex differences in a northwestern Chinese population. We first reveal sex differences regarding GM features and then introduce dyslipidemia, highlighting its intricate relationships with GM, and discuss possible altered GM functions.



MATERIALS AND METHODS

Study design

From July 2018 to January 2020, this study recruited 206 adult individuals (107 females and 99 males) from the outpatient clinics at Honghui Hospital, Xi'an Jiaotong University, China. Individuals were excluded if one of the following conditions existed: (1) With any gastrointestinal diseases, infectious or chronic diseases, serious systematic dysfunctions, or surgery histories of the gastrointestinal tract; (2) Taking any medications that could disrupt the original GM community, such as probiotics or prebiotics, antimicrobial therapies, anti-inflammatory drugs, acid-suppressing drugs, immunosuppressants, or anti-dyslipidemia/anti-dysglycemia/anti-hypertension drugs within the past month prior to sampling [33]; and (3) Females who were pregnant or lactating. The individuals who met the above conditions were included as participants in this study, and informed consent was obtained. Finally, 142 participants (73 females and 69 males) were recruited, including 81 dyslipidemia patients and 61 controls (CON) with normal serum lipid levels. Data privacy was ensured by using anonymized identifiers, and the study flow is shown in Figure 1. This study was approved by the Ethical Committee of Honghui Hospital, Xi'an Jiaotong University (Protocol Number: 201801022, approved January 8, 2018).

Measurement of anthropometric parameters

On their first visit, related medical information was documented for all participants. Body weight (W) and height (H) were measured without shoes and heavy clothing to the nearest 0.1 cm and 0.1 kg, respectively. Waist circumference (WC) was measured in the middle of the lower rib margin and the iliac crest with a nonexpandable tape to the nearest 0.1 cm in the standing position. Body mass index

DOI: 10.3748/wjg.v28.i27.3455 **Copyright** ©The Author(s) 2022.

Figure 1 Flow chart of this study. WC: Waist circumference; BMI: Body mass index; WHR: Waist circumference/height ratio; BP: Blood pressure; FPG: Fasting plasma glucose; TG: Triglyceride; TC: Total cholesterol; LDL-C: Low-density lipoprotein cholesterol; HDL-C: High-density lipoprotein cholesterol; CVAI: Chinese visceral adiposity index; GM: Gut microbiota; H_TG: High triglyceride group; H_CHO: High cholesterol group; L_HDL-C: Low high-density lipoprotein cholesterol group.

(BMI) and WC/height ratio (WHR) were calculated accordingly. Blood pressure (BP) was assessed using a medical electronic sphygmomanometer (HEM-7130 professional, OMRON, Dalian, China) on the left arm positioned at the heart level with palm face up in a sitting position. The participants were required to rest in a seated position for at least 5 min before BP assessment, with triplicate measurements at 1-min intervals. All equipment was calibrated at the beginning of the study.

Detection and computation of metabolic indicators

Venous blood samples were drawn from an antecubital vein in the morning following an overnight (at least 8 h) fast. Levels of fasting plasma glucose, TG, TC, LDL-C and HDL-C were detected by an automatic biochemical analyzer (Cobas c701, Roche, Mannheim, Germany). This instrument system was calibrated regularly. Moreover, the Chinese visceral adiposity index (CVAI) was calculated using the formula[34]: CVAI for females = -187.32 + 1.71 × age + 4.23 × BMI + 1.12 × WC (cm) + 39.76 × Log_{10}TG (mmol/L) - 11.66 × HDL-C (mmol/L), and CVAI for males = -267.93 + 0.68 × age + 0.03 × BMI + 4.00 × WC + 22.00 × Log_{10}TG - 16.32 × HDL-C.

Diagnostic criteria and grouping

In accordance with the "Guidelines for prevention and treatment of dyslipidemia in Chinese adults" (revised in 2016)[35] and the stratification standard of dyslipidemia in the primary prevention population of arteriosclerotic cardiovascular disease in China[36], dyslipidemia was defined as the presence of one or more abnormal serum lipid levels without any lipid-lowering medication: TG ≥ 1.7 mmol/L, TC ≥ 5.2 mmol/L, LDL-C ≥ 3.4 mmol/L, and/or HDL-C < 1.0 mmol/L. Subsequently, participants were divided into subgroups according to their serum lipid profiles. Specifically, patients were classified into the high TG (H_TG) group if only high TG level existed. Patients with increased serum TC and/or LDL-C levels and without HDL-C or TG abnormalities were classified into the high cholesterol (H_CHO) group. Patients were classified into the low HDL-C (L_HDL-C) group if only low serum HDL-C level existed. Participants with normal serum lipid profiles served as CON.

Fecal sample collection, DNA extraction, and 16S rRNA gene sequencing

Fresh fecal samples were collected from each participant at home, and stored in foam boxes with frozen cold packs[37]. Within 6 h after defecation, all fecal samples were transported to the Clinical Laboratory of Honghui Hospital, Xi'an Jiaotong University, and immediately stored at -80 °C until further processing. Genomic DNA was extracted from all samples using the QIAamp Fast DNA Stool Mini Kit (Qiagen, Hilden, Germany) following the manufacturer's instructions. After quality evaluation and concentration determination, DNA samples, greater than 1 μg and with an OD value between 1.8-2.0, were considered to be qualified for subsequent sequencing. Then, the V3-V4 regions of the 16S rRNA gene were amplified by universal primers (338F: 5'-ACT CCT ACG GGA GGC AGC AG-3'; 806R: 5'-GGA CTA CHV GGG TWT CTA AT-3') with barcodes, and all PCRs were performed using Phusion® High Fidelity PCR Master Mix (New England Biolabs, Ipswich, MA, United States). Next, the PCR products were mixed and purified using a GeneJET™ Gel Extraction Kit (Thermo Scientific, Waltham, MA, United States). The sequencing library for each sample was constructed with the NEB Next® Ultra ™ DNA Library Prep Kit for Illumina (New England Biolabs, Ipswich, MA, United States), and library quality was assessed on a Qubit® 2.0 Fluorometer (Thermo Scientific, Waltham, MA, United States). Finally, the generated libraries were pair-end (2 × 250 bp) sequenced on the Illumina NovaSeq 6000 platform (Illumina, San Diego, CA, United States).

16S rRNA gene sequencing analyses

UPARSE (v7.0.1001) and QIIME software (v1.7.0) were introduced for sequencing analyses. According to a similarity threshold of 97%, acquired clean reads with high quality were de novo clustered into the same operational taxonomic unit (OTU), and the representative sequence of each OTU was screened and used to annotate taxonomic information based on the RDP classifier (v2.2). The GM diversity and composition were assessed based on the annotated OTUs. The alpha diversity (α-diversity) of GM was estimated by four indices, including Chao1, abundance coverage-based estimator (Ace), Shannon and Simpson. The comparisons of these indices between groups were conducted by the Wilcoxon rank-sum test, using function *wilcox.test* from the R package stats. To investigate the significance of differences in the GM community, beta diversity (β-diversity) was estimated using the unweighted UniFrac method to calculate the distances between samples, and visualized by the principal coordinates analysis (PCoA) model. The "*WGCNA*", "*stats*" and "*ggplot2*" packages in R were utilized. The top ten GM taxa sorted by higher relative abundances at the six taxonomic levels, including phylum, class, order, family, genus and species, were identified and visualized in each group. The linear discriminant analysis (LDA) effect size (LEfSe) algorithm was applied to identify the enriched significant taxa in each group. The LDA score threshold was set to 2 on a log10 scale. The FAPROTAX (v1.2.2) database, containing 90 different types of metabolic assignments, was introduced to obtain the functional information of the GM community[38], and the differences between groups were assessed by the Wilcoxon rank-sum test, with a P value < 0.05 considered significant.

Statistical analysis

SPSS (v23.0.0.0, IBM SPSS Inc., Chicago, IL), R platform (v4.0.2, R Foundation, Vienna, Austria), GraphPad Prism (v8.4.3, GraphPad Software Inc., San Diego, CA, United States) and MedCalc (v19.0.4, MedCalc Software Bvba, Ostend, Belgium) were employed for statistical analysis and figure construction. The normal distribution of quantitative variables was assessed by the Shapiro-Wilk test. Clinical parameters are presented as the mean ± SD, and were analyzed among groups by the variance analysis (ANOVA) or Welch's ANOVA depending on the homogeneity of variance. In addition, the Games-Howell test was used for multiple comparisons if a P value < 0.05 existed. The "*ggcorrplot*" package in R was utilized for Spearman correlation analysis between clinical parameters. Moreover, Spearman correlation analysis was also applied to evaluate the potential associations between GM features and clinical parameters, using the function *cor.test (method = spearman)* in R. Receiver operating characteristic (ROC) curve analysis, with areas under the curve, was applied to evaluate the diagnostic performance of specific GM taxa. All statistical tests with a P value < 0.05 were considered significant.

The bioinformatics analyses and statistical methods/techniques mentioned in this study were conducted, verified and reviewed by our expert Ji-Han Wang, PhD, from Institute of Medical Research, Northwestern Polytechnical University, and Guo-Dong Wang, Master Degree, from Department of Quality Control, Xi'an Mental Health Center.

RESULTS

Basic information of the study population

The present study finally included 142 participants (73 females and 69 males), as shown in Figure 1. Table 1 shows the clinical characteristics of all the participants grouped by sex and serum lipid profiles. Serum lipid levels and CVAI showed differences among female subgroups as did height, WC and WHR (P value < 0.05). Serum lipid levels and CVAI showed differences among male subgroups as well (P

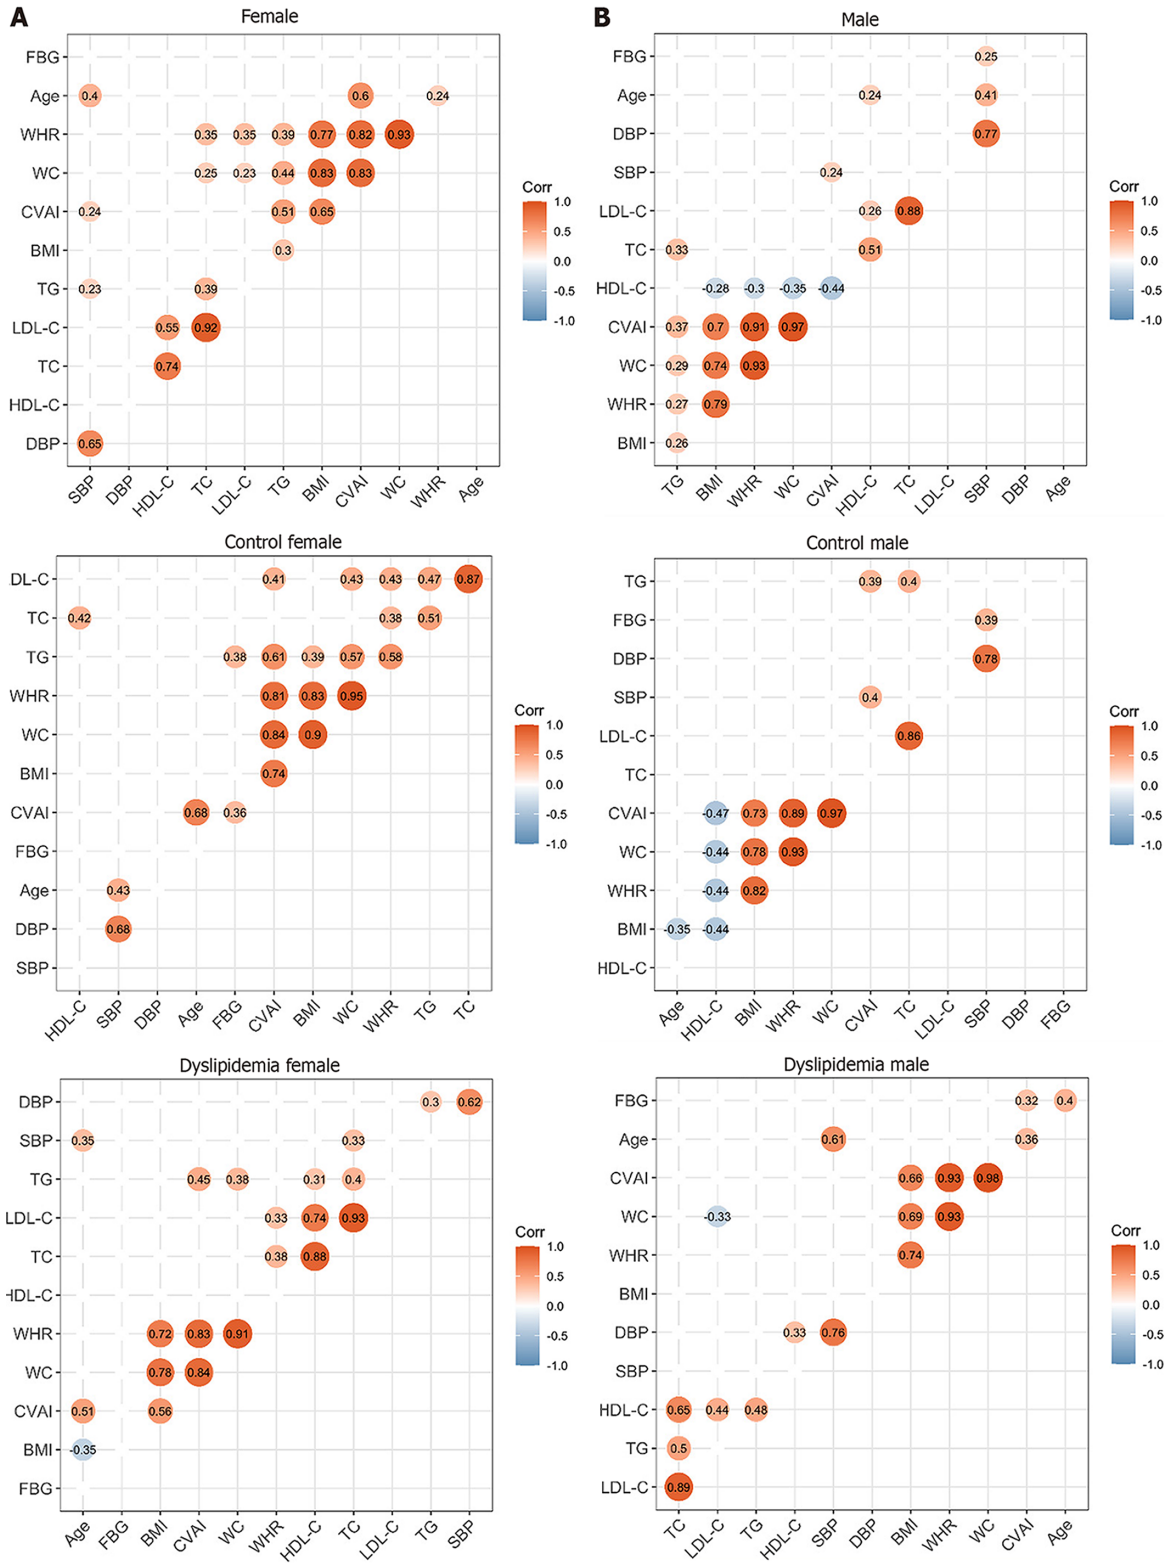
[a]$P < 0.05$.

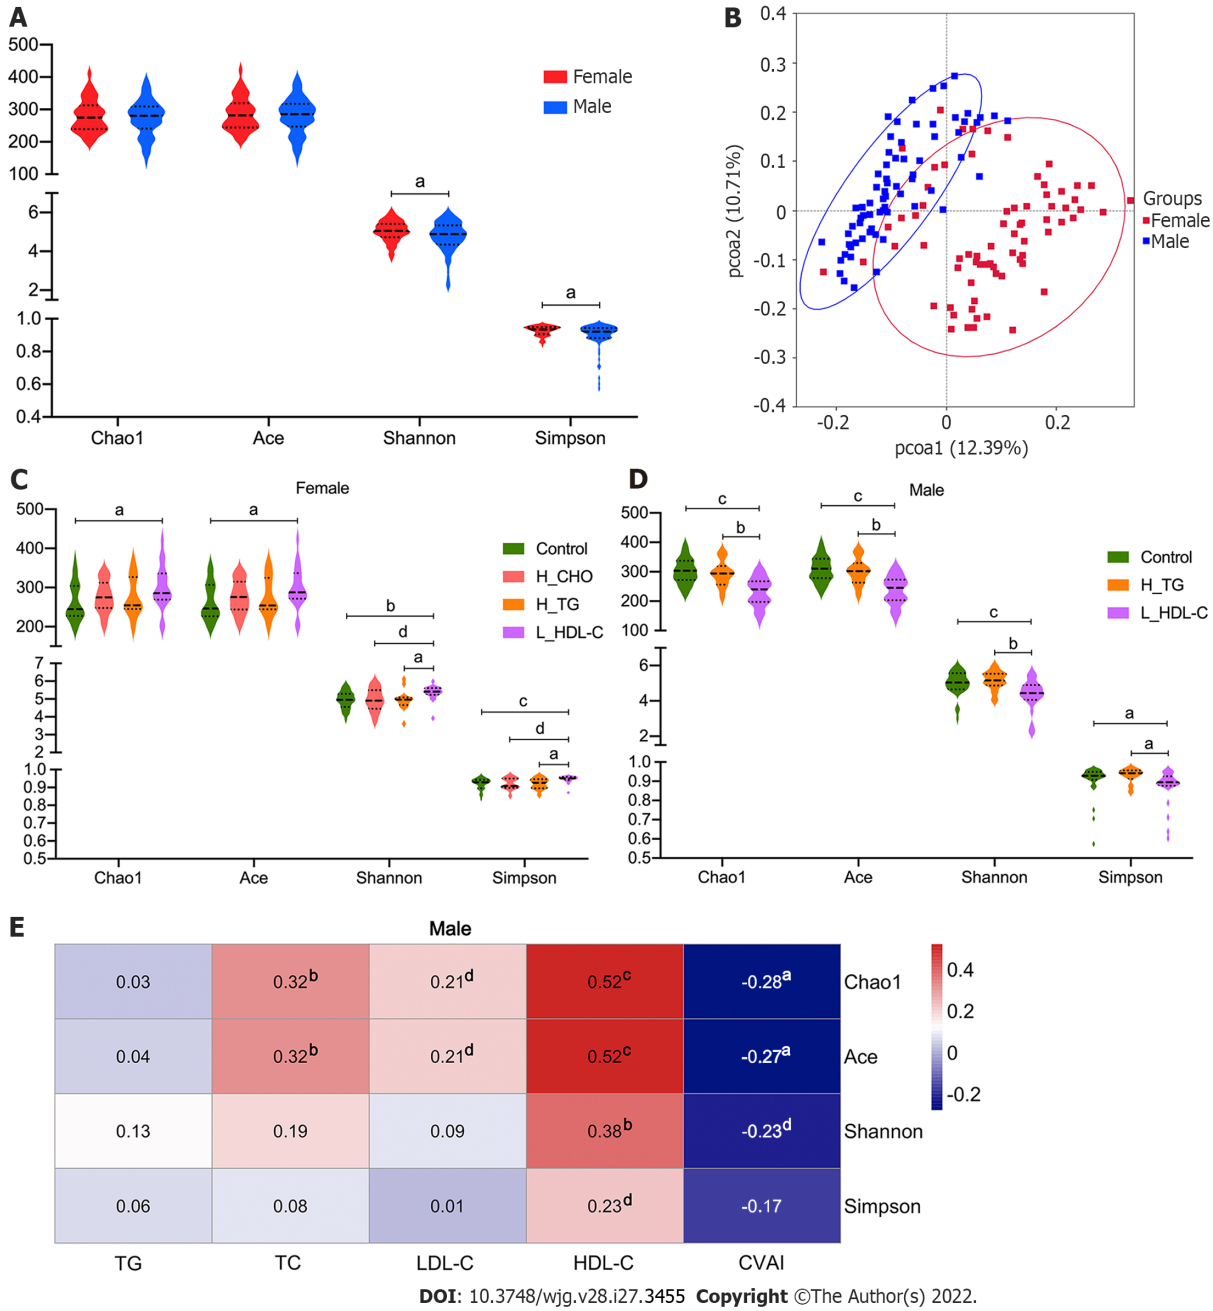
Data are presented as mean ± SD. *P* values are from the variance analysis (ANOVA) or Welch's ANOVA depending on the homogeneity of variance. CHO: Cholesterol; WC: Waist circumference; BMI: Body mass index; WHR: Waist circumference/height ratio; SBP: Systolic blood pressure; DBP: Diastolic blood pressure; FPG: Fasting plasma glucose; TG: Triglyceride; TC: Total cholesterol; LDL-C: Low-density lipoprotein cholesterol; HDL-C: High-density lipoprotein cholesterol; CVAI: Chinese visceral adiposity index.



value < 0.05). Please refer to Supplementary Table 1 for detailed information and differences between females and males. The correlation analysis between the clinical characteristics of females and males is shown in Figure 2, and indicates positive correlations between the serum lipid indicators.

Diversity analysis of GM in the study population

To identify the associations of GM features with serum lipid profiles, we performed 16S rRNA gene sequencing analyses of GM from fecal samples. After quality CON, sequencing reads from 142 fecal samples were processed to determine the OTUs. Our data indicated that females had more unique OTUs, and the number of common OTUs shared by the female subgroups was larger than that shared by the male subgroups (data not shown).



We evaluated the diversity of the GM community to assess the richness and evenness for females and males, and Shannon and Simpson indices suggested a higher α-diversity in females (*P* value < 0.05, Figure 3A). In addition, a dissimilarity between females and males was observed according to the visualized PCoA model for β-diversity analysis (Figure 3B). Since sex is an important determinant of GM and serum lipids[30,32,39], the study population was divided into a female group and a male group for the subsequent analyses.

To reveal the associations of GM diversity with serum lipid profiles based on sex differences, we conducted analogous analyses in the enrolled females and males. Our results showed that the α-diversity of GM was different in different dyslipidemia subgroups in females and males (Figure 3C and D). Of note, the α-diversity in L_HDL-C females was higher than that in CON females (*P* value < 0.05), while it was lower in L_HDL-C males than that in CON males (*P* value < 0.05). Additionally, the α-diversity of GM in H_TG males was higher than that in L_HDL-C males (*P* value < 0.05). The PCoA results suggested that the GM community in different dyslipidemia subgroups varied from that in the CON group in females and males, respectively, but could not be separated accurately and clearly (data not shown). Furthermore, the α-diversity of GM was found to be correlated with the serum lipid profiles and CVAI in males (Figure 3E). Specifically, the Chao1, Ace and Shannon indices were positively correlated with the serum HDL-C levels, while the Chao1 and Ace indices were negatively correlated

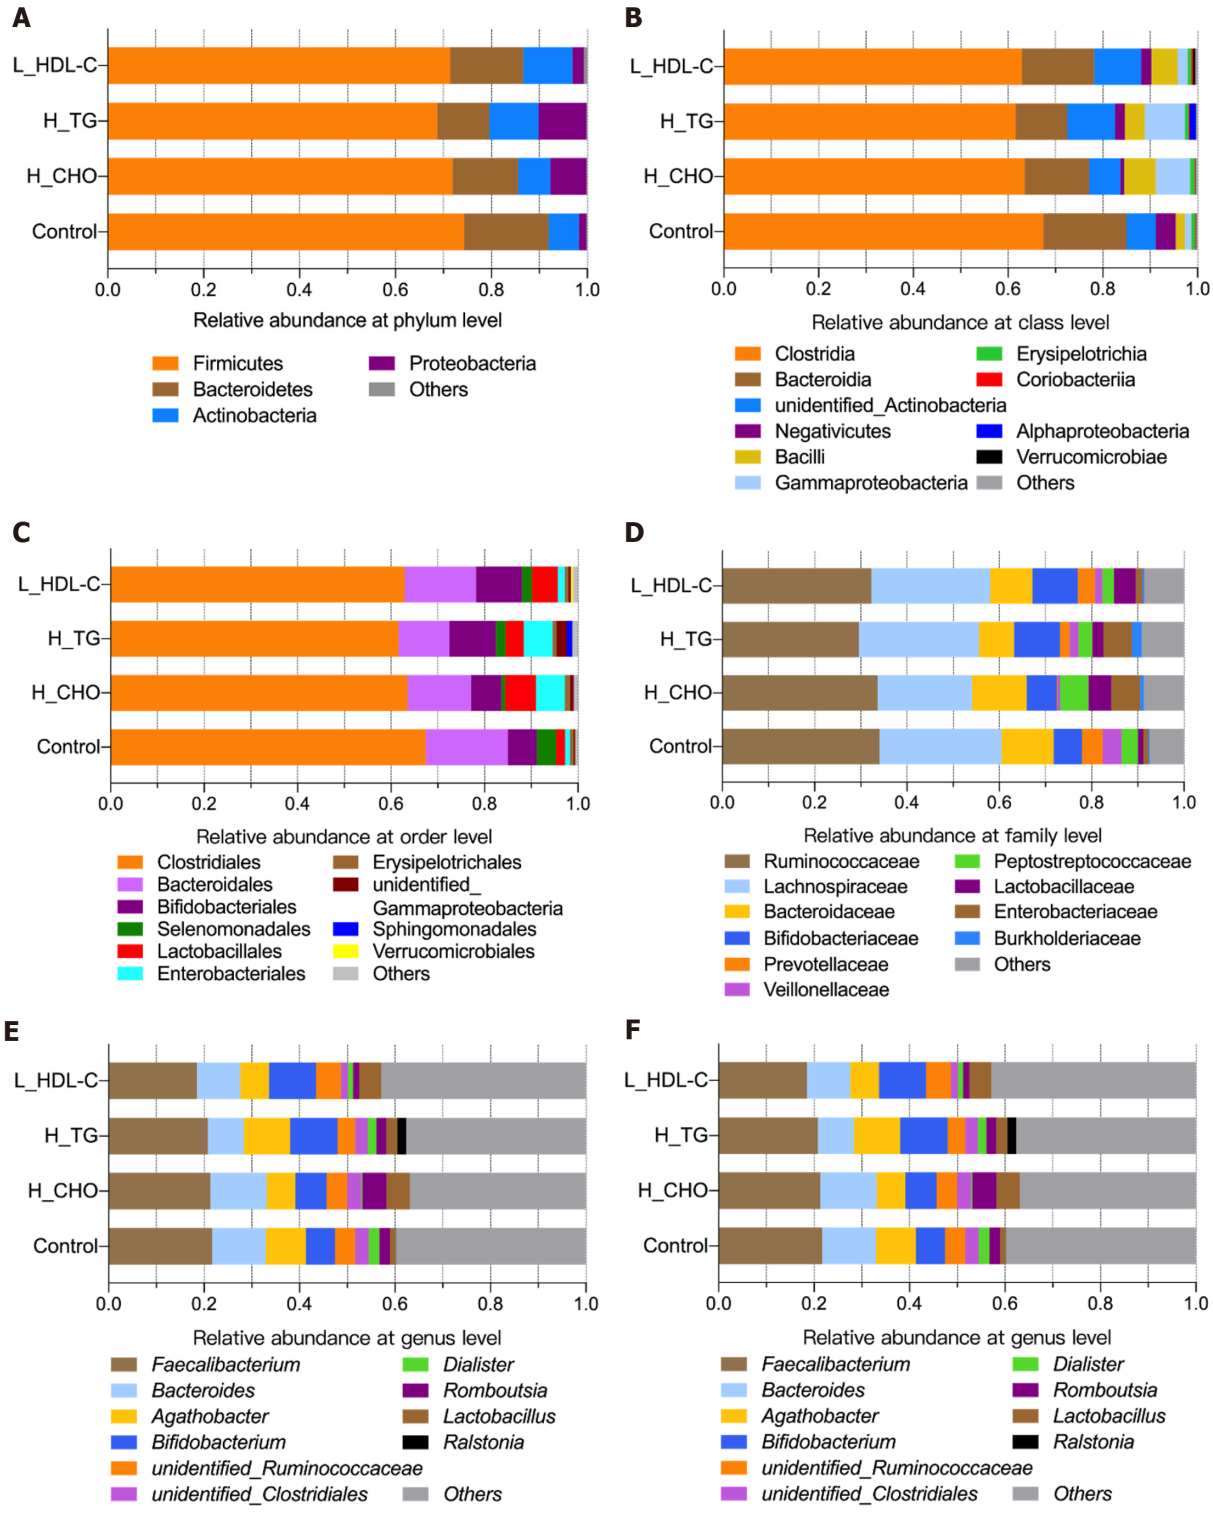
with CVAI. However, similar results could not be observed in females. The bioinformatics analyses above revealed the associations between the general state of GM and the human serum lipid profiles.

Taxonomic composition of GM in the study population

After diversity analysis, we focused on the relative abundances of GM taxa at six different taxonomic levels in different groups, and the top ten taxa with higher relative abundances at each level are shown in Supplementary Figure 1 for females and males. Similarly, the top ten taxa at each level were



identified in the female subgroups (Figure 4). Consistent with previous data, the GM composition at the phylum level included Firmicutes and Bacteroidetes as the core GM, with lower relative abundances of Actinobacteria, Proteobacteria and others. The most abundant GM taxa were Clostridia, Bacteroidia, Clostridiales, Bacteroides, Ruminococcaceae, Lachnospiraceae, Bacteroidaceae, *Faecalibacterium* and *Bacteroides*. GM taxa with relative abundances of no less than 0.0001 at each level were included in the following analyses. The relative abundances of Proteobacteria, Lactobacillaceae and *Lactobacillus* were no less than 0.010 in H_CHO females, and were greater than those in CON females (P value < 0.05); while the relative abundance of Coriobacteriia was higher in L_HDL-C females than that in CON females (P value < 0.05). In the comparison of H_CHO and L_HDL-C females, Prevotellaceae abundance was greater in L_HDL-C females (P value < 0.05), and *Lactobacillus_salivarius* abundance was greater in H_CHO females (P value < 0.05). In the comparison of H_CHO and H_TG females, *Agathobacter* abundance was higher in H_TG females (P value < 0.05), while the relative abundances of *Ruminococcus_bromii* and *Lactobacillus_salivarius* were higher in H_CHO females (P value < 0.05). Additionally, Prevotellaceae abundance was greater in L_HDL-C females than that in H_TG females (P value < 0.05). Subsequently, analogous comparison analysis was conducted in the male subgroups (Figure 5). The most abundant taxa were Clostridia, Bacteroidia, Clostridiales, Bacteroidales, Ruminococcaceae, Lachnospiraceae, *Faecalibacterium*, *Bifidobacterium*, *Bifidobacterium_pseudocatenulatum* and *Clostridium_disporicum*. In the comparison of L_HDL-C and CON males, the relative abundances of Bacteroidetes, Bacteroidia, Bacteroidales, Prevotellaceae, *unidentified_Ruminococcaceae*, *Roseburia* and *Roseburia_inulinivorans* were lower in L_HDL-C males (P value < 0.05). Meanwhile, Coriobacteriia, Coriobacteriales, Prevotellaceae, *unidentified_Ruminococcaceae*, *Roseburia* and *Roseburia_inulinivorans* were lower in L_HDL-C males than those in H_TG males (P value < 0.05). Interestingly, no differences were observed in the comparison between the H_TG group and CON group (P value > 0.05) in females or males.

LEfSe analysis was conducted in different dyslipidemia subgroups and the CON group in females and males. Compared with CON females (Figure 6), LEfSe analysis revealed the enrichment of Proteobacteria, Lactobacillaceae, *Lactobacillus* and *Lactobacillus_salivarius* in H_CHO females, and the enrichment of Coriobacteriia in L_HDL-C females. In the comparison among the three dyslipidemia subgroups in females, *Lactobacillus_salivarius* were enriched in H_CHO females, and Prevotellaceae were enriched in L_HDL-C females. Simultaneously, LEfSe analysis revealed that Prevotellaceae, *unidentified_Ruminococcaceae*, *Roseburia*, *Roseburia_inulinivorans*, Coriobacteriia, Coriobacteriales and Verrucomicrobiae were enriched in H_TG males compared with other males (Figure 7).

Associations of GM taxa with serum lipid profiles in the study population

To further explore the clinical implications of GM in dyslipidemia, Spearman correlation analysis was introduced to assess the associations between differential GM taxa and the serum lipid profiles/CVAI, and a number of reliable correlations were revealed. In females, a positive correlation of *Bacteroides_coprocola* with serum TG level was observed, while negative correlations of Bacteroidetes, Bacteroidia and Bacteroidales with CVAI were noted (P value < 0.05, Figure 8A). Moreover, more correlations were identified in males (P value < 0.05, Figure 8B). Specifically, the relative abundances of Actinobacteria, unidentified_Actinobacteria, Bifidobacteriales, Bifidobacteriaceae and *Bifidobacterium* were negatively correlated with the serum TG and TC levels, the relative abundance of *Roseburia_inulinivorans* was positively correlated with the serum TG and TC levels, and the relative abundance of *Roseburia* was positively correlated with the serum TG level. In addition, the relative abundances of Leuconostocaceae, *Weissella* and *Weissella_cibaria* were correlated with increased serum TC and LDL-C levels, and the relative abundance of *Bacteroides_vulgatus* was correlated with decreased serum LDL-C level. Furthermore, we found that the relative abundances of Bacteroidetes, Bacteroidia, Bacteroidales, Coriobacteriales, Prevotellaceae, *unidentified_Ruminococcaceae* and *Roseburia_inulinivorans* were positively correlated with serum HDL-C level, and the relative abundances of Bacteroidetes, Bacteroidia, Bacteroidales and *Bacteroides_vulgatus* were negatively correlated with CVAI in males.

To search for the specific GM taxa that may facilitate the differentiation of lipid profiles in dyslipidemia patients from CON, ROC curve analysis was conducted in the female and male subgroups (P value < 0.05, Figure 9). The GM taxa, that effectively distinguished H_CHO females from CON females, were Proteobacteria (0.724, 95%CI: 0.567-0.849), Lactobacillaceae (0.703, 95%CI: 0.544-0.832), *Lactobacillus* (0.705, 95%CI: 0.547-0.834) and *Lactobacillus_salivarius* (0.706, 95%CI: 0.548-0.835). In addition, Coriobacteriia (0.697, 95%CI: 0.546-0.822) may help discriminate L_HDL-C females from CON females. Moreover, the GM taxa in favor of the differentiation of H_TG males from CON males were Coriobacteriia (0.710, 95%CI: 0.547-0.841), Coriobacteriales (0.710, 95%CI: 0.547-0.841), Prevotellaceae (0.697, 95%CI: 0.534-0.830), *Roseburia* (0.697, 95%CI: 0.534-0.830) and *Roseburia_inulinivorans* (0.684, 95%CI: 0.520-0.820). Additionally, seven GM taxa may play a role in distinguishing L_HDL-C males from CON males: Bacteroidetes (0.676, 95%CI: 0.539-0.794), Bacteroidia (0.676, 95%CI: 0.539-0.794), Bacteroidales (0.676, 95%CI: 0.538-0.793), Prevotellaceae (0.685, 95%CI: 0.548-0.802), *unidentified_Ruminococcaceae* (0.687, 95%CI: 0.551-0.804), *Roseburia* (0.662, 95%CI: 0.524-0.782) and *Roseburia_inulinivorans* (0.682, 95%CI: 0.545-0.799).

Figure 4 The taxonomic composition of gut microbiota in females of the study population. Bar plots show the relative abundances of the top ten taxa at the six taxonomic levels, including phyla, class, orders, family, genus and species, in females. Each component of the cumulative bar chart indicates a phylum, a class, an order, a family, a genus or a species. A: Relative abundance at phylum level; B: Relative abundance at class level; C: Relative abundance at order level; D: Relative abundance at family level; E: Relative abundance at genus level; F: Relative abundance at species level. H_CHO: High total cholesterol; H_TG: high triglyceride; L_HDL-C: Low high-density lipoprotein cholesterol.

Functional analysis of GM in the study population

Finally, we evaluated the functions of the GM community using the FAPROTAX database, and obtained the main metabolic processes of microorganisms associated with different biogeochemical cycles. A total of 51 functional assignments, with relative abundances larger than 0.0001 of the average level, were obtained in females, and 38 assignments were obtained in males. Apparently, GM functions showed

abundance was increased in L_HDL-C females (P value < 0.05). Additionally, cellulolysis abundance was increased in L_HDL-C females when compared with that in H_CHO females (P value < 0.05). Compared with CON males, the relative abundances of sulfate respiration, respiration of sulfur compounds and cellulolysis were decreased in L_HDL-C males (P value < 0.05), while the relative abundance of nitrate respiration was increased in L_HDL-C males (P value < 0.05).

DISCUSSION

Dyslipidemia is considered a defect of lipid metabolism in circulation, characterized by increased or decreased levels of serum lipids. Notably, alterations in the GM community may participate in the pathogenesis of dyslipidemia, and the GM composition could be influenced by sex, host genotype and

geographic location. To our knowledge, little evidence is present in the literature on the correlations between GM and serum lipids based on sex differences[39]; hence, the initial objective of this study was to identify the associations of GM features with serum lipid profiles based on sex differences in a Chinese population.

Considered as a whole, there were significant differences in serum lipid profiles and GM features between females and males. Specifically, females have higher GM diversities, and the GM composition was quite different from that in males, which is consistent with previous data[40]. In addition, the functional analysis of GM also showed an obvious dissimilarity between females and males, further supporting our strategy of respective GM analysis in females and males[14]. Of note, the associations between GM and dyslipidemia in humans have been investigated and demonstrated by various studies, suggesting the alteration of GM in patients with impaired lipid metabolism[28,41]. For instance, Cotillard *et al*[42] noted that reduced GM richness, commonly observed in obese patients, was linked to increased serum TG and TC levels. Following that study, more studies have demonstrated negative correlations of circulating TG and LDL-C levels with GM diversity, and a positive correlation of HDL-C with GM richness[9,26,43,44]. Moreover, certain GM taxa were found to be correlated with specific lipid profiles, suggesting that different GM taxa may affect distinct classes of lipids[26,42,43]. Although the present data have not clearly defined the GM pattern of patients with dyslipidemia, these observations provide new avenues for validation and follow-up studies. Therefore, dyslipidemia female and male patients in this study were divided into a H_TG group, a H_CHO group and a L_HDL-C group, for a more targeted investigation and interpretation.

As an important indicator of the GM community and a general measure of gut health, higher GM diversities have been proposed to be associated with healthy lipid levels, such as increased HDL-C and decreased TG levels[26]. Our results showed a positive correlation between GM diversities and the serum HDL-C level in males, consistent with previous data[26]. Additionally, GM diversities were

H_CHO: High total cholesterol; H_TG: high triglyceride; L_HDL-C: Low high-density lipoprotein cholesterol.

negatively correlated with CVAI in males. As a valuable indicator of "adipose distribution and function", CVAI has been suggested to be a reliable and applicable indicator for the evaluation of visceral fat dysfunction in Chinese individuals, which is based on simple and obtainable clinical parameters and the serum lipid levels[34,45]. The CVAI is essentially correlated with lipid metabolism, and its negative correlation with GM diversities could further support the reliability of our data.

Butyrate has been suggested to facilitate the prevention and treatment of diet-induced obesity by reducing fat accumulation and insulin resistance[46,47], and the ability to produce butyrate is widely distributed among gram-positive anaerobic bacteria[48]. As members of the butyrate-producing bacteria

[48], *Roseburia* and *Roseburia_inulinivorans* have been investigated in certain diseases. By analyzing the GM composition of patients with symptomatic atherosclerosis, Karlsson *et al*[49] noted an enrichment of *Roseburia* in CVD patients, while a lower abundance of *Roseburia* was be observed in patients with diabetes[44]. In this study, we found that *Roseburia_inulinivorans* were positively correlated with the serum TG, TC and HDL-C levels, and *Roseburia* were positively correlated with the serum TG level in males. In addition, decreased *Roseburia* and *Roseburia_inulinivorans* abundances distinguished L_HDL-C males from CON males, while increased *Roseburia* and *Roseburia_inulinivorans* abundances distinguished H_TG males from CON males. Furthermore, strains of *Bifidobacterium* and *Lactobacillus* have potential therapeutic purposes[50]. An *et al*[51] once described a comparable, positive anti-obesity and lipid-lowering effect of *Bifidobacterium* spp. in obese rats fed a high-fat diet. Consistent with the evidence, our results demonstrated that the relative abundances of Bifidobacteriales, Bifidobacteriaceae and *Bifidobacterium* were negatively correlated with the serum TG and TC levels in males. However, certain favorable GM taxa, such as Lactobacillaceae, *Lactobacillus* and *Lactobacillus_salivarius*, were enriched in H_CHO females. As a probiotic supplement, *Lactobacillus* were noted to have a negative correlation with serum

lipid profiles[52]. An animal study, focused on mice fed a high-fat high-cholesterol diet and supplemented with *Lactobacillus curvatus* and/or *Lactobacillus plantarum*, revealed that these probiotic bacteria play important roles in normalizing lipid metabolism, such as decreasing TC levels in plasma and liver, and reducing the accumulation of hepatic TG[53]. Obviously, certain conflicting findings exist, which should be further investigated. Nevertheless, these observations indicate that different GM taxa associate with certain lipids, and may affect specific aspects of lipid metabolism[26,42,43].

A recent study on rats[54] demonstrated that a high-fat diet decreased the proportions of Bacteroidetes and its genera *Bacteroides* and *Prevotella*, and a study on swine indicated that decreased Bacteroidetes proportions were accompanied by decreases in the circulating TG level[55]; however, whether Bacteroidetes can alter cholesterol or TG levels in humans remains disputed. In humans, decreased Bacteroidetes proportions, including *Bacteroides_vulgatus* and *Bacteroides_dorei*, were observed in patients with coronary artery disease[56,57]. In addition, some species of *Bacteroides* were shown to be decreased in patients with CVDs[49], and may be used as biomarkers for evaluating the alleviation of obesity[54]. Our results showed that *Bacteroides_vulgatus* were negatively correlated with the serum LDL-C level but positively correlated with the serum TG level in females, while Bacteroidetes, Bacteroidia and Bacteroidales were negatively correlated with CVAI in females. Moreover, Bacteroidetes, Bacteroidia and Bacteroidales were positively correlated with the serum HDL-C level, differentiated L_HDL-C males from CON males, and were negatively correlated with CVAI in males. These observed associations may further support their roles in the favorable regulation of lipid metabolism. Interestingly, Prevotellaceae were enriched in L_HDL-C group in the comparison among the three dyslipidemia subgroups in females. However, the relative abundance of Prevotellaceae was decreased significantly in L_HDL-C males, and could distinguish L_HDL-C males from CON males. Additionally, increased Prevotellaceae also helped discriminate H_TG males from CON males in our study. Of note, Kelly *et al*[58] reported that genera within the family Prevotellaceae had different effects; some were associated with an increased and others with a decreased CVD risk profile. Meanwhile, Coriobacteriia were indicated to be enriched in L_HDL-C females, and could differentiate L_HDL-C females from CON females. Moreover, we identified that Coriobacteriales were correlated with the increased serum HDL-C level in males, and increased Coriobacteriia and Coriobacteriales could distinguish H_TG males from CON males. However, these taxa have not been studied thoroughly, and it is difficult to assess their metabolic functions in human lipid metabolism.

Different GM taxa may have distinct activities and modes of action[50,59], and certain taxa may exert synergistic and cooperative interactions[60], indicating the importance of balance in the GM community. Our results may suggest a complex interaction between GM and distinct lipid metabolisms based on sex differences, and provide new evidence of the involvement of GM in dyslipidemia. Nevertheless, more studies are required to determine which specific taxa have the potential to ameliorate dyslipidemia.

There were several limitations in this study, the most marked of which was the small sample size in each subgroup. This was a single-center study, recruiting Chinese participants near Xi'an, a central city in northwestern China. In addition, certain confounders, such as dietary habit, that could have influenced the GM composition[61], must be taken into consideration. However, elucidation of certain associations of GM taxa with host lipid metabolism in this study is still valuable. We hope that our observations will facilitate prospective studies investigating diverse aspects of GM influences on human dyslipidemia based on sex differences. In future studies, it is recommended that the sample size be increased, more confounders be considered, and various research methods be integrated to ascertain potential associations.

CONCLUSION

Based on the thorough analyses of GM features with dyslipidemia in females and males, potent associations of GM-host relations based on sex differences were revealed, and the potential of GM for dyslipidemia diagnosis was demonstrated. Although this study could not provide a conclusive association between GM and dyslipidemia, it may provide new insights into the pathogenesis of dyslipidemia.

ARTICLE HIGHLIGHTS

Research background

Dyslipidemia is a common chronic disorder, and is defined as any abnormality in blood lipid levels. In recent years, considerable progress has been made in elucidating the mechanisms of dyslipidemia, and the gut microbiota (GM) has been indicated to play a pivotal role in its pathophysiology. However, the associations between GM and dyslipidemia remain to be elucidated.

Research motivation

Although recent studies have convincingly linked GM to dyslipidemia, proving the associations between GM and host lipid metabolism remains a challenge in humans. In addition, ethnicity, geography and sex are potent factors that could influence the GM community. Therefore, it is important to clarify the relationship between GM and dyslipidemia, and to explore the importance of sex differences. In this study, we first revealed sex differences regarding the GM features, and then introduced dyslipidemia, highlighting its intricate relationships with GM and possible altered GM functions.

Research objectives

This study focused on the associations of GM features with dyslipidemia based on sex differences in a northwestern Chinese population.

Research methods

This study finally recruited 142 participants (73 females and 69 males) at Honghui Hospital, Xi'an Jiaotong University, who fulfilled the criteria for the diagnosis of dyslipidemia according to the "Guidelines for prevention and treatment of dyslipidemia in Chinese adults". The anthropometric and blood metabolic parameters of all participants were measured. According to their detected serum lipid levels, female and male participants were classified into a high triglyceride (H_TG) group, a high total cholesterol (H_CHO) group, a low high-density lipoprotein cholesterol (L_HDL-C) group, and a control (CON) group with normal serum lipid levels. Fresh fecal samples were collected for 16S rRNA gene sequencing, and UPARSE software, QIIME software, the RDP classifier tool and the FAPROTAX database were used for sequencing analyses.

Research results

Different GM features were identified between females and males, and the associations between GM and serum lipid profiles were different between females and males. In the comparison of the three dyslipidemia subgroups in females, *Lactobacillus_salivarius* were enriched in H_CHO females, and Prevotellaceae were enriched in L_HDL-C females. Compared with CON or H_TG males, Prevotellaceae, *unidentified_Ruminococcaceae*, *Roseburia* and *Roseburia_inulinivorans* were decreased in L_HDL-C males; while linear discriminant analysis effect size analysis indicated an enrichment of these above GM taxa in H_TG males in comparison to other male subgroups. Additionally, *Roseburia_inulinivorans* abundance was positively correlated with the serum TG and total cholesterol levels, and *Roseburia* were positively correlated with the serum TG level. Furthermore, Proteobacteria, Lactobacillaceae, *Lactobacillus* and *Lactobacillus_salivarius* distinguished H_CHO females from CON females, while Coriobacteriia, Coriobacteriales, Prevotellaceae, *Roseburia* and *Roseburia_inulinivorans* distinguished H_TG males from CON males. Based on the predictions of GM metabolic capabilities from the FAPROTAX database, cellulolysis was increased in L_HDL-C females compared with CON females, but was decreased in L_HDL-C males compared with CON males.

Research conclusions

This study provides evidence of the associations between GM and serum lipid profiles based on sex differences, suggesting a complex interaction between GM and distinct lipid metabolisms, and providing new insights into the pathogenesis of dyslipidemia.

Research perspectives

Future studies are needed to determine which specific taxa have the potential to ameliorate dyslipidemia, to investigate the underlying biological functions of the key GM in dyslipidemia, and to explore the differences in diet and other factors between females and males as possible causes for the observed differences in GM and the lipid profiles.

Abstract

BACKGROUND

The combined index of hemoglobin, albumin, lymphocyte, and platelet (HALP) can reflect systemic inflammation and nutritional status simultaneously, with some evidence revealing its prognostic value for some tumors. However, the effect of HALP on recurrence-free survival (RFS) in patients with gastrointestinal stromal tumors (GISTs) has not been reported.

AIM

To investigate the prognostic value of HALP in GIST patients.

METHODS

Data from 591 untreated patients who underwent R0 resection for primary and localized GISTs at West China Hospital between December 2008 and December 2016 were included. Clinicopathological data, preoperative albumin, blood routine information, postoperative treatment, and recurrence status were recorded. To eliminate baseline inequivalence, the propensity scores matching (PSM) method was introduced. Ultimately, the relationship between RFS and preoperative HALP was investigated.

RESULTS

The optimal cutoff value for HALP was determined to be 31.5 by X-tile analysis. HALP was significantly associated with tumor site, tumor size, mitosis, Ki67, National Institutes of Health (NIH) risk category, and adjuvant therapy (all $P < 0.001$). Before PSM, GIST patients with an increased HALP had a significantly poor RFS ($P < 0.001$), and low HALP was an independent risk factor for poor RFS [hazard ratio (HR): 0.506, 95% confidence interval (95%CI): 0.291-0.879, $P = 0.016$]. In NIH high-risk GIST patients, GIST patients with low HALP had a worse RFS

than patients with high HALP ($P < 0.05$). After PSM, 458 GIST patients were identified; those with an increased HALP still had significantly poor RFS after PSM ($P < 0.001$) and low HALP was still an independent risk factor for poor RFS (HR: 0.558, 95%CI: 0.319-0.976, $P = 0.041$).

CONCLUSION

HALP was significantly correlated with postoperative pathology and postoperative treatment. Furthermore, HALP showed a strong ability to predict RFS in GIST patients who underwent radical resection.

Key Words: Gastrointestinal stromal tumors; Nutrition assessment; Immuno-inflammatory-based prognostic scores; Prognosis; Propensity score

Core Tip: The combined index of hemoglobin, albumin, lymphocyte, and platelet (HALP) can reflect systemic inflammation and nutritional status simultaneously. We demonstrated that HALP has a statistically significant correlation with postoperative pathology and postoperative treatment in patients with gastrointestinal stromal tumors (GISTs). Furthermore, we revealed that a low level of HALP was an independent risk factor for poor recurrence-free survival in GIST patients following radical resection before and after propensity scores matching.

INTRODUCTION

Gastrointestinal stromal tumors (GISTs), a rare type of tumor, are the most frequent mesenchymal tumors arising from the gastrointestinal tract[1]. GISTs may occur anywhere in the digestive tract and even occasionally outside the gastrointestinal tract, with the stomach accounting for 60% and the small intestine 30% of all GISTs[2]. The morphology, immunohistochemistry, and molecular markers are helpful to the diagnosis of GISTs. Surgical resection is the standard treatment for resectable GISTs[3]. Nowadays, novel small molecular tyrosine kinase inhibitors, such as imatinib and sunitinib, have revolutionized the integrated treatment of GISTs and greatly improved the long-term prognosis of patients[4].

Some GIST-specific parameters based on postoperative pathologies, such as tumor size, primary tumor location, mitotic index, and tumor rupture, have been used to stratify the risk of recurrence for GISTs[2,5-7]. Meanwhile, a recent effort has shed light on the role of preoperative cancer-related inflammation and nutrition status in progression of various cancers, such as those of gastric[8], colorectal[9], non-small lung[10], and GIST[11-15]. Several preoperative immuno-inflammatory-based prognostic scores, such as the preoperative neutrophil-to-lymphocyte ratio (NLR), the lymphocyte-to-monocyte ratio (LMR), and the platelet-to-lymphocyte ratio (PLR), reflect the systematic inflammatory response, with some evidence supporting their prognostic ability for GISTs[13-17]. Furthermore, nutritional status, such as measured by the prognostic nutritional index (PNI), has also been shown to play an important role in GIST progression[10,11].

Recent studies have proposed a new combined index of hemoglobin, albumin, lymphocyte, and platelet (HALP) which can reflect systemic inflammation and nutritional status simultaneously[18]. It has already been reported as related to the prognosis of patients with pancreatic cancer[19], renal cancer [20], gastric cancer[18], prostate cancer[21], bladder cancer[22], esophageal cancer[23], and small cell lung cancer[24]. However, there are no studies on the relationship between HALP and recurrence in GIST patients who undergo radical resection. Therefore, this study aimed to investigate the prognostic value of preoperative HALP in resected GIST patients.

MATERIALS AND METHODS

Patient population

A flow diagram of the patient selection process is shown in Figure 1. Data from consecutive, previously untreated patients who underwent R0 resection for primary, localized GISTs at West China Hospital between December 2008 and December 2016 were included in this study. Patients who were younger than 18 years in age, without complete preoperative blood routine information or medical history, or with infectious diseases, blood counts with white blood cells (WBCs) > 10×10^9/L, neutrophils > 8×10^9/L, or lymphocytes > 5×10^9/L, other tumors, severe liver, kidney or heart diseases, emergency surgery, or follow-up less than 6 mo were excluded. In total, 591 GIST patients were enrolled for the current analysis.

This study was reviewed and approved by the Ethics Committee of the West China Hospital of Sichuan University, No. 1135(2019) and adhered to the tenets of the Declaration of Helsinki. All patients provided written informed consent.

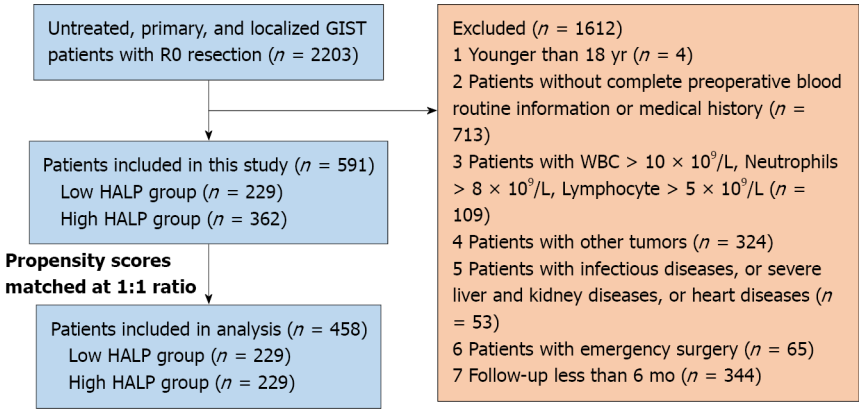
Definition

Recurrence-free survival (RFS) was defined as the time interval between the time of surgery and the time of the first documented appearance of tumor after complete resection. The HALP, PNI, NLR, PLR, and LMR were calculated using the following formulas: HALP = hemoglobin level (g/L) × albumin level (g/L) × lymphocyte count (/L)/platelet count (/L)[19]; PNI = albumin level (g/L) + 5 × lymphocyte count (n/mm^3)[25]; NLR = neutrophil count (n/mm^3)/lymphocyte count (n/mm^3)[15,16]; PLR = platelet count (n/mm^3)/lymphocyte count (n/mm^3)[14]; LMR = lymphocyte count (n/mm^3)/monocyte count (n/mm^3)[26].

Data collection

Clinicopathological data, postoperative treatment, and recurrence status were recorded. The following data of each patient were retrieved from the self-built GISTs database: Demographic characteristics, tumor sites, tumor size, mitotic index [mitosis/50 high-power field (HPF) or mitosis/50 mm^2], morphology, immunohistochemistry, molecular markers, preoperative hemoglobin, albumin, WBC count, absolute neutrophil count, monocyte count, platelet count, and lymphocyte count. Tumor risk stratification was determined based on the modified National Institutes of Health (NIH) classification [27].

Perioperative evaluation and postoperative histopathological diagnosis



For all patients, the laboratory tests were evaluated within 1 wk before operation. Preoperative blood routine and blood biochemical examination were performed by the Laboratory Department of Sichuan University West China Hospital. The parameters included complete blood cell count and serum albumin. Histopathological diagnosis was performed by the Department of Pathology of Sichuan University West China Hospital; the postoperative pathological findings included data on gross appearance, tumor size, tumor site, resection margin status, tumor cell morphology, lymph node metastasis status, and immunohistochemical staining, *etc*.

Follow-up

Abdominal/pelvic computed tomography was performed every 3-6 mo in the first 3 years after operation, and then every 6-12 mo, until 5 years after the operation, and then once a year until recurrence. Recurrence status was ascertained up to December 2020.

Statistical analysis

The optimal cutoff values for the HALP, PNI, NLR, PLR, and LMR were determined to be 31.5, 48.6, 2.60, 134.8, and 4.0, respectively, by X-tile analysis[28]. Propensity scores matching (PSM) was performed as 1:1 matching and a 0.02 caliper based on the patient's age, tumor size, tumor site, mitosis, and adjuvant targeted therapy using nearest neighbor matching with the MatchIt R package (https://cran.r-project.org/web/packages/MatchIt/MatchIt.pdf). The categorical variables are reported as n (%) and quantitative variables are reported as mean ± SD or median (range). Statistical significance of group comparisons was analyzed *via* parametric and nonparametric tests for continuous variables and *via* chi-square analysis or Fisher's test for categorical variables. Survival curves of the RFS were calculated by the Kaplan-Meier methods and compared by log-rank tests. Hazard ratio (HR) for recurrence was calculated by Cox regression analysis. Sensitivity and specificity of HALP, PNI, NLR, LMR, and PLR were defined using time-dependent receiver operating characteristic (ROC) curves, and areas under the curve (AUCs) were detected utilizing survival ROC R package[29]. All statistical analyses were performed using SPSS Statistics version 21 (SPSS 21.0; IBM Corp., Armonk, NY, United States) and GraphPad Prism version 7.0 (GraphPad Software, La Jolla, CA, United States). Statistical significance was set at $P < 0.05$ as two-sided.

RESULTS

Baseline characteristics

The demographic and clinicopathological characteristics of the 591 GIST patients are listed in Table 1 and Supplementary Table 1. The study population consisted of 280 (46.8%) male and 311 (53.2%) female patients. The median age was 57 (range: 21-86) years. The median follow-up time was 56 (range: 4-138) mo. The mean ± SD findings for the HALP, PNI, NLR, PLR, and LMR values were 45.81 ± 33.73, 49.04 ± 5.43, 2.64 ± 1.74, 152.8 ± 84.6 and 5.13 ± 3.00, respectively. The mean ± SD of tumor size was 6.16 ± 4.87 cm. One hundred ninety-one tumors (32.3%) had a mitotic index of > 5/50 HPF. A total of 34.0% (201/691) of the GIST patients received adjuvant therapy with imatinib or sunitinib. According to NIH risk classification, 72 (12.2%) patients were classified as very low risk, 178 (30.1%) patients as low risk, 114 (19.3%) patients as intermediate risk, and 227 (38.4%) patients as high risk. Recurrence occurred in 62 GIST patients.

Association of HALP and clinicopathological factors

The clinicopathological characteristics between the high and low groups of HALP were categorized and analyzed as shown in Table 1 and Supplementary Table 1. Together, 229 patients were assigned to the low HALP group and 362 patients to the high HALP group. The results demonstrated that tumor site, tumor size, mitotic index, Ki67, NIH risk category, and adjuvant therapy were significantly associated with HALP (all $P < 0.05$).

PSM analysis was further carried out to avoid confounding variables that might interfere with the association between RFS and HALP level. After 1:1 matching, PSM analysis identified 229 pairs of GIST patients. After PSM, HALP was still associated with sex, Ki67, and recurrence but not with any other clinicopathological characteristics (Table 1 and Supplementary Table 1).

Association of clinicopathological factors and RFS

Before PSM, tumor site, tumor size, mitotic index, Ki67, NIH risk category, NLR, PLR, PNI, and HALP were associated with RFS (all $P < 0.05$) (Table 2). RFS in GIST patients with low HALP was significantly worse than in those with high HALP (Figure 2). Cox multiple regression analysis showed that HALP was an independent prognostic factor for RFS in GIST patients before PSM [HR: 0.506, 95% confidence interval (CI): 0.291-0.879, $P = 0.016$].

After PSM, tumor site, tumor size, mitotic index, Ki67, NIH risk category, PNI, NLR, PLR, and HALP were still related to RFS (all $P < 0.05$) (Table 2). RFS was also significantly worse in GIST patients with low HALP than in those with high HALP (Figure 2). Furthermore, Cox multiple regression analysis showed that HALP was an independent prognostic factor for RFS in GIST patients (HR: 0.558, 95%CI: 0.319-0.976, $P = 0.041$).

Subgroup analysis

The clinicopathological characteristics of high-risk GIST patients between the high and low groups of HALP were categorized in Supplementary Table 1. Together, 125 patients were assigned to the low HALP group and 102 patients to the high HALP group. The results demonstrated that sex and Ki67 were associated with HALP (both $P < 0.05$). Not surprisingly, patients in the low HALP group had significantly worse survival than patients in the high HALP group (Figure 2). Furthermore, Cox multiple regression analysis indicated that HALP was an independent prognostic factor for RFS in GIST patients (HR: 0.469, 95%CI: 0.245-0.896, $P = 0.022$) (Supplementary Table 2).

[1]Method = nearest; Cliper value = 0.02.

[a]$P < 0.05$ was considered statistically significant.

HALP: Combination index of hemoglobin, albumin, lymphocyte, and platelet; HPF: High-power field; NIH: National Institutes of Health; PSM: Propensity scores matching; SD: Standard deviation.

Sensitivity analysis

Time-dependent ROCs were generated for HALP, PNI, NLR, LMR, and PLR to predict 5-year RFS. According to the results, the 5-year AUC reached 0.661 in the HALP group, while PNI, NLR, LMR, and PLR reached 0.622, 0.591, 0.505, and 0.627, respectively (Figure 3).

DISCUSSION

There is growing evidence that preoperative nutritional status and inflammatory response may be a potentially powerful predictor of the prognosis of cancer patients. Consistent with previous research, the present study found that preoperative inflammation scores, such as NLR and PLR, were associated with the prognosis of GIST patients, both before and after PSM[14,16,30,31] (Supplementary Figure 1). However, LMR seemed to have no effect on the RFS of GIST patients (Supplementary Figure 1), which differs from findings of previous studies[14]. In addition, the PNI, a nutritional score based on albumin levels and lymphocytes, was also related to RFS of GIST patients, both before and after PSM in the present study[11,12] (Supplementary Figure 1).

In this study, we also found that preoperative HALP was significantly correlated with tumor site, tumor size, mitosis, Ki67, NIH risk category, and adjuvant therapy (Table 1). To balance the patient characteristics and standard prognostic factors between groups, we utilized the PSM method to balance patient's age, tumor size, tumor site, mitosis, and adjuvant targeted therapy. After PSM, sex, Ki67, PNI, NLR, LMR, and PLR were still associated with HALP (Supplementary Table 1). Notably, there was no difference in standard prognostic factors (*i.e.* tumor site, tumor size, mitosis, NIH risk category, and adjuvant therapy) between the low and high HALP groups (Table 1). Given that HALP shared several parameters with PNI, NLR, LMR, and PLR, their statistically significant correlation is unsurprising. The correlation between HALP and sex may be due to the fact that the male and female patients had significantly different hemoglobin levels (123.22 ± 2.08 g/L for males and 105.46 ± 1.84 g/L for females, $P < 0.001$). Remarkably, recurrence was not associated with either sex or histologic subtype (Supplementary Table 1). Subgroup analysis by sex revealed that a low level of HALP was associated with recurrence in both male and female patients ($P = 0.048$ and $P = 0.018$, respectively) (Supplementary Figure 2).

Finally, consistent with previous research on HALP in other tumors[18,19], our findings revealed prognostic value of HALP in GIST[20-24]. HALP was an independent risk factor for GIST patients before PSM, after PSM, and in high-risk subgroups (Table 2 and Supplementary Table 3). Thus, HALP can be used to not only evaluate GIST patients' postoperative risk prior to surgery but also to assess their prognosis. Notably, the HALP index can be utilized to predict the prognosis of patients in a convenient and cost-effective manner.

Although the underlying mechanism of systemic inflammation in tumorigenesis, progression and metastasis remains obscure, some theories suggest that it stimulates angiogenesis, immunosuppression, and formation of the supporting microenvironment. Lymphocytes are well known to play a critical role in tumor growth inhibition[32-34]. A higher lymphocyte signature is associated with improved prognosis in a variety of tumors[34], whereas platelets can infiltrate the tumor microenvironment and interact directly with cancer cells[35,36], assisting circulating tumor cells in adhering to endothelial cells and establishing a niche environment prior to metastasis[37-41].

Anemia is one of the most common symptoms of GIST, which can be caused by both gastrointestinal bleeding and intratumoral bleeding[42]. Yang *et al*[43] identified GIST with gastrointestinal bleeding as an independent prognostic predictor of poor RFS. Several studies have demonstrated that low hemoglobin levels can result in tumor hypoxia, which is associated with an increased risk of local failure and distant metastasis[31,44]. Furthermore, a hypoxic tumor environment may result in limited drug accumulation and hinder drug efficacy[45]. Most importantly, anemia is a common adverse effect of imatinib[46], which may require the prescribing physician to stop the drug or reduce the dose. High levels of preoperative hemoglobin may help to prevent this adverse effect.

Low levels of serum albumin are also associated with poor long-term survival in GIST patients[44,45], which is consistent with our findings. Serum albumin is generally considered as associated with nutritional status and liver or renal function, both of which may affect the prescribing physician's decision-making, similar to hemoglobin. Additionally, tumor tissues have abnormal vascular endothelial gaps and lack effective lymphatic drainage, allowing macromolecules, such as albumin, to accumulate more readily in tumor tissue than in normal tissue[47,48]. Consequently, serum albumin is suspected of being a possible nutritional source for tumor growth, due to its elevated accumulation in tumors[49-51]. This effect is referred to as the 'enhanced permeability and retention effect'. Moreover, about 95% of imatinib is bound to serum proteins, mainly albumin and 1-acid glycoprotein, which may facilitate drug accumulation in tumors and improve therapeutic effect[52,53]. Subsequently, serum albumin levels have been shown to be an independent prognostic factor of survival in a variety of cancers, including those of colorectal[54], gastric[55], pancreatic[56], and breast[57]. As a result, it is unsurprising that HALP, which reflects systemic inflammation and nutritional status simultaneously, is associated with the risk and prognosis of GIST.

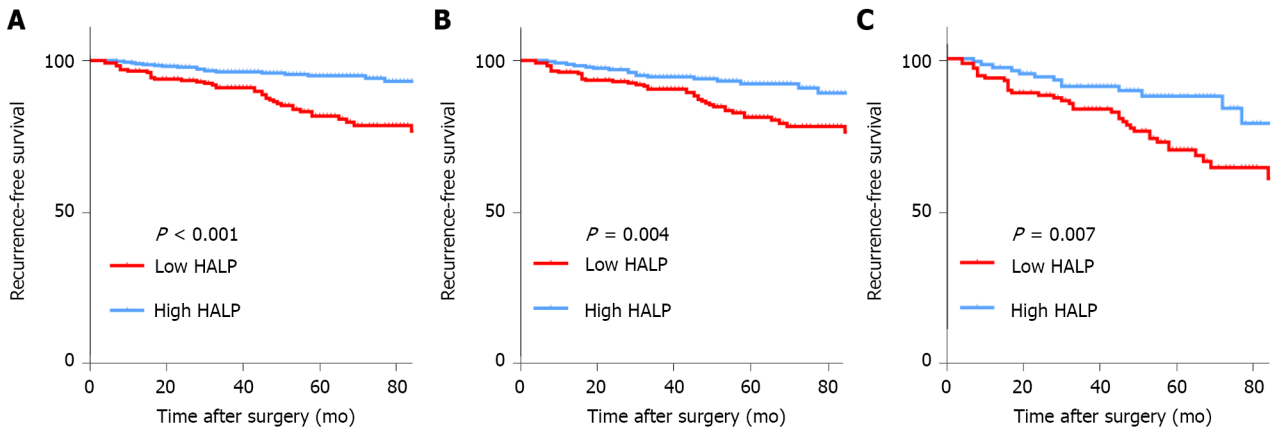

Table 2 Univariate and multivariate regression analysis of prognostic factors in patients before and after propensity scores matching

There are some limitations to this study. First, because this is a retrospective study, biases in the data collection process are possible. Second, our cases were collected between 2008 and 2016, the period during which imatinib was used for adjuvant treatment of GIST in China. Despite the adverse reaction

Figure 3 Comparison of hemoglobin, albumin, lymphocyte, and platelet and other parameters in prediction ability of 5-year recurrence-free survival by receiver operating characteristic curve analysis before propensity scores matching. AUC: Area under the curve; HALP: Hemoglobin, albumin, lymphocyte, and platelet; LMR: Lymphocyte-to-monocyte ratio; NLR: Neutrophil-to-lymphocyte ratio; PLR: Platelet-to-lymphocyte ratio; PNI: Prognostic nutritional index; PSM: Propensity scores matching; ROC: Receiver operating characteristic.

and high costs, 201/591 (34.0%) of GIST patients still received adjuvant imatinib therapy. As an important treatment after GIST, adjuvant imatinib therapy can significantly improve the prognosis of GIST patients[58], and its benefits are also shown in the present study (Supplementary Figure 3). However, there was no adequate collection and analysis of the time, dose, and adverse reactions of patients with imatinib or sunitinib therapy, which may also be related to HALP. Moreover, this study did not evaluate other clinicopathological factors related to prognosis, especially gene mutation status. Furthermore, the effect of preoperative or postoperative improvement of nutritional status or inflammation response on the prognosis of GIST remains obscure, and will require further confirmation in clinical studies.

CONCLUSION

HALP was associated with postoperative pathological data (*i.e.* tumor site, tumor size, mitosis, Ki67, NIH risk category) and adjuvant therapy. Furthermore, HALP was an independent risk factor for RFS in GIST patients who underwent radical resection.

ARTICLE HIGHLIGHTS

Research background

The combination index of hemoglobin, albumin, lymphocyte, and platelet (HALP) has been reported as associated with prognosis in many cancers but not yet in gastrointestinal stromal tumors (GISTs). Therefore, this study aimed to investigate the prognostic value of preoperative HALP in resected GIST patients.

Research motivation

At present, the risk of GIST is mainly based on postoperative pathological indicators. The motivation for this article involved the need to find a convenient, non-invasive, preoperative indicator that will assist in prognostic prediction of GIST.

Research objectives

To investigate the prognostic value of HALP in GIST patients.

Research methods

This retrospective cohort study enrolled patients with GIST using propensity scores matching to explore the relationship between HALP, postoperative clinicopathological data, and the prognostic significance of HALP.

Research results

HALP can be conveniently used preoperatively to assess risk and prognosis of GIST patients. However, the effect of improving nutritional status or immune-inflammatory status on the prognosis of GIST is still unclear and requires further confirmation through clinical studies.

Research conclusions

HALP was associated with postoperative pathological data (*i.e.* tumor site, tumor size, mitosis, Ki67, National Institutes of Health risk category) and adjuvant therapy. Furthermore, HALP was an independent risk factor for recurrence-free survival in GIST patients who underwent radical resection. This study is the first to report the prognostic significance of HALP in GIST. In this study, HALP was found to be an independent risk factor for GIST patients with R0 resection. Consistent with reports of HALP in other tumors, HALP is also associated with prognosis in GIST. HALP was also found to be an independent risk factor for GIST patients with R0 resection. In clinical practice, convenient and non-invasive preoperative HALP may be used to assist in the prediction of risk and prognosis for GIST patients.

Research perspectives

Through this retrospective cohort study, we found the prognostic significance of HALP in GIST. This study did not evaluate other clinicopathological factors related to prognosis, especially gene mutation status. Subsequent studies should employ a prospective cohort method and incorporate additional factors to further explore the prognostic significance of HALP in GIST patients.

Abstract

BACKGROUND

Contrast-enhanced ultrasound (CEUS) is considered a secondary examination compared to computed tomography (CT) and magnetic resonance imaging (MRI) in the diagnosis of hepatocellular carcinoma (HCC), due to the risk of misdiagnosing intrahepatic cholangiocarcinoma (ICC). The introduction of CEUS Liver Imaging Reporting and Data System (CEUS LI-RADS) might overcome this limitation. Even though data from the literature seems promising, its reliability in real-life context has not been well-established yet.

AIM

To test the accuracy of CEUS LI-RADS for correctly diagnosing HCC and ICC in cirrhosis.

METHODS

CEUS LI-RADS class was retrospectively assigned to 511 nodules identified in 269 patients suffering from liver cirrhosis. The diagnostic standard for all nodules was

either biopsy (102 nodules) or CT/MRI (409 nodules). Common diagnostic accuracy indexes such as sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) were assessed for the following associations: CEUS LR-5 and HCC; CEUS LR-4 and 5 merged class and HCC; CEUS LR-M and ICC; and CEUS LR-3 and malignancy. The frequency of malignant lesions in CEUS LR-3 subgroups with different CEUS patterns was also determined. Inter-rater agreement for CEUS LI-RADS class assignment and for major CEUS pattern identification was evaluated.

RESULTS

CEUS LR-5 predicted HCC with a 67.6% sensitivity, 97.7% specificity, and 99.3% PPV ($P < 0.001$). The merging of LR-4 and 5 offered an improved 93.9% sensitivity in HCC diagnosis with a 94.3% specificity and 98.8% PPV ($P < 0.001$). CEUS LR-M predicted ICC with a 91.3% sensitivity, 96.7% specificity, and 99.6% NPV ($P < 0.001$). CEUS LR-3 predominantly included benign lesions (only 28.8% of malignancies). In this class, the hypo-hypo pattern showed a much higher rate of malignant lesions (73.3%) than the iso-iso pattern (2.6%). Inter-rater agreement between internal raters for CEUS-LR class assignment was almost perfect ($n = 511$, $k = 0.94$, $P < 0.001$), while the agreement among raters from separate centres was substantial ($n = 50$, $k = 0.67$, $P < 0.001$). Agreement was stronger for arterial phase hyperenhancement (internal $k = 0.86$, $P < 2.7 \times 10^{-214}$; external $k = 0.8$, $P < 0.001$) than washout (internal $k = 0.79$, $P < 1.6 \times 10^{-202}$; external $k = 0.71$, $P < 0.001$).

CONCLUSION

CEUS LI-RADS is effective but can be improved by merging LR-4 and 5 to diagnose HCC and by splitting LR-3 into two subgroups to differentiate iso-iso nodules from other patterns.

Core Tip: This is a retrospective study to evaluate the accuracy of contrast-enhanced ultrasound Liver Imaging Reporting and Data System (CEUS LI-RADS) in correctly diagnosing hepatocellular carcinoma (HCC) and intrahepatic cholangiocarcinoma (ICC) in patients with cirrhosis. CEUS LR-5 showed a 97.7% specificity for HCC with a low sensitivity (67.6%), while the CEUS LR-4 and 5 merged class showed a 93.9% sensitivity and 94.3% specificity for HCC. CEUS LR-M predicted ICC with a 91.3% sensitivity and 96.7% specificity. CEUS LR-3 predominantly included benign lesions (28.8% of malignancies) but was heterogeneous as the hypo-hypo pattern showed a higher rate of malignant lesions (73.3%) than the iso-iso pattern (2.6%).

INTRODUCTION

Liver cirrhosis is a strong risk factor for primitive liver cancer, the seventh most commonly diagnosed malignancy worldwide and the third most common cause of cancer-related death[1]. In this scenario, the most prevalent malignant lesion is hepatocellular carcinoma (HCC), followed by intrahepatic cholangiocarcinoma (ICC); however, other types of cancer are rare. The development of a malignant lesion represents a critical point in the clinical history of chronic liver diseases since it significantly reduces life expectancy, especially in case of late diagnosis. Therefore, regular follow-up is essential for these patients with mandatory ultrasonography every 6 mo for detecting solid focal liver lesions[2-5].

Contrast-enhanced ultrasound (CEUS) is an effective, well-recognized, and safe imaging technique for visualising the onset of new nodules in liver cirrhosis, that adheres to national and international guidelines[2,6,7]. One of the initial limitations of CEUS, reported in 2010, was the possibility of missing ICC cases, since a significant proportion of the ICC nodules that develop in a cirrhotic liver show the

same enhancement pattern as HCC[8]. Since then, subsequent studies have demonstrated that the timing and intensity of washout are different in HCC and ICC. In particular, for the vast majority of ICC nodules (50%-85%), washout starts earlier than 60 *s*, while this is rarely observed in HCC. Furthermore, washout intensity during late phase is clearer in ICC than in HCC[9-14]. These findings led the American College of Radiology to release the CEUS Liver Imaging Reporting and Data System (CEUS LI-RADS), similar to previous releases for computed tomography (CT) and magnetic resonance imaging (MRI). The algorithm was officially approved in June 2016, and the latest update was published in 2017 [15].

CEUS LI-RADS is a standardized system for technique, interpretation, reporting, and data collection on focal liver lesions in patients at high risk for HCC. It encompasses features such as size, conventional ultrasound morphology, contrast enhancement behaviours, and dimensional variations in order to stratify the risk of HCC and to avoid ICC misdiagnosis[16-20]. In particular, CEUS LR-5 is a class specifically designed to include HCC. It encompasses nodules > 1 cm that show arterial phase hyperenhancement (APHE) that is neither rim nor globular, followed by a late (> 60 *s*) mild-degree washout. Other CEUS LI-RADS categories (*e.g.*, CEUS LR-4 and 3) express a very probable and intermediate risk of HCC, while CEUS LR-M has an intermediate/high risk of malignancy without a typical HCC pattern. CEUS LR-M includes lesions of any size that show arterial phase rim enhancement pattern and/or early (before 60 *s*) washout and/or marked washout.

So far, only a few studies have presented actual data from the application of CEUS LI-RADS diagnostic algorithm in cirrhotic patients with suspicious nodules[21-27]. The aim of this study was to test the capability of CEUS LI-RADS in accurately diagnosing focal liver lesions in patients affected by cirrhosis. In particular, we tested the accuracy of CEUS LR-5 and LR-M in correctly diagnosing HCC and ICC, respectively. In addition, we merged classes LR-4 and LR-5 and tested their accuracy in correctly diagnosing HCC as a joint class. Finally, we assessed the rate of malignancy for specific LR-3 class patterns.

MATERIALS AND METHODS

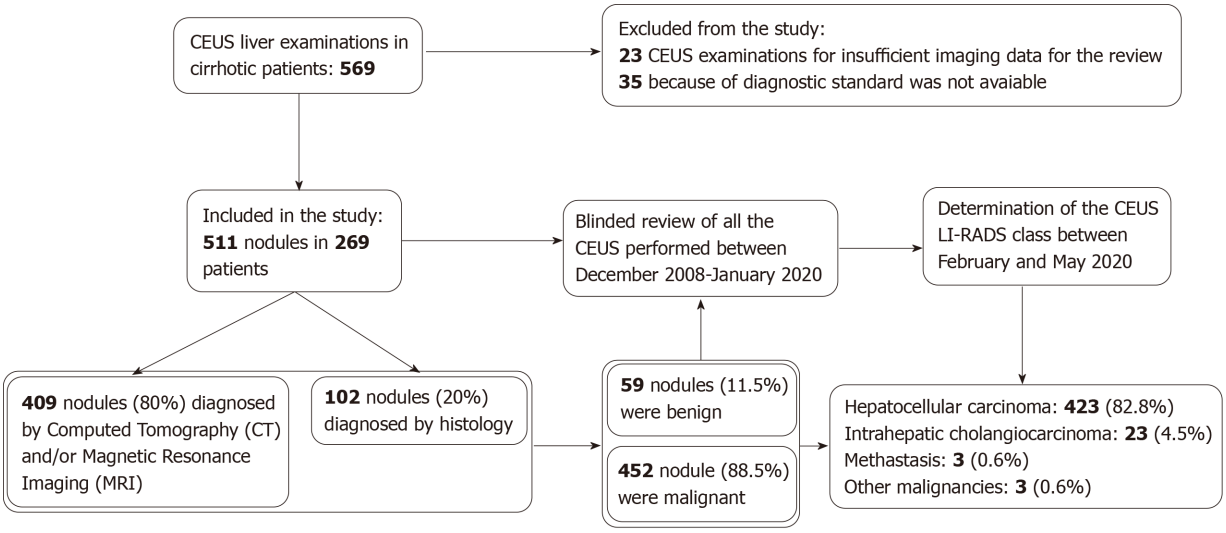
Study design and data collection

The present retrospective study involved patients with cirrhosis associated nodules that were visible using conventional ultrasound, for which it was possible to review the basal appearance and dynamic pattern of the ultrasound contrast agent. Cirrhosis was diagnosed on the basis of clinical data, biochemical parameters, imaging criteria, and elastosonography.

We reviewed all the liver CEUS performed at our centre (Medical Ultrasound Unit, University Hospital, Sassari, Italy) between December 2008 and January 2020. All examinations aimed to characterize a new nodule developed in the context of surveillance programmes for liver cirrhosis. Nodules located in different liver segments were analysed separately with individual boluses of contrast. Within the same segment, only one target nodule was included for analysis based on best visualization criteria.

CT and/or MRI, when typical for HCC or definitely benign (haemangioma, hepatic fat deposition/sparing, and hypertrophic pseudomass), were used as the gold standard imaging modalities. For all other cases, histology obtained by a percutaneous biopsy or surgical resection was considered the reference standard (Supplementary Figures 1 and 2).

Specifically, nodules showing a CT/MRI dynamic pattern with hyperenhancement during the arterial phase followed by washout in the portal or late phase (Supplementary Figures 3 and 4), were diagnosed as HCC in accordance with both the American Association for the Study of Liver Diseases (AASLD) and the Italian Association for the Study of the Liver (AISF) guidelines[2,28]. Benign lesions received a further 2-year follow-up; in case of any increase in size and/or CEUS enhancement variations, a biopsy was performed.



All cases where it was not possible to review the timing and the degree of washout on CEUS (23 cases), or a validated diagnostic reference standard, either CT/MRI scan or histology, was not available (35 cases), were excluded. The algorithm of the study is shown in Figure 1.

CEUS examination and CEUS LI-RADS classification

All CEUS examinations were performed by a physician with 15 years of experience (G.V.) using a second-generation ultrasound contrast agent (SonoVue, Bracco, Milan, Italy).

The signal coming from the bubbles was detected through the following ultrasound scanners: (1) Acuson Sequoia 512 with a 4C1 convex probe and cadence contrast pulse sequencing (CPS, Acuson Siemens, Mountain View, CA, United States) until 2014; and (2) Aixplorer (SuperSonic Imaging, S.A., Aix en Provence, France) with a convex broadband probe (SC6-1) and dedicated software also known as Power Modulated Pulse Inversion (PMPI) from January 2015 until the end of the study.

The CEUS examination was performed continuously for 120 s starting from the injection of contrast. Subsequently, short clips lasting 15-30 *s* were recorded until 5 min after injection.

Figure 1 Flow chart of the study.

The CEUS LI-RADS patterns were established after evaluation of all clips and images, with particular attention to the behaviour of intranodular contrast enhancement in dynamic phases.

The review process was independently performed by two operators (G.V. and M.A.) with 15 and 2 years of experience, respectively. In case of disagreement, the class indicated by the more experienced operator was assigned.

The reviewers were blinded to patient identity and final diagnosis. The specific targets of the review process were: (1) Nodule size; (2) the presence of APHE and the type of filling (global, rim, or peripheral discontinuous globular enhancement); and (3) the presence of washout during portal and parenchymal phases, focusing on its timing (before or after 60 *s*) and intensity (mild or marked); washout before 60 *s* was considered early, while washout happening after 60 *s* was considered late.

Inter-rater reliability of CEUS LI-RADS class assignment and of CEUS major features between the two raters (internal agreement) was evaluated for all the nodules (n = 511). Inter-rater reliability among our centre and two other operators from external centres (M.A.Z and G.I., both with more than 20 years of experience in CEUS) was also evaluated for a subgroup of 50 nodules (external agreement). To avoid an excess of typical HCCs, a total of 26 HCCs, 11 ICCs, 11 benign lesions, and 2 other malignancies were randomly selected for the external agreement analysis.

The entire process, including folder preparation, CEUS LI-RADS class assignment, and dataset preparation for analysis, was completed over a period of 5 mo. A systematic review of all CT and MRI scans was not performed.

Statistical analysis

Descriptive statistics (median, interquartile range, range, and percentage) were calculated for patients' demographic and clinical characteristics (age, sex, aetiology of cirrhosis, number, and size of nodules). The normal distribution of continuous variables was evaluated through Shapiro-Wilk test. Discrete and qualitative variables are expressed as frequencies and percentages.

Sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), diagnostic accuracy, Youden's index, relative risk, odds ratio, positive likelihood ratio, and negative likelihood ratio were calculated to assess the accuracy of different CEUS-LR classes and subclasses in diagnosing HCC (LR-5, LR-4, and LR-4 and 5 merging class), ICC (LR-M), and malignancies (LR-3). The associations between different CEUS LI-RADS classes and definite diagnosis were evaluated by Pearson's chi-square test or Fisher's exact test. To determine the uncertainty of the estimates on sensitivity, specificity, PPV, NPV, and diagnostic accuracy, 95% confidence intervals (CIs) were calculated.

Cohen's k and Fleiss' k statistics were used to evaluate the interobserver agreement among different examiners in the assignment of the CEUS LI-RADS classes and identification of APHE (absent, homogeneous, or rim-like), and washout (absent, late and mild, or early and/or marked). Additionally, a visual graphical representation of the agreement was created, based on the agreement chart proposed by Bangdiwala[29]. All statistical tests were considered significant for a P value < 0.05. Data were analysed using Stata/MP version 17.0 (Statacorp LP, TX, United States) and R version 4.1.1 (The R Foundation for Statistical Computing, Vienna, Austria).

RESULTS

A total of 511 nodules identified in 269 patients were considered in this study. The complete dataset concerning patients and nodule characteristics is shown in Table 1.

Four-hundred and fifty-two out of 511 nodules (88.5%) turned out to be malignant, consisting of 423 HCCs (82.8%), 23 ICCs (4.5%), 3 metastases (0.6%), and 3 other malignancies (0.6%). Non-invasive diagnosis was obtained for 409 nodules (80%), while histology was followed for 102 nodules (20%). Complete data concerning each definite diagnosis rate for every CEUS LI-RADS class are reported in Table 2. Table 3 shows the rates of HCC and ICC in different CEUS LI-RADS classes. The pathological findings for hepatic nodules are shown in Supplementary Table 1.

The most prevalent pattern in the arterial phase was homogeneous APHE (79.1% of all nodules), followed by isoenhancement (12.7%). In the portal and late phases, the majority of nodules showed a late and mild washout (60.7%) while the second most frequent pattern was isoenhancement (30.7%). See Table 4 and Table 5 for complete data on CEUS pattern in the arterial and venous phases, respectively.

LR-M nodules

Thirty-seven lesions (7.2%) were assigned to the CEUS LR-M class (Figure 2A). Twenty-one of these nodules turned out to be ICCs, eleven were HCCs, three were metastases, one was a lymphoepithelioma, and one was benign. CEUS LR-M predicted ICC with a 91.3% sensitivity, 96.7% specificity, 56.8% PPV, 99.6% NPV, and 96.5% diagnostic accuracy ($P < 0.001$) (Table 6). Examining the CEUS behaviour of ICC, it was observed that 16 out of 21 nodules (76%) showed a rim APHE, while 11 out of 21 nodules (52%) showed an early washout (Supplementary Table 2). HCC nodules reported as LR-M showed a rim APHE in 6 out of 11 cases (54.5%) and an early washout in 7 out of 11 cases (63.6%; Supplementary Table 3).

LR-5 nodules

A total of 288 nodules (56.4%) were categorized as CEUS LR-5 (Figure 2B), of which 286 turned out to be HCC, and 2 were benign lesions. The median diameter of these nodules was 25 mm. The conclusive diagnosis was achieved by CT/MRI for 248 nodules and by histology for 40. CEUS LR-5 class predicted HCC with a 67.6% sensitivity, 97.7% specificity, 99.3% PPV, 38.6% NPV, and 72.8% diagnostic accuracy ($P < 0.001$) (Table 6).

LR-4 nodules

One-hundred and fourteen nodules (22.3%) were reported as CEUS LR-4 (Figure 2C), of which 111 were HCC and 3 were regenerative nodules, as confirmed by histology. The median diameter of these nodules was 21.5 mm. In 95 cases, the diagnosis was given by CT/MRI and in 19 cases by biopsy. CEUS LR-4 predicted HCC with a 26.2% sensitivity, 96.6% specificity, 97.4% PPV, 21.4% NPV, and 38.4% diagnostic accuracy ($P < 0.001$) (Table 6). Table 7 show data relative to different LR-4 patterns.

LR 4-5 merged class

The merging of CEUS LR-4 and CEUS LR-5 classes predicted HCC with a 93.9% sensitivity, 94.3% specificity, 98.8% PPV, 76.1% NPV, and 93.9% diagnostic accuracy ($P < 0.001$) (Table 6).

LR-3 nodules

Sixty-six lesions (12.9%) were assigned to the CEUS LR-3 class (Figure 2D and E). Specifically, 15 of these nodules were HCCs, 2 were ICCs, 2 were other malignancies, and 47 were benign lesions. The median diameter of these nodules was 16 mm. Fifty-three lesions were diagnosed non-invasively by CT/MRI, while 13 by biopsy. CEUS LR-3 predicted benign lesions with a 79.7% sensitivity, 95.8% specificity, 71.2% PPV, 97.3% NPV, and 93.9% diagnostic accuracy ($P < 0.001$) (Table 6). Lesions belonging to the CEUS LR-3 class showed great heterogeneity. In fact, iso-iso nodules (Figure 2D) were most likely benign (only 1 malignancy out of 39 nodules), while other patterns showed a higher risk of cancer (18 malignancies out of 27). The second most frequent CEUS LR-3 pattern was the hypo-hypo pattern assigned to 15 nodules (Figure 2E), of which 11 were malignant (7 HCCs, 2 ICCs, 1 lymphoma, and 1 carcinosarcoma). The rate of malignancy for the CEUS LR-3 class and its subclasses are shown in Figure 3. We also calculated the correlation between specific CEUS LR-3 subgroups and malignancy, with analysis limited to CEUS LR-3 nodules ($n = 66$). It was observed that CEUS LR-3 iso-iso pattern predicted malignancy with a 5.3% sensitivity, 19.1% specificity, 2.6% PPV, 33.3% NPV, and 15.2% diagnostic accuracy ($P < 0.001$). Conversely, CEUS LR-3 hypo-hypo pattern predicted malignancy with a 57.9% sensitivity, 91.5% specificity, 73.3% PPV, 84.3% NPV, and 81.8% diagnostic accuracy ($P < 0.001$) (Table 6). Data concerning different LR-3 patterns are reported in Table 7.

LR 1-2 nodules

Only one nodule (0.2%) was categorized as CEUS LR-1, and five nodules (1%) as CEUS LR-2. All these nodules were found to be benign.

CEUS LI-RADS: Contrast-enhanced ultrasound Liver Imaging Reporting and Data System; HCC: Hepatocellular carcinoma; ICC: Intrahepatic cholangiocarcinoma.

Interobserver agreement

The observed agreement between the two internal raters (1 and 2) for the assignment of CEUS LI-RADS class was 95.7%, with Cohen's $k = 0.94$ (95%CI: 0.92-0.97, $P < 0.0001$), which represents an almost perfect agreement, according to Landis and Koch[30] classification. The agreement is clearly visualized in Figure 4A. Supplementary Table 4 shows the assignments of the two raters.

The observed agreement among the three raters from different centres (2, 3, and 4) for the assignment of CEUS LI-RADS class was 68% and Fleiss's k coefficient showed a value of 0.67 ($P < 0.0001$), which represents a substantial agreement. In particular, the agreement was almost perfect between raters 2 and

3 (k = 0.88, $P < 1.7 \times 10^{-68}$), substantial between raters 2 and 4 (k = 0.66, $P < 1.5 \times 10^{-14}$), and substantial between raters 3 and 4 (k = 0.61, $P < 8.5 \times 10^{-10}$). The agreement is visualized in Figure 4B-D.

With regards to specific CEUS patterns, we found a higher degree of agreement for APHE (internal k = 0.86, $P < 2.7 \times 10^{-214}$; external k = 0.8, $P < 0.001$) than for washout (internal k = 0.79, $P < 1.6 \times 10^{-202}$; external k = 0.71, $P < 0.001$).

DISCUSSION

CEUS LI-RADS is a valuable diagnostic tool for non-invasive differential diagnosis of focal liver lesions in patients with cirrhosis. Based on our experience, employing this approach improves the performance of CEUS in the characterization of nodules, especially to discriminate between HCC and ICC.

In the current study, CEUS LR-5 was extremely specific for HCC with a very high PPV (99.3%). Only two false-positive results were observed, which were not ICC. We can therefore maintain that CEUS LR-5 is an appropriate tool for non-invasive diagnosis of HCC with virtually no risk of ICC misdiagnosis. Our data agree with recent publications on the subject[22]. However, CEUS LR-5 lacked sensitivity (67.6%) due to the large number of CEUS LR-4 nodules with a final diagnosis of HCC (97.4%). The high specificity of CEUS LR-5 for HCC combined with a low sensitivity was confirmed by a recent prospective multicentric study that compared the accuracy of different CEUS algorithms for the non-

invasive diagnosis of HCC[31] and a recent meta-analysis[32].

Considering the high risk of HCC for the LR-4 class (97.4% PPV), the possibility of merging LR-4 and 5 classes was tested. By doing so, sensitivity in identifying HCC rose from 67.6% to 93.9%. The loss in specificity was low (from 97.7% to 94.3%), and was entirely attributed to two nodules > 10 mm classified as CEUS LR-4, which turned out to be benign. Data from the literature supports such an approach, showing that around 50% of HCCs do not display any washout in the portal and late venous phases on CEUS. In particular, Giorgio *et al*[33] demonstrated in their series that 55.4% of the biopsied HCC nodules < 20 mm showed this pattern after APHE. These findings were further corroborated by Leoni *et al*[34], who found that the hyper-iso pattern shows a high PPV (94%) for HCC and identifies nodules that are HCC or with a strong tendency to malignant progression. This pattern was detected in 36.2% (46 out 127) of HCCs[34].

Therefore, it should be considered that the introduction of the washout criteria in CEUS is based on findings from studies exploring the role of contrast-enhanced CT in the non-invasive diagnosis of HCC [35-37]. These findings were then extended to CEUS and MRI with little consideration for the differences in the pharmacokinetics of contrast agents among these techniques and the importance of the nodule visibility at baseline. Indeed, the requirement for washout as a diagnostic criterion is less stringent for CEUS and MRI, since these techniques have an improved capability to evaluate and determine whether APHE reflects the presence of a distinct nodule or merely abnormalities of intrahepatic vessels. CEUS, in particular, is performed for improved characterization of a nodule that has already been detected through conventional ultrasound.

Unfortunately, the introduction of washout in CEUS has significantly lowered the sensitivity of non-invasive diagnostic criteria for HCC. The inclusion of hyper-iso pattern among criteria for non-invasive HCC diagnosis might be a solution to increase CEUS sensitivity. Using this strategy, it can be concluded that there is no significant risk of overestimating the diagnosis of HCC, as in our series 98% of the

Notice hypoenhancement in all phases. The arrows show the target lesion.

nodules with the hyper-iso pattern were HCCs and only 2% were benign nodules. These considerations and results agree with another study on the combination of CEUS LR-4 and LR-5 criteria[38]. Furthermore, different studies demonstrated that the identification of washout has higher inter-rater variability than APHE identification[39,40]. These findings are also confirmed by the present study.

Regarding ICC, we observed that the majority of the nodules (21/23, 91.3%) were correctly diagnosed using the LR-M class of risk. Only two ICC cases were not assigned to this class due to a hypovascular aspect in all phases. The high sensitivity and specificity of the CEUS LR-M class for ICC (91.3% and

Figure 3 Absolute frequency (*n*) of malignancies and benign lesions in LR-3 nodules and LR-3 subgroups with different contrast-enhanced ultrasound patterns.

96.7%, respectively) in our series of patients demonstrate that this class is a valuable diagnostic tool for this type of cancer. Still, this class is not entirely specific for ICC as other types of malignancy can be found, such as HCC, metastatic lesions, and rarer malignancies[41]. We found that 11 out of 37 nodules (30%) classified as LR–M turned out to be HCC. This was due to the presence of an early washout (63.6% of nodules) and/or a rim enhancement pattern (54.5% of nodules). These observations are in agreement with the previously published literature. In particular, a multicentre retrospective study published by Terzi *et al*[22] reported that about 40% of LR-M lesions were HCCs. Another study by Wilson *et al*[16] identified that 35% of HCCs were reported to be LR-M. Several other authors have attempted to decrease the risk of HCC misdiagnosis by proposing a modified LR-M class of risk with the introduction of new criteria, such as the shortening of washout timing to < 45 *s* or the possibility to detect a significant washout to < 3 min[42-44]. Interestingly, Chen *et al*[45] were able to reduce the ICC misdiagnosis rate with CEUS LR-M from 38 to 12 cases by considering other criteria such as the presence of an intratumoral vein or an unclear boundary of the intratumoral non-enhanced area. However, we did not test these new criteria that require validation in multicentric and prospective studies. Another recent study by Huang *et al*[46] suggested that the integration of CEUS with the dosage of serum tumour markers (AFP and CA 19.9) improves the differentiation of LR-M nodules. Even though there are some limitations related to LR-M in this scenario, the adoption of this class of risk allows the improvement of diagnostic performance of CEUS for ICC, overcoming the drawbacks that resulted in the elimination of CEUS from the diagnostic flow charts of the most important hepatological international guidelines[3,8].

At present, CEUS LR-3 lesions are considered to hold an intermediate risk of malignancy, which is around 50% according to a recent study published by Terzi *et al*[22]. This rate was much lower in our case series (28.8%), which might be attributable to the lower figures of our study. Still, looking at the data from single centres in the multicentric study by Terzi *et al*[22], the rate of HCC in the CEUS LR-3 class ranged between 28.3% and 74.3%. One possible explanation for these results could be the high intrinsic heterogeneity of this class. Indeed, the algorithm only considers either the presence or absence of APHE, without any distinction between isoenhancement and hypoenhancement in all phases. However, in our clinical experience, hypo-hypo lesions are more likely to be malignant than iso-iso lesions. The present study confirmed this observation: Within the CEUS LR-3 class, the PPV for malignancy moved from 28.8% for CEUS LR-3 overall class to 2.6% for CEUS LR-3 iso-iso nodules, and 73.3% for CEUS LR-3 hypo-hypo nodules (Table 5). These considerations are in concordance with studies published before the advent of CEUS LI-RADS, when the problem of hypovascular nodules, which represent around 10% of HCC, was highlighted[47-49]. Likewise, we should be aware of the possibility of detecting ICC nodules in this class when a nodule shows hypoenhancement in all the phases; as observed in two out of 15 (13%) hypo-hypo nodules in our study. In light of these observations, we believe that it might be advantageous to split the CEUS LR-3 class into two subgroups (*e.g.*, CEUS LR-3a and CEUS LR-3b) in order to separate iso-iso lesions from other patterns. To the best of our knowledge, this is the first study suggesting a CEUS LR-3 refinement based on real-life results. We believe that more attention should be directed towards the behaviour of nodule enhancement, rather than focusing on the size of the lesion alone.

Figure 4 Bangdiwala's agreement charts of the Contrast-enhanced ultrasound Liver Imaging Reporting and Data System class assignments between different raters. In the case of perfect agreement, the *k* rectangles are represented by perfect squares and the shaded squares determined by the diagonal cell entries are exactly equal to the rectangles; lesser agreement is visualized by comparing the area of the blackened squares to the area of the rectangles. A: Agreement chart between the two internal raters (1 and 2), with the exclusion of LR-1 and LR-2 classes due to their rarity (n = 505); B-D: Agreement charts among the three raters from different centres (2, 3, and 4) for the subgroup of 50 nodules. We list the agreement charts between raters 2 and 3 (B), between raters 2 and 4 (C), and between raters 3 and 4 (D).

Finally, this study demonstrated excellent inter-rater reliability of this classification system. Therefore, the use of CEUS LI-RADS in clinical practice could improve the reproducibility of CEUS and partially reduce the gap due to the difference in experience, as suggested by a recent study[50].

Our study also has some critical shortcomings, namely, its retrospective nature and the limited number of nodules analysed. These drawbacks are primarily due to the fact that data were collected from a single centre. Another debatable aspect of our investigation is the limited number of biopsies. However, we would like to highlight that current guidelines do not routinely recommend biopsy for nodules with typical HCC pattern on CT or MRI, allowing a non-invasive diagnosis[4,28].

Further prospective multicentric studies are warranted to confirm our findings and to investigate whether our considerations could be applied to the general population of patients with cirrhosis.

CONCLUSION

The present study supports the use of CEUS LI-RADS for the characterization of focal liver lesions in liver cirrhosis and the usefulness of LR-5 and LR-M classes to diagnose HCC and ICC, respectively. Additionally, our findings suggest that the merging of LR-4 and LR-5 classes provides innovative

benefits in terms of diagnostic accuracy for HCC. Furthermore, it seems reasonable to split the CEUS LR-3 class into two subgroups to differentiate the risk of malignancy between iso-iso nodules, which are more likely to be benign, and other patterns, namely, hypo-hypo nodules, which are more likely to be malignant and not specific for HCC.

ARTICLE HIGHLIGHTS

Research background

Patients affected by liver cirrhosis are at high risk of developing hepatocellular carcinoma (HCC) and other malignancies such us intrahepatic cholangiocellular carcinoma (ICC). Diagnostic tools to characterize new-onset nodules in cirrhosis include contrast-enhanced ultrasound (CEUS), but this technique has been challenged for the possibility of misdiagnosing HCC and ICC.

Research motivation

The CEUS Liver Imaging Reporting and Data System (CEUS LI-RADS) aims to refine CEUS interpretation in order to improve the differentiation of HCC from other malignancies. Nevertheless, its effectiveness in real-life context has not yet been well established.

Research objectives

To test the accuracy of CEUS LI-RADS in correctly diagnosing HCC and ICC in cirrhosis with LR-5 and LR-M class, respectively, to evaluate the performance of LR-4 and 5 merging class in the diagnosis of HCC, and to investigate the rate of malignancies in different LR-3 patterns.

Research methods

This study consecutively collected 511 nodules in 269 cirrhotic patients from December 2008 to January 2020. A CEUS LI-RADS class was retrospectively attributed to each nodule based on review of CEUS examination. Common diagnostic accuracy indexes were assessed for the following associations: CEUS LR-5 and HCC; CEUS LR-4 and 5 merged class and HCC; CEUS LR-M and ICC; CEUS LR-3 and malignancy. The diagnostic standard was either biopsy or computed tomography/magnetic resonance imaging. The frequency of malignant lesions in CEUS LR-3 subgroups with different CEUS patterns was also determined.

Research results

CEUS LR-5 showed a 97.7% specificity for HCC with a low sensitivity (67.6%), while the CEUS LR-4 and 5 merged class showed a 93.9% sensitivity and 94.3% specificity for HCC. CEUS LR-M predicted ICC with a 91.3% sensitivity and 96.7% specificity. CEUS LR-3 predominantly included benign lesions (28.8% of malignancies) but was heterogeneous as the hypo-hypo pattern showed a higher rate of malignant lesions (73.3%) than the iso-iso pattern (2.6%).

Research conclusions

HCC diagnosis could benefit from the merging of CEUS LI-RADS classes 4 and 5. In addition, splitting LR-3 class could be advantageous to differentiate iso-iso nodules from other patterns with a higher risk of malignancy.

Research perspectives

Further prospective multicentric studies are necessary to confirm and extend our findings to the general population.

Abstract

BACKGROUND

Noninvasive, practical, and convenient means of detection for the prediction of liver fibrosis and cirrhosis in China are greatly needed.

AIM

To develop a precise noninvasive test to stage liver fibrosis and cirrhosis.

METHODS

With liver biopsy as the gold standard, we established a new index, [alkaline phosphatase (U/L) + gamma-glutamyl transpeptidase (U/L)/platelet (10^9/L) (AGPR)], to predict liver fibrosis and cirrhosis. In addition, we compared the area under the receiver operating characteristic curve (AUROC) of AGPR, gamma-glutamyl transpeptidase to platelet ratio, aspartate transaminase to platelet ratio index, and FIB-4 and evaluated the accuracy of these routine laboratory indices in predicting liver fibrosis and cirrhosis.

RESULTS

Correlation analysis revealed a significant positive correlation between AGPR and liver fibrosis stage ($P < 0.001$). In the training cohort, the AUROC of AGPR was 0.83 (95%CI: 0.78-0.87) for predicting fibrosis (≥ F2), 0.84 (95%CI: 0.79-0.88) for predicting extensive fibrosis (≥ F3), and 0.87 (95%CI: 0.83-0.91) for predicting cirrhosis (F4). In the validation cohort, the AUROCs of AGPR to predict ≥ F2, ≥ F3 and F4 were 0.83 (95%CI: 0.77-0.88), 0.83 (95%CI: 0.77-0.89), and 0.84 (95%CI: 0.78-0.89), respectively.

CONCLUSION

The AGPR index should become a new, simple, accurate, and noninvasive marker to predict liver fibrosis and cirrhosis in chronic hepatitis B patients.

Key Words: Liver; Fibrosis; Cirrhosis; Prediction; Novel noninvasive marker; Chronic hepatitis B

Core Tip: Chronic hepatitis B virus (HBV) infection is highly endemic in China, and routine assessment of chronic hepatitis B patients is greatly needed to guide management and indicate the need for treatment. In this study, we established a new index to stage liver fibrosis and cirrhosis in patients with chronic HBV infection in China. In addition, the study compared the predictive performance between the new index and other noninvasive indices. The new index is suitable for regular monitoring and is crucial for the management of patients with liver fibrosis/cirrhosis.

INTRODUCTION

Chronic hepatitis B virus (HBV) infection is a public issue that affects human health. Patients who are chronically infected with HBV have a tendency to develop liver fibrosis, liver cirrhosis and even more serious conditions, such as hepatocellular carcinoma (HCC). It has been reported that liver fibrosis can be reversed in patients with varying degrees of fibrosis by removing pathogenic factors, including HBV infection and alcohol[1,2]. It would benefit patients to obtain early diagnosis and effective treatment of liver fibrosis before the disease worsens. Hence, measures should be taken to achieve early diagnosis of liver fibrosis to avoid disease progression caused by HBV infection.

Liver biopsy has always been regarded as the gold standard to evaluate liver histology and assess the degree of fibrosis[3]. However, liver biopsy has shortcomings. Like any surgery, liver biopsy carries some risks, such as puncture of the lung or gallbladder, infection, bleeding, and pain, although these complications are rare[4]. In addition, a major problem is the sampling error and significant variability of fibrosis assessment by liver biopsy[5]. Transient elastography performed with FibroScan is a new technique to measure liver stiffness, and it has the advantages of noninvasiveness, good reproducibility and higher objectivity[6-8]. However, the FibroScan device and its maintenance are expensive, limiting the use of transient elastography in low- and middle-income countries and making it unsuitable for routine monitoring of liver fibrosis/cirrhosis in patients with chronic liver disease in economically poor areas. In recent years, researchers have been interested in finding a potential marker of liver fibrosis/cirrhosis or developing a multifactorial model from peripheral blood[9]. Noninvasive fibrosis tests based on routine laboratory indices have become available and are increasingly used to both assess and stage liver fibrosis; these include the aspartate transaminase (AST)-to-platelet (PLT) ratio index (APRI)[10], FIB-4[11] and the gamma-glutamyl transpeptidase (γ-GT) to PLT ratio (GPR)[12]. These indices are inexpensive, available and noninvasive for assessment of the stages of fibrosis/cirrhosis and can be easily performed in outpatient settings with limited conditions. Among these, the APRI was recommended by the World Health Organization as the most useful noninvasive tool to assess cirrhosis in resource-limited settings; however, FIB-4 was not recommended because it is not used for the detection of cirrhosis[13]. However, the levels of sensitivity and positive predictive value were low for APRI[14]. Therefore, there is an urgent need to find a more reliable method that is noninvasive, inexpensive, convenient and feasible for assessing liver disease stage and identifying patients who need treatment.

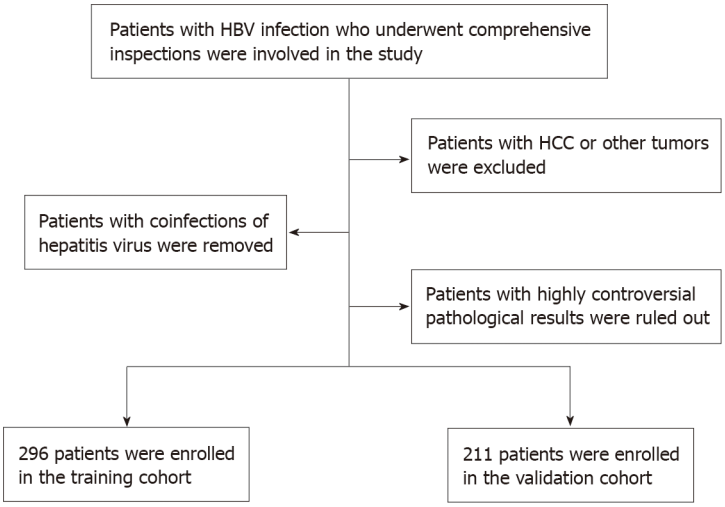
Table 1 Clinical and biochemical data of examined patients

Parameter	Training cohort (*n* = 296)[1]	Validation cohort (*n* = 211)[1]	*P* value
Age (yr)	42.47 ± 11.98	41.21 ± 11.36	0.167
Gender: Female/male (*n*)	75/221	40/171	0.091
Drinking: Yes/no (*n*)	127/169	101/110	0.268
Smoking: Yes/no (*n*)	92/204	68/143	0.784
HbeAg: Negative/positive	16/280	15/196	0.430
Fibrosis stage: F0/F1/F2/F3/F4	55/58/75/64/44	47/47/37/54/26	0.194
Activity grade: A0/A1/A2/A3/A4	16/92/113/69/6	15/72/69/52/3	0.446
WBC (× 10^9/L)	5.89 ± 2.55	6.34 ± 4.32	0.150
NEUT × 10^9/L)	3.55 ± 2.44	3.66 ± 2.61	0.611
LYMPH (× 10^9/L)	1.72 ± 0.62	1.80 ± 0.63	0.063
PLT (× 10^9/L)	171.61 ± 66.87	174.48 ± 61.62	0.636
Albumin (g/L)	41.12 ± 19.09	39.94 ± 6.07	0.380
Globulin (g/L)	29.67 ± 5.45	29.14 ± 5.80	0.298
TBIL (μmol/L)	16.51 ± 8.44	16.73 ± 7.63	0.768
DBIL (μmol/L)	6.91 ± 5.03	7.07 ± 4.33	0.699
ALT (U/L)	73.31 ± 65.41	96.85 ± 83.62	0.002
AST (U/L)	72.59 ± 63.29	77.44 ± 67.34	0.411
ALP (U/L)	97.70 ± 41.98	104.32 ± 49.25	0.104
γ-GT (U/L)	85.64 ± 69.68	97.98 ± 75.36	0.058
AGPR	1.26 ± 0.84	1.32 ± 0.89	0.431

[1]Data presented as the mean ± SD or proportions.

HbeAg: Hepatitis B e-antigen; WBC: White blood cell; NEUT: Neutrophil count; LYMPH: Lymphocyte count; PLT: Platelet; TBIL: Total bilirubin; DBIL: Direct bilirubin; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; ALP: Alkaline phosphatase; γ-GT: Gamma-glutamyl transpeptidase; AGPR: [Alkaline phosphatase (U/L) + gamma-glutamyl transpeptidase (U/L)]/platelet (10^9/L).

In this study, we tested a novel noninvasive index, the alkaline phosphatase (ALP) and γ-GT to PLT ratio (AGPR), for the assessment of liver fibrosis and cirrhosis through statistical analysis of clinical data. Moreover, we compared the diagnostic values of the AGPR, GPR, APRI and FIB-4 indices.



MATERIALS AND METHODS

Patients

The patients who participated in this study were divided into a training set and a validation set. Patients in the training set received treatment at the Affiliated Hospital of Guilin Medical University (Guilin, People's Republic of China). Patients in the validation set received treatments at the Peking University People's Hospital (Beijing, Guangxi Zhuang Autonomous Region, China). All patients were under treatment from May 2005 to October 2016, and all underwent systematic examinations, including abdominal ultrasound, routine laboratory tests and liver histological examination tests. The clinicopathologic characteristics of all patients, including age, gender, alcohol consumption, smoking status, hepatitis B e-antigen (HbeAg) status, fibrosis and cirrhosis stage, activity grade, white blood cell (WBC) count, neutrophil count (NEUT), lymphocyte count (LYMPH), PLT count, albumin, globulin, total bilirubin (TBIL), direct bilirubin (DBIL), alanine aminotransferase (ALT), AST, ALP, γ-GT and AGPR were collected and are detailed in Table 1. All patients in the study were chronically infected with HBV and were positive for hepatitis B surface antigen.

Liver histological examination

Some basic clinical examinations that ensure that patients are relatively safe when performing liver puncture surgery should be performed. In addition, physicians should obtain informed consent from

Figure 1 Selection principles of study population. HBV: Hepatitis B virus; HCC: Hepatocellular carcinoma.

the patients prior to surgery. Ultrasound localization was performed on consenting and suitable patients for liver biopsy procedures. Qualified liver tissue samples were formalin-fixed and paraffin-embedded for pathological analysis. Liver fibrosis and cirrhosis were graded as follows according to the METAVIR system: F0, no fibrosis; F1, fibrosis in the portal vein zone but no fibrous septa; F2, a small amount of fibrous septa; F3, many fibrous septa but no cirrhosis; F4, cirrhosis[15]. All biopsy samples were assessed separately by two liver pathologists who were blinded to the clinical information. If the results of their evaluation were discordant, a third highly experienced hepatopathologist blinded to patient information reviewed the contested samples. Samples were excluded from the study population if the pathologists failed to reach consensus.

Computational formula

AGPR was calculated as [ALP (U/L) + γ-GT (U/L)]/PLT count (10^9/L). APRI was calculated as (AST/ULN)/PLT count (10^9/L) × 100[10]. FIB-4 was calculated by the formula: Age (years) × AST (U/L)/[PLT (10^9/L) × ALT (U/L)$^{1/2}$][11]. The formula for GPR was γ-GT/ULN of γ-GT/PLT count (10^9/L) × 100[12].

Statistical analysis

Student's *t* test was used for continuous variables, and Pearson's χ^2 test or Fisher's exact test was used for categorical variables to compare baseline characteristics. Data are presented as the mean ± SD or proportions. Univariable logistic regression was used for the variables of age, gender, WBC, NEUT, LYMPH, PLT, albumin, globulin, TBIL, DBIL, ALT, AST, ALP, γ-GT and AGPR. The receiver operating characteristic (ROC) curves were drawn to evaluate the accuracy rate of diagnosis for the AGPR, GPR, APRI, and FIB-4. The sensitivity, specificity, positive and negative predictive values, positive and negative likelihood ratio, hazard ratio and the area under the ROC curve (AUROC) of the four non-invasive markers for fibrosis and cirrhosis staging were obtained through comparison and analysis of F0-1 *vs* F2-4, F0-2 *vs* F3-4, and F0-3 *vs* F4, respectively. Data analysis was performed using SPSS software (version 24.0). A P value < 0.05 was regarded as statistically significant.

RESULTS

Study populations of the training and validation cohorts

Patients involved in this study needed to meet certain criteria. Those criteria were as follows: (1) Study patients were infected with HBV and underwent systematic examinations, including abdominal ultrasound, routine laboratory tests and liver biopsies; (2) Patients with HCC or other tumors were excluded; (3) Patients with coinfection of HCV, HIV or HDV were excluded; and (4) Patients with highly controversial results on liver fibrosis pathological grading were excluded. Figure 1 displays the selection principles.

Clinical data related to this study are summarized in Table 1. There were no statistically significant differences between the training and validation cohorts in terms of age, gender, drinking status, smoking status, HbeAg, fibrosis stage, activity grade, WBC, NEUT, LYMPH, PLT, albumin, globulin, TBIL, DBIL, ALT, AST, ALP, γ-GT or AGPR (P > 0.05). Nonsignificant differences between the two

study groups revealed that the selection of training and validation cohorts was reasonable.

AGPR predicts significant hepatic fibrosis and cirrhosis

Univariable analyses showed that the presence of significant liver fibrosis (≥ F2) was related to gender, WBC, NEUT, PLT, albumin, globulin, TBIL, DBIL, AST, ALP, γ-GT and AGPR (Table 2). In the training cohort, correlation analysis revealed a significant positive correlation between AGPR and liver fibrosis stage (r = 0.567, P < 0.001) (Figure 2A). In the validation cohort, there was also a positive correlation between AGPR and liver fibrosis stage (r = 0.524, P < 0.001), as shown in Supplementary Table 1 and Supplementary Figure 1A. Box plots showed that liver fibrosis stage positively correlated with ALP + γ-GT (r = 0.352, P < 0.001), GPR (r = 0.509, P < 0.001), APRI (r = 0.428, P < 0.001) and FIB-4 (r = 0.416, P < 0.001) in the training cohort (Figure 2B and D-F). The severity of liver fibrosis stage correlated significantly with a gradual increase in the levels of these indicators. There was a negative correlation between PLT count and liver fibrosis stage (r = -0.362, P < 0.001) in the training cohort (Figure 2C). The severity of liver fibrosis decreased with increasing PLT count. Similar results were obtained in the validation cohort, and the specific data related to these results are shown in Supplementary Figure 1B-F and Supplementary Table 2.

Comparisons of AUROC between AGPR and other noninvasive indices

The summary AUROC, sensitivity, specificity, positive and negative predictive values, positive and negative likelihood ratios, and hazard ratios for the detection of fibrosis and cirrhosis for AGPR, GPR, APRI and FIB-4 are displayed in Table 3. In the training cohort, the AUROC of AGPR (0.83, 95%CI: 0.78-0.87) was higher than that of GPR (0.77, 95%CI: 0.72-0.82; P = 0.008), APRI (0.72, 95%CI: 0.67-0.77; P < 0.0001) and FIB-4 (0.74, 95%CI: 0.69-0.79; P = 0.0004) for the prediction of significant fibrosis (≥ F2). For the assessment of extensive fibrosis (≥ F3), the AUROC of AGPR (0.84, 95%CI: 0.79-0.88) was also higher than that of GPR (0.81, 95%CI: 0.76-0.85; P < 0.0001), APRI (0.70, 95%CI: 0.64-0.75; P < 0.0001) and FIB-4 (0.75, 95%CI: 0.69-0.80; P = 0.0005). For the diagnosis of cirrhosis (F4), the AUROC of AGPR was 0.87 (95%CI: 0.83-0.91), which was higher than that of GPR (0.80, 95%CI: 0.75-0.84; P = 0.0001), APRI (0.76, 95%CI: 0.70-0.8; P = 0.0002) and FIB-4 (0.80, 95%CI: 0.75-0.84; P = 0.022) (Figure 3A and Table 3). For identifying patients with significant fibrosis and cirrhosis, the summary sensitivities of AGPR were 83.1% and 88.6%, respectively, while the summary specificities of AGPR were 73.4% and 75.4%, respectively. The sensitivity, specificity, positive and negative predictive values, positive and negative likelihood ratios, and hazard ratios of the other noninvasive indices are detailed in Table 3. Our results

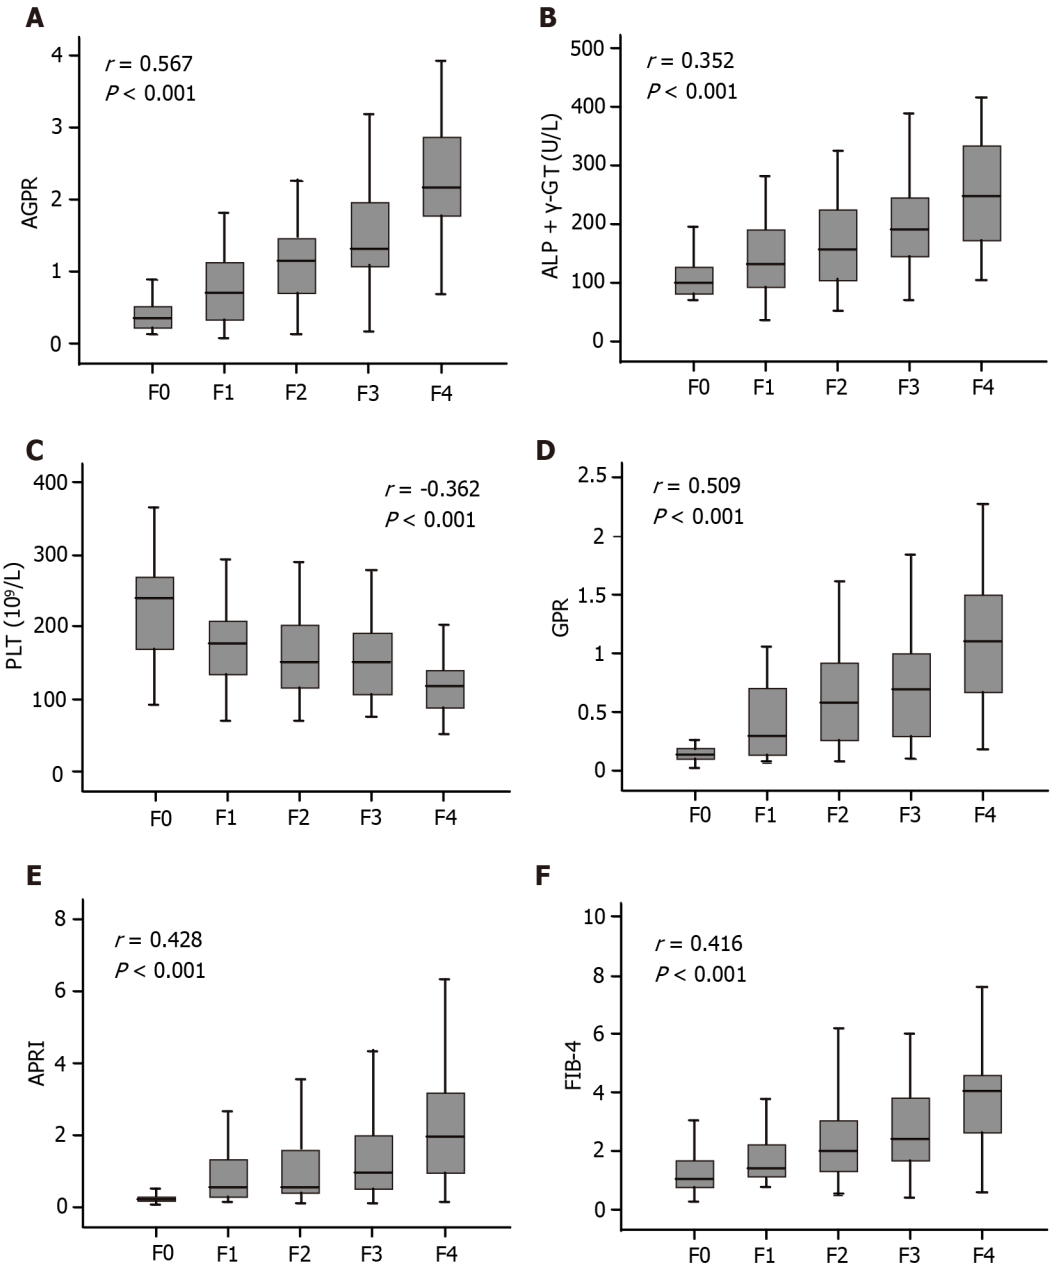
AGPR: [Alkaline phosphatase (U/L) + gamma-glutamyl transpeptidase (U/L)]/platelet count (10^9/L); AUROC: Area under the receiver operating characteristic curve; Se: Sensitivity; Sp: Specificity; PPV: Positive predictive value; NPV: Negative predictive value; LR: Likelihood ratio; HR: Hazard ratio; CI: Confidence interval; GPR: Gamma-glutamyl transpeptidase to platelet ratio; APRI: Aspartate aminotransferase-to-platelet ratio index; FIB-4: Age (years) × aspartate aminotransferase (U/L)/[platelet (10^9/L) × alanine aminotransferase (U/L)$^{1/2}$].

revealed that AGPR had the best overall performance among these noninvasive indices.

We further evaluated the diagnostic accuracy and performance of these noninvasive indices in the validation cohort. Similar to the results from the training cohort, the AUROC of AGPR was better than that of GPR (0.78, 95%CI: 0.71-0.83), APRI (0.77, 95%CI: 0.70-0.83), and FIB-4 (0.77, 95%CI: 0.71-0.83) (Figure 3B and Table 3).

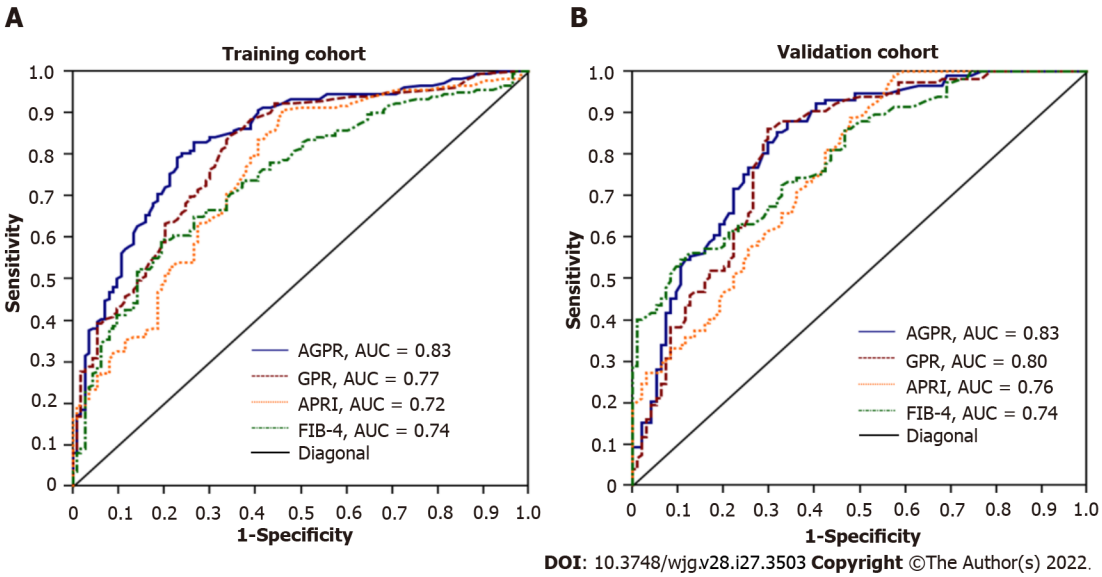


DISCUSSION

Cirrhosis is one of the top 20 causes of disability-adjusted life years and life lost years, accounting for 1.6% and 2.1% of the global burden, respectively[16]. Cirrhosis is also the 11th most common cause of death worldwide[16]. Recently, Xu *et al*[17] provided updated guidelines for the management of liver cirrhosis in China. However, better screening for early fibrosis or cirrhosis remains a challenge. Finding an inexpensive, noninvasive, convenient, feasible and precise parameter to stage liver fibrosis is the expectation of all medical staff in China. Although liver biopsy is a good measure for the assessment of liver fibrosis grade, many patients do not accept it, or they are not suitable for the test[18,19]. FibroScan is a noninvasive diagnostic technique and its diagnostic accuracy is high. However, its application is limited because of its high cost[20]. Consequently, the development of noninvasive assessment methods for liver fibrosis in patients with chronic HBV infection appears especially important in clinical practice.

In the present study, we developed a new simple, convenient and noninvasive index (AGPR) to predict significant liver fibrosis in chronic HBV-infected patients in China. The correlation coefficients between liver fibrosis stage and AGPR suggest that AGPR is a good test for the assessment of significant liver fibrosis and cirrhosis.

The AGPR index was established on the basis of ALP, γ-GT and PLT. These three indicators are clinical evaluations of features of fibrosis/cirrhosis and evidence of decompensation. Hepatitis is related to ALP[21,22] and γ-GT[23,24]. ALP is useful in the diagnosis of chronic liver diseases[25]. A study showed that serum ALP level was significantly different in patients with or without liver cirrhosis[26]. In a report, γ-GT was demonstrated to be an independent predictor of hepatic fibrosis[27]. The circulating PLT count has been recommended as a biomarker of hepatic fibrosis and cirrhosis[28]. Based on these findings, each of the three variables is related to the degree of liver fibrosis. The antiviral treatment, anti-inflammatory and hepatoprotective treatment have a greater impact on serum levels of aminotransferases, such as AST and ALT. However, according to clinical observation, ALP and γ-GT are regarded as less specific for liver injury than AST and ALT. The effects of antiviral therapy, anti-inflammatory therapy and hepatoprotective therapy on ALP and γ-GT are not as obvious as on AST and ALT. As a matter of fact, elevated serum γ-GT levels are strongly associated with alcohol consumption. However, the researchers have reported that the high-risk liver disease mortality due to elevated γ-GT was not affected by alcohol consumption[29].



A routine assessment of liver fibrosis stage for patients with chronic HBV infection is needed to guide management and to indicate the need for treatment. However, the diagnosis of liver fibrosis and compensated cirrhosis cannot be based on clinically obvious features. Noninvasive fibrosis tests are now increasingly used for evaluating liver fibrosis, reducing the need for liver biopsy. AGPR may be a new promising noninvasive fibrosis test to assist in the selection of optimal candidates for antiviral therapy. The AGPR test is inexpensive, routinely available at health-care facilities, and can be performed by untrained staff. It is suitable for conventional monitoring of hepatic fibrosis and cirrhosis. The Guidelines Development Group prioritized urgent initiation of antiviral therapy for patients with cirrhosis based on APRI score > 2 in adults, regardless of ALT or HBV DNA levels[13]. However, when applying an APRI score > 2 in this study, the sensitivity for the diagnosis of cirrhosis was only 43.2% and 50.1% in the training and validation cohorts, respectively. This suggested that more than 50% of patients with cirrhosis would be incorrectly classified as not having cirrhosis, which may lead to delayed initiation of treatment. In contrast, the sensitivity of AGPR for the diagnosis of cirrhosis was high at 88.6% and 92.3% in the training and validation cohorts, respectively. Therefore, our data suggested that AGPR may be a preferred noninvasive test to detect the presence of significant fibrosis and cirrhosis. It may serve as a simple index to make treatment decisions in patients without evidence of cirrhosis in China and other resource-limited settings where HBV infection is endemic.

Figure 2 Box plots of [alkaline phosphatase (U/L) + gamma-glutamyl transpeptidase (U/L)]/platelet (10^9/L) (A), alkaline phosphatase + gamma-glutamyl transpeptidase (B), platelet (C), gamma-glutamyl transpeptidase to platelet ratio (D), aspartate aminotransferase-to-platelet ratio index (E), and age × aspartate transaminase/platelet × alanine aminotransferase (F) according to the METAVIR fibrosis stage in the training cohort. AGPR: [Alkaline phosphatase (U/L) + gamma-glutamyl transpeptidase (U/L)]/platelet (10^9/L); ALP + γ-GT: Alkaline phosphatase + gamma-glutamyl transpeptidase; PLT: Platelet; GPR: Gamma-glutamyl transpeptidase to platelet ratio; APRI: Aspartate aminotransferase-to-platelet ratio index; FIB-4: Age × aspartate transaminase/platelet × alanine aminotransferase.

Our study has some limitations. First, the selection of samples was limited to a population with chronic HBV infection in China. Whether AGPR can be generalized to different geographical areas (the infection of hepatitis C virus is endemic) remains to be determined. Second, the time span of over 10 years for our selected samples was too long (from May 2005 to October 2016). Over this time period, substantial changes have taken place in terms of medical equipment and physical examination technologies, which may reduce the accuracy of our study results. Finally, there are many factors involved in liver fibrosis. The impact of various interference factors on the diagnostic accuracy of the AGPR index has not been fully evaluated. Some interference may affect the precision of our index.

DOI: 10.3748/wjg.v28.i27.3503 **Copyright** ©The Author(s) 2022.

Figure 3 The receiver operating characteristic analysis of [alkaline phosphatase (U/L) + gamma-glutamyl transpeptidase (U/L)]/platelet (10^9/L), amma-glutamyl transpeptidase to platelet ratio, aspartate aminotransferase-to-platelet ratio index and age × aspartate transaminase/platelet × alanine aminotransferase in the training (A) and validation cohorts (B). AGPR: [Alkaline phosphatase (U/L) + gamma-glutamyl transpeptidase (U/L)]/platelet (10^9/L); GPR: Gamma-glutamyl transpeptidase to platelet ratio; APRI: Aspartate aminotransferase-to-platelet ratio index; FIB-4: Age × aspartate transaminase/platelet × alanine aminotransferase; AUC: Area under the curve.

CONCLUSION

In summary, the AGPR index may be an accurate noninvasive test for predicting significant liver fibrosis and cirrhosis in patients with chronic HBV infection in China. In addition, it is suitable for conventional monitoring. Therefore, for the prediction of liver fibrosis and cirrhosis, the AGPR index is a promising noninvasive marker that is worthy of further attention and research.

ARTICLE HIGHLIGHTS

Research background

Patients infected with hepatitis B virus (HBV) tend to develop liver fibrosis and liver cirrhosis. Those with cirrhosis have a high risk of hepatic decompensation and hepatitis B- related hepatocellular carcinoma.

Research motivation

Liver biopsy was used to ascertain the degree of fibrosis/cirrhosis. However, as an invasive procedure, liver biopsy has many disadvantages. The Guidelines Development Group recommended the use of noninvasive tests to assist in the assessment of liver disease stage and the diagnosis of fibrosis/cirrhosis. The use of a noninvasive test can reduce the need for liver biopsy.

Research objectives

The present study aimed to develop a precise noninvasive test to stage liver fibrosis/cirrhosis and compare the diagnostic values between different noninvasive methods.

Research methods

Univariable logistic regression was used to identify significant predictive factors. Correlation analysis was performed to reveal the correlation between clinical parameters and liver stage. Receiver operating characteristic (ROC) curves were drawn to evaluate the diagnostic accuracy of different noninvasive methods.

Research results

The presence of liver fibrosis was significantly related to alkaline phosphatase and the gamma-glutamyl transpeptidase to platelet ratio (AGPR). There was a significant positive correlation between AGPR and liver fibrosis stage. The area under the ROC curve values of AGPR were 0.83, 0.84, and 0.87 for the prediction of significant fibrosis, extensive fibrosis, and cirrhosis, respectively. The AGPR index had a

better overall performance than other noninvasive indices.

Research conclusions

AGPR can be used to detect the presence of significant fibrosis, extensive fibrosis, and cirrhosis with high diagnostic accuracy, sensitivity, and specificity in patients with chronic HBV infection.

Research perspectives

The AGPR index is a promising noninvasive marker for assessing liver disease stage. The use of AGPR can help with the routine monitoring of hepatic fibrosis and cirrhosis.

Abstract

BACKGROUND

Percutaneous transhepatic cholangiography is a diagnostic and therapeutic procedure that involves inserting a needle into the biliary tree, followed by the immediate insertion of a catheter. Endoscopic ultrasound-guided biliary drainage (EUS-BD) is a novel technique that allows BD by echoendoscopy and fluoroscopy using a stent from the biliary tree to the gastrointestinal tract.

AIM

To compare the technical aspects and outcomes of percutaneous transhepatic BD (PTBD) and EUS-BD.

METHODS

Different databases, including PubMed, Embase, clinicaltrials.gov, the Cochrane library, Scopus, and Google Scholar, were searched according to the guidelines for Preferred Reporting Items for Systematic reviews and Meta-Analyses to obtain studies comparing PTBD and EUS-BD.

RESULTS

Among the six studies that fulfilled the inclusion criteria, PTBD patients underwent significantly more reinterventions (4.9 *vs* 1.3), experienced more postprocedural pain (4.1 *vs* 1.9), and experienced more late adverse events (53.8% *vs* 6.6%) than EUS-BD patients. There was a significant reduction in the total bilirubin levels in both the groups (16.4-3.3 μmol/L and 17.2-3.8 μmol/L for EUS-BD and PTBD, respectively; P = 0.002) at the 7-d follow-up. There were no significant differences observed in the complication rates between PTBD and EUS-BD (3.3 *vs* 3.8). PTBD was associated with a higher adverse event rate than EUS-BD in all the procedures, including reinterventions (80.4% *vs* 15.7%, respectively)

and a higher index procedure (39.2% *vs* 18.2%, respectively).

CONCLUSION
The findings of this systematic review revealed that EUS-BD is linked with a higher rate of effective BD and a more manageable procedure-related adverse event profile than PTBD. These findings highlight the evidence for successful EUS-BD implementation.

Key Words: Percutaneous transhepatic cholangiography; Endoscopic ultrasound; Biliary drainage; Obstructive cholangiopathy

Core Tip: Endoscopic transpapillary biliary drainage (BD) is the preferred approach for biliary decompression in patients with unresectable pancreatic cancer and obstructive jaundice. We conducted a systematic review of studies comparing the technical aspects and outcomes of two distinct approaches for BD: Endoscopic ultrasound-guided BD (EUS-BD) and percutaneous transhepatic BD (PTBD). The evaluation of six studies that fulfilled the inclusion criteria revealed that PTBD was associated with more reinterventions, postprocedural pain, and late adverse events compared with EUS-BD. Both procedures were associated with a significant reduction in the total bilirubin levels at the 7-d follow-up, and there were no significant differences in the complication rates between the two procedures. In summary, EUS-BD was associated with a higher rate of effective BD and manageable procedure-related adverse events compared with PTBD, highlighting its utility in successful BD.

INTRODUCTION

Endoscopic transpapillary biliary drainage (BD) is the preferred approach for biliary decompression in patients with unresectable pancreatic cancer and obstructive jaundice[1]. Percutaneous transhepatic cholangiography (PTC) is a diagnostic and therapeutic procedure that involves inserting a needle into the biliary tree, followed by immediately inserting a catheter to achieve percutaneous BD. During the procedure, contrast is injected into one or more bile ducts (cholangiography) and sometimes into the duodenum. PTC can be performed using fluoroscopic guidance alone or using both fluoroscopic and ultrasound guidance[2,3].

In cases of suspected malignant biliary stricture, imaging alone may not be sufficient to provide a precise diagnosis. PTC was first introduced several decades ago to visualize biliary obstructions, treat malignant obstructive jaundice palliatively, and access BD[4]. Fine needle aspiration (FNA), brush cytology, and forceps biopsy have been performed using percutaneous biliary catheterization during PTC since the 1980s[5]. For biliary stenosis, endoscopic retrograde cholangiopancreatography (ERCP) has recently been recognized as a reliable diagnostic and therapeutic procedure.

Endoscopic retrograde BD (ERBD) is the most commonly used method of biliary decompression in patients with blockage of the distal central bile duct. This technique has a success rate of 90%-95% in the United States[6]. Altered anatomy, presenting pathology (tumor infiltration, impacted stone, and duodenal compression by a pancreatic pseudocyst), previous surgery, or variations in normal anatomy (periampullary diverticula and tortuous ducts) can contribute to the failure of ERBD. The failure rate of ERBD is 6%-7% in cases with obstructive jaundice caused by a blockage or altered anatomy[7]. Percutaneous transhepatic BD (PTBD) has a lower risk of complications than surgical decompression, but it is associated with complications such as fistula formation, repeat intervention, recurrent infection, and the requirement for long-term external catheter drainage, which contribute to a low quality of life [8]. Although PTBD is associated with severe morbidity and mortality, the only relative contraindication of PTBD is perihepatic ascites[6-9]. Furthermore, PTBD usually requires separate surgery after the failure of ERCP BD, thereby increasing the morbidity associated with biliary stasis.

Endoscopic ultrasound-guided BD (EUS-BD) has become more widely used as an alternative to PTBD in patients with anatomical abnormalities, which make endoscopic transpapillary insertion of a biliary stent difficult[10]. It offers advantages of being compatible with anatomic internal drainage, being more comfortable, and resulting in a recovery associated with fewer complications and reduced expenditure [11].

EUS is an extremely useful imaging method for examining the gastrointestinal luminal wall and surrounding tissues. The proximity of the EUS probe to the area of interest enables high-resolution imaging and EUS-guided FNA tissue collection in real time. EUS has become a crucial diagnostic technique due to its high-quality imaging and FNA capacity and is also used as a treatment tool. However, until recently, its use was limited to the introduction of various drugs[12,13]. The therapeutic uses of EUS have been expanded due to larger channel echoendoscopes, which combine the benefits of real-time ultrasound and fluoroscopy imaging with the use of ERCP-based devices and procedures, such as EUS-BD. In 1996, Wiersema *et al*[14] first reported EUS-guided diagnostic cholangiography and in 2001, Giovannini *et al*[10] first reported EUS-BD in a patient with pancreatic cancer, establishing a choledochoduodenal fistula with a needle knife followed by transduodenal stenting.

These early reports were followed by modified techniques and expanded indications, such as EUS-guided hepatic gastrostomy with stent placement[15], transduodenal EUS-rendezvous (EUS-RV) biliary access[16], and EUS-guided choledocholithiasis therapy with the creation of a neo papilla[17]. Since then, several studies have reported modifications to these techniques, including the use of a covered metal stent as a conduit for interventional endoscopic procedures in the bile duct[18,19]. Few studies have compared EUS-BD and PTBD in failed ERCP cases in terms of success rate and adverse event profile[20]; therefore, we performed a systematic review of the relevant literature to investigate the combined efficacy and adverse effects of EUS-BD and PTBD.

MATERIALS AND METHODS

Literature search

This systematic review was conducted using an electronic search of different databases, including PubMed, Embase, clinicaltrials.gov, the Cochrane library, Scopus, and Google Scholar using the guidelines for Preferred Reporting Items for Systematic reviews and Meta-Analyses[21]. Two investigators independently searched for the following key terms: all field "failed EUS", all field "Percutaneous biliary drainage", and all field "EUS-guided biliary drainage". All the three search headings were connected using the Boolean operator "AND". Studies published in English comparing PTBD with EUS-BD were chronologically limited to those published from their inception to October 2021. After completing the literature search, the references were imported to Endnote citation manager (Endnote X9) for removing any duplicates, following which the abstracts were screened for potential relevance by two independent investigators. This study included intervention studies, retrospective or prospective observational studies, case reports, randomized controlled trials, and published abstracts that reported at least some adverse events. And this study also cited high-quality articles in Reference Citation Analysis (https://www.referencecitationanalysis.com).

Letters, comments, seminar proceedings, and animal studies were excluded from our analysis. Moreover, only human studies were included and limited to the English language. Publications judged to be potentially relevant underwent a full text assessment by two independent investigators to determine their inclusion. Disagreements regarding study eligibility were resolved by consensus or adjudication between the investigators.

Data extraction

The baseline study details, including study identifiers, such as first author, publication year, title, and country, and study-specific methodological data, such as sample size, study design, single-center *vs* multicenter study types, and healthcare setting, are presented in Table 1. Technical and clinical success rates, including the total number of patients enrolled, number of patients in each arm, mean age, sex ratio, comorbidity index, mean preprocedural bilirubin, mean diameter of the bile duct, etiology of biliary obstruction, and reasons for EUS failure are shown in Table 2.

Risk of bias evaluation

The GRADE checklist was used to evaluate the risk of bias in the included studies[22]. Table 3 shows a summary of the methodological qualities of studies reporting the prevalence data. Questions were answered as "yes", "no", "unclear", or "not applicable".

RESULTS

Our literature search yielded 315 manuscripts, of which 132 studies remained after excluding duplicate studies. After reviewing the title and abstract, only nine articles were left for the thorough screening of data by reviewing the full text. Further, two studies were eliminated after reading the manuscripts because they included primary EUS-BD cases wherein EUS was not attempted as the primary procedure. The third study was excluded, as it did not contain full text. A total of six studies met the abovementioned inclusion criteria of the study[23-28] (Figure 1).

DISCUSSION

The most common method for gaining access to the biliary tree is ERCP. In patients with unmodified upper gastrointestinal anatomy, the success rate of bile duct cannulation using ERCP is > 90%[25]. Affected or variant anatomy, ampullary pathology (stones, stenosis, and tumor infiltration), periampullary diverticulum, gastric outlet obstruction, indwelling duodenal stent, and previous gastric bypass surgery are the prevalent causes of failed cannulation[29]. The rate of adverse outcomes associated with PTBD and surgery is extremely high, although these approaches are traditionally used to treat these clinical conditions[30]. The most prevalent issues related to long-term PTBD therapy are drain blockage, dislocation, and cholangitis, which require multiple interventions and longer hospital stays[31]. Moreover, patients are left with a permanent external drain, resulting in poor quality of life[32]. EUS-BD has emerged as a viable, extremely safe, effective, and minimally invasive approach[33]. Using echoendoscopy and fluoroscopy, the biliary tree is accessed from the gastrointestinal lumen, a fistulous tract is created, and a stent is deployed in a single step, eliminating the need for an external drain[34]. However, the rates of success and adverse events associated with EUS-BD remain unclear. The use of EUS-BD was first reported by Giovannini *et al*[10] in 2001. Subsequently, several studies reported the

efficacy of EUS-BD as an alternative BD method after a failed ERCP. The EUS-BD procedures are divided into three techniques: (1) EUS-RV; (2) EUS-guided antegrade (EUS-AG); and (3) EUS-guided transluminal BD, including EUS-guided choledochoduodenostomy (EUS-CDS) and EUS-guided hepaticogastrostomy (EUS-HGS)[6]. In EUS-RV, the biliary duct is accessed using fluoroscopy and EUS, forming a temporary fistula, followed by guidewire placement into the duodenum *via* the biliary duct and ampulla. After guidewire placement, ERCP is performed using the EUS-placed guidewire, which is removed once biliary cannulation is obtained. Thus, EUS-RV should be performed in patients with an endoscopically accessible ampulla after unsuccessful biliary cannulation using conventional ERCP.

In EUS-AG, the intrahepatic biliary duct is accessed by creating a temporary fistula between the intestine and intrahepatic biliary duct from the upper intestine. Stent placement or balloon dilation is performed after the dilation of the fistula to achieve biliary obstruction through the fistula without reaching the ampulla using the endoscope. This technique is appropriate when reaching the biliary orifice using endoscopy is impossible or unmanageable, such as in biliary obstruction in patients with surgically altered anatomy or upper intestinal obstruction.

In EUS-guided transluminal BD, including EUS-CDS and EUS-HGS, the biliary duct is accessed followed by guidewire placement and fistula dilation under EUS guidance. For BD, a permanent fistula is created by inserting the stent between the biliary duct and the intestine. This procedure can be performed in cases where reaching the biliary orifice using endoscopy is possible or accessible; however, in patients with unresectable malignant biliary obstruction, its indication should be limited given the features of permanent fistula creation.

Recent studies have demonstrated that EUS-BD could be an alternative to PTBD in patients with inoperable malignant biliary blockage and failed ERCP. However, individual study outcomes show inconsistent results. We performed a systemic analysis to aggregate information from individual trials

and examine the overall outcomes of EUS-BD compared with PTBD. EUS-BD was associated with a lower rate of adverse events compared with PTBD. The healthcare cost of PTBD was twice that of EUS-BD due to the high reintervention rate in the PTBD group. A retrospective study by Sharaiha *et al*[28] reported that the technical success rate was comparable between PTBD and EUS-BD in patients with inoperable malignant biliary obstruction and inaccessible papilla. In a retrospective study examining patients with incurable malignant biliary obstruction with failed ERCP due to an inaccessible papilla, Bapaye *et al*[24] found that the EUS-BD group had a higher success rate of BD (92% *vs* 46%, respectively, $P > 0.05$) and a lower rate of adverse events than the PTBD group (20% *vs* 46%, respectively, $P = 0.05$) [24]. These results were partially due to the use of EUS-BD in high-volume centers by experienced endoscopists. The rates of success and the complications of EUS-BD are expected to improve with technical advances.

In the present systematic review, the only randomized controlled study comparing EUS-BD and PTBD in patients with inoperable malignant biliary blockage was conducted by Artifon *et al*[8]. The study, which included 13 patients in the EUS-BD group and 12 patients in the PTBD group, reported that EUS-BD and PTBD were comparable in terms of cost, adverse events, and clinically meaningful improvements in bilirubin levels. The bilirubin levels in the EUS-BD group declined from 16.4 μmol/L to 3.3 μmol/L, whereas the bilirubin levels in the PTBD group declined from 17.2 μmol/L to 3.3 μmol/L [8]. The postprocedural follow-up period was 7 d in both the groups. Choi *et al*[32] reported a higher technical success rate in the PTBD group than in the EUS-BD group, although the functional success rate was comparable between the two groups[35].

In most facilities, PTBD is used as an alternative technique in cases of failed ERCP. In high-volume clinics, endoscopic ultrasound-guided gallbladder drainage has begun replacing PTBD, which was developed only a decade ago as the fourth approach for biliary decompression after surgical drainage, percutaneous transhepatic drainage, and endoscopic transpapillary drainage[36]. Although the type of BD approach used in cases of failed ERCP is currently determined by local competence, EUS-BD is a less intrusive and more physiologic technique. This approach improves nutrition absorption, prevents electrolyte loss, reduces reinterventions, and eliminates the stress of external drainage[37]. EUS-BD can also be performed in a single setting before ERCP if the patient agrees.

However, EUS-BD is associated with several specific issues. Only a small number of centers have the operational skills to perform EUS-BD, whereas most centers have extensive experience and skills to perform PTBD, and interventional radiologists are well-trained and equipped to perform PTBD[25]. The inherent risk of advanced endoscopy necessitates specialized training. Therefore, EUS-BD can only be performed in high-volume treatment institutions with adequate interventional radiology and surgical backup to prevent complications such as bile leak, pneumoperitoneum, hemorrhage, and stent migration[38,39].

The invasion of the sterile biliary tree by transmural puncture from the luminal side of the gastrointestinal tract poses a modest theoretical risk of infection in EUS-BD[40]. However, such negative events should improve with the further evolution of this technique. Despite its classification as a rescue

treatment for failed ERCP, primary EUS-BD is currently compared with ERCP, and a recent study indicated similar short-term outcomes between EUS-BD and ERCP[41]. In addition, unlike ERCP, there is no risk of pancreatitis following EUS-BD. Furthermore, the clinical success rates and complications do not differ between EUS-BD and ERCP if performed by skilled endoscopists. The current systematic review revealed that EUS-BD was safe and effective when performed by skilled individuals, with a lower risk of adverse events and similar technical and clinical success rates.

Our analyses also indicated that: In patients with inoperable biliary blockage after a failed ERCP, EUS-BD was associated with a higher chance of successful BD and a lower risk of procedure-related adverse effects and infectious complications compared with PTBD. Furthermore, the number of patients with bile leaks was lower in the EUS-BD group than in the PTBD group.

CONCLUSION

Several case reports, series, and retrospective investigations regarding EUS-BD have been published to date. However, no prospective studies or comparisons of the various BD systems have been published; therefore, the technical success, functional success, adverse events, and stent patency of EUS-BD with long-term follow-up remain unknown. Prospective, randomized controlled studies are required to clarify these issues. However, it is clear that EUS-BD is clinically useful as a BD option. EUS-BD could become a first-line BD treatment instead of ERCP if the outcomes of clinical studies are positive and technologies are simplified.

ARTICLE HIGHLIGHTS

Research background

Percutaneous transhepatic cholangiography is a diagnostic and therapeutic procedure. Endoscopic ultrasound-guided biliary drainage (EUS-BD) is a novel technique that allows BD whose technicality, success rate, and outcomes are not negligible.

Research motivation

We aimed to compare the technical details and outcomes of 132 studies concerning interventional BD procedures in patients with obstructive cholangiopathy. We conducted a systematic review of six studies that met the inclusion criteria.

Research objectives

To assess the suitability and appropriability of different clinical biliary interventions in achieving optimal BD for obstructive cholangiopathy.

Research methods

An extensive systematic review was independently conducted by two investigators using an electronic search of different databases, including PubMed, Embase, clinicaltrials.gov, the Cochrane library, Scopus, and Google Scholar, using the guidelines for Preferred Reporting Items for Systematic reviews and Meta-Analyses to identify studies comparing percutaneous transhepatic BD (PTBD) and EUS-BD.

Research results

PTBD patients underwent significantly more reinterventions (4.9 *vs* 1.3), experienced more postprocedural pain (4.1 *vs* 1.9), and experienced more late adverse events (53.8% *vs* 6.6%) than EUS-BD patients. There was a significant reduction in the total bilirubin levels in both the groups (16.4-3.3 μmol/L and 17.2-3.8 μmol/L in the EUS-BD and PTBD groups, respectively; $P = 0.002$) at the postprocedural 7-d follow-up. There were no significant differences in the complication rates between the PTBD and EUS-BD groups (3.3 *vs* 3.8). PTBD was associated with a higher adverse event rate than EUS-BD in all the procedures, including reinterventions (80.4% *vs* 15.7%, respectively) and a higher rate of index procedure (39.2% *vs* 18.2%, respectively).

Research conclusions

EUS-BD might be considered as a first-line BD treatment instead of PTBD if the outcomes of clinical studies are favorable and the technical approach is simplified.

Research perspectives

EUS-BD following failed ERCP was superior to PTBD in patients with obstructive cholangiopathy.

Abstract

BACKGROUND

Sinusoidal obstruction syndrome has been reported after oxaliplatin-based chemotherapy, but liver fibrosis and non-cirrhotic portal hypertension (NCPH) are rarely reported.

CASE SUMMARY

Here, we describe the case of a 64-year-old woman who developed isolated gastric variceal bleeding 16 mo after completing eight cycles of oxaliplatin combined with capecitabine chemotherapy after colon cancer resection. Surprisingly, splenomegaly and thrombocytopenia were not accompanied by variceal bleeding, which has been reported to have predictive value for gastric variceal formation. However, a liver biopsy showed fibrosis in the portal area, suggesting NCPH. The patient underwent endoscopic treatment and experienced no further symptoms.

CONCLUSION
It is necessary to guard against long-term complications after oxaliplatin-based chemotherapy. Sometimes splenic size and platelet level may not always accurately predict the occurrence of portal hypertension.

Key Words: Non-cirrhotic portal hypertension; Sinusoidal obstruction syndrome; Isolated gastric varices; Oxaliplatin chemotherapy; Colon cancer; Case report

Core Tip: The occurrence of portal hypertension after oxaliplatin chemotherapy is mostly considered to be related to sinusoidal obstruction syndrome, and few studies clearly support non-cirrhotic portal hypertension (NCPH). We present a case of isolated gastric variceal bleeding after oxaliplatin chemotherapy. The pathological results support NCPH.

INTRODUCTION

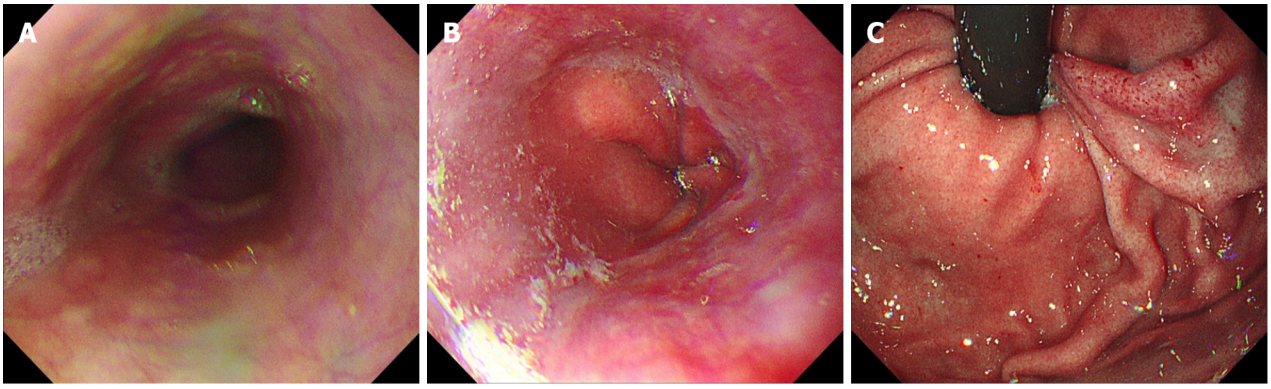
The third-generation platinum anticancer drug, oxaliplatin, is often used in combination with 5-fluorouracil or capecitabine as one of the main chemotherapy strategies for neoadjuvant/adjuvant treatment of stage III and metastatic colon cancer[1]. Oxaliplatin can induce different degrees of liver injury, from mild to acute liver failure, and sinusoidal obstruction syndrome (SOS) is a characteristic manifestation. In addition, chronic injury from endothelial cell damage and architectural distortion may develop nodular regenerative hyperplasia (NRH) and non-cirrhotic portal hypertension (NCPH) years after chemotherapy[2]. As a result, there are manifestations of portal hypertension, such as splenomegaly, thrombocytopenia, ascites, and esophagogastric varices. Since these complications occur long after chemotherapy completion, clinicians may not attribute these findings to oxaliplatin. Here, we report the case of a 64-year-old woman who was treated with eight cycles of oxaliplatin combined with capecitabine after radical resection of the right colon for ascending colon cancer. Isolated gastric variceal bleeding was diagnosed and treated endoscopically, but there was no obvious accompanying splenomegaly, thrombocytopenia, or broadened portal vein. The liver biopsy was indicative of NCPH.

CASE PRESENTATION

Chief complaints

A 64-year-old woman was transferred to our hospital on account of hematemesis and melena.

History of present illness



The patient complained of hematemesis and melena 2 d prior to presentation. She underwent hemostasis and rehydration at the previous hospital. Colonoscopy and gastroscopy were successively performed, and severe gastric varices were found before administration.

History of past illness

Laparoscopic radical resection of right colon cancer had been performed 16 mo earlier due to ascending colon cancer (pT4N2Mx). Preoperative gastroscopy did not show any abnormalities (Figure 1). She received eight cycles of oxaliplatin combined with capecitabine for 6 mo postoperatively. No tumor recurrence was found after intermittent re-examination.

Personal and family history

The patient had no known history of liver disease. She had no history of habitual use of alcohol and no significant history of exposure to liver injury-inducing drugs other than chemotherapy.

Figure 1 Gastroscopic images taken before colon cancer surgery. A: Upper esophageal segment; B: Lower esophageal segment; C: The gastric fundus. No varices were found.

Physical examination

The patient's temperature was 36.6°C, heart rate was 93 bpm, respiratory rate was 16 breaths per minute, blood pressure was 125/65 mmHg, and oxygen saturation in room air was 98%. The patient had an anemic appearance and pale palpebral conjunctiva. No signs of chronic liver disease, such as palmar erythema and spider nevus, were found. No significant enlargement of the liver or spleen was detected on palpation.

Laboratory examinations

Blood examination indicated severe anemia with normal levels of leukocytes and platelets. Prothrombin time was normal with a slight increase in plasma D-dimer level. Liver function test indicated mild hypoproteinemia with normal transaminase and bilirubin levels; renal function was normal. Liver tests were negative for hepatitis viruses; autoimmune liver diseases; and metabolic liver diseases, such as hepatolenticular degeneration and hemochromatosis (Table 1).

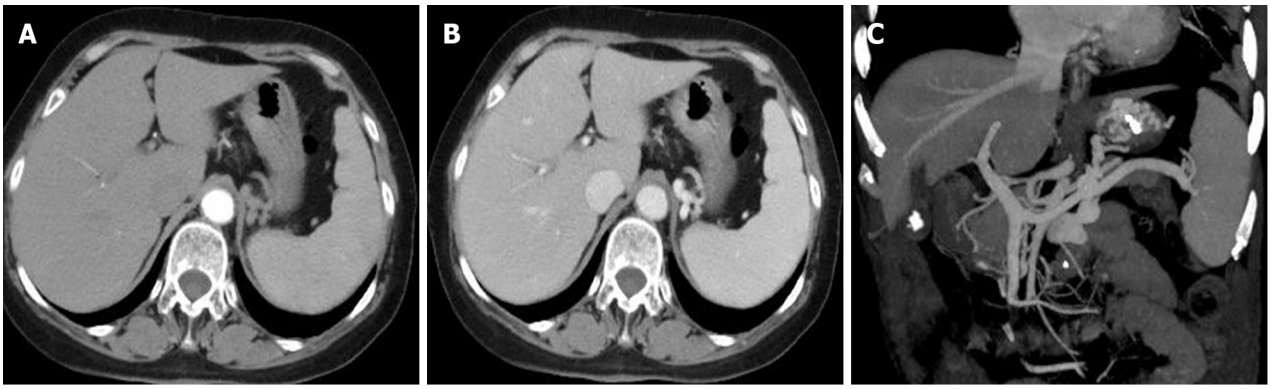
Imaging examinations

An enhanced computed tomography (CT) scan of the abdomen and pelvis showed postoperative changes of the colon, an irregular liver contour, slightly enlarged spleen, low-grade fatty liver, and varices in the gastric fundus with gastro-renal shunting (Figure 2). Contrast-enhanced ultrasonography showed that the size of the spleen was 4.2 cm × 11.2 cm. The diameter of the retropancreatic splenic vein was 0.67 cm with a mean blood flow velocity of 33.0 cm/s and volume flow of 528.7 mL/min.

Pathological examination

A transjugular liver biopsy was performed, and the hepatic venous pressure gradient (HVPG, wedged hepatic venous pressure – free hepatic venous pressure) was measured as 15 mmHg. Liver biopsy showed that the hepatic lobule was essentially complete with sinusoidal dilatation, and no pseudolobular formation was observed. Hepatocyte nuclear size slightly varied. Focal perisinusoidal fibrosis could be observed in the hepatic central vein area, which showed a diffuse distribution of necrotic hepatocytes engulfed by phagocytes. There were slight inflammatory reactions in hepatic portal areas, with slight fibrosis in the interstitium and around the bile duct. The vascular wall of the portal vein was thickened, indicating portal hypertension, and the final pathological diagnosis considered NCPH (Figure 3).

FINAL DIAGNOSIS



The final diagnosis of the presented case was NCPH due to oxaliplatin.

TREATMENT

After admission, the patient was immediately administered with octreotide (50 μg/h, iv, for 72 h), proton pump inhibitor, omeprazole (8 mg/h, iv, for 72 h), and hemocoagulase. An erythrocyte suspension of volume, 400 mL, was transfused. Gastroscopy after cessation of active gastrointestinal bleeding revealed severe isolated gastric varices in the fundus of the stomach, Lg-f, F3, Cb, and RC2

Table 1 Clinical indicators

Routine examination		Biochemical examination		Immune examination	
White blood count	11.95 x 10^9/L	Alaninetransaminase	1831 U/L	Hepatitis B surface antigen	(-)
Red blood count	1.9 x 10^{12}/L	Aspartate transaminase	31 U/L	Hepatitis C antibody	(-)
Hemoglobin	60 g/L	Alkaline phosphatase	103 U/L	Antinuclear antibody	(-)

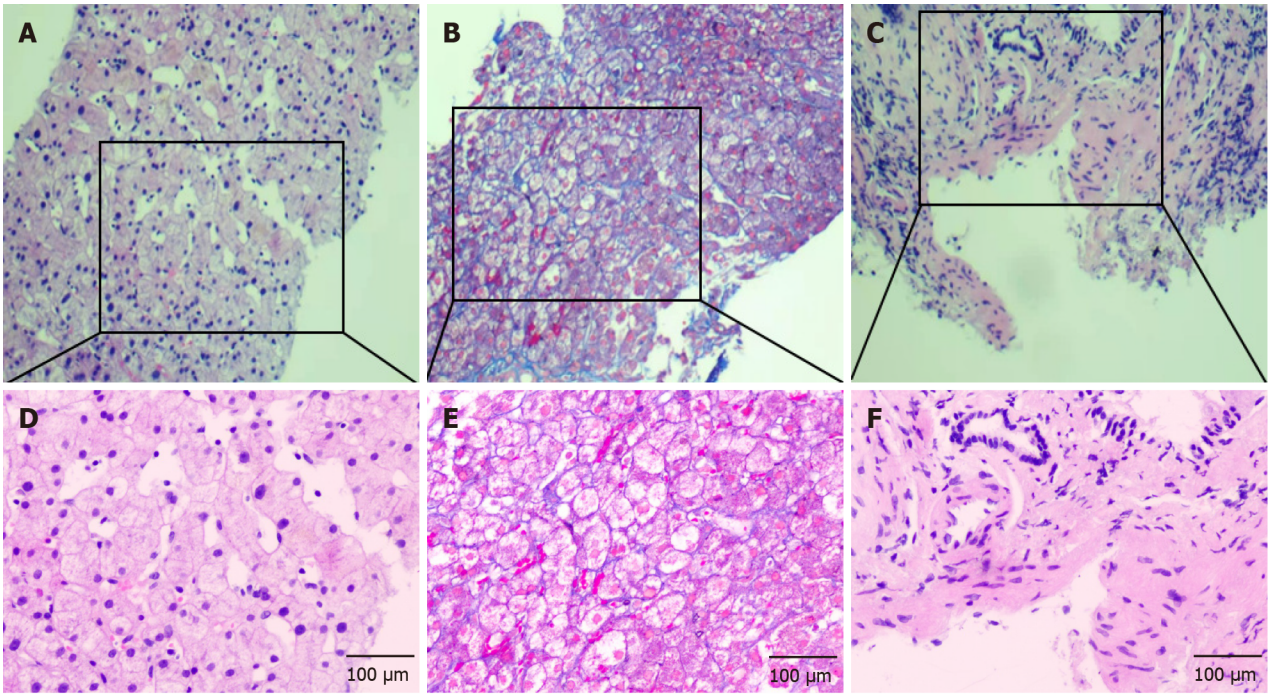
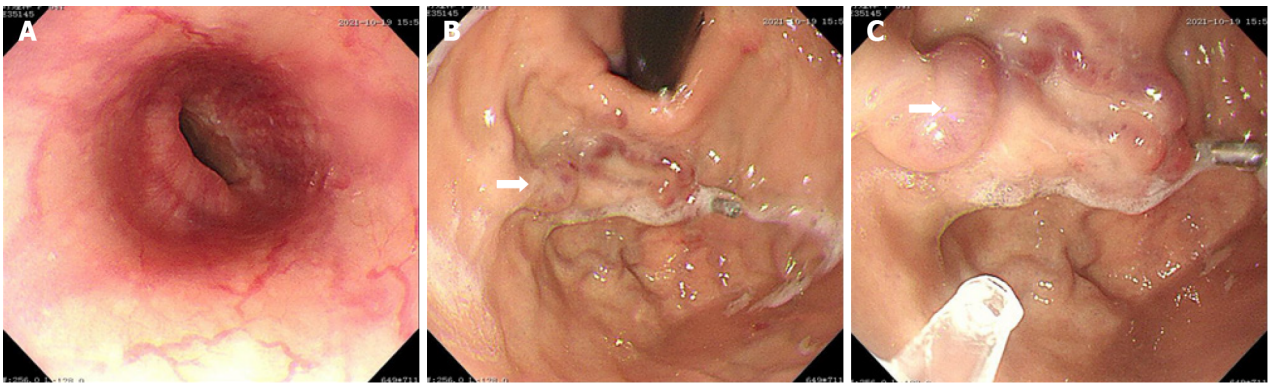
Figure 2 Abdominal enhanced computed tomography images. A: Arterial phase; B: Portal vein phase. There was no atrophy or cirrhotic features, and the liver parenchyma density was uniform; C: 3D vascular reconstruction of portal vein system. The blood flows of the portal and retropancreatic splenic veins were unobstructed without obvious widening of the inner diameters. Severe gastric fundal varices were clearly visible.



(Figure 4). Cyanoacrylate glue was injected.

OUTCOME AND FOLLOW-UP

The patient had an uneventful postoperative clinical course. Therefore, she was discharged 7 d after operation. Beta blockers were not administered because the patient' s mean heart rate was 58 ± 6 bpm. During a follow-up visit 2 mo after the operation, signs of anemia was absent and a new gastroscopy showed varices in fundus of stomach relieved obviously.



DISCUSSION

As one of the main chemotherapeutic agents for stage III and metastatic colon cancer, oxaliplatin is widely used in chemotherapy. Common side effects of oxaliplatin are neurotoxicity, gastrointestinal reactions, and hematological toxicity. In recent years, SOS has received more attention as a long-term complication of oxaliplatin use, and its reported incidence rate ranges from 19% to 52%[3,4]. SOS is an obliterative venulitis of the terminal hepatic venules, which is characterized by jaundice, right upper quadrant pain, tender hepatomegaly, ascites, and unexplained weight gain. SOS usually occurs as a result of cytoreductive therapy prior to hematopoietic stem cell transplantation. In China, it is often associated with the oral intake of plants that contain pyrrolidine alkaloids. This patient did not have any

significant history of exposure to liver injury-inducing drugs other than chemotherapy. Therefore, the liver damage was considered to be directly related to oxaliplatin-containing chemotherapy.

The mechanism by which oxaliplatin causes hepatic sinusoidal injury is relatively clear. The inflammation caused by oxaliplatin can increase the expression of many cytokines and chemokines[5], leading to atrophy and apoptosis of hepatocytes around the hepatic sinusoids, which decreases the supporting capacity. Oxidative stress[6] and glutathione depletion[7] caused by oxaliplatin metabolism could destroy the integrity and permeability of liver sinusoidal endothelial cells (LSECs). Necrotic LSECs and red blood cells can then form emboli with platelets, which causes obstruction and expansion of the hepatic sinusoids, leading to SOS. LSECs produce cytokines and inflammatory factors, such as interleukin-6, platelet-derived growth factor, tissue inhibitor of metalloproteinase, matrix metalloproteinases, and vascular endothelial growth factor. These activate hepatic stellate cells to increase collagen levels in the extracellular matrix, ultimately leading to hepatic fibrosis[8] that can progress to NRH, NCPH, and portal sclerosis in subsequent years.

In the pathological examination of our patient, there was an obvious expansion of the hepatic sinusoids with fibrosis in the hepatic sinusoids and portal areas. The lack of typical SOS manifestations, such as intrasinusoidal hemorrhage, thrombosis, and obstruction, suggested NCPH. This pathological manifestation was similar to that described by Ryuta *et al*[9]. In that case, esophageal and gastric varices were found 3.5 years after the termination of oxaliplatin-based chemotherapy, compared to 16 mo in this report. Both patients developed long-term portal complications after chemotherapy completion. Vigano *et al*[10] analyzed liver injury reversibility after the interruption of chemotherapy and reported that SOS may resolve within 9 mo. Therefore, we suspected that the sinusoidal injury in this patient was not enough to cause typical clinical presentations of SOS, which had gradually recovered after chemotherapy termination. However, fibrosis persisted in the hepatic sinusoids and portal areas, resulting in portal hypertension and severe gastric variceal bleeding.

NCPH etiology can be divided into five groups: infection, immune disorders, thrombophilia, genetic defect, and exposure history of drugs or poisons[11]. Currently, drugs that can reportedly induce NCPH include difenoxin, azathioprine, mercaptopurine, and allopurinol[12,13]. A recent study proposed that oxaliplatin is related to NCPH[2]. The main clinical manifestations of NCPH are esophagogastric varices, splenomegaly, thrombocytopenia, and ascites, with the first being the most common[14]. Park *et al*[15] investigated the predictors of portal hypertension formation related to oxaliplatin use and found that noninvasive fibrosis prediction models including, the age-platelet index, aspartate aminotransferase-to-platelet ratio index, platelet-to-spleen ratio, and fibrosis-4 score, have good predictive values. Satta *et al*[16] reported that platelet count and spleen index under CT correlated with esophagogastric variceal formation. These indicators are often used to screen whether patients need gastroscopy because they are easily obtained. However, in this case, the patient had severe isolated gastric varices accompanied by gastro-renal shunting. No obvious increase in splenic volume or thrombocytopenia during or after chemotherapy was observed, and no widening of the portal vein was observed on enhanced CT, which was different from common esophagogastric varices related to oxaliplatin. These findings exemplify why diagnoses may be missed. Apparently, gastroscopy was not performed during follow-up after surgery and chemotherapy, which is why the varices were not discovered until bleeding occurred.

Notably, NCPH is considered as pre-sinusoidal portal hypertension. Therefore, HVPG in patients with NCPH may not exactly reflect portal hypertension with measurements lower than those in patients with liver cirrhosis. A retrospective study reported that the average HVPG of patients with NCPH was 8.3 ± 4.5 mmHg, 60% of patients had normal or slightly elevated HVPG (≤ 10 mmHg), and 40% of patients had HVPG > 11 mmHg[14]. The HVPG level in our patient was 15 mmHg, which was significantly higher than normal, possibly due to hepatic sinusoidal injury and peri-sinusoidal fibrosis.

Ligation and cyanoacrylate glue injection under gastroscopy are the first-line treatment options for esophageal and gastric variceal bleeding in liver cirrhosis[17], but whether they are appropriate for esophageal and gastric variceal bleeding related to NCPH remains controversial. A previous study reported that the effect of endoscopic therapy in preventing variceal rebleeding in patients with NCPH is not ideal, compared to its effect in preventing hepatitis B cirrhosis-related portal hypertension[18]. Due to good functional liver reserve in patients with NCPH, transjugular intrahepatic portosystemic shunt (TIPS) treatment has a lower rebleeding rate, and the incidence and mortality of postoperative hepatic encephalopathy are lower[19]. For these reasons, TIPS may be used as the first-line treatment for esophageal and gastric variceal bleeding due to NCPH.

However, this report describes a patient with NCPH who underwent colon cancer resection. Therefore, it is necessary to guard against the possibility of malignant tumor recurrence and maintain good liver function, in case reoperation and additional chemotherapy rounds are required. Liver compensation ability may decrease after TIPS treatment. Instead, gastroscopic therapy was performed with successful cyanoacrylate glue injection, and the patient was discharged.

CONCLUSION

Oxaliplatin can cause hepatic sinusoidal injury and SOS, which could lead to portal hypertension years later. Splenomegaly and thrombocytopenia have a certain predictive value for SOS occurrence in patients who previously received chemotherapy, but few unique cases remain in the clinic. The formation of esophageal and gastric varices is the only manifestation of portal hypertension; therefore, these patients are likely to be misdiagnosed. Therefore, gastroscopy should be considered as part of follow-up after oxaliplatin-based chemotherapy.

Abstract

Different serological and virological markers in chronic hepatitis B patients guide staging of viral infection, and initiation and response to therapy. Due to the persistence of intrahepatic covalently closed circular DNA (cccDNA) in the hepatocyte nucleus, hepatitis B is not curable. Even after undetectable hepatitis B virus DNA levels, the persistence of hepatitis B surface antigen and novel markers such as hepatitis B core-related antigen (HBcrAg) indicate the persistence of intrahepatic cccDNA. In this study, HBcrAg levels at baseline and after 24 and 48 wk of antiviral therapy predicted hepatitis B e antigen seroconversion. Due to the poor sensitivity of assays and detectable levels in HBsAg-negative patients, the long-term utility of HBcrAg needs future research.

Key Words: Hepatitis B core-related antigen; Chronic hepatitis B; Covalently closed circular DNA; Hepatitis B e antigen seroconversion; Hepatitis B virus DNA; Pregenomic RNA

Core Tip: This study highlights the predictive role of hepatitis B core-related antigen (HBcrAg) levels at baseline, and after 24 and 48 wk of antiviral therapy for hepatitis B e antigen seroconversion in chronic hepatitis B patients. The issues related to poor sensitivity of assays and detectable levels in hepatitis B surface antigen-negative patients are major concerns. Future research on the utility of HBcrAg in hepatitis B virus (HBV) flare after nucleotide cessation, occult HBV reactivation, and risk of developing hepatocellular carcinoma is also needed.

TO THE EDITOR

We read with interest the study titled, "Serum hepatitis B core-related antigen as a surrogate marker of hepatitis B e antigen seroconversion in chronic hepatitis B" by Chi *et al*[1] in the World Journal of Gastroenterology. Hepatitis B core-related antigen (HBcrAg) and hepatitis B virus (HBV) RNA are potential serological markers of chronic hepatitis B infection and activity. In the HBV life cycle, intrahepatic covalently closed circular DNA (cccDNA) is transcribed into five RNAs of which pregenomic RNA is a precursor to synthesis of the viral genome by reverse transcription and precore mRNA is precursor to proteins hepatitis B core antigen. Hepatitis B e antigen (HBeAg) and p22cr are collectively called HBcrAg due to their identical 149 amino acid sequences. In addition, viral sequences also integrate in the host genome and can express hepatitis B surface antigen (HBsAg). Therefore, HBsAg quantification may not be exactly reflective of intrahepatic cccDNA levels. On the other hand, only cccDNA can express the viral genome. In real world settings, liver biopsy is not feasible for cccDNA quantification and a surrogate marker is needed in serum for intrahepatic cccDNA quantification. HBcrAg-related proteins can be detected in Dane particles, HBV DNA-negative Dane particles, and possibly in HBV RNA-containing virions[2]. Interestingly, nucleotide analogues (NAs) inhibit DNA polymerase and viral replication; they do not affect production of viral intermediate proteins such as HBcrAg. Therefore, even on antiviral treatment, HBcrAg can reflect cccDNA quantity and activity in hepatocytes.

This study determined the predictive role of HBcrAg for HBeAg seroconversion in chronic hepatitis B (CHB) patients. All patients were analyzed for HBcrAg, HBV RNA, and HBV DNA levels in blood and cccDNA quantification in liver biopsy specimen. Although there is treatment heterogeneity with two different cohorts of entecavir (n = 109) and pegylated-interferon (PEG-IFN) (n = 30) therapy, the authors found baseline HBcrAg levels correlating with cccDNA levels in patients with and without HBeAg seroconversion. However, the PEG-IFN group only had 30 patients, and as IFNs are immunomodulators that increase innate immune response in controlling HBV infection with higher HBeAg seroconversion rates compared to NA therapy, it may be premature to conclude that it only affects viral replication and not the production of other viral proteins. Therefore, some bias may be related to treatment heterogeneity.

This study also highlights that serum qHBcrAg levels at 24 and 48 wk of treatment better predict HBeAg seroconversion than qHBcrAg levels at baseline. Song *et al*[3] showed baseline HBcrAg levels < 4.9 log U/mL, > 2 log reduction of HBcrAg at week 28 having a positive predictive value 74% and 76%, and negative predictive value of 96% and 94%, respectively, for the prediction of spontaneous HBeAg seroconversion. In HBeAg-positive CHB patients, HBcrAg is high in the immune tolerant phase compared to the immune clearance phase. And in HBeAg-negative patients, lower HBcrAg levels are present in the inactive carrier state than in HBeAg-negative CHB. Recently Ghany *et al*[4] demonstrated a correlation of HBV RNA and HBcrAg levels with HBV DNA in different phases of CHB infection.

Wong *et al*[5] demonstrated that correlation coefficients of serum HBV DNA and HBcrAg with intrahepatic cccDNA are 0.7 and 0.64-0.7, respectively, which are similar; however, in patients on antiviral therapy with undetectable serum HBV DNA, HBcrAg is the preferred marker for estimating intrahepatic cccDNA levels. Tseng *et al*[6] recently showed risk stratification of development of cirrhosis, and its complications and liver-related mortality in CHB patients over a period of 15.9 years by baseline HBcrAg levels. Carey *et al*[7] showed that HBcrAg and HBV RNA predict clinical flares in HBeAg-negative CHB patients with suppressed HBV DNA levels on nucleotide analogue therapy. Together, HBcrAg is a promising novel serum marker but with many limitations. First, with current available assays, the lower limit of detection is 2 log U/mL, so more sensitive assays are needed. Second, one study found detectable serum HBcrAg in 40% patients with HBsAg seroclearance[8]. Finally, large-scale studies in different ethnic groups are needed to determine the predictive value of HBcrAg with certain cut-off values in clinical practice especially occult HBV reactivation, HBV flare after nucleotide analogue cessation, and risk of hepatocellular carcinoma development.

Abstract

Hepatocellular carcinoma (HCC) is the most common type of liver cancer worldwide. Viral hepatitis is a significant risk factor for HCC, although metabolic syndrome and diabetes are more frequently associated with the HCC. With increasing prevalence, there is expected to be > 1 million cases annually by 2025. Therefore, there is an urgent need to establish potential therapeutic targets to cure this disease. Peroxisome-proliferator-activated receptor gamma (PPARγ) is a ligand-activated transcription factor that plays a crucial role in the patho-physiology of HCC. Many synthetic agonists of PPARγ suppress HCC in experimental studies and clinical trials. These synthetic agonists have shown promising results by inducing cell cycle arrest and apoptosis in HCC cells and preventing the invasion and metastasis of HCC. However, some synthetic agonists also pose severe side effects in addition to their therapeutic efficacy. Thus natural PPARγ agonists can be an alternative to exploit this potential target for HCC treatment. In this review, the regulatory role of PPARγ in the pathogenesis of HCC is elucidated. Furthermore, the experimental and clinical scenario of both synthetic and natural PPARγ agonists against HCC is discussed. Most of the available literature advocates PPARγ as a potential therapeutic target for the treatment of HCC.

Key Words: Anticancer; Hepatocellular carcinoma; Natural agonists; Peroxisome proliferator-activated receptor-γ; Thiazolidinediones

Core Tip: Hepatocellular carcinoma (HCC) is the most common type of liver cancer worldwide. Viral infections and metabolic syndrome are the major risk factors for HCC, and its incidence is expected to increase to > 1 million cases annually by 2025. The crucial role of peroxisome-proliferator-activated receptor gamma (PPARγ) in HCC pathophysiology makes it a potential therapeutic target. Along with synthetic agonists, natural PPARγ agonists provide alternative and safer options for HCC treatment; however, they need to be validated clinically. This review discusses the regulatory role of PPARγ in HCC pathogenesis and experimental and clinical scenarios of PPARγ agonists in HCC treatment.

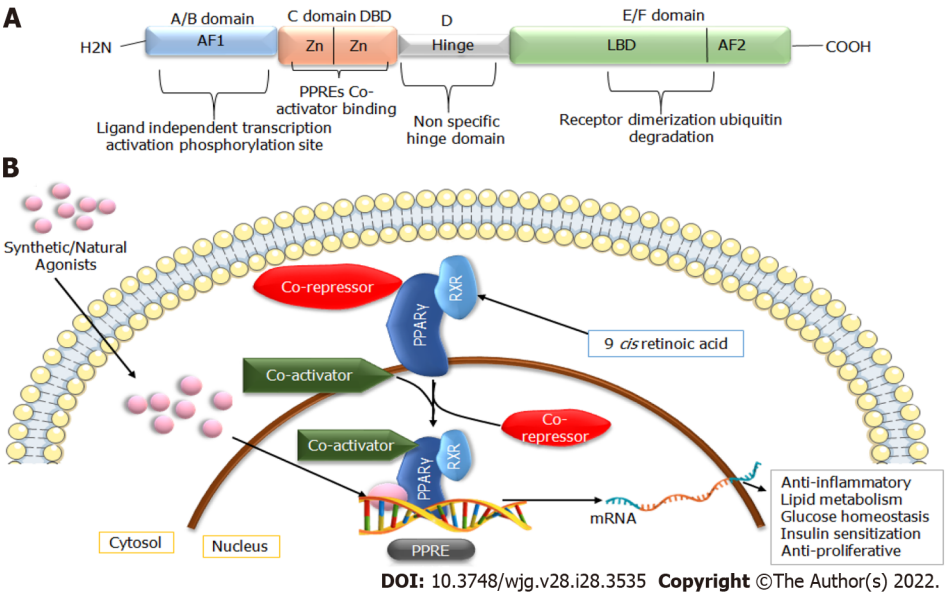
INTRODUCTION

Liver cancer is the sixth most common cause of cancer-related death worldwide, with a higher prevalence in men than women. Hepatocellular carcinoma (HCC) incidence was expected to increase to > 1 million individuals annually by 2025[1]. HCC, a primary subtype of liver cancer, primarily occurs in Asia and Africa due to the high prevalence of hepatitis B virus (HBV), hepatitis C virus, and diabetes [2]. These conditions are linked to the inflammatory response in the liver, leading to the development of HCC. Furthermore, other conditions such as obesity, dietary mycotoxin exposure, and excessive alcohol consumption are also among the risk factors for the development of HCC. These factors lead to the development of cirrhosis in 70%-80% of HCC patients. Liver transplantation is currently the best option for curing HCC, but there is a limitation to the availability of donors[3]. During the last two decades, the understanding and management of HCC have changed dramatically due to the extensive basic and clinical research, which may further help to reveal potential targets for the treatment of HCC. Sorafenib is the first-line defense therapy approved by the United States food and Drug Administration (FDA) for the advanced stages of HCC. It is a type of multikinase inhibitor that shows tumor-suppressing activity *via* targeting vascular endothelial growth factor receptor, adenosine monophosphate-activated protein kinase (AMPK), and platelet-derived growth factor receptor[4]. Apart from their therapeutic potential, sorafenib shows acquired resistance in HCC cells. The low response rate indicates that patients sensitive to sorafenib during the treatment will develop resistance within 6 mo. These negative impacts of approved drugs prompted many researchers to find novel drugs or targets to cure HCC[5].

Peroxisome proliferator-activated receptor gamma (PPARγ) is a ligand-activated nuclear receptor activated by synthetic and natural agonists[6]. It is highly expressed in adipose tissue, where it plays a central role in regulating adipose tissue function. Many studies have established the role of PPARγ in the pathophysiology of HCC. *In vitro* and *in vivo* data have shown the inhibitory role of PPARγ activation in tumor cell growth, migration, and invasion suggesting its therapeutic role in the growth regulation of HCC[7,8]. The antitumor effects of PPARγ are fulfilled by various mechanisms, including the induction of cell cycle arrest and activation of genes/proteins involved in immune and inflammatory responses[9]. Previous reports have revealed the mechanism underlying the development of HCC and suggested the presence of PPARγ in human HCC tissues, which shows a dose-dependent decrease in the growth of HCC cell lines[10]. Thus, molecules modulating PPARγ signaling pathways will provide a novel solution for the effective treatment of HCC. This review focuses on the role of PPARγ in the HCC pathophysiology and the experimental and clinical status of PPARγ agonists in the treatment of HCC.

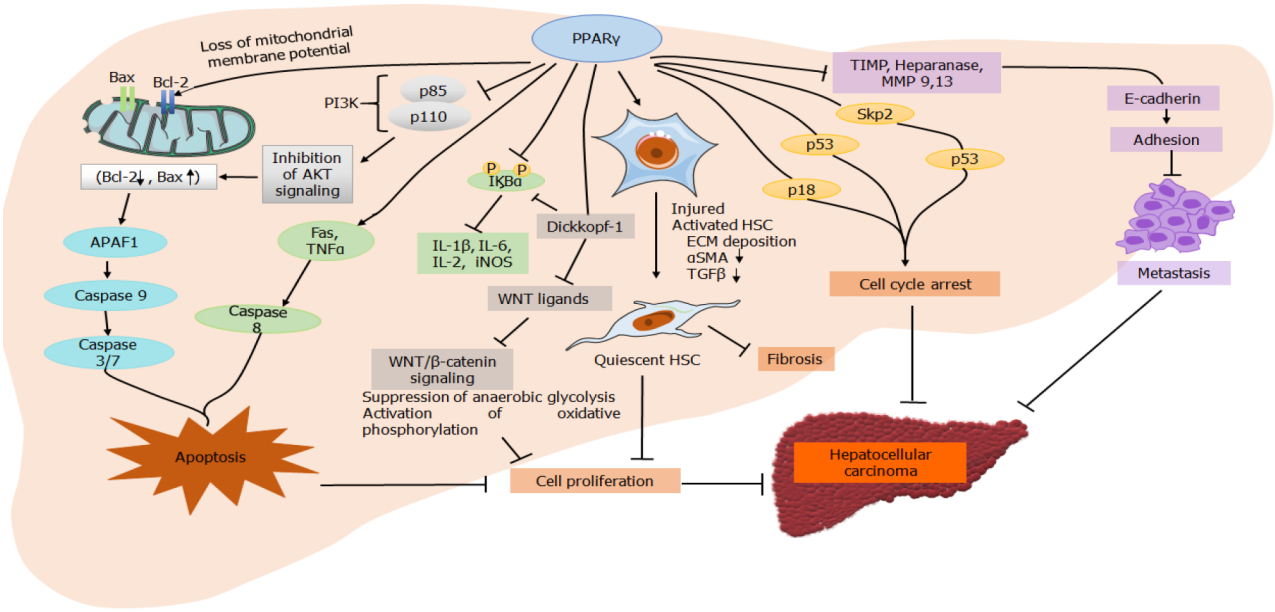
MOLECULAR ARRANGEMENT OF PPARγ



The PPARs protein belong to the superfamily of nuclear hormone factors containing 48 members. PPARs were mainly recognized for their proficiency in promoting peroxisome proliferation in the liver, and their expression is mainly regulated in response to ligand binding[11]. Three isoforms of PPARs, namely PPARα, PPARγ, and PPARδ, have been studied to a large extent. Of these isoforms, PPARγ is highly expressed in adipose tissue, where it plays a vital role in regulating lipid homeostasis, energy balance, adipogenesis, and inflammation. Due to the presence of different promotor regions and 5′ exons, PPARγ has three distinct mRNAs (PPARγ1, PPARγ2, and PPARγ3). The translation products of PPARγ1 and PPARγ3 yield identical proteins; however, PPARγ2 results in a product with an additional N-terminal region[12]. PPARγ1 and PPARγ3 are biologically expressed in different tissues (hepatocytes, muscles, and endothelial cells), whereas PPARγ2 is only widely expressed in adipose tissue[9,13]. PPARγ plays a significant role in maintaining metabolic alterations, inflammation, glucose homeostasis,

cell cycle regulation, differentiation, and migration, making it a potential therapeutic target for treating metabolic disorders and cancers[14]. The structural arrangement of PPARs is similar to steroid and thyroid hormone receptors. Its ligand-binding cavity is 3- to 4 -times higher than that of the other nuclear receptors. They can be activated by various natural and synthetic agonists, such as essential fatty acids[15,16]. The three-dimensional structure of PPARγ consists of a canonical domain shared with other nuclear receptors, named A-E from N to C terminus (Figure 1). These domains include the amino-terminal AF-1 domain, a DNA-binding domain with two zinc finger motifs, and a ligand-binding domain (LBD or E/F domain) at the C-terminus responsible for specific ligand binding at the peroxisome proliferator response element (PPRE)[16,17]. After interaction with specific ligands, the LBD facilitates the heterodimerization of PPARs with retinoid X receptor (RXR), which subsequently binds to the PPRE of the target gene. RXR is activated by the natural ligand 9-cis-retinoic acid receptor and synthetic retinoids receptors. However, in the absence of specific ligands, heterodimers bind with co-repressors, ultimately inhibiting the gene[12]. This complex subsequently recruits coactivation or co-repressors to regulate the expression of targets genes related to lipid glucose metabolisms and inflammation (Figure 1)[6].

ROLE OF PPARγ IN HCC



PPARγ plays a multifunctional role in many tissues and cell types such as adipocytes, pancreas, macrophages, liver, kidney, and skeletal muscle. It plays a regulatory role in adipocyte differentiation, lipid metabolism, and insulin sensitivity *via* downregulating leptin concentration[7]. Despite the low expression in the healthy liver, PPARγ plays a significant role in several hepatic conditions such as fatty liver, fibrosis, and HCC. Many *in vitro* and *in vivo* studies have reported that natural and synthetic PPARγ agonists inhibit tumor growth and cell migration in HCC[18]. The activation of PPARγ inhibits cell growth by inducing G0/G1 cell cycle arrest in HCC cells, which is suggested to be associated with p21, p27, and p18 upregulation (Figure 2). Furthermore, p27 upregulation downregulates S-phase kinase-associated protein-2 (Skp2) in HCC, an F-box protein component of the Skp, Cullin, F-box ubiquitin-ligase complex. p27 plays a vital role in G0/G1 arrest instead of p21[10,19]. The direct overexpression of PPARγ in hepatic cancerous cells also inhibits cell growth; however, the cells are arrested in the G2/M phase instead of the G0/G1 phase after PPARγ agonist treatment. G2/M phase arrest in PPARγ overexpression is attributed to activating cell division cycle 25C phosphatase by Ser216 phosphorylation and preventing premature mitosis[20]. Compared to wild-type mice, another study on PPARγ-deficient mice showed increased hepatocarcinogenesis after treatment of diethylnitrosamine (DENA). Growth differentiation factor 15 (GDF 15) is a target gene of PPARγ and is induced by its activation. GDF 15 overexpression in many cancers is associated with an antitumorigenic response, as it was suggested to reduce cancer cell viability and induce cell apoptosis. PPARγ activation by agonist or direct overexpression induces apoptosis by intrinsic and extrinsic pathways[21]. Activation of the extrinsic apoptosis pathway by PPARγ overexpression is attributed to the induction of tumor necrosis factor α (TNFα) and Fas, leading to the activation of downstream caspases (Figure 2). In the intrinsic pathway, PPARγ overexpression stimulates B-cell lymphoma 2 (Bcl-2)-associated X protein transcription and release into the cytosol, activating apoptotic protease activating factor 1 and caspase-9 complex, which further triggers caspase 3 and 7 to induce apoptosis[6,21]. The antitumorigenic effect of PPARγ in HCC is also suggested *via* modulation of the phosphoinositide 3-kinase (PI3K)/Akt pathway [22]. PPARγ activation attenuates p85 activation, which is essential for Akt induction, thus inhibiting PI3K/Akt signaling and inducing apoptosis[23].

Hepatic inflammation is crucial in the progression of HCC, and PPARγ plays a central role in regulating inflammation. PPARγ inhibits inflammation by interfering with nuclear factor-kappa B (NF-κB) and suppressing the production of proinflammatory cytokines (TNFα and interleukin 1 beta [IL-1β]). Activation of PPARγ by specific ligands in T-cell differentiation promotes an inflammatory response, thereby playing a significant role in the adaptive immune response. Thus, PPARγ act as an important therapeutic target for regulating inflammatory markers (TNFα, IL-2, IL-1β, and IL-6) against the progression of several diseases[7,16]. Hepatic stellate cell (HSC) activation and fibrogenic factor significantly contribute to the development of HCC (Figure 2). PPARγ is highly expressed in quiescent HSCs and has a role in their transdifferentiation. HSC activation and PPARγ are inversely related as increased expression of PPARγ inhibits HSC proliferation and induces apoptosis in activated HSCs[24]. It also reduces the expression of alpha-smooth muscle actin (αSMA) and hydroxyproline to inhibit hepatic fibrosis. Hepatic injury induces microvascular complications in the liver, stimulating various sinusoidal cells such as HSCs, liver sinusoidal endothelial cells, and Kupffer cells. PPARγ regulates the role of these cells in liver inflammation and fibrosis. The deactivation of HSCs by PPARγ agonists further reduces extracellular matrix deposition and expression patterns of matrix metalloproteinase (MMP)/tissue inhibitors of MMPs (TIMP). The expression of MMP9 and MMP13, TIMP, heparinase, and E-cadherin is associated with cancer cell migration and metastasis[25]. The expression patterns of these markers are directly linked to PPARγ activation. Reports also link PPARγ activation with autophagy in HCC. Autophagy is thought to be inhibited after autophagosome formation in the absence

Figure 2 Schematic diagram showing the protective effect of peroxisome proliferator-activated receptor γ against the progression of hepatocellular carcinoma. Activated peroxisome proliferator-activated receptor γ (PPARγ) interacts with multiple pathways, leading to cell cycle arrest, apoptosis, inhibition of cell proliferation, and cell metastasis in hepatocellular carcinoma. BAX: B-cell lymphoma 2 (Bcl-2)-associated X protein; IκBα: Nuclear factor of kappa light polypeptide gene enhancer in B-cells inhibition alpha; IL: Interleukin; TIMP: Tissue inhibitor of metalloproteinases; MMP: Matrix metalloproteinase; ECM: Extracellular matrix; αSMA: Alpha-smooth muscle actin; TGFβ: Transforming growth factor beta; iNOS: Inducible nitric oxide synthase; TNFα: Tumor necrosis factor alpha; APF1: Apoptotic protease activating factor 1.

of PPARγ, resulting in increased light chain 3 protein expression and accumulation of p62 in the autophagosome[26,27]. Therefore, induction of autophagy in HCC is linked to the activation of PPARγ in HCC. A recent study elucidated the role of PPARγ coactivator-1α (PGC1α) in suppressing HCC metastasis. The levels of PGC1α were downregulated in human HCC and associated with a poor prognosis, large tumor size, and vascular invasion[28]. However, PGC1α overexpression in the HCC cells inhibited tumor cell migration and invasion. The suppression of metastasis by PGC1α overex-

pression was suggested due to PPARγ-dependent downregulation of pyruvate dehydrogenase kinase isozyme 1 and inhibition of aerobic glycolysis through Wnt/β-catenin/pyruvate dehydrogenase kinase-1 (PDK1) axis regulation[29].

Zinc finger protein 746 (ZNF746) is a Parkin-interacting substrate (PARIS), acting as a transcriptional regulator of PPARγ co-activator 1 alpha (PGC1α) which further regulates the activity of PPARγ and is involved in the onset of HCC. The elevated levels of insoluble parkin with PARIS accretion in the hepatic cells of diethylnitrosamine (DEN)-injected mice were observed with the downregulation of PGC1α and NRF1. Moreover, Chang liver cells treated with hydrogen peroxide showed PARIS accretion and alleviation of PGC1α. As the co-activator, PGC1α is directly linked to PPARγ regulation, further monitoring the oncogenic stress promoting cancer development. Thus, the modulation of PPARγ and its co-activators can be a promising therapeutic target for HCC[30]. In a clinical study, it was subsequently observed that the expression of PGC1α is negatively associated with tumor size and vascular influx. The increased expression of PGC1α could elevate the degree of oxidative phosphorylation, further slowing down the rate of metastasis and the Warburg effect of HCC cells[31]. Rapid proliferation is the prime feature of cancerous cells for which cells need to meet the high energy demand through the aerobic glycolysis pathway rather than the pyruvate oxidation pathway. The canonical Wnt/β-catenin signaling was also targeted to observe the expression of PDK1 in the PGC1α knockdown model by employing two popular inhibitors of this signaling pathway (XAV-939 and ICG-001). Gene Set Enrichment Analysis indicated that these inhibitors alleviate the overexpression of extracellular lactate, suggesting the possible role of PGC1α in the inhibition of aerobic glycolysis *via* Wnt/β-catenin signaling. Dual-luciferase reporter assays showed that the transcriptional actions of PPARγ are significantly increased in HCCLM3 and MHCC97H cells with PGC1α augmentation. These results show that the tumor-suppressive activity of PGC1α depends on PPARγ, which makes PPARγ a key regulator of HCC[29,32]. An earlier report revealed the role of PPARγ in HCC by analyzing the mRNA and protein expression in 20 patients with cirrhosis and chronic hepatitis. The results indicated a statistically pronounced drop in levels of PPARγ in HCC compared to the non-tumorous liver tissue[33]. A report confirmed that miR-130b aids cell aggressiveness by suppressing PPARγ in human HCC[34]. Similarly, evidence on the oncogenic role of miR-1468 in HCC *via* activating the PPARγ/Akt pathway was also recently confirmed. The increased levels of miR-1468 elevated the malignant prognostic features and improved survival. Carboxy-terminal domain 2 and UPF1 RNA Helicase And ATPase were identified as the downstream targets for miR-1468, which regulate PPARγ/Akt pathway activation. Restoration of the expression of these targets partially abolished the effects of miR-1468, explaining the regulation *via* PPARγ/Akt signaling[35].

EXPERIMENTAL AND CLINICAL SCENARIOS

Many studies have explored the therapeutic effects of synthetic and natural PPARγ agonists against HCC in preclinical and clinical trials. The activation of PPARγ significantly suppresses HCC progression and invasion. Several findings have identified PPARγ as a target for tumor suppression, a mediator of apoptosis, and a suppressor of carcinogenesis and metastasis by triggering intrinsic pathways and mainly inhibiting the PI3K/Akt survival pathway[8,21,36]. The various synthetic and natural PPARγ agonists used for HCC are listed in Table 1.

SYNTHETIC PPARγ AGONISTS IN HCC

PPARγ itself and its agonists have anticancer activities, such as growth inhibition, induction of apoptosis, and cell differentiation. Thiazolidinediones (TZDs) are a class of synthetic PPARγ agonists, and many compounds of this class have been studied for their efficacy in experimental models and clinical trials. These compounds were used as a bioregulatory remedial approach to target the communicative framework of HCC in patients with non-curative HCC[37]. TZDs are also effective for glycemic control and the likelihood of HCC and hepatic manifestation in diabetic patients with chronic hepatitis B (CHB). Of the 28999 patients with CHB, 3963 patients developed HCC at a median follow-up of 7.1 years, whereas 1153 patients were administered TZD during the follow-ups. The findings showed the co-relation of TZD use with lowering the risk of poor hepatic manifestations in diabetic patients with CHB[38]. A population-based case-control study performed in 23580 diabetic patients demonstrated the negative relationship between the risk of HCC and use of TZDs. There is a time-dependent effect of TZD use on the risk of HCC. The longer the duration of TZD use, the lower the risk of HCC[39-41]. Many other reports have also suggested that the administration of PPARγ agonists ameliorates several types of cancers, *i.e.* colorectal, bladder, lung, and liver cancers. The effects are more substantial at higher cumulative dosages with longer durations[42].

Table 1 Various synthetic and natural peroxisome-proliferator-activated receptor gamma agonist used in experimental and clinical trials for hepatocellular carcinoma

Agonist name	Drug bank/ PubChem ID	Model	Concentration/dose of agonist	Effects	Ref.
Synthetic agonists					
Pioglitazone	DB01132	*In vivo* (Rats, and Mice)	3 mg/kg; 10 mg/kg	Reduced HCC progression and decreased tumor size and volume	[44]
Rosiglitazone	DB00412	*In vivo* (Orthotopic Mice) *In vitro* (MHCC97L, and BEL-7404)	50 μmol/L	Decreased HCC migration, and invasiveness	[25]
		In vitro (HepG2 and PC3)	0.1, 1, 10, 100 μmol/L	Reduced cancer growth, Increased apoptosis	[49]
		In vitro (HepG2 and Hep3B)	80 μmol/L	Restricted the oncogenic activity of SEPT2	[50]
Telmisartan	DB00966	*In vitro* (HLF, HLE, HuH-7, PLC/PRF/5, and HepG2)	10, 50 or 100 μmol/L	Inhibit proliferation, induce cell cycle arrest	[53]
		In vivo (Mice)	15 mg/kg	Reversed malignant anomalies, antioxidant, anti-inflammatory	[54]
Troglitazone	DB00197	*In vitro* (Hep G2, HuH-7, KYN-1, and KYN-2)	5, 10, 25 μmol/L	Reduced cell proliferation and increased apoptosis	[56]
		In vitro (HepG2)	5, 10, 20, 40, 80, and 100 μmol/L	Apoptosis and growth inhibition	[57]
		In vitro (Hep G2, HuH-7, KYN-1, and KYN-2)	5, 10, and 25 μmol/L	Inhibited DNA synthesis, cell cycle growth, and α-fetoprotein levels	[58]
		In vitro (PLC/PRF/5, and HuH-7)	5, 10, 20, 40, 60, 80, and 100 μmol/L	Reduced cell proliferation and increased apoptosis	[59]
		In vitro (HLF, HAK-1A, HAK-1B, and HAK-5)	10, 20, 30, 40, and 50 μmol/L	Reduced cell proliferation and increased apoptosis	[19]
Saroglitazar	DB13115	*In vivo* (Mice)	4 mg/kg	Reduced inflammation in hepatic lobules, hepatocellular ballooning, and steatosis	[61]
		In vivo (Rats)	4 mg/kg	Improved lipid profile, and histopathological changes	[62]
Natural agonists					
Cannabinol, Cannabinoids	DB14737	*In vitro* (HepG2 and HUH-7); *In vivo* (Mice)	8 μmol/L; 15 mg/kg	Increased apoptosis, autophagy, anti-proliferative	[66]
		In vitro (HEK-293T and Neuro-2a); *In vivo* (Mice)	1, 5, 10, 25 μmol/L; 20 mg/kg	Antitumor, antioxidant, anti-inflammatory	[68]
Capsaicin	DB06774	*In vivo* (Rats)	0.5 and 1 mg/kg	Inhibit hepatic injury, and collagen deposition, anti-inflammatory	[71]
Curcumin	DB11672	*In vivo* (Rats)	20 mg/kg	Attenuated histopathological, serological, proliferative, and apoptotic parameters	[77]
		In vitro (H22); *In vivo* (Mice)	5, 10, 20, 40, and 80 μmol/L; 50, 100 mg/kg	Antiproliferative, decrease tumor growth, induce apoptosis	[78]
		In vivo (Mice)	150 mg/kg	Reduced inflammation, and tumor size	[79]
		In vivo (Rats)	0.5, 1, 2, 5, 10, 15, and 20 ng/mL	Interrupted TGFβ signaling, activated hepatic stellate cells	[80]
		In vitro (SMMC7721 and Huh-7)	10, 20, 40, 80, and 160 μmol/L	Suppressed cellular proliferation	[82]
Hesperidin	DB04703	*In vivo* (Rats)	50 and 100 mg/kg	Suppressed TGFβ signaling and hepatocarcinogenesis	[85]
		In vivo (Rats)	200 mg/kg	Inhibited PI3K/Akt pathway, Antioxidant	[86]

		In vitro (HepG2); *In vivo* (Rats)	100 μmol/L; 150 mg/kg	Inhibited Wnt3a/5a signaling pathway, anti-inflammatory	[87]
Hispidulin	DB14008	*In vitro* (SMMC7721 and Bel7402); *In vivo* (mouse tumor xenograft)	10 and 20 μmol/L; 20 and 40 mg /kg	Anticancerous, inhibited cell migration	[89]
		In vitro (NCI-H460 and A549)	4, 8, 15, 30, and 60 μmol/L	Induced ROS-mediated apoptosis, anti-cancerous	[90]
Isoflavone	DB12007	*In vivo* (Bel-7402 and SK-Hep-1)*In vivo* (Mice)	75 and 12 μmol/L resp.; 25 and 7.5 mg/kg resp.	Anti-inflammatory, anti-tumorigenic, reduced the size and volume of tumor	[94]
		In vitro (Hepa 1-6 cells)	1, 5, 10, 15, 20, 25, 50, 75, and 100 μmol/L	Antitumorigenic and antiproliferative	[95]
		In vitro (HCC-LM3, SMMC-7721, Hep3B, Bel-7402, and Huh-7)*In vivo* (Mice)	40, 60, and 80 μmol/L; 20, 40, and 80 mg/kg	Suppressed aerobic glycolysis and increased apoptotic rate	[96]
Oroxyloside	14655551	*In vitro* (HepG2) and SMMC-7721); *In vivo* (Mice)	100, 200, and 300 μmol/L; 90 mg/kg	Cell cycle arrest and growth repression	[100]
Resveratrol	DB02709	*In vivo* (Rats)	100 mg/kg	Antioxidant, anti-inflammatory, anticancer	[101]
		In vitro (HepG2); *In vivo* (Rats)	7.81, 15.63, 31.25, 62.5, 125, and 250 μg/mL; 20 mg/kg	Attenuated histopathological, serological, proliferative, and apoptotic parameters	[102]
Miscellaneous					
Avicularin	5490064	*In vitro* (HuH-7)	25, 50, and 100 μg/mL	Decreased the cell migration and invasiveness	[107]
Honokiol	72303	*In vitro* (HEK-293 and 3T3-L1); *In vivo* (Mice)	1, 3, and 10 μmol/L; 100 mg/kg	Activated PPARγ/RXR heterodimers; Reduced hyperglycemia	[108]
Chrysin	DB15581	*In vitro* (MDA-MB-231 and HepG2)*In vivo* (Mice)	10 μmol/L; 10 mg/kg	Increased apoptosis	[112]
Quercetin	DB04216	*In vitro* (HepG2 and SMCC-7721); *In vivo* (Mice)	0.05, 0.1, and 0.15 mmol/L; 40 mg/kg	Promoted the autophagy	[114]
		In vitro (PATU-8988 and PANC-1)	20, 40, 80, and 160 μmol/L	Suppressed HCC *via* STAT3 pathway	[117]
		In vitro (LM3); *In vivo* (Mice)	40, 80, and 120 μmol/L; 100 mg/kg	Reduced invasiveness, Cell cycle regulation	[118]
Clinical trials					
		Population type	No. of patients		
Thiazolidinediones	NA	Hongkong	1153	Reduce the synergistic effect of diabetes with liver disorders; Reduced risk of HCC	[38],[39], [40],[41]
		Taiwanese	77396		
			32891		
			76349		
Pioglitazone	DB01132	Chinese	75	Blocked RAGE signaling; Reduced HCC	[45]
		Japanese	85	Reduced growth and invasion of HCC cells	[46]
		Thai	10000	Reduced risk of HCC	[47]
Rosiglitazone	DB00412	French	44	Reduced NASH activity and ballooning score, Ameliorated histopathological aberrations	[51]
Saroglitazar	DB13115	Indian	30	Improved glycemic index and liver stiffness	[63]
			90	Improved fibrosis score	[64]

Isoflavone	DB12007	Japanese	302	Antioxidant, reduced risk of HCC	[97]
			191	Antioxidant, reduced risk of HCC	[98]

Akt/PKB: Protein kinase B; HCC: Hepatocellular carcinoma; NASH: Non-alcoholic steatohepatitis; PI3K: Phosphoinositide 3-kinase; PPARγ: Peroxisome proliferator-activated receptor gamma; RAGE: Receptor for advanced glycation end products; ROS: Reactive oxygen species; RXR: Retinoid X receptor; SEPT2: Septin 2; STAT3: Signal transducer and activator of transcription 3; TGFβ: Transforming growth factor beta; Wnt: Wingless-related integration site.

Pioglitazone

Pioglitazone (PGZ), a PPARγ ligand, works by improving the insulin sensitivity of tissues and exhibits anticancer activity. It selectively stimulates PPARγ *via* modulating the transcriptional alterations of genes involved in glucose metabolism and insulin resistance and further decreasing the gluconeogenesis and levels of glycated hemoglobin in the bloodstream[43]. PGZ treatment inhibits fibrosis progression and HCC development and reduces tumor size in DENA-induced rats at 3 mg/kg and mice at 10 mg/kg. PGZ is suggested to exhibit protective effects by reducing mitogen-activated protein kinase (MAPK) and upregulating adiponectin levels, resulting in activation of the hepatoprotective AMPK pathway[44].

The anticancer activity of PGZ is attributed to the pathological receptors for advanced glycation end products (RAGE). HCC tissues from 75 patients showed high expression of RAGE in HCC tissues, which was closely linked to pathological staging and lymph-vascular space influx. However, PGZ treatment suppressed cellular proliferation, ameliorated apoptosis, and cell cycle arrest, which further elevated PPARγ expression and decreased the expression of RAGE, NF-κB, high mobility group box 1, p38MAPK Ki-67, MMP2, and cyclin D1. The results demonstrated that PGZ as a PPARγ agonist possibly slows down the growth and invasion of HCC cells by blocking RAGE signaling[45]. Another prospective study confirmed the effect of PGZ on HCC by investigating 85 patients with HCC and hepatitis C virus infection to investigate recurrence-free survival. The spline-model analysis showed that the lessened risk of HCC recurrence is associated with increased body weight and body mass index ≥ 23. PGZ was also observed to alleviate insulin resistance and serum adiponectin levels[46]. A lifetime Markov model was employed among the population of Thailand to study the life expectancy, quality-adjusted life years, lifetime costs, and the incremental cost-effectiveness ratios in HCC patients. The weight reduction program with the administration of PGZ demonstrated that PGZ can reduce the number of HCC cases[47]. These therapeutic potentials also have limitations. PGZ has adverse effects such as body weight gain, peripheral edema, bone loss, and heart failure. Additionally, the risk of bladder cancer significantly limits the use of this agonist in the medical field[48].

Rosiglitazone

Rosiglitazone is a member of the TZD class of insulin-sensitizing PPARγ agonists. An inhibitory effect of PPARγ was reported on the invasive and metastatic potential of HCC *in vitro* (MHCC97L and BEL-7404 cell lines) and *in vivo* (orthotopic HCC mouse model). A pronounced expression of PPARγ was demonstrated in HCC cell lines treated with adenovirus-expressing mouse PPARγ1 (Ad-PPARγ), rosiglitazone (50 μmol/L), or Ad-PPARγ plus rosiglitazone. The induction of PPARγ markedly repressed HCC cell migration, invasiveness, levels of pro-metastatic genes (MMP9, MMP13, heparanase [HPSE]), and hepatocyte growth factor. However, the levels of cell adhesion genes (E-cadherin and SYP), extracellular matrix regulator TIMP3, and tumor suppressor gene retinoblastoma 1 were elevated. Additionally, direct transcriptional regulation of the genes TIMP3, MMP9, MMP13, and HPSE regulating PPARγ levels was also validated by chromatin immunoprecipitation-PCR[25]. Bcl-2 is a well-known family of anti-apoptotic proteins regulating endogenous apoptotic pathways and are highly expressed in carcinomas. (-)-gossypol ((-)-G) is the (-) enantiomer of gossypol that acts as a small molecule to induce apoptosis in several types of cancers by inhibiting Bcl-2 proteins. In a study, rosiglitazone was employed to sensitize (-)-G to induce apoptosis at different concentrations (0.1, 1, 10, 100 μmol/L). The (-)-G induced Mcl-1 (myeloid cell leukemia-1) stability was the prime concern for its apoptotic activity. However, rosiglitazone attenuated this stability *via* Janus kinase phosphorylation, further repressing cancer growth. These results suggest that rosiglitazone can reduce cancer growth and sensitize the other apoptotic factors for performing a similar activity. The study also provides insights into the novel cancer therapeutic activity of BH3 mimetics in the case of carcinomas based on the combination of PPARγ agonists and BH3 mimetics[49]. Rosiglitazone (80 μmol/L) also inhibits HCC cell growth by restricting the oncogenic activity of septin 2[50].

A long-term clinical trial was conducted in which 53 patients underwent liver biopsies and were further treated with rosiglitazone (8 mg/d) for the next 2 years. Forty-four patients fulfilled the criteria of the extension period and underwent another biopsy. During the extension phase, serum insulin and alanine aminotransferase (ALT) levels were decreased by 26% and 24%, respectively. Non-alcoholic steatohepatitis activity, ballooning, and fibrotic stage were decreased but not on a significant scale. The treatment was continued for another 2 years, but no significant results were obtained, showing that rosiglitazone does attenuate insulin sensitivity and transaminase levels but might not significantly

improve other histopathological parameters. However, additional targets were suggested to be explored [51]. However, there is increasing evidence of bone fractures in females medicated with rosiglitazone after menopause, limiting its use. In September 2010, the FDA restricted the use of rosiglitazone based on meta-analyses of mostly short-term randomized controlled trials, which showed evidence of myocardial infection risk. However, these restrictions were removed in 2013 based on other large clinical trials by Duke Clinical Research Institute, which showed no complications regarding heart failure[52].

Telmisartan

Telmisartan (TEL) is an angiotensin II receptor blocker with a high affinity for the angiotensin II receptor type 1, whose impromptu link with HCC has been discovered; however, the underlying mechanism is not clear. TEL shows basal resemblance with a well-known PPARγ agonist, PGZ. TEL (at concentrations of 10, 50, or 100 μmol/L) inhibits the proliferation and G0 to G1 cell cycle transition leading to G0/G1 cell cycle arrest in hepatic cancer cells (HLF, HLE, HuH-7, PLC/PRF/5, and HepG2) in a dose-dependent manner. The cell cycle arrest was accompanied by reduced cell cycle-related proteins, including cyclin D1 and cyclin E. Further TEL was suggested to increase the activity of AMPK and inhibit the mammalian target of rapamycin (mTOR) pathway[53]. Another study used a DENA-induced HCC mouse model to evaluate the effects of TEL (15 mg/kg), sorafenib (SRF) (30 mg/kg), and a combination of these two agonists. The treatment downregulated the mRNA expression of NF-κBp65, AFP, TNFα, and transforming growth factor beta 1 (TGFβ1) resulting in the reversion of malignant anomalies and suppression of extracellular signalregulated protein kinase 1/2 (ERK1/2) activation. SRF and TEL showed antiproliferative, antimetastatic, and anti-angiogenic effects by improving the expression of hepatic cyclin D1, MMP2, and vascular endothelial growth factor (VEGF). However, only TEL has exhibited agonistic activity for PPARγ receptors, as indicated by the elevated PPARγ DNA-binding activity, mRNA expression of cluster of differentiation 36, heme oxygenase 1, and enhanced hepatic antioxidant capacity. Moreover, TEL and SRF both ameliorate phosphorylation-induced activation of TGFβ-activated kinase 1 (TAK1), suggesting that TAK1 might act as the core mediator for the interaction between ERK1/2 and NF-κB. TEL exerts its anticancer effects by modulating the ERK1/2, TAK1, and NF-κB signaling axis from the perspective of its PPARγ agonistic activity. Thus, TEL may be a useful PPARγ agonist for further clinical studies in the context of HCC treatment[54]. Despite its potential, it has adverse effects including headaches, dizziness, fatigue, upper respiratory tract or stomach-related infections, sinusitis, nonspecific pain, and diarrhea[55].

Troglitazone

Troglitazone (TGZ) is a member of the TZD class of drugs and acts as a PPARγ agonist. The antiproliferative and antitumorigenic effects of TGZ were studied in the BEL-7402 HCC cell line at 5, 10, and 25 μmol/L concentrations. TGZ induced cell death in a concentration-dependent manner resulting in the increased presence of fragmented DNA and terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL)-positive cells. TGZ enhanced cell cycle arrest in the G0/G1 phase and increased caspase activities (caspase 3, 6, 7, and 9), indicating increased cell apoptosis[56]. In another study, the HepG2 cell line treated with TGZ showed significant growth inhibition in a dose-dependent manner. The TUNEL assay and immunohistochemistry showed apoptosis induction and elevated expression of apoptotic proteins such as caspase 3 and survivin[57]. PPARγ was functionally expressed in hepatic cancer cell lines (HepG2, HuH-7, KYN-1, and KYN-2) with TGZ treatment. This was followed by the profound inhibition of cellular proliferation, DNA synthesis, cell cycle growth, and α-fetoprotein levels [58]. Similar results have also been shown by other groups that used other HCC cell lines such as PLC/PRF/5, HuH-7[59], HLF, HAK-1A, HAK-1B, and HAK-5 with TGZ[10,19]. The reduction in cell proliferation and increased apoptosis in most of these studies demonstrated the usefulness of TGZ for chemoprevention in HCC. Some recent studies showed the hepatotoxic effect of TGZ on diabetic patients. There is a significant elevation in liver enzymes level (ALT and aspartate aminotransferase [AST]) in 1.9% of patients with diabetes treated with TGZ for 24 to 48 wk. Furthermore, the cost of TGZ is much higher than that of other oral antihyperglycemic agents or insulin, which also limits the use of TGZ[60].

Saroglitazar

Saroglitazar is a first-class drug that acts as a dual PPARα/γ agonist. It is indicated for enhanced diabetic dyslipidemia, inflammation, steatosis, ballooning, and fibrosis progression. The agonistic effects of this drug have a favorable impact on insulin resistance and lipid profile. Saroglitazar treatment is thought to ameliorate high-fat diet-induced aberrations. The improvements were observed in hepatic lobular inflammation, hepatocellular ballooning, steatosis, and fibrosis. The effects of saroglitazar were more pronounced compared to PGZ. Transcriptomic analyses revealed the elevated expression of PPARγ in hepatic tissue with the anti-inflammatory effects of saroglitazar treatment[61]. Similarly, saroglitazar improved liver function parameters, degenerative changes, glucose and insulin levels, and lipid profile in high-fat emulsion plus lipopolysaccharide (LPS)-treated rats. The positive effects on serum leptin, TNFα, and adiponectin levels were also observed. The multiple protective roles of PPARα

/γ agonists in liver disorders suggest the usefulness of saroglitazar in managing liver cancer[62].

In a prospective observational study, 30 diabetic patients with liver fibrosis were enrolled and treated with 4 mg saroglitazar daily for 6 mo. A profound improvement in glycemic index, liver stiffness, and serum triglyceride levels of the patients was observed with no significant adverse side effects[63]. Another study conducted in 90 NAFLD patients who underwent liver biopsies, fibrosis scores, and other non-invasive parameters showed that saroglitazar treatment significantly improved the serum biomarker levels and fibrosis score. The study concluded the reversal effect of saroglitazar on fibrosis and advocated its use in treating HCC[64]. The most common adverse events associated with saroglitazar included asthenia, gastritis, chest discomfort, peripheral edema, dizziness, and tremors[65].

NATURAL PPARγ AGONISTS IN HCC

Natural PPARγ agonists have many beneficial properties including antioxidant, anti-inflammatory, antifibrotic, and antitumor effects. In addition to therapeutic effects, synthetic drugs have many adverse effects due to full PPARγ activation. Therefore, researchers are exploring potential natural PPARγ modulators with high specificity in terms of their binding at the active site and improving drug safety. The PPARγ-activating effect of natural products is recognized as having great potential in developing anticancer therapy. There are many reports on the natural PPARγ agonist against HCC in various experimental models.

Cannabinoids

The hemp plant *Cannabis sativa L.* produces approximately 60 unique compounds known as cannabinoids, of which ∆9-tetrahydrocannabinol (THC) is the most important due to its high potency and abundance in cannabis. Various studies have reported the fair safety profile of cannabinoids, in accordance with its probable antiproliferative activity on cancerous cells, may set the basis for future trials to evaluate the potential antitumor activity of cannabinoids. Vara *et al*[66] reported that cannabinoids THC and JWH-015 increased the intracellular mRNA and protein levels of PPARγ in HCC cells, and inhibition of PPARγ decreased cannabinoid-induced cell death and apoptosis. Further, increased PPARγ levels were correlated with endoplasmic reticulum stress and autophagy in HCC cells, suggesting the antiproliferative effects of cannabinoids through PPARγ-dependent pathways. The antitumor activity of THC was evaluated in patients who had failed standard therapy norms. *In vitro* studies have shown the suppression of tumor cell proliferation, and Ki67 immunostaining exhibits a reduced number of tumor cells[67]. THC is suggested to induce transcriptional modulation of the PPARγ pathway, and the activation is much more potent by cannabinoid acids than its decarboxylated products, indicating that cannabinoids act as a PPARγ agonist[68]. *Cannabis* contains some psychoactive agents that increase sociability and exert euphoric effects. Repeated use of *cannabis* has been linked to short- and long-term side effects, including respiratory and cardiovascular disorders, cognitive alterations, psychosis, schizophrenia, and mood disorders[69]. A recent study highlighted the side effects of a common preparation from *C. sativa* named *marijuana*. This study gave the putative association of the use of *cannabis* with a higher risk of gingival and periodontal diseases, oral infection, and cancer of the oral cavity[70]. Given the growing popularity of cannabinoid-based drugs for recreational and medical purposes and their potentially harmful effects, there is a need for further investigation in this field.

Capsaicin

Capsaicin (8-methyl-N-vanillyl-6-nonenamide) is a vital constituent of chili peppers belonging to the family of Capsicum. These phytoconstituents possess anti-inflammatory and chemopreventive properties. They counter various compounds' mutagenic properties and exert anticancer effects on breast, colon, prostate, and hepatic cancers. The DENA-induced models of HCC in rats and hepatic stellate cell lines were used to study the effects of capsaicin. Capsaicin was observed to inhibit hepatic injury, NF-κB activation, and collagen deposition. It has also ameliorated the levels of α-SMA, collagen type I, MMP2, TGFβ1, and TNFα. Furthermore, TGFβ1 expression and the phosphorylation of Smad2/3 were also inhibited through induction of PPARγ expression. The findings showed that capsaicin attenuates hepatic fibrosis by upregulating PPARγ expression[71]. The limitations of this natural PPARγ agonist should be mentioned. Capsaicin is a well-known irritant responsible for producing a painful, burning sensation when applied to the skin. Exposure to the eyes is painful and causes tearing, conjunctivitis, and blepharospasm[72]. Capsaicin is also a tussive agent, and inhaled capsaicin can be used to induce cough under experimental conditions. In humans, inhaled capsaicin induces a cough response immediately upon administration[73,74]. Interestingly, there is evidence that topical capsaicin can exacerbate angiotensin-converting enzyme (ACE) inhibitor-induced cough. A patient taking an ACE inhibitor for several years with no complaint of coughing reported coughing associated with applying a 0.075% capsaicin cream[75]. Additionally, oral administration of the ACE inhibitor captopril was found to cause a shift in the dose-response curve of inhaled capsaicin-induced cough in a trial with healthy adults[76].

Curcumin

Curcumin is a polyphenol compound present in *Curcuma longa* and is well known for its multiple therapeutic effects. Our previous study reported the effect of curcumin and piperine on DENA-induced HCC in rats. Curcumin prevented HCC progression by improving hepatic pathology, apoptosis induction, and inhibiting cell proliferation. However, the synergistic effect on HCC suppression was observed with the combination of curcumin and piperine[77]. Similarly, another study also reported the inhibition of cell proliferation, tumor growth, and apoptosis induction by curcumin treatment in HCC. The effect was suggested to decrease VEGF expression and PI3K/Akt signaling[78]. A study in a transgenic mouse model (expressing double HBV oncoproteins, HBx and pre-S2 in the liver) of HBV-related HCC reported the protective effects of phytosomal curcumin *via* targeting PPARγ as a key regulator. Curcumin decreased HCC formation and reduced the tumor size. Moreover, considerably more potent effects were observed on activation of PPARγ and inhibition of NF-κB. The report suggested that curcumin is an agonist for PPARγ, upregulating the genes involved in lipid metabolism, antiproliferation, and anti-inflammation. Furthermore, PPARγ activation regulates the suppression of NF-κB and subsequent pro-inflammatory cytokines. In addition, curcumin also is suggested to repress mTOR[79]. Recently, the antitumor effect of curcumin on HCC was suggested due to the involvement of miR-21 targeting TIMP3 and inhibition of the TGFβ1/Smad3 signaling pathway. The inhibition of TGFβ 1/Smad3 signaling by curcumin is reportedly linked to activation of the PPARγ gene[80,81]. It was further suggested to suppress cell proliferation through long non-coding RNA downregulation and inhibition of Wnt/β-catenin signaling[82]. The major disadvantage of this medication is the usage of high doses, which ultimately leads to liver injury in humans and experimental animals. A study showed that curcumin supplementation with paracetamol at doses of 50 and 100 mg/kg per day in experimental rabbits showed elevation of liver injury markers (ALT, AST, ALP, total protein, and albumin level) in plasma. Furthermore, levels of red blood cells and platelets were raised[83]. Also, the poor bioavailability of curcumin leads to its combined usage with other drugs such as piperine, which reportedly causes adverse drug reactions[84].

Hesperidin

Hesperidin is a flavanone glycoside found in the rind of citrus fruits including oranges and lemon. It possesses several pharmacological activities including antioxidant, anti-inflammatory, and anticancer effects. The chemopreventive efficacy of hesperidin was evaluated in DENA-induced HCC in rats. The hesperidin significantly reduced hepatic serological and tumor biomarkers along with TNFα. Furthermore, it also reduced the hepatic degenerative changes, oxidative stress, collagen deposition, TGFβ1, and NF-κB expression. However, the upregulated expression of nuclear factor erythroid 2–related factor 2, HO-1, and PPARγ suggested the effect of hesperidin *via* suppressing TGFβ signaling and subsequently activating PPARγ[85]. Another study investigated the efficacy of hesperidin *via* the PI3K/Akt pathway as a probable mechanism for curing HCC. Treatment with hesperidin elevated the protein levels of PI3K, Akt, and cyclin-dependent kinase 2 and ameliorated HCC progression[86]. In addition, hesperidin reportedly alters Wnt3a/β-catenin signaling in preventing HCC[87]. There are few reports on the bioavailability and solubility of hesperidin. Ameer *et al*[88] reported that hesperidin is absorbed across the gastrointestinal tract on oral administration, but cumulative recovery indicates low bioavailability. The factors limiting the bioavailability of hesperidin are poor water solubility and its precipitation in an acidic environment.

Hispidulin

Hispidulin, a phenolic flavonoid, exhibits anticancer activity against several types of cancers. The effect of hispidulin on HCC was studied in tumor cell lines (SMMC7721 and Bel7402) and mouse tumor xenograft models. Hispidulin activates caspase 3, triggers apoptosis, and inhibits cell migration *via* PPARγ activation, which is further linked to escalated phosphorylation of AMPK, ERK, and JNK *in vitro*. Specifically, GW9662 (a PPARγ inhibitor), compound C (an AMPK inhibitor), and PD98059 (a MEK inhibitor) negated the protective effects of hispidulin on PPARγ signaling. However, no pronounced changes in PPARγ levels were noted with pre-treatment of SP6000125 (a JNK inhibitor) *in vitro,* whereas it attenuated the anticancer activity of hispidulin. The suppression of Bel7402 xenograft tumor growth was successfully achieved by hispidulin through PPARγ activation, indicating the cardinal role of PPARγ signaling in HCC cell growth[89]. Recently, Lv *et al*[90] suggested that induction of reactive oxygen speciesmediated apoptosis through activation of the endoplasmic reticulum stress pathway is also responsible for the anticancer effect of hispidulin. Some evidence links hispidulin to its limited large-scale preparation. Studies have shown the lack of a single-dose design of hispidulin, which further limits the bioavailability[91,92].

Isoflavones

Isoflavones are a group of phytochemicals, a type of naturally occurring isoflavonoids. Studies have shown the anticancer effects of different isoflavones in the case of HCC[93]. A combination of two well-known isoflavones, Biochanin A and SB590885, was evaluated for their anticancer activities in HCC. The combination showed synergistic inhibition of cell growth and induced cell cycle arrest and apoptosis *in*

vitro. The inhibition of cellular proliferation and tumor suppression were attributed to the aberration of ERK MAPK and PI3K/Akt pathways. *In vivo*, a profound reduction in the size and volume of HCC tumors was noted, indicating the combination therapy of isoflavones as a potential lead for the management and treatment of advanced HCC[94]. The antitumorigenic and antiproliferative role of genistein was also studied in HCC *in vitro*. The isoflavone suppressed the proliferation of Hepa 1-6 cells and caused apoptosis in time- and dose-dependent manners[95]. In another study, genistein treatment suppressed aerobic glycolysis and increased the apoptotic rate in HCC cell lines. Additionally, genistein exhibited inhibitory effects on tumor progression and aerobic glycolysis. This may be identified as an effective treatment for advanced HCC[96]. Studies have reported the PPARγ-modulating effect of isoflavones and inhibition of HCC through inhibition of the PI3K/Akt pathway, and aerobic glycolysis further validates the involvement of PPARγ signaling. Clinical studies have also suggested that the more the dietary intake of flavonoids, the lesser the risk of developing HCC. In the Japanese population, a correlation between the isoflavone-rich diet and risk of HCC was observed[97,98]. Despite the therapeutic potential, some contentious health issues are associated with their intake. Soy proteins rich in isoflavones showed unfavorable effects at a higher dose, including gastrointestinal upset, constipation, nausea, allergic reactions, and loss of appetite. In animals, the intake of isoflavone (genistein) reportedly impacts the fertility and morphogenesis of ovaries. In addition, long-term use of soy extract may result in abnormal tissue growth in the uterus[99].

Oroxyloside

Oroxyloside (OAG), a flavonoid, was explored as a new dual agonist of PPARγ/α, which acts as a potent cell proliferation inhibitor in HCC-based metabolic transition. It regulates the glycolipid metabolic enzymes (PPAR-dependent or PPAR-independent), inhibits the breakdown of glucose, and promotes fatty acid oxidation, which generates acetyl-CoA for the tricarboxylic acid cycle and oxidative phosphorylation. The metabolic transition produced by OAG exhibits a profound generation of reactive oxygen species, leading to G1 cell cycle arrest and growth repression of HCC cells. OAG requires pyruvate dehydrogenase kinase 4 and β-oxidation to inhibit cell proliferation, explaining its PPARγ agonistic behavior. OAG is a new PPARγ/α agonist drug candidate and an effective therapeutic approach for HCC based on metabolic reprogramming[100]. Although many bioactive flavones' sources are very well known, information on their bioavailability and their active forms *in vivo* is limited. In particular, most flavonoid agents' absorption, metabolism, and blood delivery are poorly understood. Due to limited literature, it is difficult to elucidate the whole molecular mechanism. Hence, further studies are required to uncover their therapeutic potential against liver diseases.

Resveratrol

Resveratrol (RS) is a popular natural polyphenolic PPARγ agonist, well known for its anticancer properties, and has been recognized as the alternate mode in cancer treatment. A study revealed the effect of RS against alcohol-aflatoxin B1-induced HCC. During the progression of HCC, a decline in the antioxidant markers was effectively restored by resveratrol treatment. RS modulated the activity of the sirtuin 1 (SIRT1) enzyme in HCC by negatively regulating the levels of NF-κB, and cross-talk between this PPARγ agonist and SIRT1 signaling was observed[101]. A nano-formulation of RS using liposomes was developed to establish a specific drug delivery system for managing HCC. *In vitro* studies have revealed the increased internalization and enhanced anticancer activity of liposomal formulation (RL5) compared to naïve RS. A profound reduction in liver injury markers, hepatocyte nodules, and degenerative changes in the liver was observed in an *in vivo* HCC model. The results indicated the promising action of nano-formulation of RS and its substantial activity in controlling the severity of HCC[102]. Earlier, similar approaches were briefly reviewed by Santos *et al*[103] to study the pharmacokinetics of RS-loaded nanoparticles (RS-NPs) and study their effects on cancer tissue. A comprehensive analysis was carried out in various *in vivo* models, which revealed the markedly enhanced anticancer activity of RS-NPs. However, the poor bioavailability and rapid metabolism restricted the successful translation of resveratrol to clinical form. The *in vivo* efficacy of RS is affected due to its low solubility and low bioavailability. Oral intake of 25 mg of RS showed extremely low bioavailability; only a trace amount of unmetabolized RS was detected in plasma. The gastrointestinal tract absorbs approximately 70% of RS, but it is further metabolized by three distinct metabolic pathways leading to low bioavailability[104].

Miscellaneous

Avicularin (quercetin-3-α L arabinofuranoside), a glycoside related to quercetin, reportedly reduces obesity, inflammation, and drug resistance[105,106]. It also induces cytotoxicity in cancer cells by promoting intrinsic apoptosis pathways. One study investigated the activity of avicularin in HCC by employing HuH-7 cell lines. Avicularin inhibited cell proliferation in a dose-dependent manner and markedly decreased the cell migration and invasiveness of the cancer cells. Gene and protein expression studies revealed reduced levels of NF-κB, cyclooxygenase 2, and PPARγ. Avicularin may have the potential to modulate PPARγ to induce antineoplastic activity in HCC[107].

Honokiol (C18H18O2) is a bioactive, biphenolic phytoconstituent derived from the bark and leaves of *Magnolia Officinalis*. Honokiol exhibits various protective activities such as anticarcinogenic, anti-inflammatory, anti-angiogenic, antioxidative, and repressive potency towards the malignant conversion of papillomas to carcinomas without any noticeable toxicity effects. A group of researchers employed a great blend of *in silico, in vitro*, and *in vivo* techniques to pinpoint and validate honokiol as a potent lead for being a PPARγ agonist. The binding of honokiol into the ligand-binding pocket of PPARγ was anticipated *via* various *in silico* techniques. The luciferase reporter assay confirmed this binding and advocated that honokiol could act as a partial PPARγ agonist. Further, using 3T3-L1 and mouse embryonic cell lines, it was observed that honokiol stimulated basal glucose uptake but did not induce adipogenesis. However, the oral administration of honokiol resulted in reduced hyperglycemia and weight gain[108]. Various studies have suggested that honokiol acts as an RXR agonist forming RXR dimers and activating PPARγ/RXR heterodimers. Additionally, it also potentiates the activation of PPARγ/RXR heterodimers induced by rosiglitazone[109-111]. Also, no peer-reviewed papers proving the abuse, misuse, or dependence on or addiction to avicularin and honokiol have been retrieved yet.

Chrysin is a dihydroxyflavone belonging to the family of flavonoids. A study revealed that chrysin reduced cell viability and promoted apoptosis in all cell lines *via* inhibiting the Skp2 and low-density lipoprotein receptor-related protein 6 expression. However, reduced MMP2, MMP9, and fibronectin levels were observed[112]. Despite these interesting bioactivities, the clinical applications of chrysin have been constrained by its hydrophobicity, poor bioavailability, and degradation at alkaline pH[113]. Similarly, quercetin (QE) is a classic flavonoid and a yellow crystalline pigment present in plants, used as a food supplement to reduce allergic responses or boost immunity. It has been known to inhibit the development of various types of cancer hepatic conditions[114,115]. QE was suggested to effectively suppress HCC due to its close interaction with the signal transducer and activator of transcription 3 (STAT3) pathway[116,117]. It inhibits cell proliferation, cell cycle regulation, and invasiveness of the cancer cells by promoting the autophagy of HCC[118]. However, the bioavailability of QE is very low due to its poor aqueous solubility and instability, challenging its therapeutic application in the pharma sector[119].

CONTRADICTORY ROLE OF PPARγ

Cancer tissues display metabolic and thermodynamic aberrations with dysregulated cellular growth. Although the role of PPARγ and its agonists in HCC and other cancers have been extensively studied, as discussed above, several conflicting reports exist concerning the PPARγ expression in cancers. It is unclear whether PPARγ induction promotes or suppresses tumor growth and viability. In the case of several cancers, PPARγ mainly exhibits the down-regulated expressions while activating several other pathways like the canonical Wnt/beta-catenin pathway, PI3K/Akt pathway, STAT3 pathway, *etc*[82,87,118]. The activation of Wnt/β-catenin signaling leads to the upregulated PDK1, which leads to aerobic glycolysis and mitochondrial stress[29]. A recent report by Galbraith *et al*[120] revealed that the activation of PPARγ, in turn, induced Akt serine/threonine kinase 3 (AKT3), which eventually led to the more aggressive form of cancer. AKT3 enhances PGC1α localization to the nuclear space by repressing chromosome maintenance region 1, while the latter served as the downstream target for PGC1α. All these led to mitochondrial biogenesis, which fueled the progression of the tumor. Previous studies have also reported such inconsistent findings for PPARγ in HCC. Koga *et al*[10] tested five patients with cirrhotic livers and found no significant change in the PPARγ expressions compared to the surrounding non-cancerous tissue. Another study reported the consistently overexpressed PPARγ in HCC tissue having null expression in the surrounding tissues, even though all the patients were infected with viral hepatitis (B or C)[121]. Although the well-known inhibitory effects of PPARγ agonists are reported, they are also suggested to have PPARγ-independent effects on cancers. Troglitazone, as discussed above, has a prominent antitumorigenic role in HCC. However, there are reports of it exhibiting PPARγ-independent activity. Palakurthi *et al*[122] studied troglitazone and ciglitazone on both PPARγ-/- and PPARγ+/+ mouse embryonic stem cells considering various concentrations. Both the agonists could inhibit cellular proliferation in a dose-dependent manner by suppressing the G1-S transition. This evidence demonstrated that the antiproliferative effect was induced by suppressing the translation initiation. More similar reports back up the PPARγ-independent antitumorigenic property of PPARγ agonists[123,124]. One of the studies focused on the HCC progression in HBV-transgenic mice demonstrated that the anticancerous, antiproliferative, and apoptotic effects of TZD were more significant in PPARγ-deficient mice in comparison with the control mice, exhibiting normal PPARγ levels[125]. It is well-understood that PPARγ could potentially affect various pathways, so it is vital to understand the underlying mechanisms critically. This understanding is an absolute requirement as PPARγ may be inconsistent. However, it highlights its crucial role in tumor development, suggesting that targeted biomedical research against PPARγ could provide a highly efficacious avenue for treating and managing of HCC and various other cancers.

CONCLUSION

The majority of current studies support the fact that PPARγ may be a potential target against the progression of HCC. They have extensively explored the various signaling cascades through which PPARγ exerted inhibitory against HCC using synthetic and natural agonists in preclinical and clinical trials. PPARγ was suggested as a potential target as it suppresses cell proliferation, migration, and invasion in HCC cells through different signaling pathways. TZD, a class of synthetic PPARγ agonists, were extensively studied for their efficacy against HCC. TZD showed significant results against the progression of HCC; however, due to their adverse effect on different organs, these drugs are not approved for any cancer treatment. Therefore, increased focus was employed to identify natural and endogenous PPARγ agonists having high bioavailability and specificity in terms of their binding at the active site. Several studies reported the safety profiles and therapeutic role of natural agonists against HCC in various experiment modals. Natural agonists are also effectively reported to mediate apoptosis and inhibit cell proliferation, tumor growth, and metastasis in HCC. Few reports also highlighted the contradictory role of PPARγ in HCC. These contradictions might be due to some unidentified link between PPARγ and cancer. With the well-established role of PPARγ in the progression of HCC, better efficacy of its agonists may be achieved by a complete understanding of underlying mechanisms through which PPARγ showed therapeutic effects. Future studies should be focused on developing novel PPARγ targeting therapy for the treatment of HCC.

Abstract

Hepatitis B virus (HBV) has posed a threat to public health, mainly resulting in liver damage. With long-term accumulation of extracellular matrix, patients with chronic hepatitis B are at high risk of developing into liver fibrosis and cirrhosis and even life-threatening hepatic carcinoma. The occurrence of complications such as spontaneous bacterial peritonitis and hepatic encephalopathy greatly increases disability and mortality. With deeper understanding of the bidirectional interaction between the liver and the gut (gut-liver axis), there is a growing consensus that the human health closely relates to the gut microbiota. Supported by animal and human studies, the gut microbiota alters as the HBV-related liver fibrosis initials and progresses, characterized as the decrease of the ratio between "good" and "potentially pathogenic" microbes. When the primary disease is controlled *via* antiviral treatment, the gut microbiota dysfunction tends to be improved. Conversely, the recovery of gut microbiota can promote the regression of liver fibrosis. Therapeutic strategies targeted on gut microbiota (rifaximin, probiotics, engineered probiotics and fecal microbiota transplantation) have been applied to animal models and patients, obtaining satisfactory results.

Key Words: Hepatitis B virus; Gut microbiota; Liver fibrosis; Liver cirrhosis; Hepatic encephalopathy; Fecal microbiota transplantation

Core Tip: Intimate connection between the gut microbiota alteration and hepatitis B virus (HBV)-related fibrosis and complications has been supported by animal and human studies. Researchers and clinicians are making effort to control and reverse fibrosis by rebuilding a healthy gut microbiota. We herein discuss the gut microbiota alteration in HBV-related fibrosis and therapies targeted on reconstruction of gut microbiota homeostasis.

INTRODUCTION

Hepatitis B virus (HBV) has brought about substantial global health problems, giving rise to approximately 1.5 million new infections in 2019[1]. Balancing the pathogenic ability and immunity defense, some patients may experience chronic HBV infection, and even chronic hepatitis B (CHB). The different phrases are designed by the presence of hepatitis B e antigen (HBeAg), HBV DNA levels, alanine aminotransferase (ALT) values and liver inflammation, and CHB is mainly characterized by elevated ALT levels and moderate/severe liver diseases[2]. Chronic HBV infection tends to be asymptomatic initially, however, tissue repair against chronic inflammation may result in an immoderate accumulation of extracellular matrix (ECM), so CHB patients are at high risk of developing progressive fibrosis and life-threatening cirrhosis. Complications, such as portal hypertension, spontaneous bacterial peritonitis (SBP)[3] and hepatic encephalopathy (HE)[4], are difficult to prevent and address. With hepatocellular carcinoma (HCC) coming along stealthily[5], approximately 820000 deaths were caused by HBV infection–related causes in 2019[1].

The human intestine, as an organ directly connected with the outside world, is colonized by microbes progressively after birth[6]. The human gut microbiota is now considered to be composed of approximately 10^{14} bacteria[7], 200-300 fungal species[8] and abundant bacteriophages[9], and is increasingly seen as a significant superorganism[10]. Predominant strains in the adult intestine belong to *Bacteroidetes*, *Firmicutes*, *Actinobacteria* and *Proteobacteria*: *Bacteroidetes* and *Firmicutes* are the most dominant phyla and are mainly composed of gram-negative bacteria and gram-positive clostridia respectively[11]. The composition of the gut microbiota is influenced by age, race, nutrition, diet, immunity, disease and medication use, and has a strong interaction with the host[12-14]. The intimate association between gut microbiota homeostasis and multiple organ disease progression has been confirmed in the past decade, especially in some metabolic disorders[15], and intestinal and liver diseases[16].

The liver is closely connected with the gut *via* the gut-liver axis, defined as the bidirectional interaction between the liver and the gut *via* transport of bile acids, immunoreactive substances, nutrients, *etc.*[17]. When impairment of intestinal barriers and disturbances of the gut microbiota occur, gut-derived microbe/antigen translocation may lead to invasion of the liver. The association between gut microbiota alterations and chronic liver diseases (CLDs) has received great attention.

This review will concentrate on gut microbiota alterations in HBV-related liver fibrosis and summarize the cutting edge of new therapeutic strategies. We will summarize and discuss: (1) Gut microbiota alteration in HBV-related liver fibrosis; (2) Gut microbiota-related mechanisms of liver fibrosis; (3) Gut microbiota dysfunction in liver fibrosis complications; and (4) Gut microbiota-related treatment toward HBV-related fibrosis and complications.

GUT MICROBIOTA ALTERATION IN HBV-RELATED LIVER FIBROSIS

HBV-infected populations tend to obtain a gut microbiota that differs from that of healthy people (Table 1). Depending on host and viral factors, patients with HBV infection may experience different phrases[2]. In this part, gut microbiota alteration in the HBV persistence and different stages of HBV infection will be discussed.

HBV persistence

After the infection, HBV may be spontaneously cleared or cause chronic infection in different individuals: 95% of adult-acquired infections result in spontaneous clearance, while over 90% of newborn infections lead to chronic infections[18]. The same phenomenon has been observed in animal

Table 1 Gut microbiota alteration and additional findings in hepatitis B virus-related fibrosis

Ref.	Population (*n*)	Detection method	Gut microbiota alteration	Additional findings
Lu *et al* [30]	Healthy volunteers (*n* = 32); HBV carriers (*n* = 30); CHB (*n* = 31); Decompensated HBV-LC (*n* = 31)	qPCR	Phylum *Bacteroidetes* ↓ *Firmicutes* ↓ Family *Bifidobacteria*/*Enterobacteriaceae* ↓	Copies of operons that code for virulence factors markedly increased. Fecal sIgA and TNF-α in decompensated HBV-LC patients were higher than other groups
Xu *et al*[142]	Healthy volunteers (*n* = 15); CHB (*n* = 16); HBV-LC (*n* = 16)	qPCR	Species (*Bifidobacterium* specific) *B. catenulatum* ↓ *B. longum* ↓ *B. dentinum* ↑	*B. dentium*, which was considered to be an opportunistic pathogen, increased in HBV-LC patients. Species composition of *Bifidobacterium* shifted from beneficial to pathogenic
Wu *et al*[143]	Healthy volunteers (*n* = 38); Decompensated HBV-LC (*n* = 61); HBV-LT (after LC) (n =74)	qPCR	Species (*Lactobacilli* specific) *L. rhamnosus* ↓ *L. fermentus* ↓	Less complex fecal *lactobacilli* composition was found especially in decompensated HBV-LC patients
Wei *et al*[38]	Healthy volunteers (*n* = 120); HBV-LC (*n* = 120): CTP-A (*n* = 40); CTP-B (*n* = 40); CTP-C (*n* = 40)	Solexa sequencing	Phylum *Bacteroidetes* ↓ *Proteobacteria* ↑ Family *Enterobacteriaceae* ↑ Genera *Veillonella* ↑	A negative correlation was observed between the Child-Turcotte-Pugh scores and *Bacteroidetes* ($P < 0.01$)
Wang *et al* [23]	Healthy volunteers (*n* = 22); CHB (*n* = 85): CP-A (*n* = 76); CP-B (*n* = 9)	16S rRNA sequencing	Family *Lachnospiraceae* ↓ *Rikenellaceae*, ↓ *Porphyromonadaceae* ↓ *Ruminococcaceae* ↓ *Veillonellaceae* ↑	*Streptococcus*, *Veillonella*, *Streptococcus* and *Haemophilus* had strong correlations with liver function indices and serum metabolites. They were significantly higher in patients with higher Child-Pugh scores. The gut microbiota may be partially involved in the abnormal accumulation of serum metabolites
Deng *et al* [29]	Healthy volunteers (*n* = 20); HBV-LC (*n* = 80): CP-A (*n* = 30); CP-B (*n* = 31); CP-C (*n* = 19)	16S rRNA sequencing	Phylum *Firmicutes/Bacteroidetes* ↑ Genera *Megamonas* ↓ *Veillonella* ↓	Gut microbiota alteration mentioned on the left were all independent risk or protective factors for HBV-LC. Serum endotoxin increased in patients with higher CP classes ($P = 0.000$)
Zeng *et al* [140]	Healthy volunteers (*n* = 15); CHB (*n* = 21); HBV-LC (*n* = 25); HBV-HCC (*n* = 21)	16S rRNA sequencing	Phylum *Proteobacteria* ↑ *Bacteroidetes* ↑ *Firmicutes* ↓ Family *Bifidobacteria/Enterobacteriaceae* ↓	Higher *Bacteroidetes/firmicutes* ratio represented for higher LPS exposure
Wang *et al*	Healthy volunteers (*n* = 21); CHB (*n* = 69); F0-1 (*n* = 25);	16S rRNA sequencing	Genera *Prevotella* ↑	Genera responsible for bile acid metabolism decreased in CHB fibrosis patients

[59]	F2-4 (n = 44)		*Bacteroides* ↓ *Ruminococcus* ↓	
Chen *et al* [28]	Healthy volunteers (n = 21); HBV carriers (n = 23); CHB (n = 28); HBV-LC (n = 25)	16S rRNA sequencing	Phylum *Actinobacteria* ↑ *Bacteroidetes* ↓ *Firmicutes* ↓ *Proteobacteria* ↑	HBV-LC patients had higher bacterial network complexity with lower abundance of potential beneficial bacterial taxa
Yang *et al* [27]	Healthy volunteers (n = 31); HBV carriers (n = 24); CHB (n = 56); HBV-LC (n = 54); HBV-ACLF (n = 52)	16S rRNA sequencing	There are fluctuations in the changes	HBV carriers might be the most suitable donors for FMT for higher α diversity and abundance of potential beneficial bacteria
Wang *et al* [37]	Healthy volunteers (n = 877); CHB (n = 252); HBV-LC (n = 162); HBV-ACLF (n = 212)	16S rRNA sequencing; metagenomic sequencing	Species *Enterococcus faecium* ↑	High abundance of *Enterococcus* is associated with progression while that of *Faecalibacterium* is associated with regression of HBV-ACLF

HBV: Hepatitis B virus; CHB: Chronic hepatitis B; ACLF: Acute-on-chronic liver failure; CP: Child-Pugh scores; CTP, Child-Turcotte-Pugh scores; FMT: Faecal microbiota transplantation; LC: Liver cirrhosis; LT: Liver transplant; qPCR: Quantitative polymerase chain reaction.

experiments, in which hepatitis B surface antigen (HBsAg) of immature mice remained positive[19]. The age-related difference in immune clearance of HBV is consistent with the stabilization time of the gut microbiota, and maturation appears to facilitate HBV clearance by diminishing the tolerance phenotype and stimulating the immunoreactive pathway[19,20]. Similarly, if the gut microbiota was greatly imbalanced by antibiotics, the depletion can impair intestinal barrier function and weaken the ability of humoral and cellular immunity to clear HBV: adult mice with a mature gut microbiota managed to clear HBV after 6 wk of infection, while they failed to do so after antibiotic use[19,21].

Acute HBV infection

Due to the difficulty of studying acute HBV infection in humans, animal studies have been used: the ratio of *Firmicutes*/*Bacteroides* increased in the early stages of infection (Day 14) and decreased significantly over time (Day 49) in two mouse groups that were constructed with different plasmids[22].

Chronic HBV infection and non-end-stage CHB

Compositional changes have already occurred in the gut microbiota in early-stage CHB patients: in the Child-Pugh A and B groups, the abundance of 5 operational taxonomic units (OTUs) belonging to *Actinomyces*, *Clostridium sensu stricto*, unclassified *Lachnospiraceae* and *Megamonas* increased, while 27 OTUs decreased, which belong to *Alistipes*, *Asaccharobacter*, *Bacteroides*, *Butyricimonas*, *Clostridium IV*, *etc.* [23].

To further understand the gut microbiota dynamics in chronic HBV infection and CHB, there are also studies concentrating on the association with clinical indicators reflecting liver function and infection state. The gut microbiota of subjects from the chronic HBV infection group with normal ALT (NALT) levels was rather similar to those from the healthy volunteers, while significantly different from those from the high ALT level group[24]; however, in a recent study, the authors presented a slightly different perspective that the microbial diversity and abundance of *Lactobacillus*, *Clostridium*, and *Bifidobacterium* were lower in CHB-NALT patients than in healthy volunteers[25]. *Streptococcus*, *Veillonella*, *Streptococcus* and *Haemophilus* showed high correlations with some serum metabolites, including aromatic amino acids (phenylalanine and tyrosine), which are assumed to play pathogenic roles the progression of CHB [23]. The gut microbiota also varies according to viral load: HBV-infected individuals with a low viral load showed high diversity and carry a predominance of taxa associated with fatty acid and lipid metabolism[26].

As the disease progresses, the gut microbiota changes dynamically: the α diversity of asymptomatic HBV carriers slightly increased compared with that of healthy donators, while that of patients in the other three groups (CHB, liver cirrhosis, and acute-on-chronic liver failure (ACLF)) decreased with the severity of the disease[27]. The gut microbiota of patients with liver cirrhosis showed lower diversity and higher network complexity[28]. *Veillonellaceae* and *Lachnospiraceae* families were depleted in patients with liver cirrhosis compared with those in healthy volunteers, while *Megamonas* and *Veillonella* genera were depleted and enriched in patients, respectively[29]. Additionally, copy numbers of *Enterobacteriaceae* increased and lactic acid bacteria were depleted, with marked variation in the intestinal community of CHB patients[30]. The *Bifidobacteria*/*Enterobacteriaceae* ratio can be used for tracing the progression of liver disease[30]. With the magnitude of severity of liver disease (estimated as increasing liver Child-Pugh score), partial functional genes were correlated, such as those encoding aspartate-

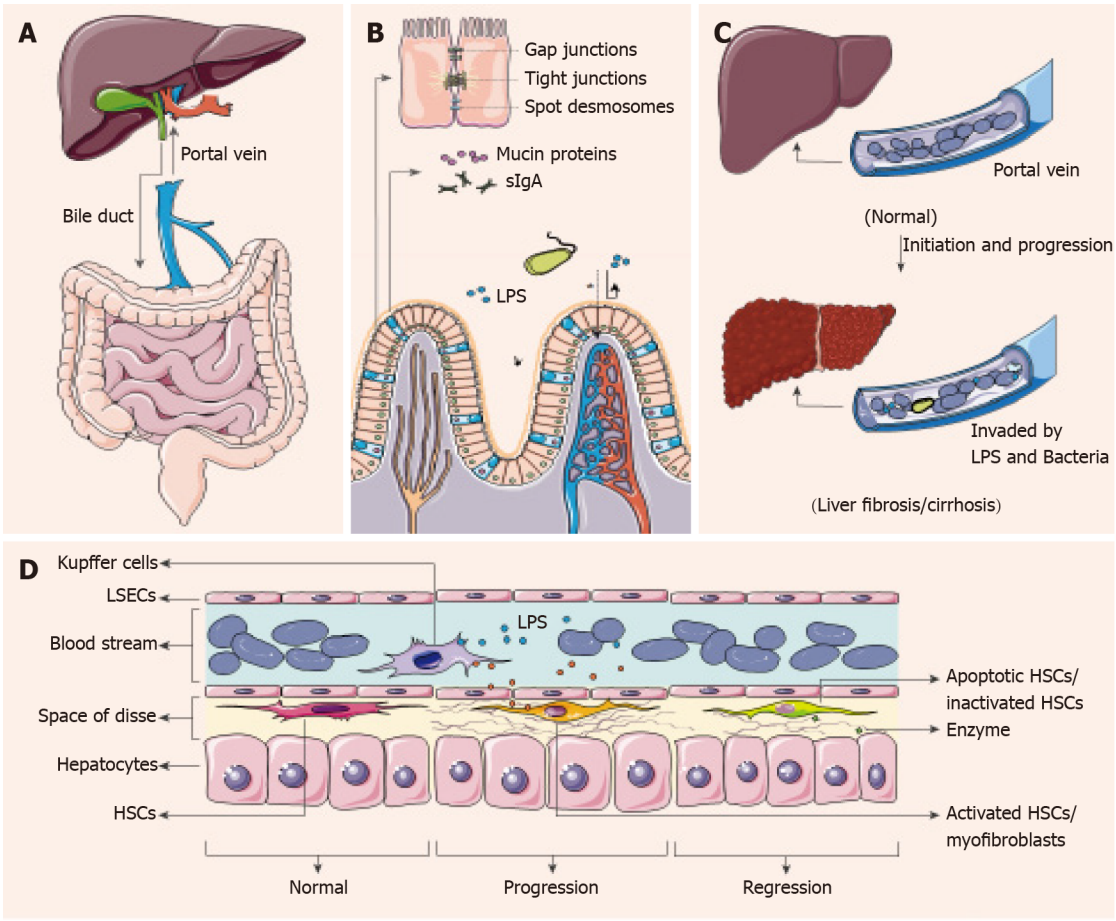
ammonia ligase, transaldolase, adenylosuccinate synthetase and IMP dehydrogenase[31]. According to the combined results of multiple studies, there is a well-acknowledged decrease in *Firmicutes* abundance and increase in *Proteobacteria* during the progression of HBV-related fibrosis.

HCC and end-stage CHB

Liver cirrhosis is a dangerous premalignant condition with an increasing incidence of genetic aberrations and an elevated risk of HCC[32,33]. HCC patients tend to present a distempered gut microbiota and abnormal metabolites[34]. The butyrate-producing genera were depleted, while lipopolysaccharide (LPS)-producing genera were enriched in liver cirrhosis and HCC patients, and *Clostridioides* abundance was generally observed to be positively related to the tumor size of HCC[35]. In another study, *Bacteroides*, *Lachnospiracea incertae sedis*, and *Clostridium XIVa* were enriched in HCC patients, and there was a consistency of positive correlation with the tumor burden[36]. By integrating the clinical characteristics and database analysis, serum bile acids may be the communication mediators between these three genera and the host transcriptome[36]. HCC can be secondary to a number of causes, including HBV, *Hepatitis C virus* (HCV) and so on. Compared with non-HBV non-HCV HCC, the abundance of *Prevotella* was much greater in HBV-related HCC group[34]. HBV-related HCC group had higher abundance of pathways related to DNA formation and function (including chaperones and folding catalysts, DNA replication proteins and chromosome), which supported that HBV can impair the normal function of DNA[34].

Additionally, dynamic alteration of gut microbiota is a valuable indicator to predict the prognosis of end-stage liver disease. The richness of *Enterococcus* was significantly higher in the HBV-related ACLF progression group, while a high abundance of *Faecalibacterium* was associated with regression (groups were divided according to the model for end-stage liver disease at discharge)[37]; a higher abundance of *E. coli* is consistent with an increasing level of LPS ligand in the circulation of patients with end-stage liver disease[38-40].

GUT MICROBIOTA-RELATED MECHANISMS OF LIVER FIBROSIS



Liver fibrosis is fibrous scar caused by excess accumulation of ECM[41]. It is driven by the chronic and persistent occurrence of parenchymal injury and the activation of the inflammatory response, followed by a continuous repair reaction and liver fibrogenesis[42]. For HBV infection, liver infringement comes from not only HBV but also gut-derived microbe/antigen translocation and abnormal metabolites.

There is a close connection between the gut and liver through known organic pipelines (bile duct and portal vein)[43], and whether there are detours needs further study. The liver produces and sends primary bile acids (BAs) and immunologic active materials (some antimicrobial peptides) through the biliary tract to assist in intestinal digestion and immunity. Conversely, the portal vein carries secondary BAs, nutrients, gastrointestinal metabolites from the gut to the liver, to provide nutrients and get detoxification and biotransformation[17,44] (Figure 1A).

In a non-disease state, intestinal physical and chemical barriers effectively block pathogens or toxic substances and decrease bacterial colonization. The barriers mainly include mucin proteins secreted by goblet cells, secretory IgA (sIgA) secreted by plasma cells in lymphoid follicles of the lamina propria and tight junctions between intestinal epithelial cells (IECs)[45] (Figure 1B). Disorders of these barriers can lead to increased intestinal permeability and translocation of microbial components or metabolites (LPS, microbial DNA) in CLD patients, allowing microbes and antigens to translocate into the portal vein[45], and subsequently induce chronic or acute inflammatory responses of different tissues and organs[46] (Figure 1C).

Intestinal barrier impairment

The gastrointestinal mucus layer is the first line of defense against microbes, and the mobility enables the layer to carry pathogens distally and reduce microbial colonization[47]. The experimental mouse models with liver cirrhosis [induced by bile-duct ligation (BDL) or tetrachloromethane (CCl_4)] show a reduced thickness of the mucus layer, with loss of goblet cells[48]. These cirrhotic mice show pathological bacterial translocation, which has not been found in healthy or pre-hepatic portal-hypertensive mice[48]. sIgA is the predominant contributor to mucosal immunity, recognizing and eliminating bacterial protein antigens, and it also participates in barrier layer limitation of microbe/antigen translocation[49]. Patients with HBV-induced decompensated cirrhosis have increased sIgA content in blood and stool[30], consistent with the increased bacterial migration. Simultaneously, intestinal tight junctions are weakened in patients with liver cirrhosis, and the expression of tight junction proteins is decreased[50,51]. Zonulin, an effective physiological regulator of tight junctions, is one of the markers of intestinal permeability[52]. Serum zonulin content is significantly increased in HBV-related liver cirrhosis and HCC patients and the levels are correlated with the stages[53].

Figure 1 Mechanism of gut microbiota-related liver fibrosis/cirrhosis. A: Gut-liver axis. The close bidirectional connection between gut and liver is mainly through the portal vein and bile duct; B: Intestinal barriers. From the intestine lumen, intestinal barriers are mainly formed by mucin proteins, sIgA and intercellular junctions, especially tight junctions between intestinal epithelial cells. The asterisk means when the intestinal barriers are weakened or broken, microbe/antigen translocation ensues; C: Liver fibrosis/cirrhosis and gut microbe/antigen translocation. Compared with normal state, gut microbe/antigen translocation and liver fibrosis/cirrhosis may drive each other in chronic hepatitis B patients; D: Mechanisms of liver fibrosis/cirrhosis process and regression. Receiving the activation signal, hepatic stellate cells (HSCs) are activated into fibroblasts to form the fiber. As the activation signal ceases, the activated HSCs are inactivated or apoptotic. When fiber degradation predominated, fibrosis is reversed. HSCs: Hepatic stellate cells; LPS: Lipopolysaccharide; LSECs: Liver sinusoidal endothelial cells.

Gut-derived microbe/antigen translocation and metabolic dysbiosis

The impairment of the intestinal barrier greatly reduces the efficiency of blocking microbe/antigen translocation. Gut-derived microbes or fragments and metabolites enter the venous system, travel through the portal vein to invade the liver. Diversity of circulating bacteria in cirrhosis patients is consistent with the presence of dysbiosis[54]. Recent studies have also supported that the occurrence of intestinal bacterial overgrowth and bacterial translocation in cirrhosis using methods such as bacterial DNA sequencing[55] and fluorescence microscopy[21] and suggested that the mechanism is associated with antimicrobial host defense[56]. Simultaneously, LPS is one of the component of the outer membrane of Gram-negative bacteria, mainly from *Enterobacteriaceae*[57]. The dysbiosis of the gut microbiota in mice leads to endotoxemia, which may bring about Kupffer Cell (KC) IL-10 production and KC-mediated T cell suppression[57]. And endotoxemia is highly related to the severity in liver diseases and complications[58].

Additionally, abnormal composition of the gut microbiota results in metabolic disorders, among which the metabolism of BAs has aroused great concern[25]. The level of fecal total BAs decreased and the ratio of conjugated and primary BAs increased in CHB patients without liver cirrhosis, which may be the prelude of following changes[25]. And there is a trend that abundance of the bacteria genera responsible for BA metabolism is decreased in CHB patients with moderate/advanced fibrosis[59,60]. There is also a link between gut bacteria-controlled BA metabolism and liver antitumor immunosurveillance *via* natural killer T (NKT) cells[61].

Immune-mediated fibrosis and regression

Pattern recognition receptors (PRRs) are highly conserved host sensors that are able to recognize

exogenous and endogenous antigens, including pathogen-associated molecular patterns (PAMPs) and host-derived damage-associated molecular patterns (DAMPs)[62]. PRRs are expressed by a plethora of immune cells, especially macrophages[63]. Macrophages could be at the center of innate immune regulation, linking microbe/antigen translocation and liver inflammation or fibrosis[64]. Recognition of PRRs sends the initial signal to active downstream adaptor proteins to undergo maturation and assemble transcription factors, such as nuclear factor (NF)-κB[65,66]. The produced cytokines then recruit inflammatory cells, drive antimicrobial activities and promote myofibroblast formation[67].

Myofibroblasts, the collagen-producing cells, are not present in healthy livers[68]. In response to toxic liver injury, myofibroblasts are mainly transformed from activated hepatic stellate cells (HSCs)[69]. There are four different stages of HSCs, namely, quiescent, activated (equivalent to collagen type I-producing myofibroblasts), inactivated and senescent[41]. Under physiological conditions, quiescent HSCs stay in the space of Disse and function as the major vitamin A storage site[70]. Simulated by several cytokines (especially transforming growth factor (TGF)-β)[71], quiescent HSCs modulate phenotypes and transform into activated HSCs, and the activated HSCs migrate and secrete ECM to produce a fibrous scar[41]. After removing the initial driver, there is a decrease in the levels of pro-inflammatory cytokines (interleukin-6, interleukin-1β and tumor necrosis factor) and TGF-β, and a rapid decline of the counts of activated HSCs[41]. Activated HSCs can be transformed into inactivated or senescent cells, and stop producing type-I collagen fibers[72]. Later, when fiber degradation by matrix metalloproteinases overwhelms fiber formation, liver fibrosis can be controlled, regressed and even reversed[73].

In conclusion, increased microbe and endotoxin loads in the portal vein cause PRR activation on immune cells, especially on macrophages, which leads to the activation of quiescent HSCs into activated HSCs[44,66]. Later, activated HSCs proliferate in response to various cytokines, secrete type-I collagen fiber and make liver fibrotic[41]. Upon cessation of underlying injury, myofibroblasts undergo inactivation or apoptosis, and fibrosis can be discontinued or reversed[41] (Figure 1D). This is the mechanism of effective treatment to control and regress liver fibrosis.

GUT MICROBIOTA DYSFUNCTION IN LIVER FIBROSIS COMPLICATIONS

As mentioned above, gut microbiota alterations may drive immune-related inflammation and fibrosis in the liver. Due to the accumulation of collagen fiber, liver stiffness is increased, bloodstream transport is blocked, healthy liver parenchyma is replaced and liver biotransformation and detoxification abilities are weakened[74]. As the disease progresses into the decompensation stage, patients may experience deadly complications, such as portal hypertension, spontaneous bacterial peritonitis (SBP) and HE. The relationship among gut microbiota alteration, liver fibrosis and portal hypertension is similar to the question of the chicken and the egg, as they drive and affect each other[75]. Compared with compensated cirrhosis, gut microbiota composition is characterized by an increase in the abundance of potentially pathogenic bacteria in the decompensation stage, especially *Alcaligenaceae*, *Porphyromonadaceae*, *Veillonellaceae* and *Enterobacteriaceae*[76].

SBP

SBP refers to the infection of ascites without an apparent intra-abdominal focus[77]. It is a severe infection and is often fatal in patients with cirrhosis and ascites[78]. The pathogen of SBP in liver cirrhosis patients is mainly from the intestinal tract.

More than two decades ago, DNA fragments of 30 bacterial isolated from ascites, mesenteric lymph nodes, portal blood, and ileal flora were compared[79]. The same bacterial strain was simultaneously isolated in ascites and in mesenteric lymph nodes and/or the ileum in 7/8 (87%) instances[79]. Intraperitoneal LPS increased TLR4 (Toll-like receptor 4, the canonical PRR for LPS) expression and amplified portal hypertension in rat liver fibrosis[80].

HE

HE is a fatal central nervous system complication caused by acute and chronic hepatitis or decompensated cirrhosis[81], which is considered consciousness disturbance after ammonia-related cerebral edema[82]. HE patients tend to have a poor prognosis and high mortality and recurrence rates, with greatly increasing economic and nursing burdens[83].

Currently, there is an increasing consensus that the gut microbiota and gastrointestinal metabolites play an important role in the initiation and progress of HE. On the basis of the gut-liver axis mentioned above, researchers proposed the concept of the gut-brain-liver axis to describe the role of the gut microbiota[84]. Cognitive dysfunction in cirrhosis is related to a decrease in the abundance of autochthonous families and an increase in *Alcaligenaceae* and *Porphyromonadaceae*[85,86].

On the one hand, gut microbiota alteration in the decompensation stage is consistent with the accumulation of microbe-derived products, including ammonia, mercaptans, benzodiazepine-like substances, and indoles[76]. These products can pass the blood-brain barrier and alter astrocyte function, resulting in osmotic or oxidative stress, mitochondrial dysfunction, neurotransmission

disorder, *etc.*[81]. On the other hand, neurotransmitters produced by the microbiota, including serotonin, dopamine, and aminobutyric acid, can act on specific receptors of exogenous primary afferent neuron cells, or cross the blood-brain barrier to act as active neurotransmitters[87]. The complex network among the enteric nervous system, the autonomic nervous system and the neuroendocrine and neuroimmunity systems of the central nervous system has a mutual impact on the gut microbiota, and the up-down or down-up regulation mechanisms need further exploration[84].

GUT MICROBIOTA-RELATED TREATMENT TOWARD HBV-RELATED FIBROSIS AND COMPLICATIONS

Based on the fibrosis regression theory mentioned above, removing the cause is the key to controlling and reversing liver fibrosis (Tables 2 and 3). For more than a decade, antiviral therapy has been recognized as an effective method to prevent, control and even reverse fibrosis and cirrhosis[88]. Rifaximin reduces the virulence of the overgrown gut microbiota[89]. With further understanding of the connection between the gut microbiota and HBV-related fibrosis, scientists have suggested that host health depends on the balance of the composition of the entire microbial community rather than one or a few dominant organisms[90]. New therapeutic strategies for HBV-related fibrosis, cirrhosis and complications have been broadened to regulate the gut microbiota through probiotic supplementation and microbiota transplantation from healthy donors.

Gut microbiota stabilization with antiviral treatment

At present, the main endpoint of all current treatment strategies is to maintain long-term suppression of HBV replication[2]. Two main options are nucleoside analogs (NAs) and interferon alpha[91]. NAs with a high barrier to HBV resistance, including entecavir (ETV), tenofovir disoproxil fumarate (TDF) and tenofovir alafenamide (TAF), are believed to be favorably safe and long-acting[92]. Antiviral treatment (AVT) exerts a positive influence on survival rate and quality of life by preventing disease progression, reversing and degrading fibrosis and cirrhosis[93,94], and even reducing HCC incidence and mortality in CHB patients[95].

ETV therapy reverses gut microbiota dysbiosis induced by HBV infection in a mouse model[96]. And in a controlled cross-sectional and longitudinal real-world study, the species abundance of the gut microbiota increased markedly after ETV treatment[97]. After 8 wk of ETV treatment, the abundance of *Clostridium sensu stricto 1*, *Erysipelotrichaceae UCG-007* and *Intestinibacter* increased significantly, and that of *Streptococcus*, *Atopobium* and *Murdochiella* was markedly reduced[97]. Although the addition of *Clostridium butyricum* (CB) to ETV failed to improve the serum biochemical, immunologic and virologic variables, addition of CB affected the gut microbiota in CHB patients treated with ETV[98]. While there is a lack of dynamic and synergetic studies on liver fibrosis outcomes and gut microbiota alterations during AVT, collaborative microbes contributing the most to antiviral-intervened HBV-related fibrosis cannot be pinpointed definitively.

Rifaximin

Rifaximin is a rifamycin-based nonsystemic antibiotic with low gastrointestinal absorption and good antibacterial activity[89,99]. The gastrointestinal tract is the main therapeutic target of rifaximin, and it has been widely used in controlling HE with infrequent side effects and a favorable long-term safety profile[100,101].

Current ideas suggest that rifaximin may have positive implications for liver cirrhosis and complications by acting on the gut microbiota. However, according to a randomized trial, there seems to be a minor impact on the composition of the gut microbiota[102]. Enrolled patients with cirrhosis and ascites were divided into two groups to receive rifaximin or placebo for 4 wk. Rifaximin decreased gut bacterial abundance, while no effect on particular species was observed; blood bacterial richness was decreased and the difference in *Pseudomonadales* abundance was relatively obvious[102]. And there was no difference in circulating markers of inflammation between the two groups[102]. Two additional studies also supported that rifaximin has little influence on gut microbiota abundance[103], but the metabolite levels altered: after rifaximin application, endotoxemia was relieved, and serum saturated and unsaturated fatty acid levels were increased significantly[104]. The former conclusion agreed with a study on experimental mice[105]. Therefore, rather than having a bactericidal effect, rifaximin seems to have direct effects on bacterial function and virulence[89].

Probiotics and synthetic probiotics

Probiotics are living nonpathogenic microorganisms, and treatment doses (at least 10^6 viable CFU/g) may help temper the gut microbiota[106]. *Lactobacillus* and *Bifidobacterium* genera are widely reported as clinically available probiotics[107]. In recent studies, probiotics have been broadly used to regulate the gut microbiota for further positive influences on primary diseases, such as gastrointestinal dysfunctions [108,109], metabolic diseases[110,111] and psychoneurotic disorders[112,113].

Table 2 Gut microbiota-related treatment toward hepatitis B virus-related fibrosis and complications (studies in animal models)

Ref.	Study populations (*n*)	Treatment and grouping (*n*)	Conclusions
Antiviral therapy			
Li *et al*[96]	AAV-mediated persistent HBV infection (AAV-HBV) mice (*n* = 10)	35 d after HBV infection, 4 wk of daily ETV treatment. ETV (*n* = 5)	Gut microbiota dysbiosis of the AAV-HBV mice was reversed by ETV treatment with restored α diversity and changed proportion of *Akkermansia*, *Lacnospiracea* and *Marvinbryantia*
Rifaximin			
Kang *et al* [105]	Germ-free mice (*n* = 16)	15 d of rifaximin 100 mg/(kg·d), or humanized with stools from a HCV-induced cirrhotic patient with MHE. Rifaximin (*n* = 4); Humanized (*n* = 4); Rifaximin + humanized (*n* = 4)	Rifaximin beneficially altered intestinal ammonia generation by regulating intestinal glutaminase expression independent of gut microbiota. MHE-associated fecal colonization resulted in intestinal and systemic inflammation. It was ameliorated with rifaximin
Engineered probiotics			
Nicaise *et al*[120]	Ornithine transcarbamoylase-deficient Sparse-fur mice; Carbon tetrachloride rats; Thioacetamide-induced acute liver failure mice	NCIMB8826 (wild-type strain *Lactobacillus plantarum*), or EV101 (engineered *Lactobacillus plantarum*, $LDH^-/AlaD^+$) oral and intrarectal administration	EV101 administration was effective in controlling hyperammonemia in constitutive animal models with a significant effect on survival, which might be involved with direct ammonia consumption in the gut
Kurtz *et al* [121]	Ornithine transcarbamylase-deficient *spfash* mice; Thioacetamide-induced acute liver failure mice; Healthy volunteers (*n* = 52)	Non-modified *Escherichia coli* Nissle 1917 (EcN), SYNB1020 (engineered EcN, Δ argR, Δ thyA, malEK:PfnrS-$argA^{fbr}$) administration	SYNB1020 converted NH3 to l-arginine in vitro, and reduced systemic hyperammonemia, improved survival in mouse models. SYNB1020 was well tolerated in healthy volunteers
Ochoa-Sanchez *et al*[122]	Bile-duct ligated rats	Non-modified EcN, S-ARG, or S-ARG + BUT administration	S-ARG converted ammonia to arginine, it was further modified to additionally synthesize butyrate, which had the potential to prevent HE
FMT			
Liu *et al* [134]	Germ-free mice	Sterile supernatant or entire stool from pre-FMT and post-FMT cirrhotic patients with HE was transplanted to Germ-free mice	Transferred microbiota mediated neuroinflammation. Cirrhosis-associated dysregulation of gut microbiota was related with frontal cortical inflammation

AAV: Adeno-associated virus; HBV: Hepatitis B virus; ETV: Entecavir; HCV: Hepatitis C virus; MHE: Minimal hepatic encephalopathy; HE: Hepatic encephalopathy; FMT: Fecal microbiota transplantation.

The role of probiotics in complications of HBV-related fibrosis and cirrhosis has been validated, especially for HE. Probiotics can drive the gut microbiota, triggering emotional brain signatures[114]. For minimal HE, probiotic therapy (*Lactobacillus acidophilus*) can improve blood ammonia and psychometric tests and reduce the risk of overt encephalopathy deterioration[115]. Further studies confirmed that patients' cognition, venous ammonia level and intestinal mucosal barrier function were significantly improved after 3 mo of probiotic use (*Clostridium butyricum* combined with *Bifidobacterium infantis*), and the predominant bacteria (*Clostridium cluster I* and *Bifidobacterium*) were obviously enriched in the probiotic-treated group, while *Enterococcus* and *Enterobacteriaceae* were depleted[116]. The combination of probiotics and lactulose is effective for the secondary prophylaxis of HE patients with cirrhosis[117]. Simultaneously, probiotics may work by promoting the growth of beneficial microbes and preventing PAMP-mediated liver inflammation and the anti-proliferative, anti-angiogenic, and anti-metastatic effects of the antioxidant can block the progress of HCC[118].

Additionally, rapid progress in synthetic biology has brought more options, which makes engineered live biotherapeutics an available and promising strategy[119]. More than one decade ago, the genetically engineered ammonia-hyperconsuming strain NCIMB8826 was verified to exhibit a beneficial effect at a lower dose than its wild-type counterpart[120]. In recent years, more engineered bacteria have been constructed to accelerate ammonia metabolism, reduce blood ammonia concentration and reduce HE incidence[121,122]. One team from Synlogic Inc. engineered oral probiotic *Escherichia coli Nissle 1917* (Ecn) to create strain SYNB1020[121]. SYNB1020 is able to convert NH_3 to L-arginine *in vivo* and reduce hyperammonemia in two mouse models (ornithine transcarbamylase-deficient spfash mice and thioacetamide-induced liver injury mice). Satisfyingly, it showed metabolic activity and good tolerance in a phase 1 clinical study of 52 healthy adult volunteers. Later, another group modified Ecn to consume and convert ammonia to arginine, which was further modified to additionally synthesize butyrate[122]. Both of these studies showed that engineered probiotics have positive therapeutic significance for hyperammonemia and underlying potential for HE prevention. However, these strains have not progressed to clinical studies in hyperammonemia patients, and the clinical effects need further study.

Table 3 Gut microbiota-related treatment toward hepatitis B virus-related fibrosis and complications (studies in human)

Ref.	Study populations (*n*)	Treatment and grouping (*n*)	Conclusions
Antiviral therapy			
Lu *et al* [97]	Healthy volunteers (*n* = 30); CHB (*n* = 30)	8 wk of daily ETV treatment. ETV (*n* = 30)	After ETV treatment, gut microbiota abundance increased markedly, blood biochemical, immunological and virological responses improved significantly
Lu *et al* [98]	Healthy volunteers (*n* = 30); CHB patients (*n* = 60)	8 wk of daily ETV treatment, or with additional CB. ETV (*n* = 30); ETV + CB (*n* = 30)	Additional CB fail to improve blood biochemical, immunological and virological responses, but affects the gut microbiota in the CHB patients treated with ETV
Rifaximin			
Bajaj *et al* [104]	Decompensated LC patients with MHE (*n* = 20):CHB (NM)	8 wk of rifaximin 550-mg BD. Rifaximin (*n* = 20)	Rifaximin affected little on gut microbiota, there was just a modest decrease in *Veillonellaceae* and increase in *Eubacteriaceae*. Rifaximin significantly improved cognition and endotoxemia, it increased increase in serum saturated and unsaturated fatty acids post-rifaximin
Lutz *et al* [144]	Decompensated LC patients with ascites (*n* = 152): Viral hepatitis (*n* = 35)	Prophylactic antibiotic treatment before the time of paracentesis. Rifaximin (*n* = 27); Other systemic antibiotics (*n* = 17)	Prophylactic rifaximin did not reduce SBP occurrence. Prophylactic rifaximin was associated with the dominant bacteria in ascites: *Escherichia coli* and *enterococci* were dominant of patients without prophylaxis, klebsiella species were mostly recovered from the rifaximin group
Kimer *et al* [102]	Decompensated LC patients (*n* = 54): CHB (NM)	4 wk of rifaximin 550-mg BD or placebo BD. Rifaximin (*n* = 36); Placebo (*n* = 18)	Rifaximin had minor effects on bacteria translocation and gut microbiota. Rifaximin showed little impact on the inflammatory state (reflected as the level of TNF-α, IL-6, IL-10, IL-18, SDF-1α, TGF-1β, CRP)
Kaji *et al* [103]	Decompensated LC patients (*n* = 30): CHB (*n* = 4)	4 wk of rifaximin 1200 mg/d. Rifaximin (*n* = 30)	Rifaximin alleviated HE and endotoxemia with improved intestinal hyperpermeability, and it is involved in a gut microbial change. Rifaximin didn't affect serum proinflammatory cytokine levels (TNF-α, IL-6, IFN-γ, IL-10)
Probiotics			
Agrawal *et al*[117]	LC patients with recovered HE (*n* = 235): CHB (*n* = 49)	3 mo of lactulose 30–60 mL/d, or 3 capsules of probiotics per day, which contained 4 strains of *Lactobacillus*. Lactulose (*n* = 80); Probiotics (*n* = 77)	Lactulose and probiotics were effective for secondary prophylaxis of HE in cirrhotic patients
Ziada *et al* [115]	Decompensated LC patients with MHE (*n* = 90): CHB (NM)	4 wk of lactulose 30–60 mL/d, or 3 capsules of probiotics per day, which contained *Lactobacillus acidophilus*. Lactulose (*n* = 30); Probiotics (*n* = 30)	Probiotic was better tolerated than lactulose. Both of them can improve blood ammonia and psychometric tests and reduce the risk of developing overt HE. Magnetic resonance spectroscopy showed more improvement in the levels of brain neurometabolites in the probiotic group
Xia *et al* [116]	Decompensated HBV-LC patients with MHE (*n* = 67)	3 mo of probiotics 1500-mg TD, which contained *Clostridium butyricum* combined with *Bifidobacterium infantis*. Probiotics (*n* = 30)	After probiotics treatment, the therapeutic bacteria were significantly enriched, while *Enterococcus* and *Enterobacteriaceae* were decreased. Probiotics contributed to the improved cognition and the decreased ammonia levels
FMT			
Ren *et al* [132]	CHB with positive HBeAg, received over 3 yr of antiviral treatment (*n* = 18)	FMT was performed by gastroscope every 4 wk until HBeAg clearance. FMT (*n* = 5)	FMT was effective on HBeAg-positive CHB, especially in patients who could not cease the oral antiviral treatment even after long-term treatment
Bajaj *et al* [135]	Decompensated LC patients with recurrent HE (*n* = 20). CHB (NM)	After 5 d of antibiotics, FMT was performed by enema, or standard of care (SOC, rifaximin/lactulose) was applied. FMT (*n* = 10); SOC (*n* = 10)	FMT increased diversity and beneficial taxa of gut microbiota, improved cognition and showed good tolerance, other than SOC
Bajaj *et al* [136]	Decompensated LC patients with recurrent HE (*n* = 20). CHB (NM)	FMT was performed by enema, or standard of care (SOC, rifaximin/lactulose) was applied. FMT (*n* = 10); SOC (*n* = 10)	Oral FMT capsules are safe and well tolerated. Post-FMT, duodenal mucosal diversity increased with higher *Ruminococcaceae* and *Bifidobacteriaceae* and lower *Streptococcaceae* and *Veillonellaceae*. Reduction in *Veillonellaceae* were noted post-FMT in sigmoid and stool
Chauhan *et al*[133]	CHB with positive HBeAg, received over 1 years of antiviral treatment (*n* = 18)	6 FMTs were performed by gastroscope every 4 wk FMT (*n* = 12)	FMT appeared to be safe and effective on HBeAg-positive CHB in viral suppression and HBeAg clearance

CHB: Chronic hepatitis B; CB: *Clostridium butyricum*; CRP: C-reactive protein; EcN: *Escherichia coli* Nissle 1917; ETV: Entecavir; HBeAg: Hepatitis B e antigen; HE: Hepatic encephalopathy; IFN: Interferon; IL: Interleukin; LC: Liver cirrhosis; MHE: Minimal hepatic encephalopathy; NM: Not mentioned; SBP: Spontaneous bacterial peritonitis; SDF-1α: Stromal cell-derived factor 1-α; TDF: Tenofovir disoproxil fumarate; TGF-1β: Transforming growth factor β-1; TNF: Tumor necrosis factor; FMT: Faecal microbiota transplantation.

Fecal microbiota transplantation

Fecal microbiota transplantation (FMT) is an emerging treatment method that transfers the gut microbiota from a healthy donor to a patient[123]. Due to its ability to directly reshape or rebuild the recipient's gut microbial communities, FMT is one of the most promising therapies balancing and stabilizing the gut microbiota[76], and it has been applied to research-based treatment in animal models of a variety of diseases[124,125] and to study the mechanisms[126,127]. In recent years, FMT has been expanded to clinical treatment for human disease as a noninvasive strategy for conditions including recurrent *Clostridium difficile* infection[128], inflammatory bowel disease[129], severe obesity and metabolic syndrome[130]. Regarding the mechanism, the gut microbiota structure can be improved by FMT, and a clinical trial employing autologous FMT supported this point[131].

Clinical trials have also aimed to determine whether CHB patients can benefit from FMT therapy. In a pilot study carried out in China, FMT showed the potential to induce HBeAg clearance in HBeAg-positive CHB patients after long-term AVT: There was a significant HBeAg level decline in the FMT group (FMT combined with AVT), while no decline in the control group (AVT only) was found[132]. The results were consistent with a nonrandomized controlled clinical trial carried out in India: after 1 year of FMT therapy for 6 terms, the FMT group (FMT + AVT) seemed to show potential effectiveness and safety compared with those of the AVT group (AVT only)[133]. Some researchers have also hypothesized that FMT of some potential beneficial bacteria can change the occurrence of disease, and HBV carriers might be the most suitable donors for slightly higher microbiota abundance[27]. However, due to the limitations of a small number of participants and a lack of randomized clinical trials, further well-designed clinical trials are needed to confirm the initial assumptions and promote clinical practicability.

Studies on FMT for HE animal models or patients show satisfactory results. In animal experiments, neuroinflammation alleviation was found in cirrhosis model mice receiving FMT[134]. In a randomized clinical trial, FMT from rationally selected donors helped reduce and improve hospitalizations and improve cognition and dysbiosis for cirrhosis with recurrent HE[135]. Later, the same team verified the safety of FMT capsules through a phase 1, randomized and placebo-controlled clinical trial[136]. In addition to integral inoculation, selective inoculation of specific strains also plays an ameliorating role. Transplanting low-urease altered Schaedler flora to mice prepared with a depleted microbiota leaded to durable reduction in fecal urease activity and ammonia production[137]. The symbiotic pair of *Lactobacillus reuteri* JBD400 and *Streptococcus rubneri* JBD420 cooperatively improved transplantation efficiency 2.3×10^3 times more than that of sole transplantation and significantly lowered blood ammonia levels [138].

CONCLUSION

Consequently, gut microbiota alteration has been observed to be related to HBV-related fibrosis initiation and progression, and it is a promising therapeutic target. According to current studies, HBV persistence and clearance show consistency with the maturity and health of the gut microbiota[19,21]. With an increase of Child-Pugh scores and the model for end-stage liver disease, the gut microbiota is characterized by a decrease in the ratio of "good" to "potentially pathogenic" bacteria, and species diversity tends to decrease[139,140]. However, it is difficult to clarify which is the initiating factor between gut microbiota alteration and HBV-related fibrosis progression. Existing studies tend to be descriptive and lack HBV-specific exploration. Gut microbiota-related mechanisms are based on the gut-liver axis and immune-mediated response, briefly including intestinal barrier impairment, PRR activation, cytokine production, HSC activation and transformation, and fiber secretion and formation [41]. When the driver is removed, activated HSCs are inhibited or become apoptotic, and fiber scars are degraded, resulting in fibrosis regression[41].

Beyond theory, quite a few studies have begun examining therapeutic inventions. AVT can effectively control or even reverse HBV-related liver fibrosis, during which the gut microbiota gradually returns to homeostasis[96,97]. Rifaximin may decrease the virulence of the overgrown gut microbiota[89]. Probiotics and FMT are the most popular gut microbiota targeted therapies, and they are moving from the laboratory to the clinic. In addition, synthetic probiotics and selective microbiota transplantation may make these therapies more precise, and bring fewer side effects.

However, current studies do have limitations. There is a lack of in-depth research on the specific molecular mechanisms of the gut microbiota. Further clinical studies are needed to determine its effectiveness in patients with HBV-induced liver cirrhosis in the real world[141]. We must also admit that age, host location, dietary habits have a great impact on the gut microbiota, which leads to the lack of consistency and comparability of the alterations in gut microbiota in different studies. Therefore, diagnosis potential of microbial markers should be considered the factors mentioned above. We are looking forward to more powerful studies to strengthen the theoretical foundation and promote clinical application.

Abstract

The management of hepatocellular carcinoma (HCC) is challenging because most patients have underlying cirrhosis, and the treatment provides, historically, a limited impact on the natural history of patients with advanced-stage disease. Additionally, recurrence rates are high for those patients who receive local and locoregional modalities, such as surgical (resection and transplantation) or image-guided (ablation and intra-arterial) therapies. Translational research has led to new concepts that are reshaping the current clinical practice. Substantial advancements were achieved in the understanding of the hallmarks that drive hepatocarcinogenesis. This has primed a successful incorporation of novel agents with different targets, such as anti-angiogenic drugs, targeted-therapies, and immune-checkpoint inhibitors. Although clinical trials have proven efficacy of systemic agents in advanced stage disease, there is no conclusive evidence to support their use in combination with loco-regional therapy. While novel local modalities are being incorporated (*e.g.*, radioembolization, microwave ablation, and irreversible electroporation), emerging data indicate that locoregional treatments may induce tumor microenvironment changes, such as hyperexpression of growth factors, release of tumor antigens, infiltration of cytotoxic lymphocytes, and modulation of adaptative and innate immune response. Past trials that evaluated the use of antiangiogenic drugs in the adjuvant setting after ablation or chemoembolization fail to demonstrate a substantial improvement. Current efforts are directed to investigate the role of immunotherapy-based regimens in this context. The present review aims to describe the current landscape of systemic and locoregional treatments for HCC, present evidence to support combination approaches, and address future perspectives.

Key Words: Liver cancer; Hepatocellular carcinoma; Immunotherapy; Systemic therapy; Ablation; Embolization

Core Tip: Management of hepatocellular carcinoma (HCC) is based on stages defined by tumor burden, liver function, and performance status. With the advent of more effective systemic treatments, such as immunotherapy and immunotherapy-based combinations, patients with advanced stage disease have better outcomes. The migration of systemic treatment to earlier stages, in combination with locoregional therapies, are expected to improve the outcomes and cure rates. Currently, the research field is moving towards an increasing interest in combining locoregional and systemic treatments for HCC.

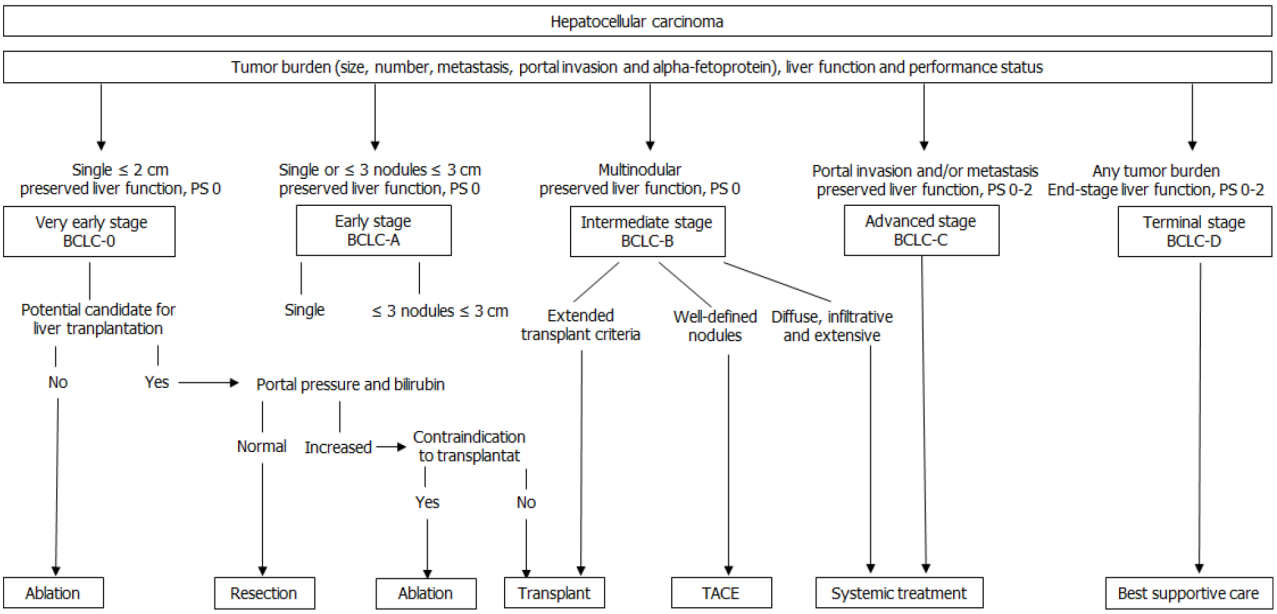
INTRODUCTION

Hepatocellular carcinoma (HCC) is a highly fatal disease, representing the fourth cause of cancer-related mortality worldwide[1]. This situation is attributed to the challenging management of patients with HCC *per se* in concomitance with an underlying liver disease and cirrhosis-related complications. Moreover, a significant proportion of patients are diagnosed with advanced stage disease, not amenable to curative options. Finally, even patients who are treated with local therapies, such as surgery and ablation, present high rates of recurrence, reaching up to 70% in 5 years[2].



Treatment options for HCC are selected based on liver function, performance status, and tumor burden (size, number of lesions, metastatic spread, and vascular invasion). These patient- and tumor-centered characteristics define the stage of the cancer, each with a different prognosis[3]. Thus, clinical practice guidelines according to both tumor presentation and liver function integrate the available evidence based on well-delineated clinical trials and recommend treatment strategies for each stage[2,4] (Figure 1).

Liver resection, local ablation, and liver transplantation are recommended for very-early and early-stage disease and are considered curative-intent treatments for HCC. Intra-arterial therapies, such as transarterial chemoembolization (TACE), are indicated for cases classified as intermediate stage (multinodular liver disease beyond Milan-criteria with preserved liver function), and systemic treatments are used for patients with advanced stage disease[3]. Therapeutic management of HCC is evolving rapidly with the incorporation of novel locoregional techniques and the increasing number of systemic agents tested in clinical trials, including immunotherapy. Each treatment approach is directed to treat HCC at different stages, and there is a lack of evidence to support the use of combined systemic and locoregional treatments. Therefore, the biological rational behind combination strategies and the urgent need to improve outcomes for this lethal disease prime intense research activity in both basic and clinical fields. This review aims to address the current landscape of systemic and locoregional treatments and the future perspectives regarding combined approaches.

SYSTEMIC TREATMENT FOR HCC: CURRENT LANDSCAPE AND PERSPECTIVES

Systemic treatment is recommended for patients with advanced stage disease (preserved liver function, performance status 0-2, metastatic spread, and/or macrovascular invasion) and for patients in earlier stages who have contra-indications or progressed after locoregional modalities according to the concept of treatment stage migration[3].

The natural history of advanced HCC is poor, with a median overall survival of 4-8 mo without active treatments[5]. Since 2008, the use of agents that target hallmarks of hepatocarcinogenesis are gradually improving prognosis and achieving substantial clinical benefit for HCC patients. Sorafenib, a multikinase inhibitor, has been shown to improve overall survival over placebo in the SHARP and Asia-Pacific trials and became the first approved drug for advanced HCC[6,7]. After almost a decade, other drugs of the same class were tested with positive results in phase III trials, such as lenvatinib (non-inferior to sorafenib in first-line)[8], regorafenib (superior over placebo in second-line for patients who tolerated sorafenib)[9], and cabozantinib (superior over placebo after sorafenib failure)[10]. These drugs

Figure 1 Treatment algorithm for hepatocellular carcinoma based on level-1 evidence. The algorithm establishes five stages according to liver function, tumor burden, and performance status. Each stage is linked to first-line treatment recommendation, although individual decisions can be defined according to patient profile and available treatment options. Adapted from Ref. [3]. BCLC: Barcelona clinic liver cancer; TACE: Transarterial chemoembolization.

share common targets, such as vascular endothelial growth factor receptor (VEGFR) and platelet-derived growth factor receptor, while some of them present, individually, more direct actions against specific targets, such as the case of lenvatinib against fibroblast growth factor receptor, and cabozantinib against mesenchymal-epithelial transition (MET) receptor. Additionally, ramucirumab, a monoclonal antibody against VEGFR, was shown to improve overall survival over placebo in patients who present with alpha-fetoprotein (AFP) ≥ 400 ng/mL after sorafenib failure and is also approved for clinical use [11]. Generally, these drugs present antiangiogenic activity and promote clinical benefit by delaying tumor progression rather than inducing a substantial reduction in tumor burden. Trials with these drugs are consistent in showing a statically significant, but modest, increase in overall survival, with survivals around 11-13 mo in the first line, a response rate of less than 10% (except for lenvatinib, with a response rate of 18.8% in the REFLECT trial), and a range of class-related adverse events, such as fatigue, arterial hypertension, skin reaction, and diarrhea[12].

In the past years, the advent of immune-based treatments, such as immune checkpoint inhibitors, brought huge advances in HCC management. The biological background for the use of immunotherapy in HCC is based on the remarkable immunotolerance of the liver due to the high antigenic load derived from the enteral-portal circulation. Additionally, HCC develops in a microenvironment of chronic inflammation and underlying liver disease. Low infiltration of CD8 + T lymphocytes, responsible for the antitumor immune response, and a marked presence of exhausted lymphocytes and regulatory T lymphocytes are described in HCC, contributing to an immunosuppressive and procarcinogenic microenvironment[13,14].

The immune checkpoint inhibitors aimed at boosting anti-tumoral immunity in the priming phase by the recognition of antigens presented by dendritic cells to lymphocytes (anti-CTLA4 agents) and in the effector phase of T-CD8 cytotoxic cells against tumor cells (anti-PD1, anti-PDL1) were tested in phase I/II trials showing durable response rates of around 15%-20%. Therefore, pembrolizumab and nivolumab (anti-PD1 drugs) received approval for use in second-line treatments[15,16]. However, comparative trials showed that immune checkpoint inhibitors as monotherapy did not improve outcomes comparing to the available treatments. In a phase III trial, nivolumab was not proven to improve survival compared to sorafenib in the first line[17] and pembrolizumab did not achieve statistical superiority over placebo in the second-line[18].

The use of combinations of agents with different mechanisms of action can improve results of immunotherapy through additive effect and because VEGF can enhance the immunosuppression of the tumor microenvironment by inhibiting the function of effector T cells, increasing the recruitment of regulatory T cells and myeloid-derived suppressor cells[19]. This combination was explored in the IMBRAVE150 trial, which randomized patients to receive sorafenib *vs* a combination of bevacizumab (an anti-VEGF antibody) and atezolizumab (an anti-PD-L1 antibody). This trial demonstrated a significant improvement in overall survival (19.2 mo *vs* 13.4 mo), and also in progression-free survival and response rate[20,21]. IMBRAVE150 trial was a landmark in HCC management and marked the transition towards the use of combined systemic therapies (using dual-immunotherapy or antian-

giogenic plus immunotherapy combinations). Several combinations showed encouraging results in phases I and II trials, such as lenvatinib plus pembrolizumab[22], pembrolizumab plus regorafenib[23], nivolumab plus ipilimumab[24], and nivolumab, ipilimumab, and cabozantinib[25]. These preliminary results suggested that combinations may yield response rates of more than 20% according to RECIST criteria, which seems to compare favorably to the rates with multikinase inhibitors. However, it is important to point out some limitations of early phase trials. Firstly, non-comparative trials are not adequate to draw definitive conclusions. Besides, the response rate is not a surrogate marker for survival benefit in HCC, even more considering that RECIST may not capture the spectrum and patterns of progression and response in patients under immunotherapy.

Recently, durvalumab and tremelimumab as a combination treatment was announced to yield survival benefit over sorafenib in a phase III trial and is expected to be incorporated in the first-line setting as an alternative to atezolizumab plus bevacizumab[26,27]. Currently, other phase III trials are awaiting results in the context of combination therapies for advanced HCC (Table 1).

ROLE OF LOCOREGIONAL THERAPIES IN HCC: IS THERE ROOM FOR IMPROVING OUTCOMES?

Liver resection is indicated in early HCC, regardless of the presence of cirrhosis, since the liver function remains compensated, and is rarely is does the patient have a clinically significant portal hypertension. However, the risk of liver decompensation after resection in patients with restricted hepatic functional reserve is a concern, especially in cases requiring major hepatectomies (3 or more segments)[2,28,29]. On the other side, liver transplantation has the advantage of treating both cirrhosis and offer curative-intent treatment for HCC. Thus, liver transplantation decreases both the risk of recurrence, since the most recurrence is in the liver, and *de novo* lesions by removing the cirrhotic liver. But its application in clinical practice is hampered by organ shortage, complexity, heterogenous availability in different worldwide regions, and the risk of progression on waiting list[30].

In patients with liver-only disease not amenable to surgical modalities, locoregional interventional procedures play a key role. Locoregional treatment is defined as imaging-guided tumor directed procedures, and it is estimated that 50% of patients with HCC might receive any of these treatments during the course of the disease[31,32]. Basically, there are two groups of locoregional therapies: (1) Ablative therapies; or (2) Intra-arterial therapies. Although both modalities are consolidated with high level evidence, emerging approaches and techniques are being increasingly adopted and are expected to improve clinical outcomes. Besides, the risk of recurrence and progression in patients treated with locoregional therapies has led to intense research activity towards combination with systemic treatment [2,4].

ABLATIVE THERAPIES

Current evidence of ablative methods in HCC

Ablative therapies induce tumor destruction through different mechanisms according to the method: Chemical [percutaneous ethanol injection (PEI)], thermal [radiofrequency ablation (RFA), microwave (MWA), and cryoablation], and short pulses of high voltage (irreversible electroporation). In general, ablative techniques are considered a curative therapy for HCC < 2-3 cm and is associated with complete responses in 70%-90% of the cases, although recurrences occur in approximately 50% of the cases within 5 years[33-35].

The most used and recommended method is RFA, which has shown survival superiority over PEI in randomized trials[33]. Tumor size, number of nodules, and Child-Pugh class are associated with prognosis in patients treated with RFA[36-38]. Comparative studies *vs* resection demonstrated that RFA seems to be inferior to surgery in tumors > 3 cm[39]. Limitations to RFA include proximity to large vessels (due to heat effect), size, and location.

MWA is another technique that has been increasingly used and has the advantage of achieving a faster heating over a larger volume and being less susceptible to heat sink effect. Most studies that addressed comparisons between RFA and MWA showed similar efficacy, with a trend toward best results with MWA in tumors > 3 cm[40-42].

Alternative techniques, such as IRE and cryoablation, are under active research, with a small series of studies showing encouraging results[43,44]. IRE has the advantage of causing less thermal damage to adjacent tissues. However, more data are still required for IRE and cryoablation in order to fully incorporate these techniques into clinical practice guidelines.

Combination of ablative and systemic treatment: rationale and current evidence

The high risk of local and distant recurrence after ablation indicates the need for adjuvant strategies to improve cure rates. Features, such as large tumors, multinodularity, and vascular invasion (macroscopic

Table 1 Clinical trials in advanced hepatocellular carcinoma with combination of systemic treatment

Study name	Design	Experimental arm	Median overall survival, mo	Response rate-RECIST, %	Grade 3 - 4 treatment-related adverse events
IMBRAVE 150[21]	Phase III; First-line	Atezolizumab + Bevacizumab	19.2	30%	36%
KEYNOTE 524/Study 116[22]	Phase Ib; First-line	Pembrolizumab + Lenvatinib	22	36%	67%
REG-PEMBRO-HCC [23]	Phase Ib; First-line	Pembrolizumab + Regorafenib	26.5	32%	86%
CHECKMATE 040[24]	Phase II; Second-line	Nivolumab + Ipilimumab (arm A)	22.8	32%	53%
STUDY 22[27]	Phase II; Second-line	Durvalumab + Tremelimumab	18.7	24%	35.1%
CHECKMATE-040[25]	Phase II; First and second-line	Nivolumab + Ipilimumab + Cabozantinib	Not-reached	26%	71%

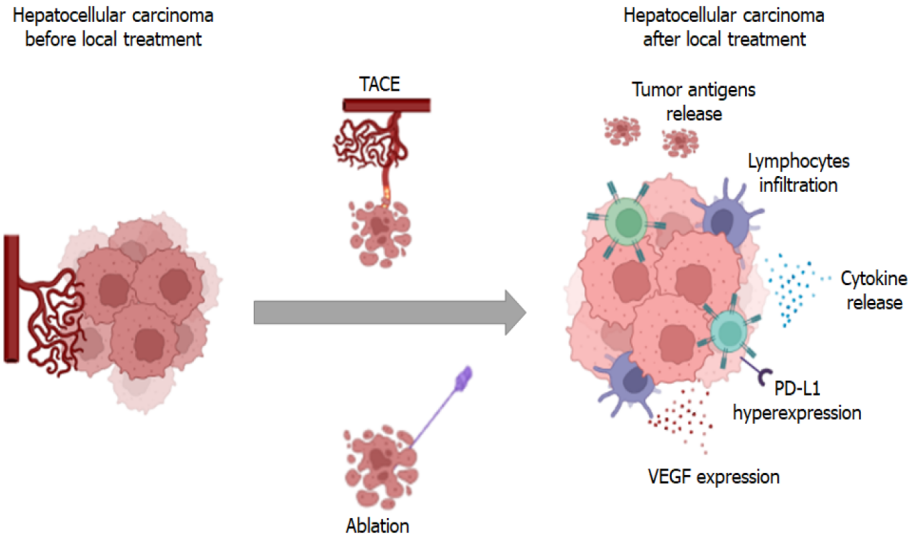
or microscopic), are significantly related to higher recurrence rates. Novel markers, such as genetic signatures, circulating microRNA, circulating non-coding RNA, circulating cell-free DNA, gut microbiota, and circulating tumor cells, have also been shown to predict the risk of recurrence[45-47].

To evaluate the impact of multikinase inhibitors with antiangiogenic activity combined with ablation, the STORM trial randomized patients treated with resection (n = 900) or ablation (n = 214) to sorafenib or placebo for a total of 4 years. Unfortunately, there was no difference in recurrence-free survival between groups, with a median to time to recurrence of 33.3 mo in the sorafenib group and 33.7 mo for the placebo group (HR = 0.94, P = 0.26)[48]. Thus, the positive results obtained with sorafenib in advanced disease have not been reproduced in the context of adjuvant post-resection or ablation. Other drugs used in the advanced stage, such as cabozantinib, regorafenib, ramucirumab, and lenvatinib have not been evaluated in patients after ablation. In sum, VEGFR-directed therapies as monotherapy do not seem to improve the results of ablation.

Recently, the immune features of localized HCC and the response to local treatment are being investigated[49-51]. The concentration of intratumor CD3 + and CD8 + T cells and the expression of programmed death ligand 1 (PD-L1) by immune and tumor cells appear to be associated with HCC aggressiveness and risk of recurrence after curative treatments, such as ablation and surgery[13]. The high expression of PD1 can lead a condition of exhausted CD8 + impairing cytotoxicity and decreasing of pro-inflammatory cytokines production and anti-tumor ability[13].

Ablation can induce stimulate inflammatory and cytokine production within the treated site. The tumor debris released upon ablation represent a tumor antigen repertoire that can boost antitumoral immunologic response. Indeed, tumor antigens can be found in dendritic cells in lymph nodes following ablation[52]. This background indicates a potential role for immune checkpoint inhibitors directed to PD1 and PD-L1 in combination with ablative therapies (Figure 2). A phase I trial including 32 patients treated with tremelimumab and ablation showed accumulation of CD8+ cells, suggesting immune system activation[53]. Preliminary results of the NIVOLVE trial were presented in 2021. In this phase II single arm trial, 55 patients after surgery (n = 33) or ablation (n = 22) received nivolumab for 12 mo. The median recurrence-free survival was 26 mo. In this trial, the authors suggested that patients with tumor-infiltrating lymphocytes, positive PD-L1, and negative staining for beta-catenin tend to develop fewer recurrences[54]; however, larger and comparative studies are needed to confirm these findings. Currently, several active trials (recruiting or waiting results) are addressing the role of immune-checkpoint inhibitors in combination with anti-VEGFR agents or alone after curative treatments, such as ablation (Table 2).

INTRA-ARTERIAL THERAPIES



Current evidence of intra-arterial therapy in HCC

Intra-arterial therapies harness the arterial supply of HCC that differs from the liver parenchyma, which receives its blood supply predominantly from the portal vein. This group of therapies are composed of transarterial embolization (TAE), chemoembolization (TACE), and selective internal radiotherapy (SIRT) or radioembolization (TARE).

The mechanism of action of TAE is based on the obstruction of the blood supply causing ischemia, while TACE adds a cytotoxic agent (most commonly doxorubicin) and a carrier agent (commonly lipiodol). Drug-eluting bead (DEB)-TACE uses microspheres carrying cytotoxic agents which are associated with a sustained drug release and, theoretically, a lower systemic exposure to chemotherapy

Figure 2 Mechanisms of tumor microenvironment changes after locoregional therapies. After local interventions, tumor immune microenvironment may change with a pronounced release of tumor antigens, cytokines, lymphocyte infiltration, and hyperexpression of vascular endothelial growth factor. TACE: Transarterial chemoembolization; PD-L1: Programmed death ligand 1; VEGF: Vascular endothelial growth factor.

[55].

Based on randomized clinical trials of TACE *vs* no active treatment and also in a large meta-analysis, this is considered the standard of care for patients with intermediate-stage [Barcelona clinic liver cancer (BCLC)-B: Multinodular disease, preserved liver function, and performance status of 0][56,57]. In published cohorts with selected patients, the median overall survival with TACE reaches 48 mo[58]. There is no definitive evidence for the superiority of TACE over TAE, although data from meta-analysis suggests that the former is associated with better outcomes[57]. A prospective trial demonstrated that DEB-TACE presents lower treatment-related toxicities and a trend towards a better objective response rate compared to conventional TACE[59].

Guidelines recommend that patients who present progression with infiltrative tumors, vascular invasion, metastatic spread, or absence of a significant response after two TACEs should be considered for systemic treatment[2,4]. The risk of liver deterioration should be carefully monitored after TACE due to the prognostic impact of liver decompensation in patients with HCC[60]. The decision to declare TACE failure and switch to systemic treatment is heterogenous in different parts of the world, and many scores have been proposed to help in this decision, although some of them still require further validation in a population treated strictly according to the BCLC algorithm[61-65]. For example, the hepatoma-arterial embolization (HAP) score includes albumin, AFP, bilirubin and tumor diameter and was concepted to predict prognosis before the first TACE in a heterogeneous cohort with around 30% of BCLC-C patients[64]. The Assessment for Retreatment with TACE (ART) score was designed to evaluate benefit of a 2nd TACE and assess Child-Pugh score, AST levels, and tumor response after the first TACE. The ART score was originally developed in a cohort that included around 20% of patients with impaired liver function (Child-Pugh B8 or more)[66].

With the availability of more effective systemic agents, the migration from TACE to systemic treatment is a key decision in the management of HCC and should not be delayed at a point of

irreversible deterioration of liver function or performance status.

TARE has been increasingly studied in HCC and has become a common practice in many centers. Data comparing TACE to TARE demonstrated in patients with early or intermediate stage a longer time to progression favoring TARE, but no survival benefit[67]. Although encouraging, there is no solid evidence that TARE should became standard of care in patients eligible to intra-arterial therapies.

A recent single-arm retrospective study including patients with solitary HCC ≤ 8 cm reported objective response rates of 88.3% and a 3-years survival of 86.6%. In this study TARE served as a neoadjuvant therapy for transplantation or resection in 21% and 6.8% of patients, respectively[68].

In uncontrolled trials, TARE was suggested to be safe in patients with portal vein invasion[69]. However, randomized trials in the setting of advanced stage HCC did not prove superiority of TARE over sorafenib in overall survival[70,71]. Therefore, TARE is not recommended as a standard therapy in patients classified as BCLC-C. There is a need to better explore the role of TARE in HCC in prospective and randomized trials, especially for subgroups of patients requiring downstaging, segmental portal vein thrombosis, and using rigorous dosimetry.

Combination of intra-arterial and systemic treatment: rationale and current evidence

Although TACE is the standard treatment for intermediate stage, only around 50% of patients present objective response rate and most of them will eventually present distant and local progression[72]. This has led to studies focused on improving the outcomes for HCC patients treated with TACE by combining multikinase inhibitors.

The rational for testing these combinations comes from the demonstration of increased intratumorally micro vessel density and VEGF expression in residual tumors after TACE, suggesting that TACE may stimulate tumor angiogenesis[73]. However, antiangiogenic drugs, such as sorafenib[74,75], brivanib [76], and bevacizumab[77], failed to demonstrated survival benefit in combination with TACE in controlled trials.

Recently, TACTIS trials randomized patients to TACE alone or combined with sorafenib and showed that sorafenib improved progression-free survival (25.2 mo *vs* 13.5 mo; P = 0.006), but with no significant impact on overall survival (36.2 mo *vs* 30.8 mo; P = 0.40)[78,79]. Currently, available evidence fails to encourage the use of multikinase inhibitors in combination with TACE as a standard practice, but there is a growing enthusiasm with the use of immunotherapy in this setting.

Similar to ablative treatments, intra-arterial therapies may modulate innate and adaptative immunity by releasing cellular debris and inflammatory cytokines and inducing T-cell responses, what is suggested to be related to improved prognosis[80,81] (Figure 2). A recent study compared HCC tissue from patients who were previously submitted to TACE to patients not treated with TACE and found that the former had a lower density of immune-exhausted effector cytotoxic and T-regs with an upregulation of pro-inflammatory pathways[82]. Considering this background, strategies aimed at blocking negative regulators such as PD-1 and CTLA4 are promising and are being investigated in phase III clinical trials (Table 3).

TARE also seems to modulate immunological microenvironment in HCC. A study that compared findings before and after TARE showed that tumor-infiltrating lymphocytes after TARE exhibited signs of immune activation, such as higher expression of granzyme-B and infiltration of CD8+Tcells, NK cells, and antigen-presenting cells[83,84]. Initial data on the combination of nivolumab and SIRT showed favorable safety profile, but efficacy data are pending[85,86].

Besides the biological background, the use of systemic treatment in earlier stages (combined with locoregional treatment) may benefit those patients who would present clinical deterioration or liver function worsening during TACE-refractoriness and would not found fit to receive further systemic treatment in that situation.

CONCLUSION

The treatment landscape of HCC management evolved rapidly in the past years. The most relevant achievements took place in the management of advanced stage disease. The median overall survival in pivotal clinical trials shifted from 5-8 mo in placebo arms[6], to almost 20 mo with immunotherapy combinations[21]. Still, some questions remain to be answer regarding the identification of predictive biomarkers and the optimal sequence in first-, second-, and later lines[87-89].

On the other, the field evolved modestly in the setting of local and locoregional stages, comprising early and intermediate stages. Patients in the early stage are offered surgical resection, liver transplantation, or ablation. Due to organ shortage and strict criteria to transplant, surgery and ablation has been widely used. Unfortunately, their recurrence rates are high and determine results in long-term mortality[33-35]. Although attempts were made, no systemic treatment has improved outcomes in early stage. Robust evidence supports those immunological changes occur after tumor ablation and the use immunotherapy is encouraging.

Patients in the intermediate stage have historically been offered TACE with the aim to achieve tumor control. Similarly, most of them will eventually present local or distant progression and will be

Table 3 Clinical trials approaching combination of systemic treatment and intra-arterial actually enrolling, recruiting or waiting for final results

considered for systemic treatment. The concomitant use of immunotherapy-based systemic agents and intra-arterial therapies may enhance anti-tumor immune response and impact positively on the outcomes. Several clinical trials are eagerly awaited.

The most promising ongoing trials approach the combination of TACE and immunotherapy, with the aim to significantly delay time-to-progression and, hopefully, increase cure rates for patients who achieve complete response with locoregional treatment. Similarly, trials that test adjuvant immunotherapy after ablation may increase cure rates by reducing the risk of recurrence and -*de novo* tumors. It is likely that biomarkers and subsets of clinical features will emerge from these trials and will support the selection of patients that will derive more benefit from combination approaches.

Finally, it is key to consider that if active trials succeed in showing a better anti-tumor efficacy with combination of locoregional and systemic treatment, a longer survival of patients with HCC will be expected. Furthermore, this will highlight the burden of cirrhosis-related complications as a competing risk of mortality and the importance of multidisciplinary teams as the standard approach for HCC.

MINIREVIEWS

Update on endoscopic ultrasound-guided liver biopsy

Shiva Rangwani, Devarshi R Ardeshna, Khalid Mumtaz, Sean G Kelly, Samuel Y Han, Somashekar G Krishna

Specialty type: Gastroenterology and hepatology

Provenance and peer review: Invited article; Externally peer reviewed.

Peer-review model: Single blind

Peer-review report's scientific quality classification

Grade A (Excellent): A
Grade B (Very good): B
Grade C (Good): C
Grade D (Fair): D
Grade E (Poor): 0

P-Reviewer: Alali AA, Kuwait; El-Karaksy H, Egypt; Treeprasertsuk S, Thailand; Zhu YY, China

Received: January 16, 2022
Peer-review started: January 16, 2022
First decision: March 8, 2022
Revised: April 21, 2022
Accepted: June 23, 2022

Abstract

Endoscopic ultrasound guided liver biopsy (EUS-LB) has emerged as a minimally-invasive alternative to the traditional (percutaneous or transjugular) liver biopsy techniques for the diagnosis of liver parenchymal diseases. Potentially, EUS-LB combines the advantages of percutaneous and transjugular liver biopsy in addressing focused sampling in addition to measuring portal pressure. Additionally, EUS-LB facilitates access to both the lobes of the liver which is not considered with the traditional percutaneous liver biopsy. Multiple studies have compared EUS-LB with conventional liver biopsy and reported comparable diagnostic yield, increased acquisition of complete portal tracts, and longer specimen length as compared to the traditional approaches. EUS-LB is associated with lesser post-procedural pain and shorter recovery time, while providing lower risk of complications when compared to traditional liver biopsy. Innovations in needle types, needle sizes and suction techniques have aimed at further optimizing the EUS-LB technique. This review article updates current literature with focus on the variations in the technique and equipment used for EUS-LB, and compares EUS-LB with traditional methods of liver biopsy.

Key Words: Endoscopic ultrasound guided liver biopsy; Liver biopsy; Percutaneous liver biopsy; Transjugular liver biopsy; Liver parenchymal disease; Portal pressure gradient

INTRODUCTION

Liver biopsy is helpful in diagnosis of parenchymal pathologies such as alcoholic liver disease, autoimmune hepatitis, viral hepatitis, metabolic liver diseases (non-alcoholic fatty liver disease, alfa-1 anti-trypsin deficiency, Wilson disease, hemochromatosis, Gaucher's disease, *etc.*), drug-induced liver injury and infiltrative liver disease (*i.e.*, malignancy, abscess, sarcoidosis, *etc.*). Tissue examination also allows for diagnosis of rare overlapping liver diseases. The liver biopsy has traditionally been obtained *via* two routes: percutaneous liver biopsy (PC-LB) and transjugular liver biopsy (TJ-LB). In recent years, endoscopic technique and hardware advancement have led to the rise of endoscopic ultrasound-guided liver biopsy (EUS-LB). There is changing epidemiology of liver disease with increased global incidence of non-alcoholic fatty liver disease over the last two decades; it has reached to an estimated global prevalence of 25%[1]. This increased prevalence has led to advancements in lesser or non-invasive diagnostic tests such as ultrasound-elastography and MRI-proton density fat fraction[2]. Although these tests provide greater diagnostic accuracy compared to traditional peripheral blood laboratory tests, liver biopsy remains the gold standard for diagnosing focal lesions and parenchymal liver disease[3]. In this review, we will compare EUS-LB with traditional liver biopsy and highlight its, advantages and disadvantages in context of changing epidemiology of liver disease. Further, we will summarize the latest advancements on EUS-LB, focusing on technique, needle types/size, and suction type.

METHODS OF LIVER BIOPSY

The first mode of acquisition of liver tissue was PC-LB, as it provides the most direct route to access the liver. Percutaneous needle aspiration biopsies have been performed since the late 19th century and popularized in the 1930s[4]. Initial PC-LB techniques used percussion to guide needle placement; however, modern PC-LB is done under ultrasound- or fluoroscopic-image guidance[5]. If hepatomegaly is present, a subcostal route for PC-LB is preferred; however, a transthoracic approach is employed in the absence of hepatomegaly. In the early days of PC-LB, interventionists preferred 14 gauge (G) or 16 G needles to provide large, intact tissue samples. In recent years, spring-loaded 18 G and 20 G needles have been common[6]. PC-LB is usually done while the patient is awake with local anesthesia, but conscious sedation is often used. Common complications of PC-LB include pain (74%), minor bleeding (30%), and infection at the biopsy site[7,8]. As the liver capsule is punctured to obtain biopsy, intraperitoneal hemorrhage is a severe, albeit rare complication[7]. Other less-common complications include pneumothorax and hemothorax if the transthoracic approach is employed (0.1%-0.9%)[7-9]. Contraindications to PC-LB include significant ascites, large body-habitus, and severe coagulopathy[5]. As it has been a long-standing method of biopsy, PC-LB is widely available. Furthermore, given its short procedure time and the fact that general anesthesia is not required, PC-LB provides a cost-effective approach to diagnosing liver diseases. Drawbacks to PC-LB include access to only the right hepatic lobe and a limited view of surrounding anatomy. Further, if real-time imaging is not used for guidance, there is an increased risk of serious complications[10].

More recently, TJ-LB has been developed to obtain liver samples in patients with contraindications to PC-LB. In this technique, an interventional radiologist cannulates the internal jugular vein and accesses one of the hepatic vein under fluoroscopic guidance. Biopsy of the right hepatic lobe is preferred because of its size and the acute angulation of the veins with the inferior vena cava[11]. This procedure can be performed in patients with high body mass index, and significant ascites. Additionally, as the liver capsule is not punctured, it is the preferred method in those with profound coagulopathies[11]. This technique provides the added benefit of assessing the hepatic venous pressure gradient (HVPG), which is an indirect measure of the absence, presence and degree of portal hypertension. HVPG

measurement will be compared to EUS-guided measurement of portal pressure in the discussion of future research and practice below. Complications from TJ-LB include pain, hematoma, hemobilia, arterial aneurysm, and major hemorrhage[11]. In addition to subverting contraindications posed by the PC-LB, advantages of TJ-LB include lack of capsular puncture and the ability to obtain a portal pressure gradient measurement[7,10,11]. One of the limitation of TJ-LB is inability to obtain tissue from a focal lesion, due to limited view of surrounding structures[10].

Endoscopic ultrasound-guided fine-needle aspiration was first done in 1993 and EUS-LB was first described by Mathew in 2007[12,13]. EUS-LB poses several advantages over the traditional LB techniques. Firstly, EUS-LB allows access to both lobes of the liver (except in patients with Roux-en-Y or gastric bypass anatomy)[10]. Secondly, like TJ-LB, EUS-LB enables a practitioner to obtain liver tissue regardless of body habitus or ascites. The most advantageous aspects of EUS-LB, when compared to PC-LB and TJ-LB, lie in its real-time multi-dimensional evaluative abilities. Those undergoing workup for liver disease often require endoscopic evaluation – the advent of EUS-LB posed a solution to facilitate patients to undergo multiple endoscopic procedures in the same session. With EUS, a liver biopsy can be performed along with simultaneous evaluation for varices (esophageal and gastric) and portal pressure measurement. Further, the use of EUS in close proximity to the liver allows for better visualization of liver lesions for targeted liver biopsies[10]. In fact, multiple studies have shown a diagnostic accuracy between 85%-90% for solid liver masses using EUS-guided FNB[14-16]. Use of ultrasound-guided technique also allows practitioners to avoid critical structures during biopsy procurement. The drawbacks to EUS-LB mirror some of the drawbacks found in PC-LB and TJ-LB. Although the number of EUS-trained practitioners have grown rapidly over the past ten years in the United States, this procedure is less widely accessible when compared to PC-LB[10]. Further, unlike TJ-LB, EUS-LB does require capsular puncture and is not readily performed in patients with severe coagulopathy. Additionally, EUS-LB does require moderate or deep sedation, as with TJ-LB.

METHODS OF LIVER BIOPSY - COMPARISONS

Recovery times and complications

With the advent of multiple modalities for obtaining liver biopsies, recent studies have comparatively evaluated these approaches. The comparison between each of the three liver biopsy methods is summarized in Table 1. With regards to length of recovery, EUS-LB patients (n = 30) experienced a shorter post-procedural monitoring time (3 h) when compared to those (n = 60) undergoing PC-LB (4.2 h, P = 0.004)[17]. A recent study done in 2021 showed the mean recovery time for those undergoing EUS-LB was 90 min *vs* 141.3 min (P = 0.004) for TJ-LB[18]. The most common minor complication in each of the three modes of liver biopsy is pain. In a 2020 study, EUS-LB had significantly less pain scores when compared to PC-LB (0/10 for EUS-LB *vs* 3.5 for PC-LB, P = 0.0009)[17]. When comparing pain in EUS-LB and TJ-LB patients, one 2019 study found a significantly higher incidence of post-procedural pain in TJ-LB patients compared to EUS-LB patients, 8% *vs* 0% (P < 0.0001), respectively[19]. Adverse events with regard to liver biopsy include, but are not limited to, severe hemorrhage, hemobilia, abdominal wall injury, and intraperitoneal injury. Although no studies have directly compared adverse event rates between the three liver biopsy modalities, adverse event rates appear to be similar across each modality – EUS-LB: 1%-2.3%, PC-LB: 0.9%-3.1%, TJ-LB: 0.56%-6.5%[18-22].

Specimen adequacy

Regarding histological adequacy of liver biopsy samples, the American Association for the Study of Liver Diseases recommends a tissue length of between 2-3 cm with greater-than-or-equal-to 11 complete portal tracts (CPT)[23]. Systematic reviews have shown a total specimen length for PC-LB to be 17.7mm (± 5.5 mm), TJ-LB: 13.5 mm (± 4.5 mm), and EUS-LB 36.9 mm (± 6.2 mm)[20,24]. CPT numbers in these same studies revealed an aggregate CPT for PC-LB of 7.7 (± 3.4), TJ-LB: 6.8 (± 2.3), and EUS-LB: 9.0 (± 3.1)[20,24]. A recent 2021 study compared each liver biopsy technique head-to-head and found that EUS-LB (n = 53) had a significantly greater mean aggregate length (22.95 mm) compared to PC-LB (n = 20) (14.5 mm) (P = 0.03) and TJ-LB (n = 20) (14.6 mm) (P = 0.02)[18]. Further, both EUS-LB and TJ-LB provided a greater number of CPTs when compared to PC-LB: EUS-LB (19.36), TJ-LB (20.2), PC-LB (9.1) (EUS-LB *vs* PC-LB: P < 0.0001, EUS-LB *vs* TJ-LB P = 1)[18].

TECHNIQUE OF EUS-GUIDED LIVER BIOPSY

Since the inception of EUS-LB in 2007 with a Tru-Cut core biopsy needle (QuickCore, Cook Medical, Winston Salem, NC, United States), multiple studies have aimed at optimizing EUS-LB technique[13]. These changes coincided with procedural upgrades and improvements in needle technology. Incorporating these advancements into EUS-LB comes with technical (skills and training) and logical challenges (cost and availability). However, the essential technique of EUS-LB remains unchanged.

Table 1 Comparison of liver biopsy methods[1]

	Percutaneous liver biopsy	Transjugular liver biopsy	Endoscopic ultrasound-guided liver biopsy
Most common form of anesthesia	Local	Moderate sedation	Moderate sedation, deep sedation
Imaging	Fluoroscopy, ultrasound	Fluoroscopy	Ultrasound
Capsular puncture	Yes	No	Yes
Ability to evaluate focal hepatic lesions	No	No	Yes
Liver lobe access	Right	Right	Right, left
Contraindications	INR > 1.5, body habitus, significant ascites	Venous thrombosis, cholangitis	INR > 1.5
Post-procedural pain	+++	+	+
Post-procedural minor bleeding	+	+	+
Adverse event rate	+	+	+
Post-procedural recovery time	+++	++	+
Specimen length	+	+	+++
Total complete portal tracts	+	++	+++
Procedure cost	+	++	+++
Institutional availability	+++	++	+

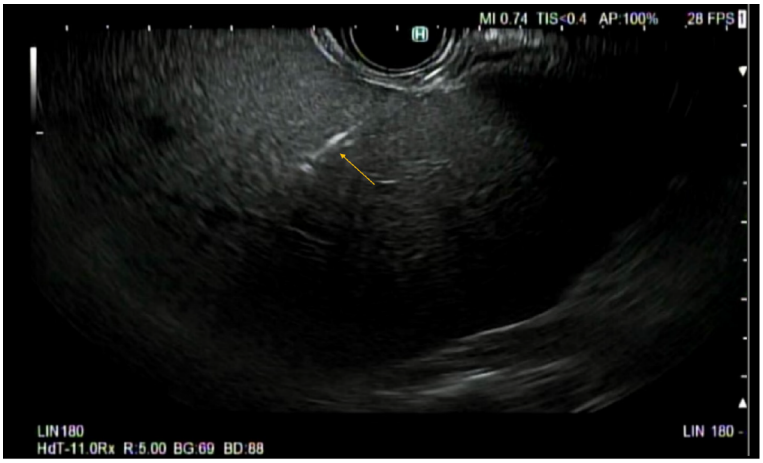
+: Low/less; ++: Medium; +++: High/most; INR: International normalized ratio.



General technique

Patients undergoing EUS-LB are either moderately sedated with short-acting benzodiazepines and opiates or deeply sedated with propofol, per the availability of dedicated anesthetists. The patients are prone positioned and a linear array echo-endoscope is inserted for endo-sonography. Once the area of interest is identified, the stylet is removed, and a needle primed (with heparin or saline) or unprimed (air) is inserted[6,10]. Per endoscopist and center preference, the needle should be attached either to a wet suction (saline or heparin) or a dry suction (air). Before needle puncture, color Doppler should be used to ensure there are no vascular structures in the trajectory of the needle. Suction should be applied *via* a syringe once adequate liver parenchymal penetration is achieved (depending on the needle selection). Figure 1 shows the echoendoscopic image of a needle passing through into the left hepatic lobe. In 1 pass, actuations or fanning back-and-forth motions can be done with continued suction to allow for improved tissue acquisition[25]. Multiple such passes can be done overall to increase tissue acquisition. After each pass, the needle should be removed from the echo-endoscope and the tissue should be stored in formalin solution directly for preservation[6,10]. This gross tissue can be analyzed for adequacy and should guide the decision if more passes are required. Following the procedure, patients can be discharged after 1-2 h observation in the recovery unit.

Accessing liver parenchyma requires identification of endoscopic gastric landmarks. The left lobe of liver adjoins the gastroesophageal junction can be accessed through the gastroesophageal junction in the proximal stomach. The right lobe of the liver can be accessed through the duodenal bulb[26]. Among patients with altered anatomy, EUS-LB is limited. For Roux-en-Y gastric bypass patients, only left liver lobe biopsy is feasible through the transgastric approach[10].

Suction

Suction can be applied in a wet or dry fashion. In dry suction, an empty 10 cc or 20 cc syringe is applied to maintain suction after passing the needle into the liver parenchyma. In wet suction, the needle lumen is primed with fluid, causing negative pressure at the needle tip. As outlined above, wet suction utilizes either saline or heparin. A 2018 study compared wet heparin suction technique with dry suction technique. The study showed significantly increased aggregate specimen length (wet: 49.2 mm, dry: 23.9 mm, P = 0.003) and number of CPTs (7.0 *vs* 4.0, P = 0.01) for wet suction compared to dry suction techniques[27]. With wet suction, the sample is suspended in a column of fluid—leading to reduced shearing forces as it is not in contact with the needle wall. This likely leads to increased CPTs and intact specimen length for wet suction technique. To our knowledge, no studies directly comparing wet suction with saline *vs* heparin have been performed.

In contrast, specimens can be obtained without applying suction *via* stylet, in a "slow-pull" technique. A 2020 meta-analysis showed that FNB with a slow-pull technique provided similar total specimen length (44.3 mm *vs* 53.9 mm, $P = 0.40$) when compared to suction application; however, the slow-pull technique provided improved CPT than suction (30 *vs* 14.6, $P < 0.001$)[28]. Authors hypothesize that this stems from reduced fragmentation of the tissue specimen as it is subjected to an environment of less negative pressure with the slow-pull technique.

Needle pass/Actuation

Needle pass refers to the number of times a needle is introduced into the liver parenchyma through puncture of the liver capsule, while actuation refers to the number of back-and-forth motions are made in a specified needle pass. Through our literature review, it appears the 1-pass 1-actuation technique is the most common mode of EUS-LB acquisition[25,29]. There are few studies that have been done comparing needle pass and needle actuation with regards to pain, adverse events, and specimen quality. A 2021 study showed that EUS-LB using a 1-pass, 3-actuation technique ($n = 40$) provided longer liver cores with more CPTs than a 1-to-1 technique ($n = 40$), with an equivalent safety profile: CPT (24.5 *vs* 17.25, $P < 0.008$), aggregate specimen length (12.85 cm *vs* 6.89 cm $P < 0.001$)[25].

Needle selection: Size

When considering needle selection, a EUS-LB practitioner must take needle size and type into account. With regards to needle size, multiple studies have been done to determine the optimal needle size for EUS-LB. In the early days of EUS-LB, large 14G – 16 G spring-loaded cutting needles were used; however, these needles had varied diagnostic yields ranging from 29%-100%[30,31]. As time progressed, researchers found that smaller-gauge needles provided better results than their 14-16 G counterparts. In a 2017 study, 18 G percutaneous, 19 G FNA, 19G FNB, and 22 G FNB needles were compared on human cadaveric tissue to test for tissue adequacy. The study showed that a 19 G needle provided a significantly greater number of CPTs when compared to its 22 G and 18 G counterparts (6.2 *vs* 3.5 *vs* 3.2, respectively, $P < 0.001$ for both comparisons)[32]. In a similar study in 2019 on fresh bovine liver, 19 G and 20 G fork-tip needles yielded similar CPTs and total specimen length; however, both the 19 G and 20 G fork-tip needles significantly outperformed their 22 G fork-tip counterpart in terms of CPTs and specimen length[33].

More recent *in vivo* studies have confirmed the superiority of 19 G needles when compared to 22 G needles. A recent (2021) study showed that 19 G Franseen tip needle performed better than a 22 G Franseen tip needle in terms of specimen adequacy (19 G: 81.5%, 22 G: 66.7%, $P < 0.01$)[34]. The researchers posit that the 22 G samples had greater fragmentation, leading to reduced intact specimen length and CPT, reducing histological adequacy. The advantage of 19 G compared to 22 G needle was also shown in core needles, where 19 G core needles had a greater CPT (8.8 *vs* 3, $P < 0.0001$), longer core length (2.5 cm *vs* 1.1 cm, $P < 0.0001$), and a higher rate of pathological diagnostic samples (85% *vs* 10%, $P < 0.0001$) when compared to 22 G core needles[35].

Needle selection: Tip and design

As noted earlier, large spring-loaded cutting needles were initially used to perform EUS-LB. As EUS-LB grew, practitioners noted that fine-needle biopsy (FNB) needles may provide better samples in the endoscopic setting. In 2015, Dewitt *et al*[36] showed that a 19 G FNB histology needle performed better

than a 19 G spring-loaded cutting needle and provided longer specimens (19.4 mm *vs* 4.3 mm, P = 0.0001), greater CPTs (10.4 *vs* 1.3, P = 0.0004), and a higher percent of diagnostic histology (85% *vs* 57%, P = 0.006)[36].

Holding needle gauge constant, Franseen needle types have shown to be superior than their counterparts in recent studies. A 2019 study showed that a 19 G Franseen needle provided lengthier specimens when compared to a 19 G FNA needle for *in vivo* EUS-LB (2.09 cm *vs* 1.47 cm, P < 0.001), more CPTs (42.6 *vs* 18.1, P < 0.001), and similar pain scores[37]. In the late portion of the last decade, EUS-LB has been most commonly performed with either Franseen or Fork-Tip biopsy needles. Multiple studies have compared the effectiveness with regards to specimen quality and adverse events between these two needles. A 2020 study showed a similar adverse event and abdominal pain profile between the use of 19 G Franseen and fork-tip needles[29]. The Franseen needle, however, had a significantly greater total specimen length when compared to the fork-tip needle (3.1 cm *vs* 2.7 cm, P = 0.01) and greater total CPTs (24.0 *vs* 19.55, P < 0.01)[29]. The Franseen tip has also shown equal-to-superior diagnostic yield when compared to fork-tip, with one study showing nonsignificant-difference in histological adequacy rates but an increased number of CPTs (14.4 *vs* 9.5, P < 0.001) and another study showing a higher diagnostic yield of 97.2% for Franseen tip compared to 79.4% for fork-tip (P < 0.001)[38,39].

FUTURE RESEARCH AND PRACTICE

Portal pressure gradient

In trained hands it has become possible to obtain accurate measures of portal pressure gradients by various approaches[36]. The measure of the portal pressure gradient is primarily done through the transjugular approach. Although described as the gold standard, the hepatic venous pressure gradient (HVPG) is actually an indirect measure of portal pressure calculated by subtracting the free hepatic venous pressure from the wedge hepatic venous pressure[40]. In contrast, EUS-guided measurement of portal pressure is a direct measurement of sinusoidal pressure rather than an estimate, and may prove to be more accurate[40]. To obtain EUS-guided measurement of portal pressure, endoscopists first puncture the hepatic vein *via* a transgastric transhepatic approach, with the needle hooked up to a digital manometer *via* non-compressible tubing[41]. Once obtaining hepatic vein pressure averages, endoscopists then turn their attention to the portal vein, which is accessed in a transgastric transhepatic approach usually at the umbilical portion of the portal vein. Once the portal vein pressure is obtained, the portal pressure gradient is calculated by subtracting the mean portal vein pressure from the mean hepatic vein pressure[41]. These readings are usually obtained with a small-gauge (25 G) FNA needle [40,41].

Since the HVPG can be obtained without performing a liver biopsy, it is a very safe procedure when performed alone, mainly imparting the risk associated with right internal jugular access[9,11]. Therefore, it is essential to ensure that EUS-guided measurement of portal pressure is performed with specific indications to ensure safety. For example, patients with splenomegaly may benefit from EUS-LB and EUS-guided measurement of portal pressure to confirm whether cirrhosis and portal hypertension are the underlying causes of splenomegaly. However, if a patient has esophageal or gastric varices, it can be safely assumed that the portal pressure is 10 mmHg or higher and the patient has clinically significant portal hypertension[40]. That information should be used to determine whether EUS-guided measurement of portal pressure is warranted at the time of the procedure.

Concomitant EUS-LB with other endoscopic procedures

EUS-LB provides an exciting new method for liver tissue acquisition. A novel application is for special patient populations such as liver transplant recipients (LTRs). Laboratory abnormalities in liver transplant patients often requires an extensive workup including imaging, liver biopsy, and ERCP. Combining EUS-LB with ERCP can potentially provide a "one-stop-shop" for evaluation in this patient population. This will hopefully reduce the time, cost, and healthcare resources needed to accurately diagnose and treat post-transplant liver function abnormalities. Our group at Ohio State University, has recently submitted a case series of 12 consecutive LTRs with abnormal liver function tests (Han S, Jalil S, Groce JR, Krishna SG, Lara L, Lee P, Limkemann A, Papachristou GI, Mumtaz K. Feasibility of Single-Session EUS-guided Liver Biopsy and ERCP in Liver Transplant Recipients with Abnormal Liver Function Tests), who underwent concomitant EUS-LB and ERCP. In this case series, tissue adequacy was obtained in 100% of patients with the most common diagnoses including anastomotic stricture (75%) and T-cell mediated rejection (66.7%). Seven (58.3%) patients had dual diagnoses of T-cell mediated rejection and anastomotic stricture. There were no 30 d adverse events. Authors concluded that **s**ingle-session EUS-guided LB and ERCP for the evaluation of elevated liver function tests in LTRs appears to be safe and feasible, but larger studies are needed to verify these findings.

Similarly, a recent study published by Hajifathalian *et al*[42] on concomitant EUS-LB and portal pressure gradient measurement reported 24 (100%) and 23 (96%) patients had successful portosystemic gradient (PSG) measurement and EUS-liver biopsy, respectively. Analysis revealed a significant

association between both PSG and liver stiffness measured on transient elastography (P = 0.01) and FIB-4 score (P = 0.02). There was no significant correlation between the fibrosis stage on histology and measured PSG (P = 0.56)[42].

Lastly, EUS-LB has been discussed anecdotally as a more effective option in pediatric population, as it may reduce patient anxiety when compared to PC-LB or TJ-LB – although, to our knowledge, formal studies in pediatric populations are yet to be done.

CONCLUSION

Overall, EUS-LB provides unique advantages when compared to its counterparts: ability to evaluate the GI tract and pancreato-biliary system, while obtaining access to both lobes of the liver. It also has proven to produce more histologically/pathologically complete samples than PC-LB and TJ-LB. EUS-LB appears to be a safe, diagnostic modality for obtaining liver tissue. Concomitant EUS-LB, EUS portal pressure gradient measurement and other endoscopic procedure (simple endoscopy and ERCP) is another emerging area in the field of endo-hepatology.

Abstract

Hepatocellular carcinoma (HCC) is among the most common cancers and it is a major cause of cancer-related deaths. Non-alcoholic fatty liver disease (NAFLD) affects approximately one fourth of individuals worldwide and it is becoming one of the most important causes of HCC. The pathogenic mechanisms leading to NAFLD-related HCC are complex and not completely understood. However, metabolic, fibrogenic, oncogenic, inflammatory and immunological pathways seem to be involved. First-line therapy of advanced HCC has recently undergone major changes, since the combination of atezolizumab and bevacizumab was

proven to increase survival when compared to sorafenib. Other immune-oncology drugs are also demonstrating promising results in patients with advanced HCC when compared to traditional systemic therapy. However, initial studies raised concerns that the advantages of immunotherapy might depend on the underlying liver disease, which seems to be particularly important in NAFLD-related HCC, as these tumors might not benefit from it. This article will review the mechanisms of NAFLD-related hepatocarcinogenesis, with an emphasis on its immune aspects, the efficacy of traditional systemic therapy for advanced NAFLD-related HCC, and the most recent data on the role of immunotherapy for this specific group of patients, showing that the management of this condition should be individualized and that a general recommendation cannot be made at this time.

Key Words: Non-alcoholic fatty liver disease; Hepatocellular carcinoma; Hepatocarcinogenesis; Immunology; Immunotherapy; Tyrosine kinase inhibitors

Core Tip: Non-alcoholic fatty liver disease (NAFLD) is an important cause of hepatocellular carcinoma (HCC). While the treatment of advanced HCC has recently undergone a revolution led by immunotherapy, concerns have been raised that NAFLD-related HCC might not respond well to these new therapies. This review will approach the pathophysiology of NAFLD-related liver cancer, the evidence on traditional systemic treatments and the most recent data on immunotherapy for this particular group of patients, showing that the management of this condition should be individualized.

INTRODUCTION

The incidence of liver cancer worldwide was 11.6/100000 individuals in 2020 and its mortality rate reached 10.7/100000 in the same year, making it the sixth most common cancer and the second cause of cancer-related mortality[1]. Furthermore, it is estimated that its incidence rate will continue to increase until 2030[2]. Hepatocellular carcinoma (HCC) is by far the most common among primary liver cancers [3,4].

Non-alcoholic fatty liver disease (NAFLD) has a striking prevalence of 25% worldwide[5], which highlights its relevance as an underlying cause of HCC[6]. In the year of 2019, for instance, NAFLD was estimated to be associated with 36300 new cases of HCC, as well as with 34700 HCC-related deaths[7]. As it would be expected, the burden of NAFLD as a cause of HCC seems to be growing. It is estimated that the age-standardized incidence rate of NAFLD-related liver cancer will raise from 0.92 to 1.18/100000 individuals between 2018 and 2030[2]. Moreover, while a multinational cohort study demonstrated that NAFLD was responsible for 9% of HCC cases followed between 2005 and 2015 in South America (an area with high prevalence of NAFLD)[8], the same group verified that it was responsible for 34% of cases followed between 2019 and 2020[9].

Cirrhosis in general predisposes to HCC, and the annual incidence of HCC in patients with NAFLD-related cirrhosis ranges between 0.5% and 2.6%[10-13]. However, some specific mechanisms associated with NAFLD, which will be further discussed in this article, also allow for the development of HCC in the absence of cirrhosis, making NAFLD itself etiologically associated to hepatocarcinogenesis[6,14-16]. According to a meta-analysis, approximately 38% of NAFLD-related HCCs would develop in non-cirrhotic settings[17]. Still, it must be highlighted that the risk of developing HCC is much lower in patients with NAFLD who do not have cirrhosis than in those with NAFLD-related cirrhosis, as it has been recently shown in another meta-analysis (incidence of 0.03 *vs* 3.78/100 person-years)[18].

Significant progress has been recently made in the treatment of advanced HCC, when immunotherapy was proven superior to the systemic therapy used for over a decade[19,20]. Table 1 shows a summary of the most important randomized controlled trials on systemic therapy for advanced HCC.

Nevertheless, initial studies raised concerns that the advantages of immunotherapy might depend on the underlying liver disease, and that patients with NAFLD-related HCC might benefit less from it[21,22]. Considering the epidemiological importance of NAFLD-related HCC, this article aims to review the

mechanisms behind NAFLD-related hepatocarcinogenesis, with an emphasis on its immune aspects, the knowledge gathered over the years on the efficacy of traditional systemic therapy for advanced NAFLD-related HCC, and the most up-to-date evidence on the role of immunotherapy for this specific group of patients.

PATHOPHYSIOLOGY OF NAFLD-RELATED HCC

The underlying pathogenic mechanisms leading to NAFLD-related HCC are complex and not completely understood[10,23,24]. Metabolic dysfunction as well as inflammatory, fibrogenic and oncogenic pathways are involved, which are in turn modulated by a myriad of factors. These include, among others, genetic and epigenetic changes, different degrees of dysregulation of multiorgan metabolic and endocrine signaling, altered immunologic responses and changes in gut microbiota[24,25].

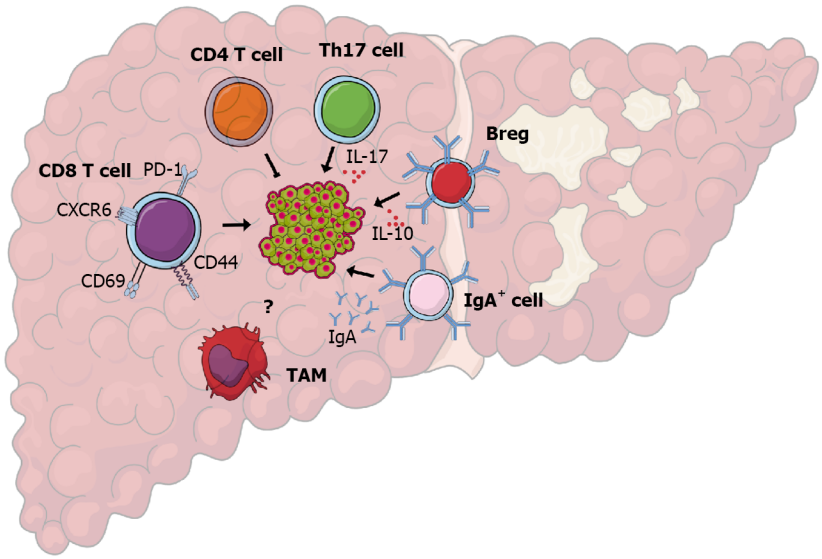
A disturbed systemic metabolic milieu characterized mainly by insulin resistance and a low-grade inflammatory state seems to be a key in promoting carcinogenesis in a fat-laden liver. Both type 2 diabetes and obesity are known risk factors for NAFLD-related HCC, which may act additively with other metabolic syndrome traits (*i.e.*, dyslipidemia and hypertension) in increasing the risk of HCC development[25,26]. However, the precise molecular mechanisms underpinning the connection between metabolic dysfunction and HCC remain incompletely understood. Metabolic dysfunction-related changes in lipid metabolism (including uncontrolled lipolysis in adipose tissue leading to fatty acid overflow towards the liver and stimulation of hepatic de novo lipogenesis) lead to hepatocyte lipid overload that, in turn, triggers some compensatory adaptations such as downregulation of carnitine palmitoyltransferase 2, which may promote hepatocarcinogenesis. Accumulation of acylcarnitine has been suggested as a potential mechanism in this regard[27]. Also, changes in sterol regulatory element-binding proteins transcription factors, key regulators of sterol and fatty acid biosynthesis, may contribute through interaction with tumor suppressor genes such as p53[28].

Importantly, lipid overload also leads to the occurrence of oxidative stress, endoplasmic reticulum stress, mitochondrial dysfunction, cell injury and cell death, all triggering inflammatory responses and activating fibrogenic processes[29]. Moreover, numerous signaling pathways are also dysregulated, including activation of interleukin (IL)-6/Janus kinase/signal transducer and activator of transcription (STAT) pathway and insulin-like growth factor, among others[30].

Of note, in the setting of a chronic inflammatory microenvironment, death of hepatocytes by different mechanisms (necrosis, apoptosis, pyroptosis and other forms of the cell death) determines a compensatory hepatocyte proliferation. This proliferative response is associated with genetic and epigenetic changes that play a pivotal role in hepatocarcinogenesis. Among these genetic changes, different studies have identified mutations in the telomerase reverse transcriptase promoter, *p53* gene and wingless-related integration site (Wnt)/β-catenin signaling pathway genes as the most consistent genetic changes during HCC development[26]. Finally, epigenetic modifications have been shown to be involved in HCC progression in the context of NAFLD. A broad range of changes in chromatin remodeling, histone alterations, DNA methylation, and noncoding RNA expression has been described and reviewed recently[31]. Such processes have diagnostic, prognostic, and therapeutic implications[32].

Experimental evidence generated in mouse models and some human data strongly suggest that altered gut microbiota may be an important contributing factor to HCC development in the setting of NAFLD/nonalcoholic steatohepatitis (NASH)[33]. The occurrence of dysbiosis is common in NAFLD/NASH, as well as in its commonly associated comorbidities, such as obesity and type 2 diabetes. Nevertheless, although microbiome changes have been characterized in different studies involving subjects with NASH or NAFLD-related cirrhosis, there is considerable variability across different reports, and only few studies have focused specifically on NAFLD-related HCC. Ponziani *et al* [34] showed that cirrhotic NAFLD-related HCC patients had a microbiome profile enriched in Bacteroides and Ruminococcaceae compared to patients with NAFLD-related cirrhosis without HCC [34]. This microbiota profile was associated with increased levels of some circulating proinflammatory cytokines. However, it remains unclear if this is just an epiphenomenon or has pathogenetic relevance.

Mechanistically, dysbiosis leads to altered intestinal permeability, which in turn contributes to hepatic inflammation *via* toll-like receptor 4 (TLR4) stimulation by bacterial derived products. Sustained hepatic inflammation triggered by this pathway can then contribute to hepatocarcinogenesis through multiple mechanisms[23]. Consistent with this proposed mechanism, TLR4 ablation has been shown to prevent HCC development in NASH models[35]. Additionally, changes in gut microbiota critically influence bile acid metabolism. Thus, animals fed with a NASH-promoting diet exhibit a change in their bile acid pool composition, which become enriched in secondary bile acids, particularly deoxycholic acid[33]. Moreover, microbiome changes may induce the transition of hepatic stellate cells (HSCs) in the stroma into a senescence-associated secretory phenotype, which are cells associated with suppression of antitumor immunity[36].



Specific genetic polymorphisms that influence NAFLD susceptibility and severity, such as patatin-like phospholipase domain containing protein 3 (PNPLA3), transmembrane 6 superfamily member 2 and membrane bound O-acetyltransferase domain containing 7, have been linked to a higher risk for NAFLD-related HCC[26]. Of these polymorphisms, the I148M variant of PNPLA3 is one of striking relevance in HCC development[37]. Carriage of this variant critically influences triacylglycerol remodeling in hepatocytes, and recent evidence shows that it also influences fibrogenesis and carcinogenesis by impairing retinol release from HSCs[38].

NAFLD-related HCC generally emerges in the setting of cirrhosis, but may arise also in a non-cirrhotic liver. Some pathways have been shown to play a role in this scenario. Increased STAT-3 signaling has been shown to be associated to the development of HCC independently of NASH and fibrosis. Also, disruption of circadian homeostasis has been shown to be related to HCC development independently of cirrhosis[39].

In summary, pathobiological mechanisms of hepatocarcinogenesis result from a complex interaction of the above-mentioned factors leading to uncontrolled proliferative responses, dysregulation of DNA-damage-response pathways, activation of survival signaling, angiogenesis, evasion of immune surveillance, genomic instability and ultimately to cancer development. It is likely that, in NAFLD patients, mechanisms leading to HCC vary from one subject to another given the heterogenous population grouped under the acronym[40]. Precision medicine approaches based on advanced biomarkers may help identify those at higher risk of developing HCC in order to include them in surveillance programs or, once diagnosed, may allow treatment with targeted therapies.

IMMUNE ASPECTS OF NAFLD-RELATED HCC

Emerging evidence suggests that the chronic inflammatory process of NAFLD and NASH sets the basis for the development of HCC[41]. In addition, there seems to be a role for innate and adaptive immune cells in the pathogenesis of NAFLD-related HCC (Figure 1). However, the immune mechanisms that are specific to NAFLD as the underlying cause of HCC are largely unclear. For example, numerous studies have demonstrated the critical involvement of hepatic macrophages, including resident Kupffer cells

DOI: 10.3748/wjg.v28.i28.3595 **Copyright** ©The Author(s) 2022.

Figure 1 Immune mechanisms in nonalcoholic fatty liver disease-related hepatocellular carcinoma pathogenesis. Studies using human specimens and mouse models have shown that activated non-alcoholic steatohepatitis-associated, programmed cell death protein 1 + CD8 T cells can cause non-specific cell death of hepatocytes and promote hepatocellular carcinoma development. T helper 17 cell-derived interleukin-17, immunoglobulin A-producing cells promote non-alcoholic steatohepatitis-derived hepatocellular carcinoma development, while an overall loss of CD4 T cells may increase tumor burden size. Bregs are abundant in hepatocellular carcinoma and promote disease progression, but are not specific to nonalcoholic fatty liver disease-related hepatocellular carcinoma. The role of tumor associated macrophages in the progression of nonalcoholic fatty liver disease-related hepatocellular carcinoma is unclear. Figure created in the Mind the Graph platform, available at www.mindthegraph.com. Th: T helper; PD-1: Programmed cell death protein 1; IL: Interleukin; Bregs: Regulatory B cells; IgA: Immunoglobulin A; CXCR6: C-X-C Motif Chemokine Receptor 6; TAM: Tumor associated macrophages.

and recruited monocyte-derived macrophages in the pathogenesis of NASH[42]. The activation of Kupffer cells is crucial for tumor development in the early stage of chemical-induced carcinogenesis[43] and tumor-associated macrophages play a prominent role in promoting HCC once a primary tumor is established[44]. Nevertheless, the role of hepatic macrophages in NAFLD-related HCC has not been investigated yet.

Regarding the role of adaptive immunity as a central player in the progression of NAFLD-related HCC, several reports have shown increased recruitment of adaptive immune cells such as T and B lymphocytes into the liver of these patients. For instance, whole-exome sequencing of livers from patients with NAFLD-related HCC shows enrichment of gene signatures associated with T lymphocytes suggesting increased hepatic T cell accumulation[45]. Notably, studies show that HCC cases from NAFLD-related cirrhosis display features of immune exhaustion, indicating a state of dysfunction likely due to stimulation by tumor antigens[45].

Experimental murine models of NAFLD-related HCC have shed light on the potential mechanisms by which T cells regulate HCC development. In a mouse model of NAFLD-related HCC that recapitulates metabolic disease, intrahepatic CD8 T cells become activated and express CD44 and CD69, suggesting that they can directly induce liver damage through interactions with hepatocytes[46]. Indeed, genetic ablation of CD8 T cells in this mouse model ameliorates liver damage, NASH, and HCC development, suggesting that CD8 T cells directly instigate disease progression[46]. The increased T cell infiltration in NAFLD-related HCC has been attributed to the inactivation of T cell protein tyrosine phosphatase in hepatocytes and increased expression of T cell chemoattractants[47]. Mechanistically, NASH programs CD8 T cells to acquire an activated exhausted phenotype and express increased levels of programmed cell death protein 1 (PD-1) in response to metabolic signals as well as to IL-15, instigating their non-specific killing of hepatocytes and disease progression[48]. In addition to exhaustion markers, NASH-derived PD-1 positive CD8 T cells express high levels of effector function molecules such as tumor necrosis factor α, interferon γ, and granzyme[21]. The increased activity of exhausted PD-1 positive CD8 T cells in the NASH liver is not limited to accelerating liver damage but can result in impaired immune surveillance and subsequent HCC[21].

In contrast to the accumulation of CD8 T cells, lipid dysregulation has been shown to cause a loss of CD4 T cells in tumor-free and tumor-bearing environments in the liver of mice with NASH induced by a methionine and choline-deficient L-amino acid-defined diet[49]. Importantly, depletion of total CD4 T cells promoted hepatic carcinogenesis in a MYC oncogene model of HCC, suggesting that the overall function of CD4 T cells is to provide antitumor immunity[49]. However, nutrient overload induces a subset of CD4 T cells known as T helper-17 cells that produce large amounts of IL-17A to promote tumorigenesis in NAFLD-related HCC[50]. Overall, these findings suggest that the exhaustion of hepatic CD8 T cells and the loss of CD4 T cells in NASH compromise the hepatic antitumor surveillance

and increase the susceptibility to HCC.

In addition to T cells, emerging evidence suggests that immunoglobulin A (IgA)-producing B cells play a critical role in the progression of NAFLD-related HCC. In humans, the number of tumor-infiltrating B cells correlates with tumor progression[51]. Likewise, patients with HCC that have fewer tumor-infiltrating plasma cells present a better prognosis[52]. Feeding a high fat diet to major urinary protein-urokinase-type plasminogen activator transgenic mice, a reliable model of NAFLD-related HCC, instigates IgA-producing cells to interfere with the protective role of anti-tumor cytotoxic CD8 T cells[53]. The IgA positive B cells inhibit the activity of CD8 T cells through the expression of programmed death-ligand 1 (PD-L1) and the production of the immunosuppressive cytokine IL-10[53]. Regulatory B cells, a subset of B cells, can also inhibit anti-tumor immunity through IL-10 production and promote HCC growth through direct interactions with the tumor cells[54]. As B cells promote NAFLD through the production of pro-inflammatory cytokines and regulation of intrahepatic T cells in NASH[55], future studies are needed to clarify the precise role of liver B cells in NAFLD-related HCC.

TRADITIONAL SYSTEMIC TREATMENT FOR ADVANCED NAFLD-RELATED HCC

Systemic therapy for HCC is relatively young in comparison to other cancers, becoming available only after 2007, with the arrival of sorafenib, a multikinase inhibitor that showed improved survival against placebo in both the SHARP and Asia-Pacific trials[56,57]. For 10 years, sorafenib was the only available systemic therapy for HCC, until the field expanded significantly over the last 5 years with trials showing benefit from regorafenib, lenvatinib, cabozantinib and ramucirumab[58-61]. All of these studies were performed on HCCs from multiple etiologies, but primarily viral hepatitis-related tumors. Recently, attention has shifted to the importance of HCC etiology as a predictor of response to systemic therapy. This issue has been most evident in HCC immunotherapy, but potentially applies to other systemic therapies as well.

NAFLD-related HCC represents a unique conundrum for systemic therapy, as metabolic issues beyond that of HCC may play a role[62]. Individuals with NAFLD-related HCC are more likely to be obese, and are more likely to be on hormone-related medications, both of which could affect the pharmacokinetics of systemic therapy. Indeed, a small study showed that patients on sorafenib who were receiving metformin for diabetes mellitus had worse survival than those on insulin, regardless of the cause of HCC[63].

Due to the temporal dynamics of HCC systemic therapy in the last 15 years, most of the available data is from sorafenib studies. Sorafenib is known to perform best when used in patients with viral hepatitis-related HCC, particularly hepatitis C infection. However, most studies addressed hepatitis C *vs* alcohol-related HCC, or viral hepatitis *vs* other causes of HCC, clouding the understanding of the role of sorafenib in NAFLD-related HCC specifically[64-66]. An international study, presented only in abstract form, found similar overall survival (OS) in patients treated with sorafenib with NAFLD-related HCC *vs* other causes [hazard ratio (HR): 0.94, 95% confidence interval (CI): 0.76-1.16, $P = 0.57$]. However, the NAFLD portion of the study included only 187 patients (3.5% of the total cohort), and further details are awaited with the full peer-reviewed version[67]. A recent retrospective subgroup analysis including 483 NAFLD-related HCC patients treated with sorafenib also found no significant difference in univariate analysis of survival between NAFLD and other etiologies (10.2 mo *vs* 12.3 mo; HR: 1.06; 95%CI: 0.83-1.34, $P = 0.63$)[68].

Information on NAFLD-related HCC for other non-immune forms of systemic therapy remains rather elusive, although very recent studies are shedding some light on the field. The initial trials for regorafenib (RESORCE), cabozantinib (CELESTIAL) and ramucirumab (REACH-2) included very limited numbers of patients with NAFLD-related HCC (6.6%, 9.3% and 7.9% respectively), and most subgroup analyses did not specifically evaluate NAFLD-related HCC[58-60]. The CELESTIAL trial for cabozantinib indicated benefit of the drug across all subgroups of etiologic factors and found no difference for OS between viral hepatitis-related HCC and other etiologies (HR: 0.76, 95%CI: 0.63-0.92 *vs* HR: 0.72, 95%CI: 0.54-0.96). However, the "other etiologies" group included all non-viral hepatitis-related tumors, with the NASH proportion conforming 43 patients. Also, this trial evaluated cabozantinib as second line therapy[58].

More recently, retrospective studies have evaluated lenvatinib in NAFLD-related HCC, suggesting an advantage for this multikinase inhibitor in this group of patients. A multicenter analysis of 236 NAFLD-related HCCs treated with lenvatinib (19% of the entire cohort) found a better OS for NAFLD-related HCC compared to other etiologies (22.2 mo *vs* 15.1 mo, HR: 0.69, 95%CI: 0.56-0.85, $P = 0.0006$)[68]. A Japanese study (also retrospective) of lenvatinib in unresectable tumors involving 103 NAFLD-related HCCs found no difference in OS compared to other etiologies, but the progression free survival (PFS) was better in the NAFLD group (median 9.3 mo *vs* 7.5 mo, $P = 0.01$)[69]. Furthermore, the retrospective multicenter ELEVATOR study, in which 200 patients were treated with lenvatinib, observed a similar survival in patients with viral and non-viral (NASH and alcoholic steatohepatitis) related HCC[70].

This early evidence suggests that sorafenib or cabozantinib are not particularly better (or worse) for NAFLD-related HCC, and that the use of lenvatinib might pose an advantage, with no specific data, so

far, for regorafenib. Nevertheless, it should be noted that better studies are needed in order to draw significant conclusions.

IMMUNOTHERAPY FOR ADVANCED NAFLD-RELATED HCC

In recent years, besides several tyrosine kinase inhibitors and a monoclonal antibody against vascular endothelial growth factor (VEGF) receptor-2 being added to the treatment armamentarium, immunotherapy with immune checkpoint blockers has been extensively investigated in patients with HCC[71]. Nivolumab, pembrolizumab, and the combination of nivolumab plus ipilimumab have been approved by the United States Food and Drug Administration (FDA) based on very promising phase II studies [72], but nivolumab and pembrolizumab failed to reach their primary endpoints in subsequent phase III trials in first- and second-line, respectively[73,74].

Atezolizumab plus bevacizumab

Overexpression of VEGF has been associated with liver cancer development and progression, and small phase II studies have shown modest anti-tumor efficacy of bevacizumab as monotherapy in advanced HCC[75]. In addition to the antiangiogenic effects, there is increasing evidence that anti-VEGF therapies may enhance the efficacy of anti-PD-1 and anti-PD-L1 by reversing VEGF-mediated immunosuppression and promoting T-cell infiltration in tumors[76]. Based on these observations, the PD-L1 inhibitor atezolizumab was evaluated together with the VEGF inhibitor bevacizumab in the phase III IMbrave150 study. The combination significantly improved all efficacy endpoints with a statistically significant and clinically meaningful survival benefit compared to sorafenib[19,77]. Side effect profiles of the drugs were in line with their respective mechanism of action and no new safety signals were observed. Additionally, patient-reported outcomes revealed that deteriorations in quality of life were significantly delayed in the combination arm compared to the sorafenib arm[78]. The combination has been approved by the FDA and by the European Medicines Agency (EMA), and it is currently regarded as the standard of care in first-line therapy of advanced HCC.

Atezolizumab plus cabozantinib

In the COSMIC-312 trial, in which 837 patients with HCC were randomized to be treated with atezolizumab plus cabozantinib, sorafenib in monotherapy or cabozantinib in monotherapy (2:1:1), PFS was 6.8 mo for the group receiving combination therapy, compared to 4.2 mo for the group under sorafenib (HR: 0.63, 95%CI: 0.44-0.91, P = 0.0012). Regarding OS, an interim analysis did not demonstrate a significant difference between combination treatment and monotherapy with sorafenib (HR: 0.90, 95%CI: 0.69-1.18, P = 0.438). Finally, the interim analysis on the comparison between cabozantinib and sorafenib showed a tendency favoring cabozantinib regarding PFS (HR: 0.71, 95%CI: 0.51-1.01)[79].

Dual checkpoint inhibition

Two antibodies against cytotoxic T-lymphocyte-associated protein 4 (CTLA-4) have been investigated in advanced HCC. The combination of nivolumab and ipilimumab has already shown improved OS in HCC patients in the phase I/II CheckMate040 study[80,81]. The pure immune-oncology (IO) combination achieved a high overall response rate with a promising OS of almost 23 mo. The most common immune related adverse events were rash, hepatitis, and adrenal insufficiency. Based on these results, the FDA approved nivolumab plus ipilimumab as second-line treatment for patients with advanced HCC previously treated with sorafenib. Currently, the checkmate 9DW study evaluates the efficacy of nivolumab plus ipilimumab compared to sorafenib or lenvatinib as first-line therapy.

Similar to ipilimumab, tremelimumab has also been studied as an anti-CTLA-4 antibody in HCC. Based on promising phase II data, the combination of durvalumab and tremelimumab was compared with durvalumab in monotherapy or sorafenib in monotherapy as first-line therapy for unresectable HCC in the HIMALAYA trial. Regarding the comparison between combination therapy and monotherapy with sorafenib, there was a significant improvement in OS favoring combination therapy (16.4 mo *vs* 13.8 mo, HR: 0.78, 95%CI: 0.65-0.92, P = 0.0035), and durvalumab plus tremelimumab may be approved by the FDA and EMA in the near future as an additional option for first-line treatment in HCC. Finally, monotherapy with durvalumab was noninferior to sorafenib regarding OS (HR: 0.86, 95%CI: 0.73-1.03)[82].

Etiology of liver disease and immunotherapy

A very recent study suggested that clinicians might need to consider the underlying liver disease for treatment selection in HCC. Pfister *et al*[21] provided provocative preclinical and limited clinical evidence that patients with NAFLD-related HCC may benefit less from immune checkpoint inhibition than patients with viral hepatitis-related HCC. Regarding preclinical data, authors evaluated immunotherapy in mice with NAFLD-related HCC. Despite the hepatic abundance of PD-1 positive CD8 T cells with features of exhaustion and effector functions in mice with NASH, which might be suggestive of a good response to immunotherapy, none of the pre-existing tumors regressed with treatment, and there

was evidence indicating that immunotherapy could even play a role in hepatocarcinogenesis in mice with NASH. In the same publication, a meta-analysis of three randomized controlled phase III trials failed to demonstrate evidence of survival improvement for patients with non-viral hepatitis-related HCC receiving immunotherapy. The authors also investigated a cohort of 130 HCC cases, in which 13 were NAFLD-related and had OS after immunotherapy of 5.4 mo, significantly lower than that of patients with HCCs related to other causes of liver disease (11.0 mo, P = 0.023). Finally, authors validated these findings in yet another cohort of 118 individuals with HCC, in which 11 were NAFLD-related and had OS of 8.8 mo, while patients with HCC related to other causes of liver disease had OS of 17.7 mo (P = 0.034)[21]. Nevertheless, important remarks on this study have been made in an editorial, which highlighted that patients with NASH were not separated from those with other non-viral hepatitis etiologies of liver disease in the meta-analysis presented in the paper, and that the small number of patients evaluated in the cohorts must be kept in mind when considering their results[83].

In the same line, both the Checkmate-459 and the IMBrave150 trials found that HR for OS was worse in patients with non-viral hepatitis-related HCC compared with patients with viral hepatitis-related cancer. However, neither study distinguished between patients with NASH and alcoholic steatohepatitis. In addition, it should be noted that the poor HRs in the non-viral hepatitis group were not solely due to the shorter survival in the IO arm, but also to a surprisingly long survival in the sorafenib arm of both trials[19,84]. Similarly, in the COSMIC-312 trial, when a subgroup analysis on etiology of the underlying liver disease was performed, the benefit of atezolizumab plus cabozantinib on PFS seemed to be driven by the hepatitis B-related HCC group, and there was no significant difference between combination therapy and sorafenib for patients with non-viral hepatitis related-HCC (HR: 0.92, 95%CI: 0.60-1.41)[79].

Another recent meta-analysis of randomized controlled trials helped fuel this debate, when it also demonstrated that immune checkpoint inhibitors were significantly more effective for viral hepatitis-related HCCs than for tumors associated with other kinds of liver disease. On the other hand, the etiology of liver disease did not seem to interfere with the efficacy of tyrosine-kinase inhibitors or anti-VEGF therapies[22].

In contrast to these observations, underlying liver disease (viral hepatitis *vs* alcohol *vs* NASH) did not significantly impact PFS and OS in a recent real-world cohort treated with atezolizumab and bevacizumab[85]. Moreover, in the HIMALAYA trial, the benefit of the combination of durvalumab and tremelimumab on OS persisted in the subgroup analysis in patients with non-viral hepatitis related-HCC (HR: 0.74, 95%CI: 0.57-0.95)[82].

Perhaps the decision to start immunotherapy might be guided by prognostic biomarkers, rather than solely by the etiology of liver disease. Several predictive biomarkers for immunotherapy response have been proposed, including PD-L1 expression[86] and evidence of activated Wnt/β-catenin signaling[87], but currently no validated biomarker exists to guide treatment decisions in HCC patients undergoing immunotherapy. The recently proposed CRAFITY score (C reactive protein and alpha-fetoprotein in ImmunoTherapY) may be an easy-to-use tool to predict outcomes of patients undergoing immunotherapy for HCC, regardless of Child-Pugh class and performance status[88].

CONCLUSION

As the field moves forward, and with early evidence suggesting a potential decreased response of NAFLD-related HCC to immunotherapy, studies of non-immune systemic therapy for this group of patients should become more frequent and more robust. Moreover, randomized controlled trials evaluating immunotherapy in this particular group of patients are of the utmost importance. Multiple issues should be taken into account in such studies, including the strict definition of NAFLD, metabolic associated fatty liver disease or NASH, the heterogeneity of this group which includes lean NAFLD, NAFLD related to metabolic syndrome and others, as well as the impact of other co-morbidities and medication profiles.

Abstract

Proton pump inhibitors (PPIs), the most commonly used antisecretory medications in the management of reflux illness, virtually eliminate elective surgery for ulcer disease, and relegate anti-reflux surgery to patients with gastroesophageal reflux disease (GERD) who are inadequately managed by medical therapy. However, PPI medications still leave some therapeutic demands of GERD unmet. Furthermore, up to 40%-55% of daily PPI users have chronic symptoms, due to PPI refractoriness. Potassium-competitive acid blockers (P-CABs) transcend many of the problems and limits of PPIs, delivering quick, powerful, and extended acid suppression and allowing for treatment of numerous unmet needs. Recently, it has become clear that compromised mucosal integrity plays a role in the etiology of GERD. As a result, esophageal mucosal protection has emerged as a novel and potential treatment approach. An increasing body of research demonstrates that when P-CABs are used as primary drugs or add-on drugs (to regular treatment), they provide a considerable extra benefit, particularly in alleviating symptoms that do not respond to PPI therapy.

Key Words: Potassium-competitive acid blocker; Gastroesophageal reflux disease; Proton pump inhibitors; Treatment outcome; Proton pump inhibitor-refractory patients; Esophageal mucosal resistance

Core Tip: The potassium-competitive acid blocker (P-CAB) has been discovered as a possible acid suppression therapeutic option. At the enzyme level, P-CABs compete with K^+ to suppress acid formation; the binding location of these compounds is separate from the probable pocket that K^+ occupies. When the P-CAB binds to the enzyme, it stops K^+ from attaching and activating it. According to clinical trials, P-CABs are extremely selective for gastric H^+, K^+-ATPase, restricting stomach acid production while acting quickly. Such medicines, which can have a rapid onset of action and a longer duration, may offer considerable advantages to individuals suffering from gastroesophageal reflux disease and other acid-related disorders.

INTRODUCTION

Gastroesophageal reflux, the reflux of stomach contents into the esophagus, usually occurs after large and fatty meals. Nonetheless, under normal settings, efficient esophageal cleaning mechanisms return the bulk of the refluxed material to the stomach, and symptoms do not occur. However, when stomach reflux is severe or physically aggressive, it causes symptoms and difficulties, as well as a decrease in quality of life, thus creating gastroesophageal reflux disease (GERD)[1,2]. Since the 1990s, the prevalence of GERD has grown consistently, particularly in East Asia and North America (2.5%-7.8%, and 10%-20%, respectively)[3-5]. Heartburn and regurgitation are common esophageal symptoms, accompanied by consequent chest discomfort and dysphagia. Chronic cough, hoarseness of voice, and asthma are other extra-esophageal symptoms that have been linked to GERD in population-based research. The three GERD phenotypes are erosive esophagitis (EE), non-erosive reflux disease (NERD), and Barrett's esophagitis. Their responses to therapy vary greatly. Of note, the majority (70%) of GERD patients have an endoscopically normal mucosa and are regarded as having NERD.

Pharmacologic, endoscopic, and surgical options for GERD treatment are now available. The most often recommended drugs for GERD treatment in clinical practice are proton pump inhibitors (PPIs) and histamine-2 receptor antagonists. Other, less potent agents typically used to treat mild or intermittent symptoms or as adjunct therapies include antacids, sucralfate, baclofen, alginate, and prokinetics[6,7]. The goals of GERD management include symptom relief, esophageal inflammation healing, esophageal inflammation maintenance and prevention, and quality of life enhancement. PPIs have long been thought to be the basis of GERD treatment. Because of their significant and consistent antisecretory action, PPIs have proven particularly useful in treating EE, managing symptoms, and preventing GERD-related complications such as esophageal ulcers, esophageal bleeding, and peptic stricture. Overall, PPIs have been regarded as a relatively safe class of drugs, with many patients taking them for an extended time. Despite the success of PPIs in addressing many aspects of GERD, there are still many unmet needs[8-10]. Advanced EE, NERD, overnight heartburn, maintenance therapy, and refractory GERD are among them.

Furthermore, PPIs are ineffective for postprandial heartburn and are currently not recommended for atypical or extra-esophageal GERD presentations as well as GERD complications[11,12]. Importantly, prolonged PPI medications have been linked to side effects, generating worries among physicians and patients alike about their safety profile. This review looks at the development and quality of present and potential acid suppression medications, focusing on the potassium-competitive acid blocker (P-CAB) class and exploring their clinical studies.

ROLE OF POTASSIUM ION IN ACID SECRETION

Gastric acid is essential for food and water purification and digestion. Gastric juice has an extremely low pH (pH = 1) because parietal cells in the oxyntic mucosa of the stomach secrete H^+ and Cl^- ions to make hydrochloric acid. These cells secrete 1-2 L of hydrochloric acid every day. The action of gastric H^+/K^+-ATPase in the apical membrane of parietal cells promotes a very high concentration of H^+ in the lumen compared to plasma. The potassium ion plays an essential role in activating gastric H^+/K^+-ATPase and is required for the enzyme to function. At rest, H^+/K^+-ATPase is confined to tubulovesicular regions of a parietal cell with low K^+ concentrations and membranes that are impermeable to K^+. As a result, the enzyme is incapable of activating and transporting H^+ ions. When the parietal cell is stimulated, the tubulovesicular components merge with the cell's apical membrane. After being exposed to K^+-containing luminal fluid, the H^+/K^+-ATPase enzyme can begin to exchange H^+ for K^+[13-15]. Due to its

important involvement in the production of gastric juice, K^+ is a possible therapeutic target for acid blockers. One technique is to block the K^+ channels that allow ions to flow through the apical membrane of parietal cells, while another is to compete with K^+ at the level of the parietal cells' H^+/K^+-ATPase.

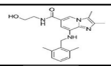
P-CABs

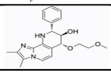
The surface of the stomach H^+/K^+-ATPase (the proton pump) is exposed to the extremely acidic parietal cell canaliculus, which has a high affinity for K^+ during acid secretion. Given the significance of the cation for enzyme activity, drugs that compete for K^+ binding have the potential to inhibit acid secretion. The mechanism of action of P-CAB is based on this premise. P-CABs were initially developed in the 1980s and have been studied by many pharmaceutical companies worldwide due to their ability to block the proton pump quickly, efficiently, and reversibly. Schering-Plough was one of those companies that developed a prototype P-CAB, SCH28080. Although the mechanism of action was not fully known at that time, this drug was discovered to lower stomach acid output in humans[16,17]. SCH28080 was later demonstrated to inhibit gastric H^+/K^+-ATPase by competing with K^+[18,19]. However, clinical development of SCH28080 was halted due to hepatotoxicity produced by repeated treatment. This condition sparked research into several kinds of SCH28080 derivatives, such as imidazopyridine derivatives (BY841), imidazo-naphthyridine derivatives (soraprazan), imidazo-thienopyridines (SPI-447), quinolone derivatives (SK&F96067)[20-23], pyrrolo-pyridazine derivatives (CS-526), pyrimidine derivatives (revaprazan), and pyrrole derivatives [vonoprazanm (VPZ)][24-26].

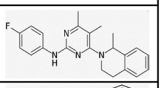
These novel antisecretory medicines vary from PPIs in that they compete with K^+ and cause a dose-dependent selective and reversible inhibition of the proton pump. Because they aren't prodrugs that need to be activated in parietal cells like PPIs, they start working right away, and control of acid secretion begins within the first day of treatment after starting the first dose. In addition, their dissociation from the proton pump is sluggish, and they can stay in the stomach mucosa for up to 24 h. As a result, unlike PPIs, which are less effective at night, their acid inhibitory action persists throughout the day and night[27,28]. Table 1 compares the key differences in the mechanisms of action of P-CABs and PPIs.

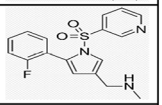
ACTION MECHANISM OF P-CABs

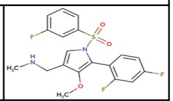
P-CABs are classified into many chemical classes (Figure 1). They are a varied class of medications while having a similar mechanism of action. P-CABs are lipophilic, weak bases with limited pH stability and high pKa values. They may concentrate in acidic environments because of the combination of these properties. In the parietal cell canaliculi (pH = 1), a P-CAB with pKa of 6.0 would be 100000-fold larger than in the plasma (pH = 7.4). *In vitro* and *in vivo* investigations using AZD0865 and revaprazan showed a concentrated P-CAB in the gastric mucosa[29-31]. By binding ionically to the enzyme, P-CAB inhibits gastric H^+/K^+-ATPase and prevents further activation by K^+. P-CABs are expected to bind at or near the K^+ binding site, preventing the K^+ from accessing the site (Figure 2). Although these novel drugs exhibit quick and potent antisecretory action, not all of their attractive pharmacodynamic features have translated into therapeutic advantages due to their hepatotoxicity and insufficient efficacy. In addition, linaprazan (AZD0865) failed to outperform standard-dose PPIs in the treatment of peptic ulcers and reflux esophagitis (RE)[32,33]. Soraprazan (BY359) and CS526 (R105366) have fulfilled their proof of effectiveness and safety goals in phase II tests, but data on these medicines have not been published[34].

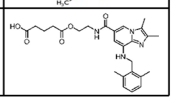










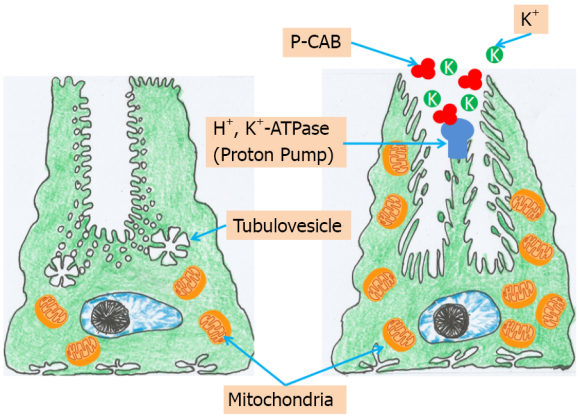


PHARMACOKINETICS AND PHARMACODYNAMICS OF P-CABs

P-CABs reach peak plasma concentrations quickly after oral administration, in part because they are acid-stable and may be administered as immediate-release formulations. In healthy men, a single dose of revaprazan (100 to 200 mg) resulted in peak plasma concentrations at 1.7 to 1.8 h, which declined to a mean elimination time (T1/2) of 2.2 h to 2.4 h with repeated administration. The pharmacokinetics and concentration-time profiles of revaprazan were comparable following repeated administration (on day 7) to those reported after the initial dosage on day 1[35]. In 2004, Yu *et al*[36] conducted a single-blind, dose-rising, parallel-group, randomized, placebo-controlled trial in 46 healthy subjects. In the single-dose research, plasma concentrations of revaprazan attained peak values 1.3 h to 2.5 h after administration and thereafter decreased mono-exponentially with a terminal T1/2 of 2.2 h to 2.4 h in dosage groups up to 200 mg. Revaprazan has linear pharmacokinetic properties, with negligible accumulation after numerous doses. The onset of pharmacological effects was quick, with the greatest benefits shown on the first day of treatment with repeated doses. They concluded that revaprazan was safe, well-tolerated, and efficiently suppressed acid secretion by increasing intragastric pH in a dose-dependent manner.

Table 1 Main differences in the mechanisms of action between proton pump inhibitors and potassium-competitive acid blockers[12]

Proton pump inhibitors	Potassium-competitive acid blockers
Prodrug requires transformation to the active form, sulphenamide	Direct action on the H^+/K^+ ATPase after protonation
Sulphenamide binds covalently to H^+/K^+-ATPase	P-CABs bind competitively to the K^+ binding site of H^+/K^+-ATPase
Irreversible binding to the proton pump	Reversible binding to the proton pump
The full effect after repeated doses	The full effect after the first dose
PK affected by genetic polymorphism	PK not affected by genetic polymorphism
PD effect more significant during the daytime	PD effect lasting for both the daytime and nocturnal hours
Meal-dependent antisecretory activity	Meal-independent antisecretory activity
Concentrate in parietal cell acid space (1000-fold higher than in plasma)	Super concentrates in parietal cell acid space (100000-fold higher than in plasma)
Duration of effect related to the half-life of the sulphenamide-enzyme complex	Duration of effect related to the half-life of the drug in plasma



P-CAB: Potassium-competitive acid blocker; PD: Pharmacodynamic; PK: Pharmacokinetic.

P-CABs	Chemical class	Development phase	Company	Chemical structure
P-CABs whose development has been stopped				
Linaprazan (AZD0865)	Imidazopyridine	Stopped after phase III	AstraZeneca	
CS526 (R105266)	Pyrrolopyridazine	Stopped after phase I	Sankyo and Ube/ Novartis	
Soraprazan (BY359)	Imidazonaphthyridine	Stopped after phase II	Altana	
Available P-CABs in the market				
Revaprazan (YH1885)	Pyrimidine	Marketed in South Korea and India	Yuhan	
Vonoprazan (TAK-438)	Pyrrole	Marketed in Japan; Phase III in Europe /United States	Takeda and Phathom	
Tegoprazan (RQ-00000004)	Benzimidazole	Marketed in South Korea	Raqualia	
P-CABs under active study				
Fexuprazan (DWP14012)	Pyrrole	Phase III in South Korea	Daewoong	
X842 (Linaprazan pro-drug)	Imidazopyridine	Phase II in Europe	Cinclus Pharma

Figure 1 Differences in chemical classes and chemical structures of potassium-competitive acid blockers[12]. P-CAB: Potassium-competitive acid blocker.

In 2015, Sakurai *et al*[37] conducted 2 phase I, single rising-dose, randomized, double-blind, placebo-controlled trials in 84 volunteers from Japan using 1-120 mg VPZ and 63 healthy males from the United Kingdom using 1-40 mg VPZ to evaluate the pharmacokinetics, pharmacodynamics, safety, and tolerability. They discovered that VPZ plasma concentration-time profiles exhibited fast absorption at all doses, with a median T_{max} of up to 2 h. $T_{1/2}$ was predicted to be up to 9 h. The acid suppression effect was dose-dependent, with a 24-h intragastric pH 4 holding time for 40 mg VPZ being 92% in Japanese males and 87% in British males. They determined that single oral doses of 20-120 mg VPZ suppressed gastric acid production in healthy male participants in a quick, deep, and 24-h manner. Furthermore, VPZ was well tolerated at all dosages tested, suggesting that it might be used as an alternate therapy for

Figure 2 Potassium-competitive acid blockers inhibit gastric H⁺/K⁺-ATPase by binding ionically to the enzyme and prevent further activation by the K⁺[7]. P-CAB: Potassium-competitive acid blocker.

acid-related diseases.

Recently, Han *et al*[38] performed a phase I, randomized, placebo-controlled study in 56 healthy volunteers without *Helicobacter pylori* infection to evaluate the safety, tolerability, pharmacokinetics, and pharmacodynamics of tegoprazan (TPZ). They found that TPZ was well tolerated. The majority of the adverse events were mild and resolved without any long-term consequences. On day 7, despite multiple dosages of TPZ, there was no accumulation in the plasma. The pharmacodynamics study found that TPZ suppressed gastric acid rapidly in a dose-dependent manner. They concluded that TPZ was well tolerated and demonstrated rapid and potent gastric acid suppression.

Sunwoo *et al*[39] conducted a randomized, double-blind, double-dummy, placebo-controlled study to evaluate a single ascending dose and multiple ascending doses of fexuprazan (FPZ) in 120 healthy male subjects without *Helicobacter pylori* (*H. pylori*) infection. They discovered that FPZ was well tolerated and suppressed gastric acid output for 24 h after delivery. In the multiple ascending doses trial, FPZ plasma concentrations grew in a dose-proportional way, but it did not appreciably accumulate in the plasma in the single ascending dosage study. They concluded that FPZ showed an immediate, long-lasting gastric acid suppression effect and was safe.

In 2020, Hwang *et al*[40] conducted a single- and multiple-dose, randomized, double-blind, placebo-controlled trial to elucidate the pharmacodynamics, pharmacokinetics, and safety of FPZ among healthy volunteers of Korean, Caucasian, and Japanese descent. FPZ (40, 60, or 80 mg for Koreans; 40 or 80 mg for Caucasians; 20, 40, or 80 mg for Japanese) or a placebo were given to ten participants in each group at random. Gastric acid suppression was shown to be consistent across ethnic groups. After successive doses of 40 mg, the mean percentages of time when the intragastric pH was over 4 in Korean, Caucasian, and Japanese participants were 64.3 percent, 62.8 percent, and 70.3 percent, respectively. Furthermore, the 80 mg dose that could effectively suppress gastric secretion was 94.8%, 90.6%, and 90.6% for the Korean, Caucasian, and Japanese subjects, respectively. They determined that FPZ suppressed stomach acid in the same way in Korean, Caucasian, and Japanese patients, and that the pharmacokinetic and pharmacodynamic correlations, as well as the safety, were the same in all three ethnic groups. The FPZ could be utilized regardless of ethnicity.

X842 is a linaprazan prodrug that is currently under development. X842 has a $T_{1/2}$ of 10 h and enables improved intragastric pH regulation over 24 h. Linaprazan was established in a phase I study that used a single dose or multiple escalating dosage design to assess the drug's safety and tolerability in healthy volunteers as the primary endpoint[41]. X842 was shown to be safe and well tolerated by the participants in the study. During the trial, no severe or significant adverse events were recorded. When both pharmacodynamics and pharmacokinetics were evaluated, precise dose linearity was identified. The mean median intragastric pH at each X842 dosage was never less than 4.

P-CABs EFFICACY IN GERD

VPZ efficacy in GERD

In 2015, Ashida *et al*[42] undertook a parallel-group, dose-ranging, multicenter, randomized, double-blind trial in 732 patients with EE to assess the effectiveness and safety of VPZ *vs* lansoprazole (LPZ). The eligible EE individuals were randomized 1:1:1:1:1 to undergo an 8-wk therapy with LPZ 30 mg, VPZ 5 mg, VPZ 10 mg, VPZ 20 mg, and VPZ 40 mg. They discovered that with VPZ 5, 10, 20, and 40 mg,

and LPZ 30 mg, the proportion of healed EE individuals at week 4 was 92.3%, 92.5%, 94.4%, 97.0% and 93.2%, respectively. When corrected for baseline Los Angeles (LA) grades A/B and C/D, all VPZ regimens were non-inferior to LPZ 30 mg therapy. With VPZ 5, 10, 20, 40 mg, and LPZ 30 mg, the proportions of healed EE individuals were 87.3%, 86.4%, 100%, 96.0%, and 87.0%, respectively, for LA grades C/D. The incidence of adverse events was the same in all groups. They indicated that VPZ was efficacious and comparable to LPZ in the treatment of EE. For severe EE (LA grades C/D), they advised VPZ doses of 20 mg or more.

Furthermore, Ashida *et al*[43] performed another parallel-group comparison, multicenter, randomized, double-blind trial to evaluate the non-inferiority, long-term efficacy, and safety as maintenance therapy of VPZ 20 mg compared with LPZ 30 mg in 409 endoscopically confirmed EE patients (LA grades A-D). They discovered that the proportion of patients with healed EE up to week 8 for VPZ (203/205) and 95.5% for LPZ (190/199) was 99.0% for VPZ (203/205) and 95.5% for LPZ (190/199), demonstrating the non-inferiority of VPZ 20 mg therapy. There were a few EE recurrences (< 10%) for long-term maintenance evaluation in patients treated with VPZ 10 mg or 20 mg. They stated that the comparative trial demonstrated the non-inferiority of VPZ 20 mg to LPZ 30 mg in EE, and that VPZ was well tolerated and efficacious among long-term maintenance EE patients (Table 2).

In 2017, Iwakiri *et al*[44] conducted a randomized, double-blind, multicenter trial of VPZ 20 mg or 40 mg in 19 patients with PPI-resistant (LPZ 30 mg) EE to measure stomach and esophageal pH over 24 h. Patients with endoscopically proven PPI-resistant EE received VPZ 20 mg (9 cases) or VPZ 40 mg (10 cases) for 8 wk after a 7- to 14-d run-in period with LPZ 30 mg therapy. The percentage of stomach pH 4 [pH 4 holding time ratio (HTR)] increased significantly in both groups from baseline: In the 20 mg group, it increased from 73.21% to 96.46%, and in the 40 mg group, it increased from 69.97% to 100.00%. There were no significant increases in esophageal pH 4 HTRs from baseline. After 8 wk of treatment, the healing rate in patients with baseline EE grades A-D was 60.0% in the 20 mg group and 71.4% in the 40 mg group. They concluded that VPZ 20 mg and 40 mg substantially suppressed gastric acid secretion over 24 h with considerably higher gastric pH at 4 HTR, resulting in an EE repair rate greater than 60%.

In the same year, Yamashita *et al*[45] conducted a study to evaluate the effects of VPZ and PPIs in 8 RE patients using multichannel intraluminal impedance-pH. They found that the mucosal lesions in 7/8 patients (87.5%) with persistent gastric mucosal injury after completing an 8-wk standard PPI therapy had entirely healed after VPZ therapy. From 26.5% to 78.0%, there was a considerable rise in stomach pH > 4 HTR. In addition, a decrease in esophageal pH of 4 HTR was seen, although it was not statistically significant. The overall number of reflux events, comprising acid and proximal reflux episodes, as well as the time it took for acid to clear, were both dramatically reduced. They concluded that VPZ should be used in patients with PPI-refractory RE.

In 2018, Ashida *et al*[46] conducted a study to compare VPZ 10 mg (n = 202) and 20 mg (n = 204) with LPZ 15 mg (n = 201) as maintenance treatment in 607 patients with healed EE. EE recurrence rates with LPZ 15 mg, VPZ 10 mg, and VPZ 20 mg were 16.8%, 5.1%, and 2.0%, respectively, throughout a 24-wk maintenance period. VPZ was shown to be non-inferior to 15 mg LPZ. The 10 mg and 20 mg VPZ were significantly lower than the LPZ at 15 mg. The EE recurrence rate, on the other hand, did not change substantially between the two VPZ dosages. They determined that VPZ 10 mg and 20 mg were non-inferior to LPZ 15 mg as maintenance treatment for individuals with healed EE.

A retrospective cohort study that recruited 55 patients with symptomatic GERD (NERD = 30, EE = 25) treated with VPZ 10 mg who had been followed for more than 1 year was conducted by Shinozaki *et al*[47]. They discovered that taking VPZ 10 mg for one month relieved GERD symptoms in 89% of patients and was maintained in 82% after one year without further treatment. In 47% of cases, 1-year maintenance treatment resulted in long-term relief of GERD symptoms. Nine of the forty-nine responders experienced a return of GERD symptoms, while VPZ dosage escalation relieved symptoms in 67% (6/9) of patients. Postprandial discomfort, postprandial distress, constipation, and diarrhea significantly decreased after 1 m and remained stable after a year. After 1 year of therapy, the endoscopic healing rate of EE was 95%. They concluded that 1 year of VPZ therapy reduces GERD symptoms significantly, and endoscopic healing of EE is good. VPZ is an efficient and beneficial long-term treatment for GERD.

In 2019, Oshima *et al*[48] conducted a randomized, placebo-controlled experiment in 32 patients with endoscopically proven EE who had heartburn at least once a week to see how quickly VPZ and LPZ relieve heartburn. For 14 d, the patients were given either VPZ 20 mg or LPZ 30 mg before breakfast. They found that heartburn was relieved earlier with VPZ than with LPZ. Furthermore, on day 1, VPZ and LPZ totally cured heartburn in 31.3% and 12.5% of patients, respectively. With VPZ medication, significantly more patients experienced full nighttime heartburn resolution compared with LPZ treatment. They concluded that during the first week of therapy, VPZ provided more prolonged heartburn relief than LPZ.

Recently, Akiyama *et al*[49] studied the efficacy of VPZ 20 mg in 13 patients with PPI-refractory GERD who exhibited continued pathological esophageal acid exposure (EAE). Among 13 patients who were observed by multichannel intraluminal impedance-pH at baseline (PPI treatment) and after VPZ 20 mg therapy, the median gastric acid exposure times of the VPZ group were lower than those of the PPI group, both during daytime and nocturnal observations. Furthermore, during the 24-h monitoring period, VPZ 20 mg treatment resulted in lower median EAE values (4.5%) than PPI therapy (10.6%).

Table 2 Clinical studies regarding the efficacy of potassium-competitive acid blocker in gastroesophageal reflux disease treatment

Ref.	Country/region	Study design	Patients, *n*	Diagnosis	Treatment groups	Duration of treatment, wk	Clinical outcomes
Ashida *et al*[42]	Japan	Multicenter, randomized, double-blind	732	EE	LPZ 30 mg; VPZ 5 mg; VPZ 10 mg; VPZ 20 mg; VPZ 40 mg	8	All VPZ regimens were non-inferior to LPZ 30 mg treatment. The proportions of healed EE subjects were 87.3%, 86.4%, 100%, 96.0%, and 87.0% with VPZ 5, 10, 20, 40 mg, and LPZ 30 mg, respectively
Ashida *et al*[43]	Japan	Multicenter, randomized, double-blind	607	EE	LPZ 15 mg; VPZ 10 mg; VPZ 20 mg	24	The EE recurrence rates were 16.8%, 5.1%, and 2.0% with LPZ 15 mg, VPZ 10 mg, and VPZ 20 mg, respectively, over the 24-wk maintenance period
Shinozaki *et al*[47]	Japan	Retrospective cohort	55	NERD = 30; EE = 25	VPZ 10 mg	4	The VPZ 10 mg for 1-mo alleviated GERD symptoms in 89% and were sustained in 82% after 1 yr without further therapy
Oshima *et al*[48]	Japan	Randomized placebo control	32	EE	LPZ 30 mg; VPZ 20 mg	2	The heartburn was relieved earlier with VPZ than with LPZ, and it was completely relieved in 31.3% and 12.5% of patients on day 1 with VPZ and LPZ, respectively
Akiyama *et al*[49]	Japan	Retrospective cohort with prospective study	13	PPI-refractory GERD	PPIs switch to VPZ 20 mg	8	The median gastric acid exposure times of the VPZ 20 mg were lower than the median gastric acid exposure times of the PPI treatment in both daytime and nocturnal observations. The VPZ 20 mg outperforms PPIs in stomach acid suppression, EAE control, symptom alleviation, and esophagitis healing in patients with PPI-refractory GERD
Mizuno *et al*[50]	Japan	Open-label, single-center, prospective study	50	PPI-refractory RE	PPIs switch to VPZ 20 mg for 4 wk and VPZ 10 mg	48	VPZ 10 mg prevented the recurrence of esophageal mucosal breaks in 43 of 50 (86.0%) patients. VPZ 10 mg is clinically efficacious for the long-term maintenance of healed RE
Xiao *et al* [51]	China, South Korea, Taiwan, Malaysia	Phase III, double-blind, multicenter study	481	EE	LPZ 30 mg; VPZ 20 mg	8	The 8-wk EE healing rates in the VPZ and LPZ groups were 92.4% and 91.3%, respectively. VPZ 20 mg was not inferior to LPZ 30 mg in EE healing at 8 wk
Okanobu *et al*[52]	Japan	Randomized control study	73	EE	VPZ 10 mg; VPZ 20 mg	Each dose for 4 wk and VPZ 10 mg for 8 wk	VPZ 10 mg had the same result as VPZ 20 mg in mucosal healing and symptom reduction at 4 wk and throughout the trial
Matsuda *et al*[53]	Japan	Multicenter, randomized, cross-over study	122	Erosive GERD	VPZ 10 mg; LPZ 15 mg	Every 2nd day for 4 wk and cross-over for more 4 wk	GERD symptoms were significantly reduced with VPZ 10 mg every other day, as measured by the FSSG and the gastrointestinal symptom rating scale
Lee *et al* [54]	South Korea	Randomized, double-blind, parallel-group comparison study	302	EE	TPZ 50 mg; TPZ 100 mg; EPZ 40 mg	4 and 8	At week 8, the cumulative healing rates for TPZ 50 mg, TPZ 100 mg, and EPZ 40 mg were 98.9%, 98.9%, and 98.9%, respectively
Kim *et al* [55]	South Korea	Phase III, double-blind, placebo-controlled, multicenter study	324	NERD	TPZ 50 mg; TPZ 100 mg; placebo	4	The proportions of heartburn-free days and full-resolution rates of heartburn were significantly higher in both TPZ groups than in the placebo group
Lee *et al* [56]	South Korea	Phase III, multicenter, randomized, double-blind trial	260	EE	FPZ 40 mg; EPZ 40 mg	8	FPZ 40 mg was non-inferior to EPZ 40 mg. FPZ 40 mg provided better symptom relief in patients with moderate to severe heartburn, with the effect lasting throughout the night

EAE: Esophageal acid exposure; EE: Erosive esophagitis; EPZ: Esomeprazole; FPZ: Fexuprazan; FSSG: Frequency scale for the symptoms of gastroesophageal reflux disease; GERD: Gastroesophageal reflux disease; LPZ: Lansoprazole; NERD: Non-erosive reflux disease; PPI: Proton pump

inhibitor; RE: Reflux esophagitis; TPZ: Tegoprazan; VPZ: Vonoprazan.

EAE normalization occurred in 46% of VPZ-treated people, and it was connected to complete stomach acid reduction (P = 0.005). Reflux symptoms (P = 0.01) and EE (P = 0.01) improved after switching to VPZ 20 mg. They concluded that VPZ 20 mg outperforms PPIs in stomach acid suppression, EAE control, symptom alleviation, and esophagitis healing in patients with PPI-refractory GERD.

Mizuno *et al*[50] carried out a study to assess the effectiveness of VPZ 10 mg as a maintenance treatment for healed RE in 50 patients who completed 48-wk maintenance therapy. Maintenance therapy with VPZ 10 mg at 48 wk avoided the recurrence of esophageal mucosal breaches in 43 of 50 patients (86.0%). Throughout the 48-wk maintenance therapy, the symptomatic non-relapse rate for acid reflux-related symptom score on the frequency scale for GERD symptoms and acid reflux score on the gastrointestinal symptom rating scale was 70.0% and 72.0%, respectively. They determined that VPZ 10 mg is clinically efficacious for the long-term maintenance of healed RE.

In 2020, Xiao *et al*[51] conducted a phase III, double-blind, multicenter study in 468 endoscopically confirmed EE patients and randomly assigned them to take either VPZ 20 mg (238) or LPZ 30 mg (230) once daily for 8 wk. They found that the 8-wk EE healing rates in the VPZ and LPZ groups were 92.4% and 91.3%, respectively. Moreover, in patients with a baseline LA classification of C/D, VPZ had higher 2-wk, 4-wk, and 8-wk EE healing rates than LPZ. Overall, the rates of EE healing appeared to be greater with VPZ than with LPZ. They concluded that VPZ is not inferior to LPZ in EE healing at 8 wk, and the two treatment groups had identical safety results.

Last year, Okanobu *et al*[52] performed a randomized control study to evaluate the efficacy of VPZ 10 mg (n = 36) compared with VPZ 20 mg (n = 37) in 73 patients with EE. The patients were given each dose for four weeks as an initial treatment, followed by eight weeks of maintenance therapy with VPZ 10 mg. The endoscopic healing rates of the 20 mg and 10 mg groups were 94.6% and 94.4%, respectively, after four wk. In both treatment groups, the frequency scale for GERD symptoms decreased significantly, from 13 to 4 and 14 to 3, respectively, in the 20 mg and 10 mg groups. The scores have plummeted to 2 after 12 wk. They determined that after 4 wk and throughout the experiment, VPZ 10 mg medication had a similar therapeutic response to VPZ 20 mg treatment in terms of mucosal repair and symptom reduction. These results were also the same in LA classification grade A/B patients but not in grade C/D patients.

A prospective, multicenter, open-label, randomized cross-over trial with two periods was conducted by Matsuda *et al*[53] to clarify the efficacy and superiority of VPZ 10 mg every other day over LPZ 15 mg in the maintenance management of 122 erosive GERD patients. They observed that 93.6% of the VPZ group and 82.1% of the LPZ group had well-controlled symptoms, with a significant difference (P = 0.003) using McNemar's test. The VPZ-LPZ and LPZ-VPZ groups, respectively, had 96.7% and 80.0% of patients well managed throughout the first four weeks (P = 0.007). For the second 4 wk, 94.4% of patients in the VPZ-LPZ and 76.7% of patients in the LPZ-VPZ groups were well controlled following 6 consecutive days a week (P = 0.009). They found that taking VPZ 10 mg every other day decreased GERD symptoms considerably, as indicated by the frequency scale for the gastrointestinal symptom rating scale and GERD symptoms.

TPZ efficacy in GERD

Lee *et al*[54] conducted a parallel-group, multicenter, randomized, double-blind comparative trial in 302 Korean patients with endoscopically confirmed EE in 2019. The patients were randomly assigned to receive TPZ 50 mg, TPZ 100 mg, or EPZ 40 mg for 4 wk or 8 wk. They confirmed that at week 8, the cumulative healing rates for TPZ 50 mg, TPZ 100 mg, and EPZ 40 mg were 98.9% (91/92), 98.9% (90/91), and 98.9% (87/88), respectively. Both TPZ dosages were non-inferior to EPZ 40 mg, and TPZ was well tolerated.

Kim *et al*[55] undertook a multicenter, double-blind, placebo-controlled, phase III trial in 324 Korean patients with NERD in 2021 to investigate the safety and effectiveness characteristics of TPZ relative to placebo. They were randomized into three groups with TPZ 50 mg, TPZ 100 mg, and placebo once daily for 4 wk. After 4 wk of therapy with TPZ 50 mg, TPZ 100 mg, or placebo, 42.5% (45/106), 48.5% (48/99), and 24.2% (24/99) of patients achieved full relief of significant symptoms. TPZ 50 mg and 100 mg performed better than the placebo by a substantial statistical difference. Both the TPZ and placebo groups had significantly greater percentages of heartburn-free days and full-resolution rates of heartburn. Furthermore, no apparent change in the occurrence of treatment-emergent adverse events was observed.

FPZ efficacy in GERD

In a phase III, multicenter, randomized, double-blind trial, FPZ, the antisecretory action of a pyrrole derivative with a quick and full onset was tested. A total of 260 adult patients with endoscopically proven EE (LA grades A to D) were given either FPZ 40 mg or EPZ 40 mg *per* day. The cumulative proportion of patients with healed mucosal breaks, as evaluated by endoscopy, was the main outcome

measure at week 8. The healing rate, symptoms, and quality of life were assessed at week 4, and it was discovered that FPZ was non-inferior to EPZ, with the groups having identical cumulative healing rates at 8 wk and equivalent rates at 4 wk. In individuals with moderate to severe heartburn, FPZ provided superior symptom alleviation that lasted throughout the night. The medication was well tolerated, with similar rates of side effects across treatment groups[56].

SAFETY OF P-CABs

Despite the fact that PPIs are one of the safest pharmacological classes available and have been used for almost 30 years, the number of papers on delayed-release PPI safety has skyrocketed, with many extensively discussed subjects appearing in high-profile journals[57,58]. Clinical studies and subsequent meta-analyses have revealed that VPZ has outstanding short and medium-term safety when compared to the performance of PPIs[42-53,59,60]. Because serum gastrin and pepsinogen I levels in healthy volunteers and GERD patients mirrored the antisecretory effect of VPZ, hypergastrinemia associated with long-term therapy may be a concern[61,62]. Clinical studies and subsequent meta-analyses have revealed that VPZ has outstanding short and medium-term safety when compared to the performance of PPIs[63]. Long-term PPI therapy has been associated with dysbiosis and changes in the gut microbiome, and similar changes have now been reported with VPZ[64-66]. Lipopolysaccharide biosynthesis proteins and lipopolysaccharide biosynthesis were the most dramatically elevated pathways in response to VPZ. They are most likely caused by an increase in intraluminal pH and are analogous to *H. pylori* responses to external pH changes. Because lipopolysaccharide is a potent immune response stimulator generated by Gram-negative bacteria, these data imply that VPZ may increase bacterial growth[67-69].

CONCLUSION

Many of the disadvantages and limitations of delayed-release PPIs are overcome by P-CABs. Mucosal healing in acid-related disorders is linked to the duration and degree of acid suppression, and also the length of treatment. Given the challenges in achieving good symptom management, particularly at night, with presently available delayed-release PPIs once daily, this novel family of medicines, P-CABs, delivers immediate, powerful, and extended acid suppression. They have the potential to address many of the unmet therapeutic needs in GERD, such as obtaining immediate heartburn relief and fast and specific healing of severe RE. The benefits of long-term acid suppression extend to *H. pylori* eradication, where intragastric pH control, especially at night, is crucial. Moreover, VPZ may be an optimum dual therapy as a straightforward, dependable, and successful first-line treatment for GERD. More thorough evaluations of VPZ, TPZ, and FPZ are needed, especially in Europe and North America. After extensive worldwide use of P-CABs, clinicians will justify whether it is effective, safe, and superior to currently available treatment with PPIs. In our opinion, VPZ or other P-CABs should be reserved for difficult-to-treat acid-related illnesses and unmet requirements, where the benefit-to-risk ratio is predicted to be the best.

Abstract

Multidisciplinary pediatric aerodigestive centers have been proposed to address the needs of children with complex multi-system problems affecting the respiratory and upper gastrointestinal tracts. The setup of a multidisciplinary service allows for the complex coordination needed between different subspecialties. This allows for rapid communication and family-centered decision making and agreement on further diagnostic and/or therapeutic next steps such as offering triple endoscopy when indicated. Triple endoscopy entails performing rigid upper airway assessment, flexible bronchoscopy and upper gastrointestinal endoscopy and has been linked to reduced time to diagnosis/treatment, reduced costs and anesthesia exposure. This review summarizes the available literature on the structure and benefits of multidisciplinary pediatric aerodigestive services.

Key Words: Aerodigestive; Multidisciplinary; Pediatric; Triple endoscopy

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Multidisciplinary pediatric aerodigestive programs serve patients with multisystem problems affecting the respiratory and upper gastrointestinal tracts and require the participation and expertise of essential subspecialists including gastroenterologists. This setup allows for coordinated diagnostic and therapeutic interventions such as triple endoscopy. Benefits include reducing time to diagnosis and/or treatment, reducing healthcare costs and limiting exposure to radiation and anesthesia, providing a strong example of value-based healthcare delivery.

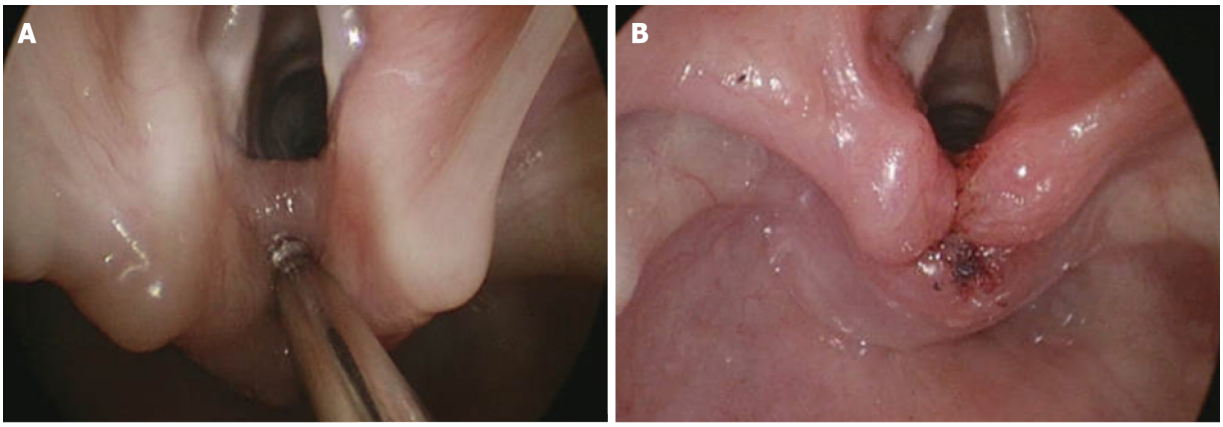
INTRODUCTION

Multidisciplinary programs for complex medical conditions such as cystic fibrosis and asthma have been shown to optimize the value of healthcare delivery by improving outcomes and reducing cost[1,2]. There is growing literature supporting this concept for aerodigestive programs[3,4]. Multidisciplinary pediatric aerodigestive programs have been proposed to address the specific needs of children with complex multi-system problems affecting the respiratory and upper gastrointestinal (GI) tracts. Conditions managed by aerodigestive programs are diverse and may include structural or physiological airway disease, chronic parenchymal lung disease, lung injury from aspiration or infection, dysphagia, and esophageal mucosal, motility and anatomic abnormalities[1,5]. One main aim of this coordinated interdisciplinary approach is to allow for expedited patient evaluation in a single clinical setting, including diagnostic and therapeutic interventions. Several benefits have been attributed to aerodigestive programs, as opposed to independent evaluations by different subspecialists at different times. Benefits include shorter time to diagnosis, reduced radiation and anesthesia exposure and lower healthcare related costs. The purpose of the review is to shed light on the structure, services and impacts of aerodigestive programs and to highlight the need for gastroenterology expertise and involvement within these programs.

Advances in the care of critically ill infants and children have created a growing population of patients with complex chronic multi-system diseases requiring a collaborative multispecialty approach to their management[6]. This includes multidisciplinary aerodigestive programs that focus on children with a combination of multiple and interrelated congenital and/or acquired conditions affecting airway, breathing, feeding, and concerns about growth/nutrition (Table 1). Key service components of an aerodigestive program include a pediatric otolaryngologist, pediatric pulmonologist and pediatric gastroenterologist along with a speech language pathologist, social worker and nutritionist. The first consensus statement on aerodigestive programs, published in 2018, provided a definition of an aerodigestive patient, specified needed participation of vital pediatric disciplines and their levels of expertise, and highlighted essential care components, assessments and therapies including endoscopic procedures [5].

Results of a survey published in 2019 noted the number of pediatric aerodigestive programs to be rapidly proliferating with diffuse geographic presence throughout the United States, with the largest subset operating in academic centers[7]. This was a recent phenomenon as a considerable percent of these programs had been operating for just a few years.



AERODIGESTIVE PROGRAM SERVICES

Aerodigestive programs not only offer expertise from different specialties in a single setting, but also enable the coordination of evaluation and intervention. Depending on patient presentation and the differential diagnoses, management includes education, discussion of potential treatment options and risks and benefits of treatment modalities and further testing. Evaluation can include a list of airway and GI interventions offered individually or in combination.

From the airway perspective, evaluation can include awake in-office flexible laryngoscopy and swallow assessment. Further workup may include drug induced sleep endoscopy, direct laryngoscopy and rigid bronchoscopy, while therapeutic interventions targeting specific pathology such as endoscopic repair of laryngeal cleft (Figure 1), laser excision of cysts, balloon dilation of subglottic stenosis and more advanced open airway interventions. These procedures have benefits and risks which should be taken in consideration and clearly discussed with caregivers. Some evaluation can take place without sedation while others require various levels of sedation, often performed in the operating room with the assistance of anesthesia services.

Table 1 Common aerodigestive problems (with overall among subspecialists)

Pulmonary	Otolaryngology	Gastroenterology
Chronic cough	Tracheostomy dependence	Dysphagia
Stridor	Stridor	Feeding intolerance
Wheezing	Noisy breathing	Gastroesophageal reflux disease
Recurrent pneumonia	Recurrent croup	Eosinophilic esophagitis
Tracheomalacia	Laryngeal cleft	Esophageal stricture
Bronchomalacia	Laryngeal stenosis	Congenital esophageal anomalies
Chronic lung disease	Laryngomalacia	Malnutrition
Need for ventilatory support	Vocal cord paralysis	Feeding tube dependence
	Subglottic stenosis	
	Tracheal stenosis

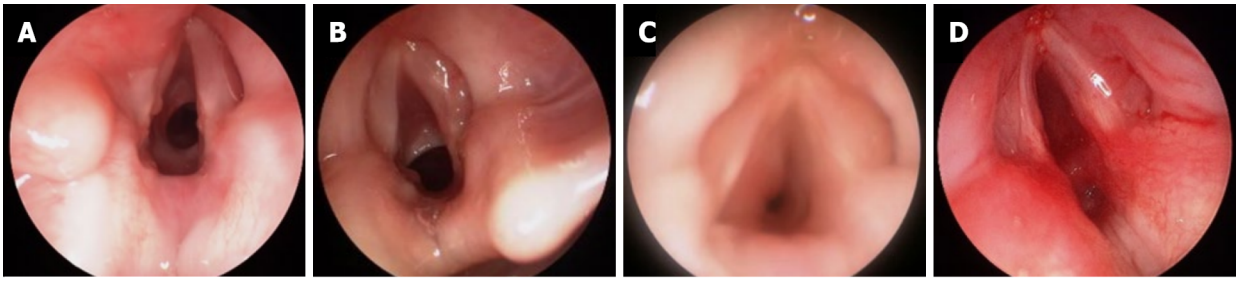

Figure 1 Endoscopic assessment and management for a laryngeal cleft which can contribute to aspiration. A: Probing of interaytenoid region to assess for cleft; B: Post laryngeal cleft repair using laser and suturing.

Awake in-office flexible laryngoscopy allows for a non-sedated evaluation of the upper airway. This allows for the assessment of upper airway dynamics and abnormalities such as vocal cord lesions and vocal cord movement, tongue base obstruction, hypopharyngeal collapse, adenoid or tonsillar hypertrophy and laryngomalacia. Assessment of dysphagia and aspiration can also be undertaken during in-office flexible laryngoscopy, *via* a procedure referred to as Fiberoptic Endoscopic Evaluation of Swallowing. Even though an invaluable tool for assessment of airway and swallowing abnormalities in the children, in-office flexible laryngoscopy has some disadvantages including limited assessment of structures below the vocal cords and dependence on patient compliance. In addition, therapeutic airway interventions are not possible in the office setting.

Drug induced sleep endoscopy (DISE) allows for upper airway evaluation using a flexible endoscope while a patient is in a pharmacologically induced sleep-like state. During DISE, an endoscope is passed through the nares to assess the nasopharynx, oropharynx, larynx, and in some cases the trachea. The procedure is often carried out either with propofol or dexmedetomidine sedation, which simulates natural sleep and can demonstrate lesions causing obstruction that may not be evident on an awake in-office flexible laryngoscopy[8].

Rigid endoscopy is considered the gold standard for diagnostic airway assessment of structures below the vocal cords, including trachea and bronchi. It offers better optics, ability to size areas of narrowing and provides an opportunity to perform a variety of interventions (Figure 2). This procedure requires patient sedation and thus is not hampered by patient tolerance or compliance. Spontaneous breathing can be maintained, which allows for examination of the dynamic status of the airway. The sedated status allows for surgical interventions such as biopsy, laryngeal cleft injection or suturing, epiglottopexy, balloon dilation, vocal cord injection, and laryngotracheal reconstruction[9,10].

Upper GI evaluation may include video fluoroscopic evaluation of swallowing, contrast imaging for esophageal strictures, impedance pH testing for gastroesophageal reflux disease (GERD), esophageal manometry for motility disorders and mucosal endoscopic assessment for esophagitis including eosino-

Figure 2 Endoscopic grading of subglottic stenosis. A: Grade I: 0%-50% obstruction; B: Grade II: 51%-70% obstruction; C: Grade III: 71%-99%; D: Grade IV: No detectable lumen.

philic esophagitis (EoE). Aerodigestive patients often have feeding problems and are at high risk for malnutrition, necessitating feeding tube placement and use[11]. Some patients can be managed with nasogastric and gastrostomy tubes while others require jejunal feeds due to persistent GERD and/or intolerance to intragastric feeds. The choice, placement and maintenance of feeding tubes can be managed by a pediatric gastroenterologist within an aerodigestive program[12].

Specific patient categories presenting to an aerodigestive clinic may have a particularly higher risk for upper GI abnormalities contributing the symptoms. These include patients previously treated for esophageal atresia and tracheoesophageal fistula (Figure 3). Common complications among these patients include esophagitis[13], recurrent respiratory tract infection, tracheomalacia and poor growth with increased healthcare utilization[14-16]. Pediatric gastroenterology input can be crucial to evaluate for anatomic and mucosal esophageal abnormalities and for persistent tracheoesophageal fistula, which can be difficult to diagnosis. Simultaneous tracheal and esophageal endoscopic assessment can help in challenging cases when imaging modalities are not definitive (Figure 4).

In some patients, flexible bronchoscopy, flexible upper GI endoscopy, direct laryngoscopy, and rigid bronchoscopy are indicated and can be offered in combination aptly named as "triple endoscopy". A triple endoscopy provides efficient, organized and thorough evaluation of the patient's disorders without requiring multiple, separate procedures under anesthesia. This allows for complementary modalities for evaluation of upper GI and airway structures and dynamics and facilitates real-time discovery, discussion, and planning amongst all the specialists involved, allowing for excellent, patient-centric care. A consensus on the core data elements to be gathered during triple endoscopy has been published[17]. From the gastroenterology standpoint, the importance of assessing for EoE is highlighted due to potential contribution to aerodigestive symptoms. An upper endoscopy should therefore be considered as part of a triple endoscopy in patients presenting with symptoms potentailly arising from esophageal mucosal disease (especially EoE) as well as anatomic GI disorders (such as esophageal strictures). Another common indication for triple endoscopy is in the preoperative evaluation of children undergoing open airway reconstructive surgery (like patients with tracheostomies moving towards decannulation). Triple endoscopy has also shown high yield in the evaluation of chronic cough, aspiration, apparent life-threatening episodes, recurrent croup and recurrent pneumonias. Triple endoscopy can assess factors that can predict outcomes of open airway reconstruction such as laryngo-tracheal reconstruction, cricotracheal resections and tracheal resections, allowing for risk modification to optimize patient outcomes. Triple endoscopy serves to provide a comprehensive assessment including evaluating grade of subglottic stenosis, ruling out secondary airway lesions (such as tracheobron-chomalacia). Active esophageal disorders, like EoE and GERD, have been linked to unfavorable effect outcomes of open airway reconstruction so it is important for identify these conditions and optimize their management[18,19]. In this patient population, flexible bronchoscopy with bronchoalveolar lavage provides evidence of bacterial colonization which can direct prophylactic antibiotics. Patients with tracheostomies, frequently evaluated by aerodigestive programs, commonly have airway colonization with *Pseudomonas aeruginosa*. Pseudomonal wound infection during open airway reconstruction surgeries leads to increased morbidity[20,21]. Implementation of culture directed antibiotics prior to or during open airway reconstruction surgery can therefore improve outcomes. Studies have demonstrated that specific subsets of aerodigestive patients are more likely to have abnormal mucosal histology on upper GI endoscopy and/or abnormal impedance pH testing[22,23]. This includes those with previously diagnosed asthma, feeding difficulty, and esophageal atresia with or without tracheoesophageal fistula, with 40%-50% yield on upper GI testing[22]. Findings noted included reflux esophagitis and EoE. It is important to note that in many studies a large percent of patients (> 50%) were on acid suppressive therapy which may have treated underlying proton pump inhibitor responsive eosinophilia (now considered a subset of EoE) which requires prolonged treatment and monitoring[24].

AERODIGESTIVE PROGRAM OUTCOMES

As aerodigestive programs expand, there has been more emphasis on measuring program impact on patients, their families and the healthcare system. Clinical outcomes typically followed can include documented improvement in swallowing (control of aspiration), frequency of respiratory infections, rate of decannulation in patients with tracheostomies and overall patient mortality. Other important outcomes studied include time to reach a diagnosis and/or initiate treatment, impact of health-related quality of life, healthcare costs and utilization.

Studies have demonstrated numerous positive impacts of aerodigestive programs. These include lower technical direct cost (by as much as 70%) and fewer inpatient days after enrolling patients in an aerodigestive program[3]. Frequency of unnecessary evaluation (swallow studies and impedance pH testing) dropped when such programs were established[24,25]. Aerodigestive programs have been linked to improved patient quality of life and reduced caregiver burden[11]. Studies have also noted

shortened time to diagnosis (6 d *vs* 150 d, $P < 0.001$), fewer specialist consultations, lower hospital charges, less radiation exposure and reduced anesthesia exposure when aerodigestive programs were established[4,26]. The benefit of reducing anesthesia exposure is of particular interest in infants and young children in terms of diminishing neurocognitive risks associated with repeated exposure to anesthetics[27].

Further advantages of triple endoscopy include a significant reduction in mean anesthesia time (54 min *vs* 89 min, $P < 0.0001$) compared to having the 3 procedures done separately[28]. Charges and direct costs for triple endoscopy were also significantly lower as compared to performing these as separate procedures[28]. It is important to note that not all patients who present to an aerodigestive require a triple endoscopy. Patients with isolated surgical pathology such as cystic lesions (for example vallecular cyst) are likely to only require otolaryngologist intervention only.

CONCLUSION

Aerodigestive programs have specific requirements for essential subspecialist participation and expertise which includes gastroenterology services. These programs offer numerous advantages in the management of complex multi-system problems affecting the respiratory and upper GI tracts especially with the diverse and overlapping contributions of conditions leading to a range of patient signs and symptoms. The setup of an aerodigestive program allows for diagnostic and therapeutic interventions, offered individually or in combination. Benefits of aerodigestive programs have been demonstrated and include reducing time to diagnosis and/or initiating of treatment, reducing healthcare costs and limiting patient radiation and anesthesia exposure, providing a strong example of value-based healthcare.

Abstract

Acute liver failure (ALF) is a severe and life-threatening condition in which rapid deterioration of liver function develops in a patient who has no preexisting liver disease. Mesenchymal stem cells (MSCs) are immunoregulatory stem cells which are able to modulate phenotype and function of all immune cells that play pathogenic role in the development and progression of ALF. MSCs in juxtacrine and paracrine manner attenuate antigen-presenting properties of dendritic cells and macrophages, reduce production of inflammatory cytokines in T lymphocytes, suppress hepatotoxicity of natural killer T (NKT) cells and promote generation and expansion of immunosuppressive T, B and NKT regulatory cells in acutely inflamed liver. Due to their nano-sized dimension and lipid envelope, intravenously injected MSC-derived exosomes (MSC-Exos) may by-pass all biological barriers to deliver MSC-sourced immunoregulatoy factors directly into the liver-infiltrated immune cells and injured hepatocytes. Results obtained by us and others revealed that intravenous administration of MSCs and MSC-Exos efficiently attenuated detrimental immune response and acute inflammation in the liver, suggesting that MSCs and MSC-Exos could be considered as potentially new remedies in the immunotherapy of ALF. In this review, we emphasize the current knowledge about molecular and cellular mechanisms which are responsible for MSC-based modulation of liver-infiltrated immune cells and we discuss different insights regarding the therapeutic potential of MSCs in liver regeneration.

Key Words: Mesenchymal stem cells; Acute liver failure; Therapy; Immunomodulation; Regeneration

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Due to their potent immunoregulatory, angiomodulatory and hepatoprotective properties, mesenchymal stem cells and their exosomes suppress detrimental immune response, prevent apoptosis and promote survival of injured hepatocytes which results in an enhanced repair and regeneration of acutely injured liver.

INTRODUCTION

The liver is the largest solid organ in the human body. It consists of large sections (lobes) which are divided in a thousand, hexagonally-shaped small units (lobules)[1]. The lobule is the main structural unit of the liver consisting of a portal triad, hepatocytes and a central vein[1]. The liver is essential organ which performs many functions including bile production, removal of waste products and toxins from the bloodstream, regulation of blood clotting, storage of fat-soluble vitamins, minerals (copper, iron) and glycogen[1]. The liver conjugates bilirubin, handles cholesterol homeostasis, regulates sex hormone metabolism and produces proteins which are important for optimal functioning of endocrine, gastrointestinal, reproductive and immune system. Since liver regulates many vital functions, severe and massive liver injury results in the development of life-threatening multi-organ dysfunction[1].

Acute liver failure (ALF) is a clinical syndrome characterized by rapid deterioration of liver function followed by ascites, coagulopathy, hepatic encephalopathy and multi-organ failure which occur in a patient who has no preexisting liver disease[2]. An annual incidence of ALF is 5.5-6.2 cases per million population per year[3]. ALF is a consequence of severe drug-induced liver injury, hepatic ischemia, invasion of hepatotropic viruses and develops due to the generation of detrimental immune response against foreign or self-antigens, released from injured hepatocytes[4].

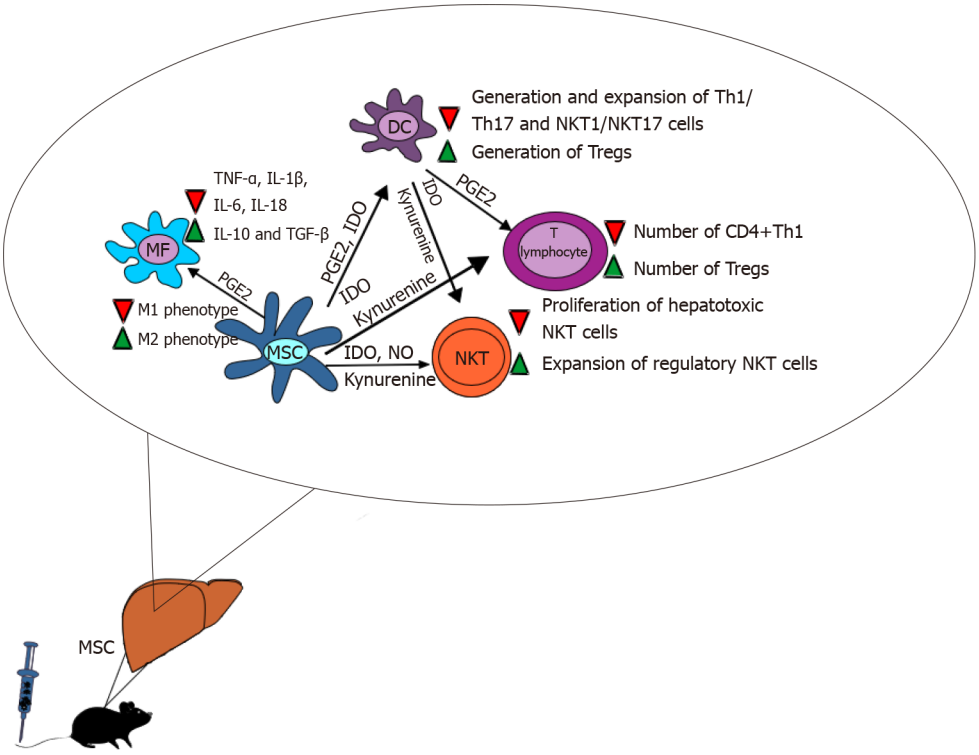
Pathogen-associated molecular patterns expressed on invading pathogens or damage-associated molecular patterns and alarmins released from damaged-hepatocytes activate liver resident professional antigen presenting cells [dendritic cells (DCs) and Kupffer cells][2,5]. Activated DCs present lipid antigens to the liver natural killer T (NKT) cells in CD1-dependent manner, enabling their activation and polarization in inflammatory, interferon gamma (IFN-γ)-producing NKT1 and interleukin (IL)-17-producing NKT17 cells[6]. Additionally, activated liver DCs capture microbial proteins and self-proteins released from injured hepatocytes, and present them to the antigen-specific naïve CD4+ and CD8+ T cells[7]. DC-derived IL-12 induce activation and differentiation of naïve CD4+T cells in effector, IFN-γ-producing Th1 cells while DC-sourced IL-1, IL-6 and IL-23 induce generation of IL-17 and IL-22-producing effector Th17 cells[7].

Activated Kupffer cells produce tumor necrosis factor alpha (TNF-α) and IL-1β which induce enhanced expression of E and P selectins on liver endothelial cells, enabling massive influx of circulating neutrophils and monocytes in the injured livers[2,5]. Additionally, activated Kupffer cells release Th1 and Th17 cell-attracting chemokines (CXCL3 and CCL20) and recruit effector CXCR3-expressing CD4+Th1 cells and CCR6-expressing CD4+Th17 cells in the inflamed livers[6]. NKT1/Th1 cell-derived IFN-γ and NKT17/Th17 cell-sourced IL-17 induce enhanced synthesis of hepatotoxic TNF-α , nitric oxide (NO) and reactive oxygen species in Kupffer cells and liver-infiltrated neutrophils, resulting in massive necrosis of hepatocytes[6,7].

Transplantation of bio-artificial livers and hepatocytes could provide support of liver function temporarily and are therefore used as therapeutic approaches for the treatment of ALF[8]. Restored liver function and reduced incidence of extra hepatic complications were observed in ALF patients who underwent transplantation of hepatocytes[2]. However, short-term viability of engrafted hepatocytes and immune rejection against major histocompatibility complex (MHC) miss-matched transplanted hepatic cells significantly limited therapeutic efficacy of liver transplantation. Immunosuppressive therapy managed to temporarily improve survival of ALF patients who underwent liver transplantation [8,9]. Nevertheless, continuous and long-term use of immunosuppressive drugs may induce severe and life-threatening immunosuppression which may be fatal for ALF-treated patients[9]. Accordingly, there is an urgent need for the development and therapeutic use of new immunoregulatory and hepatoprotective agent which could create immunosuppressive microenvironment in injured liver, suppress

detrimental immune response, alleviate liver inflammation and, at the same time, promote hepatocyte proliferation without causing severe, systemic immunosuppression.

Mesenchymal stem cells (MSCs) are adult stem cells that reside in almost all postnatal organs, where participate in the elimination of microbial pathogens, suppress detrimental immune response, promote survival of injured parenchymal cells and enhance tissue repair and regeneration[10]. A large number of experimental and clinical studies demonstrated therapeutic efficacy of MSCs and their secretome in the treatment of ALF[11,12]. MSCs were either directly transplanted in the injured livers or were infused *via* peripheral, portal, splenic veins and hepatic artery. Sang *et al*[13] and Cao *et al*[14] demonstrated that MSCs administered *via* portal vein had better capability to attenuate liver inflammation, reduce necrosis and promote liver regeneration than MSCs which were transplanted *via* hepatic artery, peripheral vein or MSCs which were directly injected in the damaged livers. Teshima and colleagues observed that MSCs which were transplanted *via* splenic vein more efficiently suppressed liver inflammation and enhanced liver regeneration than MSCs which were injected *via* peripheral vein[15]. Opposite to these findings were results reported by Sun *et al*[16] who showed that there was no significant difference in the regeneration of acutely injured livers of animals that received MSCs *via* hepatic artery, portal or peripheral vein, suggesting that route of MSCs injection was not crucially important for their therapeutic effects in the treatment of ALF.



mmUpon engraftment, transplanted MSCs in juxtacrine (cell-to-cell contact-dependent signaling) and paracrine manner [through the activity of MSC-sourced soluble factors: Prostaglandin E2 (PGE2), IL-10, transforming growth factor beta (TGF-β), indoleamine 2, 3 dyoxigenase (IDO), NO, hepatic growth factor (HGF), IL-1 receptor antagonist] modulate phenotype and function of all immune cells that play pathogenic role in the development and progression of acute liver injury[11,12]. MSCs also produce various growth and angiomodulatory factors [HGF, IL-6, vascular endothelial growth factor, basic fibroblast growth factor (bFGF)] which support survival and proliferation of injured hepatocytes[10,13]. Herewith, in this review article, we summarized current knowledge about molecular and cellular pathways that were responsible for hepatoprotective, immunoregulatory and angiomodulatory effects of MSCs and their secretome in the therapy of ALF. An extensive literature review was carried out in March 2022 across several databases (MEDLINE, EMBASE, Google Scholar, ClinicalTrials.gov). Keywords used in the selection were: "mesenchymal stem cells", "secretome", "exosomes", "acute liver injury", "immunomodulation", "immunosuppression", "hepatocytes", "differentiation", "ischemia", "angiomodulation", "therapeutic potential", "liver repair and regeneration". All journals were considered, and an initial search retrieved 125 articles. The abstracts of all these articles were subsequently reviewed by two of the authors (CRH and VV) to check their relevance to the subject of this manuscript. Eligible studies had to delineate the effects of MSCs and their secretome on hepatocyte survival, phenotype and function of liver-infiltrated immune cells, and their findings were analyzed in this review.

MSC-DEPENDENT MODULATION OF LIVER-INFILTRATED IMMUNE CELLS

A large number of experimental studies demonstrated that hepatoprotective effects of MSCs were mainly relied on the immunoregulatory properties of MSCs[17-20]. MSCs attenuated acute liver inflammation and promoted liver regeneration by inducing immunosuppressive phenotype of liver macrophages, DCs, T lymphocytes and NKT cells[21-24].

MOLECULAR MECHANISMS RESPONSIBLE FOR MSC-BASED SUPPRESSION OF INFLAMMATORY MACROPHAGES IN INJURED LIVERS

Wang and colleagues showed that beneficial effects of MSCs in the attenuation of ALF were relied on the suppression of inflammatory M1 macrophages which hold central function in initiating acute liver inflammation[17]. Murine BM-MSCs alleviated murine D-galactosamine (D-Gal)-induced ALF by inducing generation of immunosuppressive M2 phenotype in liver macrophages in PGE2-dependent manner (Figure 1). MSC-derived PGE2 bound to the EP4 receptor and inhibited TGF-β-activated kinase 1-driven activation of nucleotide-binding and oligomerization domain-like receptor 3 (NLRP3) inflammasome in Kupffer cells[17]. PGE2-dependent suppression of NLRP3 inflammasome in liver macrophages resulted in down-regulated secretion of inflammatory cytokines (IL-1β, IL-6 and IL-18) which led to the alleviation of acute liver inflammation[17]. Additionally, MSC-sourced PGE2 induced phosphorylation and activation of transcriptional factor STAT6 which modulated mammalian target of rapamycin (mTOR) signaling that resulted in the generation of immunosuppressive M2 phenotype in liver macrophages. By producing anti-inflammatory cytokines (IL-10 and TGF-β), M2 macrophages attenuated on-going inflammation and promoted repair and regeneration of D-Gal-injured livers[17]. Similar findings were reported by Miao and colleagues who provided evidence that PGE2-dependent repression of NLRP3 inflammasome in Kupffer cells was mainly responsible for beneficial effects of BM-

DOI: 10.3748/wjg.v28.i28.3627 **Copyright** ©The Author(s) 2022.

Figure 1 Mesenchymal stem cells-based modulation of immune cells in acute liver injury. Mesenchymal stem cells (MSCs), in prostaglandin E2 (PGE2) dependent manner, prevent generation of inflammatory (M1) phenotype and induce generation of immunosuppressive (M2) phenotype in liver macrophages by down-regulating synthesis of inflammatory cytokines [tumor necrosis factor alpha, interleukin (IL)-1β, IL-6, IL-18] and by promoting production of anti-inflammatory cytokines (IL-10 and transforming growth factor beta). Increased indoleamine 2, 3 dyoxigenase (IDO) activity and enhanced secretion of PGE2 are mainly responsible for MSC-based generation of tolerogenic dendritic cells (DCs) which suppress expansion of Th1/Th17 lymphocytes and natural killer T (NKT) 1/NKT17 cells, but favor proliferation of immunosuppressive T regulatory cells (Tregs). MSC-generated tolerogenic DCs, in PGE2-dependent manner, suppress expansion of inflammatory CD4+ Th1 cells and induce expansion of Tregs, while in IDO/Kynurenine-dependent manner attenuate proliferation of hepatotoxic NKT cells and induce expansion of NKT regulatory cells (NKTregs). MSC-sourced nitric oxide, in autocrine manner, induces enhanced IDO activity in MSCs. MSC-derived IDO and Kynurenine suppress proliferation of inflammatory Th1 and NKT cells in the liver and were mainly responsible for MSC-dependent expansion of immunosuppressive Tregs and NKTregs in injured livers. MSCs: Mesenchymal stem cells; PGE2: Prostaglandin E2; TNF-α: Tumor necrosis factor alpha; IL: Interleukin; TGF-β: Transforming growth factor beta; IDO: Indoleamine 2, 3 dioxygenase; NKT: Natural killer T cells; Tregs: T regulatory cells; NKTregs: Natural killer T regulatory cells; NO: Nitric oxide.

MSCs in the attenuation of acute liver injury during lipopolysaccharide (LPS)-induced sepsis in mice [18]. BM-MSC-sourced PGE2 generated immunosuppressive phenotype and increased IL-10 production by modulating activity of extracellular signal-regulated kinase 1 (ERK1) in Kupffer cells[18].

Liu *et al*[19] who analyzed the frequency of F4/80-expressing macrophages in the livers of CCL4+MSC-treated mice confirmed that MSC-based therapy significantly altered phenotype and function of Kupffer cells in inflamed livers. During the initial phase of ALF (first 48 h after CCL4 injection), significantly higher number of inflammatory M1 macrophages was observed in injured livers while immunosuppressive M2 macrophages were dominant subpopulation of liver macrophages during the recovery phase (7 d after CCL4 injection)[19]. Intravenous injection of murine MSCs (5×10^5 cells/mice) which were obtained from compact bone attenuated liver inflammation and completely regenerate CCL4-injured livers. During the injured phase, the number of inflammatory monocyte-derived macrophages was significantly increased by MSC treatment while during the recovery phase of acute liver injury MSCs favored generation and expansion of immunosuppressive M2 macrophages, crucially contributed to the creation of immunosuppressive microenvironment in regenerated livers[19].

Hua *et al*[20] demonstrated that amnion-derived MSCs (A-MSCs) suppressed inducible nitric oxide synthase (iNOS) activity and NO production, attenuated synthesis of inflammatory cytokines (TNF-α, IL-6) and induced generation of anti-inflammatory phenotype in liver macrophages by promoting production of immunosuppressive IL-10. A-MSC-dependent modulation of liver macrophages was relied on modulation of autophagy, as evidenced by down-regulated expression of microtubule-associated protein 1 light chain 3 in A-MSC-treated Kupffer cells[20]. Single injection of A-MSCs (1×10^6 cells/mice) alleviated acetaminophen (APAP)-induced ALF in mice by inducing alternative activation of Kupffer cells. Liposome-induced macrophage depletion almost completely diminished beneficial effects of A-MSCs, indicating that macrophages were the main cellular targets of A-MSCs in the treatment of APAP-induced ALF[20].

THE CROSS-TALK BETWEEN MSCS, DCS, T LYMPHOCYTES AND NKT CELLS IN INJURED LIVERS

We and others demonstrated that MSCs and their secretome [MSC-derived conditioned medium (MSC-CM)] attenuated antigen-presenting properties of liver-infiltrated DCs, reducing their capacity for the generation and expansion of inflammatory Th1/Th17 and NKT1/NKT17 cells in injured livers[21-24]. MSC-sourced PGE2 and IDO were mainly responsible for the suppression of DC-dependent activation of liver T and NKT cells (Figure 1)[21-24].

Zhang *et al*[21] showed that intravenously injected BM-MSCs prevented progression of *Propionibacterium acnes* (*P. acnes*)-induced ALF in mice by inducing regulatory phenotype in liver DCs. MSCs-treated livers had normal morphology and structure without any signs of massive hepatocyte injury. MSCs down-regulated production of Th1 cell-attracting chemokines (CXCL9, CXCL10, CCL3, CCL21) which resulted in reduced influx of CXCR3 and CCR5-expressing effector CD4+ Th1 cells and CCR7-expressing memory CD4+ Th1 cells in the livers of *P. acnes*-treated mice[21]. Accordingly, only small number of liver-infiltrating lymphocytes was observed around the central veins of *P. acnes* + MSC-treated mice. Flow cytometry analysis of liver-infiltrated CD4+T cells revealed decreased expression of activating markers (CD44, CD69), indicating that MSCs suppressed activation of CD4+ T cells in *P. acnes* -treated animals[21]. MSCs attenuated ALF in mice by suppressing production of inflammatory and hepatotoxic cytokines (TNF-α and IFN-γ) in liver CD4+Th1 cells which was followed by the attenuation of systemic inflammation and by complete restoration of liver function[21]. Reduced number of CD4+ Th1 cells was accompanied with increased presence of FoxP3-expressing CD4+ CD25+ T regulatory cells (Tregs) in the livers of *P. acnes* + MSC-treated mice. Suppression of Th1 cell-driven liver inflammation was a consequence of MSC-dependent modulation of hepatic DCs[21]. DCs isolated from the livers of *P. acnes* + MSC-treated animals had regulatory phenotype, characterized by low expression of co-stimulatory molecules (CD80, CD86), decreased production of Th1 cell-related inflammatory cytokines (TNF-α, IL-1β, IL-12) and increased production of immunosuppressive cytokines (IL-10 and TGF-β) which induced generation and expansion of FoxP3-expressing CD4+ CD25+ Tregs in injured livers[21]. MSCs induced generation of regulatory phenotype in CD11c+ B220- precursor DCs through the activation of PI3K signaling pathway. By activating EP4 receptor, MSC-sourced PGE2 induced phosphorylation of PI3K and ERK1/2 kinases and elicited generation of tolerogenic, immunosuppressive phenotype in liver DCs[21]. Importantly, MSC-generated DCs possessed potent immunosuppressive and hepatoprotective properties. Passive transfer of MSC-generated regulatory DCs induced generation of hepatic Tregs, attenuated liver inflammation and prevented development of ALF in *P. acnes*-treated mice[21]. MSCs and DC-dependent expansion of Tregs was responsible for beneficial effects of MSCs since Treg depletion completely abrogated MSC-based attenuation of acute liver inflammation[21,22].

By using Concanavalin (Con A) and alpha-galactoceramide (α-GalCer)-induced hepatitis as murine models of ALF, we showed that MSC-dependent modulation of the cross-talk between DCs and NKT play important role in MSC-based attenuation of ALF[22-25]. Intravenously injected BM-MSCs significantly alleviated serum levels of AST and ALT, reduced apoptosis of hepatocytes and improved survival of Con A- and α-GalCer-treated mice[22-24]. Cellular make-up of the livers of MSC-treated animals revealed significantly reduced number of hepatotoxic, FasL, NKG2D and CD107-expressing NKT cells, indicating that MSCs suppressed cytotoxic properties of NKT cells[23]. The same phenomenon was observed in Con A- and α-GalCer-treated mice that received BM-MSC-CM, suggesting that MSCs suppressed NKT cell-driven liver inflammation in paracrine manner[22,23]. Among various MSC-derived immunosuppressive factors, NO and Kynurenine (IDO metabolite) were present in the highest concentration in BM-MSC-CM[23]. Additionally, inhibition of iNOS and IDO activity completely diminished hepatoprotective properties of MSCs, confirming the importance of NO and IDO/Kynurenine for MSC-dependent suppression of ALF[23,24]. MSC-sourced NO inhibited proliferation of hepatotoxic NKT cells while MSC-derived IDO induced generation of regulatory and immunosuppressive phenotype in NKT cells[23,25]. Additionally, MSC-sourced IDO prevented trans-differentiation of NKT regulatory cells (NKTregs) in inflammatory NKT17 cells by activating general control nonderepressible 2 (GCN2) kinase which suppressed protein kinase B/mTOR-dependent synthesis of inflammatory cytokines IL-17 and IL-22 in NKTregs[23,25].

In addition to their direct immunoregulatory effects on hepatotoic NKT cells, BM-MSCs and BM-MSC-CM suppressed effector functions of liver NKT cells indirectly, through the modulation of phenotype and function of hepatic DCs[25]. Liver DCs play important role in MSC-dependent suppression of liver NKT cells since their depletion abrogated hepatoprotective effects of MSCs and aggravated liver injury in MSC-treated mice[23,25]. MSCs attenuated antigen-presenting properties of hepatic DCs by down-regulating expression of MHC class II and co-stimulatory molecules on their membranes and by reducing synthesis of NKT1 and NKT17 cell- related inflammatory cytokines (TNF-α , IL-β, IL-12, IL-23, IFN-γ, IL-17)[22-25]. In similar manner as it was observed by Zhang *et al*[16], we also noticed that MSCs induced generation of regulatory and tolerogenic phenotype in hepatic DCs[22-25]. Increased IDO activity and enhanced production of anti-inflammatory cytokines (TGF-β and IL-10) were observed in the DCs which were isolated from the livers of Con A + MSCs and α-GalCer + MSCs-treated

mice[23]. MSC-generated regulatory DCs induced generation and expansion of IL-10 and TGF-β-producing NKTregs, contributing to the creation of immunosuppressive microenvironment in injured livers[24]. Additionally, BM-MSCs reduced presence of inflammatory, IFN-γ and TNF-α-producing NKT1 and IL-17-producing NKT17 cells in the livers of Con A + MSCs and α-GalCer + MSCs-treated mice which resulted in alleviated liver inflammation[24]. MSC-sourced IDO and its metabolite Kynurenine were mainly responsible for MSC-dependent generation of regulatory DCs[24,25]. Inhibition of IDO activity in MSCs attenuated their capacity for the generation of tolerogenic phenotype in hepatic DCs and diminished their hepatoprotective and immunosuppressive effects[24].

MSCS AS POTENTIALLY NEW THERAPEUTIC AGENTS IN REGENERATIVE HEPATOLOGY

MSCs represent heterogeneous population of immunoregulatory and angiomodulatory stem cells which possess enormous differentiation potential[25]. All subpopulations of MSCs spontaneously differentiate into the cells of mesodermal origin[25]. However, under appropriate conditions, MSCs may generate cells of ectodermal and endodermal origin, including hepatocyte-like cells (HLCs)[26-29].

Local tissue microenvironment, particularly oxygen supply and cytokines/growth factors released by parenchymal and tissue-resident immune cells modulate phenotype of MSCs[25,26]. MSCs are usually derived from bone marrow, adipose tissue, amniotic fluid, placenta, umbilical cord, dental pulp, compact bone and peripheral blood[10]. The development origin significantly affects potential for differentiation and other functional characteristics of tissue-specific MSCs[26]. BM-MSCs possess great genomic stability after long-term propagation[26]. An improved engraftment and increased life span are the main characteristics of adipose tissue-derived MSCs (AT-MSCs)[26]. Dental pulp-derived MSCs, amniotic fluid derived MSCs and placental derived MSCs have increased capacity for differentiation in neural cells, while BM-MSCs, AT-MSCs and umbilical cord derived MSCs (UC-MSCs) have great differentiation potential towards the cells of endodermal origin, including HLCs[26].

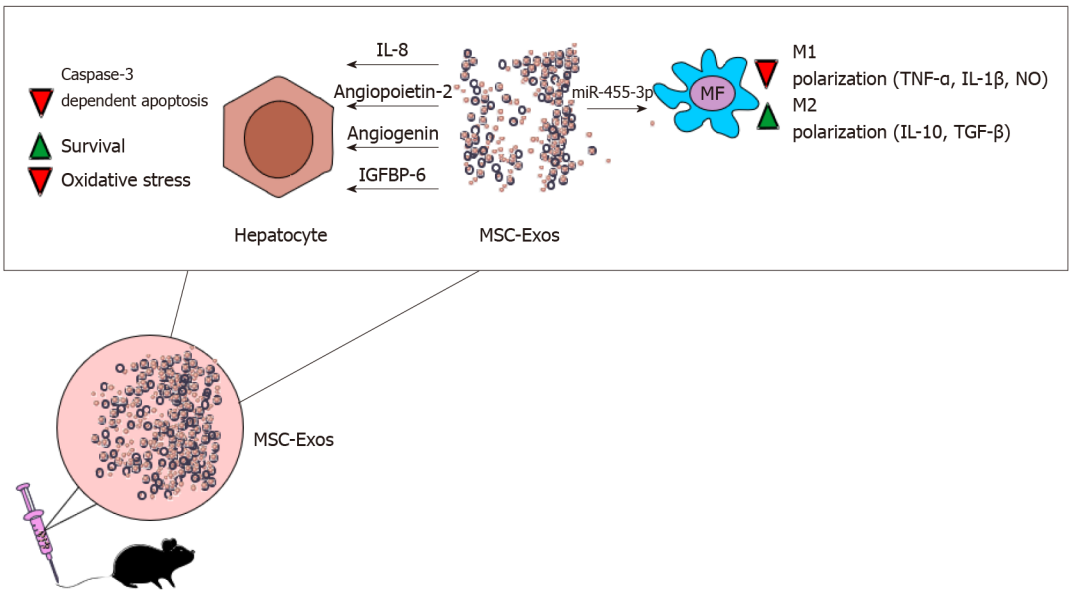
Accordingly, a large number of evidence demonstrated that human BM-MSC-, AT-MSC- and UC-MSC-derived HLCs represent valuable and promising cell source for the regeneration of injured livers [25-29].

Two step protocol is the most usually used for the generation of human MSC-derived HLCs[29]. After isolation from BM, AT and UC, MSCs are, under standard conditions (at 37 ℃ in a humidified atmosphere containing 5% CO_2), cultured in complete Dulbecco's modified Eagle's medium (DMEM) supplemented with fetal bovine serum (FBS) until they reach 75%-80% of confluence. Then, MSCs are cultured for 48 h in the FBS-free DMEM medium supplemented with endothelial growth factor (20 ng/mL) and basic fibroblast growth factor (bFGF, 10 ng/mL) to be committed towards endodermal lineage[29]. Afterwards, MSCs were seven days exposed to HLC step-1 differentiation medium, consisting of HGF (20 ng/mL), bFGF (10 ng/mL) and nicotin-amide (0.61 g/L). By binding to the c-met receptor on differentiated cells, HGF activates intracellular signaling molecules (Grb2-associated binder-1, son of sevenless), ERK kinase and mitogen-activated protein kinase which are important in the early stages of hepatogenesis[29]. Intracellular signaling elicited by HGF/c-met are enhanced by nicotin-amide which acts as selective kinase inhibitor that improves cell survival and proliferation during the initial stage of endodermal patterning. Finally, MSCs are cultured in HLC step-2 differentiation medium consisting of oncostatin (OSM, 20 ng/mL), dexamethasone (1 mmol/L) and insulin, transferrin and selenium (ITS, 50 mg/mL). OSM promotes maturation of hepatocytes, dexamethasone induces enhanced expression of liver-enriched transcription factors [CCAAT/enhancer-binding protein alpha (C/EBPα), hepatocyte nuclear factor (HNF)-4α], while ITS promotes the proliferation and survival of differentiated HLCs[29]. At the end of the differentiation process, HLCs generated from BM-, AT- and UC-MSCs, fully obtain hepatocyte-like polygonal morphology with cytoplasmic granulation and prominent centrally positioned nucleus[29]. Exposition to HLC differentiation mediums do not alter telomerase activity and do not induce genetic instability in human BM-, AT- and UC-MSC-derived HLCs[29].

MSC-derived HLCs had gene expression profile similar to fetal or adult hepatocytes[25-29]. During the early stage of differentiation, MSC-derived HLCs express several early hepatocyte differentiation markers [alfa-fetoprotein, cytokeratin (CK)7, GATA4, HNF1α, HNF3β, HNF4α, C/EBPα] while during the late stage of differentiation, MSC-derived HLCs express cell markers of mature hepatocytes (forkhead transcription factor which has a crucial role in hepatocyte differentiation), hepatocyte-specific gap junction protein connexin 32 and hepatocyte paraffin 1, localized in hepatocytes mitochondria). Finally, at the end of differentiation, MSC-derived HLCs are able to produce hepatocyte-specific proteins (albumin, fibrinogen, transferrin) and enzymes (cytochrome P450 subtypes 3A4 and 1A1, phosphoenolpyruvate carboxykinase 1 and carbamoylphosphate synthetase[26-29].

The analysis of functional characteristics of BM-, AT- and UC-MSCs-derived HLCs revealed that AT-MSC- and BM-MSC-derived HLCs had the higher capacity for glycogen storage than UC-MSCs-derived HLCs and their gene expressions were more consistent with the normal hepatocyte-differentiation profile[30]. Albumin gene expression increased progressively during the differentiation process of AT-

MSC- and BM-MSC-derived HLCs. In contrast, only transitory expression of albumin was observed in UC-MSC-derived HLCs (between day 7 and day 25). Additionally, HLCs which were generated from AT-MSCs and BM-MSCs displayed clusters arrangements and had increased proliferation rate compared to UC-MSC-derived HLCs which were not expanded as expected, hampering their potential for *in vivo* use[30]. Accordingly, only therapeutic potential of AT-MSC-derived HLCs and BM-MSC-derived HLCs was examined *in vivo*, in murine model of CCL4-induced acute liver injury[30]. Intravenously injected human AT-MSC-and BM-MSC-derived HLCs (1×10^6 cells), managed to completely regenerate CCL4-injured livers of immunodeficient mice. Hepatocytes isolated from the livers of CCL4-treated mice displayed normal morphology two weeks after the transplantation of human AT-MSC- and BM-MSC-derived HLCs. Importantly, hepatocytes in the regenerated livers of experimental mice express human albumin and CK19 confirming that they were generated from transplanted human AT-MSC- and BM-MSC-derived HLCs[30]. Accordingly, both AT-MSCs and BM-MSCs represent valuable cell source for the generation of functional HLCs which may repopulate and regenerate injured livers of ALF patients[30]. Nevertheless, it should be noted that progression of ALF is mainly a consequence of immune cell-dependent massive damage of hepatocytes[2,6]. Accordingly, detrimental immune response could induce injury of engrafted HLCs as well. Therefore, co-transplantation of MSC-derived HLCs and immunosuppressive MSCs should be explored as new therapeutic approach which could successfully regenerate injured livers of ALF patients.



THERAPEUTIC POTENTIAL OF MSC-EXOS IN THE TREATMENT OF ACUTE LIVER INJURY

Although results obtained in animal studies strongly suggest that MSCs could be considered as new therapeutic agents in regenerative hepatology, there are several safety issues which limit clinical use of MSCs[31]. Firstly, MSCs are not constitutively immunosuppressive cells[32]. MSCs may adopt phenotype and function under the influence of biological factors to which they are exposed. When MSCs engraft in the tissue with low level of TNF-α and IFN-γ, they obtain pro-inflammatory MSC1 phenotype and secrete large number of bioactive factors which aggravate on-going inflammation. On the contrary, when MSCs are exposed to the high levels of TNF-α and IFN-γ, they acquire immunosuppressive MSC2 phenotype and produce immunoregulatory factors that suppress inflammatory immune cells[32]. Since local tissue concentration of TNF-α and IFN-γ differ in initial and recovery phases of acute liver inflammation, there is a concern that MSCs which will be engrafted in the injured livers with low level of TNF-α and IFN-γ may obtain pro-inflammatory MSC1 phenotype and may aggravate on-going inflammation[31,32]. Additionally, TGF-β and bone morphogenetic protein, released by macrophages in inflamed and regenerated tissues, may induce spontaneous and unwanted chondrogenic and osteogenic differentiation of MSCs[33]. Possible unwanted differentiation of transplanted MSCs represents an important safety concern which limits clinical use of MSCs in regenerative hepatology[33].

MSC-Exos are nano-sized extracellular vesicles which contain all of MSC-sourced immunoregulatory and angiomodulatory factors[34]. Due to their nano-sized dimension and lipid envelope, intravenously injected MSC-Exos by-pass all biological barriers and deliver their cargo (miRNAs) anti-inflammatory cytokines, growth factors) directly into the target liver-infiltrated immune cells and injured hepatocytes. Since the majority of MSC-dependent beneficial effects in attenuation of liver inflammation were relied on the activity of MSCs-sourced bioactive factors[25], administration of MSC-Exos is considered as an alternative therapeutic approach to MSC-based therapy since it addresses all safety concerns related to the transplantation of MSCs[34]. A detailed proteomic analysis revealed that MSC-Exos contained proteins that regulate hepatocyte survival, oxidative stress, tissue remodeling, activation and migration of immune cells[34]. Accordingly, several experimental studies demonstrated therapeutic potential of MSC-Exos in the treatment of ALF[35-37].

After intravenous injection, MSC-Exos obtained from MB-MSC-Exos migrated in the liver, attenuated D-Gal/LPS-induced acute liver inflammation and improved survival of in D-Gal/LPS-treated mice suffering from ALF[35]. By delivering immunosuppressive molecules and trophic factors in inflamed livers [IL-8, angiopoietin-2, angiogenin, insulin-like growth factor binding protein-6 (IGFBP-6)] MB-MSC-Exos attenuated caspase-3-dependent apoptosis of injured hepatocytes[35]. MB-MSCs-sourced IL-8 inhibited TNF-α-induced activation of caspase-3 and prevented apoptosis of hepatocytes while angiopoietin-2, angiogenin and IGFBP-6 promoted survival of hepatocytes by preventing the progression of ischemia-induced injury in inflamed livers[35].

The importance of anti-apoptotic effects of MSC-Exos in the treatment of ALF was confirmed in murine model of CCL4-induced acute liver injury[36]. Jiang and colleagues demonstrated that hepato-protective effects of Exos isolated from the secretome of human UC-MSCs (UC-MSC-Exos) were relied on their capacity to inhibit caspase 3 and Bcl-2-associated X protein-driven apoptosis of hepatocytes [36]. Additionally, significant decrease of oxidase metabolite 8-hydroxy-2-deoxyguanosine was observed in CCL4-injured livers 24 h after administration of UC-MSC-Exos, indicating that UC-MSC-Exos-dependent inhibition of oxidative stress in injured hepatocytes was, at least partially, responsible

Figure 2 Molecular mechanisms responsible for the beneficial effects of mesenchymal stem cell derived exosomes in attenuation of acute liver failure. By delivering interleukin (IL)-8, angiopoietin-2, angiogenin, insulin-like growth factor binding protein-6, mesenchymal stem cell derived exosomes (MSC-Exos) attenuate oxidative stress, suppress caspase-3-dependent apoptosis and promoted survival of hepatocytes in acutely injured livers. MSC-Exos, in miRNA-455-3p-dependent manner, alleviate on-going liver inflammation by inhibiting inflammatory, tumor necrosis factor alpha, IL-1β and nitric oxide-producing M1 macrophages and by promoting generation of immunosuppressive, transforming growth factor beta-β and IL-10-producing M2 macrophages. Abbreviations: MSC-Exos: Mesenchymal stem cell derived exosomes; IL: Interleukin; IGFBP6: Insulin like growth factor binding protein 6; TNF-α: Tumor necrosis factor alpha; NO: Nitric oxide.

for the alleviation of ALF in experimental mice[36].

As evidenced by Shao and colleagues, MSC-Exo-sourced miR-455-3p was crucially responsible for MSC-dependent immunosuppression in ALF[37]. MSC-derived miR-455-3p modulated activation of PI3K and attenuated synthesis of inflammatory cytokines IL-6, G-CSF, IL-17, IP-10, and MCP-1 in liver macrophages[37]. Significantly reduced necrosis of hepatocytes, down-regulated serum levels of aspartate aminotransferase, alanine transaminase and bilirubin were observed in CCL4 + miR-455-3p-treated mice. Additionally, miR-455-3p significantly reduced presence of CD68-expressing macrophages in the liver and decreased total number of circulating inflammatory CD14+ CD16+ and CCR2+ CD16+ monocytes in peripheral blood of CCL4-treated animals, indicating that beneficial effects of miR-455-3p was mainly relied on the suppression of inflammatory monocytes/macrophages[37] (Figure 2).

CONCLUSION

MSCs possess potent immunoregulatory, angiomodulatory and hepatoprotective properties[25,38]. Results obtained in experimental studies showed that MSCs and MSC-Exos were able to efficiently attenuate acute liver inflammation and to promote enhanced repair and regeneration of injured liver tissue, suggesting their potential clinical use in the therapy of ALF[25,38].

However, it should be noted that there are several issues that need to be addressed before MSCs and their exosomes could be offered as new remedy in regenerative hepatology. The optimal tissue source, dose, and frequency of MSCs/MSC-Exos should be defined. Up-coming studies should also precisely determine all MSC-sourced immunoregulatory and hepatoprotective factors which are responsible for their beneficial effects. Afterwards, bioengineering of MSCs which will massively produce these bioactive molecules should be performed. It is highly expected that these newly developed MSCs and their exosomes will have significantly enhanced efficacy in in the treatment of ALF.

Abstract

Pancreatic cancer is highly aggressive and lethal. Due to the lack of effective methods for detecting the disease at an early stage, pancreatic cancer is frequently diagnosed late. Gemcitabine has been the standard chemotherapy drug for patients with pancreatic cancer for over 20 years, but its anti-tumor effect is limited. Therefore, FOLFIRINOX (leucovorin, fluorouracil, irinotecan, oxaliplatin) as well as combination therapies using gemcitabine and conventional agents, such as cisplatin and capecitabine, has also been administered; however, these have not resulted in complete remission. Therefore, there is a need to develop novel and effective therapies for pancreatic cancer. Recently, some studies have reported that combinations of gemcitabine and targeted drugs have had significant anti-tumor effects on pancreatic cancer cells. As gemcitabine induced DNA damage response, the proteins related to DNA damage response can be suitable additional targets for novel gemcitabine-based combination therapy. Furthermore, KRAS/RAF/MEK/ERK signaling triggered by oncogenic mutated *KRAS* and autophagy are frequently activated in pancreatic cancer. Therefore, these characteristics of pancreatic cancer are potential targets for developing effective novel therapies.

In this minireview, combinations of gemcitabine and targeted drugs to these characteristics, combinations of targeted drugs, combinations of natural products and anti-cancer agents, including gemcitabine, and combinations among natural products are discussed.

Key Words: Pancreatic cancer; Gemcitabine; Targeted drug; Combination therapy

Core Tip: Gemcitabine has been the standard chemotherapy drug for patients with pancreatic cancer; however, its effectiveness is limited. Therefore, various combination therapies involving gemcitabine and targeted drugs are being explored. A review of combination therapies based mainly on clinical studies has been published recently; therefore, this minireview focuses on the findings of basic studies and discusses combinations of gemcitabine and targeted drugs, combinations of targeted drugs, combinations of natural products and anti-cancer agents, including gemcitabine, and combinations among natural products.

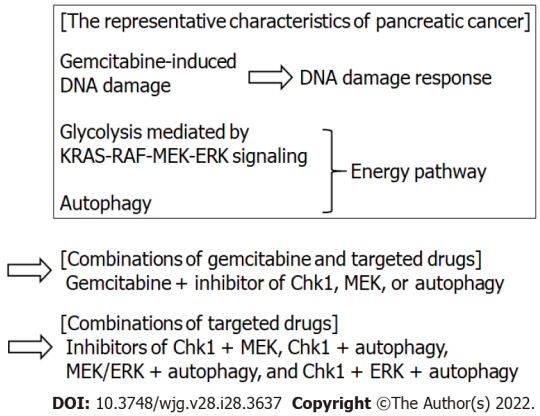
INTRODUCTION

Pancreatic cancer is fatal and has a 5-year survival rate of approximate 10%[1]. It is estimated that pancreatic cancer will become the second most common cause of cancer-related deaths in the United States by 2030[2]. Pancreatic cancer is frequently diagnosed at a late stage owing to the lack of effective methods for detecting it at earlier stages and non-specific symptoms. Therefore, there is an urgent need to develop both novel effective therapies for pancreatic cancer that has progressed to a late stage and effective methods for detecting pancreatic cancer at an early stage.

Gemcitabine is the standard treatment for patients with pancreatic cancer. However, as the anti-tumor effect of gemcitabine is limited, FOLFIRINOX (leucovorin, fluorouracil, irinotecan, oxaliplatin) as well as combination therapies of gemcitabine and conventional agents, such as cisplatin and capecitabine, has also been administered[3-5]. Although these combination therapies improved overall survival compared to gemcitabine alone, they did not achieve complete remission. In addition, the incidence of toxicity associated with these combination therapies has increased[3-6].



Recent studies have attempted to identify effective combinations of gemcitabine and targeted drugs for pancreatic cancer. As gemcitabine, a well-known DNA-damaging agent, induced DNA damage response, the proteins related to DNA damage response can be suitable additional targets for novel gemcitabine-based combination therapy. Furthermore, KRAS/RAF/MEK/ERK signaling triggered by oncogenic mutated *KRAS* and autophagy, which are described as the characteristics of pancreatic ductal adenocarcinoma (PDAC), are frequently activated. Therefore, these characteristics are promising targets for effective novel therapeutic strategies[7-12]. An excellent review on effective combination therapies for pancreatic cancer was published recently[13]. This review was based mainly on the findings of preclinical and clinical studies[13]; therefore, this minireview focuses on the findings of basic studies and discusses combinations of gemcitabine and targeted drugs, combinations of targeted drugs, combinations of natural products and anti-cancer agents, including gemcitabine, and combinations among natural products.

COMBINATIONS OF GEMCITABINE AND TARGETED DRUGS

Gemcitabine, a well-known DNA-damaging agent, has been the standard first-line drug for patients with pancreatic cancer. However, the efficacy of gemcitabine in pancreatic cancer is limited and a novel gemcitabine-based combination therapy is required. In this section and Figure 1, combinations of gemcitabine and targeted drugs to enhance the anti-tumor effect are summarized.

Gemcitabine and Chk1 inhibitor

Quinone-methide triterpenoid pristimerin induces lysosomal degradation of checkpoint kinase 1 (Chk1) and augments the expression of γ-H2AX, which is a biomarker of DNA damage following gemcitabine treatment[14]. Furthermore, the combination of gemcitabine and pristimerin was shown to increase apoptosis of pancreatic cancer cells[14]. The Chk1 inhibitor MK-8776 also enhances the sensitivity of multiple human cancer cell lines, including pancreatic cancer cells, to gemcitabine[15]. The DNA damage response mediated by Chk1 in pancreatic cancer stem cells was greater than that in non-pancreatic cancer stem cells, indicating that Chk1 inhibition selectively sensitizes pancreatic cancer stem cells to gemcitabine[16]. The combination of Chk1 inhibition and gemcitabine reduces the ability of tumor initiation in pancreatic cancer stem cells[16]. The anti-tumor effect of the combination of gemcitabine and doublecortin-like kinase 1 (Dclk1) inhibitor has also been reported[17]. The latter significantly decreased the expression of gemcitabine-induced phosphorylated Chk1 in pancreatic cancer cells. The combination of gemcitabine and Dclk1 inhibitor did not arrest the cell cycle at the S

Figure 1 The representative characteristics of pancreatic cancer as potential targets for effective combination therapy.

phase and allowed cell cycle progression[17]. In addition, the combination of gemcitabine and Dclk1 inhibitor increased the rate of γ-H2AX-positive cells compared to individual treatments. The combination of gemcitabine and Dclk1 inhibitor induced PARP1 cleavage as well as caspase-3 activation and significantly decreased the survival rate of pancreatic cancer cells compared to gemcitabine treatment alone[17].

Gemcitabine and KRAS antibody/MEK inhibitor

Oncogenic *KRAS* mutations are present in approximately 90% of pancreatic cancer cases. Consequently, KRAS and its downstream proteins, such as RAF, MEK, and ERK, are activated in pancreatic cancer cases and contribute to the progression of the disease. Therefore, inhibitors targeting these proteins may be effective in inhibiting this progression.

Antibodies that bind intracellularly to the activated GTP-bound form of oncogenic KRAS mutants have been developed and significantly sensitize pancreatic cancer cells to gemcitabine[18,19]. These antibodies synergistically increase the anti-tumor effect of gemcitabine by inhibiting the RAF/MEK/ERK signaling pathway downstream of KRAS[18,19]. The antibodies are internalized in the cytoplasm by endocytosis through the tumor-associated receptors of extracellular epithelial cell adhesion molecules[19]. These antibodies synergistically increase the anti-tumor effect of gemcitabine by inhibiting KRAS/RAF/MEK/ERK signaling in pancreatic cancer cells[18,19].

The MEK inhibitor, trametinib, both alone and in combination with gemcitabine, was shown to exhibit significantly enhanced anti-tumor effects compared to gemcitabine alone[20]. The combination of gemcitabine and trametinib also increased the inhibition of tumor growth in pancreatic cancer patient-derived orthotopic xenografts in nude mice compared to trametinib alone[20]. Moreover, the combination of the MEK inhibitors, trametinib and cobimetinib, prevented tumor growth in gemcitabine-resistant pancreatic cancer patient-derived orthotopic xenografts in nude mice[21]. These results suggest that such combinations have therapeutic potential against pancreatic cancer.

Gemcitabine and autophagy inhibitor

Gemcitabine has significantly been shown to increase autophagy induction in human pancreatic cancer cells, and combined treatment with gemcitabine and chloroquine, an autophagy inhibitor, triggered a marked boost in reactive oxygen species (ROS) levels and increased lysosomal membrane permeability [22]. Consequently, proteases, including cathepsins, are released from lysosomes into the cytoplasm, leading to apoptosis. Thus, the combination of gemcitabine and chloroquine has an anti-tumor effect on pancreatic cancer cells through the apoptotic pathway by lysosomal dysfunction *via* a marked boost of ROS[22]. Cancer stem cells are considered to be responsible for the recurrence and chemoresistance of cancer. The expression of the markers of cancer stem cells, aldehyde dehydrogenase 1, CD44, and CD133, was found to be positively correlated with the expression of LC3 type II, an autophagy marker, in pancreatic cancer tissues[23]; this suggests an association between autophagy and cancer stem cells. Indeed, autophagy inhibition decreased the activity of sphere formation of pancreatic cancer stem cells, and gemcitabine and autophagy inhibition markedly reduced the populations of cancer stem cells[23].

COMBINATIONS OF TARGETED DRUGS

Recent studies have demonstrated that combinations of targeted drugs have potential for developing novel and effective therapy for pancreatic cancer. In this section and Figure 1, combinations of targeted drugs for PDAC therapy are summarized.

ERK and autophagy inhibitors

KRAS suppression or ERK inhibition was shown to decrease both glycolytic and mitochondrial functions and to increase autophagic flux in PDAC, suggesting that ERK inhibition enhances dependence on autophagy[24]. The combination of ERK and autophagy inhibitors synergistically enhanced anti-tumor activity in KRAS-driven PDAC *via* the dysfunction of the energy pathways consisting of glycolysis and autophagy[24]. It has been reported that inhibition of the KRAS/RAF/MEK/ERK signaling pathway elicits autophagy, resulting in protection of PDAC cells from cytotoxic effects[25]. The combination of MEK1/2 and autophagy inhibitors showed synergistic anti-tumor effects against PDAC cells *in vitro* and promoted the regression of patient-derived xenografts of PDAC in mice[25]. Furthermore, the effect of the combination of trametinib and chloroquine was not limited to PDAC and resulted in similar responses in patient-derived xenografts of *BRAF*-mutated colorectal cancer and *NRAS*-mutated melanoma[25].

ERK, Chk1, and autophagy inhibitors

Screening of druggable genes by genetic loss-of-function using CRISPR-Cas9 and small interfering RNA revealed that components of the ATR-Chk1 DNA damage response pathway were modulators of sensitivity to ERK inhibitor treatment in *KRAS-mutant* PDAC[26]. Chk1 inhibition suppressed the growth of both PDAC cell lines and organoids and activated ERK signaling and autophagy, suggesting that Chk1 inhibition enhances dependence on ERK signaling and autophagy[26]. These findings provide a mechanistic basis for the effectiveness of the inhibition of Chk1, ERK, and autophagy. Indeed, this triple combination of inhibitors synergistically enhanced the anti-tumor effect in *KRAS-mutant* PDAC [26].

2-deoxyglucose and MEK inhibitor

Pooled shRNA library screening was used in an orthotopic xenograft model to identify multiple glycolysis genes as potential targets that may sensitize PDAC cells to MEK inhibition[27]. Apoptosis in KrasG12D-driven PDAC cells was synergistically induced, *in vitro*, *via* the combination of 2-deoxyglucose, a glycolysis inhibitor, and a MEK inhibitor; the same also inhibited tumor growth of PDAC xenografts, leading to prolonged overall survival in a genetically engineered PDAC mouse model[27]. Molecular and metabolic analyses revealed that the combined inhibition of glycolysis and ERK signaling synergistically caused apoptosis by inducing lethal stress in the endoplasmic reticulum. These results indicate that the combination of 2-deoxyglucose and a MEK inhibitor may be an effective approach for targeting KRAS-driven PDAC[27].

Replication stress response and autophagy inhibitors

PDAC exhibits high basal lysosomal activity and relies on lysosome-dependent recycling pathways, such as autophagy, to generate substrates for metabolism[28]. Kinase inhibitor screening revealed that the replication stress response inhibitor and chloroquine, an autophagy inhibitor that works *via* the functional inhibition of lysosomes, were synthetically lethal in PDAC cells[28]. Chloroquine induces replication stress due to aspartate depletion, and a replication stress response inhibitor and chloroquine synergistically inhibit tumor growth in PDAC[28].

Immune checkpoint and autophagy inhibitors

Major histocompatibility complex class I (MHC-I) molecules are selectively degraded *via* autophagy in PDAC[29]. Consequently, the expression of MHC-I at the cell surface is reduced, and MHC-I is localized predominantly within autophagosomes and lysosomes. Autophagy inhibition was shown to restore the expression of MHC-I at the cell surface and improve antigen presentation[29]. Furthermore, autophagy inhibition synergizes with dual immune checkpoint blockade therapy (anti-PD1 and anti-CTLA4 antibodies) to enhance the anti-tumor immune response and reduce tumor growth in syngeneic host mice[29].

COMBINATIONS OF NATURAL PRODUCTS AND ANTI-CANCER AGENTS, INCLUDING GEMCITABINE

The use of natural products as adjunctive therapies for pancreatic cancer has a great potential due to the anti-cancer efficacy and low toxicity. Yue *et al*[30] summarized combinations of natural products and anti-cancer agents, including gemcitabine, and combinations among natural products. They focused on the following: combinations of natural products and gemcitabine (for example, cucurbitacin B and gemcitabine[31], glaucarubinone and gemcitabine[32], escin and gemcitabine[33], and gum mastic and gemcitabine[34]); combinations of natural products and other agents, such as all-trans retinoic acid and sulindac (for example, 12-O-tetradecanoylphorbol-13-acetate and all-trans retinoic acid[35], parthenolide and sulindac[36], and triptolide and hydroxycamptothecin[37]); and combinations among natural products (for example, sulforaphane and quercetin[38], wogonin, apigenin, and chrysin[39], and

metformin and aspirin[40]).

While agents from purified chemical compounds generally target single molecules, natural products mostly consist of multiple components that concurrently act on various molecular targets. Therefore, natural products are expected to have various functions, including improvement of anti-cancer efficacy, enhancement of immune system, and reduction of side effects[41].

CONCLUSION

In general, it is widely accepted that combination therapy is more effective than monotherapy. In this minireview, combinations of gemcitabine and targeted drugs, combinations of targeted drugs, combinations of natural products and anti-cancer agents, including gemcitabine, and combinations among natural products are described. Hereafter, preclinical and clinical studies are needed to examine the possibility for clinical applications. Concurrently, additional basic studies that attempt to identify combinations that synergize anti-cancer effects are needed to find the better treatment options.

Abstract

BACKGROUND

Ulcerative colitis (UC) is a chronic, nonspecific intestinal inflammatory disease. Acupuncture and moxibustion is proved effective in treating UC, but the mechanism has not been clarified. Proteomic technology has revealed a variety of biological markers related to immunity and inflammation in UC, which provide new insights and directions for the study of mechanism of acupuncture and moxibustion treatment of UC.

AIM

To investigate the mechanism of electroacupuncture (EA) and herb-partitioned moxibustion (HM) on UC rats by using proteomics technology.

METHODS

Male Sprague-Dawley rats were randomly divided into the normal (N) group, the dextran sulfate sodium (DSS)-induced UC model (M) group, the HM group, and the EA group. UC rat model was prepared with 3% DSS, and HM and EA interventions at the bilateral Tianshu and Qihai acupoints were performed in HM or EA group. Haematoxylin and eosin staining was used for morphological evaluation of colon tissues. Isotope-labeled relative and absolute quantification (iTRAQ) and liquid chromatography-tandem mass spectrometry were performed for proteome analysis of the colon tissues, followed by bioinformatics analysis and protein-protein interaction networks establishment of differentially expressed

proteins (DEPs) between groups. Then western blot was used for verification of selected DEPs.

RESULTS

The macroscopic colon injury scores and histopathology scores in the HM and EA groups were significantly decreased compared to the rats in the M group ($P < 0.01$). Compared with the N group, a total of 202 DEPs were identified in the M group, including 111 up-regulated proteins and 91 down-regulated proteins, of which 25 and 15 proteins were reversed after HM and EA interventions, respectively. The DEPs were involved in various biological processes such as biological regulation, immune system progression and in multiple pathways including natural killer cell mediated cytotoxicity, intestinal immune network for immunoglobulin A (IgA) production, and FcγR-mediated phagocytosis. The Kyoto Encyclopedia of Genes and Genomes pathways of DEPs between HM and M groups, EA and M groups both included immune-associated and oxidative phosphorylation. Network analysis revealed that multiple pathways for the DEPs of each group were involved in protein-protein interactions, and the expression of oxidative phosphorylation pathway-related proteins, including ATP synthase subunit g (ATP5L), ATP synthase beta subunit precursor (Atp5f), cytochrome c oxidase subunit 4 isoform 1 (Cox4i1) were down-regulated after HM and EA interventions. Subsequent verification of selected DEPs (Synaptic vesicle glycoprotein 2A; nuclear cap binding protein subunit 1; carbamoyl phosphate synthetase 1; Cox4i1; ATP synthase subunit b, Atp5f1; doublecortin like kinase 3) by western blot confirmed the reliability of the iTRAQ data, HM and EA interventions can significantly down-regulate the expression of oxidative phosphorylation-associated proteins (Cox4i1, Atp5f1) ($P < 0.01$).

CONCLUSION

EA and HM could regulate the expression of ATP5L, Atp5f1, Cox4i1 that associated with oxidative phosphorylation, then might regulate immune-related pathways of intestinal immune network for IgA production, FcγR-mediated phagocytosis, thereby alleviating colonic inflammation of DSS-induced UC rats.

Core Tip: Ulcerative colitis (UC) is a nonspecific inflammatory bowel disease with unclear etiology. Acupuncture and moxibustion are benefit to UC by improving colonic mucosa damage, regulating inflammatory cytokines. In recent years, proteomic technology has been widely used in the study of UC, revealing a variety of biological markers related to immunity and inflammation in UC. We applied isotope-labeled relative and absolute quantification proteomics technology to identify UC-relevant protein targets and further explore the mechanism of acupuncture and moxibustion. It was found that electroacupuncture and herb-partitioned moxibustion could regulate the expression of multiple proteins, such as ATP synthase subunit g, ATP synthase beta subunit precursor 1, cytochrome c oxidase subunit 4 isoform 1 that associated with oxidative phosphorylation, that might regulate immune-related pathways, thereby alleviating colonic inflammation of dextran sulfate sodium-induced UC rats.

INTRODUCTION

Ulcerative colitis (UC) is a chronic, nonspecific inflammatory disease, with lesions are mainly confined to the large intestinal mucosa and submucosal layer. Mucosal inflammation at the affected site is characterized by a diffuse distribution and its clinical manifestations mainly include abdominal pain, diarrhoea, mucus pus and blood in stool[1]. UC has a prolonged disease course, which can lead to the development of colorectal cancer, accounting for 10% to 15% of deaths among patients with UC, and is listed as one of the refractory diseases by the World Health Organization. Epidemiological data show that the prevalence of UC in Asia has increased exponentially in recent years, and the growth rate of UC

in some East Asian countries including China has increased in multiples over the past decade[2,3].

The pathogenesis of UC is not yet clear, but it is believed to be related to genetic susceptibility, epithelial barrier deficiency, immune disorders, and environmental factors[4]. The modern treatment methods for UC mainly include glucocorticoids, immunosuppressants, 5-aminosalicylic acid, and biological agents (monoclonal antibodies), but it is prone to relapse after drug withdrawal, and multiple drugs have adverse side effects. Therefore, active exploration of the pathogenesis of UC, identification of disease biomarkers, and screening of specific therapeutic targets are important for the diagnosis and treatment of UC. As one of the unique treatments of traditional Chinese medicine, acupuncture and moxibustion have significant efficacy and advantages in the treatment of UC[5-7], but the specific mechanism requires further clarification.

In recent years, proteomic technology has been widely used in the study of UC[8,9], revealing a variety of biological markers related to immunity and inflammation in UC[10]. The activity of mitochondrial oxidative phosphorylation complex in intestinal tissues of UC patients decreases, and the dysfunction of mitochondrial oxidative phosphorylation may be involved in the pathogenesis of UC, but it is not clear whether acupuncture and moxibustion have a regulatory effect on it. Therefore, our study used isotope-labeled relative and absolute quantification (iTRAQ) proteomics technology to quantitatively analyse proteins in the colon tissues of UC rats, to analyse the biological functions of differentially expressed proteins (DEPs) and observe changes of immune and oxidative phosphorylation-associated protein expression profiles in colon tissues of UC rats and regulatory effect of acupuncture and moxibustion, in order to identify UC-relevant protein targets and further explore the mechanism of effects of acupuncture and moxibustion on UC.

MATERIALS AND METHODS

Animals

Healthy clean grade naïve male Sprague-Dawley (SD) rats, aged 6 wk, with body weight of 180 ± 20 g were purchased from Shanghai Slac Laboratory Animal Co., Ltd. [Laboratory Animal Use Permit No. SYXK (Shanghai) 2014-0008] and housed in the Experimental Animal Center of Shanghai University of Traditional Chinese Medicine. The animal protocol was designed to minimize pain or discomfort to the animals. The housing environment was a 12 h circadian rhythm, with a room temperature of 20 ± 2 °C and 50%-70% indoor humidity, 4 rats per cage, and rats were free to standard food and pure water. This study was approved by the Ethics Committee of the Experimental Animal Center of Shanghai University of Traditional Chinese Medicine. We tried all efforts to minimize animal suffering.

Dextran sulfate sodium-induced UC model preparation

For preparing the UC rat model, the rats received 3% dextran sulfate sodium (DSS, molecular weight: 36000-50000, MP Biomedicals, United States) in drinking water by oral for 7 d, and then were switched to pure water for 7 d, and the same procedures were repeated once (drinking 3% DSS solution for 7 d, followed by drinking pure water for 7 d)[11]. After modeling, rats were anaesthetized *via* intraperitoneal injection with 2% pentobarbital sodium (30-40 mg/kg) (P3761, Sigma, United States) for tissue collection, the gross injury and hematoxylin and eosin (HE) staining were used to evaluate whether the model was successfully established.

Grouping and interventions

After one week of adaptive feeding, 32 rats were randomly divided into the normal (N) group, the DSS-induced UC model (M) group, the herb-partitioned moxibustion (HM) group, and the electroacupuncture (EA) group, with 8 rats in each group. UC rat model was prepared by DSS except for the N group. After model establishment, the rats in the HM and EA group were treated with corresponding treatment at Tianshu (ST25, bilateral) and Qihai (CV6) acupoints[12]. In the HM group, Chinese medicine powder containing Coptis chinensis, Radix aconiti lateralis, Cortex Cinnamomi, Radix aucklandiae, Flos carthami, Salvia miltiorrhiza, and Angelica sinensis was mixed and stirred with yellow wine to make herbal cake, then an herbal cake was prepared with a thickness of 0.5 cm and a diameter of 1 cm using a specific mould, and conical moxa cones weighing approximately 90 mg were made with moxa (Nanyang Hanyi Moxa Co., Ltd., Nanyang, China) by a mould. The rats were supine immobilized on a self-made fixator, the prepared moxa cone was placed on the top of herbal cake, and the herbal cake was placed at the ST25 and CV6 acupoints, then the moxa cone was ignited using line incense, 2 moxa cones per acupoint per time, once a day for 7 d (Figure 1)[13]. In the EA group, the rats were also supine immobilized on the self-made fixator, a 0.25 mm × 25 mm acupuncture needle was inserted into the ST25 and CV6 acupoints for 5 mm, then the needle handle was connected to a Han's-200 acupoint nerve stimulator, with a frequency of 2/100 Hz and a current of 1 mA. The needle was kept for 10 min per time, once a day for a total of 7 d[14]. The rats in the N group and the M group did not receive any treatment, but only the same grasping fixation as that in the treatment groups at 10 o'clock every day for a total of 7 d.

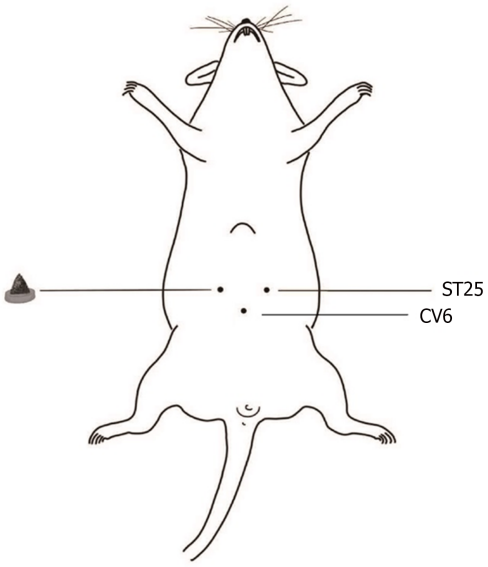

Figure 1 Schematic diagram of herb-partitioned moxibustion at the rat Tianshu (ST25, bilateral) and Qihai (CV6) acupoints.

Collection of colon tissue and macroscopic scoring of colon injury

After the intervention, rats were anaesthetized with intraperitoneal injection of 2% pentobarbital sodium. The abdominal cavity was exposed and the entire colon from the pubic symphysis to the distal cecum was collected, and the length of the colon was recorded. The distal colon with a length of 6-8 cm was collected and cut longitudinally along the mesentery, observed the gross morphology, the macroscopic scoring of the colon was performed according to the following parameters: Hyperemia, wall thickening, ulceration, inflammation extension, and damage no damage, score 0; hyperemia without ulcers, score 1; hyperemia and wall thickening without ulcers, score 2; one ulceration site without wall thickening, score 3; two or more ulceration sites, score 4; 0.5 cm extension of inflammation or major damage, score 5; 1 cm extension of inflammation or severe damage, score 6[15]. Then was cut into two parts transversely, one part was fixed in 4% paraformaldehyde for morphological observation, and the remaining part was placed in liquid nitrogen for 1 h and transferred to a -80 °C freezer for future detection.

Morphological observation of the colon

Colon tissues fixed in 4% paraformaldehyde fixative solution were dehydrated, embedded in paraffin, and sliced into 4 μm sections for HE staining with the following steps: Dewaxing in xylene I and II solutions for 20 min each; elution in 100%, 95%, 90%, 80%, and 70% ethanol for 5 min each; rinsing with double distilled water for 5 min × 2 times; haematoxylin staining for 2-3 min; rinsing with running water for 10 min; 1% hydrochloric acid ethanol differentiation solution for 1-2 s; rinsing with running water for 5 min; eosin dye staining for 2-3 min; dehydration in 70%, 80%, 90%, and 100% ethanol for 1-2 s each; xylene I and II solutions for 15 min each. After drying and sealing, the colon sections were observed under a light microscope and microscopic scoring of the colon was performed according to the following parameters: Damage/necrosis, inflammatory cell infiltration, submucosal edema, and hemorrhage of mucosa. Colonic gross damage scores were recorded according to the severity of changes: No change, score 0; mild, score 1; moderate, score 2; severe, score 3[16].

Proteomic analysis

Protein extraction and enzymatic digestion: Colon samples from 3 rats in each group were randomly collected and ground into powder, and an appropriate amount of radioimmunoprecipitation assay (RIPA) protein lysis buffer (R0010, Solarbio, United States) was added (150 μL RIPA was add to 20 mg colon tissue), high-abundance protein in the sample was removed, a 5-fold volume of 10% trichloroacetic acid/cold acetone was added to the sample and precipitated at -20 °C overnight. The precipitated proteins were centrifuged at 4 °C, 15000 g for 20 min, the supernatant was removed, and samples were air-dried and precipitated after repeating the above steps several times. After lysis, samples were centrifuged at 25000 g for 20 min at 4 °C, and the supernatant was the protein solution. A total of 100 μg of protein solution was collected from each sample, and trypsin (2.5 μg) was added to the protein solution at a ratio of 40: 1 of protein: Enzyme, enzymolysis at 37 °C for 4 h. Trypsin was then added according to the above ratio and continue enzymolysis at 37 °C for 8 h.

Peptide labelling and separation: The digested peptide fragments were desalted using a Strata X column and vacuum-dried. The peptide samples were dissolved in 0.5 M triethylammonium

bicarbonate, and then were were labeled with iTRAQ (iTRAQ8-plexreagent kit, Sigma, United States) and maintained at room temperature for 2 h. The Shimadzu LC-20AB liquid chromatography system (separation column: 5 μm, 4.6 mm × 250 mm Gemini C18) was used for liquid phase separation of samples. Dried peptide samples were redissolved in 2 mL of mobile phase A (5% ACN, pH 9.8), the solution was loaded, and gradient elution was performed at a flow rate of 1 mL/min as follows: 5% mobile phase B (95% ACN, pH 9.8) for 10 min, 5%-35% mobile phase B for 40 min, 35%-95% mobile phase B for 1 min, mobile phase B for 3 min, and equilibration with 5% mobile phase B for 10 min. The elution peak was monitored at a wavelength of 214 nm, and 1 fractionated peptide was collected every minute. The chromatographic elution peaks were combined with the samples to obtain 20 fractionated peptides, which were then freeze-dried.

High-performance liquid chromatography: The dried peptide samples were redissolved using mobile phase A (2% ACN, 0.1% FA) and centrifuged at 20000 g for 10 min. The supernatant was collected and loaded onto the column, and samples were separated by a Prominence nano LC (LC-20AD, Shimadzu, Japan). The sample was first enriched in a trap column and desalted, and the tandem self-assembled C18 column (75-μm inner diameter, 3.6-μm pore size, 15-cm length) was used. Separation was performed at a flow rate of 300 nL/min through an effective gradient: at 0-8 min, 5% mobile phase B (98% ACN, 0.1% FA); at 8-43 min, mobile phase B increased linearly from 8% to 35%; at 43-48 min, mobile phase B increased from 35% to 60%; at 48-50 min, mobile phase B increased from 60% to 80%; at 50-55 min, 80% mobile phase B; and at 55-65 min, 5% mobile phase B.

Mass spectrometric detection: The separated peptides were transferred into an electrospray ionization tandem mass spectrometer: TripleTOF 5600 (SCIEX, Framingham, United States) and theion source was Nanospray III source (SCIEX, Framingham, United States). During data collection, the parameters of the mass spectrometer were set as follows: An ion source spray voltage of 2300 V, a nitrogen pressure of 30 psi, atomizer 15, and a spray interface temperature of 150 °C. High-sensitivity mode was used for scanning. The cumulative time of primary mass spectrometry scanning was 250 ms, and the cumulative of secondary mass spectrometry scanning time was 100 ms.

iTRAQ quantification and bioinformatics analysis

ITRAQ quantification was performed using IQuant software. The selection of significantly DEPs in a single experiment were as follows: Fold change (FC) ≥ 1.2 was set as up-regulation and FC ≤ 0.83 as down-regulation, as well as Q-value < 0.05. The Gene Ontology (GO) database was used for functional annotation analysis of DEPs. The Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway database was used for pathway enrichment analysis of DEPs. The protein-protein interaction network was performed using STRING software with an interaction confidence of 0.7 (the maximum confidence was 1). Cytoscape (v.3.7.1) software was used to visualize the enrichment analysis results. Figure 2 showed the process of proteomics detection and analysis.

Western blot analysis

We selected DEPs in UC that were reversed by HM and EA for verification by using western blot method. Total proteins were extracted from colon tissues using RIPA buffer supplemented with protease and phosphatase inhibitors. Protein concentration was measured with the bicinchoninic acid protein concentration assay kit. The proteins were separated by polyacrylamide gelelectrophoresis method, with the voltage of concentrated glue was 90 V and that of separating glue was 120 V (BIO-RAD, 1645050), then the separated proteins were transferred to polyvinylidene fluoride membranes. The modified membranes were blocked with 5% bovine serum albumin in TBST, and then was incubated overnight at 4 °C with primary antibody. The antibody dilutions were prepared according to the instructions [Synaptic vesicle glycoprotein 2A (Sv2a), 1: 1000; nuclear cap binding protein subunit 1 (Ncbp1), 1: 800; Cps, 1: 5000; cytochrome c oxidase subunit 4 isoform 1 (Cox4i1), 1: 2000; ATP synthase beta subunit precursor 1 (Atp5f1), 1: 1000; doublecortin like kinase 3 (Dclk3), 1: 800)]. The membranes were washed with western detergent at room temperature for 6 times, 5 min each and then were incubated with secondary antibodies at room temperature for 1 h. Followed by washed with western detergent at room temperature for 6 times, 5 min each. The membranes were stained with enhanced chemiluminescence solution and visualized in a gel imager system (Tanon, 4600).

Statistical analysis

The western blot analysis data were analyzed with SPSS 20.0 statistical software. Data that consistent with the normal distribution were presented as mean ± SD, and one-way analysis of variance was used for comparison between groups, followed by the Fisher's Least significant difference method if data met the homogeneity of variance. For data that did not meet the normal distribution were presented as medians (P_{25}, P_{75}), and nonparametric test was used for comparison. $P < 0.05$ was considered statistically significance.

RESULTS

Effects of HM and EA on DSS induced UC rats

In the N group, rats were active and energetic, and their feces were moderately hard and soft. The rats in the M group had loose, bloody stools and decreased activities. Compared with the M group, the activity of rats in the HM and EA groups was obviously improved, and the stool gradually took shape without obvious mucus and blood. We found that the colon in the N group did not exhibit adhesion or bleeding points; the colonic mucosal surfaces were clean and smooth. In contracts, the colon in the M group exhibited significant adhesion and multiple bleeding points; the inner wall was not smooth, and partially visible scattered ulcers and thickened intestinal walls were observed. In the HM and EA groups, the adhesion and the bleeding points were decreased (Figure 3A).

The morphological changes of colon tissues were observed using HE staining. The colonic mucosal epithelium of the normal group was intact, with clear tissue structure, regular arranged glands, and no congestion, oedema or ulcers were evident. While the mucosal epithelium of UC rats was absent, ulcers had formed, with a loss or reduction of glands and goblet cells, and substantial inflammatory cells were infiltrated in mucosa and submucosa. After HM and EA interventions, the mucosal epithelium was restored, with healed ulcer, increased glands and goblet cells, decreased mucosal and submucosal inflammatory cell infiltration and congestion (Figure 3B).

The macroscopic colon injury scores and histopathology scores in the M group were significantly increased than that in the N group ($P < 0.01$). Conversely, the macroscopic colon injury scores and histopathology scores in the HM and EA groups were significantly decreased compared to the rats in the M group ($P < 0.01$) (Figures 3C and D). The colonic length of the rats in the M group were significantly decreased compared with the N group, the colonic length of the rats in the HM and EA groups were significantly increased compared with the M group ($P < 0.01$) (Figure 3E).

iTRAQ quantification of DEPs

The volcano plot in Figure 4 described the DEPs between the groups. The quantitative results showed that 202 DEPs were identified in DSS-induced UC rats compared with the N group, of which 111 were up-regulated and 91 were down-regulated; 117 DEPs were identified in HM group compared with the M group, of which 41 were up-regulated and 76 were down-regulated; 145 DEPs were identified in EA group compared with the M model group, of which 59 were up-regulated and 86 were down-regulated (Table 1, Figure 5).

Comparison of the M/N and HM/M groups showed that among these proteins, 25 DEPs were common to N, M and HM groups, with 17 [Sv2a, Igkv13-85, Ncbp1, Aldo-keto reductase family 1 member B8, Rathemoglobin beta-chain, Ribosomal protein S8 (RpS8), Fga, Rps2-ps6, carbamoyl phosphate synthetase 1 (Cps1), Txn, ATP synthase subunit g (ATP5L), Cox4i1, Atp5h, Necap2, Atp5f1, Papss2, Acly] up-regulated in UC but were down-regulated by HM, and 8 [Spout1, calcium-activated chloride channel regulator 1 (CLCA1), Sval1, Hspb7, Peptidyl-prolyl cis-trans isomerase, Aldh1a1, Lyz2, Dclk3] down-regulated in UC but were up-regulated by HM (Figure 5A, Table 2). Comparison of the M/N and EA/M groups showed that 15 DEPs were common to N, M and EA groups, with 9 (Sv2a, Ncbp1, Rat hemoglobin beta-chain, Fga, Cps1, ATP5L, Cox4i1, Atp5f1, Lmod1) up-regulated in UC but were down-regulated by EA, and 6 (Spout1, Sh3bgrl3, Peptidyl-prolyl cis-trans isomerase, MHC class I RT1.Aw3 protein, Tkt, Dclk3) down-regulated in UC but were up-regulated by EA (Figure 5B, Table 3).

GO enrichment analysis for DEPs

GO annotation of DEPs between groups describes the characteristics of genes and gene products in terms of molecular functions, cellular components and biological processes. 53 GO functions were significantly differentiated between the M and the N group, 52 GO functions are significantly differentiated between the M group and the HM group, and 51 GO functions are significantly differentiated between the M group and the EA group. The GO functional annotations of DEPs in the M/N, HM/M, and EA/M comparisons were basically similar. Biological process was the most favorable enrichment component, in which DEGs were significantly enriched in cellular process, metabolic process, biological regulation and so on. Cellular component analysis was enriched in cell part, cell, organelles, macromolecular complexes, *etc.* Molecular functions mainly included binding, synaptic activity, structural molecule activity, molecular function regulation, molecular sensor activity, and transcriptional regulation activity (Figure 6).

KEGG pathway enrichment analysis for DEPs

KEGG pathway enrichment analysis was performed for DEPs between the groups, we found that these DEPs were mainly enriched in inflammation responses and immune-related pathways. The pathways in which DEPs between the N and M groups mainly enriched included primary immunodeficiency, the noncanonical nuclear factor-kappaB (NF-κB) signalling pathway, natural killer cells mediated cytotoxicity, intestinal immune network for immunoglobulin A (IgA) production, FcγR-mediated phagocytosis, and complement and coagulation cascades (Figure 7A, Table 4). The pathways in which DEPs between the HM and the M groups mainly enriched included primary immunodeficiency,

oxidative phosphorylation, nitrogen metabolism, natural killer cells mediated cytotoxicity, the intestinal immune network for IgA production, FcγR-mediated phagocytosis, complement and coagulation cascades, and B cell receptor signalling pathway (Figure 7B, Table 5). The pathways in which DEPs between the EA and the M groups mainly enriched included the phosphoinositol-3 kinase (PI3K)-protein kinase B (Akt) signalling pathway, oxidative phosphorylation, intestinal immune network for IgA production, and the calcium signalling pathway (Figure 7C, Table 6).

Protein-protein interactions analysis

The STRING database (v.11.0) was used to construct the protein-protein interactions (PPIs) network for the transcription factors with an interaction score > 0.7 (high confidence) among the groups. Cytoscape (v.3.7.1) software was used to visualize the enrichment results. The statistical significance was set as $P < 0.05$. The analysis showed extensive interactions among the DEPs between groups (Figure 8). A total of 100 DEPs (63 up-regulated proteins and 37 down-regulated proteins) were included in the PPI network constructed by DEPs between the N and M groups, and Nme2 served as the junction point of two pathways, indicating that it was important for screening key candidate proteins. 38 DEPs (8 up-regulated proteins and 30 down-regulated proteins) were included in the PPI network constructed from DEPs between the M and HM groups, in which ribosomal pathway-related proteins were all down-regulated, and oxidative phosphorylation pathway-related proteins, including Atp5o, ATP5L, Atp5f, Atp5h, Cox4i1 were also down-regulated. 55 DEPs (19 up-regulated proteins and 36 down-regulated proteins) were included in the PPI network constructed from DEPs between the EA and M groups. In addition, proteins involved in inflammation regulation such as serpins were identified (serpinb6 in M/N comparisons, serpinc1 in HM/M and EA/M comparisons).

Western blot verification

We verified the expression of some DEPs that could be regulated by HM and EA. The western blot results showed that, compared with the N group, the expression of Sv2a, Ncbp1, Cps1, Cox4i1, Atp5f1 proteins were increased in the colon of UC rats, while the expression of Dclk3 protein was decreased ($P < 0.01$). HM and EA interventions can significantly down-regulate the expression of Sv2a, Ncbp1, Cps1, Cox4i1, Atp5f1 proteins and up-regulate Dclk3 protein ($P < 0.01$). It indicated that the western blot

verification results were consistent with the iTRAQ results (Figure 9).

DISCUSSION

UC is a type of inflammatory bowel disease (IBD) characterized by chronic recurrent, and the specific aetiology and pathogenesis of UC are still not clear. Proteomics is a discipline that systematically quantifies all the proteins in cells or organisms and elucidates their biological functions, it has enormous potential for early diagnosis, prevention, and prognosis prediction of diseases[17,18]. In recent years, proteomics has gradually been applied to the study of UC, providing strong support for the research of pathogenesis, clinical diagnosis, and treatment of UC. A study has been found that 7 protein genes were differentially expressed in the intestinal tissues of UC patients using proteomics, including prohibitin, heat shock proteins, alpha-1 antitrypsin, ventralis intermedius, caspase-1, cytokeratin 20, Filamin Ainteracting protein 1, FLNa[19]. Another study analysed the transcriptome and proteome characteristics of the colon of UC patients, and found that the expression of genes and proteins related to immune and inflammatory responses in UC patients were dysregulated. At the same time, the complement cascade, metabolic processes, and peroxisome proliferator-activated receptor signal transduction were inhibited[20]. Therefore, iTRAQ proteomic technology can also be a feasible method to reveal potential targets for UC drug therapy[8].

In the present study, we performed proteomic analysis using iTRAQ labelling combined with mass spectrometry technology to identify DEPs in colon of DSS-induced UC rats, and selected DEPs that could be reversed by HM and EA. DSS has been widely used to prepare experimental colitis to study the new drug therapy, immunity and mechanism of action[21-23]. Our results showed that HM and EA improved the colonic mucosal injury of UC rats. At the same time, we have compared the normal and

DSS-induced UC rats using iTRAQ labelling and found that 202 protein genes were differentially expressed between the two group. Among them, galectin-3, an up-regulated protein, is an endogenous lectin with extensive immunomodulatory functions, and can promote the inflammatory response in DSS-induced colitis by activating the NLR family pyrin domain containing 3 inflammasome[24]. Moreover, galectin-3 has also been shown to be a key regulator of inflammation and can be a potential biomarker for IBD[25]. s100a9 is a subunit of calprotectin with pro-inflammatory activity, and the level of s100a9 was significantly increased in the faeces of DSS-induced colitis mice compared with normal mice[26,27]. This is consistent with the upregulation of s100a9 in UC colon tissue in our study. Guanylate cyclase activator 2A (GUCA2A) is the ligand of guanylate cyclase C, which is mainly expressed in intestinal epithelial cells, and can regulate intestinal barrier function and intestinal homeostasis through the cyclic guanosine monophosphate-dependent signalling pathway[28]. down-regulation of GUCA2A can injure the intestinal mucosa barrier and affect the growth and repair of intestinal epithelial cells in IBD patients[29]. Interestingly, we found that the expression of GUCA2A was down-regulated in UC colon tissue, which was consistent with previous findings. These results suggest that galectin-3, s100a9 and GUCA2A may be potential biomarkers of UC.

After receiving the HM intervention, a total of 117 DEPs were identified, of which 25 proteins were reversely regulated by HM, including 17 proteins up-regulated in UC but were down-regulated by HM, and 8 down-regulated in UC but were up-regulated by HM. Among the 17 proteins down-regulated by HM, ATP5L, Atp5f, and Atp5h are the subunits of ATP synthase that involved in energy metabolism and oxidative phosphorylation; Cox4i1 is an important regulatory subunit of cytochrome c oxidase and is mainly associated with mitochondrial oxidative phosphorylation; Cps1, the carbamyl phosphate synthetase 1, was over-expressed in the non-dysplastic tissue of UC progressors[30]; RpS8 is a small subunit protein of ribosomes that plays a critical role in regulation of protein translation. Although it is unclear whether these proteins play a role in UC, ATP-induced energy metabolism disorders and intestinal epithelial mitochondrial damage are important pathogenesis of UC[31]. Therefore, changes in the expression of these proteins may be related to the occurrence of UC and the therapeutic effect of HM. Further studies should be performed to clarify the exact mechanisms of these oxidative phosphorylation proteins. Among the 8 proteins up-regulated by HM, CLCA1 is one of the major non-mucinous proteins in intestinal mucus, which is normally expressed in the gastrointestinal tract and is most abundant in the intestinal mucosa. Studies have shown that CLCA1 regulates the structural

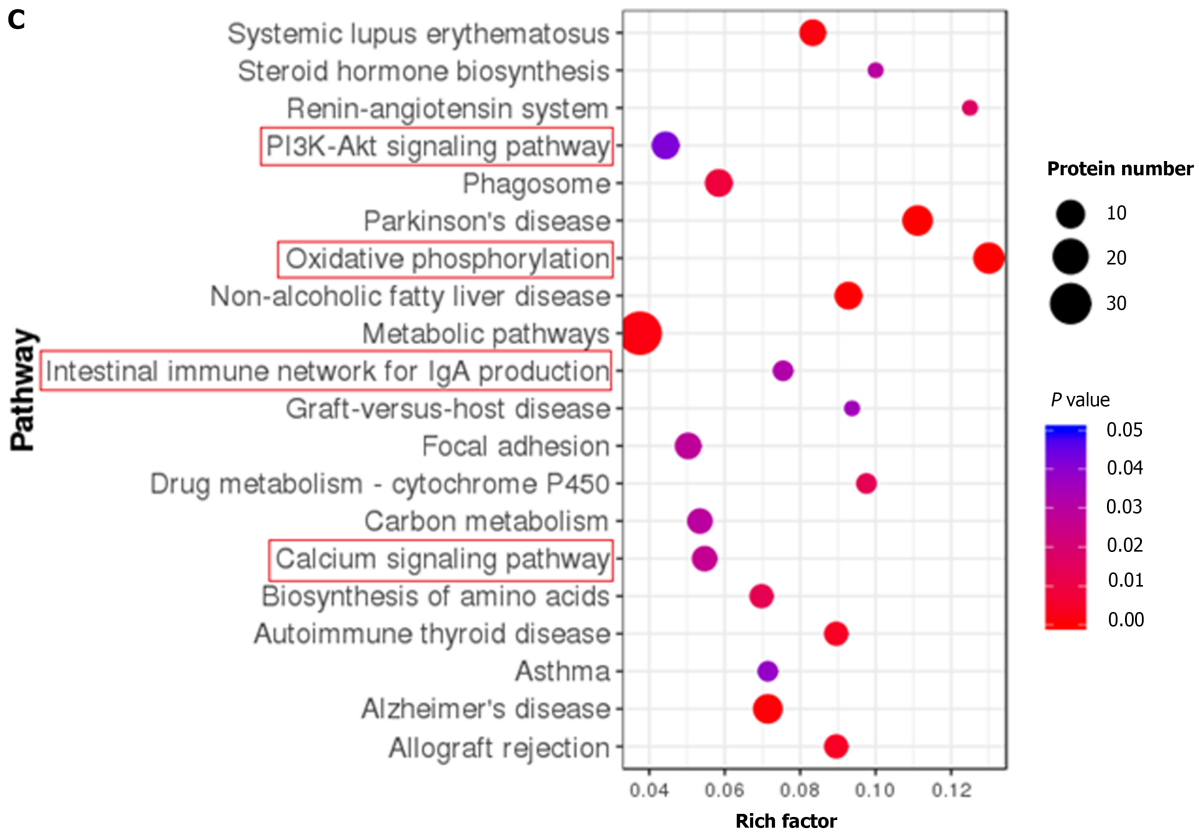

Figure 7 Kyoto Encyclopedia of Genes and Genomes pathway enrichment of differentially expressed proteins between groups. A: Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway enrichment of differentially expressed proteins (DEPs) between the normal and dextran sulfate sodium-induced ulcerative colitis model group; B: KEGG pathway enrichment of DEPs between the dextran sulfate sodium-induced ulcerative colitis model and herb-partitioned moxibustion group; C: KEGG pathway enrichment of DEPs between the dextran sulfate sodium-induced ulcerative colitis model and electroacupuncture group. Each point in the KEGG pathway enrichment plot represents a KEGG pathway, with the left axis showing the pathway name and the abscissa showing the enrichment factor, which represents the ratio of the number of DEPs annotated to that pathway to the number of proteins annotated to that pathway for that species' protein. A larger enrichment factor indicates more reliable enrichment of DEPs in the pathway.

arrangement of mucus, participate in the mucus processing, and plays an important role in regulating intestinal homeostasis and intestinal inflammation[32-34]. CLCA1 can also exert a tumor suppressor effect in colorectal cancer (CRC) by inhibiting the Wnt/β-catenin signalling pathway and epithelial-mesenchymal transition process[35]. The serum concentration and mRNA expression of CLCA1 in CRC tissues were negatively correlated with metastasis and tumor staging[36,37]. These findings suggest that CLCA1 may play an important role in moxibustion in inhibiting the development and carcinogenesis of UC. While 15 proteins were reversely regulated by EA, of which 9 up-regulated in UC but were down-regulated by EA, and 6 down-regulated in UC but were up-regulated by EA. We found EA could also regulate the expression of Atp5f, Cox4i1, Cps1 that explained above, but the functions of other reversely regulated proteins in UC and immune inflammation remain unknown and require further validation and study.

We further explored the potential functions of DEPs by GO and KEGG functional enrichment analyses. GO analysis revealed that the majority of the DEPs were primarily involved in cellular process, metabolic process, biological regulation in biological processes, cell part, cell, organelles, macromolecular complexes in cellular component, and binding, synaptic activity, structural molecule activity, molecular function regulation, molecular sensor activity, and transcriptional regulation activity in molecular function. The results indicated that most differentially abundant proteins were associated with cell structure and catalytic activity which play an important role in cell function. For KEGG analysis, we found that these DEPs were mainly enriched in inflammation responses and immune-related pathways, such as primary immunodeficiency, NF-κB signalling pathway, natural killer cells mediated cytotoxicity, intestinal immune network for IgA production and so on. It has been confirmed that inflammatory response and immune response play an important role in UC. Numerous literature evidence that NF-κB pathway plays an essential role in pathogenic development of UC[38]. In addition, PPI network analysis showed that DEPs related to ribosomal pathways and oxidative phosphorylation pathways were all down-regulated by HM. As we all know that classical signalling pathways, such as the NF-κB signalling pathway, PI3K-Akt signalling pathway, have been confirmed to be associated with UC[39-42], and IgG receptor FcγR also plays an important role in UC intestinal immunity and inflam-

mation[43,44]. The intestinal immune network for IgA production and Fc epsilon RI signalling pathway may also the UC-specific signalling pathway. A study on pathway enrichment analysis of differentially expressed genes between IBD and healthy individuals revealed that primary immunodeficiency, complement and coagulation cascades, and nitrogen metabolism pathways may also play a key role in the progression of IBD[45]. Multiple algorithm analysis found that calcium signalling pathway was involved in the process of UC[46]. This is consistent with our findings at the protein level. Therefore, the abnormality of above pathways may be the key to the pathogenesis of UC, and HM and EA may play the therapeutic role in UC through the regulation of key molecules in these pathways. In addition, we found that proteins involved in inflammation regulation such as serpins were identified (serpinb6 in M/N comparisons, serpinc1 in HM/M and EA/M comparisons). Serpins are the largest known family of serine proteinase inhibitors, which regulate innate immunity by inhibiting the serine proteinase cascades that initiate immune responses such as melanization and antimicrobial peptide production [47]. Several human serpins have been shown to regulate serine proteases associated with processes such as inflammation and immune responses[48]. And increased activity of serine proteases is demonstrated in IBD patients and may contribute to the onset and the maintenance of the disease[49]. This appears to be a novel finding that will require additional research.

We also found that both HM and EA reversed the expression of Sv2a, Ncbp1, Rat hemoglobin beta-chain (Fragment), Fga, Cps1, ATP5L, Cox4i1, Atp5f1, Spout1, Peptidyl-prolyl cis-trans isomerase, Dclk3 proteins, while the rest is what they can reverse individually. The KEGG pathways of DEPs between HM and M groups, EA and M groups were also partly different. These results may reflect the commonness and characteristics of the therapeutic effects of HM and EA. So, the effects of HM and EA on UC may involve the differently regulating proteins and pathways. In addition, based on the results

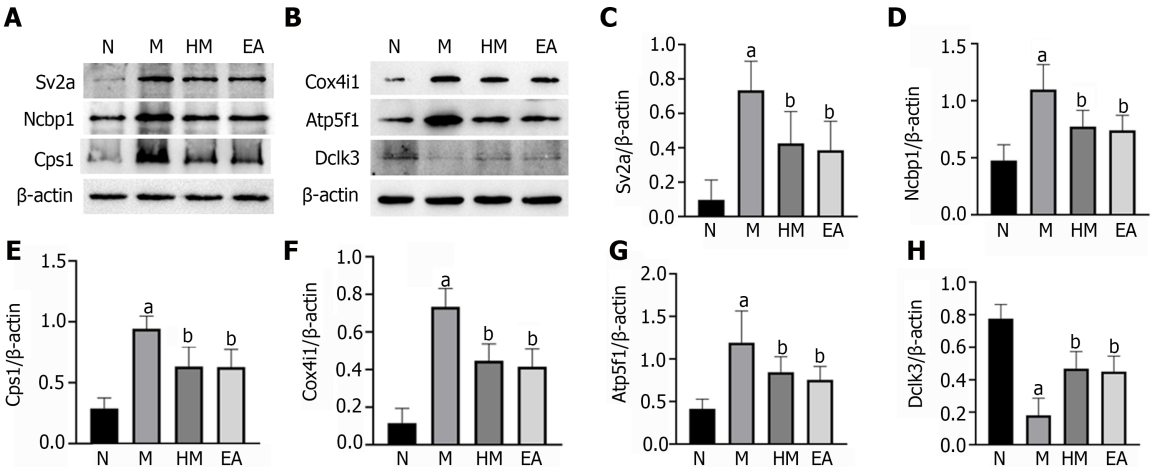

Figure 9 Verification of differentially expressed proteins expressions by western blot. A and B: Band diagrams of protein expressions. of proteomics, we selected 6 DEPs that could be reversed by HM and EA for verification. We found that both HM and EA decreased the expression of Sv2a, Ncbp1, Cps1, Cox4i1, Atp5f1 and increased the expression of Dclk3, which were consistent with the iTRAQ results, confirming the reliability of the iTRAQ results. Cox4i1 is the main subunit of cytochrome c oxidase, a key enzyme in energy metabolism, and plays an important role in mitochondrial oxidative phosphorylation. Defects in oxidative phosphorylation leads to a decrease in cellular ATP production. Studies have reported that the activity of mitochondrial respiratory chain complexes in UC patients is reduced, and mucosal ATP is absent[50, 51]. Atp5f1 is a nuclear gene responsible for encoding the F0 subunit of ATP synthase, which is closely related to energy metabolism. Studies have found that the high expression of Cps1 plays an important role in the formation stage from UC to colitis associated cancer[52]. The intestinal mucosa of UC patients has been under chronic stress for a long time. The dynamic balance between oxidation and antioxidant defense mechanisms in the body is broken, causing mitochondrial damage, weakened oxidative phosphorylation, and reduced energy supply, which in turn causes cell apoptosis and colonic mucosal barrier dysfunction. The above results showed that HM and EA play a therapeutic effect on UC for mitochondrial function and energy metabolism. However, the role of Sv2a, Ncbp1 and Dclk3 in UC or mitochondrial oxidative phosphorylation has not been reported yet, and further research is needed.

In summary, iTRAQ proteomics was used in this study to identify DEPs in the colon of DSS-induced UC rats, as well as proteins that could be regulated by EA and HM, and analysed the function of these DEPs. However, the specific mechanisms of these DEPs were still unclear. They may be involved in one or more regulatory pathways, thus participate in the pathogenesis of UC and the mechanism of EA and HM treatments. The underlying mechanisms may require further study through animal and cell experiments.

CONCLUSION

In conclusion, our study used proteomics to provide evidence that EA and HM might regulate immune-related pathways by regulating the expression of ATP5L, Atp5f1, Cox4i1 that associated with oxidative phosphorylation, thereby alleviating colonic inflammation of DSS-induced UC rats. Further investigations at the role of these proteins in UC will be helpful for revealing the pathogenesis and the mechanism of acupuncture and moxibustion on UC.

ARTICLE HIGHLIGHTS

Research background

Ulcerative colitis (UC) is a chronic, nonspecific intestinal inflammatory disease with unclear etiology. Our previous studies have confirmed that acupuncture and moxibustion is effective in treating UC, but the mechanisms of treatment is still not completely clarified. Proteomic technology has revealed a

variety of biological markers related to immunity and inflammation in UC, which provide new insights and directions for the study of mechanism of acupuncture and moxibustion treatment of UC.

Research motivation

The mechanisms of UC and the therapeutic targets of acupuncture and moxibustion treatment are complicated, and whether acupuncture and moxibustion play a therapeutic role in UC by regulating proteome changes remains unclear.

Research objectives

The present study aims to investigate the underlying mechanism of electroacupuncture (EA) and moxibustion on UC rats by using isotope-labeled relative and absolute quantification (iTRAQ) proteomics technology.

Research methods

Male Sprague-Dawley rats were randomly divided into the normal (N) group, the DSS-induced UC model (M) group, the herb-partitioned moxibustion (HM) group, and the EA group. 3% DSS was used to establish the UC rat model except for the N group, and HM and EA at the Tianshu (bilateral) and Qihai acupoints were performed respectively. Haematoxylin and eosin staining was used for morphological evaluation of colon tissues. iTRAQ and liquid chromatography-tandem mass spectrometry were performed for proteome analysis of the colon tissues, followed by bioinformatics analysis and protein-protein interaction networks establishment of differentially expressed proteins (DEPs) between groups. Then western blot was used for verification of selected DEPs.

Research results

Our study revealed that HM and EA could regulate the expression of multiple proteins in colon of DSS-induced UC model rat. The DEPs were involved in various biological processes such as biological regulation, immune system progression and in multiple pathways including natural killer cell mediated cytotoxicity, intestinal immune network for immunoglobulin A production, and FcγR-mediated phagocytosis. Network analysis revealed that multiple pathways for the DEPs of each group were involved in protein-protein interactions. Subsequent verification of selected DEPs [synaptic vesicle glycoprotein 2A, nuclear cap binding protein subunit 1, carbamoyl phosphate synthetase 1, cytochrome c oxidase subunit 4 isoform 1 (Cox4i1), ATP synthase beta subunit precursor (Atp5F1), doublecortin like kinase 3] by western blot confirmed the reliability of the iTRAQ data.

Research conclusions

HM and EA might regulate immune-related pathways by regulating the expression of ATP5L, Atp5f1, Cox4i1 that associated with oxidative phosphorylation pathways, thereby alleviating colonic inflammation of DSS-induced UC rats.

Research perspectives

The present study revealed the possible molecular mechanisms of acupuncture and moxibustion treatment on UC, it may provide new light on clinical therapy of acupuncture and moxibustion treatment of UC.

Abstract

BACKGROUND

In Korea, infliximab was approved for use in children with ulcerative colitis (UC) in October 2012.

AIM

To compare the clinical course of UC before and after the introduction of biological agents, and to compare with the IBSEN study.

METHODS

Patients under 18 years of age, who were diagnosed with UC and followed from January 2003 to October 2020, were included in the study. Group A (n = 48) was followed for at least 2 years between January 2003 and October 2012, and Group B (n = 62) was followed for at least 2 years between November 2012 and October 2020. We compared endoscopic remission, drug composition, relapse rate, steroid-free period, and the quality of life of each group. We plotted the clinical course of the included patients using the pediatric UC activity index score, and compared our patients with those in the IBSEN study.

RESULTS

After 2 years of treatment, colonoscopy evaluation revealed different outcomes in the two treatment groups. Remission was confirmed in 14 patients (29.2%) of Group A, and in 31 patients (50.0%) of Group B (P < 0.012). The median cumulative corticosteroid-free period was 3.0 years in Group A and 4.4 years in Group B. Steroid-free period of Group B was significantly longer than that of Group A (P < 0.001). There was a statistically significant difference between the two groups in evaluation of the relapse rate during the observation period (P < 0.001). The plotted clinical course graphs of Group A showed similar proportions to the

graphs in the IBSEN study. However, in Group B, the proportion of patients corresponding to curve 1 (remission or mild severity after initial high activity) was high at 76% (47/62).

CONCLUSION

The incidence of relapse has decreased and the steroid-free period has increased after the introduction of the biological agent. The clinical course also showed a different pattern from that of IBSEN study. The active use of biological agents may change the long-term disease course in moderate to severe pediatric UC.

Key Words: Colitis; Ulcerative; Children; Infliximab; Relapse; Steroid

Core Tip: This was a retrospective study that assessed how the introduction of biological agents has altered the disease course over time in pediatric ulcerative colitis (UC). Endoscopic remission, relapse rate, steroid-free period, and the quality of life of each group were evaluated as outcomes. Clinical course was plotted with the pediatric UC activity index score, and compared to that of the IBSEN study. The incidence of relapse has decreased and the steroid-free period has increased after the introduction of biological agents. The clinical course also showed a different pattern from the IBSEN study.

INTRODUCTION

Ulcerative colitis (UC) is a chronic inflammatory bowel disease (IBD) that was first described in 1875 by two English physicians. Although it has been the subject of many studies over the years, the etiology remains unknown[1]. The potential causes explained in the literature include immune system dysfunction, genetics, changes in normal intestinal bacteria, environmental factors, and a combination of any or all of these variables[2]. The incidence of UC is higher in developed countries than in less developed ones, which is thought to be the result of reduced exposure to intestinal infections and a Western-style diet and lifestyle[3]. As people in Asia adopt more Westernized dietary habits, the incidence rate is gradually increasing in that part of the world[4].

The age of onset of UC can be anywhere from 15 to 30 to > 60 years, and the incidence of UC is lower than that of Crohn's disease in children[5]. For this reason, the number of large-scale studies and long-term follow-up studies for pediatric patients with UC is insufficient, and more studies are needed to evaluate the clinical course of UC in such patients. The IBSEN study evaluated the long-term clinical course and outcomes of 423 adult patients with UC during the first 10 years. Mortality risk and cumulative colorectal resection were evaluated as clinical outcomes. The proportion of patients who relapsed and who remain in remission was evaluated as a clinical course. In addition, the authors divided the disease course of UC into four types and showed them in graphs, which became a representative figure of this paper[6]. However, this study was done before any biological agents were approved as treatments. No studies have compared the clinical course of UC before and after the introduction of biological agents in a single cohort.

Infliximab was first introduced in Europe in 1999 for the treatment of Crohn's disease[7]. Since the introduction of infliximab, several studies have reported improvements in clinical outcomes with infliximab treatment[8-11]. Nevertheless, relapse has been observed in patients treated with infliximab, and many studies have been conducted on factors that can predict relapse in these patients[12-14]. Therefore, we assessed what changes have occurred in the long-term clinical course of UC since the introduction of biological agents as treatment.

In Korea, infliximab was approved for use in adults with UC in May 2007, and in children in October 2012. Since long-term follow up is possible due to the characteristics of pediatric patients, the aim of this study was to compare the clinical course of UC before and after the introduction of biological agents. Another goal of this study was to compare the clinical course of our patients to that in the IBSEN study.

MATERIALS AND METHODS

Patients

Patients under 18 years of age, who were diagnosed with UC and had been followed from January 2003 to October 2020, were included in this study. Initially, the total number of patients was 138, but patients who had been observed for less than 2 years were eliminated. Finally, 110 patients were selected as the study group (Figure 1). All patients were children and adolescents under 18 years of age at the time of diagnosis, but some patients became adults during the follow-up period. UC was diagnosed in accordance with the guidelines of the European Society for Pediatric Gastroenterology, Hepatology and Nutrition (the Porto criteria)[15]. This study was approved by the institutional review board of Samsung Medical Center (IRB File No. SMC 2020-12-005).

Study design

This was a retrospective study. The first goal was to evaluate how the active use of biological agents causes a change in the clinical course of UC. This was done using data from patients who were treated after the approval of infliximab in October 2012. With the cut-off date of October 2012, the patients were divided into two groups, A and B. Group A had been followed for at least 2 years between January 2003 and October 2012, and Group B had been followed for at least 2 years between November 2012 and October 2020. Since the two groups were classified according to a time difference, we first checked whether there was any difference in the baseline characteristics of the patients, and then conducted a comparative analysis.

Both patient groups were evaluated by laboratory tests (including hemoglobin, albumin, erythrocyte sedimentation rate [ESR], and C-reactive protein [CRP]), colonoscopy, abdominal computed tomography (CT), and pediatric UC activity index (PUCAI) score at the time of diagnosis. Laboratory tests were performed and a PUCAI score questionnaire was submitted at each outpatient follow-up visit, which took place at intervals of 1-3 mo. We confirmed that there were no clinical differences between the two groups in terms of demographic characteristics, the extent and severity of disease according to the laboratory test and colonoscopy results, or the PUCAI score at the time of diagnosis. The fecal calprotectin test has only been available in Korea since 2017 and thus could not be included as a comparative test. Based on the colonoscopy findings, disease extent was classified into E1 (proctitis), E2 (left colitis), E3 (right colitis), and E4 (pancolitis) according to the Paris classification[16], and severity was classified from 0 to 3 using the Mayo endoscopic subscore (MES)[17].

Evaluation of clinical course including relapse and clinical outcome

Colonoscopy was performed at the time of initial diagnosis and at intervals of 1 to 2 years during the follow-up period. The colonoscopy was performed with a CF scope after sedation with midazolam and pethidine. All procedures reached the cecum and the entire colon was examined. Characteristic endoscopic findings of UC such as peri-appendiceal patches, demarcation line, mucosal edema, decreased vascularity of loss of vascularity, and superficial tiny ulcers were observed and described. We reviewed the colonoscopy findings at 2 and 5 years after the start of treatment. Remission was defined as endoscopic mucosal healing, which means that no lesion was observed and the MES was 0 with histological healing (Geboes grade 0-1). The reason for excluding MES 1 is that the authors aimed at deep remission because they experienced cases of MES 1 that relapsed easily. In addition, we investigated the drugs prescribed to both groups of patients during the follow-up period.

To compare the clinical course between the groups, the number of relapses that occurred during the follow-up period was investigated, along with the time interval at which the first relapse occurred (from the time of diagnosis) and the time interval of each relapse when multiple relapses occurred in the same patient. Since the follow-up period was different for each patient, the relapse rate was finally evaluated between the two groups. Clinical relapse was defined as a PUCAI score > 10 with modification of treatment (addition of steroids or biologic agents). To evaluate the clinical risk factors for relapse, age, PUCAI score, disease extent, MES, and initial use of corticosteroids were statistically analyzed. Situations in which symptoms temporarily worsened due to infections such as gastroenteritis were excluded.

In addition, the corticosteroid-free period, cumulative colectomy, and changes in PUCAI score during the follow-up period were evaluated as clinical outcomes of both groups. As another quality of life-related factor, patients who did not experience relapse but were hospitalized or admitted to the emergency room for antibiotic use or blood transfusions were also investigated and the rates of such patients were compared between the groups.

The second goal of this study was to actually draw a clinical course using PUCAI score in these two patient groups and compare these distributions to the four predefined curves, depicting different clinical courses of UC, as published in the IBSEN study[6].

Statistical analyses

The demographic and clinical characteristics of the study groups at initial diagnosis and the clinical outcomes of the study groups were compared using the χ^2 test and Mann-Whitney test. Steroid-free

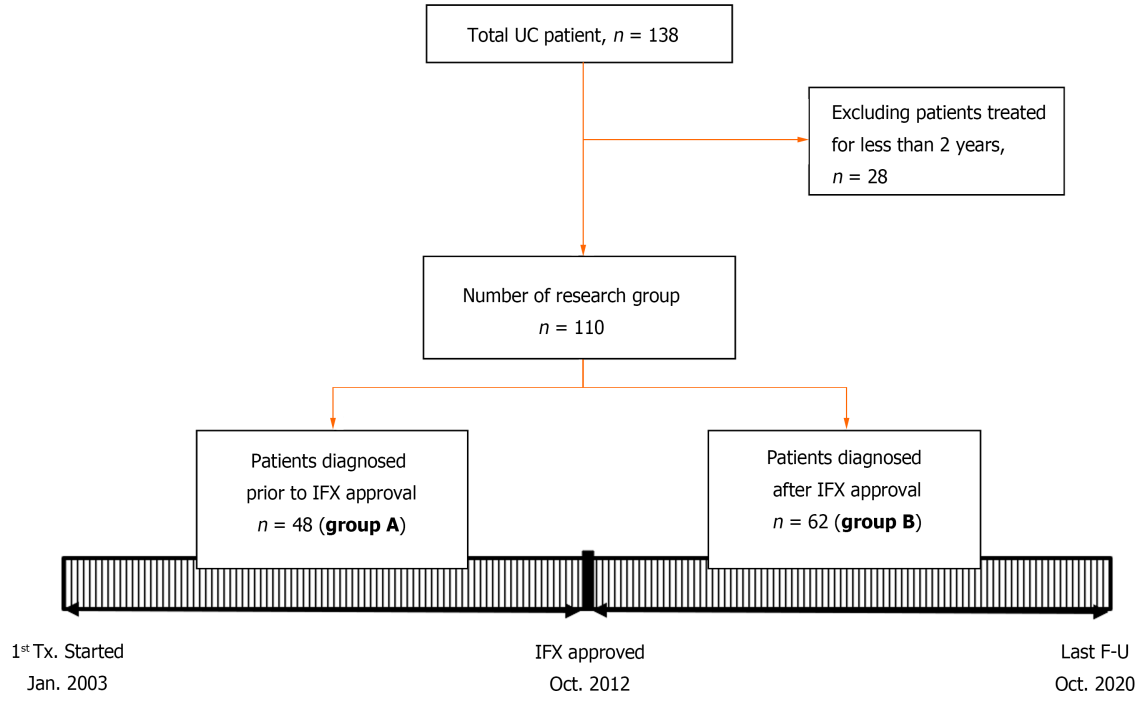

Figure 1 Patient group classification. F-U: Follow-up; IFX: Infliximab; Jan: January; *n*: Number; UC: Ulcerative colitis; Oct: October; Tx: Treatment.

survival curves were presented for the whole cohort using the Kaplan-Meier method. Differences in survival curves between the two groups were evaluated using the log-rank test. Repeated event data for relapses were exhibited by estimating mean cumulative function (MCF), which is the average number of cumulative events experienced by an individual in the study at each point in time since the start of follow-up[18,19]. Univariable/multivariable analyses of the associations between relapse rate and other factors were analyzed by Cox's proportional hazard regression using count process[20] because of multiple events for relapse. Multivariable analysis was performed by selecting variables with $P < 0.1$ in univariate analysis. The 95% confidence intervals (CIs) of the hazard ratio (HR) using robust sandwich covariance estimate to account the within subject correlation[21] were estimated. All of the above statistical analyses were conducted using SAS version 9.4. MCF was analyzed using reReg 1.4.0 package in R 4.0.4 (Vienna, Austria; http://www.R-project.org/. $P < 0.05$ was considered statistically significant.

RESULTS

Baseline characteristics

Table 1 shows the patient characteristics and disease severity information of Group A (n = 48) and Group B (n = 62) at the time of diagnosis, as well as information on the medications that were used for treatment. The median age at the time of diagnosis of UC was 14.4 years for Group A and 15.8 years for Group B. There was no significant difference between the two groups. The median value of the total follow-up period was 3.3 years in Group A and 4.5 years in Group B, and there was no significant difference between the two groups. Serum hemoglobin, albumin, ESR, and CRP levels confirmed by laboratory tests at the time of diagnosis also did not show any significant difference between the two groups.

Based on the results of endoscopy performed at the time of diagnosis, the disease extents of the two groups were classified according to the Paris classification, and severity was evaluated using the endoscopy subscore. There was no difference in disease severity between the two groups, but regarding disease extent, Group B patients had a higher rate of pancolitis and lower rate of proctitis. In Group A, 18 patients (37.5%) had proctitis and 16 (33.3%) had pancolitis, but in Group B, 13 (21%) had proctitis and 34 (54.8%) had pancolitis.

Within 3 mo of diagnosis, most patients in both groups were treated with 5-aminosalicylate and immunosuppressants, primarily azathioprine. In both groups, about 50% of patients used corticosteroids to reduce disease activity at the time of diagnosis. Among the 21 patients who used corticosteroids in Group A, 8 (38.1%) showed dependence and 1 (4.8%) showed refractory findings. In Group B, 9/30 (30.0%) of patients were corticosteroid-dependent and 1/30 (3.3%) was corticosteroid-refractory. There was no statistical difference between the two groups.

Table 1 Demographic and clinical features of the two groups before and after infliximab approval

	Group A (*n* = 48)	Group B (*n* = 62)	*P* value

Comparison of drug composition after 2 and 5 years of treatment

When the drugs that were used for treatment were investigated at the 2-year follow-up visits, 5 patients in Group B did not use any drugs, but no patient in Group A terminated drug treatment (Supplementary Figure 1). In Group A, most patients were still using 5-aminosalicylate (97.9%) and azathioprine (89.6%). In Group B, 96.8% of patients used 5-aminosalicylate as an initial treatment, but at 2 years, some patients had discontinued the use of drugs and 74% of patients were still using the drugs. Also, only 58.1% of the patients in Group B maintained azathioprine treatment at 2 years. In the case of infliximab, on the other hand, more than half of patients in Group B started infliximab treatment within 2 years of diagnosis, and 34 patients were maintaining infliximab. In line with the above results, a statistically significant difference was found between the two groups in the composition of the treatment drugs at the time of the 2-year follow-up visits.

After 5 years, drug composition was re-evaluated in patients who were treated for more than 5 years (Group A = 24 patients, Group B = 31 patients). The same 5 patients in Group B continued to not use any drugs, and 2 patients in Group A also terminated drug treatment. In Group A, mesalazine (87.5%)

and azathioprine (58.3%) use had been tapered and discontinued in many patients. Nevertheless, the proportion of patients using oral drugs was still high compared to Group B (mesalazine: 48.4%, azathioprine: 45.2%). In Group B, the percentage of patients taking infliximab and other biological agents increased (67.7%) after 5 years. In terms of drug composition, the rate of use of mesalazine and infliximab was significantly different, with *P* values of 0.003 and 0.001, respectively (Supplementary Figure 1).

Comparison of disease states after 2 and 5 years of treatment

The patients underwent colonoscopy to re-evaluate disease extent and severity after 2 years of treatment (Table 2). In Group A, remission was confirmed in 14 patients and the proportion of each category of disease extent decreased slightly in comparison to the time of diagnosis, but the differences were small and pancolitis patients still accounted for 27.1% of the total. On the other hand, although the incidence of pancolitis was significantly higher in Group B at the time of diagnosis, 50% of the patients reached remission, and the number of pancolitis patients was significantly reduced to 4 (6.5%). In addition, severity according to the MES also showed a significant difference between the two groups ($P = 0.037$). A large percentage of patients in both groups had moderately severe disease at the time of diagnosis, but after 2 years of treatment, more had mildly severe disease; this was especially true in Group B, in which the percentage of patients with subscores of 0 or 1 was high. In Group B, 53.2% of cases was evaluated as normal or inactive.

Colonoscopy findings were analyzed again after 5 years of treatment (Table 2). As with year 2, the proportion of patients who reached remission at 5 years was greater in Group B (41.9%) than in Group A (12.5%). Overall, a higher proportion of cases in Group B was evaluated as E1 or E2, so disease severity in Group B was still milder than that in Group A ($P = 0.016$). Regarding MES, 41.9% of patients in Group B maintained an inactive disease state, whereas 12.5% of patients in Group B remained low. In Group A, 58.3% of cases was evaluated as moderate, and evidence of the disease was often difficult to see as it was well controlled. In Group B, 51.6% of patients had mild disease. The difference in disease severity between the two groups was statistically significant ($P < 0.001$).

Comparison of clinical outcomes during the total follow-up period

Disease relapse occurred in 23 patients (47.9%) in Group A and 16 (25.8%) in Group B, which was a significant difference ($P = 0.027$) (Table 3). The total cumulative number of relapses was also significantly higher in Group A (40 in Group A *vs* 22 in Group B; $P = 0.006$). In addition, although the difference was not significant, the number of relapses that occurred per person per year was also higher in Group A, with a ratio of 0.44 (Group A) *vs* 0.25 (Group B). The first relapse occurred at a median of 1.2 years after diagnosis in Group A, but in Group B, relapse occurred after a median interval of 1.95 years; thus, first relapse seemed to be delayed in Group B. The time interval between each relapse was investigated in patients who experienced multiple relapses. In Group A, relapse occurred approximately every 1.3 years, whereas relapse took about 1.7 years in Group B, showing that the interval between relapses was relatively wide in Group B. Since each patient's follow-up period was different, we also evaluated the relapse rate by comparing the cumulative hazard rate up to a specific point in time. There were statistically significant differences ($P < 0.001$) between the two groups, as shown in Figure 2.

The PUCAI scores at each outpatient visit during maintenance treatment (excluding times at which the patients had relapsed) were significantly lower in Group B than in Group A ($P < 0.001$) (Table 3). The PUCAI score at the time of relapse was also compared, which showed that the PUCAI score was significantly lower in Group B than in Group A ($P < 0.001$).

Because Group B patients were treated with infliximab, the frequency of steroid use was lower in that group (Table 3). The corticosteroid-free period was compared between the two groups. The median value of the cumulative corticosteroid-free period was 3.0 years in Group A and 4.4 years in Group B. The steroid-free period of Group B was significantly longer than that of Group A ($P < 0.001$). Figure 3 shows the analysis of corticosteroid-free survival curve after initiation of treatment using the Kaplan-Meier method. Over the course of 2 years, the likelihood of remaining corticosteroid-free in Group A was 21%, while it was 88% in Group B ($P = 0.003$).

Only 1 patient underwent colectomy in Group A. At the time of colectomy, the patient used mesalazine, azathioprine, methylprednisolone, and antibiotics. The patient finally underwent total proctocolectomy due to persistent uncontrolled hematochezia at 3 years after diagnosis.

Evaluation of risk factors related to relapse

Since relapse was often observed in both Group A and Group B, the risk factors associated with an increase in relapse rate were investigated in all patients who experienced relapse using Cox's proportional hazard regression for counting processes (Table 4). Since all patients were not followed up for the same period of time, the relapse rate was evaluated but not simply the number of relapses. All factors that were analyzed reflected the status at the time of diagnosis. Young age (> 10 years), PUCAI score over 45, disease extent according to the Paris classification, MES, and initial corticosteroid use were investigated as potential risk factors. In univariable analysis, MES, and initial corticosteroid use were identified as clinical risk factors with statistical significance ($P = 0.010$ and < 0.001) In multivariable

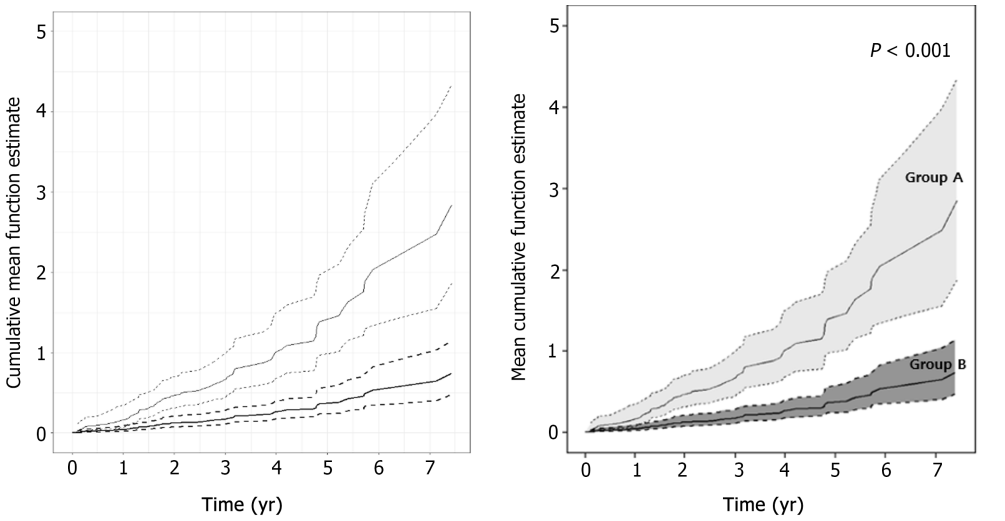
analysis, only severe status remained an independent risk factor with statistical significance (P = 0.015).

Supplementary Figure 2 shows a comparison of the timing of the start of infliximab treatment after diagnosis among non-relapsed and relapsed patients who used infliximab. In the group of 29 non-relapsed patients, the majority (22, 75.9%) of them began infliximab treatment within 3 mo. On the other hand, in the group that experienced relapse, there were many patients who first used oral drugs or steroids and then began to use infliximab after 6 mo as the disease progressed.



Clinical course curve: Comparison with the IBSEN study

In the IBSEN study, patients were asked to choose which of four predefined patterns best reflected their clinical course (Figure 4A). The predefined patterns were as follows: remission or mild severity of intestinal symptoms after initial high activity, increase in the severity of intestinal symptoms after an initial period of low activity, chronic continuous symptoms, or chronic intermittent symptoms[6]. These curves do not include the curve of the patients whose disease is consistently well controlled after showing mild disease activity at the time of diagnosis; they were probably included in curve 1 in the IBSEN study. In the current study, we plotted the clinical courses of all patients in both groups using the PUCAI score at each outpatient visit and the PUCAI score at relapse. We separated the patients with mild initial disease activity (PUCAI < 35) from the group with good disease control after treatment and drew a new curve (curve 5). Therefore, the proportion of patients corresponding to curve 1 was different from the IBSEN study. In this study, 27.1% of patients in Group A were included in curve 5, and 29.2% of patients showed moderate to severe initial disease activity and maintained well after treatment; they were included in curve 1 (Figure 4B). When these two were combined, it was 56%, which was similar to

Table 4 Univariable and multivariable analysis of the association between relapse rate and other factors

Figure 2 Mean cumulative function for multiple relapses over time. The Y-axis is a cumulative relapse rate, which represents the cumulative hazard rate up to a specific point in time. The dotted line represents the 95% confidence interval for the cumulative risk rate. Group A: Thin black line; Group B: Thick black line.

the ratio of curve 1 in the IBSEN study. In the case of Group B, 27.4% of patients were included in curve 5 and the proportion was similar to Group A (Figure 4C). The patients of curve 1 in Group B were 48.4%, showing an increase in the proportion of patients compared to Group A. When combined with patients with mild disease initial activity, it was 76%, which was higher than that of curve 1 patients in the IBSEN study.

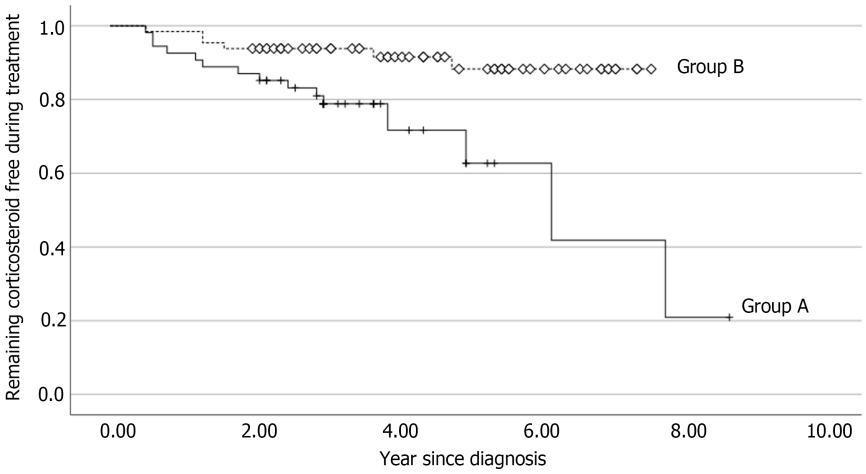

Figure 3 Analysis of corticosteroid-free survival curve after initiation of treatment using Kaplan-Meier method. The solid line represents the proportion of patients who were treated from January 2003 to September 2012 and did not receive corticosteroids. The dotted line represents the same proportion among patients who were treated from October 2012 to October 2020. In the former group, the 2-yr corticosteroid-free retention rate is 21%; in the latter group, the rate is 88% (log-rank test, $P = 0.003$).

The other clinical courses were also classified among patients with similar types and compared with the predefined curves of the IBSEN study. Patients in Group A were distributed among the four types in similar proportions as patients in the IBSEN study (Figure 4B). However, in Group B, the percentage of patients corresponding to curve 4 was relatively small (16%) (Figure 4C).

DISCUSSION

Many previous papers have cited young age at diagnosis as a risk factor for poor clinical outcomes such as relapse and colectomy in pediatric UC patients[22-25]. Thus, research on children with UC is vital. This study evaluated the ways in which the clinical course of children and adolescents with UC changed when the treatment options were diversified after the introduction of biological agents. Infliximab was approved in Korea in 2012 and is now widely used in patients with moderate to severe UC, but many patients who exhibit a good response to oral medication continue to be treated with oral medication only. Here, we compared the clinical course of patients before and after approval of the biological agent according to the passage of time, rather than directly comparing patients who used infliximab to those who did not, as was done in previous studies[8,26,27].

Table 1 shows the characteristics of the included patients. It is evident that the two groups had similar characteristics and differed only in terms of the initial disease extent. The difference in initial disease extent is thought to be due to the rise in incidence of IBD over time as dietary habits become more Westernized; accordingly, the severity of the disease is increasing in newly diagnosed patients[28-30]. Since all patients in this study were followed for at least 2 years, drug and endoscopic evaluation were performed in every patient at 2 years post-diagnosis; it was thus possible to assess changes in the disease extent after 2 years to follow up on this difference in initial disease extent. Only half of all included patients were followed for more than 5 years, but the two groups still exhibited a statistically significant difference in disease extent and severity at 5 years. Despite the high proportion of pancolitis at initial diagnosis, many patients in Group B reached remission. This finding indicates that, in patients with broad disease extent and severity, there is an active and ongoing need for biological agents such as infliximab.

The number of patients who relapsed, the total number of relapses, and the relapse rate were significantly lower in Group B than in Group A. Though both measures significantly differed between the two groups, because every patient had a different follow-up period, we assume that the relapse rate is a more relevant outcome than the total number of relapses (Figure 2). We believe that the higher relapse rate in Group A is attributable to the differences in treatment. Most of the patients with relapse in Group B initially showed pancolitis. Many previous studies have identified disease extent as a risk factor for relapse[23,31,32]. Our risk factor analysis also demonstrated that the initial disease severity (MES) was a significant risk factor for relapse, with P values of 0.006 in the univariate analysis and 0.0149 in the multivariate analysis (Table 4). The worse the initial disease state, the worse the prognosis; this relationship may be taken for granted, but it is important information to keep in mind when establishing a treatment strategy. We thought it was strange that disease extent was not significantly associated with relapse, so we delved a bit deeper into the issue. As a result, pancolitis at initial diagnosis was identified as a risk factor in the univariate analysis in Group A. In Group B, the relapse

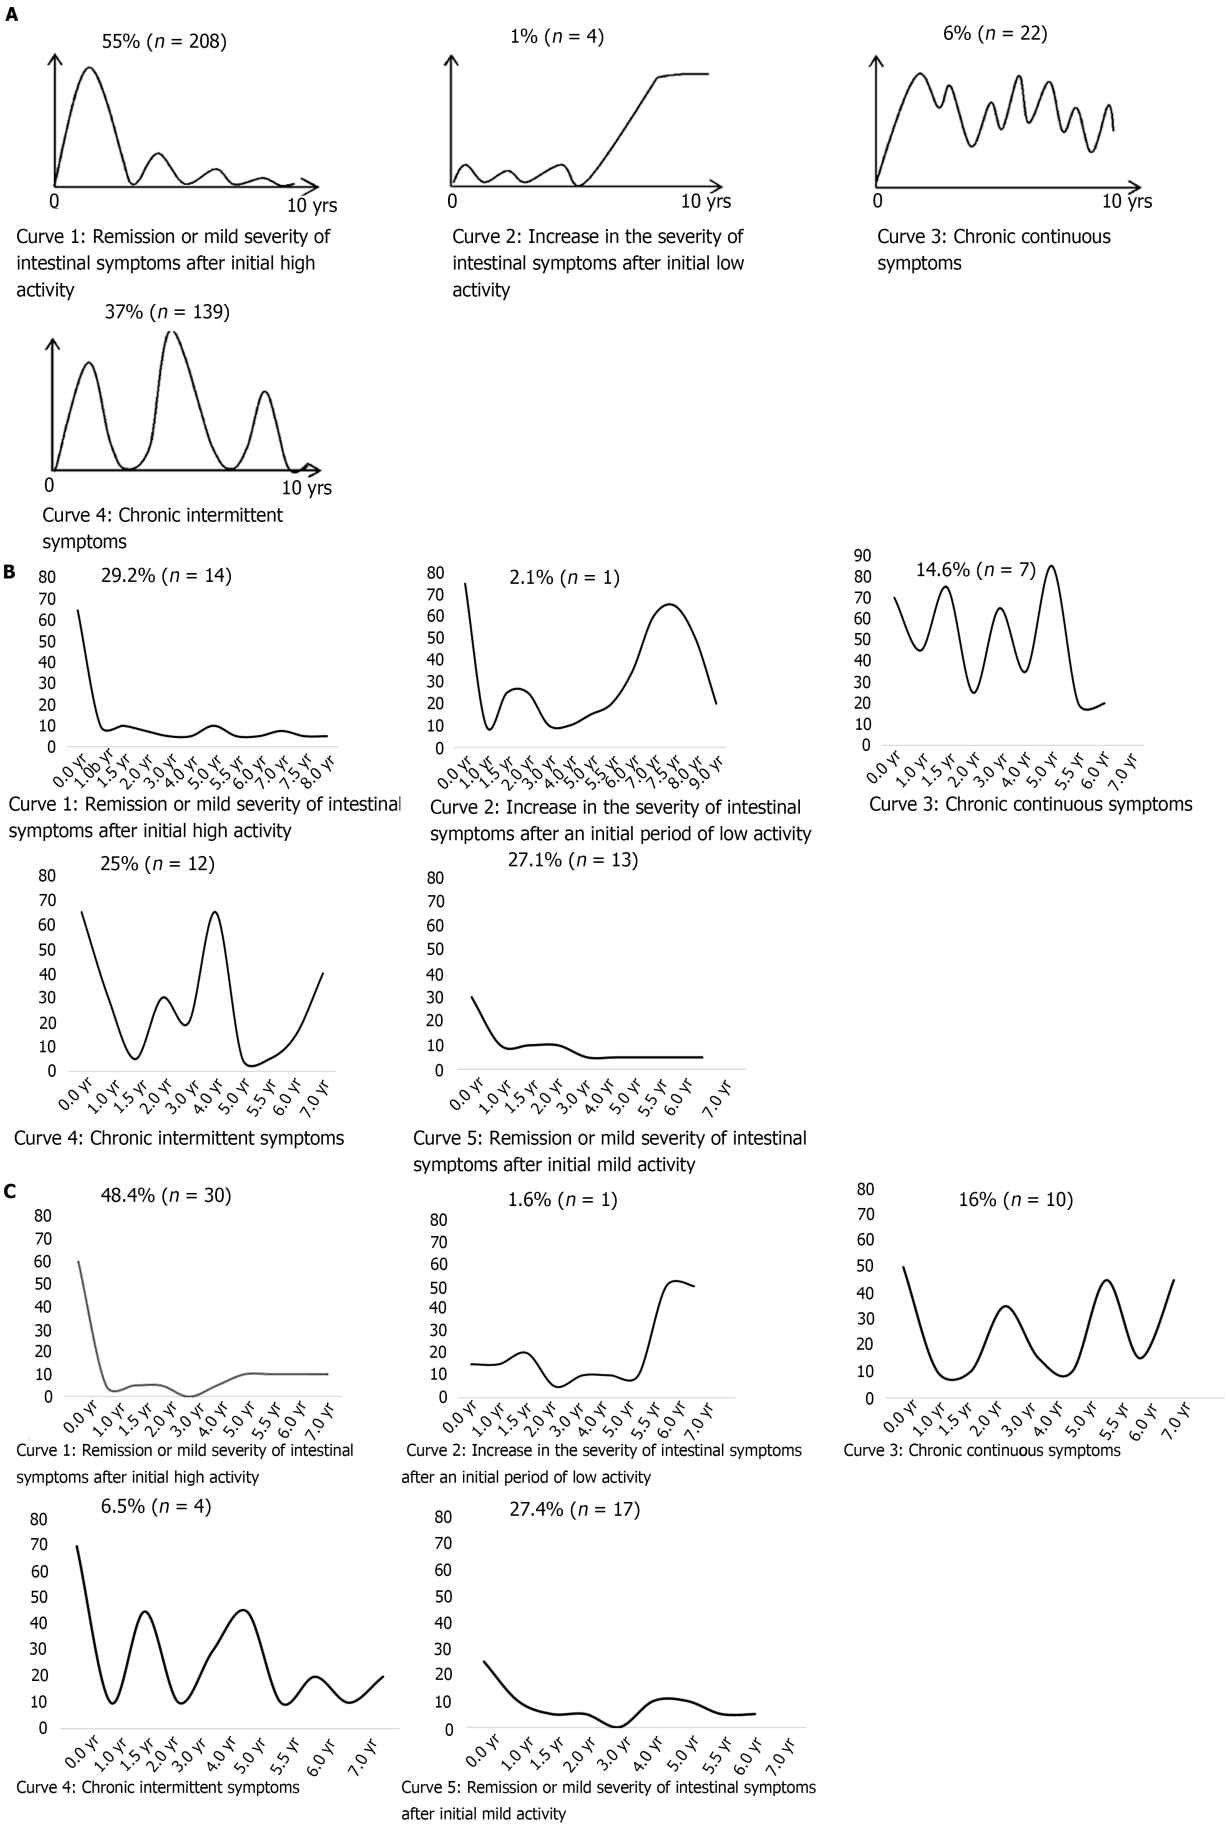

Figure 4 Comparison of clinical course curves of the IBSEN study. A: Graphs of self-identified clinical course in the IBSEN study[6]; B: Actual clinical

course according to pediatric ulcerative colitis activity index prior to the introduction of infliximab (Group A); C: Actual clinical course according to pediatric ulcerative colitis activity index after the introduction of infliximab (Group B). *n*: Number.

rate was relatively low, so statistical evaluation was not possible. In our opinion, disease extent can indicate how long a patient has been suffering from the disease without appropriate treatment. Therefore, it is less likely to be related to relapse rate than disease severity.

As with the endoscopic findings, a high PUCAI score and the use of corticosteroids, which indirectly indicate greater initial disease severity, were also identified as risk factors for relapse. We wondered whether the time at which the patients started infliximab treatment would change the clinical course in relapsed patients even in Group B. Rapid use of infliximab can be expected to reduce the risk of relapse in patients with severe disease, as shown in Supplementary Figure 2. In the non-relapsed group, there were 16 patients with pancolitis at the time of diagnosis, but no relapse occurred among those who received infliximab within 3 mo of diagnosis (Supplementary Figure 2). Since all of our patients were treated with mesalazine and azathioprine for severe disease before receiving additional treatments such as corticosteroids and infliximab, they received similar medications at similar times with the exception of infliximab. Therefore, we propose that the active use of infliximab for initial treatment of moderate to severe UC is important.

As the field of IBD research has expanded and more treatments have been developed, there have been many studies on the quality of life of IBD patients[33-35]. The average PUCAI score during maintenance treatment can be considered an important factor in terms of improving quality of life and preventing relapse. The PUCAI scores during maintenance treatment and at the time of relapse were significantly lower in Group B, indicating that the daily lives of patients in Group B may have been more enriching.

Perhaps the most important factors in evaluating the clinical outcome of treatment are how long the steroid-free period was maintained and whether colectomy was performed[31]. As children and adolescents are not yet finished growing, using steroids more sparingly can prevent osteoporosis and slow growth, which are the typical side effects of steroids[36]. It can also prevent hirsutism, moon face, and buffalo hump in adolescent patients, who tend to be sensitive to appearance. We confirmed that steroid dependency could be avoided through the use of biological agents in patients with high-severity UC (Figure 3). Since colectomy, like the length of the steroid-free period, is an important factor when evaluating long-term outcomes, other studies have also reported on colectomy rates according to treatment[37-39]. In this study, only 1 patient in Group A underwent colectomy due to uncontrolled hematochezia, so it was not possible to compare colectomy as a long-term outcome.

The IBSEN study has been cited in several papers because it is a representative paper that evaluated the clinical course of UC on a large scale[40,41]. The IBSEN study developed predefined curves to represent the clinical course of the disease (Figure 4A). Each patient was asked to choose which predefined graph was most similar to their clinical course. We wondered whether the actual clinical course is represented by these curves and whether the clinical course differs between adults and children. We also wondered whether the clinical course changed after the introduction of biological agents. Therefore, we plotted the clinical course using PUCAI scores. The PUCAI score was chosen because laboratory results such as ESR and CRP are only weakly correlated with symptoms in patients with UC. The shapes of our graphs are similar to the four curves of the IBSEN study. However, there are some differences. The biggest difference is that we separated the patients whose initial disease activity was mild and disease was well controlled from curve 1, which was not shown in the IBSEN study. We believe that patients with such clinical features were also included in curve 1 in the IBSEN study. What was newly confirmed in the process of dividing into curves 1 and 5 is that the proportion of patients in curve 5 was similar in Group A and Group B. It is an epidemiologically convincing finding that the proportion of mild cases is similar over time.

In Group A, if the patients in curve 1 and those in curve 5 were combined, the ratio was similar to that of curve 1 in the IBSEN study. Since the patients of Group A received treatments that were similar to those given in the IBSEN study, the proportion of patients corresponding to each curve was similar. In the case of curve 2, the relapse that occurred in the second half did not persist as relapses tended to do in the IBSEN study, and instead showed a trend towards improvement with treatment. In addition, curve 3 differed in that it showed a lower baseline than the IBSEN curve when disease was partially controlled.

When comparing the graphs of the two groups, fewer patients in Group B than Group A corresponded to curves 3 and 4, and more corresponded to curve 1, indicating that the disease course of patients in Group B was better controlled. Therefore, the proportion of Group B patients corresponding to each curve was also different from the IBSEN study. As mentioned above, the relapse rate dropped after the introduction of infliximab and patients showed improved clinical outcomes. Similarly, the disease course appeared to be changing due to the change in treatment. Taken together, this study suggests that the course of chronic diseases may change over time due to the expanded availability of different types of therapeutic drugs.

The main limitation of this study is that the time difference between the two groups may have introduced some degree of bias. The diagnostic environment and degree of training of the clinicians may have improved over time. To minimize this bias, we evaluated the patients' baseline characteristics using objective indicators and found that there were no significant differences between the two groups. Also, when assessing disease extent and Mayo subscore from the colonoscopy findings, the same experts evaluated all patients using the same criteria. Another limitation is that it was conducted at a single center. However, this hospital is one of the biggest pediatric IBD centers in Korea and has the advantage of having a steady patient cohort through long-term care.

CONCLUSION

As patients with moderate and severe UC have been treated with infliximab since its introduction almost a decade ago, the rate of relapse has decreased and the steroid-free period has increased. In addition, based on the PUCAI score and objective colonoscopy results, the disease is better controlled and patients' quality of life has improved. Before the introduction of the biological agent, the clinical course of pediatric patients showed patterns that resembled those in the IBSEN study, but since its introduction, the proportion of patients who have reached remission has significantly increased. The current goal of treatment for IBD is to change the disease course for a better quality of life, and appropriate treatment with biologic agents may be an option for achieving that goal.

ARTICLE HIGHLIGHTS

Research background

There are many articles comparing the clinical outcomes of patients treated with biological agents *vs* those who did not use biological agents, but no studies have compared the disease course of UC by era before and after the introduction of biological agents. The authors assessed how introduction of new treatment altered disease course over time.

Research motivation

The number of large-scale and long-term follow-up studies for pediatric patients with ulcerative colitis (UC) is insufficient. A representative paper dealing with the clinical course of adult UC is the IBSEN study. This paper dealt with the clinical course before the introduction of biological agents. If the use of biological agents in pediatric UC changed the clinical course of UC, it would be helpful in future treatment decisions.

Research objectives

The aim of this study was to compare the clinical course of pediatric UC by era before and after the introduction of biological agents, and to compare them with clinical course curve of the IBSEN study.

Research methods

Infliximab was approved for use in children in October 2012 in Korea. Group A (n = 48) was followed between January 2003 and October 2012, and Group B (n = 62) was followed between November 2012 and October 2020. Endoscopic remission, drug composition, relapse rate, steroid-free period, and the quality of life of the groups were evaluated as outcomes. Clinical course was plotted with the pediatric UC activity index score, and compared to the curve of the IBSEN study.

Research results

Despite a higher rate of pancolitis, patients in Group B had a higher rate of achieving endoscopic remission, longer steroid-free periods and reduced relapse rate. Unlike the clinical course curve of the IBSEN study, we drew one more independent curve (curve 5), and the proportion of the patients in Group B corresponding to curve 1 (remission or mild severity after initial high activity) was higher. In terms of quality of life, the number of hospitalizations and emergency room visits have improved after the introduction of biological agents. Comparison of treatment costs is also an important issue that needs future research.

Research conclusions

The active use of biological agents may change the long-term disease course in moderate to severe pediatric UC. Growth can also be achieved by reducing the use of steroids.

Research perspectives

Because biological agents are an expensive treatment option, whether there is a difference in economic

quality of life caused by treatment with biological agents is also an important topic for future research.

FOOTNOTES

Author contributions: Kwon Y designed and performed the research and wrote the paper; Kim MJ designed the research and supervised the report; Kim ES and Choe YH designed the research and contributed to the analysis.

Institutional review board statement: This study was reviewed and approved by the Ethics Committee of the Samsung Medical Center (IRB File No. SMC 2020-12-005).

Informed consent statement: Patients were not required to give informed consent to the study because the analysis used anonymous clinical data that were obtained after each patient agreed to treatment by written consent.

Conflict-of-interest statement: The authors have no conflict of interests to declare.

Data sharing statement: No additional data are available.
