(63.6%) exhibited progression of pouch adenoma. The cumulative risks of pouch adenoma development at 5, 10, and 15 years after pouch surgery were 15.2%, 29.6%, and 44.1%, respectively. Severe colorectal polyposis (with more than 1000 polyps) was a significant risk factor for pouch adenoma development (hazard ratio, 2.49; 95% confidence interval: 1.04-5.96; $P = 0.041$).

CONCLUSION

Pouch adenomas occur at a fairly high rate in association with FAP after restorative proctocolectomy, and a high colorectal polyp count is associated with pouch adenoma development.

Core Tip: This is a retrospective study that evaluated the cumulative incidence and risk factors for pouch adenoma in association with familial adenomatous polyposis following restorative proctocolectomy. The incidence of pouch adenoma was 25.3%, and the cumulative risk 15 years after pouch surgery was 44.1%. Severe colorectal polyposis was a significant risk factor for pouch adenoma development. In our series, 62% of adenomas did not recur after endoscopic removal, but 63% of patients under observation showed progression. There was no spontaneous adenoma diminution or disappearance. Close endoscopic pouch surveillance is essential, and new pouch adenoma management guidelines are needed.

INTRODUCTION

Familial adenomatous polyposis (FAP) is a genetic syndrome caused by an adenomatous polyposis coli (*APC*) gene mutation that has an incidence of 1 in 10000 births[1]. This genetic variation is characterized by extensive polyposis in the colon and rectum, and patients with FAP have a lifetime colorectal cancer risk of 100% by the age of 35 to 40 years[2]. Hence, prophylactic surgical intervention is required for these individuals, and the currently favorable therapeutic option is a total proctocolectomy and ileal pouch-anal anastomosis (TPC/IPAA)[2]. TPC/IPAA increases life expectancy among patients with FAP by eliminating their metachronous colorectal cancer risk[3]. The postoperative disease course is determined by extracolonic manifestations, including duodenal adenoma and carcinoma, and desmoid tumors[4].

Cancers of the terminal ileum are extremely rare, and this region thus represents a far lower disease risk than the remaining rectal mucosa after ileorectal anastomosis. Notably, however, several studies have found a 35%-57% incidence of ileal pouch adenomas associated with FAP, which can progress to malignancy[5-11]. Given that most of these prior studies involved small sample sizes and were retrospective in nature, definitive results on these cancers are lacking, and the risk factors associated with pouch adenoma development remain to be established. Although these data are limited, the pouch adenoma incidence is reported to be quite high; therefore, long-term periodic surveillance is required. Most clinical guidelines recommend annual endoscopic surveillance of the anal transition zone (ATZ) mucosa after TPC/IPAA as a surgical management strategy for FAP patients. According to the National Comprehensive Cancer Network guidelines, this surveillance interval should be shortened to 6 mo if the adenoma is large or has advanced histology. However, there are currently no specific criteria directing more frequent surveillance. Moreover, with the currently implemented management approaches for pouch adenoma, uncertainty remains regarding the specific indications for endoscopic or surgical intervention[12-14]. More information is, therefore, needed regarding the incidence, natural course, and risk factors associated with pouch adenoma.

We investigated the cumulative incidence and time to development of pouch adenomas. In an FAP cohort after TPC/IPAA, we analyzed the clinical factors associated with pouch adenoma development.

MATERIALS AND METHODS

Study sample

Data on all patients with FAP who underwent pouch surgery at Asan Medical Center, Seoul, South Korea between November 1989 and December 2018 were identified from the hospital database. The FAP patients were identified by the presence of more than 100 colorectal adenomas. The indication for TPC/IPAA was FAP with or without malignancy. We excluded patients with attenuated FAP with fewer than 100 polyps (as per histopathology reports), as well as patients who did not receive TPC/IPAA. Demographic data, surgical details, original histopathology, and details of follow-up pouch endoscopic and pathologic findings were captured retrospectively. The definition of pouch adenoma included lesions that occurred in the ileum above the anastomosis site. Pouch adenoma progression was defined as an increase in the number or size of these lesions, as well as the development of dysplasia or malignancy, evident on histopathological examination. The severity of the duodenal polyposis in each case was assessed using the Spigelman classification[15] (Table 1). The study protocol was approved by the institutional review board of Asan Medical Center (registration No. 2021-0309) in accordance with the Declaration of Helsinki.

Surgical techniques of IPAA

An anal mucosectomy leaving a short rectal muscular cuff above the dentate line and transanal hand-sewn ileoanal anastomosis were performed for 72 of our enrolled FAP patients (75.8%). The remaining 23 patients (24.2%) underwent double-stapled anastomosis adjacent to the dentate line at the ATZ. The pouch construction in all patients was J-shaped using two ileal limbs of 15 cm in length.

Follow-up protocols

The regular follow-up protocols for our study patients included clinical examinations, pouch and upper gastrointestinal endoscopy, and abdominoperineal computed tomography. Pouch endoscopy was performed within 1 postoperative year. Subsequently, for patients who underwent a mucosectomy, endoscopic examinations were performed once every 2 years in the absence of any polyps. If polyps were observed during endoscopic follow-up, they were removed regardless of size. In patients with multiple polyps, those larger than 5 mm in diameter were removed, or a biopsy specimen was collected. More intensive follow-up was performed, at intervals of 6-12 mo, if warranted by the size, number, or pathologic characteristics of identified polyps. Patients with colorectal cancer in our cohort were followed at 6-mo intervals for 5 years and annually thereafter. Additionally, testing for carcinoembryonic antigens was conducted every 6 mo, and chest computed tomography was performed annually.

Statistical analysis

The quantitative variables in this study are expressed as medians with interquartile ranges (IQRs) or ranges, and categorical variables are summarized as frequencies and percentages. The clinicopathological variables for the patients with and without pouch adenomas were compared using the Kruskal-Wallis test and Fisher's exact test. The time to pouch adenoma formation was defined as the time from the date of surgery to the date of detection of the first histologically confirmed adenoma. Pouch adenoma–free survival was calculated using the Kaplan-Meier method. Multivariate Cox regression analysis based on backward elimination was used to assess the impact of variables on pouch adenoma–free survival with adjustment for variables reported to be associated with pouch adenoma–free survival in previous reports (colorectal polyp burden, time interval after IPAA, presence of desmoid tumors, and presence of gastric polyps and duodenal adenomas) in addition to basic patient characteristics, such as age and sex. Hazard ratios (HRs) with 95% confidence intervals (CIs) were also calculated. Statistical significance was established with a two-sided test at $P < 0.05$. All statistical analyses were performed using SPSS Statistics for Windows, version 25.0 (IBM Corp., Armonk, NY, United States).

RESULTS

A total of 175 patients with FAP who underwent pouch surgery were identified from the hospital database. Among these patients, we excluded 48 with attenuated FAP with fewer than 100 polyps according to histopathology reports. We also excluded six patients who underwent total colectomy procedures with ileorectal anastomosis, two who underwent end-ileostomy without ileal pouches, and one whose pouch was removed due to postoperative bleeding. We further excluded 23 patients who did not undergo postoperative follow-up sigmoidoscopy. The final study cohort, thus, comprised 95 patients with FAP who underwent TPC/IPAA (Figure 1).

The characteristics of the 95 FAP patients enrolled in this study are summarized in Table 2. The median follow-up period after pouch surgery was 88 mo (IQR, 61-141 mo). The median age at the time of IPAA was 32 years (IQR, 24-41 years). The median number of follow-up endoscopies was 5 (IQR, 3-7).

IPAA: Ileal pouch anal anastomosis; IQR: Interquartile range; ATZ: Anal transition zone; GI: Gastrointestinal.

We observed that 24 (25.3%) of our study patients had adenomas that had been histologically confirmed in the pouch mucosa above the anastomosis. The median time to first pouch adenoma detection was 52 mo (IQR, 28.3-114.3 mo). Adenomas arising from the ATZ below the anastomosis were detected in seven (7.4%) patients. Upper gastrointestinal endoscopy was also performed for all patients. Gastric polyps were present in 70 (73.3%) patients; these were mainly fundic gland polyps (75.7%) as per biopsy results. Duodenal adenomas were confirmed in 46 (48.5%) patients. Twenty-four, 12, and 10 patients were classified as having Spigelman stages I, II, and III lesions, respectively, and there were no stage IV cases. Twenty-three (24.2%) patients developed desmoid tumors. At the time of surgery, 43 (45.3%) patients had colorectal cancer.

Mutation analysis

Information on the underlying germline mutation was available for 40 (42.1%) FAP patients, among whom 28 (70.0%) harbored *APC* mutations, most commonly within exon 15 of the *APC* gene (64.3%). No significant difference was found in terms of the distribution of germline mutations between patients with and without pouch adenomas ($P = 0.21$).

Presence and distribution of pouch adenomas

The cumulative incidences of pouch adenomas at 5, 10, and 15 years after IPAA were 15.2%, 29.6%, and 44.1% (95%CI: 7.2%-22.4%, 15.8%-41.1%, and 25.3%-58.2%), respectively (Figure 2). Among the 24

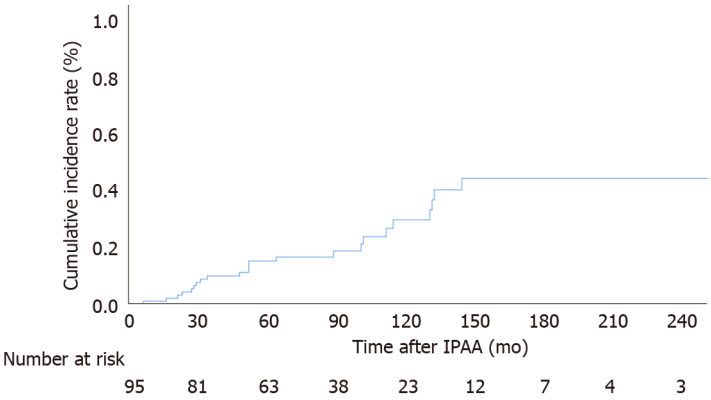
patients with pouch adenomas, 13 (54.2%) had fewer than 12 countable lesions, whereas others had numerous polyps within the pouch. All countable adenomas were removed endoscopically regardless of size. Only one patient had to undergo a transanal excision to remove a pouch adenoma 31 mm in diameter. The median value of the maximum diameter was 3 mm (range, 2.0-31.0 mm). Tubular adenomas were detected in 23 (95.9%) patients, and tubule-villous adenomas were detected in two (8.4%) patients. There were no cases of high-grade dysplasia or malignancy in our study sample. During follow-up for the 13 patients who underwent complete removal of all detected adenomas, eight (61.5%) patients had no recurrence, and four (38.5%) developed recurrent adenomas, which were endoscopically resected. The remaining patient in this group was lost to follow-up, and the disease course after adenoma removal was not documented. For the 11 (45.8%) patients with numerous polyps within the pouch, only those larger than 5 mm were removed, and surveillance biopsy specimens were collected. In four (36.4%) patients, the adenomas remained unchanged, while seven (63.6%) patients exhibited pouch adenoma progression (Figure 3).



Clinical characteristics of study patients with and without pouch adenomas

Comparisons of the clinical characteristics among the FAP patients according to the presence of pouch adenomas are presented in Table 2. Compared with patients without adenomas, the pouch adenoma group had a significantly higher mean number of colorectal polyps at the time of surgery (700 *vs* 250, $P = 0.001$). Severe polyposis involving more than 1000 colorectal polyps was also significantly more common in the pouch adenoma group ($P = 0.006$). Additionally, patients with pouch adenomas (relative to those without pouch adenomas) were more likely to have duodenal adenomas (66.7% *vs* 42.3%, $P = 0.039$). There was no significant intergroup difference in the Spigelman adenoma stage distributions ($P = 0.30$) and no differences in the gastric polyp status (absent or present) or gastric polyp burden. Nonsteroidal anti-inflammatory drug (NSAID) treatment for desmoid tumors-including with celecoxib and meloxicam—was more common among patients without pouch adenomas, but this difference was not statistically significant (4.2% *vs* 19.7%, $P = 0.07$). There were no differences between the clinical characteristics of the study patients when stratified by the presence of colorectal cancer at the time of surgery ($P = 0.38$).

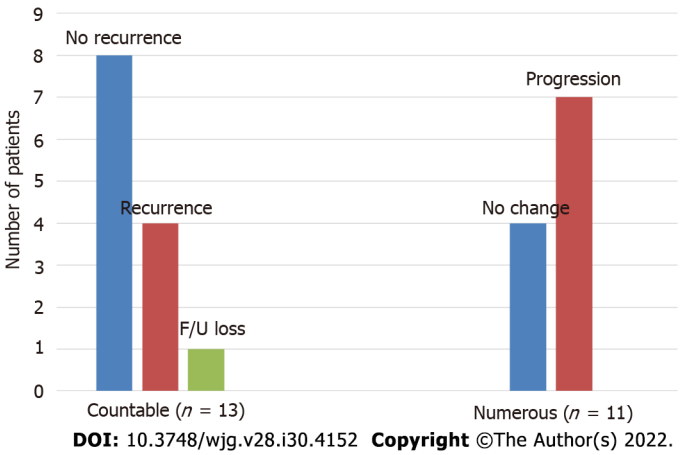
Associations between different clinical factors and pouch adenoma–free survival

Associations between different patient factors and pouch adenoma–free survival were evaluated (Table 3). Among the clinical factors analyzed, multivariate analysis revealed severe colorectal polyposis (with more than 1000 polyps) to be a significant risk factor for pouch adenoma development (HR, 2.49; 95%CI: 1.04-5.96; P = 0.041) (Figure 4). The presence of gastric polyps or a duodenal adenoma had no significant association with pouch adenoma development (P = 0.28 and 0.54, respectively).

DISCUSSION



TPC/IPAA is now being implemented as a standard treatment to eliminate the risk of colorectal cancer in patients with FAP. However, the postoperative development of adenomas in the ileal pouch in these individuals has raised new concerns about appropriate postoperative surveillance and management approaches. In this study cohort, the incidence of pouch adenoma was 25.3% at a median follow-up of 88 mo (IQR, 61-141 mo) after IPAA. The cumulative risk of pouch adenoma was 15.2%, 29.6%, and 44.1% at 5, 10, and 15 years after TPC/IPAA, respectively. There were no cases of high-grade dysplasia or carcinoma in our cohort. We found that a higher colorectal polyp burden at the time of surgery was positively associated with the occurrence of pouch adenoma formation (P = 0.001). These results are consistent with the findings reported in prior studies[9,10,16-18].

Several potential risk factors associated with pouch adenoma development have been investigated previously, but they remain controversial. Consistent with the findings of Tonelli *et al*[10], we found in

Table 3 Risk factors associated with pouch adenoma-free survival

Variable	Univariate analysis		Multivariable analysis	
	HR (95%CI)	*P* value	HR (95%CI)	*P* value
Age	0.97 (0.93-1.01)	0.12

our present analyses that a high colorectal polyp count at the time of IPAA was positively associated with pouch adenoma development. This result is likely to be assumed to be more aggressive disease. However, other authors have not observed an association between the severity of colonic disease and development of pouch adenoma[5].

Mutations of the *APC* gene predispose the carrier to benign polyps and malignancies in the upper gastrointestinal tract. Therefore, the risk of developing small bowel adenomas remains in these individuals even after TPC/IPAA. In this context, gastric or duodenal adenomas may be relevant to development of pouch adenoma. Ganschow *et el*[9] analyzed these variables previously and found that the presence of a gastric adenoma was a significant risk factor for developing a pouch adenoma (P = 0.0019). Several investigator groups have also reported that the presence of a duodenal adenoma is associated with pouch adenoma formation[10,16]. Tonelli *et al*[10] observed that the severity of duodenal polyposis was also relevant in this regard. As with the findings of other studies, our experience has been that patients who develop pouch adenomas are more likely to have had duodenal adenomas, although this was not observed to be a significant risk factor in our present multivariate analysis.

Figure 4 Pouch adenoma-free survival according to colorectal polyp burden at the time of ileal pouch-anal anastomosis. IPAA: Ileal pouch-anal anastomosis.

There has been little research conducted on the association between the site of an *APC* mutation and the occurrence of pouch adenoma. No such association has been identified in earlier studies[9,10,16], nor was such an association identified in our present analysis. However, in previous reports and in our present series, *APC* mutation data were not available for all subjects. Moreover, the low number of patients who underwent this mutation analysis in our present series and in prior study cohorts could not yield the statistical power needed to determine whether the *APC* mutation site is associated with the tendency to develop pouch adenomas. Additionally, a recently published study of genotype-phenotype associations between *APC* mutations and pouch adenomas found that patients with either indel/deletion mutations or exon 15 mutations had a higher tendency for pouch adenoma formation (P = 0.002 and 0.019, respectively)[19]. Hence, further larger-scale research is required to investigate the association between underlying germline mutations and pouch adenoma development.

Several authors have implicated colonic metaplasia of the ileal mucosa—an adaptive response of the neorectum—as a predisposing condition to the onset of ileal adenoma development[20]. Advanced adenomas with high-grade dysplasia were observed in about 18% of previous study samples[5,18]. However, no case of an advanced adenoma was detected in our present study cohort, possibly because adenomas were aggressively removed from our patients, even if small. If ileal pouch adenomas progress to carcinoma, following the classic adenoma-carcinoma sequence, a higher number and larger size of polyps may be associated with the severity of the dysplasia. Tajika *et al*[18] reported that the postoperative time interval was significantly associated with the maximum ileal pouch adenoma size (P = 0.0214). Progression of a pouch adenoma to invasive carcinoma appears to be rare, with an incidence of less than 1% in patients that undergo IPAA[8,9,19]. Moreover, the majority of carcinomas observed after IPAA arise in the residual rectal mucosa or anal canal, although several cases of carcinoma inside the ileal pouch have been described in the past few years[18]. Tonelli *et al*[10] found that the development of malignancy in the terminal ileum can present with a rapid disease course and does not seem to follow the classic adenoma-carcinoma sequence. In some patients, ileal polyps are not detected by endoscopic follow-up until the development of a pouch carcinoma, and the mean interval between pouch construction and the diagnosis of carcinoma can be very short (range, 3-16.4 years).

Clinically, the treatment of pouch adenomas depends on the number, size, shape, and histological features—as for the gastric or duodenal polyps. According to the American Society for Gastrointestinal Endoscopy and British Society of Gastroenterology guidelines, all types of gastric or duodenal polyps detected *via* endoscopy need to be sampled using biopsy forceps for evaluation[21-23]. In the case of adenomatous polyps, these guidelines recommend complete endoscopic removal when it is safe to do so, given the higher probability of malignant transformation[22,23]. Endoscopic follow-up should be repeated at 6 mo for incompletely resected polyps or for those with high-grade dysplasia; it can be conducted again at 12 mo for all other polyps[22]. Although the data are currently limited, 62% of our cohort did not develop adenoma recurrence after adenoma removal, whereas 63% of our patients under observation showed progression. There was no spontaneous diminution or disappearance of any adenoma in our study cohort. Hence, it is important to be aware of the risk of pouch neoplasia when caring for FAP patients after IPAA, and—to enable evaluation and treatment at the same time—we recommend endoscopic resection when the adenoma is detected. If numerous polyps are present, random biopsy sampling is required, and polyps larger than 5 mm should be removed.

Interestingly, our FAP patients who used NSAIDs as a treatment for desmoid tumors rarely developed pouch adenomas. This finding is presumed to be related to the chemopreventive effect of these drugs. Chemoprevention with NSAIDs is a treatment option considered to facilitate the management of the remaining rectum or pouch in selected postoperative patients[13]. In a prior randomized controlled study, patients with FAP and attenuated FAP treated with celecoxib following prophylactic surgery showed reductions in polyp number and diameter[24]. NSAIDs may thus be considered if not all of the numerous polyps within the pouch can be removed, although there are currently no Food and Drug Administration–approved drugs for this indication.

There were some limitations to this study. First, this was a retrospective cohort study with a small sample size, and there may have been unknown confounders. However, as we were investigating a rare disease, there have been few studies to date that have analyzed a substantial number of affected patients. Therefore, in relative terms, our sample size was large, and the patients were followed for a considerable length of time. A second limitation was that whereas all of the patients had a clinical phenotype of 100 or more colorectal polyps and biopsy-confirmed FAP, *APC* genetic mutation analysis was only performed for about 50% of the patients. This limited the strength of our findings related to these mutations. Additionally, there was no consistent endoscopic treatment standard in our cohort. When a polyp was countable, it was removed regardless of its size. In patients with multiple polyps, however, the individual judgment of the endoscopist determined whether to perform endoscopic resection or observation. The indications used for polyp removal were, therefore, not clear.

Overall, our study findings provide further evidence for the need for standardized endoscopic surveillance of FAP patients following TPC/IPAA. Pouch endoscopy should be performed yearly for these patients, and standardized biopsy and removal protocols are needed if pouch adenomas are observed. Furthermore, surveillance should be tailored depending on the presence and characteristics of the pouch adenoma. In the future, validation of whether an annual endoscopic interval is appropriate is required, as is an evaluation of the feasibility and effectiveness of endoscopic resection of a pouch adenoma.

CONCLUSION

In conclusion, pouch adenomas occur at a fairly high rate over time in association with FAP after IPAA. A high colorectal polyp count increases the risk of developing a pouch adenoma in this patient population. In our experience, the progression of pouch adenomas to high-grade dysplasia or carcinoma is rare. However, this risk is not negligible, and the long-term risk of this cannot presently be well quantified. Close surveillance of the pouch should thus be mandatory, and new guidelines for the management of pouch adenomas are essential.

ARTICLE HIGHLIGHTS

Research background

Restorative total proctocolectomy is now being implemented as a standard treatment to eliminate the risk of colorectal cancer in patients with familial adenomatous polyposis (FAP). However, the postoperative development of adenomas in the ileal pouch in these individuals has raised new concerns about appropriate postoperative surveillance and management approaches.

Research motivation

More information is needed regarding the incidence, natural course, and risk factors associated with pouch adenoma.

Research objectives

To investigate the cumulative incidence and time to development of pouch adenomas and analyze the clinical factors associated with pouch adenoma development among patients with FAP after restorative proctocolectomy.

Research methods

A retrospective cohort study was carried out with 95 consecutive patients with FAP who underwent restorative proctocolectomy at Asan Medical Center (Seoul, South Korea) from November 1989 to December 2018.

Research results

The cumulative risks of pouch adenoma development at 5, 10, and 15 years after pouch surgery were 15.2%, 29.6%, and 44.1%, respectively. Severe colorectal polyposis (with more than 1000 polyps) was a

significant risk factor for pouch adenoma development (hazard ratio, 2.49; 95% confidence interval: 1.04-5.96; $P = 0.041$).

Research conclusions

We recommend endoscopic resection when the adenoma is detected. If numerous polyps are present, random biopsy sampling is required, and polyps larger than 5 mm should be removed. Close surveillance of the pouch should be mandatory, and new guidelines for the management of pouch adenomas are required.

Research perspectives

In the future, validation of whether an annual endoscopic interval is appropriate is required, as is an evaluation of the feasibility and effectiveness of endoscopic resection of a pouch adenoma.

Abstract

BACKGROUND

The critical diagnostic criteria for esophagogastric junction outflow obstruction (EGJOO) were published in the latest Chicago Classification version 4.0 (CCv4.0). In addition to the previous criterion [elevated integrated relaxation pressure (IRP) in supine position], manometric diagnosis of EGJOO requires meeting the criteria of elevated median-IRP during upright wet swallows and elevated intrabolus pressure. However, with the diagnostic criteria modification, the change in manometric features of EGJOO remained unclear.

AIM

To evaluate the esophageal motility characteristics of patients with EGJOO and select valuable parameters for confirming the diagnosis of EGJOO.

METHODS

We performed a retrospective analysis of 370 patients who underwent high-resolution manometry with 5 mL water swallows × 10 in supine, × 5 in upright position and the rapid drink challenge (RDC) with 200 mL water from November 2016 to November 2021 at Peking University First Hospital. Fifty-one patients with elevated integrated supine IRP and evidence of peristalsis were enrolled, with 24 patients meeting the updated manometric EGJOO diagnosis (CCv4.0) as the EGJOO group and 27 patients not meeting the updated EGJOO criteria as the isolated supine IRP elevated group (either normal median IRP in upright position or less than 20% of supine swallows with elevated IBP). Forty-six patients with normal manometric features were collected as the normal high-resolution manometry (HRM) group. Upper esophageal sphincter (UES), esophageal body, and lower esophageal sphincter (LES) parameters were compared between groups.

RESULTS

Compared with the normal HRM group, patients with EGJOO (CCv4.0) had significantly lower proximal esophageal contractile integral (PECI) and proximal esophageal length (PEL), with elevated IRP on RDC ($P < 0.05$ for each comparison), while isolated supine IRP elevated patients had no such feature. Patients with EGJOO also had more significant abnormalities in the esophagogastric junction than isolated supine IRP elevated patients, including higher LES resting pressure (LESP), intrabolus pressure, median supine IRP, median upright IRP, and IRP on RDC ($P < 0.05$ for each comparison). Patients with dysphagia had significantly lower PECI and PEL than patients without dysphagia among the fifty-one with elevated supine IRP. Further multivariate analysis revealed that PEL, LESP, and IRP on RDC are factors associated with EGJOO. The receiver-operating characteristic analysis showed UES nadir pressure, PEL, PECI, LESP, and IRP on RDC are parameters supportive for confirming the diagnosis of EGJOO.

CONCLUSION

Based on CCv4.0, patients with EGJOO have more severe esophagogastric junction dysfunction and are implicated in the proximal esophagus. Additionally, several parameters are supportive for confirming the diagnosis of EGJOO.

Key Words: Esophagogastric junction outflow obstruction; High-resolution manometry; Esophageal motility disorders; Upper esophageal sphincter; Proximal esophagus

Core Tip: This is a retrospective study to evaluate the motility features of esophagogastric junction outflow obstruction (EGJOO). This is the first detailed study of EGJOO based on the latest Chicago Classification. Patients with EGJOO showed more substantial abnormalities at the esophagogastric junction than patients who met the previous criteria, and the motility disorder of EGJOO is implicated in the proximal esophagus. Additionally, the upper esophageal sphincter nadir pressure, proximal esophageal contractile integral, proximal esophageal length, lower esophageal sphincter resting pressure, and integrated relaxation pressure on rapid drink challenge contribute to confirming the diagnosis of EGJOO.

INTRODUCTION

Esophagogastric junction outflow obstruction (EGJOO) is a common type of esophageal motility disorder in patients with dysphagia or chest pain. EGJOO includes a group of heterogeneous disorders with common manometric features for esophageal outflow obstruction. Progress has been made toward understanding the manometric features and symptoms of patients who meet the EGJOO criteria[1-5]. The Chicago Classification version 4.0 (CCv4.0) updated the critical diagnostic criteria for the manometric diagnosis of EGJOO, including increased median-integrated relaxation pressure (IRP) in supine and upright positions, ≥ 20% elevated intrabolus pressure (IBP) in the supine position, and evidence of peristalsis[1]. A clinically relevant conclusive diagnosis of EGJOO requires a manometric diagnosis of EGJOO as described above, and clinically relevant symptoms with at least one of the complementary tests, including timed barium esophagram and functional lumen imaging probe. Additional provocative tests including rapid drink challenge (RDC), solid test swallows, or pharmacologic provocation may also strengthen the confidence in an EGJOO diagnosis and helps to identify the causes of symptoms, particularly in borderline cases. Compared with the previous version (v3.0)[6], the new diagnostic criteria provided a more rigorous definition for EGJOO by adding criteria for median IRP in the secondary position, IBP, clinically relevant symptoms, and complementary tests, which aid in distinguishing pathological motility disorder and abnormal manometry caused by mechanical effect, opioid use, or other nonpathological motility disorders[7]. However, the change in manometric features of EGJOO with the diagnostic criteria modification remained unclear. This study aims to investigate the esophageal motility features of patients with the manometric diagnosis of EGJOO and to identify high-resolution manometry (HRM) parameters that are supportive for confirming the diagnosis of EGJOO.

MATERIALS AND METHODS

Patient and data selection

Patients who completed esophageal HRM and upper gastrointestinal endoscopy from November 2016 to November 2021 at Peking University First Hospital were retrospectively analyzed. Exclusion criteria included: (1) Patients under 18 years of age; (2) A history of upper gastrointestinal or mediastinal surgery; (3) Previous endoscopic treatment for esophageal motor disorders; (4) Diseases with abnormal intraabdominal pressure, such as intestinal obstruction or ascites; (5) Use of opiates; and (6) Secondary factors identified by upper gastrointestinal endoscopy or endoscopic ultrasonography, especially for hiatal hernia, infiltrative disease, mechanical obstruction, and extrinsic compression. The normal HRM group was obtained from patients who underwent HRM for mild symptoms such as dysphagia, retrosternal pain, regurgitation, or heartburn, with normal HRM results. The patients also fulfilled normal results in pH-monitoring and upper gastrointestinal endoscopy, in order to exclude the possibility of organic diseases. Demographic data, including age, gender, body mass index (BMI), previous medical and surgical history were collected, and symptoms were extracted from self-report questionnaires completed by patients before HRM. The Institutional Review Board (IRB) of the Peking University First Hospital approved the study protocol (2022-099). The IRB waived the requirement for informed consent because our retrospective analysis used completely anonymized data.

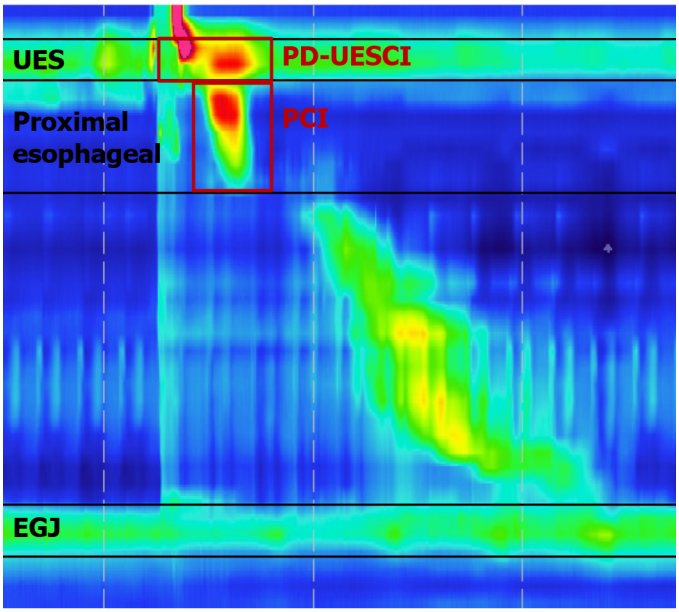
HRM protocol

HRM studies were conducted according to standard clinical protocol, using a 4.2-mm outer diameter, 36-sensor solid-state HRM catheter (ManoScan™, Medtronic, Los Angeles, CA, United States)[8]. Experienced nurses performed nasal canal anesthesia and transnasal placement of the solid-state manometry catheter with the patient sitting upright after an 8-h fast. Sensors were positioned to ensure a complete record of the hypopharynx, esophagus, and proximal stomach. The manometric protocol consisted of a landmark phase captured during a quiet rest in the supine position at the beginning, followed by ten 5-mL ambient temperature water swallows in the supine position, then five 5-mL water swallows in the upright position, with 30 s between each swallow, and finally a RDC of 200 mL water in the upright position.

HRM data analysis

HRM Clouse plots were analyzed using computerized HRM analysis software (Manoview, Medtronic). All pressure measurements were referenced to the gastric pressure.

Upper esophageal sphincter parameters[9,10]: Upper esophageal sphincter (UES) parameters were measured within the UES high-pressure zone defined by a 20-mmHg isobaric contour, consisting of UES length (UESL), UES resting pressure (UESP), nadir pressure (UESNP), and postdeglutitive UES contractile integral (PD-UESCI). PD-UESCI was measured by the smart mouse at the beginning of the deglutitive UES relaxation to the end of the proximal esophageal contraction or the beginning of the transition zone (Figure 1).



Proximal esophageal parameters[9,11]: Proximal esophageal parameters measured from the lower border of the UES to either a break between the proximal and distal segment or the area with the lowest pressure between the proximal and distal segment of the contraction in patients showed no break in the 20-mmHg isobaric contour. Measurements of the proximal esophageal segment included proximal esophageal segment length (PEL), proximal latency (PL, defined as the time interval between UES relaxation to the transition zone), and proximal esophageal contractile integral (PECI, = amplitude × duration × length, measured using a 20-mmHg pressure threshold).

Esophageal body parameters[12]: Esophageal shortening during RDC (ES-RDC) was defined as an upward lift of lower esophageal sphincter (LES) for more than 1 cm, as measured by the length variation between the baseline position of the LES before RDC and its maximal axial position during RDC or within 60 s after the start of RDC. The distal latency (DL) and distal contraction integral (DCI) were calculated automatically using the ManoView system.

Esophagogastric junction parameters[13]: The LES resting pressure (LESP), IBP were calculated automatically using the ManoView system. The median IRP in the supine and upright positions was selected from a list of IRP in each position. The IRP on RDC was assessed in the window beginning with dilatative UES relaxation to the end of esophagogastric junction (EGJ) relaxation for free drinking lasting less than 30 s, or during the first 30 s of the window for free drinking lasting longer.

Statistical analysis

Statistical analysis was performed using SPSS 25.0, and GraphPad Prism 8.0. The chi-square test was used for the comparison of categorical variables. The Student's *t*-test and analysis of variance were used to compare quantitative data with normal distribution between groups, and the results are expressed as mean ± SD. Multivariate analysis was performed with stepwise variable selection. The receiver-

Figure 1 Key metrics of Clouse plots used in our study. The postdeglutitive upper esophageal sphincter (UES) contractile integral was measured using a 20-mmHg pressure threshold from the beginning of the deglutitive UES relaxation to the end of the proximal esophageal contraction or the beginning of the transition zone. The proximal esophageal contractile integral was measured using a 20-mmHg pressure threshold from the lower border of the UES to either a break between the proximal and distal segment or the area with the lowest pressure between the proximal and distal segment of the contraction in patients showed no break in the 20-mmHg isobaric contour. UES: Upper esophageal sphincter; PD-UESCI: Postdeglutitive upper esophageal sphincter contractile integral; PCI: Proximal contractile integral; EGJ: Esophagogastric junction.

operating characteristics (ROC) curve was used to illustrate the diagnostic ability of the HRM parameters for EGJOO. A P value < 0.05 was considered statistically significant.

RESULTS

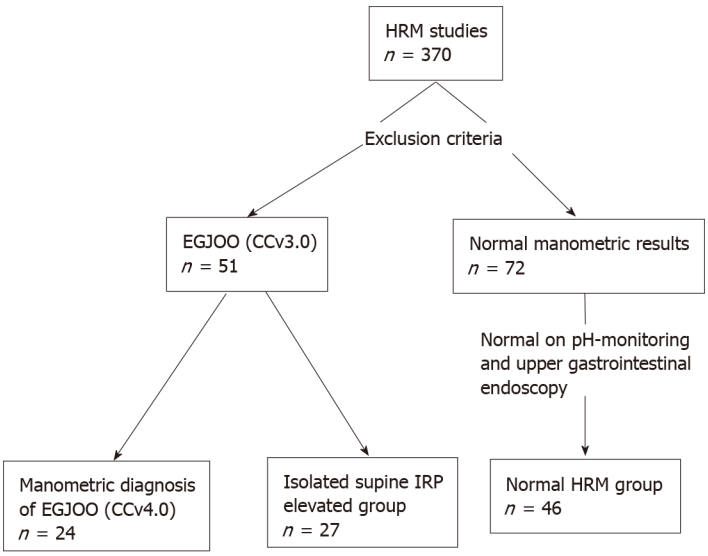
Patient characteristics

Fifty-one patients (33 female, 59.5 ± 1.7 years) fulfilling the criteria of EGJOO (CCv3.0) were identified, with supine IRP ≥ 15 mmHg (Medtronic) and evidence of peristalsis. Among them, 24 patients (14 female, 62.7 ± 2.7 years) met the manometric definitions of EGJOO (CCv4.0), while 27 patients (19 female, 56.6 ± 11.1 years) failed to meet the updated EGJOO criteria formed the isolated supine IRP elevated group, with either normal median IRP in upright position or less than 20% of supine swallows with elevated IBP. The normal HRM group comprised 46 patients (24 female, 50.2 ± 2.2 years) with normal HRM results (Figure 2). Patients in the EGJOO group were older than the normal HRM group. There was no difference in gender or BMI between these three groups. As for symptoms, among the 24 patients with manometric diagnosis of EGJOO (CCv4.0), there were seven with dysphagia and five with retrosternal pain that might be clinically relevant. Symptoms were also counted in isolated supine IRP elevated group and normal HRM group as shown in Table 1. The occurrence of dysphagia, retrosternal pain, and regurgitation did not differ between these three groups. Among the 24 patients with manometric diagnosis of EGJOO (CCv4.0), there were five patients with spastic features, five with hypercontractile features, two with ineffective motility, and twelve with no evidence of peristalsis disorders.

Esophageal HRM parameters

Table 2 details the differences in manometric parameters among EGJOO, isolated supine IRP elevated group, and the normal HRM group.

UES parameters: UESNP was significantly higher in the EGJOO group and the isolated supine IRP elevated group than in the normal HRM group. There was no significant difference in UESL, UESP, and PD-UESCI between the three groups.



Proximal esophageal parameters: Proximal esophageal contractile function was weaker in the EGJOO group than in the normal HRM group, specifically PEL and PECI. Consistently, PEL was lower in the EGJOO group than in the isolated supine IRP elevated group. There was no difference in PL in the EGJOO group, isolated supine IRP elevated group, and the normal HRM group.

Table 1 Patient characteristics

	EGJOO (*n* = 24)	Isolated supine IRP elevated (*n* = 27)	Normal HRM (*n* = 46)	*P* value
Demographics

Figure 2 Patient flow. HRM: High-resolution manometry; EGJOO: Esophagogastric junction outflow obstruction; CCv3.0: Chicago Classification version 3.0; CCv4.0: Chicago Classification version 4.0; IRP: Integrated relaxation pressure.

Esophageal body parameters: There was no significant difference in DL, DCI, and ES-RDC among the three groups.

EGJ parameters: Patients with EGJOO exhibited stronger contractile function in EGJ than in the isolated supine IRP elevated group and the normal HRM group, including LESP, IBP, median supine IRP, median upright IRP, and IRP on RDC.

The multivariate analysis revealed that PEL, LESP, and IRP on RDC are factors associated with EGJOO (Table 3).

Relationship between symptoms and parameters

We compared parameters based on symptoms for the 51 patients with elevated IRP. Patients with dysphagia showed significantly lower PD-UESCI (377.60 ± 36.67 *vs* 517.14 ± 30.47 mmHg·s·cm, $P = 0.017$), PECI (200.25 ± 39.18 *vs* 315.08 ± 30.24 mmHg·s·cm, $P = 0.048$) and PEL (4.43 ± 0.42 *vs* 5.75 ± 0.24 cm, $P = 0.008$) than patients without dysphagia. PEL was higher in patients with retrosternal pain, compared to patients without the symptom (6.43 ± 0.46 *vs* 5.23 ± 0.24 cm, $P = 0.046$) (Figure 3).

Predictors of EGJOO

The ROC analysis discovered HRM parameters that helped identify EGJOO (Table 4). The area under the curve (AUC) of LESP in predicting EGJOO is 0.85, with the optimal cutoff at 40.20 mmHg, yielding a

Table 2 High-resolution manometry parameters of the patients

HRM findings	EGJOO (*n* = 24)	Isolated supine IRP elevated (*n* = 27)	Normal HRM (*n* = 46)	*P* value

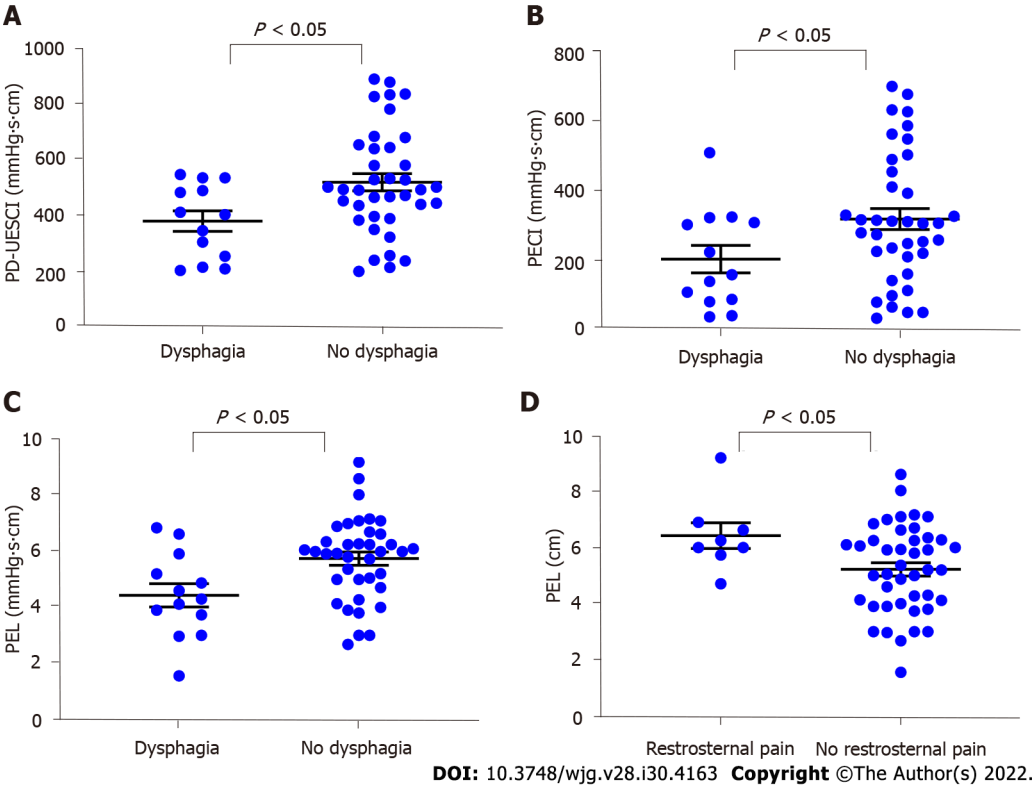
sensitivity of 68.2% and specificity of 85.1%. IRP on RDC achieved an AUC value of 0.81, with the optimal cutoff at > 10.75 mmHg and sensitivity and specificity of 50.0% and 98.5%, respectively. UESNP, PEL, and PECI showed the best predictive value for EGJOO, with cutoff values of 1.15 mmHg (AUC 0.66), 4.76 cm (AUC 0.67), 312.35 mmHg·s·cm (AUC 0.67), respectively.



DISCUSSION

In this study, we mainly assessed the clinical and manometric characteristics of EGJOO based on the Chicago Classification version 4.0 (CCv4.0) to reveal potential changes in esophageal dynamics based on

Table 4 Receiver-operating characteristic analysis for esophagogastric junction outflow obstruction

	Cutoff	AUC	95%CI	Sensitivity (%)	Specificity (%)

Figure 3 Comparisons of parameters according to symptoms in 51 patients with elevated integrated relaxation pressure. A: Patients with dysphagia showed lower postdeglutitive upper esophageal sphincter contractile integral than patients without dysphagia; B: Patients with dysphagia showed lower proximal esophageal contractile integral than patients without dysphagia; C: Patients with dysphagia showed lower proximal esophageal length (PEL) than patients without dysphagia; D: Patients with retrosternal pain showed higher PEL than patients without retrosternal pain. PD-UESCI: Postdeglutitive upper esophageal sphincter contractile integral; PECI: Proximal esophageal contractile integral; PEL: Proximal esophageal length.

the new diagnostic criteria, and we identified parameters that help distinguish the EGJOO.

Based on our observations, older people had a higher likelihood of being diagnosed with EGJOO according to manometric results. The EGJOO group showed no significant difference in symptom distribution pattern compared with the isolated supine IRP elevated group and the normal HRM group. Therefore, more manometric features and additional examinations are required for a better understanding of EGJOO.

The nadir UES residual pressure (UESNP) was reported to be higher in EGJOO (CCv3.0) than in normal controls[2,14]. Within EGJOO, higher UESNP was observed in motor disorders compared to mechanical etiologies and was a potential predictor of symptom recurrence after myotomy, with a cutoff level of 2 mmHg[2]. Based on our initial findings, patients with EGJOO and isolated supine IRP had significantly higher UESNP than the normal HRM group. The findings support the hypothesis that the UES is hypertonic with impaired relaxation, which may serve as a protective mechanism to facilitate esophageal clearance and prevent aspiration pneumonitis under IRP elevation[15]. Further ROC analysis revealed that UESNP elevation might serve as a feature for confirming EGJOO.

Previous studies have linked proximal esophageal motility abnormalities to achalasia[9]. The PECI of type 1 achalasia patients was weaker than that of healthy volunteers, but there was no difference between EGJOO (CCv3.0) and health volunteers, and patients with aberrant PECI had more severe upper gastrointestinal symptoms than patients with normal PECI[9]. It is worth noting that EGJOO (CCv4.0) group had weaker PECI than the normal HRM group, while patients with isolated IRP elevation had no difference compared to the normal HRM group. PECI resulted in a limited value for confirming the diagnosis of EGJOO. Furthermore, our findings suggest that PEL is lower in patients with EGJOO than patients with isolated elevated supine IRP or normal HRM, which might also serve as a feature that strengthens the confidence in an EGJOO diagnosis. The above results indicate that based on the updated criteria, EGJOO dysfunction may involve the proximal esophagus, while patients with isolated supine IRP elevated had no such features. It is reasonable to speculate that patients with EGJOO have common changes in proximal esophageal dynamic features, although further studies are required to reveal the underlying pathophysiological mechanism.

With our current analysis of symptoms, postdeglutitive contraction of the UES and proximal esophagus were weaker, and PEL was significantly lower in patients with dysphagia compared to patients without the symptom, indicating that in patients with impaired EGJ relaxation, dysphagia may represent a potential dysfunction of the UES and proximal esophagus.

Esophageal shortening has been proposed as an outcome of longitudinal muscle contraction, and esophageal shortening during the rapid drink test was mainly associated with impaired EGJ relaxation or major peristalsis disorders, particularly achalasia[12]. In our study, the incidence of ES-RDC had a marginal difference between the three groups, which is comparable with the motor pattern observed in achalasia.

In this study, LESP increased progressively from normal HRM to the isolated supine IRP elevated and EGJOO groups, with significant differences between groups. LESP was critical in the evaluation of EGJ obstruction. Furthermore, ROC curve analysis revealed that LESP had the highest differential diagnostic efficacy of EGJOO, indicating that the value of LESP is helpful in the assessment of EGJOO.

CCv4.0 also highlights the role of ancillary manometric evaluations, such as RDC, to identify the causes of symptoms and elicit evidence of obstruction. Our study performed IRP on RDC, which was significantly higher in the EGJOO group than in other groups, while the isolated supine IRP elevated group showed no difference compared with the normal HRM group, indicating that Chicago Classification updates filtered out EGJ dysfunction with more severe obstruction. It is worth noting that IRP on RDC greater than 12 mmHg (Medtronic software) indicates achalasia and may correlate with symptom severity[1,13,16]. The ROC analysis revealed that a high IRP on RDC is useful for confirming the diagnosis of EGJOO with high specificity (98.5%), but low sensitivity (50.0%).

Based on CCv3.0, a significant proportion of EGJOO is associated with the effect of artifact, hiatal hernia, mechanical obstruction, opioid effect, or gastric volvulus, but not primary LES dysfunction. Hence, numerous studies focused on the identification of primary motility disorders and excluded motility patterns secondary to medication use, mechanical obstruction, previous surgery, or endoscopic interventions[3,4,17], which are critical in making appropriate therapeutic decisions. Since the morphology of LES is affected by position, the CCv4.0 defines IRP in the upright position and IBP; thus, the Chicago Classification update has reduced the number of clinically irrelevant diagnoses and improved the specificity for EGJOO diagnosis[7,17,18], enabling us to avoid irreversible treatment for these conditions. According to the results of this study, patients with EGJOO had multiple abnormalities in EGJ parameters compared with the isolated supine IRP elevated group, including LESP, IBP, median supine IRP, median upright IRP, and IRP on RDC, implying that the Chicago Classification update aids in the selection of EGJOO with more severe EGJ dysfunction.

Due to the limitations of the retrospective study, our study lacked data on treatment and outcomes of patients, larger cohorts are required to explore the prognostic value of the parameters mentioned above. Based on CCv4.0, additional provocative tests such as solid test swallows, or pharmacologic provocation were recommended, and complementary tests are required for a conclusive, actionable diagnosis of clinically relevant EGJOO, while our study did not include the tests mentioned above and mainly focused on the changes in the manometric diagnosis of EGJOO. Moreover, it is necessary to further investigate the pathophysiological mechanism of the changes in proximal esophageal motility of patients with EGJOO.

CONCLUSION

Conclusively, our current analysis revealed that patients with EGJOO had multiple changes in esophageal parameters based on Chicago Classification updates, especially more severe dysfunction at the esophagogastric junction than the previous diagnostic criteria, and showed multiple abnormalities at the proximal esophagus. The results illustrate that EGJOO is implicated in the proximal esophagus, and Chicago Classification updates improved the specificity for EGJOO diagnosis. Accordingly, we have expanded the valuable parameters for confirming the diagnosis of EGJOO based on CCv4.0, including UESNP, PEL, PECI, LESP, and IRP on RDC. With the advancement of EGJOO research, more

contributions will be provided to the diagnosis and treatment of this type of disorder.

ARTICLE HIGHLIGHTS

Research background

The critical diagnostic criteria for esophagogastric junction outflow obstruction (EGJOO) were published in the latest Chicago Classification version 4.0 (CCv4.0). However, as a result of the diagnostic criteria modifications, the changes in manometric features of EGJOO remained unclear.

Research motivation

To investigate the changes of EGJOO manometric features according to the Chicago Classification updates.

Research objectives

This study focused on evaluating the esophageal motility characteristics of patients with EGJOO, and selecting valuable parameters that are supportive for confirming the diagnosis of EGJOO.

Research methods

A total of 97 patients were enrolled, with 24 patients that met the updated manometric diagnosis of EGJOO (CCv4.0), 27 patients that only met the previous criteria, and 46 patients with normal manometric features served as the normal high-resolution manometry (HRM) group for this study. We collected clinical data, HRM parameters, and conducted comparisons among groups. Factors associated with EGJOO were illustrated by multivariate analysis. Furthermore, valuable parameters that strengthen the confidence in an EGJOO diagnosis were selected by the receiver-operating characteristic analysis.

Research results

EGJOO patients revealed significantly decreased proximal esophageal contractile integral (PECI) and proximal esophageal length (PEL) compared to the normal HRM group, and the features were related to dysphagia. EGJOO patients also had more severe dysfunction of the esophagogastric junction including lower esophageal sphincter resting pressure (LESP), intrabolus pressure, median supine integrated relaxation pressure (IRP), median upright IRP, and IRP on rapid drink challenge (RDC) than patients that only met the previous criteria. Further multivariate analysis revealed that the PEL, LESP, and IRP on RDC are factors associated with EGJOO. Additionally, the upper esophageal sphincter nadir pressure, PECI, PEL, LESP, and IRP on RDC contributes to confirming the diagnosis of EGJOO.

Research conclusions

The updates of Chicago Classification have improved the precision for identification of EGJ dysfunction that may reduce over-diagnosing for EGJOO. The motility disorder of EGJOO is implicated in the proximal esophagus, and the changes of proximal esophagus may relate to dysphagia. Additionally, there are valuable parameters that can be applied for confirming the diagnosis of EGJOO.

Research perspectives

Further investigations are required to reveal the pathophysiological mechanism of the abnormal proximal esophageal motility showed in EGJOO patients, and larger cohorts are required to explore the prognostic value of the parameters mentioned above.

Abstract

BACKGROUND

This is the first study on the epidemiology of inflammatory bowel diseases (IBDs) in Rio Grande do Sul (RS), the southernmost state of Brazil with the country's fifth largest population. Crohn's disease (CD) and ulcerative colitis (UC) are collectively termed IBDs. They have high incidence and prevalence rates in high-income countries, although in recent years there has been a change in the classic geographical distribution of IBDs, with growing rates in traditionally low-incidence regions.

AIM

To estimate the incidence and prevalence of IBDs in the RS state, Brazil, between 2014 and 2019.

METHODS

This is a cross-sectional descriptive observational study. Patients with IBD who had initiated treatment and met the inclusion criteria of the RS state free drug distribution program were included. Data were obtained from registration or renewal records of the RS state specialty pharmacy. The male, female, and total

populations were estimated according to mid-year data from the Brazilian Institute of Geography and Statistics, which served as a reference for calculating the incidence and prevalence rates of IBDs during the study period. Results were described using mean, standard deviation, and range.

RESULTS

We included 1082 patients with IBD, of whom 57.5% were female and 42.5% were male. Patients with CD accounted for 72.45% of the sample, and those with UC accounted for 27.54%. IBD prevalence during the study period was 9.51 per 100000 population, of which 6.89 corresponded to people with CD and 2.62, to people with UC. Incidence rates per 100000 population/year were 2.54 in 2014, 2.61 in 2015, 1.91 in 2016, 0.80 in 2017, 0.83 in 2018, and 0.96 in 2019. The mean IBD incidence rate per 100000 population was 1.61, of which 1.17 corresponded to CD and 0.44, to UC. The mean age was 41 years, and patients were mostly aged 30-40 years. Prevalence by region was higher in the state capital metropolitan area: 12.69 per 100000 population.

CONCLUSION

Our results demonstrated an IBD prevalence of 9.51% and incidence of 1.61 per 100000 population. The patients were predominantly female, and CD was more prevalent than UC.

Core Tip: This is the first study in the state of Rio Grande do Sul to address the epidemiology of inflammatory bowel diseases (IBDs). We assessed the incidence and prevalence of IBDs between 2014 and 2019, including 1082 patients (57.5% female and 42.5% male). Crohn's disease corresponded to 72.45% of the analyzed cases and ulcerative colitis, to 27.54%. Prevalence was 9.51% and the mean incidence rate was 1.61 per 100000 population. The mean age was 41 years, and the capital metropolitan area had the highest prevalence. This study showed a similar prevalence to other studies and a decrease in annual incidence rates.

INTRODUCTION

Inflammatory bowel diseases (IBDs) are characterized by a chronic inflammatory process that compromises the digestive tract. The main presentations are Crohn's disease (CD) and ulcerative colitis (UC), which are chronic idiopathic diseases causing inflammation of the gastrointestinal tract, with individual clinical and pathophysiological characteristics[1-3]. Children and young adults are more commonly affected[4]. Although uncommon, the chronicity, severity, progression, and morbidity of IBDs can significantly affect the patient's quality of life and are associated with an increased risk of hospitalizations and surgery[3,4].

IBDs are contemporary health conditions of industrialized societies. The prevalence of IBDs continues to increase steadily in Western countries, and their incidence is growing in newly industrialized countries. The global spread of IBDs seems to be associated with the Westernization of human diets and environments, affecting the gut microbiota and increasing the risk of IBDs in genetically susceptible individuals. It is therefore important to deepen our understanding of these events to delay the progression of IBDs[5].

Despite the paucity of population-based studies from low- and middle-income countries, epidemiological studies of IBDs have shown increased incidence and prevalence of CD and UC in different parts of the world. The increasing epidemiology of IBDs in newly industrialized countries in Latin America resembles that of high-income countries. Although a stabilization of incidence rates has been observed in many Western countries, the global burden of IBDs is still high, with an estimated prevalence exceeding 0.3% of the population in North America and Europe and 0.7% in Canada in 2018[6].

In newly industrialized countries, obstacles to conducting epidemiological studies of IBDs include the lack of disease surveillance systems and reliable unified health care databases, which are available in high-income countries. In countries of continental dimensions with economic problems such as Brazil,

an additional challenge is the country's generally disorganized health care system, which can result in inadequate records and, consequently, few population-based studies[6]. In this respect, Rio Grande do Sul (RS), the southernmost state of Brazil with the country's fifth largest population, still does not have a specific study on the epidemiology of IBDs. Therefore, the purpose of this study was to estimate the incidence and prevalence of IBDs in the state of RS.

MATERIALS AND METHODS

Study design

This is a cross-sectional descriptive observational study. All patients who had initiated treatment for IBD and met the inclusion criteria for the free drug distribution program of the state of RS between 2014 and 2019 were included. Drugs for the treatment of CD and UC are dispensed by the specialty pharmacy [*Farmácia de Medicamentos Especializados* (FME), or FME for short, in Portuguese] according to clinical protocols and therapeutic guidelines published by the Brazilian Ministry of Health. In Brazil, access to care is provided through private health insurance or the Unified Health System, which is a universal health care system funded by federal taxes and operated by state or municipal governments that includes the public provision of core physician and hospital services without copayments or patient charges. Approximately 22% of the population in the state of RS have private health insurance and only occasionally use the public health system. Therefore, because the FME is a government program within the Brazilian Unified Health System, it is responsible for supplying specialty medications to approximately 78% of the state population, all of them users of the public health system. Data from private health insurance companies are not included in this study.

Demographic characteristics and incidence and prevalence data were obtained from registration or renewal records of the FME. We requested from the State Health Department and its affiliated School of Public Health the data of patients included in the specialty medication distribution programs of the FME, which were provided through administrative and judicial means[7].

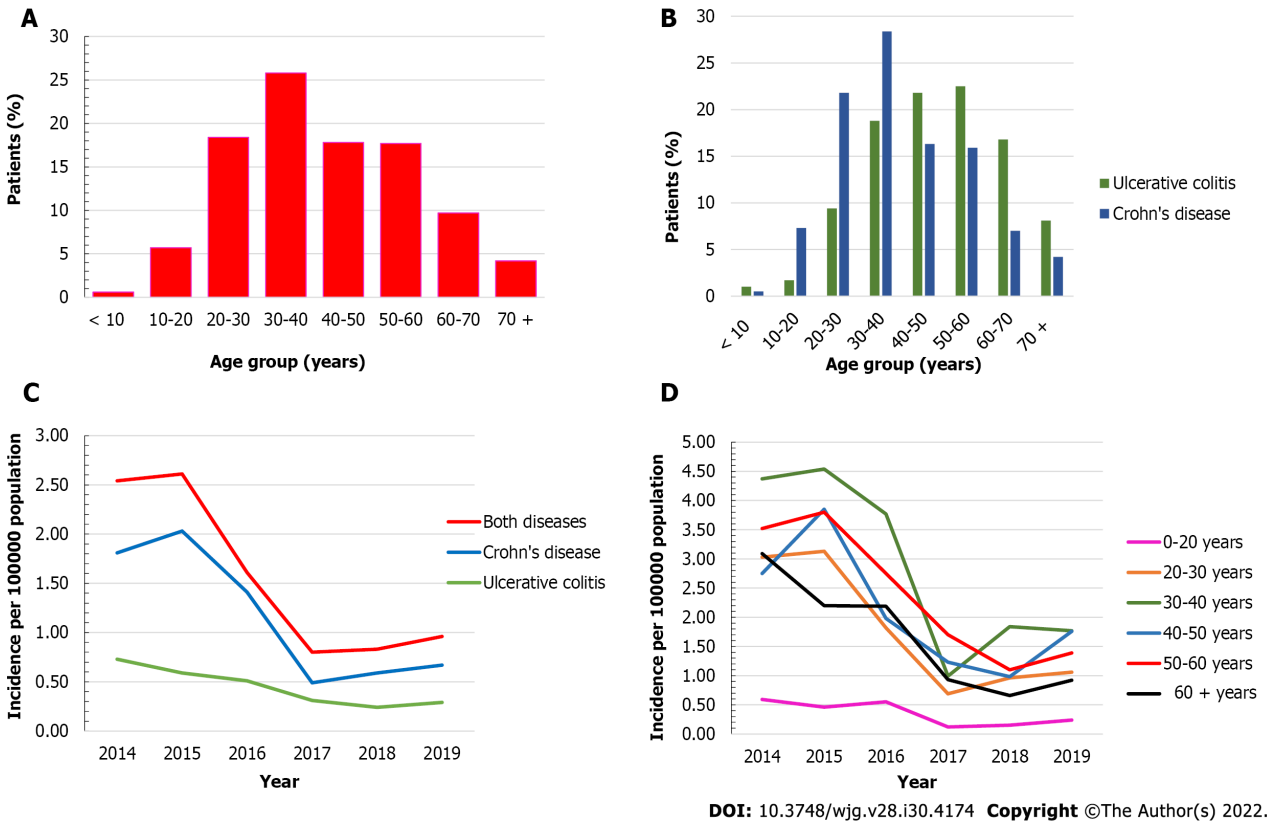
As variables to be analyzed, we included CD or UC diagnosis using International Classification of Diseases codes K50 and K51, date of treatment initiation, sex, and age.

Data analysis

Quantitative variables, such as age, were described using mean, standard deviation, and range. Categorical variables were expressed as counts and percentages. Disease prevalence and incidence were estimated by dividing the annual case notifications by the total estimated population of that year and presented as cases per 100000 population. Binomial distribution was used for obtaining 95% confidence intervals. All comparisons between rates assumed the binomial distribution and were based on the chi-square test. Findings with $P \leq 0.05$ were deemed statistically significant. All estimates of incidence and prevalence were calculated considering the population of the state of RS between 2014 and 2019[8]. Data analysis was conducted using IBM-SPSS, version 25.0.

Ethical considerations

This study did not involve the collection of biological material from participants. Data obtained with the data collection instrument were coded to preserve the participants' privacy and anonymity. All investigators signed a data use agreement.



The study was conducted after approval by the Research Ethics Committees of Pontifícia Universidade Católica do Rio Grande do Sul, Certificate of Presentation for Ethical Appreciation No. 25551019 9 0000 5336, and of the State Health Department and its affiliated School of Public Health, Certificate of Presentation for Ethical Appreciation No. 25551019 9 3001 5312. The study followed the guidelines of Resolution No. 466/12 of the Brazilian National Health Council and the Brazilian General Data Protection Law No. 13709.

RESULTS

This study involved 1082 patients with IBD of a total population of 11377239 people. Of these, 784 (72.45%) had CD and 298 (27.54%) had UC.

Age

Patient age ranged from 1 to 91 years, with a mean of 41 years and standard deviation of 15 years. The highest IBD incidence was between 20 and 60 years of age, and patients were mostly aged 30-40 years (Figure 1A). The highest incidence occurred between the ages of 30 and 40 years for CD, and between the ages of 50 and 60 years for UC. UC affected a higher percentage of people aged 40 years or more ($P < 0.01$), whereas CD affected a higher percentage of people under 40 years of age ($P < 0.01$) (Figure 1B).

Figure 1 Age distribution and incidence rates of patients with inflammatory bowel diseases. A: Age distribution of patients with inflammatory bowel diseases (IBD) (n = 1082), state of Rio Grande do Sul, Brazil, 2014-2019; B: Age distribution of patients with Crohn's disease (n = 784) and ulcerative colitis (n = 298), state of Rio Grande do Sul, Brazil, 2014-2019; C: Annual IBD incidence rates, new cases per 100000 population/year in the state of Rio Grande do Sul (Brazil), 2014-2019; D: Annual IBD incidence rates by age group, new cases per 100000 population/year in the state of Rio Grande do Sul (Brazil), 2014-2019.

Sex

Of all patients with IBD, 622 (57.5%) were female and 460 (42.5%) were male (female-to-male ratio of 1.35:1.00; $P < 0.001$).

Considering CD only, 432 (55.10%) patients were female and 352 (44.89%) were male (female-to-male ratio of 1.23:1.00; $P < 0.001$). For UC, 190 (63.75%) were female and 108 (36.25%) were male (female-to-male ratio of 1.76:1.00; $P < 0.001$).

Incidence and prevalence

Overall, IBD prevalence was 9.51 per 100000 population during the study period (2014-2019), of which 6.89 corresponded to CD and 2.62, to UC. Table 1 shows the sex distribution of prevalence for each disease.

Figure 1C shows the annual incidence rates of IBD in the state of RS. The mean incidence rate was 1.61, of which 1.17 corresponded to CD and 0.44, to UC.

Table 2 shows annual incidence percentages. There was a 62% reduction in the accumulated incidence between 2014 and 2017 ($P < 0.015$). A statistically significant reduction in incidence was observed when comparing 2014 and 2019 ($P < 0.001$).

Figure 1D shows that, when listing annual incidence rates by age group, all groups showed reductions in 2017, with increases in the following years.

DISCUSSION

Historical data on the geographical distribution of IBDs worldwide have shown higher incidence and prevalence rates in high-income countries with predominantly White populations. More recently, IBDs have shown an increasing frequency in all continents, including low- and middle-income countries[2].

In Brazil, IBDs are not notifiable diseases. Therefore, data on the incidence and prevalence of CD and UC are scarce, and health systems lack adequate records. These data would be useful for better organization and political and economic planning of the public health system[9,6].

Table 1 Prevalence of inflammatory bowel diseases in the state of Rio Grande do Sul between 2014 and 2019 (per 100000 habitants)

Item	CD	UC	IBD
Female	7.40	3.26	10.66
Male	6.35	1.95	8.30
Total	6.89	2.62	9.51

CD: Crohn's disease; UC: Ulcerative colitis; IBD: Inflammatory bowel disease.

Table 2 Annual percentages of incidence rates

Year	Percentage
2014-2015	↑ 3%
2014-2015	↓ 26%
2014-2015	↓ 58%
2014-2015	↑ 3%
2014-2015	↑ 15%

In North America, 6.30 to 23.82 new cases per 100000 population are estimated per year for CD, and 8.8 to 23.14 new cases per 100000 population for UC. Prevalence rates are far higher than those in Brazil, with 96.3 to 318.5 cases/100000 population for CD and 139.8 to 286.3 cases/100000 population for UC[1,10].

A cohort study published in the United Kingdom reported incidence and prevalence rates much higher than those in Brazil between 2000 and 2018. The study estimated incidence rates of 28.6, 10.2, and 15.7/100000 population for IBD, CD, and UC, respectively, and prevalence rates of 725, 276, and 397/100000 population[11].

In the state of RS, we observed a predominance of CD during the study period (CD 72.54% and UC 27.54%), which differs from previous studies published in Brazil reporting a predominance of UC[2,3,12,13]. This is consistent with a study conducted in the Southeast region of Brazil by Souza *et al*[14], who reported an increase in CD cases in comparison with UC. These differences between countries and regions may reflect differences in environmental risk factors and genetic predispositions, such as those observed in Europe, where the incidence of NOD2 mutations appears to be higher in the central part of the continent, corresponding to areas with a higher proportion of CD cases[15].

According to the present study, the state of RS had a mean annual IBD incidence rate of 1.61 new cases per 100000 population/year (CD = 1.17 and UC = 0.44 new cases per 100000 population/year) between 2014 and 2019, which is consistent with the results reported by Kaplan *et al*[5] in a systematic review considering 147 studies on IBD worldwide. This comprehensive review demonstrated a CD incidence of 0-3.5 new cases per 100000 population/year, and an UC incidence of 0.19-6.76 new cases per 100000 population/year in Brazil[1]. In comparison, the systematic review by Selvaratnam *et al*[16] on the epidemiology of IBD in South America showed higher incidence rates, ranging from 4.3 to 5.3 per 100000 population/year for UC and from 0.74 to 3.5 per 100000 population/year for CD between 1990 and 2018. Similarly, a Brazilian study conducted in the state of Sao Paulo reported higher incidence rates than those found in the state of RS, with rates of 6.14 for CD and 7.16 for UC (per 100000 population/year)[3].

Regarding IBD prevalence, the mean rate observed during the study period (2014-2019) was 9.51 cases per 100000 population, of which 6.89 corresponded to CD and 2.62, to UC. Prevalence in the state of RS was higher than that reported for Brazil in a systematic review by Ng *et al*[1], with rates ranging from 0.9 to 6.75 cases/100000 population for CD and from 2.42 to 21 cases/100000 population for UC. Prevalence was also higher in a systematic review on IBD epidemiology conducted in South America, reaching 15-24.1/100000 population for UC and 2.4-14.1/100000 population for CD[16]. Similarly, in the Brazilian study by Gasparini *et al*[3], overall prevalence rates were 24.3 for CD and 28.3 for UC per 100000 population.

If we were to analyze the state of RS according to the epidemiological transition theory proposed by Gilaad G Kaplan and Joseph W Windsor in 2021, where each region of the world is at an epidemiological stage (Emergence, Acceleration in Incidence, Compounding Prevalence, and Prevalence Equilibrium), RS would be in the Compounding Prevalence stage, where a steady increase in the population living with IBD is observed despite stabilization or even a decrease in incidence[17].

Regarding patient age, studies show a clear predominance of IBD in individuals aged 20 to 50 years. In our study, the mean age was 41 years. The highest IBD incidence was between 20 and 60 years of age, and patients were mostly aged 30-40 years. The highest incidence was at 30-40 years of age for CD, and at 50-60 years of age for UC. UC showed a trend toward an increased incidence among patients aged 50 to 60 years, and these results are consistent with those of national and international studies[3,11]. A limitation of this variable is that patients were selected through the FME, which provides the age that the patients begin to receive the free specialty medications rather than their age at diagnosis.

Regarding the sex distribution of patients with IBD, we observed a predominance of female patients for both CD and UC, which is consistent with the Brazilian studies conducted by Victoria *et al*[12] in the state of Sao Paulo and Lima Martins *et al*[13] in the state of Espírito Santo. However, our findings differ from those reported in the state of Piauí by Parente *et al*[2], who found a male-to-female ratio of 1.2:1.0 for patients with CD, but with no significant association when considering sex in statistical analyses. Patients with UC, on the other hand, were mostly female (male-to-female ratio of 1.8:1.0, statistically significant)[2].

CONCLUSION

Based on the methodology used in this study, our results demonstrated an IBD prevalence of 9.51% and incidence of 1.61 per 100000 population in the state of RS between 2014 and 2019. The patients were predominantly female, and CD was more prevalent than UC. Our prevalence rate was similar to that reported in previous Brazilian studies. Mean CD and UC incidence rates were, respectively, 1.17 and 0.44 new cases per 100000 population, decreasing until 2017 and increasing afterwards. Women were more affected than men by both CD and UC. IBD occurred more frequently in major urban centers, where the referral centers that care for patients with IBD are often located. The highest IBD incidence was observed in patients aged 20 to 60 years, predominantly between the ages of 30 and 40 years; this was slightly higher than the mean values reported in previous studies.

This is the first study to estimate IBD incidence and prevalence in the state of RS. Our findings suggest that detailed studies in this field are needed to properly understand in which epidemiological stage the state of RS currently is. We believe that the difficulty in keeping accurate epidemiological records and the consequent underestimation of disease burden result from a disorganized health care system, associated with economic problems, inadequate records, lack of population-based studies, and the inaccurate diagnosis of IBD as an infectious disease before the proper knowledge of CD and UC.

ARTICLE HIGHLIGHTS

Research background

First study on the epidemiology of inflammatory bowel diseases (IBDs) in Rio Grande do Sul (RS), the southernmost state of Brazil. IBDs have high incidence and prevalence rates in high-income countries, although in recent years there has been a change in the classic geographical distribution of IBDs, with growing rates in traditionally low-incidence regions.

Research motivation

The importance of this study lies in the lack of research on the incidence and prevalence of IBDs in the state of RS. A challenge for future studies is related to access to data of all patients with IBDs, as these are not notifiable diseases in Brazil.

Research objectives

To determine the incidence and prevalence of IBD in the state of RS. The relevance of the results lies in the lack of knowledge of such data until the present study.

Research methods

This is an observational study of IBDs from the state of RS between 2014 and 2019. Drugs for the treatment of Crohn's disease (CD) and ulcerative colitis (UC) are dispensed by the specialty pharmacy. The variables analyzed were incidence, prevalence, age, sex, and CD or UC.

Research results

These are the first data on the incidence and prevalence of IBDs in the state of RS. However, these are not comprehensive data, as only patients from the public health system were included. Studies also including patients from the private health insurance sector are needed.

Research conclusions

The most relevant of the following questions should be briefly answered: What are the new theories that this study proposes? This study showed a similar IBD prevalence to other Brazilian studies and a decreasing incidence. What are the new methods that this study proposed? We propose that studies covering patients from both public and private health sectors should be conducted.

Research perspectives

Future studies should include a larger sample to provide a more reliable understanding of the real epidemiology of IBDs in the state of RS.

ACKNOWLEDGEMENTS

We thank the RS State Health Department pharmacy and its affiliated School of Public Health for making their data available, and CAPES for the funding that contributed to the improvement of higher education.

Abstract

BACKGROUND

Prospective studies of the long-term outcomes of patients with hepatitis C virus (HCV) infection after treatment with interferon-based therapy (IBT) or direct-acting antivirals (DAA) are limited in many Asian countries.

AIM

To elucidate the incidences of hepatocellular carcinoma (HCC) and

death/transplantation based on treatment with IBT or DAA, to compare the outcomes of the sustained virologic response (SVR) to IBT and DAA, and to investigate outcome-determining factors after SVR.

METHODS

This cohort included 2054 viremic patients (mean age, 57 years; 46.5% male; 27.4% with cirrhosis) prospectively enrolled at seven hospitals between 2007 and 2019. They were classified as the untreated group (n = 619), IBT group (n = 578), and DAA group (n = 857). Outcomes included the incidences of HCC and death/transplantation. The incidences of the outcomes for each group according to treatment were calculated using an exact method based on the Poisson distribution. A multivariate Cox regression analysis was performed to determine the factors associated with HCC or death/transplantation, followed by propensity score matching to confirm the results.

RESULTS

During a median of 4.1 years of follow-up, HCC and death/transplantation occurred in 113 and 206 patients, respectively, in the entire cohort. Compared with the untreated group, the incidences of HCC and death/transplantation were significantly lower in the IBT group [adjusted hazard ratio (aHR) 0.47, 95%CI: 0.28-0.80 and aHR 0.28, 95%CI: 0.18-0.43, respectively] and the DAA group (aHR 0.58, 95%CI: 0.35-0.96, and aHR 0.19, 95%CI: 0.20-0.68, respectively). Among 1268 patients who attained SVR with IBT (n = 451) or DAA (n = 816), the multivariable-adjusted analysis showed no differences in the risks of HCC (HR 2.03; 95%CI: 0.76-5.43) and death/transplantation (HR 1.38; 95%CI: 0.55-3.49) between the two groups. This was confirmed by a propensity score-matching analysis. Independent factors for HCC after SVR were age, genotype 1, and the presence of cirrhosis.

CONCLUSION

Treatment and achieving SVR with either IBT or DAA significantly reduced the incidences of HCC and mortality in the Asian patients with HCV infection. The risks of HCC and mortality were not significantly different regardless of whether SVR was induced by IBT or DAA.

Key Words: Hepatitis C virus; Direct-acting antiviral; Sustained virologic response; Hepatocellular carcinoma; Mortality

Core Tip: Treatment and sustained virologic response (SVR) with either interferon-based treatment (IBT) or direct-acting antiviral (DAA) significantly reduced the incidences of hepatocellular carcinoma and mortality in our Asian prospective cohort. The risks of HCC and all-cause of mortality were not significantly different regardless of whether SVR was induced by IBT or DAA. After achieving SVR, age, the presence of cirrhosis, and genotype 1 hepatitis C virus infection were indicators of worse clinical outcomes.

INTRODUCTION

Hepatitis C virus (HCV) is a major cause of liver cirrhosis, hepatocellular carcinoma (HCC), and liver-related and overall mortality. In 2019, the World Health Organization estimated that 58 million people worldwide had chronic HCV infection[1]. Currently, this substantial public health burden can be reduced by active screening and treatment with highly tolerable direct-acting antivirals (DAA), which result in a cure rate of more than 95% in terms of the sustained virologic response (SVR)[2-4].

From the identification of HCV to the introduction of DAA therapy, interferon (IFN)-based therapy (IBT) was the only option for HCV treatment, with an approximate SVR rate of 50%[5]. Although IBT-induced SVR includes a wide variety of adverse effects and narrow indications, it significantly reduces the incidence of HCC and long-term mortality[6,7]. Furthermore, DAA-induced SVR has resulted in

reductions in hepatic fibrosis[8,9], portal hypertension[10], hepatic decompensation[11], HCC incidence [11,12], and liver-related and overall mortality[11,13]; however, the follow-up durations were relatively short.

To reach the HCV elimination goal of 2030, it is imperative to understand the regional epidemiology and outcomes of HCV. However, prospective studies of the long-term outcomes after treatment with IBT or DAA are limited in many Asian countries, where hepatitis B virus (HBV) is the major cause of liver-related complications. Additionally, comparative studies of the outcomes of SVR induced by IBT and DAA are scarce.

We established a prospective, nationwide, multicenter HCV cohort (the Korea HCV cohort study) funded by the Korean National Institute of Health in 2007. Using these data, we aimed to elucidate the clinical outcomes, including HCC, hepatic decompensation, and all-cause death, among Korean patients with chronic HCV infection. We compared the outcomes based on the antiviral treatments (untreated, IBT, and DAA) and analyzed patients after achieving SVR (IBT-SVR and DAA-SVR groups). Additionally, we investigated outcome-determining factors after SVR.

MATERIALS AND METHODS

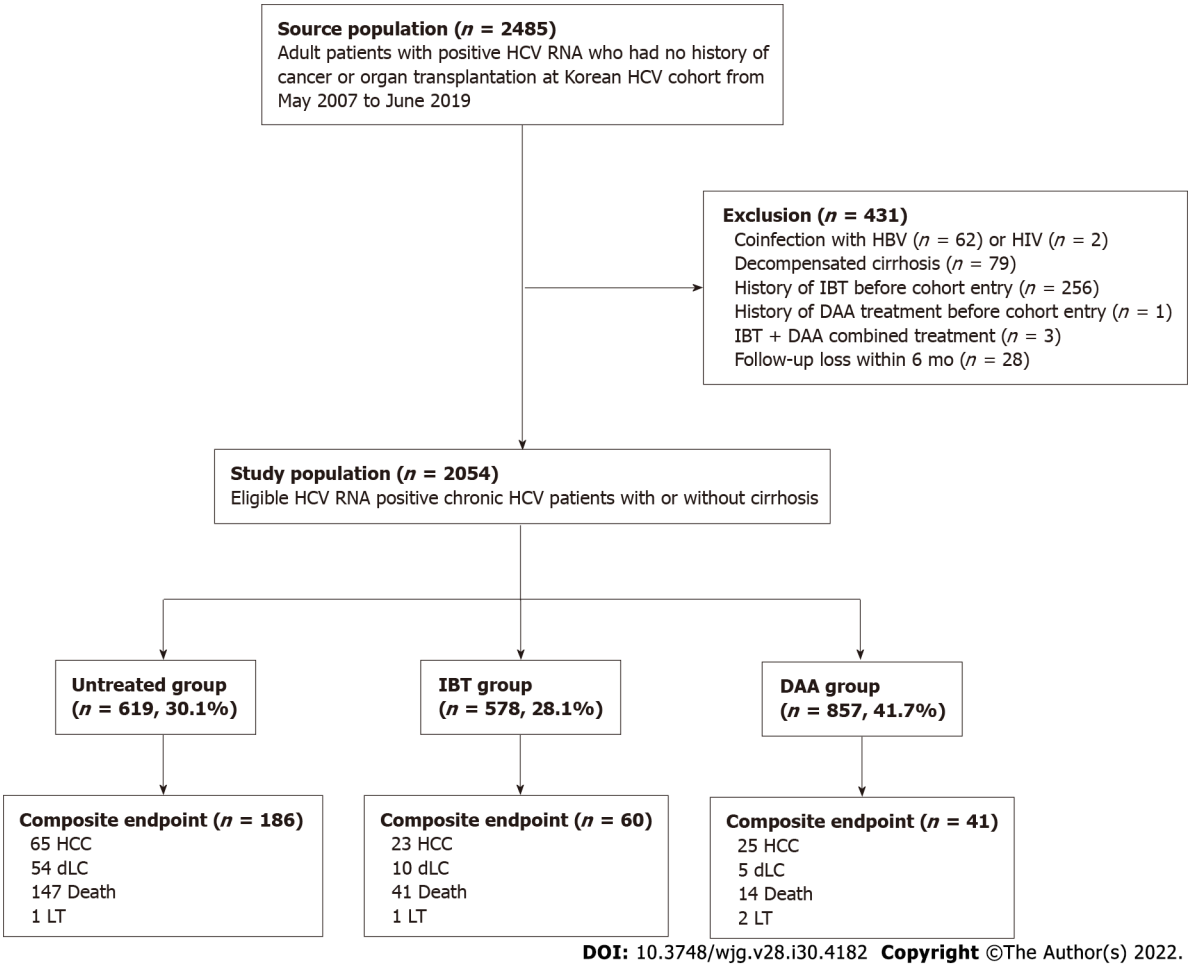
Study subjects

The Korea HCV cohort is a prospective cohort of 2485 adult patients with HCV RNA positivity at seven tertiary centers nationwide enrolled from January 2007 to June 2019 in South Korea. Patients who met any of the following criteria were excluded: Positive serology for HBV surface antigen (n = 62) or HIV (n = 2); decompensated cirrhosis at enrollment (n = 79); previous antiviral treatment before cohort entry (n = 260); and less than 6 mo of follow-up (n = 28). Additionally, patients who had HCC before or at the time of cohort entry were excluded.

Therefore, 2054 viremic patients with or without compensated cirrhosis were analyzed as the entire cohort, which was further classified into three groups based on their treatment: untreated group (n = 619; 30.2%); IBT group (n = 578; 28.1%); and DAA group (n = 857; 41.7%). Patients in the untreated group did not receive IBT or DAA treatment during the entire follow-up period. Subject selection, classification, and overall outcomes are summarized in Figure 1.

In the entire cohort, 1267 patients achieved SVR (61.7%) with IBT (n = 451) or DAA (n = 816); these patients comprised the SVR cohort. Diagnostic criteria for liver cirrhosis were based on histology or at least one clinical sign of portal hypertension, such as cirrhotic features on radiological images, platelet count less than 100,000/mm^3, and documented gastroesophageal varices without hemorrhage. The study protocol was approved by the Institutional Review Board of seven hospitals, and each enrolled patient provided written informed consent.

Data collection at baseline and follow-up visits



At the time of enrollment, trained research coordinators at the seven hospitals interviewed the patients using a standardized questionnaire that included demographic and socioeconomic factors (age, sex, body mass index, education level, and occupation), health behaviors (smoking and alcohol consumption), comorbidities (extrahepatic cancers, thyroid disease, psychiatric disease, diabetes, kidney disease, cerebrovascular disease, and cardiovascular disease), and lifetime exposure to risk factors for HCV infection.

Laboratory data at baseline and follow-up visits were collected from the medical records, including the anti-HCV antibody, serum HCV RNA level, HCV genotype, HBV surface antigen, HBV core antibody immunoglobulin G (anti-HBc IgG), white blood cell count, hemoglobin, platelet count, aspartate aminotransferasel (AST), alanine aminotransferase, alkaline phosphatase, total bilirubin, albumin, creatinine, prothrombin time (PT) and alpha-fetoprotein (AFP). The following three non-invasive serum fibrosis assessment scores were calculated at the index date: The fibrosis-4 (FIB-4) index [14], the AST-to-platelet ratio index (APRI) score[15], and the albumin-bilirubin (ALBI) score[16].

The results of imaging studies, such as abdominal ultrasonography or computed tomography, liver pathology, and transient elastography (FibroScan®, Echosens, Paris, France), were collected when available. Detailed information about antiviral treatment, including therapeutic regimens, duration, and achievement of SVR, was collected from the patients' medical records. These data were entered into the established electronic case report form on the authorized website of the Korean Centers for Disease Control Korea HCV cohort study (http://is.cdc.go.kr/) by the research coordinators. All input data were quality-controlled by independent statistical researchers (Baik D, Choi HY, and Ki M) at least four times per year.

Follow-up evaluations

All patients underwent regular clinical assessments every 3 to 12 mo, and HCV treatment was recommended by their attending physicians according to the treatment guidelines for HCV infection unless there were contraindications or patient's refusal. If the patients were treated, then SVR was evaluated, and regular follow-up visits every 6 to 12 mo after SVR were encouraged. HCC surveillance

Figure 1 Patient flow diagram. DAA: Direct-acting antivirals; dLC: Decompensated liver cirrhosis; HBV: Hepatitis B virus; HCC: Hepatocellular carcinoma; HCV: Hepatitis C virus; IBT: Interferon-based treatment; HIV: Human immunodeficiency virus; LT: Liver transplantation.

using abdominal ultrasonography and serum AFP tests every 6 to 12 mo were recommended according to the pretreatment fibrosis stage. If the patients did not adhere to the regular follow-up schedule, then research coordinators called the patients or their families to encourage them to attend the clinic and to check their survival status, disease progression to hepatic decompensation, or development of HCC. The end of follow-up was defined as the date of death/liver transplantation (LT), or the last follow-up date (June 30, 2020).

Measurement of liver-related outcomes

Outcomes included the incidences of HCC, hepatic decompensation, and death/LT. HCC was diagnosed according to pathology or typical imaging criteria observed on dynamic computed tomography and/or magnetic resonance imaging in accordance with the Korean Liver Cancer Study Group guidelines (similar to major international guidelines)[17]. Decompensated liver cirrhosis was defined as the presence of ascites, jaundice, variceal bleeding, encephalopathy, or a combination of these [18]. All-cause mortality or death/LT was directly documented or indirectly indicated as disqualification from the National Health Insurance status provided in the electronic medical records. In Korea, enrollment in the National Health Insurance is compulsory for all individuals; therefore, disqualification from the National Health Insurance indicates death or emigration in most cases[19]. To verify the survival status, physician-confirmed death certificate data, including the date and cause of death, were obtained from the Statistics Korea mortality database, which was established in 1981.

To calculate the outcomes of the entire cohort, the index date of the entire cohort was defined as the date of cohort entry when HCV RNA positivity was confirmed by the referred clinics. To compare the outcomes of patients with SVR induced by IBT and patients with SVR induced by DAA, the index date for the SVR cohort was defined as the initiation day of the antiviral treatment. SVR was evaluated using an intention-to-treat analysis; therefore, patients who received at least one dose of IBT or DAA were included.

Statistical analysis

Baseline characteristics of the patients were compared using the chi-square test for categorical variables, and a one-way analysis of variance (ANOVA) or *t*-test was used for continuous variables. For multiple comparisons, a one-way ANOVA was used followed by a Bonferroni correction. The total follow-up (in person-years) of each group was calculated by multiplying the cohort population size by the average follow-up in years. Survival time was calculated as the time from cohort entry (the entire cohort) or the start of the first treatment (SVR cohort) until the date of death/LT or the last available follow-up date. A few patients who received a second course of DAA treatment because of failure of the first DAA treatment were censored at the time of retreatment.

The incidences and 95% confidence intervals (CI) of the outcomes for each group based on treatment were calculated using an exact method based on the Poisson distribution. Cumulative incidence curves for outcome development were estimated using the pseudo-Kaplan–Meier method with a clock reset procedure for patients treated with IBT or DAA during follow-up and compared using the log-rank test. Therefore, patients who had received IBT and subsequent DAA treatment were considered as the DAA group, but the period between IBT and DAA treatment was included in the IBT group with no event.

A time-varying Cox regression model was used to determine the factors associated with outcomes, and the adjusted hazard ratio was estimated for the entire cohort and the SVR cohort. In the models, baseline variables (sex, body mass index, alcohol, smoking, HCV genotype) were adjusted, and age, antiviral treatment, laboratory data, achievement of SVR, and presence of cirrhosis were considered time-dependent variables. A multivariate Cox regression analysis was performed to determine the factors associated with HCC or death/LT, and the adjusted hazard ratio was estimated for the SVR cohort at the time of IBT or DAA initiation. Covariates with $P < 0.05$ in the univariate Cox regression model were used as covariates for the multivariate Cox regression analyses. To confirm the multivariate analysis results for the SVR cohort, significant differences in characteristics at the time of initiation of each treatment were adjusted by propensity score (PS) matching for all possible variables, including the time from cohort entry to treatment. We used nearest-neighbor matching with a caliper size of 0.1 and matched the patients using a 1:1 ratio. The covariate balance was considered to be achieved if the absolute standardized difference between the two groups was ≤ 0.1.

All *P*-values were two-sided, and $P < 0.05$ was considered significant. SPSS (version 21; IBC Corp., Armonk, NY, United States) and R (version 4.0.4; http://cran.r-project.org/) software were used for statistical analyses. The R package of *MatchIt* was used for matching analyses.

RESULTS

Baseline characteristics of the entire cohort

The demographic, clinical, and laboratory characteristics of the entire cohort ($n = 2054$), untreated group ($n = 619$; 30.1%), IBT group ($n = 578$; 28.1%), and DAA group ($n = 857$; 41.7%) at the index date are provided in Table 1. The mean age of the patients was 57 years; 46.5% were men and 27.4% had compensated cirrhosis.

Compared with the untreated and DAA groups, the IBT group was significantly younger, had a higher proportion of genotype 2, lower rates of alcohol consumption, cirrhosis and high FIB-4 index values (≥ 3.25), and fewer comorbidities.

Among the DAA group, 14.0% had been treated with an IFN-based regimen after cohort enrollment, and 86.0% were treatment-naive. DAA treatments administered were sofosbuvir plus ribavirin (32.1%), daclatasvir plus asunaprevir (26.3%), elbasvir plus grazoprevir (13.7%), glecaprevir plus pibrentasvir (13.7%), ledipasvir plus sofosbuvir (9.1%), and ombitasvir plus paritaprevir plus ritonavir plus dasabuvir (3.9%).

Incidences of HCC, decompensation, and death/LT in the entire cohort according to treatment, SVR, or the presence of liver cirrhosis

The median time periods between cohort entry (index date) and the end of follow-up were 5.6 years [interquartile range (IQR), 3.4-8.2] for the untreated group, 7.9 years (IQR, 6.1-9.7) for the IBT group, and 3.5 years (IQR, 2.0-5.5) for the DAA group (Table 1). During this period, 113 patients developed HCC, 69 patients experienced hepatic decompensation, 202 patients died (119 Liver related and 83 non-liver related), and four patients underwent LT.

As shown in Table 2, the estimated HCC incidence rates per 100 person-years for the untreated group, IBT group, and DAA group were 1.98 (95%CI: 1.56-2.52), 0.59 (95%CI: 0.39-0.89), and 1.16 (95%CI: 0.78-1.71), respectively (Table 2). The incidence rates of hepatic decompensation per 100 person-years for the untreated group, IBT group, and DAA group were 1.62 (95%CI: 1.24-2.11), 0.25 (95%CI: 0.14-0.47), and 0.23 (95%CI: 0.10-0.55), respectively. The incidence rates of death/LT per 100 person-years for the untreated group, IBT group, and DAA group were 3.33 (95%CI: 2.85-3.91), 0.87 (95%CI: 0.64-1.18), and 0.65 (95%CI: 0.40-1.06), respectively. The incidence rates of all three outcomes were significantly lower in the IBT and DAA groups compared with the untreated group. However, the

[1]Significant alcohol intake is defined as weekly ≥ 210 g for men and ≥ 140 g for women.

Data were presented as mean ± SD, median (interquartile range), or *n* (%). AFP: Alpha-feto protein; ALBI: Albumin-bilirubin; ALP: Alkaline phosphatase; ALT: Alanine aminotransferase; APRI: Aspartate aminotransferase to platelet ratio index; AST: Aspartate aminotransferase; BMI: Body mass index; DAA: Direct acting antivirals; FIB-4: Fibrosis-4; HCV: Hepatitis C virus; IBT: Interferon-based therapy; INR: International normalized ratio; PT: Prothrombin time; WBC: White blood cell.

incidence of HCC in the non-cirrhotic group was not significantly different between the untreated and DAA groups, while the incidences of decompensation and death/LT were significantly lower in the DAA group compared with the untreated group. The cumulative outcome incidences for the untreated, IBT, and DAA groups are shown in Figure 2, and those for the non-cirrhotic and cirrhotic subgroups are shown in Supplementary Figures 1 and 2, respectively.

Multivariable analyses of factors associated with HCC, decompensation, and death/LT in the entire cohort

A multivariable time-varying Cox regression analysis with the untreated group as a reference showed that IBT [hazard ratio (HR), 0.47; 95%CI: 0.28-0.80; $P = 0.005$] and DAA groups (HR, 0.58; 95%CI: 0.35-0.96; $P = 0.035$) were independently associated with a significantly lower risk of HCC (Table 3, model 1). Other independent HCC risk factors were older age (HR, 1.06; 95%CI: 1.03-1.08; $P < 0.001$), male sex (HR, 2.50; 95%CI: 1.37-4.55; $P = 0.003$), genotype 1 (HR, 2.25; 95%CI: 1.45-3.48; $P < 0.001$), the presence of cirrhosis (HR, 3.81; 95%CI: 2.38-6.10; $P < 0.001$), significant alcohol consumption (HR, 2.20; 95%CI: 1.14-4.24; $P = 0.027$), prolonged PT (HR, 2.66; 95%CI: 1.13-6.24; $P = 0.025$), and higher AFP level (HR, 2.12; 95%CI: 1.48-3.05; $P < 0.001$) (Table 3, model 1).

The death/LT incidence decreased independently after antiviral treatment with IBT (HR, 0.28; 95%CI: 0.19-0.43; $P < 0.001$) or DAA (HR, 0.19; 95%CI: 0.10-0.35; $P < 0.001$) (Table 3, model 1). In contrast, older age (HR, 1.05; 95%CI: 1.03-1.06; $P < 0.001$), male sex (HR, 1.70; 95%CI: 1.24-2.33; $P < 0.001$), the presence of cirrhosis (HR, 1.88; 95%CI: 1.34-2.64; $P < 0.001$), lower body mass index (HR, 0.94; 95%CI: 0.89-0.99; $P = 0.019$), lower albumin level (HR, 0.35; 95%CI: 0.25-0.51; $P < 0.001$), and prolonged PT (HR, 2.34; 95%CI: 1.06-5.16; $P = 0.034$) independently increased mortality/LT rates. Antiviral treatment, cirrhosis, albumin level, and PT were independently associated with the risk of decompensation (Table 3, model 1).

We established another multivariable model (model 2) by replacing the achievement of SVR instead of IBT or DAA treatment. A multivariate time-varying Cox regression analysis of the combined outcomes of the untreated and no SVR groups as a reference showed that SVR induced by either IBT or DAA significantly decreased the risk of HCC (HR, 0.41; 95%CI: 0.26-0.65; $P < 0.001$), decompensation (HR, 0.10; 95%CI: 0.04-0.29; $P < 0.001$), and death/LT (HR, 0.26; 95%CI: 0.17-0.39; $P < 0.001$) (Table 3, model 2).

Comparison of the clinical outcomes of the IBT-SVR group and DAA-SVR group in the SVR cohort: Unadjusted and PS-matched results

The SVR cohort comprised 1,268 chronic HCV patients who achieved SVR with IBT or DAA (IBT-SVR group, $n = 451$; DAA-SVR group, $n = 817$). The SVR rates of the IBT and DAA groups were 67.5% and 95.3%, respectively. The baseline characteristics at the time of initiation of treatment of the IBT and DAA groups according to SVR are shown in Supplementary Table 1. The incidence rates of HCC, decompensation, and death/LT were significantly lower in the IBT-SVR group than in the IBT-no SVR group (Supplementary Table 2). In contrast, the incidence rate of death/LT was significantly lower in the DAA-SVR group than in the DAA-no SVR group, whereas the incidence rates of HCC and decompensation did not reach statistical significance, probably because of the short follow-up or rare incidence of decompensation (Supplementary Table 2).

Total number of patients, 2197; number of hepatocellular carcinomas, 113; number of deaths, 202; number of transplantations, 4; number of decompensations, 69. AFP: Alpha-feto protein; aHR: Adjusted hazard ratio; BMI: Body mass index; CI: Confidence interval; DAA: Direct acting antivirals; HCV: Hepatitis C virus; IBT: Interferon-based therapy; PT: Prothrombin time; SVR: Sustained virologic response.

In the SVR cohort (5880.4 patient-years), 30 patients developed HCC, 6 patients had decompensation, 35 patients died, and no patient underwent LT during follow-up. The cumulative incidence rates of HCC at 2 and 5 years were 0.6% and 1.6%, respectively for non-cirrhotic patients with SVR (n = 985), and 4.8% and 10.1%, respectively, for cirrhotic SVR patients (n = 283). The cumulative HCC risk according to the presence of cirrhosis, FIB-4 index, APRI score, and ALBI score were significantly different (Supplementary Figure 3). However, HBcIgG positivity (HR, 0.39; 95%CI: 0.05-2.89; P = 0.358) and the presence of fatty liver disease (HR, 0.16; 95%CI: 0.02-1.18; P = 0.072) were not significant risk factors for the development HCC.

Comparisons of the clinical characteristics and outcomes of the IBT-SVR and DAA-SVR groups before and after PS matching (Table 4) yielded 213 matched pairs of patients from the IBT-SVR and DAA-SVR groups with no significant between-group differences in all baseline variables. Before PS matching, the DAA-SVR group had a significantly higher risk of HCC than the IBT-SVR group (HR, 3.53; 95%CI: 1.47-8.49; P = 0.005) (Supplementary Figure 4A), whereas the risks of decompensation (HR, 2.45; 95%CI: 0.33-18.37; P = 0.382) and death/LT (HR, 1.44; 95%CI: 0.62-3.34; P = 0.400) did not reach statistical significance (Supplementary Figure 4B and C). However, after PS matching, the DAA-SVR group showed no significant differences in the risks of HCC (HR, 2.72; 95%CI: 0.63-11.81; P = 0.179), decompensation (HR, 9.74; 95%CI: 0.42-224.81; P = 0.155), and death/LT (HR, 2.18; 95%CI: 0.47-10.15; P = 0.318) compared with the IBT-SVR group (Figure 3).

Multivariable-adjusted analyses of factors associated with outcomes of the SVR cohort

According to the multivariable-adjusted analysis, the DAA-SVR group did not show any independent differences in the development of HCC (HR, 2.03; 95%CI: 0.76-5.43; P = 0.160) or death/LT (HR, 1.38; 95%CI: 0.55-3.49; P = 0.494) compared with the IBT-SVR group (Table 5). Covariates independently associated with a higher incidence of HCC were older age (HR, 1.05; 95%CI: 1.01-1.10; P = 0.025), genotype 1 (HR, 3.02; 95%CI: 1.18-7.68; P = 0.021), and the presence of cirrhosis (HR, 3.18; 95%CI: 1.33-7.68; P = 0.009) after adjustment for the antiviral treatment regimen, sex, alcohol consumption, diabetes mellitus, albumin level, PT, and AFP level (Table 5). Additionally, covariates independently associated with death/LT risk were the presence of cirrhosis (HR, 2.97; 95%CI: 1.42-6.20; P = 0.004) and PT (HR, 5.27; 95%CI: 1.01-27.53; P = 0.049).

DISCUSSION

We analyzed the incidence rates of HCC, decompensation, and all-cause death/LT in a large, prospective, Asian cohort including 2054 patients with chronic HCV infection. During a median follow-up period of 4.1 years, the risks of HCC, decompensation, and all-cause mortality were significantly lower after treatment with IBT or DAA compared with no treatment.

After statistical adjustment, including a time-varying Cox analysis and PS-matched analysis, the risks of HCC, decompensation, and all-cause mortality were not significantly different regardless of whether SVR was achieved after IBT or DAA treatment; however, the follow-up duration of the DAA group was shorter than that of the IBT group. After achieving SVR, independent factors associated with HCC risk were no treatment, age, male sex, HCV genotype 1, cirrhosis, alcohol consumption, PT, and pretreatment AFP level, whereas independent factors associated with all-cause mortality were cirrhosis and PT.

There are limited studies of the association between antiviral treatment (IBT or DAA) and all-cause mortality, especially those involving Asian cohorts. Many studies focused on liver-related mortality rather than all-cause mortality as the primary outcome after SVR achievement. However, extrahepatic mortality should be considered for patients with HCV because HCV is associated with increased cardiovascular disease events[20] and extrahepatic malignancies such as bile duct cancers and diffuse large B-cell lymphoma[21,22]. Moreover, Tada *et al*[23] reported that IBT could reduce all-cause mortality and HCC risk even in patients who did not achieve SVR. However, the effect of DAA treatment in the absence of SVR on clinical outcomes is unknown. Therefore, this study focused on the effect of treatment on the outcomes including all-cause mortality in the entire cohort, and the effect of SVR induced by IBT and DDA on the outcomes in the SVR cohort.

Recent 5-year follow-up studies after DAA treatment showed that SVR is associated with a gradual but significant reduction in liver fibrosis in terms of FIB-4, METAVIR, transient elastography, and Child-Pugh score[24,25], whereas another study showed that induced SVR was associated with a reduced risk of clinical disease progression in patients with Child-Pugh A cirrhosis but not in patients

Figure 2 Cumulative incidences of hepatocellular carcinoma, decompensation, and death/transplantation in entire cohort. A: Cumulative incidence of hepatocellular carcinoma in the untreated, interferon-based treatment (IBT), and direct-acting antivirals (DAA) groups; B: Cumulative incidence of decompensation in the untreated, IBT, and DAA groups; C: Cumulative incidence of death/transplantation in the untreated, IBT, and DAA groups. DAA: Direct-acting antivirals; HCC: Hepatocellular carcinoma; IBT: Interferon-based treatment.

with Child-Pugh B/C cirrhosis[26]. In this context, our study showed an approximately 85% reduction in the risk of decompensation after IBT or DAA treatment in Child-Pugh A patients, with decompensated cirrhotic patients being excluded from enrollment.

This study demonstrated that treatment with IBT and DAA resulted in risk reductions of 72% (median follow-up, 94.8 mo) and 81% (median follow-up, 42 mo) for all-cause mortality, respectively, compared with no treatment after multivariate adjustment. Similar to previous studies[27], our results showed that even IBT, with its probable adverse events and lower SVR rates, had long-term beneficial effects on mortality. Regarding the benefit of DAA treatment, Butt *et al*[28] (n = 6790), using the Electronically Retrieved Cohort of HCV Infected Veterans (ERCHIVES) data in the United States in

Figure 3 Cumulative incidences of hepatocellular carcinoma, decompensation, and death/transplantation in the matched sustained virologic response cohort. A: Cumulative incidence of hepatocellular carcinoma in the interferon-based treatment-sustained virologic response (IBT-SVR) and direct-acting antivirals-sustained virologic response (DAA-SVR) groups; B: Cumulative incidence of decompensation in the IBT-SVR and DAA-SVR groups; C: Cumulative incidence of death/Liver transplantation in the IBT-SVR and DAA-SVR groups. DAA: Direct-acting antivirals; HCC: Hepatocellular carcinoma; IBT: Interferon-based treatment; SVR: Sustained virologic response.

2017, reported that DAA treatment and the achievement of SVR reduced all-cause mortality by 57% and 43%, respectively, within the first 18 mo of treatment. A prospective cohort study performed in France (n = 9895; follow-up, 33.4 mo) reported a 52% reduction in the risk of all-cause mortality in the DAA-treated group compared with the untreated group in 2019[11]. Compared with these studies, our results showed a higher reduction in the risk of all-cause mortality with DAA treatment. This may be related to the low proportion of patients with advanced fibrosis in the DAA group in our cohort. Additionally, the follow-up duration of this study was relatively longer than the durations used for those studies.

During this study, the achievement of SVR by IBT or by DAA resulted in a 59% reduction in the risk of HCC compared with no treatment or no SVR after multivariable adjustment, similar to previous studies[29,30]. Nonetheless, our results also showed that the HCC risk remained after SVR achievement.

Despite the achievement of SVR, the absolute risk of HCC remains high for patients with cirrhosis; therefore, according to international guidelines, they should be enrolled in an HCC surveillance program[2-4]. However, there is little evidence of the benefits of HCC surveillance for non-cirrhotic chronic HCV patients with SVR, because of the low residual HCC risk. During this study, the non-cirrhotic group had an HCC risk of 0.26 per 100 person-years (5-year cumulative incidence of 1.6%). In particular, the low FIB-4 (5-year cumulative incidence of 0.3%) group had a very low risk of HCC during this study. These results are similar to those of the retrospective REAL-C cohort study that targeted Eastern Asians (5-year cumulative incidence: 1.35 for the non-cirrhotic group and 0.13 for the low FIB-4 group)[30]. These results support the European guidelines, which do not recommend HCC surveillance for fibrosis 0 to 2[4]. However, more long-term follow-up data after achieving SVR are needed.

Identifying the risk factors associated with HCC after SVR is important to the development of a reasonable surveillance strategy. An East Asian retrospective study suggested that among the cirrhotic DAA-SVR group, age older than 60 years, ALBI scores of 2 or 3, and pretreatment AFP > 10 ng/mL were associated with HCC risk; however, among the non-cirrhotic group, only AFP > 10 ng/mL was significant[30]. Additionally, there are many factors associated with HCC risk after SVR, such as clinical factors (age, sex, presence of diabetes, HCV genotype 3, history of IBT), laboratory parameters (platelet count, AFP), and fibrosis stage (determined by histology or estimation by Fibroscan®, FIB-4, APRI, or the presence of esophageal varices) before DAA treatment and at follow-up (determined by Fibroscan®, FIB-4, APRI, alanine aminotransferase, AFP, albuminemia, or VITRO score)[31]. In our study, age, cirrhosis, and HCV genotype 1 (compared with genotype 2) were independent risk factors for HCC after SVR. Therefore, it is necessary to test the HCV genotype even in the therapeutic era of pangenotypic regimens to develop a follow-up strategy after SVR according to the regional distribution of HCV genotypes. These factors should be considered when establishing an optimal HCC prediction model.

Previous studies have suggested a similar risk of HCC development with IBT and DAA treatment [32]. Interestingly, a recent meta-analysis suggested that IBT is better than DAA for preventing the occurrence of HCC in chronic hepatitis C patients after achieving SVR[33]. Biologically, IFN family members, especially class I IFN (IFN-α, IFN-β), have important anti-HCC effects[32]. However, some investigators have suggested that the sudden decrease in viral load caused by DAA treatment causes immune distortion, thus deregulating the antitumor response and releasing precancerous foci from immune surveillance[34,35]. Although it can be explained theoretically, there is little clinical evidence regarding the difference in the HCC risk for patients with DAA-SVR and IBT-SVR. Our results showed significant clinical differences between the IBT-SVR and DAA-SVR groups. Both the multivariable analysis and PS matching analysis showed that the effect of IBT-SVR was not different from that of DAA-SVR on the HCC incidence and all-cause mortality. Recently, some studies reported different effects of IBT-SVR and DAA-SVR on the incidence of diabetes[36] and hematologic malignancies[37]. Therefore, long-term studies of the effects of DAA-SVR are warranted.

To meet the 2030 HCV elimination target of the WHO[1], active testing and enhanced linkage to treatment are important. In this study, 30.1% of patients remained untreated, and this percentage should be reduced. Indeed, the untreated group showed a higher mortality rate of 23.7% (88 Liver related deaths and 59 non-liver related deaths) during the median follow-up of 5.6 years. In the untreated group, 3 patients received IBT after HCC diagnosis, and 19 patients received DAA treatment after HCC diagnosis or a decompensation event. The majority of the untreated patients (78.8%, 457/619) were enrolled in the Korean HCV cohort before June 2015, when the first DAA was introduced, and 46.7% (289/619) died or were lost to follow-up before June 2015. Although DAA therapy is covered by the National Health Insurance System, 30% of the drug price is an out-of-pocket expense of the patients, equaling to approximately 3000 United States dollars. Even in the DAA era, the main reasons for non-treatment are the relatively high price of DAA, old age, and extrahepatic or advanced hepatic malignancy.

One of the strengths of our study was that it was a long-term study involving a prospective, Asian cohort that included both IBT and DAA groups. This study used a well-established protocol, guidelines and database, and the data, including death outcomes, were verified under government guidance. To date, few reports have evaluated and compared clinical outcomes (HCC, death, and decompensation) after IBT and DAA treatment, especially in Asia, where HCV is less prevalent than HBV.

This study had several limitations. First, because it was an observational study, the findings may show selection and confounding biases. Despite this limitation, it would be useful for comparing the effectiveness of IBT and DAA because of the relatively low incidence of clinical events. Second, we used clinical and radiological criteria to diagnose cirrhosis; therefore, some patients with advanced fibrosis may have been included in the non-cirrhotic group. However, we attempted to correct this point using a non-invasive liver fibrosis biomarker. Third, there was a disparity in the follow-up periods of the IBT and DAA groups because of the later introduction of DAA (since 2015 in Korea). Additional long-term follow-up studies evaluating the outcomes of patients with SVR are warranted. Forth, the presence of anti-HBc IgG in HCV patients has been implicated in HCC development, and a non-negligible risk of HBV inactivation during DAA treatment (0.91%)[38]. However, approximately 30% of our patients were not tested for anti-HBc IgG, and none of the anti-HBc IgG-positive patients were tested for HBV DNA during DAA treatment. Likewise, the role of fatty liver in the outcomes of HCV patients was not

completely evaluated owing to missing data. Finally, compared with the IBT era, diagnostic imaging modalities and treatment options for HCC have improved in the DAA era. Therefore, these points could have affected the clinical outcomes of the IBT and DAA groups.

CONCLUSION

This study showed that antiviral treatment significantly reduced the incidences of HCC, decompensation, and mortality in an Asian population, regardless of the use of IBT or DAA. After achieving SVR, age, the presence of cirrhosis, and HCV genotype 1 were indicators of worse clinical outcomes. Therefore, an adequate HCC surveillance strategy after SVR that considers age, the presence of cirrhosis, and genotype should be developed. Additional studies evaluating the long-term DAA outcomes of SVR patients are also warranted.

ARTICLE HIGHLIGHTS

Research background

Sustained virologic response (SVR) with either interferon-based therapy (IBT) or direct acting antivirals (DAA)-induced SVR significantly reduces the incidence of hepatocellular carcinoma (HCC) and long-term mortality in patients with hepatitis C virus (HCV) infection.

Research motivation

Prospective studies of the long-term outcomes for patients with HCV infection after treatment with IBT or DAA are limited in many Asian countries.

Research objectives

We aimed to elucidate the incidences of HCC and death/transplantation based on treatment with IBT or DAA. And, we aimed to compare the outcomes of the SVR to IBT and DAA. Finally, we aimed to investigate outcome-determining factors after SVR.

Research methods

The cohort included 2054 viremic patients (mean age, 57 years; 46.5% male; 27.4% with cirrhosis) prospectively enrolled at seven hospitals between 2007 and 2019. They were classified as the untreated group (n = 619), IBT group (n = 578), and DAA group (n = 857).

Research results

Compared to the untreated group, the incidences of HCC and death/transplantation were significantly lower in the IBT group and the DAA group. SVR induced by IBT or DAA did not show significant differences in the risk of HCC and all-cause mortality. After achieving SVR, age, presence of cirrhosis, and genotype 1 HCV infection were indicators of worse clinical outcomes.

Research conclusions

Treatment and SVR with either IBT or DAA significantly reduced the incidences of HCC and mortality in the Asian prospective cohort.

Research perspectives

This study was a long-term study involving a prospective, Asian cohort that included both IBT and DAA groups. This study used a well-established protocol, guidelines and database, and the data, including death outcomes, were verified under government guidance.

ACKNOWLEDGEMENTS

We deeply appreciate the clinical research coordinators (Lee DE, Kim NH, Jeong DH, Na SM, Kang HY, Jo AR, Han SH, Chung ES, Jeong HY, and Lee HM) for their dedication to this study and the officials of the Korea Disease Control and Prevention Agency (Lee MS, Seong JH, Lee JK, Kee MK, Chung HM, Choi BS, Kim KS, Kang C, Kim SS, and Jee YM) for their strong support of this study.

Abstract

BACKGROUND

Previous meta-analyses, with many limitations, have described the beneficial nature of minimal invasive procedures.

AIM

To compare all modalities of esophagectomies to each other from the results of randomized controlled trials (RCTs) in a network meta-analysis (NMA).

METHODS

We conducted a systematic search of the MEDLINE, EMBASE, *Reference Citation Analysis* (https://www.referencecitationanalysis.com/) and CENTRAL databases to identify RCTs according to the following population, intervention, control, outcome (commonly known as PICO): P: Patients with resectable esophageal cancer; I/C: Transthoracic, transhiatal, minimally invasive (thoracolaparoscopic), hybrid, and robot-assisted esophagectomy; O: Survival, total adverse events, adverse events in subgroups, length of hospital stay, and blood loss. We used the Bayesian approach and the random effects model. We presented the geometry of the network, results with probabilistic statements, estimated intervention effects and their 95% confidence interval (CI), and the surface under the cumulative ranking curve to rank the interventions.

RESULTS

We included 11 studies in our analysis. We found a significant difference in postoperative pulmonary infection, which favored the minimally invasive intervention compared to transthoracic surgery (risk ratio 0.49; 95%CI: 0.23 to 0.99). The operation time was significantly shorter for the transhiatal approach compared to transthoracic surgery (mean difference -85 min; 95%CI: -150 to -29), hybrid intervention (mean difference -98 min; 95%CI: -190 to -9.4), minimally invasive technique (mean difference -130 min; 95%CI: -210 to -50), and robot-assisted esophagectomy (mean difference -150 min; 95%CI: -240 to -53). Other comparisons did not yield significant differences.

CONCLUSION

Based on our results, the implication of minimally invasive esophagectomy should be favored.

Key Words: Surgery; Esophageal cancer; Esophagectomy; Network meta-analysis; Minimally invasive; Laparoscopy

Core Tip: Minimally invasive laparoscopic techniques should be the preferred approach for the treatment of esophageal cancer, due to the lower incidence of postoperative pulmonary complications.

INTRODUCTION

Esophageal cancer is the eighth most common type of cancer worldwide[1], with an incidence of 5.2 per 100000 for squamous cell cancer (SCC) and 0.7 per 100000 for adenocarcinoma (AC)[2]. While the prognosis varies between the two histological diagnoses, both AC and SCC are associated with poor clinical outcomes, with a 5-year survival rate of 20%[3].

Surgical therapy plays an essential role in the treatment of esophageal cancer. However, it cannot be routinely used due to the late diagnosis, as symptoms usually occur when the cancer is already unresectable[4]. Traditionally, open surgical interventions are performed, including transhiatal and transthoracic techniques. A meta-analysis comparing these two open surgical modalities did not find a significant difference in 5-year survival[5]. While both techniques are successful in terms of removing the neoplasm, open esophagectomies are associated with significant limitations, most importantly, postoperative morbidity[6,7].

A transition to non-open surgical techniques has been the trend in almost every field of surgery in recent years[8]. A wide variety of non-open techniques are available, including minimally invasive surgery (thoracolaparoscopic) surgery or even robot-assisted esophagectomy[9,10]. In the form of hybrid surgical intervention, a combination of open and non-open technique is available[11].

Previous meta-analyses have compared the different types of surgical techniques, with variable success and significant limitations[12-19]. To date, convincing evidence is missing regarding the optimal surgical approach of resectable esophageal cancer, as it is presented in a recent guideline[20].

Network meta-analysis (NMA) is a relatively novel methodology, which allows the direct and indirect comparison of multiple interventions, thus providing more information than traditional meta-analyses. Indirect comparisons can be made in the case of missing trials comparing two interventions if those are compared with a third intervention[21]. Several meta-analyses were carried out focusing on esophageal cancer surgery, but none of those addressed the problem of the wide variety of surgical techniques.

The purpose of our study was to provide objective evidence considering the surgical treatment of resectable esophageal cancer by comparing each treatment modality in the form of an NMA and possibly rank the different approaches.

MATERIALS AND METHODS

The NMA was conducted according to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses-NMA guideline[22].

Protocol

The NMA protocol was registered in advance in PROSPERO under the number CRD42020160978. Analyses of the mortality and quality of life could not be carried out due to the low number of reporting articles. The risk of bias was assessed using an updated risk assessment tool.

Search strategy and inclusion criteria

We conducted a systematic search of the MEDLINE (*via* PubMed), EMBASE, *Reference Citation Analysis* (https://www.referencecitationanalysis.com/) and Cochrane Central Register of Controlled Trials (CENTRAL) from initiation until 2019 November to identify studies, comparing at least two types of esophagectomies from transthoracic, transhiatal, hybrid, laparoscopic or robot-assisted approach treating esophageal cancer without the restriction of histological subtype and an NMA was performed. The following search key was used: (((esophagus OR oesophagus OR esophageal OR oesophageal) AND (tumor OR tumour OR malign* OR cancer OR adenocarcinoma OR carcinoma)) AND (esophagectomy OR oesophagectomy OR Ivor-Lewis OR „Ivor Lewis" OR hybrid OR laparoscop* OR „minimal invasive")) AND random*. We also reviewed the reference lists of eligible articles for further studies. Only randomized controlled trials (RCTs) were included.

Selection and data extraction

After the removal of duplications, two independent reviewers (Szakó L, Engh MA) executed the selection first by title, second by abstract, last by full text following pre-discussed aspects. Data extraction was done by the same two independent reviewers (Szakó L, Engh MA) onto a pre-established Excel worksheet (Office 365, Microsoft, Redmond, WA, United States). Extracted data consisted of the year of publication, name of the first author, study design, country, applied surgical modalities, mortality, overall survival rate (referred as survival), adverse events (AEs), blood loss, length of hospitalization, length of surgical procedure, and demographic data including age, male-female ratio, and SCC/AC ratio. Disagreements regarding both selection and data extraction were resolved by consensus. If consensus could not be reached, a third reviewer (Dömötör RZ) resolved the disagree-ment.

Statistical analysis

The Bayesian method was used to perform pairwise meta-analyses and NMAs. All analyses were carried out using a random effects model. To ensure the interpretability of the NMA results (pooled of direct and indirect data), we presented the geometry of the network, the results with probabilistic statements, and estimates of intervention effects along with their corresponding 95% confidence intervals (CIs), as well as forest plots for ranking the interventions, we chose to use the surface under the cumulative ranking (SUCRA) curve, which provides a numerical summary of the rank distribution of each treatment.

Risk of bias assessment and quality of evidence

The risk of bias assessment was performed at the individual study level, according to the Revised Cochrane risk-of-bias tool for RCTs[23].

The Grading of Recommendations Assessment, Development, and Evaluation system was used to assess the certainty of evidence into four levels: high, moderate, low, and very low. The certainty of the evidence was classified into four levels: high, moderate, low, and very low. Two independent reviewers (Szakó L, Engh MA) decided the overall quality of the evidence[24]. Disagreements were resolved by consensus. If consensus could not be reached, a third reviewer (Dömötör RZ) resolved the

disagreement.

RESULTS

Selection process

The database search yielded 3335 records, of which 2002 articles were left after removing duplicates. Twenty-one full-text articles were screened for eligibility. Finally, we included 11 RCTs (25-35), including 1525 patients, in the quantitative synthesis (Figure 1). Baseline characteristics of the enrolled studies are presented in Table 1[25-35].

Outcomes

A significant difference was found for pulmonary infection, which favored the minimally invasive intervention compared to transthoracic surgery (relative risk [RR]: 0.49, 95%CI: 0.23-0.99) (Figure 2). Operation time was significantly shorter for the transhiatal approach compared to transthoracic surgery (mean difference: -86 min, 95%CI: -150 to -29 min), hybrid intervention (mean difference -99 min, 95%CI: -190 to -9.4 min), minimally invasive technique (mean difference -130 min, 95%CI: -210 to -53 min), and robot-assisted esophagectomy (mean difference -150 min, 95%CI: -250 to -52 min) (Figure 3). We did not find significant differences regarding survival (Supplementary Figures 1-5), total AEs (Supplementary Figure 6), cardiac AEs (Supplementary Figure 7), anastomotic leakage (Supplementary Figure 8), atrial fibrillation (Supplementary Figure 9), wound infection (Supplementary Figure 10), total pulmonary AEs (Supplementary Figure 11), vocal chord paralysis (Supplementary Figure 12), length of hospital stay (Supplementary Figure 13), and blood loss (Supplementary Figure 14). The ranking and detailed results of the comparisons of the interventions are presented in the supplementary files (Supplementary Figures 1-14).

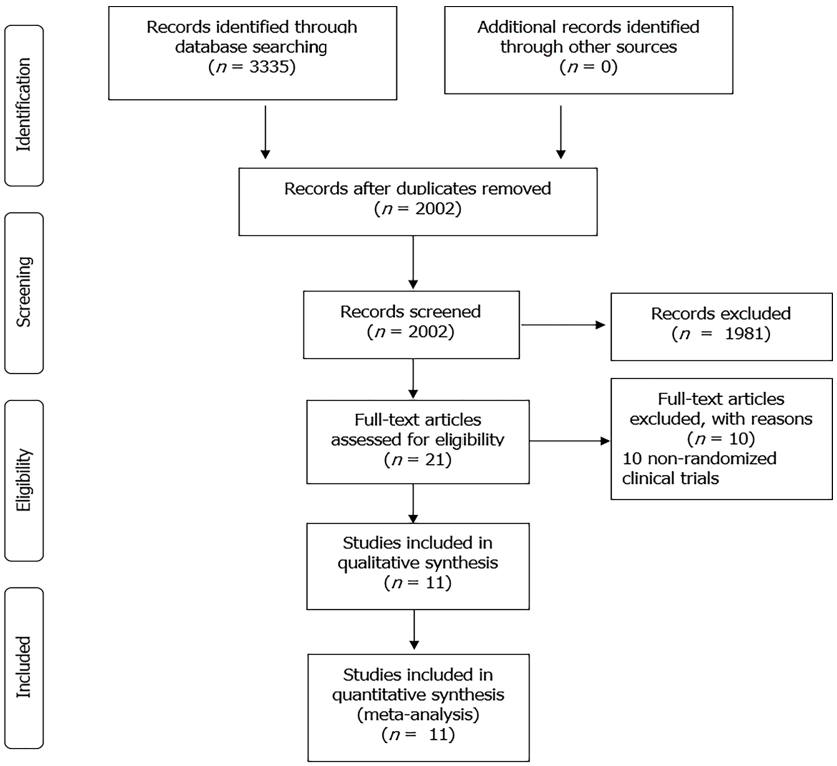
Risk of bias is indicated according to each domain of the Revised Cochrane risk-of-bias tool for randomized trials[23]. By the assessment of overall risk of bias, low risk of bias was given in the case of low risk of bias by every domain; if one or two domains were assessed as unclear risk of bias, unclear overall risk of bias was given, and if at least three domains were accompanied with unclear risk of bias, the overall risk of bias was assessed as high risk of bias.



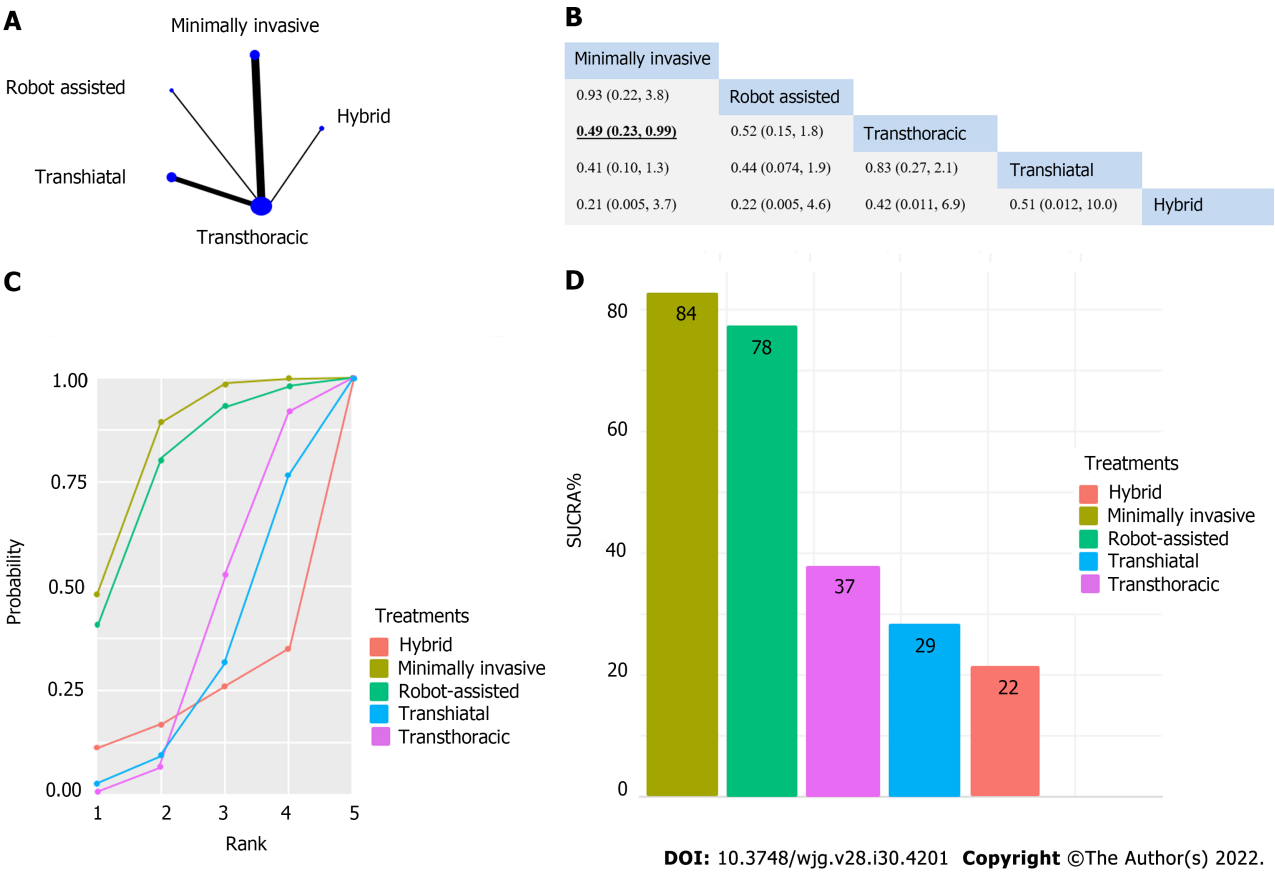


Figure 1 Results of the selection process according to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses guidelines. Available from: https://prisma-statement.org//prismastatement/flowdiagram.aspx.

Risk of bias assessment and grade of evidence

Results of the risk of bias assessment for the outcome of survival were assessed following the Cochrane Risk of Bias Assessment Tool 2. Details are shown in Table 2.

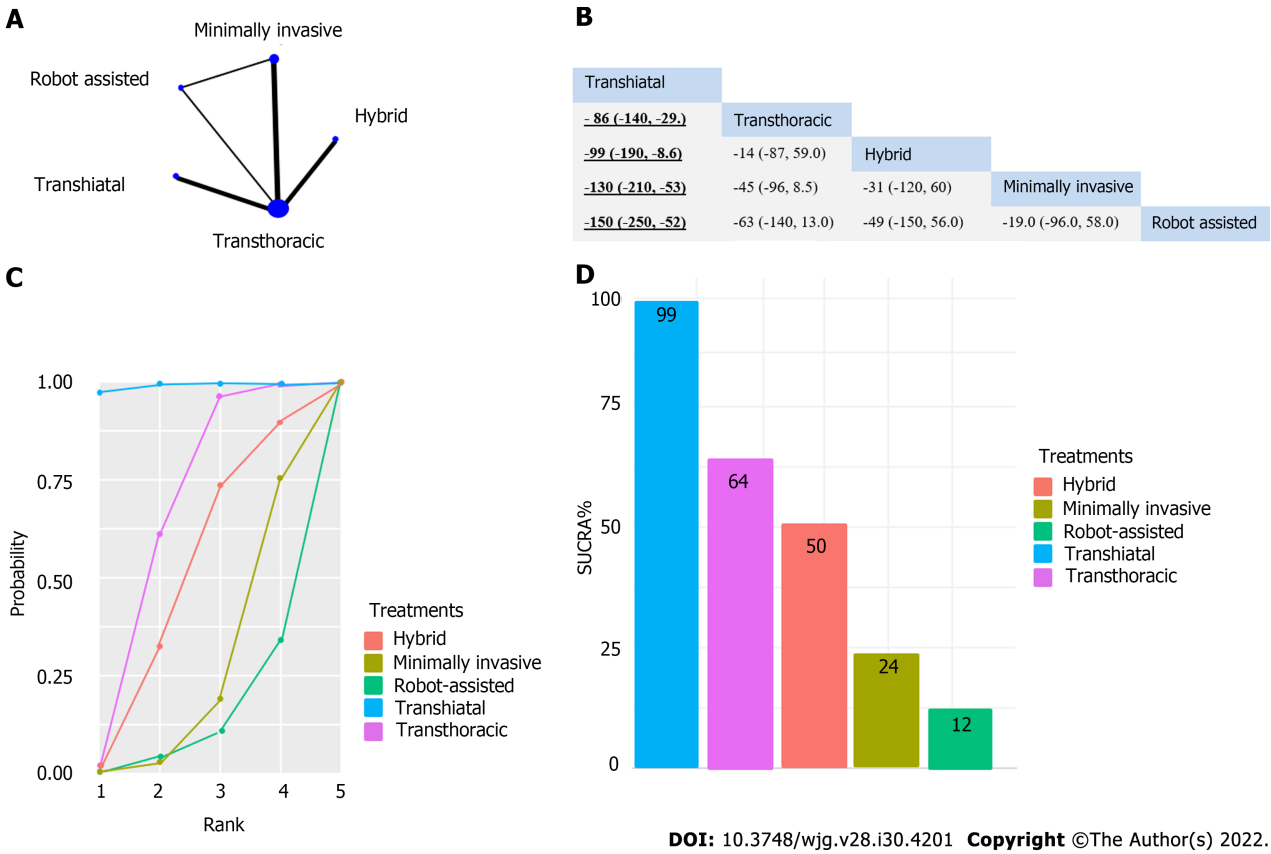
Figure 2 A significant difference was found considering pulmonary infection, which favored the minimally invasive intervention compared to transthoracic surgery. A: The network of eligible studies for pulmonary infection (the width of the lines is proportional to the number of trials comparing every pair of treatments, and the size of every circle is proportional to the number of randomly assigned participants [sample size]); B: League table of the analysis for pulmonary infection. Comparisons should be read from left to right. The values are presented in risk ratios, with corresponding credible interval. Significant result is in TextTitle and underlined; C: Cumulative probability of treatment rank; D: Treatment rank in SUCRA% histogram.



The results of the certainty of evidence are presented in Supplementary Table 1.

DISCUSSION

Our NMA confirmed the superiority of the minimally invasive esophagectomy over transthoracic open surgery regarding one of the main complications during these procedures, namely pulmonary infection. On the other hand, non-open surgical techniques require significantly more time to perform compared to open techniques. While statistically significant results were only achieved in the case of pulmonary infection, a clear tendency was demonstrated by the SUCRA curves, showing a preference for non-open techniques, which is also supported by the individual studies.

The results of previous meta-analyses and systematic reviews are not congruent regarding the comparison of minimally invasive and open surgical techniques. Kauppila *et al*[14] described the superiority of minimally invasive esophagectomy (MIE) regarding quality of life (QoL), which our work failed to analyze, as there were not enough RCTs reporting on QoL. Guo *et al*[13] also described the advantages of minimally invasive techniques regarding total complication rate, intraoperative blood loss, wound infection, and pulmonary infection, supporting our findings. MIE was also favorable in the analysis of Wang *et al*[19] considering blood loss. Besides blood loss and hospital stay, fewer respiratory complications were also shown by MIE in a meta-analysis conducted by Nagpal *et al*[15]. The work of Yibulayin *et al*[18] also supports the superiority of MIE in terms of in-hospital mortality and postoperative morbidity. By contrast, Dantoc *et al*[12] focused on oncological outcomes in their meta-analysis, where significant differences could not be proven. Sgourakis *et al*[17] showed that open surgery was more beneficial in terms of anastomotic stricture, while morbidity favored MIE. Oor *et al*[16] also described the benefit of open surgery in the case of hiatal hernia. The above comprehensive studies show that the inclusion of non-randomized studies carries a notable limitation.

Although the results of our analysis are only supportive in terms of pulmonary complication, the future perspectives are promising regarding minimally invasive esophagectomy, as the limelight shifts towards robot-assisted surgical techniques. The technique is time consuming, but with the development

DOI: 10.3748/wjg.v28.i30.4201 **Copyright** ©The Author(s) 2022.

Figure 3 Operation time was significantly shorter for transhiatal approach compared to transthoracic surgery, hybrid intervention, minimally invasive technique, and robot-assisted esophagectomy. A: The network of eligible studies for operation time [the width of the lines is proportional to the number of trials comparing every pair of treatments, and the size of every circle is proportional to the number of randomly assigned participants (sample size)]; B: League table of the analysis for operation time. Comparisons should be read from left to right. The values are presented in weighted mean difference (minutes), with corresponding credible interval. Significant results are in TextTitle and underlined; C: Cumulative probability of interventions rank; D: Intervention ranking in surface under the cumulative ranking (SUCRA)% histogram.

of new robotic platforms, the benefit of less AEs and more precise procedure will overcome this limitation[36]. The steep learning curve will be possibly managed by allowing the intervention to be carried out only in larger centers, as it has been seen in northern countries[37]. Despite the missing cumulative evidence, minimal invasive techniques have become the gold standard interventions for esophageal cancer since the TIME study. The results of this RCT provide evidence for using minimally invasive surgery for patients with resectable esophageal cancer aimed toward improving postoperative outcomes (especially pulmonary complication) and QoL with comparable oncologic results[25].

Considering the strengths of our analysis, by the inclusion of only RCTs, we managed to achieve a higher quality of evidence than previous works. Furthermore, a thorough methodology was applied. With the application of NMA, we were also able to make indirect comparisons. To date, this work is the most comprehensive review of the available RCTs.

One of the limiting factors of our study was the low number of cases and limited number of direct comparisons. Other limitations were the different enrollment criteria of the individual studies considering the histological subtype and stage of esophageal cancer. Furthermore, our analysis included many indirect comparisons, with weak direct comparisons. Additionally, we only included studies published until 2019.

We emphasize the application of MIE over open surgical techniques. Further analyses should focus on the outcomes of robot-assisted esophagectomies, and direct comparisons should be carried out between robot-assisted esophagectomy and thoracolaparoscopic intervention. Following recent trends, the centralization of upper gastrointestinal surgery is suggested, thus achieving the possibility of the implementation of such techniques without the limitation originating from the low number of cases and the learning curve of minimally invasive techniques.

CONCLUSION

While practice is already shifting towards the application of minimally invasive techniques, it should be

noted that clear evidence is still needed to form guidelines. As we aimed to fill this void, we were only able to prove the beneficial nature of these techniques regarding pulmonary infection. To further assess any other potential differences between the techniques, RCTs and systematic analysis of these trials are needed.

ARTICLE HIGHLIGHTS

Research background

The differences considering esophagectomies as the most applied curative methodology in the case of esophageal cancer are not clearly described. Minimally invasive techniques have become more popular in the belief of their superiority, although objective evidence is missing.

Research motivation

Recent guidelines are not yet clear considering the usage of minimally invasive esophagectomies. The authors wanted to provide the most objective evidence available, considering the differences between every subtype of minimally invasive and open esophagectomies.

Research objectives

The authors aimed to find every randomized controlled trial (RCT) providing comparative information about at least two types of esophagectomies, and pool the results using NMA.

Research methods

After establishing our clinical question using the population, intervention, control, outcome (commonly known as (PICO) framework a systemic search was carried out using three different databases. The results of the search were pooled, duplications were removed, suitable studies were selected, from which the data extraction was carried out onto a data sheet. With the help of biostatisticians, a network meta-analysis was performed. The quality of the included studies was assessed, as well as the grade of evidence.

Research results

Eleven articles were included in our analysis, according to which the minimally invasive surgical technique was superior compared to the transthoracic open approach in terms of pulmonary infection, while transthoracic surgery took less time to perform than any other surgical technique.

Research conclusions

The authors conclude that minimally invasive surgical techniques should be performed, whenever possible, for resectable esophageal cancer.

Research perspectives

The conduction of additional RCTs evaluating the same problem would be welcomed, while we hope that our work will help clinicians in the decision-making of the selection of the right surgical technique.

FOOTNOTES

Author contributions: Szakó L conceptualized the work, contributed to establishment of the search key, selection strategy, data extraction, interpretation of the results, and writing of the manuscript; Németh D and Farkas N performed the bio-statistical analyses, and contributed to the interpretation of the results and writing of the manuscript; Kiss S helped was involved in the conceptualization, coordination of the work, and writing the manuscript; Dömötör RZ conceptualized, wrote, and critically appraised the manuscript; Engh MA was involved in the conceptualization, data extraction, risk of bias assessment, writing of the manuscript, and language revision of the manuscript; Hegyi P contributed to the conceptualization, interpretation of the results, critical appraisal, and writing of the manuscript; Erőss BM conceptualized the work, interpreted the results, critically appraised and wrote the manuscript; Papp A provided supervision, and was involved in the conceptualization, interpretation of the results, critical appraisal, and writing of the manuscript.

Conflict-of-interest statement: All authors have no conflicts of interest to declare.

PRISMA 2009 Checklist statement: The authors have read the PRISMA 2009 Checklist, and the manuscript was prepared and revised according to the PRISMA 2009 Checklist.

Abstract

BACKGROUND

Traumatic neuromas result from nerve injury after trauma or surgery but rarely occur in the bile duct. However, it is challenging to diagnose traumatic neuromas correctly preoperatively. Although some previous reports have described the imaging features of traumatic neuroma in the bile duct, no features of traumatic neuromas in the bile duct have been identified by using contrast-enhanced ultrasound (CEUS) imaging before.

CASE SUMMARY

A 55-year-old male patient presented to our hospital with a 3-mo history of abdominal distension and anorexia and history of cholecystectomy 4 years ago. Grayscale ultrasound demonstrated mild to moderate intrahepatic bile duct dilatation. Meanwhile, a hyperechoic nodule was found in the upper extrahepatic bile duct. The lesion approximately 0.8 cm × 0.6 cm with a regular shape and clear margins. The nodule of the bile duct showed slight hyperenhancement in the arterial phase and isoenhancement in the venous phase on CEUS. Laboratory tests showed that alanine aminotransferase and aspartate aminotransferase were increased significantly, while the tumor marker carbohydrate antigen 19-9 was increased slightly. Then, hilar bile duct resection and end-to-end bile ductal anastomosis were performed. The histological examination revealed traumatic neuroma of the extrahepatic bile duct. The patient had an uneventful recovery after surgery.

CONCLUSION

The current report will help enhance the current knowledge regarding identifying traumatic neuromas by CEUS imaging and review the related literature.

Core Tip: A traumatic neuroma results from nerve injury after trauma or surgery but rarely occurs in the bile duct. Herein, we present some of the sonographic features of ultrasound and contrast-enhanced ultrasound in a case of a traumatic neuroma. We report this unusual case and review the related literature to improve the diagnosis and differential diagnosis of a traumatic neuroma of the bile duct and related imaging findings.

INTRODUCTION

A traumatic neuroma is a chronic reparative proliferative response of the nerve after trauma or surgery. It is composed of disorganized nerve fiber bundles with fibrous stroma, Schwann cells, perineural cells, axons, and endoneural fibroblasts[1]. The common sites of traumatic neuromas are the necks and extremities[2,3]. Although some studies have described traumatic neuromas in the bile duct, cases of sonographic features of contrast-enhanced ultrasound (CEUS) have not been published before. The clinical manifestation and imaging examination of a traumatic neuroma of the bile duct are not specific, which makes it challenging be accurately diagnosed preoperatively. Herein, we report a traumatic neuroma of the extrahepatic bile duct with detailed ultrasonographic imaging features. We also reviewed the literature on the imaging findings for traumatic neuromas.

CASE PRESENTATION

Chief complaints

A 55-year-old man was admitted to our hospital with unexplained abdominal distension and anorexia 3 mo ago.

History of present illness

The patient suffered from unexplained abdominal distension and anorexia for 3 mo. The patient developed darkened urine 2 mo ago. He experienced a weight loss of 5 kg over the course of the disease. He underwent contrast-enhanced computed tomography (CECT) examination at a local hospital, and a lesion was found in the extrahepatic bile duct, which was believed to be a tumor.

History of past illness

The patient underwent cholecystectomy for gallbladder stones with an uneventful postoperative recovery 4 years ago. He had a 10-year history of hypertension.

Personal and family history

There was no other personal or family history of acute or chronic disease.

Physical examination

The patient showed no tenderness, rebound tenderness or muscle tension on abdominal palpation.

Laboratory examinations

The liver function tests demonstrated increased levels of alanine aminotransferase (185 IU/L, normal range: < 50 IU/L), aspartate aminotransferase (148 IU/L, normal range: < 40 IU/L) and total bilirubin (37.0 μmol/L, normal range: 5 μmol/L to 28 μmol/L). Tumor markers included carbohydrate antigen 19-9 (98.6 U/mL, normal range: < 22 U/mL), carcinoembryonic antigen (0.97 ng/mL, normal range: < 5 ng/mL), and alpha-fetoprotein (4.67 ng/mL, normal range: < 7 ng/mL).

Imaging examinations

The patient underwent an abdominal ultrasound (US) examination by a Resona7 US system (Mindray Medical International, Shenzhen, Guangdong Province, China) equipped with an SC6-1U (1-6 MHz)

transducer. The US revealed mild to moderate dilatation of the intrahepatic bile duct, and the diameter of the upper extrahepatic bile duct was 1.2 cm (Figure 1A). A hyperechoic nodule sized 0.8 cm × 0.6 cm was found in the upper extrahepatic bile duct with an almost regular shape and slightly clear margins (Figure 1B). The patient underwent CEUS with the patient's consent for further diagnosis. A 2.4-mL US contrast agent SonoVue (Bracco, Milan, Italy) suspension was injected through the left cubital vein followed by a flush with 5 mL saline. In the arterial phase, the nodule showed slight heterogeneous hyperenhancement without rim-like enhancement (Figure 1C). The nodule appeared heterogeneous isoenhancement in the venous phase (Figure 1D). Additional CECT in our hospital showed a hypoenhancement nodule approximately 1.3 cm × 1.0 cm in size in the upper extrahepatic bile duct (Figure 2).

FINAL DIAGNOSIS

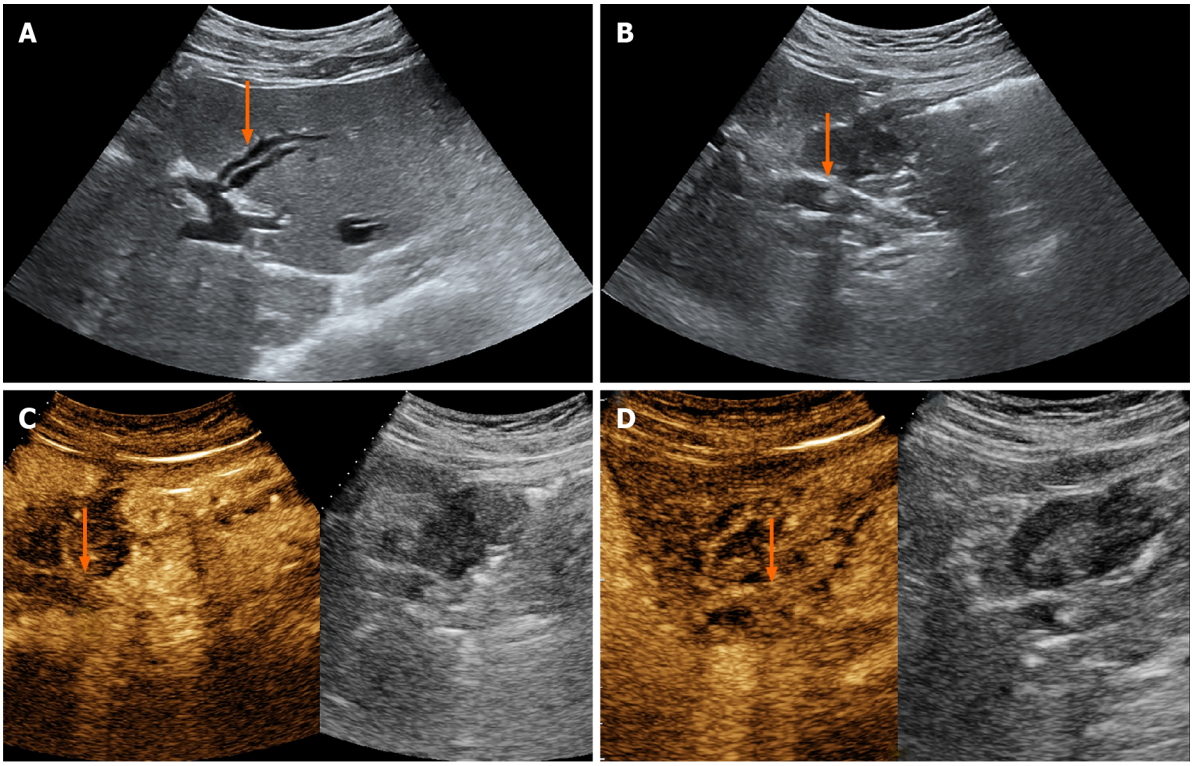
Based on the incidence of bile duct diseases, imaging findings and laboratory tests, the patient's clinical diagnosis was hilar cholangiocarcinoma. However, postoperative pathology of the common bile duct lesion showed a neoplastic proliferation of submucosal nerve tissue and fibrous tissue (Figure 3A), and an immunohistochemistry marker was positive for S-100 (Figure 3B). The above pathological findings indicated that the lesion in the bile duct was a traumatic neuroma.

TREATMENT

During the surgery, intraoperative frozen pathology showed no tumor cells within the bile duct lesion. Therefore, hilar bile duct resection and end-to-end bile ductal anastomosis (EE) were performed. The patient recovered uneventfully after surgery.

OUTCOME AND FOLLOW-UP

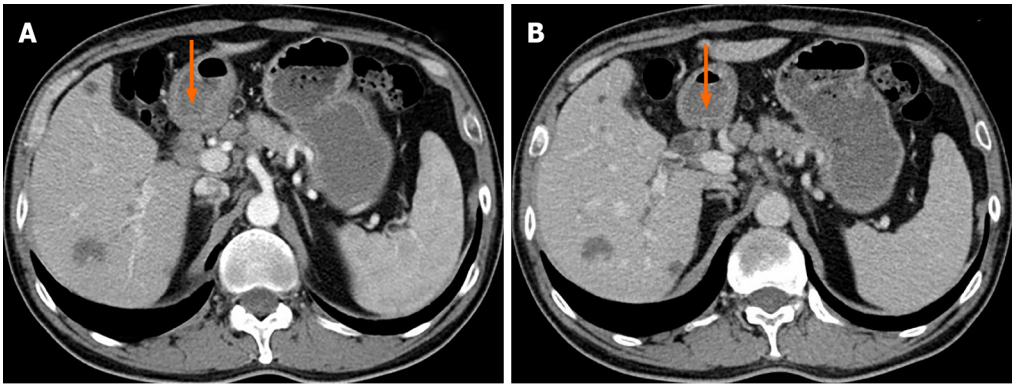
There was no obvious abnormality on CECT for half a year after the operation.



DISCUSSION

Extrahepatic bile duct masses are commonly malignant tumors, while benign tumors account for only 6%[4-7]. Consequently, the possibility that extrahepatic bile duct lesions are traumatic neuromas is easily overlooked. It has been reported that most traumatic neuromas of the biliary tract arise in the cystic duct stump after cholecystectomy[8]. If a nerve is transected and its continuity cannot be reestablished, a traumatic neuroma may develop[9].

We reviewed the literature from 2000 to 2021 and found 18 publications regarding the imaging features of traumatic neuromas in the bile ducts[2,10-26]. The clinical findings and imaging features of these 18 reported cases are summarized in Table 1. Finally, 22 patients were included in the literature review for further analysis. The age of patients ranged from 17 to 81 years of age, and there was a significant male predominance, with 15 males (68.2%), 2 females, and 5 patients of unreported sex. Most cases were secondary to cholecystectomy, but a few were secondary to liver transplantation, hepatectomy and hilar cholangiocarcinoma. The major symptoms found in these patients were jaundice, abdominal pain, and weight loss, while some patients had no apparent symptoms.



Unfortunately, no specific imaging features for traumatic neuromas of the bile duct have been found at present. Although some imaging modalities, such as US, computed tomography (CT), and nuclear magnetic resonance imaging (MRI), are valuable to some extent, it remains a challenge to diagnose traumatic bile duct neuromas preoperatively[17]. Imaging findings in these 22 patients varied from nodules or masses to localized bile duct stenosis with dilatation of the upper bile duct. It has been reported in the literature that the US imaging findings of extraabdominal nerve tumors and traumatic neuromas are generally hypoechoic masses, larger than the nerve trunk and continuous with the nerve [27]. However, the nerve injury related to cholecystectomy may be too small, so we could not find that the nerve is connected to traumatic neuroma of the bile duct. US was performed in 5 of the 22 patients, 2 of whom showed hypoechoic nodules, and the remaining 3 patients showed stenosis and dilatation of the bile ducts. However, our patient's US sonogram showed a hyperechoic nodule, indicating that the echogenicity of the nodule of traumatic neuroma was variable.

CECT was performed in 2 of the 18 cases, and an enhancing nodule was seen, which was consistent with the CECT findings of our patient. Traumatic neuromas also show enhancement on MRI when a contrast agent is used[28], which may be related to a damaged peripheral nerve blood barrier that occurred during a prior insult to the nerve[29-32]. One of these 18 cases described the enhancement

Figure 2 Contrast-enhanced computed tomography images of the patient. Contrast-enhanced computed tomography showed a hypoenhancement nodule in the upper extrahepatic bile duct (orange arrow).

pattern of traumatic neuroma on MRI in detail, which showed a marked homogeneously enhanced nodule that was iso-intense to the aorta in the atrial phase and a homogeneously enhanced nodule that was iso-intense to the aorta in the portal phase. There have been a few reports of other imaging techniques for diagnosing traumatic neuromas, such as magnetic resonance cholangiopancreatography, endoscopic US, contrast-enhanced harmonic endoscopic ultrasonography, intraductal ultrasonography and percutaneous transhepatic cholangiography. None of these imaging methods revealed specific features for traumatic neuromas.

It is challenging to distinguish bile duct traumatic neuroma from other lesions before surgery, so it is often misdiagnosed. The diagnosis of bile duct traumatic neuroma was correctly diagnosed in 1 of the 18 cases examined and confirmed by biopsy. The remaining cases were not correctly diagnosed, and it was difficult to distinguish between benign and malignant lesions in most cases. Therefore, surgery would be performed on a large proportion of patients. Once the patient underwent surgery, an intraoperative frozen section examination helped to confirm that the lesion was benign and extensive surgical

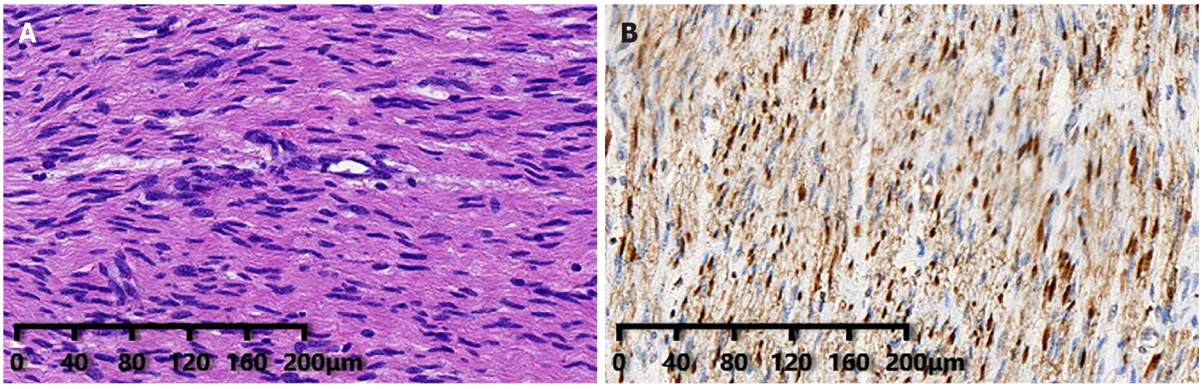

Table 1 Traumatic neuroma of the bile duct reported in the literature between 2000 and 2020

Ref.	Age	Sex	Symptoms	Location	Imaging findings	Preoperative diagnosis	Treatment
Shimura *et al*[10]	70	F	Abdominal discomfort	Extrahepatic bile duct	US: Hypoechoic tumor, bile duct slightly dilated CT: Round, hyperdense, distinct margin tumor Angiography: No encasement of the surrounding major vessels Endoscopic retrograde cholangiography: A protuberant nodule Intraductal ultrasonography: A smooth hypoechoic tumor	Did not indicate bile duct carcinoma	Bile duct excision and a Roux-en-Y hepaticojejunostomy
Watanabe *et al*[11]	48	M	Jaundice	Extrahepatic bile duct	Cholangiogram *via* the percutaneous transhepatic biliary drainage tube: The extrahepatic bile duct severely stenotic	ND	Bile duct excision and a Roux-en-Y hepaticojejunostomy
Iannelli *et al* [12]	81	M	Jaundice	Common bile duct	US: Dilatation of the intrahepatic bile ducts MRCP: A focal stricture	ND	Bile duct excision and a Roux-en-Y hepaticojejunostomy
Ueno *et al*[2]	60	M	Jaundice	Mid-common bile duct	US: Dilatation of the bile ducts, a mildly echogenic mass CT: Dilatation of the bile ducts, a markedly enhanced nodule MRI: Dilatation of the bile ducts. Homogeneous enhanced nodule with an iso-intense to the aorta, both in the arterial and portal phase Percutaneous transhepatic cholangiography: Dilatation of the bile ducts and a smooth stricture	Could not confirm benign or malignant nature	Bile duct excision and a hepatojejunal anastomosis
Choi *et al* [13]	46	M	Increased liver enzymes	Right hepatic duct	CT: A mass approximately 2 cm MRI: A mass approximately 2 cm	A bile duct cancer could not be excluded	Right hemihepatectomy
Kim *et al*[14]	76	M	ND	Mid-bile duct	CT: A small enhancing nodule MRC: Eccentric wall thickening of the bile duct consistent with a neoplasm	ND	Segmental resection with a Roux-en-Y hepaticojejunostomy
Cheng *et al* [15]	33	F	Jaundice and weight loss	Remnant choledochal cyst	MRI: A mass	Cholangiocarcinoma	Excision of the remnant choledochal cyst and a new hepaticojejunostomy
Cheng *et al*	56	M	Jaundice, abdominal	Distal	US: Dilatation of bile	Ampullary or	Pancreaticoduodenectomy

[16]			pain and weight loss	extrahepatic bile duct	duct MRI: Dilatation of bile duct, a filling-defect in the distal bile duct and a thickened biliary wall around the ampulla of Vater	periampullary carcinoma	
Cheng *et al* [17]	68	M	Progressive jaundice and abdominal pain	Bifurcation of the left and right hepatic duct	MRI: A mass with enhancement, a stricture of the hilar bile duct, dilatation of bile ducts	Cholangiocarcinoma	Excision of the mass and a new Roux-en-Y hepaticojejunostomy
Navez *et al* [18]	ND	ND	Jaundice (3 patients) or liver function test alteration (1 patient), a retro-obstructive choleperitoneum on the downstream biliary stenosis (1 patient)	Anastomotic biliary stricture	CT: Anastomotic biliary stricture (4 patients) MRI: A markedly homogeneous high intensity nodule enhanced on portal-phase (1 patient), anastomotic biliary stricture (4 patients)	ND	Traumatic biliary neuromas resection combined with hepaticojejunostomy (1 patient); traumatic biliary neuromas resection and duct-to-duct biliary reconstruction protected by a T-tube (4 patients)
Terzi *et al* [19]	17	F	Persistent elevated transaminase and bilirubin levels	Anastomotic biliary	Percutaneous transhepatic cholangiography: A biliary stricture at the anastomosis	ND	Resection of the bile duct stricture and a Roux-en-Y hepaticojejunostomy
Toyonaga *et al*[20]	76	F	A bile duct nodule	Proximal common bile duct	CT: An 8 mm, smooth, and uniformly enhanced nodule Contrast enhanced endoscopic ultrasonography: A clear boundary and a low echoic nodule, uniformly enhanced at early Cholangioscopy: A smooth elevated lesion, covered with normal mucosa	Submucosal tumor	Biopsy, observation for 1 year, no changes to the nodule
Yang *et al* [21]	65	M	Jaundice	Right bile duct	MRI: A 1.0 cm × 1.5 cm mass	Cholangiocarcinoma	Resection of the mass and Roux-en-Y hepaticojejunostomy.
Hirohata *et al*[22]	60	F	No chief complaint	Junction of the cystic duct	US: A 6 mm round tumor, surrounding lymph nodes were not swollen MRI: A slightly high signal on T2 and the periphery remnant cystic duct of the tumor presented as a high-intensity lesion on T2 EUS: A residual cystic duct tumor with enhancement ERCP: Not invade the common bile duct	Cholangiocarcinoma	Surgery
Yasuda *et al* [23]	76	M	ND	Stump of the dilatated cystic duct	EUS: A hypoechoic oval mass with a hyperechoic rim on the surface, 14 mm in	Amputation neuroma	Biopsy, observation

					diameter, hypervascularity Cholangiogram: A hemispherical defect Cholangioscopy: A hemispherical mass covered with thin normal cystic duct epithelium		
Lalchandani *et al*[24]	41	M	Epigastric pain, weight loss, tea-colored urine	Common hepatic duct	US: Dilation of the bile ducts ERCP: A 3-4 cm stricture	Acute cholangitis	First: Biliary stent Finally: Bile duct resection and hepaticojejunostomy
Kim *et al*[25]	72	M	A duodenal subepithelial tumor during a medical checkup	Near the duodenal wall and the cystic duct stump	CT: A 1.4 cm mass EUS: An 18 mm hypoechoic mass	Duodenal subepithelial tumor	Resection of the mass and duodenal wall, en-block resection of the mass and cystic duct origin
Nechi *et al*[26]	76	M	Jaundice	The transition zone between the common hepatic duct and the main bile duct	US: Dilation of the bile ducts, a 5 mm hypoechoic nodule MRI: Dilation of the common hepatic duct	Could not confirm benign or malignant nature	Resection of the main bile duct with a choledocho-duodenal anastomosis

ND: Not described; US: Grayscale ultrasound; CT: Computed tomography; CECT: Contrast-enhanced computed tomography; MRI: Magnetic resonance imaging; MRC: Magnetic resonance cholangiogram; MRCP: Magnetic resonance cholangiopancreatography; EUS: Endoscopic ultrasonography; ERCP: Endoscopic retrograde cholangiopancreatography.

resection of the traumatic neuroma was avoided[2,3]. The primary treatment reported in the literature consists of bile duct excision and hepaticojejunostomy (HJ). Although HJ is frequently recommended for reconstruction, the indications, surgical options and suture selection are also controversial. Some investigators also recommend EE because it is more physiological and can maintain physiological balance [33]. It is possible to achieve excellent long-term results and high quality of life using both HJ and EE when it is feasible for the proximal and distal ductal ends to permit EE[34]. Therefore, the choice of the optimum method is strictly correlated with the morphological nature of the lesion, which is different from one stage to the other, depending upon the moment of detection, and therefore have different surgical implications[35]. The surgeon found that the anastomosed edges blood supply was good and that there was no tension of the anastomosed edges in this patient. Therefore, according to the actual conditions of patients, as well as to maintain physiological balance, our hospital professor implemented EE for this patient.

In this patient, the symptoms of anorexia, weight loss and jaundice mimicked those often caused by malignant tumors of extrahepatic bile ducts. CEUS and CECT showed enhancement of the nodule. Based on the incidence of bile duct diseases and imaging findings, the surgeons misdiagnosed it as cholangiocarcinoma. Periductal infiltrative cholangiocarcinomas account for the majority of extrahepatic cholangiocarcinomas[36]. Extrahepatic cholangiocarcinomas may show hyperenhancement, isoenhancement, or hypoenhancement in the early phase of CEUS, and most of them show hypoenhancement in the late phase[37]. If we find a nodule in the bile duct, we should rule out the diagnosis of cholangiocarcinoma when the nodule does not show hypoenhancement in the late phase of CEUS. However, when traumatic neuroma presents as localized bile duct stenosis, it is relatively difficult to distinguish it from malignant lesions. When a patient has a history of biliary system surgery and the tumor markers are not significantly elevated, suspicion of traumatic neuroma increases. If conditions permit, patients can be protected from unnecessary surgeries by confirming the diagnosis with a biopsy. CEUS is beneficial for differentiating cholangiocarcinoma from traumatic neuromas, but more cases are needed to summarize the sonographic features of this disease. Recognizing of traumatic neuromas may aid in preoperative work up, planning, and patient counseling[24].

CONCLUSION

It is difficult to correctly diagnose traumatic neuroma of the bile duct before surgery. We should rule out malignant differential diagnoses, such as cholangiocarcinoma preoperatively, to avoid unnecessary surgery. The enhancement mode of CEUS may provide information to distinguish traumatic neuromas from malignant lesions. We need to combine the history of biliary tract surgery, clinical findings, imaging findings and laboratory tests to diagnose this disease.

Abstract

The expression of angiopoietin (ANGPT) 1, ANGPT2, vascular endothelial growth factor (VEGF) A, VEGFB, VEGFC, VEGFD, and placental growth factor (PGF) is significantly higher in tumor tissues than in normal tissues in both unpaired and paired hepatocellular carcinoma (HCC) samples. ANGPT2, VEGFB, VEGFC, and PGF are primarily involved in regulating the activation of the epithelial-mesenchymal transition pathway; ANGPT1 is primarily involved in regulating the activation of the RAS/mitogen-activated protein kinase and receptor tyrosine kinase (RTK) pathways; VEGFA is engaged in regulating the RTK activation pathway; and VEGFD is mainly involved in regulating the activation of the tuberous sclerosis protein/mammalian target of rapamycin pathway. There is a significant difference in overall survival between HCC patients with high and low expression of ANGPT2, PGF, VEGFA, and VEGFD. Disease free survival (DFS) is significantly shorter in HCC patients with high ANGPT2, PGF, and VEGFA expression than in those with low ANGPT2, PGF, and VEGFA expression.

Key Words: Hepatocellular carcinoma; Angiogenesis; Marker; Bioinformatics analysis; Pathway

Core Tip: We found that the expression of angiogenesis markers was significantly higher in tumor tissues than in normal tissues in both unpaired and paired hepatocellular carcinoma (HCC) samples. These angiogenesis markers are mainly involved in regulating the activation of the EMT pathway, the RAS/mitogen-activated protein kinase and receptor tyrosine kinase pathways, and the tuberous sclerosis protein/mammalian target of rapamycin pathway. In addition, there was a significant difference in overall survival between HCC patients with high and low expression of angiopoietin-2 (ANGPT2), placental growth factor (PGF), vascular endothelial growth factor A (VEGFA), and VEGFD. Disease free survival was significantly shorter in HCC patients with high ANGPT2, PGF, and VEGFA expression than in those with low ANGPT2, PGF, and VEGFA expression.

TO THE EDITOR

We read with read interest the article by Choi *et al*[1], in which they initially evaluated plasma levels of angiogenesis biomarkers in hepatocellular carcinoma (HCC) patients, and then assessed their roles in forecasting overall survival (OS) and progression-free survival (PFS), indicating that the plasma level of angiopoietin (ANGPT) 2 was related to tumor stage, liver function, and cancer invasiveness, and that ANGPT2 performed better in predicting OS and PFS than alpha-fetoprotein (AFP), ANGPT1, and vascular endothelial growth factor (VEGF).

We appreciate the authors' unique perspective in exploring the prognostic role of plasma levels of ANGPT1, ANGPT2, and VEGF in HCC. However, there are some errors in the original text that may cause confusion for readers. For example, the survival curve in figure 3B in the original article should have represented the survival curve between the high and low ANGPT2 expression subgroups, which the authors incorrectly labeled as ANGPT1. Second, it is well known that the VEGF family includes VEGFA, VEGFB, VEGFC, VEGFD, VEGFE, and placental growth factor (PGF)[2,3], so to which VEGF do the authors refer in the text? Usually, VEGF refers to VEGFA, but the authors should have clarified it in the text.

Moreover, it might make the results more significant if the authors could improve the outcome by demonstrating the differential expression of ANGPT1, ANGPT2, and VEGF in normal tissues and HCC tissues as a whole, for example, the analysis of HCC samples in the Cancer Genome Atlas database using bioinformatics. We found that the expression of ANGPT1, ANGPT2, VEGFA, VEGFB, VEGFC, VEGFD, and PGF was significantly higher in cancer samples than in corresponding normal samples in both unpaired and paired HCC samples (Figures 1A and B). Detailed statistical results are reported in Tables 1 and 2.

We also found that ANGPT2, VEGFB, VEGFC, and PGF are mainly involved in regulating the activation of the EMT pathway; ANGPT1 is prominently involved in regulating the activation of the RAS/mitogen-activated protein kinase and receptor tyrosine kinase (RTK) pathways; VEGFA is engaged in regulating the activation of the RTK pathway; and VEGFD is mainly involved in regulating the activation of the tuberous sclerosis protein/mammalian target of rapamycin pathway (Figure 1C). These results are consistent with those of previously reported studies[4-7]. Our findings could be a supplement to Choi *et al*'s study[1]. In the future, the roles of ANGPT1, ANGPT2, and VEGF in the development of HCC should be further explored.

Choi *et al*[1] found that OS was significantly shorter in the high ANGPT2 and high AFP subgroups than in the low ANGPT2 and AFP subgroups, respectively, though the differences in OS rates were not significant between the high and low ANGPT1 subgroups or between the high and low VEGF subgroups. Our study found that OS was significantly shorter in patients with high ANGPT2, PGF, VEGFA, or VEGFD expression than in those with low expression, respectively (Figures 2A-D; $P < 0.05$). However, there was no significant difference in survival time between patients with high and low expression of ANGPT1, VEGFB, VEGFC, and AFP (Figures 2E-H; $P > 0.05$). Prognostic data for HCC came from Liu *et al*[8].

In addition, we also analyzed the differences in disease free survival (DFS) between patients with high and low angiogenesis marker expression. We found that DFS was significantly shorter in the high ANGPT2, PGF, and VEGFA groups than in the low ANGPT2, PGF, and VEGFA groups, respectively (Figures 3A, B and C; $P < 0.05$). However, there was no significantly difference in DFS between groups with high and low expression of AFP, ANGPT1, VEGFB, VEGFC, and VEGFD (Figures 3D-H; $P > 0.05$). The above results confirm that the study performed by Choi *et al*[1] is of great value and that our discovery could be a supplement to their research.

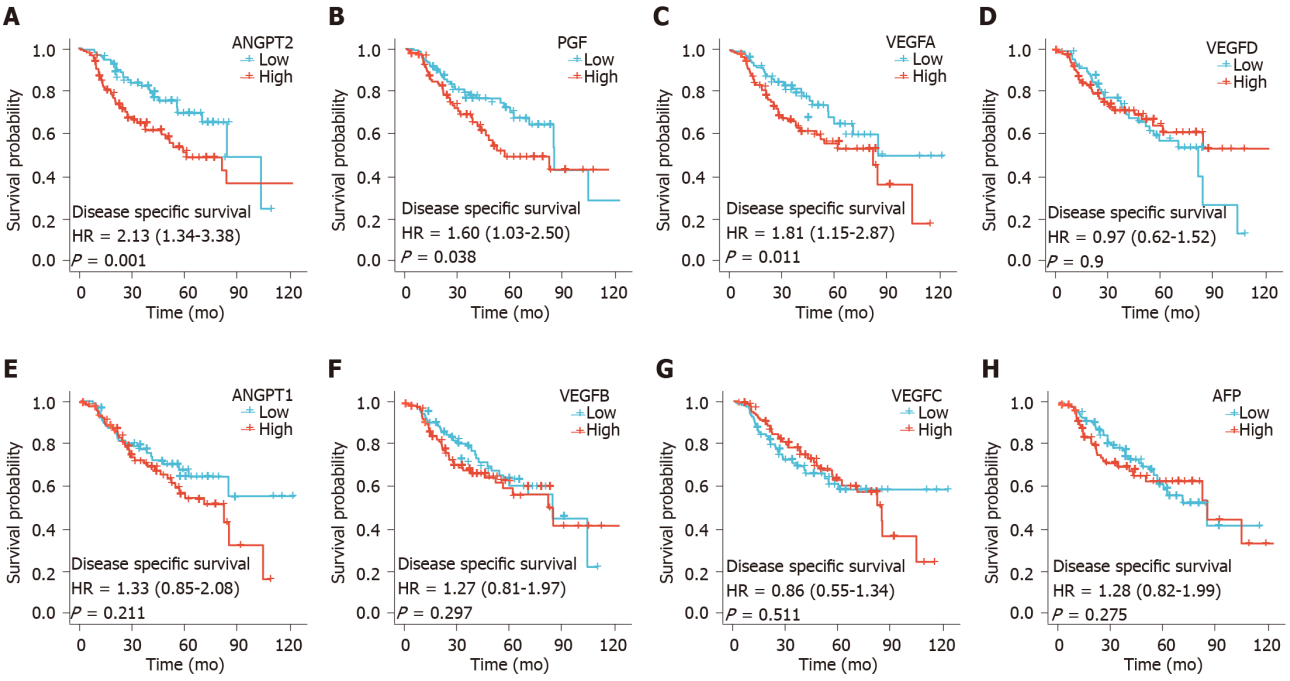
Figure 1 Roles of angiopoietins 1 and 2, vascular endothelial growth factors A-D, and placental growth factor in development of hepatocellular carcinoma. Data source: UCSC XENA (https://xenabrowser.net/datapages/) mRNA-Seq data of TPM format for GTEx and TCGA processed uniformly *via* the Toil process[11]. Liver hepatocellular carcinoma tissue data from TCGA and corresponding normal tissue data from GTEx were used. A: Differential expression of angiopoietin (ANGPT) 1, ANGPT2, vascular endothelial growth factor (VEGF) A, VEGFB, VEGFC, VEGFD, and placental growth factor (PGF) in hepatocellular carcinoma (HCC) and normal tissue samples; B: Differential expression of ANGPT1, ANGPT2, VEGFA, VEGFB, VEGFC, VEGFD, and PGF in paired HCC and normal samples. The expression in cancer tissues is represented in orange, and that in normal tissues is displayed in blue; C: Pathway analysis for ANGPT1, ANGPT2, VEGFA, VEGFB, VEGFC, VEGFD, and PGF in HCC. ANGPT: Angiopoietin; PGF: Placental growth factor; VEGF: Vascular endothelial growth factor; AFP: Alpha-fetoprotein; EMT: Epithelial-mesenchymal transition; AR: Androgen receptor; ER: Estrogen receptor; P13K/AKT: Phosphatidylinositol 3 kinase/AKT; RAS/MAPK: RAS/mitogen-activated protein kinase; RTK: Receptor tyrosine kinase; TSC/mTOR: TSC/mammalian target of rapamycin.



Statistical analysis

We utilized R (version 4.0.3) to perform statistical analyses and display the results. The differential expression analysis of angiogenesis markers between HCC tissues and corresponding normal tissues was performed using the Wilcoxon rank-sum test, and the results are presented by using R-package "ggplot2"[9]. Survival analysis was completed through log-rank test and COX regression. Pathway analysis was performed based on the online database GSCALite (http://bioinfo.life.hust.edu.cn/web/GSCALite/)[10].

Abstract

We read with great interest the article that retrospectively analyzed 814 patients with primary gastric cancer, who underwent minimally invasive R0 gastrectomy between 2009 and 2014 by grouping them in laparoscopic *vs* robotic procedures. The results of the study highlighted that age, American Society of Anesthesiologists status, gastrectomy type and pathological T and N status were the main prognostic factors of minimally invasive gastrectomy and showed how the robotic approach may improve long-term outcomes of advanced gastric cancer. According to most of the current literature, robotic surgery is associated with a statistically longer operating time when compared to open and laparoscopic surgery; however, looking at the adequacy of resection, defined by negative surgical margins and number of lymph nodes removed, it seems that robotic surgery gives better results in terms of the 5-year overall survival and recurrence-free survival. The robotic approach to gastric cancer surgery aims to overcome the difficulties and technical limitations of laparoscopy in major surgery. The three-dimensional vision, articulation of the instruments and good ergonomics for the surgeon allow for accurate and precise movements which facilitate the complex steps of surgery such as lymph node dissection, esophagus-jejunal anastomosis packaging and reproducing the technical accuracy of open surgery. If the literature, as well as the analyzed study, offers us countless data regarding the short-term oncological results of robotic surgery in the treatment of gastric cancer, satisfactory data on long-term follow-up are lacking, so future studies are necessary.

Key Words: Gastric cancer; Robotic gastrectomy; Laparoscopy; D2 lymphadenectomy; Long-term outcomes; Morbidity

Core Tip: Laparoscopic and robotic approaches are compared in the treatment of gastric cancer focusing on the prognostic factors as well as the oncological benefits brought about. While the long-term outcomes of laparoscopic surgery have been increasingly cited in recent years, only a few studies have analyzed the long-term results of the robotic approach, underlining the importance of future studies. A relevant aspect of robotic gastrectomy is the possibility to perform a more accurate lymph node dissection, which results in a longer survival with advanced gastric cancers.

TO THE EDITOR

We read with interest the Nakauchi *et al*[1] study, which retrospectively examined 814 patients with primary gastric cancer undergoing a minimally invasive R0 gastrectomy, between 2009 and 2014 in Kanazawa (Japan), comparing the laparoscopic and robotic approach and looking at the 5-year overall survival (OS) and recurrence-free survival (RFS). We were pleased to see from the results of the study that the robotic approach could improve the long-term outcomes of advanced gastric cancer. The authors observed that the robotic approach led to significantly better RFS compared to the laparoscopic one in patients with p-Stage II/III tumors, although no significant difference in OS was detected, nor in OS and RFS in p-Stage patients treated with laparoscopy or robotics.

The study also revealed that age > 65 years, American Society of Anesthesiologists physical status 3, total or proximal gastrectomy, and disease status T4 and N positive, are all independent prognostic factors[1]. Since gastric cancer is the fifth most common malignancy in the world and the third cause of cancer death, it is worth it to identify the most appropriate technical approach for this disease being minimally invasive surgery the standard approach for several GI surgery procedures[2,3].

Surgical treatment remains the only therapeutic option with curative intent. Total or subtotal gastrectomy, associated with D2 lymphadenectomy, represents the therapeutic gold standard for gastric cancer. We must acknowledge that the traditional surgical approach, open surgery, remains the most widespread surgical technique. Although, laparoscopy has become almost constant in general surgery, the use of the laparoscopic technique for gastric surgery is yet scarce in the case of malignancies. As supported by various authors, laparoscopy has several technical drawbacks and limitations, including two-dimensional vision, stiffness of instruments, limited range of motion, amplification of hand tremors and uncomfortable surgical placement which makes some fundamental surgical steps, such as D2 lymphadenectomy, extremely complex[2,4].

According to the paper discussed, the pN factor is strongly associated with survival after gastric cancer treatment, confirming the thesis that laparoscopy in gastric cancer is more adequate in the earlier stages. In contrast, the safety and oncological adequacy of laparoscopic-assisted radical D2 gastrectomy for advanced gastric cancer are still under discussion[5]. From the meta-analysis, it emerges that the main variables associated with a statistically significant advantage of laparoscopic technique over open surgery are represented by: Reduced blood loss, lower complication rate, faster recovery and reduced pain at the expense of a longer surgical time and fewer lymph nodes removed, therefore a potential worse local control of the disease[6,7].

Alongside laparoscopy, robotic technology allows us to overcome the technical difficulties of laparoscopy, thanks to the three-dimensional vision, instruments' articulation and greater ergonomics for the surgeon, offering a better therapeutic approach to the minimally invasive treatment of stomach tumors. Thus, the short and medium term results of robotic gastric surgery can be almost compared with open and laparoscopic procedure when taken into account surgeon experience and technical implementation of the robotic system.

We fully agree with the authors, who have shown a significantly lower morbidity in the group of patients treated with robotics than in the laparoscopic group, as widely discussed in many studies. A recent meta-analysis, which compared laparoscopy with robotics in the treatment of gastric cancer, highlighted that the robotic approach appears to achieve better surgical results in the short term, also thanks to the ability to recover a greater number of lymph nodes, namely lymph nodes in station n. 7, 8a, 9 and 11p, which are avowedly more difficult to reach, ensuring a more appropriate staging and chemotherapy plan[8].

A study conducted in Japan reported, among the advantages of robotic surgery, a lower intraoperative blood loss, with a consequent reduction in the dissemination of cancer cells in the peritoneal cavity during surgery and, therefore, a better prognosis. Another aspect highlighted is a lower risk of dehiscence of the esophagus-jejunal anastomosis, along with a lower incidence of internal hernias[9-11]. From the short-term results it emerges that robotic gastrectomy is a safe technique that potentially allows to extend the number of patients treatable with a minimally invasive approach, overcoming the technical difficulties of laparoscopy, offering some benefits in terms of blood loss, conversion rate, overall number of lymph nodes removed and in suprapancreatic areas, procedure-specific postoperative morbidity and shorter length of hospital stay[12].

Robotic gastrectomy is a safe and effective surgical technique when performed by experienced surgeons, however, it is associated with a longer operative time and a higher economic value than laparoscopic and open approaches[13,14]. Indeed, one of the factors that slows down the spread of robotic surgery is the particular technical expertise required while handling the robotic devices, resulting in a steeper learning curve for the specialized operator. The cost and longer timeframe of robotics make future studies necessary[15], as well as the need for randomized controlled trials comparing the two techniques with a long-term follow-up, on which publications are still scarce given the relatively recent diffusion of the technique[16].

Given the greater cost of robotics, we want to underline one of the limitations of the study discussed here, represented by possible errors in the selection of patients. The availability of robotic devices is strongly dependent on the wealth of the country and of the individual; both patients who are aware of the advantages of the robotic approach and experienced surgeons who are able to perform this novel technique could lead to an overuse of the technique. In Western countries, robotic devices are associated with longer operative time, and higher costs but fewer post-operative complications resulting in lower hospitalization costs, and shorter hospital stays[17].

In conclusion, the study discussed here provides valid results on the correct therapeutic management of patients with gastric cancer, with the aim to bridge over some of the difficulties and technical limitations that laparoscopy encounters in major surgery. Essentially, laparoscopic D2 lymphadenectomy remains a challenging procedure: In particular, the dissection of the lymph nodes along the celiac, hepatic and splenic arteries makes this approach technically complicated and time-consuming even for well-trained surgeons. It is in this context that robotic surgery is worth looking at and it represents a useful tool that overcomes some limitations of conventional laparoscopic techniques, even if greater surgical and anesthetic times and the higher costs have to be considered when compared to open surgery.

Although, in accordance with the international literature that ascribes better results to robotic surgery in perioperative outcomes in terms of blood loss, and postoperative complications, future studies of higher quality are necessary due to the lack of data on long-term results, given the relatively recent diffusion of the technique. In a long-term perspective, considering the need for further studies on larger samples of patients from Western countries, we believe that robotic technology for gastric cancer surgery, taking into account the many advantages it offers, can become a gold standard[18].

Abstract

Alcohol intake is a risk factor for cancer development and metastatic disease progression. Extracellular vesicle (EV)-mediated interorgan communication is assumed to be significant in boosting tumorigenic pathways and disease progression. Recent research indicates that exosomes have a variety of roles in the development of cancer during pathophysiological conditions. The involvement of EV signaling during cancer progression in the alcohol environment is unknown. Therefore, understanding communication networks and the role of EVs as biomarkers can contribute significantly to developing strategies to address the serious public health problems associated with alcohol consumption and cancer.

Key Words: Exosomes; Liver metastasis; Alcohol-associated liver disease; Cancer

Core Tip: In this letter to the editor, we discussed the reality that alcohol consumption is a risk factor that acts by itself to favor the appearance of the carcinogenic process and its harmful evolution towards metastatic pathology. One of the hypotheses that have been suggested as important in metastasis and communication between cells and/or organs is the traffic of extracellular vesicles/exosomes that can play or promote tumorigenesis locally and even at a distance from the primary tumor. Unraveling these communication mechanisms and therapeutic possibilities may lead to new ways to combat cancer's worsening, as metastasis, in the future.

TO THE EDITOR

We have read with great attention and particular interest the review by Kuracha *et al*[1] entitled: "Role of cell-free network communication in alcohol-associated disorders and liver metastasis". The authors highlight the many implications of extracellular vesicle (EV) (exosome) communications across organs in this review, focusing on the role of EVs in alcohol-related illnesses and cancer metastasis. It is crucial to consider the impact of EV cargo and release along a multi-organ axis on tumorigenic pathways and metastatic disease.

Alcohol consumption negatively impacts people's health and quality of life, contributing to more than 5% of the global disease burden and early death[2,3]. Alcohol intake has been linked to several neoplastic diseases, including colorectal, head and neck, esophageal, liver, breast, and pancreatic cancers[4,5]. On the other hand, recent research suggests that exosomes have different functions in disease progression during pathophysiological circumstances. Exosomes from tumors have been found to operate as regulatory factors in cancer development, promoting cell migration and proliferation and creating a pre-metastatic niche for cells resistant to treatment[6,7].

Hepatocytes and non-parenchymal cells produce and release EVs at higher rates in response to alcohol-mediated stress[8]. The EVs produced can alter gene expression and target cell function, prolonging liver damage[8]. Bidirectional exosomal communication between organs, including the liver, brain, intestine, and lungs, can also happen in addition to intra-organ transmission mediated by EVs. The gut-liver axis maintains bilateral interactions in an environment where alcohol is present, which results in gut dysbiosis and the progression of liver impairment[9,10].

In addition to persistent alcoholism, endotoxin transfer during sepsis and brain inflammation are caused by loss of intestinal barrier integrity. Alcohol dependency and its regulatory consequences, such as altered immunological function and neurological and endocrine signaling, are hypothesized to be influenced by alcohol-induced gut dysbiosis[11,12]. Acute respiratory distress syndrome, bacterial infection, and hepatopulmonary syndrome are also linked to persistent alcohol exposure on the liver-lung axis (ARDS)[13,14].

The significance of alcohol-induced EV communication in cancer initiation and progression is unknown until now because of the high prevalence of alcohol drinking and cancer-related risk. The therapeutic significance of the function of these exosomes has been highlighted by identifying EVs as critical mediators of communication networks within and across organ systems[7,15,16]. Clinical evaluation of EVs in body fluids provides another measure for understanding exosomes as valid and valuable diagnostic biomarkers and therapeutic targets.

Communication between malignant and non-cancerous cells, mediated by nanometric vesicles, is thought to be an essential part of tumor growth and its subsequent spread through the body. By promoting oncogene overexpression, stromal cell remodeling, immune system regulation, and angiogenesis, tumor-derived exosomes may control the course of cancer[17]. Cancer cells' ability to grow anchorage-independently is thought to be enhanced, and their morphological changes may be modulated by the transfer of tumor-causing material through EVs[18].

Additionally, miRNA-enriched EVs have also been demonstrated in cell-cell communications and the conversion of cells into populations with enhanced motility[19]. The involvement of EV signaling during cancer progression in the alcohol environment is unknown. Recent studies have shown that the exosomal content (proteins, miRNA, non-coding RNA) can help diagnose and treat cancer[20-22]. Therefore, comprehending EVs and communication networks as biomarkers can considerably aid in developing methods to deal with the serious public health issues brought on by alcohol intake and cancer.

ABOUT COVER

Editorial Board Member of *World Journal of Gastroenterology*, Mortada H F El-Shabrawi, MD, FAASLD, Professor, Department of Paediatrics, Kasr Alainy School of Medicine, Cairo University, Cairo 11562, Egypt. melshabrawi@kasralainy.edu.eg

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 edition of Journal Citation Reports® cites the 2021 impact factor (IF) for *WJG* as 5.374; IF without journal self cites: 5.187; 5-year IF: 5.715; Journal Citation Indicator: 0.84; Ranking: 31 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2021 is 8.1 and Scopus CiteScore rank 2021: Gastroenterology is 18/149.

Abstract

While great strides in improving survival rates have been made for most cancers in recent years, pancreatic ductal adenocarcinoma (PDAC) remains one of the solid tumors with the worst prognosis. PDAC mortality often overlaps with incidence. Surgical resection is the only potentially curative treatment, but it can be performed in a very limited number of cases. In order to improve the prognosis of PDAC, there are ideally two possible ways: the discovery of new strategies or drugs that will make it possible to treat the tumor more successfully or an earlier diagnosis that will allow patients to be operated on at a less advanced stage. The aim of this review was to summarize all the possible strategies available today for the early diagnosis of PDAC and the paths that research needs to take to make this goal ever closer. All the most recent studies on risk factors and screening modalities, new laboratory tests including liquid biopsy, new imaging methods and possible applications of artificial intelligence and machine learning were reviewed and commented on. Unfortunately, in 2022 the results for this type of cancer still remain discouraging, while a catastrophic increase in cases is expected in the coming years. The article was also written with the aim of highlighting the urgency of devoting more attention and resources to this pathology in order to reach a solution that seems more and more unreachable every day.

Key Words: Pancreatic cancer; Pancreatic ductal adenocarcinoma; Early diagnosis; Liquid biopsy; Pancreatic cancer biomarkers; Artificial intelligence; Pancreatic cancer screening

Core Tip: Pancreatic ductal adenocarcinoma is one of the solid neoplasms with the worst prognosis. Surgical resection is the only potentially curative treatment. In 80% of patients, pancreatic ductal adenocarcinoma is discovered at a stage too advanced for surgery. The aim of this review was to summarize all the possible strategies available today for the early diagnosis of pancreatic ductal adenocarcinoma and the paths that research must take to make this goal ever closer. The article highlights the urgency of devoting more attention and resources to this pathology in order to reach a solution that seems more and more unreachable every day.

INTRODUCTION

Pancreatic ductal adenocarcinoma (PDAC) is ranked as the seventh leading cause of cancer deaths worldwide, while it ranks fourth in the Western world, just behind lung, colorectal and breast cancers. Rahib *et al*[1] estimated that it will become the second leading cause of cancer death by 2030. The 2020 global cancer statistics reported a total of nearly 496000 new cases of PDAC and more than 466000 related deaths. PDAC mortality is almost overlapping with incidence[2].

The 5-year survival rate of PDAC is less than 10%[3]. A study that included 84275 patients showed that the 5-year survival rate increased from 0.9% in 1975 to 4.2% in 2011, considering all stages of PDAC. In patients undergoing surgical resection, it increased from 1.5% to 17.4%[4], while in unresected patients by 0.8% in 1975 and 0.9% in 2011. The high mortality and poor improvement in survival rates over the years are due to several factors. First, the retroperitoneal location of the pancreas results in the appearance of symptoms only when the neoplasm has reached considerable size, and diagnosis is often made at an advanced stage of the disease. Second, PDAC is inherently characterized by a fierce biology with early metastasis, and in fact about half of patients have metastatic disease at the time of presentation. Third, PDAC drastically weakens patients, limiting the possibility of aggressive treatments. Finally, through the desmoplastic reaction, it shows resistance to many antineoplastic therapies[5,6].

The 5-year survival rate for patients with stage 0 (in situ) according to the Union for International Cancer Control classification is 85.8%, while that of patients with stage IA is 68.7%. In the early stages of the disease, therefore, the prognosis is relatively good[7,8]. Early diagnosis of the disease is therefore essential.

Our efforts should focus on recognizing risk factors that contribute to the development of the disease in order to define the population at risk that could benefit from a screening protocol and on researching new techniques for early diagnosis[9-12].

RISK FACTORS AND STRATIFICATION

Several non-modifiable and modifiable risk factors are correlated with PDAC. Non-modifiable risk factors include the patient's age, ethnicity, gender, blood type, microbiota, diabetes mellitus, family history and genetic predisposition, while modifiable risk factors include tobacco use, alcohol consumption, diet, pancreatitis, obesity and socioeconomic status[12]. According to some studies, one-third of all cancers could be prevented through lifestyle improvement. The EPIC study, for example, evaluated the association between healthy lifestyle index score and pancreatic cancer[13,14]. A three-point increase in this score, achieved through adherence to healthy behaviors, is associated with a 16%-23% lower risk[15]. No smoking, making your home/workplace smoke-free, maintaining a normal body weight, having a diet rich in grains, legumes, and vegetables and limiting alcohol intake are key factors in the prevention of PDAC.

According to several studies, the new onset of diabetes in an elderly patient should suggest PDAC, especially if such a finding is associated with unintentional weight loss[16-18]. A study by Pelaez-Luna *et al*[19] evaluated the use of computed tomography (CT) scans in asymptomatic patients at the time of diabetes diagnosis and found a higher likelihood of detecting potentially resectable tumors compared with scans performed 6 mo later. However, CT-based screening of all elderly patients with new-onset diabetes (NOD) is not feasible[18]. Screening programs and guidelines will likely be updated when the features that differentiate pancreatic cancer-associated diabetes from other cases of NOD are identified.

The creation of a pancreatic cancer risk prediction model based on the integration of multiple risk factors could contribute to its early detection[20]. Sharma *et al*[21] developed a model called Enriching New-Onset Diabetes for Pancreatic Cancer that weights the scores of three factors including weight change, blood glucose change and age at diabetes onset in patients with NOD. A score of at least three points in the Enriching New-Onset Diabetes for Pancreatic Cancer model was able to identify individuals who developed PDAC within 3 years of the onset of diabetes with good sensitivity and specificity[21].

In addition to the strictly environmental risk factors, familial pancreatic cancer and genetic syndromes (hereditary breast and ovarian cancer syndrome, Lynch syndrome, familial atypical multiple melanoma, Peutz-Jegher syndrome, Li-Fraumeni syndrome and hereditary pancreatitis) are added. Familial pancreatic cancer is defined by the occurrence of PDAC in at least two first-degree relatives and accounts for up to 10% of all cases of PDAC[22].

Patients at high risk for developing PDAC include those with inherited risk factors (both genetic syndromes and familial pancreatic cancer), those with NOD and those with cystic lesions of the pancreas.

Pancreatic cysts are found in approximately 8% of individuals over the age of 70 years[23] and include intraductal papillary mucinous neoplasms (IPMN) and mucinous cystic neoplasms, both of which are precursors to PDAC. IPMN and mucinous cystic neoplasms are collectively referred to as mucinous cystic lesions. In contrast to the third precursor lesion, pancreatic intraepithelial neoplasia, which can be identified only at surgical histopathology, mucinous cystic lesions are easy to detect and are found incidentally in 3% of CT subjects[23]. Therefore, their identification offers the potential for early diagnosis of PDAC. However, there are two problems. First, not all pancreatic cystic lesions are IPMN or mucinous cystic neoplasms. Many are cystic lesions without risk of malignant transformation, and therefore do not require surveillance. Second, most IPMN and mucinous cystic neoplasms do not progress to PDAC. Over the years, evidence has been found to predict the possibility of progression to PDAC[23].

In mucinous cystic neoplasms the presence of eggshell calcification, larger tumor size or a mural nodule on cross-sectional imaging is suggestive of malignancy[24]. Regarding IPMN, worrisome (main duct 5-9 mm, enhancing mural nodule < 5 mm, thickened, enhancing cyst wall, branch duct IPMN > 3 cm, abrupt caliber change in main duct with upstream atrophy, lymphadenopathy, pancreatitis, increased serum 19-9, cyst growth > 5 mm over 2 years) and high-risk features (main duct > 1 cm, enhancing, mural nodule > 5 mm, jaundice) have been defined[25].

However, these clinical features are still imperfect in differentiating between benign cysts and mucinous cystic lesions that harbor high-grade dysplasia or PDAC and require surgical resection and mucinous cystic lesions that have low-grade dysplasia and are safe to look at.

For the time being, a screening program is offered to individuals with a strong family history and/or genetic predisposition to develop pancreatic cancer and subjects with mucinous cystic lesions of the pancreas. The primary goals of screening are the detection of high-grade dysplastic precancerous lesions (IPMN and pancreatic intraepithelial neoplasia) and T1N0M0 pancreatic cancer that are more amenable to potentially curative resection[26].

The current recommendation is to perform endoscopic ultrasound (EUS) or magnetic resonance imaging (MRI)/magnetic resonance cholangiopancreatography. Screening is recommended at age 50 years or 10 years before the youngest relative with PDAC in familial pancreatic cancer cases. In other settings, screening is performed between the ages of 35 years and 45 years. In case the patient had a normal pancreas on imaging, it is recommended to repeat the procedure every year alternating EUS and magnetic resonance cholangiopancreatography. However, no consensus has been found on the preferred modality and optimal timing/frequency. This reflects the absence of robust data in the literature and underscores the lack of biological tools to detect precancerous lesions early.

IMAGING

There are several imaging methods that can identify pancreatic cancer at an early stage. Contrast-enhanced CT and MRI according to Japanese guidelines[27] are the first methods to be performed in patients with suspected PDAC based on clinical symptoms, serum pancreatic enzymes, tumor markers and transabdominal US. They are supplemented by EUS and endoscopic retrograde cholangiopancreatography (ERCP).

A study evaluated the diagnostic accuracy of US, CT, MRI, and EUS in 200 cases of PDAC stage 0/1. Only 20% of patients were symptomatic[28]. The diagnostic accuracy was 67.5%, 98.0%, 86.5%, and 86.5%, respectively. According to some authors, CT and US are procedures with limitations in the early detection of pancreatic cancer because only indirect signs, such as pancreatic duct dilatation, localized pancreatic atrophy or local fat changes in the pancreatic parenchyma, can be detected with these methods[20].

Two systematic reviews[29,30] evaluated the performance of EUS in the diagnosis of pancreatic cancer. In the first review, EUS was shown to have higher sensitivity than CT (91%-100% *vs* 53%-91%),

while in the second review, Kitano *et al*[30] reported that EUS was more sensitive than US and CT (94% *vs* 67% and 98% *vs* 74%, respectively).

However, conventional EUS does not distinguish carcinoma from other etiologies very well because most pancreatic tumors, including benign ones, have a hypoechogenic appearance. Contrast-enhanced EUS can improve imaging of parenchymal perfusion and microvessels in pancreatic pathology. This method has higher sensitivity (94.5% *vs* 83.1%) and specificity (84.1% *vs* 78.6%) than conventional EUS [31,32].

Endoscopic ultrasonography guided fine needle aspiration (EUS-FNA) represents the first-line method for pathological diagnosis. In relation to lesion size, the accuracy of EUS-FNA is 93.4% for lesions ≥ 20 mm, 83.5% for lesions of 10-20 mm and 82.5% for lesions of 10 mm or less[33]. Sometimes CT, MRI and EUS fail to detect early stage pancreatic tumors and it is difficult to collect specimens with EUS-FNA. In this situation, especially with regard to PDAC in situ, the only available imaging finding is localized stenosis of the main pancreatic duct. Detailed evaluation of the pancreatic duct by ERCP and subsequent cytology of pancreatic juice become extremely important for diagnosis. In this context, ERCP has a sensitivity and specificity of 57.9% and 90.6%[34]. The sensitivity of pancreatic juice cytology in the diagnosis of PDAC in situ is 72.2%-100%[28,35].

ERCP is particularly useful in distinguishing autoimmune pancreatitis from PDAC, especially in patients[36] with atypical pancreatic parenchymal findings, such as focal enlargement of the pancreas and mass formation.

Ikemoto *et al*[37] proposed a recent algorithm for early diagnosis of PDAC in stage 0 and IA, with a promising long-term prognosis. In addition to pancreatic laboratory tests, US should be performed earlier in patients with risk factors in order to identify asymptomatic patients. Patients with an obvious tumor are managed according to conventional algorithms. Patients who do not have an overt pancreatic tumor but have indirect findings, such as abnormalities of the main pancreatic duct, cystic lesions or pancreatic atrophy, should be evaluated by MRI with magnetic resonance cholangiopancreatography. If the MRI shows abnormalities suggestive for PDAC, EUS-FNA is performed[37].

ARTIFICIAL INTELLIGENCE APPLIED TO IMAGING

Great hopes are now pinned on artificial intelligence (AI) for solving the most difficult problems in medicine, and these include the early diagnosis of PDAC. AI is the ability of a computer to perform functions and reasoning typical of the human mind completely autonomously. In the deepest sense, it is the ability of a machine to learn and improve automatically based on experience, provided directly through data. In this way, AI becomes a powerful tool for discovering signals that are difficult for humans to infer or describe and for expanding the frontiers of our scientific capabilities.

Muhammad *et al*[38] used AI to predict the risk of developing PDAC. By analyzing variables such as demographic data, comorbidities and family history, they built a model capable of predicting the development of PDAC with good accuracy [area under the curve (AUC) of 0.85][38,39].

The application of AI in the field of radiology is also very promising, as AI is capable of analyzing thousands of images on a pixel-by-pixel level, does not make human errors and achieves data processing in a short time[40]. Several studies have reported the application of AI in EUS image analysis of pancreatic diseases. Das *et al*[41] evaluated the performance of AI in differentiating PDAC from normal pancreas and chronic pancreatitis. The algorithm they used identified neoplasia with an AUC of 0.93. A recent study by Zhu *et al*[42] reported an overall accuracy of 94% by AI in distinguishing pancreatic cancer from chronic inflammation. CT is the most explored medical imaging modality with AI. Liu *et al*[43] reported an AUC of 0.963 for the diagnosis of PDAC using CT with the AI platform. In addition, the time to diagnosis was 20 s/case, certainly less than the time needed by radiologists. The same authors, in more recent work, found 99% accuracy for analysis based on the use of AI. In this study, AI provided higher sensitivity than radiologists (0.983 *vs* 0.929, respectively)[44]. AI missed 3 (1.7%) of 176 PDACs (1.1-1.2 cm), while radiologists missed 12 (7%) of 168 PDACs (1.0-3.3 cm), of which 11 (92%) were correctly detected by AI.

Two important ongoing projects should be noted. Project Felix is a multidisciplinary study led by Johns Hopkins University, which compared 156 PDAC cases and 300 healthy controls using deep learning computer models with manually segmented images. In an initial report, they reported a sensitivity and specificity of 94% and 99%, respectively[45]. The analysis was subsequently expanded to 575 normal patients and 750 patients with PDAC. The second ongoing project is being conducted by the Alliance of Pancreatic Cancer Consortium Imaging Working Group[46]. The goal of the project is to create a shared repository by collecting pre- and post-diagnosis CT, MRI and US images of patients with PDAC to develop AI that can predict the onset of pancreatic cancer and/or diagnose it at an early stage [47].

LIQUID BIOPSY

Serum biomarkers

Carbohydrate antigens: The most validated serum tumor marker in terms of diagnostic, prognostic and surveillance capacity for pancreatic cancer is CA19-9. The sensitivity and specificity of elevated CA19-9 to detect PDAC are 79% and 82%, respectively[48,49].

However, the use of CA19-9 has several limitations. Approximately 10% of the Caucasian population has reduced CA19-9 production due to Lewis antigen dependence. In addition, there are several conditions that result in the increase of the biomarker, such as obstructive jaundice, liver cirrhosis, chronic pancreatitis and cholangitis. The low positive predictive value of CA19-9 limits its application as a screening tool for larger populations[48,50-52]. Other carbohydrate antigens have been evaluated for early diagnosis of pancreatic cancer, such as CA125, CA72-4[53], CA50, CA199 and CA242[48,54]. The solitary diagnostic potential of these biomarkers could not be verified; however, they could help in discriminating between benign and malignant pancreatic lesions in combination with CA19-9[48].

Circulating tumor DNA and circulating tumor cells: New and interesting diagnostic tools in the field of pancreatic cancer are circulating tumor DNA (ctDNA) and circulating tumor cells (CTCs). In patients with malignancies, cell-free circulating DNA (cfDNA) molecules are released from tumor cells by apoptosis, necrosis or active release and are called ctDNA. The ctDNA contains mutations specific to the cancer cells from which they are released[55,56]. Thanks to these DNA molecules, it is therefore possible to trace the presence or absence of cancer.

However, a recent meta-analysis evaluated the role of ctDNA in the diagnosis of PDAC and found a rather low sensitivity[57]. This happens because in the early stages the rate of necrosis and apoptosis is lower and not enough ctDNA is released into the circulation (in the early stages of PDAC, only one molecule of circulating tumor DNA can be detected for every 5 mL of plasma)[57]. This challenge could be solved with technological advances, and ctDNA could become an important tool for early diagnosis.

CtDNA has been studied together with other biomarkers to improve its sensitivity and specificity. The combination of KRAS mutations in ctDNA and CA19-9 proved to be particularly interesting. Indeed, it showed a sensitivity and specificity of 0.98 and 0.77, respectively, to differentiate PDAC from chronic pancreatitis and sensitivity and specificity of 0.82 and 0.81 to differentiate PDAC from benign pancreatic tumors[56,58]. Combining the KRAS mutation in ctDNA with four protein biomarkers (CEA, CA19-9, hepatocyte growth factor and osteopontin) identified 64% of patients with pancreatic cancer with a specificity of 0.99[59]. This strategy seems to be very promising; however, it needs validation through studies on large populations.

Analysis of epigenetic alterations in cfDNA also seems to play an important role. By assessing the methylation status of two genes (*ADAMTS1* and *BNC1*) in cfDNA, it seems possible to identify pancreatic cancer early with a sensitivity of 0.95 and specificity of 0.92[60]. In a pilot study, it was reported that a model combining changes in 5-methylcytosine and 5-hydroxymethylcytosine in cfDNA achieved a sensitivity of 0.94 and specificity of 0.95, with an AUC of 0.99 for the diagnosis of PDAC[61].

The ability of targeted cfDNA methylation analysis to detect and localize multiple cancer types at all stages was evaluated. Among patients included with PDAC at different stages, a sensitivity of 0.63 in stage I, 0.83 in stage II, 0.75 in stage III and 1.0 in stage IV was found[62]. These changes in cfDNA methylation could be very useful for monitoring risk groups[63].

CTCs can be isolated tumor cells or cells organized in a group to form a tumor microthrombus[64] and are detected in 21%-100% of patients with PDAC[65]. According to some studies, they can be detected in 75%-80% of patients with early-stage tumors[66] and up to 88% of patients with precursor lesions, predominantly IPMNs[67-69]. Notably, CTCs identify patients with high-grade dysplasia, indicating its potential to stratify high-grade IPMNs against low-grade IPMNs and other benign cysts [67]. In a meta-analysis, the sensitivity, specificity and AUC for PDAC diagnosis of ctDNA, exosomes and CTCs were evaluated. They were 0.64, 0.92 and 0.94 for ctDNA, 0.93, 0.92 and 0.98 for exosomes and 0.74, 0.83 and 0.81 for CTCs, respectively[57]. This lower AUC of CTCs is due to the possibility that CTCs become trapped in the liver when traveling through the portal vein[57]. The ability to detect CTCs by analyzing portal vein blood is greatly increased. They can be found in 100% of patients with metastatic PDAC[70] and in 58% of resectable patients[71]. As with ctDNA, the low amount of CTCs in the early stages is the main factor hindering their use as biomarkers[57].

RNA, metabolites and exosomes: The most significant microRNAs are *miR-21*, *miR-25* and *miR-233*. *miR-21* has a sensitivity for early diagnosis of 0.90 and a specificity of 0.72, while *miR-25* has a sensitivity of 0.75 and 0.93, respectively[72,73]. In contrast, *miR-233* has proven useful in the differential diagnosis between benign and malignant IPMNs[74]. The microRNAs offer a cumulative sensitivity for early-stage pancreatic cancer of 0.79 and a specificity of 0.74[75]. The combined use of CA19-9 and microRNAs can improve diagnostic accuracy, especially *miR-216*[76-77].

Potentially useful biomarkers also include long non-coding (lnc)RNAs. *SNHG15* lncRNA expression is found to be increased in patients with pancreatic cancer compared to healthy controls[78]. Permuth *et al*[79] demonstrated that the differential diagnosis between malignant and nonmalignant IPMNs can be made through the combination of eight lncRNAs. In addition, some lncRNAs (*HAND2-AS1*, *CTD-*

2033D15.2 and *lncRNA-TGF*) are early markers of IPMNs[80]. Other lncRNAs that might be useful in the early detection of pancreatic cancer and IPMN are *HOTAIR*, *MALAT1*, *MEG3*, *H19*, *PVT1*, *HOTTIP*[81], *HAND2-AS1*, *CTD-2033D15.2* and *lncRNA-TGF*[82].

The role of serum metabolites in pancreatic cancer has become of interest with the advent of metabolomic technologies involving nuclear magnetic resonance and mass spectrometry[83]. An important study was performed by Michálková *et al*[84], who developed a nuclear magnetic resonance-based model that included 12 metabolites (3-hydroxybutyrate, lactate, glutamine, alanine, valine, lysine, citrate, histidine, isoleucine, glutamate, acetone and dimethylamine). The model has 94% accuracy, 100% sensitivity and 90% specificity in distinguishing patients with PDAC from healthy individuals[84].

Another study compared the metabolomic profiles of serum samples from patients with NOD and those with PDAC and NOD[85]. This identified 62 different metabolites and found that a panel including N-succinyl-L-diaminopimelic and PE (18:2) had high sensitivity (93.3%) and specificity (93.1%). Currently, studies focusing on metabolomics are expensive and consequently rare; however, it is offering great results on the early diagnosis of PDAC. Further studies are desperately needed.

Recent studies are focusing on multimarker panels in combination with CA19-9. The combined use of eight proteins (S100A11, ITGB5, PPY, ERBB3, SCAMP3, RET, 5-NT, CEACAM1) discriminated with fair accuracy between patients with early stage I/II PDAC and healthy individuals[48,86].

A new and still much to be studied chapter in PDAC concerns the study of exosomes. Kitagawa *et al*[87] studied molecules of exosomal mRNA (*CCDC88A*, *ARF6*, *Vav3* and *WASF2*) and nucleolar RNA (*SNORA14B*, *SNORA18*, *SNORA25*, *SNORA74A* and *SNORD22*) and obtained excellent results for early-stage neoplasia. Tumor-specific expression of exosome surface proteins, the so-called tumor-specific surfaceome, can also be analyzed. Castillo *et al*[88] characterized six PDAC-specific surfaceome proteins, such as CLDN4, EPCAM, CD151, LGALS3BP, HIST2H2BE and HIST2H2BF. These proteins were suggested as promising biomarkers for PDAC diagnosis by the authors. Yu *et al*[89] developed a signature with long RNAs from plasma extracellular vesicles. This signature identified stage I/II pancreatic cancer with very high accuracy and performed better than CA19-9 in distinguishing PDAC from chronic pancreatitis (AUC 0.931 *vs* 0.873)[89]. Serum biomarkers are summarized in Table 1.

Pancreatic juice and pancreatic cyst fluid

In addition to blood, other body materials can be exploited to diagnose PDAC. For example, pancreatic juice collected during ERCP and cyst fluid obtained by EUS-FNA can be analyzed for specific markers. They include KRAS and GNAS mutants (the latter specific for IPMNs) as well as TP53, SMAD4, PIK3CA, PTEN and AKT1, which are generally related to IPMN-associated tumors[90-92].

Biomarkers still under study include mucins (MUCs). Normal pancreatic tissue expresses low levels of MUCs, whereas in branch duct IPMNs there is upregulation of the mucin gene and even more pronounced changes in PDAC[93-95]. MUC4 and MUC16 are 100% specific for pancreatic cancer but have sensitivities of 63% and 67%, respectively[95]. The combined biomarker panel consisting of MUC5AC and CA19-9 also showed excellent performance in distinguishing pancreatic cancer subjects from healthy controls[96].

It also seems possible to distinguish pancreatic cystic lesions with high-grade dysplasia or malignancy by assessing interleukins (IL-1b, IL-5 and IL-8) present in pancreatic juice or by using the monoclonal antibody Das-1. Das-1 can detect pancreatic cysts at risk of malignancy with a sensitivity of 88% and specificity of 98%[97-99].

In recent work by Majumder *et al*[100], a panel of three methylated DNA markers (C13orf18, FER1L4 and BMP3) in pancreatic juice discriminated cases from controls with good accuracy. Using a specificity cutoff value of 86%, the panel distinguished patients with any stage of pancreatic cancer from controls with a sensitivity of 83% and identified patients with stage I or II PDAC or IPMN with high-grade dysplasia with a sensitivity of 80%[100].

Saliva

Progress has also been made in saliva evaluation. A recent study[101] identified seven upregulated genes (*MBD3L2*, *KRAS*, *STIM2*, *DMXL2*, *ACRV1*, *DMD* and *CABLES1*) and five downregulated genes (*TK2*, *GLTSCR2*, *CDKL3*, *TPT1* and *DPM1*) in subjects with PDAC compared with healthy controls or those with chronic pancreatitis. It was possible to discriminate patients with pancreatic cancer with sensitivity and specificity greater than 90% by combining the mRNAs of *MBD3L2*, *KRAS*, *ACRV1* and *DPM1*[101]. Xie *et al*[102] evaluated the expression of lncRNAs and found an upregulation of *HOTAIR* and *PV1T* in the PDAC group compared with controls and benign pancreatic cancers. The combination of salivary *HOTAIR* and *PVT1* differentiated PDAC from healthy controls with a sensitivity of 78.2% and specificity of 90.9% and PDAC from benign tumors with a sensitivity of 81.8% and specificity of 95%[103].

Urine

Radon *et al*[104] used three protein biomarkers (REG1A, TFF1 and LYVE1) to form a powerful urinary panel that could detect patients with stage I-II PDAC with an accuracy of more than 90%. Brezgyte *et al*[105] found increased levels of *miR-143*, *miR-204* and *miR-223* and reduced levels of *miR-30e* in the urine

Table 1 Serum biomarkers

Carbohydrate antigens	CtDNA	miRNA	lncRNA	Metabolites
CA19-9	KRAS	*miR21*	*SNHG15*	3-hydroxybutyrate
CA125	ADAMTS1	*miR25*	*HOTAIR*	Lactate
CA72-4	BNC1	*miR233*	*MALAT1*	Glutamine
CA50	5-methylcytosine	*miR216*	*MEG3*	Alanine
CA242	5-hydroxymethylcytosine	*miR-92-a-5p*	*H19*	Valine
		miR-125b-3p	*PVT1*	Lysine
		miR-532e5p	*HOTTIP*	Citrate
		miR-663	*HAND2-AS1*	Histidine
		miR-1469	*CTD-2033D15.2*	Isoleucine
				Glutamate
				Acetone
				Dimethylamine
				N-succinyl-L-diaminopimelic
				PE (18:2)
Exosomal mRNA molecules	**Exosomal small nucleolar RNA molecules**	**Exosome surfaceome**	**Exosomal long RNAs**	**Others**
CCDC88A	*SNORA14B*	*CLDN4*	*FGA*	CTCs
ARF6	*SNORA18*	*EPCAM*	*KRT19*	ITGB5
Vav3	*SNORA25*	*CD151*	*HIST1H2BK*	PPY
WASF2	*SNORA74A*	*LGAL53BP*	*ITIH2*	ERBB3
	SNORD22	*HIST2H2BE*	*MARCH2*	SCAMP3
		HIST2H2BF	*CLDN1*	RET
			MAL2	5-NT
			TIMP1	CEACAM1
				S100A11

CtDNA: Circulation tumor DNA; miRNA: MicroRNA; lncRNA: Long non-coding RNA; CTC: Circulating tumor cells.

of patients with stage I PDAC compared with the healthy population. However, further studies are needed to validate their clinical utility.

A case-control study that included 914 PDAC patients found the superiority of a panel of metabolites (proline, sphingomyelin, phosphatidylcholine, isocitrate, sphinganine-1-phosphate, histidine, pyruvate, ceramide, sphingomyelin) over CA19-9 in discriminating early-stage PDAC from chronic pancreatitis [106]. According to the authors, the metabolic panel could result in changes in the diagnostic pathway and treatment stratification for one-third of the included patients[106]. Biomarkers of pancreatic juice and cystic fluid, saliva and urine are listed in Table 2.

ARTIFICIAL INTELLIGENCE AND BIOMARKERS

AI can be applied to the identification of biomarkers. Zhang *et al*[107] identified a nine gene pair signature that can distinguish PDAC patients from non-PDAC patients. Alizadeh Savareh *et al*[108] evaluated the best miRNAs using a machine learning method to aid in the early detection of PDAC. The final model included *miR-92a-2-5p*, *miR-125b-3p*, *miR-532e5p*, *miR-663a and miR-1469* with a high performance in differentiating PDAC from controls (accuracy, 0.93; sensitivity, 0.93 and specificity, 0.92).

Table 2 Pancreatic juice and cyst fluid biomarkers, saliva biomarkers, urine biomarkers

Pancreatic juice and cyst fluid biomarkers			
Mutant genes	**Mucins**	**Interleukins**	**Methylated DNA markers**
GNAS	MUC4	IL-1b	C13orf18
KRAS	MUC16	IL-5	FER1L4
TP53	MUC5AC	IL-8	BMP3
SMAD4			
PIK3CA			
PTEN			
AKT1			
Saliva biomarkers			
Upregulated genes	**Downregulated genes**	**LncRNA**	
MBD3L2	*TK2*	*HOTAIR*	
KRAS	*GLTSCR2*	*PVT1*	
STIM2	*CDKL3*		
DMXL2	*TPT1*		
ACRV1	*DPM1*		
DMD			
CABLES1			
Urine biomarkers			
Protein markers	**MiRNA**	**Metabolites**	
REG1A	*miR-143*	CA19.9	
TFF1	*miR-204*	Proline	
LYVE1	*miR-223*	Sphingomyelin (d18:2, C17:0)	
	miR-30e	Phosphatidylcholine	
		Isocitrate	
		Sphinganine-1-phosphate	
		Histidine	
		Pyruvate	
		Sphingomyelin (d17:1, C18:0)	

miRNA: MicroRNA; lncRNA: Long non-coding RNA.

WHAT STRATEGIES TO AVOID A FORETOLD CATASTROPHE

As we have already mentioned in the introduction, the current predictions for PDAC give us a glimpse of a catastrophe on the horizon. If the increase in annual PDAC cases continues at the current rate, we will soon have a staggering number of cases without the weapons to stem this foretold catastrophe. The only option is to arm ourselves and not arrive unprepared for this hard battle. What strategies should we adopt to prepare for this ordeal? Undoubtedly first, we need to make academia, industry and the politics/economic world understand the urgency of finding solutions quickly, trying to interact with each other according to specific competencies. On the one hand, academia and industry will have to move forward together, as quickly as possible, in those research paths that we have broadly summarized in this article. On the other hand, the political/economic world, made aware of the emergency to be faced, will have to commit itself both to allocating more funding for research in this field and to lavishing more funding on public health. If public health had sufficient funds to subject all patients of a certain age to a simple screening ultrasound of the abdomen, perhaps many patients could be saved. But at present, with current resources, this scenario remains a pipe dream.

CONCLUSION

In this article, we have summarized all the possible strategies we have available today for the early detection of PDAC and the paths that research must pursue to make this goal ever closer. Unfortunately, in 2022 the results for this type of cancer still remain discouraging, while a catastrophic increase in cases is expected in the coming years. The article has been written with the aim of highlighting the urgency of devoting more attention and resources to this pathology in order to reach a solution that seems more and more unreachable every day.

Abstract

After more than four decades of hepatitis B virus (HBV) vaccine implementation, its safety and efficacy in preventing HBV infection have been proven and several milestones have been achieved. Most countries have included HBV immunization schedules in their health policies and progress has been made regarding universalization of the first HBV vaccine dose at birth. All of these actions have significantly contributed to reducing both the incidence of HBV infection and its related complications. However, there are still many drawbacks to overcome. The main concerns are the deficient coverage rate of the dose at birth and the large adult population that has not been reached timely by universal immunization. Additionally, the current most widely used second-generation vaccines do not induce protective immunity in 5% to 10% of the population, particularly in people over 40-years-old, obese (body mass index > 25 kg/m^2), heavy smokers, and patients undergoing dialysis or infection with human immunodeficiency virus. Recently developed and approved novel vaccine formulations using more potent adjuvants or multiple antigens have shown better performance, particularly in difficult settings. These advances re-launch the expectations of achieving the World Health Organization's objective of completing hepatitis control by 2030.

Core Tip: Second-generation vaccines induce the production of anti-hepatitis B surface antibodies (anti-HBs). Anti-HBs levels ≥ 10 mIU/mL prevent against infection. More than 90% of immunized persons achieve protective anti-HBs levels 1 mo after completing the three-dose vaccination schedule. Although antibody titers significantly drop during the 1st years after vaccination, memory immunity is sufficient to prevent infection regardless of the antibody levels. In some specific settings showing lower immune response rates, schemes with larger or additional doses and novel vaccine formulations are recommended.

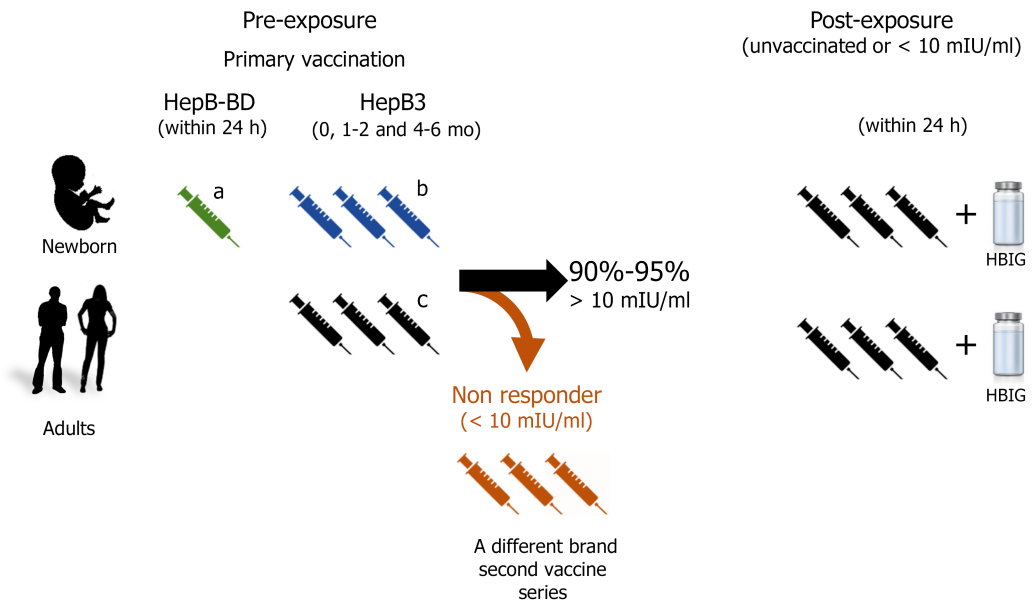
INTRODUCTION

Hepatitis B infection has been a major public health concern for a long time. Identification of the hepatitis B virus (HBV) in the 1960s and the subsequent development of a safe and effective vaccine were the kickoff to begin to retrace the path and achieve the desired control of this health problem.



First-generation vaccines based on heat-treated plasma derived from hepatitis B surface antigen (HBsAg)-positive donors raised concerns about its safety and availability to meet the vaccine manufacturer's needs. Shortly afterwards, second-generation DNA vaccines prepared in yeast transfected with recombinant plasmids encoding small HBV surface proteins (SHBs) were developed and approved in 1986[1]. Lastly, third-generation vaccines have been produced in mammalian cells that express and secrete SHBs and middle pre-S2 proteins (MHBs) or the three HBV envelope proteins (SHBs, MHBs, and large HBs).

It is worth noting that several studies have compared the immune response to plasma-derived first-generation vaccines to the recombinant second-generation ones. Most of the studies showed that the lowering rate of anti-HBs was higher in people receiving the recombinant HBV vaccine. However, plasma-derived vaccines were replaced by the recombinant ones due to safety concerns about human blood-derived products[2-5]. In addition, it has been shown that third-generation vaccines containing the pre-S2 and pre-S1 antigens would induce a higher anti-HBs response than second-generation ones, particularly in people ≥ 45-years-old[6-8]. Moreover, compared to plasma-derived vaccines, it has been observed that the HBsAg seropositive rate drops by about 71% and that the anti-HBc seropositive rate decreases by approximately 65% when recombinant HBV vaccines are used, supporting their higher effectiveness[4].

The HBV vaccine has been introduced progressively in the national vaccination calendars. Currently, second-generation HBV vaccines have been widely implemented for newborns in most countries. The pentavalent vaccine formulation protecting against diphtheria, pertussis, tetanus, hepatitis B, and *Haemophilus influenzae* type B is administered in three doses, 4 wk apart (recommended dosing at 6, 10, and 14 postnatal wk), and aims to lessen horizontal transmission. In addition, a monovalent single dose of the HBV vaccine (HepB-BD) administered within 24 h after delivery is also recommended to reduce mother-to-child transmission (Figure 1). The advised immunization schedule for the adult population includes three vaccine doses (HepB3) according to the individuals' age. Immunocompromised adults or patients on dialysis treatment require higher or additional doses of HBV vaccines. Recently, a novel vaccine (Heplisav-B) with a different adjuvant was approved for adult immunization with a recommended schedule of two doses 1 mo apart.

Since 1990, the proportion of children receiving all three doses of the HBV vaccine has increased globally from 1% to 85%. By 2020, the HBV vaccine was introduced to 190 countries with 83% of three-dose coverage rate. Few countries with very low endemicity that consider HBV infection as a limited public health problem provide the HBV vaccine to only well-defined risk groups. Likewise, a dose of HepB-BD has been introduced in the national calendar of 113 countries. Figure 2 shows the HBV worldwide three-dose infant vaccine coverage and the HBsAg seroprevalence[2,9]. However, the at birth dose coverage rate is poor (estimated at 43%) with remarkable disparities according to region and development level[10-12].

Universal vaccination is the most effective strategy to prevent and control HBV infection. In 2016, the World Health Organization (WHO) set the goal of controlling HBV by 2030. The proposed targets include the 90% global coverage of three-dose infant vaccination by 2020, birth-dose vaccination of 50%

Figure 1 Recommended hepatitis B virus vaccination schemes. The hepatitis B immunization schedule is flexible, but minimal intervals and ages need to be observed. The recommended dose varies (5-40 μg of hepatitis B surface antigen protein/mL) depending on the individuals' age and the vaccine brand. [a]Monovalent hepatitis B vaccine 0.5 mL must be used for the at birth immunization (HepB-BD). Immunocompromised adults or patients under dialysis require larger or additional doses of the hepatitis B vaccine; [b]Combined hepatitis B, diphtheria, tetanus, adsorbed acellular pertussis, inactivated poliovirus vaccine. This vaccine cannot be administered at birth, before 6 postnatal weeks, or at age ≥ 7 years; [c]Heplisav-B is a vaccine recently approved for adults; it has a novel adjuvant and its recommended schedule is two doses 1 mo apart. HepB3: Three doses of hepatitis B vaccine; HepB-BD: Monovalent single dose of the hepatitis B virus vaccine; HBIG: Hepatitis B Immunoglobulin.

of infants by 2020, and of 90% of them by 2030[13].

MILESTONES ACHIEVED WITH THE HBV VACCINE

One of the goals of the strategy to achieve HBV control by 2030 is to reduce HBsAg prevalence to 0.1% in 5-year-old children and many countries are already on track to that milestone[14].

The global implementation of the HBV vaccine as part of the national health policies has contributed to directly reducing the global burden of infection, and indirectly, the HBV-related mortality. After the inclusion of HBV vaccination schedules, several surveillance studies have shown an overtime global HBsAg prevalence decrease in most countries[15], either in hyperendemic ones or in those with low or medium HBV infection prevalence[16-20].

Taiwan was the first country to implement a mass vaccination program against HBV in 1984 and it is the paradigm of its impact on the control of hepatitis. After 30 years of sustained immunization programs, the prevalence of HBsAg has decreased from 9.8% in the pre-vaccination period to 0.5% in the cohort reached by HBV vaccination protocols[21]. The main reason for Taiwan's success was its high three-dose hepatitis infant vaccine coverage rate, which increased from 88.9% in 1985[22,23] to 98.1% in 2018[21].

In the United States, since first HBV vaccine recommendations, the infection incidence has decreased by approximately 90%, from 9.6/100000 cases in 1982 to 1.0/100000 cases in 2018[24]. Similarly, in China, where the coverage of the three-dose vaccine schedule has increased from 30.0% to 93.4% and the at birth dose increased from 22.2% to 82.6%, the HBsAg prevalence decreased from 5.5% to 0.9% between 1992 and 2005[25]. In Argentina, a country with low HBV endemicity, the HBV vaccine was included in newborns' schedules in 2000 and, later in 2003, the catch-up strategy was implemented in 11-year-old adolescents. Currently, the coverage rate of protective antibodies is significantly higher in persons born after 1992 than in those born previously (Figure 3A)[26,27]. In fact, new infections generally occur in the population over 20-years-old not reached by vaccination[28]. These results emphasize the need to raise awareness among people not reached by universal HBV immunization programs and to focus vaccination campaigns on this group.

However, the most outstanding HBV preventive action impact has been detected in regions that were hyperendemic before introduction of the vaccine. In a Southern Italian area, where the vaccine was introduced in 1991, the HBsAg prevalence dropped from 13.4% in 1978 to 0.91% in 2006[29]. Likewise, in Alaska, where one of the highest HBV infection incidences has been reported, universal childhood

Figure 3 Anti-hepatitis B surface antibodies titers by age. A: The anti-hepatitis B surface antibodies (anti-HBs) titer was determined in 765 blood donors. In 2000, vaccination against hepatitis B virus was included in the Argentine newborns' National Vaccination Calendar. In 2003, the catch-up strategy for 11-year-old children was implemented. Therefore, individuals under 28-years-old are reached currently by the universal vaccine implementation. On average, protective levels of anti-HBs (> 10 mIU/mL) were detected in 75.2% of the population reached by universal vaccination (< 28-years-old) and in 32.2% of the not reached population (> 28-years-old); B: Anti-HBs kinetics. The anti-HBs titer was determined in 132 children born after 2000. In the first 2 years, the median anti-HBs titer fell from 196.2 mIU/mL to less than 10 mIU/mL (black line). Five years post-vaccination, about 20% of the population showed anti-HBs levels below 10 mIU/mL. aHBs: Anti-hepatitis B surface antibodies.

vaccination was implemented for newborns in 1993. The HBsAg prevalence dropped from 13% detected before the HBV vaccination program, to 0% HBsAg-positive children less than 10-years-old[30].

Although slowly and delayed, a significant reduction in the hepatocellular carcinoma annual average incidence has been observed concomitantly with the HBV infection incidence decline, particularly in those countries where early vaccine protocols have been introduced[31-33].

IMMUNITY

HBV vaccine-induced protective immunity

Several studies have shown that HBV vaccines induced both humoral and cellular immunity providing long-term protection[34,35]. On the one hand, neutralizing antibodies are elicited and two types of them have been identified. The first type targets the "a" determinant and neutralizes cell viral penetration by blocking the interaction with heparan sulfate[36], required by the virus at an early stage of hepatocyte entrance[37]. The second type targets the high-affinity receptor-binding site of the HBV pre-S1 domain and blocks the binding to the Na^+-taurocholate cotransporting polypeptide receptor preventing the infection of hepatocytes[38,39]. On the other hand, immune memory cells are generated, which upon contact with the HBV can be activated to expand rapidly. This response has been well demonstrated in studies that administered a booster dose to previously vaccinated persons whose antibody titers had fallen below protective titers[16,40-42].

Pre-exposure: Efficacy and effectiveness studies carried out in animal models first and then in human beings have shown that the HBV vaccine induces the production of neutralizing antibodies against HBV surface antigen (anti-HBs)[43]. Two main questions raised suddenly once the HBV vaccine was developed: What are the levels of antibodies that protect against infection and how long does immunity last? Soon after the release of the vaccine, several studies have shown that anti-HBs levels ≥ 10 mIU/mL, determined 1 to 3 mo after the complete three-dose vaccination scheme administration, were a surrogate marker for vaccine-induced protective immunity[44-46].

The overall response rate to the HBV vaccine, defined as individuals achieving anti-HBs levels > 10 mIU/mL, is 90% to 95% of immunized persons. Different factors such as host genetics, age, body weight, smoking, and concomitant disease have been shown to affect the response rate to the vaccine [47]. These variations probably rely on the strength of the cellular immune response. Velu *et al*[48] have characterized the cellular immune response and the cytokine profile of vaccine responders and non-responders to investigate the immunization outcome underlying mechanisms. The authors reported that HBsAg-specific interferon gamma, interleukin 10, and tumor necrosis factor alpha secretion correlated with the HBV vaccine-induced humoral immune response. Likewise, non-responders had lower levels of T helper type 1 (Th1) and Th2 cytokines. In addition, Körber *et al*[49] observed a higher frequency of regulatory B cells in HBV vaccine non-responders. Regulatory B cells suppress immunopathology by skewing T-cell differentiation. Overall, these results suggest that impaired lymphocyte activation is associated with a weak or no response to HBV vaccination.

Notably, although the HBV vaccine induces protective immunity against infection it would not be sterilizing. Consequently, vaccinated people can become infected although episodes are usually asymptomatic and self-limited[50-52]. These benign infection results are possibly due to long-lasting HBV cellular immunity induced by the vaccine despite antibody loss against HBV surface antigens[53].

Post-exposure: Immunization with HBV vaccines combined with different injection sites of HBV immunoglobulin administration, within 12 h after birth, showed a greater than 85% efficacy in preventing infection in infants born to HBsAg-positive mothers[54]. In adult persons, post-exposure prophylaxis is also recommended depending on the individual's vaccination and anti-HBs status. In unvaccinated subjects or with non-protective levels of anti-HBs, the HBV vaccine has shown high efficacy in preventing infection when administered within 24 h after percutaneous or mucosal exposure to HBV-positive blood. Additional post-exposure immunoprophylaxis is not suggested in individuals who achieved anti-HBs protective levels after vaccination.

Although, as previously mentioned, the massive implementation of the HBV vaccine substantially reduced the incidence and prevalence of the infection, few works have addressed the effectiveness of the vaccine and most of them have been carried out in high endemic countries. In general, a 70% to 94% effectiveness range has been reported, depending mainly on the follow-up time, the exposure risk rate (HBsAg prevalence of the population), and the studied cohort age[18,23,55]. A recent study showed an approximately 58% effectiveness in a birth cohort (mean age, 12 years) and 85% in participants at least 20-years-old[56]. The lower efficacy observed in the birth cohort could be a consequence of a lower level of exposure.

HOW LONG DO THE ANTIBODIES LAST?

Protective antibodies levels tend to decrease over time, especially during the 1st years after vaccination [57]. In a study carried out by our group, including 132 children born after infants' vaccine implementation, we observed that anti-HBs titers were significantly higher 1 year post-vaccination compared to the 2 years and 3 years earliest vaccinated population (Figure 3B). In addition, approximately 20% of the 5-year post-vaccination cohort showed anti-HBs levels lower than 10 mIU/mL[27]. These results are in line with a study conducted in Germany, where anti-HBs levels were determined in 106 teenagers, mean age 13.7-years-old, after primary vaccination. Forty percent of cases had anti-HBs levels < 10 mIU/mL. However, almost all (97%) teenagers who received a booster vaccine achieved anti-

HBs levels ≥ 100 mIU/mL regardless of their pre-booster levels[58]. Besides time elapsed since primary vaccination, a systematic meta-analysis including 46 studies analyzed the anti-HBs levels from 5 years to 20 years after the primary vaccination and identified the vaccination dose and the less than 6-mo interval between the last dose and the previous one as the main factors associated with anti-HBs titer loss[59]. On the other hand, the duration of antibody levels is directly correlated with the titers reached when completing the vaccination scheme[60].

Another interesting issue regarding antibodies duration refers to the subjects' age at the time of vaccination. Numerous studies have shown that vaccination in adolescence generates higher and long-lasting titers compared to children vaccinated at birth[61-64], being the age at the time of vaccination an independent variable associated with an anti-HBs titer < 10 mIU/mL. However, childhood HBV vaccination, together with other vaccines, guarantees a higher coverage rate.

Overall, it is widely accepted that a large proportion of vaccinated individuals, particularly those immunized during childhood, rapidly lose their anti-HBs titers below protective levels[40]. However, it has also been extensively described that individuals who achieved anti-HBs protective titers at the time of vaccination, show a rapid anamnestic response when boosted[41,42], suggesting that memory immunity plays a decisive role in the protection against clinical disease and the development of a carrier state regardless of anti-HBs antibody levels[35]. In this regard, it has been observed that even in the lack of anti-HBs, a significant amount of HBsAg-specific memory T and B cells are detected in vaccine responders. For this reason, although it remains a controversial issue, vaccine booster doses are not recommended currently for children and adults with normal immune status, despite the overtime drop of anti-HBs antibody titers[35,65]. Nonetheless, the anti-HBs titer decline could represent a problem for high-risk groups.

MANAGEMENT OF SPECIAL POPULATIONS

Adult persons with increased risk factors for infection are one of the WHO identified obstacles to HBV elimination as a public health problem[66,67]. These groups mainly include health care providers, illicit injected drug users, sexually active individuals (more than 1 partner in the past 6 mo), persons with diabetes, dialysis patients, and people living with human immunodeficiency virus (HIV). The last two groups, in addition to showing a higher risk of HBV infection compared to the general population[68-70] due to the frequent use of percutaneous materials and the common route of HBV and HIV transmission, have shown suboptimal responses to HBV immunization[71,72]. Patients on dialysis have also shown a diminished response to the HBV vaccine probably due to a uremic-associated suppression of the immune system that leads to a significant progressive reduction of the percentage and count of lymphocytes CD3+, CD4+, and CD8+ and a disturbance of antigen-presenting cells that results in an inability to sustain a satisfactory antibody titer over time[73-76]. In fact, in this population subset, the rate of seroprotection level ranges from 33.3% to 86%[77].

It has been reported that patients living with HIV present a poor initial HBV immunization response, lower seroconversion rates, and difficulty in maintaining immunity over time, mainly due to B-cell dysfunction[67,71,78,79]. For this group, the efficacy of the standard vaccine scheme in the era of the highly active antiretroviral therapy ranges from 17.5% to 71%[80-83].

Consequently, for patients on dialysis and/or living with HIV, other approaches are recommended to enhance the HBV vaccine immune response. For patients undergoing dialysis therapy, alternative strategies include the use of adjuvants, additional vaccination cycles, different vaccine formulations, greater number and concentration of doses, greater frequency of doses, dual vaccination, alternative administration routes, and/or use of booster vaccines[67,72,84-86]. On the other hand, for HIV-infected individuals with negative or < 10 mIU/mL anti-HBs levels after a primary vaccine series, a second HBV vaccine series using larger or additional doses is recommended[71,87]. Furthermore, revaccination should be attempted after HIV viral load suppression and CD4 cell count improvement[83].

RATE OF RESPONSE TO HBV VACCINE

As mentioned above, the average response rate to the HBV vaccine is greater than 90% with 5% to 10% vaccinated persons failing to mount a protective immunity level once the vaccination schedule is completed. The response to the vaccine ultimately relies on the individual immune system; however, different factors impairing the response rate have been identified. Response rates can drop drastically when more than one of these factors are present.

Host genetics

Several studies have addressed, through different experimental approaches, the role of genetic polymorphisms in the response to the HBV vaccine. Single nucleotide polymorphisms in HLA loci[88-92], ILs (with a key role in the cellular and humoral response interplay)[93,94], or even other genes have

been associated with the response rate to HBV vaccination[90,95,96]. However, these findings have not been widely validated in different cohorts and should be considered with caution.

Age

One of the most recognized consequences of aging is the declination of the immune function and the concomitant vaccination response reduction. The HBV vaccine response rate decreases in people 40-years-old and even more in people older than 60 years[97,98]. This highlights the need to vaccinate the population not covered by health policies before they reach 40-years-old, which will result in important cost-benefit profits.

Body weight

Overweight and obesity are a growing public health problem worldwide that affects all age groups[99]. They are caused by the deposition of lipids into the adipose tissue and are defined as a body mass index ≥ 25 kg/m.

Shortly after the HBV vaccine was developed and implemented, obesity was found to be a factor impairing the strength of the immune response[100]. This finding has been widely validated in subsequent studies[101,102]. This drawback is not only attributed to the HBV vaccine but has also been described for other vaccines[103,104]. Adipose tissue has a role in modulating the immune system through different pathways, inducing a chronic pro-inflammatory state[105,106], which in the end is associated with immune system dysfunction. This includes the chronic activation of cells of the innate immune system and consequent local and systemic inflammation[107]. In addition, Frasca *et al*[108] described a percentage decrease of switched memory and transitional B cells and an increase of late/exhausted memory B cells with the consequent impaired response to the vaccine.

Smoking

As described for obesity, the link between tobacco smoking and impaired vaccine response has been proposed to be mediated by inflammation[109]. However, data from different studies are less robust. Some studies have reported lower responses to vaccination while others showed no association[110]. This controversy could be based on the level of daily cigarette intake. A recent study reported that subjects in the non-responder group were almost exclusively 'heavy smokers' defined as consumers of ≥ 10 cigarettes per day[111]. The development of new vaccine formulations including either additional antigens or more potent adjuvants could represent a solution to improve the response rate of individuals affected by these factors as well as for dialyzed or immunosuppressed patients.

NEW FORMULATIONS

As previously mentioned, one of the main drawbacks of the second-generation vaccines is the poor induction of immune response in 5% to 10% of the general population and individuals presenting detrimental factors that impair vaccine response. Therefore, efforts have been made to find more effective formulations to overcome this limitation. Two advances have been reported in recent years. One of them is the development and evaluation of new and more powerful adjuvants to enhance immunogenicity[112,113].

Heplisav-B (HepB-CpG), a single-antigen vaccine with a novel immunostimulatory adjuvant, has been approved for its use in people at least 18-years-old. This vaccine is administered in two doses, 1 mo apart[114]. The new adjuvant is a small synthetic cytidine-phosphate-guanosine oligodeoxynucleotide containing non-methylated CpG patterns, similar to those present in microbial DNA. This structure acts as an agonist of the toll-like receptor 9 that enhances the immune response. Several studies have shown higher response rates to other second-generation vaccines both in general population[115-117] and in persons with detrimental factors for vaccination response[118-120]. In addition, the two doses-1 mo apart-simplified schedule could help increase patient compliance and raise the coverage rate.

Alternatively, third-generation vaccines derived from mammalian cells, containing the medium and large HBV envelope proteins have been developed. The advantage of this approach is that antigens display the same *in vivo* post-translational modifications and protein folding.

In 2021, Sci-B-Vac was licensed, and phase III trials showed faster seroprotection and higher response rates than the second-generation vaccines[8,121]. These data making turn Sci-B-Vac of particular interest for its use in people with poor or no response. Particularly, Sci-B-Vac has shown greater efficacy in HIV-infected individuals' immunization and in the prevention of vertical infection transmission[122,123]. Furthermore, the multiple antigen display of the third-generation vaccines would protect against HBV vaccine breakthrough infections caused by the HBV S gene mutants widely described[124-126]. The results obtained through novel vaccine formulation approaches suppose a contribution to the prophylaxis of HBV infection and represent a promising future.

CURRENT CHALLENGE

Beyond significant advances in the prevention of HBV infection, several pitfalls have been identified that need to be overcome in order to eliminate HBV as a health problem[127]. Particularly, in developing countries, sustainable financial mechanisms are required to scale up screening interventions and ensure access to vaccines.

Regarding the at birth dose, out-of-hospital deliveries, shortage of monovalent vaccine formulation in some regions, insufficient training of health care providers, weak monitoring and reporting systems, and low government commitment impair its implementation. On the other hand, in the adult population not covered by universal vaccination, promoting information, raising consciousness about risk, and finally focusing and promoting vaccination campaigns should improve immunization strategies for this group.

CONCLUSION

The worldwide application of HBV vaccines has led to a significant decrease in HBV infection incidence and its related death rates. As a general strategy, surveys are necessary to identify local constraints (in regions or countries) in order to achieve the implementation of WHO guidelines, both at the prophylaxis and diagnostic levels. Increasing efforts to improve vaccination coverage and raise awareness among populations not reached by universal vaccination will contribute significantly to achieving the WHO goals by 2030. Although HBV vaccines induce protective immunity in more than 90% of immunized people, there are particular settings where the efficacy is lower. In recent years, new formulations containing new adjuvants or other HBV antigens in addition to HBs, that could overcome the limitations of current presentations.

Abstract

In this comprehensive evidence-based analysis of ulcerative colitis (UC), a causal role is identified for colonic epithelial hydrogen peroxide (H_2O_2) in both the pathogenesis and relapse of this debilitating inflammatory bowel disease. Studies have shown that H_2O_2 production is significantly increased in the non-inflamed colonic epithelium of individuals with UC. H_2O_2 is a powerful neutrophilic chemo-tactic agent that can diffuse through colonic epithelial cell membranes creating an interstitial chemotactic molecular "trail" that attracts adjacent intra-vascular neutrophils into the colonic epithelium leading to mucosal inflammation and UC. A novel therapy aimed at removing the inappropriate H_2O_2 mediated chemotactic signal has been highly effective in achieving complete histologic resolution of colitis in patients experiencing refractory disease with at least one (biopsy-proven) histologic remission lasting 14 years to date. The evidence implies that therapeutic intervention to prevent the re-establishment of a pathologic H_2O_2 mediated chemotactic signaling gradient will indefinitely preclude neutrophilic migration into the colonic epithelium constituting a functional cure for this disease. Cumulative data indicate that individuals with UC have normal immune systems and current treatment guidelines calling for the suppression of the immune response based on the belief that UC is caused by an underlying immune dysfunction are not supported by the evidence and may cause serious adverse effects. It is the aim of this paper to present experimental and clinical evidence that identifies H_2O_2 produced by the colonic epithelium as the causal agent in the pathogenesis of UC. A detailed explanation of a novel therapeutic intervention to normalize colonic H_2O_2, its rationale, components, and formulation is also provided.

Core Tip: Ulcerative colitis (UC) is a chronic inflammatory bowel disease that has resisted all efforts to uncover its cause and cure. However, an evidence-based systems medicine approach has provided compelling evidence that the secretion of hydrogen peroxide (H_2O_2) from colonic epithelial cells is the etiological agent responsible for this debilitating illness. H_2O_2 is a highly potent chemotactic agent that can attract neutrophils into the colonic epithelium, and significantly elevated production of H_2O_2 has been documented in the non-inflamed colonic epithelium of individuals with UC. Treatment to normalize colonic H_2O_2 leads to long-lasting histologic remission.

INTRODUCTION

Treating ulcerative colitis (UC) has never been easy. The natural history of UC is one of worsening and progressive disease, and no currently available approved medication can cure the life-long repeating episodes of rectal bleeding, diarrhea, and abdominal pain that are experienced by individuals suffering from this illness[1]. The difficulty in choosing from currently available non-curative therapies was underscored by a recent study, which concluded that the majority of clinical guidelines for the treatment of UC are based on low or very low-quality evidence[2]. Thus, we are left with therapies that cannot cure and have a disappointing track record when it comes to treatment.

The distress engendered by the lack of effective treatment is universal with the majority of UC patients in a 10-country global survey reporting poor disease control, mental exhaustion, and adverse impact on quality of life[3]. This is consistent with other multi-country studies reporting that UC was not controlled in over 87% of participants[4]. The real-world effects of non-curative low-quality therapy are evident by the high degree of medical treatment failure that is responsible for up to a 30% colectomy rate in patients with this illness[5]. With a dismal 40% one-year clinical remission rate for current drugs that alter the immune response, and similar upcoming drugs no more effective, there is no reason to believe that any treatment focused on modifying the immune response will improve current patient outcomes[6]. We are thus left to conclude that this class of therapeutics has reached the limit of clinical effectiveness, and any hope for effective therapy or a cure can only arrive with a fundamentally new approach in our understanding and treatment of this disease.

Almost all treatments for UC consist of agents that modify, alter, or suppress the immune response[7, 8]. This is based on the belief that an underlying immune abnormality is the cause of this condition. But is this assumption evidence-based? Unfortunately not, despite extensive research conducted since the mid-20th century, no evidence of a causal antecedent immune vulnerability has been uncovered in individuals with UC or their first-degree relatives[9]. Additionally, studies in UC patients have revealed normal immune responses when compared to healthy controls[10,11]. Thus, the evidence indicates that an immune abnormality is not the cause of UC, and treatment directed against the immune response cannot bring about a cure, restore healthy colonic functionality, or a normal quality of life.

Faced with these facts, we must consider that the immune response in UC is an accompanying effect of a separate underlying phenomenon that has a causal role in the development of this disease. In other words, the immune system is doing what it's programed to do given the stimulus it is subjected to. But if there's nothing wrong with the immune system then what stimulus could cause inflammation of the colon leading to UC and how can we treat it? The next section describes a novel evidence-based pathogenesis that provides answers to these questions.

UC: AN EVIDENCE-BASED PATHOGENESIS

A causal role for colonic epithelial cell hydrogen peroxide in the pathogenesis of UC

In order to understand the pathogenesis of UC and develop an effective treatment, we need to answer several questions. Starting with what we can see, we must explain why the inflammation typically begins in the rectum and advances contiguously to more proximal regions of the colon without sparing intervening mucosa. We also need to identify the molecular mechanism that initiates the inflammation in the first place. In other words, how the inflammation begins. This raises the question of what causes this mechanism to initially appear and reappear over and over again after (apparently) successful treatment leading to life-long relapse. Finally, we need to derive the genetic predisposition that makes this all possible. Understanding the overlapping lineal sequence of events leading up to UC and the

mechanism of relapse is crucial for effective therapeutic intervention and long-term remission so as to permanently alter the natural history of disease. Stated differently, we will start with what we can see (the inflammation) and work our way upstream until we arrive at the inception of disease, which originates from the interaction of a shared genetic predisposition with exposomal elements giving rise to a final common pathway that must be present among all individuals with UC; at all times basing our conclusions on the known experimental evidence.

Neutrophils are the first responders into the colonic epithelium in UC with the formation of neutrophilic cryptitis and neutrophilic crypt abscesses, which are hallmarks of active inflammation[12-14]. This typically begins in the rectum causing mucosal inflammation, which advances proximally and contiguously (without skipping). Once in contact with bacteria in the rectal epithelium, neutrophils are activated to release large amounts of hydrogen peroxide (H_2O_2). Studies have shown that a single neutrophil can produce enough H_2O_2 to diffuse into and oxidize nearly all the hemoglobin contained in ten intact surrounding red blood cells[15].

H_2O_2 is a cell-membrane permeable, highly potent neutrophilic chemotactic factor that attracts neutrophils into the colonic epithelium[16]. Studies have demonstrated that neutrophils can respond to and migrate towards an H_2O_2 concentration variation of 100 picomolar, which is a difference of approximately five molecules of H_2O_2 between the leading and trailing halves of the neutrophil[17]. H_2O_2 is also a powerful oxidizing agent that disintegrates tight junctional proteins[18-21]. This leads to increased paracellular permeability and decreased epithelial resistance, which is characteristically observed in UC[22-25].

The resulting H_2O_2 mediated increase in paracellular permeability facilitates antigenic translocation across the colonic epithelium while simultaneously creating an H_2O_2 chemotactic gradient, both of which act cooperatively to attract other neutrophils into the advancing proximal edge of the inflammatory field thereby extending colonic inflammation from the rectum, in a contiguous fashion, to more proximal regions of the colon. The inflammation only halting upon encountering sufficient circumferential epithelial reductive capacity to neutralize the advancing wave of neutrophil released H_2O_2, resulting in a sharp demarcation between healthy and diseased tissue. This redox tug-of-war between epithelial reductive capacity and neutrophilic H_2O_2 explains the characteristic proximal migratory behavior of colonic mucosal inflammation in UC. This interpretation is supported by studies showing that neutrophil accumulation within epithelial crypts and in the intestinal mucosa directly correlates with clinical disease activity and epithelial injury in individuals with UC[26]. Stated differently, neutrophils in the crypts of Lieberkühn secrete large amounts of H_2O_2 that attracts other neutrophils into the epithelium. Continuous secretion of H_2O_2 by neutrophils overwhelms epithelial reductive (antioxidant) capacity causing additional neutrophils to enter the inflammatory field. This advances the inflammation in a proximal direction until sufficient epithelial reductive (antioxidant) capacity is encountered to stop further proximal advance.

On a cellular level, neutrophils in the colonic epithelium can be thought of as microscopic H_2O_2 factories, whose function can be replaced by exogenous H_2O_2. This interpretation is supported by rectal H_2O_2 infusion studies in mice resulting in sharp inflammatory tissue delineation from normal tissue, contiguous inflammatory proximal extension, and rectal inflammatory persistence (discussed below), which are also characteristic of human UC[27]. Additionally, the colonic introduction of H_2O_2 in humans results in classic UC[28]. Although this explains proximal extension, the next step is to explicate what causes these white blood cells (neutrophils) to move into the colonic epithelium in the first place causing inflammation and why it typically starts in the rectum?

Neutrophils are attracted into the colonic epithelium by H_2O_2 secreted by the colonic epithelium

Neutrophils are not the only cells in the body that produce H_2O_2. All living cells in the body generate H_2O_2 from metabolic reactions, including colonic epithelial cells (colonocytes)[29]. Studies have shown increased production of H_2O_2 in ascending non-inflamed colonic epithelium from patients with UC[30]. This indicates a pre-inflammatory build-up of H_2O_2 within colonocytes. In other words, H_2O_2 builds up in colonic epithelial cells prior to the appearance of inflammation satisfying the absolute requirement of chronology for the cause (H_2O_2) to precede the effect (colitis).

H_2O_2 is membrane permeable and can easily diffuse through the colonic epithelial cell membrane to the extracellular space[29]. Once outside the colonocyte, H_2O_2 initiates inflammation *via* the same mechanism as H_2O_2 secreted by neutrophils, *i.e.*, oxidative disintegration of tight junctions and neutrophilic chemotaxis. Other studies have shown that reductive capacity (ability to neutralize H_2O_2) progressively decreases from proximal to distal regions of the colon with rectal epithelial cells having the least protection against the buildup of H_2O_2[31]. This causes the rectum to be the initial location in the colonic epithelium where H_2O_2 will build up and, upon diffusion to the colonocyte extracellular space, attract neutrophils into the rectal epithelium causing inflammation and colitis. And due to its diminished reductive capacity, the rectum will be the last colonic region to heal resulting in a persistent ulcerative proctitis that is experienced by many patients.

Studies in genetically engineered mice that are unable to neutralize colonic H_2O_2 [glutathione (GSH) peroxidase knock-out mice] develop colitis analogous to human UC[32]. This indicates that colonic epithelial cells can generate enough H_2O_2, which upon extracellular diffusion, can initiate colonic inflammation and colitis. The mechanism behind the initial increase in colonocyte H_2O_2 giving rise to

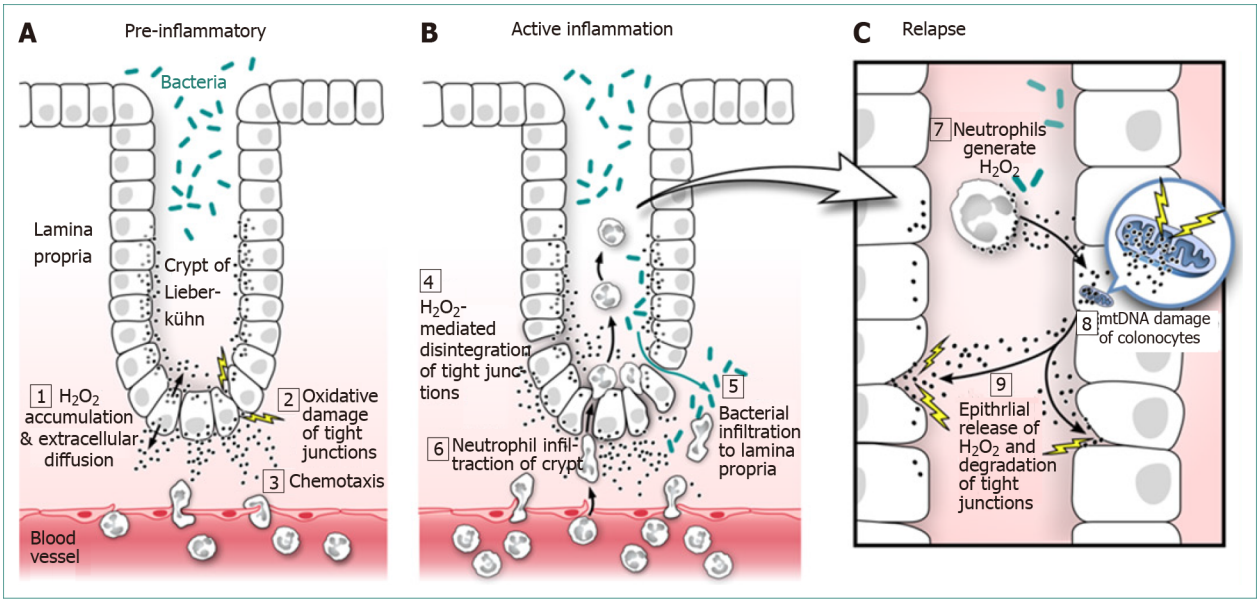
human UC will be discussed below in the section on oxidative stressors.

In other words, H_2O_2 is a normal immune signaling molecule that attracts neutrophils. Neutrophils cannot determine which cell is secreting H_2O_2; whether it's another neutrophil calling for help fighting an infection or a colonic epithelial cell leaking H_2O_2. In the latter case, neutrophils are simply doing what they are programmed to do given the stimulus (H_2O_2) they are exposed to. The development of UC indicates a healthy functioning innate immune system responding to a normal immune chemotactic factor (H_2O_2) being inappropriately secreted by the colonic epithelium. The correct treatment (discussed below) is not to abrogate this normal response with drugs that suppress essential innate normal immune reactivity but to restore colonic redox homeostasis so as to prevent colonocyte secretion of H_2O_2.

In summary, H_2O_2's unique properties of cell membrane permeability, long life, potent oxidizing potential, and neutrophilic chemotactic capability combine to promote colonocyte extracellular diffusion followed by oxidative disintegration of colonic epithelial tight junctional proteins, which facilitates bacterial translocation from the colonic lumen into the sterile subjacent lamina propria while simultaneously (and chemotactically) attracting neutrophils into the colonic epithelium, both of which lead to colonic inflammation, and eventual UC (Figures 1A and 1B). H_2O_2 initially accumulates in colonocytes and diffuses to the extra-cellular space in the rectal epithelium, which has the least tissue reductive capacity of the entire colon.

Neutrophils in the subjacent epithelial vasculature migrate along the interstitial H_2O_2 concentration gradient to the source of the H_2O_2 in the rectal epithelium. Once exposed to lumenal antigens, neutrophils are activated to secrete large amounts of H_2O_2, which promotes further neutrophilic infiltration while migrating the advancing edge of the inflammatory field to more proximal regions of the colon as described above. H_2O_2 also causes vasodilation and severe damage to blood vessels with destruction of endothelial cells and disruption of endothelial cell tight junctions[33-35]. This leads to erythrocyte extravasation and bleeding into the colonic lumen as commonly observed in UC. Thus, the effects of H_2O_2 on the innate immune system and vasculature explain both the microscopic and macroscopic features that characterize UC. The next section provides an evidence-based explanation for relapse. Following this, the concept of oxidative stress is discussed, which provides an evidence-based mechanism to explicate why H_2O_2 builds up in the colonic epithelium to begin with.

Relapse: An acquired "hard-wired" vicious cycle of inflammation



Once complete histologic remission has been achieved and the colonic epithelium is free of inflammatory cells, neutrophils can, once again, migrate back into the colonic epithelium after medication is withdrawn. This resumption of inflammation after a period of quiescent disease is called relapse, also known as a flare. Stated differently, if UC were simply a function of exposure to environmental factors, neutrophils would not migrate back into the colonic epithelium causing mucosal inflammation and relapse after exposure has ceased and medication is withdrawn.

Relapse indicates that a fundamental change has occurred in colonic epithelial cells before and/or during mucosal inflammation leading to increased production of H_2O_2, which continues to diffuse throughout the extracellular space resulting in neutrophilic chemotactic migration into the colonic epithelium and eventual relapse. This is consistent with the significantly elevated intracellular colonocyte H_2O_2 production observed in the non-involved colonic epithelium in patients with UC[30]. The question is why do colonocytes in individuals with UC produce more H_2O_2 than normal?

The answer is suggested by the susceptibility of mitochondrial DNA (mtDNA) to H_2O_2-induced oxidative damage. Due to their lack of histones, limited repair capability, and high single strand exposure time, mtDNA is highly susceptible to H_2O_2-induced oxidative damage[36,37]. H_2O_2 induced oxidative damage to mtDNA introduces base mutations into the mitochondrial genome, which miscode during transcription of electron transport chain (ETC) complexes resulting in nucleotide mispairing and the incorporation of faulty protein subunits into the ETC. These acquired mitochondrial ETC mutations cause increased ETC electron leakage that produces increased amounts of superoxide, which is converted to excess H_2O_2. The end result is a dysfunctional mitochondrial ETC that generates higher levels of cellular H_2O_2, which upon extracellular diffusion initiates a relapse of colonic inflammation (Figure 1C)[38].

The elevated colonocyte H_2O_2 resulting in mtDNA mutations originates from two sources. The initial increase in colonocyte H_2O_2 is intracellular and originates from oxidative stress exposure (discussed in the next section). This is augmented by a large exogenous source of H_2O_2 supplied by neutrophils that stream into the colonic epithelium and fill up the crypts of Lieberkühn. Being cell membrane permeable, H_2O_2 can easily diffuse into surrounding epithelial stem cells and transition amplification cells, which give rise to the surface epithelium. This "back flow" of H_2O_2 into colonocytes would ordinarily be neutralized by the cell. However, colonocyte reductive capacity has already been compromised by the initial rise in cellular H_2O_2 due to oxidative stress exposure. This allows intracellular H_2O_2 to diffuse unimpeded throughout the colonocyte into mitochondria leading to mtDNA oxidative damage and acquired mutations.

A causal role for mitochondrial ETC generated H_2O_2 in the development of relapse is consistent with the onset of impaired mitochondrial beta-oxidation in the weeks leading up to relapse, which is reported to be caused by H_2O_2 induced oxidative inhibition of mitochondrial thiolase, a necessary

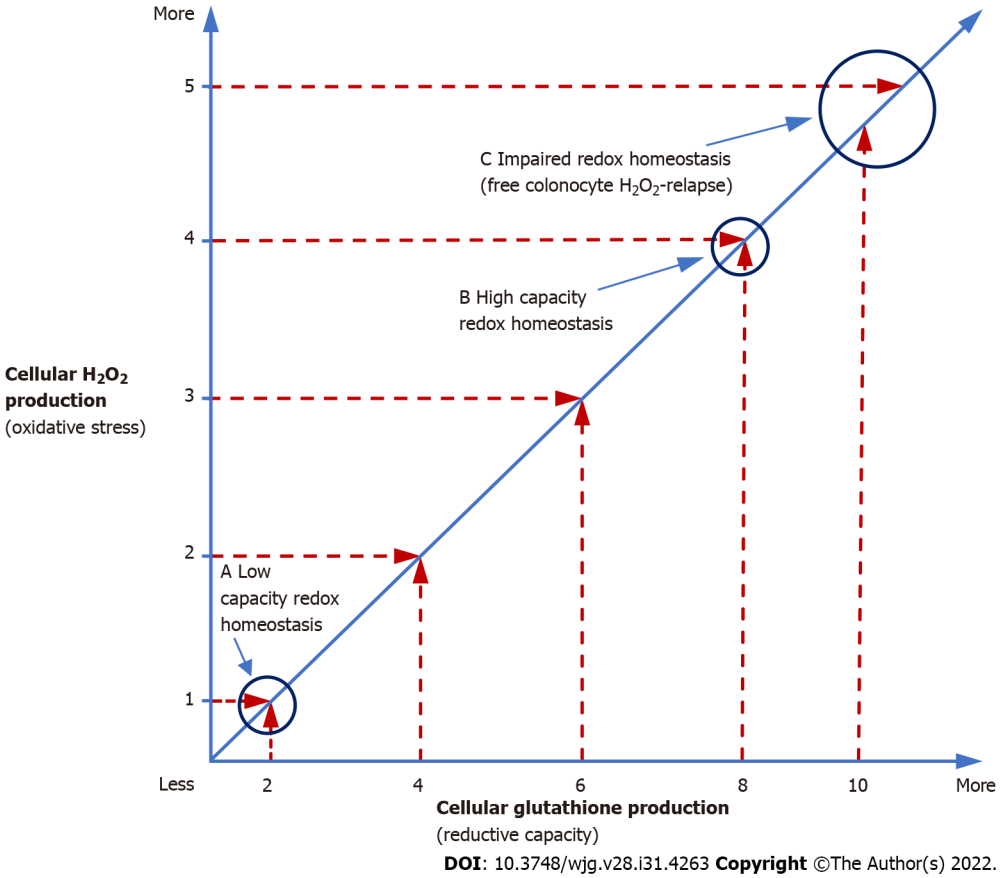
Figure 1 Ulcerative colitis: Evidence-based pathogenesis and relapse. A: Pre-inflammatory; B: Active inflammation; C: Relapse. Hydrogen peroxide (H_2O_2) is produced by all cells of the body, mainly as a toxic by-product of cellular metabolism and must be immediately neutralized to prevent cell damage. If produced in excess by colonocytes (colonic epithelial cells), H_2O_2 easily diffuses through the cell membrane; 1: To the extracellular space where its unique properties of long life, potent oxidizing power, and the ability to attract neutrophils (neutrophilic chemotaxis) combine to promote oxidative damage of colonocyte tight junctions; 2: While attracting neutrophils into the colonic epithelium; 3: Continued H_2O_2 exposure leads to oxidative disintegration of tight junctional proteins and increased colonic epithelial paracellular permeability; 4: Increased paracellular permeability promotes bacterial translocation into the sterile lamina propria; 5: And facilitates neutrophil migration up the H_2O_2 concentration gradient into the crypts of Lieberkühn; 6: Both of which lead to colonic inflammation and eventual ulcerative colitis. Neutrophils exposed to bacteria in the crypts become activated and produce large amounts of H_2O_2 that diffuses into colonic epithelial cells; 7: Which adds to the already high colonocyte H_2O_2 load. The increased colonocyte H_2O_2 oxidizes mitochondrial DNA (mtDNA) introducing genetic mutations that miscode when transcribing for electron transport chain (ETC) proteins; 8: Faulty ETC proteins exhibit additional electron leakage leading to greater H_2O_2 production creating a vicious cycle of mtDNA damage and ever greater H_2O_2 production, which contributes to and increases the frequency and severity of relapse; 9: This amounts to a "hard-wired" genetic reprogramming that promotes colonic inflammation as discussed below. H_2O_2: Hydrogen peroxide; mtDNA: Mitochondrial DNA.



enzyme in the mitochondrial beta-oxidation pathway[39-41]. The involvement of ETC-generated H_2O_2 in UC relapse is supported by reports of intractable UC in the setting of inherited ETC disfunction[42]. At birth, all mtDNA is normally identical. This is called homoplasmy. After H_2O_2-induced base mutations are introduced into the mitochondrial genome, all mtDNA is no longer identical. The simultaneous occurrence of genetically dissimilar cellular mtDNA (normal and mutated) is called mitochondrial heteroplasmy[43]. Studies have shown a significant degree of heteroplasmic mtDNA in the colonic epithelium of individuals with UC[44,45]. The presence of colonocyte mitochondrial heteroplasmy in UC will constitutively generate higher amounts of H_2O_2 leading to additional mtDNA damage and greater H_2O_2 production creating a self-amplifying vicious cycle of ever-increasing colonocyte H_2O_2[46]. This constitutive internally reinforcing production of colonocyte H_2O_2 perpetuates mucosal inflammation leading to relapse upon withdrawal of medication. The increased basal production of colonocyte H_2O_2 promotes more frequent episodes of relapse and leads to refractory disease as colonocyte H_2O_2 increases and UC becomes less responsive to medication.

Up until now, we have an H_2O_2-based mechanism that explains how UC begins, why inflammation extends proximally throughout the colon, and how mitochondrial heteroplasmy promotes a constitutive increase in colonocyte H_2O_2 that contributes to relapse. What we are missing is why colonocyte H_2O_2 becomes elevated in the first place. To understand this, we need to discuss the concept of oxidative stress as outlined in the next section for it is exposure to oxidative stress that initiates *de novo* development (and relapse) of UC.

OXIDATIVE STRESS

The invisible force that increases H_2O_2 and leads to UC

We are all subjected to oxidative stress since the moment of conception. But what is oxidative stress? More importantly, how can we define oxidative stress in a manner that is relevant for diagnosing disease, understanding pathogenesis, and advancing therapeutic intervention. Since most biological effects of reactive oxidant species are mediated by H_2O_2[47], and since cellular GSH is principally responsible for supplying the reducing equivalents (electrons) needed to neutralize H_2O_2[48,49], a

DOI: 10.3748/wjg.v28.i31.4263 **Copyright** ©The Author(s) 2022.

Figure 2 Redox homeostasis. Redox homeostasis is more than just a balance between oxidizing [hydrogen peroxide (H_2O_2)] and reducing agents (glutathione). In the above graph, redox homeostasis (slanted line) is maintained at both low and high H_2O_2 production rates (a and b), but the cell is functioning at a higher oxidative capacity (high capacity redox homeostasis) (b), when more H_2O_2 is being produced compared to times when lesser amounts of H_2O_2 are being generated (a). Mitochondria, the site of most cellular H_2O_2 production, do not synthesize their own glutathione and only contain 10% of the total cellular supply of this vital reducing equivalent that must be generated in the cytoplasm and imported into mitochondria, which takes time[53]. Once depleted, mitochondrial glutathione can take several hours to restore to normal levels[46]. In contrast to the limited supply of mitochondrial glutathione, studies have shown that mitochondrial electron transport chain production of H_2O_2 can increase up to 15 × during periods of high metabolic demand[54]. Any increase in H_2O_2 production forces the cell to utilize additional glutathione in order to maintain redox balance which may lead to high capacity redox homeostasis (b). Since about 30% of cell thiols (*i.e.*, glutathione) normally undergo oxidation per hour[55], the additional oxidative stress imposed by high capacity redox homeostasis can, over time, deplete available glutathione and overwhelm colonocyte reductive capacity creating a state of impaired redox homeostasis (c) followed by H_2O_2 build-up and extracellular diffusion, which can lead to *de novo* ulcerative colitis or relapse. High capacity redox homeostasis is consistent with increased H_2O_2 production observed in the non-inflamed ascending colonic epithelium of individuals with ulcerative colitis[30]. H_2O_2: Hydrogen peroxide.

clinical working definition of oxidative stress can be summarized as any stimulus that increases the amount or production of H_2O_2 or elevates the risk of its occurrence by decreasing cellular reductive (antioxidant) capacity (*i.e.*, GSH). Stimuli that fulfill this definition are called oxidative stressors.

Oxidative stressors can be external (*i.e.*, environmental) or internal (originating in the body). Many oxidative stressors can be identified by the medical history and targeted for elimination by changes in diet and lifestyle. Clinically assessing the risk that oxidative stress will increase H_2O_2 leading to worsening disease requires a working understanding of redox homeostasis. Redox homeostasis refers to the balance that is achieved when there is sufficient cellular reductive capacity (GSH) to neutralize the H_2O_2 being produced. Thus, an oxidative stressor is a stimulus that places additional demands on the cell's capacity to neutralize H_2O_2 and maintain redox homeostasis. Over time, oxidative stress can disrupt the cell's ability to maintain this critical balance. When this occurs it is called impaired redox homeostasis, which can lead to the build-up of colonocyte H_2O_2 resulting in extracellular diffusion, mucosal inflammation, and UC as described above. Thus, identifying and eliminating oxidative stressors in order to assist in restoring colonic redox homeostasis is critical for the maintenance of long-term remission in UC. In order to maintain redox homeostasis, colonocytes utilize as much GSH as needed to neutralize the H_2O_2 that is being produced by the cell. In this reaction, two molecules of GSH react with one molecule of H_2O_2 *via* the action of GSH peroxidase (GPx) to yield one molecule of GSH disulfide (GSSG) and one molecule of water, as illustrated below.

$$2\,GSH + H_2O_2 \xrightarrow{GPx} GSSG + H_2O_2$$

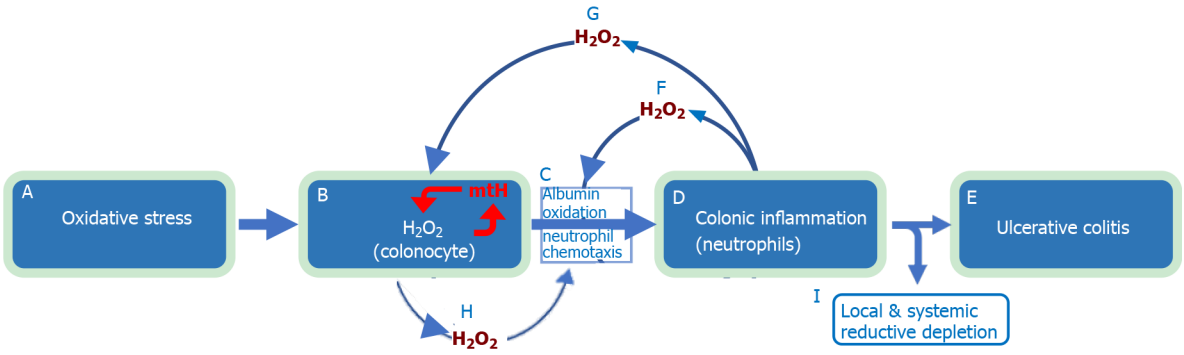
At higher levels of H_2O_2 production significantly more GSH is consumed compared to lower levels of H_2O_2 production in order to maintain a 2 (GSH) to 1 (H_2O_2) balance or redox homeostasis. However, higher levels of GSH consumption enhance the risk of GSH depletion after which free H_2O_2 can begin to accumulate within the cell[50].

Thus, all redox homeostasis is not the same. Redox homeostasis maintained at high levels of H_2O_2 production [high capacity redox homeostasis (HCRH)] increases the risk of GSH depletion and subsequent accumulation of intracellular H_2O_2 (Figure 2). HCRH indicates that the cell has a greater capacity to oxidize substrate such as GSH and is consuming GSH at greater rates than normal. As long as the substrate being oxidized is GSH, redox homeostasis can be maintained and the cell is protected from the toxic effects of H_2O_2 buildup. However, if GSH is depleted due to excessive utilization by HCRH, H_2O_2 is free to diffuse throughout the cell and oxidize other molecules in the colonocyte such as enzymes and DNA. This can lead to metabolic disturbances such as impaired mitochondrial beta-oxidation in addition to oxidative nuclear DNA mutations in tumor suppression and oncogenes that promote colorectal cancer as well as mtDNA mutations (mitochondrial heteroplasmy) that increase cellular H_2O_2 production and facilitate disease relapse[30,51,52] (Figure 2).

Even if redox homeostasis is maintained during HCRH, the high demand for GSH may sequester this vital reducing agent away from other critical metabolic functions that depend upon GSH such as elimination of toxic xenobiotics and electrophiles, regulation of apoptosis and cell division, GSH dependent enzymes, maintenance of reduced vitamins C and E for cell membrane protection, and glutathionylation of proteins/enzymes to protect against irreversible oxidative damage[56-58]. Thus, HCRH may consume GSH needed for other cellular activity and compromise colonocyte and colonic functionality independent of the development of UC.

Exposure to multiple contemporaneous oxidative stressors facilitates progressively greater production of H_2O_2 that increases the risk of reaching HCRH, which can lead to impaired redox homeostasis with the development of symptomatic UC (Figure 2C). This explains why the initial appearance of UC can be very explosive since HCRH may lead to sudden depletion of GSH causing significant acute increases in cellular H_2O_2, which can lead to severe mucosal inflammation as large amounts of colonocyte H_2O_2 diffuse to the cell exterior. Lesser amounts of colonocyte extracellular H_2O_2 can account for the pre-symptomatic systemic inflammation observed in individuals who go on to develop UC[59]. Seemingly insignificant oxidative stressors can lead to relapse for individuals functioning at HCRH. This should prompt a search for other unrecognized oxidative stress exposures to prevent relapse. Lastly, an important distinction to keep in mind is that oxidative stress is not the same as oxidative damage. Oxidative stress appears before oxidative damage occurs, while oxidative damage always indicates previous or ongoing oxidative stress. Rectal bleeding in UC is an indication of severe concurrent oxidative (H_2O_2 induced) tissue damage caused by exposure to oxidative stress.

In summary, oxidative stress increases H_2O_2 in the body. Oxidative stressors mediate the effects of oxidative stress on the body. As H_2O_2 increases, colonocytes utilize greater amounts of GSH to maintain redox balance leading to HCRH, which can deplete cellular GSH leading to *de novo* UC or relapse. The increased H_2O_2 production rates observed in the non-inflamed colonic epithelium of individuals with UC indicate the presence of HCRH[30]. The effects of multiple oxidative stressors are additive, each contributing to the cellular H_2O_2 load. HCRH may lead to a GSH deficiency state and cellular disfunction**.** In the next section, we put it all together and derive the genetic susceptibility that predisposes to the development of UC.



PUTTING IT ALL TOGETHER

Predisposition, pathogenesis, pathophysiology, and relapse

Based on the cumulative data, we can now construct an evidence-based natural history of UC. The disease begins with exposure to one or more oxidative stressors, which increase the production of colonocyte H_2O_2. Over time, cellular reductive capacity is overwhelmed as the colonocyte is no longer able to maintain HCRH and H_2O_2 accumulates in the cell. This is followed by H_2O_2 diffusion through the cell membrane to the extracellular space within the crypts of Lieberkühn and the surrounding cellular microenvironment. This results in oxidative damage to interepithelial tight junctions and increased paracellular permeability accompanied by the creation of an H_2O_2 diffusion gradient that envelops the subjacent microvasculature.

The combined effect of colonic epithelial antigenic translocation due to increased paracellular permeability and H_2O_2 gradient-guided neutrophilic chemotaxis results in directed migration of neutrophils from the subjacent vasculature into the crypts of Lieberkühn along with the formation of neutrophilic cryptitis and crypt abscesses. Continued neutrophilic infiltration into the colonic epithelium leads to mucosal inflammation and UC (Figures 3A-E).

The rectum, having the lowest reductive capacity of the intestinal tract, is the initial site of H_2O_2 accumulation and the first region to experience inflammation, which proceeds in a proximal direction as continuous secretion of large amounts of neutrophil released H_2O_2 overcomes colonic epithelial reductive capacity in a circumferential manner resulting in a sharp demarcation between healthy and

DOI: 10.3748/wjg.v28.i31.4263 **Copyright** ©The Author(s) 2022.

Figure 3 Natural history of ulcerative colitis. The evidence-based natural history of ulcerative colitis begins with exposure to oxidative stressors (a), which increases colonocyte hydrogen peroxide (H_2O_2) (b). The increase in colonocyte H_2O_2 facilitates extracellular diffusion which overwhelms (oxidizes) local interstitial serum albumin antioxidant defense (60% of serum albumin is interstitial), leading to directed migration of neutrophils (chemotaxis) into the colonic epithelium (c) and mucosal inflammation (d) with subsequent development of ulcerative colitis (e). Large amounts of H_2O_2 are released by neutrophils into the extracellular space (f) with further oxidation of interstitial albumin and exhaustion of tissue antioxidant capacity (c). This worsens colonic inflammation (d) leading to local and systemic reductive depletion (i) as albumin is circulated through the colonic interstitium into tissue lymphatics and back into the systemic circulation. Neutrophil released H_2O_2 "back flows" into colonocytes (g) adding to the already elevated intracellular H_2O_2 levels resulting in mitochondrial DNA damage and mitochondrial heteroplasmy (b, red mtH). Mitochondrial heteroplasmy introduces mutations into the electron transport chain protein subunits, which generate additional H_2O_2 *via* enhanced electron leakage setting up a vicious cycle of ever increasing colonocyte H_2O_2 (b, red arrows). Increased colonocyte H_2O_2 diffuses into the extracellular space (h) causing disease relapse (c, d, e). The combination of local and systemic reductive depletion along with a ready supply of H_2O_2 from colonocytes and neutrophils (b and d) creates a mucosal inflammation that is self-amplifying, forward propagating, and auto-initiating (relapsing). Elimination of neutrophilic inflammation (d) by any means (*i.e.*, immunosuppressive agents) will not stop relapse from occurring as colonocyte H_2O_2 continues to diffuse into the extracellular space (c, h). Conversely, normalizing colonocyte H_2O_2 alone will not stop the inflammation, which has become self-sustaining. This indicates that simultaneous elimination of all pathological sources contributing H_2O_2 to the inflammatory field must be achieved to ensure long-term remission and normal colonic functionality. Systemic reductive depletion may contribute to other serious health hazards as detailed below. H_2O_2: Hydrogen peroxide.

diseased tissue (epithelial cells at the same circumferential level have the same reductive capacity). Mucosal inflammation may reach more proximally and regress distally over time as a result of fluctuations in colonic epithelial reductive capacity due to changes in oxidative stress exposure (diet, stress, *etc.*) and epithelial repopulation.

The large amount of H_2O_2 released by neutrophils in the inflammatory field is chemotactic for other neutrophils in the subjacent vascular bed. This causes epithelial inflammation to become self-propagating and auto-amplifying (Figure 3F), which enables prolonged contact between neutrophils and surrounding colonocytes. This close contact facilitates the back-flow of neutrophil-derived H_2O_2 into adjacent colonocytes that adds to the already high colonocyte H_2O_2 load due to oxidative stress exposure (Figure 3G).

High intracellular colonocyte H_2O_2 promotes diffusion into mitochondria leading to mtDNA oxidation and the formation of acquired mtDNA mutations (mitochondrial heteroplasmy-mtH) (Figure 3B red arrows), which miscode during translation of ETC protein subunits. The resulting ETC mutations facilitate a higher degree of electron leakage and greater H_2O_2 formation causing additional mtDNA damage and the creation of a vicious cycle, which maintains a high intracellular colonocyte H_2O production that facilitates spontaneous relapse upon withdrawal of medication or exposure to ever-present oxidative stressors (Figure 3H).

Thus, based on the data, the derived genetic predisposition leading to UC is the inability of the colonic epithelium to cope with (neutralize) an oxidant (H_2O_2) load forcing the colonocyte into a state of impaired redox homeostasis after which free H_2O_2 begins to accumulate in the cell (Figure 2C). Pathogenesis begins with impaired colonocyte redox homeostasis leading to the intracellular accumulation of H_2O_2 after HCRH has exhausted cellular reductive capacity (Figure 2C). The pathophysiology commences with the influx of neutrophils into the colonic mucosa, which defines the beginning of what will eventually become the symptomatic phase of the illness. However, extracellular colonocyte diffusion of H_2O_2 does not inexorably lead to UC due to the presence of a secondary "back-up" system of antioxidant defense provided by human serum albumin (HSA) (Figure 3C) as discussed in the following section.

HSA: The link between colonocyte and systemic redox homeostasis

Although UC is traditionally thought of being limited to the colon, the significant decrease reported in total blood antioxidant capacity (erythrocytes and plasma) in individuals with UC suggests that excess colonic production of H_2O_2 is causing impaired systemic redox homeostasis as well[60-62]. In other words, the capacity of the blood to remove H_2O_2 in UC patients is compromised. Why would colonic production of H_2O_2 affect systemic redox homeostasis and what effect might this have on the severity of UC and overall patient health?

Systemic redox homeostasis is provided by HSA and erythrocytes, both of which are highly effective scavengers of H_2O_2. Their combined action maintains blood H_2O_2 at very low levels, in the range of 0.8-6 μM for healthy individuals[63]. HSA can directly scavenge H_2O_2 *via* a reduced surface cysteine thiol (cys34)[64]. In addition, the HSA molecule itself has a GSH-linked thiol peroxidase activity that can remove circulating H_2O_2[65]. The significant anti-oxidant scavenging ability of HSA represents approximately 70% of the free radical trapping ability of human serum[64]. Since 60% of HSA is present in the interstitial space, this indicates that HSA acts as an extracellular backup anti-oxidant defensive layer (after intracellular colonocyte GSH) that protects against the development of UC by preventing the interstitial accumulation and diffusion of colonocyte released H_2O_2 from reaching the subjacent epithelial blood vessels and attracting neutrophils into the colonic epithelium leading to colonic mucosal inflammation and UC. Interstitial albumin has a turnover of 4% per hour after which it recycles back to the systemic circulation[66]. This suggests that each day the entire blood supply of reduced albumin is exposed to excess colonic H_2O_2 with a significant portion becoming oxidized.

Red blood cells also provide a significant level of systemic anti-oxidant defense. Erythrocytes contribute up to 30% of whole blood reductive capacity. Erythrocytes are highly permeable to H_2O_2[67]. With a normal mean inter-erythrocytic distance of 3 μm, a molecule of H_2O_2 in the circulation will encounter a red blood cell before it encounters HSA[68]. Free serum H_2O_2 will diffuse into red blood cells where it is neutralized by significant anti-oxidant enzymatic defenses comprised of catalase and GSH[67]. Whereas H_2O_2 released by colonocytes or infiltrating epithelial neutrophils during active UC can oxidize HSA in the interstitial space, decreased red blood cell reductive capacity (*i.e.*, decreased erythrocyte GSH) implies that colonic H_2O_2 is diffusing directly into the systemic circulation and into erythrocytes with depletion of total blood reductive capacity. The inability of interstitial HSA to completely remove colonic H_2O_2 will lead to H_2O_2 accumulation and a greater degree of tissue damage accompanied by neutrophilic infiltration resulting in increased severity of disease, which contributes to relapse (Figure 3F). This is supported by studies showing that the loss of blood reductive capacity (inability to remove H_2O_2) is associated with worsening UC[62]. The critical role of reduced albumin for the maintenance of colonic interstitial redox homeostasis is illustrated by studies showing that the onset and progression of experimental murine colitis were prevented by reduced (reductively enhanced) albumin, which, in turn, was strongly associated with an improved systemic reductive capacity[69].

Reduced albumin also directly neutralized H_2O_2 and prevented the *in vitro* loss of tight junctional proteins in human intestinal cell tissue treated with H_2O_2[69]. This indicates that reduced albumin can act as an interstitial reducing agent (antioxidant) and delay/prevent the onset of UC by neutralizing interstitial H_2O_2 released by colonocytes before the H_2O_2 can initiate chemotactic directed migration of neutrophils into the colonic epithelium. This implies that oxidized, or decreased albumin levels would offer less protection and hasten the development of UC. This is consistent with worsening UC observed in association with anemia and hypoalbuminemia[70,71]. Other studies report a significant inverse relationship between low serum albumin and risk of colectomy[72]. Conversely, studies in UC patients have shown that mucosal healing is positively associated with high (> 4.4 mg/dL) serum albumin[73].

Although low HSA can be secondary to colonic protein loss, and improved HSA levels may follow mucosal healing, the association of high HSA levels with a protective effect in conditions without colitis such as Bell's palsy and coronary artery disease implies an independent association with an intrinsic property of HSA such as oxidation status and not just as a biomarker for worsening colitis[74,75]. Thus, it is reasonable to assume that it is not just worsening colitis that causes low albumin but low serum albumin reductive capacity causing worsening colitis that increases albumin loss. HSA oxidation status should be part of screening lab work as oxidized albumin is inherently proinflammatory and associated with the progression of other diseases in addition to UC[76,77]. The proinflammatory nature of oxidized albumin and subsequent loss of systemic reductive capacity may be reflected in the worsening health and the high healthcare resource utilization in the year leading up to the diagnosis of UC[78]. This insight provides a critical therapeutic window of opportunity to restore systemic redox homeostasis and prevent UC if HSA is found to be significantly oxidized. In summary, once symptomatic UC develops, local and systemic reductive depletion is likely. At this point, colonocytes have already been exposed to genotoxic levels of H_2O_2 for many months or years setting the stage for molecular oxidative alterations that lead to life-long relapse (Figures 3A-H). However, the oxidative nature of these changes offers the possibility of reversal with a therapeutic reducing agent (detailed in treatment section below).

HOW OXIDATIVE STRESSORS GENERATE H_2O_2 IN THE BODY

Oxidative stress: Sources, classification, and definition

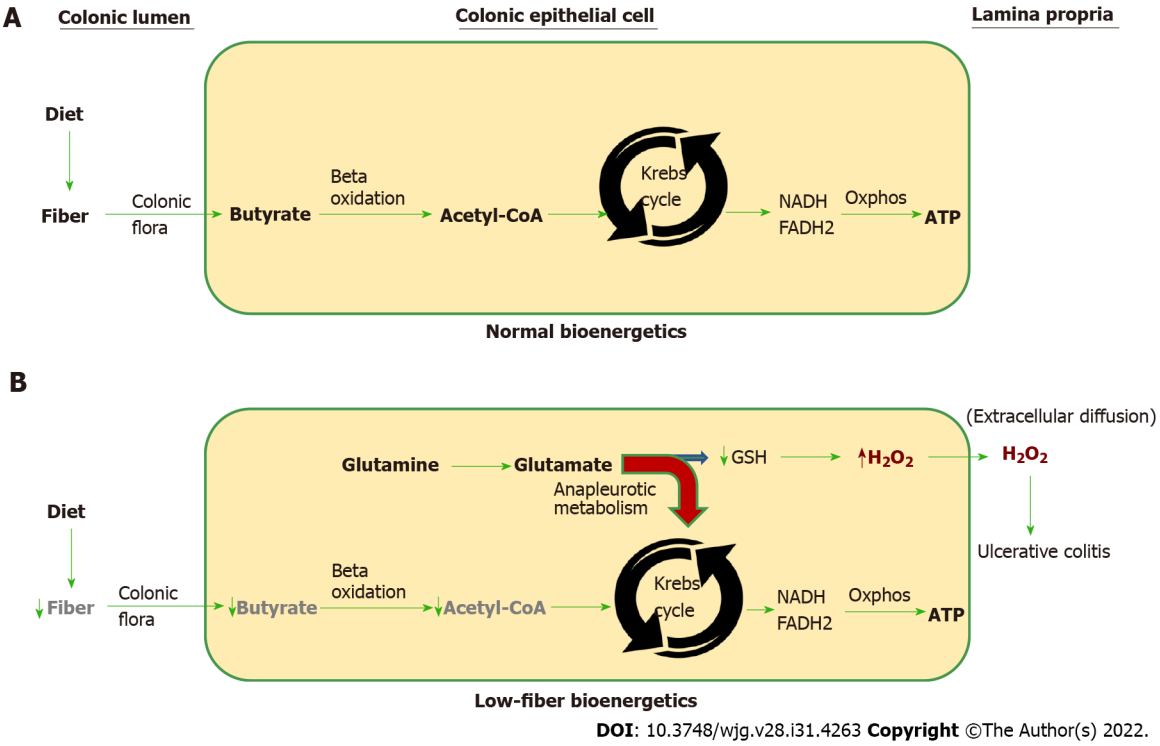
H_2O_2 is produced by many different cellular enzymatic reactions. Using the advanced search option in the BRENDA enzyme database limited to "homo sapiens" as the organism and "H_2O_2" as the product in the subitem text field returned 29 different enzymes acting upon 188 distinct molecular substrates[79]. This does not include non-enzymatic reactions such as the auto-oxidation of oxyhemoglobin or subunits of the mitochondrial ETC, which is considered the principal source of H_2O_2 in the body. Oxidative stressors are extremely diverse in their mechanism of action with some increasing the substrate for a

single enzyme while others can affect every H_2O_2 generating system in the body by inhibiting critical anti-oxidant enzyme systems needed for H_2O_2 removal. Individuals with UC are usually contemporaneously affected by more than one oxidative stressor but the commonality among all oxidative stressors, however, is the production of H_2O_2. Consequently, oxidative stressors are additive since they all increase the H_2O_2 load in the body. This may cause different individuals with UC to be more or less affected by the same oxidative stressor depending on the pre-existing H_2O_2 load in the colonocyte and state of redox homeostasis, which can change over time (Figure 2).

This can also result in the individual tolerance for the same oxidative stressor to vary with age, comorbidity, lifestyle and exposure duration and intensity. Thus, based on the evidence, it is reasonable to conclude that all factors that increase the risk of relapse or developing *de novo* UC are oxidative stressors that increase H_2O_2 in the body. Conversely, all oxidative stressors are risk factors for relapse or the development of UC. A convenient method of classification is grouping oxidative stressors as exogenous (originating external to the body) or endogenous (originating inside the body). The following section details the mechanism of action for several reported and/or common oxidative stressors associated with UC.

Exogenous oxidative stressors

Diet has been implicated in the pathogenesis and pathophysiology of UC[80]. 65% of surveyed individuals with UC believe that food is a significant trigger for relapse with 50% asserting that diet contributed to the initial development of disease[81]. This suggests that dietary factors exert their effect on the pathogenesis of UC by means of a common mechanism within the molecular chain of events leading to the onset of disease.



Dietary fat

Studies have shown that a high-fat low-fiber "westernized" type diet is associated with the development of UC, and high-fiber low-fat diets reduce systemic inflammatory biomarkers in patients with this illness[82,83]. Additionally, diets high in total fat and certain fatty acids are associated with exacerbation of UC[82,84,85]. But how does dietary fat initiate or worsen UC? Peroxisomes play an indispensable role in the metabolism of fatty acids obtained from dietary fat[86]. Peroxisomes are involved in the metabolism of dietary lipids such as medium chain, long chain, and very long chain fatty acids and cholesterol in addition to pristanic and phytanic acids[86,87]. Peroxisomal metabolism of fatty acids generates large amounts of H_2O_2, which is estimated to be about 35% of total cellular H_2O_2 production[88]. This is in line with data implicating peroxisomal H_2O_2 as an important source of cellular oxidative stress[89]. This implies that excess peroxisomal generated H_2O_2 can overwhelm the cell's reductive (antioxidant) capacity and accumulate to the point of causing cellular dysfunction. This is consistent with previous data ascribing a causal role for H_2O_2 in the pathogenesis of UC and implies that high fat diets contribute to the pathogenesis and relapse of UC by generating large amounts of peroxisomal H_2O_2. Excess peroxisomal generated H_2O_2 can diffuse into the cytoplasm and overwhelm the colonocyte's ability for its removal leading to extracellular diffusion and the development or relapse of UC as described above. Thus, high fat diets are risk factors for the development of UC because they are oxidative stressors that generate large amounts of peroxisomal H_2O_2[89]. Low fat diets ameliorate colonocyte oxidative stress by decreasing production of peroxisomal H_2O_2 and in so doing promote remission of UC.

Fiber

As mentioned above, low fiber diets are associated with the development and worsening of UC. But how does fiber interface with the pathogenesis and relapse of this illness? The colonic epithelium utilizes short chain fatty acids (*i.e.*, butyrate) for most of its energy requirements[90]. The production of butyrate starts with the fermentation of dietary soluble fiber by colonic bacteria. Butyrate is rapidly absorbed by colonic epithelial cells *via* passive diffusion and cell membrane transport proteins[91]. Once in the cytoplasm, butyrate is transported *via* the carnitine shuttle into mitochondria where it undergoes beta-oxidation. The resulting acetyl-coenzyme A (CoA) enters the Krebs cycle, which generates reducing equivalents (NADH, FADH2) that provide the energy for oxidative phosphorylation and ATP production[92]. This process provides up to 70% of colonocyte energy supplies (Figure 4A)[93,94].

A decrease in the available dietary soluble fiber will diminish the amount of butyrate absorbed by colonic epithelial cells and less butyrate will be available to undergo mitochondrial beta-oxidation. With decreased beta-oxidation of butyrate generating less acetyl-CoA, the colonocyte may not have enough fuel for the Krebs cycle to produce sufficient reducing equivalents (NADH, FADH2) in order to power oxidative phosphorylation and provide the energy for the biosynthesis of ATP. Without sufficient ATP to fuel critical cellular functions, the colonocyte will die. To increase ATP production, the colonocyte diverts glutamate into the Krebs cycle (*via* alpha keto-glutarate) in order to replace Krebs cycle intermediary metabolites that would otherwise be supplied by dietary fiber, which is in low supply (Figure 4B). Glutamate (an amino acid) is derived from the amino acid glutamine (the storage form of glutamate), and studies have shown cellular diversion of glutamine into the Krebs cycle as a consequence of impaired mitochondrial pyruvate transport underscoring glutamine's role as a backup

DOI: 10.3748/wjg.v28.i31.4263 **Copyright** ©The Author(s) 2022.

Figure 4 Normal *vs* low-fiber colonocyte bioenergetics. A: The normal vectorial bioenergetic flux beginning with soluble dietary fiber that is converted to short-chain fatty acids (*i.e.*, butyrate) by bacteria in the colonic lumen. Butyrate is rapidly absorbed by colonic epithelial cells (colonocytes). Once inside the colonocyte, butyrate undergoes mitochondrial beta-oxidation to generate acetyl-coenzyme A (CoA), which is processed by the Krebs cycle that produces NADH and FADH2. The high-energy electrons present in NADH and FADH2 are used to drive oxidative phosphorylation (Oxphos) resulting in the biosynthesis of ATP, which fuels most of the cell's energy needs; B: Low fiber intake decreases available butyrate needed for acetyl-CoA production. Under these energy-restricted conditions, glutamate is diverted into the Krebs cycle and away from the synthesis of glutathione (GSH). Diversion of glutamate into the Krebs cycle is called anapleurotic metabolism (red curved arrow) and is needed to replenish depleted Krebs cycle intermediary metabolites that would otherwise be supplied by dietary soluble fiber, which can no longer perform this role due to a low fiber diet. Since glutamate is needed for the synthesis of GSH, the sequestration of glutamate as a replacement energy source restricts the amount of glutathione the cell is able to synthesize. GSH is the principal reducing equivalent required to neutralize cellular hydrogen peroxide (H_2O_2). Insufficient glutathione will cause cellular H_2O_2 to increase, which upon extracellular diffusion may initiate neutrophil chemotaxis into the colonic epithelium and *de novo* ulcerative colitis or disease relapse. Interruption of colonocyte bioenergetic flux anywhere along the pathway from the microbiome to acetyl CoA will increase colonocyte anapleurotic metabolism and cellular H_2O_2, which can lead to ulcerative colitis. H_2O_2: Hydrogen peroxide; CoA: Coenzyme A.

energy supply during times of limited acetyl-CoA availability[95].

Studies on isolated colonocytes from germ-free rats (that cannot produce butyrate) report a 45% increase in glutamine use by these cells compared to conventionally reared animals[96]. Other studies using isolated colonocytes from germ-free mice demonstrated 16-fold lower NADH/NAD+ ratios as well as 56% lower ATP levels[97]. Colonization of germ-free mice with flora from conventional mice or butyrate-producing bacteria rescued the colonocyte energy deficit as did butyrate exposure to isolated colonocytes from germ-free mice[97]. This indicates that butyrate is a critical source of energy for colonocyte ATP production and colonocytes will compensate for the loss of butyrate by diverting glutamine (*via* glutamate) into the Krebs cycle to maintain the production of ATP.

However, the continued Krebs-cycle oxidation of glutamine as a backup energy source (*i.e.*, during prolonged low-fiber diets) entails significant consequences for the colonocyte. Glutamine is the precursor to glutamate, which is necessary for GSH synthesis. The diversion of glutamate into the Krebs cycle (called anapleurotic metabolism) to sustain cellular energy requirements restricts glutamate's availability for the biosynthesis of GSH, which is critical for the elimination of cellular H_2O_2[98]. Studies have shown that disrupting mitochondrial pyruvate uptake directs glutamine into the Krebs cycle and away from GSH synthesis[99]. Because GSH is critical for the elimination of cellular H_2O_2, a decrease in GSH synthesis will lead to increased colonocyte H_2O_2 and subsequent diffusion through the cell membrane to the extracellular space, which may precipitate *de novo* UC, worsen existing UC, or contribute to relapse (Figure 1B). Thus, low fiber diets are oxidative stressors because they increase the risk of colonocyte intracellular H_2O_2 buildup.

The critical importance of (soluble) dietary fiber for colonic bioenergetics and redox homeostasis is underscored by what occurs with the complete absence of colonic fiber. Diversion colitis is a reactive colonic inflammatory response in the by-passed segment of the large intestine as a result of fecal stream diversion secondary to colostomy or ileostomy. Under these circumstances, there is no dietary fiber entering the defunctioned segment of the large intestine. This results in a colitis affecting nearly all individuals undergoing this procedure within 1 to 3 years after colonic diversion[90]. Histopathology

soon after onset shows an influx of neutrophils into the colonic epithelium (analogous to UC)[100]. This suggests the alternate use of glutamate to compensate for the complete lack of lumenal butyrate decreases colonocyte GSH enough to raise cellular H_2O_2 to levels that facilitate extracellular diffusion and the development of colitis. It also implies that H_2O_2 plays a prominent causal role in the development of diversion colitis as well[101].

This interpretation is consistent with a case report of a healthy 36-year-old male who developed UC after following an extremely low carbohydrate diet for weight loss, which resolved without medication upon the institution of a semi-vegetarian diet[102]. Studies have demonstrated significant declines in fecal butyrate and butyrate-producing bacteria in individuals with reduced dietary carbohydrates[103]. The decrease in colonocyte butyrate can be reversed with butyrate enemas that significantly increased colonic epithelial GSH, which is consistent with a GSH sparing effect of butyrate inferred from Figure 4B[104].

Butyrate enemas also significantly reduced mucosal inflammation in patients with refractory UC [105]. This can be attributed to the butyrate-mediated increase in colonocyte GSH and subsequent reduction in colonic epithelial H_2O_2. This is supported by studies showing that butyrate prevents H_2O_2-induced DNA damage in isolated human colonocytes[106]. Thus, colonic butyrate has a critical role in maintaining colonocyte redox-homeostasis by preventing the anapleurotic metabolism of glutamate and subsequent decrease in colonic epithelial GSH, which leads to elevated colonocyte H_2O_2 and UC[107].

The crucial role of GSH in the elimination of cellular H_2O_2 can be seen in GPx knockout mice that lack this key enzyme needed to utilize GSH for the elimination of H_2O_2. Knockout mice lacking GPx develop colitis[32]. Colitis also occurs concomitantly with experimental beta-oxidation inhibition in mice, and in pigs subsequent to vitamin B-5 (pantothenic acid) deficiency. Vitamin B-5 is necessary for CoA synthesis, without which there is no acetyl CoA[108,109]. This suggests that disruption of bioenergetic flux at any point along the metabolic pathway from lumenal fiber to the formation of acetyl CoA will result in increased colonocyte H_2O_2 and colitis (Figure 4B).

Based on these data, we can reasonably predict that alterations in the colonic flora (microbiome dysbiosis) that lead to impaired short-chain fatty acid (*i.e.*, butyrate) production will contribute to the development and relapse of UC by increasing colonocyte H_2O_2. A diverse set of adverse environmental exposures can shift the colonic microbiome towards dysbiosis and impaired butyrate production. These include high fat/low fiber/high protein diets, food additives in processed food, smoking and alcohol ingestion[110-113]. Other diverse factors such as infant delivery and feeding methods, medications, enteric endocrine disruptors, psychological stress can also facilitate microbiome dysbiosis[114-117]. Long term dietary patterns that include soft drinks and artificial sweeteners may tip the balance towards dysbiosis[118,119]. Thus, microbiome dysbiosis is an oxidative stressor that can increase colonocyte H_2O_2 and contribute to the onset of UC[120].

Lastly, as mentioned above, H_2O_2, being membrane permeable, can diffuse into the colonocyte nucleus leading to oxidative nuclear DNA mutations in tumor suppression and oncogenes that promote colorectal cancer[51,52]. Studies have shown that mice fed a total western diet develop a neutrophil predominant colitis and colorectal cancer[121]. This is analogous to histological findings in human UC, which also carries an enhanced risk of colorectal cancer. Taken together, when the evidence supporting a causal role for H_2O_2 in UC and its associated colon cancer is viewed in light of biological mechanisms leading to increased colonocyte H_2O_2 subsequent to low-fiber high-fat diets, it is reasonable to conclude that the increased incidence of UC and colorectal cancer associated with the (low-fiber high-fat) western diet[9,97,122] is mediated through elevated colonocyte H_2O_2. This raises the possibility of primary prevention *via* changes to reduce dietary oxidative stress (*i.e.*, high fiber, low fat *etc*) and/or the administration of an oral reducing agent (detailed in the treatment section below).

Alcohol

Several studies have found that alcohol consumption increases the risk of onset, relapse, and gastrointestinal symptoms in individuals with UC[123]. Alcohol is biomembrane permeable, and after ingestion is distributed to all tissues in the body[124]. Alcohol metabolizing enzymes in the colonic epithelium can generate large amounts of H_2O_2[124]. Alcohol metabolism by alcohol dehydrogenase generates acetaldehyde, which is converted to acetic acid by aldehyde dehydrogenase. Both these reactions generate NADH, which feeds into the mitochondrial ETC causing increased electron leakage and enhanced generation of H_2O_2[124]. The increased amount of colonocyte H_2O_2 can overwhelm cellular reductive capacity and diffuse to the extracellular space leading to relapse or the onset of UC.

Cytochrome P450 2E1 (CYP2E1) is a second alcohol oxidizing enzyme that is highly expressed in the human intestine and is upregulated by chronic alcohol exposure[125]. CYP2E1 has the highest catalytic activity among the members of CYP enzymes in metabolizing ethanol[126]. CYP2E1 consumes NADPH when metabolizing ethanol to acetaldehyde and in the process generates large amounts of H_2O_2[126, 127]. NADPH is also required for the recycling of oxidized GSH (GSSG) back to reduced GSH by GSSG reductase[49]. This can reduce the availability of GSH for the elimination of H_2O_2 and contribute to increased colonocyte H_2O_2 levels. The total combined effect of alcohol metabolism is excess production of colonocyte H_2O_2 that can overwhelm cellular reductive capacity leading to extracellular H_2O_2 diffusion and *de novo* UC or relapse by the mechanisms detailed above. CYP2E1 is also upregulated by ethanol, which magnifies the oxidative stress caused by this alcohol metabolizing enzyme.

Antibiotics

Due to their widespread use, antibiotics represent a significant source of oxidative stress within the population. Studies have shown an association between antibiotic use and the development of UC[128]. Although antibiotics are administered to eradicate pathogenic bacteria they also indiscriminately kill beneficial commensal bacteria that make up the colonic microbiome leading to a decrease in species diversity including a reduction in bacterial species that produce butyrate[129]. A decrease in colonic butyrate can lead to metabolic changes favoring increased colonocyte production of H_2O_2 (Figure 4). Antibiotic-induced microbiome depletion (dysbiosis) can last for years and act cooperatively with other oxidative stressors such as a high-fat diet[130,131]. This can hasten colonocyte H_2O_2 build-up (HCRH) and the development of UC.

However, microbiome depletion is not the only mechanism by which antibiotics generate excess colonocyte H_2O_2. Studies have shown that antibiotics induce the production of significant amounts of H_2O_2 in both bacteria and human intestinal epithelial cells, which in the latter was caused by an alteration to the ETC[132-135]. Since H_2O_2 is cell membrane permeable, bacterial H_2O_2 can diffuse across epithelial cell membranes and add to the already increased antibiotic-induced colonic epithelial cell H_2O_2 load. This can lead to mtDNA oxidative damage with the formation of colonocyte mitochondrial heteroplasmy and ever-increasing production of intracellular H_2O_2 resulting in HCRH (Figure 2). Increased cellular production of H_2O_2 can overwhelm colonocyte reductive (antioxidant) capacity and lead to a buildup of colonocyte H_2O_2 that will facilitate the development of UC years later. Because virtually everyone is exposed to antibiotics at one time or another, they exert a selective oxidative pressure that can manifest as UC in individuals with a predisposing genetic makeup encoding for a diminished reductive capacity that facilitates the buildup of H_2O_2.

Psychological stress: A common oxidative stressor leading to H_2O_2 production

Stress is a significant risk factor for UC. Up to 40% of patients with UC report psychological stress as an exacerbating factor[136]. Psychological stress can cause *de novo* UC and worsen existing disease[137-141]. Psychological stress exposure is reported to induce mucosal inflammatory responses and can result in colonic hypermotility that may be sufficient to occlude the lumen[142,143]. But why is psychological stress pro-inflammatory in the colon and how does stress initiate or worsen UC?

The coordinated movement of food along the gastrointestinal (GI) tract is dependent on 5-hydroxytryptamine (serotonin) mediated regulation of smooth muscle tone, motility, and peristalsis[144]. 95% of serotonin is stored in enterochromaffin cells (EC) that are present in the GI tract mucosa[145]. Serotonin is released from EC cells and stimulates enteric nerve terminals to initiate a peristaltic wave[144,146]. However, the amount released is much more than needed and the excess serotonin is rapidly taken up by colonic epithelial cells and metabolized by colonocyte monoamine oxidase (EC#1.4.3.4)[144]. This prevents hyper-stimulation and excessive bowel motility that can lead to colonic spasms. Mono-amine oxidase catalyzes the oxidative deamination of serotonin in a process that generates H_2O_2; the reaction catalyzed is $RCH2NHR' + H_2O + O_2 \rightarrow RCHO + R'NH_2 + H_2O_2$[147].

Studies have shown that psychological stress causes prolonged increases in colonic motility[148]. Stress-induced colonic hypermobility and spasm will release large amounts of serotonin into the colonic mucosa that is metabolized to H_2O_2 within colonocytes. The excess colonocyte H_2O_2 can acutely overwhelm the enterocyte's antioxidant capacity resulting in H_2O_2 accumulation and eventual UC after extracellular diffusion. This mechanism is supported by studies showing that serotonin has a key role in the pathogenesis of experimental colitis[149].

Thus, psychological stress has a pernicious effect on the course of UC but UC is also psychologically stressful with studies reporting that patients with UC are engaged in a continuous "fight" to maintain health-related normality[150]. This sets up a self-sustaining bidirectional cycle of continuous psychological stress that contributes to increased frequency and severity of disease[151]. Although stress can cause or worsen UC, stress reduction is generally not effective at altering the activity or course of disease sufficiently to induce remission[152,153]. This is not surprising since the principal driving force behind the auto-propagating nature of inflammation in UC is H_2O_2 release by activated infiltrating mucosal neutrophils and not the metabolism of serotonin, which has its principal effect as a contributing factor in the stress-induced pathogenesis and relapse of UC[26,149].

Cigarette smoking: Releasing the brakes

Since reports in the early 1980s, numerous studies included in three meta-analyses (1989, 2006 and 2021) have established that cigarette smoking is significantly protective against the development of UC compared to non-smokers while smoking cessation is a significant risk factor for developing UC or experiencing disease relapse with increased severity of illness[154-158]. Additionally, as noted below, cigarette smoking also affects the therapeutic response after smoking cessation. But why is cigarette smoking protective against the onset of UC?

Nicotine, an addictive chemical present in tobacco, was initially considered as a possible protective factor. Nicotine is effective at inducing remission when begun at the time of or soon (up to 4 wk) after smoking cessation (early relapse)[159,160] However, nicotine is largely ineffective when therapy is administered for disease relapse several months or years after smoking cessation (late relapse) with

studies concluding that nicotine therapy is of minimal value in the treatment of UC and questions whether nicotine is the active protective component of smoking that decreases risk and inflammation in UC[161-164]. In contrast, the resumption of smoking is reported to be an effective therapy for induction and long-term maintenance of remission in patients with early or late relapse[159,160,165]. Indeed, studies have reported that resumption of smoking is highly effective for induction of remission in refractory disease years after smoking cessation; with nicotine being effective if treatment is begun at the same time as smoking cessation[160]. Thus, in ex-smokers, nicotine is effective for remission induction in early relapse while the resumption of smoking is effective in both early and late relapse.

Taken together, the data indicate that there are two distinct oxidative stressors with distinct short and long-term mechanisms of action both of which are caused by the latent and repressed effects of active smoking and are only unmasked by smoking cessation. The initial mechanism manifests soon after smoking cessation and lasts for days to under a month. In contrast, the second mechanism becomes predominant many months to years later reaching a peak of the highest risk of relapse within 2 to 5 years of smoking cessation[166].

The initial oxidative stressor is the physiological and psychological stress of nicotine withdrawal, which is manifest shortly after smoking cessation and peaks within the first week, and lasts up to one month[167]. Nicotine withdrawal symptoms can include anger, irritability, frustration, anxiety, depression, insomnia, restlessness, and constipation[167]. These same psychological emotions of anger, resentment, emotional conflict, hostility, anxiety, and psychological tension were observed under direct observation to cause significant colonic hypermotility and spasm[168]. Thus, it is reasonable to conclude that nicotine withdrawal secondary to smoking cessation can result in colonic hypermotility with increased colonic serotonin secretion and enhanced monoamine oxidase production of H_2O_2 (see above section-psychological stress). Under these circumstances, the administration of nicotine will decrease colonic hypermotility and lower colonic serotonin production, which decreases colonocyte H_2O_2 leading to remission. Resumption of cigarette smoking also provides the nicotine needed to treat early relapse due to nicotine withdrawal.

In other words, nicotine-induced remission is due to the relief of nicotine withdrawal symptoms (and accompanying colonic hypermotility) during early relapse after smoking cessation. Nicotine treatment is rendered minimally effective after nicotine withdrawal symptoms (and colonic hypermotility) have subsided. Colonic hypermotility (from any cause) is an oxidative stressor that increases colonocyte H_2O_2, which can overwhelm colonocyte reductive (antioxidant) capacity leading to extracellular diffusion and UC.

The second oxidative stressor caused by cigarette smoking cessation is due to disinhibition of the colonocyte ETC. Studies quantifying the effect of cigarette tar on mitochondrial ETC activity report an 82% inhibition rate on whole chain respiration[169]. Under normal conditions, the ETC is fueled by electron flux provided by reducing equivalents (NADH and FADH2) generated by the multi-enzyme Krebs cycle[170]. H_2O_2 is produced by spontaneous auto-oxidation of the ETC (electron leakage). These leaked electrons combine with vicinal oxygen within the mitochondrial matrix to form superoxide, which is converted to H_2O_2 by superoxide dismutase. H_2O_2 is subsequently neutralized by GPx using GSH as a reducing co-factor.

Under conditions of ETC inhibition during active smoking, less ETC-generated H_2O_2 is produced, which affords protection against the development of UC. However, while smoking, upregulation of bioenergetic enzyme systems can be expected as the colonocyte attempts to overcome the smoking-induced inhibition and restore normal mitochondrial bioenergetics[171]. Upon smoking cessation, the inhibition is slowly lifted and increased production of ETC "fuel" is metabolized producing supraphysiological amounts of H_2O_2 as a result of increased ETC auto-oxidation (electron leakage). Colonocytes respond to this oxidative stress by producing additional GSH for H_2O_2 neutralization. This creates a condition of HCRH (Figure 2) that can eventually overwhelm colonocyte reductive capacity leading to cellular H_2O_2 build-up and eventual *de novo* UC as H_2O_2 diffuses to the extracellular interstitial space attracting neutrophils into the colonic epithelium from the subjacent microvasculature.

Smoking resumption inhibits ETC activity, which decreases colonic epithelial cell H_2O_2 leading to remission. Nicotine does not inhibit the ETC and cannot induce remission of late UC relapse (years after smoking cessation). This interpretation is supported by studies that demonstrated significantly improved clinical manifestations such as bloody stool, diarrhea, and abdominal pain in UC patients treated with metformin[172]. Further, UC patients treated with metformin showed a significant decrease in histological and endoscopic disease scores in addition to significantly diminished erythrocyte sedimentation rate (a biomarker of systemic inflammation) and significantly decreased indices of colonic local oxidative stress (tissue malonaldehyde and myeloperoxidase)[172].

But how does metformin improve UC and how is it related to cigarette smoking? Metformin is a biguanide antihyperglycemic agent used to treat type 2 diabetes. Its mechanism of action includes inhibition of mitochondrial glycerol 3-phosphate dehydrogenase (of the glycerolphosphate shuttle-EC 1.1.5.3) and inhibition of ETC complex I both of which are major contributors of electrons to the ETC in mitochondria[173-175]. Inhibition of electron flux by metformin is analogous to the ETC inhibitory effects of cigarette smoking. This implies that both smoking and metformin improve UC by decreasing mitochondrial production of H_2O_2. This is supported by studies showing that targeted inhibition of glycerol 3-phosphate dehydrogenase decreases cellular production of H_2O_2[176].

In summary, the evidence supports two distinct oxidative stress mechanisms to explain the effects of smoking cessation on UC. Early relapse after smoking cessation (within days) is mediated by the oxidative stress induced by the physiological effects of nicotine withdrawal while late relapse (months to years) is mediated by a slow rise in colonocyte H_2O_2 due to disinhibition of mitochondrial H_2O_2-generating metabolic pathways. Conversely, cigarette smoking affords protection against early and late UC relapse by providing nicotine and decreasing colonocyte production of H_2O_2, respectively.

Mercury

Mercury is a major environmental contaminant and a significant source of occupational exposure[177]. Occupational inhalation of mercury vapor is reported to cause a recurrent relapse of UC[178]. Mercury forms stable bonds with thiol groups present on GSH in addition to inhibiting GPx, both of which are critical for the removal of cellular H_2O_2[179-181]. This results in the inactivation of the entire GSH-based antioxidant system. The compromise of this critical system by mercury prevents neutralization of H_2O_2, which can accumulate to excessive levels inside colonocytes leading to extracellular diffusion and UC relapse as described above. Thus, mercury is an oxidative stressor that increases cellular H_2O_2 by preventing its elimination from the cell. Mercury is a pervasive contaminating xenobiotic whose exposure is likely to be insidious, bio-accumulative, and additive to other contemporaneous oxidative stress exposures.

PERFLUOROOCTANOIC ACID

Perfluorooctanoic acid (PFOA) is a ubiquitous environmental contaminant that was used to manufacture non-stick pans in addition to other commercial products such as stain and water-resistant fabrics. Introduced into the environment in the 1950s, PFOA can be found in the serum of virtually all residents of industrialized countries. Human exposure occurs *via* many sources including contaminated drinking water, food, and house dust. Due to the high dissociation energy of its carbon-fluorine bond, PFOA is resistant to vertebrate metabolism and environmental degradation[182]. As a result, PFOA is called a "forever-chemical" because it is not biodegradable and has a long elimination half-life of 3.5 years[183].

Studies have demonstrated a significant exposure-response relationship between PFOA serum levels and subsequent UC but no association with Crohn's disease (CD)[183]. Other studies have reported significantly increased serum PFOA in UC patients compared to a combined group of CD (positive control for intestinal inflammation) and normal individuals (negative non-diseased control)[184]. The specific association of PFOA with UC suggests that PFOA's effect is acting in concert with a unique predisposing genetic makeup to select a subset of individuals for the development of UC. In other words, PFOA's mechanism of action in all exposed individuals is the same but the genetic predisposition in a subset of individuals is permissive for the development of UC.

A related halogenated chemical, 2-bromooctanoic acid, after conversion to the sodium salt 2-bromooctanoate, is reported to cause an acute murine colitis analogous to human UC after rectal installation[108]. This suggests the possibility that PFOA might be acting in the same manner as 2-bromooctanoate since halogenated carbon compounds, as a group, have a high resistance to degradation[185].

In human UC, beta-oxidation is inhibited as a secondary effect caused by rising levels of colonocyte H_2O_2[30]. Since 2-bromooctanoate causes murine UC accompanied by inhibition of beta-oxidation and the related halogenated chemical PFOA causes UC and is not biodegradable this suggests that intracellular H_2O_2 is increased as a result of the colonocyte's high expenditure of energy (ATP) in a futile attempt to metabolize and remove these non-biodegradable halogenated xenobiotics from the cell. Since almost all cellular ATP is produced as a result of mitochondrial ETC activity, which also generates most of the cell's H_2O_2, this implies that the initial buildup of H_2O_2 occurs in mitochondria where beta-oxidation is also located. Increased mitochondrial H_2O_2 will inhibit mitochondrial thiolase, the last enzyme in the beta-oxidation cascade, leading to inhibition of mitochondrial beta-oxidation[30].

In other words, the colonocyte's persistent metabolic response in an attempt to eliminate these non-biodegradable chemicals leads to increased H_2O_2 generated by the ETC, which inhibits mitochondrial beta-oxidation followed, sometime later, by UC as H_2O_2 diffuses out of the colonocyte into the extra cellular space. This mechanism is consistent with studies showing inhibition of beta-oxidation in UC patients is followed shortly after by a relapse of disease[41]. H_2O_2-induced inhibition of mitochondrial beta-oxidation (*via* mitochondrial thiolase inhibition) increases the anapleurotic metabolism of glutamine, which decreases the biosynthesis of GSH contributing to the excess colonocyte H_2O_2 load (Figure 4). This mechanism is also consistent with a genetic predisposition that impairs the colonocyte's ability to neutralize an H_2O_2 load. Within this redox framework, inhibition of colonocyte beta-oxidation is a secondary effect of colonocyte xenobiotic (PFOA or bromooctanoate) metabolism, which generates excess ETC H_2O_2 that impairs mitochondrial beta-oxidation *via* H_2O_2 induced inhibition of mitochondrial thiolase. This raises the possibility of primary prevention with an oral reducing agent for communities at risk for the adverse effects of PFOA exposure. A causal role for H_2O_2 can be tested in the

laboratory by the prevention of PFOA (or 2-bromooctanoate) induced murine colitis with an oral reducing agent (see treatment section below).

Lastly, PFOA's adverse effects are not limited to UC. Lymphocytes are highly sensitive to the toxic effects of H_2O_2 and undergo apoptosis at very low levels of H_2O_2 exposure of less than 1 μm[186]. Studies showing a significant association between PFOA serum levels and decreased antibody response to vaccination are consistent with this mechanism of action[182]. Thus, PFOA resistance to cellular metabolism and degradation is likely to result in excess H_2O_2 production in any cell contaminated by this xenobiotic.

Endogenous oxidative stressors: A look inside

In UC, lifelong episodes of relapsing inflammation affecting the same colonic regions previously inflamed indicate that inflammation has fundamentally changed the colonic epithelium compared to the pre-morbid state. Since the character of the inflammation does not change over time and neutrophils continue to be the first responders streaming into the colonic epithelium, this suggests that H_2O_2 is still the chemotactic agent involved but from a new source. The evidence points to new endogenous sources of H_2O_2 that combine with pre-existing sources of H_2O_2 to increase the likelihood of relapse.

Microbiome: An oxidative dysbiosis

Although disruption of the colonic microbiome can contribute to the onset of UC by decreasing butyrate production, which leads to increased colonocyte H_2O_2 (Figure 4), UC can also adversely affect the microbiome. Studies have shown a 10 × increase in H_2O_2 producing bacteria in biopsies of inflamed colonic tissue in individuals with UC compared to normal controls[120]. These H_2O_2-producing bacteria are adherent to the colonic mucosa. This suggests that chronically high levels of H_2O_2 in the inflammatory field create an environment that selects for bacteria that produce H_2O_2, which are those able to tolerate the abnormally high levels of lumenal oxidative stress. Over time, this oxidative dysbiosis may replace large portions of the normal microbiome, which may not be able to survive under conditions of high H_2O_2-induced oxidative stress. The H_2O_2 released by bacteria can contribute to relapse by diffusing through the epithelium to the subjacent vascular layer where it serves as a chemotactic agent to attract neutrophils into the colonic epithelium. This creates a microbiome, which is a pro-inflammatory endogenous oxidative stressor that contributes to the onset or relapse of UC by continuous H_2O_2 production. A recent analysis examining the pathogenesis of UC concluded that "*disease onset is triggered by events that alter the healthy balance of the gut microbiota, perturb the mucosal barrier, and abnormally stimulate gut immune responses*"[12]. H_2O_2 does all three.

CYP2E1 induction: A vicious cycle

As explained above CYP2E1 is an alcohol inducible enzyme that is involved in the metabolism of ethanol and other xenobiotics entering the body. H_2O_2 is within the chain of molecular events that upregulate inducible CYP2E1[187]. This implies that chronically elevated colonocyte H_2O_2 from any source (*i.e.*, ethanol or xenobiotic metabolism, oxidative stress exposure, *etc*) can upregulate CYP2E1. In other words, elevated colonocyte H_2O_2 can upregulate CYP2E1 without ethanol exposure. This can cause increased sensitivity to CYP2E1 substrates, which can lead to heightened H_2O_2 production in areas of previous inflammation when exposed to ethanol or other xenobiotics metabolized by this enzyme. Studies have shown the cells with upregulated CYP2E1 produced higher amounts of H_2O_2 that can exit the cell[188]. This can cause increased H_2O_2 production upon exposure to CYP2E1 substrates such as alcohol and other xenobiotics, which increases the risk of relapse or *de novo* UC. Under these circumstances, upregulated CYP2E1 becomes an endogenous oxidative stressor.

Mitochondrial heteroplasmy: Hard-wired for inflammation

Intracellular H_2O_2 is normally kept within a very low picomolar range to prevent oxidative damage from this very powerful oxidizing agent[186,189]. Over time, colonocytes from individuals with UC are exposed to higher levels of H_2O_2 due to multiple oxidative stressors including infiltrating epithelial neutrophils (mucosal inflammation), microbiome (oxidative dysbiosis), CYP2E1 induction (alcohol and xenobiotic exposure), peroxisomal beta-oxidation (high-fat diet) and ETC hyperactivity (smoking cessation), *etc.* The increase in colonocyte H_2O_2 can overwhelm cellular antioxidant systems resulting in mitochondrial genetic damage[44,45]. This occurs because mtDNA is highly susceptible to H_2O_2-induced oxidative damage due to a lack of introns or histones, proximity to the ETC where H_2O_2 is produced, and inefficient DNA repair mechanisms compared to nuclear DNA[37,38].

As mentioned above, H_2O_2-induced mitochondrial genetic damage introduces mutations into mtDNA resulting in a different genetic sequence for some of the hundreds of mitochondrial chromosomes present in a cell. The simultaneous occurrence of normal and mutated mtDNA is called mitochondrial heteroplasmy. The presence of mitochondrial heteroplasmy (mtDNA mutations) causes miscoding during the transcription of ETC proteins leading to the biosynthesis of faulty and mutated ETC subunits. The mutated ETC disrupts electron flow causing electron loss at a greater rate than normal (increased electron leakage). These electrons combine with vicinal molecular oxygen to form superoxide that is converted to H_2O_2 by superoxide dismutase. Since the ETC and mtDNA are both in close

proximity to each other within the mitochondrial matrix, any excess H_2O_2 produced by the ETC can easily diffuse over to any one of the 2-10 chromosomes contained within a mitochondrion leading to additional mtDNA mutations and greater H_2O_2 production[190]. This positive biofeedback mechanism establishes a vicious cycle that leads to ever-increasing levels of colonocyte H_2O_2.

The presence of mitochondrial heteroplasmy (and the resulting increase in colonocyte H_2O_2) can contribute to the tendency of UC to worsen over time with more frequent and severe episodes of relapse [7]. Relapse may occur in response to increasingly minor (oxidative) stressors due to the already high intracellular colonocyte H_2O_2. Thus, the accumulation of colonocyte H_2O_2 transforms otherwise innocuous insults into 'second hit' stimuli. The "first hit" being the pre-existing excess of colonocyte H_2O_2. For example, in individuals with inactive UC, low to moderate red wine consumption (1-3 glasses daily) increased colonic epithelial paracellular permeability in areas previously affected by mucosal inflammation[123,191]. Increased colonic paracellular permeability is characteristic of individuals with UC[24,25]. And H_2O_2 is reported to increase paracellular permeability by disrupting cellular tight junctions[20,22,192-194]. Under these circumstances, it takes less alcohol to increase colonocyte H_2O_2 to the point where it diffuses out of the cell causing oxidative damage to tight junctions with subsequent increases in colonic paracellular permeability. This explains the second hit phenomenon in UC. In summary, mitochondrial heteroplasmy is unique because it is an ever-present self-amplifying intracellular oxidative stressor that facilitates the establishment of HCRH (Figure 2), which contributes to both the increased frequency of relapse and/or severity of disease.

Homocysteine: Inhibition of GPx

Several studies have reported significantly elevated levels of tissue and serum homocysteine in children and adults with UC[195-198]. A significant positive association between elevated homocysteine and UC was confirmed by two meta-analyses in 2011 and 2018[199,200]. Homocysteine inhibits GPx, the principal antioxidant enzyme system used by the cell to remove (neutralize) H_2O_2[201,202]. Furthermore, homocysteine-induced inhibition of GPx occurs at physiologic levels of serum homocysteine[203]. Inhibition of GPx can increase cellular H_2O_2, especially during oxidative stress exposure, which acutely increases cellular H_2O_2 production. Thus, homocysteine is a significant endogenous oxidative stressor that can increase colonocyte H_2O_2 and contribute to *de novo* UC or disease relapse.

EVIDENCE-BASED TREATMENT

Therapy: Targeting H_2O_2

A causal role for H_2O_2 in the pathogenesis of UC implies that induction of remission can be achieved by eliminating extracellular colonocyte H_2O_2 while maintenance of remission is attained by normalizing intracellular levels of colonocyte H_2O_2. The overall objective is to abrogate the H_2O_2 molecular chemotactic "trail" that is guiding the directed migration of subjacent intravascular neutrophils to the source of H_2O_2 emanating from the colonic epithelium. Without an interstitial H_2O_2 gradient signal to follow, neutrophils are no longer attracted into the colonic epithelium, which effectively terminates the inflammatory response. These were the goals that guided the formulation of a novel therapy, which consists of a topical multicomponent enema (described below) administered with a systemic oral reducing agent [R-dihydrolipoic acid (RDLA)] that targets extracellular and intracellular colonocyte H_2O_2 respectively. RDLA is the reduced form of the biologically active 'R' enantiomer of lipoic acid and is the only form that should be administered as the oxidized form (described below) might worsen UC.

We administered the enema once daily (usually at bedtime) for 2 wk followed by once every other day for two weeks. Oral RDLA 300 mg twice daily was initiated when enema therapy was begun. Treatment with RDLA was continued for 4-6 mo. The components of the enema are mesalamine [5-aminosalicylic acid (5-ASA)], budesonide, sodium cromolyn, and sodium butyrate. The enema formulation and evidence-based rationale for the inclusion of each component of the entire therapy are discussed below. The severity or extension of the disease was not a consideration when initiating therapy since, in theory, all patients with UC should respond to a reduction of colonic H_2O_2. Our only consideration was whether the patient could tolerate the therapy.

Enema formulation

The enema was formulated by adding the following components to a standard 60-milliliter enema bottle containing 4 g of mesalamine (5-ASA) from which 20 milliliters were removed (and discarded): (1) 15 milliliters of 1 molar sodium butyrate (1.7 g); (2) 5 milliliters of sodium cromolyn (total 100 mg); and (3) 1 milliliter of budesonide (5 mg/mL). Gentle swirling should follow the addition of each component to ensure uniform dispersal. The total ending volume is 61 milliliters. The combination enema is easily made by a compounding pharmacist. We only used the original enema bottle containing mesalamine to formulate this therapy as other bottles may have residual chemicals that can worsen UC.

Results of treatment

The novel treatment was offered to 36 patients with refractory UC as part of the practice of medicine (average MAYO score 8.6, range 3-12) and the results were published as a case series in which 85% achieved complete histologic remission in under 8 wk[204]. Although long-term follow-up was not part of the case series, a case report was generated after I was contacted by a patient included in this case series[205]. The patient had a 39-year history of refractory UC, which had progressed to severe pancolitis at the time of treatment when he was being considered for a total colectomy. His follow-up colonoscopy, which was performed 12 years later in 2019, showed completely normal colonic biopsies with no signs of UC. To date, (14 years after treatment) the patient relates having uninterrupted completely normal bowel movements. Based on the available data, this appears to be the first documented cure of UC. The video of an in-house clinical presentation of the first five patients to receive this new therapy with before-and-after treatment histology presented by the attending physician and attending pathologist is available[206].

Within this evidence-based redox framework, the general therapeutic intervention for all UC patients is the same regardless of duration or severity of illness, course, relapsing frequency, mucosal inflammatory distribution, age of onset, previous medications, or extra intestinal manifestations. Modifications may be required for those patients who are intolerant to any of the components in the therapy. In patients who are intolerant of topical (enema) therapy, treatment can be initiated with RDLA alone, which as an amphipathic membrane-permeable antioxidant (H_2O_2 neutralizing) and reducing (cellular electron-donating) agent may restore colonocyte redox homeostasis and resolve mild-moderate cases of UC with more severe cases improving enough to begin topical (enema) therapy if needed.

Severe UC

Up to 25% of patients with UC will experience severe disease requiring hospitalization either on initial presentation or during the course of their illness[207]. Severe UC presenting with multiple daily episodes of bloody diarrhea and signs of systemic toxicity is a life-threatening emergency with significant morbidity, high risk of colectomy, and a pre- and post-operative mortality of up to 3% and 5% respectively[8,207,208]. In these individuals, oral and/or topical therapy may not be possible or advisable. The evolution of UC to this extreme degree indicates severe depletion of both colonic and systemic reductive capacity[61,62]. The exceptionally high rate of current medical treatment failure for severe UC and the observation that remission is associated with restoration of colonic redox homeostasis[208,209], suggests that patients with severe UC should be considered for therapy with an intravenous reducing agent such as sodium thiosulfate (STS) as part of their overall treatment regimen in order to rapidly reduce systemic and colonic H_2O_2, restore redox homeostasis and promote mucosal healing. Given that current management of acute severe UC is not based on high-quality evidence, the need for effective therapy is all the more pressing[210].

STS is an odorless, water-soluble, small inorganic molecule (MW-158.11 g/mol) that is normally produced in mitochondria as a product of sulfide oxidation pathways[211]. STS is on the World Health Organization's (WHO) list of essential medicines and is supplied for intravenous use due to rapid gastric degradation[211]. STS is a direct-acting reducing agent that can donate two electrons to chemically neutralize H_2O_2 upon contact[212]. STS will also reduce the oxidized form of GSH (GSSG) back to reduced GSH, which is needed to neutralize H_2O_2 and maintain cellular redox homeostasis[213]. The advantage of STS is that it does not depend upon biological antioxidant enzyme systems for its therapeutic action. This is beneficial in critical settings when rapid reduction of H_2O_2 and restoration of redox homeostasis are required.

The basic chemical reaction for the reduction of H_2O_2 with STS is: $4\ H_2O_2 + S_2O_3^{2-} \rightarrow 2\ SO_4^{2-} + 2\ H^+ + 3\ H_2O$[212]. Based on the above chemical reaction and evidence implicating a causal role for H_2O_2 in the pathogenesis of UC, STS is expected to abrogate the interstitial neutrophilic chemotactic effect being exerted by H_2O_2 and thus prevent neutrophil migration into the colonic epithelium, which perpetuates colonic inflammation. The reduction of extracellular colonic mucosal H_2O_2 by STS can act as a sink that will facilitate the diffusion of intracellular colonocyte H_2O_2 to the extracellular space where it can be neutralized by STS.

H_2O_2 can impair smooth muscle contraction and interrupt neuromuscular transmission leading to reduced colonic muscle tone and lowered colonic lumenal pressure, which is postulated to play an essential role in the development of toxic megacolon, a life-threatening complication of UC[214-218]. Thus, reducing agents such as STS or RDLA may have a role in treating or preventing toxic megacolon. Once severe UC is resolved, patients should be discharged on an oral reducing agent such as RDLA for an indefinite period of time to lower the risk of relapse.

STS is well tolerated and approved for use in cyanide poisoning with a recommended dose of 12.5 g over slow IV infusion (10-20 min) in adults and 250 mg/kg in children[219,220]. Similar dosing regimens can be considered in UC with repeat dosing guided by clinical status. STS is an accepted therapy for calciphylaxis due to chronic renal failure and is administered to mitigate the adverse effects of cisplatin toxicity during the treatment of solid tumors[213].

MAINTENANCE: TARGETING OXIDATIVE STRESSORS

Although therapeutic intervention to lower H_2O_2 and restore colonic redox homeostasis is a critical part of overall therapy, elimination of contributing lifestyle and dietary habits that increase cellular H_2O_2 (environmental oxidative stressors, Figure 3A) must be part of the long term strategy to maintain remission. A complete list of environmental oxidative stressors and their mechanisms is beyond the scope of this paper however, some general evidence-based guidelines can be made. Stress and alcohol ingestion are major oxidative stressors and should be avoided. A low-fat diet with adequate amounts of dietary fiber, especially soluble fiber, is extremely important to minimize colonic oxidative stress[83,221-223].

Eating food that is free of pesticides, chemicals and additives is critical for maintaining a healthy microbiome. High levels of iron in red meat and some tap water are oxidative stressors and should be avoided[224,225]. Certain fish contain high levels of mercury[226,227]. Mercury is an oxidative stressor and therefore it is prudent to minimize ingestion of fish containing high levels of mercury. Studies have shown that sugar and sugar-sweetened drinks are also associated with UC[228,229]. So it is best to avoid high sugar-containing foods and drinks.

Carrageenan is a non-nutritive food additive that is used as a thickening agent in many foods. Although considered safe, food-grade carrageenan can be converted to a colitis-promoting small-molecular (degraded) carrageenan when exposed to H_2O_2[230,231]. Since H_2O_2 is present in the inflammatory field it (H_2O_2) can convert food-grade carrageenan to the degraded variety in the colon of individuals with UC. Studies report that degraded carrageenan can penetrate colonocytes and generate superoxide, which is converted to H_2O_2[232]. Thus, carrageenan is an oxidative stressor that generates intracellular colonic H_2O_2 and should avoid by individuals with UC.

Smoking cessation is a strong oxidative stressor and should be undertaken very slowly in patients with UC to avoid relapse. RDLA can be administered during smoking cessation to counteract oxidative stress. Patients should be very cautious with vitamin supplementation because studies have shown that certain vitamins such as vitamin B6 (pyridoxine) have been associated with the development of UC [233]. Pyridoxine used in supplements and food fortification is converted to the biologically active pyridoxal by pyridoxine 4-oxidase (EC1.1.3.12), which produces H_2O_2 as a by-product[234]. Adequate sleep (at least 6 h) and regular moderate exercise are very important for individuals with UC to reduce stress[235,236]. Based on the data indicating a compromised reductive capacity, all UC patients should be maintained on an oral reducing agent (*i.e.*, RDLA) for an indefinite period of time. The following section provides a detailed explanation regarding the scientific basis for each component of the therapy.

Rationale for multicomponent enema therapy

As mentioned above, the compound enema contains four components: Mesalamine (5-ASA), budesonide, sodium cromolyn, and sodium butyrate. The therapeutic rationale for the compound enema is based on the mechanism of action for each component to act in an additive fashion in order to decrease colonic H_2O_2 as indicated below. The base component, 5-ASA has an anti-inflammatory effect that is limited to the specific type of inflammation present in UC and does not have a positive therapeutic action on colonic inflammation in general[237]. This suggests that 5-ASA's mechanism of action is directed at the causal agent responsible for the inflammation in UC. This is in contrast to other currently available therapeutic agents used to treat UC, which have a more general immunosuppressive action in the colon. 5-ASA's mechanism of action is that of a topically-acting extracellular tetra-valent reducing agent capable of donating up to 4 electrons per molecule for the reduction (neutralization) of H_2O_2 and other oxygen radials[238,239]. Since 5-ASA is able to induce and maintain histologic remission in active UC, this indicates that 5-ASA can neutralize extracellular neutrophil-derived H_2O_2 in the inflammatory field leading to induction of remission while the sustained topical epithelial presence of 5-ASA maintains remission by neutralizing H_2O_2 diffusing from colonocytes.

Neutralization of colonocyte-derived H_2O_2 by 5-ASA prevents the establishment of an H_2O_2 mediated neutrophilic chemotactic gradient, which attracts neutrophils into the colonic epithelium leading to relapse. This is supported by the observation that 5-ASA's histologic remission rate of nearly 45% is the highest of any currently available therapeutic approved to treat UC suggesting 5-ASA's ability to neutralize colonic H_2O_2 is interrupting a fundamental underlying biological process (*i.e.*, neutrophilic chemotaxis) in the molecular chain of events leading to UC[240].

Butyrate, a short-chain fatty acid normally produced by the colonic microbiome as a colonocyte fuel source, is the second component. Butyrate reduces the anapleurotic metabolism of glutamine, which increases colonocyte GSH. This augments the colonocyte's capacity to neutralize intracellular H_2O_2 (Figure 4). Studies have shown significantly increased colonic epithelial GSH after topical butyrate administration, and high fiber diets that generate increased fecal butyrate are reported to maintain prolonged remission in patients with UC[104,241].

The third component, cromolyn sodium, is a mast cell stabilizer that inhibits the secretion of histamine by mast cells, which accumulate in large amounts at sites of tissue injury in UC[242-244]. Mast cells are significantly activated in UC and undergo intense degranulation resulting in the secretion of significantly greater amounts of histamine that is concentrated at sites of colonic inflammation in UC [245-248]. Rectal biopsies of patients with UC contained significantly higher amounts of histamine

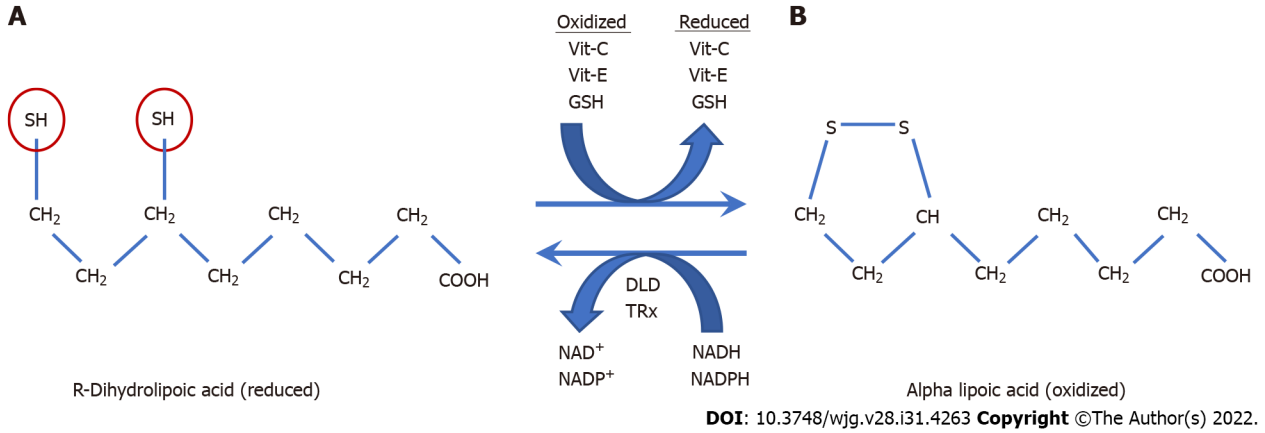
compared to normal controls[249,250]. Histamine is degraded by diamine oxidase (EC 1.4.3.22) whose activity is especially high in the intestinal mucosa and the inflammatory field with H_2O_2 being the product of this reaction[245,251,252]. Thus, cromolyn prevents histamine from being secreted from mucosal mast cells, which precludes its conversion to H_2O_2 that can significantly contribute to the intensity and persistence of colonic inflammation in UC. This is consistent with studies reporting that histamine drives the severity of inflammation in a murine model of experimental UC[253].

Budesonide is the fourth component and is a topically acting corticosteroid that inhibits neutrophil infiltration into the colon by down-regulating neutrophil and endothelial surface adhesion molecules, which prevents neutrophil attachment to the endothelium and subsequent directed migration into the colonic epithelium[254]. Neutrophils produce a large amount of H_2O_2 *via* surface NADPH oxidase[255]. Corticosteroids reduce the expression of neutrophil surface NADPH oxidase thus decreasing neutrophil production of H_2O_2[254]. The combination of inhibited neutrophilic epithelial migration and decreased production of H_2O_2 significantly reduces this large source of H_2O_2, which is a significant driving factor of mucosal inflammation in UC.

RATIONALE FOR RDLA

Targeting H_2O_2 with RDLA

RDLA, the oral component of the therapy, is the biologically active (dextrorotatory) reduced enantiomer of alpha-lipoic acid (the oxidized form)[256]. Alpha-lipoic acid is synthesized in mitochondria and plays an essential role as a co-factor for several multi-enzymatic complexes involved in mitochondrial energy metabolism[257]. Alpha-lipoic acid is enzymatically reduced to RDLA (the reduced form) *via* dihydrolipoamide dehydrogenase (E.C. 1.8.1.4) in mitochondria. Thus, alpha-lipoic acid acts as an oxidizing agent that may worsen colonocyte redox homeostasis and should not be administered to patients with UC (Figure 5).



Aside from its enzymatic role in energy metabolism, RDLA is a powerful biological reducing (antioxidant) agent that can be administered orally[263]. RDLA's dithiol group can donate electrons to reduce (reactivate) oxidized forms of other cellular antioxidants such as vitamin-C, vitamin-E, and GSH [264]. RDLA is both a water and lipid-soluble (amphipathic) molecule so it is delivered *via* the bloodstream to all cells of the body where it diffuses through cell membranes to deliver needed reducing equivalents for the reduction of H_2O_2 and synthesis of GSH[265]. Studies in mice demonstrate that the recycling of GSH is critical for cell survival when exposed to oxidative stress (*i.e.*, H_2O_2)[266]. Other studies show that GSH protects rat intestinal epithelial cells from H_2O_2-induced injury[267]. RDLA's capacity to directly react with H_2O_2 combined with its ability to significantly increase cellular GSH, the principal cellular H_2O_2 reducing agent, underlie RDLA's ability to combat the high levels of colonocyte H_2O_2 in UC.

RDLA significantly increases nuclear factor E2-related factor 2, a master antioxidant transcription factor that mediates the expression of antioxidant genes, including those for GSH synthesis[268]. This significantly increases the cellular capacity to synthesize GSH and neutralize H_2O_2. RDLA is reported to reduce nuclear transcription factor-kappa B and adhesion molecule expression[268], which downregulates the inflammatory response and decreases neutrophilic infiltration into the colonic epithelium contributing to the resolution of inflammation and colitis. Thus, RDLA prevents colonocyte cell death during periods of oxidative stress (H_2O_2 exposure) and promotes *de novo* synthesis and recycling of GSH in order to keep cellular GSH high and H_2O_2 low. Hence, RDLA's mechanism of action indicates that it can significantly contribute to inducing and achieving remission in UC.

Studies have shown that restoration of depleted mitochondrial GSH can reverse oxidant (*i.e.*, H_2O_2) induced mtDNA damage, which leads to mitochondrial heteroplasmy[46]. Since RDLA is highly effective at increasing cellular GSH, this suggests that RDLA will be also effective at reversing H_2O_2 induced mtDNA oxidative damage and subsequent mitochondrial heteroplasmy that is postulated to contribute to life-long relapse. This is supported by the continuous 14-year biopsy-proven histologic remission in a patient with a 39-year history of severe refractory UC after treatment with a regimen containing RDLA[205].

RDLA is generally considered safe and is approved for the treatment of diabetic peripheral neuropathy in Europe[269]. Oral lipoic acid at doses as high as 1800 mg/d for 6 mo and 1200 mg/d for 2 years did not result in serious adverse effects when used to treat diabetic peripheral neuropathy[270,271]. Studies indicate that 40% of RDLA is quickly absorbed systemically after oral dosing and rapidly distributed to tissues[263]. RDLA undergoes renal excretion and intracellular beta-oxidation[268,272], which provides a second pathway to increase cellular GSH by decreasing the anapleurotic metabolism of glutamate (Figure 4).

RDLA is the only amphipathic orally administered therapeutic that is both an intracellular and extracellular anti-oxidant (H_2O_2 neutralizing) and reducing agent (electron-donating for maintenance of redox homeostasis). Given these highly unique and desirable therapeutic properties, which are essential for long-term remission in UC, RDLA should be made widely available and be included on the WHO's list of essential medications. STS, an intravenous reducing agent, is already on the WHO's list of

Figure 5 R-dihydrolipoic acid. A: R-dihydrolipoic acid (RDLA) is the reduced form of alpha lipoic acid (the oxidized form); B: The reducing equivalents of RDLA are provided by its two thiol groups (red circles) that are each capable of donating one electron. RDLA has a redox potential of -290 millivolts which is only exceeded by NADH and NADPH with a redox potential of -320 and -400 millivolts respectively[258]. Due to its very low (more negative) redox potential, RDLA can directly or indirectly reduce all other cellular antioxidants and many types of oxygen radicals[256]. These include vitamin-C, vitamin-E, glutathione, thioredoxin, glutaredoxin, catalase, glutathione peroxidase, and peroxiredoxin[258-261]. Alpha-lipoic acid is reduced by dehydrolipoamide dehydrogenase and Thioredoxin reductase, which use NADH and NADPH as reducing co-factors respectively[262]. The amphipathic nature of RDLA (lipid and water-soluble) allows it to diffuse throughout cellular compartments to transport reducing equivalents where needed and assist in neutralizing excess hydrogen peroxide. The elimination of excess intracellular cellular hydrogen peroxide is essential in order to restore cellular redox homeostasis and prevent ulcerative colitis relapse caused by extracellular diffusion of colonocyte hydrogen peroxide. Vit: Vitamin; DLD: Dehydrolipoamide dehydrogenase; TRx: Thioredoxin reductase; GSH: Glutathione.

essential medications and thus RDLA, a therapeutically active oral reducing agent should also be included. In addition to UC, emerging evidence suggests that RDLA (and STS) may have a preventive and/or therapeutic role in other diseases in which the evidence indicates a causal role for H_2O_2 such as systemic lupus erythematosus, sepsis, and diabetes[273-275].

In summary, an evidence-based analysis of the pathogenesis and therapy of UC indicates that treatment of inflammation is no longer the main objective of this illness. Instead, the primary goal is the restoration of colonic and systemic redox homeostasis by therapeutic normalization of colonic H_2O_2, which removes the molecular chemotactic signal that initiates and maintains colonic inflammation and is responsible for disease relapse.

DISCUSSION

The existence of an unpredictable, unexplainable, and incurable disease such as UC indicates that we are guided by the wrong theory of pathogenesis in our quest to develop effective treatment and find causes and cures. Currently, there are two, mutually exclusive, mechanisms of disease that have been put forward to explain how UC develops and guide therapeutic development. Both mechanisms attempt to answer the same question; why do white blood cells (neutrophils) suddenly leave the surrounding blood vessels and head straight into the epithelial lining of the large intestine causing inflammation, bleeding, and UC?

The first hypothesis is consensus-based, agreed upon among researchers in the field, and posits an immune abnormality as a primary event in the development of UC while the second mechanism is evidence-based and maintains that the immune system is completely normal but only appears to be "attacking" the colon due to the inappropriate secretion of a neutrophilic chemoattractant, H_2O_2, by the colonic epithelium, which draws neutrophils into the epithelial lining. Despite decades of intensive research, no evidence of any antecedent immune abnormality has ever been identified in individuals with UC or their immediate relatives, and studies of basic immune functionality in UC patients are normal[10,11]. Due to the absence of a biologically plausible mechanism, the term "immune dysregulation" has been coined to explain the presence of neutrophils in the colonic epithelium. In contrast, studies have demonstrated significantly increased H_2O_2 production in non-inflamed colonic epithelium prior to the appearance of mucosal inflammation, satisfying the absolute chronological requirement that the cause (H_2O_2) must precede the effect (inflammation). Since H_2O_2 is cell membrane permeable, once it leaves the colonocyte H_2O_2 can establish a chemotactic gradient "trail" that neutrophils can follow right into the colonic epithelium after exiting the subjacent vasculature. Hence, within this framework and in line with previous data, the immune system in UC is normal. Neutrophils are just doing what they are biologically programmed to do when exposed to H_2O_2; a normal chemotactic immune signaling agent being inappropriately secreted by the colonic epithelium.

On a clinical level, immune dysregulation cannot explain any of the basic characteristics that define UC such as why people develop this disease to begin with, what is the genetic predisposition, why it always starts in the rectum, what causes proximal inflammatory progression, why the loss of intestinal hemostasis leading to bloody diarrhea, what is the mechanism behind relapse, what causes colonic epithelial crypt abscesses, why are smoking cessation, low fiber and high-fat diets risk factors for UC, what dietary and lifestyle changes will help prevent relapse, what therapeutic intervention will provide long-lasting remission and how can we effectuate a cure, to name a few. In other words, immune dysregulation, as a mechanism of disease, has no explanatory power, which is essential for understanding a disease process. In comparison, a redox mechanism of disease based on colonocyte buildup of H_2O_2 explains these basic observations and provides a consistent and clear mechanistic foundation to understand the hereto-forth puzzling observations that characterize UC.

Despite the absence of any hard evidence for an immune abnormality, this hypothesis continues to be the main focus of ongoing investigation by "leading researchers" in the field who have issued consensus statements asserting that a "dysregulated immune response" is the "widely accepted" cause of UC[276, 277]. A consequence of leading researcher support for immune dysregulation is the near-total focus of therapeutic development on proprietary and costly drugs that alter the immune response in a limited number of commercially viable but non-curative ways[6]. As a result, induction trials for new drug development have reached an unsurpassable therapeutic ceiling of 20%-30% indicating that treatment aimed solely at modifying the immune response cannot alter the natural history of the disease, which is essential for achieving universal long-lasting remission in patients with UC[278]. In other words, immune dysregulation as a mechanism of disease has no predictive power to identify a discreet causal agent, which can be targeted for effective treatment and curative potential.

In contrast, the evidence-based identification of H_2O_2 as a causal agent in UC has guided the development of highly effective treatment with at least one documented, biopsy-proven, histologic remission lasting 14 years to date without any episodes of intervening relapse, in a patient with a 39-year history of refractory UC[205]. This is the basis of bench-to-bedside translational medicine that integrates basic science discoveries into predictable effective treatments and potential cures. A causal therapeutic target eliminates much of the "trial and error" that defines the history of current UC therapeutic development[279].

Nevertheless, what leading researchers think is highly relevant for patients with UC. A consensus mechanism of disease put forth and agreed upon among researchers means that clinicians do not have an evidence-based pathogenesis to guide clinical decision-making. This forces clinicians to rely on a variety of clinical variables including the severity of disease, colonic inflammatory distribution, age of onset, previous medication, disease duration, disease course, relapse frequency, and extra-intestinal manifestations to make bedside patient care determinations[7]. Since each one of these variables can be different for every patient, the number of treatment guidelines must be numerous enough to encompass all these different patient combinations. These treatment guidelines, in turn, are not founded on evidence that defines the pathogenesis but instead rely on an ever-growing and changing database of empirical studies incorporating one or more of these myriad clinical variables. The interpretation of these clinical studies is consensus-driven by committee and thus inherently subjective, leading to numerous clinical recommendations for UC that range in number from 32 to 124 treatment guidelines depending on the country of origin[2].

Committee members may also disagree about the relevance of any particular study for the treatment of UC leading to differences in the number of treatment guidelines between medical societies in the same country with the American Gastroenterological Association espousing 24 treatment recommendations while the American College of Gastroenterology supports 49 clinical treatment guidelines for the treatment of this highly debilitating inflammatory bowel disease[280-282]. Moreover, due to the "inconsistencies regarding recommendations" between the two societies, a "Guide to Guidelines in UC" was published in an effort to reconcile the differences among leading clinicians in the field[283]. In contrast, an evidence-based H_2O_2 mechanism of disease only has one guideline for the treatment of UC that does not change, which is to normalize colonic H_2O_2.

The current degree of therapeutic uncertainty when treating patients with UC is the inevitable result of not having an evidence-based mechanism of disease as the foundation for clinical decision-making and therapeutic development. In other words, since there is no evidence for an antecedent immune vulnerability in UC, treatment with the sole aim of suppressing the immune response is not anchored in an evidence-based pathogenesis. The end result is subjective and malleable clinical guidelines with shifting therapeutic targets generating different empirical treatments, the majority of which are based on low or very low-quality evidence while being permeated by high degrees of conflict of interest[2]. Patients ultimately bear the brunt of these fluid upstream decisions because treatments based on low-quality evidence cannot alter the natural history of disease leading to a high degree of medical treatment failure and a 30% colectomy rate[5]. The high degree of medical treatment failure, in turn, fuels endless fund-raising to pay for research in order to find a more effective therapy. And research, unfortunately, continues to be guided by the same consensus immune dysregulation hypothesis ultimately degenerating into a perpetual sisyphean iterative endeavor.

Perhaps the most relevant outcome when applying the predictive power of an H_2O_2 evidence-based mechanism of disease to UC is the expectation of indefinite remission and normal colon functionality once excess colonic H_2O_2 is neutralized. Given a causal role for H_2O_2 in UC, the elimination of excess colonic H_2O_2 would abrogate the molecular signal for directed neutrophil migration into the colonic epithelium leading to long-term histologic (and biochemical) remission. Accordingly, colonic inflammation is not the principal focus of treatment, instead, the primary therapeutic goal is to remove the H_2O_2 mediated chemotactic signal attracting neutrophils into the colonic epithelium.

This represents a functional cure as long as intracellular colonocyte H_2O_2 remains normal and unable to diffuse into the extracellular microenvironment. Treatment limited to reducing inflammation does not address H_2O_2 emanating from colonocytes, and thus cannot cure. The continued build-up of colonocyte H_2O_2 while being treated with these drugs can increase mitochondrial heteroplasmy with worsening disease and/or lead to colon cancer due to the genotoxic effects of H_2O_2[50,51].

From a redox medicine perspective, inflammation (neutrophil infiltration) is just one source of H_2O_2 that must be addressed. Other sources contributing H_2O_2 to the colonic inflammatory field in UC such as mast cells (histamine), EC (serotonin), and microbiome oxidative dysbiosis must also be considered for optimal therapeutic intervention to induce remission. Environmental oxidative stressors and mitochondrial heteroplasmy, which channel H_2O_2 *via* the colonocyte into the colonic epithelium have a crucial role in provoking relapse and must be addressed in order to achieve long-lasting remission.

Additionally, the common metabolic origin of cellular H_2O_2 suggests that H_2O_2-mediated intestinal inflammation is not solely confined to the colon. A recent analysis concluded that a shared mechanism underlies UC and UC-associated ileitis, which develops in up to 35% of patients with UC[284]. This is supported by studies in UC patients showing impaired ileal butyrate oxidation in both terminal ileum and colon, which in the latter was associated with H_2O_2 induced inhibition of mitochondrial thiolase, the last enzyme in the butyrate beta-oxidation cascade[30,285]. This suggests that excess H_2O_2 is responsible for impaired ileal butyrate oxidation in the small intestine as well. Moreover, the neutrophilic epithelial infiltration, cryptitis, and crypt abscesses that characterize UC-associated ileitis is analogous to the typical histopathological changes observed in UC[286]. This strongly implies that H_2O_2 is also elevated in the small intestine leading to mucosal inflammation and metabolic derangements. Thus, treatments that simply target colonic inflammation do not address the consequences of elevated ileal H_2O_2, which may lead to small bowel inflammation and interfere with the absorption of nutrients. In contrast, treatment with a systemic reducing agent such as RDLA has the potential of resolving UC-associated ileitis.

The interdisciplinary nature of evidence-based analysis can provide clues to understanding and effectively treating other serious conditions that are linked to UC whose medical therapy has so far been suboptimal. Studies have shown that H_2O_2 can effectively inhibit neuromuscular transmission[216]. Protection against H_2O_2-induced inhibition of neuromuscular transmission was associated with the cellular ability to eliminate H_2O_2[287]. Other studies have demonstrated that H_2O_2 contributes to motor disfunction in human UC[218]. This suggests a potential causal role for H_2O_2 in the motility dysfunction that is thought to underlie toxic mega colon and small bowel bacterial overgrowth, both of which are associated with symptomatic UC[214,288]. It also implies that therapeutic intervention with reducing agents (STS or RDLA) to reduce colonic H_2O_2 may be an effective therapeutic option in treating or preventing these serious conditions.

At the other end of the clinical spectrum, up to 2% of asymptomatic individuals undergoing screening colonoscopy were shown to have typical histologic inflammatory features of UC with two-thirds developing symptomatic disease (rectal bleeding) within 5 years[289,290]. Despite having a high probability of developing symptomatic UC and the possibility of increased risk of colon cancer, clinicians are in a quandary regarding the appropriate treatment for these asymptomatic individuals since all medications used to treat UC can have serious side effects and there are no data regarding their effectiveness at this very early asymptomatic stage[291-293]. However, the presence of preclinical neutrophilic inflammation implies that H_2O_2 has begun "leaking" out of colonocytes and is attracting neutrophils into the colonic epithelium. The use of an oral reducing agent (RDLA) to normalize colonocyte H_2O_2 and restore redox homeostasis would be a logical choice at this stage due to its recognized safety profile and ability to enhance cellular reductive capacity in order to reduce colonic H_2O_2. If future studies show that this is an effective treatment, it will be possible to prevent symptomatic disease from developing while UC is still in a preclinical asymptomatic stage.

All things considered, with current therapy and under the best of circumstances, UC patients must undergo life-long surveillance colonoscopy for colon cancer, which cannot detect all neoplastic lesions leading to a high mortality rate[29,294,295]. And although total colectomy has been touted as a cure for the approximately 30% of UC patients who fail medical therapy or develop colon cancer, studies have shown that patients who have undergone ileal pouch/anal anastomosis have higher disability scores than patients with active UC[296]. In contrast, maintenance therapy with an oral reducing agent has the potential of eliminating the need for colectomy, lifelong colonoscopies, and, by removing excess colonic H_2O_2, may significantly reduce the incidence of UC-associated colorectal cancer.

An evidence-based theory of UC identifying H_2O_2 as a causal therapeutic target not only has the potential of highly effective and inexpensive treatment that may be curative but opens the door to population-wide primary prevention by increasing total reducing equivalents (antioxidants) in our food

supply. This is supported by studies demonstrating a decreased risk of developing UC with diets high in anti-oxidants (reducing agents)[297]. Dietary intervention can be successful in reducing the incidence of UC because, in contrast to established disease with high levels of colonic H_2O_2 that require treatment with powerful reducing agents, intervention before colonocytes develop HCRH (while intracellular H_2O_2 is still low) requires much less reductive capacity, which can be supplied by increasing the amount of reducing equivalents (antioxidants) in the food supply. This public health level intervention may prevent UC from developing in the entire population before it even starts.

CONCLUSION

The evidence supports a causal role for colonocyte H_2O_2 in the pathogenesis and pathophysiology of UC. Treatment to reduce and maintain normal colonic H_2O_2 levels leads to long-term histologic remission (complete mucosal healing) in patients with refractory disease. The treatment is inexpensive and well tolerated. Lifestyle modifications to reduce oxidative stress exposure will help maintain remission. This is the first time that a causal evidence-based therapeutic target with curative potential has been identified for UC. The inclusion of multiple components to address the different sources of H_2O_2 within the colitic inflammatory field contributes to its singular effectiveness but also slows its acceptance by a healthcare system dominated by single molecular therapeutics.

H_2O_2 is a normal by-product of cellular metabolism that can accumulate within colonic epithelial cells. H_2O_2's unique properties of cell membrane permeability, long life, potent oxidizing potential, and the ability to attract white blood cells combine to promote colonocyte extracellular diffusion followed by oxidative disintegration of colonic epithelial tight junctional proteins while simultaneously attracting white blood cells into the colonic epithelium, both of which lead to colonic inflammation and eventual UC. This makes it appear as if the immune system is "attacking" the colon when in reality the immune response is behaving as it is normally programmed to respond. The abnormality is the inappropriate secretion of H_2O_2 by the colonic epithelium and not the immune response.

The pleiotropic effects of H_2O_2 have misdirected the careers of multiple generations of researchers into searching for a non-existent primary immune abnormality as the cause of UC. Extensive research since the mid-20th century has failed to uncover a primary immune vulnerability to explicate this illness. Cumulative evidence does not support any form of immune dysregulation in the pathogenesis of UC. This line of research is not evidence-based and should be abandoned. The continued search for immune dysregulation as the cause of UC leads to enormous research waste and endless fundraising that will never find the cause or cure for this disease while at the same time encouraging the treatment of UC with expensive immune altering agents that drive up healthcare costs, do not cure and are associated with lower quality of life, higher rates of colon cancer and other serious adverse effects. Continued research to uncover a primary immune abnormality as the cause of UC reinforces a false sense of hope for millions of individuals suffering from this illness who are desperately waiting for a cure that will never materialize with this line of research. Only by following the evidence can we cure disease.

Evidence-based medical research will eventually displace consensus-driven hypothesis in the highly competitive race for research funding as the National Institute of General Medical Sciences begins to shift funding priorities to grant applications that can clearly explicate falsifiable disease mechanisms that are "associated with the pathogenesis and resolution" of disease[298]. This pathogenesis initiative has begun with sepsis in July 2019 and is likely to be expanded as a requirement to obtain scarce research funding for other diseases as well. Under these guidelines, the current consensus-based immune dysregulation hypothesis invoked to explain UC does not meet this threshold for Federal research funding since it neither provides a coherent falsifiable pathogenesis nor a means of disease resolution.

A causal role for colonic H_2O_2 in the pathogenesis of UC is biologically plausible and supported by both experimental and clinical evidence. H_2O_2 satisfies all the basic requirements for an etiological agent leading to the development of UC and is worthy of continued and expanded research to confirm a potential causal role in the pathogenesis of this debilitating inflammatory bowel disease affecting millions worldwide. It is incumbent upon the research community to follow up on this highly promising line of research that raises the real possibility of targeted and highly effective treatment with curative potential.

Future directions

Complex diseases such as UC arise as an emergent systems property of its individual, *in vivo*, interacting constituent elements. The physical proximity of the colonic epithelium, innate immune system, and colonic lumenal contents gives rise to the disease phenotype we call UC in response to colonocyte extracellular diffusion of H_2O_2. Complex chronic diseases such as UC are not amenable to a reductionist analytical laboratory approach that examines each contributing element outside of its disease-producing *in vivo* context[299]. The prevalence of "incurable" complex chronic diseases continues to rise because they have slipped through the cracks of our current reductionist methodology of medical research that is not designed to detect emergent systems diseases such as UC. The shortcoming of laboratory research

to deal with chronic complex diseases can be overcome with graduate programs dedicated to theoretical (systems) medicine, which looks at the big picture to help guide laboratory researchers down a focused experimental pathway to discovering causes and cures of disease[300]. With chronic disease mortality accounting for 60% of all global deaths as well as 70% of all deaths in the United States, and 60% of Americans suffering from at least one chronic disease with 40% afflicted with two or more chronic ailments, chronic disease has become the leading driver of the United States' $3.5 trillion in annual health care cost[301-303]. We simply cannot win the war against encroaching chronic disease by experimentation alone. This underscores the critical need for collaboration between systems medicine (theoretical systems pathogenesis) and laboratory-based experimentalists (reductionist medical research) before the financial, emotional, and familial burden becomes too much to bear and society begins to destabilize under the weight of too many sick people.

Abstract

Esophageal adenocarcinoma (EAC) and adenocarcinoma of the esophagogastric junction (EGJA) have long been associated with poor prognosis. With changes in the spectrum of the disease caused by economic development and demographic changes, the incidence of EAC and EGJA continues to increase, making them worthy of more attention from clinicians. For a long time, surgery has been the mainstay treatment for EAC and EGJA. With advanced techniques, endoscopic therapy, radiotherapy, chemotherapy, and other treatment methods have been developed, providing additional treatment options for patients with EAC and EGJA. In recent decades, the emergence of multidisciplinary therapy (MDT) has enabled the comprehensive treatment of tumors and made the treatment more flexible and diversified, which is conducive to achieving standardized and individualized treatment of EAC and EGJA to obtain a better prognosis. This review discusses recent advances in EAC and EGJA treatment in the surgical-centered MDT mode in recent years.

Key Words: Multidisciplinary therapy; Esophageal adenocarcinoma; Adenocarcinoma of esophagogastric junction; Endoscopic resection; Surgery

INTRODUCTION

Currently, esophageal cancer is ranked 7th in incidence and 6th in overall mortality worldwide, with approximately 70% of cases occurring in males[1]. The most common subtypes of esophageal cancer are esophageal adenocarcinoma (EAC) and esophageal squamous cell carcinoma (ESCC). The two subtypes have very different etiologies; therefore, their incidence varies greatly in different countries and regions. Although its morbidity is much lower than that of ESCC in low-income countries, EAC accounts for two-thirds of esophageal cancer cases in high-income countries. Furthermore, owing to demographic changes, the burden of EAC is expected to increase in the future[2]. Obesity, gastroesophageal reflux disease (GERD), and Barrett's esophagus are some of the main risk factors for EAC. The increasing incidences of obesity and GERD are likely responsible for the continuing increase in the incidence of EAC. Additionally, reduction in chronic *Helicobacter pylori* (*H. pylori*) infection has been shown to be negatively correlated with EAC[2].

Adenocarcinoma of the esophagogastric junction (EGJA) is a type of cancer that develops at the junction of the esophagus and stomach, and is traditionally known as cardia cancer. According to the standard set by Siewert *et al*[3] in 1987, esophagogastric carcinoma is defined as a tumor located within 5 cm of the esophagogastric junction (EGJ). Type I was defined when the tumor center was located 1-5 cm above the EGJ, Type II when located from 1 cm above to 2 cm below the EGJ, and Type III when located 2-5 cm below the EGJ. Type II is also known as "real" carcinoma of the cardia. This classification also coincides with the distribution of the cardiac glands[4]. The American Joint Committee on Cancer 8th edition suggests that when the tumor center is located 2 cm below the EGJ or within 2 cm without invasion, it should be staged according to the TNM staging of gastric cancer. When the tumor center is located within 2 cm below the EGJ or with invasion, it should be staged according to the TNM staging of esophageal cancer[5]. Siewert type I EGJA is treated as esophageal cancer, Siewert type III EGJA is classified as gastric cancer, while controversies still exist in the treatment principles for Siewert type II EGJA[6,7]. Evidence indicates that the etiology of EGJA, which is negatively related to *H. pylori* infection and correlates with obesity and GERD injury, is similar to the risk factors for EAC[8].

Currently, surgery remains the primary treatment method for EAC and EGJA. However, due to the anatomical location, gastrointestinal surgeons and thoracic surgeons have different opinions regarding the treatment options. Perioperative therapies, including neoadjuvant and adjuvant therapies, are also gaining attention in the treatment of EAC and EGJA. The importance of multidisciplinary therapy (MDT) in the diagnosis and treatment of tumors has been increasingly emphasized. Clinicians from multiple departments, including radiologists, endoscopists, surgeons, and oncologists, have joined the MDT team to participate in clinical decision making, which has been conducive to the individualization of the diagnosis and treatment of EAC and EGJA.

ENDOSCOPIC RESECTION: GROWING IN IMPORTANCE

For years, surgery has been the only radical treatment for esophageal and EGJ cancer. However, in recent decades, with the development of techniques, endoscopic therapy has gained popularity. Endoscopy has already been used for the early diagnosis of malignant tumors of the esophagus and EGJ, and in suitable patients, endoscopic treatment can be performed. However, endoscopic resection still has limitations and is more commonly used as a diagnostic method than a treatment. A retrospective cohort study demonstrated that, compared to patients who did not undergo continuous endoscopic examination, patients who underwent continuous endoscopy before the diagnosis of EAC were associated with less advanced locoregional staging, better prognosis and survival[9].

Endoscopic radical therapy includes endoscopic tumor resection and ablation of surrounding precancerous tissues to prevent recurrence. The most widely used techniques are endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD). EMR is a relatively safe procedure, with a low risk of postoperative complications. However, it should be noted that during EMR operations, the involved Barrett's esophagus requires treatment; otherwise, locoregional EMR operations may lead to a high rate of recurrence[10]. Research has shown that the prognosis is relatively acceptable, with approximately 96% of patients achieving complete remission, with a 10-year survival rate of 75%[11]. ESD technology is more demanding than EMR technology. Both EMR and ESD have similar postoperative adverse events, but their incidence is higher following ESD[12]. The most common complications are stenosis, perforation, and bleeding[10]. According to a study, in the postoperative assessment, the recurrence rate after radical resection at 22.9 mo of follow-up was 0.17%[13].

The risk of lymphatic metastasis is relatively low in T1a cancer, but appears to increase with the depth of submucosal infiltration[14]. For EAC, the lymphatic metastasis rate is 0-2% in T1a cancer, and 0-22%, 0-30%, 20%-70% when T1b cancers infiltrate the upper third, the middle third, and the lower third of the submucosa, respectively[15-17]. Therefore, patient selection is essential for endoscopic therapy. EAC endoscopic resection is indicated in T1 carcinomas of differentiation grade G1/G2 without lymphatic invasion, venous invasion, or ulceration. In addition to these criteria, for T1b, infiltration less than 500 μm in depth and less than 20 mm in size is required[14]. Current guidelines usually recommend that additional surgery should be performed after endoscopic resection when the risk of lymphatic metastasis or residual cancer is too high to cure[18]. Meanwhile, if the specimen resected by endoscopic therapy reveals a positive margin on histological examination, additional esophagectomy is also required. Based on some cases of T1 carcinoma that underwent esophageal endoscopic resection with additional esophagectomy, among which 17/30 were cases of EAC, researchers concluded that esophagectomy could achieve further removal of residual advanced cancer or lymphatic metastases in 13% of patients. However, postoperative severe morbidity was 43% and mortality was 7%; therefore, the benefits and risks of close follow-up *vs* surgery should be considered[19].

In addition, Barrett's esophagus has been demonstrated to be a significant risk factor for esophageal and EGJ carcinomas. The pathological basis of Barrett's esophagus is the change in mucosal cells caused by long-term exposure to gastric acid, which can develop into adenocarcinoma. Compared to the normal population, patients with Barrett's esophagus have a relative risk of 11.3 of developing adenocarcinoma[20]. Due to the relatively high rate of 25% developing into carcinoma, precursor intraepithelial neoplasia in Barrett's esophagus is usually necessary for endoscopic resection[21]. Additionally, removal of low-grade intraepithelial neoplasia is recommended[22].

SURGERY: REMAINS THE MAINSTAY OF TREATMENT

Surgical options for esophagus adenocarcinoma

According to the guidelines, the transthoracic approach is usually recommended for the treatment of esophageal carcinoma. For cancers located in the proximal one-third of the esophagus, thoracic esophagectomy can be expanded to three fields, including cervical lymph node dissection. However, controversy remains between transthoracic esophagectomy combined with intrathoracic anastomosis (Ivor-Lewis esophagectomy) and three-field esophagectomy combined with esophagogastrostomy (McKeown esophagectomy); the recommendations of concerned guidelines vary from country to country[7]. It is recommended that the absence of suspicious lymph node enlargement indicates a preference for extended two-field thoracoabdominal lymphadenectomy (conventional thoracoabdominal and upper mediastinal lymphadenectomy), whereas, suspicious lymph node enlargement supports the option of three-field cervical and thoracoabdominal lymphadenectomy (cervical and thoracoabdominal lymphadenectomy and upper mediastinal lymphadenectomy)[23]. Furthermore, to investigate the precise lymphatic staging, at least 15 Lymph nodes should be obtained[24]. In recent years, studies have compared two-field approach lymphadenectomy with three-field approach lymphadenectomy for postoperative overall survival (OS) and disease-free survival. The results suggest that there are no significant differences in prognosis between the two approaches[25].

Additionally, studies have shown that lymph node harvest during esophagectomy is associated with improved postoperative survival. A study by Lutfi *et al*[26] demonstrated that during lymphadenectomy, when 7 lymph nodes were harvested, OS improved significantly, and when 25 Lymph nodes were harvested, it showed maximum OS benefits. Other researchers also came to a similar conclusion regarding the influence of lymphadenectomy on postoperative survival after neoadjuvant therapy; when the number of lymph node dissections reached 25, postoperative life expectancy was the highest [27].

Surgical options for adenocarcinoma of EGJ

Although many studies have compared the transthoracic approach to the transhiatal approach, because of the special anatomical location of EGJA, the optimal surgical option is still under debate and recommendations are inconsistent[7]. Based on 14 studies published over the last 30 years, Tseng *et al*

[28] concluded that the Siewert classification had a significant influence on the surgical options. The transthoracic approach was recommended for Siewert type I EGJA, and extended gastrectomy for Siewert type III EGJA. Siewert type II EGJA can be resected using a transthoracic or transhiatal approach, and each approach has similar effects on surgical results and overall prognosis. The surgical method should be determined according to patient factors, such as risk factors and general condition, and also depends on the preference of the surgeon[28]. The advantages of the transthoracic approach are better mediastinal lymph node dissection and better proximal resection margin, as it has the advantages of better para-celiac and para-aortic lymph node dissection, avoidance of thoracotomy-associated morbidity, and preferable postoperative quality of life[28].

Based on the analysis of the results of the Siewert type II EGJ carcinoma surgical treatment conducted by the JCOG9502 trial, the consensus of Chinese experts suggested that the transhiatal approach is recommended for esophageal invasion < 3 cm, and the right thoracoabdominal two-incision surgical approach is preferred for esophageal invasion ≥ 3 cm[29]. Currently, surgical treatment for true EGJA in Japan is generally determined by esophageal invasion of 3 cm and gastric invasion of the upper one-third as a demarcation[4]. Ivor-Lewis esophagectomy combined with upper or middle mediastinal lymphadenectomy is recommended for esophageal invasion ≥ 3 cm. For esophageal invasion < 3 cm, an extended proximal transdiaphragmatic gastrectomy was performed for distal invasion within the upper third of the stomach, and an extended total transdiaphragmatic gastrectomy was performed for invasion that exceeded the upper third of the stomach; meanwhile, a lower mediastinal lymphadenectomy was also required[4]. Nishiwaki *et al*[30] proposed that the distance from the EGJ to the proximal margin of the primary tumor (esophageal invasion) could be an indicator of mediastinal lymph node metastasis in Siewert type II tumors. The results showed that a distance ≥ 2 cm in esophageal invasion was associated with a higher risk of mediastinal lymph node metastasis. When esophageal infiltrates reach 3 cm, the risk was even higher, and the transthoracic approach should be considered for upper and middle mediastinal lymphatic dissection[30]. These results are consistent with the guidelines and current surgical options (Figure 1).

The optimum range of lymphatic dissection has not reached a consensus. According to previous studies, for Siewert type III EGJA, the incidence of lymphatic metastasis in groups No. 1, 2, 3, and 7 was higher than 20 %, metastasis in groups No. 5, 6, 11d, and 12a was less than 5 %, and metastasis in groups No. 107, 111, and 112 was much lower and close to zero. Compared with Siewert type III EGJA, the incidence of lymphatic metastasis in Siewert type II EGJA was significantly lower in the abdominal lymph nodes and higher in the lower mediastinal lymph nodes[31].

To date, only retrospective trials have been conducted on the surgical choice of Siewert type II EGJA, and research has not indicated any difference between the two surgical approaches. The CARDIA trial is the first randomized trial to compare transthoracic esophagectomy with transhiatal extended gastrectomy for Siewert type II EGJA, and the trial is ongoing (DRKS00016923). Esophagectomy is expected to achieve better radical resection and thorough mediastinal lymphatic dissection, leading to better OS, while the quality of life is still acceptable[32].

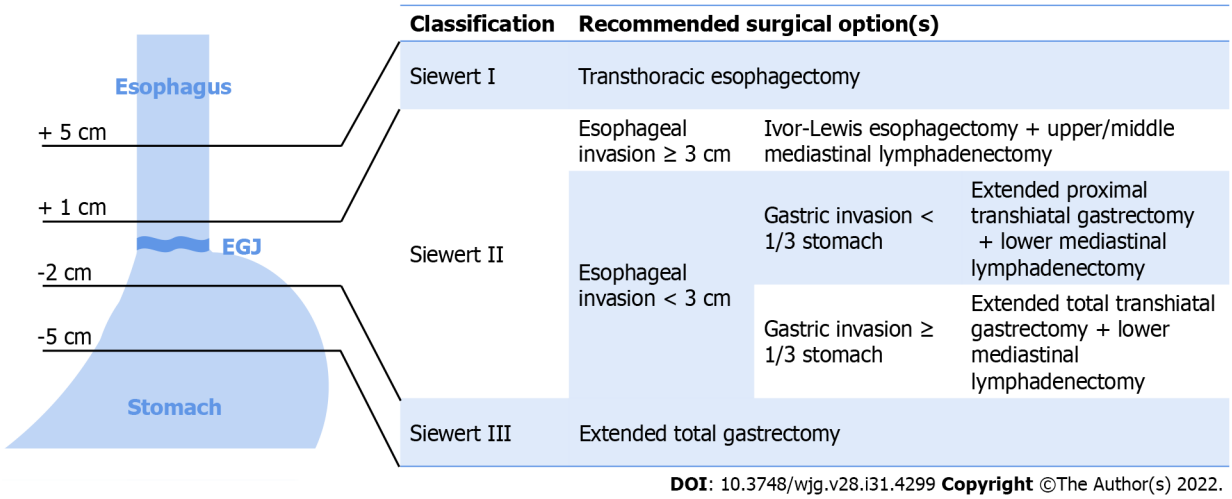
PERIOPERATIVE CHEMOTHERAPY AND RADIOTHERAPY: EXIST CONTROVERSY

Perioperative treatment includes multiple options, among which chemotherapy (CT), radiotherapy (RT), and chemoradiotherapy (CRT) are the most commonly used regimens. Neoadjuvant therapies benefit tumors by reducing tumor volume, tumor stage, *etc*., and therefore improve the surgical resection rate and prognosis. Postoperative therapies are mainly used to eliminate tumors that have not been completely resected and possible metastases, prolong postoperative survival and reduce the recurrence rate. Over the years, many researchers have made efforts to explore the best perioperative therapy for adenocarcinoma of esophagus and EGJ (Table 1).

RT in adenocarcinoma of esophagus and EGJ

Compared to many other tumors, including gastric carcinoma, RT plays a more important role in the treatment of EAC and EGJA. A Chinese research group included 4160 patients with Siewert type II EGJA to investigate whether perioperative RT benefits patients. The results indicate that neoadjuvant RT improves prognosis in more advanced patients (T3 or with lymphatic metastases) and is more effective in T4 tumors. For stage T1-2, surgery alone is preferred[33]. Furthermore, studies have shown that CRT is superior to RT alone in many aspects, such as tumor downstaging, R0 resection, and pathological complete response (pCR)[34,35], especially in patients with fairly good tolerance for CT. A study analyzed 101 patients with esophageal cancer who underwent CRT or RT alone. The primary endpoints were OS, progression-free survival, local control rate, and toxicity. The results showed that RT was safe and feasible and could partially compensate for the absence of CT[36]. However, because many elderly patients included in the cohort were not eligible for CT, the conclusion has limitations.

CT in adenocarcinoma of esophagus and EGJ



The validity of perioperative CT and concurrent CRT has been widely discussed and is considered the

Table 1 Some clinical studies of perioperative therapy in recent years

Ref.	Cancer	Cases	Groups	Conclusion
RT in EAC and EGJA				
Zhou *et al*[33], 2021	EGJA (Siewert II)	4160	nRT *vs* RT	nRT improves prognosis in patients with more advanced tumors
Klevebro *et al*[35], 2016	Esophageal or EGJ cancer	181	nCRT *vs* nCT	nCRT group had higher complete response rate, R0 resection rate, and lower lymph-node metastases, without significantly affecting survival
Ristau *et al*[36], 2021	EC	101	RT *vs* CT	RT could partially compensate for CT
CT in EAC and EGJA				
Mokdad *et al*[37], 2018	Lower EAC or EGJA	10086	CT *vs* observation	Most patients benefited from adjuvant CT for OS
Papaxoinis *et al*[38], 2019	Lower EAC or EGJA	312	nCT *vs* CT	No significant differences; only patients with postoperative microscopic residual disease benefited from postoperative CT
Davies *et al*[39], 2014	EAC or EGJA	584	Downstaging after nCT *vs* no response	Tumor stage after nCT is more closely associated with prognosis and eligibility for surgery
Bunting *et al*[41], 2018	EAC	286	Toxicity of nCT *vs* no toxicity	Toxicity can lead to adverse consequences, such as failure to complete CT, loss of opportunity for surgical resection, and poor OS
CRT in EAC and EGJA				
Shapiro *et al*[44], 2015	Esophageal or EGJ cancer	368	nCT + surgery *vs* surgery alone	Patients with resectable esophageal or EGJ carcinoma benefited more from nCRT plus surgery than surgery alone
Zafar *et al*[46], 2020	Lower EAC or EGJA	13783	nCRT *vs* nCT	nCRT group was more likely to achieve pCR; OS was not statistically different
Al-Sukhni *et al*[47], 2016	EAC or EGJA	6986	nCRT *vs* nCT	nCRT group showed no difference in improving survival in resectable tumor
Samson *et al*[48], 2016	EC	7338	nCRT *vs* nCT	nCRT lead to more downstaging of tumor, but it is not an individual prognostic factor
Li *et al*[50], 2021	EGJA (Siewert II/III)	170	nCRT *vs* nCT	nCRT provided better survival and improved R0 removal and pCR rates more than nCT in patients with locally advanced EJGA
Tian *et al*[51], 2020	Gastric or EGJ adenocarcinoma	1048	Perioperative CRT *vs* perioperative CT	Perioperative CRT was associated with a higher pCR rate but increase the risk of mortality
Noordman *et al*[52], 2018	Esophageal or EGJ cancer	368	nCRT + surgery *vs* surgery alone	Physical function and frailty remained relatively low in nCRT group, but no adverse effects on long-term HRQoL were observed
Noordman *et al*[53], 2019	Esophageal or EGJ cancer	96	nCRT	HRQoL reduced in short-term, but would return to baseline
Noordman *et al*[54], 2018	Esophageal or EGJ cancer	363	nCRT + surgery *vs* surgery alone	nCRT had no significant effect on postoperative HRQoL
Nilsson *et al*[55], 2020	Esophageal or EGJ cancer	249	Standard TTS *vs* prolonged TTS	Time to surgery (TTS) after nCRT had no significant effect on short-term prognosis

RT: Radiotherapy; EAC: Esophageal adenocarcinoma; EGJA: Adenocarcinoma of the esophagogastric junction; EGJ: Esophagogastric junction; TTS: Time to surgery; HRQoL: Health-related quality of life; CT: Chemotherapy; CRT: Chemoradiotherapy; pCR: Pathological complete response; OS: Overall survival; nRT: Neoadjuvant radiotherapy; nCT: Neoadjuvant chemotherapy; nCRT: Neoadjuvant chemoradiotherapy.

standard treatment option. Mokdad *et al*[37] included 10086 patients with EGJ cancer who received adjuvant CT or postoperative observation. Patients who underwent adjuvant CT were relatively younger and more likely to have advanced disease. In the long-term, the OS of patients who received CT was clearly better at 1 year (94% *vs* 88%), 3 years (54% *vs* 47%), and 5 years (38% *vs* 34%). In other words, most patients benefited from adjuvant CT for OS[37]. Another group included 312 patients (210 with EGJA and 102 with EAC) who underwent radical surgery after neoadjuvant CT (nCT). The experimental group received postoperative CT based on ECX (epirubicin, cisplatin, and capecitabine) regimen, while the control group did not. No significant differences were found in the primary prognostic data between the two groups. Only patients with postoperative microscopic residual disease (R1) benefited from postoperative CT[38].

Figure 1 Siewert classification of adenocarcinoma of the esophagogastric junction and recommended surgical options[3,4,28,29]. The tumors that centered 1-5 cm above esophagogastric junction (EGJ) are defined as Siewert type I, transthoracic esophagectomy is recommended. the tumors centered from 1 cm above to 2 cm below the EGJ are Siewert type II. For Siewert type II tumor with esophageal invasion ≥ 3 cm, Ivor-Lewis esophagectomy with upper/middle mediastinal lymphadenectomy is propriate surgical option; for esophageal invasion < 3 cm, extended proximal transhiatal gastrectomy or extended total trashiatal gastrectomy with lower mediastinal lymphadenectomy are recommended according to whether gastric invasion exceeded 1/3 of the stomach. The tumors that centered 2-5 cm below EGJ are defined as Siewert type III and extended total gastrectomy is the optimal surgical option. EGJ: Esophagogastric junction.

The purpose of nCT in tumor downstaging is to facilitate resection and improve the postoperative prognosis. Compared with the clinical stage before nCT, the tumor stage after nCT is more closely associated with prognosis and eligibility for surgery[39]. For borderline resectable cancers of the esophagus and EGJ, neoadjuvant therapy is usually recommended, followed by evaluation of the tumor stage according to the guidelines. Davies *et al*[39] reported that patients who received neoadjuvant therapy had a lower local recurrence rate (6% *vs* 13%) and systemic recurrence rate (19% *vs* 29%), along with improved survival. Predictors of postoperative survival after nCT have also been discussed. The results showed that pT staging, pN staging, and resection status were strong predictors of survival, including patients who underwent surgery alone or who received neoadjuvant therapy. Patients who achieved R1 resection or pT3/4 stage after neoadjuvant therapy had better OS than those who achieved the same outcome after surgery alone[40]. In addition, the adverse effects associated with neoadjuvant therapy, also known as toxicity, require attention. Bunting *et al*[41] reported 67 (23.4% of 286 cases) patients who experienced toxicity during nCT. Toxicity can lead to adverse consequences, such as failure to complete CT (47% *vs* 17%), loss of opportunity for surgical resection (17.9% *vs* 7.8%), and poor OS (median survival of 20.7 mo *vs* 37.8 mo). Even if patients who missed surgery were excluded, median survival was shorter in patients with toxicity responses (26.2 mo *vs* 47.8 mo)[41].

CRT in adenocarcinoma of esophagus and EGJ

Perioperative concurrent CRT is widely used to treat EAC and EGJA. The INT0116 trial, the first randomized controlled study of postoperative adjuvant CRT for gastric and EGJ carcinoma, showed that postoperative 5-FU and tetrahydrofolic acid combined with RT significantly extended OS and relapse-free survival in patients with advanced gastric and EGJ carcinoma[42]. This illustrates the importance of CRT in perioperative adjuvant therapy. Currently, adjuvant CRT is the standard treatment for gastric and EGJ carcinoma in the United States[43]. The CROSS study conducted by a Netherlands group in 2015 concluded that the OS of the long-term follow-up of 368 patients with resectable esophageal or EGJ carcinoma benefited more from neoadjuvant CRT (nCRT) followed by surgery than surgery alone. For patients with adenocarcinoma, the median OS of the group that received nCRT plus surgery was 43.2 mo, longer than 27.1 mo of the group that received surgery alone. Therefore, nCRT followed by surgery could be considered the standard treatment for patients with resectable locally advanced EAC or EGJA [44]. The importance of nCRT in the treatment of esophageal and EGJ carcinoma has been widely recognized. After sufficient evaluation of perioperative treatment options, the American Radium Society gastrointestinal expert panel established appropriate criteria that recommended nCRT for patients with resectable non-metastatic EAC or EGJA, cT3 or lymphatic metastasis, and high-risk manifestations. In patients with pathological evidence of lymphatic metastasis without neoadjuvant treatment, adjuvant CRT is recommended[45].

Compared with surgery alone, CT and CRT promote the survival of patients with EAC and EGJA. However, whether CRT is superior to CT remains under debate. Among the 13738 patients with EAC and EGJA who received nCT or nCRT and eventually underwent surgery, patients who underwent nCRT were 2.7 times more likely to achieve pCR than those who underwent nCT; however, OS was not statistically different[46]. Similarly, many studies have shown that nCRT is associated with a higher

pCR rate, higher R0 resection rate, lower lymphatic metastasis rate, and is more likely to achieve downstaging before surgery than nCT; however, previous studies have not been able to reveal the effect on postoperative survival[35,47,48]. Several studies have suggested improvements in postoperative survival in patients treated with nCRT compared with those treated with nCT. Smyth *et al*[49] showed a 4% increase in the 3-year OS in patients who received adjuvant CT after CRT plus surgery. Since most recurrent EGJAs occur within three years after surgery, this may indicate an increase in the curative ratio and that postoperative CT improves survival even after neoadjuvant therapy[49]. In another study of 170 patients with Siewert type II/III EGJA, Li *et al*[50] showed that nCRT provided better survival and improved R0 removal and pCR rates more than nCT in patients with locally advanced EJGA. However, Tian *et al*[51] drew the opposite conclusion after retrospectively reviewing 1048 patients with gastric adenocarcinoma and EGJA who underwent preoperative CT or CRT. While perioperative CRT was associated with a higher pCR rate (13.1% *vs* 8.2%), preoperative CRT appeared to increase the risk of mortality[51].

In addition to the effectiveness of nCRT, its adverse effects and impact on the postoperative quality of life are also factors that must be considered. In the postoperative follow-up, a total of 386 patients with EAC who underwent surgery alone or nCRT plus surgery were followed up for 105 mo. Although the physical function and frailty of the patients remained relatively low, no adverse effects on long-term health-related quality of life (HRQoL) were observed in patients with preoperative nCRT. This finding supports the application of nCRT in patients with EAC[52]. Other similar trials conducted by the same group showed a significant reduction in HRQoL, but eventually HRQoL returned to baseline within eight weeks[53], and nCRT had no significant effect on postoperative HRQoL compared with patients who received surgery alone[54]. That is, nCRT did not cause irreversible long-term changes in HRQoL, which confirmed the safety of nCRT.

Further, there has been some discussion regarding the timing of surgery after neoadjuvant therapy. The current routine is 4-6 wk. Nilsson *et al*[55] randomly assigned 249 patients with esophageal or EGJ cancer into two groups: standard timing of surgery (4-6 wk) or prolonged timing of surgery (10-12 wk). The primary endpoint was overall postoperative complications, and the secondary endpoints were severity of complications, 90-d mortality, and inpatient stay. Data analysis showed that the timing of surgery after nCRT had no significant effect on short-term prognosis[55], while a meta-analysis in 2018 suggested a different opinion. A total of 15086 patients from 13 studies were included. Enrolled patients were divided into two groups based on the time of surgery (shorter or longer than the 7-8 wk interval). A subgroup analysis of patients with adenocarcinoma did not show significant differences in pCR rates, and a prolonged interval was significantly associated with increased mortality. An extended interval was also detrimental to the 2-year and 5-year OS[56].

Furthermore, researchers have compared the prognosis of patients with EAC after surgery alone and in combination with neoadjuvant therapy to clarify whether current treatment strategies could obtain any benefit. Although many patients are predicted to benefit from neoadjuvant therapy, their responses to therapy vary. It is estimated that the total restricted mean survival time would have a 7% gain if optimal therapy was applied instead of actual therapy[57]. This suggests that individualized treatment could benefit patients the most, but how to select individuals with better reactions to specific treatment options and achieve such benefits remains to be further studied.

DEFINITIVE CRT: FOR UNRESECTABLE TUMORS

At diagnosis, tumors in a considerable proportion of patients are no longer indicated for surgery because of tumor invasion of vital organs, main vessels, or nerves (T4b) or the occurrence of distant metastasis (M1)[5]. Neoadjuvant therapy might achieve tumor downstaging in some cases; however, for patients who refuse surgery or have unresectable tumors, definitive CRT (dCRT) remains the only option[23]. With the improvement in concurrent CRT, the 5-year survival of patients with unresectable tumors significantly improved from 0-14% to 20%-25%, indicating that the aim was transformed from palliative to efficient treatment[58]. It was about three decades ago when dCRT first attracted attention. Early randomized trials have shown that the median survival and 5-year survival of patients who received CRT were superior to those who received RT alone[59], and subsequent research confirmed the superiority of CRT over RT[58].

Locoregional recurrence was the main cause of treatment failure in patients who underwent dCRT. In a retrospective study of 184 patients with esophageal carcinoma, locoregional recurrences occurred in 41% of the cases, mostly within 12 mo after cessation of dCRT, and almost all occurred in 24 mo. Among the cases that recurred at the primary tumor site, only 57% occurred within the scope of radiation, which suggests that RT is valid in reducing locoregional recurrences[60]. However, the therapeutic doses of dCRT are still under discussion. In a cohort study, 12638 patients with metastatic esophageal cancer were divided into three groups: CT alone, combined with palliative RT, and combined with definitive RT. The median OS of the patients treated with CRT was 11.3 mo for the definitive dose radiation group and 7.5 mo for the palliative dose group. Thus, in CRT, compared to a lower dose of radiation, patients benefit more from definitive dose radiation[61]. In contrast, another study compared

RT of standard dose with high dose in dCRT, which enrolled 260 patients with esophageal cancer. The results showed that the 3-year local progression-free survival rates were 70% and 73%, respectively, which suggested that higher doses of RT did not necessarily improve the clinical outcome, as assumed [62]. Therefore, the current recommended dose of radiation for dCRT benefits clinical outcomes more than higher or lower doses.

CONCLUSION

Surgery has long been the only radical treatment available for EAC and EGJA. In recent decades, with the development of various other techniques as well as the concept of MDT, increased treatment options could be applied in patients with EAC or EGJA. There is no doubt that surgery is always one of the most important treatments; however, it is no longer the only solution. Clinicians with MDT teams can tailor the regimens for patients. At the same time, more options face more challenges. There are still many controversies, such as the optimal treatment for specific patient groups and the proper timing for applying certain treatments. Moreover, the implementation of MDT is also problematic because not every region or medical center can perform every treatment independently. It is worth exploring and discussing how to make MDT a useful and efficient method to guide treatment. It should be clarified that the final goal is to provide a standardized, efficient, and individualized treatment to each patient to improve OS and quality of life.

Abstract

BACKGROUND

Individuals within specific risk groups for pancreatic ductal adenocarcinoma

(PDAC) [mucinous cystic lesions (MCLs), hereditary risk (HR), and new-late onset diabetes mellitus (NLOD)] represent an opportunity for early cancer detection. Endoscopic ultrasound (EUS) is a premium image modality for PDAC screening and precursor lesion characterization. While no specific biomarker is currently clinically available for this purpose, glypican-1 (GPC1) is overexpressed in the circulating exosomes (crExos) of patients with PDAC compared with healthy subjects or those harboring benign pancreatic diseases.

AIM

To evaluate the capacity of GPC1$^+$ crExos to identify individuals at higher risk within these specific groups, all characterized by EUS.

METHODS

This cross-sectional study with a prospective unicentric cohort included 88 subjects: 40 patients with MCL, 20 individuals with HR, and 20 patients with NLOD. A control group (CG) was submitted to EUS for other reasons than pancreatic pathology, with normal pancreas and absence of hereditary risk factors (n = 8). The inclusion period was between October 2016 and January 2019, and the study was approved by the Ethics Committee of Centro Hospitalar Universitário de São João, Porto, Portugal. All patients provided written informed consent. EUS and blood tests for quantification of GPC1$^+$ crExos by flow cytometry and carbohydrate antigen 19-9 (CA 19-9) levels by ELISA were performed in all subjects. EUS-guided tissue acquisition was done whenever necessary. For statistical analysis, SPSS® 27.0 (IBM Corp., Armonk, NY, United States) version was used. All graphs were created using GraphPad Prism 7.00 (GraphPad Software, San Diego, CA, United States).

RESULTS

Half of MCLs harbored worrisome features (WF) or high-risk stigmata (HRS). Pancreatic abnormalities were detected by EUS in 10.0% and 35.0% in HR and NLOD individuals, respectively, all considered non-malignant and "harmless." Median levels of GPC1$^+$ crExos were statistically different: MCL [99.4%, interquartile range (IQR): 94.9%-99.8%], HR (82.0%, IQR: 28.9%-98.2%), NLOD (12.6%, IQR: 5.2%-63.4%), and CG (16.2%, IQR: 6.6%-20.1%) (P < 0.0001). Median levels of CA 19-9 were within the normal range in all groups (standard clinical cut-off of 37 U/mL). Within HR, individuals with a positive history of cancer had higher median levels of GPC1$^+$ crExos (97.9%; IQR: 61.7%-99.5%), compared to those without (59.7%; IQR: 26.3%-96.4%), despite no statistical significance (P = 0.21). Pancreatic cysts with WF/HRS were statistically associated with higher median levels of GPC1$^+$ crExos (99.6%; IQR: 97.6%-99.8%) compared to those without (96.5%; IQR: 81.3%-99.5%) (P = 0.011), presenting an area under the receiver operating characteristic curve value of 0.723 (sensitivity 75.0% and specificity 67.7%, using a cut-off of 98.5%; P = 0.012).

CONCLUSION

GPC1$^+$ crExos may act as biomarker to support the diagnosis and stratification of PDAC precursor lesions, and in signaling individuals with genetic predisposition in the absence of EUS abnormalities.

Key Words: Glypican-1; Circulating exosomes; Endoscopic ultrasound; Pancreatic cancer risk groups; Pancreatic cancer precursor lesions; Genetic predisposition

Core Tip: Patients with mucinous cystic lesions (MCLs), hereditary risk (HR), and new-late onset diabetes mellitus represent a target for early pancreatic ductal adenocarcinoma (PDAC) detection. Within these groups, we evaluated the capacity of glypican-1 positive (GPC1$^+$) circulating exosomes (crExos) to identify individuals at higher risk, all characterized by endoscopic ultrasound (EUS). High levels of GPC1$^+$ crExos were present in MCL and in individuals with HR (predominantly in those with history of cancer), even in the absence of EUS abnormalities. GPC1 may represent a biomarker to support the diagnosis and stratification of PDAC precursor lesions, and indicate genetic predisposition.

INTRODUCTION

Pancreatic ductal adenocarcinoma (PDAC) is considered one of the deadliest malignant diseases around the world, and is estimated to become the second leading cause of cancer-related deaths in the United States in 2030[1]. Most patients present with advanced disease at diagnosis, with only 20% being candidates for surgical treatment, the only chance for cure[2,3].

In its early stages, PDAC usually develops with few or no symptoms, and current sectional imaging modalities are inadequate to detect early small lesions[3]. Endoscopic ultrasound (EUS) is a highly accurate diagnostic technique for pancreatic lesions, with its role majored by the possibility of performing EUS-guided tissue acquisition[4-6].

Among PDAC precursor lesions are pancreatic intraepithelial neoplasias (PanINs) and mucinous cystic lesions (MCLs)[7,8]. While the former are very difficult to identify by available imaging modalities, the latter can be more clearly detected and characterized, specially by magnetic resonance imaging (MRI)/magnetic resonance cholangiopancreatography (MRCP) and EUS[5,9].

Along with the improvement of imaging diagnostic accuracy, the search for a biomarker that could adequately identify PDAC at early stages or its high-risk precursor lesions is a top research priority. The only biomarker approved for clinical use is carbohydrate antigen 19-9 (CA 19-9), but it lacks sensitivity and specificity for PDAC early detection, being mostly reserved for monitoring response to therapy and disease progression[10]. In recent years, several molecules have been tested to serve this purpose[11,12]. Among these, membrane-anchored proteoglycan glypican-1 (GPC1) has been shown to be a good candidate. We previously studied GPC1 in circulating exosomes (crExos) and found that it could identify PDAC patients among healthy individuals with perfect accuracy[13]. In addition, $GPC1^+$ crExos correlated with tumor burden and patients' survival. Moreover, in a genetically engineered mouse model of PDAC, GPC1 was overexpressed in crExos even before the tumor could be detected by MRI [13]. Finally, we also showed higher levels of $GPC1^+$ crExos in MCL compared to controls, although the number of patients was very limited[13]. Several studies have demonstrated the role of GPC1 in PDAC [14-18]. Considering the distinct methodologies that some of the studies adopted to study GPC1 in circulation, some support the potential of $GPC1^+$ crExos as a biomarker for early detection of PDAC[14, 15,19], while others only demonstrate their correlation with disease burden[16-18].

At present, while 90% of PDAC cases are sporadic, only individuals harboring increased hereditary risk (HR), either kindreds of familial pancreatic cancer (FPC) (7%) or belonging to other cancer syndromes with increased risk of PDAC (3%), are candidates for screening[20-22]. Nevertheless, there are other well-defined PDAC-associated risk groups that deserve special attention and can constitute a refined population to be surveilled in order to increase the rate of early detection and improve overall survival. One of these groups is composed by individuals older than 50 years with a recent (< 36 mo) diagnosis of type II diabetes mellitus (DM). Increasing epidemiological, clinical, and experimental evidence shows that new-onset DM can be a clinical manifestation of asymptomatic PDAC or harbinger the disease and offers the promise for early detection in these individuals[3,23-26]. In fact, although the complex and multidirectional relationship between the two entities is not fully understood, new-late onset DM (NLOD) has been recognized as an entity signaling a 6- to 8-fold increased risk of developing PDAC in 3 years[27].

We previously showed that levels of $GPC1^+$ crExos discriminate PDAC from chronic pancreatitis (CP) with high accuracy[28]. In this work, we aimed to determine the capacity of $GPC1^+$ crExos to identify individuals at higher risk of developing PDAC, comparing its levels with EUS pancreatic abnormalities (PA) within specific risk groups: MCL, HR, and NLOD.

MATERIALS AND METHODS

Design of the study and population

This cross-sectional study with a prospective unicentric cohort included 88 subjects: 40 patients with MCLs, 20 individuals with HR, 20 patients with NLOD, and 8 individuals in the control group (CG). The inclusion period was between October 2016 and January 2019, and the study was approved by the Ethics Committee of Centro Hospitalar Universitário de São João (CHUSJ) (ID No. CES 327-15), Porto,

Portugal. All patients provided written informed consent and underwent blood sample collection at the time of EUS.

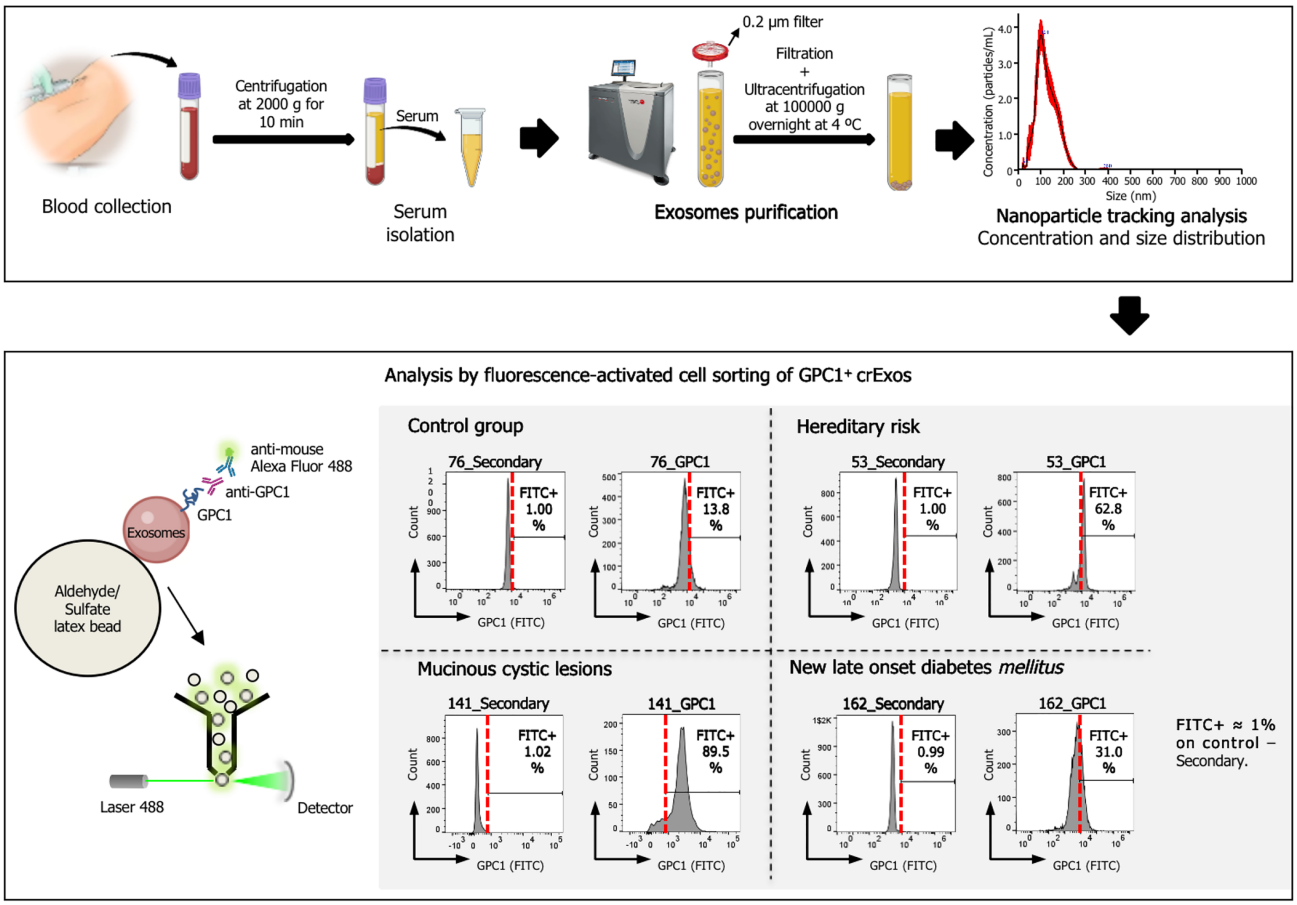
In the MCL group, we considered for inclusion both intraductal papillary mucinous neoplasms (IPMNs) and mucinous cystic neoplasms (MCNs). For its diagnosis, we used both imagiological and cyst fluid analysis criteria. We have assumed IPMN etiology when EUS and/or MRCP clearly showed communication of the cyst(s) with the pancreatic ductal system. In this situation, branch-duct type (BD-IPMN) were presumed if multiple and no dominant main pancreatic duct (MPD) dilation was seen. Main-duct IPMN (MD-IPMN) was considered if a segmental or diffuse dilatation of the main duct > 5 mm was observed without any other cause of obstruction. Mixed-type IPMN (MT-IPMN) was defined when features of MD-IPMN and BD-IPMN coexisted[29]. MCN was assumed when a mucin-producing cyst forming epithelial neoplasia of the pancreas with a distinctive ovarian-type stroma was present, typically with no communication with the ductal system[30].

We performed EUS-guided fine needle aspiration (FNA) in almost all cystic lesions included. Mucinous nature was supported by a fluid carcinoembryonic antigen (CEA) > 192 ng/mL and/or fluid glucose < 50 mg/dL[31]. In relation to amylase content, if > 250 U/L, a diagnosis of IPMN was likely, whereas levels < 250 U/L suggested MCN. If the aspirated content was sufficient, a sample was also evaluated by experienced cytopathologists.

In the HR group, we considered for inclusion FPC (family history of PDAC in at least two first-degree, or in three or more first- and second-degree relatives) and PDAC susceptibility gene mutation carriers[20,22,32,33]. All of these individuals had a clinically and genetically established diagnosis and have been followed in a dedicated consultation for hereditary digestive cancers in our institution. They underwent detailed evaluation of family history, and verification of cancer diagnoses by review of medical records and genetic testing.

In the NLOD group, we included patients aged ≥ 50 years who had been diagnosed with type II DM within a period of 36 mo[23,24]. Diagnosis of type II DM was made according to the American Diabetes Association and consisted of: Fasting plasma glucose level ≥ 126 mg/dL, a 2-h plasma glucose level of ≥ 200 mg/dL during a 75-g oral glucose tolerance test, a random plasma glucose level of ≥ 200 mg/dL in a patient with classic symptoms of hyperglycemia or hyperglycemic crisis, or a hemoglobin A1c level of ≥ 6.5%[34].

In the CG, individuals who underwent EUS for other reasons than pancreatic pathology were included with a normal pancreas and absence of hereditary/familial risk factors. The exclusion criteria were patients unable or unwilling to give informed consent, individuals younger than 18 years of age, pregnancy or breast feeding, contraindications to endoscopic procedures or contrast administration, contraindications to computed tomography (CT) or MRI, coagulopathy (prothrombin time > 50% of control, activated partial thromboplastin time > 50 s, or international normalized ratio > 1.5), patients on chronic anticoagulation, platelet count < 50000/μL, and inability to tolerate sedated upper endoscopy due to cardiopulmonary instability or other contraindication to endoscopic procedures.



At the time of inclusion, immediately before EUS examination, a blood sample was collected for complete blood count as well as renal, liver, and pancreatic chemistry at the CHUSJ laboratory. A separate blood sample collected at the same time was used to quantify CA 19-9 serum levels (ab108642, CA 19-9 Human ELISA Kit; Abcam, Cambridge, MA, United States) and GPC1 expression in crExos by fluorescence-activated cell sorting (FACS) (Figure 1). For CA 19-9, the standard clinical cut-off of 37 U/mL was used. A complete personal and family clinical history was registered, and demographic data was recorded [age, body mass index (BMI)], previous history of pancreatic disease, smoking and drinking habits, history of diabetes and duration since diagnosis, digestive and systemic symptoms. Laboratory values and previous results of cross-sectional imaging (CT, MRI, or magnetic resonance cholangiopancreatography) were registered. The results of the EUS evaluation at the time of inclusion in the study as well as transechoendoscopic or surgically collected specimens were also recorded.

All subjects were observed, examined, and followed-up at the Department of Gastroenterology of CHUSJ (Porto, Portugal) until death or July 2021.

EUS, tissue acquisition techniques, and fluid/specimen analyses

All EUS evaluations were performed by three experienced endoscopists under deep sedation (propofol or pethidine plus midazolam as assisted by an anesthesiologist). Linear scopes from Olympus® (GT-UCT140, GT-UCT180; Tokyo, Japan) and Pentax® (EG-3670UTK, EG-3870UTK; Tokyo, Japan) along with Olympus® EU-ME2 and Hitachi Avius® (Tokyo, Japan) image processors were used.

PA were classified into major and minor changes. Major changes comprised cystic lesions, CP-like parenchymal changes, and solid lesions. Minor ones constituted changes in pancreatic echogenicity compatible with lipomatous transformation[35,36]. EUS high-risk stigmata (HRS) and worrisome features (WF) were categorized according to the International consensus of Fukuoka guidelines for the management of IPMN of the pancreas[29]. A main duct dilatation ≥ 10 mm or an enhancing mural nodule > 5 mm were classified as HRS, whereas a main duct dilatation between 5 and 9 mm, an enhancing mural nodule < 5 mm, a cyst diameter > 3 cm, the presence of thickened/enhancing cyst walls, an abrupt change in pancreatic duct caliber with distal pancreatic atrophy, and lymphadenopathy were considered WF.

Figure 1 Schematic representation of the workflow for the analysis of circulating exosomes from control group, mucinous cystic lesions, hereditary risk and new-late onset diabetes mellitus patients for the expression of glypican-1. Scheme illustrating the workflow of our study of the expression of glypican-1 (GPC1) on exosomes retrieved from patients' blood samples, from blood collection to the analysis by flow cytometry of GPC1$^+$ circulating exosomes (crExos). A representative histogram of the percentage of beads bound to GPC1-positive crExos (GPC1$^+$ crExos) that were isolated from the serum of a control group, composed by individuals submitted to endoscopic ultrasound for other reasons than pancreatic pathology, as well as the following pancreatic ductal adenocarcinoma risk groups: Mucinous cystic lesions, hereditary risk, and new-late onset diabetes mellitus. Red dashed lines in each histogram depict the start of the fluorescein isothiocyanate (FITC)-positive gate (anti-immunoglobulin G) Alexa Fluor 488), which was determined for each patient separately by considering FITC+ approximately 1% on control–secondary–but maintained between control and GPC1 samples. GPC1: Glypican-1; FITC: Fluorescein isothiocyanate; crExos: Circulating exosomes.

Doppler, elastography, and contrast-enhanced EUS image acquisition (sulphur hexafluoride microbubbles; SonoVue®, Bracco, Italy) were used for assistance in the characterization of mural nodules and thickened cyst walls.

EUS-FNA was performed in almost all cystic lesions, preferably with a 22 G needle (Wilson-Cook Medical, Winston, NC, United States and Boston Scientific, Natick MA, United States) in a single pass, and along with antibiotic prophylaxis (single intravenous infusion of 200 mg ciprofloxacin). The fluid collected was sent for amylase, glucose, and CEA quantification, and also, if in enough volume, for cytological examination. Solid or indeterminate lesions, mural nodules, or suspicious thickenings of the cyst wall or septa were punctured in a distinct pass, preferably with a 22 G fine needle biopsy. Adverse events related to EUS procedures were registered and monitored.

Microscopic examinations of specimens resulting from EUS-FNA/B and/or surgical resection were analyzed by experienced pathologists in pancreatic diseases and contextualized to patients' clinical history and imaging findings. Cytological evaluation was performed according to the Papanicolaou Society of Cytopathology System for Reporting Pancreaticobiliary Cytology[37].

Collection of human blood samples

At the same time of EUS performance, blood samples were collected at the Department of Gastroenterology of CHUSJ. Serum samples were obtained by centrifugation of the whole blood sample at 2000 g for 10 min at 4 °C and collection of the supernatant. The resultant serum samples were then aliquoted and stored at -80 °C prior to analysis.

Isolation of exosomes by ultracentrifugation of serum samples and nanoparticle tracking analysis

Human serum samples were allowed to thaw on ice with periodic agitation to avoid degradation. A volume of 200 µL serum was retrieved into a new tube and centrifuged at 10000 rpm for 2 min at 4 ºC. The recovered supernatant was diluted in 200 µL NaCl prior to filtration into 14 mL Open-Top Thinwall Ultra-Clear Tubes (Beckman Coulter, Inc., Brea, CA, United States) using a 0.2 µm pore filter (Whatman International Ltd., England, United Kingdom). The tubes were filled with NaCl, and the samples were ultracentrifuged at 100000 g overnight at 4 °C. The next day, the supernatant was carefully and thoroughly discarded and the exosomes' pellet was resuspended in 300 µL of 1 × phosphate-buffered saline (PBS). To determine particle concentration and size distribution, nanoparticle tracking (NTA) (NanoSight NS300) was performed using 10 µL of the exosomes sample dissolved in 1 × PBS at a 1:100 dilution. The remaining exosomes sample was saved at -20 ºC for downstream analysis.

GPC1 analysis by FACS of exosomes coupled to beads

Using the exosomes concentration previously obtained by NTA analysis as a reference, an equal number of exosomes was used for downstream FACS analysis. A total of 3.0×10^9 exosomes were coupled to 4 µm aldehyde/sulfate latex beads (A37304; Thermo Fisher Scientific, Waltham, MA, United States) that had been previously equilibrated at room temperature (through resuspension of 5 µL beads in 100 µL of 1 × PBS and rotation at room temperature for 15 min). The sample volume was adjusted to 300 µL with 1 × PBS. Upon incubation in a rotator at room temperature for 15 min and then at 4 ºC for 30 min to allow the formation of exosomes-bead complexes, 300 µL glycine 1 M in 1 × PBS was added to the sample, followed by incubation at room temperature for 1 h with continuous rotation. Samples were centrifuged at 12000 rpm for 2 min and the supernatant was discarded. The pellet containing the exosomes-bead complexes was subjected to a blocking step with 100 µL of 10% bovine serum albumin (BSA) in 1 × PBS and then incubated with continuous rotation at room temperature for 45 min. The samples were centrifuged at 12000 rpm for 2 min and divided into two tubes: Control and GPC1-incubated samples. Control samples were incubated with a solution of 2% BSA in 1 × PBS, whereas experimental samples were incubated with anti-GPC1 (1:240 dilution in a solution of 2% BSA in 1 × PBS, MAB8351; Abnova, Taipei, Taiwan) overnight in a rotator at 4 ºC. The next morning, the samples were spun at 12000 rpm for 2 min and the pellet was washed twice with 2% BSA in 1 × PBS, with centrifugation at 12000 rpm for 2 min between washes. Following incubation with an Alexa-488-tagged secondary antibody (anti-mouse A-21202; Thermo Fisher Scientific) for 30 min with continuous rotation at room temperature of both control and experimental samples, samples were washed again twice with 2% BSA in 1 × PBS. Finally, samples were resuspended in 300 µL of 2% BSA in 1 × PBS for BD Accuri C6 or BD FACS Canto II analysis (BD Biosciences, Haryana, IN, United States). Using the control samples of each patient (*i.e.* exosomes-bead complexes from each patient only incubated with secondary antibody) as a reference, the fluorescein isothiocyanate (FITC) voltage was adjusted until the percentage of FITC+ beads was 1%. Then, using the same gate and FITC voltage, the percentage of beads bound with $GPC1^+$ crExos in the experimental sample was determined for each patient separately. Data were analyzed using FlowJo software.

Statistical analyses

Categorical variables are described as absolute and relative frequencies and continuous variables as mean and standard deviation, median, percentiles, minimum, and maximum. Hypotheses were tested regarding the distribution of continuous variables *via* the independent samples *t*-test/one-way analysis of variance (ANOVA) or nonparametric Mann-Whitney and Kruskal-Wallis test depending on normal or non-normal distribution, respectively, and considering the nature of the hypothesis. The chi-squared and ANOVA tests were used for categorical variables analysis. Pearson's correlation coefficient was used to assess the statistical relationship/association between two continuous variables. The diagnostic accuracy of $GPC1^+$ crExos was assessed by receiver operating characteristic curve (ROC) considering 95% confidence intervals. Area under the ROC curve (AUROC) was calculated. SPSS® 27.0 (IBM Corp., Armonk, NY, United States) version was used. All graphs were created using GraphPad Prism 7.00 (GraphPad Software, San Diego, CA, United States). The statistical review of the study was performed by a biomedical statistician.

RESULTS

Population demographic characteristics

The baseline demographic characteristics of the 88 individuals included in the study (40 MCL, 20 HR, 20 NLOD, and 8 CG) are summarized in Table 1. The overall female:male ratio was 1.6:1 and did not differ statistically among groups. The mean age of the population was 60.3 ± 12.6 years. The older individuals belonged to the MCL group, with a median age of 67.2 ± 8.9 years, whereas the younger individuals were in the HR group, with a median age of 48.7 ± 10.8 years ($P < 0.001$). Patients in the NLOD group presented with a significantly higher BMI (29.9 ± 4.5 kg/m^2; $P < 0.001$).

Data are presented as *n* (%) or mean ± SD. BMI: Body mass index; CG: Control group; HR: Hereditary risk; MCL: Mucinous cystic lesion; NLOD: New-late onset diabetes mellitus; NS: Non-significant; PDAC: Pancreatic ductal adenocarcinoma; SD: Standard deviation.

No statistically significant differences were observed in relation to smoking or drinking habits among the studied groups. Overall, 10.2% of the population were active smokers and 22.7% ex-smokers (more than 5 years of abstinence). In relation to alcohol consumption, 43.2% were considered active drinkers (average ingesting amounts of > 30 g or > 40 g alcohol *per* day, in case of female or male individuals, respectively).

Family history of PDAC was present in 23.9% of the entire population, with the highest proportion observed in the HR group (65.0%; $P < 0.001$). In the HR group, 17 (85.0%) individuals were diagnosed with Lynch Syndrome, 1 (5.0%) with Peutz-Jeghers syndrome, and the remaining 2 (10%) with FPC. Six individuals with Lynch Syndrome had a previous personal history of cancer, mostly colorectal ($n = 5$), but all were disease-free at the time of inclusion. Detailed information about this group, including the type of harbored mutation(s), can be found in Table 2. In the NLOD group, the mean time between inclusion in the study and establishment of DM diagnosis was 20.9 ± 8.6 mo.

EUS findings and other clinicopathological features

Main PA detected by EUS is illustrated in Figure 2A-F and constituted cystic lesions (with or without WF/HRS), CP-like parenchymal changes, and lipomatous transformation of pancreatic parenchyma. The EUS features of cystic lesions in the MCL group are described in Table 3. Of the 40 cases included, 39 (97.5%) were IPMNs, and most (89.8%) were classified as BD-IPMNs. Sixty percent of patients presented with multiple cysts, with a mean size of the dominant lesion of 28.1 ± 14.1 mm. In respect to WF and/or HRS, mural nodules, wall thickening, and a dilated MPD were identified in 10%, 7.5%, and 15% of the lesions, respectively. Nineteen of the forty MCL patients (47.5%) underwent additional study with MRCP.

The clinicopathological characteristics of the study population, particularly the type of PA found in EUS among the different groups, the results of EUS-guided tissue acquisition, surgical treatment and specimen analysis, as well as information on cancer detection during follow-up and mortality rate, are summarized in Table 4. Besides the MCL group, where PA in the form of cyst(s) were present in all patients by definition, PA were also detected during the EUS exam in 10.0% and 35.0% of the subjects belonging to HR and NLOD groups, respectively. Half of the lesions in the MCL group were considered to harbor WF or HRS, in contrast to the PA found in the other groups that were all "harmless" in terms of ultrasonographic appearance (CP-like parenchymal changes, lipomatous transformation and infracentimetric simple cystic lesions). EUS-FNA/B was performed only in the MCL group in 35 of the 40 patients (87.5%), either to confirm the diagnosis or in the presence of WF or HRS (Figure 2G and H). Malignancy was detected in 3 patients; in 1, the malignancy was detected in a subsequent EUS exam performed during follow-up (this case was previously reported by our team[38]). The result of cytological exam was considered inconclusive in 37.1% of the procedures. Of the 88 patients of the

[1]One of 3 patients with malignant cytology was diagnosed during follow-up.

CG: Control group; CP: Chronic pancreatitis; EUS: Endoscopic ultrasound; FNA/B: Fine needle aspiration/biopsy; F-up: Follow up; HR: Hereditary risk; HRS: High risk stigmata; MCL: Mucinous cystic lesion; NLOD: New-late onset diabetes mellitus; NS: Non-significant; PA: Pancreatic abnormality; WF: Worrisome features.

The mean follow-up period of the entire cohort was 32 ± 8.6 mo and did not differ statistically among groups (*P* = NS). Five of the 88 individuals (5.7%) died during follow-up, but only one of these due to cancer progression. Two of the other deaths were related to post-operative complications in a 74-year-old and 75-year-old patients, one was related to a pulmonary carcinoma that developed 1 year after inclusion in a 72-year-old patient, and the remaining one corresponded to an 85-year-old patient that did not survive to an infectious respiratory insufficiency. The 2 other patients submitted to surgical resection of malignant cysts were alive and disease-free after 45 mo of follow-up.

Exosomal GPC1 levels are elevated in MCL lesions with WF/HRS and HR groups

The overall median levels of $GPC1^+$ crExos coupled to beads were statistically different among the studied groups: MCL [99.4%, interquartile range (IQR): 94.9%-99.8%], HR (82.0%, IQR: 28.9%-98.2%), and NLOD and CG groups (12.6%, IQR: 5.2%-63.4% and 16.2%, IQR: 6.6%-20.1%, respectively) ($P < 0.0001$) (Figure 3A and Table 5).

The crExos concentration and their median size were significantly higher in NLOD patients (6.05E+10/mL; IQR: 4.83-7.22 and 100.7 nm; IQR: 89.2-110.1, respectively) compared to all other groups ($P < 0.001$ and $P = 0.012$, respectively) (Figure 3B and C and Table 6).

In turn, overall median levels of CA 19-9 were 18.4 U/mL (IQR: 8.3-206) and did not differ statistically between groups: MCL: 20.4 U/mL (IQR: 14.0-35.8), HR: 16.9 U/mL (IQR: 11.7-18.1), NLOD: 18.8

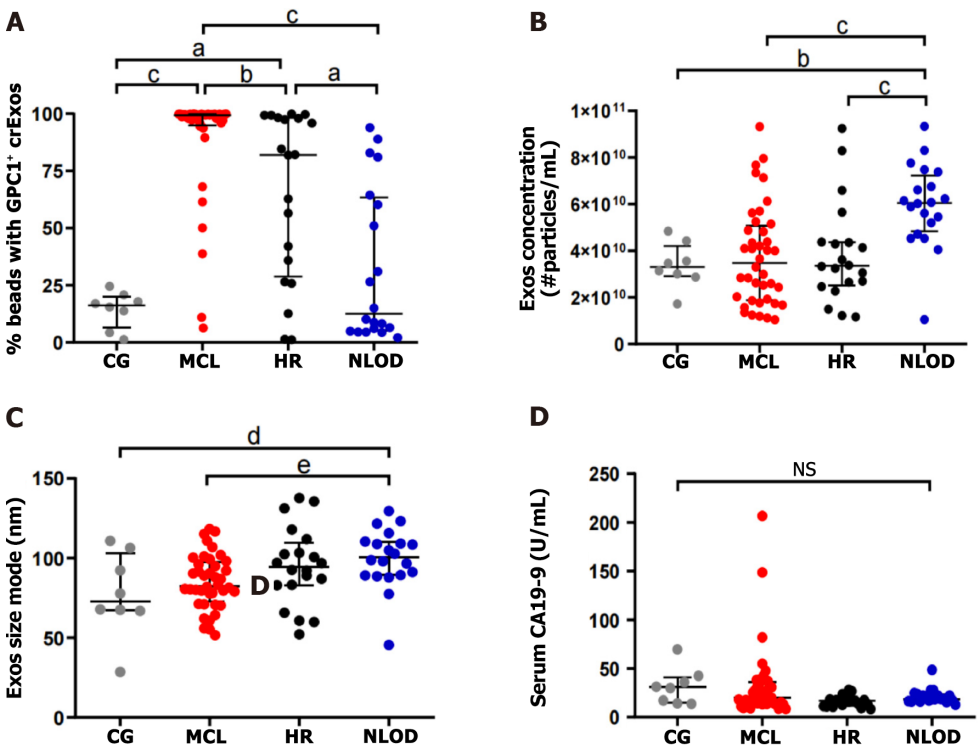
U/mL (IQR: 12.8-48.7) and CG: 30.6 U/mL (IQR: 13.7-69.6) (*P* = NS) (Figure 3D and Table 5). All CA 19-9 median levels were considered in the normal range considering the clinical standard cut-off (37 U/mL).

We further investigated the profile of both biomarkers in a sub-analysis in two distinct settings. First, among the HR group, we evaluated $GPC1^+$ crExos and CA 19-9 levels according to the presence or absence of personal cancer history (Figure 4A and B). In the individuals with a positive history of cancer (5 colorectal and 1 cancer of the endometrium), although not statistically significant, we observed higher median levels of $GPC1^+$ crExos (97.9%; IQR: 61.7%-99.5%) compared to those with a negative history (*n* = 14) (59.7%; IQR: 26.3%-96.4%) (*P* = 0.21). In relation to CA 19-9 median levels, they did not differ among these two subgroups (17.5 U/mL; IQR: 10.7%-20.1% and 16.3 U/mL; IQR: 12.2%-19.5%, respectively) (*P* = NS).

Second, in the total number of patients harboring pancreatic cystic lesions (40 in the MCL group, 2 diagnosed in the HR group, and 2 in the NLOD group), we studied the levels of $GPC1^+$ crExos and CA 19-9 according to the presence or absence of WF/HRS in the EUS examination (Figure 4C and D). When WF or HRS were present (*n* = 20), patients presented with statistically significant higher median levels of $GPC1^+$ crExos (99.6%; IQR: 97.6%-99.8%) compared to those with endosonographic "harmless" lesions (*n* = 24) (96.5%; IQR: 81.3%-99.5%) (*P* = 0.011) (Figure 4C). The levels of $GPC1^+$ crExos presented an AUROC value of 0.723 in differentiating the group of cystic lesions with WF/HRS from those without (sensitivity 75.0% and specificity 67.7% for a cut-off of 98.5% (*P* = 0.012) (Figure 4E). CA 19-9 median levels did not statistically differ between these two subgroups (22.9 U/mL; IQR: 14.1-35.8 and 17.4 U/mL; IQR: 13.7-29.8, respectively) (*P* = NS) (Figure 4D).

DISCUSSION



MCLs are established as PDAC precursor lesions, with different risks considering morphologic

Figure 3 Glypican-1-positive circulating exosomes levels are different among the studied groups, whereas the levels of carbohydrate antigen 19-9 do not differ and are within the normal range in the entire population. A: Scatter dot plot representing the percentage of beads bound to glypican-1-positive exosomes (GPC1$^+$ crExos) in the control group (CG) (n = 8), mucinous cystic lesions (MCLs) (n = 40), hereditary risk (HR) (n = 20) and new-late onset diabetes mellitus (NLOD) (n = 20), (Mann-Whitney U Test, $^aP < 0.02$, $^bP = 0.005$, $^cP < 0.001$); B: Scatter dot plot representing exosomes concentration measured by nanoparticle tracking analysis depicting the number of exosomes/0.666 mL serum derived from CG (n = 8), MCL (n = 40), HR (n = 20), and NLOD (n = 20) donors (Mann-Whitney U Test, $^bP = 0.005$, $^cP < 0.001$); C: Scatter dot plot representing exosomes mode size distribution determined by nanoparticle tracking analysis from CG (n = 8), MCL (n = 40), HR (n = 20), and NLOD (n = 20) donors (Mann-Whitney U Test, $^dP = 0.018$, $^eP = 0.04$); D: Scatter dot plot representing the serum carbohydrate antigen 19-9 concentration (U/mL) as determined by enzyme-linked immunoassay in CG (n = 8), MCL (n = 40), HR (n = 20), and NLOD (n = 20), (Kruskal-Wallis Test, P = NS). Data are shown as the median ± interquartile range. NS: Non-significant; GPC1: Glypican-1; CA 19-9: Carbohydrate antigen 19-9; crExos: Circulating exosomes.

appearance as well as cytological findings resulting from guided tissue acquisition. While the diagnostic and management of pancreatic cysts differs between international guidelines[29,39-42], they all agree that the risk of malignancy should be based, essentially, in the assessment of the classical WF/HRS, which was initially defined in the Fukuoka consensus[43].

Our cohort mainly constituted IPMNs, most of which were BD-IPMN type and half of the lesions presented with WF and/or HRS[29]. Malignancy was suspected by EUS in two advanced lesions with main duct involvement, which were confirmed by cytology. Interestingly, the third confirmed malignant cyst corresponded to a case we have previously reported[38], and was diagnosed during a follow-up examination of an apparently "inoffensive" cystic lesion in the index EUS. Our results have confirmed the limited utility of the use of cytology alone for cyst etiological characterization[44,45], as 37% of the results of EUS-FNA of the cyst fluid were considered inconclusive by pathologists. This limitation of cyst fluid cytological analysis tends to be overwhelmed by the referral for surgical resection of indeterminate suspicious lesions. In fact, 15 of the 40 patients with MCL proposed for surgical treatment, after evaluation by a multidisciplinary team, corresponded to 3 cases with a positive cytology for malignancy and 12 patients with indeterminate/inconclusive results of EUS-FNA. The surgical specimen confirmed malignancy in all 3 cases with previous diagnosis and in the remaining 12 revealed benign IPMNs with low grade dysplasia. The overtreatment of some of these patients is an important issue, as the morbidity and mortality of pancreatic surgery is not negligible[46,47]. In the present cohort, 2 of the 5 deaths recorded were precisely due to complications after surgery, both in patients harboring benign lesions. This observation supports the drive of research, justifying the need to evaluate the role of upcoming biomarkers, like exosomal GPC1, in complement with EUS evaluation, for the stratification of MCL, ultimately contributing to refine the criteria for surgical treatment or continued surveillance. In

Figure 4 Glypican-1-positive circulating exosomes are higher in individuals with personal history of cancer within the hereditary risk group, and among patients harboring pancreatic cystic lesions when worrisome features/high-risk stigmata are present. A: Scatter dot plot representing the percentage of beads bound to glypican-1 (GPC1)-positive circulating exosomes (GPC1⁺ crExos) in subjects in the hereditary risk (HR) group, without (n = 14) and with (n = 6) a personal history of cancer (HxCancer) [Mann-Whitney U Test, P = non-significant (NS)]; B: Scatter dot plot representing the serum carbohydrate antigen 19-9 (CA 19-9) concentration (U/mL) as determined by enzyme-linked immunoassay (ELISA) in subjects in the HR group, without (n = 14) and with (n = 6) HxCancer (Mann-Whitney U Test, P = 0.21); C: Scatter dot plot representing the percentage of GPC1⁺ crExos coupled to beads in subjects harboring pancreatic cystic lesions, without (n = 24) and with (n = 20) worrisome features (WF) or high-risk stigmata (HRS) (Mann-Whitney U Test, [f]P = 0.011); D: Scatter dot plot representing the serum CA 19-9 concentration (U/mL) as determined by ELISA in subjects harboring pancreatic cystic lesions, without (n = 24) and with (n = 20) WF/HRS (Mann-Whitney U Test, P = NS); E: Receiver operating characteristic curve of the cohort of pancreatic cystic lesions without (n = 24) or with (n = 20) WF/HRS, regarding the GPC1⁺ crExos levels (% beads with GPC1⁺ crExos). [1]Under nonparametric assumption; [2]Null hypothesis: True area = 0.5. Data are shown as the median ± interquartile range. NS: Non-significant; GPC1: Glypican-1; crExos: Circulating exosomes; WF: Worrisome features; HRS: High-risk stigmata.

this setting, our preliminary results initially reported were promising, as the levels of GPC1⁺ crExos were equally elevated in patients with PDAC and with MCLs[48,49]. The findings in the present study confirm these observations, as the median levels of GPC1⁺ crExos observed in the MCL group (significantly higher than in the other studied groups) were in the same magnitude as the ones registered for PDAC patients, that we have recently reported using the same methodology[28]. Moreover, when we analyzed the levels GPC1⁺ crExos among all pancreatic cystic lesions (MCL group plus those detected in the screening EUS in HR and NLOD groups), we found that they were statistically more elevated when WF/HRS were present, suggesting that this biomarker can, in fact, have a role in the risk stratification of these PDAC precursor lesions.

This is the first study to access the profile of GPC1⁺ crExos in HR and NLOD individuals, and our results showed that the median levels of this biomarker were statistically more elevated among the HR group when compared to NLOD patients and controls. Considering our previous published observations[28], these levels of GPC1⁺ crExos in HR individuals were also higher than those registered among patients with CP (28.4%), but not as elevated as in those with PDAC (99.7%). Interestingly, our results also showed a tendency of the individuals with a history of previous cancer (mainly colorectal) to present higher levels of GPC1⁺ crExos when compared to those without. While PA were detected in only 10% among HR individuals, all representing simple cystic lesions, these observations may suggest a potential role of GPC1⁺ crExos as a marker of genetically determined predisposition for cancer development, even in the absence of "harmful" pancreatic lesions.

Important studies have recently been published[24-26] and prospective investigational projects are ongoing[50] demonstrating the importance to access the magnitude of the risk to develop PDAC among NLOD patients and to define PDAC incidence during long-term follow-up. This justified the inclusion of NLOD patients in our investigation cohort. We found PA in EUS in 35% of the NLOD patients, comprising simple cystic lesions, CP-like changes and lipomatous parenchymal transformations, all of them considered "harmless", not requiring further investigation. Despite the highest median values of exosomes' size and particle concentration being registered in this group, the percentage of crExos positive for GPC1 was low and not statistically different from the CG. This finding is in accordance with the lack of sufficient evidence, at the present, to include these patients in regular screening programs for PDAC early detection.

Some limitations of this study should be pointed out, namely the sample size, the possibility of a referral bias giving the nature of our tertiary center, the relatively short period of patients' follow-up, and the cut-off found to stratify patients with cystic lesions and WF/HRS from those without. Also, the impossibility to include PanIN lesions in the study that would certainly power the analysis of GPC1 profile among PDAC pathological precursors. Lastly, the technique of exosomes isolation and analysis can still hamper its translation to clinical use. Despite these restraints, our results open the door for future studies to determine the value of this biomarker in the stratification of risk groups.

CONCLUSION

In summary, we demonstrate that GPC1$^+$ crExos levels are elevated in MCL, in the same magnitude of PDAC patients. These levels were statistically higher in cysts harboring WF/HRS. High levels were also registered among individuals with HR for PDAC (predominantly in those with history of previous cancer). Longitudinal studies will clarify the potential of exosomal GPC1 as a biomarker for the diagnosis and stratification of PDAC precursor lesions, as well as in signaling individuals with genetic predisposition for this neoplasia, ultimately contributing to refine screening and surveillance strategies.

ARTICLE HIGHLIGHTS

Research background

Most of the patients with pancreatic ductal adenocarcinoma (PDAC) are diagnosed with advanced disease at which stage treatment is inefficient. In order to improve survival, new strategies to identify and stratify individuals at risk of developing PDAC [*i.e.* individuals with hereditary risk (HR), mucinous cystic lesions (MCLs) and new-late onset diabetes mellitus (NLOD)] are urgently needed. Endoscopic ultrasound (EUS) is one of the imaging modalities with better performance for the study of the pancreas. In turn, carbohydrate antigen 19-9 (CA 19-9), the only biomarker approved for clinical use, is still imperfect as it lacks sensitivity and specificity. Glypican-1 (GPC1) represents a promising candidate since it has been demonstrated to be overexpressed in circulating exosomes (crExos) of patients with PDAC, possibly allowing early detection.

Research motivation

To contribute to further evaluate the capacity of GPC1$^+$ crExos to act as a potential biomarker for the investigation of individuals at risk for PDAC development, allowing for the early detection of the disease or its high-grade precursor lesions. Ultimately, we aim to contribute to improve patient's survival.

Research objectives

We aimed to determine the capacity of GPC1$^+$ crExos to identify individuals at higher risk to develop PDAC by comparing EUS pancreatic abnormalities (PA) with its levels within specific risk groups: HR, MCL and NLOD.

Research methods

We conducted a cross-sectional study with a prospective unicentric cohort including individuals with HR, MCL and NLOD, along with a control group (CG). All subjects were submitted to EUS at time of inclusion, with detailed characterization of detected PA. At the same time, blood samples were analyzed for GPC1$^+$ crExos and CA 19-9 by flow cytometry and ELISA, respectively. EUS-guided tissue acquisition was performed whenever necessary. SPSS® 27.0 version was used for statistical analysis and all graphs were created using GraphPad Prism 7.

Research results

We found that: Individuals harboring MCL globally presented with the highest levels of GPC1$^+$ crExos;

these levels were increased in the presence of worrisome features and or high-risk stigmata characterized by EUS; GPC1$^+$ crExos levels were also elevated among individuals with HR for PDAC (predominantly in those with personal history of cancer), even in absence of harmful PA in EUS examination; and NLOD patients presented with GPC1$^+$ crExos levels as low as those observed in the CG.

Research conclusions

Our study supports the role of GPC1$^+$ crExos in the diagnosis and stratification of PDAC precursor lesions, namely MCL, and its eventual capacity in signaling individuals with genetic predisposition for this neoplasia, even when no harmful PA are detected by EUS.

Research perspectives

Our data encourage longitudinal studies to confirm the potential of exosomal GPC1 as a biomarker to be used in the future in the management of individuals at risk for PDAC.

Abstract

BACKGROUND

Bile acids play an important role in the amelioration of type 2 diabetes following duodenal-jejunal bypass (DJB). Serum bile acids are elevated postoperatively. However, the clinical relevance is not known. Bile acids in the peripheral circulation reflect the amount of bile acids in the gut. Therefore, a further investigation of luminal bile acids following DJB is of great significance.

AIM

To investigate changes of luminal bile acids following DJB.

METHODS

Salicylhydroxamic acid (SHAM), DJB, and DJB with oral chenodeoxycholic acid (CDCA) supplementation were performed in a high-fat-diet/streptozotocin-induced diabetic rat model. Body weight, energy intake, oral glucose tolerance test, luminal bile acids, serum ceramides and intestinal ceramide synthesis were analyzed at week 12 postoperatively.

RESULTS

Compared to SHAM, DJB achieved rapid and durable improvement in glucose tolerance and led to increased total luminal bile acid concentrations with preferentially increased proportion of farnesoid X receptor (FXR) - inhibitory bile acids within the common limb. Intestinal ceramide synthesis was repressed with decreased serum ceramides, and this phenomenon could be partially antagonized by luminal supplementation of FXR activating bile acid CDCA.

CONCLUSION
DJB significantly changes luminal bile acid composition with increased proportion FXR-inhibitory bile acids and reduces serum ceramide levels. There observations suggest a novel mechanism of bile acids in metabolic regulation after DJB.

Key Words: Bariatric surgery; Duodenal-jejunal bypass; Farnesoid X receptor; Ceramide; Bile acids; Liver fat accumulation

INTRODUCTION

Duodenal-jejunal bypass (DJB) can induce rapid and durable amelioration of type 2 diabetes mellitus[1-3]. The underlying mechanisms remain incompletely understood. Our previous research has proved that bile acids play an important role in the amelioration of type 2 diabetes following DJB[4], and found that serum taurine-conjugated bile acids are preferentially elevated postoperatively[5]. However, the clinical relevance of the specific alterations of serum bile acids is still not known. Bile acids in the peripheral circulation reflect the amount of bile acids that could not be totally reabsorbed by hepatocytes during the enterohepatic circulation[6]. Therefore, the alterations of serum bile acids might be a secondary change of the bile acids within the gut, and a further investigation of luminal bile acids following DJB is of great significance.

Bile acids are traditionally known as lipid absorption-facilitating agents. It was not until recent years that the role of bile acids as signaling molecules in modulating metabolism has be unveiled. The intestinal lumina, where bile acid concentrations are high, is the main place for bile acid signaling. Two major receptors, including Takeda G-protein-coupled receptor 5 (TGR5) and nuclear farnesoid X receptor (FXR) are responsible for luminal bile acid sensing. TGR5 expression is detected in a variety of enteroendocrine cells and acute exposure of TGR5 to luminal bile acids lead to significant secretion of glucagon-like peptide 1 (GLP-1), which is a vital hormone for maintaining normal incretin effect in type 2 diabetes[7,8]. The interaction between bile acids and FXR is more complicated, as different subtypes of bile acids have distinct effect on the downstream pathway of FXR[9]. Chenodeoxycholic acid (CDCA) represents the most potent FXR stimulator while ursodeoxycholic acid (UDCA) and β-muricholic acid (β MCA) are FXR inhibitors[9-11]. Therefore, the net effect of luminal bile acids on FXR depends on the proportion of FXR-stimulating bile acids rather than the total amount of bile acids.

Intestinal FXR could affect lipid metabolism and this process is closely related to ceramide synthesis. Intestine-selective FXR inhibition downregulates the expression of ceramide synthesis-related genes sphingomyelin phosphodiesterase 3 (Smpd3) and serine palmitoyltransferase long chain base subunit 2 (Sptlc2), resulting in decreased concentrations of ceramides within the small intestine, portal system and peripheral circulation[12]. Decreased ceramides inhibit the expression of sterol regulatory element binding protein-1 (SREBP-1) in the liver[12], which is a key enzyme in the process of hepatic fat accumulation. Coincidentally, the changes in lipid metabolism after intestine-selective FXR inhibition is similar to the changes following DJB that hepatic fat accumulation is alleviated and the key transcriptional regulators and enzymes involved in hepatic *de novo* lipogenesis are downregulated[13]. Therefore, we

hypothesized that the net effect of luminal bile acids on intestinal FXR might be inhibitory after DJB which leads to decreased ceramide synthesis. To test this hypothesis, we measure the changes of individual luminal bile acid and ceramide concentrations within the enterohepatic circulation after DJB in a high-fat diet (HFD)/streptozotocin (STZ)-induced diabetic rat model.

MATERIALS AND METHODS

Animals and surgical procedures

Eight-week-old male Wistar rats (220 g on average, purchased from Huafukang Biotech, China) were individually housed with a 12 h light/dark cycle under constant temperature (24-26 °C) and humidity (50%-70%). All rats were fed with HFD (42% carbohydrate, 18% protein and 40% fat, as a total percentage of calories, Huafukang Biotech, China) with no restriction to tap water for 1 mo to induce insulin resistance. After fasting for 12 h, 30 mg/kg STZ (Sigma Aldrich, United States) dissolved in sodium citrate buffer (pH 4.2) was injected into the peritoneal cavity. Random blood glucose concentrations were measured with a glucometer (Roche Diagnostics, Germany) from tail veins 72 h later. Thirty rats with random blood glucose ≥ 16.7 mmol/L were considered diabetic and were matched into salicylhydroxamic acid (SHAM) group (n = 10), DJB group (n = 10) and DJB + CDCA group (n = 10). One month later, surgery was performed as we previously reported[5]. Body weight and calorie intake were recorded daily. All rats were sacrificed after 12 h fasting at week 12 postoperatively. All procedures involving animals were reviewed and approved by the Ethics Committee on Animal Experiment of Shandong University Qilu Hospital.

CDCA gavage

Without fasting, rats in the DJB + CDCA group were administrated with CDCA suspension (100 mg/kg suspended in 3 mL tap water) by intragastric gavage three times a week since week 5 postoperatively. The gavage procedure ceased after week 11.

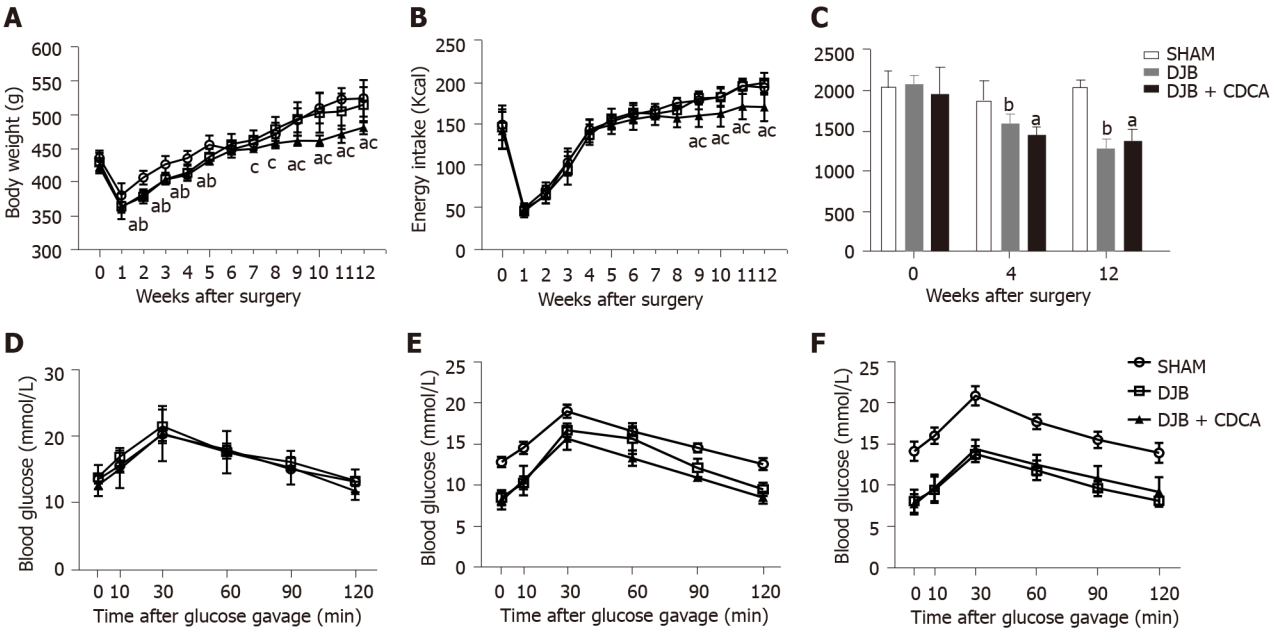
Oral glucose tolerance test

At week 4 and week 12, after 12 h fasting, the rats were administrated with 20% of glucose (1 g/kg) by intragastric gavage. Blood glucose concentrations were measured at t = 0, 10, 30, 60 and 120 min.

Blood sample preparation

Peripheral blood samples were collected from the retrobulbar venous plexus after 12 h fasting before sacrificing. Portal venous blood samples were collected directly from the portal vein. After centrifugation, the supernatant was stored at -80 °C until analysis.

Luminal bile acid detection



Three independent intestinal segments (3 cm each) was excised at the proximal, medium and distal sites within the common limb, respectively, without prior flushing. The control intestinal segments from SHAM group were excised at the corresponding anatomic location. Total luminal bile acids from intestinal segments were extracted by 9 mL 50 % tert-butyl alcohol for 1 h at 37 °C. After centrifugation, the supernatant was collected for bile acid analysis. Total bile acids were measured by Roche Cobas 8000 system using enzyme cycling method and individual bile acid species was measured using high-pressure liquid chromatography coupled with tandem mass spectrometry as we previously described [5].

Western blot

Small intestinal mucosa were flushed with saline and then scratched. Total protein was extracted by RIPA lysis buffer (KeyGEN, China) with protease and phosphatase inhibitor cocktail (KeyGEN, China) and was quantified using bicinchoninic acid protein assay kit (Beyotime, China). Equivalent amount of small intestinal mucosal protein were loaded on 10% sodium dodecyl sulfate-polyacrylamide gel electrophoresis gels (Bio-Rad, United States) and separated by electrophoresis. Then, proteins were transferred onto 0.45 μm polyvinylidene fluoride membranes (Millipore, Ireland). After being blocked in 5 % skim milk powder (Beyotime, China) for 2 h, the membranes were incubated with primary antibodies to Smpd3 (Abcam, United Kingdom) and Sptlc2 (Invitrogen, United States) overnight, followed by incubation in horseradish peroxidase-conjugated secondary antibodies (Proteintech, China) for 60 min. The protein bands were visualized by ECL solution (Millipore, United States) and their density was assessed with LI-COR Odyssey Imager (LI-COR Biosciences, United States).

RNA analysis

The expression of smpd3 and sptlc2 in the small intestine was analyzed by real-ime quantitative polymerase chain reaction (RT-qPCR). RNA was isolated using Trizol reagent (Invitrogen, United States), and the concentration of RNA was measured using the NanoDrop spectrophotometer

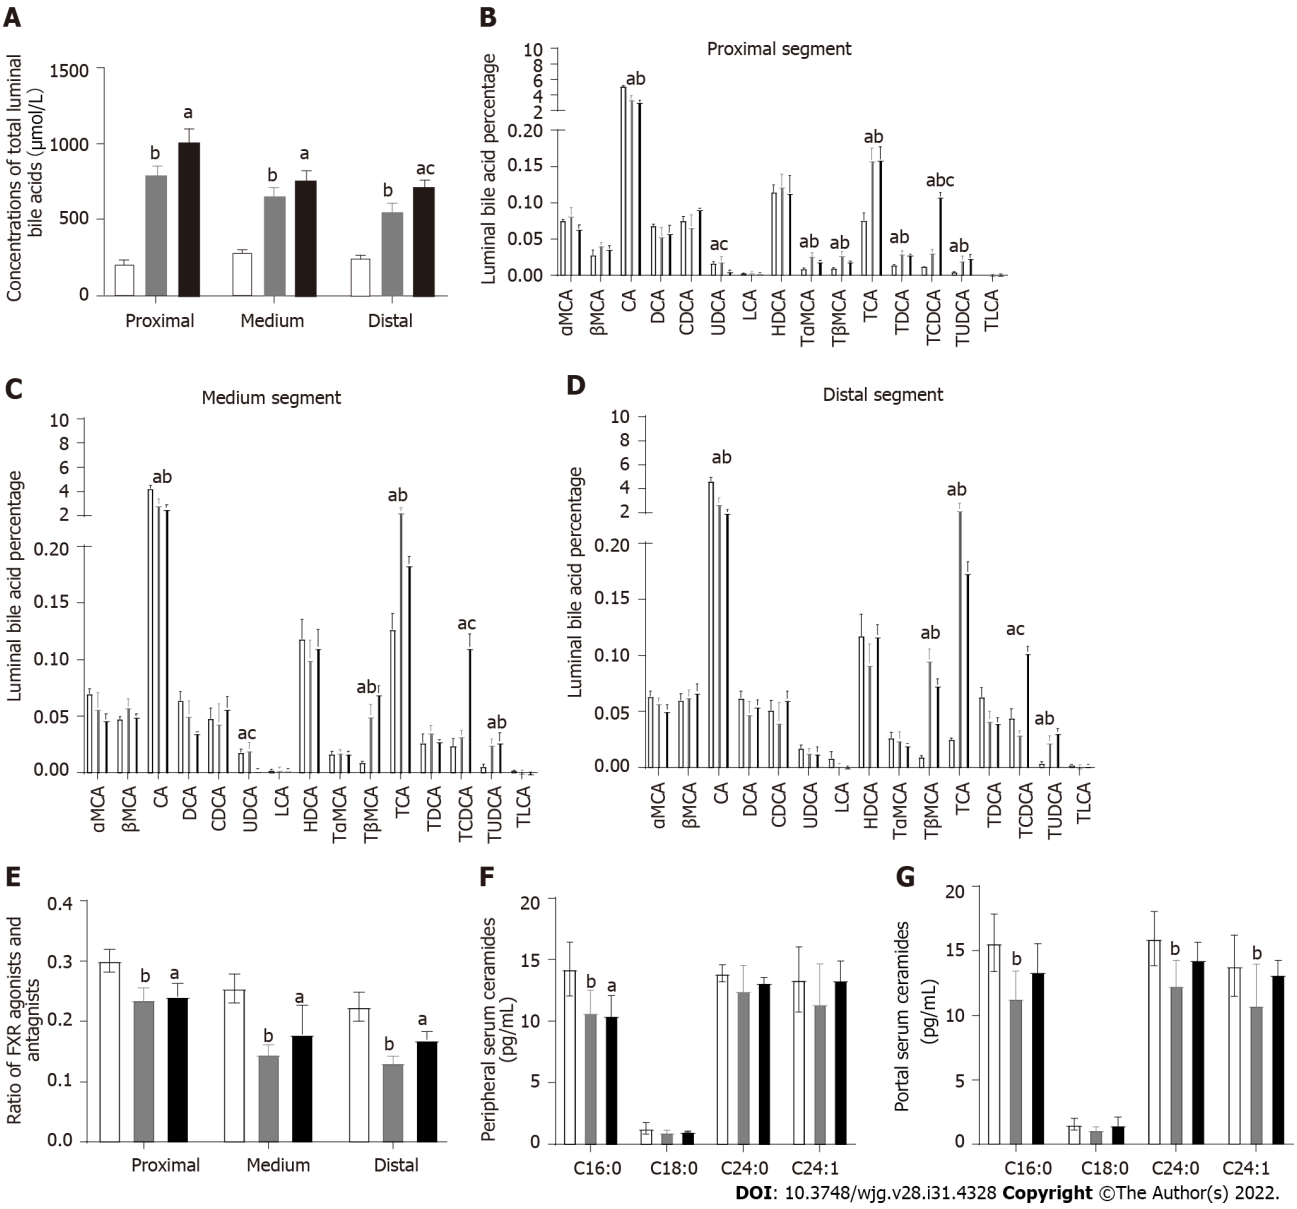
(NanoDrop Technologies, United States). RNA was then reverse transcribed into complementary DNA (cDNA) using a ReverTra Ace qPCR RT Kit (TOYOBO, Japan). Amplification of messenger RNA (mRNA) was carried out using SYBR Green Real-time PCR Master Mix Kit (TOYOBO, Japan) at a range of temperatures in a Roche Lightcycle 2.0 system (Roche, Switzerland). The housekeeping gene gapdh was used as an internal reference, and mRNA levels for each target were then calculated by the $2^{-\Delta\Delta Ct}$ method. The primers were smpd3 (forward primer: 5′-ACTCGCTCGCAAGGCTCAATAATG-3′, reverse primer: 5′-CTGAAGCTGGCTGCACTGATGG-3′), sptlc2 (forward primer: 5′-CGCCTTCCT-GAAGTGATTGCTCTC-3′, reverse primer: 5′-AGTCTACTACACCACGCCCTGAAG-3′), and gapdh (forward primer: 5′-ACCCTGTTGCTGTAGCCATATTC-3′; reverse primer: 5′-ACCCTGTTGCTGTAGC-CATATTC-3′).

Ceramide detection

Ceramide concentrations peripheral circulation and the portal vein were measured as previously described using Ceramide LIPIDOMIX Mass Spec Standard (#330712X-1EA, Avanti, United States) as standards[14].

Statistical analysis



Data are mean ± SEM. Area under the curve (AUC) for oral glucose tolerance test (OGTT) was calculated by trapezoidal integration. Intergroup comparisons were performed by one-way analysis of variance followed by Bonferroni *post hoc* comparisons. $P < 0.05$ was considered statistically significant. All calculations were performed using SPSS version 25.0.

RESULTS

One rat in SHAM group died of intestinal obstruction. Two rats in DJB group and 2 rats in DJB + CDCA group died of anastomotic leak. At the end of the study, the number of rats alive in SHAM, DJB and DJB + CDCA groups were 9, 8 and 8, respectively.

Body weight and energy intake

At baseline, both body weight and energy intake were comparable between three groups. After surgery, both body weight and energy intake decreased sharply in all three groups and increased gradually thereafter. At week 2-5 postoperatively, body weight of the rats in DJB and DJB + CDCA groups was significantly less than that in SHAM group ($P < 0.05$ all). At week 7-12 postoperatively, body weight of

FXR: Farnesoid X receptor; SHAM: Salicylhydroxamic acid; DJB: Duodenal-jejunal bypass; CDCA: Chenodeoxycholic acid; αMCA: α-muricholic acid; UDCA: Ursodeoxycholic acid; LCA: Lithocholic acid; HDCA: Hyocholic acid; TLCA: Taurine-conjugated lithocholic acid.

the rats in DJB + CDCA group was significantly less than that in DJB group ($P < 0.05$ all) (Figure 1A). At week 9-12 postoperatively, body weight of the rats in DJB + CDCA group was significantly less than that in SHAM group ($P < 0.05$ all). At week 9-12 postoperatively, energy intake of the rats in DJB + CDCA group was significantly less than that in SHAM and DJB groups ($P < 0.05$ all) (Figure 1B).

OGTT

There was no difference in glucose tolerance between three groups at baseline based on AUC_{OGTT}. At week 4 and 12, glucose tolerance was significantly improved with DJB and DJB + CDCA groups compared to SHAM group based on AUC_{OGTT} ($P < 0.05$ each). There was no difference between DJB and DJB + CDCA groups, or between week 4 and week 12 within each group (Figures 1C-F).

Luminal bile acids

Total luminal bile acid concentrations were significantly less with SHAM group compared to both DJB and DJB + CDCA groups in either proximal, medium or distal segment in the common limb ($P < 0.05$ all). In the distal segment, luminal total bile acid concentrations were significantly greater with DJB +

CDCA group than DJB group ($P < 0.05$), while this difference was not significant in the proximal or medium segment (Figure 2A).

In the proximal segment (Figure 2B), CA accounted for over 20% of the total luminal bile acids in all three groups, and was significantly greater with SHAM group than DJB and DJB + CDCA groups ($P < 0.05$). The percentages of α-muricholic acid (αMCA), βMCA, deoxycholic acid, CDCA, lithocholic acid (LCA), hyocholic acid (HDCA), and taurine-conjugated LCA (TLCA) were comparable between all three groups. The percentage of UDCA was less with DJB + CDCA group compared to SHAM and DJB groups ($P < 0.05$). The percentages of taurine-conjugated forms of αMCA, βMCA, CA, DCA, CDCA and UDCA were all greater with DJB and DJB + CDCA groups compared to SHAM group ($P < 0.05$). The percentage of TCDCA was greater with DJB + CDCA group than DJB group ($P < 0.05$).

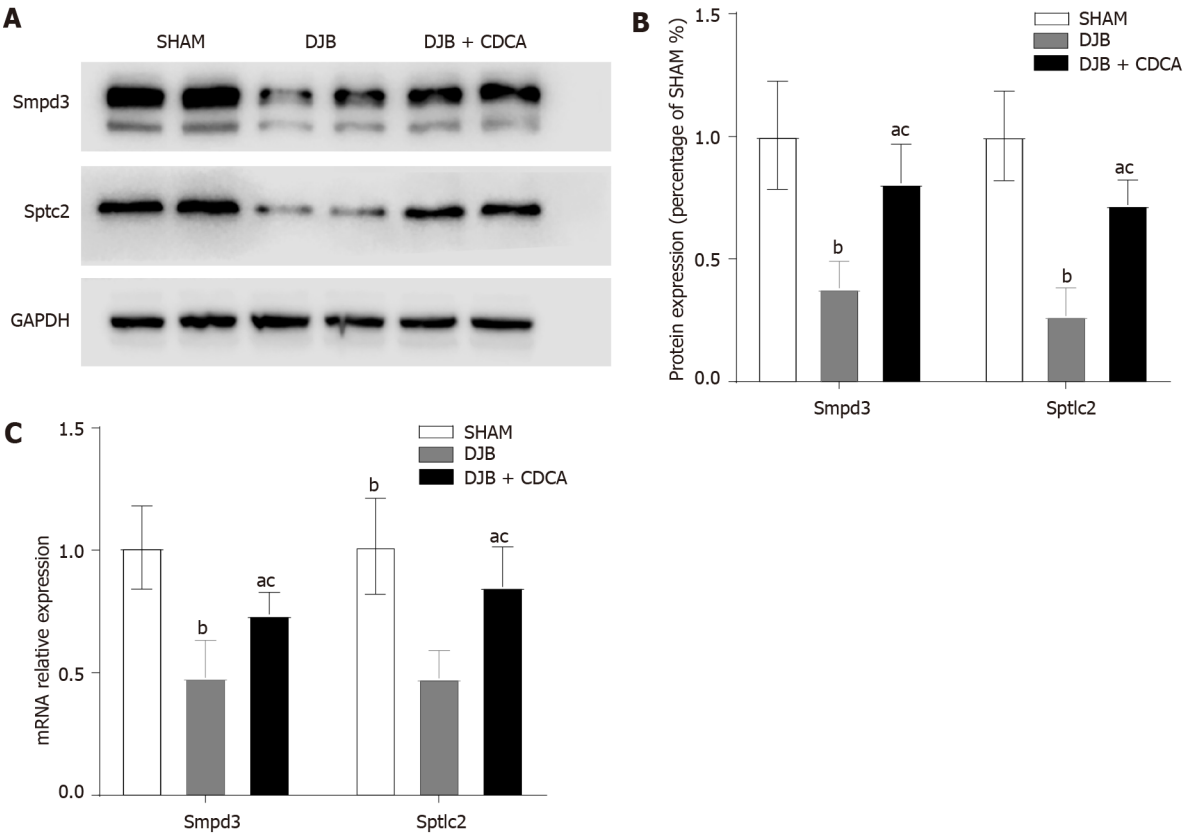
In the medium segment (Figure 2C), the difference in TαMCA and TDCA between three groups was no longer significant compared to the proximal segment. The percentage of TβMCA increased to more than 5% in DJB and DJB + CDCA groups which was significantly greater than SHAM group ($P < 0.05$). The percentage of TCDCA was comparable between SHAM and DJB groups, which was significantly less than DJB + CDCA group ($P < 0.05$).

In the distal segment (Figure 2D), the percentage of TβMCA, TCA and TUDCA was significantly greater with DJB and DJB + CDCA groups compared to SHAM group ($P < 0.05$), without any difference between the former two groups. The percentage of CA was significantly less with DJB and DJB + CDCA groups compared to SHAM group ($P < 0.05$). There was no difference in the percentage of UDCA between three groups. The percentage of other individual bile acids was comparable to that in the medium segment. The ratio of FXR agonists (including CA, TCA, DCA, TDCA, CDCA, TCDCA, LCA, and TLCA) and antagonists (including αMCA, TαMCA, βMCA, TβMCA, UDCA, TUDCA and HDCA) in DJB and DJB + CDCA groups was decreased compared to SHAM group in either proximal, medium or distal segment ($P < 0.05$). No difference was observed between DJB group and DJB + CDCA group (Figure 2E).

Ceramides

At week 12, in the peripheral circulation, serum C16:0 ceramide concentrations were lower with DJB and DJB + CDCA groups compared to SHAM group ($P < 0.05$); no difference in C18:0, C24:0 or C24:1 ceramides between three groups (Figure 2F). In the portal vein, serum C16:0, C24:0 and C24:1 ceramide concentrations were lower with DJB group compared to SHAM group ($P < 0.05$); there was no difference in either ceramide species between DJB and DJB + CDCA groups or between DJB + CDCA and SHAM groups (Figure 2G).

Expression of Smpd3 and Sptlc2



At week 12, the expression of Smpd3 and Sptlc2 were lower with DJB and DJB + CDCA groups than SHAM group at both protein and mRNA levels ($P < 0.05$). Compared to DJB + CDCA group, the expression of Smpd3 and Sptlc2 with DJB group were even lower at both protein and mRNA levels ($P < 0.05$) (Figures 3A, 3B and 3C).

DISCUSSION

In the present study, we performed SHAM, DJB and DJB + CDCA procedures in a HFD/STZ induced diabetic rat model, and for the first time, demonstrated the changes of luminal individual bile acids in the distal small intestine. We also found that the subsequent changes of the bile acids within the distal common limb after DJB elicited inhibitory effect on regional ceramide synthesis and this phenomenon could be partially antagonized by luminal supplementation of FXR activating bile acid CDCA.

DJB was initially designed to investigate the weight loss independent mechanisms of bariatric surgery[3]. This procedure has no effect on weight loss but could induce fast and sustainable amelioration of type 2 diabetes[4]. Consistent with other bariatric procedures[15,16], serum bile acid concentrations were also increased following DJB, and this phenomenon is clearly related to reconstruction of the gastrointestinal tract[5]. *Via* the biliopancreatic limb, bile acids contact the distal small intestine, where luminal bile acid reabsorption mainly occurs, more rapidly and lead to early and increased reabsorption of luminal bile acids in the small intestine. A recent study has proved that in the biliopancreatic limb, increased reabsorption of luminal bile acids has already commenced as a result of highly concentrated bile acids as well as lack of lipids[17]. While in the alimentary limb, only trace amount of luminal bile acids could be detected[4]. Decreased luminal bile acids lead to marked luminal sodium insufficiency, and hence, intestinal uptake of glucose in the alimentary limb is significantly decreased[18], which represents another mechanism in controlling postprandial glucose excursion. The common limb is where food and bile mix up and the major place for intestinal FXR expression. Therefore, we concentrated on bile acid milieu within the common limb rather than the biliopancreatic or alimentary limb because the common limb is the place mostly close to physiological conditions.

To our knowledge, the present study is the first study reporting luminal bile acid changes after DJB. Most clinical and animal studies concentrated on serum or fecal bile acids, as the intestinal lumen is

SHAM: Salicylhydroxamic acid; DJB: Duodenal-jejunal bypass; CDCA: Chenodeoxycholic acid; Smpd3: Sphingomyelin phosphodiesterase 3; Sptlc2: Serine palmitoyltransferase long chain base subunit 2.

deep inside and *in vivo* study of luminal contents, particularly in the small intestine, is technically difficult and ethically challenging. Consistent with our previous findings of serum bile acid changes after DJB, the total amount of luminal bile acids and the proportion of FXR-inhibitory bile acids were both increased. These specific changes have at least two clinical relevance. First, concentrated luminal bile acids stimulate TRG5 on the surface of enteroendocrine cells and leads to potentiated GLP-1 secretion[4]; second, increased proportion of FXR-inhibitory bile acids has inhibited expression of FXR downstream pathways and reduced biosynthesis of intestinal-derived ceramides[12]. Compared to TGR5, FXR appears to be a more important and complicated receptor in metabolic regulation; in the absence of FXR, the ability of bariatric surgery to reduce body weight and improve glucose tolerance is substantially reduced while these metabolic benefits are largely preserved when TGR5 is deficient[19-20]. Whole body FXR knock-out mice were associated with elevated serum triglycerides, cholesterols, free fatty acids and severe liver fat accumulation, but were protected from diet- or genetically- induced obesity[21]. In contrast, liver-specific FXR knock-out mice were not protected from diet-induced obesity and insulin resistance[22], suggesting the distinct role of hepatic and intestinal FXR activation in improving glucose tolerance and insulin resistance. In the small intestine, the role of FXR is controversial. After bariatric surgery, increased serum fibroblast growth factor 19 (FGF19) concentrations have been thought to play a role in the remission of human diabetes[15]. And intestinal FXR activation by luminal bile acids has been thought as a major source of increased serum FGF19. However, no direct evidence was available to confirm the state of intestinal FXR activation, and other tissues may also be sources of FGF19. In contrast, more studies support that intestinal FXR activation would damage metabolic homeostasis by reducing energy expenditure and impairing glucose tolerance[12,14,23]. To investigate the direct influence of bile acids on intestinal FXR, bile diversion procedure was reported by three separate studies[4,24,25], including one from our group[4]. Surprisingly, all three studies showed activated intestinal FXR in response to direct bile acid stimulation. However, in contrast, in DJB, the effect of bile acids on intestinal FXR within the common limb was inhibitory. The discrepancy suggests the biliopancreatic limb may have altered the luminal bile acid composition by premature bile acid reabsorption.

Consistent with our hypothesis, both ceramides in the portal vein and in the peripheral circulation were decreased in response to increased proportion of luminal FXR-inhibitory bile acids. Ceramides are signaling molecules and are associated with obesity and insulin resistance at high concentrations[26]. Decreased ceramides inhibits the expression of SREBP-1 in the liver and alleviates hepatic fat accumulation, thus increasing hepatic insulin sensitivity[12]. Our previous study found that DJB suppressed hepatic *de novo* lipogenesis and alleviates liver fat accumulation by inhibiting SREBP-1. However, the mechanisms underlying were unknown. Based on results from the present study, we have unveiled at least one mechanism accounting for alleviated hepatic fat accumulation. Therefore, manipulation of luminal bile acid composition towards FXR-inhibitory trend may have metabolic beneficial effects.

The present study has several limitations. First, bile acids are mixture with a variety of individual bile acids. As bile acids are mainly conjugated with taurine in rodents[27], we only tested luminal unconjugated and taurine-conjugated bile acids. Second, CDCA is not dissolved in water and we used CDCA suspension for gavage, which may have compromised CDCA absorption to a certain degree. Third, the results from the present study were based on a diabetic rat model and should be interpreted with caution due to species gap.

CONCLUSION

In conclusion, DJB significantly changes luminal bile acid composition with increased proportion of FXR-inhibitory bile acids and reduce serum ceramide levels. There observations suggest a novel mechanism of bile acids in metabolic regulation after DJB.

ARTICLE HIGHLIGHTS

Research background

Bile acids have proved to be signaling molecules in mediating metabolic benefits and circulating bile acids were found to be increased following duodenal-jejunal bypass (DJB). However, whether and how the bile acids take effect in the amelioration of metabolic disorders after DJB remain unknown.

Research motivation

Circulating bile acids reflect the amount of bile acids within the gut. It has been proved that luminal bile acids take effect *via* Takeda G-protein-coupled receptor 5 and nuclear farnesoid X receptor (FXR). However, different subtypes of bile acids have distinct effect on the downstream pathway of FXR and hence, a further investigation of luminal bile acids after DJB is of great significance.

Research objectives

To investigate changes and mechanisms of luminal bile acids in mediating metabolic benefits following DJB.

Research methods

Salicylhydroxamic acid (SHAM), DJB, and DJB with oral chenodeoxycholic acid (CDCA) supplementation were performed in a high-fat-diet/streptozotocin-induced diabetic rat model. Body weight, energy intake, oral glucose tolerance test, luminal bile acids, serum ceramides and intestinal ceramide synthesis were analyzed at week 12 postoperatively.

Research results

Compared to SHAM, DJB achieved rapid and durable improvement in glucose tolerance and led to increased total luminal bile acid concentrations with preferentially increased proportion of FXR - inhibitory bile acids within the common limb. Intestinal ceramide synthesis was repressed with decreased serum ceramides, and this phenomenon could be partially antagonized by luminal supplementation of FXR activating bile acid CDCA.

Research conclusions

DJB significantly changes luminal bile acid composition with increased proportion FXR-inhibitory bile acids and reduces serum ceramide levels. There observations suggest a novel mechanism of bile acids in metabolic regulation after DJB.

Research perspectives

Mechanisms of bile acids in mediating metabolic benefits after bariatric surgery.

Abstract

BACKGROUND

The mechanisms underlying diabetes remission after duodenal-jejunal bypass (DJB) remain elusive. In DJB surgery, the duodenum is excluded. However, the duodenum has emerged as an important regulator of glucose homeostasis, and elevated duodenal SIRT1 leads to improved hepatic insulin sensitivity. After DJB, bile acids (BAs) in the duodenum are not mixed and diluted by the ingested food. And activation of BA receptors promotes SIRT1 expression in many tissues. We hypothesized that BA-mediated upregulation of SIRT1 may contribute to diabetic control after DJB.

AIM

To investigate the surgical effects of DJB on duodenal SIRT1 expression and uncover the potential crosslinks between BAs and SIRT1.

METHODS

Twenty diabetic rats were randomly allocated to the sham (n = 10) and DJB (n = 10) groups. Body weight, food intake, fasting blood glucose (FBG), serum and intraduodenal total BA (TBA) levels were measured accordingly. Oral glucose tolerance test (OGTT) and intraperitoneal pyruvate tolerance test (ipPTT) were performed to evaluate the effects of surgeries on systemic glucose disposal and hepatic gluconeogenesis. The key genes of BA signaling pathway in the duodenal mucosa, including farnesoid X receptor (FXR), small heterodimer partner (SHP), and Takeda G-protein-coupled receptor 5 (TGR5) were evaluated by real-time quantitative polymerase chain reaction 8 wk postoperatively. The duodenal SIRT1, AMPK, and phosphorylated AMPK (p-AMPK) levels were evaluated by western blotting. Rat small intestine epithelial IEC-6 cells were treated with

GW4064 and INT-777 to verify the effects of BAs on SIRT1 expression in enterocytes.

RESULTS

The DJB group exhibited body weight and food intake comparable to those of the sham group at all postoperative time points. The FBG level and area under the curve for the OGTT and ipPTT were significantly lower in the DJB group. The DJB group exhibited higher fasting and postprandial serum TBA levels than the sham group at both 2 and 8 wk postoperatively. At 8 wk after surgery, the DJB group showed higher intraluminal TBA concentration, upregulated mRNA expression of FXR and SHP, and elevated protein expression of SIRT1 and p-AMPK in the descending and horizontal segments of the duodenum. Activation of FXR and TGR5 receptors by GW4064 and INT-777 increased the mRNA and protein expression of SIRT1 and promoted the phosphorylation of AMPK in IEC-6 cells.

CONCLUSION

DJB elevates intraduodenal BA levels and activates the duodenal BA signaling pathway, which may upregulate duodenal SIRT1 and further contribute to improved glucose homeostasis after DJB.

Key Words: Duodenal-jejunal bypass; Diabetes mellitus; Bile acids; Sirtuin 1; Duodenum; High-fat diet

Core Tip: The intrinsic mechanisms of diabetes remission after duodenal-jejunal bypass (DJB) surgery are complicated. Duodenal SIRT1 is a novel therapeutic target for diabetes, and increased duodenal SIRT1 is linked to improved hepatic insulin sensitivity and decreased hepatic glucose output. The animal study demonstrated that DJB increased intraduodenal bile acid (BA) levels, activated the BA signaling pathway, and upregulated SIRT1 expression in the duodenal mucosa. Our cell experiments proved that farnesoid X receptor and Takeda G-protein-coupled receptor 5 activation increased SIRT1 expression in rat small intestine epithelial cells, indicating that increased intraluminal BAs and activation of BA receptors contributed to increased duodenal SIRT1 after DJB.

INTRODUCTION

Diabetes is one of the fastest-growing global health issues. The International Diabetes Federation reported that the global prevalence of diabetes in adults was approximately 10.5% in 2021, expected to rise to 12.2% in 2045[1]. Bariatric surgery is much more effective and persistent in diabetes control than conventional medical therapy[2]. Duodenal-jejunal bypass (DJB) is a well-designed experimental procedure investigating the weight-independent anti-diabetic mechanisms of Roux-en-Y gastric bypass (RYGB). It can improve glucose homeostasis in both diabetic rats and patients[3-5], however, the underlying mechanisms remain unclear. A critical anatomical alteration of DJB is the exclusion of the duodenum. In addition, DJB liner, which mimics the duodenal-jejunal exclusion effects of RYGB, also improves glucose homeostasis[6]. Duodenal mucosal resurfacing, an endoscopic procedure that involves circumferential hydrothermal ablation and subsequent regeneration of the duodenal mucosa, elicits dramatic and durable glycemic improvements in patients with type 2 diabetes mellitus (T2DM)[7]. These findings suggest that the bypassed duodenum may play an important role in diabetic control after DJB.

The duodenum was primarily viewed as a digestive organ. However, accumulating evidence demonstrates that the duodenum has emerged as a key regulator of metabolic diseases, including diabetes[8]. The duodenal mucosa is exposed to various endogenous and exogenous chemical stimuli, such as macro- and micronutrients, gastric acid, bile acids (BAs), digestive enzymes, microorganisms, and drugs[9,10]. The duodenum is densely innervated by the enteric autonomous nervous system (ENS). Through chemical sensors located in the mucosa and ENS, the duodenum detects changes in luminal contents and further triggers a gut-brain negative feedback loop to inhibit exogenous nutrient intake and endogenous liver nutrient production[10,11]. In healthy rats, short-term intraduodenal

intralipid infusion inhibits hepatic glucose production (HGP) *via* the gut-brain-liver neural axis. However, this suppressive effect is negated in insulin-resistant rats[12]. Metformin and resveratrol, two well-known anti-diabetic drugs, can activate specific duodenal energy sensors (AMPK and SIRT1, respectively) even before being absorbed into the systemic circulation, and further trigger the gut-brain-liver network to reverse insulin resistance and inhibit HGP[13,14].

SIRT1 is a conserved mammalian nicotinamide adenine dinucleotide (NAD+)-dependent protein deacetylase that acts as a key metabolic sensor in various metabolic tissues, including the liver, skeletal muscle, adipose tissue, and pancreas. It directly links the cellular metabolic status to the regulation of gene expression, thus modulating various cellular processes, such as glucose metabolism, inflammation, and stress response[15,16]. SIRT1 is also expressed in the duodenal mucosa, which is significantly inhibited in high-fat diet (HFD)-fed insulin-resistant rats. Duodenum-specific knockdown of SIRT1 is sufficient to induce hepatic insulin resistance and increase hepatic glucose output in normal chow-fed rats[14]. To the best of our knowledge, the anti-diabetic effects of DJB surgery that could be linked to duodenal SIRT1 have not been investigated.

DJB hinders the duodenum from contacting the ingested chyme, therefore, the BAs released into the duodenum will not be mixed and diluted by food. In addition to their widely known roles in facilitating lipid absorption, BAs have recently been recognized as novel endocrine molecules that modulate glucose, lipids, and energy metabolism[17,18]. Activation of BA receptors, including the nuclear farnesoid X receptor (FXR) and membrane Takeda G-protein-coupled receptor 5 (TGR5), upregulates SIRT1 expression in the liver and brain, respectively[19,20]. These findings raise the possibility that DJB might upregulate duodenal SIRT1 by increasing intraluminal BAs, which might further contribute to the improved glucose homeostasis after DJB. Therefore, this study aimed to investigate the impact of DJB on duodenal BA signaling and SIRT1 expression in HFD and streptozotocin (STZ)-induced diabetic rats, and further explore the roles of BAs in modulating SIRT1 expression.

MATERIALS AND METHODS

Animals

Eight-week-old male Wistar rats were purchased from the Laboratory Animal Center of Shandong University (Jinan, China) and individually housed in ventilated cages in a controlled environment (12 h light/dark cycle, 24 ± 2 °C, humidity 50%-60%). The rats had *ad libitum* access to rodent chow and water. The diabetic rat model was established by HFD (40% fat, Huafukang Biotech, China) feeding for 4 wk to induce insulin resistance, followed by subsequent intraperitoneal injection of low-dose STZ (35 mg/kg, Sigma, United States) to induce mild insulin deficiency and hyperglycemia. After 72 h of STZ administration, 20 diabetic rats with random blood glucose ≥ 16.7 mmol/L were selected and randomly allocated to the sham (n = 10) and DJB (n = 10) groups. All animal protocols were approved by the Ethics Committee on Experimental Animals of Cheeloo College of Medicine, Shandong University.

Surgical procedures

The rats were deprived of solid food but were given free access to water and 10% enteral nutrition powder (Ensure, Abbott Laboratories B.V., Netherlands) two days preoperatively. Complete fasting was initiated 12 h preoperatively. All operations were conducted under anesthesia with 10% chloral hydrate (3 mL/kg). DJB and sham surgeries were performed as previously described[21].

DJB: First, a midline incision was made in the upper abdomen and the duodenum was then transected 1 cm distal to the pylorus and the stump was sealed. Next, the jejunum was transected approximately 10 cm distal to the ligament of Treitz, and the distal limb of the jejunum was anastomosed to the proximal duodenum in an end-to-end manner. Finally, the biliopancreatic limb was anastomosed to the jejunum 15 cm distal to the duodenojejunal anastomosis in a Roux-en-Y manner.

Sham: Sham surgery was performed *via* an incision comparable to that of the DJB group. The intestines were transected at the same sites where enterotomies were performed in DJB, and re-anastomosis was made *in situ*. The operation time was prolonged equally to that of the DJB group to achieve similar surgical and anesthetic stress.

The rats were only given access to water during the first 24 h postoperatively, followed by 10% enteral nutrition powder for three days, and thereafter a standard rodent chow until the end of this study. Body weight and food intake were recorded preoperatively and once a week postoperatively. Fasting blood glucose (FBG) levels were measured at baseline and at 1, 2, 4, 6, and 8 wk postoperatively.

Oral glucose tolerance test

Oral glucose tolerance test (OGTT) was performed 2 and 8 wk postoperatively. The rats were administered with 20% glucose (1 g/kg body weight) by oral gavage after overnight fasting. Blood samples were collected from the tail vein at baseline and at 15, 30, 60, 120, and 180 min after glucose administration to measure blood glucose levels. The area under the curve for the OGTT (AUC_{OGTT}) was

calculated by trapezoidal integration.

Intraperitoneal pyruvate tolerance test

The intraperitoneal pyruvate tolerance test (ipPTT) was conducted 2 and 8 wk postoperatively to evaluate hepatic gluconeogenic capacity and hepatic insulin resistance. After 12 h of fasting, 10% pyruvate solution (1 g/kg body weight) was administered intraperitoneally into conscious rats. Blood glucose levels were monitored at baseline and at 15, 30, 60, and 120 min after injection. The AUC for ipPTT (AUC_{ipPTT}) was calculated using trapezoidal integration.

Systemic and duodenal BAs parameters

Fasting and postprandial systemic total BAs (TBAs) were measured 2 and 8 wk postoperatively. The rats were fasted for 12 h and then administered with 10% Ensure (10 mL/kg body weight) *via* intragastric gavage. Blood samples were collected from the retrobulbar venous plexus into chilled SST tubes at baseline and 60 min after gavage to measure the systemic TBAs.

Eight weeks after the surgery, the rats were euthanized immediately after blood collection. Intestine segments of 0.5 cm length were excised from the descending and horizontal duodenum separately without rinsing. TBAs in the duodenum lumen were extracted by mixing the duodenal segments with 1 mL of 50% tert-butyl alcohol for 1 h at 37 °C. After centrifugation, the supernatant was collected and stored at -80 °C until analysis. BAs were measured with an automatic biochemistry analyzer (Roche Cobas 8000 system) using an enzyme cycling method.

Cell culture

Rat small intestine epithelial IEC-6 cells were purchased from Fuheng Biology (Shanghai, China), and cultured in Dulbecco's Modified Eagle Medium (Gibco, CA, United States) supplemented with 10% fetal bovine serum (Gibco, CA, United States), and maintained under standard culture conditions (in incubators at 37 °C in a 5% CO_2/95% air atmosphere). To investigate the effects of FXR and TGR5 activation on SIRT1, AMPK, and phosphorylated AMPK (p-AMPK) expression, IEC-6 cells were treated with GW4064 (5 μM, 24 h) and INT-777 (10 μM, 1 h) respectively, and the control groups were treated with an equal volume of dimethyl sulfoxide. At the end of the study, cells were harvested for protein and gene expression analyses.

Real-time quantitative polymerase chain reaction

Total mRNA of the duodenal mucosa and IEC-6 cells were extracted using TRIzol Reagent (Cwbio, China). The total mRNA was then reverse-transcribed into cDNA using a HiFiScript cDNA Synthesis Kit (Cwbio, China) according to the manufacturer's instructions. The cDNA was subjected to real-time quantitative polymerase chain reaction (RT-qPCR) quantitation with UltraSYBR Mixture (Cwbio, China) on a RT-qPCR system (Hehui biotech, China). GAPDH was used as an internal control. Primers used in this study are listed in Table 1.

Enzyme-linked immunosorbent assay

The duodenal mucosa was immediately flash-frozen in liquid nitrogen after the rats were euthanized. The cyclic adenosine 3′, 5′-monophosphate (cAMP) concentration in the duodenal mucosa was measured using an enzyme-linked immunosorbent assay kit according to the manufacturer's instructions (Sigma-Aldrich, United States).

Western blotting

Total proteins of the duodenal mucosa and IEC-6 cells were extracted with RIPA lysis buffer (Beyotime, China) and analyzed using a BCA protein assay kit (Beyotime, China). The primary antibodies used in western blotting were SIRT1 (Cell Signaling Technology, United States), AMPK (Cell Signaling Technology, United States), p-AMPK (Cell Signaling Technology, United States), and GAPDH (Proteintech, China). The protein bands were visualized using ECL solution (Millipore, United States), and band densitometry was assessed with ImageJ software.

Statistical analysis

Quantitative data were expressed as mean ± SD. The intergroups differences were evaluated by the Student's *t*-test except for blood glucose levels in the OGTT and ipPTT studies, which were analyzed by two-way repeated measures ANOVA (mixed model ANOVA) followed by Bonferroni's multiple comparison test. All analyses were performed using SPSS (Version 26). The criterion for statistical significance was set at $P < 0.05$.

Table 1 Primer sequence

FXR: Farnesoid X receptor; SHP: Small heterodimer partner; TGR5: Takeda G-protein-coupled receptor 5.

RESULTS

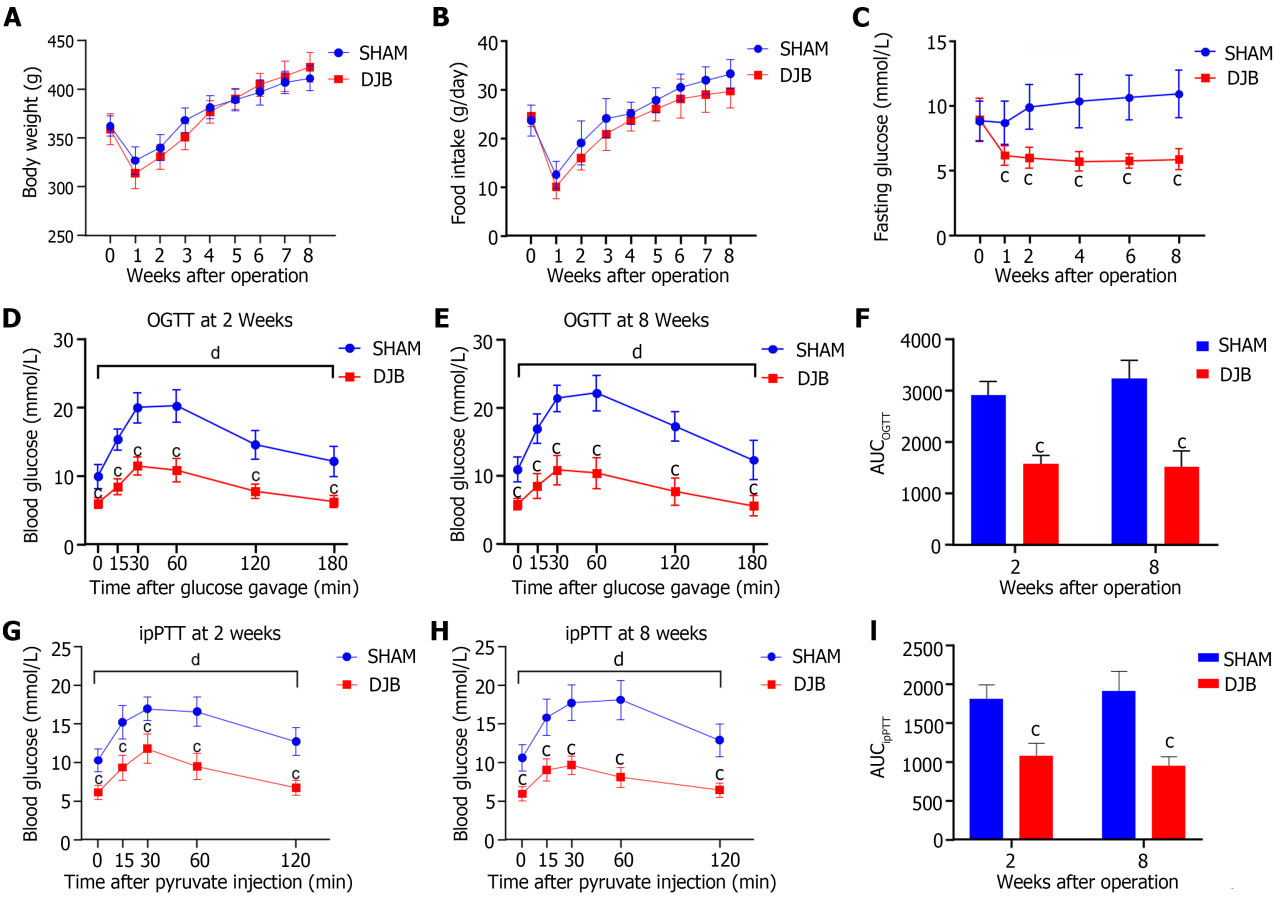
Effects of DJB on body weight and food intake

Body weight and food intake were comparable between the two groups before operation. Due to surgical stress, unrestored gastrointestinal function, and decreased food intake, the body weight of both groups fell to a minimum point in the first week after surgery. As food intake increased, the body weight of both groups gradually recovered to preoperative levels approximately 4 wk after operation. As a nonrestrictive surgery, the DJB group exhibited similar body weight and food intake as the sham group at all measured time points postoperatively (Figures 1A and B).

DJB rapidly improved glucose homeostasis in diabetic rats

There were no significant differences in FBG levels between the two groups preoperatively. The FBG of the DJB group rapidly and significantly declined as early as one week postoperatively and was maintained at a relatively stable level. While the FBG of the sham group was not alleviated after operation and showed a tendency to deteriorate over time. Compared to the sham group, the DJB group exhibited lower FBG at all postoperative time points (Figure 1C).

Consistent with rapidly reduced FBG, the DJB group showed significantly lower blood glucose excursion and AUC_{OGTT} during the OGTT studies at 2 and 8 wk postoperatively (Figures 1D-F), indicating improved glucose tolerance and increased systemic glucose disposal after DJB. To evaluate the impact of DJB on hepatic gluconeogenic capacity, ipPTT was conducted at 2 and 8 wk postoperatively. As shown in Figures 1G-I, the DJB group exhibited reduced glucose excursion and AUC_{ipPTT} in response to intraperitoneal pyruvate challenge, implying that DJB improved hepatic insulin sensitivity and decreased hepatic glucose output in diabetic rats early after surgery.



DJB increased systemic and intraduodenal TBAs, and activated duodenal BA signaling

Compared with the sham group, the DJB-operated rats exhibited elevated fasting and postprandial serum TBAs at 2 and 8 wk postoperatively (Figure 2A). Altered food and digestive juice flow in the gastrointestinal tract also affected luminal TBAs after DJB. As shown in Figure 2B, the DJB group displayed elevated intraluminal TBAs in both the descending and horizontal duodenum 8 wk postoperatively.

To determine the effects of increased intraduodenal TBAs on duodenal BA signaling, the mRNA levels of FXR, TGR5, and small heterodimer partner (SHP) in the duodenal mucosa were evaluated by RT-qPCR eight weeks after surgery. The mRNA expression of FXR and its target gene SHP were concurrently increased in the duodenal mucosa of the DJB group (Figures 2C and D), indicating that the BAs-FXR-SHP pathway was activated. As a membrane bound receptor, TGR5 activation leads to cAMP accumulation in cells. Although DJB did not enhance TGR5 gene expression in the duodenal mucosa (Figures 2C and D), it increased the cAMP content in the horizontal duodenum (Figure 2E). cAMP also tended to increase in the descending duodenum of the DJB group despite no statistical significance (Figure 2E). These results suggest that the duodenal TGR5 receptor may also be activated after DJB.

DJB increased SIRT1 expression and promoted phosphorylation of AMPK in the duodenal mucosa

The ipPTT studies suggested that hepatic gluconeogenesis was reduced after DJB. Elevated duodenal SIRT1 and p-AMPK are associated with suppressed hepatic glucose output *via* the gut-brain-liver neural loop[13,14]. Therefore, to elucidate the underlying mechanism of improved hepatic insulin sensitivity and glucose homeostasis after DJB, duodenal SIRT1 and p-AMPK expression were investigated by western blotting eight weeks after surgery. As shown in Figure 3, DJB increased SIRT1 expression and promoted phosphorylation of AMPK in both the descending and horizontal parts of the duodenum.

FXR and TGR5 activation increased SIRT1 expression and promoted phosphorylation of AMPK in IEC-6 cells

To verify whether increased SIRT1 and p-AMPK could be attributed to activated BA signaling in the duodenal mucosa, we treated rat small intestine epithelial IEC-6 cells with FXR and TGR5 agonists, respectively. Upon FXR activation by GW4064, the mRNA expression of FXR, SHP, and SIRT1 were all dramatically upregulated in IEC-6 cells (Figure 4A). Although INT-777 stimulation did not induce TGR5 transcription, it promoted the mRNA expression of SIRT1 (Figure 4B). In line with the increased mRNA expression, the protein levels of SIRT1 were also significantly elevated upon the activation of both BAs receptors (Figures 4C, D, F and G). Although FXR and TGR5 agonists did not increase the gene and protein expression of AMPK, they both promoted AMPK phosphorylation in IEC-6 cells (Figures 4C, E, F and H). These results indicate that the activated BA signaling pathway contributes to the upregulation of SIRT1 and the phosphorylation of AMPK.

DISCUSSION

In this study, we performed DJB and sham surgeries on diabetic rats induced by HFD and STZ, and demonstrated that DJB elevated intraduodenal TBAs, activated the BA signaling pathway and upregulated SIRT1 expression in the duodenal mucosa. By using specific BA receptor agonists, we proved that FXR and TGR5 activation increased SIRT1 expression and promoted phosphorylation of AMPK in rat small intestine epithelial cells, indicating that increased intraluminal BAs and activation of BA receptors contributed to the increased duodenal SIRT1 after DJB.

SIRT1 is an evolutionarily conserved NAD+-dependent deacetylase that belongs to the Sirtuins family (SIRT1-SIRT7)[22]. SIRT1 acts as a key metabolic sensor in the liver, skeletal muscles, adipose tissues, pancreatic islets, and other metabolic tissues. It plays an important role in various aging-related

diseases, including insulin resistance, diabetes, obesity, hepatic steatosis, and cardiovascular diseases [22,23]. Liver-specific deletion of SIRT1 impairs hepatic and systemic insulin sensitivity in mice[24]. Muscular SIRT1 levels are decreased in patients with T2DM and HFD-induced insulin-resistant rats, and overexpression of SIRT1 in skeletal muscle improves muscular insulin sensitivity[25,26]. Adipose tissue-specific ablation of SIRT1 results in increased fat deposition, impaired glucose tolerance and insulin sensitivity in mice[27]. SIRT1 activation protects the function and morphology of residual pancreatic β-cells and induces β-cell regeneration from progenitor cells, thus improving glucose homeostasis[28].

Sleeve gastrectomy (SG) upregulates hepatic SIRT1 and dramatically ameliorates hepatic steatosis in HFD-fed obese mice[29]. RYGB activates the AMPK/SIRT1/PGC-1α pathway in the skeletal muscle of diabetic Zucker fatty rats, which contributes to diabetes remission[30]. Laparoscopic bariatric surgery increases SIRT1 levels in the peripheral blood of patients with obesity and T2DM, which is higher in the effective than in the ineffective group[31]. The effects of bariatric surgeries on duodenal SIRT1 expression have not been investigated previously. Duodenal SIRT1 is a novel therapeutic target for insulin resistance and diabetes. HFD-fed insulin-resistant rats exhibit significantly downregulated SIRT1 in the duodenal mucosa, and duodenum-specific knockdown of SIRT1 is sufficient to induce hepatic insulin resistance in normal chow-fed rats[14]. Our study is the first to demonstrate that DJB promotes SIRT1 expression in the duodenal mucosa. As duodenal SIRT1 activation further inhibits HGP and improves hepatic insulin sensitivity by triggering the gut-hypothalamus-liver neural network[14], we postulate that increased duodenal SIRT1 at least partly accounts for the improved hepatic insulin resistance and glucose homeostasis after DJB.

As an indispensable energy sensor, SIRT1 expression is closely related to energy status and environmental stress[32]. The SIRT1 transcription is usually activated during fasting, which transforms the metabolic status from gluconeogenesis to fat mobilization and fatty acid oxidation[32]. Chen *et al*[33] demonstrated that calorie restriction (CR) increased both pancreatic and hepatic SIRT1 expression in rats. Additionally, Civitarese *et al*[34] reported that CR for 6 mo promoted muscular SIRT1 expression in healthy overweight individuals. In mammalian cells, acute nutrient deprivation increases SIRT1 transcription by activating the Forkhead transcription factor Foxo3a[35]. Although food intake is not reduced after DJB, the duodenum is hindered from contact with ingested food, which might result in a duodenum-specific CR status, thus further inducing duodenal SIRT1 expression. Furthermore, gastric acids are not expelled into the duodenum after DJB, which increases the pH of duodenal content. The deacetylation activity of SIRT1 is pH-dependent, and higher pH attenuates the inhibition of SIRT1 by nicotinamide[36].

Increased intraduodenal BAs might be another key contributor to elevated duodenal SIRT1 after DJB. It is well documented that circulating BAs are increased after numerous metabolic surgeries, including DJB, SG, and RYGB[3,37,38]. By using genetically modified animal models, it has been proven that both FXR and TGR5 are required for the metabolic benefits of SG[39,40]. As demonstrated by our study, DJB not only elevated serum TBAs, but also significantly increased intraduodenal TBAs. Similarly, Ueno *et al* [41] demonstrated that DJB increased conjugated BAs in the bypassed jejunum just distal to the ligament of Treitz. Furthermore, we observed higher SHP mRNA and cAMP concentrations in the duodenal mucosa of DJB-operated rats, indicating that FXR and TGR5 signaling were activated after DJB. Whether causality exists between activated BA signaling and increased SIRT1 in enterocytes has not been investigated.

Numerous studies have suggested that BAs serve as upstream signaling molecules for SIRT1 in various tissues. FXR activation upregulates SIRT1 expression by promoting the transcription of SHP and repressing the transcription of p53 and miR34a in the livers of normal mice[19]. In diabetic *db/db* mice, TGR5 activation increases both the mRNA and protein levels of SIRT1 in the kidneys[42]. Similarly, TGR5 activation upregulates SIRT1 expression in the brains of Sprague Dawley rats[20]. These studies suggest that activation of duodenal FXR and/or TGR5 might account for the increased duodenal SIRT1 after DJB. To verify our hypothesis, we used GW4064 and INT-777 to activate FXR and TGR5 in IEC-6 cells and showed that both agonists increased SIRT1 expression in enterocytes. We also found that GW4064 increased FXR gene expression in IEC-6 cells in accordance with the elevated FXR mRNA in the duodenal mucosa after DJB. Similar changes in FXR mRNA were also observed in mouse mesangial cells after GW4064 stimulation[43].

In addition, we demonstrated that DJB promoted phosphorylation of AMPK in the duodenal mucosa, which might also contribute to improved glucose homeostasis after DJB, as duodenal AMPK activation improves hepatic insulin sensitivity and inhibits hepatic glucose output *via* the gut-hypothalamus-liver neural axis[13]. Jiao *et al*[4] reported that DJB promoted phosphorylation of AMPK in both the liver and skeletal muscle, which contributed to the restoration of normoglycemia after surgery. Likewise, SG enhances AMPK phosphorylation in both the liver and monocytes[44]. Similarly, RYGB exhibits anti-diabetic properties *via* AMPK activation in the liver and Kupffer cells[45]. Actually, as two important energy sensors in cells, AMPK and SIRT1 mutually regulate each other, share many common target molecules, and have similar effects on diverse processes such as glucose and energy metabolism[46]. Our study suggests that activated duodenal AMPK might also be attributed to elevated duodenal BAs because both FXR and TGR5 activation promoted phosphorylation of AMPK in IEC-6 cells.

There are some limitations in our study. First, we only investigated changes in TBAs in the duodenum after DJB. There are numerous components in the BA pool, and different components may exert different metabolic effects. Second, our study did not provide sufficient information on whether

Figure 4 Activation of farnesoid X receptor and Takeda G-protein-coupled receptor 5 increased SIRT1 and promoted phosphorylation of AMPK in rat small intestine epithelial IEC-6 cells. A and B: Effects of farnesoid X receptor (FXR) and Takeda G-protein-coupled receptor 5 (TGR5) activation on SIRT1, AMPK, and key genes involved in BA signaling pathway; C: Western blot images of SIRT1, phosphorylated AMPK (p-AMPK), and total AMPK (t-AMPK) in IEC-6 cells after FXR activation; D and E: The relative intensity of SIRT1 and p-AMPK/t-AMPK in IEC-6 cells after FXR activation. F: Western blot images of SIRT1, p-AMPK, and t-AMPK in IEC-6 cells after TGR5 activation; G and H: The relative intensity of SIRT1 and p-AMPK/t-AMPK in IEC-6 cells after TGR5 activation. $^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$ GW4064 or INT-777 *vs* control group. p-AMPK: Phosphorylated AMPK; t-AMPK: Total AMPK; FXR: Farnesoid X receptor; SHP: Small heterodimer partner; TGR5: Takeda G-protein-coupled receptor 5.

duodenal SIRT1 is indispensable for DJB-induced diabetic control, therefore, duodenum-specific SIRT1 loss- and gain-of-function animal models would be necessary for future studies.

CONCLUSION

DJB upregulates SIRT1 expression in the duodenal mucosa, which may partly account for surgery-induced diabetic control. Increased intraduodenal TBA levels and activated duodenal BA signaling pathway may contribute to the upregulation of duodenal SIRT1 after DJB.

ARTICLE HIGHLIGHTS

Research background

Duodenal-jejunal bypass (DJB) induces rapid and significant amelioration of type 2 diabetes mellitus in various diabetic rat models, while the mechanisms have not been fully elucidated. Duodenal SIRT1

regulates hepatic glucose production and hepatic insulin sensitivity through a gut-brain-liver axis, and activation of bile acid (BA) receptors promotes SIRT1 expression in many tissues. This study aimed at uncovering the roles of duodenal BAs and SIRT1 in the diabetic control after DJB.

Research motivation

To expand and deepen our understanding on the mechanisms underlying diabetes control after DJB, and to provide new ideas and targets for the non-surgical treatment of diabetes in the future.

Research objectives

To investigate the effects of DJB on the duodenal BA signaling pathway and SIRT1 expression in a diabetic rat model, and further reveal the roles of BAs in modulating SIRT1 expression in enterocytes.

Research methods

DJB and sham surgeries were performed on rats with diabetes induced by high-fat diet and low-dose streptozotocin. The effects of surgeries on metabolic parameters were compared accordingly. The intraduodenal BA concentration, the key genes of BA signaling pathway and SIRT1 in the duodenal mucosa were evaluated 8 wk postoperatively. Rat small intestine epithelial IEC-6 cells were treated with GW4064 and INT-777 to verify the effects of BA receptor activation on SIRT1 expression in enterocytes.

Research results

DJB rapidly and dramatically improved glucose homeostasis in the diabetic rats independently of body weight and food intake. DJB increased both systemic and intraduodenal total BAs, activated the BA signaling pathway and promoted SIRT1 expression in the duodenum mucosa. Activation of BA receptors including farnesoid X receptor and Takeda G-protein-coupled receptor 5 increased the mRNA and protein expression of SIRT1 in IEC-6 cells.

Research conclusions

DJB increases intraduodenal BA levels and activates the duodenal BA signaling pathway, which may further contribute to the improved hepatic insulin resistance and glucose homeostasis by upregulating SIRT1 expression in the duodenal mucosa.

Research perspectives

Our findings provide evidence that BA-mediated upregulation of SIRT1 in the duodenum contributes to the diabetic control after DJB. This study also implicates that duodenal BAs and SIRT1 might be potential targets for improving hepatic insulin sensitivity and systemic glucose homeostasis, which lays the groundwork for developing duodenal BA and SIRT1-specific treatments to alleviate diabetes.

Abstract

BACKGROUND

Hepatic alveolar echinococcosis (AE) is most commonly found in retrohepatic inferior vena cava (RHIVC). *Ex vivo* liver resection and autotransplantation (ELRA) can better realize the radical resection of end-stage hepatic AE with severely compromised hepatocaval confluences, and reconstruction of the affected vessels. Currently, there is a scarcity of information regarding RHIVC reconstruction in ELRA.

AIM

To propose reasonable RHICV reconstruction strategies for *ex vivo* liver resection and autotransplantation.

METHODS

We retrospectively summarized the clinical data of 114 patients diagnosed with hepatic AE who treated by ELRA in our department. A total of 114 patients were

divided into three groups according to the different reconstruction methods of RHIVC: Group A with original RHIVC being repaired and reconstructed (n = 64), group B with RHIVC being replaced (n = 43), and group C with RHIVC being resected without reconstruction (n = 7). The clinical data of patients, including the operation time, anhepatic phase, intraoperative blood loss, complications and postoperative hospital stay, were analyzed and the patients were routinely followed up. The normally distributed continuous variables were expressed as means ± SD, whereas the abnormally distributed ones were expressed as median and analyzed by analysis of variance. Survival curve was plotted by the Kaplan-Meier method.

RESULTS

All patients were routinely followed up for a median duration of 52 (range, 12-125) mo. The 30 d mortality rate was 7.0% (8/114) and 7 patients died within 90 d. Among all subjects, the inferior vena cava (IVC)-related complication rates were 17.5% (11/63) in group A and 16.3% (7/43) in group B. IVC stenosis was found in 12 patients (10.5%), whereas thrombus was formed in 6 patients (5.3%). Twenty-two patients had grade III or higher complications, with the complication rates being 17.2%, 16.3%, and 57.1% in the three groups. The average postoperative hospital stay in the three groups was 32.3 ± 19.8, 26.7 ± 18.2, and 51.3 ± 29.4 d (P = 0.03), respectively.

CONCLUSION

ELRA can be considered a safe and feasible option for end-stage hepatic AE patients with RHIVC infiltration. The RHIVC reconstruction methods should be selected appropriately depending on the defect degree of AE lesions in IVC lumen. The RHIVC resection without any reconstruction method should be considered with caution.

Core Tip: We retrospectively summarized and analyzed the clinical data of 114 patients diagnosed with hepatic alveolar echinococcosis (AE) treated by *ex vivo* liver resection and autotransplantation (ELRA) in our department between August 2010 and December 2020. This study is the first and largest cohort to specifically compare the different inferior vena cava (IVC) reconstruction methods in ELRA. We present a more quantitative IVC reconstruction strategy for end-stage hepatic AE patients with retrohepatic IVC infiltration based on the outcomes of this study and our experience.

INTRODUCTION

Echinococcosis is an infectious zoonotic parasitic disease[1,2]. Notably, 90% of the global burden of this disease occurs in China, and echinococcosis has been a major public health problem in the Northwestern area of China[3,4]. Hepatic alveolar echinococcosis (AE) has been considered invasive growth and systematic metastasis[5,6], but its insidious onset and slow progression usually contribute to the delayed diagnosis. The mortality rate within 10 years after diagnosis is over 90% if the lesion is inadequately or not treated[7-9]. To date, radical surgery combined with albendazole treatment has been considered the best option for AE patients[10,11]. However, it is difficult to perform radical hepatectomy *in vivo* when AE lesion invades the hepatocaval confluence[12]. Generally, only 35%-40% of patients can be treated with conventional radical resection[7]. Fortunately, *ex vivo* liver resection and autotransplantation (ELRA) can better realize the radical resection of end-stage hepatic AE with severely compromised outflow tract, and reconstruction of the affected vessels[13].

Retrohepatic inferior vena cava (RHIVC) is often severely invaded by AE lesions, and resection of the invaded duct segment often presents a variety of irregular shapes, resulting in different inferior vena cava (IVC) reconstruction methods and the complex process. Proper RHIVC reconstruction may simplify graft liver implantation, which is a key element to postoperative recovery. To the best of our

knowledge, there have been few studies on the reconstruction of IVC in ELRA worldwide[14,15], and no clear consensus has been reached on the optimal strategy. This research reported our experience with 114 hepatic AE patients using different IVC reconstruction methods in ELRA. This is the study with the largest sample size to date, which provides a quantitative strategy of IVC reconstruction for end-stage hepatic AE patients with RHIVC infiltration.

MATERIALS AND METHODS

Patients

A total of 114 patients with end-stage hepatic AE who received ELRA at the First Affiliated Hospital of Xinjiang Medical University between August 2010 and December 2020 were retrospectively analyzed. All patients were divided into three groups: Group A was the repaired and reconstructed group (n = 64) that sought reconstruction of the original RHIVC by self-suture or vascular patch, group B was the RHIVC replacement group (n = 43) that completely replaced the RHIVC with substitute vessels, and group C was the RHIVC resection without reconstruction group (n = 7) that excised the invaded RHIVC segment without reconstruction (Table 1).

Medical ethical approval

This study was approved by the Ethics Committee of First Affiliated Hospital of Xinjiang Medical University and conducted in accordance with the Helsinki Declaration[16]. Written and signed informed consent was obtained from all patients or their legal custodians.

Preoperative assessment

All subjects underwent comprehensive preoperative evaluation, including abdominal computed tomography angiography (CTA) and hepatic magnetic resonance imaging, to assess the location of the lesion, the extent of vessel and bile duct involvement. For patients whose CTA results suggested RHIVC severe stenosis or occlusion, IVC digital subtraction angiography was also performed. The predicted autograft liver mass (GLM) was detected by a three-dimensional reconstruction system.

Surgical procedures

More details of the ELRA procedures are reported in our previous study[13]. Here, we focused on the reconstruction of IVC. First, we ligated and resected the IVC between the upward side of the confluence of three hepatic veins and the site at 1 cm above the confluence of renal vein, and removed it together with the liver. Then the RHIVC was reconstructed *in vitro* individually depending on the defect of lumen wall after radical resection of AE lesion. When the defect was less than 120° of the lumen circumference, it was considered that directly suturing the defect of wall did not affect vascular tension or patency, and thus self-suture repair was performed. When the defect was more than 120° of the circumference, we repaired the lumen defect with vascular patches such as ligamentum teres hepatis and internal jugular veins, because direct suturing might lead to stenosis in this case. Moreover, the RHIVC was replaced in patients with extensive defect and being unable to obtain adequate vascular patches. The hepatic veins of autograft liver were anastomosed with an alternative vessel. In this case, the position and angle of anastomosis were relatively freely controlled, which facilitated the increased reflux of hepatic outflow and further improved the recovery of autograft liver function (Figure 1).

Uniquely, for some patients in this study, the preoperative CTA and IVC venography showed that the RHIVC segment was completely occluded, and suitably compensated by the collateral branches. During the operation, we further verified whether the RHIVC was completely occluded and whether the collateral circulation was sufficient. Finally, for the 7 patients, the AE infiltrated segment of IVC was resected without any reconstruction, the proximal end of IVC was anastomosed with autogenous hepatic vein, and the distal end was closed directly (Figure 1).

Postoperative management and follow-up

After surgery, all patients received systemic anticoagulant therapy. Low-molecular-weight heparin was used in the 1st week, and prothrombin time (PT) and international normalized ratio (INR) were closely observed. In the 2nd week, oral tablets were substituted, and patients in group A and group C were recommended to withdraw these drugs 1 mo later when the PT and INR returned to normal levels. Patients in group B, however, needed to continue the medication for a long term and closely observe the coagulation index regularly. Each patient was regularly followed up, and serological tests, liver function tests and CTA scans were performed every 3-6 mo after discharge. Postoperative complications were assessed according to the Clavein-Dindo classification system[17]. All patients were administered with albendazole (10 mg/kg/d) routinely for 2 years[18].

Statistical analyses

The statistical software IBM SPSS 22.0 (IBM Corp, Armonk, NY, United States) was used for data

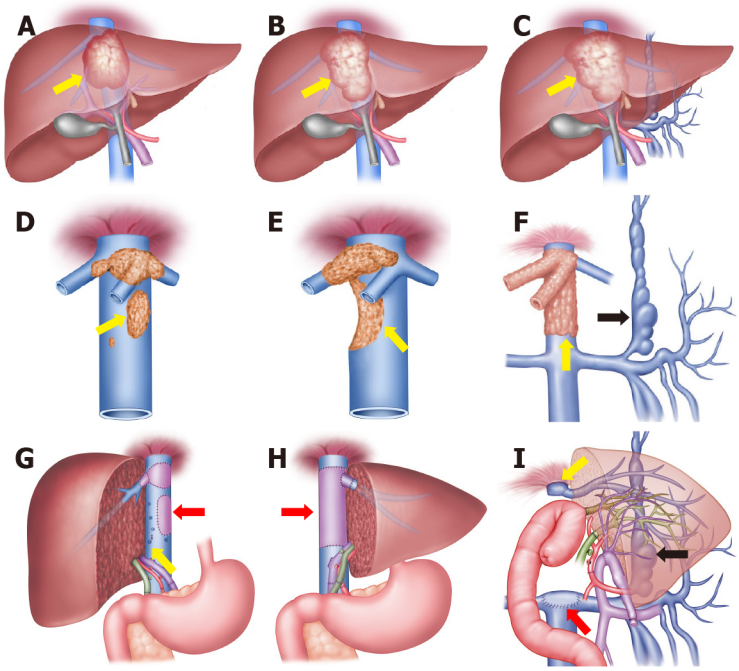
RESULTS

Patient characteristics

Altogether 114 patients were treated by ELRA, including 50 males (43.9%) and 64 females (56.1%), with an average age of 36.2 ± 11.8 (range, 15-64) years. Preoperative PTCD or ERCP was performed in 25 patients to reduce the bilirubin levels and biliary obstructions. There were 21 patients with a previous history of hepatectomy. Albendazole therapy was administered to 27 patients. The average GLM was 828.3 ± 250.8 g. There were no significant differences in basic clinical data among the three groups ($P > 0.05$; Table 1).



Intraoperative outcomes

Intraoperative reassessment confirmed that AE lesions invaded the RHIVC in all patients, and RHIVC repair or reconstruction was needed. Among them, the self-suture repairing was performed in 52 patients with a defective RHIVC lumen less than 120° of circumference after R0 resection. The lumen defect was repaired with autologous vascular patches in 12 patients whose defect was 120°-180° of wall circumference. Meanwhile, 43 patients had defect exceeding 180° of circumference with extensive range and difficulty in reestablishing with autogenous patches. For these cases, the RHIVC was replaced with artificial vascular grafts ($n = 38$) or allogeneic vascular ($n = 5$). In another 7 patients, preoperative imaging examination indicated that the RHIVC segment was occluded and a collateral circulation network was formed. During the operation, stable systemic hemodynamics with no obvious intestinal congestion was found after the IVC was ligated. Finally, the RHIVC was resected without reconstruction (Figure 2). The average operation time was 16.7 ± 2.9 h for group A, 15.5 ± 3.1 h for group B, and 16.9 ± 4.1 h for group C ($P = 0.56$), and the average anhepatic phase was 418.4 ± 108.3, 383.9 ± 117.0, and 337.4 ± 108.7 min in groups A, B and C ($P = 0.41$; Table 2).

Postoperative and follow-up outcomes

All patients were followed up with a median duration of 52 (range, 12-125) mo, except for 1 patient who was lost to follow-up at 6 mo after the operation. No intraoperative death occurred. The 30 d mortality rate was 7.0% (8/114) and another 7 patients died within 90 d (15/114). Among all subjects, the IVC-related complication rates were 17.5% (11/63) in group A and 16.3% (7/43) in group B. IVC stenosis was found in 12 patients (10.5%), and thrombus was formed in 6 patients (5.3%). Twenty-two patients experienced grade III or higher complications according to the Clavin-Dindo classification system, and the complication rates were 17.2%, 16.3% and 57.1%, in the three groups (Table 3). The average

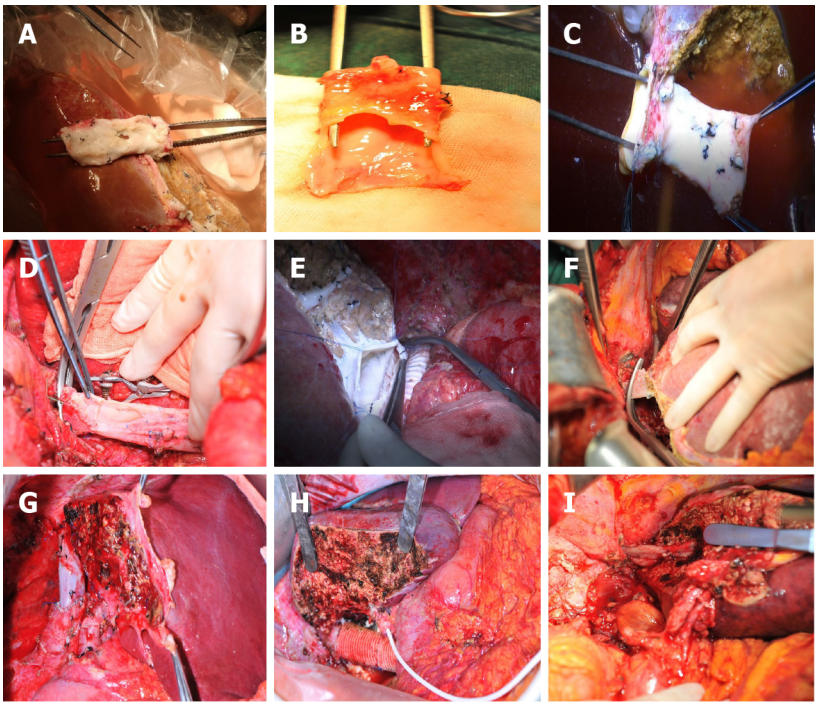
postoperative hospital stay was 32.3 ± 19.8 d for group A, 26.7 ± 18.2 d for group B and 51.3 ± 29.4 d for group C (P = 0.03). Obviously, patients in group B obviously required a shorter postoperative hospital stay than the other two groups.

Kaplan-Meier survival analysis curve and log-rank test were used to observe the postoperative survival for the three groups based on the follow-up results. The survival rates of group A and group B were quite close, whereas that of group C was lower, but the differences were not statistically significant (P = 0.81). The early periods after surgery, especially in the 1st month, witnessed the high mortality rate (Figure 3).

DISCUSSION



Hepatic AE is also known as "parasitic cancer," which is ascribed to its tumor-like characteristics with infiltration of vessels or biliary structures and distant metastasis[19]. The insidious onset and slow progression of AE usually contribute to the delayed diagnosis, and hepatic veins and RHIVC are often invaded by the time when treatment is sought in more than half of the patients, thus depriving them of the opportunity for traditional surgical resection[20,21]. In 1986, the Liver Transplantation Center of Bezancon Hospital in France was the first to report allogeneic liver transplantation (ALT) for an end-stage hepatic AE patient[22]. Since then, more successful clinical cases and treatment experience with liver transplantation for end-stage hepatic AE have been reported worldwide[23-26]. However, a shortage of donor livers and a significant recurrence rate have limited the further development of ALT for hepatic AE[24,27]. In 2010, our center first applied ELRA to manage a patient with end-stage hepatic AE[28]. Compared with ALT, this technique requires no graft donor or immunosuppressive treatment, and is more affordable[29,30]. In particular, it is more suitable for patients with severe invasion of RHIVC and intrahepatic veins whose are unresectable by traditional surgical methods. Notably, the corresponding reconstruction of autograft liver RHIVC remains the most challenging step in the ELRA procedures, since no uniform fixed pattern is available and individual design is required. To date, very few studies have investigated the reconstruction of IVC in ELRA worldwide (Table 4), and no clear consensus has been reached on the optimal reconstruction strategy. In this study, we analyzed the largest series of end-stage hepatic AE cases with seriously infringed RHIVC who received ELRA treatment, and discussed the safety and effectiveness of three different IVC reconstruction methods.

Reconstruction options for the RHIVC are assessed individually from preoperative evaluation and intraoperative reassessment of vascular defect. In our center, the repairing and reconstruction method was used when the defect in the RHIVC was less than 180° of the lumen circumference after radical resection of the lesion. The average operation time and anhepatic phase of this pattern were relatively

longer than the other two methods, which was attributed to the diversity and complexity of this approach. RHIVC stenosis occurred in 10 patients, but only 1 developed lower limb edema, and the symptoms disappeared after balloon dilation. Meanwhile, no clinical symptoms were found in the other 9 patients. It seemed that IVC stenosis after surgery might be related to the longer cold ischemia time and tunica intimal injury during the reconstruction process. In this regard, strict management of the

Figure 3 Kaplan-Meier survival analysis curve.

reconstruction time and shortening the cold ischemia phase as much as possible are the key factors for preventing IVC stenosis[31]. Based on previous reports[32,33] and our experience, the ligamentum teres hepatis is applied most often as a vascular patch, due to its convenience and strong plasticity. Postoperative patency and prognosis of these patients are satisfactory, suggesting that reconstruction with autogenous materials may be the optimal choice for RHIVC, although the process is complex and demanding.

Generally, replacement of the RHIVC is indicated for patients those with a large defect after resection that cannot be repaired by suture or patch. In the present study, 38 patients had the RHIVC replaced with artificial vessels, and 5 were treated with the cryopreserved allogeneic vascular donated after citizen death (DCD). Due to the shortage of resources, rejection, high preservation requirements and time restrictions, DCD vessels are not the first choice for substitute material. In our center, the expanded polytetrafluoroethylene artificial vessel (Sokang Corp, Shanghai, China)[34] is generally preferred. RHIVC replacement with artificial vascular is not only convenient, but also effectively shortens the anhepatic phase and operation time. On the other hand, artificial vessels are associated with potential risk, including venous thrombosis, artificial vascular malformation, and distortion or stenosis of anastomoses caused by postoperative liver hyperplasia. In our research, thrombosis of artificial vessels occurred in 5 patients, among them, 2 died of liver failure due to simultaneous thrombosis of the IVC and portal vein. Another 3 patients developed lower limb or scrotal edema, and the symptoms recovered after symptomatic treatments, including thrombolysis and anticoagulation. In addition, stenosis of anastomoses was found in 2 patients. As there may not be any clinical means for decreasing the incidence of graft thrombosis and stenosis apart from anti-coagulation and anti-infective treatment, we recommend that replacement of RHIVC with artificial materials should be avoided when it can be reestablished with autogenous materials.

Hepatic AE behaves like a slow-growing "warm cancer," and occlusion and severe stenosis of the IVC is a chronic process, which provides sufficient time for the establishment of collateral circulation. The obstructed blood flow can induce expansion of lumbar vein plexus, azygos vein and hemiazygos vein on both sides of the spine, as well as the formation of a functional collateral circulation network[32] Although the extent of vascular invasion is a vital indicator for the choice of reconstruction method, it remains controversial whether the IVC should be reconstructed for patients with adequate collateral circulation. Blair *et al*[35] proposed that, for low-grade retroperitoneal sarcoma, resection without reconstruction was performed after the establishment of collateral circulation. In addition, Hardwigse *et al*[36] also reported IVC resection without reconstruction in 6 patients with hepatic carcinoma. Unlike malignant tumors, the parasite grows relatively slow, which provides enough time for the organism to form collateral circulation. Among our subjects, 7 received RHIVC resection without reconstruction, since a sufficient collateral path was formed, but the outcomes were unsatisfactory. To be specific, postoperative complications occurred in all 7 patients, and their survival rate was only 71.1%. One patient died of liver failure on the 14th day after operation, and another one died of multiple organ failure caused by severe abdominal infection on the 38th day after operation. There is little previous information available concerning resection without reconstruction of the RHIVC in ELRA (Table 4). Before this study, Du *et al*[37] reported 8 patients receiving IVC resection without reconstruction, thus supporting this approach from the most reported cases at that time. In their subjects, 1 patient died of upper gastrointestinal bleeding, and 3 developed lower extremity or scrotal edema. Comparatively, the complication rate and postoperative hospital stay in our study were relatively high, which might be related to the immature collateral circulation or pathway destruction by excessive traction of diaphragm. It cannot be determined whether these poor outcomes are related to not providing reconstruction, and more studies are needed for further elucidation. To be sure, a comprehensive preoperative evaluation system and a meticulous intraoperative procedure are essential to the success of this method.

Figure 4 Strategy for retrohepatic inferior vena cava reconstruction in *ex vivo* liver resection and autotransplantation. CTA: Computed tomography angiography; D represents the defect of retrohepatic inferior vena cava lumen after resection; DSA: Digital subtraction angiography; RHIVC: Retrohepatic inferior vena cava.

Surgical planning based on a reasonable strategy can improve the success rate of operation and reduce related complications. In this study, although adverse outcomes were not entirely avoided, the postoperative complications and prognosis were acceptable, showing that our approaches were relatively safe and effective on end-stage hepatic AE with infiltrating outflow vessels of the liver. Based on the outcome of the present study and our experience, the following strategies are recommended for IVC reconstruction in hepatic AE patients treated by ELRA: (1) When the wall defect of the IVC after radical resection is less than 120° of the lumen circumference, the self-suture method can be used; (2) If the defect is 120°-180° of circumference, repair with autogenous vascular patches is the optimal choice; (3) When the defect has exceeded 180° of circumference and is difficult to repair by autologous patches, the RHIVC should be replaced. However, the strict anticoagulation therapy must be provided postoperatively; and (4) The RHIVC resection without reconstruction approaches are suitable when the IVC is completely blocked and the collateral circulation is fully formed (Figure 4). Although this study reports a retrospective single-center experience, it is also the largest cohort to specifically compare the different IVC reconstruction methods in ELRA, which can serve as a reference for IVC reconstruction in liver transplantation.

CONCLUSION

In short, ELRA can be considered a safe and feasible option for the end-stage hepatic AE patients with RHIVC infiltration. The RHIVC reconstruction approaches should be selected appropriately according to the lumen defect degree after radical resection. It should be emphasized that RHIVC resection without reconstruction should be considered with caution, and RHIVC reestablishment may be more beneficial for patients with poor compensation. Regrettably, the strategy does not consider the length of the wall defect, since it is related to the location, angle, elasticity and tension of the vessel, all of which are hard to be quantified without a larger dataset of cases. Therefore, prospective, multicenter studies with long-term follow-up are necessary to further evaluate and improve the strategy presented here.

ARTICLE HIGHLIGHTS

Research background

Ex vivo liver resection and auto-transplantation (ELRA) can better realize the radical resection of end-stage hepatic alveolar echinococcosis (AE) with severely compromised hepatocaval confluences, and the

reconstruction of the affected vessels.

Research motivation

There are no clear consensus has been reached on the strategy for retrohepatic inferior vena cava (RHIVC) reconstruction in ELRA.

Research objectives

To provide a strategy of RHIVC reconstruction for end-stage hepatic AE patients with hepatocaval confluence infiltration.

Research methods

The clinical data of 114 patients, including the operation time, anhepatic phase, intraoperative blood loss, complications and postoperative hospital stay, were analyzed and the patients were routinely followed up.

Research results

We found a lower survival rate in group C (resection without reconstruction method) than in groups A (self-suture repairing method) and B (replacement method). Also, the complications rate was higher in group C.

Research conclusions

The RHIVC reconstruction methods should be selected appropriately depending on the defect degree of AE lesions in IVC lumen.

Research perspectives

Our strategies can serve as a reference for IVC reconstruction in liver transplantation.

Abstract

BACKGROUND

The biological behavior of carcinoma of the esophagogastric junction (CEGJ) is different from that of gastric or esophageal cancer. Differentiating squamous cell carcinoma of the esophagogastric junction (SCCEG) from adenocarcinoma of the esophagogastric junction (AEG) can indicate Siewert stage and whether the surgical route for patients with CEGJ is transthoracic or transabdominal, as well as aid in determining the extent of lymph node dissection. With the development of neoadjuvant therapy, preoperative determination of pathological type can help in the selection of neoadjuvant radiotherapy and chemotherapy regimens.

AIM

To establish and evaluate computed tomography (CT)-based multiscale and multiphase radiomics models to distinguish SCCEG and AEG preoperatively.

METHODS

We retrospectively analyzed the preoperative contrasted-enhanced CT imaging data of single-center patients with pathologically confirmed SCCEG (n = 130) and AEG (n = 130). The data were divided into either a training (n = 182) or a test group (n = 78) at a ratio of 7:3. A total of 1409 radiomics features were separately

extracted from two dimensional (2D) or three dimensional (3D) regions of interest in arterial and venous phases. Intra-/inter-observer consistency analysis, correlation analysis, univariate analysis, least absolute shrinkage and selection operator regression, and backward stepwise logical regression were applied for feature selection. Totally, six logistic regression models were established based on 2D and 3D multi-phase features. The receiver operating characteristic curve analysis, the continuous net reclassification improvement (NRI), and the integrated discrimination improvement (IDI) were used for assessing model discrimination performance. Calibration and decision curves were used to assess the calibration and clinical usefulness of the model, respectively.

RESULTS

The 2D-venous model (5 features, AUC: 0.849) performed better than 2D-arterial (5 features, AUC: 0.808). The 2D-arterial-venous combined model could further enhance the performance (AUC: 0.869). The 3D-venous model (7 features, AUC: 0.877) performed better than 3D-arterial (10 features, AUC: 0.876). And the 3D-arterial-venous combined model (AUC: 0.904) outperformed other single-phase-based models. The venous model showed a positive improvement compared with the arterial model (NRI > 0, IDI > 0), and the 3D-venous and combined models showed a significant positive improvement compared with the 2D-venous and combined models ($P < 0.05$). Decision curve analysis showed that combined 3D-arterial-venous model and 3D-venous model had a higher net clinical benefit within the same threshold probability range in the test group.

CONCLUSION

The combined arterial-venous CT radiomics model based on 3D segmentation can improve the performance in differentiating EGJ squamous cell carcinoma from adenocarcinoma.

Core Tip: In this study, multiscale and multiphase computed tomography (CT)-based radiomics models were constructed and evaluated to discriminate squamous cell carcinoma and adenocarcinoma of the esophagogastric junction (CEGJ) before operation. The results demonstrated that the combination of multiphase 3D CT radiomics features could improve the differentiation performance than 2D CT radiomics or single-phase-based radiomics. Therefore, radiomics method could help open up a new field for noninvasive diagnosis and personalized management of CEGJ.

INTRODUCTION

Carcinoma of the esophagogastric junction (CEGJ) is defined as a carcinoma whose center is located within 5 cm above and below the esophagogastric anatomical junction and crosses the esophagogastric junction (EGJ). Due to the short and narrow EGJ site and the up-and-down invasive nature of the CEGJ, its biological behavior is different from that of gastric or esophageal cancer[1-3]. The Siewert staging, which is widely accepted in academia, classifies CEGJ into types I, II, and III based on the distance between the tumor center and the EGJ[4]. Because of the infiltrative growth pattern of the tumor, the distance between the tumor center and the EGJ in CEGJ is difficult to measure accurately, and Siewert staging is often not easy to determine directly. Squamous cell carcinoma of the esophagogastric junction (SCCEG) has different clinicopathological features from adenocarcinoma of the esophagogastric junction (AEG). Based on the results from previous research, mediastinal lymph node metastases are more likely to occur in SCCEG above the EGJ, whereas metastases from the AEG under the EGJ probably appear in the abdomen[5,6]. Differentiating SCCEG from AEG can indicate Siewert stage and whether the surgical route for patients with CEGJ is transthoracic or transabdominal, as well as aid in determining the extent of lymph node dissection. With the development of neoadjuvant therapy,

preoperative determination of pathological type can help in the selection of neoadjuvant radiotherapy and chemotherapy regimens.

Clinically, medical imaging plays a supporting role in pathological classification and tumor staging. Conventional computed tomography (CT), magnetic resonance imaging, and positron emission tomography rely primarily on the visual assessment of the imaging physician and have limitations in early identification of the pathological type of CEGJ. Although histological biopsies are commonly used in clinical practice, some patients have contraindications or low tolerance, and the biopsy sample is limited to the mucosal surface, which may provide an inadequate assessment of the entire tumor status [7]. Therefore, it is important to explore a reliable, practical, and non-invasive preoperative histological staging method for CEGJ, which is clinically important for neoadjuvant radiotherapy, surgical approach selection, and lymph node dissection in CEGJ patients. Radiomics technique uses a combined medical-industrial approach to transform traditional images into digital quantitative features, which has potential for digging the potential biological characteristics and heterogeneity of tumor images and has been widely and non-invasively used in the diagnosis, differential diagnosis, and disease evaluation[8-12]. Radiomics technique has also been studied in the differential diagnosis of squamous lung cancer and adenocarcinoma[13,14]. However, it is still unclear whether radiomics features extracted from CT images would be useful in predicting pathological type in patients with CEGJ.

Both of two-dimensional (2D) cross section or three-dimensional (3D) volume in CT images could be delineated for radiomics feature extraction. The reported radiomics-based gastric cancer studies have either utilized 2D or 3D segmentation[12,15]. However, it remains unclear whether to apply 2D or 3D regions of interest (ROIs) for pathological typing. The selection of 2D or 3D ROIs for outlining can influence radiomics feature values, feature stability, feature screening, and discriminative model performance[16-18]. And the controversy still exists for the performance of diagnosis or prognosis between 2D and 3D radiomics in tumor[16-18].

Therefore, in the current study, we aimed to construct and evaluate the multiscale and multiphase CT-based radiomics to discriminate SCCEG and AEG. The developed CT-based models might provide assistance in the personalized and precise treatment of clinical CEGJ patients, especially in the selection of surgical approach and determination of the extent of lymph node dissection.

MATERIALS AND METHODS

Patient selection

With institutional review board approval (ethical approval number: 2021-ky-1070-002) and waiver of the written informed consent, we retrospectively collected patients with SCCEG confirmed by gastroscopy and surgical pathology at the First Affiliated Hospital of Zhengzhou University from January 2010 to June 2021. The patient enrollment criteria included: (1) CT-enhanced abdominal examination within 30 d before surgery; (2) Complete clinicopathological data available; (3) The lesion covers at least 3 slices on CT cross section, and the maximum plane diameter is not less than 2 cm; and (4) No neoadjuvant chemoradiotherapy prior to CT examination. The exclusion criteria included: (1) Patient's history of other malignant tumors in combination; (2) Poor CT image quality or lack of raw DICOM data; and (3) Combined heart, lung, and other important organ dysfunction which could not allow CT examination to be performed. Finally, 130 patients with SCCEG were included, including 87 males and 43 females, aged 38-89 (65.72 ± 8.84) years, with a disease duration of 5 d to 4 years and main symptoms of dysphagia, obstructive sensation of eating, and abdominal pain. Another 130 patients with AEG who were matched with the SCCEG patients were also recruited, including 93 males and 37 females, aged 31-83 (62.95 ± 9.91) years.

CT image acquisition

Informed consent forms were signed before all patients underwent contrast-enhanced CT scans. CT scans were acquired using a 64-row CT scanner (GE Healthcare, Discovery CT 750 HD, United States) or 256-row CT scanner (GE Healthcare, Revolution CT, United States). Preparation for the examination: fasting for more than 8 h before the examination, intramuscular injection of scopolamine 10-20 mg 15-20 min before the examination to reduce gastrointestinal motility (Hangzhou Minsheng Pharmaceutical PG Roup Co., Ltd. Specifications: 10 mg/mL), and perform breath-holding exercises. Drink 800-1 000 mL of warm water 10 to 15 min before the examination. Scanning parameters: tube voltage 120 kV, tube current using automatic milliampere second technology, pitch 1.375/1.1; field of view (FOV) of 500 mm; 512 mm x 512 mm matrix, scan thickness 0.625mm to 5 mm, scan spacing 0.625mm to 5mm. Scan area: at least encompasses the lower esophagus to the lower border of both kidneys. Enhancement scan: 90-100 mL of non-ionic contrast agent was injected through the elbow vein using a high-pressure syringe (GE Medical Systems, iopromide, 370 mg/mL).

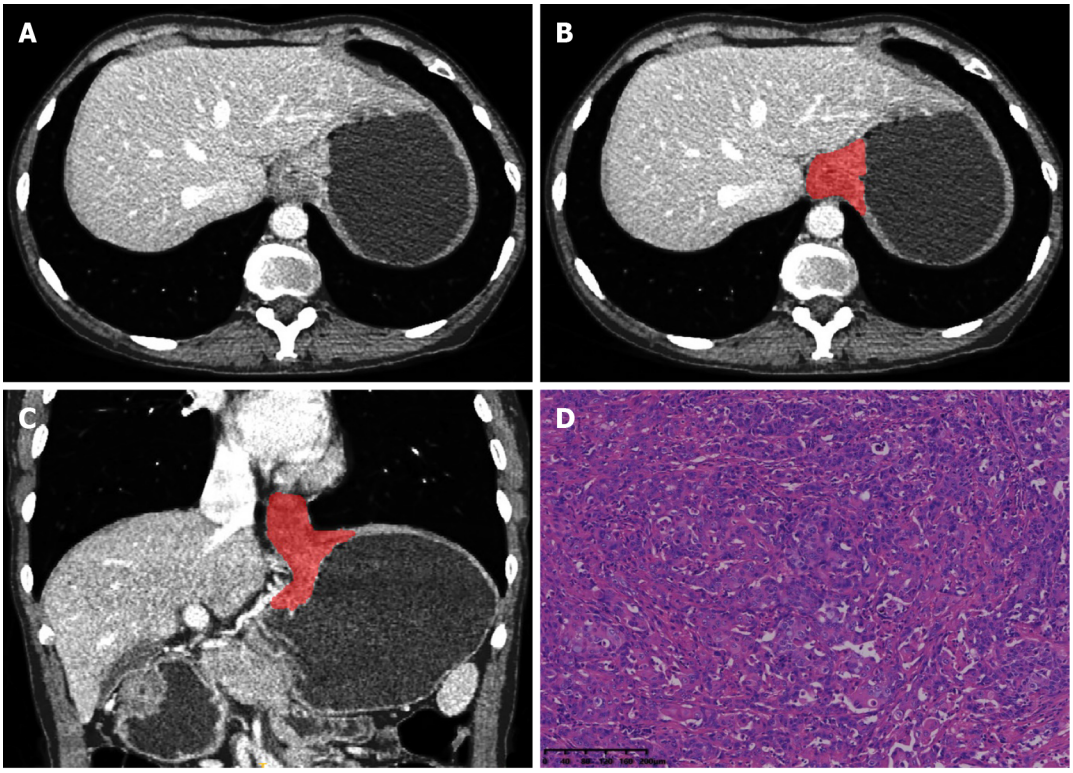
Image processing and segmentation

The arterial- and venous-phase CT images were isotropically resampled with a voxel size of 1 mm × 1 mm × 1 mm by using the trilinear interpolation in the Artificial Intelligence Kit software (A.K, version:

3.3.0.R, GE Healthcare, United States), in order to minimize the effect of different scanning protocols or equipment on quantitative inhomogeneity of histological features[19]. 2D ROIs were outlined along the largest cross-sectional area in the axial plane of CT images. After delineating the tumor cross-sectional area slice-by- slice in the axial plane, 3D ROIs were finally merged into volume of interest (VOI) (Figures 1 and 2). Care should be taken to avoid the gastric cavity and stomach contents, fatty tissue around the stomach wall, and blood vessels when segmenting. The 2D ROI or 3D VOI delineation was conducted by a radiologist (Chen YJ, 6 years of experience in imaging diagnosis). In order to ensure the reliability and reproducibility of the radiomics features, 30 patients were randomly selected to be segmented in a 2D and 3D manner. For inter-observer agreement analysis, when the radiologist (Chen YJ) conducted the first-time whole-dataset segmentation, another radiologist (Huang WP, 7 years of experience in imaging diagnosis) delineated the selected 30 patients at the same period. For intra-observer agreement analysis, the radiologist (Chen YJ) repeatedly conducted the segmentation 1 mo after the first-time delineation.

Radiomics feature extraction

The 2D or 3D radiomics features were extracted with open-source Python package Pyradiomics[20]. There were respectively 1409 radiomics features extracted from 2D or 3D ROIs in the arterial or venous phase. The original images and the transformed images based on different filters were mainly used for feature extraction. A total of 107 features were extracted from the original images, including 18 intensity statistical and 14 shape-based features. There were 75 textural features extracted from Gray Level Cooccurrence Matrix (GLCM), Gray Level Run Length Matrix (GLRLM), Gray Level Size Zone Matrix (GLSZM), Gray Level Dependence Matrix (GLDM), and Neighboring Gray Tone Difference Matrix (NGTDM). In addition, the same number of first-order grayscale statistical features and texture features were extracted based on different transformed images. A total of 744 features were extracted based on wavelet decomposition images with eight filter channels, 279 features were extracted based on Laplacian of Gaussian (LoG) transform images (sigma parameters selected as 1.0 mm, 3.0 mm, and 5.0 mm), and 279 features were extracted based on Local Binary Pattern (LBP) filtered images (2^{nd} order spherical harmonic function, spherical neighborhood operator with radius 1.0 and fine fraction 1)[20]. The features were extracted by discretizing the CT values within the ROIs based on a fixed interval width (bin width = 25 HU). The 2D and 3D radiomics features extracted from the randomly selected patients were used to calculate the intra-/inter-class correlation coefficients (ICCs). 2D or 3D features with intra- and inter-observer ICC values simultaneously greater than 0.75 were retained, which meant that the features with good repeatability were involved in the further analysis[18,21].



Feature selection and model construction

The 260 cases of data were divided into a training group and an internal test group by randomly stratified sampling at a ratio of 7:3. The training group was mainly used for preprocessing parameter determination, and feature screening and modeling, and the same treatment process, parameters, and model were applied to the test group for internal test. The same method was used for feature preprocessing and feature screening in the arterial and venous phase training samples, and independent arterial and venous radiomics models were established. The feature selection and final modeling procedure were performed as follows. The features were first preprocessed by excluding features with variance < 1.0, filling missing values with the median and *Z*-score normalization, and excluding collinear features with a cut-off value of correlation coefficients larger than 0.7. Then the Mann-Whitney *U*-test or *t*-test was used to select features with a significant difference between two classes ($P < 0.05$). The least absolute shrinkage and selection operator (LASSO) logistic regression (minimum binomial deviance) with 10-fold cross validation was conducted to avoid overfitting and the features with non-zero coefficients were retained[22]. Finally, the retained features were inputted into backward stepwise logistic regression with the minimum Akaike Information Criterion (AIC) to develop the regression radiomics model. The "Radscore" of each patient was calculated according to the formula (Radscore = $\beta_0 + \sum\beta_i x_i$, β_0 is a constant term and βi is the regression coefficient of the feature *x*i).

Four independent radiomics models were constructed, including: 2D arterial-phase model ($Radscore^{AP_2D}$), 2D venous-phase model ($Radscore^{VP_2D}$), 3D arterial-phase model ($Radscore^{AP_3D}$), and 3D venous-phase model ($Radscore^{VP_3D}$). Two combined models were derived based on the established independent model Radscore according to the regression formula (Radscore = $\beta_0 + \sum\beta_i x_i$, β_0 is a constant term and βi is the logistic regression coefficient of the model score *x*i). And the 2D arterial-venous combined model 3 ($Radscore^{AP_VP_2D}$) and 3D arterial-venous combined model ($Radscore^{AP_VP_3D}$) were established.

Evaluation of model predictive performance

The performance of the models was evaluated by using receiver operating characteristic curve (ROC) analysis to obtain the area under the ROC curve (AUC). The sensitivity, accuracy, negative predictive value, and positive predictive value were calculated based on the cut-off values corresponding to the maximum Youden index to evaluate the discrimination performance of the models. The cut-off values of the training group were applied to the test group to obtain their corresponding ROC parameters in

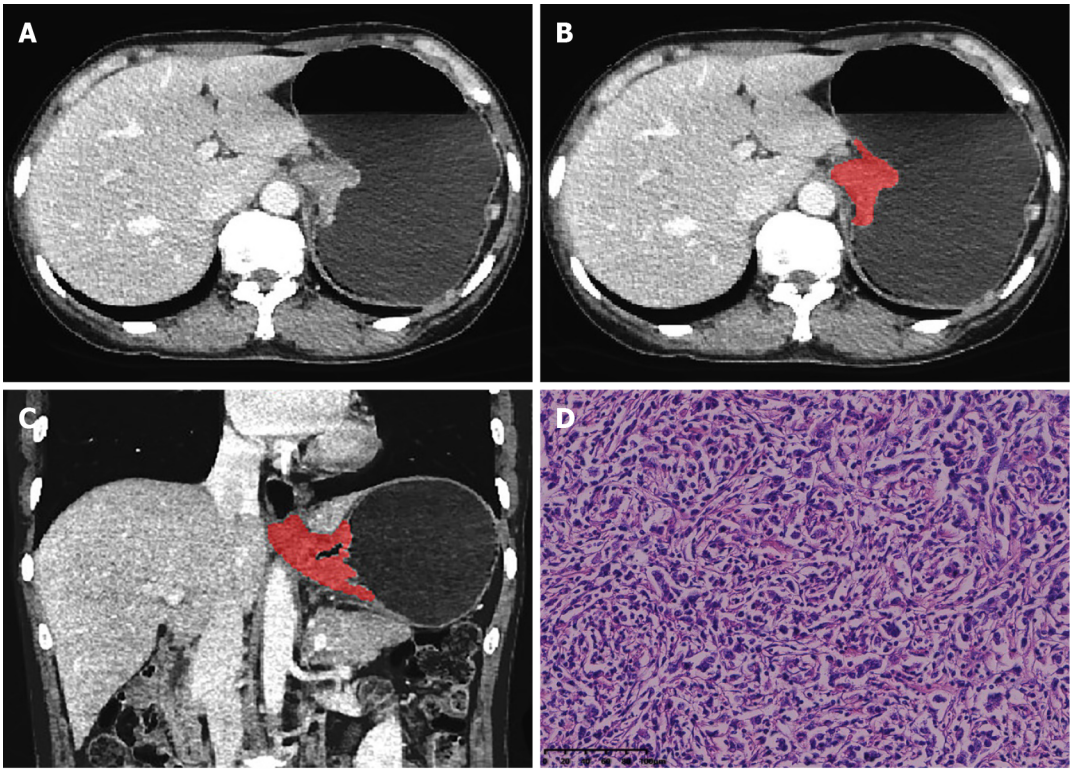
the test group. The calibration curve analysis and the Hosmer-Lemeshow test were used for evaluating model calibration and the goodness of fit ($P > 0.05$ indicates a good model fit). Delong's test was used to compare the AUC between paired models. Continuous net reclassification improvement (NRI) and integrated discrimination improvement (IDI) were used to assess ability of the models in improving the classification effectiveness[18]. The decision curve analysis (DCA) was used to assess the net clinical benefit or clinical utility of each model at different threshold probabilities.



Statistical analysis

R software (version 3.6.3, http://www.r-project.org) was applied for statistical analyses in the current study. Radiomics features and Radscore are continuous variables, and data normality was tested using kurtosis and skewness values, and comparisons between two groups were made using independent samples *t*-test (for data with a normal distribution) or Mann-Whitney *U* test (for data not following a normal distribution). Categorical variables were tested by chi-square test or Fisher's exact test. A two-sided $P < 0.05$ was considered statistically significant. The optimism of the prediction accuracy of the model was validated using 1000-times Bootstrap in the training group. The following R packages were applied: "icc" for intra-/inter-class correlation coefficient; "glmnet" for logistic regression; "pROC" for ROC analysis; "rmda" for DCA; calibration function in the "rms" package for calibration analysis, and the "PredictABEL" package for NRI and IDI analysis.

RESULTS

Feature screening and model construction

Arterial phase model based on 2D ROI: A total of 175 radiomics features (ICCs > 0.75) were retained among 1409 features. There were 61 and 6 features retained rafter variance and correlation analysis, respectively. Among 6 features screened by univariate analysis and 10-fold cross validation LASSO regression (Figure 3A and B), 5 were further selected by stepwise logistic regression analysis. The Radscore^{AP_2D} is summarized in Supplementary Figure 1. The results of ICCs for individual features are shown in Supplementary Table 1 and the multivariable logistic regression results of features involved in the model are summarized in Supplementary Table 2. ROC curves for single 2D arterial features to identify SCCEG and AEG are shown in Supplementary Figure 2A and The 2D arterial model radiomics

features and the differences of Rad-score^{AP_2D} in the training and test groups are shown in Supplementary Table 3.

Venous phase model based on 2D ROI: A total of 275 radiomics features (ICCs > 0.75) were retained among 1409 features. There were 124 and 12 features kept after variance and correlation analysis, respectively. Among 6 features screened by univariate analysis and 10-fold cross validation LASSO regression (Figure 3C and D), 5 were kept by stepwise logistic regression analysis. The Radscore^{VP_2D} is summarized in Supplementary Figure 3. The results of ICCs for individual features are shown in Supplementary Table 4 and the multivariable logistic regression results of features involved in the model are summarized in Supplementary Table 5. ROC curves for single 2D venous features to identify SCCEG and AEG are illustrated in Supplementary Figure 2C and The 2D venous model radiomics features and the differences of Rad-score^{VP_2D} in the training and test groups are shown in Supplementary Table 6.

Arterial phase model based on 3D ROI: A total of 714 radiomics features (ICCs > 0.75) were retained among 1409 features. There were 358 and 27 features kept after variance and correlation analysis, respectively. Among 15 features screened by univariate analysis and 10-fold cross validation LASSO regression (Figure 3E and F), 10 were kept by stepwise logistic regression analysis. The Radscore^{AP_3D} is summarized in Supplementary Figure 4. The ICCs for individual features are shown in Supplementary Table 7 and the multivariable logistic regression results of features involved in the model are summarized in Supplementary Table 8. ROC curves for single 3D arterial features to identify SCCEG and AEG are shown in Supplementary Figure 2E and the 3D arterial model radiomics features and the differences of Rad-score^{AP_3D} in the training and test groups are summarized in Supple-mentary Table 9.

Venous phase model based on 3D ROI: A total of 774 radiomics features (ICCs>0.75) were retained among 1409 features. There were 355 and 23 features kept after variance and correlation analysis, respectively. Among 8 features screened by univariate analysis and 10-fold cross validation LASSO regression (Figure 3G and H), 7 were kept by stepwise logistic regression analysis, and the Radscore^{VP_3D} is summarized in Supplementary Figure 5. The ICCs result for individual features are shown in Supplementary Table 10 and the multivariable logistic regression results of features involved in the model are summarized in Supplementary Table 11. ROC curves for single 3D venous features to identify SCCEG and AEG are shown in Supplementary Figure 2G and The 3D venous model radiomics features and the differences of Rad-score^{VP_3D} in the training and test groups are summarized in

The dotted line indicates the location of the selected optimal log(λ) value.

Supplementary Table 12.

2D arterial-venous combined model

By combining Radscore^{AP_2D} and Radscore^{VP_2D}, the 2D arterial-venous combined model was derived and the Radscor^{AP_VP_2D} is described in Supplementary Figure 6.

3D arterial-venous combined model

By combining Radscore^{AP_3D} and Radscore^{VP_3D}, the 3D arterial-venous combined model was derived and the Radscor^{AP_VP_3D} is summarized in Supplementary Figure 7.

In this study, a total of 10 candidate radiomics feature parameters were screened out in 2D arterial and venous phase images, mostly first-order features and texture features extracted based on Log transformed or wavelet transformed images, and the main categories included 4 first-order features, 2 GLRLM features, 2 GLSZM features, 1 GLDM feature, and 1 NGTDM feature. More features were screened out in the 3D arterial phase and venous phase images—17 in total, and the main categories included 6 first-order features, 4 GLDM features, 4 NGTDM features, 1 GLRLM feature, 1 GLSZM feature, and 1 GLCM feature.

Radiomics model performance

The AUC, specificity, sensitivity, accuracy, positive predictive value, and negative predictive value of the 6 models developed in this study to discriminate SCCEG from AEG in the training and test groups

are summarized in Table 1, and the ROC curves are shown in Figure 4. The model optimism was assessed by 1000-times bootstrap as shown in Table 2. It indicated that the 2D-arterial, 2D-venous, 3D-arterial, and 3D-venous model presented a degree of optimism less than 0.1 during repeated sampling. The Delong test results in the training and test groups are shown in Supplementary Table 13. All the 2D models had an AUC greater than 0.800 in the test group, except for the arterial model, which had an AUC of 0.752 in the test group. The AUC values of the venous model were higher than those of the arterial model (0.849 *vs* 0.808 and 0.831 *vs* 0.752) in both the training and test groups. All the 3D models had a higher AUC in the venous model than in the arterial model. In the combined models, both the 3D and 2D models were higher than their independent phase model both in the training and test groups. When comparing the performance between 2D and 3D models, the results showed that no matter for the independent phase model or the multi-phase-combined model, 3D models performed with a higher AUC than 2D models. Among all the models, the 3D-arterial-venous combined model had the highest AUC values of 0.904 and 0.901 in the training and test groups, respectively. As some statistical significance was not obvious during the Delong test, continuous NRI and IDI analyses were performed to evaluate the ability of each model for improving the classification and the results are shown in Supplementary Table 14. In both the training and test groups, the venous model demonstrated a positive improvement in discrimination over the arterial model (NRI > 0, IDI > 0), the 3D-venous model demonstrated a significant positive improvement in discrimination over the 2D-venous model (P < 0.05), both in the 3D model and in the 2D model, the combined model demonstrated a significant positive improvement in discrimination over the arterial model (P < 0.05); the 3D combined model reflected a significant positive improvement in discrimination compared with the 2D combined model (P < 0.05). In addition, the calibration curve (Figure 5) and the results of the Hosmer-Lemeshow test (Supplementary Table 15) indicate that the six models had good calibration. The clinical utility of the model was confirmed by the decision curve (Figure 6), in which the 3D-arterial-venous combined model and the 3D-venous model had higher net benefits in the test group within a threshold probability interval of 0.3-1.

DISCUSSION

In the current study, the multiscale and multiphase CT-based radiomics method was used to preoperatively discriminate SCCEG and AEG. The results showed that the combination of multiphase 3D CT radiomics features could improve the differentiation performance. Therefore, radiomics method could help open up a new field for noninvasive diagnosis and personalized management of CEGJ. Histopathology biopsy is a commonly used clinical method, and these radiomics features are considered to be complementary to histology biopsy but not a complete substitute for histopathology at this time. Repeat biopsy or endoscopic ultrasound deeper biopsies should be recommended if upper endoscopic biopsies are inconclusive or if it conflicts with the results suggested by radiomics features. Radiomics can provide an adequate reference if the patient has contraindications and low tolerance to endoscopic biopsy.

Previous studies have focused on the quantitative parameters of spectral CT. Zhou *et al*[23] found that the normalized iodine concentration, the $K_{40\text{-}70\ keV}$, and the effective atomic number in the arterial phase could identify SCCEG and AEG; the AUC values were 0.720, 0.730, and 0.706, respectively. Radiomics uses mathematically describable imaging features to comprehensively analyze tumor heterogeneity[24], and has not been validated for identifying SCCEG from AEG. Therefore, we tried to use radiomics features to identify the pathological type of CEGJ by comprehensively considering the effectiveness of different phases and segmentation method. In this study, more features were screened out in the 3D models of different phases than in the 2D models, which is related to the fact that the 3D ROIs contain the lesion as a whole and the extracted features have a larger distribution. The results showed that the efficacy of the venous features was higher than that of the arterial features in identifying SCCEG from AEG. Pathologically, squamous carcinoma grows faster and tends to grow in a swelling superposition with denser tissue structure, while adenocarcinoma mostly grows in an appendicular pattern with looser tissue structure[25]. With the prolongation of scanning time, the contrast agent continuously penetrates into the interstitial space of tumor cells, and more textural features appear in the venous phase, which better reflects the heterogeneous characteristics of squamous carcinoma. Tumor vascularization is a kind of biological behavior that reconstructs nutrition connection and promotes tumor development. Pathologic types, tumor origin, and structure of the microvasculature affect the enhancement pattern and radiomics-based parameters.

We found that among the features retained in the venous model, Dependence variance (GLDM) and Large dependence high gray level emphasis (GLDM) had larger weight in the 3D and 2D models, respectively. GLDM mainly describes the degree of dependence between voxel gray levels, and the SCCEG group reflects the high "Dependence variance" of 3D gray levels and the "Large dependence high gray level emphasis" of 2D gray levels, which reflects the large gray level heterogeneity of squamous cancer tissue in 3D features and the high gray level distribution in 2D features from texture features. The uneven distribution of tumor vessels in squamous carcinoma lesions is prone to tumor cell

degeneration and necrosis, and it is speculated that the grayscale distribution of squamous carcinoma lesions has some complexity in different transformed images. In addition, features prevalent in the arterial and venous models are Busyness (NGTDM), Dependence variance (GLDM), first order grayscale features. NGTDM features can also represent a certain degree of grayscale distribution inhomogeneity. NGTDM describes the difference between adjacent grayscale values and average grayscale values within the quantized distance of the adjacent grayscale difference matrix, and the squamous carcinoma exhibits a high "Busyness", representing rapid intensity changes between pixels and their neighbors and reflecting the heterogeneous nature of the tissue. In addition, the first-order statistical gray value features calculated based on different dimensions and different phases of images were selected into each model simultaneously, indicating that the images of the SCCEG group in different phases and dimensions have lower gray values, which may be attributed to the histopathological inhomogeneity of microvessels within squamous carcinoma, less blood supply than adenocarcinoma, and lower gray statistical values in squamous carcinoma than adenocarcinoma.

Figure 5 Calibration curves of 2D-arterial model, 2D-venous model, 3D-arterial model, 3D-venous model, 2D arterial-venous combined model, and 3D arterial-venous combined model to identify squamous cell carcinoma of the esophagogastric junction and adenocarcinoma of the esophagogastric junction. A: Training group; B: Test group.

For both of 2D and 3D models, the AUC difference was statistically significant between the arterial-venous combined model and the independent arterial model, while not significant between the arterial-venous combined model and the independent venous model. It suggested that the venous phase might contribute more predictive information compared with the arterial phase. Combining the NRI and IDI index results, the venous model showed a positive improvement in discrimination compared to the arterial model, and the 3D model showed a significant positive improvement in discrimination compared to the 2D model as well.

Most previous radiomics studies varied in the utilization of 2D or 3D segmentation. However, different delineation methods may result in different feature values and predictive performance. The study of different dimensional outlining approaches and the corresponding model performance can guide radiomics practice in related disease areas. Zhao *et al*[15] developed a dual-energy CT–based nomogram for noninvasive identification of the status of HER2 expression in gastric cancer, and both 2D and 3D radiomics nomograms performed well. Huang *et al*[18] found that the efficacy of the 3D model was superior to the 2D model when they developed 2D and 3D radiomics models to predict the aggressiveness of pancreatic solid pseudopapillary tumors. This study showed that in the discrimination of SCCEG and AEG, the use of 3D radiomics-based on CT images will be beneficial to improve the discrimination, but the time required for 3D segmentation was significantly longer than that of 2D, so it is also necessary to consider the improvement and optimization of automatic 3D lesion segmentation.

This study still has some limitations. First, the lesion morphology of CEGJ is not fixed, and manual segmentation methods are required. While the lesion travels along the gastric and esophageal walls in a tortuous manner, the consistency and stability of the annotation will affect the efficacy of the model. In this study, features with ICCs > 0.75 were used for subsequent analysis, which ensured the robustness of the radiomics features to some extent. More candidate semi-automatic or automatic segmentation algorithms would be welcomed to improve clinical efficiency. Second, our study was previously reported to include data on squamous cell carcinoma of the cardia or distal esophagus, but it is still a single-center retrospective study with a small sample size, especially for SCCEG, which inevitably

Figure 6 Decision curves for 2D-arterial model, 2D venous model, 3D-arterial model, 3D venous model, 2D arterial-venous combined model, and 3D arterial-venous combined model. A: Training group; B: Test group. The black horizontal line indicates no lesions as squamous cell carcinoma (NONE) and the grey line indicates all lesions as squamous cell carcinoma (ALL). The colored lines of each model respectively illustrate the net benefit brought to each patient. The closer the decision curves to the black and gray curves, the similar the clinical decision net benefit of the model compared with "treat ALL" or "treat NONE" decision. When comparing different models, the higher the model curve within the same threshold probability, the higher the clinical net benefit resulting from the model.

generates selectivity bias when paired with a larger number of AEGs. Future multicenter, prospective, large sample studies are needed to further improve and validate the diagnostic efficacy and generalization ability of the model. In addition, the main purpose of the current study was to evaluate the usefulness of 2D- or 3D-based radiomics methods and clinical data or laboratory test indicators were not included. There is much room for improvement of model reliability, which will be further collected in future studies in order to obtain a more comprehensive understanding.

CONCLUSION

In conclusion, multi-scale and multi-phase radiomics models based on CT imaging data were developed and validated for differentiating SCCEG from AEG before the operation in our study. The 3D radiomics model combining arterial and venous phase images showed encouraging performance than the corresponding 2D model. These models require further validation as decision support tools to guide clinical practice and develop individualized treatment plans for CEGJ patients. Currently, histopathological biopsy is still the common method of diagnosis.

ARTICLE HIGHLIGHTS

Research background

Differentiating squamous cell carcinoma of the esophagogastric junction (SCCEG) from adenocarcinoma of the esophagogastric junction (AEG) can indicate Siewert stage and whether the surgical route for patients with carcinoma of the esophagogastric junction (CEGJ) is transthoracic or transabdominal, as well as aid in determining the extent of lymph node dissection. With the development of neoadjuvant therapy, preoperative determination of pathological type can help in the selection of neoadjuvant radiotherapy and chemotherapy regimens.

Research motivation

Radiomics technique uses a combined medical-industrial approach to transform traditional images into digital quantitative features, which has potential for digging the potential biological characteristics and heterogeneity of tumor images and has been widely and non-invasively used in the diagnosis, differential diagnosis, and disease evaluation. However, to the best of our knowledge, there is no literature that has evaluated whether a radiomics signature derived from computed tomography (CT) images would be useful in predicting pathological type in patients with CEGJ.

Research objectives

In the current study, we proposed a CT radiomics-based classification method by considering the performance of 3D or 2D segmentation and multiple CT imaging phases to discriminate SCCEG and AEG.

Research methods

We retrospectively analyzed the preoperative contrasted-enhanced CT imaging data of single-center patients with pathologically confirmed SCCEG (n = 130) and AEG (n = 130). One thousand four hundred and nine radiomics features were separately extracted from 2D or 3D regions of interest in arterial and venous phases. Totally, 6 logistic regression models were established based on 2D and 3D multi-phase features.

Research results

The venous model showed a positive improvement compared with the arterial model (NRI > 0, IDI > 0), and the 3D-venous and combined models showed a significant positive improvement compared with the 2D-venous and combined models (P < 0.05). Decision curve analysis showed that the combined 3D-arterial-venous model and 3D-venous model had a higher net clinical benefit within the same threshold probability range in the test group.

Research conclusions

The combined arterial-venous CT radiomics model based on 3D segmentation can improve the performance in differentiating EGJ squamous cell carcinoma from adenocarcinoma.

Research perspectives

These models require further validation as decision support tools to guide clinical practice and develop individualized treatment plans for CEGJ patients.

Abstract

BACKGROUND

Hepatocellular carcinoma (HCC) is the most common primary liver malignancy with a rising incidence worldwide. The prognosis of HCC patients after radical resection remains poor. Radiomics is a novel machine learning method that extracts quantitative features from medical images and provides predictive information of cancer, which can assist with cancer diagnosis, therapeutic decision-making and prognosis improvement.

AIM

To develop and validate a contrast-enhanced computed tomography-based radiomics model for predicting the overall survival (OS) of HCC patients after radical hepatectomy.

METHODS

A total of 150 HCC patients were randomly divided into a training cohort (n = 107) and a validation cohort (n = 43). Radiomics features were extracted from the entire tumour lesion. The least absolute shrinkage and selection operator algorithm was applied for the selection of radiomics features and the construction of the radiomics signature. Univariate and multivariate Cox regression analyses were used to identify the independent prognostic factors and develop the predictive nomogram, incorporating clinicopathological characteristics and the radiomics signature. The accuracy of the nomogram was assessed with the concordance index, receiver operating characteristic (ROC) curve and calibration

curve. The clinical utility was evaluated by decision curve analysis (DCA). Kaplan–Meier methodology was used to compare the survival between the low- and high-risk subgroups.

RESULTS

In total, seven radiomics features were selected to construct the radiomics signature. According to the results of univariate and multivariate Cox regression analyses, alpha-fetoprotein (AFP), neutrophil-to-lymphocyte ratio (NLR) and radiomics signature were included to build the nomogram. The C-indices of the nomogram in the training and validation cohorts were 0.736 and 0.774, respectively. ROC curve analysis for predicting 1-, 3-, and 5-year OS confirmed satisfactory accuracy [training cohort, area under the curve (AUC) = 0.850, 0.791 and 0.823, respectively; validation cohort, AUC = 0.905, 0.884 and 0.911, respectively]. The calibration curve analysis indicated a good agreement between the nomogram-prediction and actual survival. DCA curves suggested that the nomogram had more benefit than traditional staging system models. Kaplan–Meier survival analysis indicated that patients in the low-risk group had longer OS and disease-free survival (all $P < 0.0001$).

CONCLUSION

The nomogram containing the radiomics signature, NLR and AFP is a reliable tool for predicting the OS of HCC patients.

Key Words: Hepatocellular carcinoma; Radiomics; Contrast-enhanced computed tomography; Survival prediction

Core Tip: The prognosis of hepatocellular carcinoma (HCC) patients remains poor even after radical resection. Therefore, a precise and reliable tool to predict the prognosis of HCC patients is urgently needed. We established a predictive model incorporating radiomics features extracted from preoperative contrast-enhanced computed tomography images, alpha-fetoprotein and neutrophil-to-lymphocyte ratio to predict the overall survival of patients with HCC, and the model was visualized *via* a nomogram. The nomogram showed good accuracy for survival prediction.

INTRODUCTION

Primary liver cancer is the sixth most common malignancy and the third leading cause of cancer-related mortality in the world. Hepatocellular carcinoma (HCC) accounts for 75%-85% of primary liver cancers [1]. Presently, the main therapies for HCC include surgical resection, local ablation, interventional embolization and liver transplantation. For HCC patients with early-stage disease, hepatectomy and liver transplantation are the mainstay curative treatments. Due to the insidious onset and lack of evident clinical symptoms in the early stage, patients with HCC are often diagnosed at an advanced stage. Even after surgical resection, the prognosis of HCC patients remains poor due to postoperative recurrence and metastasis. It has been reported that the recurrence rate within 5 years reaches 60%[2].

Alpha-fetoprotein (AFP) has been widely applied as a biomarker of HCC for diagnosis, monitoring treatment response, assessing prognosis and detecting early recurrence. However, the specificity of AFP for diagnosing HCC is 99%-100%, but the sensitivity is only 20% to 45%[3]. Moreover, nearly 31% of patients with HCC are AFP negative[4]. Therefore, AFP still has limitations as a biomarker of HCC. It has been reported that the tumour microenvironment is closely related to the initiation and progression of HCC[5]. Recent studies have shown that a high density of tumour-infiltrating lymphocytes is associated with favourable outcomes[6]. The neutrophil-to-lymphocyte ratio (NLR) was reported to be an independent prognostic factor for patients with HCC[7,8].

Radiomics is a new method of medical image analysis that uses a series of data-mining algorithms or statistical analysis tools for the high-throughput extraction of quantitative metric features[9,10] to obtain prognostic and predictive information for clinical decision support. It has been recognized that

intratumor heterogeneity is often associated with tumour subtyping and can significantly impact prognosis and response to treatment[11,12]. Traditional radiological analysis is mainly based on naked-eye observation, which primarily focuses on tumour size and anatomical location but ignores intratumor heterogeneity. Radiomics features are able to provide a comprehensive overview of intratumor heterogeneity in a noninvasive manner[13]. Several recent studies indicate that radiomics features may potentially be a useful diagnostic and prognostic biomarker in liver cancer and other tumour types[14-16].

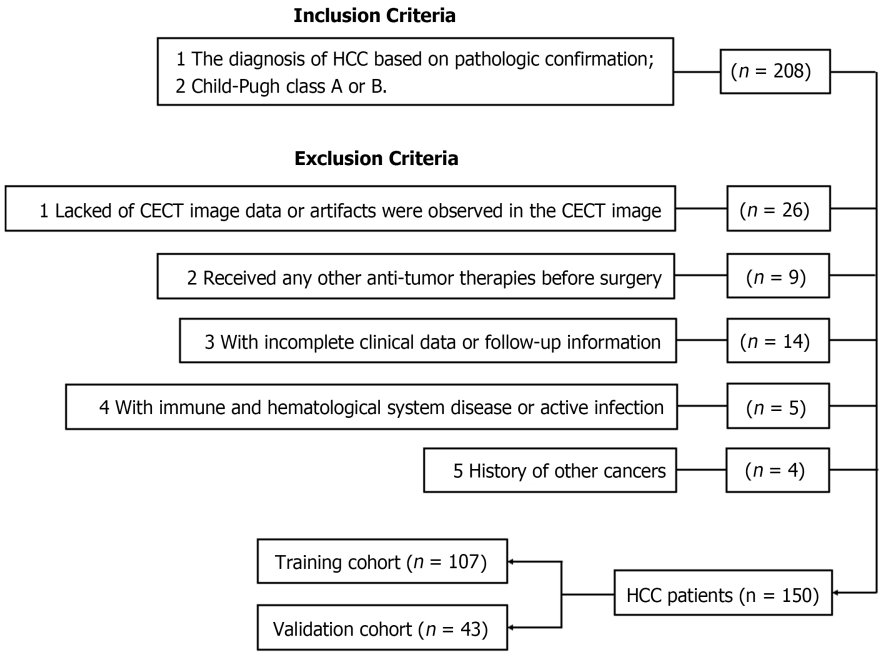
Due to the insufficiency of accurateness and objectiveness for prognostic markers in the prognostic evaluation of HCC patients, a precise and reliable tool to predict the prognosis of HCC patients is urgently needed. In the present study, we aimed to develop and validate a model based on contrast-enhanced computed tomography (CECT) images and clinical-pathologic characteristics to predict the overall survival (OS) of HCC patients.

MATERIALS AND METHODS

This study was composed of the following steps: (1) Patient recruitment and data collection; (2) CECT image acquisition, tumour segmentation, region of interest (ROI) selection, radiomics feature extraction and radiomics signature construction; (3) The radiomics signature and clinical-pathologic characteristics were combined to build a predictive model and visualized *via* a nomogram; and (4) Evaluation of the predictive model using receiver operating characteristic (ROC) curves, calibration curves, decision curve analysis (DCA) and Kaplan–Meier curves.

Patients

This retrospective study was approved by the research ethics committee of the Affiliated Hospital of Guilin Medical University and conducted in accordance with the Declaration of Helsinki. Informed consent was obtained from all patients.



A total of 208 HCC patients who underwent radical resection at the Affiliated Hospital of Guilin Medical University with pathologically confirmed HCC were recruited from January 2014 to September 2017. Among them, 150 individuals fulfilled the inclusion and exclusion criteria (Figure 1). Radical resection was defined as a completed resection of the tumour mass with pathologically confirmed negative margins and no residual tumour or new lesion observed in two observations at an interval of no less than 4 wk. All tumour tissue samples were diagnosed by at least two experienced pathologists independently. All patients underwent CECT scans and haematological examinations before surgery. The 150 enrolled HCC patients were randomly divided into a training cohort (n = 107) and a validation cohort (n = 43) at a ratio of 2.5:1. Demographic and clinical-pathologic data were collected from medical records, including age, sex, alanine aminotransferase, AFP, American Joint Committee on Cancer tumor, node and metastasis (TNM) stage, Barcelona clinic liver cancer (BCLC) stage, hepatitis B surface antigen (HBsAg) and NLR.

Each patient was followed up *via* outpatient review. Routine postoperative examinations, including routine blood tests, liver function tests, renal function tests, serum AFP levels and abdominal ultrasonography, were performed every 2 mo after surgery within 2 years and then every 6 mo thereafter. A CECT scan was recommended if the examination results were abnormal or tumour recurrence was suspected. For patients who did not attend the follow-up visit, follow-up information was obtained by phone. OS was defined as the time from surgery to death or the last follow-up date, while disease-free survival (DFS) was defined as the time from surgery to tumour first intrahepatic and/or extrahepatic recurrence, death, or the last follow-up date.

CECT scan protocols and image preprocessing

Abdominal CECT scans were performed with two scanners: A Lightspeed VCT XT (GE Healthcare, United States) and an Optima CT660 (GE Healthcare, United States). The scanner was operated in cine mode, and the parameters were as follows: tube voltage of 120 kV, automatic tube current modulation with noise index of 8, tube rotation speed of 600 ms, pitch of 0.985:1, collimator of 0.625 mm. Iopromide (Ultravist 300, Bayer-Schering Pharma, Germany) was given intravenously in a volume of 1.5 mL/kg at a rate of 4 mL/s *via* the antecubital vein. The slice thickness and interval of the arterial and portal venous phase images was 5 mm. All images were reconstructed into images with a 1.25 mm slice thickness and 1.25 mm interval. All data were transferred to an advanced workstation (AW 4.7).

All CECT images in this study met the criteria delineated by the American Association for the Study of Liver Disease guidelines[17]. CECT images were exported in digital imaging and communication in medicine (DICOM) format from the picture archiving and communication system database. All DICOM images were converted to neuroimaging informatics technology initiative format by the SimpleITK package (version 1.2.0) of Python software (version 3.7).

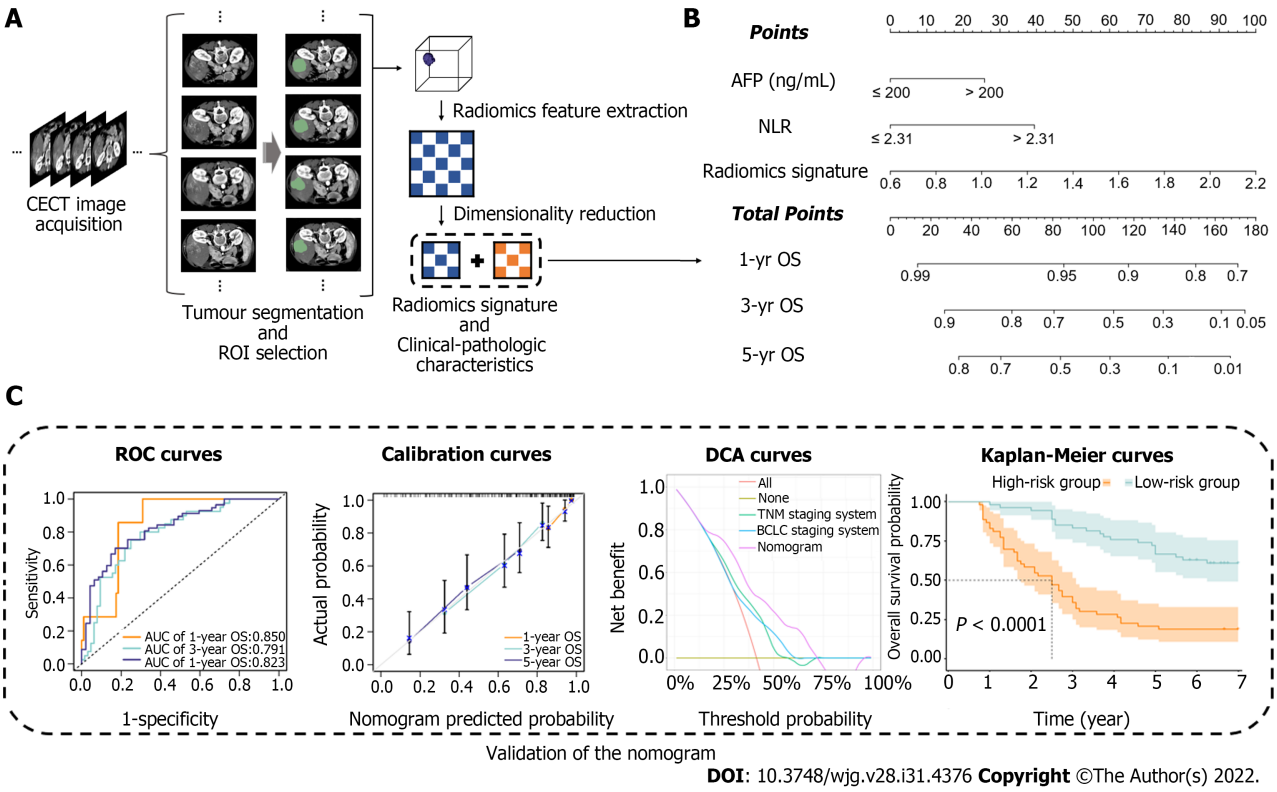
Figure 1 Flowchart of the patient selection process. HCC: Hepatocellular carcinoma; CECT: Contrast-enhanced computed tomography.

Radiomics analysis and radiomics signature construction

Tumour segmentation was performed by 3D Slicer software (version 4.11.20210226). ROIs were drawn on each layer of the tumour in the horizontal plane from the upper boundary to the lower boundary. Tumour lesions were semiautomatically outlined on all arterial phase and portal venous phase images, and manual corrections were implemented whenever necessary. The images were reviewed independently by two blinded radiologists with 7 and 8 years of experience, and a third radiologist resolved any discrepancies. For patients with multiple tumours, only the largest tumour was selected.



CECT image normalization and radiomics feature extraction were conducted by the Pyradiomics package (version 3.0.3) of Python software. The radiomics features extracted from ROIs included first order features, shape features (2D and 3D), gray level co-occurrence matrix features, gray level size zone matrix features, gray level run length matrix features, gray level dependence matrix features and neighbouring gray tone difference matrix features. Due to the large number of features, dimensionality reduction was essential. The least absolute shrinkage and selection operator (LASSO) algorithm with a 10-fold cross-validation approach was used to reduce the data dimension in the training cohort. Afterwards, the radiomics score, which was defined as the radiomics signature, was generated by linearly combining the selected radiomics features and their weighted coefficients. The workflow of radiomics analysis and radiomics signature construction is shown in Figure 2A. Afterwards, the concordance index (C-index) and ROC curve analysis were used to estimate the predictive value of the radiomics signature for 1-, 3- and 5-year OS.

Selection of the optimal cut-off value for NLR

According to our previous study[18], the optimal cut-off value for NLR in predicting the prognosis of HCC patients after curative resection was 2.31, which had both maximum sensitivity and specificity [area under the curve (AUC) = 0.723, 95%CI: 0.664–0.777].

Statistical analysis

Normality of distributions was tested by the Shapiro–Wilk test. Clinical-pathologic characteristics were compared by Student's *t* test and are presented as the mean ± SD for continuous variables conforming to a normal distribution. Nonnormally distributed continuous variables were compared using the Wilcoxon signed rank test and are presented as the median with interquartile range. Categorical variables were compared using the Pearson χ^2 test. Univariate and multivariate regression analyses were performed in the training cohort using the Cox proportional hazards model to identify the independent predictors for nomogram construction. The rms and regplot packages were used to establish a nomogram and calibration curve. The ROC curve analysis was performed using the timeROC package. The C-index, ROC curve and calibration curve were used to assess the accuracy of the nomogram. The Kaplan–Meier method and log-rank test were conducted to compare the different survival rates between the low- and high-risk subgroups in different cohorts. We built two predictive models based on BCLC and TNM staging systems. Patients were categorized into stage 0, stage A, stage

B and stage C according to BCLC staging system; grade I, grade II, grade III and grade IV according to TNM staging system. DCA was conducted to compare the abovementioned two traditional staging systems with the nomogram. All statistical analyses were performed using SPSS software (version 24.0) or R software (version 4.1.2) and accepted as significant at $P < 0.05$.

RESULTS

Demographic and clinicopathological characteristics

A total of 150 HCC patients were enrolled in this study according to inclusion and exclusion criteria, with an average age of 49.9 years (range, 20-75 years), and 130 patients were male. A total of 136 patients were diagnosed with cirrhosis, while 137 patients were classified as Child–Pugh class A. A total of 124 patients were positive for HBsAg. Patients were randomly divided into a training cohort (n = 107) and a validation cohort (n = 43). The demographic and clinical-pathologic characteristics are summarized in Table 1. There were no significant differences in variables between the two cohorts.

Radiomics signature construction

In total, 1926 radiomics features were extracted from the ROIs. Based on the training cohort, radiomics features were reduced to 7 survival-related features by using the LASSO algorithm. The name of the selected features and the formula of the radiomics score are shown in Supplementary Table 1. The C-indices of the radiomics signature for predicting OS in the training and validation cohorts were 0.689 (95%CI: 0.626–0.751) and 0.746 (95%CI: 0.650–0.842), respectively. The ROC curves of the radiomics signature for predicting 1-, 3- and 5-year OS are shown in Figure 3 (AUC = 0.648, 0.753 and 0.807, respectively, in the training cohort; AUC = 0.921, 0.840 and 0.891, respectively, in the validation cohort).

Development and validation of the predictive nomogram

Based on the univariate regression analysis (Table 2), four variables with $P < 0.05$ were enrolled in the multivariate regression analysis. The results of multivariate regression analysis are displayed as forest plots (Figure 4). AFP [hazard ratio (HR), 1.8; 95%CI: 1.06–3.1, P = 0.03], NLR (HR, 2.5; 95%CI: 1.45–4.3, P

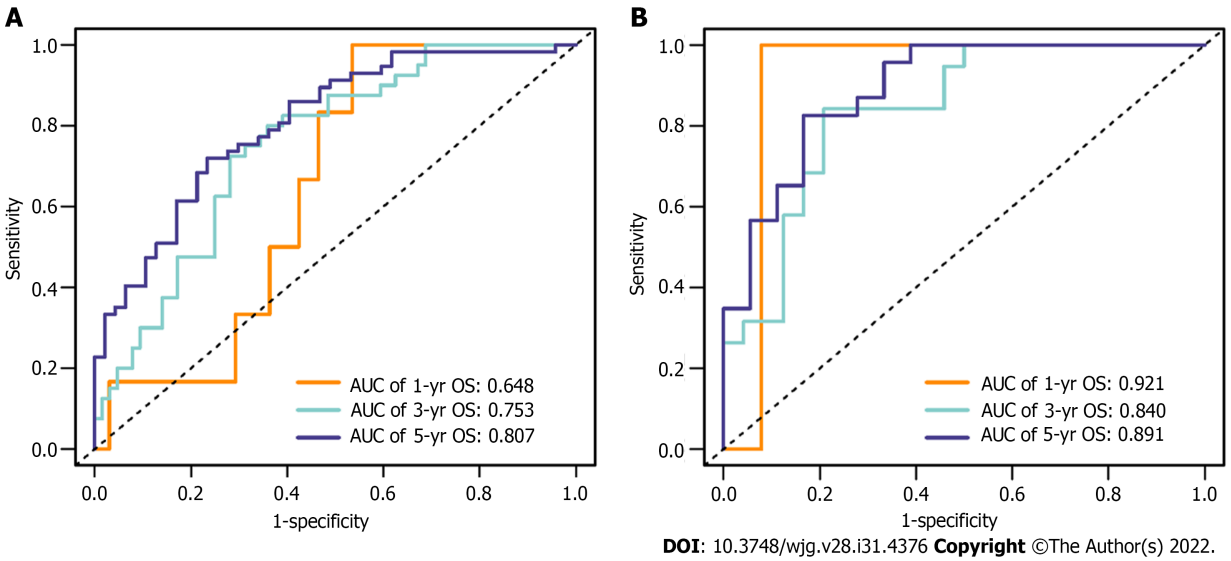
< 0.001) and radiomics signature (HR, 3.7; 95%CI: 1.25–10.7, P = 0.018) were identified as independent predictors of OS. The abovementioned three variables were included to develop the predictive model and visualized *via* a nomogram (Figure 2B). The C-indices of the nomogram in the training and validation cohorts were 0.736 (95%CI: 0.681–0.791) and 0.774 (95%CI: 0.697–0.851), respectively. The AUC values of 1-, 3-, and 5-year OS were 0.850, 0.791 and 0.823, respectively, in the training cohort (Figure 5A) and 0.905, 0.884 and 0.911, respectively, in the validation cohort (Figure 5B). The calibration curves of the nomogram demonstrated good agreement between the predicted and actual survival probabilities (Figure 5C and D).

Evaluation of clinical practicality and risk stratification ability



DCA curves showed that the nomogram received more net benefit than the BCLC staging system model and TNM staging system model in predicting 3- and 5-year OS at reasonable threshold probability (Figure 6).

To further explore the risk stratification ability of the nomogram, we calculated the total points of the nomogram for each patient. The total points conformed to a normal distribution in the training and validation cohorts. Patients were categorized into low- and high-risk subgroups based on whether the total points of the patient were lower (training cohort ≤ 89.8; validation cohort ≤ 66.0) or higher (training cohort > 89.8; validation cohort > 66.0) than the median points of each cohort. Kaplan–Meier curves indicated that patients in the low-risk subgroup had significantly longer OS and DFS, with all P < 0.001 (Figure 7).

Table 2 Univariate Cox regression analysis in the training cohort

Variables	Univariate Cox regression analysis		
	HR	95%CI	*P* value
Age, yr	0.993	0.971-1.016	0.545

DISCUSSION

In this study, we developed a nomogram for predicting the survival of HCC patients after radical hepatectomy. Seven radiomics features were selected from 1926 radiomics features, and then integrated into a single radiomics signature to comprehensively estimate CECT images. We included AFP, NLR and radiomics signature to build the predictive nomogram. The C-indices of the nomogram in the training cohort and validation cohort were 0.736 and 0.774, respectively. The AUCs and the calibration curve indicated satisfactory accuracy in both the training and validation cohorts (AUC of 1-, 3- and 5-year survival = 0.850, 0.791, 0.823 and 0.905, 0.884, 0.911, respectively). The high AUCs of the nomogram

Figure 4 Forest plot of variables with multivariate regression analysis in the training cohort. Variables with a *P* value < 0.05 were considered significantly associated with the overall survival of hepatocellular carcinoma patients. ALT: Alanine transaminase; AFP: Alpha fetoprotein; NLR: Neutrophil-to-lymphocyte ratio; HR: Hazard ratio.

indicate a high accuracy in predicting OS. In DCA, comparing the traditional staging system with our nomogram with respect to predictive ability and clinical practicality, the predictive nomogram was superior to the traditional staging system (BCLC and TNM staging system) in predicting 3- and 5-year survival.

To our knowledge, our radiomics-based model that contains NLR and AFP to predict survival in patients with HCC is entirely novel. A few previous studies[19,20] have investigated the capability of radiomics analysis in predicting the prognosis of HCC patients, and these studies analysed the largest cross-sectional area, whereas entire-tumour analysis was conducted in this study, which can provide more comprehensive information and more effective evaluation of the tumour. Thus, compared with previous studies, radiomics analysis in this study may achieve better performance. Various models combining radiomics features with clinical-pathologic factors to predict prognosis have been developed. Nevertheless, very few studies have enrolled radiomics features and NLR as variables to build a prognostic prediction model for HCC patients. Wang *et al*[21] established an magnetic resonance imaging-based radiomics model incorporating a few clinical factors for predicting the 5-year survival of patients with HCC after radical surgery. The mean AUC in the validation cohort was 0.7578 (95%CI: 0.7056–0.8100).

As precision medicine has developed, accurate prediction of patient prognosis is the principal component of individualized therapy and improving patient prognosis. It has been reported that intratumor heterogeneity is common in a variety of tumours and correlated with clinical outcomes[22]. However, information about intratumor heterogeneity obtained from routine clinical examinations is limited. Radiomics analysis refers to computer-aided data mining of quantitative high-throughput imaging features extracted from medical images[9,10], and it has been reported that radiomics features have potential prognostic value in liver cancer[14], lung cancer[15] and breast cancer[16]. Compared with the interpretation of traditional radiology, radiomics could provide comprehensive information regarding intratumor heterogeneity that may be unable to be obtained by the naked eye of radiologists. To a certain extent, radiomics overcomes these limitations of traditional radiology. As a biomarker associated with HCC, AFP has been widely used for early diagnosis and monitoring of HCC. AFP was considered an independent risk factor for postoperative survival; moreover, patients with low serum AFP levels had longer OS after radical resection. However, AFP still has some limitations in the prognosis prediction of HCC. Prior studies have reported that AFP has no ability to predict prognosis in small HCC (diameter ≤ 3 cm)[23]. Immune cells such as neutrophils, macrophages and lymphocytes within the tumour microenvironment have been confirmed to affect tumour development and progression[24]. There is evidence suggesting that lymphocytes can inhibit tumour proliferation, invasion, and metastasis by enhancing immune surveillance[25]. Moreover, tumour-infiltrating lymphocytes were associated with better outcomes in a variety of tumours, probably linked to tumour infiltration, antitumor activity, lymphocyte induction and inhibition of angiogenesis[26]. One study indicated that neutrophils promote tumour invasion[27]. Neutrophils can inhibit the proliferation of lymphocytes and induce lymphocyte apoptosis[28]. Patients with an elevated NLR level have relative neutrophilia and lymphocytopenia. Therefore, a high NLR indicates a poor prognosis, and this has been confirmed in numerous cancers, including gastric cancer[29], colorectal cancer[30] and pancreatic cancer [31]. To date, there is growing attention to the potential of NLR to be a prognostic biomarker in patients with HCC[32,33]. The NLR is a modality of measuring systemic inflammation that is relatively inexpensive and conveniently obtained from routine preoperative blood tests. In our previous study, the optimal cut-off value of NLR was determined to be 2.31 for predicting the prognosis of patients with HCC, and this was confirmed by not only our previous retrospective trial but also other prospective clinical trials[32]. In summary, NLR is a potential independent predictor for HCC.

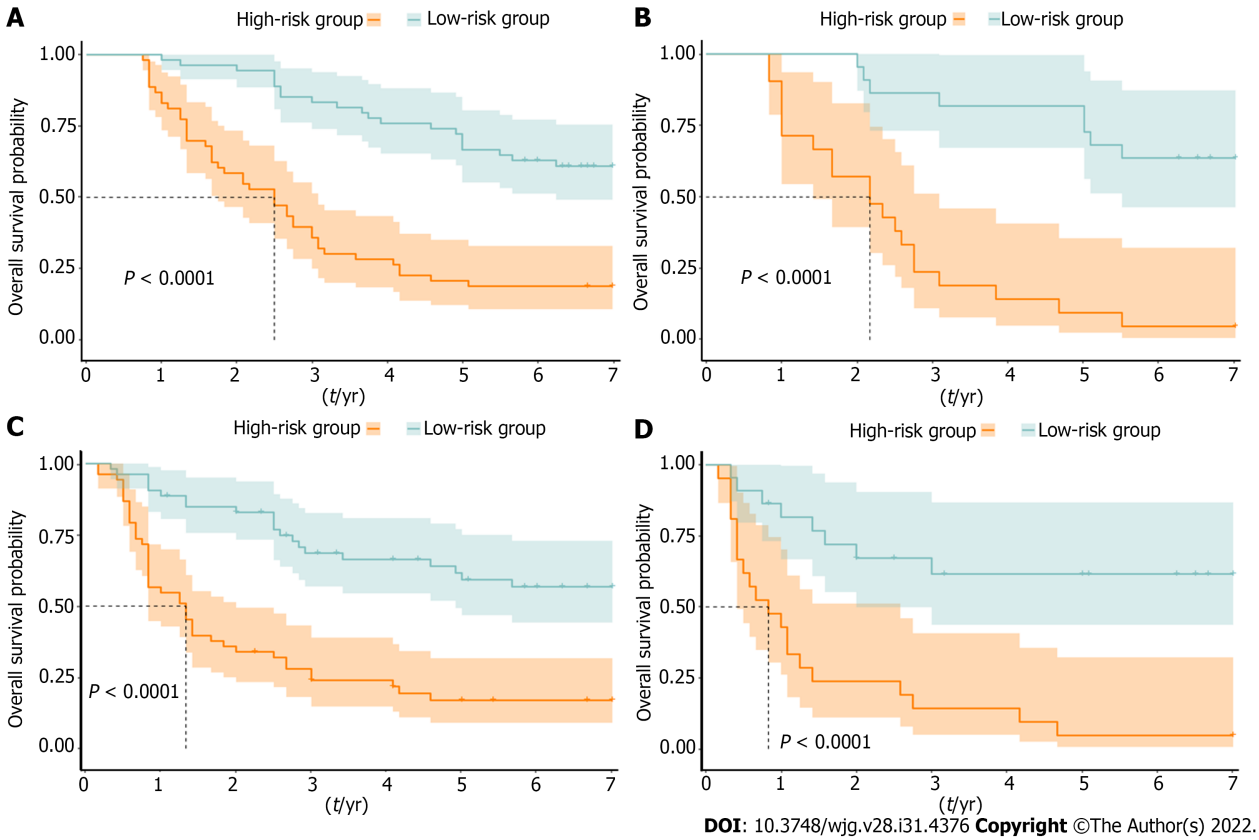
Figure 5 Accuracy of the nomogram for predicting 1-, 3- and 5-year OS in the training and validation cohorts was evaluated by receiver operating characteristic curves and calibration curves. A and B: Receiver operating characteristic curves of the nomogram in the training cohort (A) and validation cohort (B); C and D: Calibration curves of the nomogram in the training cohort (C) and validation cohort (D). In the calibration curve, the nomogram-predicted survival probability is represented on the x-axis, and the actual outcome of overall survival is represented on the y-axis. A closer fit of the coloured lines to the ideal grey line indicates better accuracy in predicting OS. OS: Overall survival; AUC: Area under the curve.

As a standardized and noninvasive imaging modality, CECT is widely utilized for diagnosis, staging, clinical decision-making and treatment response monitoring across numerous cancer types. An advantage of radiomics analysis is that it was performed on existing CECT images as a routine preoperative examination for patients with malignant tumours. Moreover, the variables included in this nomogram were easily acquired from routine blood examinations.



All CECT images were reconstructed with a slice thickness of 1.25 mm, and a previous report showed that slice thickness does not considerably influence the stability of the parameters[34].

The current study has several limitations. First, this study was a single-centre retrospective study. Insufficient data heterogeneity could be a major limitation of single-centre studies. Therefore, more patients from other centres are needed to further validate the reliability and clinical applicability of this prognostic model. Second, HCC is considered to be related to various aetiological factors, including alcohol, aflatoxin, hepatitis B virus and hepatitis C virus. Different aetiologies might result in different outcomes in HCC. Hepatitis B virus was the main aetiology of HCC in the present study. Thus, future studies are required to validate the efficacy and accuracy of this predictive model in HCC with different aetiologies. Third, the different contrast agents or the different injection speeds may affect the quantification of radiomic features[35] and thus affect the accuracy of the model. To overcome this limitation, multi-institutional validation and cross-validation are required in the future. Fourth, regions of interest were outlined semiautomatically and corrected manually when necessary. Hence, a certain degree of selection bias of the ROIs might be created by the different observers. This is a challenging problem for radiomics analysis to eliminate or reduce biases. Fifth, the correlation between radiomics features and biological behaviour remains unknown. Recently, radio-genomics has become an emerging area that integrates radiomics and genomics. Radio-genomics is the discipline that studies the relationship

Figure 7 Risk stratification ability of the nomogram was estimated by the Kaplan–Meier method and log-rank test in the training and validation cohorts. A and B: Kaplan–Meier curves between the low- and high-risk subgroups of overall survival in the training cohort (A) and validation cohort (B); C and D: Kaplan–Meier curves between the low- and high-risk subgroups of disease-free survival in the training cohort (C) and validation cohort (D). Patients with hepatocellular carcinoma in the training and validation cohorts were divided into low- and high-risk subgroups according to whether the total points of each patient were lower or higher than the median points of each cohort.

between image phenotypes and genomics, which may contribute to precision medicine development [36]. Further research is still required to determine the potential correlation between radiomics and genomics in HCC. In future studies, we will incorporate genomic characteristics associated with HCC prognosis to construct a more comprehensive radio-genomics predictive model.

CONCLUSION

In conclusion, the nomogram combining the radiomics signature, NLR and AFP may contribute to postoperative outcome prediction and clinical treatment decision-making for HCC patients.

ARTICLE HIGHLIGHTS

Research background

Hepatocellular carcinoma (HCC) is the most common primary liver malignancy. The prognosis of HCC patients remains poor. Radiomics is an artificial intelligent-based method for obtaining prognostic and predictive information which may contribute to clinical outcomes improvement.

Research motivation

Currently, a few studies have analysed the largest cross-sectional area of HCC tumour. In this study, we have analysed the entire-tumour to build a more comprehensive prognostic prediction model with clinical characteristics. We aimed to develop a radiomics model for predicting the overall survival of HCC patients after hepatectomy.

Research objectives

In this study, we aimed to develop a radiomics model based on contrast-enhanced computed tomography (CECT) images for predicting the overall survival of HCC patients after radical hepatectomy.

Research methods

A total of 150 HCC patients were enrolled and randomly divided into a training cohort (n = 107) and a validation cohort (n = 43) at ratio 2.5:1. Radiomics features were extracted from the CECT images. In training cohort, the least absolute shrinkage and selection operator algorithm was applied for radiomics features selection and radiomics signature construction. Univariate and multivariate Cox regression analyses were used to develop the predictive model. The accuracy of the model was assessed with the concordance index, receiver operating characteristic curve and calibration curve. The clinical practicality was evaluated by decision curve analysis. The survival between the low- and high-risk subgroups was compared using Kaplan–Meier methodology.

Research results

In total, seven radiomics features were selected to construct the radiomics signature. Alpha-fetoprotein, neutrophil-to-lymphocyte ratio and radiomics signature were identified as independent risk predictors to build the predictive model. The C-indices of the model in the training and validation cohorts were 0.736 and 0.774, respectively. In receiver operating characteristic curve for predicting 1-, 3-, and 5-year overall survival, area under the curve (AUC) = 0.850, 0.791 and 0.823, respectively in training cohort; AUC = 0.905, 0.884 and 0.911, respectively in validation cohort. The calibration curve analysis indicated a good agreement between the model-prediction and actual survival. Decision curve analysis suggested that the predictive model had more benefit than traditional staging system models. In Kaplan–Meier survival analysis, patients in the low-risk group had longer overall survival and disease-free survival.

Research conclusions

The predictive model is a reliable tool for predicting the overall survival of HCC patients after radical hepatectomy.

Research perspectives

More precise and reliable tool to predict the prognosis of HCC patients is urgently needed. Radiomics is a new method for obtaining prognostic and predictive information. In this study, we aimed to develop a predictive model based on CECT images and clinical-pathologic characteristics to predict the overall survival of HCC patients.

Abstract

BACKGROUND

Hepatitis B virus (HBV) nucleos(t)ide analog (NA) therapy reduces liver disease but requires prolonged therapy to achieve hepatitis B surface antigen (HBsAg) loss. There is limited North American real-world data using non-invasive tools for fibrosis assessment and few have compared 1st generation NA or lamivudine (LAM) to tenofovir disoproxil fumarate (TDF).

AIM

To assess impact of NA on virological response and fibrosis regression using liver stiffness measurement (LSM) (*i.e.*, FibroScan®).

METHODS

Retrospective, observational cohort study from the Canadian HBV Network. Data collected included demographics, NA, HBV DNA, alanine aminotransferase (ALT), and LSM. Patients were HBV monoinfected patients, treatment naïve, and received 1 NA with minimum 1 year follow-up.

RESULTS

In 465 (median 49 years, 37% female, 35% hepatitis B e antigen+ at baseline, 84% Asian, 6% White, and 9% Black). Percentage of 64 (n = 299) received TDF and 166 were LAM-treated with similar median duration of 3.9 and 3.7 years, respectively. The mean baseline LSM was 11.2 kPa (TDF) *vs* 8.3 kPa (LAM) (P = 0.003). At 5-year follow-up, the mean LSM was 7.0 kPa in TDF *vs* 6.7 kPa in LAM (P = 0.83). There was a significant difference in fibrosis regression between groups (*i.e.*, mean -4.2 kPa change in TDF and -1.6 kPa in LAM, P < 0.05). The last available data on treatment showed that all had normal ALT, but more TDF patients were virologically suppressed (< 10 IU/mL) (n = 170/190, 89%) *vs* LAM-treated (n = 35/58, 60%) (P < 0.05). None cleared HBsAg.

CONCLUSION

In this real-world North American study, approximately 5 years of NA achieves liver fibrosis regression rarely leads to HBsAg loss.

Key Words: Nucleos(t)ide analog therapy; Functional cure; Hepatitis B virus surface antigen loss; Fibrosis regression; Liver stiffness measurement; Transient elastography

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: In summary in this real-world diverse cohort study of chronic hepatitis B patients in Canada, long-term nucleo(s)ide analog (either 1st or 2nd generation) therapy suppresses hepatitis B virus DNA and improves hepatic inflammation and liver fibrosis, as determined by non-invasive testing (*i.e.*, transient elastography). In patients treated for up to 5 years, none achieved hepatitis B surface antigen loss (functional cure), highlighting the need for improved therapeutic strategies to reduce the life-long burden of antiviral therapy.

INTRODUCTION

Hepatitis B virus (HBV) nucleos(t)ide analog (NA) therapy is associated with fibrosis regression, reduced risk of hepatocellular carcinoma (HCC) and improved clinical outcomes[1]. The ultimate goal of HBV therapy is hepatitis B surface antigen (HBsAg) loss and considered a functional cure enabling treatment cessation, but rarely achieved with current NA. Without HBsAg clearance, stopping treatment may lead to severe viral and biochemical flares. Studies of European patients reported HBsAg loss in 20% patients after stopping long-term NA therapy. HBsAg loss among Asian virally suppressed patients was very low (< 5%) suggesting there are important differences among different groups of patients in terms of off-treatment response[2,3]. The approved 2nd generation NA, *i.e.*, entecavir (ETV),

tenofovir disoproxil fumarate (TDF) and tenofovir alafenamide (TAF) potently reduce serum viral load (HBV DNA) but they rarely achieve a functional cure despite prolonged therapy[4]. Studies in large Asian cohorts have compared the effect of NA with a low genetic barrier to drug resistance (*i.e.*, lamivudine, LAM) to higher potency (*i.e.*, ETV, TDF/TAF) NA on liver fibrosis regression and viral response[5]. A single centre Asian study of 124 patients treated with anti-HBV NA documented HBV DNA suppression but all had persistently detectable HBsAg, and none achieved intrahepatic viral marker reduction (*i.e.*, HBV covalently closed circular (ccc) DNA)[5]. A large retrospective Korean study showed lower risk of death or transplantation with ETV compared to LAM but no difference in HCC risk[6]. A recent global study involving 299 centers in 24 countries investigated outcomes after 10 years of follow-up of clinical trial patients treated with ETV or alternative NA[2]. The data revealed that 5305 Chinese ETV recipients maintained virological response with lower risk of HBV-related serious adverse events including HCC. However, approximately 17% of the cohort, and similar rate in other cohorts, continued to identify HBV-related liver disease progression[5,7]. Liver disease complications have also been reported in a Korean study of 440 cirrhotic patients (mostly genotype C) after 5 years of ETV therapy, with a 15% rate of liver disease decompensation in those with > 90% treatment adherence and 41% decompensation in patients with < 90% adherence[8].

There is limited real-world data evaluating the clinical impact of 1st *vs* 2nd generation long-term NA therapy in North American chronic hepatitis B (CHB) patients. These patients maybe characterised by greater diversity and genotype heterogeneity based on a diverse regions of origin. Disparities in access to HBV NA is a global issue. Similarly, in Canada, NA reimbursement criteria vary by provincial or territorial jurisdiction[9]. Until recently, antivirals with a high barrier to resistance such as TDF and ETV were not funded as first line therapies for CHB in two large population provincial health jurisdictions [*i.e.*, British Columbia (BC) and Ontario (ON)][9]. In particular, there were historic differences in reimbursement criteria with LAM utilized as first line in BC and ON, and TDF historically (before 2018) only reimbursed for persons with advanced fibrosis and/or decompensated cirrhosis. In BC and ON, HBV patients could access TDF if they failed LAM, developed resistance or very rarely, had intolerance to LAM. In this retrospective, multi-centre cohort study of 465 CHB patients followed in 8 provinces across Canada, we aim to assess HBV viral response, biochemical remission, liver fibrosis regression and HBsAg sero-clearance after treatment with median 4 years of either a 1st or 2nd line NA therapy.

MATERIALS AND METHODS

This was a retrospective observational cohort study, utilizing the Canadian Hepatitis B Network cohort data from January 1st, 2012-December 1st, 2019. Participating clinics provided data from electronic and/or paper charts. De-identified information was entered into a registry REDCap® database housed at the University of Calgary (U of C) under an approved U of C Conjoint Ethics Research Board (CHREB) protocol (Ethics ID # REB16-0041), and appropriate legal data sharing agreements[10]. Study subjects provided written informed consent to participate, or were included with a waiver of consent, according to local REB approval. Data extracted included demographics (age, sex, ethnicity), antiviral regimens, HBV DNA, hepatitis B e antigen (HBeAg), alanine aminotransferase (ALT) and liver stiffness measurement (LSM) prior to and during therapy. Inclusion: Adult patients >18 years, with known chronic HBV (*i.e.*, HBsAg persistence > 6 mo duration), HBV monoinfected, treatment naïve at baseline, and were on only a single antiviral agent for the study duration. Exclusion: Participants were excluded if they had received previous HBV therapy, had a liver transplant or were co-infected with other hepatotropic viruses (*e.g.*, HCV and HDV) or with HIV. ETV treated patients were also excluded for direct comparison of only two antiviral drugs. Persons who had their antiviral regiment switched (includes LAM-resistant patients switching to TDF) were also excluded. All patients had a minimum of 12 mo follow-up from treatment initiation, with at least annual HBV DNA evaluation using commercial assays (*i.e.*, sensitivity 20 IU/mL or 50 copies/mL, Abbott and/or < 20 IU/mL, Roche) and serial LSM performed using FibroScan® (Echosens, Paris, Fr). Liver fibrosis, based on Metavir staging, was classified as F0-F1 (< 7.3 kPa), F2-F3 (7.3-9.5 kPa) and F4 or cirrhosis (> 9.5 kPa)[11]. CHB management and treatment monitoring was directed by the center physician(s) and based on the Canadian consensus guidelines[12].

Statistical analyses

For all analyses, patients with missing data were excluded. Continuous data were summarized with the mean, 95% confidence interval (CI) and count (n). For comparisons between treatment groups (LAM *vs* TDF) at a given time point, two-tailed *t* test was used. Repeated measures analysis of variance (ANOVA) with post hoc test was used to compare continuous variables at different time points for each treatment group. Categorical data were summarized as proportion using mean % (n/n known). Fisher's exact test was used for comparison between dichotomous data. A linear mixed model was used to identify change over time in a multivariable linear mixed regression analysis. A *P* value of less than 0.05 was considered to be statistically significant. Statistical analyses were performed using SAS/STAT® software, IBM SPSS Statistics 27.0.1.0 and/or GraphPad Prism 9.0.

RESULTS

Characteristics of the study population

The study population included 465 patients who were treatment naïve at baseline. The mean age was 49 (SD 12.9) years, 37% were female, and 35% were HBeAg (+) at baseline. Most were Asian (84%, *n* = 345) (albeit from different East and/or South-East Asian) countries, 9% Black (*n* = 37), and 6% White (*n* = 25). Patients either received TDF (*n* = 299, 65%) or LAM (*n* = 166, 35%) therapies with similar median treatment duration of 3.9 and 3.7 years, respectively. There was no difference between treatment groups in sex or ethnicity. However, TDF treated individuals were more likely to be HBeAg positive (Table 1). Historically, patients from one provincial health jurisdiction (*i.e.*, British Columbia), only had access to TDF as first line therapy if they had cirrhosis. Thus, a greater proportion of persons in the TDF group also had advanced fibrosis (> stage F3/4) at baseline, compared to LAM (Table 1).

Summary of follow-up evaluation and outcomes

The mean baseline LSM prior to treatment was greater in TDF treated recipients (11.2 kPa, 95%CI: 9.9-12.4) than in those receiving LAM (8.3 kPa, 95%CI: 7.2-9.5) (Table 1). At baseline, serum HBV DNA and ALT levels were similar in both groups (Table 1). Compared to baseline, only TDF treated group achieved significant HBV DNA decline at 5 years follow up (p=0.0011) compared to LAM treated group (*P* = 0.37) (Figure 1A).

By year 5, 194/299 (64.9%) TDF patients had undetectable HBV DNA (< 10 IU/mL) than 88/166 (53.0%) LAM patients (*P* = 0.012, Chi-square test, Supplementary Table 1). Furthermore, a higher proportion of TDF treated patients had suppressed HBV DNA (< 10 IU/mL) (*n* = 170/190, 89%) *vs* LAM-treated (*n* = 35/58, 60%) (*P* < 0.05), but none achieved functional cure (HBsAg loss) at the end of the study period.

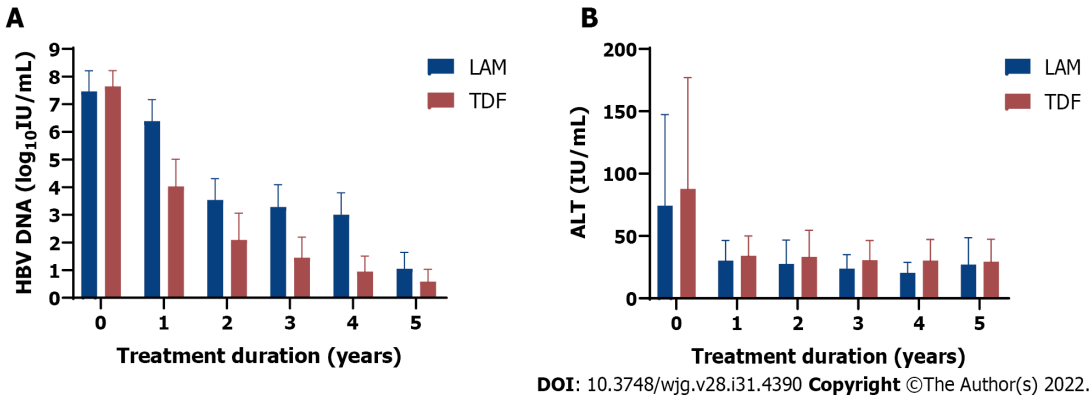
Both treatment groups had decline in ALT from baseline to 5-year follow-up (*P* = 0.014 for LAM and *P* < 0.0001 for TDF) (Figure 1B). As well, ALT normalization was achieved for both treatment groups by 1-year follow-up. More specifically, by year 5, 167/299 (55.9%) TDF patients achieved ALT normalization compared to 74/166 (44.6%) LAM patients (*P* = 0.020, Chi square test, Supplementary Table 2).

In patients with available serial long-term LSM data, NA treatment also led to improvement in liver inflammation and fibrosis regression with lower mean LSM at 5-year follow-up (7.0 kPa, 95%CI:5.8-8.2 for TDF and 6.7 kPa, 95%CI: 4.9-8.6 for LAM treated patients). Multivariable linear mixed regression with a linear mixed model showed a significant difference in fibrosis regression between antiviral treatment groups. Mean fibrosis regression was greater in TDF treated patients with -4.2 kPa change compared to -1.6 kPa in LAM recipients from baseline, *P* < 0.05 (Figure 2).

As well, by 4-year follow-up, LSM improved by ≥ 1 stage in 92/299 (20.8%) TDF patients compared to 29/166 (17.5%) LAM patients (*P* = 0.002, Chi square test).

Of the 26 HBeAg positive patients that received LAM treatment, 6 patients became HBeAg negative (23.1%). Of the 99 HBeAg positive patients that received TDF treatment, 27 patients (27.3%) achieved HBeAg loss. No data was available on LAM resistance however all patients enrolled in the study were on a single NA agent. It is standard clinical practice to switch to TDF in individuals who developed LAM resistance (and criteria for public formulary drug reimbursement in some provinces). Genotype data was not available in most patients.

DISCUSSION



In this multi-centre, retrospective real-world Canadian study, we assessed clinical outcomes in CHB patients receiving long-term NA therapy. Both 1st generation (LAM) and higher potency antivirals (TDF) reduces HBV DNA and improves liver inflammation and fibrosis based on serial LSM evaluation even after ALT normalization. This study highlights the effectiveness of both antiviral drugs in inducing fibrosis regression in a diverse HBV patient cohort. However, up to 5-year follow-up period no CHB patients achieved HBsAg loss or functional cure. A clinically relevant proportion of patients continued to show low-level viremia, especially if treated with LAM. Persons with LAM- resistance switched to TDF were not included to avoid bias of 2 different regimens. Data on antiviral resistance testing is not available, and it is likely these patients would have been switched to TDF in both BC and ON pharmacare reimbursement criteria. The clinical implications of low-level viremia, especially association with residual HCC risk is unclear and requires further study[13,14].

Many studies including randomized clinical trials, observational cohorts and meta-analyses demonstrate that NA treatment improves clinical outcomes for persons living with chronic hepatitis B [1]. Observational studies from clinical databases also reflect real-world practice and complement clinical trials[15,16]. Single centre real-world Canadian studies have observed reduced HCC risk[17]. The majority of observational studies conducted on long-term NA therapy outcomes were done in HBV-endemic countries with a particular focus on Asia. Canada is non-endemic for HBV but due to high rates of immigration from many endemic regions, CHB remains an important health issue and affects a diverse, multi-ethnic population as persons have from multiple regions and encompasses 40 countries

Table 1 Summary of baseline characteristics of 465 study patients who were treated with either lamivudine or tenofovir disoproxil fumurate enrolled in the Canadian hepatitis B virus network

	LAM treated (*n* = 166)	TDF treated (*n* = 299)	*P* value
Age (yr)	51.6 (49.7-53.6)	47.2 (45.7-48.6)	< 0.001[c]
Male sex	58.4% (97/166)	64.9% (194/299)	0.194

Figure 1 Comparison of clinical outcomes in 465 chronic hepatitis B patients receiving 1st generation (lamivudine or LAM, solid bar) *vs* 2nd generation (tenofovir disoproxil fumarate or TDF, dotted bar) hepatitis B virus nucleos(t)ide analog therapy from baseline (pre-treatment) followed for up to 5 years. A: Hepatitis B virus DNA decline (log_{10} IU/mL); B: Mean alanine aminotransferase (IU/mL) decline from baseline after starting lamivudine or tenofovir disoproxil fumarate. Mean with error bars representing standard deviation is plotted. LAM: Lamivudine; TDF: Tenofovir disoproxil fumarate; HBV: Hepatitis B virus; ALT: Alanine aminotransferase.

as based on Canadian HBV Network Data. Compared to other published real-world studies, the data is also relevant/applicable in a single-payer universal health care system with equal access care albeit differences in medication re-imbursement providing for the unique aspect of this study. The Canadian health care system does provide some financial assistance to cover the cost of antiviral therapy, and other associated costs (*i.e.*, physician visits, hospitalization, laboratory monitoring, diagnostic imaging

Figure 2 Comparison of lamivudine *vs* tenofovir disoproxil fumarate on liver stiffness measurement over time. A: Liver stiffness measurement change from baseline (before treatment) and while on treatment; mean with error bars representing standard deviation is plotted; B and C: Comparison of fibrosis severity at baseline, 1-2 years, and 3-4 years post-treatment for lamivudine (B) and for tenofovir disoproxil fumarate (C). F0-F1 (yellow), F2-F3 (red), and F4 (purple). LSM: Liver stiffness measurement; LAM: Lamivudine; TDF: Tenofovir disoproxil fumarate.

etc.) is reimbursed by provincial health care plans.

Our study is similar to previous published work that highlights the benefits of antiviral treatment in improving liver fibrosis. A systemic review and meta-analysis including 34 published studies of treated and untreated CHB patients also found low rates of NA-induced HBsAg seroclearance, highlighting the need for improved curative therapies[18]. In fact, HBsAg seroclearance generally occurred in untreated individuals with less active disease[18], and is consistent with retrospective data from the Canadian HBV Network of CHB patients comparing outcomes in individuals that remained HBsAg positive *vs* those with HBsAg loss[19].

The current study is limited by retrospective data and missing data at all defined time-points, including serial lab and LSMs, and highlights the limitation of real-world studies (*i.e.*, missed appointments, adherence and incomplete clinician documentation or reporting). We also excluded patients treated with the other approved 2nd generation NA (*i.e.*, ETV) for purposes of the study analysis to compare a single 1st *vs* 2nd generation NA therapy. Moreover, although our cohort was multi-ethnic most patients were Asian, albeit individuals were born in many different east and south-east Asian countries. Additionally, there was missing ethnicity data on 52 patients (11%). Overall, this data represents immigration from up to 40 countries, based on Canadian HBV Network Data. The 2016 Canadian census reported the top Asian countries of birth for recent immigrants are Philippines, India, China, Iran, Pakistan, Syria and South Korea and Syria (www.statcan.gc.ca). There is increasing data on LSM for assessment of liver inflammation and HBV-related fibrosis, although transient elastography is not widely available in resource limited countries compared to other non-invasive fibrosis markers such as aspartate aminotransferase to platelet ratio index (APRI) and Fibrosis4 (FIB4) calculator[20]. It is noteworthy that our analysis represents the largest North American study conducted to date on long-term follow-up with NA therapy utilizing this novel technology.

CONCLUSION

In summary in this real-world diverse cohort study of chronic hepatitis B patients in Canada, long-term nucleo(s)ide analog (either 1st or 2nd generation) therapy suppresses HBV DNA and improves hepatic inflammation and liver fibrosis, as determined by non-invasive testing (*i.e.*, transient elastography). In patients treated for up to 5 years, none achieved HBsAg loss (functional cure), highlighting the need for improved therapeutic strategies to reduce the life-long burden of antiviral therapy.

ARTICLE HIGHLIGHTS

Research background

Therapy of hepatitis B virus (HBV) with nucleos(t)ide analogues (NA) can be associated with fibrosis regression. There are both low and high potency agents approved for therapy and access to these therapies maybe variable. There is limited real-world data comparing these agents on their effect to result in fibrosis regression and long term outcomes.

Research motivation

Although high-potency agents are considered the standard of care, there has been variable access to these agents and indeed ongoing use of these agents in 1st world countries to include Canada. It is thus

important to provide evidence in outcomes to include fibrosis regression between the high and low potency NA's. This study may impact the use of these agents in the future, and allow consideration for switching from low to high potency agents if possible.

Research objectives

To assess HBV viral response, biochemical remission, liver fibrosis regression and hepatitis B surface antigen (HBsAg) sero-clearance after treatment with either a 1st or 2nd line NA therapy. These objectives were realized and the future impact would be the consideration of utilizing 1st *vs* 2nd line NA's. Further, other outcome measure to include HBsAg loss and development of hepatocellular carcinoma (HCC) may be considered.

Research methods

We performed a retrospective observational cohort study utilizing a National network in HBV. Novel aspects that allowed this study is the utilization of a National Network which was able to capture differences in NA utilization based on regional differences of reimbursement. The strength of this study lies in the diversity that the Canadian HBV Network provides. The utilization of liver stiffness by transient elastography in a North American cohort for this objective is also unique.

Research results

As per differences in utilization, a larger proportion of patients with advanced fibrosis were initiated with tenofovir disoproxil fumarate (TDF) compared to LAM. At the end of the study period there were similar stages of fibrosis between the 2 groups. There was an increased fibrosis regression in those treated with a high potency compared to a low-potency NA. More patients in the TDF group also achieved virological suppression, though alanine amino transferase (ALT) normalization was similar.

Research conclusions

In this diverse cohort treatment with low and high potency NA's achieves high rates of viral suppression, ALT normalization and a large proportion achieve fibrosis regression. The strength of national collaboration within a network is exemplified in this study in particular taking advantages of diversity within an overall similar medical system. These differences within a Network can be a powerful tool to answer research questions and can reduce a number of biases inherent when comparing populations/studies between countries or regions.

Research perspectives

The future direction would include potential for long-term outcomes with differential NA usage to include HBsAg loss or seroconversion and any differences in development of HCC albeit in a population with differences in stage of fibrosis at baseline. This study population and Network provides a unique perspective to answer this question.

Abstract

BACKGROUND

Microvascular invasion (MVI) of small hepatocellular carcinoma (sHCC) (≤ 3.0 cm) is an independent prognostic factor for poor progression-free and overall survival. Radiomics can help extract imaging information associated with tumor pathophysiology.

AIM

To develop and validate radiomics scores and a nomogram of gadolinium ethoxybenzyl-diethyl-enetriamine pentaacetic acid (Gd-EOB-DTPA)-enhanced magnetic resonance imaging (MRI) for preoperative prediction of MVI in sHCC.

METHODS

In total, 415 patients were diagnosed with sHCC by postoperative pathology. A total of 221 patients were retrospectively included from our hospital. In addition, we recruited 94 and 100 participants as independent external validation sets from two other hospitals. Radiomics models of Gd-EOB-DTPA-enhanced MRI and diffusion-weighted imaging (DWI) were constructed and validated using machine learning. As presented in the radiomics nomogram, a prediction model was developed using multivariable logistic regression analysis, which included radiomics scores, radiologic features, and clinical features, such as the alpha-fetoprotein (AFP) level. The calibration, decision-making curve, and clinical usefulness of the radiomics nomogram were analyzed. The radiomic nomogram was validated using independent external cohort data. The areas under the receiver operating curve (AUC) were used to assess the predictive capability.

RESULTS

Pathological examination confirmed MVI in 64 (28.9%), 22 (23.4%), and 16 (16.0%) of the 221, 94, and 100 patients, respectively. AFP, tumor size, non-smooth tumor margin, incomplete capsule, and peritumoral hypointensity in hepatobiliary phase (HBP) images had poor diagnostic value for MVI of sHCC. Quantitative radiomic features (1409) of MRI scans) were extracted. The classifier of logistic regression (LR) was the best machine learning method, and the radiomics scores of HBP and DWI had great diagnostic efficiency for the prediction of MVI in both the testing set (hospital A) and validation set (hospital B, C). The AUC of HBP was 0.979, 0.970, and 0.803, respectively, and the AUC of DWI was 0.971, 0.816, and 0.801 ($P < 0.05$), respectively. Good calibration and discrimination of the radiomics and clinical combined nomogram model were exhibited in the testing and two external validation cohorts (C-index of HBP and DWI were 0.971, 0.912, 0.808, and 0.970, 0.843, 0.869, respectively). The clinical usefulness of the nomogram was further confirmed using decision curve analysis.

CONCLUSION

AFP and conventional Gd-EOB-DTPA-enhanced MRI features have poor diagnostic accuracies for MVI in patients with sHCC. Machine learning with an LR classifier yielded the best radiomics score for HBP and DWI. The radiomics nomogram developed as a noninvasive preoperative prediction method showed favorable predictive accuracy for evaluating MVI in sHCC.

Core Tip: Microvascular invasion (MVI) accounts for approximately 20% of small hepatocellular carcinoma (sHCC) (≤ 3.0 cm) and is a poor independent prognostic factor for progression-free survival and overall survival. However, no studies have been published on the preoperative prediction of the MVI of sHCC. This multi-center study was developed and validated radiomics scores and nomogram of gadoxetic acid-enhanced magnetic resonance imaging (EOB-MRI) for the preoperative prediction of MVI in sHCC. The results demonstrated that AFP and conventional EOB-MRI features have poor diagnostic accuracy for MVI in patients with sHCC. The radiomics scores of HBP and diffusion-weighted imaging can improve the ability to predict MVI. As a noninvasive preoperative prediction method, the radiomics nomogram presented in this study showed a favorable predictive accuracy in evaluating MVI of sHCC, which may help reassess the clinical therapeutic regimen for patients with sHCC.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the fourth most common cause of cancer-related death and ranks sixth in terms of incident cases worldwide[1]. HCC is an important public health problem worldwide, and the death rate has increased over the past few years[2,3]. The cut-off size to define small HCC (sHCC) has been adopted as 3.0 cm[4]. Although the prognosis of sHCC is better than other types of HCC, the higher postoperative recurrence rate results in poor long-term outcomes after resection of sHCC[5]. Previous studies have confirmed that tumor size, higher tumor stage, worse histological differentiation, and the presence of microvascular invasion (MVI) are significant risk factors for short-term recurrence of HCC[6-8]. In particular, the incidence of MVI, which is an independent poor prognostic factor for progression-free survival and overall survival of patients with sHCC, is generally about 20% in sHCC[9]. The presence or absence of MVI also suggests the need for different therapeutic options for HCC. Research has indicated that transcatheter arterial chemoembolization combined with intensity-modulated radiotherapy and sorafenib showed obvious clinical benefits in HCC patients with MVI[10]. Enlarged hepatectomy may be necessary for patients with sHCC and MVI.

Pathological examination of postoperative specimens is the gold standard for the diagnosis of MVI [11]. However, postoperative specimens exhibit hysteresis, which is not ideal for guiding treatment. In addition to being an invasive method, biopsy carries some risks of bleeding or tumor seeding[12]. Gadolinium ethoxybenzyl-diethylenetriamine pentaacetic acid (Gd-EOB-DTPA) contrast-enhanced liver magnetic resonance imaging (MRI) is a noninvasive examination used to diagnose a variety of liver diseases[13] and can be used to assess liver function in patients with various stages of liver disease[14]. Gd-EOB-DTPA MRI has been used to predict MVI based on tumor size, non-smooth tumor margin, incomplete capsule, and peritumoral hypointensity in the hepatobiliary phase[15-18]. However, sHCC has a small size, regular margin, complete capsule (or no capsule), and is usually free of peritumoral hypointensity. Therefore, it is difficult to predict the MVI of sHCC using traditional GD-EOB-DTPA MRI features.

Radiomics is an emerging field that attempts to quantify tumor heterogeneity related to the tumor parenchyma and microenvironment, including cellularity, extracellular matrix deposition, angiogenesis, necrosis, and fibrosis[19,20]. Machine learning is a scientific method of algorithms and statistical models that uses computers to interpret or predict patterns and inferences[21]. In many medical situations, medical imaging can be analyzed by machine learning through a series of processes, such as image registration, image segmentation, object detection, classification, and outcome prediction[22,23]. Automated computer algorithms can be used for quantitative image analysis, which can objectively quantify the heterogeneity of an image by measuring the spatial variation in the pixel intensity[24]. Radiomics with quantitative analysis provides a potential method for the diagnosis and prognosis of cancers[25,26]. Although a few studies have explored the feasibility of using radiomics based on computed tomography (CT) or MRI features to predict MVI in HCC[27-29], to our knowledge, previous studies have not investigated the prediction of MVI in sHCC. Therefore, this study aimed to explore the diagnostic value of liver Gd-EOB-DTPA MRI features in MVI of sHCC and to construct and validate the predictive efficacy of radiomics signatures and a nomogram for MVI in sHCC. This study also aimed to confirm the best modeling sequences, including images of T1 weighted imaging (T1WI), T2 weighted imaging (T2WI), diffusion-weighted imaging (DWI), and post-Gd-EOB-DTPA enhancement images of the arterial phase (AP), portal vein phase (PVP), and hepatobiliary phase (HBP), for extracting radiomics signatures by machine learning.

MATERIALS AND METHODS

Study cohort

The ethical review board of our institution approved this multi-center and external validation study (No. 2019 KY-E-134). This study adhered to the principles of the Declaration of Helsinki and the requirement for informed consent was waived. First, we retrospectively searched our institution's (Guangxi Medical University First Affiliated Hospital, Hospital A) departmental electronic database for patients with consecutive hospital visits who had undergone upper-abdomen MRI between January 2016 and June 2020. A total of 221 patients were enrolled who met the following inclusion criteria: (1) Patients received Gd-EOB-DTPA enhanced upper-abdomen MRI and small HCC (tumor size ≤ 3.0 cm) were diagnosed; (2) no macrovascular tumor invasion on MRI *(i.e.*, no tumor thrombus in the hepatic or portal veins); (3) primary HCC were diagnosed by histopathologic examination within two weeks after the MRI examination; and (4) MR images were of sufficient image quality. The exclusion criteria of this study were: (1) Patients who had undergone previous hepatobiliary surgery or liver-directed therapy (*i.e.*, transarterial chemoembolization or ablation); and (2) the lesions were diagnosed other than primary HCC. Second, we continuously recruited 94 and 100 participants as independent external validation sets from two other hospitals (Affiliated Hospital of Guilin Medical University and West China Hospital, Hospital B and C) between July 2020 and August 2021 using the same inclusion and exclusion criteria. All patients underwent hepatectomy and pathologic assessment within two weeks of the MRI

examination. The alpha fetal protein (AFP), Child-Pugh grades (grade A to C), and model for end-stage liver disease (MELD) scores were also analyzed and calculated for all patients (Figure 1).

Histopathologic analysis

Two experienced pathologists performed all the histological analyses in our central pathology laboratory. The Edmondson-Steiner classification was used to identify the major histological grades of HCC. When a tumor within a vascular space was lined by the endothelium, MVI was confirmed to be visible only microscopically, and the sites of positive MVI were documented. All disagreements were resolved by consensus.

MRI examination

All patients underwent 3.0 T MRI with six sequences of Gd-EOB-DTPA enhancement and DWI (Discovery MR750, GE Healthcare, Waukesha, WI, United States; Prisma and MAGNETOM Verio, Siemens Healthcare, Erlangen, Germany), including T1WI, T2WI, DWI, and post-injection phases of EOB as AP, PVP, and HBP. Detailed descriptions of the imaging acquisition protocols are summarized in Supplementary Table 1. For advanced DWI image quality, respiratory triggering, propeller, and resolve technical proposals were adopted.

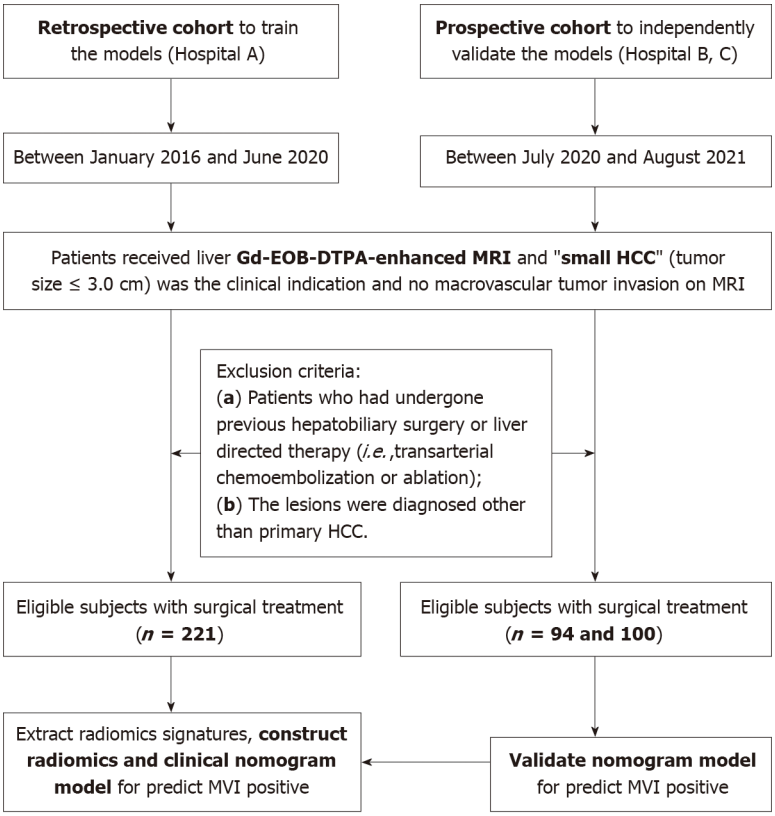
Conventional radiological features analysis

Conventional radiological features were carefully evaluated based on the Liver Imaging Reporting and Data System (LI-RADS v2018), which included the tumor size, AP hyperenhancement, blood products in mass, capsule, corona enhancement, delayed central enhancement, diffusion restriction, fat or iron in mass more than the adjacent liver, fat or iron sparing in a solid mass, mosaic appearance, hepatobiliary phase hypointensity, hepatobiliary phase isointensity, and nodule-in-nodule appearance. The following MRI features were selected in this study: (1) Tumor size; the maximum diameter was measured on HBP axial images; (2) non-smooth tumor margin, which was defined as nodular with extranodular growth or multinodular confluence; (3) incomplete capsule, the region where the tumor border with liver tissue has no or incomplete capsule on portal venous phase or delayed phase; and (4) peritumoral hypointensity on HBP, wedge-shaped hypointense located outside of the tumor margin on HBP. After independent evaluation by three senior radiologists, discussions were conducted to reach a consensus wherever discrepancies occurred.

RADIOMICS SIGNATURES AND REPRODUCIBILITY ANALYSIS

Segmentation of the volume of interests

The Digital Imaging and Communications in Medicine images were transferred to the Big Data Intelligent Analysis Cloud Platform (Huiying Medical Technology Co., Ltd., Beijing, China). Two experts in liver MRI (senior radiologists with 15 and 25 years of experience) reviewed all images, and a radiologist manually segmented all target lesions who were blinded to the clinical information, creating a segmented volume of interest (VOI). After completion of the VOIs by a junior radiologist, the VOIs were reviewed by a senior radiologist for validation. To minimize the intensity variations caused by different scanning equipment and scanning parameters, these MR images were normalized by the standard deviation (μ-3σ, μ + 3σ) before feature extraction, and all delineated VOIs were automatically analyzed (Figure 2).



As two radiologists measured the radiomics features to assess reproducibility, we calculated the intraclass correlation coefficient (ICC). When the ICC was > 0.80, consistency was considered excellent.

Features extraction

We extracted 1409 quantitative imaging features from VOIs using the cloud platform big data intelligent analysis (http://radcloud.cn/). The features were categorized into four groups. The first-order statistical features were considered as group 1 (including a total of 18 descriptors), which delineated the distribution of voxel intensities in the MR images through common and basic metrics. Group 2 included shape- and size-based features (containing 14 three-dimensional features) that reflected the shape and size of the lesion areas. Group 3 included features of two-order texture, gray-level co-occurrence, and gray-level run-length texture matrices that were used to calculate those features, and 75 texture features were extracted to quantify the heterogeneity of lesions. The higher-order filter features such as group 4, Laplacian, wavelet, logarithmic, and exponential filters were applied to medical images, and then the first-order statistics and texture features were extracted based on the filtered image (1302 filter features).

Features selection

The least absolute shrinkage and selection operator (LASSO) was used to decrease irrelevance and redundancy. We performed a 10-fold cross-validation to select the optimal feature subset in LASSO regression, which was based on binomial deviance minimization criteria from the training cohort with a

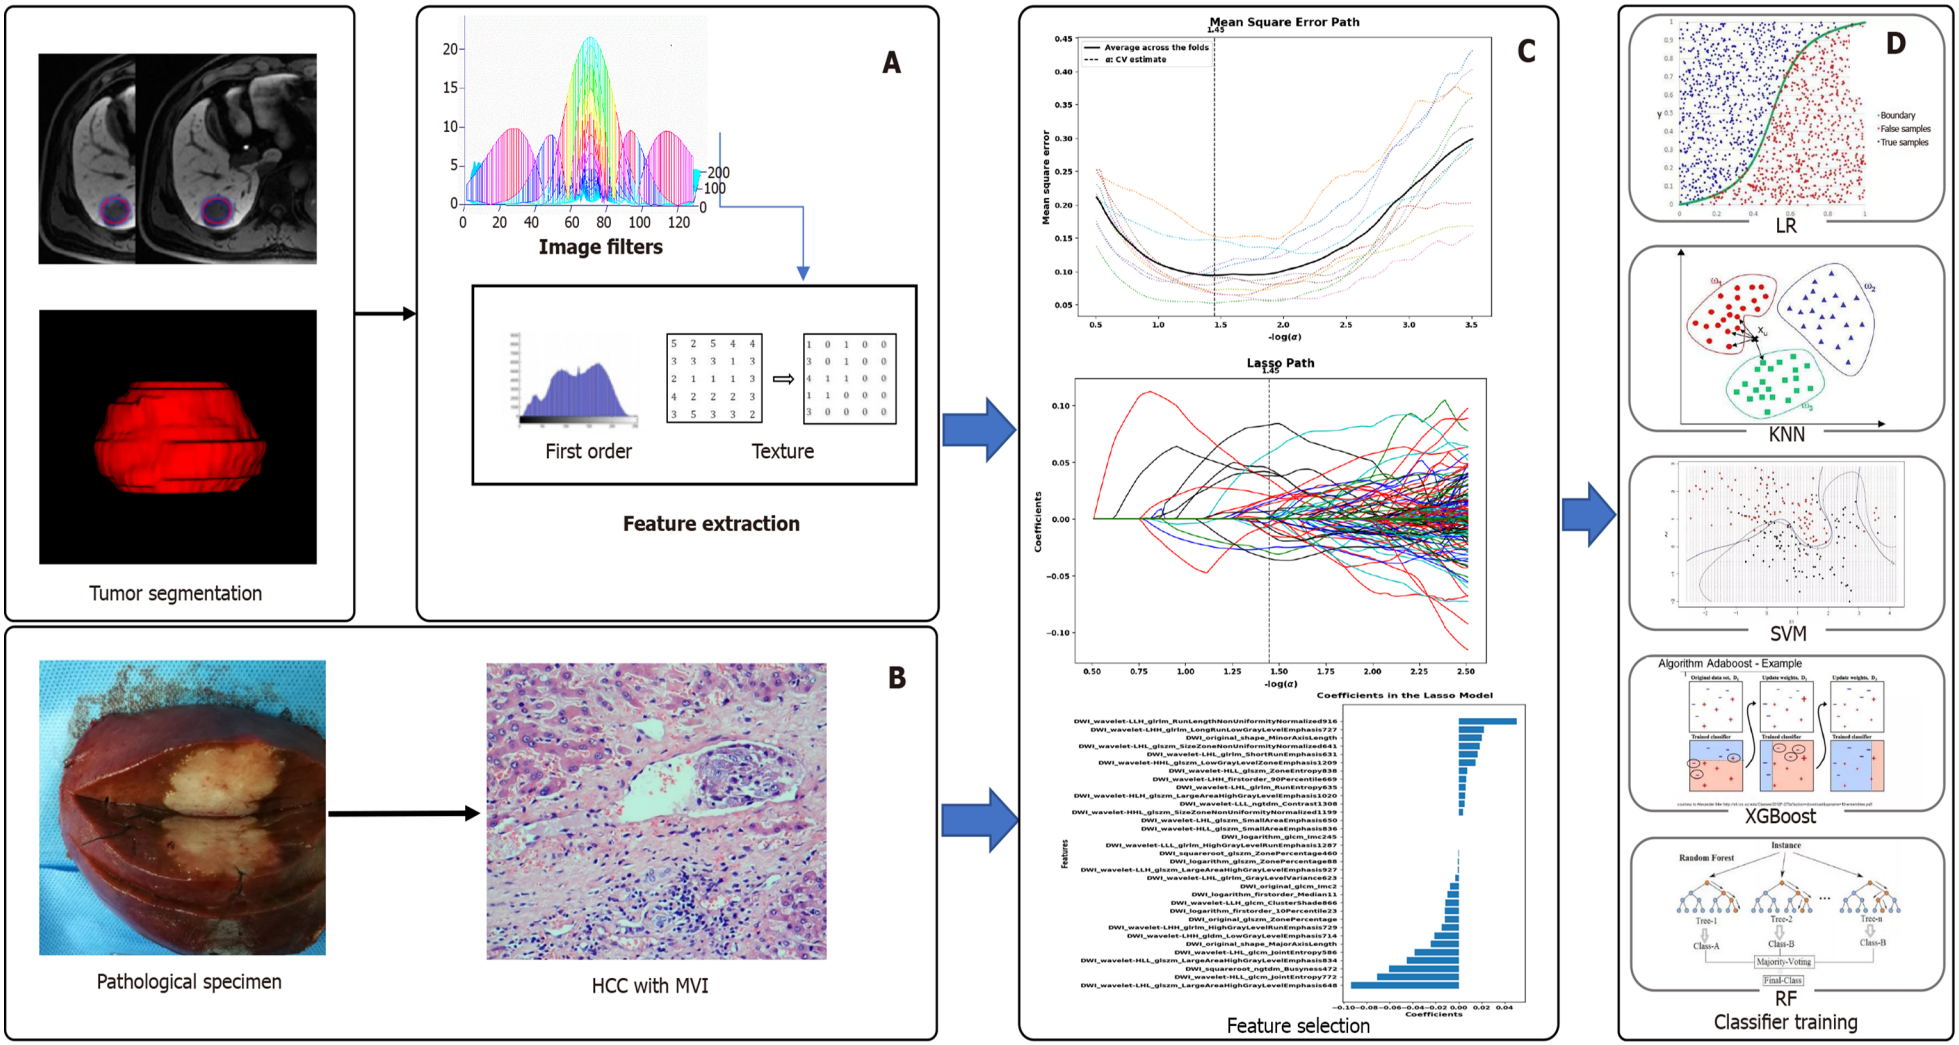
Figure 1 Flow diagram of the study cohort. A total of 415 participants were included in this multi-center study.

maximum iteration of 2000. A variance threshold of 0.8 was used for the selected eigenvalues of the variance.

Model development and validation



The retrospective data (Hospital A) were separated from the training and testing datasets using a random method with a ratio of 7:3, and external data (Hospitals B and C) as the independent validation sets. After feature qualification, based on the selected features, several machine learning classifiers can be used for classification analysis, creating models that can separate or predict MVI-positive data. In this study, radiomics-based LASSO models (machine learning) were constructed using T1WI, T2WI, DWI, AP, PVP, and HBP. We selected K-nearest neighbor (KNN), support vector machine (SVM), extreme gradient boosting (XGBoost), random forest (RF), logistic regression (LR), and decision tree (DT) as the machine learning classifiers, and the effectiveness of the model was improved using the validation method (Figure 2).

Confirmation of radiomics nomogram

R package (version 3.0, http://www.r-project.org/) was used to analyze the radiomics nomogram. Multivariate logistic regression analysis was performed to develop a model for predicting MVI, and all variables associated with MVI at a significant level were candidates for stepwise multivariate analysis. A nomogram was constructed based on the results of the multivariate logistic regression analysis. The receiver operating characteristic (ROC) curve was used to calculate the discrimination performance of the established models, and the values of the area under the curve (AUC) were compared using the Delong non-parametric approach. The calibration of the radiomics model was assessed using calibration curves. External data from the independent validation sets (hospitals B and C) were used to test the performance of the radiomics model. Finally, we constructed decision curves by calculating the net benefits for a range of threshold probabilities.

Statistical analyses

MedCalc 16.2.1 (Ostend, Belgium) and SPSS (version 22.0; Armonk, NY, United States) were used for the statistical analyses. The Kolmogorov-Smirnov method was used to identify the normal distribution of continuous variables. The differences in categorical and continuous variables were compared using the χ^2 test, Fisher's exact test, two-sample *t*-test, or Mann-Whitney *U* test, respectively. ROC analyses were performed to evaluate the predictive performance of MVI for sHCC. The Youden index was used for determining the cut-off values. Then, the AUC, sensitivity, and specificity were calculated, and a *Z*

RESULTS

Patients and serological examinations

A total of 415 patients with qualified sHCC were enrolled in the final study (Figure 1). In hospitals A, B, and C, the mean participant age was 51.2 ± 10.9 (range 29-78) years, 53.04 ± 10.59 (range 28-77) years, and 54.01 ± 10.82 (range 28-85) years, respectively. Histological examination confirmed MVI in 64 (28.9%), 22 (23.4%), and 16 (16.0%) patients. The number of patients with hepatitis B, C and alcoholic hepatitis were 162 (73.3%), 21 (9.5%), 29 (13.1%); 71 (75.6%), 10 (10.6%), 8 (8.5%); and 82 (82.0%), 6 (6.0%), 2 (2.0%), respectively. The numbers of patients with cirrhosis were 173 (78.3%), 69 (73.4%), and 70 (70%), respectively. The median serum AFP levels were 26.10 (range 0.98-25451.00) ng/mL, 9.34 (range 1.09-6740.42) ng/mL, and 31.070 (range 0.713-4587.000) ng/mL, respectively. The median serum total bilirubin levels were 12.5 (range 2.9-64.6) μmol/L, 17.4 (range 3.6-446.9) μmol/L and 13.2 (range 4.4-47.2) μmol/L, respectively. The median direct bilirubin levels were 3.9 (range 1.0-17.0) μmol/L, 4.5 (range 1.0-218.9) μmol/L and 5.50 (range 1.50-26.84) μmol/L, respectively. The MELD scores were 13.9 ± 4.8 (range 7.0-26.9), 13.8 ± 5.8 (range 6.0-35.5) and 11.8 ± 4.5 (range 5.2-25.6). The number of Child-Pugh classes A, B, and C were 205 (93.2%), 13 (5.9%), 2 (0.9%), 81 (86.2%), 12 (12.8%), 1 (1.1%), 86 (86.0%), 13 (13.0%), and 1 (1.0%), respectively. There were 32 (14.5%), 142 (64.3%), 47 (21.2%); 12 (12.8%), 68 (72.3%), 14 (14.9%) and 8 (8.0%), 71 (71.0%), 21 (21.0%) cases that were histological grades I, II, and III, respectively (Table 1).

Conventional radiological features

In the group comparison of MVI-positive and negative, the AFP and tumor size were 33.91 (range 1.4-25451.0) and 22.52 (range 0.98-18929.00) (ng/mL) ($P = 0.026$), 2.34 ± 0.56 and 1.92 ± 0.67 (cm) ($P = 0.036$) in hospital A; 38.97 (range 1.90-6740.40) and 5.43 (range 1.10-2018.79) (ng/mL) ($P = 0.01$), 2.43 ± 0.57 and 2.11 ± 0.66 (cm) ($P = 0.047$) in hospital B; 109.72 (range 0.80-2278.00) and 24.41 (range 0.71-4587.00) (ng/mL) ($P = 0.032$), 2.47 ± 0.43 and 2.21 ± 0.64 (cm) ($P = 0.054$) in hospital C. In the MVI-positive group, the proportion of patients with non-smooth tumor margin, incomplete capsule, and peritumoral hypointensity was 39.7% (27/68) ($P = 0.019$), 40.3% (25/62) ($P = 0.02$), and 51.5% (17/33) ($P = 0.002$) in hospital A; 52.9% (9/17) ($P = 0.003$), 59.5% (25/42) ($P = 0.062$), and 35.7% (5/14) ($P = 0.304$) in hospital B; and 31.3% (10/32) ($P = 0.004$), 14.6% (6/41) ($P = 0.759$), and 63.6% (14/22) ($P = 0.002$) in hospital C (Table 2).

For discriminating MVI-positive, in hospital A, B and C the AUC of AFP was 0.597 [95% confidence interval (CI):0.528-0.662], 0.683 (95%CI):0.528-0.662] and 0.669 (95%CI:0.568-0.760), respectively; the AUC of tumor size was 0.675 (95%CI:0.609-0.736), 0.639 (95%CI:0.553-0.735) and 0.576 (95%CI:0.473-0.675), respectively; the AUC of non-smooth tumor margin was 0.580 (95%CI:0.512-0.646), 0.649 (95%CI:0.544-0.745) and 0.682 (95%CI:0.581-0.771), respectively; the AUC of incomplete capsule was 0.577 (95%CI:0.509-0.643), 0.595 (95%CI:0.489-0.695) and 0.521 (95%CI:0.419-0.622), respectively; the AUC of peritumoral hypointensity on HBP was 0.582 (95%CI:0.514-0.648), 0.551 (95%CI:0.445-0.654) and 0.667 (95%CI:0.565-0.758), respectively (Table 3).

Radiomics signatures

There were 155 and 66 patients with sHCC in the training and test datasets, respectively. The proportions of MVI-positive patients were 27.1% and 29%, respectively. There were no significant differences in patient characteristics between the training and testing cohorts ($P > 0.05$). Among the 1409 radiomics features in each T1WI, T2WI, DWI, AP, PVP, and HBP model, 443, 483, 467, 554, 462, and 453 features were selected based on a variance threshold of over 0.80. After LASSO analysis, five, 22, 33, four, eight, and 30 features were selected for T1WI, T2WI, DWI, AP, PVP, and HBP, respectively.

Robustness analysis results

We found that 70.5% (993/1409) of the features extracted from T1WI images had excellent consistency (ICC > 0.8), and all five features selected for modeling had excellent consistency (ICC median, 0.969; minimum, 0.877; maximum, 1.000). The features of 51.9% (731/1409) extracted from T2WI images had excellent consistency (ICC > 0.8), and most of the 22 features selected for modeling had good consistency (ICC median, 0.701; minimum, 0.41; maximum, 0.94). The features of 60.04% (846/1409) extracted from DWI images had excellent consistency (ICC > 0.8), and most of the 33 features selected for modeling had excellent consistency (ICC median, 0.869; minimum, 0.41; maximum, 0.98). The features of 67.8% (956/1409) extracted from AP images had excellent consistency (ICC > 0.8), and the ICC of the four features selected for modeling were 0.902, 0.884, 0.734, and 0.891. The features of 62.1% (875/1409) extracted from PVP images had excellent consistency (ICC > 0.8), and most of the eight features selected for modeling had excellent consistency (ICC median = 0.844, minimum = 0.500, maximum = 1.000). The features of 82.5% (1163/1409) extracted from HBP images had excellent consistency (ICC > 0.8), and most of the 30 features selected for modeling had excellent consistency (ICC

Predictive performance of the machine learning classifiers

The machine learning classifiers used in this study were KNN, LR, MLP, RF, SVM, and DT. In general, all classifiers achieved satisfactory performance, with LR being the best machine learning method. To predict MVI, T1WI, T2WI, DWI, AP, PVP, and HBP radiomics models were constructed and validated. In the testing set, the AUCs were 0.776 (95%CI: 0.611-0.895), 0.813 (95%CI: 0.651-0.922), 0.971 (95%CI: 0.858-0.999), 0.788 (95%CI: 0.642-0.894), 0.790 (95%CI: 0.630-0.904) and 0.979 (95%CI: 0.911-1.000). In validation hospital B, the AUCs were 0.834 (95%CI: 0.742-0.904), 0.825 (95%CI: 0.732-0.896), 0.816 (95%CI: 0.678-0.876), 0.810 (95%CI: 0.715-0.884), 0.847 (95%CI: 0.758-0.913) and 0.970 (95%CI: 0.912-0.994). In validation hospital C, the AUCs were 0.766 (95%CI: 0.672-0.844), 0.761 (95%CI: 0.669-0.839), 0.801 (95%CI: 0.710-0.871), 0.824 (95%CI: 0.737-0.892), 0.833 (95%CI: 0.748-0.898) and 0.803 (95%CI: 0.680-0.834) (Figure 3, Table 4).

Development and validation of MVI predicting nomogram

The C-indexes of the radiomics and clinic combined nomogram with the model of T1WI, T2WI, DWI, AP, PVP and HBP were 0.771 (95%CI: 0.695-0.836), 0.895 (95%CI: 0.834-0.940), 0.990 (95%CI: 0.957-0.999), 0.774 (95%CI: 0.706-0.833), 0.746 (95%CI: 0.668-0.814) and 0.990 (95%CI: 0.944-0.993) in the training set,

respectively; 0.846 (95%CI: 0.594-0.883), 0.917 (95%CI: 0.640-0.915), 0.970 (95%CI: 0.843-0.997), 0.794 (95%CI: 0.615-0.876), 0.831 (95%CI: 0.650-0.916) and 0.971 (95%CI: 0.892-0.999) in the testing set, respectively; 0.895 (95%CI: 0.775-0.925), 0.886 (95%CI: 0.746-0.906), 0.843 (95%CI: 0.685-0.881), 0.886 (95%CI: 0.695-0.899), 0.918 (95%CI: 0.791-0.934) and 0.912 (95%CI: 0.918-0.996) in validation hospital B, respectively; 0.830 (95%CI: 0.667-0.850), 0.808 (95%CI: 0.654-0.867), 0.869 (95%CI: 0.694-0.899), 0.874 (95%CI: 0.674-0.884), 0.870 (95%CI: 0.732-0.887) and 0.808 (95%CI: 0.635-0.892) in validation hospital C, respectively (Figure 4, Table 5).

Decision curve analysis showed adequate performance for radiomics nomogram models for predicting MVI in sHCC. The proposed radiomics model to predict MVI showed a greater advantage than the "clinicoradiological" scheme ($P < 0.05$). There was no significant difference in predictive efficacy between the combination nomogram model and the single radiomics model ($P > 0.05$) (Figure 5).

DISCUSSION

In this multi-center study, we analyzed the clinical and imaging data of 415 patients with sHCC who underwent DWI, Gd-EOB-DTPA-enhanced MRI, and hepatectomy. We used a machine learning approach to construct radiomics signatures and nomogram models for preoperative prediction of MVI and then independently validated the machine learning and nomogram models. Our data showed that clinical and common MRI radiological features, including AFP, tumor size, non-smooth tumor margin, incomplete capsule, and HBP peritumoral hypointensity, have limited diagnostic value for MVI of sHCC. The LR classifier was the best machine learning method, and the radiomics scores of HBP and DWI had great diagnostic efficiency for predicting MVI of sHCC. The nomogram model of combined radiomics scores, APF, and common MRI features exhibited good calibration and discrimination in the training, testing, and independent external validation cohorts.

Gd-EOB-DTPA with a pendant ethoxybenzyl group covalently attached to gadopentetate dimeglumine is a hepatocyte-specific MRI contrast agent that can be taken up by hepatocytes *via* the organic anion transporting polypeptides[30]. Gd-EOB-DTPA, which has dual extracellular and hepatobiliary

properties that provide structural and functional information on liver lesions, can also provide information on nonspecific gadolinium chelates during dynamic enhancement[31,32]. Granito *et al*[33] reported that Gd-EOB-DTPA-enhanced MRI may improve the sensitivity of noninvasive diagnosis of small HCC nodules in patients with cirrhosis, and the double hypointensity in the portal/venous and HBP can be regarded as an MRI pattern, which is highly suggestive of hypovascular hepatocellular carcinoma. This previous study revealed that large tumor size, incomplete capsule, non-smooth tumor margin, peritumoral enhancement on AP, and peritumoral hypointensity on HBP could achieve predictive AUCs of up to 0.85 for MVI of HCC[34]. However, for small HCC (large tumor size ≤ 3 cm), the common MRI radiologic features are smooth tumor margin, complete capsule (or no capsule), and no peritumoral hypointensity in HBP. In this study, the results from three hospitals showed that these conventional MRI radiologic features had limited value in evaluating MVI for sHCC.

Based on these characteristics, we established a Gd-EOB-DTPA MRI radiomics model using machine learning to construct and validate radiomics models for predicting MVI of sHCC. Machine learning has demonstrated capabilities to learn and even master complex tasks, making it useful for computer-aided diagnosis and decision support systems[21]. Radiomics refers to a technique of high-throughput extraction of quantitative imaging features or textures to decode histology and create a high-dimensional dataset[35]. However, it was thought that the parameters of the MRI scanner would not have an obvious influence on the results of radiomics analysis after the images were standardized when a previous multi-center study[36] did not demand the same MRI scanners and parameters. However, to minimize the possible influence of other factors, a unified MRI scanner and image standardization process were used in our study. Furthermore, whole-tumor volume analysis was used to decrease sampling bias.

Although previous studies have verified that the radiomics features of CT imaging could predict MVI status in patients with HCC preoperatively, it has high diagnostic efficiency, and the AUC can reach approximately 0.85[27,37]. In addition, Feng *et al*[38] evaluated Gd-EOB-DTPA-enhanced MRI quantitative features of peri- and intratumoral regions, providing a radiomics model for MVI prediction in patients with HCC. In the validation cohort, the AUC, sensitivity, and specificity were 0.83%, 90.00%, and 75.00%, respectively. However, none of these studies predicted the MVI for sHCC or provided a clinical nomogram. In this study, we extracted radiomics signatures from images of Gd-EOB-DTPA-

enhanced MRI and then built the model using T1WI, T2WI, AP, PVP, and HBP. The results illustrated that radiomics has the best modeling in HBP and DWI when the LR and classifier of machine learning are utilized, producing great diagnostic efficiency for predicting MVI. Furthermore, the independent external validation results confirmed this efficiency. This may be because the post-Gd-EOB-DTPA contrast enhancement images provide structural and functional information on HBP lesions. The LR algorithm is used to establish a cost function for a classification or regression problem and then solve the optimal model iteratively through the optimization method.

Our results also demonstrate that the radiomics characteristics of DWI images can accurately predict the MVI of sHCC. DWI is an MRI technology that can reflect the motion of water molecules *in vivo* and can be used to assess tumor cellularity[39]. HCC with MVI is more likely to have higher cellularity and poor differentiation than HCC without MVI[40]. Okamura *et al*[41] suggested that the apparent diffusion coefficient (ADC) value is a valuable predictor of poor differentiation and MVI and is significantly related to tumor recurrence. Kim *et al*[42] illustrated that the tumor-to-liver ADC ratio was a significant independent parameter for the MVI of sHCC and the degree of lymphocyte infiltration. Our research further extracted the radiomics characteristics of the tumor, which were based on DWI images that confirmed that the quantitative characteristics of the radiomics had good performance for predicting the MVI of sHCC.

A nomogram was built in our study, which converted each regression coefficient proportionally in multivariate logistic regression to a 0- to 100-point scale. The effect of features with the absolute value of the highest β coefficient was assigned 100 points. The total points of the independent variables were

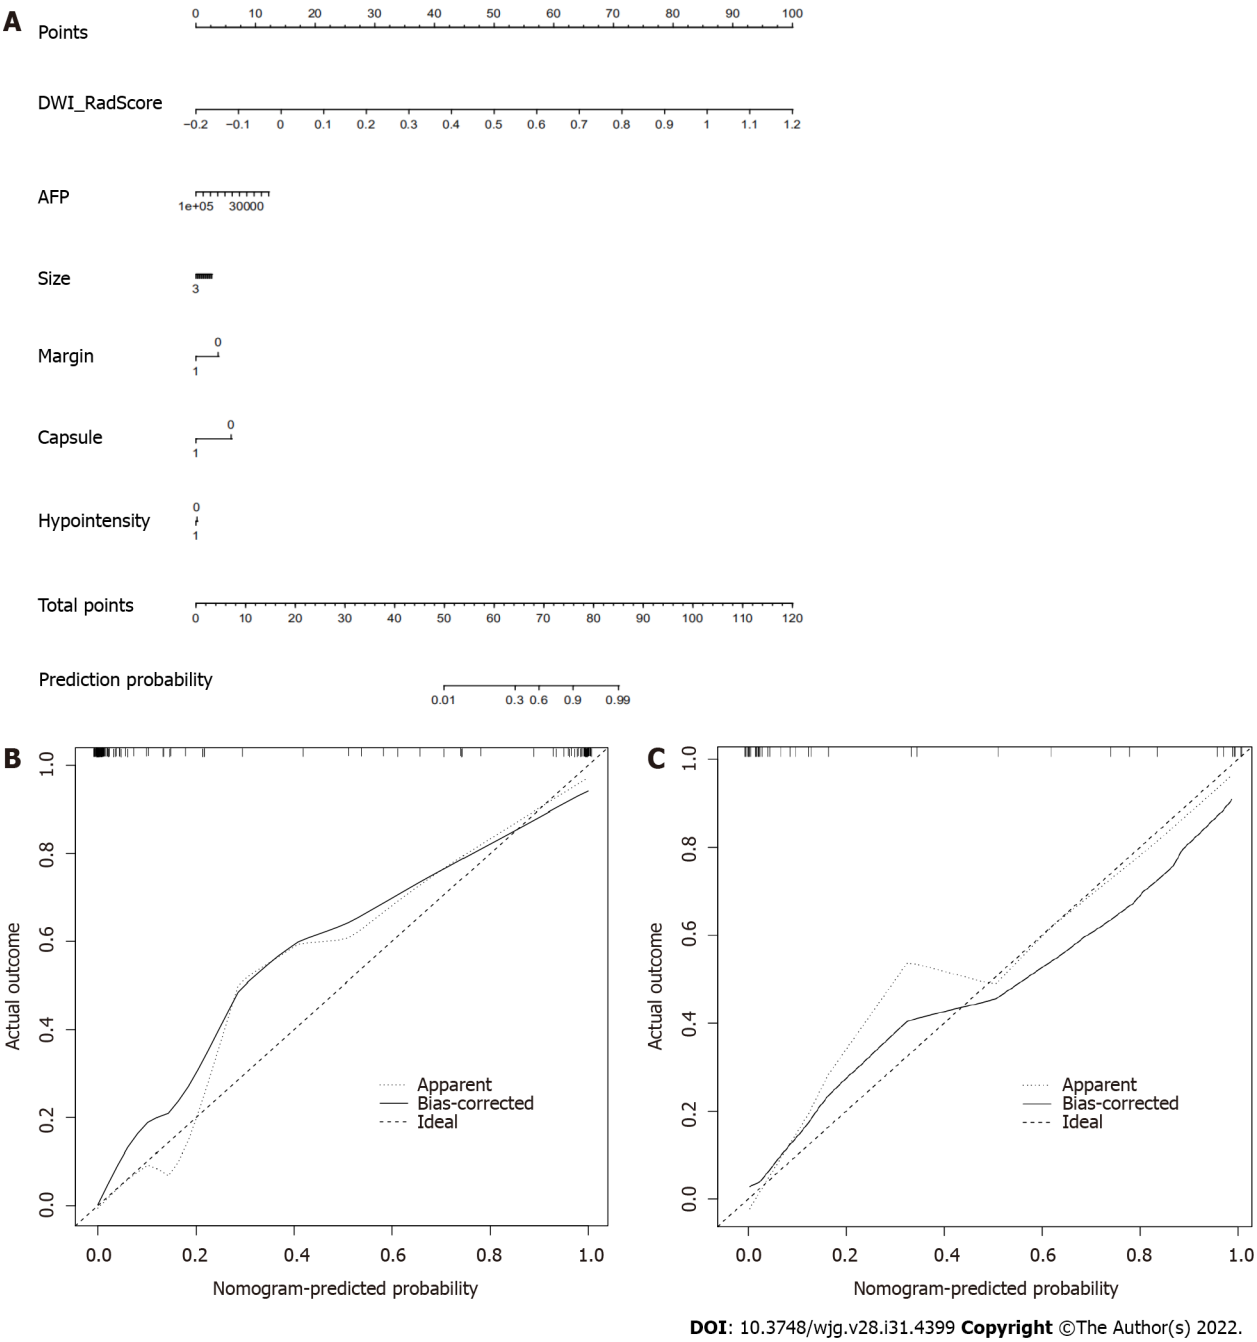
converted to the predicted probabilities. The concordance index (C-index) was used to predict the performance of the nomogram and calibration with 1000 bootstrap samples to decrease the overfitting bias[43]. Our study incorporated six factors: radiomics signatures, APF, tumor size, non-smooth tumor margin, incomplete capsule, and peritumoral hypointensity. Radiomics combined with the clinico-radiological factors nomogram model achieved good concordance indices in predicting MVI in the training and validation cohorts. In particular, the nomogram with HBP and DWI radiomics model showed excellent predictive efficiency in the two external validation datasets, and decision curve analysis further confirmed the clinical usefulness of the nomogram.



Nonetheless, this study had several limitations. First, the included patient population in this study had an inevitable bias in the inter-center distribution, although the application of radiomics and clinical nomogram was ensured by the multi-center nature of this study. To investigate the impact factors of bias on the baseline, we analyzed the age, AFP levels, liver function, and tumor size. Further larger-scale studies with more balanced subjects are needed to validate our results. Second, given the difficulty of collecting scalable medical imaging data for small HCC, many patients with small HCC who underwent transarterial chemoembolization or ablation could not be enrolled in the model of radiomics signatures and clinical nomogram to predict MVI. Given larger medical imaging datasets, deep networks are expected to improve prediction accuracy. Third, due to the lack of prognostic analysis in this study, we analyzed the different prognoses of sHCC patients with positive and negative MVI, which were predicted using a radiomics nomogram.

have poor diagnostic accuracies for MVI in sHCC. The radiomic signatures of HBP and DWI can further improve the ability to predict MVI. Furthermore, as a noninvasive preoperative prediction method, the radiomics nomogram showed favorable predictive accuracy for evaluating MVI in sHCC, which may help reassess the clinical therapeutic regimen for patients with sHCC.

ARTICLE HIGHLIGHTS

Research background

Microvascular invasion (MVI) of hepatocellular carcinoma (HCC) is an independent poor prognostic factor.

Research motivation

It is difficult to determine MVI of small hepatocellular carcinoma (HCC) (≤ 3.0 cm) by preoperative MRI conventional features.

Research objectives

To develop and validate radiomics scores and nomogram of gadolinium ethoxybenzyl diethylenetriamine pentaacetic acid (Gd-EOB-DTPA)-enhanced magnetic resonance imaging (MRI) for preoperative prediction of MVI in sHCC.

Research methods

Radiomics models of Gd-EOB-DTPA enhanced MRI and diffusion weighted images were constructed and validated by machine learning from data sets of three hospitals. A nomogram prediction model was developed using multivariable logistic regression analysis which included the radiomics scores, radiologic features, and alpha-fetoprotein (AFP) level.

Research results

AFP and MRI conventional features had poor diagnostic value for MVI of small HCC. The nomogram model (combined radiomics and clinic features) exhibited good calibration and discrimination in the testing and two external validation cohorts (in the two external validation cohorts, C-index was 0.912 and 0.808, respectively).

Research conclusions

As a noninvasive preoperative prediction method, the MRI radiomics nomogram shows favorable predictive accuracy for evaluate MVI in sHCC.

Research perspectives

This clinical prediction model may help in the selection of treatment options for small HCC.

Abstract

BACKGROUND

Autoimmune liver disease (AILD) has been considered a relatively uncommon disease in China, epidemiological data for AILD in patients with cirrhosis and acute decompensation (AD) is sparse.

AIM

To investigate the prevalence, outcome and risk factors for AILD in cirrhotic patients complicated with AD in China.

METHODS

We collected data from patients with cirrhosis and AD from two prospective, multicenter cohorts in hepatitis B virus endemic areas. Patients were regularly followed up at the end of 28-d, 90-d and 365-d, or until death or liver transplantation (LT). The primary outcome in this study was 90-d LT-free mortality. Acute-on-chronic liver failure (ACLF) was assessed on admission and during 28-d hospitalization, according to the diagnostic criteria of the European Association for the Study of the Liver (EASL). Risk factors for death were analyzed with logistic regression model.

RESULTS

In patients with cirrhosis and AD, the overall prevalence of AILD was 9.3% (242/2597). Prevalence of ACLF was significantly lower in AILD cases (14%) than those with all etiology groups with cirrhosis and AD (22.8%) ($P < 0.001$). Among 242 enrolled AILD patients, the prevalence rates of primary biliary cirrhosis (PBC), autoimmune hepatitis (AIH) and PBC-AIH overlap syndrome (PBC/AIH) were 50.8%, 28.5% and 12.0%, respectively. In ACLF patients, the proportions of PBC, AIH and PBC/AIH were 41.2%, 29.4% and 20.6%. 28-d and 90-d mortality were 43.8% and 80.0% in AILD-related ACLF. The etiology of AILD had no significant impact on 28-d, 90-d or 365-d LT-free mortality in patients with cirrhosis and AD in both univariate and multivariate analysis. Total bilirubin (TB), hepatic encephalopathy (HE) and blood urea nitrogen (BUN) were independent risk factors for 90-d LT-free mortality in multivariate analysis. The development of ACLF during hospitalization only independently correlated to TB and international normalized ratio.

CONCLUSION

AILD was not rare in hospitalized patients with cirrhosis and AD in China, among which PBC was the most common etiology. 90-d LT-free mortality were independently associated with TB, HE and BUN.

Key Words: Prevalence; Autoimmune liver disease; Cirrhosis and acute decompensation; Mortality; Acute-on-chronic liver failure

Core Tip: Autoimmune liver disease (AILD) has been regarded as a relatively rare disease in China. Our study reported that the overall prevalence of AILD was 9.3% hospitalized patients with cirrhosis and acute decompensation, among which primary biliary cirrhosis was the most prevalent type. In AILD patients with cirrhosis and acute decompensation, the etiology types of AILD had no significant effect on short-term mortality, total bilirubin, hepatic encephalopathy (HE) and blood urea nitrogen were independently associated with 90-d mortality in multivariate analysis. Strategies are needed to prevent presence of HE and closely monitor the changes of liver and renal function in clinical practice. These data will be a crucial complement to the public epidemiology research on AILD in Asian-Pacific regions.

INTRODUCTION

Autoimmune liver disease (AILD) includes primary biliary cirrhosis (PBC), autoimmune hepatitis (AIH), primary sclerosing cholangitis (PSC) and immunoglobulin G 4-related diseases (IgG4-RD)[1-3]. Some patients display clinical manifestations of two different entities based on clinical and histological features, which is described as "overlap syndrome", among which PBC-AIH overlap syndrome (PBC/AIH) is the most common[4]. AILD has been considered to be a relatively rare etiology of chronic liver disease (CLD) in China where viral hepatitis has a high prevalence. However, recent findings indicated that the prevalence of AILD is increasing in the Asia-Pacific region. In Japan, AIH prevalence increased from 8.7 to 23.9 per 100000 population from 2004 to 2016[5]. In a city in northern China, PBC prevalence rose from 0.5 to 8.0 per 100000 population in the past 10 years[6]. Several studies have illustrated the prevalence and clinical characteristics of AILD in general population[7-9]. Few studies have been conducted to investigate the nature history of AILD, especially in the late stage of CLD-cirrhosis and acute decompensation (AD).

The Chinese Acute on Chronic Liver Failure (CATCH-LIFE) study consisted of two prospective, multicenter cohorts that enrolled hospitalized patients with CLD of various etiologies, most of whom had cirrhosis and complicated with AD. It is nationally representative of hospitalized CLD patients in China. In this study, we used the data from the CATCH-LIFE study to investigate the following: (1) The prevalence and short-term outcome of AILD in patients with cirrhosis and AD; (2) The impact of AILD etiology on mortality; and (3) Risk factors for 90-d mortality in AILD patients with cirrhosis and AD.

MATERIALS AND METHODS

Patients

Data were collected from 2 prospective, observational cohorts of the CATCH-LIFE study which enrolled hospitalized patients with CLD and acute events, from January 2015 to December 2016 and July 2018 to January 2019, respectively. The rationale and design of the cohorts have been described elsewhere[10, 11]. The medical ethics boards of the Shanghai Renji Hospital, approved the study. Written informed consent were obtained from every participant or his or her legal surrogates before enrollment.

Cirrhosis was diagnosed according to a computed tomography/magnetic resonance imaging scan, clinical symptoms, laboratory tests and medical history[12]. AD was defined as ascites, variceal hemorrhage, hepatic encephalopathy (HE), infection and jaundice within 1 mo[13]. The diagnosis of AILD was exclusionary. The following patients were excluded: Coinfections with other viruses [hepatitis A virus, hepatitis B virus (HBV), hepatitis C virus and hepatitis E virus], alcoholic liver disease, nonalcoholic fatty liver disease, schistosomiasis, metabolic liver diseases, chronic drug-induced liver disease, and cryptogenic liver disease.

PBC was defined according to the American Association for the Study of Liver Diseases clinical guidance in 2008[14], with at least 2 of the following: (1) Elevated serum alkaline phosphatase (ALP) [> 1.5 folds the upper limit of normal (ULN)] or gamma glutamyl transpeptidase (GGT) (> 3 ULN); (2) Positive test for antimitochondrial antibodies (AMA) (titer > 1:40); and (3) Compatible liver biopsy suggestive of suppurative destructive cholangitis (ductopenia, cholestasis, fibrosis and portal inflammation). AIH was defined based on simplified criteria (score > 6) proposed by the International

Autoimmune Hepatitis Group in 2008[15]. PBC/AIH overlap syndrome was strictly diagnosed according to the Paris Criteria proposed by Chazouillères *et al*[16] in 1998, which associated PBC and AIH either synchronously or consecutively. Presence of at least 2 of the 3 criteria was required. PBC criteria were the following: (1) ALP > 2 ULN or GGT > 5 ULN; (2) A positive serology for AMA; and (3) A liver biopsy specimen indicating florid bile duct lesions. AIH criteria were the following: (1) Serum alanine transaminase (ALT) > 5 ULN; (2) IgG > 2 ULN or a positive serology for anti-smooth muscle antibodies; and (3) A liver biopsy indicating moderate to severe periportal or periseptal lymphocytic piecemeal interface hepatitis.

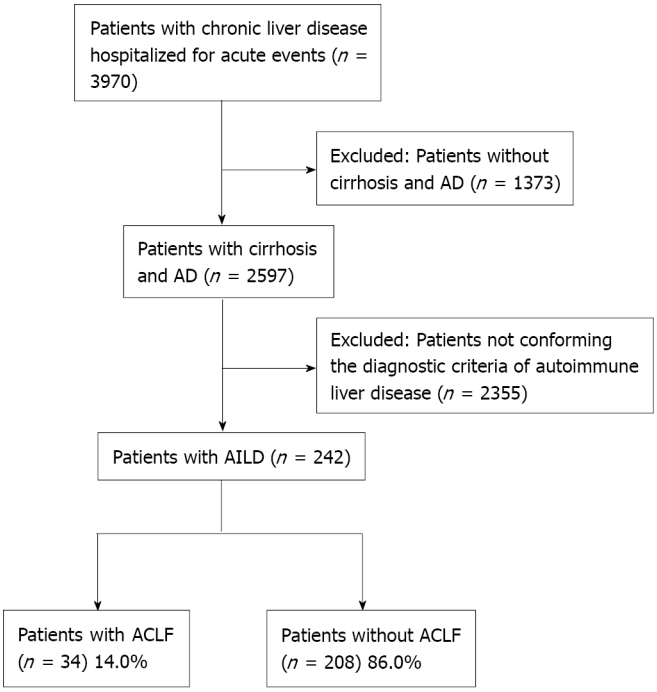
Some uncommon etiologies of AILD in this study, such as PSC, PBC-PSC overlap syndrome, AIH-PSC overlap syndrome and IgG4-RD were categorized into a "others" group, as the number of cases of "others" was quite small to allow robust statistical analysis. Acute-on-chronic liver failure (ACLF) was diagnosed based on the European Association for the Study of the Liver (EASL) criteria[17]. Just as follows: (1) ACLF grade 1: Single kidney failure or single cerebral failure with renal dysfunction (1.5 mg/dL < creatinine < 1.9 mg/dL) or other single organ failure [serum bilirubin ≥ 12 mg/dL for liver; (international normalized ratio) INR = 2.5 for coagulation; vasopressors to maintain arterial pressure for circulation; $PaO_2/FiO_2 \leq 200$ or $SpO_2/FiO_2 \leq 214$ for respiration] with renal dysfunction and/or mild HE; (2) ACLF grade 2: The presence of 2 organ failures; and (3) ACLF grade 3: The failure no less than 3 organs.

Data collection

Demographics, medical history, imagological examination and laboratory parameters were obtained from every participant on admission. Participants were regularly followed up for 28 d, 90 d and 365 d until death or liver transplantation (LT). Development of ACLF was assessed on admission and during hospitalization within 28 d, respectively. The primary outcome of this study was 90-d LT-free mortality. The secondary outcome was ACLF development during 28-d hospitalization.

Statistical analysis

Continuous variables were summarized as mean (SD) or median (interquartile range) according to their distribution, while categorical variables were summarized as frequency (proportion). Comparisons between four groups were performed using Kruskal-Wallis test for continuous variables, Chi-square test or Fisher's exact test for categorical variables. The impact of the etiology of AILD on short-term mortality were analyzed using a multivariable logistic regression model, adjusting for potential confounders, including demographics (age, sex) and AD events (HE, gastrointestinal bleeding, infection and ascites). Logistic regression was also used to determine the risk factors for 90-d mortality and ACLF development during hospitalization. Variables with P values less than 0.1 were included in the multivariate logistic regression model[18,19]. All continuous variables were log2 transformed before entering the model. Two-tailed P values of 0.05 were considered statistically significant. Statistical analysis was conducted using R 3.6.2 and SPSS 19.0.



RESULTS

Prevalence of AILD and ACLF in patients with cirrhosis and AD

A total of 3970 patients from CATCH-LIFE study were screened, 2597 of whom had cirrhosis and AD. Eventually, 242 patients conforming the diagnostic criteria of AILD were finally enrolled (Figure 1). In patients with cirrhosis and AD, the overall prevalence of AILD was 9.3% (242/2597). Prevalence of ACLF was significantly lower in AILD cases (14%) than those with all etiology groups with cirrhosis and AD (22.8%) ($P < 0.001$). Distribution of participating centers in this study and number of AILD patients enrolled from each center were displayed in Figures 2A and 2B, respectively. Among the 242 enrolled AILD patients, 234 (96.6%) are from eastern China, where 94% of Chinese population resides; 8 (3.4%) are from western China, where 6% of Chinese population resides. Due to Renji Hospital accounted for 60.3% (146/242) of the total enrolled patients, we further analyzed district distribution of patients enrolled from Renji Hospital. Actually, these patients were from 20 different district all over the country (Figure 2C), the number of patients from each district was shown in Figure 2D. Distribution of patients enrolled from Renji Hospital were also consistent with population density distribution (divided by Hu Line) in China.

Baseline characteristics and outcomes among different etiologies in AILD patients

Baseline characteristics of 242 AILD patients with cirrhosis and AD categorized by etiology are depicted in Table 1. 123 (50.8%) patients showed PBC, 69 (28.5%) displayed AIH, 29 (12.0%) had AIH-PBC overlap syndrome (AIH/PBC) and 21 (8.7%) patients manifested other uncommon etiologies of AILD. Most patients were female (81.0%) and their mean age was 56.04 years. Patients with PBC/AIH had higher white blood cell ($P < 0.001$) and neutrophil-lymphocyte (NL) ratio ($P < 0.001$) levels than patients with PBC, AIH or others. ALT ($P < 0.001$) and AST ($P = 0.04$) levels were higher in the AIH/PBC group.

Figure 1 Flow chart of the study. AD: Acute decompensation; AILD: Autoimmune liver disease; ACLF: Acute-on-chronic liver failure.

In addition, the PBC group tended to have lower hemoglobin (P = 0.003) and higher ALP (P < 0.001) levels than other AILD etiologies.

Baseline characteristics of 34 ACLF patients categorized by etiology are shown in Table 2. PBC (41.2%) was still the most common etiology among ACLF patients with AILD, followed by AIH (29.4%), AIH/PBC overlap syndrome (20.6%) and others (8.8%). However, as the number of patients in some subgroups was small, the results may not be robust and require further validation in a larger population. At the end of 28-d and 90-d, no patients were lost to follow up. At the end of 365-d, 3 (1.2%) patients were lost to follow-up. Short-term (28-d, 90-d and 365-d) LT-free mortality of AILD patients with cirrhosis and AD are presented in Figure 3. Generally, among AILD patients with cirrhosis and AD, 90-d LT-free mortality were 17%. AIH/PBC had higher 28-d, 90-d and 365-d mortality, although the results were not statistically significant. Among patients with AILD-related ACLF, 28-d and 90-d mortality were 43.8% and 80.0%, respectively.

The impact of etiology on mortality

To investigate the effect of etiology on short-term (28-d, 90-d and 365-d) LT-free mortality in AILD patients with cirrhosis and AD, we constructed 3 models to gradually control other potential confounding factors (Table 3). Both univariate (unadjusted) and multivariate (adjusted I and adjusted II) analyses showed that compared to PBC, AIH patients were at lower risk for death at 90-d and 365-d, whereas PBC/AIH patients were at higher risk for death at all time periods. However, none of the associations were statistically significant. Subgroup analysis was conducted according to Child Turcotte Pugh and model for end-stage liver disease (MELD) score, there was no heterogeneity in the impact of etiology types on 90-d LT-free mortality in different AILD subgroups, as was shown in Supplementary Figure 1.

Risk factors of short-term mortality in AILD patients with cirrhosis and AD

Logistic regression model was conducted to assess the risk factors for 90-d LT-free mortality. Univariable analysis identified 10 variables on admission correlated with 90-d prognosis: Bacterial infection, HE, total bilirubin (TB), INR, blood urea nitrogen (BUN), albumin, ALT, white blood cell, NL-ratio and sodium (Supplementary Table 1). Variables with P < 0.1 were selected into multivariable model for further analysis. Only HE, TB and BUN were found to be independently associated with 90-d mortality in AILD patients with cirrhosis and AD (Figure 4). We also investigated risk factors for ACLF development during hospitalization (Table 4). 21 ACLF patients diagnosed on admission were excluded from analysis. Multivariable analysis revealed that only TB (P = 0.046) and INR (P = 0.048) independently correlated with ACLF development.

DISCUSSION

The current study is the first nationwide investigation of the prevalence and short-term outcome of end-stage AILD in China, which is a traditional HBV high endemic area. Our study showed that the overall prevalence of AILD was 9.3% in tertiary hospitalized patients with cirrhosis and AD. PBC was responsible for half of AILD cases. The prevalence of ACLF was significantly lower in AILD patients than those with all etiology groups with cirrhosis and AD. Short-term mortality were extremely high in AILD-related ACLF.

Figure 2 Distribution and the number of autoimmune liver disease patients enrolled from each of center and from Renji Hospital. A: District distribution of each enrolled center; B: The number of patients enrolled from center; C: Population distribution of patients from Renji Hospital; D: The number of patients enrolled from each of the 20 districts. Approximately 94% of the total Chinse population resides east of the dividing line (Hu Line) in the figure, and 6% resides west of the line; 13 centers lie in eastern China, and 1 lies in western China.

EASL-CLIF study reported that the prevalence of ACLF was 30.9% in alcohol-related cirrhosis and AD, whereas COSSH study showed that the prevalence of ACLF reached up to 26.2% in patients with HBV-related cirrhosis and AD[17,20]. However, in this study, among 242 AILD patients with cirrhosis and AD, only 34 (14%) had ACLF, the prevalence was significantly lower than that of patients with other etiology types. One plausible explanation may be that AILD patients have distinct clinical characteristics (higher severity, higher prevalence of infection and lower prevalence of organ failures) that differ distinctly from those of patients with other etiologies, which led to lower prevalence of ACLF but higher short-term mortality.

Despite having higher levels of inflammation and liver injury, PBC/AIH had similar short-term mortality rates compared to PBC individually after adjusting for confounding factors. Neuhauser *et al* [21] and Yang *et al*[22] showed that a more aggressive clinical course and worse clinical consequences were observed in patients with PBC/AIH than patients with pure PBC. Based on these results, some experts suggested that PBC/AIH should be identified and aggressively treated. Notably, these studies only evaluate the univariate prognostic value of etiology and did not take confounders into consideration. It is, therefore, likely that they fail to objectively reveal the independent impact of etiology on the prognosis of AILD. PBC, AIH and PBC/AIH are all complex disorders but result in significant morbidity and mortality. Once progressed to liver failure, no effective treatment is clinically available. Herein, our results clearly showed that presence of HE, higher TB and BUN levels, rather than liver disease etiologies, were independently associated with short-term mortality in AILD patients with

cirrhosis and AD. Therefore, in clinical management of AILD, physicians are supposed to pay more attention to the presence of HE and closely monitor the changes of liver and renal function.

This study had several strengths. With national samples, our multicenter data provided an overview of epidemiological features of end-stage AILD in China, where it is considered uncommon. Thus, we presented a national view of the disease. Indeed, most of the studies in this field originated from single center or other geographic areas[7,23-25]. We focused on the role of the etiology on short-term mortality. Moreover, we clarified that HE, TB and BUN were significant risk factors of short-term mortality in AILD patients with cirrhosis and AD. These data will be an important complement to the public epidemiological data of AILDs in Asian-Pacific regions.

There were still several limitations in our study. First, since AILD is a relatively rare disease, the number of patients recruited in our study was not quite large, especially ACLF patients. The limited sample size could also slightly reduce the accuracy of the results of risk factor analysis. Second, one of our centers, Renji hospital, is a nationwide center of AILD. Thus, some degree of selection bias could be present in the prevalence rates of AILD due to the participation of this center. However, our further

TB	1.56	1.03-2.47	0.046
INR	4.31	1.15-21.70	0.048

Variables with $P < 0.1$ in univariate analysis were selected into multivariate analysis. Acute-on-chronic liver failure diagnosed on admission was excluded from the analysis. Continuous variables were log transformed before entering the model (base 2). ALT: Alanine transaminase; AST: Aspartate transaminase; ALP: Alkaline phosphatase; GGT: Gamma glutamyl transpeptidase; OR: Odds ratio; CI: Confidence interval; TB: Total bilirubin; INR: International normalized ratio.

analysis showed that patients recruited from Renji Hospital were from 20 different districts all over the country, the population distribution of these patients were also consistent with that of Chinese population density.

CONCLUSION

In conclusion, our study showed that AILD was not rare in China. The etiology of AILD had no significant impact on short-term mortality in AILD patients with cirrhosis and AD. HE, elevated levels of TB and BUN were significantly associated with high 90-d mortality in these patients. Strategies are

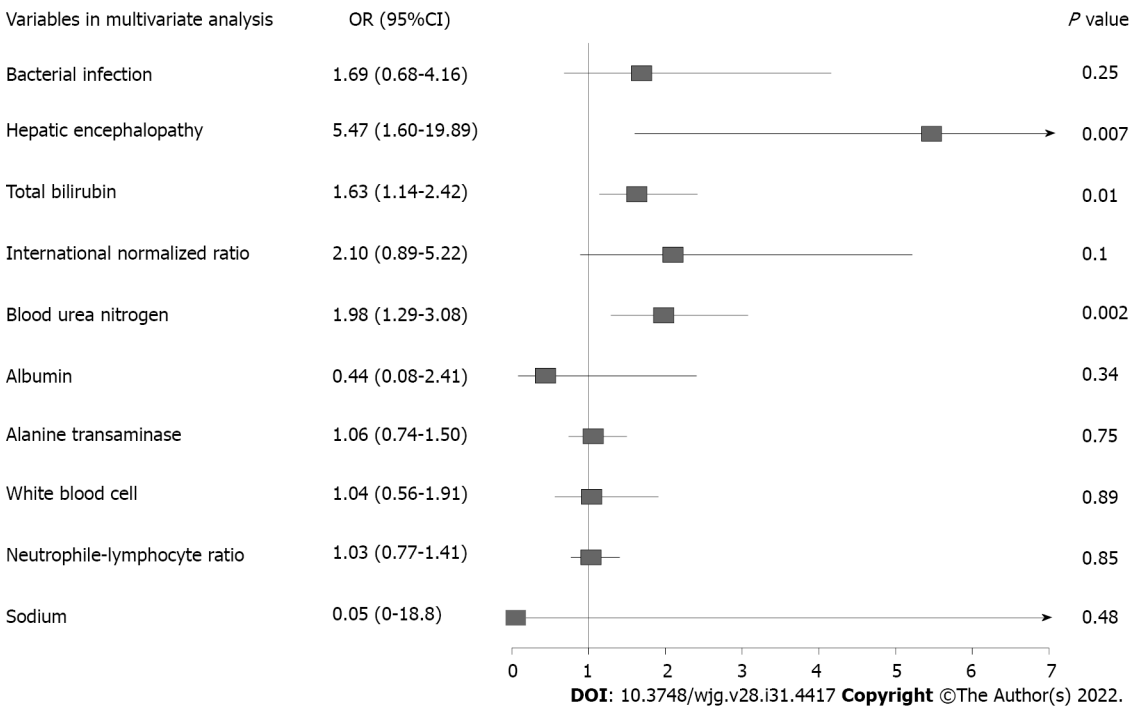

Figure 4 Multivariate analysis of 90-d liver transplantation free mortality in autoimmune liver disease patients with cirrhosis and acute decompensation. OR: Odds ratio; CI: Confidence interval.

needed to the presence of HE and closely monitor the changes of liver and renal function in clinical practice. These data will be a crucial complement to the public epidemiology of AILD in Asian-Pacific regions.

ARTICLE HIGHLIGHTS

Research background

Epidemiological research on autoimmune liver disease (AILD) in patients with end-stage liver disease is sparse in Asian-pacific areas.

Research motivation

This study aimed to provide a national view of epidemiological features of end-stage AILD in China.

Research objectives

To investigate the disease burden and risk factor of short-term mortality in AILD patients with cirrhosis and acute decompensation (AD), and thus provide clues on clinical management.

Research methods

Data were collected from two prospective, multicenter cohorts which enrolled patients with chronic liver disease and acute exacerbation from China. Logistic regression model was conducted to analyze risk factors.

Research results

The overall prevalence of AILD was 9.3% (242/2597) in patients with cirrhosis and AD, among which primary biliary cirrhosis was the most prevalent type. The etiology of AILD had no significant impact on short-term mortality in patients with cirrhosis and AD in univariate and multivariate analysis. Total bilirubin, hepatic encephalopathy (HE) and blood urea nitrogen independently correlated with 90-d LT-free mortality in multivariate analysis.

Research conclusions

AILD was not rare in hospitalized patients with cirrhosis and AD in China. 90-d mortality was independently associated with severity of the disease.

Research perspectives

In clinical management of AILD, strategies are needed to prevent presence of HE and closely monitor the changes of liver and renal function.

ACKNOWLEDGEMENTS

We acknowledge the following Chinese (Acute on) Chronic Liver Failure Consortium members and participants for their hard work. Department of Gastroenterology, Renji Hospital, School of Medicine, Shanghai Jiao Tong University - Shi-Jin Wang, Wen-Yi Gu, Liang Qiao, Yan Zhang; Clinical Research Institute, Shanghai Jiao Tong University School of Medicine, Shanghai, China, Zhang Wei-Tuo; Centre of Integrative Medicine, Beijing Ditan Hospital, Capital Medical University - Qun Zhang, Yi-Xin Hou, Yu-Xin Li, Yun-Yi Huang; Department of Infectious Diseases, Southwest Hospital, Third Military Medical University (Army Medical University) - Jie Xia; Yi Zhou; Bao-Yan Xu; Shu-Ning Sun, Yun-Jie Dan, Wen-Ting Tan; Department of Infectious Disease, Hunan Key Laboratory of Viral Hepatitis, Xiangya Hospital, Central South University - Jun Chen, Ruo-Chan Chen, Xiao-Xiao Liu; Department of Infectious Diseases, Institute of Infection and Immunology, Union Hospital, Tongji Medical College, Huazhong University of Science and Technology - Jing Liu, Ling Xu, Shue Xiong; Hepatology Unit, Department of Infectious Diseases, Nan-fang Hospital, Southern Medical University - Xiu-Hua Jiang, Bei-Ling Li, Cong-Yan Zhu; Department of Hepatology, First Hospital of Jilin University - Chang Jiang, Xiao-Yu Wen, Na Gao, Chun-Yan Liu; Department of Infectious Disease, Taihe Hospital, Hubei University of Medicine - Yuan-Yuan Chen, Sen Luo, Qing Lei; Department of Liver Intensive Care Unit, Shanghai Public Health Clinical Centre, Fudan University - Xue Mei, Liu-Juan Ji, Jie-Fei Wang; Department of Infectious Diseases and Hepatology, Second Hospital of Shandong University - Tao Li, Xuan-Qiong Fang, Zi-Yu Wang; Liver Disease Centre, First Affiliated Hospital of Xinjiang Medical University - Rong-Jiu Zheng, Nan Li; Department of Infectious Disease, Henan Provincial People's Hospital - Hui-Ming Jin; Affiliated Hospital of Logistics University of People's Armed Police Force - Hai Li, Qing Zhang, Xue-Qun Zheng; Department of Infectious Diseases, Affiliated Hospital of Logistics University of People's Armed Police Force - Shao-Yang Wang. We thank all the patients participated in the study.

Abstract

BACKGROUND

T1b gallbladder carcinoma (GBC) is defined as a tumor that invades the perimuscular connective tissue without extension beyond the serosa or into the liver. However, controversy still exists over whether patients with T1b GBC should undergo cholecystectomy alone or radical GBC resection.

AIM

To explore the optimal surgical approach in patients with T1b gallbladder cancer of different pathological grades.

METHODS

Patients with T1bN0M0 GBC who underwent surgical treatment between 2000 and 2017 were included in the Surveillance, Epidemiology, and End Results database. The Kaplan-Meier method and log-rank test were used to analyze the overall survival (OS) and disease-specific survival (DSS) of patients with T1b GBC of different pathological grades. Cox regression analysis was used to identify independent predictors of mortality and explore the selection of surgical methods in patients with T1b GBC of different pathological grades and their relationship with prognosis.

RESULTS

Of the 528 patients diagnosed with T1bN0M0 GBC, 346 underwent simple cholecystectomy (SC) (65.5%), 131 underwent SC with lymph node resection (SC + LN) (24.8%), and 51 underwent radical cholecystectomy (RC) (9.7%). Without considering the pathological grade, both the OS ($P < 0.001$) and DSS ($P = 0.003$) of T1b GBC patients who underwent SC (10-year OS: 27.8%, 10-year DSS: 55.1%) alone were significantly lower than those of patients who underwent SC + LN (10-year OS: 35.5%, 10-year DSS: 66.3%) or RC (10-year OS: 50.3%, 10-year DSS: 75.9%). Analysis of T1b GBC according to pathological classification revealed no

significant difference in OS and DSS between different types of procedures in patients with grade I T1b GBC. In patients with grade II T1b GBC, obvious survival improvement was observed in the OS (P = 0.002) and DSS (P = 0.039) of those who underwent SC + LN (10-year OS: 34.6%, 10-year DSS: 61.3%) or RC (10-year OS: 50.5%, 10-year DSS: 78.8%) compared with those who received SC (10-year OS: 28.1%, 10-year DSS: 58.3%). Among patients with grade III or IV T1b GBC, SC + LN (10-year OS: 48.5%, 10-year DSS: 72.2%), and RC (10-year OS: 80%, 10-year DSS: 80%) benefited OS (P = 0.005) and DSS (P = 0.009) far more than SC (10-year OS: 20.1%, 10-year DSS: 38.1%) alone.

CONCLUSION

Simple cholecystectomy may be an adequate treatment for grade I T1b GBC, whereas more extensive surgery is optimal for grades II-IV T1b GBC.

Core Tip: T1b gallbladder carcinoma (GBC) is defined as a tumor that invades the perimuscular connective tissue without extension beyond the serosa or into the liver. However, controversy still exists over whether patients with T1b GBC should undergo cholecystectomy alone or radical GBC resection. In this study, we included patients with different histological grades of T1b GBC and compared the survival time of patients who underwent simple cholecystectomy, cholecystectomy with lymph node resection, or radical cholecystectomy to explore the optimal surgical approach for these patients.

INTRODUCTION

Gallbladder carcinoma (GBC) is the most common malignant tumor of the biliary tract, accounting for 80%-95% of malignant tumors of the biliary tract. The overall average survival of patients with GBC is only 6 mo, and the 5-year survival rate is < 5%[1,2]. According to global cancer statistics from 2020, 115949 people have been diagnosed with GBC worldwide and 84965 have died from this condition[3]. The treatment effect of adjuvant therapy, chemotherapy, radiotherapy, and targeted therapy on GBC remains unsatisfactory despite recent improvements in diagnosis and treatment methodology, and surgical resection remains the first choice for the treatment of GBC.

Different surgical resection methods are used to treat GBC, based on staging. According to the current tumor-node-metastasis (TNM) staging system of the American Joint Committee on Cancer (AJCC) guidelines, simple cholecystectomy (SC, gallbladder removal alone) is the appropriate treatment for patients with Tis or T1a GBC, radical cholecystectomy (RC, including cholecystectomy, lymph node (LN) dissection, and liver wedge resection) or expanded radical resection of GBC is recommended for patients with T1b-T3 GBC, and surgery is not recommended for T4 GBC[4-6]. However, whether patients with T1b GBC undergo SC or RC had remained controversial for a long time. A previous study found that the long-term survival rate of patients with T1b GBC after SC was equivalent to that after RC [7]. Some studies have also found that the prognosis of patients with T1b who underwent RC of GBC is significantly improved compared to that of patients who underwent cholecystectomy alone[8,9]. Therefore, whether patients with T1b GBC undergo SC or RC remains a clinical problem that surgeons must address.

Recent studies have found that, in addition to TNM staging, tumor pathological grading plays an important role in tumor prognosis and surgical selection. Studies have pointed out that low-grade tumors in the tongue[10], breast[11], and thyroid[12] have a significantly worse prognosis than high-grade tumors in the same locations. Furthermore, studies have pointed out that the median survival of patients with grade I GBC is significantly better than that of patients with grade II-IV GBC, indicating that tumor grade is also an extremely important indicator of the prognosis of GBC[13]. However, a question worthy of discussion is whether pathological classification can be used as the basis for the selection of surgery (SC or RC) in T1b patients.

In the present study, we obtained the treatment and survival data of patients with T1b GBC from the Surveillance, Epidemiology, and End Results (SEER) database[14], analyzed the survival of patients with different histological grades of T1b GBC, and compared the survival of patients who underwent SC, cholecystectomy with LN resection, and RC to assess the optimal surgical approach.

MATERIALS AND METHODS

Data source

The SEER database was established by the National Cancer Institute and contains follow-up information from patients with cancer. We used the SEER-18 database, derived from 18 regional registries representing approximately one-third of the US population, to collect data on patients with GBC between 2000 and 2017, including patient age, sex, histological codes, tumor histology, TNM stage (6th AJCC TNM staging system), tumor grade, surgical information, and patient survival.

Study population

Tumor histology and site codes were used to identify patients in the SEER database with GBC between 2000 and 2017. A total of 15671 patients were included in this study. Patients were excluded from our study for the following reasons: patients did not undergo surgery, patients with GBC other than T1bN0M0, incomplete follow-up data, unknown surgical resection range, tumor grade, or histological data. According to the 6th edition of the AJCC staging system, all T1b patients were staged according to clinical classification based on physical examination, imaging, endoscopy, biopsy, surgical exploration, and other relevant examinations; 528 patients with T1bN0M0 GBC were included (Figure 1). According to the surgical treatment information in the SEER database, patients who underwent SC without LN resection in our study were categorized as SC, those who underwent cholecystectomy with LN resection were categorized as SC + LN, and patients who underwent cholecystectomy and any type of liver resection with extensive LN dissection were categorized as RC. The major outcomes of this study were overall survival (OS) and disease-specific survival (DSS).

Statistical analysis

Both continuous and categorical variables (such as age and sex, tumor grade, tumor histological type, surgical approach, *etc.*) are presented as numbers (n) and percentages (%). Kaplan-Meier survival curves were generated to analyze the OS and DSS between the different groups, and the *P* values for the survival curves were determined using the log-rank test. A multivariate Cox proportional hazards model was built to verify the independent role of prognostic factors, and variables with a *P* value of < 0.1 on the log-rank test were incorporated into the model. The final model was built using a stepwise selection method, and the results were presented as adjusted hazard ratios (HRs) with corresponding 95% confidence intervals (CIs) and *P* values. All *P* values were two-sided, and values of $P < 0.05$ were considered statistically significant. Statistical analyses were performed using the statistical software Statistical Product and Service Solutions (SPSS) IBM (version 19.0).

RESULTS

General characteristics of patients with T1b GBC

In this retrospective study, 528 patients had pathologically confirmed T1bN0M0 GBC between 2000 and 2017. Of these, 385 (72.9%) were women, and 143 (27.1%) were men. The histological types were adenocarcinoma (73.3%), papillary adenocarcinoma (15%), and other tissue types (11.7%). The tumor pathological classification was grade I (30.5%), grade II (50.9%), and grades III and IV (18.6%). Therefore, grade III and grade IV GBC were combined into the same subgroup for analysis in the present study as few patients had grade IV GBC. Among the 528 patients with GBC, 346 underwent SC (65.5%), 131 underwent SC + LN (24.8%), and 51 underwent RC (9.7%) (Table 1).

Univariate analysis performed using the log-rank test revealed that the histological type ($P = 0.059$) and tumor grade ($P = 0.056$) did not significantly affect the 10-year OS of patients with T1b GBC. Younger age ($P < 0.001$) and female sex ($P = 0.007$) were associated with better OS, and patients who underwent RC (50.3%) or SC + LN (35.5%) achieved better OS than those who underwent SC (27.8%) ($P < 0.001$). The 10-year DSS was not significantly affected by histological type ($P = 0.058$), similar to the OS, and DSS rates were significantly higher in younger ($P = 0.023$) and female patients ($P = 0.016$). The DSS was also significantly affected by the extent of surgery, and the 10-year DSS of patients who underwent RC (75.9%) or SC + LN (66.3%) was higher than that of patients who underwent SC (55.1%) ($P = 0.002$). Although tumor grade had no significant effect on the 10-year OS of patients with T1b GBC, we found that the 10-year DSS of patients with grade III and IV tumors (48.9%) was significantly lower than that of patients with grade I (64.7%) or II tumors (62.1%) ($P = 0.002$) (Table 1).

The impact of different surgical methods on the OS and DSS of patients with T1b GBC, regardless of pathological grade

Kaplan-Meier survival curves were generated for different types of surgery in patients with T1b GBC. The 10-year OS of patients who underwent more extensive surgery, including SC + LN (35.5%) and RC (50.3%), was significantly better than that of patients who underwent SC alone (27.8%) ($P < 0.001$) (Figure 2A). Consistent with OS, we found that the 10-year DSS of patients who underwent SC + LN (66.3%) or RC (75.9%) was significantly higher than that of patients who underwent SC (55.1%) ($P = 0.003$) (Figure 2B).

Using multivariate Cox regression analysis incorporating age, sex, tumor grade, tumor histological type, and surgery type, we confirmed that age, sex, and surgery type were independently associated with OS in patients with T1b GBC. Patients who underwent SC + LN (HR: 0.71, 95%CI: 0.53-0.95, $P = 0.020$) or RC (HR: 0.54, 95%CI: 0.32-0.89, $P = 0.015$) experienced a significant OS benefit compared to patients who underwent SC alone. Independent factors affecting DSS were sex, tumor grade, and surgery type, consistent with OS, and patients who underwent SC + LN (HR: 0.56, 95%CI: 0.37-0.83, $P = 0.020$) or RC (HR: 0.49, 95%CI: 0.27-0.92, $P = 0.015$) had improved DSS compared with patients who underwent SC. Table 2 shows the results of the multivariate Cox regression analysis of patients with T1b GBC based on the 10-year OS and DSS. Based on the above results, we concluded that patients with T1b GBC who underwent RC or SC + LN treatment had better OS and DSS than those who underwent SC, regardless of the pathological grade (Table 2).

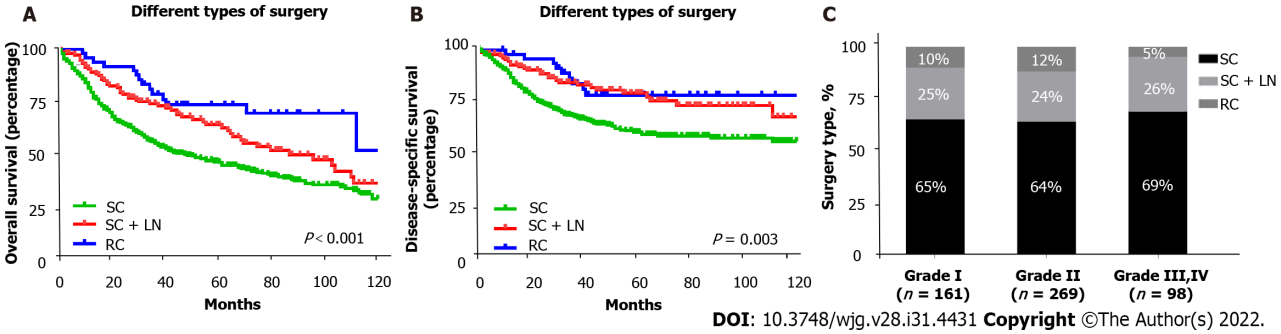
The influence of operation methods on OS and DSS in patients with T1b GBC of different pathological grades

To verify the role of tumor grading in choosing the surgical approach for patients with T1b GBC, we divided the 528 patients with GBC into three subgroups based on tumor grade and analyzed the impact of different surgical approaches in each subgroup on 10-year OS and DSS. The type of surgery varied slightly between the different tumor grades, and Figure 2C shows the proportion of different surgical approaches in each subgroup. Of the 161 patients with grade I T1b GBC, 105 underwent SC (65%), 40 underwent SC + LN (25%), and 16 underwent RC (10%); of the 269 patients with grade II T1b GBC, 173 underwent SC (64%), 64 underwent SC + LN (24%), and 32 underwent RC (12%). Of the 98 patients with grade III or IV T1b GBC, 68 underwent SC (69%), 25 underwent SC + LN (26%), and 5 underwent RC (5%) (Figure 2C). Interestingly, no statistically significant differences were observed in OS (P = 0.734) and DSS (P = 0.953) between the different surgical types in patients with grade I T1b GBC (Figure 3A and B). However, an obvious improvement in the OS of patients with grade II T1b GBC who underwent SC + LN (34.6%) or RC (50.5%) was observed compared to that of patients who underwent SC (28.1%) (P = 0.002). The DSS of patients who underwent SC + LN (61.3%) or RC (78.8%) was also much higher than that of patients who underwent SC (58.3%) (P = 0.039) (Figure 3C and D). Moreover, the OS and DSS of patients with grade III and IV T1b GBC were both significantly affected by the type of surgery, and SC + LN (48.5%) or RC (80%) had a far more beneficial effect on OS than SC (20.1%; P = 0.005). Similar to OS, the DSS in patients who underwent SC + LN (72.2%) or RC (80%) was also much higher than that of patients who underwent SC (38.1%) (P = 0.009) (Figure 3E and F). These results show that patients with grade I T1b GBC who undergo SC can attain a survival benefit equivalent to that associated with SC + LN or RC.



The influence of surgical methods on OS and DSS in patients with grade I T1b GBC

To further verify that surgery type did not significantly affect OS and DSS in patients with grade I T1b GBC, we conducted a univariate analysis of 161 patients with grade I T1b GBC. Using the log-rank test, we found that age (P = 0.022) and sex (P = 0.030) significantly affected the OS of patients with grade I

Figure 2 Overall survival and disease-specific survival of 528 patients with T1b gallbladder cancer who received different surgical treatment assessed using Kaplan-Meier analysis, and the proportions of different surgical approaches. A: Overall survival of patients with T1b gallbladder cancer (GBC) received simple cholecystectomy (SC), SC with lymph node resection (SC + LN), or radical cholecystectomy (RC) ($P < 0.001$); B: Disease-specific survival of patients with T1b GBC who received SC, SC + LN, or RC ($P = 0.003$); C: The proportions of different surgical approaches in patients with different pathological grades of gallbladder cancer. SC: Simple cholecystectomy; LN: Lymph node resection; RC: Radical cholecystectomy.

T1b GBC, whereas the histological type of the tumor ($P = 0.799$) and surgical method ($P = 0.734$) had no significant effect on OS. Age ($P = 0.431$), sex ($P = 0.071$), tumor histological type ($P = 0.562$), and surgical method ($P = 0.953$) did not significantly affect DSS in patients with grade I T1b GBC (Table 3).

Subsequently, we performed multivariate Cox regression analysis based on age, sex, tumor grade, tumor histological type, and surgery type and found that age and sex were independent influencing factors for OS in patients with grade I T1b GBC; older age was associated with poor OS (HR: 1.67, 95%CI: 1.07-2.59, $P = 0.023$), and women had better OS (HR: 0.62, 95%CI: 0.40-0.96, $P = 0.031$). The histological type of the tumor and surgical method were not independent factors for OS in patients with grade I T1b GBC. Age, sex, histological tumor type, and surgical method were not independent risk factors for DSS in patients with grade I T1b GBC. Lastly, we verified that the type of surgery did not affect the OS and DSS of 161 patients with grade I T1b GBC (Table 4).

DISCUSSION

The current staging of GBC follows the TNM staging system of the AJCC guidelines, in which primary tumor invasion (T) is a crucial factor in the AJCC staging criteria that determines the surgical approach for GBC[15]. The goal of surgical intervention for GBC is to achieve R0 resection, which is the most important factor in predicting long-term survival. According to the staging system of the AJCC

guidelines, Tis refers to the tumor in situ, T1a lesions invade the lamina propria, T1b lesions invade the muscular layer, T2 Lesions invade the connective tissue around the gallbladder muscle without extending to the serosal membrane or liver, T3 tumors perforate the gallbladder serosa or penetrate the liver or one other adjacent organ, and T4 tumors are defined as those that invade the main portal vein, hepatic artery, or two or more adjacent organs[16]. According to the recommendations of the National Comprehensive Cancer Network (NCCN) diagnosis and treatment guidelines, surgical treatment for Tis and T1a GBC should be SC, and RC is the first choice for the treatment of GBC with T1b-T3, whereas surgery is not recommended for T4[17]. Nevertheless, previous studies have also pointed out the controversy in the treatment of T1b, and some studies still reported long-term survival after SC for patients with T1b GBC that is comparable to that after radical resection and did not recommend extended cholecystectomy or radical resection for T1b GBC[18,19]. Therefore, controversy about the surgical treatment of T1b GBC has existed in clinical practice for many years. For example: (1) Should patients with GBC diagnosed as T1b by pathology undergo radical resection; (2) incidental CBC (IGBC) is defined as cholecystectomy for benign gallbladder lesions, but the postoperative pathological diagnosis is GBC[20,21]; and (3) should patients with T1b IGBC undergo another surgical procedure so that RC can be performed?

Tumor grade was categorized as well-differentiated (grade I), moderately differentiated (grade II), poorly differentiated (grade III), or undifferentiated (grade IV), depending on the pathological morphology of the tumor. As an important tumor index, pathological grading plays a crucial role in the prognosis and treatment of many tumors. For example, patients with differentiated T1N0M0 thyroid cancer should undergo total thyroidectomy, whereas patients with undifferentiated T1N0M0 thyroid cancer require total thyroidectomy and LN dissection[22]. However, to our knowledge, the role of tumor grade in the selection of surgical treatment for T1b GBC has not yet been explored. In our study, 528 cases of T1bN0M0 GBC were grouped according to the pathological grade. By analyzing the survival of patients with various pathological grades of GBC following different surgical methods, we found that both DSS and OS of patients with grade II-IV T1b GBC who underwent extensive surgery improved markedly compared to those who underwent SC. However, SC had a comparable survival benefit for both OS and DSS in patients with grade I T1b GBC compared to patients who underwent SC + LN or RC. Using Cox regression analysis, we also found that surgery type was not an independent

factor associated with survival in patients with grade I T1b GBC. These results indicate that the surgery type does not significantly affect OS or DSS in patients with grade I T1b GBC. Patients with grade I T1b GBC who undergo SC alone could obtain a similar survival benefit compared with those treated with SC + LN or RC, and more extensive surgery is the optimal treatment for T1b patients with grade II-IV tumors.

Thus, according to the NCCN guidelines and our research results, we propose the following answers to the two questions given above: (1) For GBC found during the operation, if perioperative frozen pathological examination reveals the TNM stage to be T1b, tumor histopathology should continue to be graded. If the pathological grade is confirmed to be grade I T1b GBC, SC should be performed, and patients with grade II-IV T1b GBC should undergo RC; and (2) for patients with T1b IGBC, the finding should be combined with the pathological grade to decide whether to perform surgery again; patients with grade II-IV T1b IGBC should undergo a second operation and radical resection of GBC to obtain survival benefits. Patients with grade I T1b IGBC do not need to undergo reoperation, which prevents the pain caused by the second operation and saves the patient money in terms of medical expenses.

To the best of our knowledge, this study is the first to use the SEER database, one of the largest population databases, to evaluate the role of tumor grading in choosing surgical approaches for patients with T1b GBC. However, our findings have some unavoidable limitations. First, this study is a retrospective analysis, and the SEER database lists only initial surgical treatment, so patients who underwent subsequent treatment may be included in our study. Furthermore, information on tumor recurrence, metastasis, or progression was also not available in the SEER database. Hence, prospective and multi-center studies of patients with T1b GBC are needed to further verify the impact of surgical methods on the prognosis of T1b patients with different pathological grades to provide a more appropriate, evidence-based rationale for determining the optimal surgical method for patients with T1b GBC of different pathological grades, and patients with grade I T1b GBC who underwent SC should be monitored for tumor recurrence, metastasis, or progression to validate the findings of our study.

CONCLUSION

We demonstrated a comparable survival benefit for patients with grade I T1b GBC who underwent SC, SC + LN or RC, whereas patients with grade II-IV T1b GBC benefit from SC + LN or RC, suggesting that SC may be a suitable treatment for patients with grade I T1b GBC, whereas RC or expanded radical resection is more suitable for those with grade II-IV T1b GBC.

Figure 3 The overall survival and disease-specific survival of patients with T1b gallbladder cancer stratified by pathological grades and surgical treatment using Kaplan-Meier analysis. A: Overall survival (OS) of patients with grade I T1b gallbladder cancer (GBC) by type of surgery (P = 0.734); B: Disease-specific survival (DSS) of patients with grade I T1b GBC by type of surgery (P = 0.953); C: OS of patients with grade II T1b GBC by type of surgery (P = 0.002); D: DSS of patients with grade II T1b GBC by type of surgery (P = 0.039); E: OS of patients with grade III, IV T1b GBC by type of surgery (P = 0.005); F: DSS of patients with grade III, IV T1b GBC by type of surgery (P = 0.009). SC: Simple cholecystectomy; LN: Lymph node resection; RC: Radical cholecystectomy.

ARTICLE HIGHLIGHTS

Research background

The surgical treatment of T1b gallbladder cancer has been controversial.

Research motivation

To solve the problem of choosing the surgical treatment for T1b gallbladder cancer.

Research objectives

To explore the optimal surgical approach in patients with T1b gallbladder cancer of different pathological grades.

Research methods

Analysis of survival differences in patients with different pathological grades of T1b gallbladder cancer who received different surgical treatment methods.

Research results

Patients with grade I T1b gallbladder cancer who underwent simple cholecystectomy attained a survival benefit equivalent to that of simple cholecystectomy with lymph node resection or radical cholecystectomy.

Research conclusions

Simple cholecystectomy is an adequate treatment for grade I T1b gallbladder carcinoma (GBC), whereas expanded radical resection is more suitable for grade II-IV T1b GBC.

Research perspectives

Simple cholecystectomy is a suitable treatment for patients with grade I T1b GBC.

Abstract

BACKGROUND

Health utility assessments have been developed for various conditions, including chronic liver disease. Health utility scores are required for socio-economic evaluations, which can aid the distribution of national budgets. However, the standard health utility assessment scores for specific health conditions are largely unknown.

AIM
To summarize the health utility scores, including the EuroQOL 5-dimensions 5-levels (EQ-5D-5L), EuroQol-visual analogue scale, short from-36 (SF-36), RAND-36, and Health Utilities Index (HUI)-Mark2/Mark3 scores, for the normal population and chronic liver disease patients.

METHODS
A systematic literature search of PubMed and MEDLINE, including the Cochrane Library, was performed. Meta-analysis was performed using the RevMan software. Multiple means and standard deviations were combined using the StatsToDo online web program.

RESULTS
The EQ-5D-5L and SF-36 can be used for health utility evaluations during antiviral therapy for hepatitis C. HUI-Mark2/Mark3 indicated that the health utility scores of hepatitis B patients are roughly 30% better than those of hepatitis C patients.

CONCLUSION
The EQ-5D-5L is the most popular questionnaire for health utility assessments. Health assessments that allow free registration would be useful for evaluating health utility in patients with liver disease.

Key Words: Quality of life; EuroQOL 5-dimensions 5-levels; Short from-36; RAND-36; Health Utilities Index-Mark

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: This study summarized current knowledge about health utility assessments, including the EuroQOL 5-dimensions 5-levels (EQ-5D-5L), EuroQol-visual analogue scale, short from-36, RAND-36, and Health Utilities Index-Mark2/Mark3. The EQ-5D-5L is the most popular questionnaire for health utility assessments. Health utility assessments need to be used widely and routinely.

INTRODUCTION

The quality of health is an important factor when assessing medical management rather than simple survival periods[1,2]. Health utility is an important factor in medical assessments and socio-economic politics[3]. National health budgets have risen steadily in various countries, and governments need to deeply consider the need to maintain a socio-economic balance[4]. Therefore, health benefits should be compared with social costs to avoid national financial collapse.

It is difficult to quantify health quality at regular intervals[5]. We are developing wearable devices that can automatically obtain health data, including data regarding mental health. Some health utility assessments require the use of questionnaires, which are associated with low compliance and involve bothersome calculations[2,6,7]. Before launching our novel health utility assessment tool, we performed this meta-analysis in order to summarize the currently available health utility assessment tools. The most useful questionnaire for evaluating health status depending on liver disease status or sex is unclear. In addition, no universal health utility assessment values for specific liver diseases or the normal population have been reported. Therefore, we conducted a meta-analysis to estimate health utility assessment values for specific populations.

The EuroQOL 5-dimensions 5-levels (EQ-5D-5L) is the simplest instrument for evaluating health utility and has been widely translated into various languages with high reliability and validity[6,8-10]. It only involves five questions and five answering levels. The health utility scores produced by the EQ-5D-5L can be used to calculate quality-adjusted life year (QALY) values[8]. The Health Utilities Index Mark 2/Mark 3 is another instrument for evaluating health utility scores and can also be used to obtain QALY values[11]. However, the Health Utilities Index is complicated, as it involves 45 questions, which take a long time to answer. The short-form 36-item (SF-36) is also widely used to evaluate health quality, although it does not directly involve QALY evaluations[9,12,13].

There are two types of SF-36, and the copyrights to these tools belong to The RAND Corporation (Santa Monica, CA, United States)[14] and QualityMetric (Johnston, RI, United States), respectively[15]. However, most researchers do not actively consider which version they use[12]. Therefore, the exact method and results of such assessments are not always described in the literature (Table 1).

In this meta-analysis, we describe the scores obtained with various health utility indexes (HUIs) in normal healthy populations or patients with different types of liver disease (Table 2)[16-32].

MATERIALS AND METHODS

Literature search

The PICOS scheme was used to set appropriate inclusion criteria. A systematic literature search of PubMed and MEDLINE, including the Cochrane Library, was performed independently by two authors (Ishunuki T and Ota S). The search was limited to human studies whose findings were reported in English. No restrictions were placed on the type of publication, the publication date, or publication status. The search strategy was based on different combinations of words for each database. For the PubMed database, the following combination was used: (("liver"[MeSH Terms] OR "liver"[All Fields] OR "livers"[All Fields] OR "liver s"[All Fields]) AND "qol"[All Fields]) AND (1990/1/1: 3000/12/12[pdat]). For the MEDLINE database, the following combination was used: [quality of life (QOL) and Liver].

Study selection

The two independent authors screened the titles and abstracts of the primary studies identified in the database search. Duplicate studies were excluded. The following inclusion criteria were employed for the meta-analysis: (1) Studies that compared QOL in patients who had liver disease; (2) Studies that compared QOL between male and female patients with liver disease; (3) Studies that reported at least one QOL outcome; and (4) If the same institute reported more than one study, only the most recent or the highest-level study was included.

Data extraction

The same two authors extracted the following primary data: (1) The questionnaires used for each QOL evaluation; (2) The first author, year of publication, and type of study; (3) The etiology of the disease and the number of times each intervention was performed; and (4) The timing of the evaluations.

Statistical analysis

Meta-analyses were performed using the RevMan software (version 5.3.; The Cochrane Collaboration). The mean differences (MD) between groups were calculated for continuous variables. The interquartile ranges of the data were transformed by dividing them by 1.35 to produce alternative standard deviation values. Multiple means and standard deviations were combined using the StatsToDo online web program (https://www.statstodo.com/index.php).

The chi-square test was used to evaluate heterogeneity, and the Cochran Q and I^2 statistics were reported. The I^2 value describes the percentage variation between studies in degrees of freedom. P values of <0.05 were considered significant.

RESULTS

EQ-5D-5L

The EQ-5D-5L has been widely investigated as a tool for evaluating general health in normal populations and patients with different stages of liver disease (Table 3)[17,18,22,25-27,30,32]. Health utility indices should be affected by age, sex, ethics, religion, and geography. However, the EQ-5D-5L produced similar utility indices for groups with different health statuses (Table 3), such as normal healthy individuals (0.8413 ± 0.1905) and hepatitis C virus (HCV)-infected patients with compensated or decompensated cirrhosis (0.8113 ± 0.2261 and 0.7903 ± 0.2182), HCV-infected patients exhibiting a sustained virologic response (SVR) (0.846 ± 0.1816), and patients with hepatocellular carcinoma 0.8127 ± 0.2084).

In general, the EQ-5D-5L produces significantly higher scores in males than in females (Figure 1A) (0.8267 ± 0.229 *vs* 0.7922 ± 0.239; $P < 0.001$). The mean total EuroQol-visual analogue scale score for the general population was found to be 79.796 ± 17.614 in two independent studies (Table 4)[26,30].

SF-36

The SF-36 consists of eight scales, including physical functioning (85.07 ± 15.40); role limitations due to physical health problems (RP)(82.50 ± 25.15); bodily pain (BP) (77.62 ± 17.55); general health perceptions

O: The eligible study including the analyses; Δ: The excluding outcomes due to different conditions; EQ-5D-5L: EuroQol 5-dimensions 5-levels; EQ-VAS: EuroQol-visual analogue scale; HUI-mark: Health utility index mark; SF-36: Short from-36; CLDQ: Chronic liver disease questionnaire; SF-6D: Short form 6-dimensions; HQLQv2: Hepatitis Quality of Life® survey version 2; HADS: Hospital anxiety and depression scale; HCV: Hepatitis C virus.

(GH) (63.37 ± 14.16); vitality, energy, or fatigue (VT) (63.37 ± 14.16); social functioning (SF) (86.97 ± 15.13); role limitations due to emotional problems (RE) (83.94 ± 23.57); and general mental health (63.37 ± 14.16). Although the eligible healthy controls differed among countries and age groups, the health utility scores produced by each scale were similar (Table 5)[16,17,22,23].

Compensated liver cirrhosis vs sustained virologic response

Patients with hepatitis C had achieved an SVR exhibited significantly better health utility scores for each SF-36 scale (Figure 2)[22,29,31] and the EQ-5D-5L (Figure 1B)[18,19,22,32] than those with compensated liver cirrhosis (Table 6)[18,19,22,29,31,32]. In particular, significant differences in the scores for RP (61.5 ± 31.6 *vs* 73.3 ± 27.3), GH (64.8 ± 20.9 *vs* 74.8 ± 18.5), VT (70.5 ± 24.0 *vs* 78.1 ± 18.4), RE (56.8 ± 32.0 *vs* 68.1 ± 27.3), and the EQ-5D-5L (0.6863 ± 0.3065 *vs* 0.846 ± 0.1816) were seen between these groups. These results indicate that health utility indices improve by 10%-20% after patients with hepatitis C achieve an SVR.

DISCUSSION

Which HUI should be used for normal populations or patients with chronic liver disease?

In this meta-analysis, we summarized the findings of previous studies examining health utility evaluations in patients with chronic liver disease. Various questionnaires have been used to evaluate health utility in different populations/at different times. The EQ-5D-5L is the most popular of the questionnaires used to examine health utility scores internationally[17].

One of the concerns regarding the application of health utility scores is their sensitivity[33]. For example, the health utility scores produced by the EQ-5D-5L for patients with compensated cirrhosis and decompensated cirrhosis did not differ significantly (Table 3). On the other hand, the health utility scores for hepatitis C patients with compensated liver cirrhosis and those who achieved an SVR differed significantly according to both the SF-36 and EQ-5D-5L (Table 6). This indicated that both questionnaires are suitable for evaluating health utility in hepatitis C patients after viral elimination. Although the health utility scores derived from the EQ-5D-5L were calculated from 5 questions, the score range of the EQ-5D-5L (123.3%) was greater than that of the SF-36 (105.8%-119.2%). Therefore, the EQ-5D-5L could be suitable for evaluating health utility scores in this specific disease state. On the other hand, EQ-5D-5L-derived health utility scores are based on only five personal factors, mobility, self-care, usual activities, pain/discomfort, and anxiety/depression. Therefore, their sensitivity and any ceiling effects should be validated in each language and ethnic group.

It is well known that the prevailing subtype of viral hepatitis differs depending on the geographic region[34]. Hepatitis B is the prevailing subtype in East Asia[13], whereas hepatitis C is the most common in Western countries[35]. Both types of hepatitis can be controlled by nucleic acid analogs[36]. In this meta-analysis, the HUI scores of hepatitis C patients were roughly 30% lower than those of hepatitis B patients. The differences between hepatitis B and hepatitis C need to be investigated using the EQ-5D-5L and SF-36 in future.

The second concern regarding the use of questionnaires for health assessments relates to the number of questions in each questionnaire. The EQ-5D-5L consists of only five questions[8], whereas the other tools consist of 36[14-16] or 45[11] questions. The number of questions affects study compliance, especially in the elderly[37]. If possible, the number of questions should be minimized.

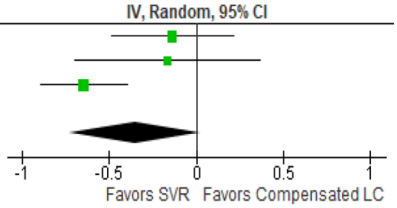
LC: Liver cirrhosis; SVR: Sustained virologic response; SF-36: Short from-36; EQ-5D-5L: EuroQol 5-dimensions 5-levels.

The last concern is about gaining permission to use such questionnaires for health utility assessments. It takes great effort to develop a questionnaire. However, health utility assessments need to be repeated continuously. In certain human health emergencies, the use of some vaccines has been allowed without patent royalties having to be paid[38]. Commercial companies that own the rights to health assessments should reconsider their policies regarding their use.



CONCLUSION

Health assessments that allow free registration would be useful for evaluating health utility in patients with liver disease. Alternatively, a portable QOL tracker could be used to perform QOL evaluations of any patient-reported outcome, and we are currently developing such a tracker.

ARTICLE HIGHLIGHTS

Research background

The most useful questionnaire for evaluating health status depending on liver disease status or sex is unclear.

Research motivation

No universal health utility assessment values for specific liver diseases or the normal population have been reported.

Research objectives

The objective of this study was to conduct a meta-analysis to estimate health utility assessment values for specific populations in the liver disease.

Research methods

A systematic literature search was performed using PubMed and MEDLINE, including the Cochrane Library.

Research results

The short from-36 and EuroQOL 5-dimensions 5-levels (EQ-5D-5L) can be used for health utility evaluations during antiviral therapy for hepatitis C.

Research conclusions

The EQ-5D-5L is the most popular questionnaire for health utility assessments. Health assessments that allow free registration would be useful for evaluating health utility in patients with liver disease.

Research perspectives

Alternatively, a portable quality of life (QOL) tracker could be used to perform QOL evaluations of any patient-reported outcome in future.

ACKNOWLEDGEMENTS

We thank Sandy Tan and Miyako Nara for their valuable discussions and help in preparing this manuscript.

Abstract

BACKGROUND

Low-grade myofibroblastic sarcoma (LGMS) is a rare malignant tumor. It has no specific clinical manifestations and commonly occurs in the head and neck, extremities and other body parts, with the liver not as its predisposing site.

CASE SUMMARY

We report a case report of a 58-year-old man with right upper abdominal pain for 11 d. Contrast-enhanced computed tomography (CECT), CE magnetic resonance imaging and CE ultrasound (US) all showed a cystic-solid mass in the right liver. As the initial clinical diagnosis was hepatic cystadenoma, surgical resection was performed, and the postoperative pathology indicated hepatic LGMS. The 3-mo follow-up showed favorable recovery of the patient. However, at 7-mo follow-up, two-dimensional US and CECT showed a suspected metastatic lesion in the right-middle abdomen.

CONCLUSION

Hepatic MS is particularly rare and easily misdiagnosed, more cases will contribute to the understanding and the diagnosis accuracy.

Key Words: Myofibroblastic sarcoma; Liver; Cystic-solid mass; Imaging; Diagnosis; Case report

Core Tip: Myofibroblastic sarcoma (MS) is a rare malignant spindle-shaped cell tumor derived from mesenchymal tissue, and it is particularly rare in the liver. Pathological examination is the gold standard for the diagnosis of hepatic MS. There are different biological characteristics of different lesions and protocols for surgical treatment; therefore, we should pay attention to more information conducive to differential diagnosis in order to improve the preoperative diagnosis, and to choose an appropriate surgical approach.

INTRODUCTION

Myofibroblastic sarcoma (MS) is a rare mesenchymal spindle-shaped cell tumor, first discovered by Mentzel *et al*[1] in 1998. According to the differential degree of myofibroblasts, it can be divided into low, intermediate and high grade. The first two are collectively called low-grade MS (LGMS)[2]. MS is common in the head and neck, limbs and trunk, but it is extremely rare in the liver. So far, there are only four English language reports available. Here, we present a case of LGMS of the liver.

CASE PRESENTATION

Chief complaints

Right upper abdominal pain for 11 d.

History of present illness

A 58-year-old Chinese man presented with right upper abdominal pain without obvious predisposing factors 11 d prior to the visit. The symptom was not associated with eating and body position. He experienced no nausea or vomiting, no chills or fever, and no significant weight loss.

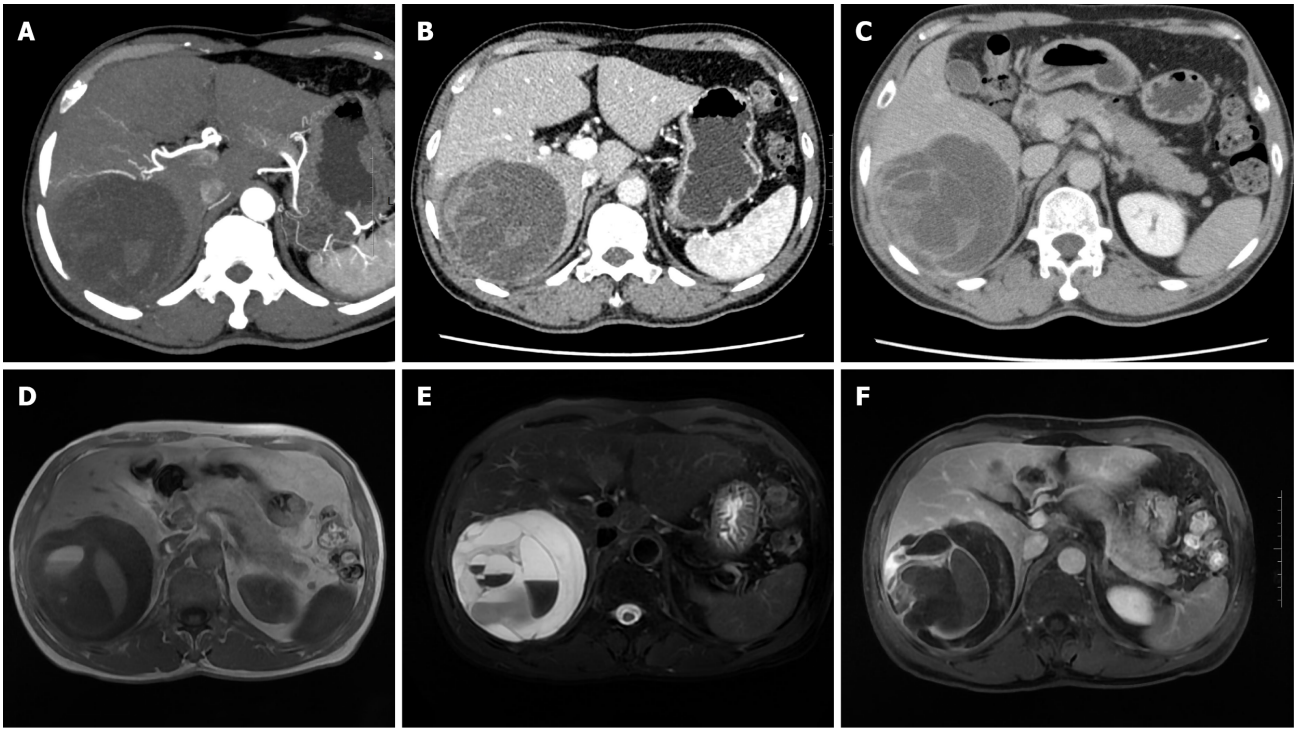
History of past illness

Right inguinal hernia surgery had been performed at another hospital 3 years prior to the present visit.

Personal and family history

No history of hepatitis and family or genetic history was claimed.

Physical examination



Physical examination showed a flat and soft abdomen without tenderness and rebound pain, and no palpable mass was found. The rest of the physical examination showed no abnormalities.

Laboratory examinations

Cholesterol (5.3 mmol/L) and low density lipoprotein (3.78 mmol/L) were elevated. Routine blood, liver function, renal function and prothrombin tests were normal. Complete quantitative detection of hepatitis B was negative. Alpha-fetoprotein (AFP), carcinoembryonic antigen (CEA) and carbohydrate antigen 19-9 (CA19-9) were normal.

Imaging examinations

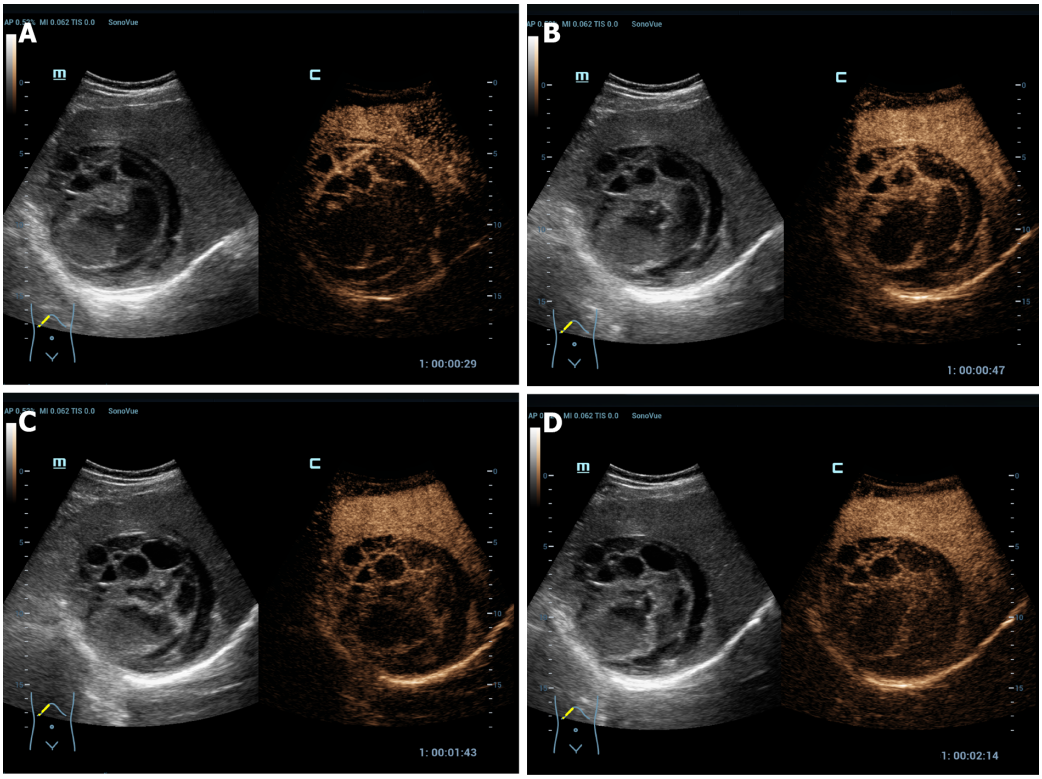
Abdominal contrast-enhanced computed tomography (CECT) and hepatic vascular imaging showed that there was a cystic-solid hypodense mass with a size of approximate 99 mm × 92 mm in the right liver. Septa, which were slightly enhanced along with the solid parenchyma, were visible in the mass. The right hepatic vein was displaced due to the compression of the mass supplied by the right hepatic artery (Figure 1A-C). Abdominal CE-magnetic resonance imaging and diffusion-weighted imaging (DWI) showed: (1) A cystic-solid mass with low signal on T1-weighted imaging and high signal on T2-weighted imaging in the right liver, about 101 mm × 98 mm in size; (2) multiple uneven septa and fluid-fluid levels in the lesion; (3) DWI and apparent diffusion coefficient showed high signal and high B value, respectively; and (4) after enhancement, solid components and internal septa of the tumor were significantly enhanced accompanied by unenhanced cystic components (Figure 1D-F).

DOI: 10.3748/wjg.v28.i31.4456 **Copyright** ©The Author(s) 2022.

Figure 1 Abdominal contrast-enhanced computed tomography and hepatic vascular imaging examination, and magnetic resonance imaging examination. A: The right hepatic cystic-solid mass was supplied by the right hepatic artery, and the twisting of the supplying artery was seen; B and C: The portal phase and delayed phase, respectively; the solid portion and the septum were enhanced, and the intracapsular septum was clearly displayed; D and E: The lesions were low signal on T1-weighted imaging and high signal on T2-weighted imaging, with multiple septa of uneven thickness and fluid-fluid levels; F: After enhancement, the solid components and septa of the mass were significantly enhanced, but the cystic components were not.

Ultrasound (US) examination showed a 123 mm × 98 mm mixed-echo mass with regular shape and clear boundary in the right liver. The anechoic dark area was the main portion of the mass. The parenchymatous septa with uneven thickness were visible in the mass in which no obvious parasitic body sonogram was found. Color Doppler flow imaging showed punctate blood flow signals in the mass. CEUS showed that the peripheral and internal septa of the tumor were hyper-enhanced in the arterial phase, iso-enhanced in the portal and delayed phases, and unenhanced in the anechoic area in these three phases (Figure 2). Based on the above-mentioned examination, the mass was preliminarily identified as hepatic cystadenoma.

FINAL DIAGNOSIS



The postoperative pathology diagnosis of the presented case is LGMS of right liver (Figure 3).

TREATMENT

The patient underwent laparoscopic right hepatectomy under general anesthesia after preoperative investigations were completed.

OUTCOME AND FOLLOW-UP

The patient recovered well after the operation with the surgical incision healed uneventfully. No apparent event was observed at the postoperative 3-mo follow-up. However, at the 7-mo follow-up, two-dimensional ultrasound and CECT showed a 100 mm × 40 mm cystic-solid lesion occurring in the right middle abdomen, which showed similar properties to a liver lesion. The mass wall was enhanced after enhancement (Figure 4). The patient refused further surgery although the clinician initially believed that metastasis had probably occurred.

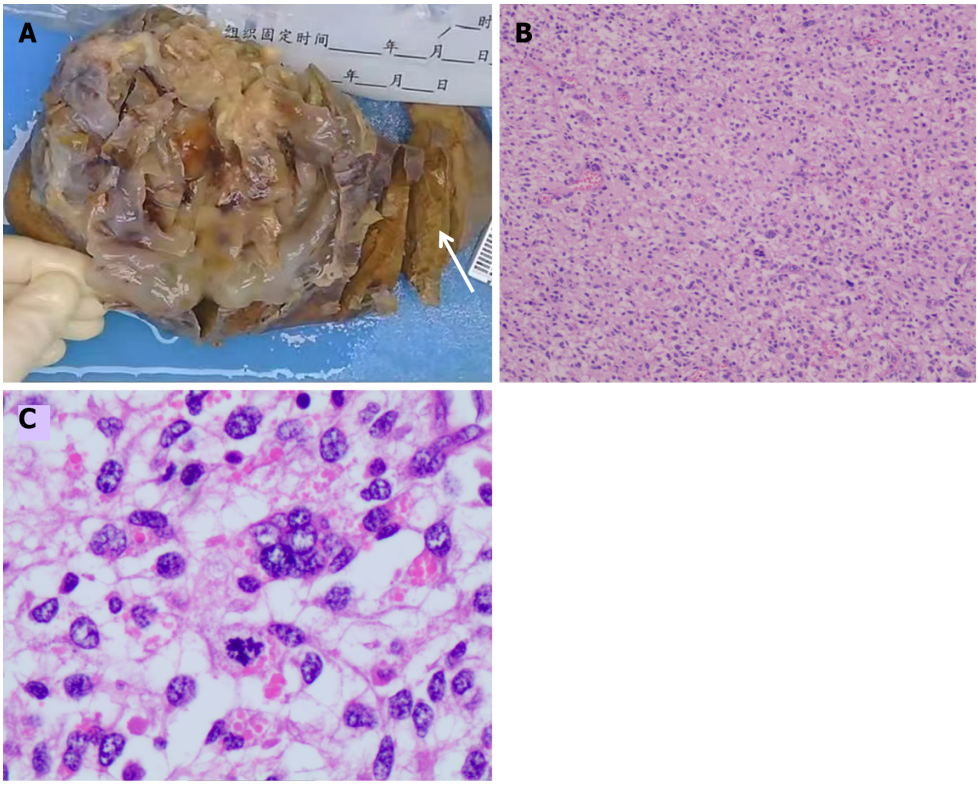

Figure 2 Contrast-enhanced ultrasound examination. The peripheral parenchyma and internal septa of the mixed-echo mass showed hyper-enhancement in the arterial phase, and iso-enhancement in the portal and delayed phases. A: Arterial phase; B: Early portal phase; C: Late portal phase; D: Delayed phase.

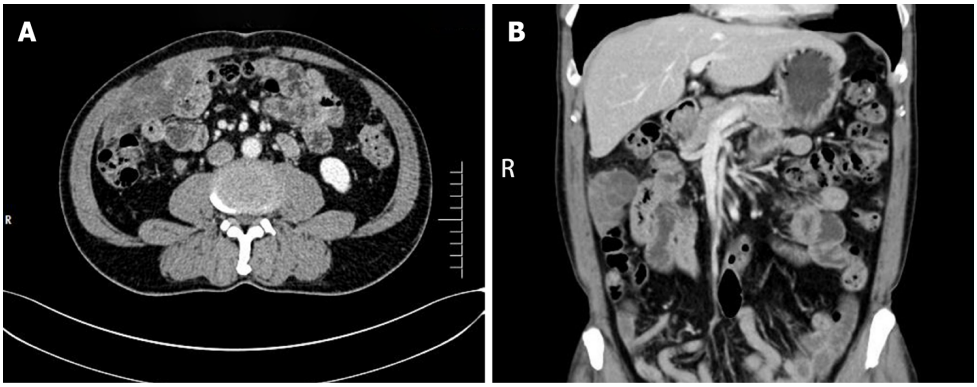
DISCUSSION

MS is a rare histological type of hepatic sarcoma. Given its rarity, the etiology is not clear, and most of the relevant reports are case reports or case series. Only seven relevant case reports[3-9] were obtained after a comprehensive literature search was conducted by us in CNKI, PubMed and Web of Science databases, involving seven patients (four men, three women; aged 25–38 years, n = 5; > 60 years, n = 2). As described in the WHO classification, males are slightly more predisposed for this disease than females; thus, not surprisingly, the present case was male. Most of the MSs were identified due to the swelling lesion detected or during physical examination. In the literature reports, five of the seven patients presented with abdominal distension and pain, and another two were asymptomatic. As for the present patient, the complaint was right upper abdominal pain. He had no history of hepatitis, although two of the seven patients reported previously had a history of hepatitis B. Serological examination, such as routine blood, liver function, renal function, and AFP and other tumor markers such as CEA, CA19-9 (all of which were in the normal range), was available for six of the seven patients reported previously and for the patient reported here. The remaining patient reported previously had impaired liver function. The lesions reported were mostly located in the right liver, and cystic-solid tumor was found in five cases, but no relevant data were available for the other two cases. For the present case, a cystic-solid tumor located in the right liver was also observed. Among the seven cases reported previously, five were misdiagnosed as liver cancer or hydatid disease as their preliminary clinical diagnosis, while the present case was misdiagnosed as hepatic cystadenoma. Surgical resection was performed in six of the seven patients, and liver lesions were found and biopsy was performed at 3 mo after surgery for the remaining patient initially diagnosed with retroperitoneal inflammatory myofibroblastic tumor. The pathological diagnosis for the current patient was LGMS infiltrated in the liver. Currently, surgical resection of MS is the preferred treatment, although primary treatment, prognosis and follow-up treatment are not clear. More data are needed to obtain reliable conclusions about the role of follow-up treatment such as radiotherapy and chemotherapy.



No specific clinical signs and symptoms were established currently due to the low incidence of hepatic MS, which was generally manifested as abdominal distension or discomfort and/or abnormal liver function, sometimes accompanied by sweating and weight loss. Although there was no clear report on tumor recurrence and metastasis, most hepatic MSs were observed as cystic-solid masses, showing infiltrative and destructive growth.

At present, hepatic MS is mainly diagnosed by histopathology and immunohistochemistry. Under light microscopy, the tumor tissue of the present case was mainly composed of spindle-shaped cells

DOI: 10.3748/wjg.v28.i31.4456 **Copyright** ©The Author(s) 2022.

Figure 3 Gross pathology specimen and pathological microscopy. A: A cystic-solid mass was seen with the naked eye, with soft texture and inconspicuous tumor capsule; its cut surface was polycystic, with yellowish jelly-like substances inside the cysts, and the cyst wall thickness was 1 mm-12 mm; no cirrhotic changes were observed in the peripheral liver tissue (arrow); B and C: Spindle-shaped cells are arranged in fascicles under light microscope, eosinophilic cytoplasm with atypia and mitotic figures were seen.

DOI: 10.3748/wjg.v28.i31.4456 **Copyright** ©The Author(s) 2022.

Figure 4 Abdominal contrast-enhanced computed tomography examination at 7-mo follow-up. A and B: The right middle abdomen of the patient in contrast-enhanced computed tomography showed a cystic-solid lesion, with the similar property as a liver lesion. After enhancement, the mass wall was enhanced.

with a diffuse infiltrative distribution. The cytoplasm was eosinophilic and the nucleus was polymorphic. Abnormal mitotic figures were present. The histopathological findings of this case are consistent with those previously reported. In the immunohistochemical study of the cases reported previously, expression of vimentin, smooth muscle actin (SMA) and desmin was commonly observed, along with partially positive actin. No hepatocyte markers, epithelial markers, S100, CD117, CD34, myogenin, pan-cytokeratin (CK-Pan) and h-caldesmon were not found in the tissue[10]. In the of the case reported here, immunohistochemical study was positive for vimentin, SMA and desmin, and negative for HePar-1, Glypican-3, CK-Pan, myogenin, Ard-1, MYOD1, SOX10 and CD31, with an approximately 10% Ki-67 index. As can be seen, the present case is mostly similar to those reported previously for this profile.

To date, due to lack of specific manifestations in imaging examinations, hepatic MS is easily misdiagnosed as liver cancer, hepatic hydatid disease, cystadenoma and other space-occupying lesions, and it is difficult to make a diagnosis in clinical practice as well. The hepatic MS reported here was mainly observed as a cystic-solid mass with well-defined borders and regular morphology. The cystic components within the mass were separated by septa of varying thickness, with a partially visible fluid-fluid levels. After enhancement, the solid portion and septa of the mass were enhanced to different degrees, with inconspicuous regression for the degree and velocity.

CEUS of this case showed that the peripheral and internal septa of the tumor were hyper-enhanced in the arterial phase, isoenhanced in the portal and delayed phases, while in two of the seven cases reported in the literature, the portal and delayed phases were hypo-enhanced. Hence, the CEUS features of hepatic MS require more case data.

Hepatic MS needs to be differentiated from liver cancer (particularly with liquefaction and necrosis), hepatic hydatid disease, and cystadenoma. When liver cancer is accompanied by liquefaction and necrosis, three-phase non-enhanced areas in the lesions may also be found, but most of them are patchy or irregular. Moreover, the substantial portion of the mass shows high enhancement in the arterial phase, and low enhancement in the portal and delayed phases. The process behaves in a fast-in and fast-out mode. In contrast, the non-enhancing area of hepatic MS lesions was separated by the internal septa of the mass, and the parenchyma and internal septa of the mass were not significantly regressed after enhancement. Patients with liver hydatid disease generally have a history of living in pastoral areas or exposure to pathogens. The typical imaging manifestations are mainly cystic masses, showing the mother and daughter sporocysts, with varying degrees of eggshell-like cyst wall calcification, intracystic streamer sign, lily sign, and cyst-within-cyst. Liver cystadenomas are cystic-solid masses with predominantly cystic components, along with mural nodules (papillary-solid components protruding into the cystic cavity on the cyst wall) as specific signs. Mural nodules show nodular enhancement in the portal phase and can continue to enhance in the delayed phase. Imaging examination can clearly show the size, location, border, number, blood supply, and internal and surrounding adjacent tissues of the tumor. However, there is currently no characteristic diagnostic basis for the imaging manifestations of hepatic MS.

The presented case was misdiagnosed for several reasons. First, the patient had no specific clinical history, presentation and abnormal laboratory indexes. Second, the preoperative imaging images were similar to those of cystadenoma. The internal separation of the mass was uniform, the blood flow of the mass was not abundant, and there was no washout after enhancement. Therefore, imaging diagnosis was limited to benign lesions, and malignant behavior was not considered.

In summary, MS of the liver has no characteristic manifestations in clinical performance, serological indicators and imaging findings. Therefore, there is a need to accumulate a large number of cases with complete data to provide meaningful research data for the diagnosis and treatment strategies of MS of the liver.

CONCLUSION

Due to the rarity of hepatic MS, more clinical data and in-depth research are needed to further analyze its pathological mechanism, biomarkers, and imaging manifestations. Improving the understanding of the imaging manifestations of hepatic MS will help improve the preoperative diagnosis rate and assist clinicians in performing precise surgical resection and follow-up treatment.

ACKNOWLEDGEMENTS

We are very grateful to Dr. Jiang Jia-Rui (Department of Pathology, Xiangya Hospital, Central South University) for providing professional guidance to the pathological analysis.

Abstract

We recently read with interest the article, "Novel frontiers of agents for bowel cleansing for colonoscopy". This is a practical narrative review, which could be of particular importance to clinicians in order to improve their current practice. Although we appreciate the venture of our colleagues, based on our in-depth analysis, we came across several minor issues in the article; hence, we present our comments in this letter. If the authors consider these comments further in their relevant research, we believe that their contribution would be of considerable importance for future studies.

Key Words: Colonoscopy; Bowel preparation; Polyethylene glycol; Post-polypectomy syndrome; Post-polypectomy complications

Core Tip: Colonoscopy is the gold standard investigation for the detection and treatment of colorectal neoplasia. The effectiveness and safety of the procedure mainly depends on the quality of bowel preparation (BP). Although international guidelines underline methods to ensure adequate BP, inadequate BP occurs in approximately one-third of the colonoscopies. The search for an ideal regimen to improve BP remains. The article by the authors addressed this issue successfully, but we detected several minor issues. Therefore, we would like to share our views and opinions on this interesting review.

TO THE EDITOR

We read with great interest the frontier article, "Novel frontiers of agents for bowel cleansing for colonoscopy"[1]. Although the authors follow the infrastructure of the updated version of the European Society of Gastrointestinal Endoscopy Guideline on bowel preparation (BP) for the main part of their article, they do not make absolutely clear to the reader the way they selected the studies included in their own updated review[2]. Despite this shortcoming, in general the authors summarize the major findings of several reference studies successfully. The salient highlight of this article is that Di Leo *et al* [1] address the issue of BP holistically, from cleansing agents to the multifaceted outcomes of the currently followed BP strategies in specific populations, such as those with congestive heart failure or chronic renal failure, disclosing areas that need to be further investigated. However, we believe that the most striking point of this article is the introduction of the novel term "post colonoscopy syndrome," which sums up all the minor complications that an individual could develop post colonoscopy, worsening his/her quality of life. Therefore, this research has a strong reference and practical value for future studies, overcoming limitations. Nevertheless, through our in-depth reading, we found several shortcomings and anticipate a discussion with the authors.

Initially, we agree with the authors that the assessment of the quality of BP is of utmost importance. Adequate BP is crucial, not only to the efficacy and safety of colonoscopies but also for awarding privileges to the endoscopists[3]. However, there are no universally accepted criteria that endoscopists can use for the assessment of the quality of BP. As a result, at least five quality assessment scales have been currently fully or partially validated and used in daily practice for the assessment of the quality of BP, inducing significant heterogeneity when quality results are compared among different studies. The unanimous approval of a single scale is expected to resolve this issue but is still awaited[3]. By comparing the specific characteristics of all available scales, the authors can disclose areas that need to be further investigated, facilitating endoscopists to reach consensus. However, in this article, the authors only refer to the Ottawa Bowel Preparation Quality Scale, Boston Bowel Preparation Scale and the partially validated Aronchick Scale, excluding other validated scales, such as the Harefield Cleansing Scale, which was the first scale to be developed[3]. This limitation leaves an initial critical step underdiscussed in this review, perpetuating confusion.

In their summary of current evidence, the authors focus on high and low volume polyethylene glycol (PEG)-based preparations, leaving non-PEG-based solutions that have been found to be of equal efficacy to PEG-based formulas under-reviewed. The reason behind this exclusion is not mentioned. However, it constitutes an omission. For example, in this article, the authors do not discuss lactulose, a semi-synthetic derivative of lactose that after fermentation stimulates intestinal motility and increases osmotic pressure within the colon. Accumulated evidence from clinical trials suggest that lactulose has similar efficacy to PEG-based solutions with acceptable safety when used for BP not only in individuals undergoing ambulatory colonoscopy but also in those undergoing colonoscopy for lower gastrointestinal bleeding[4-6]. These results expand the armamentarium of our available solutions for BP; hence, all the relevant information should be supplemented in this review.

In addition to the under-discussed non-PEG based solutions, the authors provided sparse data regarding the safety of using non-PEG based and PEG-based preparations in specific populations. Although the authors quote evidence on the effectiveness and safety of these agents in various patient populations included in this review, their efficacy and safety in patients with liver cirrhosis are not examined. The reason behind this exclusion is not mentioned by the authors, leaving a critical step under-discussed in this review. Patients with cirrhosis demonstrate alterations in physiology and hemodynamics that make them vulnerable to develop electrolyte imbalances during BP[7]. Osmotically balanced solutions have been shown to be effective and safe for the management of hepatic encephalopathy in this patient population[8]. However, little is known regarding their safety when used for BP as patients with liver cirrhosis are often excluded from randomized controlled trials comparing different bowel cleansing agents. In a recent study that examined the safety and efficacy of low volume and high volume PEG based solutions in 166 patients with liver cirrhosis, it was shown that both formulations can be effectively and safely used for BP with low volume formulations showing better acceptability and compliance[9]. Considering the absence of an established BP protocol in patients with liver cirrhosis, we believe that all the relevant information should be included in this review, allowing the reader to acquire a detailed overview of the subject.

Another shortcoming lies at the reference of the agents intended to improve patient experience. More specifically, the authors suggest that the menthol candy drops improve BP in the candy drops-added group compared to controls, with no benefit in side effects. However, in the reference trial, other than

the efficacy, the trial authors state that menthol drops improved nausea (24.5% drops *vs* 4% controls; P = 0.04). Since this finding is important, this detail should be clarified[10].

Finally, the authors attempted to shed light on the pathophysiology of minor post colonoscopy complications that mainly included the symptoms of pain, discomfort and bloating, defined as post colonoscopy syndrome (PCS). We agree that the post BP changes in microbiota composition contribute to the occurrence of PCS. However, we believe that this is the tip of the iceberg. In order to understand the pathophysiology of PCS accurately, researchers should look into the complex mechanisms of abdominal pain and study the impact of BP in all of them[11]. Previous evidence suggested that mucosal changes occurring secondary to colonic over-distension during colonoscopy as well as stress, inflammation, ischemia, pH, bacterial products, immune mediators and neurotransmitters can all be related to visceral pain[12-16]. However, whether BP can have a negative impact is unknown. Future studies should aim to investigate these complex relationships and unravel the exact role of BP in the pathophysiology of PCS, as their results may allow clinicians to mitigate the negative effects and increase the individual acceptance of colonoscopy.

In summary, this review can be a valuable reference study, guiding clinicians in their daily practice. We offer our evidence-based considerations on the shortcomings of this review in an effort to further increase the value of the review and direct more comprehensive future studies. But, whether BP can have a negative impact is unknown. Future studies should aim to investigate these complex relationships and unravel the exact role of BP in the pathophysiology of PCS, as their results may allow clinicians to mitigate the negative effects and increase the individual acceptance of colonoscopy. In summary, this review can be a valuable reference study, guiding clinicians in their daily practice. We offer our evidence-based considerations on the shortcomings of this review in an effort to further increase the value of the review and direct more comprehensive future studies.

Abstract

This letter is regarding the study titled 'Targeted puncture of left branch of intrahepatic portal vein in transjugular intrahepatic portosystemic shunt (TIPS) to reduce hepatic encephalopathy'. Prior to the approval of TIPS dedicated stents (Viatorr stents) in China in October 2015, Fluency covered stents were typically used. As Fluency covered stents have a strong support force and axial elastic tension, a 'cap' may form if the stent is located too low at the end of the hepatic vein or too short at the end of the portal vein during surgery, leading to stent dysfunction. Since the blood shunted by the stent is from the main trunk of the portal vein, the correlation between the incidence of postoperative hepatic encephalopathy and the location of the puncture target (left or right portal vein branch) is worth discussion. Notably, no studies in China or foreign countries have proven the occurrence of left and right blood stratification after the accumulation of splenic vein and mesenteric blood flow in the main trunk of the portal vein in patients with cirrhotic portal hypertension.

Key Words: Viatorr stent; Portosystemic shunt; Transjugular intrahepatic; Hypertension; portal; Left and right portal vein branches

Core Tip: This Letter to the Editor aims to analyse the effect of establishing a shunt in the left or right portal vein branch in transjugular intrahepatic portosystemic shunt on the incidence of postoperative hepatic encephalopathy in patients with cirrhotic portal hypertension. Based on preliminary clinical experience, it is thought that there is no difference in the incidence of hepatic encephalopathy among patients regardless of the use of a COOK bare stent or Viatorr stent with an inner diameter of 8 mm if a shunt is established in the left or right portal vein branch.

TO THE EDITOR

We read the article of Luo *et al*[1] titled "Targeted puncture of left branch of intrahepatic portal vein in transjugular intrahepatic portosystemic shunt (TIPS) to reduce hepatic encephalopathy" and are very interested in its conclusions. We think that therapy by "targeted puncture of the left branch of the intrahepatic portal vein in TIPS to reduce hepatic encephalopathy" is worthy of discussion.

First, Luo *et al*[1] performed a retrospective analysis of portal hypertension patients receiving TIPS from January 2000 to January 2013. During this period, a shunt was established using a Fluency stent (BARD, Voisins le Bretonneux, France) or Viatorr stent (W.L. Gore & Associates, Flagstaff, AZ, United States). However, the shunts were established in TIPS mainly using Fluency covered stents in China before the approval of TIPS dedicated stents (Viatorr stents) in China in October 2015. As Fluency covered stents have a strong support force and axial elastic tension, a 'cap' may form if the stent is located too low at the end of the hepatic vein or too short at the end of the portal vein during the operation, thereby leading to stent dysfunction. Since the blood shunted by the stent is from the main trunk of the portal vein, as shown in Figure 2 of Luo *et al*'s paper (the stent is inserted into the main trunk of the portal vein at the end of the portal vein for shunts in both the left and right portal vein branches), the correlation between the incidence of postoperative hepatic encephalopathy and the location of the puncture target (left or right portal vein branch) is worthy of discussion.

As pointed out by Luo *et al*[1], prior studies have reported that the backflow blood from the splenic and superior mesenteric veins is not thoroughly mixed but rather enters the left and right portal vein branches separately, *i.e.*, the blood from the superior mesenteric vein mainly flows into the right branch, while the blood from the splenic vein mainly flows into the left branch[2-3]. In a study on corrosion casting of the portal vein and hepatic artery ramifications in dogs, this study focused on explaining the anatomical features of the hepatic portal vein and hepatic artery in animals instead of the blood flow features of the portal vein system[2]. The author team believes that a substantial difference between animals and humans. In a study using carbon dioxide angiography, iodinated contrast medium was used to replace traditional angiography[3]. This study included chronic liver disease patients receiving percutaneous transhepatic puncture of the portal vein with the tube inserted into the splenic vein; a mechanical injection system was used to inject a total volume of 30 mL of contrast medium at a speed of 5 mL/s. Notably, a difference was observed in blood mixing at the left and right sides of the main trunk of the portal vein. An early study conducted in United States of America found that an increase in the pressure in the portal vein was followed by a decrease in hepatic blood inflow and blood flow rate and grading of liver function due to hepatic sinusoidal obstruction, perisinusoidal fibrosis and portal vein obstruction in cirrhosis was related to the portal blood flow rate; furthermore, portal hypertensive liver function damage was obvious, and the portal blood flow rate was low[4]. In the hyperdynamic splanchnic circulatory state, the progressive decrease in the portal blood flow rate suggests aggravation of hepatic parenchymal lesions and increased portal blood flow resistance. The author team believes that the blood flow rate decreased after splenic vein and mesenteric blood flows accumulated in the main trunk of the portal vein in cirrhotic portal hypertension patients, and so it was necessary to define the presence of different blood flow rates after the blood flows accumulated in the main trunk of the portal vein so as to achieve left and right blood stratification in the natural state. However, it is controversial at home and abroad whether there is difference between splenic vein blood flow velocity and mesenteric blood flow velocity in cirrhotic patients with portal hypertension after the accumulation of the main portal vein in the natural state. In a study conducted in 2020 in China, 15 patients with liver cirrhosis and upper gastrointestinal haemorrhage received TIPS, and blood samples were collected from the left branch, right branch and main trunk of the portal vein during the operation[5]. In these patients, the plasma ammonia concentration (μmol/L) was 96.4 ± 17.6 for the left branch *vs* 113.5 ± 18.4 for the right branch *vs* 106.9 ± 38.7 for the main trunk, without any statistically significant differences ($P > 0.05$). This study provides important evidence for the comparison of blood bacterial metabolites in the left and right branches of the cirrhotic portal vein.

TIPS dedicated stents (Viatorr stents) have been adopted for surgery at the Center since March 2016. In previous studies, COOK bare stents with an inner diameter of 8 mm were used to establish a shunt[6-7]. Although such a stent should be long enough at the end of the portal vein, the shunted blood was from the portal vein branches, so whether a shunt was established in the left or right portal vein branch had no significant effect on the incidence of hepatic encephalopathy. In a study conducted in China in 2020, 120 cirrhotic portal hypertension patients received TIPS using Viatorr stents. Intraoperative portal vein angiography showed that a shunt was established in the left portal vein branch for 52 patients and in the right portal vein branch for 68 patients[8]. There was no statistically significant difference in the

incidence of postoperative hepatic encephalopathy (χ^2 = 0.159, P = 0.69) between the left portal vein and right portal vein branch shunting groups. A recent study reported that the incidence of hepatic encephalopathy decreased significantly by controlling the inner diameter of the stent, *i.e.*, using a Viatorr stent with an inner diameter of 8 mm[9]. The bare area of a Viatorr stent may guarantee a smooth blood flow in the portal vein and prevent more blood not metabolised by the liver from directly entering the systemic circulation.

There is no information in the TIPS guidelines circulated in North America regarding differences in the incidence of postoperative hepatic encephalopathy when shunts are established in different portal vein branches[10-11]. We believe that there are no differences in the incidence of hepatic encephalopathy among postoperative patients when using a Viatorr stent with an inner diameter of 8 mm when the shunt is established in the left or right portal vein branch. As the postoperative medium and long-term efficacy of TIPS are related to clinical procedures, postoperative management of patients and other factors, future studies with larger sample sizes and multicentre randomised controlled trials are warranted.

Abstract

Irritable bowel syndrome (IBS) is an important health care concern. Alterations in the microbiota of the gut-brain axis may be linked to the pathophysiology of IBS. Some dietary intake could contribute to produce various metabolites including D-amino acids by the fermentation by the gut microbiota. D-amino acids are the enantiomeric counterparts of L-amino acids, in general, which could play key roles in cellular physiological processes against various oxidative stresses. Therefore, the presence of D-amino acids has been shown to be linked to the protection of several organs in the body. In particular, the gut microbiota could play significant roles in the stability of emotion *via* the action of D-amino acids. Here, we would like to shed light on the roles of D-amino acids, which could be used for the treatment of IBS.

Key Words: Irritable bowel syndrome; D-amino acid; Gut microbiota; Colitis; Probiotics; Fecal microbiota transplantation

TO THE EDITOR

With great interest, we have read the article by Mamieva *et al*[1]. As irritable bowel

DOI: 10.3748/wjg.v28.i31.4471 **Copyright** ©The Author(s) 2022.

Figure 1 Gut microbiota could contribute to the production of D-amino acids, which might play key roles in irritable bowel syndrome *via* direct action on the gut and/or indirect action through the gut-brain axis with emotional stability. Fecal microbiota transplantation consists of fecal microbiota infusion from a healthy donor into a recipient subject, which has been also shown to be a promising therapy for irritable bowel syndrome. Arrowheads mean stimulation and/or augmentation whereas hammerheads represent inhibition. Note that some critical events such as reactive oxygen species production, immune activation, and/or cytokine-induction have been omitted for clarity.

syndrome (IBS) could exacerbate the patients' quality of life, it is a considerable health care concern. Although the underlying pathophysiological mechanisms are not clear, the role of low-grade inflammation and mucosal immune activation appears to be obvious in the signs of IBS. IBS is a functional gastrointestinal disorder, and some probiotic supplementation may reduce the symptoms[2]. In addition, fecal microbiota transplantation expects recommendations for the treatment of IBS, suggesting that alterations in the gut microbiota-brain axis are linked to the pathophysiology of IBS (Figure 1). It has been revealed that some cytokines and neurotransmitters as well as several microbial metabolites including short chain fatty acids (SCFAs) such as acetate, lactate, butyrate, and propionate produced by the bacteria in the gut could modulate the integrity of brain function[1]. The bidirectional communication between the gut microbiota and the brain is well-known as the gut-brain axis, which could play an important role in the stability of emotion[3]. As shown in the article by Mamieva *et al*[1], the microbiota could influence the pathogenetic factors of IBS through the production of several microbial metabolites. Here, we would like to add the efficacy of D-amino acids for the alteration of IBS condition.

Mice treated with D-serine prior to the induction of colitis exhibited a reduction in the colonic inflammation that was not seen in mice fed L-serine[4]. In addition, D-serine efficiently suppressed the progression of chronic colitis. Therefore, D-serine might have effective properties as a preventive strategy and/or a treatment for colitis[4]. In addition, several studies have shown the significance of D-amino acids in clinical usage[5]. For example, D-methionine protects against the intestinal damage through anti-oxidative and anti-inflammatory effects, which could improve the gut microbiome imbalance by enhancing the growth of beneficial bacteria[6]. Protective effects of low-dose D-serine have been also shown to suppress the renal damage, which may promote the proliferation of kidney epithelial cells[7]. In addition, D-cysteine administration could defend the kidney from ischemia-reperfusion injury, which may be beneficial for the treatment of several renal diseases[8]. Gastroprotective effect with D-cysteine but not with L-cysteine has been shown *via* the effects of decreasing cellular damage, edema, and epithelium loss[9]. Treatment with D-aspartate may bring positive effects in the nervous system[10]. Furthermore, D-cycloserine is a glutamatergic N-methyl-D-aspartate receptor agonist which has been revealed to support the stability of emotion[11]. Furthermore, the activity of ovarian development with D-tryptophan is more effective than that with L-tryptophan[12]. These data suggest that D-amino acids could have beneficial and/or protective effects on various tissues, which might be favorable to the treatment of IBS (Figure 1). In particular, the emotional stability *via* the action of D-amino acids seems to be important[13], because it has been shown that different types of physiological and/or psychological stressors are known to contribute to the development, maintenance, and exacerbation of IBS[14].

The gut microbiota has a large genetic capacity to produce D-amino acids which are utilized as nutrients to support bacterial growth[15]. D-amino acids are essential elements of peptidoglycans in the cell wall of bacteria. Hence, higher levels of D-amino acids have been basically related to the mass of the gut microbiota[16]. Many bacterial species encode specific racemases that can convert L-amino acids to D-amino acids, which are frequently present in the peptidoglycan-containing bacteria in the gut microbiota[17]. Accordingly, the lumen of the gastro-intestinal tract in mammals may be rich in free D-amino acids that might be derived from such bacteria or fermented foods. Probably, the source of D-

amino acids in mammals may mostly be from their gut microbiota. For example, D-alanine production is linked to the relative abundance of bacterial species such as *Enterococcus* and *Lactobacillus* in the gut microbiota[18]. Therefore, the metabolism of D-amino acids in the body might be modified by the alteration of gut bacterial communities affecting the host health and/or homeostasis[19]. Reduction of the amount of several D-amino acids may promote senescence through the increase of reactive oxygen species production[20,21].

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 edition of Journal Citation Reports® cites the 2021 impact factor (IF) for *WJG* as 5.374; IF without journal self cites: 5.187; 5-year IF: 5.715; Journal Citation Indicator: 0.84; Ranking: 31 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2021 is 8.1 and Scopus CiteScore rank 2021: Gastroenterology is 18/149.

Abstract

Little was known about mammalian colon mucus (CM) until the beginning of the 21st century. Since that time considerable progress has been made in basic research addressing CM structure and functions. Human CM is formed by two distinct layers composed of gel-forming glycosylated mucins that are permanently secreted by goblet cells of the colonic epithelium. The inner layer is dense and impenetrable for bacteria, whereas the loose outer layer provides a habitat for abundant commensal microbiota. Mucus barrier integrity is essential for preventing bacterial contact with the mucosal epithelium and maintaining homeostasis in the gut, but it can be impaired by a variety of factors, including CM-damaging switch of commensal bacteria to mucin glycan consumption due to dietary fiber deficiency. It is proven that impairments in CM structure and function can lead to colonic barrier deterioration that opens direct bacterial access to the epithelium. Bacteria-induced damage dysregulates epithelial proliferation and causes mucosal inflammatory responses that may expand to the loosened CM and eventually result in severe disorders, including colitis and neoplastic growth. Recently described formation of bacterial biofilms within the inner CM layer was shown to be associated with both inflammation and cancer. Although obvious gaps in our knowledge of human CM remain, its importance for the pathogenesis of major colorectal diseases, comprising inflammatory bowel disease and colorectal cancer, is already recognized. Continuing progress in CM exploration is likely to result in the development of a range of new useful clinical applications addressing colorectal disease diagnosis, prevention and therapy.

Key Words: Colon; Colon mucus; Mucins; Goblet cells; Gut microbiota; Inflammatory bowel disease; Colorectal cancer

Core Tip: Until recently colon mucus (CM) importance was largely ignored because its structure and functions were obscure. It is now known that human CM comprises a dense inner layer impenetrable for bacteria and a loose outer layer providing a habitat for abundant commensal microbiota. Mucus barrier integrity is essential for maintaining homeostatic balance between colonic mucosa and gut microbiota, and its impairment opens direct bacterial access to the epithelium, which induces inflammation and can cause severe disorders, including inflammatory bowel disease and colorectal cancer. Recent advances in colorectal mucus exploration and emerging new clinical applications based on this knowledge are discussed.

INTRODUCTION

The latest estimates of global cancer incidence and mortality provided for 2020 show that colorectal cancer (CRC) ranks third in terms of incidence and second in terms of mortality[1]. More than 1.9 million new CRC cases and over 935000 deaths caused by this disease were registered worldwide by GLOBOCAN in 2020[1]. Being the most prevalent type of gastrointestinal (GI) neoplasia, CRC is also the most preventable due to its association with modifiable life-style factors[2]. Besides, colorectal tumors are often curable as they grow slowly and can be detected and treated early if effective screening is applied[2,3]. One important biological feature of CRC is its origination from the colonic epithelium, enormous surface of which constitutes the interface between the human body and potentially carcinogenic gut content. Indeed, the intestinal lumen is inhabited by billions of diverse microorganisms forming a unique microbial ecosystem within the host's organism[4]. Microbial density inside the human colon reaches 10^{12} bacterial cells per gram of predominantly anaerobic colonic content that is, nevertheless, indispensable for host development and physiology[5]. This complex and sometimes aggressive ecosystem permanently interacts with the single layer of intestinal epithelial cells that are highly active, being involved in various absorption and secretion processes.

The immense surface of the intestinal mucosa defines the utmost importance of the continuous interplay between its epithelium and gut microbiota. Until the first decade of the XXI century bacteria were presumed to directly contact the epithelial cells[6]. Only in 2008 a research group from Gothenburg (Sweden) convincingly demonstrated the existence of a well-structured system of protective mucus that effectively separates the epithelium from gut content[7]. That seminal study was followed by impressively productive exploration of the gut mucus and its functional significance in health and disease. This review is focused on recent developments in this field, particularly highlighting the emerging evidence of the importance of colon mucus (CM) for the pathogenesis of inflammatory bowel disease (IBD) and colorectal tumors, as well as associated problems of colorectal disease diagnosis, prevention and treatment.

CM COMPOSITION AND STRUCTURAL CHARACTERISTICS

It is now well established that all surfaces of the columnar epithelia lining inner cavities of the human body are overlayed by mucus, which can be generally defined as a complex viscoelastic substance usually secreted by goblet or mucous cells and protecting the underlying epithelium[6,8]. Distinct mucus types naturally adapted for organ-specific functions are described for the GI tract, the respiratory system, the reproductive organs and the ocular surface[6,8,9]. Although mucus composition is organ-specific, its constituents always comprise water (90%-95%), electrolytes, lipids and various proteins[8]. The high water content makes normal CM transparent, which could be one of the reasons of the late discovery of its structure[6,7] schematically presented in Figure 1.

The review is focused on the colon, therefore further discussion is largely devoted to the CM, properties of which are determined by its specific proteins, mucins, defining structural and functional characteristics of this substance[10]. All GI tract mucins are densely decorated with complex carbohydrates or glycans[11]. It is important to stress that the high degree of mucin O-glycosylation protects the peptide bonds, hence rendering these proteins inert to the proteolytic action of the host's proteases[11,12]. There are 22 genes encoding mucins, the presence of phosphotransferase system (PTS)-rich sequences [tandem repeat units rich in proline, threonine (Thr) and serine (Ser)] being their characteristic feature[8-10]. In these proteins a large proportion of the Ser and Thr residues are O-glycosylated with the creation of a "bottle brush" configuration important for high water-binding capacity and gel-

forming properties[8-10,13,14]. GI tract mucins can be subdivided into two classes comprising: (1) Transmembrane mucins that have a transmembrane domain enabling them to be anchored in the apical cell membrane; and (2) Gel-forming mucins that are synthesised and secreted by the goblet cells (GCs), thus being the key CM components[8,10,13,14].

Transmembrane mucins

The transmembrane mucins of epithelial cells are a family of large and extended glycoproteins that are attached to the apical cell membrane through a single-pass transmembrane domain involved in intracellular signaling. This family includes MUC1, MUC3, MUC4, MUC12, MUC13, MUC15, MUC16, MUC17, MUC 21 and MUC22 that vary in length and the presence of several specific domains[14,15]. All transmembrane mucins have PTS domains, which are heavily O-glycosylated, but glycosylation patterns along the GI tract vary, also being different in health and disease[15]. The transmembrane mucins MUC3, MUC12 and MUC17 cover the apical cell membrane of enterocytes and colonocytes, forming the attached protective glycan-rich diffusion barrier, called glycocalyx (Figure 1). It was reported that MUC3 is expressed throughout the whole intestine, MUC12 appears to be colon-specific, and MUC17 is abundant in the small intestine but is also found in the transverse colon[11,13,14]. The transmembrane mucins do not belong to the CM, and their precise role in health and disease remains to be fully elucidated. Detailed discussion on this subject can be found in a recent review by Pelaseyed and Hansson[15].

Gel-forming mucins

The gel-forming mucins of the GI tract are synthesised and secreted by the mucosal GCs. The most abundant and best characterized of the secreted mucins is MUC2, the main element of the mucus overlaying mucosal surfaces of the small intestine and colon. Other gel-forming mucins of the GI tract are MUC5AC (expressed in the stomach), MUC5B (weakly expressed in the colon) and MUC6 (expressed in the stomach and duodenum)[13,14]. The structural organization of the GI mucus was initially determined in rodents, and it was shown that mouse stomach and colon have two distinct

layers of dense (inner) and loose (outer) mucus, whereas this pattern is absent in the small intestine, where only a single layer of loose mucus is present[7,11,16]. It is now known that in the human colon the thickness of the dense inner mucus layer is about 200-300 μm, and the loose outer layer is at least twice as thick[6,10,11]. Figure 1 schematically shows the structure of the human CM. It should be stressed that, despite almost identical protein profiles dominated by MUC2, the two CM layers are essentially different[16]. In the normal conditions the dense inner layer is permanently renewed by colonic GCs producing MUC2, which remains anchored to the GCs and attached to the epithelium[10]. Remarkably, the high density of the inner CM layer appears to make it devoid of bacteria[7,11,16]. At a certain distance from the epithelial surface (over 200 μm in humans), the inner mucus is abruptly replaced by the loose outer CM layer, where commensal bacteria live and thrive[16]. The two mucus layers form a sharp border separating them. According to the current paradigm, the dense inner layer is converted into the loose outer mucus by endogenous (host's) proteases, however it is impossible to exclude that gut bacteria populating the outer layer also contribute to the conversion[7,10,11,16]. It is also worth noting that alongside the mammalian colon there are longitudinal differences in both microbiota composition and MUC2 O-glycan pattern distribution in the CM. It the mouse CM was generally characterized by the abundance of highly charged fucosylated glycans, but glycan sulfation level was higher in the distal colon, whereas sialic acid was more common in the proximal colon[17]. It was suggested that the observed differences in mucin glycan structures might be involved in the bacterial selection process by bacterial adhesin - mucin glycan interactions[17]. All these important basic findings are further discussed below in relation to interactions between gut microbiome, CM and colonic epithelium.

GOBLET CELLS AND THEIR ROLE IN CM FORMATION AND MAINTENANCE

Mucus production

Intestinal GCs are responsible for the continuous synthesis and secretion of gut mucus. The details of the complex process of MUC2 synthesis in the GCs are described in recent reviews[8,12,14], but it is useful to note that MUC2 monomers form C-terminal dimers and N-terminal trimers in the endoplasmic reticulum, and the extensive O-glycosylation of the large PTS domain of MUC2 occurs in the Golgi apparatus. The MUC2 polymer is then densely packed in the secretory granules of the GCs under conditions of the low pH and high calcium concentration[11,14,18]. It is believed that the formation of secretory granules occurs during the maturation of GCs coinciding with their migration from the crypt bottom towards the luminal surface[10]. Finally, the secretory granules undergo exocytosis by fusion with the apical membrane, thus releasing their content to the surface of the epithelium. Upon its release, which is accompanied by an increase in pH and a decrease in calcium concentration, the densely packed mucin expands over than 1000-fold[6,10]. The secreted MUC2 immediately unfolds into large net-like planar sheets that are then assembled in porous lamellar networks forming the dense inner CM layer[12,19,20]. The stability of the inner mucus layer is further increased by the formation of isopeptide bond crosslinks catalyzed by transglutaminase 3 produced by GCs and neighbouring colonocytes[21].

The process of permanent mucus renewal is very intense, inner layer renewal time in the mouse colon being only about 1 h[22]. It was also observed that GCs of the luminal surface epithelium produce mucus faster than their counterparts located in the crypt epithelium[22], and it has later been shown that the properties of mucus generated by GCs of the colonic surface epithelium (intercrypt GCs) differ from those of mucus secreted by crypt-resident GCs. Intercrypt GCs have a specific transcript profile and produce less dense and more penetrable mucus compared to the mucus "plumes" synthesised by crypt-resident GCs and possessing more stringent barrier properties[23] (Figure 1). Single GC analysis revealed that within the colonic epithelium there are several different GC clusters, all originating from stem cells at the bottom of the crypt but forming two distinct "differentiation trajectories". One of them, termed "canonical" GCs, is characterized by the expression of typical GC markers, whereas the other one expresses enterocyte-associated genes and was designated as "noncanonical"[23]. The intercrypt GC population appears to be predominantly composed of the most differentiated "canonical" GCs continuously secreting mucus at baseline. In contrast, "noncanonical" GCs, which are more abundant in the crypts and contribute to mucus "plume" secretion, are likely to be more responsive to external stimulation[23]. These results are in agreement with the identification of at least five clusters of GCs with distinct gene expression profiles in the human colon[24].

The discovery of colonic GC diversity inevitably leads to questions on functional differences between GC subpopulations and alternative regulatory mechanisms governing CM production in health and disease. The emerging evidence of GC participation in controlling immune responses in the gut is especially important in this context[25]. In 2012, McDole *et al*[26] reported that small intestinal GCs could endocytose low molecular weight soluble antigens from the gut lumen, being capable of delivering them through GC-associated antigen passages (GAPs) to underlying $CD103^+$ dendritic cells of the intestinal *Lamina propria*. Further studies of this group revealed the existence of this antigen-presenting phenomenon in the colon as well, when acetylcholine-induced GAP formation in colonic GCs was observed[27]. These GAPs could even translocate live commensal bacteria across the

epithelium following antibiotic treatment[28]. It is also believed that GAP formation may be associated with compound exocytosis by GCs, but not primary exocytosis[29]. Hence, the process of GAP formation involves both endocytosis and exocytosis, the two interlinked pathways closely related to autophagy[30], and it was not surprising that autophagy proteins were found to control mucin granule accumulation in colonic GCs[31]. Among autophagy-related factors associated with intestinal GCs, the NOD-like receptor family pyrin domain containing 6 (NLRP6) inflammasome has recently attracted considerable interest[32]. Wlodarska *et al*[33] first demonstrated that the NLRP6 inflammasome acts as a major orchestrator of mucin granule exocytosis in the colon. This theme was further developed by the identification of sentinel GCs localized at the colonic crypt entrance and capable of endocytosing microbe-derived ligands of toll-like receptors (TLRs) from the lumen. This, in turn, triggers the TLR pathway stimulation and leads to the activation of NLRP6 inflammasome. The response provokes compound exocytosis of MUC2 from the sentinel GCs, entailing their death and inducing enhanced mucus production from adjacent GCs through intercellular gap junction signaling[34]. Nevertheless, the described NLRP6 inflammasome involvement does not seem to be important for either CM formation or its function at baseline[35]. Taken together, these results suggest that NLRP6 modulates GC function and CM secretion only in response to interactions with TLR agonists, being inactive in the normal conditions[33]. The role of GCs in monitoring extracellular environment, interacting with the gut microbiota and communicating with the immune cells of the *Lamina propria*, is being actively studied and discussed[25,29,36], but further research is required for its comprehensive clarification.

Other products of goblet cells and protective properties of the CM

Although MUC2 is the main product of the GCs in the colon, mucin granules of these cells also contain other mucus components, such as Fc fragment of immunoglobulin (Ig) G-binding protein, calcium-activated chloride channel regulator 1, zymogen granule protein 16 (ZG16), anterior gradient 2, and trefoil factor 3[11,12]. Some of these proteins possess antibacterial properties. In particular, the lectin-like protein ZG16 prevents bacterial penetration into the inner CM layer[37]. Likewise, proteins resistin-like molecule beta, predominantly synthesised by colon GCs[38], and cathelin-related antimicrobial peptide, which is produced by both epithelial cells in colonic crypts and mucosal macrophages[39], were demonstrated to be bactericidal. Moreover, the loose outer mucus layer in the colon is likely to be intermixed with distally moving loose mucus generated in the small intestine and rich in antimicrobial peptides (AMPs) secreted by Paneth cells located in the mucosa of the small intestine[40]. Besides, the process of mucus barrier formation appears to be even more complex as it has recently been shown that in mice mucus abundantly produced in the proximal colon and encapsulating the faecal material considerably differs from that secreted in the distal colon for secondary strengthening the encapsulation process[41]. However, given numerous species-specific differences, direct extrapolation of these results to humans remains impossible until the matter is comprehensively investigated[42]. In any case, the presence of a range of AMPs probably produced at different sites throughout the GI tract was clearly demonstrated in human rectal mucus samples[43]. It can be added that secretory IgA antibodies produced by plasma cells residing in the intestinal *Lamina propria* were shown to be transported to the mucus by transcytosis[44], and IgA in the colon is concentrated in the outer mucus layer[45]. Finally, it should be mentioned that the steep oxygen gradient keeping the inner CM layer relatively well oxygenated also prevents anaerobic luminal pathogens from reaching the epithelium[46]. The presence of all these factors and the permanent distal movement of the outer CM with the peristaltic waves[10,47], contribute to the protection of the inner CM layer from bacterial invasion.

INTERACTIONS BETWEEN CM AND GUT MICROBIOTA

The human gut harbors a highly diverse community of commensal bacteria usually referred as microbiota, which exhibits both longitudinal and cross-sectional variation in both location and density [48,49]. Microbiota composition in the normal human colon is dominated by Bacteroidetes and Firmicutes phyla, with the presence of members of a few other phyla and strong variability between individuals[48,50]. Notably, dietary fiber digestion is one of the most important functions of the gut microbiota as these plant polysaccharides are largely indigestible by human glycoside hydrolases[51]. The anaerobic fermentation of fiber-derived sugars by gut lumen bacteria produces short-chain fatty acids (SCFAs), including butyrate, acetate and propionate. These SCFAs obviously pass through the intestinal mucus (Figure 1) before being taken up and utilized by the epithelium (butyrate provides up to 70% of colonocyte energy supply). SCFAs are indispensable for both intestinal homeostasis and a variety of effects on tissues and organs beyond the gut (see review by van der Hee and Wells[52]). Remarkably, abundantly glycosylated mucins of the CM can also be targeted by gut bacteria as nutrient sources[50]. Hence, mucin-decorating glycans are thought to constitute a critical resource utilized by commensals to enable them to thrive when diet-derived glycans are limited[53]. This suggestion was experimentally proven by the observations of gut microbiota switch to consuming host-secreted mucus glycoproteins during chronic or intermittent dietary fiber deficiency in mice[54]. The diet-induced microbiota behavior change was, however, unfavorable for the host, leading to CM barrier degradation

and lethal colitis development[54].

The described observations demonstrate that both the loose mucus of the small intestine and the loose outer CM layer serve as both energy sources and habitats for human gut microbiota[50]. In the colon of experimental animals (information regarding human microbiota is scarce) the outer mucus layer harbors a mixed population of commensals with the typical presence of *Akkermansia muciniphila* and bacteria of *Bacteroides* genus (*e.g.*, *Bacteroides thetaiotaomicron*, *Bacteroides fragilis*, *Bacteroides vulgatus*)[48-50]. Outer CM layer also contains *Rumminococcus gnavus*, *Rumminococcus torques*, and *Desulfovibrio desulfuricans*, as well as probiotic *Lactobacillus reuteri*, *Lactobacillus rhamnosus*, *Lactobacillus johnsonii*, *Bifidobacterium breve* and *Bifidobacterium longum*[55]. In addition, bacteria of relatively aerotolerant phyla (Proteobacteria, Actinobacteria) were reported to be occasionally present even closer to the mucosal surface[48,49].

It has been hypothesised that in health CM not only constitutes a physical barrier between bacteria and the epithelium but provides a bioactive environment selectively favorable for beneficial commensals and hostile for intruding pathogens[56]. As mentioned above, mucin glycoproteins provide nutrition for mucus-dwelling bacteria that are able to degrade them, like *Akkermansia muciniphila*, *Bacteroides fragilis* and *Rumminococcus gnavus*[50,53,56]. However, mucin glycans may not be the preferred carbon sources for some host commensals, including *Bacteroides thetaiotaomicron*[57]. Interestingly, this human gut symbiont was recently shown to possess a unique ability to initiate degradation of the complex sulphated O-glycans of the distal colon[58]. The activities of 12 sulfatases produced by this species were collectively sufficient for degrading all known sulphate linkages in mucin O-glycans, but only a single key sulfatase was disproportionally important for the utilization of sulphated O-glycans[58]. This example illustrates the challenging complexity of mucin degradation pathways that may become relevant for the development of future therapeutic applications.

CM is also responsible for the spatial organization of mucus-dwelling bacteria. Mucin-based networks with varying pore size and adhesiveness provide three-dimensional scaffolds for bacterial settlement, thus governing the process of bacterial colonisation[56]. Adhesiveness modulation by the host can also be employed as a mechanism altering microbiota composition[59]. Heterogenous glycan patterns of mucins affect bacterial motility and aggregation and prevent certain pathogens from aggregating and forming biofilms[56]. In addition, CM is believed to control the traffic of small signaling molecules, thereby regulating microbial behavior, and in some circumstances mucin glycans probably exert signaling functions themselves[56].

The diversity of mucin-decorating glycans constitutes a highly variable element of human CM and influences both gut microbiota behavior and host susceptibility to infectious and metabolic diseases[53,60]. Its importance for microbial community composition can be illustrated by the dependence of the latter on the presence of a functional copy of the galactoside 2-alpha-L-fucosyltransferase 2 (*FUT2*) gene encoding FUT2 that facilitates the attachment of the L-fucose monosaccharide to O-glycans, producing α (1,2)-fucosylated glycans[61]. The *FUT2* is one of the genes responsible for the expression of ABO histo-blood group antigen precursors in gut mucus[53,60-62]. Individuals with at least one functional *FUT2* allele are termed "secretors", although the gene does not actually regulate the secretion of proteins bearing α(1,2)-fucosylated glycans[60]. The homozygosity for the loss-of-function *FUT2* mutations (found in about 20% of Caucasians) defines "non-secretors"[53,60,62]. Interestingly, considerable differences in CM bacterial profiles were repeatedly detected between "secretors" and "non-secretors". Rausch *et al*[62] found that in healthy "secretors" the probiotic *Lactobacillus* genus was more prominent, whereas a clear association of the "non-secretor" status with the genus *Prevotella* was observed. Other *FUT2* genotype-associated phylotype changes, including the decrease of *Roseburia* and *Faecalibacterium* in endoscopic lavage samples from "non-secretors" or probiotic *Bifidobacterium* decrease in faeces from "non-secretors" were also reported[63,64]. In contrast, a few relatively large studies failed to detect any associations between *FUT2* genotype and gut microbiome shifts[65-67]. However, an even larger genome-wide association study (GWAS) comprising 8956 German individuals from five independent cohorts confirmed the previously identified associations of ABO histo-blood groups and FUT2 secretor status with *Bacteroides* and *Faecalibacterium* species[68]. These discrepancies are not surprising since GWAS studies assessing gut microbiome changes are usually based upon using homogenised stool samples. The use of this crude approach means that it is impossible to find out which bacteria are where, how their gene expression and functions are related to the local environment and how their spatial organization changes in disease[48]. It can be argued that samples obtained by mucosal biopsy, colonic lavage or CM collection are much more reliable and informative for analysing the microbiota populating CM. However, it is obvious that O-glycans associated with MUC2 strongly influence the composition of the commensal microbial population confined to the outer mucus layer in the colon.

It was already stated before that there are longitudinal differences in both microbiota composition and MUC2 O-glycan pattern distribution in the mammalian gut[17]. The distribution of O-glycosyl-transferases produced by the epithelial cells along the colon correlated well with the pattern of O-glycans[69]. These regional-specific characteristics of the gut glycan pattern are certainly acquired after birth, as neither sialic acid nor fucose gradients exist along the foetal intestine[70]. The differences developing in the postnatal life are thought to be related to the establishment of luminal microbiota acting as a potent environmental factor that provokes dramatic gene expression shifts in the host epithelium[70]. This view is supported by mouse experiments demonstrating that commensal

colonisation promotes structural and physiological adaptations of mucus barrier properties, thus contributing to intestinal homeostasis[71,72]. The complex interplay between gut microbiota and colonic mucosa continues into the maturity of the host and becomes even more important during ageing. In mice ageing causes a progressive decrease of CM thickness that is accompanied by considerable changes in faecal microbiota composition and more frequent contacts of luminal bacteria with the epithelium [73]. A similar reduction of CM layer thickness, primarily attributed to the reduced number of GCs, was observed in ageing rats[74]. Interestingly, a recent report shows that indoles produced by commensal bacteria can act *via* the aryl hydrocarbon receptor and interleukin 10 to restore the depleted population of colonic GCs in aged animals, hence supporting homeostasis[75]. Although age-related changes in the human CM system are poorly studied, it is notable that the intestinal microbiota composition in elderly subjects substantially differed from that in young adults, with a greater proportion of *Bacteroides* species and distinct abundance of *Clostridium* groups in the elderly[76].

To conclude this section of the review it is important to clarify that the gut mucus barrier, albeit essential, is just an element of the complex mechanism responsible for protecting the host's organism from unwanted risks. The immune system is the key driving force of this mechanism playing a central role in shaping the composition of the microbiota and defining its spatial distribution in close proximity to host tissues. Nevertheless, resident microorganisms interact with the immune system and influence the development of immune responses. Disruption of this complex and dynamic cross-talk can have deleterious consequences for host health contributing to the pathogenesis of many diseases including IBD and cancer[77].

CONSEQUENCES OF GUT MUCUS DETERIORATION EXPOSING COLONIC EPITHELIUM

CM and underlying epithelium: Host cells are released into mucus in the normal physiological conditions

It is well established that the intestinal epithelium is renewed every 4-5 d[78], and, before the discovery of CM structure and recognition of its importance[6], it was presumed that terminally differentiated enterocytes or colonocytes undergo spontaneous apoptosis and are finally "shed into the gut lumen" [78]. This simplistic notion needed to be revised, given the complexity of the two-layered CM structure and high density of the inner mucus layer[6,10,11]. Our group previously demonstrated that in healthy individuals exfoliated colonocytes are rarely found in CM samples collected either from the surface of the rectal mucosa or non-invasively[79,80]. Similarly, only small numbers of normal exfoliated colonocytes in mucus-containing surface washes of stool samples obtained from healthy volunteers were observed in earlier studies[81-83]. In view of the proven existence of the two-layered CM structure (Figure 1), an immediate question emerges: How exfoliated colonocytes and occasional neutrophils released from the epithelial surface manage to penetrate the dense inner mucus layer impenetrable for much smaller bacteria? No satisfactory answer has hitherto been found, but it was previously assumed that shed cells could be "trapped in the mucus" and degraded there[7].

Remarkably, well-preserved colonocytes were identified in all quoted studies that analysed CM[47, 79-83]. One could argue that intrarectal mucus collection might mechanically detach epithelial cells from the mucosa[79], however this explanation is not valid when CM is obtained non-invasively or from the surface of freshly excreted stool[80-83]. Although it is possible to hypothesise that the transport of the released cells might be assisted by the rapid CM layer renewal[22], or that focal partial cleavage of MUC2 may occur at sites of colonocyte exfoliation or neutrophil migration[16], mechanisms of this phenomenon remain obscure. In contrast, abundant presence of both exfoliated colonocytes and migrating inflammatory cells in CM samples obtained from patients with IBD and CRC is easy to explain by the structural damage of the CM barrier observed during these conditions and considered below. Despite the existing uncertainties on the mechanisms involved in cell accumulation in the mucus, it is indisputable that this easily accessible substance presents a highly informative material for multiple diagnostic applications.

CM barrier damage and its consequences in gut inflammation predisposing to CRC

CM presents the first defensive barrier against the luminal microbiota, its dense inner layer making bacterial contact with the colonic epithelium hardly possible in the healthy gut[7]. Although loose mucus of the small intestine contains commensal bacteria, it is rich in antimicrobial substances, and its permanent production by GCs in the normal conditions creates a continuous mucus flow preventing bacteria from reaching the epithelium[11,84]. Therefore, only severe CM impairment can lead to exposing the epithelial surface to direct contacts with the microbiota. The unique importance of MUC2-rich mucus for colonic epithelium protection was graphically demonstrated by the development of spontaneous colitis in *MUC2*-knockout mice unable to produce MUC2[85]. Likewise, microbiota-induced mucus layer defects were observed in genetically obese mice[86]. Experimentally modelled dietary fiber deficiency also led to CM barrier degradation, bacterial invasion of the mucosa and lethal colitis development[54]. The composition of intestinal microbiota is now recognised as a key factor for defining properties of the inner mucus layer[71,72], and it was clearly demonstrated that dysbiosis in

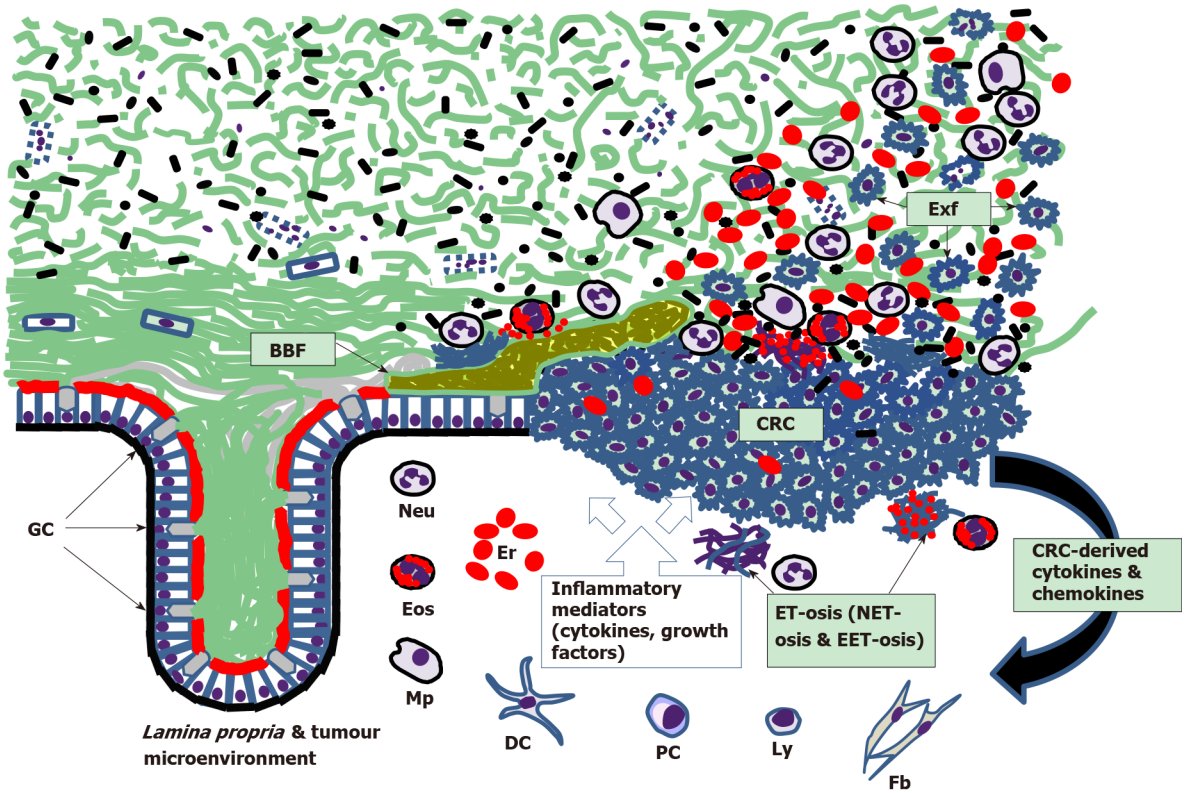
the mucus preceded experimental colitis development[87]. Results of all these experimental studies clearly demonstrate that the loss of CM barrier integrity combined with dysbiosis usually results in opportunistic invasion of the colonic mucosa by resident bacteria, inevitably leading to inflammation [77].

In patients with IBD, comprising ulcerative colitis (UC) and Crohn's disease (CD), CM deterioration and the abundance of mucolytic bacteria were observed[88,89]. Aforementioned mucus microbiota shifts related to *FUT2* "non-secretor" genotype entailed an increased risk of developing CD[62]. The gut bacteria in IBD patients are often confined to mucosa-adhering biofilms that can be defined as matrix-enclosed multispecies bacterial communities forming higher-order structures[90,91]. Mucosal biofilms were frequently found in IBD patients and patients with irritable bowel syndrome (IBS), and, sometimes, in clinically healthy individuals[88,91,92]. These findings indicate that bacterial biofilm formation does not immediately lead to inflammation development, being, at least to some extent, compatible with the preservation of homeostasis control by the immune system. Probable involvement of biofilms in IBS pathogenesis may open new ways for devising diagnostic approaches and therapeutic strategies addressing this highly prevalent condition[92].

Patterns of alterations in the colonic mucosa, its mucus layers and gut microbiota composition tend to differ between CD and UC[84]. For example, it was shown that a global expression of mucin genes was reduced in CD patients[93], whereas it was elevated in patients with UC[94]. Conversely, UC was also found to be associated with decreased numbers of mucosal GCs[95,96], as well as signs of CM layer reduced thickness and disruption[95,97,98]. In addition, the secretory response of colonic GCs to microbial challenge in active UC seems to be impaired, with the number of sentinel GCs significantly reduced and protective mucin sulphation decreased[99,100]. Intestinal mucosa dysfunction in IBD was further confirmed by signs of transcriptomic dysregulation of some key genes involved in colonic barrier maintenance, especially those encoding transmembrane mucins MUC1, MUC4 and MUC22 [101]. Consequently, the inner mucus layer of UC patients could be easily penetrated by luminal bacteria[98]. The observed dysregulation of transmembrane mucin synthesis might also indicate possible alterations of colonocyte glycocalyx[101].

The extreme complexity of IBD pathogenesis is generally admitted[102], and this fascinating subject is beyond the scope of this review. Nevertheless, a few more points related to IBD need to be addressed here, especially given the clearly elevated probability of CRC development in IBD patients[103]. In particular, modern Western diet characterized by limited dietary fiber intake is now regarded as a major risk factor for both IBD and CRC[104-106]. Consequently, diet correction may constitute an effective approach to disease prevention. Experimental studies demonstrate that fiber addition to the diet and administration of probiotic microbiota, especially *Bifidobacterium* species, can restore CM layer functionality and provide anti-inflammatory effects[107,108]. Likewise, tea polyphenols and citrus flavonoids were shown to protect CM integrity[109,110]. These findings look promising, however further research is required for designing dietary interventions targeting CM and suitable for treating IBD patients and preventing CRC development in this risk group.

Another consequence of CM barrier deterioration in IBD patients is related to the phenomenon of massive inflammatory cell migration from the *Lamina propria* of colonic mucosa to the impaired CM layer. Neutrophil and eosinophil biomarkers are abundantly present in stool samples from IBD patients, and stool calprotectin quantification is widely used for diagnosing UC and CD[111,112]. However, the scale of inflammatory cell migration towards the gut lumen became evident only recently. We were able to demonstrate that numerous immune cells can be found in CM samples obtained from IBD patients either intrarectally[79,113], or using non-invasive collection from the anal area following defaecation[80, 114,115]. Cytological analysis of the collected CM revealed that neutrophils were the most abundant cell type, but macrophages, eosinophils (especially in UC patients), plasma cells and lymphocytes were frequently detected as well[114]. The collected cells were very well preserved and looked viable, as phagocytosis and erythrophagocytosis by neutrophils and macrophages could be seen[114]. It was also hypothesised that neutrophils and eosinophils migrating to the loosened CM of IBD patients can easily undergo extracellular DNA trap formation (ET-osis), cell death producing the formation of antibacterial "extracellular traps" composed of released DNA and globular proteins [also called ET-osis exerted by neutrophils (NET-osis)][116]. This hypothesis, also assuming that CM in IBD serves as a supporting milieu for immune responses expanding from the mucosa, is discussed in detail elsewhere[116]. Taken together, recent advances in CM research suggest that even partial loss of this protective barrier compromises its function at different levels, including impaired control of the relationship between gut microbiota and mucus, dysregulation of CM layer maintenance by the epithelium and immune cells of the *Lamina propria*, insufficient production of AMPs and defects in the process of autophagy[117,118]. Initial signs of intestinal barrier impairment may precede the onset of clinical IBD manifestations by years[119], this interval probably constituting a good window of opportunity for applying preventive interventions and early therapeutic measures.



CM CHANGES ASSOCIATED WITH COLORECTAL NEOPLASIA

Although inflammation-related changes involving CM can contribute to colorectal tumor development [120], sporadic CRC grows slowly, early stages of this neoplasia being confined exclusively to colorectal mucosa[3]. However, it is evident that, like in active IBD, CM from CRC patients is very rich in cells shed from tumor surface (Figure 2). It is well established that numerous CRC markers can be detected in stool samples obtained from CRC patients[121,122], and the presence of cancer cells on the stool surface is well documented[79-81,123-125]. CM overlaying tumor surface, which was initially defined as "mucocellular layer"[126], serves as a medium accepting and preserving all cells and biomolecules released by the neoplastic tissue. This diagnostically informative material could be obtained from CRC patients by intrarectal collection with an inflatable device designed for this purpose[79]. Human DNA measurements in the mucus collected from tumor surface and at equal distances proximally and distally from tumor margins (resected colon segments were examined) revealed significantly higher DNA levels in the samples collected distally, hence confirming distal movement of the CM[79]. The latter finding of our group resulted in devising a completely non-invasive technique for CM sampling by swabbing the anal area immediately following defaecation[80]. The new method has recently been successfully applied for non-invasive CRC detection[127,128]. These findings confirm that CM constitutes a uniquely informative biological material possessing an enormous diagnostic potential owing to abundant presence of various biomarkers, comprising a wide range of proteins and nucleic acids[116,127,128]. While the described diagnostic importance of CM for CRC detection becomes obvious, this biological substance also emerges among major pathogenetic factors contributing to colorectal carcinogenesis. The key mechanisms of CM involvement in this process are probably related to the loss of homeostatic balance between CM layers and gut microbiota, which exposes the mucosa to both commensal and pathogenic bacteria and triggers cascades of unfavorable host responses that may eventually lead to neoplastic growth[120,129-131]. CM depletion effect was graphically demonstrated experimentally, when mice genetically deficient in the MUC2 were shown to develop colorectal tumors[132,133]. Furthermore, colon tumor development was observed in mice with colon-specific loss of *Atonal homolog 1* gene, which determines normal differentiation of secretory cells, comprising GCs[134]. GC depletion during 1,2-dimethylhydrazine-induced colon carcinogenesis in rats was reported as well[135]. In human colorectal tumors, MUC2 expression was decreased, and the degree of expression inhibition correlated with the progression from adenomas to advanced carcinomas[136]. In terms of prognostic significance, reduced MUC2 expression in CRC patients corresponded to poorer prognosis[137,138]. However, different types of CRC display different mucin expression patterns, as several mucin-encoding genes are overexpressed in mucinous carcinomas[139-141]. Mucus synthesis in the colonic GCs involves MUC2 O-glycosylation, and this process was found to be impaired in genetically modified mice predisposed to colitis-associated carcinogenesis[142,143]. Likewise, aberrant O-glycosylation was observed in malignant tumors removed from CRC patients[144]. All these findings indicate that CRC-associated changes in colon mucin gene expression and protein synthesis may occur either because of intrinsic genetic and immune disturbances or due to interactions of the preneoplastic or neoplastic epithelium with the microbial populations of the gut, impact of which needs to be considered as well.

It is now recognized that colorectal tumor development strongly depends on compositional and ecological changes of the microbiota[145]. Recent metagenomic studies revealed differences between gut bacterial communities in CRC patients and healthy individuals, the latter category being characterized by a lower abundance of potentially protective taxa (*e.g.*, *Roseburia*) combined with an increased presence of pro-carcinogenic taxa, such as *Bacteroides*, *Escherichia*, *Fusobacterium*, and *Porphyromonas*[145-147]. However, the existing body of evidence on CRC-related gut microbiome alterations was generated mostly by molecular analyses of faecal material that may not reliably reflect changes in CM-dwelling bacteria. For this reason, this theme will not be further discussed here, and a comprehensive review by Wong and Yu[145] can be recommended to interested readers.

In contrast, recent reports suggesting that bacterial biofilms formed on the surface of the colonic epithelium may be implicated in carcinogenesis deserve close attention[90,148]. This association is especially intriguing since bacterial biofilms can be easily identified endoscopically[92], thus potentially presenting a very good early indicator of neoplastic transformation risk. Biofilms in the colon of CRC patients are typically confined to the CM overlaying tumor surface or margins and seem to replace the inner mucus layer[148-150], which is apparently damaged during tumor growth. There is no clarity regarding mechanisms of biofilm carcinogenicity, but it was suggested that certain individuals are predisposed to form these bacterial structures, which may be capable of driving neoplastic transformation[149,151]. Proximal CRC and, especially, mucinous carcinomas were strongly associated with the presence of bacterial biofilms, whereas they were observed relatively rarely in distal CRC cases [149,150,152]. This pattern suggests that biofilms tend to specifically contribute to the serrated pathway of colorectal carcinogenesis[153].

The analysis of biofilm bacterial composition in CRC patients has revealed that human gut commensal *Bacteroides fragilis* capable of generating enterotoxigenic strains[154], as well as oral pathogens *Fusobacterium nucleatum*, *Parvimonas micra* and *Peptostreptococcus stomatis* were the main species detected in these biofilms[150]. Further work of the same group demonstrated the presence of patchy bacterial biofilms dominated by enterotoxigenic *Bacteroides fragilis* and colibactin-expressing

Escherichia coli on the surface of the colonic mucosa of patients with familial adenomatous polyposis [155]. In these patients the biofilms were not confined to polyp surface, and no association with proximal tumor location could be observed[155]. Interestingly, co-colonisation of tumor-prone mice with the bacterial strains of these biofilms caused DNA damage in the colonic epithelium of the animals and accelerated carcinogenesis[155]. These findings were later confirmed in three murine models, where bacterial biofilm homogenates obtained from either CRC patients or healthy individuals manifestly promoted colon carcinogenesis[156]. Notably, *Fusobacterium nucleatum* did not seem to be required for carcinogenesis in these experiments, which might indicate that it is possibly involved at later stages of CRC development[156]. Overall, these results strongly suggest that polymicrobial biofilms may now be regarded as a colon carcinogen.

The reviewed advances in defining CM role in CRC development highlight a previously obscure area of pathogenetically important interplay between multiple elements. These elements include CM, gut microbiota (both mucus-dwelling and luminal), colonic epithelial cells (normal, malignant and especially mucus-producing GCs) and immune cells (both belonging to the tumor microenvironment or adjacent *Lamina propria* and actively migrating to CM through the epithelium). Figure 2 schematically depicts some of these interactions. Progressive CM deterioration results in its loosening that initially exposes colonic epithelium to occasional contacts with gut commensals and can later lead to possible pathogen invasion to the mucosa. CM deficiency probably triggers: (1) Epithelial homeostasis dysregulation accompanied by the loss of control over cell renewal process; and (2) Cascades of inflammatory responses exerted by both immune cells of the tumor microenvironment and adjacent *Lamina propria* and free immune cells migrating through colonic epithelium to the loosened CM. Although these events may potentially be reversible, one needs to be aware of less favorable scenarios, such as the development of IBS, IBD and colorectal tumors. The reported formation of bacterial biofilms in healthy individuals and patients with IBD, polyps and CRC illustrates this range of scenarios[92,149,155]. However, biofilm formation may depend on the genetic background of the host[153], and appears to be just one of at least a few possible pathways eventually leading to CRC.

Of course, there is no chance to properly discuss here multiple molecular pathways of CRC development[120], or complex impacts of immune responses affecting this process[157]. Nevertheless, a few more points directly related to the CM deserve to be addressed at the end. One of them concerns the process of antibacterial extracellular DNA trap formation or ET-osis by effector immune cells (termed NET-osis when exerted by neutrophils) that massively migrate to the loosened CM in both IBD and

CRC[116]. It is apparent that this process basically constitutes an element of a protective inflammatory response aiming to eliminate bacteria contacting colonic epithelium, but arriving neutrophils and eosinophils inevitably undergo degranulation and ET-osis, thus releasing cytotoxic factors (Figure 2) that damage host cells and probably induce poorly regulated compensatory proliferation of normal or malignant epithelial cells, which can stimulate neoplastic growth. The role of the ET-osis in CRC is being discussed but remains largely obscure and needs further exploration[116,158]. The other important point is related to possible ways of preserving CM integrity and avoiding its deterioration in view of CRC prevention. This goal can be achieved by establishing proper communication between the host and gut microbiota *via* balanced dietary patterns preventing dysbiosis development[131]. Indeed, diet is a major determinant of CRC risk, with red meat consumption increasing the risk and fiber uptake being protective[159]. Interestingly, both effects can be mediated by the CM. SCFAs (especially butyrate) produced by luminal microbiota during dietary fiber fermentation stimulates MUC2 expression in the colon and promotes proliferation of normal colonocytes[160], whereas cancer cell proliferation tends to be inhibited by butyrate because of the low differentiation of these cells[161]. There is no doubt that fiber-rich diets and SCFAs are beneficial for CM preservation and CRC prevention, but additional investigations are indispensable for designing effective dietary intervention schemes. On the other hand, it was shown that CM damage inflicted by sulphide-producing and mucin-degrading bacteria can faciliate epithelial hyperproliferation in the colon induced by heme-rich diet modelling high red meat consumption[162]. In that experimental model antibiotic treatment allowed normalizing gut microbiota composition, reinforcing the mucus barrier and eliminating the abnormal proliferation[162]. These examples demonstrate that both dietary corrections and drug therapy can be considered for CM protection and restoration with the purpose of preventing CRC.

The on-going progress in exploring the role of the CM in the pathogenesis of major colorectal diseases, especially CRC, is impressive, however many important points remain obscure. Therefore, thoroughly designed further studies are needed for elucidating fine mechanisms governing structural and functional CM changes in disease. It can be expected that numerous innovative practical applications addressing colorectal disease diagnosis, prevention and treatment will be developed once this challenging goal is achieved.

CONCLUSION

The presented analysis of the existing information regarding mammalian and human CM shows that this area was actively explored only since the beginning of the 21st century. Considerable progress has been made in basic research of CM structure and function, especially in experimental models. It is now evident that in the normal mammalian colon the CM is formed by two distinct layers composed of gel-forming glycosylated mucins that are permanently secreted by goblet cells of the colonic epithelium. The inner layer is dense and impenetrable for bacteria, whereas the loose outer layer provides a habitat for abundant commensal microbiota. Mucus barrier integrity is essential for preventing bacterial contact with the mucosal epithelium and maintaining homeostasis within the GI tract, but it can be impaired by a variety of factors, including CM-damaging switch of commensal bacteria to mucin glycan consumption due to dietary fiber deficiency. It is already proven that impairments in CM structure and function can lead to colonic barrier deterioration that opens direct bacterial access to the epithelium. Bacteria-induced damage dysregulates epithelial proliferation and causes inflammatory responses that may expand to the loosened CM and eventually result in severe disorders, including colitis and colorectal neoplasia. Recently described formation of bacterial biofilms within the inner CM layer was shown to be associated with both inflammation and cancer. Although obvious gaps in our knowledge of human CM remain, its importance for the pathogenesis of major colorectal diseases, comprising IBD and CRC, is generally recognized. Continuing progress in the field of CM exploration promises considerable future achievements and is likely to result in the development of a range of new useful clinical applications addressing colorectal disease diagnosis, prevention and therapy.

Abstract

Celiac disease (CeD) is a chronic gluten-induced enteropathy with plethoric manifestations. The typical manifestations of CeD such as chronic diarrhea and malabsorption are widely recognized, however, many patients have atypical manifestations like iron deficiency anemia, idiopathic short stature, hypertransaminesemia or infertility, *etc.* These patients often present to the primary care physicians and/or non-gastrointestinal specialties. However, due to a lack of awareness among the healthcare professionals about the various atypical manifestations, many patients are not screened for CeD. In this review, we have summarized the available literature about the prevalence of CeD in various gastrointestinal (chronic diarrhea) and non-gastrointestinal conditions (iron deficiency anemia, short stature, cryptogenic hypertransaminesemia, cryptogenic cirrhosis or idiopathic ataxia *etc.*) where the diagnosis of CeD should be considered. In addition, we also discuss special scenarios where screening for CeD should be considered even in absence of symptoms such as patients with type 1 diabetes, Down's syndrome, and first-degree relatives of patients with CeD. Further, we discuss the diagnostic performance and limitations of various screening tests for CeD such as IgA anti-tissue transglutaminase antibodies, anti-endomysial antibodies and anti-deamidated gliadin antibodies. Based on the current recommendations, we propose a diagnostic algorithm for patients with suspected CeD.

Key Words: Screening; Diagnosis; Serology; High-risk group; Small intestine; Enteropathy

Core Tip: In this review article, we have summarized the available literature about the prevalence of celiac disease (CeD) in various gastrointestinal (chronic diarrhea) and non-gastrointestinal conditions (such as iron deficiency anemia, short stature, cryptogenic hypertransaminesemia, cryptogenic cirrhosis or idiopathic ataxia *etc.*).We thereby share the various clinical indications for screening for CeD. Also, we elucidate the diagnostic performance of various serological assays along with their limitations and propose an algorithm to diagnose patients with suspected CeD.

INTRODUCTION

Celiac disease (CeD) is an immune-mediated enteropathy that affects approximately 0.7% of the world population[1]. The disease is related to a complex interplay between genetic, environmental and host immunity-related factors. It is triggered by ingestion of gluten, a protein present in cereals such as wheat, barley, and rye in genetically-predisposed individuals. The phenotypic expression of CeD is variable. It ranges from being clinically asymptomatic to severely symptomatic disease[2,3]. Also, CeD once thought to affect only small intestines, is now considered a multi-system disorder. While there are convincing clinical and epidemiological evidence of involvement of extra-small intestinal organs, the exact pathogenesis of their involvement remains unexplored. It is likely that the human leukocyte antigen (HLA)-DQ2 restricted gliadin peptide induced T-cells which originate in the small intestine, circulate in peripheral blood and home in other organs leading to organ specific cell injury[4,5].

The clinical manifestations of CeD may be related to the gastrointestinal tract, called "classical CeD" seen in 50%-60% of all cases or non-gastrointestinal symptoms called "non-classical CeD" accounting for 40%-50% of cases[6,7]. The non-classic symptoms like short stature anemia, dyspepsia, infertility or hypertransaminesemia could be the sole manifestations of CeD making the clinical diagnosis more elusive. Additionally, CeD can co-exist with type 1 diabetes or other autoimmune diseases and its clinical manifestations may remain submerged with the manifestations of primary disease or it may remain clinically silent[8,9].

Because of its diverse manifestations, patients with CeD may present to healthcare professionals other than gastroenterologists or pediatricians such as hematologists with anemia, endocrinologists for short stature or type 1 diabetes, or gynecologists with infertility. The lack of typical manifestations combined with unfamiliarity with the disease lowers the index of suspicion for CeD in such clinical settings. This results in the missed diagnosis of CeD and about 85%-90% of the patients with CeD remain undiagnosed[10-12]. A delay in the diagnosis and institution of appropriate treatment adds to significant morbidity and even mortality in these patients[13].

Over past two decades, certain group of patients with conditions like short stature, iron deficiency anemia, type 1 diabetes, first-degree relatives have been reported to have a much higher prevalence of CeD compared to the general population[2,14]. Assiduous screening in these conditions can improve the detection of CeD compared to population-based screening for CeD. However, while most gastrointestinal societies agree that there is not enough evidence to recommend screening for CeD in the general population, they offer varying recommendations about which at-risk groups should be routinely screened for CeD[15,16].

In the present review, we summarize the present literature regarding the prevalence of CeD in many conditions to facilitate identification of high-risk groups who could benefit from screening for CeD. We have sub-grouped the indications for screening as definitive (when the data to support the screening is robust), probable (when the data to support screening exists but heterogenous) and possible (when there is a biological plausibility, but the evidence is insufficient). Later, we also highlight about the screening strategy for CeD once a decision for screening has been made based on clinical indication.

REVIEW METHODOLOGY

Relevant studies were searched utilizing MEDLINE, EMBASE and Scopus databases. Also, additional studies were cross-referenced from the various articles. Studies were identified with the medical subject heading terms and keywords–"celiac disease", "celiac", "coeliac disease", "tissue transglutaminase antibody", "endomysial antibody", "anti-endomysium antibody". They were combined using the set operator AND with keywords for relevant medical condition/risk factor (type 1 diabetes mellitus, irritable bowel syndrome, first degree relatives *etc.*). Studies from all languages were reviewed for

appropriateness to the clinical question and potentially relevant papers were assessed in detail.

Terms, definitions and analysis

For the purpose of this manuscript, CeD is defined as: (1) Villous abnormalities of modified marsh grade 2 on duodenal biopsies along with positive celiac-specific serology [anti-tissue transglutaminase antibody (anti-tTG Ab), anti-endomysial antibody (AEA), anti-deamidated gliadin peptide or antigliadin antibody (anti-DGP Ab)]; and (2) presence of at least modified marsh 2 lesion on duodenal histology along with unequivocal clinical and/or histological response to a gluten free diet (GFD). Seroprevalence of CeD is defined as the prevalence of positive anti-tTG Ab and/or AEA and/or anti-DGP Ab. Pooled prevalence of CeD in the manuscript refers to pooled prevalence of biopsy-proven CeD.

DEFINITE INDICATIONS FOR SCREENING FOR CED

Patients with chronic diarrhea

The classical gastrointestinal symptoms of CeD include chronic or intermittent diarrhea, steatorrhea, abdominal bloating, flatulence, and weight loss[7]. A proportion of patients with CeD may have mild gastrointestinal manifestations such as bowel dysmotility, abdominal pain/discomfort, and bloating, and with this symptom complex, they are can be labelled as having functional gastrointestinal diseases including irritable bowel syndrome (IBS).

One of the classic manifestations of CeD, both in the children and adults, is chronic diarrhea which occurs secondary to diffuse enteropathy and malabsorption. Chronic diarrhea in children is often associated with failure to thrive, irritability and distension of the abdomen. Chronic diarrhea is a predominant manifestation in 43%-85% of patients with newly diagnosed CeD. Conversely, the prevalence of CeD in patients referred to secondary care with chronic diarrhea has been reported to range from 3% to 12.2%[17,18]. Given the high occurrence of CeD in patients with chronic diarrhea and the delay in diagnosis of CeD, several gastroenterology societies such as American Gastroenterological Association, and British Society of Gastroenterology has recommended screening for CeD as first line investigation in patients with chronic diarrhea[17,19]. Therefore, all patients presenting with chronic diarrhea should be screened for CeD.

Patients with iron deficiency anemia

Anemia affects approximately 12%-69% patients in the western countries and 85%-90% of Indian patients with CeD[20-25]. Iron deficiency anemia (IDA) could be an isolated manifestation of CeD even in the absence of GI symptoms. Iron deficiency is the commonest form of anemia in CeD[20,26,27].

In a review including 2998 patients from 18 studies, Mahadev *et al*[14] have reported prevalence of CeD in patients presenting with iron deficiency anemia. Of 2998 patients with IDA included in this meta-analysis, the estimated pooled prevalence of CeD was reported to be 3.2% (95%CI: 2.6-3.9). Thus, approximately 1 in 31 patients with IDA have CeD. The authors did not find any relationship between the age and gender of the participant and the prevalence of CeD in patients with IDA. However, the prevalence of CeD in them vary significantly with geographic region. The prevalence of CeD in iron deficiency anemia is significantly higher in Asian countries (4.1% in Turkey and 6.4% in Iran) compared to that in the European countries (2.4%). It is important to note that the prevalence of iron deficiency anemia could vary based on the geographical region and according to the socio economic strata of the society[28]. They also found that smaller studies were more likely to report higher prevalence of CeD compared to studies with larger sample size. However, even in larger studies (those including > 200 patients), the pooled prevalence of CeD in patients with IDA was still significantly higher (2.7%) than that in the general population. Thus, the prevalence of CeD in patients with IDA is at-least 2-3 times higher prevalence of CeD than in the general population. Considering the overall high prevalence, all patients with iron deficiency anemia should be screened for CeD.

Patients with short stature

The manifestations of CeD start in childhood and hence growth failure/restriction is an important manifestation of CeD. Short stature is more frequent in those diagnosed during childhood/adolescence than patients diagnosed in adulthood. Importantly, institution of GFD in these patients can result in early catch-up growth for the initial 2-3 years[2,29,30]. Early diagnosis and compliance with GFD in patients with CeD result in rapid recovery and patients may achieve normal adult height.

Several studies have estimated the prevalence of CeD in children with idiopathic short stature. We systematically reviewed and meta-analyzed 17 studies and 3759 patients (1582 with all-cause short stature and 2177 with idiopathic short stature), and found that the pooled seroprevalence of CeD based on positive anti-tTG Ab and AEA is 11.2% (95%CI: 4.0-21.2) and 9.7% (95%CI: 2.7-20.2) for all-cause and idiopathic short stature, respectively. Similarly, pooled prevalence of biopsy-confirmed CeD is 7.4% (95%CI: 4.7-10.6) and 11.6% (95%CI: 4.1-22.2), for all-cause and idiopathic short stature, respectively[31].

In summary, approximately 1 in 14 patients with all-cause short stature and 1 in 9 patients with idiopathic short stature has biopsy-confirmed CeD. Therefore, all patients with CeD should be screened for CeD.

Patients with type 1 diabetes

Because of sharing of genetic susceptibility, especially HLA, type 1 diabetes is often associated with CeD [3,6]. In a systematic review and meta-analysis by Elfström *et al*[32] of 27 studies including 26605 patients with type 1 diabetes, the pooled prevalence of CeD was 6% (95%CI: 5-6.9) of CeD. Thus, more than 1 in 18 patients with type 1 diabetes mellitus have biopsy-proven CeD. The prevalence of CeD in children patients with type 1 diabetes is much higher (6.2%, 95%CI: 6.1- 6.3) than those with adult patients with type 1 diabetes (2.7%, 95%CI: 2.1-2.3) ($P < 0.001$). There is no geographical variation and almost a similar prevalence of CeD is reported in type 1 diabetes from all over the world. Therefore, all patients with type 1 diabetes should be screened for CeD[32].

First-degree relatives of patients with CeD

Because of sharing of genetic susceptibility, first-degree relatives (FDRs) of patients with CeD are at a higher risk of developing CeD in comparison to the general population. The prevalence of CeD in FDRs of patients with CeD has been extensively investigated and it ranges widely in the literature from 1.6% to 38%[33-35]. Singh *et al*[36] in a systematic review and meta-analysis including 41 studies, has reported 708 CeD patients amongst 10252 FDRs suggesting a pooled prevalence of CeD of 7.5% (95%CI: 6.3-8.8) in them. Among the FDRs, the risk of having CeD is highest amongst siblings, followed by offspring and the least in the parents. Daughters and sisters of the CeD patients are at the highest risk (1 in 7 and 1 in 8, respectively) of developing CeD. The risk of developing CeD is 1 in 13 in sons, 1 in 16 in brothers, 1 in 32 in mothers and 1 in 33 in fathers[36]. Majority of studies reporting prevalence of CeD in FDRs have been cross-sectional and there is a lack of longitudinal studies for assessment of risk of developing CeD over time or over lifetime. It is still unclear if there is role for repeat screening every few years after an initial negative screening or repeat screening should be reserved for FDRs who develop symptoms. Based on the abovementioned high-quality data, all FDRs of index patients with CeD should be screened for CeD.

The data on the prevalence of CeD in second-degree relatives (SDRs) of patients with CeD is sparse [37,38]. In a meta-analysis of two eligible studies including 641 SDRs, Weinstein *et al*[39] observed a pooled prevalence of CeD in SDRs to be 2.3% (95%CI: 1.3-3.8). The current literature on this topic has several limitations including availability of few studies, small sample size, and high risk of bias. Given these limitations, the magnitude of risk of CeD in SDRs is not clear. Therefore, in view of insufficient data, screening of SDRs of patients with CeD for CeD is not justifiable at the present time.

Patients with dermatitis herpetiformis

Dermatitis herpetiformis is among the most common manifestations of CeD and could be the first extra-intestinal manifestations to be clinically recognized. It presents as a cluster of intensely pruritic papules and/or vesicles, followed by erosions and excoriations. The most common sites are elbows, knees, scalp, and buttocks, typically along the extensor surface of the upper and lower extremities.

The extent of skin lesions may vary from small area to more diffuse involving many sites at one time [40,41]. Furthermore, these lesions may appear intermittently and may be absent at the time of examination.

The pathognomonic histology with immunohistochemistry or immunofluorescence shows granular IgA deposits and neutrophil infiltrates in the papillary dermis. Almost 85% of these patients with a Caucasian ethnicity carry HLA-DQ2 mutations while the remaining have HLA-DQ8[42]. Typically, only two-third patients with DH have villous abnormalities and one third of them have no enteropathy[43]. A survey of 1138 biopsy-confirmed patients with CeD, found a 9.8% prevalence of DH in patients with CeD[44].

A study from Finland have also shown that 17% of patients with CeD have DH[45]. Therefore, all patients with a diagnosis of DH should be screened for CeD, even in the absence of intestinal manifestations.

Patients with Down's syndrome

The prevalence of CeD in patients with Down's syndrome has been extensively investigated. Based on data from 31 studies including 4383 patients with Down syndrome, a recent meta-analysis reported a pooled prevalence of CeD in them to be 5.8% (95%CI: 4.7-7.2)[46]. Prevalence of CeD was higher in the studies including only children with Down syndrome than in those including both adults and children with Down's syndrome. The higher prevalence of CeD in Down syndrome is independent of the geographical location as studies from Europe, America and Asia have all shown higher prevalence of CeD among patients with Down syndrome. Based on this high-quality evidence, all patients with Down syndrome should be screened for CeD.

PROBABLE INDICATIONS FOR SCREENING FOR CED

Patients with liver diseases

Patients with CeD can have a variety of liver related manifestations that ranges from elevation of serum transaminases to cirrhosis. Elevated transaminases can be seen in 27% (95%CI: 13-44) of newly diagnosed patients with CeD and they normalize in 63% to 90% of patients within 1 year of GFD[47].

Cryptogenic hypertransaminesemia

Sainsbury *et al*[47] in a systematic review including six studies has reported a pooled prevalence of biopsy-proven CeD of 3.6% amongst patients with cryptogenic hypertransaminesemia. In a study of 463 adults with CeD[48], 40.6% patients had elevated AST/ALT levels at the time of diagnosis compared to 24.2% CeD patients after initiation of GFD. The quality of evidence has been considered high due to very large effect size without any significant imprecision. Given the high prevalence of CeD in patients with cryptogenic hypertransaminesemia, and a potential for reversal of serum transaminases level with GFD, it is justifiable to screen patients with cryptogenic hypertransaminesemia for CeD.

Cryptogenic cirrhosis

Undetected CeD can lead to persistent liver injury progressing from elevated liver biochemistries to cirrhosis of the liver[49-53]. In one of the earlyreports, Kaukinen *et al*[52] found a reversal in the hepatic dysfunction after initiation of GFD in four patients awaiting liver transplantation and eventually three of them were remitted from liver transplantation list. In a recent prospective study by Wakim-Fleming *et al*[54], of 204 consecutive biopsy proven patients with liver cirrhosis, CeD was reported in 2.5% of the patients. There was improvement in liver function tests with initiation of GFD in these patients.

However, these studies had serious limitations including small sample size (all subjects with less than 100 subjects), selection bias, imprecision and inconsistent results. Given these limitations, the quality of evidence is poor to suggest a true estimate of prevalence of CeD in cryptogenic cirrhosis. In view of the data of improvement in liver functions with GFD, it may be worthwhile to screen the patients with cryptogenic cirrhosis for CeD.

Patients with auto-immune hepatitis

Recently, in a systematic review of eight eligible studies, the prevalence of biopsy-proven CeD was 3.5% (95%CI: 1.6-5.3) amongst 567 individuals with autoimmune hepatitis, which is clearly higher than that in the general populations[55]. However, these studies had serious limitations including small sample size, selection bias, imprecision and inconsistent results. Despite these limitations, we suggest screening for CeD in all patients with autoimmune hepatitis because of the relatively higher pooled prevalence of CeD in these subjects compared to the general population.

Patients with irritable bowel syndrome

Patients with CeD may have minor gastrointestinal infection including diarrhea, abdominal pain, bloating sensation without any definitive manifestations for malabsorption. Such patients are often diagnosed as irritable bowel syndrome in general clinical practice, unless screened for CeD. In a study by Irvine *et al*[56] including 22 studies with 6991 patients with IBS, the reported pooled prevalence of CeD was 3.3% (95%CI: 2.3-4.5) in them.

The pooled prevalence of CeD in patients with IBS varies significantly with the IBS subtype and their geographical location. The prevalence of CeD is higher in patients with diarrhea-predominant IBS (pooled prevalence 5.4%, 95%CI: 3.3-7.8) compared to those with constipation-predominant IBS [1.8% (95%CI: 0.9-3.0)] and mixed form of IBS [3.1% (95%CI: 1.7-5.1)].

Interestingly in the above meta-analysis, all but one study was from secondary or tertiary care referral centers. Furthermore, 20 of the 22 studies were from Europe and Asia with pooled prevalence of CeD in patients with IBS in them was 3.9% (95%CI: 2.1-6.3) and 3.7% (95%CI: 2.2-5.6), respectively. The only study from North America, which also evaluated celiac serology positive individuals with IBS further with duodenal biopsies, did not find an increased prevalence of CeD in patients with IBS. A recent study from Iraq found a prevalence of 5% among 100 patients with IBS[57].

Thus, the utility to screening for CeD in individuals with IBS in primary care settings or the general population remains unclear. Based on available evidence, it may be justifiable to screen patients with diarrhea predominant-IBS and mixed IBS presenting to secondary or tertiary care centers for CeD in Europe and Asia.

Patients with osteoporosis

Patients with CeD are at an increased risk for developing varying degrees of osteopenia and osteoporosis. Patients with untreated CeD have low bone mineral density agnostic to the clinical presentation[58,59]. The reported pooled prevalence of osteoporosis and osteopenia is 14.4% (95%CI: 9-20.5) and 39.6% (95%CI: 31.1-48.8), respectively in 563 pre-menopausal women and men with CeD[60]. Along with osteoporosis, patients with CeD are also at a higher risk of developing bone fractures. A comparative meta-analysis of 20995 patients with CeD and 97777 controls from eight studies published

between 2000 and 2007, found that patients with CeD have a 43% higher risk for developing non-traumatic fracture compared with controls[61]. Also a recent study found that patients with newly diagnosed CeD have low bone marrow density and this improves after initiation of GFD[62].

Laszkowska *et al*[63] performed a systematic review and meta-analysis to estimate the prevalence of CeD in patients with osteoporosis. They pooled data on 3188 patients with osteoporosis from eight studies and reported a weighted pooled prevalence of CeD to be 1.6% (95%CI: 1.1-2.0). The authors observed a positive correlation between underlying prevalence of CeD in the general population and the prevalence of CeD in osteoporosis suggesting the prevalence of CeD in patients with osteoporosis is higher in the areas with higher prevalence of CeD in the general population. Therefore, the prevalence of CeD does not appear to be significantly higher in patients presenting with osteoporosis than that in the general population. Given these findings, while all individuals with new diagnosis of osteoporosis may not need screening for CeD, however patients with osteoporosis having additional symptoms of CeD such as iron deficiency anemia, chronic diarrhea should be screened for CeD.

POSSIBLE CONDITIONS FOR SCREENING FOR CED

Patients with dyspepsia

In a systematic review and meta-analysis, we pooled the data from 19 studies involving 9711 patients with dyspepsia in whom initial screening for CeD was performed either by using celiac serological test (anti-tTG ab or AEA) followed by duodenal mucosal biopsy in seropositive patients or the duodenal mucosal biopsy alone in all eligible patients[64]. The pooled prevalence of CeD has been found to be 1.4% (95%CI: 0.9-1.8) in patients with dyspepsia. Another meta-analysis including ten studies also reported the prevalence of CeD to be 1% in patients with dyspepsia[65]. As the prevalence of CeD in patients with dyspepsia is almost like that in the general population, patients with dyspepsia may not be a higher risk of having CeD. It is, however, still unclear if patients with refractory dyspeptic symptoms are at higher risk of having CeD.

Women with infertility

The patients with CeD can delayed menarche, early menopause, recurrent abortions, infertility, intrauterine growth retardation, and low birth weight (preterm and small for gestational age babies)[66,67]. Additionally, reports have suggested that women with infertility have conceived after initiation of GFD with a diagnosis of CeD[68,69]. Furthermore, there are multiple studies reporting the prevalence of CeD in women with infertility in women who had been investigated for the causes of infertility earlier (unexplained or idiopathic infertility) and those women with infertility who were never investigated for infertility (all cause infertility).

Women with unexplained or idiopathic infertility

Based on case-control studies, two previous meta-analyses have reported that women with unexplained infertility have 5-6 times increased odds of having CeD compared to the general population[70,71]. However, a recent meta-analysis did not find an increased prevalence of CeD in women with unexplained infertility[72]. They reported a pooled prevalence of 0.6% for biopsy-proven CeD in women with unexplained infertility which is very close to the prevalence of CeD in the general population. Of note, a common limitation of all three meta-analyses is the small sample size of primary studies. Based on the current evidence, it is not clear if all women with unexplained infertility should be screened for CeD or not and more research is needed in this area.

Women with "all-cause infertility"

In a systematic review and meta-analysis, Glimberg *et al*[72] pooled the data from 11 eligible studies including 1617 women with "all-cause" infertility and found a prevalence of 0.7% (95%CI: 0.2-1.2) for biopsy-proven CeD. Based on abovementioned data, screening women with all-cause infertility for CeD, may not be justified. However, as above, more studies are needed to further explore the prevalence of CeD in women with infertility.

Patients with idiopathic cardiomyopathy

There are only a few studies which have systematically explored the prevalence of CeD in patients with idiopathic cardiomyopathy[73-77]. The prevalence of CeD in these studies have ranged from 0% to 5.7%. Most of these studies have limitations including a high risk of bias, small sample size and heterogenous patient population included in these studies. Given these serious limitations in the quality of evidence, the present level of evidence does not support screening of patients with idiopathic cardiomyopathy for CeD. Future studies with better study design, larger sample size and various geographic regions should be undertaken for estimation of risk of CeD in patients with cardiomyopathy.

Patients with autoimmune thyroid diseases

In a recent systematic review and meta-analysis, Roy *et al*[78] estimated the pooled prevalence of CeD to be 1.6% (1.3%-1.9%) among 6024 patients with autoimmune thyroid diseases from 15 studies. The review has included even those studies where patients having villous abnormalities of modified marsh grade 1 and 2 have been included as CeD. When the analysis was restricted to those with villous abnormalities of modified Marsh 3, a pooled prevalence of CeD declined to 1.4% (95%CI: 1-1.8) in them. The prevalence of CeD is lower in patients with hypothyroidism (1.4%, 95%CI: 1-1.9) than patietns with hyperthyroidism (2.6%, 95%CI: 0.7-4.4). The available data do not support that routine screening for CeD will likely not be of benefit for majority of patients with autoimmune thyroid diseases. However, larger studies with rigorous methodology are needed in this area.

Patients with idiopathic epilepsy

Several studies have evaluated the prevalence of CeD in patients with idiopathic epilepsy[79-81]. In a systematic review, a pooled prevalence of CeD in patients with idiopathic epilepsy is 2.1% (95%CI: 1.6-2.6, n = 3389) has been reported[80]. The quality of the studies included in this review have major limitations including high overall risk of bias (which decreases our confidence in the estimate), inconsistency (several studies showing no increased risk while others showing increased risk), and imprecision. Based on the presently available data, screening of patient with idiopathic epilepsy for CeD cannot be recommended. There is a need for multicentric studies including larger sample size for better estimation of risk of CeD in patients with idiopathic epilepsy.

Patients with idiopathic cerebellar ataxia

The neurological manifestations of CeD and gluten-related disorders are broad, conditions like ataxia and peripheral neuropathy are well recognized, others such as migraine, epilepsy, dementia, cognitive impairment and depression have also been reported[82-85]. Patients with idiopathic sporadic ataxia and a positive anti-gliadin antibodies AGA) (either IgG or IgA or both) with or without presence of enteropathy are diagnosed as gluten ataxia[83].

Gluten ataxia commonly presents as a sporadic ataxia and most patients do not have associated enteropathy. A systematic review and meta-analysis have found higher odds of anti-gliadin antibodies positive in patients with idiopathic cerebellar ataxia (OR 4.2, 95%CI: 3.1-5.9) as compared to controls [86]. The odds of a positive AGA have not been found to be higher in patients with hereditary ataxia (OR 1.41, 95%CI: 0.82-2.44). Most of the studies included in the review are cross-sectional, and the results show significant imprecision or inconsistency. Considering that treatment response in gluten ataxia would depend on the duration of the ataxia and that GFD may positively impact the ataxia, patients with idiopathic or undiagnosed ataxia should be screened for gluten ataxia using IgG and IgA anti-gliadin antibody[87,88].

A very few studies have evaluated presence of CeD in patients in patients presenting with ataxia. In a study by Hadjivassiliou *et al*[89], reported that 24% patients with gluten sensitivity ataxia had CeD. While Pellecchia *et al*[90] found all 3 patients with a positive IgG anti-gliadin Ab to behave CeD. Bushara *et al*[91] biopsied seven of the nine patients with gluten sensitivity ataxia and none were diagnosed to have CeD. Small number of patients, high risk of bias and heterogenous results of these studies limit drawing of a robust conclusion. Therefore, based on the available data, no definitive recommendation can be made to screen patients with sporadic and idiopathic ataxia for CeD.

Patients with dental enamel defects

Only 2 studies have examined the occurrence of CeD in patients with dental enamel defects[92,93] and in them the prevalence of CeD ranged between 7.7%-17.8%. In one of these studies, one year of GFD resulted in significantly higher reversal of enamel changes in CeD patients compared to those without CeD (48% *vs* 3.4% patients, $P < 0.001$), suggestive of a causal association[92] Despite the relatively higher prevalence estimate of CeD seen in these studies, there is likelihood of some publication bias and these studies had very small sample size.

In two recent case-control studies, patients with CeD had higher dental enamel defects and other oral manifestations like aphthous ulcers were much higher compared to controls[94,95]. For these reasons, large-scale community-based studies across different socio-cultural and geographical populations need to be undertaken to ensure accounting for confounding factors that influence oral health as well as generalizability of the results. Until such time, screening of adults or children with dental enamel defects for CeD is not clear.

We have summarized the reported prevalence of CeD in the various clinical conditions based on the organ systems in Figure 1 and based on the indication in Table 1.

HOW TO SCREEN FOR CED?

While there is significant heterogeneity among clinicians in selecting the medical conditions where they

screen patients for CeD; there also exists significant variation in selecting the screening tool for CeD. Currently, celiac specific serological tests are the first-line investigations for screening for CeD. Duodenal biopsies showing villous atrophy, crypt hyperplasia and increase in intra-epithelial lymphocytes on a gluten-containing diet continues to be 'gold standard' for patients with CeD. Given the invasive nature of upper GI endoscopy, limited availability in resource limited countries and associated cost, this 'gold-standard' can however not be applied to all patients who need to be screened for CeD.

The specific celiac serological tests include IgA anti-tTG Ab, IgA AEA, and IgG anti-DGP Ab. While IgA/IgG AGA had been used screening for CeD in the past, however, given their poor specificity and

Figure 1 Summary of the prevalence of celiac disease in various associated conditions based on the various systems. The reported prevalence per the present literature, the studies may be limited by the number and quality of studies available.

sensitivity they are no longer recommended to be used for screening for CeD. In the section below, we briefly discuss the utility of three commonly used celiac-specific serological tests for screening for CeD.

IgA anti-tTG Ab

Given its widespread availability, ease of performance and lower costs compared to other celiac specific serological tests, IgA anti-tTG Ab is the most used serological test for screening for CeD. Recent systematic review has shown that pooled sensitivity and specificity of anti-tTG Ab for CeD are 92.8% (95%CI: 90.3-94.8) and 97.9% (95%CI: 96.4-98.8), respectively. IgA anti-tTG Ab testing should be combined with total serum IgA levels to rule out IgA deficiency which is 10-15 times more common in patients with CeD compared to general population[96]. In patients with IgA deficiency, duodenal biopsies or further serologic testing such as IgG- based anti-deamidated gliadin peptide antibodies (anti-DGP Ab) should be pursued.

Despite their widespread use and high sensitivity, these anti-tTG Ab assays have high inter-assay variability in their diagnostic performance[97,98]. Although anti-tTG Ab assays are the first-line investigation to screen for CeD, healthcare providers should realize that false-negative rate of a single IgA anti-tTG Ab assay can be over 20% suggesting a single negative IgA anti-tTG Ab assay cannot be relied upon as a sole test to rule out CeD especially if clinical suspicion for CeD is high[97]. In these cases, a negative IgA anti-tTG Ab assay must be followed with duodenal biopsies.

Moreover, the issue of diagnostic performance of these assays is further complicated by the fact that there is significant intra-assay variation in the performance of IgA anti-tTG Ab assays in racially and geographically distinct population[98]. Majority of the studies of diagnostic performance of IgA anti-tTG Ab assays (including the manufacturer provided validation studies) are performed in Caucasian studies and unfortunately, these results cannot be extrapolated to other ethnic populations. However, sensitivity of these assays can be improved without significantly compromising the specificity if receiver operator curve-based cut-offs can be developed for each population. Thus, multi-institutional collaborative workshops at national and international levels using coded and blinded standardized sera from well-defined patients with CeD (with varying levels of titers) and healthy controls are necessary to identify and validate population-specific cut-off values as well as the best performing IgA anti-tTG Ab assays for each population. Till then, diagnostic performance of commonly available anti-tTG Ab assays should be studied at each center performing anti-tTG Ab testing.

Finally, recent guidelines now allow for a diagnosis of CeD to be established without duodenal biopsy in a subset of patients with CeD; on the basis of high levels of anti-tTG Ab [× 10 fold upper limit of normal (ULN)] and positive AEA in a second sample[99]. However, these guidelines are often not interpreted correctly and many healthcare providers interpret low level titers as diagnostic of CeD. Even with anti-tTG Ab titers as high as 10-fold ULN, a confirmatory AEA testing on a second sample might not be obtained given either due to inappropriate interpretation of the guidelines or the lack of availability of AEA testing. This can lead to 'overdiagnosis' of CeD as anti-tTG Ab at low titers have poor positive predictive value for CeD. Therefore, there is urgent need for widespread dissemination of diagnostic algorithms and guidelines among primary care physicians, gastroenterologists, and non-

Table 2 The sensitivity and specificity of the screening tests for celiac disease

Test	Sensitivity	Specificity
Anti-tissue transglutaminase antibody[97]	92.8% (95%CI: 90.3-94.8)	97.9% (95%CI: 96.4- 98.8)
Anti-endomysial antibody[97]	73% (95%CI: 61-83)	99.0% (95%CI 98.0-99.0)
Deamidated gliadin peptide antibodies[97]	87.8% (95%CI: 85.6-89.9)	94.1% (95%CI: 92.5-95.5)
Point-of care tests (107)		
Anti-anti-tissue transglutaminase antibody + Anti-gliadin antibody	94.0% (95%CI: 89.9-96.5)	94.4% (95%CI: 90.9-96.5)
IgA anti-tissue transglutaminase antibody	90.5% (95%CI: 82.3-95.1)	94.8% (95%CI: 92.5-96.4)

gastroenterology specialists.

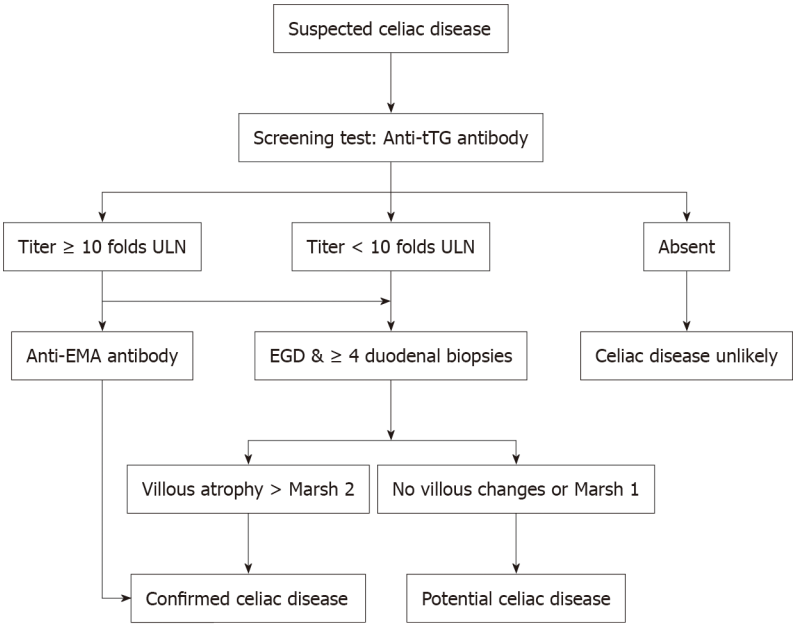
AEA

AEA is an indirect immunofluorescence-based testing requiring rhesus monkey esophagus or human umbilical cord as substrates. Therefore, it can only be performed in specialized laboratories and is much more labor intensive compared to ELISA based assays. Moreover, the results are based on subjective interpretation of the results. Based on a recent systematic review, the pooled sensitivity and specificity of AEA for the diagnosis of AEA were 73.0% (95%CI: 61.0-83.0) and 99.0% (95%CI: 98.0-99.0), respectively[96]. Given the limitations of the testing described above, AEA is not an ideal screening test for CeD outside of referral centers. Although a positive AEA testing is very highly suggestive of CeD (given specificity approaching 100%), a negative AEA should not be relied upon to rule out CeD.

IgG anti-DGP Ab

IgG anti-DGP Ab are the latest serologic assays for CeD and have been shown to have pooled sensitivity of 87.8% (95%CI: 85.6-89.9) and pooled specificity of 94.1% (95%CI: 92.5-95.5)[96]. Although pooled sensitivity of IgG anti-DGP Ab assays is high, it is still lower than pooled sensitivity of IgA anti-tTG Ab assay. Furthermore, several studies have shown that isolated IgG anti-DGP Ab in patients with normal serum IgA levels do not increase the yield of the diagnosis of CeD. Therefore, currently IgG anti-DGP Ab cannot be used to replace IgA anti-tTG Ab as the first line strategy to screen for CeD. Its role in CeD diagnosis is as a complementary assay to be used in patients with IgA deficiency (where IgA anti-tTG Ab assays cannot be relied upon).

Point of care tests



Recently, point of care tests (POCTs) for CeD are commercially available in Europe. Studies have reported significant variability in their sensitivity (70% to 100%) and specificity (85% to 100%). The pooled sensitivity and specificity of all POCTs (based on anti-tTG Ab or anti-DGP Ab or anti-tTG Ab + Anti-gliadin antibodies) for diagnosing CeD has been reported to be 94.0% (95%CI: 89.9-96.5) and 94.4% (95%CI: 90.9-96.5), respectively[100]. The pooled positive and negative likelihood ratios for POCTs are 16.7 and 0.06, respectively. The pooled sensitivity and specificity for IgA anti-tTGAb based POCTs are 90.5% (95%CI: 82.3-95.1) and 94.8% (95%CI: 92.5-96.4), respectively. However, this pooled sensitivity appears to be lower compared to standard ELISA based IgA anti-tTG Ab assay. Therefore, wherever available anti-tTG Ab should be used as first line screening test. However, POCTs can be an excellent alternative in areas with limited access to laboratory-based testing. All the above tests are summarized in Table 2.

Further testing

Once the screening test is positive in an individual suspected to have CeD, the health-care professional should follow the suggested guidelines by many Gastroenterology professional Societies for further evaluation[15,19]. We have suggested a testing schematic for the various indications for suspected CeD in Figure 2.

CONCLUSION

There is good evidence to suggest screening of patients with chronic diarrhea, iron deficiency anemia, short stature, dermatitis herpetiformis, type 1 diabetes, Down's syndrome, as well as first-degree relatives of CeD. The possible indications for screening of CeD include cryptogenic elevated transaminases, cryptogenic cirrhosis autoimmune hepatitis, IBS, autoimmune thyroid disease, and osteoporosis/osteoporosis. There is need for systematic studies for many conditions such as rheumatological diseases, psoriasis, cardiomyopathy, neurological diseases, and liver diseases for the prevalence

of CeD in them. Screening for CeD is a well standardized, simple, and relatively inexpensive process and it provides an opportunity for early detection of CeD in them.

ACKNOWLEDGEMENTS

We acknowledge the support of Department of Biotechnology, Government of India, for creation of Indian Consortium on Celiac Disease and National Celiac Disease Biorepository. We do appreciate the support from Research Section of our institution for facilitating the research on Celiac disease.

Abstract

The advantage of endoscopic submucosal dissection (ESD) is that it is less invasive than surgery. ESD is one of the best treatments for older patients as surgery in this age group of patients is difficult. However, it is unclear how much lower the physical stress of ESD is compared with that of surgery. Thus, objective methods are required to assess physical stress in patients who have undergone ESD. The current review of ESD aimed to summarize the recent advancements in the assessment of physical stress during the perioperative period, focusing on changes in energy metabolism and serum opsonic activity (SOA). Based on metabolic changes, resting energy expenditure (REE) was measured using an indirect calorimeter. The stress factor calculated from the REE and the basal energy expenditure computed using the Harris-Benedict equation can be used to assess physical stress. SOA was assessed using the chemiluminescence method, wherein the use of chemiluminescent probes (*i.e.*, lucigenin and luminol) allowed quantification of reactive oxygen species generated by neutrophils. Using an auto luminescence analyzer, the results were evaluated based on the maximum light emission and area under the emission curve. These quantifiable results revealed the minimal invasiveness of ESD.

Key Words: Physical stress; Endoscopic submucosal dissection; Indirect calorimeter; Resting energy expenditure; Chemiluminescence; Serum opsonic activity

Core Tip: Concerning the degree of physical invasiveness of patients before and after endoscopic submucosal dissection (ESD), assessment methods based on changes in energy metabolism using an indirect calorimeter and serum opsonic activity (SOA) measured by lucigenin- and luminol-dependent chemiluminescence are useful and easy to measure. During the perioperative period of ESD, the increase in resting energy expenditure and stress factor were lower than those reported for surgery, and SOA changes involved a minor increase in the production of lower-toxicity reactive oxygen species. These assessment methods demonstrated that the physical stress of ESD is less invasive than that of surgery.

INTRODUCTION

Endoscopic treatment for early-stage cancer is indicated when there is a very low probability of lymph node metastasis and when curative en bloc resection is possible[1-3]. Endoscopic submucosal dissection (ESD) is widely used for early gastrointestinal cancer because it is a safe and effective treatment that can preserve function[4-7]. In addition, ESD has a higher rate of en bloc curative resection than endoscopic mucosal resection[8]. Therefore, ESD enables a more precise histopathological diagnosis. ESD is also performed on early gastrointestinal cancer lesions, where surgery was previously common, and often results in a curative resection[9,10]. The most significant advantage for patients is that the physical stress associated with ESD is less than that associated with surgery. From the above, ESD is one of the best treatment options for older patients who are considered difficult to operate on[11-14]. However, it is unclear how much lower the physical stress of ESD is than that of surgery; thus, objective methods are required to assess the physical stress of patients who have undergone ESD. With the increase in the number of older people, the number of patients undergoing ESD for early intestinal cancer is increasing. With advances in endoscopic diagnosis, intestinal cancer will be detected at an earlier stage, and more patients will be treated with ESD. Therefore, it is desirable to develop a method that can evaluate physical stress, even in older patients who are subjected to ESD.

Moreover, ESD is an endoscopic surgery performed on various gastrointestinal tracts, and it is expected that physical stress will differ depending on the organ involved. There is a difference between gastric and colorectal ESD in terms of both technical difficulty and perioperative management. In our facility, because gastric ESD is performed orally, patients fasted after dinner the night before ESD and underwent ESD with pethidine hydrochloride and midazolam or diazepam. In contrast, colorectal ESD requires bowel cleansing prior to colonoscopy. During fasting for ESD, patients are supplied with a drip transfusion and undergo whole bowel irrigation the previous evening and the day of ESD. As patients may need to change their posture to make the ESD procedure easier, colorectal ESD is performed in the awakened state with the analgesic pethidine hydrochloride. Thus, it can be presumed that physical stress in the perioperative period of gastric ESD differs from that of colorectal ESD. Therefore, an assessment method that can compare the physical stress of ESD procedures for different organs is needed.

The current review aimed to summarize the recent advances in physical stress assessment during the perioperative period of ESD, focusing on the changes in energy metabolism and serum opsonic activity (SOA). Additionally, the physical stresses during the perioperative period of gastric and colorectal ESD in comparison to surgery are discussed.

EARLY INVESTIGATIONS

Serum levels of interleukin (IL)-6, IL-8, tumor necrosis factor-α, and C-reactive protein fluctuate during the perioperative period[15-18]. Myre *et al*[19] reported that high and low doses of remifentanil affect the release of catecholamines (norepinephrine and epinephrine) differently during laparoscopic fundoplication. However, there have been no effective blood tests to assess physical invasiveness to date.

A report on ESD in the early stages of gastric cancer points out that increased salivary amylase activity in patients may indicate intraoperative stress[20]. However, this change is a hyperacute reaction of the endocrine system, and it is not possible to assess the physical invasion of ESD throughout the perioperative period.

ASSESSMENT OF PHYSICAL STRESS BY ENERGY METABOLISM

Surgical invasion alters metabolism, and the increased physical stress causes an increase in the patient's energy requirements[21-23]. The patient is subject to two principal metabolic responses: The responses to starvation and stress[24-26]. In addition, the energy requirements are associated with a degree of physical invasiveness[27].

Therefore, changes in resting energy expenditure (REE) measured using an indirect calorimeter can be used to evaluate physical stress. An indirect calorimeter measures the amount of oxygen consumed and the amount of carbon dioxide produced during metabolism and the energy consumption[21]. On the other hand, basal energy expenditure (BEE) is calculated using the Harris-Benedict equation based on the patient's height and body weight. It reflects the energy requirements of each patient[28]. Previous studies have compared BEE during the surgical perioperative period[29-32], but there are few reports using REE measurements. It is presumed that the measurement of REE is more complicated than that of BEE, and few facilities have the calorimeter required for the measurement. On the other hand, the greatest advantage of this method is acceptability for the patients. Because these methods require only exhalation, the patient can rest on the bed, and the measurement time is approximately 5 min each time.

The stress factor (SF) can be done by measured energy expenditure divided by the predicted energy expenditure using the Harris-Benedict equation and the active factor and assess the perioperative physical stress of ESD, even in older patients. According to Long's method[28], the total energy expenditure is defined as the product of BEE, SF, and the activity factor, and it is theoretically the same as the REE measured at rest. Since the activity factor on the day of ESD is the same as that on postoperative day (POD) 1, the SF on POD 1 can be calculated by setting SF on the day to be 1.0[33,34]. From the above, SF is a marker indicating the degree of hypermetabolic state[33,34]. The values of SFs are recognized as 1.1 for low invasiveness, 1.2 for medium invasiveness, and 1.8 for high invasiveness [28], and these values are used as indicators to determine perioperative energy management.

As shown in Table 1, the changes in the perioperative REE and SFs differed between gastric and colorectal ESD[33,34]. Regarding gastric ESD, the REE and REE/BEE increased significantly from the day of gastric ESD to POD 1. The SF for gastric ESD on POD 1 was calculated as 1.07, setting the SF on the day to 1.0[33]. There was no significant difference in REE on the day of ESD and POD 1 for colorectal ESD. However, REE/BEE was significantly higher on POD 1 than on the day of ESD. The SF for colorectal ESD on POD 1 was calculated as 1.06[34].

Regarding the perioperative REEs in surgery for gastric and colorectal cancer, Fredrix *et al*[26] reported that REE on the 7th and 8th PODs was 1.069% compared to the preoperative value. With respect to the SF on the third day after the surgery, Inoue *et al*[35] reported it was 1.4 for moderate invasive surgery such as subtotal gastrectomy or colectomy, and 1.6 for highly invasive surgery such as total gastrectomy. In our previous studies, REEs and SFs were evaluated on POD 1 when the patient was presumed to have the highest degree of physical and psychological stress; however, they remained low compared to those for surgeries[33,34].

ASSESSMENT OF PHYSICAL STRESS BY SOA

Opsonization is a humoral immune response involving the complement system that facilitates the capture and uptake of foreign substances by neutrophils and other phagocytes. An increase in SOA causes neutrophil activation and stimulates the secretion of reactive oxygen species (ROS)[36,37], which is associated with physical stress[38-40]. Among ROS, superoxide anions (O^{2-}) and hydrogen peroxide (H_2O_2) induce DNA fragmentation in cells, causing inflammation and tissue damage[37]. In sports medicine, there have been many reports that physical stress is evaluated by changes in SOA, an index of the immune capacity of non-specific neutrophils[39-41].

The chemiluminescence method is easy to perform, requiring only a blood sample and enabling the quantification of ROS produced by neutrophils[38-40]. This method is useful because the collected biological samples can be measured simultaneously under the same conditions. It detects ROS using chemiluminescent probes (*i.e.*, lucigenin and luminol).

O^{2-} is produced by neutrophils. Its formation is mediated by NADPH oxidase, which is activated by phagocytosis, and converted to H_2O_2 by superoxide dismutase[36,37]. Furthermore, each ROS has a different oxidation potential. When neutrophils release azurophilic granules containing myeloperoxidase (MPO), H_2O_2 reacts with Cl^- to produce hypochlorous acid (HOCl), which is a more powerful oxidant than H_2O_2[36,37]. Lucigenin is associated with the detection of O^{2-}, whereas luminol reflects the total amount of ROS produced by MPO, including HOCl[36,37]. Thus, the oxidative stress measured by luminol-dependent chemiluminescence is generally considered more toxic as it reflects all types of ROS in a sample.

To measure SOA in the peripheral blood, zymosan, an activator of the alternative complement pathway found in *Saccharomyces cerevisiae*, was opsonized in serum samples of patients who underwent ESD. Lucigenin- and luminol-dependent chemiluminescence were used to detect and quantify the ROS secreted by the neutrophils of a healthy volunteer against these opsonized zymosan molecules[36,37,

Table 1 Perioperative changes in resting energy expenditure, resting energy expenditure/basal energy expenditure, and stress factors by endoscopic submucosal dissection

	ESD preoperative state	ESD postoperative state
Gastric cancer		
REE (kcal)	1170.3 ± 209.0	1238.4 ± 235.5[c]
REE/BEE	0.96 ± 0.11	1.03 ± 0.14[c]
Stress factor		1.07
Colorectal cancer		
REE (kcal)	1107.0 ± 204.4	1139.9 ± 185.2[c]
REE/BEE	0.96 ± 0.12	1.00 ± 0.13[c]
Stress factor		1.06

[c]$P < 0.001$ *vs* endoscopic submucosal dissection (ESD) preoperative state.

Data are presented as mean ± SD. The stress factor on ESD in the postoperative state was computed by setting the stress factor on the day of ESD to be 1.0. ESD: Endoscopic submucosal dissection; REE: Resting energy expenditure; BEE: Basal energy expenditure.

42]. The emission curve measured by the chemiluminescence method was evaluated using an autoluminescence analyzer, focusing on the peak height and the area under the curve. For each measurement, the serum of a healthy volunteer was used as the standard value for ROS production. The results of the chemiluminescence method were calculated as a percentage compared to standard serum levels[36,37,42]. Changes in SOA, measured by the chemiluminescence method, are valuable in assessing the physical stress associated with endoscopic treatment of early-stage cancer[42].

As shown in Table 2, a significant increase in the peak height and area under the curve of lucigenin-dependent chemiluminescence was observed for gastric ESD on POD 1 and 4. Both of these percentages tended to decrease on POD 4 compared with those on POD 1. However, there was no significant increase in these parameters for luminol-dependent chemiluminescence on POD 1 and 4. In contrast, for colorectal cancer, the peak height and area under the curve of lucigenin-dependent chemiluminescence showed no significant difference in POD 1 but a significant increase in POD 4 compared with those on the day of ESD. Furthermore, no significant changes in these parameters were noted on luminol-dependent chemiluminescence during the perioperative period, similar to gastric ESD[42]. In contrast, previous studies on patients undergoing gastrointestinal surgery with different degrees of surgical stress found higher SOA measured by luminol-dependent chemiluminescence[43,44]. The difference in SOA between ESD and surgery suggests that ESD is less invasive.

Based on the results of the chemiluminescence method, changes in SOA during the perioperative period of ESD were associated with a slight increase in the production of less toxic ROS. The difference in the peak height of SOA between gastric and colorectal ESD, measured by lucigenin-dependent chemiluminescence, may be related to the difference in stimulation to post-ESD ulcers. Both gastric and colorectal ESD patients started eating meals 2 d after the procedure. Post-gastric ESD ulcers are immediately stimulated by gastric acid and oral bacteria. In cases of colorectal ESD, feces are defecated by intestinal tract-cleaning compositions, and the population of gut microbiota is markedly reduced before ESD. Therefore, SOA may have increased significantly on POD 4 because the post-ESD ulcer is stimulated by feces after resuming meals.

CONCLUSION

The current review summarizes the methods to assess the physical invasiveness of ESD in patients based on changes in REE measured using an indirect calorimeter and SOA measured by the chemiluminescence method. These methods are easy to perform and non-invasive, even in older patients. In addition, the results showed that changes in perioperative physical stress differed between gastric and colorectal ESD. The increases in perioperative REE and SF after ESD were lower than those reported for surgery. The perioperative changes in SOA after ESD were associated with slight increases in the production of less toxic ROS. These findings suggest that ESD does not cause significant physical stress.

In recent years, laparoscopic and less-invasive surgeries have become widespread. Further multicenter studies are needed to compare the changes in REE and SFs between ESD and less-invasive surgeries. There are also new procedures for endoscopic therapies, such as peroral endoscopic myotomy (POEM) and laparoscopic endoscopic cooperative surgery (LECS). In the future, it will be important to evaluate the physical stress of these procedures as well.

Table 2 Endoscopic submucosal dissection perioperative changes in serum opsonic activity measured by lucigenin- and luminol-dependent chemiluminescence

	The day of ESD	POD1	POD4
Gastric cancer			
Lucigenin			
Peak height (%)	100.6	106.3[b]	105.9[b]
	(71.4-178.5)	(78.5-282.4)	(77.6-214.4)
Area under the curve (%)	98.4	105.6[b]	103.5[b]
	(48.7-184.7)	(64.8-265.3)	(66.0-222.8)
Luminol			
Peak height (%)	98.4	100.1	99.6
	(62.7-168.3)	(63.6-199.2)	(69.7-186.6)
Area under the curve (%)	99.7	102.6	101.8
	(68.2-155.7)	(68.0-182.9)	(73.2-170.7)
Colorectal cancer			
Lucigenin			
Peak height (%)	102.3	105.2	105.3[a]
	(71.4-132.7)	(61.8-137.4)	(65.7-137.1)
Area under the curve (%)	99.4	101.9	102.6[a]
	(68.2-134.3)	(60.9-140.0)	(64.0-139.7)

Abstract

Barrett's esophagus (BE) is a condition that results from replacement of the damaged normal squamous esophageal mucosa to intestinal columnar mucosa and is the most significant predisposing factor for development of esophageal adenocarcinoma. Current guidelines recommend endoscopic evaluation for screening and surveillance based on various risk factors which has limitations such as invasiveness, availability of a trained specialist, patient logistics and cost. Trans-nasal endoscopy is a less invasive modality but still has similar limitations such as limited availability of trained specialist and costs. Non-endoscopic modalities, in comparison, require minimal intervention, can be done in an office visit and has the potential to be a more ideal choice for mass public screening and surveillance, particularly in patents at low risk for BE. These include newer generations of esophageal capsule endoscopy which provides direct visualization of BE, and tethered capsule endomicroscopy which can obtain high-resolution images of the esophagus. Various cell collection devices coupled with biomarkers have been used for BE screening. Cytosponge, in combination with TFF3, as well as EsophaCap and EsoCheck have shown promising results in various studies when used with various biomarkers. Other modalities including circulatory microRNAs and volatile organic compounds that have demonstrated favorable outcomes. Use of these cell collection methods for BE surveillance is a potential area of future research.

Key Words: Barrett's esophagus; Screening; Surveillance; Non-endoscopic; Cytosponge; Esophacap; Esocheck

Core Tip: This review summarizes the non-endoscopic modalities available for the screening and surveillance of Barrett's esophagus which include esophageal imaging devices (trans-nasal endoscopy, esophageal capsule, tethered capsule endomicroscopy), cell collection devices (Cytosponge, Esophacap, Esocheck), circulatory micro-RNAs and volatile organic compounds. There is promise using some of the noninvasive modalities for mass screening in BE and a role in surveillance is yet to be determined.

INTRODUCTION

The esophagus is normally lined by stratified squamous epithelium. The mucosa of the esophagus is regularly exposed to gastric acid and bile through reflux from the stomach which can result in mucosal damage. The injury is usually repaired by regeneration of the squamous mucosa. However, in some patients, the mucosal damage is repaired resulting in a metaplastic columnar epithelium with gastric and intestinal features. The condition is termed Barrett's esophagus (BE) and is recognized as the major risk factor for the development of esophageal adenocarcinoma (EAC)[1]. It is estimated that as many as 5.6% of United States adults have BE based on modeling using EAC rates[2]. Of note, endoscopic prevalence is widely variable based on geographic location of the population studied[3-6]. Current estimates are likely an underrepresentation given that upper endoscopy is required for diagnosis. Mean age at BE identification is approximately 55 years and is two to threefold more common in men than in women[7,8]. Among patients undergoing upper endoscopy, compared to Caucasians, African Americans have a significantly lower BE prevalence[9,10]. Accepted BE risk factors besides Caucasian race include age > 50, male, chronic (> 5 years) or frequent (> once weekly) gastroesophageal reflux disease (GERD), smoking, obesity (Body mass index > 35), and family history of BE or EAC (first degree relative)[11].

Endoscopy is currently the mainstay for BE diagnosis and management. An endoscopic approach is inappropriate for mass screening as it is not cost effective resulting in missed opportunities to discover patients with undiagnosed BE. Current screening guidelines target individuals with GERD and multiple risk factors for endoscopy to detect BE then enroll those with it into a surveillance program. However, this approach does not take into consideration that most EAC cases do not have a diagnosis of BE prior [12]. This provides an excellent opportunity for non-endoscopic techniques to be used as a public health tool for screening (identification of disease) and surveillance. Individuals belonging to the low risk BE strata are best suited for non-endoscopic modalities as they require minimal intervention whereas the high risk BE group would require more precise but also more invasive endoscopic based technologies [13]. Non-endoscopic techniques provide cost-effective, less invasive screening tools and more importantly increase the ease of accessibility to screening opportunities.

WHO DO WE SCREEN

Screening for BE is recommended in patients with multiple known risk factors including chronic or frequent GERD, age greater than 50 years, male sex, Caucasian race, smoking, obesity along with family history of a 1st degree relative with BE or EAC. Currently, screening the general population with only GERD symptoms is not recommended per society guidelines[14,15].

ESOPHAGEAL IMAGING DEVICES

Currently, high-definition white light endoscopy is the mainstay of BE screening and surveillance. Despite being safe and well-tolerated, it is invasive and associated with higher costs and side effects [16]. Trans-nasal endoscopy (TNE, Figure 1) has been proposed as a less invasive alternative to screen for BE. TNE is an ultra-thin endoscope (diameter < 6 mm) used in the outpatient setting to directly visualize the distal esophagus. This has occurred in primary care offices[17,18] and mobile vans for community BE screening[19]. Drawbacks of TNE are limited availability, cost, decontamination facility for reuse, and need for trained operators.

Figure 1 Trans-nasal endoscopy. Courtesy: Image obtained from public domain.

ESOPHAGEAL CAPSULE ENDOSCOPY

Esophageal capsule endoscopy (ECE), similar to small bowel capsule endoscopy, consists of a wireless capsule containing a camera, battery, and radio transmitter. Images are transmitted to a digital receiver and transferred to a computer for analysis[20]. A meta-analysis of 9 studies comprising of 618 patients showed a pooled sensitivity of 78% and specificity of 86% (EGD as the reference had sensitivity and specificity of 78% and 90% respectively)[21]. The suboptimal diagnostic accuracy is contributed to rapid esophageal transit time. Newer versions of ECE have been developed to overcome this issue and allow prolonged imaging. PillCam ESO (Medtronic Inc, Minneapolis, MN) was initially approved by Food and Drug Administration in 2004 and a second-generation device (PillCam ESO2, Figure 2A) with cameras at both ends of the capsule. The second-generation device captures images (PillCam ESO2, Figure 2B) at a rate of 18 frames per seconds (fps)[22]. A third-generation capsule (PillCam UGI) with a wider angle of view (174°) and higher recording rate (35 fps) is under investigation with pilot data suggesting inferiority to standard endoscopy regarding BE detection[23]. Another solution for the rapid esophageal transit issue is the detachable string magnetically controlled capsule endoscopy (also known as wireless magnetically controlled capsule endoscopy or WMCCE) which has been shown to be feasible and well tolerated in various studies[24-26]. A recent prospective multicenter study showed sensitivity of 92% and specificity of 80% for high-risk esophageal varices[27]. With regards to cost-effectiveness of ECE compared to traditional endoscopy, the results have been equivocal[28-30]. More studies are needed to determine of this modality is viable and cost-effective for BE screening.

TETHERED CAPSULE ENDOMICROSCOPY

Another variant of ECE is optical coherence tomography tethered capsule endomicroscopy (OTC-TCE, Figure 3) which uses optical-frequency domain imaging technology that rapidly acquires high-resolution, 3-dimensional, cross-sectional images of the entire esophagus[31,32]. In a proof-of-concept study of 13 subjects (7 normal volunteers and 6 with known BE), no complications were reported, and 12/13 patients reported preference of this method over conventional endoscopy[33]. The feasibility and safety of this method was further demonstrated in a recent multi-center study of 147 patients with known BE, and a blinded comparison of maximum extent of BE measured by OTC-TCE and EGD showed a strong correlation (r = 0.77-0.79, P < 0.05)[34]. In this study, high-quality microscopic images of the entire esophageal wall were obtained in the majority of the cases (93.7%). Larger prospective studies are needed to assess diagnostic yield and cost-effectiveness in the general population setting.

CELL COLLECTION DEVICES WITH BIOMARKERS

Various devices have been designed for esophageal cell collection. These samples can be analyzed cytologically and coupled with various biomarkers.

Cytosponge™—Trefoil Factor Family Protein 3

The Cytosponge (Medtronic, Minneapolis, MN, Figure 4) is a 30 mm polyurethane sponge, compressed withing a gelatin capsule and attached to a string[13]. Once patient swallows the capsule and it reaches the stomach, the capsule opens up and reveals the sponge. As the string is pulled back, the Cytosponge collects cells from the lining of the entire esophagus and oropharynx. Although several biomarkers have

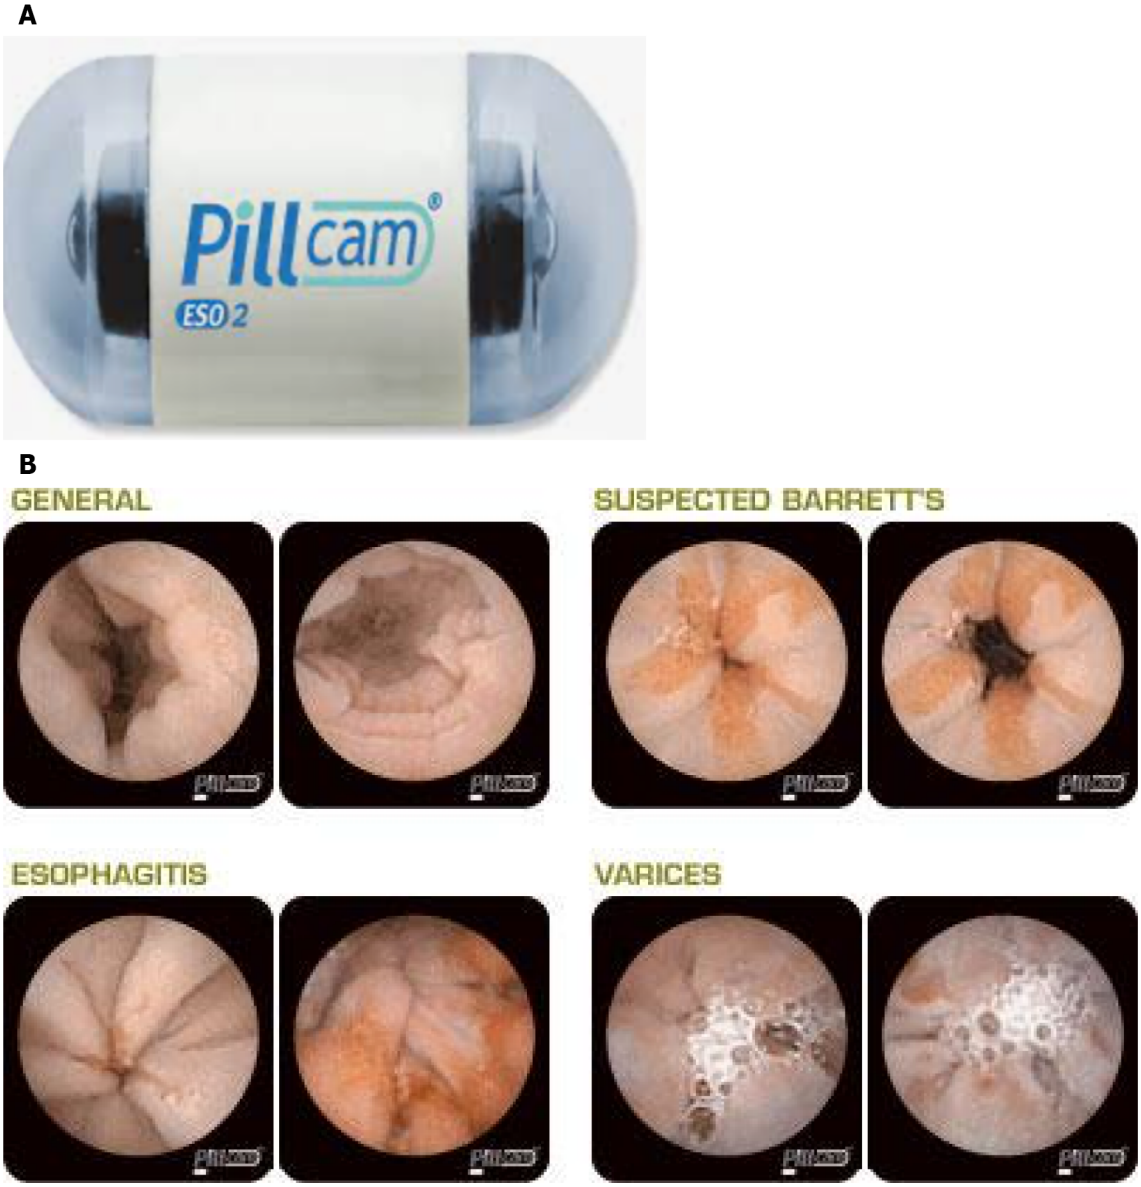

Figure 2 PillCam ESO2 and image. A: PillCam ESO2; B: PillCam ESO2 images showing normal, esophagitis, suspected Barrett's and varices. Courtesy: Image obtained from public domain.

been used with Cytosponge including a multi-gene next-generation sequencing panel, differentially methylated genes, and microRNAs, the most well-established biomarker used with Cytosponge has been trefoil factor family protein 3 (TFF3) immunohistochemical staining[35-37].

In a multicenter case-control study of 11 United Kingdom hospitals (total subjects = 1,110; 463 dyspepsia controls and 647 BE patients), Cytosponge-TFF3 was performed prior to endoscopy[38]. BE was diagnosed with specificity of 92.4% and sensitivity of 79.9% (87.2% in patients with larger circumferential BE than 3 cm). Fitzgerald *et al*[39] in the BEST3 trial, a multicenter RCT study in 109 United Kingdom general practice clinics, demonstrated in patients with GERD symptoms, Cytosponge-TTF3 results in improved detection of BE, treatable dysplasia, and early cancer. In a systematic review of 13 studies, this method was shown to be cost-effective and well-tolerated through multiple patient populations[40]. Another patient-level review of 5 prospective trials assessing Cytosponge performance in patients with reflux disease, BE and eosinophilic esophagitis, also showed tolerability and safety of this device [41].

The advantage of Cytosponge is that it is not operator-dependent, it is quick, and does not require specialized equipment or extensive training, so it could easily be applied to a primary care setting[40].

EsophaCap™

EsophaCap (CapNostics, Concord, NC, Figure 5) is a sponge on string device similar to Cytosponge, albeit smaller and softer[42]. EsophaCap has been used in a pilot trial using a panel of 2 methylated DNA markers (MDM), 3-VAV2 and zinc finger protein 682-ZNF682, on whole esophageal brushings (49

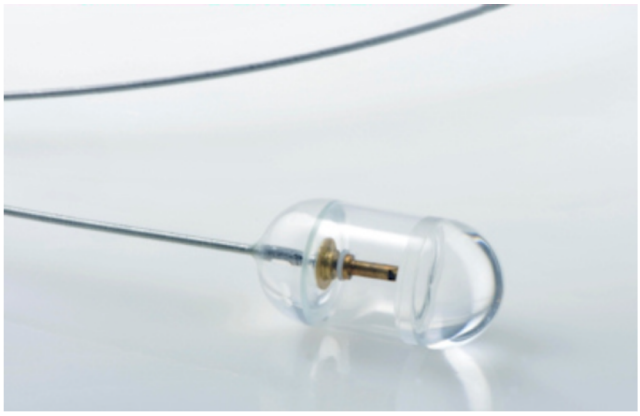

Figure 3 Tethered capsule endomicroscopy. Courtesy: Image obtained from public domain.

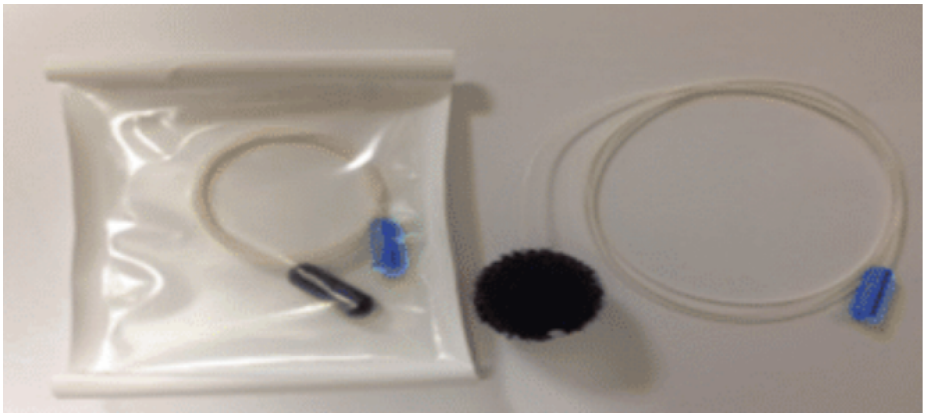

Figure 5 EsophaCap (CapNostics, Concord, NC). Courtesy: Image obtained from public domain.

BE case and 36 controls), and in 40 subjects (20 BE cases and 20 controls) randomly assigned to swallow EsophaCap[42]. Overall, 80% of MDM candidates showed high accuracy for BE (AUCs 0.84-0.94) with sensitivity and specificity of 100%. The EsophCap was swallowed and withdrawn in 98% of subjects with no reported major complications, and 32% had minimal abrasions. More recently, in the same group conducted a multi-center case-cohort study of 268 subjects swallowed the capsule, but 201 met the inclusion criteria (112 cases and 89 controls) using the two previously mentioned MDMs and included 3 additional markers (NDRG4, FER1L4, and ZNF568)[43]. Cross-validated sensitivity and specificity were 92% and 94% respectively. EsophaCap was well tolerated in most patients (performed mostly by non-physicians) and 95% preferred the device over endoscopy. Currently a case-control trial is ongoing to identify potential biomarkers for the early detection of BE, esophageal carcinoma (both adenocarcinoma and squamous cell carcinoma) using EsophaCap (ClinicalTrial.gov ID: NCT04214119).

EsoCheck™

EsoCheck (Lucid Diagnostics, New York, NY, Figure 6) is a balloon-based sampling device which consists of a collapsible balloon attached to thin silicone catheter connected to a syringe[13]. Once EsoCheck is swallowed and is in the stomach, the balloon is inflated by injecting air into the catheter and withdrawn through the distal 3-6 cm of the esophagus, collecting epithelial cells. After sampling the area described above, the balloon is deflated which leads to its retraction into to the capsule, thereby protecting the sample from bio-contamination from the mid or proximal esophagus as well as oropharynx.

Several biomarkers including MDMs have been used with EsoCheck. In a pilot study, Moinova *et al* [44] performed a genome-wide screening and identified high-frequency methylation within the CCNA1 DNA locus. They tested CCNA1 and VIM DNA methylation (already an established BE biomarker) using EsoCheck in 173 individuals with or without BE and showed an AUC = 0.95 for discriminating metaplasia and neoplasia *vs* normal individuals for both, and with both biomarkers combined, the panel had a sensitivity of 95% and specificity of 91%. The results were replicated in an independent validation cohort of 149 subjects. The device was generally well-tolerated but 28 (18%) of subjects could not swallow the pill and 9% had poor DNA yield.

A new multi-center, single-arm trial is underway to study of the screening efficacy of a new generation EsoCheck device in combination with EsoGuard (2-marker MDM panel) in at risk population (ClinicalTrial.gov ID: NCT042293458).

OTHER METHODS

Circulatory MicroRNAs

MicroRNAs (miRNAs) are short (approximately 18-25 nucleotides in length) non-coding RNAs which regulate gene expression by binding to mRNAs to inhibit their translation or facilitate their degradation [45]. miRNAs play role in cell growth, differentiation and migration and can be dysregulated in malignancy[46]. Several miRNAs have been shown to be differently expressed in patients with BE. In a quantitative real-time PCR analysis of 60 disease/normal-paired tissues from 30 patients with esophagitis or BE, miR-143, miR-145, miR-194, and miR-215 were significantly higher, while miR-203 and miR-205 were lower in BE tissues[47]. Analysis on circulating miRNA levels confirmed that miR-194 and miR-215 were significantly upregulated in BE patients. Additionally, serum miR-130a was also shown to be elevated in BE and EAC patients[48]. Pavlov *et al*[49] in a study of 69 patients showed serum miR-320e and miR-199a-3p to be significantly lower in BE compared to patients with normal epithelium. Investigators have recently reported miR-4485-5p as a novel biomarker of esophageal dysplasia worthy of continued investigation[50]. These markers provide a non-invasive method, requiring only a patient's peripheral blood sample and likely increasing acceptability and tolerability, but validation studies are needed in larger cohorts to demonstrate adequate sensitivity as well as specificity for widespread use.

Volatile Organic Compounds

Detection of cancer through exhaled breath using volatile organic compounds (VOC) has shown promising results for various cancers[51,52]. Two techniques have been used in patients with BE or esophageal cancer, which are gas chromatography-mass spectrometry and electronic nose (E-nose) apparatus[53-56]. The gas chromatography method was used to analyze exhaled breath samples from 81 patients (including 48 esophageal cancer patients) and 129 controls (including 16 patients with BE), and although this method was able to discriminate esophageal cancer from controls (AUC = 0.97), it was not able to identify patients with BE[56]. The drawback of this method is that it is costly and labor-intensive. The electronic nose apparatus, which consists of an array of 3 metal oxide sensors, uses a chemical to electrical interface to measure VOC profiles associated with various diseases and can be combined with machine learning[57]. In cross-sectional study of 122 patients with dysplastic BE, breath samples while in a fasting state were analyzed in real-time using the e-nose device[54]. Subjects were at various stages of treatment or surveillance. The data was introduced into an artificial neuronal network to discriminate differences in subjects stratified by the presence or absence of BE on biopsies. The test showed the ability to detect BE with a sensitivity of 82%, specificity of 80%, and accuracy of 81% (AUC = 0.79). In another proof-of-concept study of 402 patients (129 patients with BE and 141 patients with GERD symptoms), 5-minute breath samples were collected, and the test was able to identify BE patients with a sensitivity of 91% and specificity of 74%[53]. Other advantages of E-nose compared to the gas chromatography-mass spectrometry is cost and portability. More validation studies at the general population level are needed for use as a potential BE screening method.

FUTURE TRENDS

Circulatory tumor DNA (CtDNA), miniscule amounts of fragmented DNA originating from tumor cells, has been proposed as a part of multi-cancer early detection (MCED) project. The Circulating Cell-free Genome Atlas trial in a prospective, case-controlled observational study showed that a blood-based MCED test using CtDNA in combination with machine learning could detect cancer signals for multiple cancer types and predict cancer signal origin with promising accuracy[58]. Most recently, a large multi-center MCED trial called PATHFINDER study began recruiting participants across 31 United States sites to examine DNA methylation patterns in blood samples to detect various cancers including esophageal cancers[59]. Since BE is a pre-malignant condition, more specific studies need to be conducted in the future to assess feasibility.

SURVEILLANCE

Patients with BE are currently recommended to enter a surveillance endoscopic program based on histological findings and degree of dysplasia[14,60]. This has been associated with a significant mental burden on these patients, presenting as various forms of anxiety and stress related to thoughts of disease progression as well as potential implications of the test, with many finding the program physically burdensome and intrusive[61]. This opens up opportunity for non-invasive surveillance options, which could even be performed in the setting of regular outpatient clinic visits. These modalities can potentially facilitate access to care for a larger population of patients and increase compliance similar to non-invasive tests for colorectal cancer screening programs[62]. As such, non-endoscopic cell collection methods have the potential for use in BE surveillance but so far, no studies have compared their use with conventional endoscopy for the purpose of BE surveillance, leaving this important area ripe for future investigation.

CONCLUSION

Despite advances in screening and surveillance programs for BE, their lack of efficiency is demonstrated by the fact that only one in ten cases of EAC is diagnosed within a surveillance program. Upper endoscopy remains the gold standard but barriers exist to function as an effective screening tool which include high cost, invasiveness, possible complications, need for a trained specialist, and patient desirability. Screening guidelines have been published by several societies that are based on risk factors and do not include the general population. Less invasive modalities have been proposed for BE screening (Table 1). TNE has been used in outpatient settings including offices and mobile medical vans with some success. ECE has shown promising results, and newer generations have attempted to circumvent the issue of rapid esophageal transit with higher frame rates, wider angle view, and magnetic control. OTC-TCE is capable in acquiring high-resolution, 3-dimensional cross-sectional esophageal images with safety and feasibility been demonstrated in multi-center studies. Various cell collection devices coupled with biomarkers have been used for BE screening. Cytosponge, in combination with TFF3, is a cost-effective and well-tolerated method. Similar devices including EsophaCap and EsoCheck have shown promising results when used with various biomarkers and multi-center large-scale trials are currently underway. Circulatory MicroRNAs have been proposed for BE screening as they are expressed differently in this population. VOC using gas chromatography-mass

Table 1 Non-endoscopic methods for detection of Barrett's esophagus

Device name	Application	Detection method	Company	FDA approved	Commercially available
Esophageal capsule endoscopy (ECE)	Swallowed	Direct visualization	Given imaging	Yes (First generation: 2004)	Three generations (SB1, SB2, SB3)
Tethered capsule endomicroscopy (OTC-TCE)	Swallowed	Direct visualization	N/A	No	No
Cytosponge	Swallowed	Cell collection	Medtronic	Yes (2018)	Yes
Esophacap	Swallowed	Cell collection	PAVmed (previously CapNostics)	Yes (2021)	No
EsoCheck	Swallowed	Cell collection	PAVmed (Lucid Diagnostics)	Yes (2019)	Yes
Circulatory microRNAs	Blood sample	miRNA collection	N/A	No	No
Volatile organic compounds (VOC)	Breath sample	VOC collection	Aeonose (Netherlands)	No	No

spectrometry and electronic nose have been used to identify BE or EAC with varying success. Finally, CtDNA is now being used as a part of "multi-cancer early detection" campaign which may play a role in detection of pre-cancer states such as BE. Using these non-invasive methods could also play a role as a surveillance tool once patients are identified with BE. Large future studies are desired to demonstrate the efficacy and feasibility for the BE surveillance population.

Abstract

The microbiota impact on human diseases is well-known, and a growing body of literature is providing evidence about the complex interplay between microbiota-immune system-human physiology/pathology, including cancers. Together with the defined risk factors (*e.g.*, smoke habits, diet, diabetes, and obesity), the oral, gut, biliary, and intrapancreatic microbiota contribute to pancreatic cancer development through different pathways including the interaction with the immune system. Unfortunately, a great majority of the pancreatic cancer patients received a diagnosis in advanced stages not amenable to be radically treated and potentially cured. Given the poor pancreatic cancer prognosis, complete knowledge of these complicated relationships could help researchers better understand the disease pathogenesis and thus provide early potential non-invasive biomarkers, new therapeutic targets, and tools for risk stratification that might result in greater therapeutic possibilities and eventually in a better and longer patient survival.

Key Words: Gastrointestinal tumors; Hepatopancreatobiliary tumors; Pancreatic cancer; Gut microbiota; Dysbiosis; Cancer development; Carcinogenesis

Core Tip: Despite improvements in traditional patient treatment, pancreatic cancer remains a tumor with an increasing incidence and a poor prognosis, often diagnosed in late stages. The oral, gut, biliary, and intrapancreatic microbiota might contribute to pancreatic cancer through different pathways including a complex interplay with the immune system. Comprehending these complicated relationships could help researchers better understand the pathogenesis of pancreatic cancer, thus providing new promising options for early diagnosis, therapeutic targets, and risk stratification hoping that could translate into better and longer patient survival.

INTRODUCTION

Pancreatic cancer (PanCa), with its most common subtype ductal adenocarcinoma, is a relatively uncommon but highly lethal neoplasm. Despite years of research, the PanCa patients are often diagnosed in advanced stages having less than a 30% chance of being alive 1 year after diagnosis and less than a 10% 5-year survival rate[1-3].

The human body is colonized by a huge number of microorganisms, which include bacteria, archaea, viruses, and fungi. This articulate community with the environment and the microorganism metabolites is known as microbiota. Usually, the commensal community lives in equilibrium with the host in a condition defined as "eubiosis;" however, if for some reason the equilibrium is broken, a condition called dysbiosis occurs[4]. A growing body of the literature reported the complex interplay of the microbiota with the immune system and the intestinal barrier in a bidirectional influence that plays a key role in health and disease, including cancer[5-7].

Evidence about the potential causal role of microbiota on PanCa development is still scarce, but it is gaining great attention over the last few years[8,9]. The oral, gut, biliary, and intrapancreatic microbiota seem to contribute to PanCa initiation and development. Furthermore, microbiota both act through a direct effect or indirectly through the interaction with the immune system or through the production of circulating toxins. Understanding these complicated relationships could help researchers better define the causes of different pathologies, including PanCa, and thus provide new therapeutic targets and tools for risk stratification[10].

Finally, given the diagnosis frequently made in advanced stages and the poor prognosis of this tumor together with the lack of markers able to detect an early PanCa, the chance to use the gut microbiota as an early non-invasive biomarker might result in greater therapeutic possibilities and, eventually, in a better and longer patient survival[11].

This review aims to provide the current state of the microbiota immunity axis impact in every step of PanCa, trying to highlight potential promising new therapeutic options.

CANCER DEVELOPMENT

Although often no identifiable risk factors can be found, genetic factors, lifestyle, and chronic pancreatitis are well-recognized[12]. It is notable that most of them cause dysbiosis too[1,12].

Because an estimated 70% of the bacteria in the human body have not been grown yet, studying the human microbiota is a difficult endeavor[13]. A breakthrough in DNA sequencing occurred in the mid-2000s thanks to next-generation sequencing[14]. Through gene sequencing, metagenomics, metatranscriptomics, metaproteomics, and metabolomics (the recently introduced "meta-omics" techniques) analysis of strain composition, production of metabolites, and other bacterial activities can be performed [15,16]. Consequently, the significant microbiota impact on human physiology and pathology has been increasingly acknowledged over the years. Although the evidence is still in its infancy, being a small part of more complex mechanisms, the potential role of the microbiome itself and microbiome-immune system interplay on PanCa onset and development has been recently advocated.

Different microbial compositions in healthy people and disease

Although whether changes in the balance between microbial species could be a cause or an effect of disease onset and development is difficult to state[17], microbial composition analyses have been performed in different districts including the oral cavity, duodenum, gut, bile, and pancreatic tissue. Conflicting results can be found in analyzing the studies, but the influence of other risk factors (for

example, smoking habit) may create bias and at least, partially explain some differences.

Association between periodontal disease or oral dysbiosis and several kinds of cancers (oral, hematological, digestive tract, prostate, uterus, lung, and breast) has been reported with different strengths of association[18]. In analyzing this relationship, PanCa has been one of the most studied cancers[16,18]. *Porphyromonas gingivalis, Fusobacterium,* and *Aggregatibacter actinomycetemcomitans* in the oral microbiota were related to a higher risk of developing PanCa[17,19,20]. Similarly, analyzing the saliva, the presence of *Streptococcus* and *Leptotrichia* was associated with a higher risk of human PanCa, and *Granulicatella adiacens* was found to be increased in these patients. On the contrary, the presence of *Veillonella* and *Neisseria* was associated with a lower risk of PanCa, and *Streptococcus mitis* appeared to be reduced in these patients[21-23]. Higher representation of *Prevotella* and *Vaillonella* was more frequently found in patients with jaundice[22].

Fusobacterium, Rothia, Actinomyces, Corynebacterium, Atopobium, Peptostreptococcus, Catonella, Oribacterium, Filifactor, Campylobacter, Moraxella, and *Tannerella* were more abundant in the PanCa patients' tongue coatings, while *Haemophilus, Porphyromonas,* and *Paraprevotella* were more abundant in healthy people. *Haemophilus* and *Porphyromonas* or *Leptotrichia* and *Fusobacterium* represented unique signatures able to identify healthy people or patients with PanCa[24].

Helicobacter pylori (*H. pylori*) is a well-known pathogenetic agent in gastric cancer, and its role in colorectal cancer development has also been suggested[25]. Being more represented in the stomach and duodenum of the PanCa patients than in controls, *H. pylori* could also have a role in the development of this cancer. It elicits chronic mucosal inflammation and alters the gut microbiota causing bacterial translocation[3,26]. However, this relationship is particularly argued due to the frequent associations with several other known risk factors thus precluding definitive conclusions[9].

Association between gut dysbiosis and several kinds of cancers (breast, lung, digestive tract, and above all colorectal) has been reported. Lower gut microbial biodiversity was found in stool samples of PanCa patients[27]. Furthermore, significantly higher levels of mucus-degrader Verrucomicrobia and Bacteroidetes including the Gram-negative bacteria lipopolysaccharide (LPS) producers *Prevotella* and *Hallella* together with other LPS producers *Veillonella*, *Klebsiella*, *Selenomonas*, and *Enterobacter* have been found in the gut microbiota of PanCa patients compared to healthy people. In parallel, lower levels of other Firmicutes, notably the butyrate-producers *Coprococcus* and *Anaerostipes*, have been found[2,27,28]. However, the exact clinical correlation is still unknown, and further studies are needed. Finally, higher levels of *Bifidobacterium pseudolongum* were documented in both gut and tumor specimens[28].

The pancreas is considered a sterile organ because of its alkaline pH and the presence of digestive enzymes that make bacterial proliferation difficult[29]. However, some potential ways through which microbes could reach it have been recently proposed even if definitive conclusions cannot be drawn. They include colonization from the duodenum or the biliary tract following reflux and colonization through the lymphatic and/or portal system[28]. Finally, the potential tissue contamination during sample collection and processing is another way of colonization. The majority of the human PanCa tissues were found to be colonized, mainly by *Gammaproteobacteria*[30-33], and a greater abundance of bacteria and fungi have been found in PanCa tissue of both human and animal models[28,30,31].

Acinetobacter, Enterobacter, Pseudomonas, Delftia, Enterococcus, Streptococcus, Corynebacterium, Propionibacterium, Sphingomonas, and *Staphylococcus* with a significant *Klebsiella* predominance were found in the human PanCa group compared to the healthy control (samples from organ donations)[32]. In addition, higher levels of *Malassezia* species in cancer tissue were related to PanCa progression, while *Candida, Aspergillus,* or *Saccharomyces* species did not cause cancer development after repopulation following mycobiome ablation[34]. In animal models, a relatively higher abundance of *Lactobacillus* was found in the pancreatic tissue of the control group, while a relatively higher abundance of *Fusobacterium* species and Proteobacteria were found in the pancreatic tissue of the cancer group[17,33]. Furthermore, significant differences have been discovered in microbiota composition found in different PanCa stages [28].

Finally, bile contamination, mainly related to biliary stenting and endoscopic procedures, was significantly found in patients affected by PanCa. The more represented species in bile samples (collected during endoscopic procedures or surgery) were *Escherichia coli* (*E. coli*) and different species of *Pseudomonas*, *Enterobacter*, and *Enterococcus*[34-37].

The main microbiota modifications are summarized in Table 1.

Pathogenetic PanCa models

The pathogenetic relationship between microbiota and PanCa is far from being completely understood, and the proposed potential pathogenetic mechanisms are derived mainly from animal models[17]. The microbiota promotes carcinogenesis in direct or indirect ways. Indirect action could be elicited through the production of circulating toxins or harmful metabolites or through the interaction with the immune system. Both innate and adaptive immune responses are active in fighting human cancers[38]. The anticancer immunological mechanisms include the cytotoxic CD 8+ T cells, T helper (Th) cells, mature dendritic cells, macrophages, and natural killer cells. Myeloid-derived suppressor cells (MDSCs) are immature myeloid cells able to suppress both innate and adaptive immunity with different mechanisms, promoting regulatory T cell development and simultaneously inhibiting the effector T cells and natural killer cells[39].

Table 1 Different microbial compositions in patients affected by pancreatic cancer

Anatomical district	Microbiota	Implications
Oral		
	Higher microbial biodiversity	Confer higher risk of developing PanCa[17,19,20,23]
	Porphyromonas gingivalis, Fusobacterium	
	Aggregatibacter actinomycetemcomitans	
	Streptococcus, Leptotrichia, Neisseria elongata	
	Granulicatella adiacens	More abundant in PanCa than control[23]
	Fusobacterium, Rothia, Actinomyces	
	Corynebacterium, Atopobium	
	Peptostreptococcus, Catonella	
	Oribacterium, Filifactor	
	Campylobacter, Moraxella, Tannerella	
	Fungi:	
	Candida	
Gut		
	Bacteroidetes	More abundant in PanCa than control[27,28]
	Prevotella, Hallella	
	Proteobacteria	
	Klebsiella, Enterobacter	
	Verrucomicrobia	
	Bifidobacterium pseudolongum	
	Veillonella	
	Firmicutes	Less abundant in PanCa than control[27]
	Coprococcus, Anaerostipes	
Pancreas		
	Proteobacteria	More abundant in PanCa than control[17,28,30-33]
	Gammaproteobacteria	
	Pseudomonas, Acinetobacter, Enterobacter	
	Delftia, Klebsiella, Sphingomonas	
	Firmicutes	
	Enterococcus, Streptococcus, Staphylococcus	
	Fusobacteria	
	Fusobacterium species	
	Acinetobacteria	
	Bifidobacterium pseudolongum	
	Corynebacterium, Propionibacterium	
	Lactobacillus	Less abundant in PanCa than control[17,33]
	Fungi	Confer higher risk of PanCa progression[31]
	Malassezia	

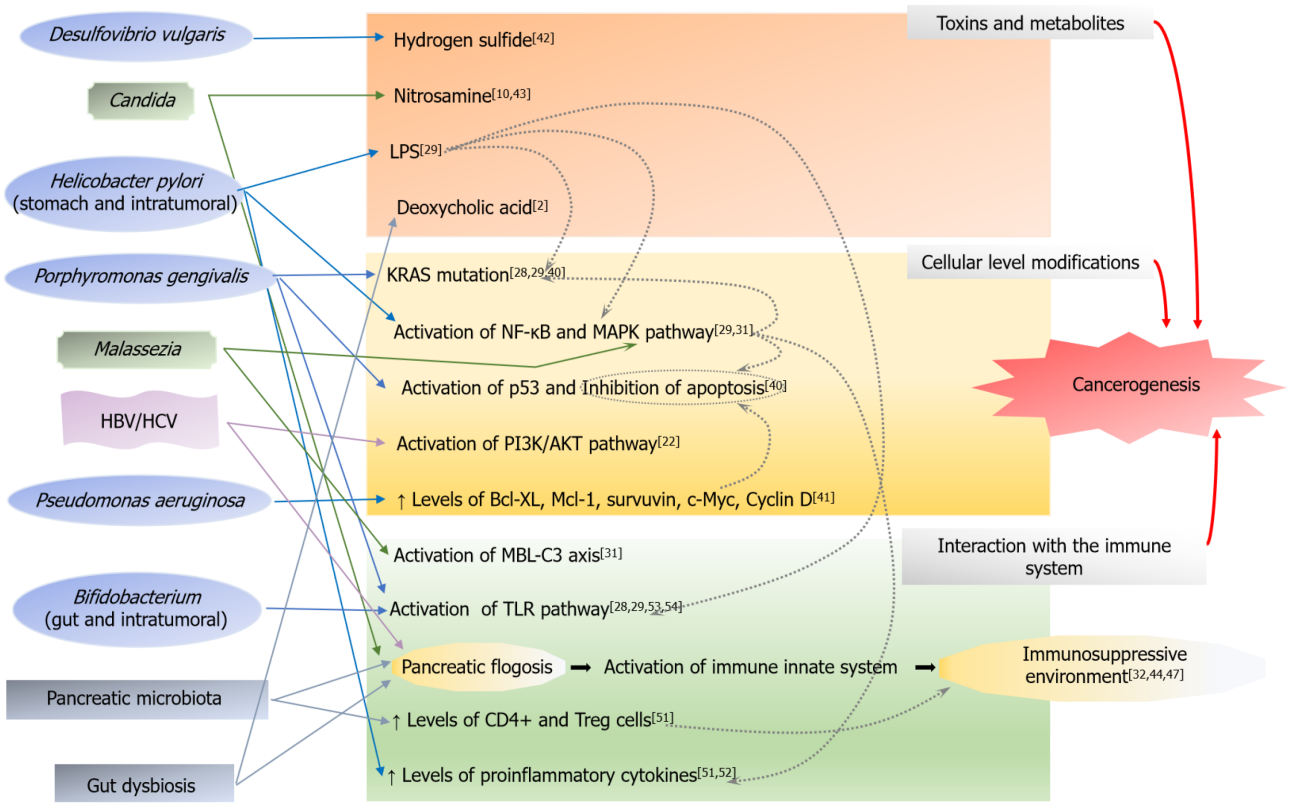
PanCa: Pancreatic cancer.

Most of these models have also been reported in other cancer types.

A direct carcinogenic effect of *Porphyromonas gingivalis* is related to the apoptosis inhibition of the epithelial cells, the activation of the *p53* gene, and the induction of *KRAS* mutation, the latter two through the production of the enzyme peptidyl-arginine deiminase[40]. *KRAS* mutation can be found in almost all PanCa. Interestingly, germ-free *KRAS*-mutated mice demonstrated slower PanCa progression suggesting that gene mutation itself is not sufficient to cause cancer development[28,29]. Intestinal microbiota has a direct long-distance effect on PanCa development through up/downregulation of pro/anti-cancer pathways[32]. *Pseudomonas aeruginosa* is related to higher levels of the anti-apoptotic and pro-proliferative proteins Bel-XL, Mcl-1, survivin, c-Myc, and cyclin DI[41]. The hepatotropic viruses that cause hepatitis B or C can contribute to PanCa development through the modulation of the PI3K/AKT signaling pathway and tissue inflammation[22].

One of the most common bacterial components related to cancer development is LPS, which is a direct cause of *KRAS* gene mutation and can stimulate nuclear factor-κB that further increases *KRAS* mutation risk. Furthermore, LPS is an activator of the toll-like receptor (TLR) signaling pathway thus enhancing pancreatic inflammation[21,29]. *H. pylori* is an LPS producer[29]. Deoxycholic acid, a bacterial metabolite of cholic acid, promotes carcinogenesis through the activation of the epidermal growth factor and STAT3 signaling pathway[2]. *Desulfovibrio vulgaris* and other sulfate-reducing bacteria produce genotoxic hydrogen sulfide when the diet is enriched in proteins and fats[42]. Other carcinogenic bacterial metabolites from proteolytic fermentation include phenols, ammonia, and other nitrogen-rich products. *Candida* induces PanCa through the production of the carcinogen nitrosamines or acetaldehyde[10,43].

Finally, many studies highlighted the role of the immune system on PanCa[44-46]. The activation of the immune system by the microbiota of different districts can cause local and/or systemic inflammation that worsen dysbiosis sustaining a vicious circle. For example, *H. pylori* presence in the stomach is related to reduced production of acid/achlorhydria that might trigger dysbiosis[9]. Gut dysbiosis induces chronic pancreatic inflammation. Pancreatic microbiota can further elicit an inflammatory response interacting with both innate and specific immune systems. The immunosuppressive cells, regulatory T cells and MDSC, are predominant at the expense of cytotoxic T lymphocytes, indicating that the phenotype is immunosuppressive[32,44,47]. This aspect implies that the immune system is faulty, most likely due to cancer itself, which causes local and systemic immunological dysfunction escaping the immune system's detection[48,49].



Furthermore, the tumor microenvironment contributes to the development of PanCa promoting a Th2 polarization with the production of higher levels of interleukin (IL)-17 and IL-10 and reduced production of interferon-γ, which promotes cancer progression[28,50]. The presence of this microenvironment kind and a dense stroma represents a unique PanCa peculiarity[51]. Interestingly, smoke habits impact microbiota inducing immunosuppression with reduced levels of IgG and the making of biofilms, hence possibly promoting the proliferation of harmful bacteria[30]. In an experimental setting, Pushalkar *et al*[28] demonstrated that germ-free mice did not show PanCa progression, while fecal microbiota transplantation received from sick mice hampered Th1 differentiation of CD4+ and activation of CD8+ T cells hence causing cancer progression.

In humans, *Citrobacter freundii* was found to be associated with immunosuppression and the activation of several oncogenic pathways. Furthermore, the enrichment of nine microbes including *Acidovorax ebreus* and *Shigella sonnei* was related to the downregulation of tumor-suppressive pathways and immune dysregulation with reduced levels of M2 macrophages, activated memory, and CD8+ T cells[51]. *H. pylori* infection of human PanCa tissue was reported to be associated with higher levels of IL-8 and vascular endothelial growth factor and with the proliferation of several factors including nuclear factor-κB, activator protein 1, and serum response element[52].

Malassezia can interact with the MAPK pathway causing the production of high levels of proinflammatory cytokines, including IL-6, and can activate mast cells[31]. Similarly, *Trichosporon* can increase the level of IL-6, tumor necrosis factor-α, and interferon-γ[8]. *Candida* triggers inflammatory response (Th17-mediated), activating the MDSCs[10,43]. *Porphyromonas gingivalis* and *Aggregatibacter* activate, similarly to *Bifidobacterium pseudolongum*[53], the TLR signaling pathway increasing the risk of PanCa development in both animal models and humans[28,54]. Different studies documented that mice deficient in pattern recognition receptors signaling, including TLR 4, TLR7, TLR9, and mincle, show less PanCa progression[53,55,56].

In this scenario, another critical pattern recognition receptors is the mannose-binding lectin (MBL). The complement cascade is triggered when MBL binds to the glycans of the fungal wall, for example, *Malassezia*. The MBL-C3 axis might be involved in cancer development given that extratumoral suppression of MBL or C3 was associated with a lower risk of PanCa onset and MBL- or C3-deficient mice showed greater defense against PanCa progression[31].

Each component of the microbiota might be implicated in PanCa through different pathogenetic mechanisms and the role of fungal dysbiosis is still far from being completely explored and understood. Figure 1 summarizes this complex relationship.

Figure 1 Pathogenetic models. This figure aims at simplifying the complex interplay between microbiota in different anatomical districts and the immune system in carcinogenesis. Each component of the microbiota might be implicated in pancreatic cancer through different pathogenetic mechanisms. LPS: Lipopolysaccharide; NF-kB: Nuclear Factor kB; HBV/HCV: Hepatitis B/C virus; MBL: Mannose-binding lectin; TLR: Toll-like receptor; Treg: T regulatory.

CURRENT TREATMENTS FOR PanCa

Impact of microbiota in surgical treatment

Whenever technically feasible and oncologically appropriate, surgical treatment is the best chance of cure that could be offered to the patients.

In a small prospective study, both pre- and postoperative gut microbiota was found to be enriched in *Akkermansia, Aeromonas, Enterobacteriaceae, Bacteroidales* and decreased in *Lachnospiraceae, Prevotella,* and *Faecatitalea*. Furthermore, *Bacteroides* were more frequently associated with higher postoperative morbidity, longer hospital stays, and longer intensive care unit stay[57].

When patients present with severe jaundice, a biliary drain is required before surgery. On the one hand, biliary drain could cause bile contamination; on the other hand, it could restore physiologic bile flow permitting the maintenance of gut eubiosis. The percentage of bile contamination in stented patients was reported to be up to 92% of the samples collected during surgery, while fungal presence was found in 25% of the patients. Fungal presence was directly related to the longer period between biliary drain positioning and surgery[58]. A frequent presence of at least one bacterial species showing antibiotic resistance was also reported, and these patients presented with significantly higher rates of postoperative morbidity[37]. In a large retrospective analysis of 1964 patients undergoing pancreatoduodenectomy and receiving preoperative biliary drain, 30.8% of them presented biliary contamination with the most common contaminants being *Enterococcus, Klebsiella*, and *Enterobacter*.

Postoperative pancreatic fistula (POPF) is the main postoperative complication following pancreatic surgery, and it is related to higher morbidity rates. Bile contamination was an independent risk factor for POPF grade B/C with an odds ratio of 1.33. Furthermore, bile contamination was associated with wound and catheter infections[36]. Similar data were reported in successively published papers[59]. Coppola *et al*[60] found in the bile different microbes related to different complications: *E. coli*, *Klebsiella pneumoniae (K. pneumoniae)*, and *Enterococcus faecalis* were prevalent in surgical site infections; *E. coli*, *K. pneumoniae*, *Enterococcus faecalis*, and *Enterococcus faecium* were more abundant in POPF; and *E. coli*, *Enterococcus faecalis* and *Enterococcus faecium* were found in delayed empty gastric syndrome. Abe *et al*[61] analyzed the cultures of drainage fluid from patients undergoing pancreatic surgery. They found that the presence of *Enterobacter* species, *Enterococcus* species, and *Candida* species was significantly associated with clinically relevant POPF. Furthermore, the presence of *Candida* species resulted in being an independent factor for POPF C and POPF-related hemorrhages[61,62]. On the contrary, in other

studies (with a restricted number of patients), bactobilia or fungal bile contamination were not reported to be associated with higher POPF rates or different global morbidity and mortality rates[58,63]. Different population samples and geographic bias in defining POPF or in sample collection and analysis could at least partially explain the differences.

Impact of microbiota in chemotherapy response

In the setting of advanced stages, traditional chemotherapy, mainly based on the FOLFIRINOX regimen (5-fluorouracil, oxaliplatin, and irinotecan) or gemcitabine with or without cisplatin or nab-paclitaxel, has a pivotal role. Chemoresistance is one of the most challenging aspects of systemic treatment.

Microbiota affects gemcitabine response thus influencing patients' prognoses. Most of the PanCa-associated abundant bacteria, including *K. pneumoniae* and other species from the *Gammaproteobacteria*, are cytidine deaminase producers. The production of this enzyme results in higher gemcitabine degradation and consequent chemoresistance[30]. Consistently, quinolone administration in patients infected with *K. pneumoniae* allowed for a better prognosis[64]. Nevertheless, gemcitabine use can alter the gut microbiota composition being a potential cause of PanCa progression[65], and the use of antibiotics increases side effects[66]. Adding *Lactobacillus paracasei* improved gemcitabine response in mouse models[67]. Similarly, *Lactobacillus spp*. reduced diarrhea, which is one of the most common side effects of chemotherapy based on irinotecan[42].

Although evidence is still scarce, the use of oncolytic viruses, mostly adenovirus, in combination with gemcitabine may improve its efficacy through different mechanisms including an antitumor immunity booster activity[68].

Other relations between microbiota and response to chemotherapy have been tested for other kinds of solid cancer, and specific data on PanCa are still needed[42].

Impact of microbiota in immunotherapy

Immunotherapy resulted in a game-changer in the treatment of several solid malignancies in the recent decade, and the inhibition of immunological checkpoints has been the most explored strategy for eliciting an antitumor immune response[69,70]. The immune checkpoint inhibitors are monoclonal antibodies targeting molecules, such as the programmed cell death protein 1/programmed death-ligand 1 or cytotoxic T-lymphocyte antigen 4 expressed by tumor or immune cells.

PanCa is one of the cancers for which no immunotherapeutic drugs have been licensed since many clinical trials have failed to show a benefit in terms of response rate and survival[42]. The weak success of the immune checkpoint inhibitor treatment is due to the immunologically "cold" phenotype characterized by the low mutation load and limited expression of neoantigens in PanCa in addition to the immunosuppressive action of the resident stromal cells. Although the fine mechanism of interaction between the microbiota and the immune system in PanCa needs to be examined in-depth, the combination of immune checkpoint inhibitors and chemotherapy could produce promising results. For example, specific polymeric nanoformulations of oxaliplatin and doxorubicin can upregulate the damage-associated molecular patterns expression in PanCa models, activating dendritic cell maturation and adaptive immune response[71]. These two nanoformulations act both by preventing tumor growth and by showing a prophylactic action through inoculation in Pan02 mouse models.

Vaccines are the most effective way to overcome the PanCa hypoimmunogenicity, and nanotechnologies can enhance their immunostimulatory effects[72].

Recent studies have highlighted the importance of stromal macrophages demonstrating the possibility to restore antitumor immunity. The employment of TLR agonists and kinase inhibitors can induce an M1-like polarization. Different PanCa models have been treated with nanoformulations with the ability to reprogram the macrophages phenotype, showing excellent results[73,74].

OTHER IMPLICATIONS OF MICROBIOTA ALTERATIONS AND OTHER FUTURE PERSPECTIVES

Modifying microbiota composition to reduce the risk of PanCa development

As previously reported, several modifiable risk factors have been recognized including smoking habits, alcohol abuse, and diet (high meat intake and low fruit consumption). It is expected that about a quarter of PanCa could be avoided by acting on these factors[9,75]. Since most of them are strictly connected with the microbiota, the possibility to modulate its composition or function could be a promising tool against cancer. There is an ongoing phase II randomized clinical trial (NCT04631445) analyzing the effect of a ketogenic diet in metastatic patients receiving chemotherapy, but unluckily the microbiota evaluation is not included.

A growing number of studies are analyzing the potential role of the so-called "next-generation probiotics" or "live biotherapeutics" that includes short-chain fatty acids producers. These microbes are implied in maintaining the intestinal barrier integrity with the reduction of bacterial translocation and in the reduction of fungal overgrowth[2]. But, to date, specific results of the effects on PanCa are lacking.

In animal models, the 4-wk oral administration of the probiotics *Lactobacillus paracasei* and *Lactobacillus reuteri* alone or combined with an intraperitoneal injection of gentamicin was related to a lower chance of developing precursors of PanCa. Furthermore, they allowed a lower increase of liver enzymes caused by gemcitabine[76]. Similarly, oral administration of the probiotic *Aspergillus oryzae* showed an antitumoral activity. The heptelidic acid was the involved bacterial-produced molecule able to pass the intestinal barrier, reach other organs, and induce apoptosis through the p38 MAPK signaling pathway [77].

In experimental studies with xenografts, Sethi *et al*[50] found that administration of oral antibiotics causing bacterial depletion achieved an antitumor effect through a switch from Th2 immune phenotype toward a Th1 differentiation of CD4+ T cells, with the activation of CD8+ T cells, lower levels of MDSCs, and finally an increase in M1 macrophage differentiation together with lower levels of the protumor IL-17a and IL-10 in the tumor microenvironment. Furthermore, these changes were not seen in T and B cells-deprived animals. Similarly, the administration of oral antibiotics to wild-type mice caused a reduction of the PanCa size by 50% through the reversing of the immunosuppressive tumor microenvironment[28].

Further research about microbial engineering strategies that could allow on-site recruitment of CD8+ T cells *via* interferon-γ production or interaction with the complement cascade is strongly warranted[2].

Despite few specific studies being available, the fecal microbiota transplant through modifying the entire gut microbiota ecology, could represent a great opportunity in PanCa treatment. Experiments in fecal microbiota transplantation animal models confirmed the responsibility of gut microbiota in the modulation of the intratumoral microbiome[78].

Drug delivery systems are bio-responsive elements able to change and thus release drugs in a particular microenvironment (*e.g.*, low level of pH, hypoxia, or presence of specific enzymes). Consequently, the drug delivery systems have been recently proposed as a promising instrument for microbiota modulation through the delivery of pre/probiotics with the capability of depleting protumoral bacteria and eliminating their toxins[79].

However, specific studies are needed to introduce this promising tool in routine clinical practice.

Microbiota as a biomarker of PanCa

Since complete PanCa prevention is not expected, an early diagnosis would be of great help in widening the chance to cure the patients.

Within the species found to be increased/decreased in the saliva of the affected patients compared to the control group, *Neisseria elongata* and *Streptococcus mitis* resulted in a distinguishing signature of PanCa with a sensitivity of 96.4% and a specificity of 82.1% representing a potential biomarker for early cancer detection[23]. In the saliva of the PanCa patients, the ratio of *Leptotrichia* and *Porphyromonas* was reported to be significantly higher compared with the control group[53]. The presence of a high level of serum antibodies against *Porphyromonas gingivalis* was found to be associated with a two-fold higher risk of developing PanCa within 5 years, while high levels of anti-commensal microbe antibodies seemed related to a reduced risk of PanCa[11].

Kim *et al*[80] found that altered human microbiota composition evaluated with microbial extracellular vesicles from blood samples could represent a novel biomarker. Six species, *Ruminococcaceae UCG-014, Lachnospiraceae NK4A136 group, Akkermansia, Turicibacter, Ruminiclostridium,* and *Lachnospiraceae UCG-001*, were more abundant, while four species, *Stenotrophomonas, Sphingomonas, Propionibacterium*, and *Corynebacterium*, were less represented in PanCa patients. With these findings, a prediction model for PanCa was built, and the related area under the receiver operating characteristic curve was 1.000[80].

Furthermore, experiments with spontaneous PanCa in animal models demonstrated that the polyamine metabolism of some gut bacteria including *Lactobacillus* was significantly dysregulated in the very early stages of PanCa[1].

Unfortunately, none of the presented potential biomarkers is available in clinical practice[21]. So, further studies are strongly warranted to validate new diagnostic tools.

Prognostic value of changes in the microbiota of the PanCa patients

One of the most frequently asked questions by patients affected by cancers is about their prognosis. The finding of further prognostic markers, other than the well-known staging systems, could help doctors answer this patient concern.

Riquelme *et al*[78] compared the disparity in microbiota composition of the PanCa tissue of the patients with different prognoses using 16S rRNA gene sequencing. Long-term survivors (alive 5 years after surgery) showed the highest alpha-diversity and a particular signature composed of *Pseudoxanthomonas, Streptomyces, Saccharopolyspora,* and *Bacillus clausii* with an area under the curve of 97.5%. Furthermore, this group of bacteria was associated with greater activation of CD8+ T cells. Furthermore, gut microbiome from short-term survival could induce PanCa onset in a mouse model through the establishment of an immunosuppressive environment suggesting the role of both intrapancreatic and gut microbiome[28,78]. Tumors showing a lower immunosuppressive environment (more neoantigens MUC16 - CA 125 - and CD8+ T cells) confer longer survival rates[81].

Using data from The Cancer Genome Atlas, Chakladar *et al*[51] found that only *Acidovorax ebreus* was linked to a high tumor grade. A significantly higher microbial biodiversity in metastatic and short-survival patients with a predominant percentage of Proteobacteria, particularly *Acidovorax ebreus* and members of the *Gammaproteobacteria*, was also reported. *Citrobacter freundii* and *Shigella sonnei* were associated with the dysregulation of cancer-associated pathways. Furthermore, they found different microbes associated with survival and metastasis. Analyzing The Cancer Genome Atlas database, a prognostic score was proposed by other authors. The high tumor score was associated with p53 mutation, higher tumor mutational burden, and unfavorable and immunosuppressive tumor microenvironment. This high score was found to be related to increased cell proliferation and a higher chance of achieving a positive margin following surgery[82].

In a study with almost 300 PanCa patients, the presence of *Fusobacterium* species was found to be an independent factor of higher mortality[83]. Similarly, the presence of *Pseudomonas aeruginosa* was found to be a negative prognostic biomarker[41].

CONCLUSION

The complex interplay between microbiota and the immune system at different anatomical districts (mostly gut and pancreas/intratumor) might have a role in both the onset and progression of PanCa. Due to the poor prognosis of this tumor despite global advances in surgery and perioperative management, every effort to find new potential targets is welcome. Modifications in microbial composition related to cancer onset could be both a promising target for microbiota shaping and cancer treatment and a potential biomarker for early cancer detection. With the progressive advances in microbiota knowledge, new possibilities for treatment and patient stratification could be expected in the coming years with an improved prognosis for patients with PanCa.

Abstract

Hepatocellular carcinoma (HCC) is the sixth most common cancer. The main risk factors associated with HCC development include hepatitis B virus, hepatitis C virus, alcohol consumption, aflatoxin B1, and nonalcoholic fatty liver disease. However, hepatocarcinogenesis is a complex multistep process. Various factors lead to hepatocyte malignant transformation and HCC development. Diagnosis and surveillance of HCC can be made with the use of liver ultrasound (US) every 6 mo. However, the sensitivity of this imaging method to detect HCC in a cirrhotic liver is limited, due to the abnormal liver parenchyma. Computed tomography (CT) and magnetic resonance imaging (MRI) are considered to be most useful tools for at-risk patients or patients with inadequate US. Liver biopsy is still used for diagnosis and prognosis of HCC in specific nodules that cannot be definitely characterized as HCC by imaging. Recently the American College of Radiology designed the Liver Imaging Reporting and Data System (LI-RADS), which is a comprehensive system for standardized interpretation of CT and MRI liver examinations that was first proposed in 2011. In 2018, it was integrated into the American Association for the Study of Liver Diseases guidance statement for HCC. LI-RADS is designed to ensure high sensitivity, precise categorization, and high positive predictive value for the diagnosis of HCC and is applied to "high-risk populations" according to specific criteria. Most importantly LI-RADS criteria achieved international collaboration and consensus among liver experts around

the world on the best practices for caring for patients with or at risk for HCC.

Key Words: Hepatocellular carcinoma; Hepatocarcinogenesis; Computed tomography; Magnetic resonance imaging; Liver Imaging Reporting and Data System

Core Tip: Worldwide, hepatocellular carcinoma (HCC) is the sixth most common malignancy and fourth cause of cancer-related death. Progress on the diagnosis and treatment possibilities of HCC has been made over the past decades. We herein review the available knowledge on the carcinogenesis, surveillance of HCC, and relevant data with the Liver Imaging Reporting and Data System (LI-RADS) algorithm that was recently integrated into the American Association for the Study of Liver Diseases clinical practice guidelines. LI-RADS aims to avoid false-positive examinations and ensure high sensitivity and positive predictive value in high-risk populations with simultaneous achievement of probabilistic categorization of the tumor.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the sixth most common cancer and the third leading cause of cancer-related death worldwide[1]. Up to 90% of HCC cases arise on the background of established liver cirrhosis or advanced fibrosis, which has been developed due to a known etiology[2]. The most predominant risk factors for HCC worldwide are hepatitis B virus (HBV), hepatitis C virus (HCV), alcohol consumption, and nonalcoholic fatty liver disease[3].

The prognosis of HCC is significantly influenced by the disease stage at the time of diagnosis. Patients with HCC detection at an early stage can be treated with potentially curative therapies[4]. Imaging plays an important role in the early diagnosis of HCC, both in the context of surveillance strategies of at-risk populations and in the phase of confirmatory studies for a new liver nodule. Most importantly, imaging studies for the diagnosis of HCC, usually performed with computed tomography (CT) or magnetic resonance imaging (MRI), have approximately 100% specificity. Therefore, HCC is among the few malignancies for which management can be established on the basis of noninvasive imaging, without histologic confirmation[5].

CT and MRI are extensively used in clinical practice for the diagnosis of HCC. However, their diagnostic accuracy is decreased when strong criteria are not applied. In addition, the variable algorithms and recommendations from different scientific societies have created some degree of confusion in the interpretation of the radiological findings. To standardize the performance of liver imaging in patients with risk factors for developing HCC, the American College of Radiology (ACR) introduced in 2011 the first version of the Liver Imaging Reporting and Data System (LI-RADS)[6]. The LI-RADS criteria were created to standardize the terminology used for HCC imaging, allow probabilistic categorization, and provide personalized medical care[7]. It has been updated in 2013, 2014, 2017, and 2018 and is considered a dynamic document, which can be expanded and refined in response to new knowledge and user feedback[8].

In this pictorial review, we analyze the rational for the radiological diagnosis of HCC, present the LI-RADS criteria and associate them with characteristic images per category in order to enhance the familiarization of clinicians with the use of this system in clinical practice.

HEPATOCARCINOGENESIS AND IMAGING CORRELATES

Hepatocarcinogenesis is a complex multistep process characterized by alterations at several levels (molecular, cellular, and histologic levels). Chronic liver inflammation can lead to continuous cycles of persistent cell injury, death, and regeneration, causing subsequent genetic damage and epigenetic alterations of hepatocytes[9]. Various factors lead to hepatocyte malignant transformation and HCC

development, such as genetic susceptibility, mutual interplays between viral and non-viral risk factors, cellular microenvironment, immune cells, and the severity of the underlying chronic liver disease. An altered microenvironment plays a significant role in all stages of neoplastic growth, from the early mutation stage, through to invasion, and eventually, to metastatic stage[10,11].

The molecular pathogenesis of HCC varies according to the distinct etiologies[10]. HBV and HCV are the two main viruses, which can be implicated in the development of HCC[12]. HBV genome integration can target cancer-relevant genes, and protein x can alter the expression of growth-control genes and inactivate the tumor suppressor p53 leading to HCC development[12,13]. On the other hand, HCV infection is not characterized by oncogenic effects; however mutations can result from oxidative stress caused by chronic inflammation[12]. Alcohol-induced hepatocarcinogenesis is another risk factor for developing HCC. Chronic alcohol intake is associated with proinflammatory cytokine production and oxidative stress, which can lead to the development of fibrosis, cirrhosis, and ultimately HCC[14]. Aflatoxin-B1 also plays a role in hepatocarcinogenesis. This fungal toxin is associated with a specific *p53* mutation and activation of oncogenes such as the Human Harvey-ras proto-oncogene[15,16].

Irrespective of etiology, cirrhosis is the main underlying cause for most HCC cases. During cirrhosis, regenerating nodules are developed, which provide an appropriate microenvironment for the development of normal hepatocytes to dysplastic hepatocytes to neoplastic lesions and culminating in HCC through the subsequent agglomeration of multiple DNA alterations[17]. Histologically, abnormal precursor hepatic lesions including cirrhotic nodules, low-grade dysplastic nodules, and high-grade dysplastic nodules dedifferentiate and progressively develop to form early and eventually advanced HCCs[5]. This continuum biologic procedure may happen simultaneously at various rates in different parts of the liver.

During hepatocarcinogenesis, the vascular supply of the nodules modifies together with malignant progression and the number of intranodular portal tracts diminishes progressively, while the number of unpaired arteries increases. Eventually, HCC is supplied mainly by the abnormal hepatic artery system *via* neoangiogenic unpaired arteries[18]. It is important for both clinicians and radiologists to understand these hemodynamic changes during hepatocarcinogenesis as these are correlated with the enhancing pattern precursor hepatic lesions and finally of HCCs on imaging studies. Arterial phase hyperenhancement and portal venous and/or delayed phases wash-out relative to the background liver on contrast enhanced multiphasic CT and MRI are the most important imaging features of HCC and are correlated with the blood supply of the nodules with malignant transformation.

Features during hepatocarcinogenesis also include tumor capsule and fibrous septa formation and fat accumulation within hepatocytes during the early phases (dysplasia and early HCC), while fat usually regresses with the progression to overt HCC.

Iron may also accumulate within hepatocytes during the dysplastic phases of hepatocarcinogenesis and usually also regresses with progression to HCC. Finally organic anionic transporting polypeptides expression declines during hepatocarcinogenesis (organic anion transporting polypeptide 8 expression levels decrease during hepatocarcinogenesis prior to reduction in portal tracts and increases in unpaired arteries). It is worth noting that abnormal venous drainage of HCCs occurs during hepatocarcinogenesis from hepatic veins to sinusoids and then to portal veins, which may explain why HCC has a tendency to spread through the portal venous system rather than hepatic veins[5].

HCC DIAGNOSIS

Early diagnosis of HCC is enhanced by the use of surveillance strategies in certain populations that are at risk of developing HCC. Typically these patients include cirrhotic patients with Child-Pugh stage A and B as well as cirrhotic patients with Child-Pugh stage C awaiting liver transplantation[19,20]. Regarding patients with chronic hepatitis B, the use of risk scores (especially PAGE-B) is recommended to prioritize patients for surveillance[21]. Finally, it is recommended that patients with severe fibrosis enter surveillance programs on an individual basis after careful assessment of their risk[19,20]. Regarding tools that should be used for surveillance, most international societies recommend only the use of abdominal ultrasound (US) every 6 mo, as the use of alpha-fetoprotein is still controversial[19,20]. CT or MRI may be utilized for surveillance in selected patients with inadequate US visualization or at high risk for inadequate US[20].

Once a new nodule is discovered in the liver of a cirrhotic patient, further imaging work-up with either CT or MRI is recommended[19,20]. These modalities are also the gold standard for HCC diagnosis outside the use of surveillance programs. The peculiar vascular derangement that occurs during hepatic carcinogenesis, as previously described, correlate with imaging phases and have led to the implementation of accurate non-invasive criteria for HCC diagnosis. Integration of LI-RADS version 2018 into the American Association for the Study of Liver Diseases (AASLD) HCC clinical practice guidelines, was a major step. As a result, the AASLD management suggestions are directly associated with the LI-RADS categories[20].

The routine use of liver biopsy is not suggested for the diagnosis of HCC[20]. Biopsy shortcomings include risks associated with the procedure. Another important issue is that small lesions < 2 cm are

often difficult to target in a cirrhotic liver leading to high false negatives. However, the role of tumor tissue analysis in HCC is essential in cases of a cirrhotic patient that lacks typical imaging characteristics or in cases where molecular profiling is needed to determine systemic therapy options[22]. It should also be noted that the diagnosis should be confirmed with pathology in non-cirrhotic patients[19]. In all of these cases, the pathological diagnosis of HCC should be based on International Consensus recommendations using appropriate histopathological analyses and immunohistochemistry[23,24].

DESCRIPTION OF LIRADS

LI-RADS has provided a standardized guidance, which contributes to a universal language for liver imaging findings. All LI-RADS diagnostic tables can be found for free at the ACR website (https://www.acr.org/ClinicalResources/Reporting-and-Data-Systems/LI-RADS). By philosophy, LI-RADS diagnostic algorithm is developed to ensure high specificity and positive predictive value (PPV) for HCC diagnosis to avoid false-positive examinations. To obtain a high PPV, LI-RADS should be used only to populations at high risk for developing HCC[25]. This "high-risk population" includes adult patients with liver cirrhosis (except for vascular causes of cirrhosis), chronic HBV infection with or without cirrhosis, and patients diagnosed with current or prior HCC (Figures 1 and 2)[26].

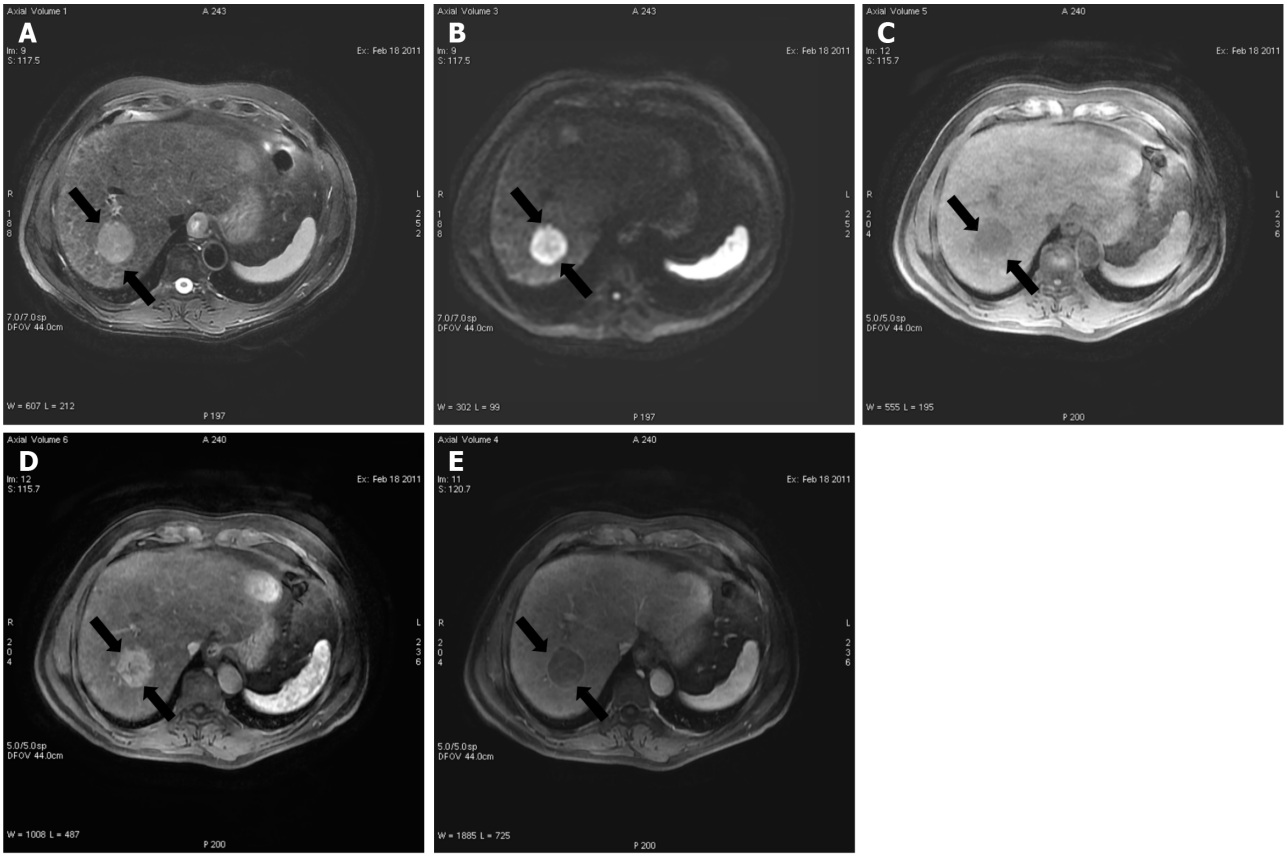
Determining patients who meet the at-risk criteria is not always easy. Cirrhotic patients are usually diagnosed based only on clinical signs, symptoms, and diagnostic markers with or without histological confirmation.

Measurement of liver stiffness using FibroScan could be a useful predictor of HCC appearance in patients with chronic hepatitis B and/or C[26]. If the patient is considered with a high pre-test probability of HCC, LI-RADS may be used with a recommendation that the referring physician confirms the patient's risk status (Figure 3).

Although HCC may develop in patients with non-alcoholic fatty liver disease/steatohepatitis without cirrhosis, sufficient data are lacking to support that LI-RADS would provide an adequately high PPV for HCC in this sub-cirrhotic population group[27]. LI-RADS does not apply to patients < 18-years-old and patients with liver cirrhosis due to vascular diseases (*e.g.*, cardiac hepatopathy, Budd-Chiari syndrome), because the above-mentioned diseases are characterized by hypervascular benign liver lesions in liver imaging, which raise the probability of false positive results and reduce the PPV for HCC diagnosis[17].

LI-RADS CATEGORIES

LI-RADS CT/MRI Diagnostic Algorithm version 2018 (v2018) is characterized by eight diagnostic categories, which are used for individual liver lesions with increasing probability of HCC and malignancy with higher categories. The several LI-RADS categories do not have an exact association to the histologic categories but instead reflect the probability of individual liver lesions being benign, HCC, or non-HCC malignancy. The LI-RADS CT/MRI algorithm is used in a stepwise manner starting with LR-not categorizable (NC). It is followed by LR-tumor in vein (TIV), LR-1, LR-2, and LR-M. Once the above categories are excluded, the CT/MRI diagnostic table is used to determine an observation LR-3, LR-4, or LR-5 category (Figure 4). LI-RADS criteria uses the term observation to generically refer to an area with an imaging appearance that is distinctive from the rest of the liver. Such an area may be a true lesion or a pseudolesion.



LR-NC

CT and MRI need to meet minimal technical requirements to yield the desired diagnostic accuracy. For CT, multidetector CT (≥ 8 detectors) is requisite, whereas for MRI, 1.5 or 3 T magnets are required according to LI-RADS guidance. Administration of intravenous contrast and acquisition of a multiphase liver protocol including images before contrast, late hepatic arterial phase, portal venous phase, and delayed phase images is required to allow for diagnosis of HCC[20]. The most important characteristic is the acquisition of a technically adequate and well-timed arterial phase.

LI-RADS guidance strongly suggests that imaging should be performed during the late arterial phase, *i.e.* when the hepatic artery and portal vein are both enhanced, as this correlates with the time when arterialized tumor tissue is maximally enhanced relative to background liver (Figure 5). If an observation cannot be categorized due to image degradation or omission, then radiologists may choose to assign an LR-NC category (Figure 6). LI-RADS currently does not provide guidance on scoring the severity of artifact. In these cases, radiologists should use their judgment in suggesting either repeat or alternative imaging within 3 mo to better characterize the liver lesion.

LR-TIV

The presence of TIV should be ruled out. LR-TIV category is defined by definite enhancing tissue with a vein, indicating the presence of TIV. Whenever is possible the most likely etiology of TIV should be

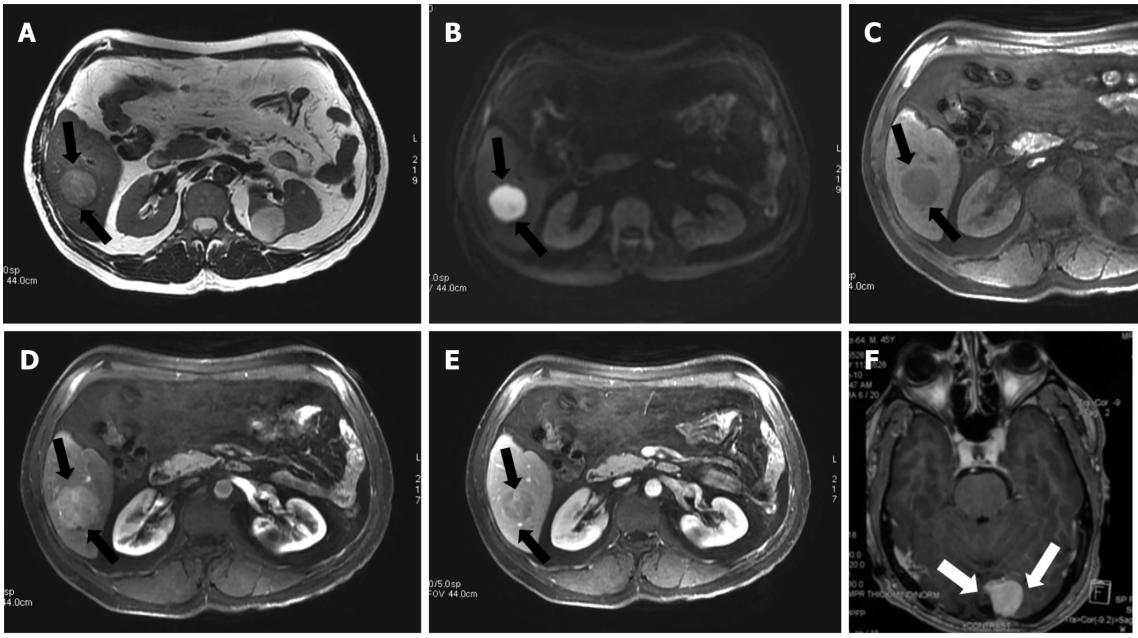
Figure 1 A 52-year-old male with hepatocellular carcinoma and chronic hepatitis B. A: A segment VII mass showed a high signal on the short tau inversion recovery image; B: High on diffusion-weighted imaging; C: Low on unenhanced volumetric interpolated breath-hold examination image; D: Non-rim arterial phase hyperenhancement on arterial phase; E: Washout and enhancing capsule on portal phase. Lesion showed typical imaging findings of hepatocellular carcinoma categorized as LR-5 according to Liver Imaging Reporting and Data System criteria.

assigned (due to HCC or non HCC malignancy) (Figures 7 and 8).

LR-1 definitely benign

LR-1 is applied to observations that are benign. Management should be returned to routine surveillance at 6 mo intervals.

LR-2 probably benign



LR-2 is applied to observations that are probably benign. Management should be returned to routine surveillance at 6 mo intervals (Figure 9).

LR-M

LR-M for HCC observations display imaging characteristics of malignancy but not features that are specific. The LR-M category was created to maintain the specificity of the LI-RADS guidance for diagnosis of HCC while not losing sensitivity for liver malignancies. LR-M features include a targetoid or non-targetoid mass with infiltrative appearance, marked diffusion restriction, necrosis, or other characteristics suggestive of non-HCC malignancy[28]. Targetoid mass is defined by rim enhancement in the arterial phase, peripheral washout, and progressive central enhancement on delayed phases. Although any liver malignancy can appear with characteristics of LR-M, the most common entities in patients at increased risk for developing HCC are intrahepatic cholangiocarcinoma (CCA), combined tumors (CCA-HCC), and atypical HCC. LR-M observations are commonly biopsied to propose the appropriate treatment (Figure 10).

LI-RADS diagnostic table

If the above categories (LR-TIV, LR-M, LR-1, and LR-2) are considered and excluded, the radiologist should use the LI-RADS diagnostic criteria based on combinations of major imaging features. The diagnostic table includes the predominant imaging characteristics of HCC in order to generate categories ranging from intermediate probability to definite HCC (LR-3, LR-4, LR-5). For CT and MRI, the LI-RADS predominant characteristics consist of the following: (1) Size; (2) The presence of non-rim

DOI: 10.3748/wjg.v28.i32.4540 **Copyright** ©The Author(s) 2022.

Figure 2 A 45-year-old man with a segment VI lesion. A: The lesion demonstrated a high signal on T2 weighted image; B: High on diffusion-weighted imaging; C: Low on volumetric interpolated breath-hold examination; D: Non-rim arterial-phase hyper-enhancement on arterial-phase image; E: Washout on portal phase. If we applied Liver Imaging Reporting and Data System (LI-RADS) criteria, the erroneous diagnosis of hepatocellular carcinoma could be made. However, the patient did not meet the at-risk criteria to apply LI-RADS. Histologic examination of the lesion demonstrated metastatic hemangiopericytoma; F: Magnetic resonance imaging of the brain, axial post-contrast T1-weighted image showed an extra-axial lobulated, occipital enhancing mass corresponding to recurrence of hemangiopericytoma 12 mo after total surgical excision.

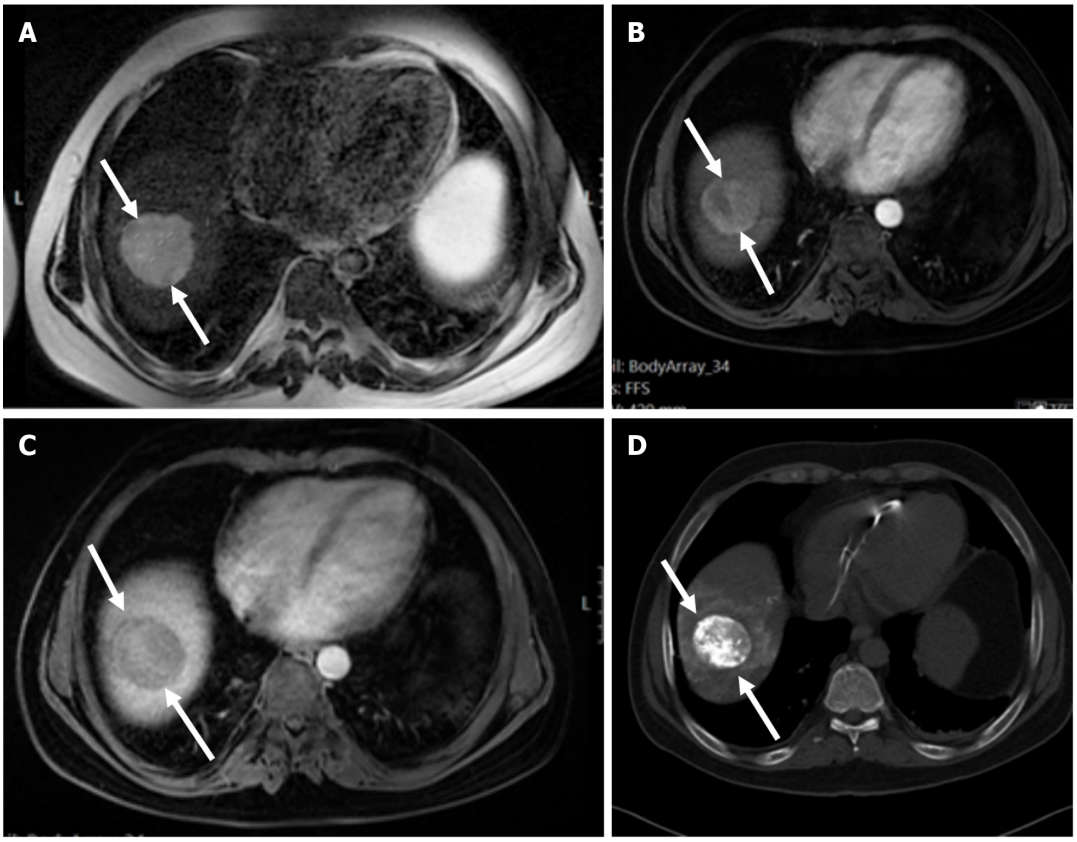
arterial phase hyperenhancement (APHE), which is defined by the appearance of enhancement that is unequivocally significantly than that of the background liver[29]. On MRI the enhancing portion must have higher intensity and on CT higher attenuation than background liver in the arterial phase; (3) Non-peripheral washout, which is defined as a visually assessed temporal decrease in enhancement in whole or at least in part relative to composite liver tissue from earlier to later phase leading to hypoenhancement; and (4) Enhancing capsule, which is defined as a smooth, uniform, and sharply outlined area of enhancement around a liver lesion which is either thicker or more conspicuous than fibrotic tissue detected in chronic liver disease.

It is worth mentioning that no single major imaging characteristic in the algorithm is specific enough to categorize a liver lesion as LR-5, and that LI-RADS liver lesions less than 10 mm in diameter cannot be categorized as LR-5.

LR-3 intermediate probability of malignancy

Liver lesions categorized as LR-3 have intermediate probability of being considered HCC, and the recommendation is to undergo short follow-up imaging in 3 to 6 mo (Figures 11 and 12).

LR-4 probably HCC



Observations categorized as LR-4 have a high probability of being considered definite HCC, and the suggestion is for an individualized multidisciplinary approach that may comprise biopsy, probable treatment, or follow-up (Figure 13).

LR-5 definitely HCC

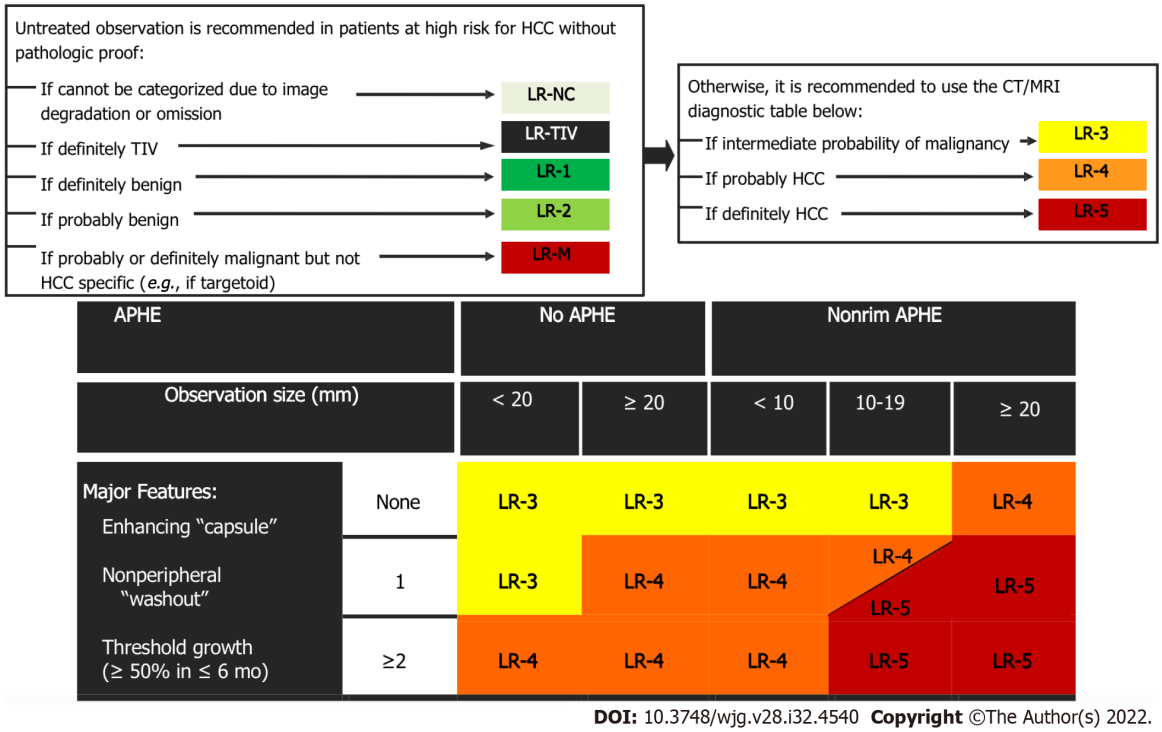
It is worth noting that for LR-5 categorization, non-rim APHE must be present. The criteria for LR-5 category has a PPV approaching 100% in patients at high risk for developing HCC. Liver lesions categorized as LR-5 are considered definite HCC and therefore staging and treatment is suggested without biopsy (Figures 14-17).

Ancillary features

Ancillary features (AFs) can be used at the radiologist's discretion to adapt the category and to enhance the ability for reaching the final diagnosis. Although AFs are an important component of LI-RADS, their impact may be small (Figure 13). Various AFs likely can be taken out from LI-RADS criteria without compromising diagnostic performance[30].

DOI: 10.3748/wjg.v28.i32.4540 **Copyright** ©The Author(s) 2022.

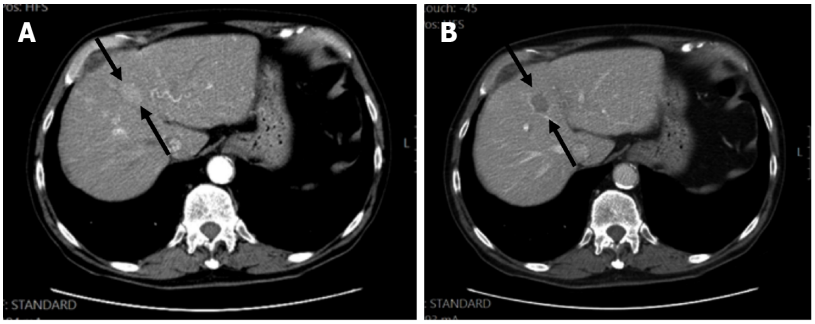
Figure 3 A 47 mm liver mass was incidentally found, in a 40-year-old man with beta thalassemia, during cardiac magnetic resonance investigation for myocardial iron overload. A-C: On abdominal magnetic resonance imaging, the lesion demonstrated high signal intensity on T2 weighted image (A), arterial phase hyperenhancement on post-contrast arterial phase (B), and washout on portal phase (C). Although there are no current evidence-based guidelines for patients with beta thalassemia without cirrhosis, the hepatologist confirmed the patient's risk status and proposed that Liver Imaging Reporting and Data System (LI-RADS) should be applied. According to the LI-RADS criteria, the lesion was categorized as LR-5 (definite hepatocellular carcinoma); D: Unenhanced computed tomography scan after transarterial chemoembolization showed accumulation of iodized oil (arrow) within the tumor.



Treatment response algorithm (LI-RADS)

LI-RADS treatment response guidance (LR-TR) offers imaging criteria for evaluation of the success rate of locoregional therapy (Figures 17, 18, and 19). However, the guidance is not created for evaluating the response to systemic therapy, which is often at the patient-level rather than a lesion-level evaluation.

LI-RADS IN CLINICAL PRACTICE



The LI-RADS "lexicon" provide strict diagnostic criteria and reporting guidelines in order to enhance the consistency and clarity of radiologist interpretation and reporting. Subsequently, the communication between radiologists and clinicians has been improved. The adoption of a universal liver imaging lexicon is of great importance. This lexicon was designed to standardize the terminology used to describe liver imaging findings and is suggested for use in various patient settings including patients with cirrhosis, chronic HBV infection, current or prior HCC and following loco-regional therapy to assess tumor response[31,32]. In this sense, the integration of LI-RADS into the AASLD HCC clinical practice guidelines was a major achievement. However, global unification of diagnostic algorithms of HCC is still an unmet need.

Variability in terminology and definitions creates confusion between clinicians and challenges the significance of the published literature. For example, multiple terms have been used to describe nodules without APHE that are hypointense in the hepatobiliary phase of a gadoxetate-enhanced MRI examination[33]. The LI-RADS Hepatobiliary Agent Working Group suggests standardized terminology for these nodules: "hepatobiliary phase hypointense nodules without APHE." A single term with a uniform definition enhances the ability of scientific investigators to define and pool data associated with these nodules and assists radiologists and referring clinicians in interpreting their clinical significance [31]. However, there are still areas of uncertainty. Non-cirrhotic patients at increased risk for developing HCC, such as those with chronic HCV infection or nonalcoholic steatohepatitis with advanced fibrosis,

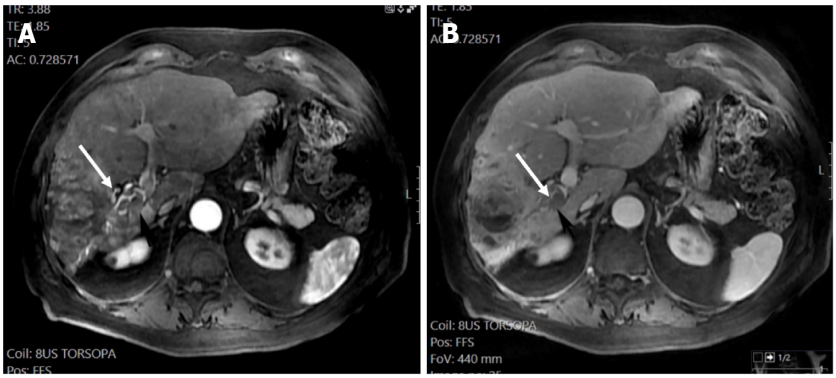
DOI: 10.3748/wjg.v28.i32.4540 **Copyright** ©The Author(s) 2022.

Figure 4 Diagnostic algorithm of liver lesions in computed tomography/magnetic resonance imaging (Liver Imaging Reporting and Data System v2018 CORE). Observations in the cell LR-4 and LR-5 are categorized based on one additional major feature: LR-4 if enhancing "capsule" and LR-5 if nonperipheral "washout" or threshold growth. APHE: Arterial phase hyperenhancement; CT: Computed tomography; HCC: Hepatocellular carcinoma; MRI: Magnetic resonance imaging; TIV: Tumor in vein.

DOI: 10.3748/wjg.v28.i32.4540 **Copyright** ©The Author(s) 2022.

Figure 5 Hepatocellular carcinoma in a 60-year-old man with hepatitis C. A: Computed tomography scan, late arterial phase were the hepatic artery and portal vein are both enhanced, showed a segment VIII lesion measuring 27 mm with non-rim arterial phase hyper-enhancement; B: In the portal phase, washout was seen.

do not meet criteria for diagnosis of HCC with the use of LI-RADS. This is an example of an important gap in the generalized implementation of the LI-RADS criteria which necessitates further research.



CONCLUSION

The diagnosis of HCC in clinical practice is based on imaging, using mainly CT and MRI. As the early diagnosis of HCC is associated with the overall prognosis, accurate identification of potential malignant liver lesions using these modalities is essential. LI-RADS is a comprehensive guidance that provides standardized interpretation and reporting of CT and MR liver imaging. LI-RADS is suggested to be used only to patients at high risk for developing HCC in a step-wise fashion that analyzes all the relevant radiologic characteristics according to a pre-defined manner. Clinicians that care for patients with liver disease must be familiar with the characterization of liver lesions using the LI-RADS criteria as this offers correct assessment of liver lesions and truthful communication between specialties.

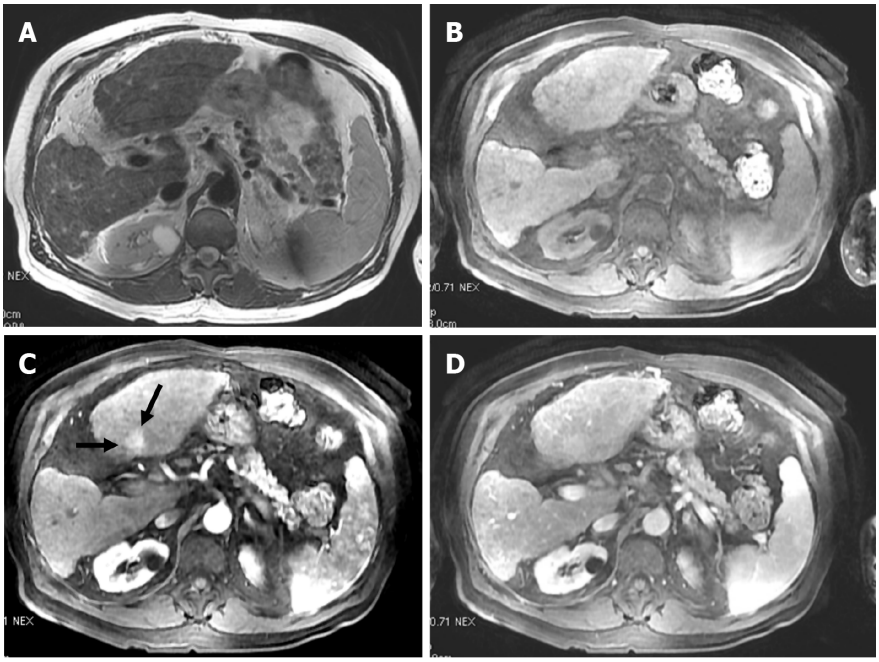
Figure 8 Two-dimensional transthoracic echocardiogram revealed a mobile right atrial mass protruding from the inferior vena cava, in a patient with chronic hepatitis B and cirrhosis. A-C: Axial T1 weighted image (T1WI) (A), arterial post-contrast (B) and portal phase (C) showed direct right atrial extension of hepatic segment VIII-IVA tumor through the inferior vena cava, categorized as LR-tumor in vein (arrows); D and E: Coronal T2 weighted image (D) and coronal post-contrast T1WI (E) showed better craniocaudal tumor extension (arrows).



DOI: 10.3748/wjg.v28.i32.4540 **Copyright** ©The Author(s) 2022.

Figure 9 Coronal T2 weighted image and axial short tau inversion recovery image. A and B: Coronal T2 weighted image (T2WI) (A) and axial short tau inversion recovery image (B) showed a 2 cm lesion in segment VII with high signal intensity (bright) within a nodular liver consistent with cirrhosis; C: Post-contrast image showed nodular peripheral enhancement; D: On delay image, the lesion showed progressive filling. In progressive cirrhosis, hemangiomas are likely to decrease in size, become more fibrotic, and are difficult to diagnose radiologically. However, the bright signal on T2WI and the enhancement pattern was pathognomonic for hemangioma of the liver consistent with LR-2.

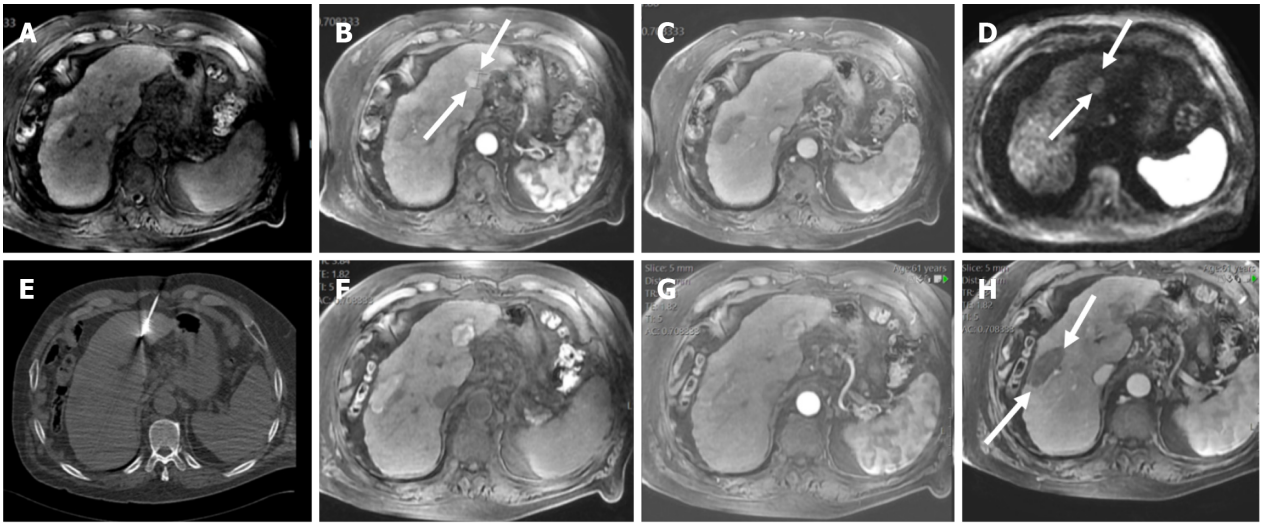
Figure 16 LR-5 observation. A and B: Axial short tau inversion recovery (A) and T2 weighted (B) showed a segment VI observation with relative high signal intensity (arrows); C: On pre-contrast volumetric interpolated breath-hold examination image, peripherally high signal was seen; D: In the arterial phase, multiple hyperenhanced nodules within nodule were seen (arrows); E: In the portal phase, segmental washout was seen (arrows) categorized as LR-5.



DOI: 10.3748/wjg.v28.i32.4540 **Copyright** ©The Author(s) 2022.

Figure 17 LR-5 observation. A and B: Axial post-contrast images arterial (A) and portal phase (B) showed an ablation defect in segment VI without residual areas of arterial enhancement or washout. This was classified as LR-treatment response non-viable; C-E: Later pre-contrast (C) arterial (D) and portal (E) phase showed a new nodule (arrows) measuring 12 mm with strong arterial enhancement and washout categorized as LR-5. If a new tumor arises within or adjacent to a treated lesion, this observation should be assigned a new non-treated LI-RADS category.

DOI: 10.3748/wjg.v28.i32.4540 **Copyright** ©The Author(s) 2022.

Figure 18 LR-5 observation. A and B: Axial T2 weighted (A) and volumetric interpolated breath-hold examination (B) show a segment VI observation with high signal intensity (arrows); C and D: On arterial phase (C) strong enhancement is seen, better depicted on subtracted image (D); E: On portal phase washout is seen categorized as LR-5; F: Unenhanced computed tomography scan after TACE shows accumulation of iodized oil (arrow) within the tumor; G and H: However on post-contrast follow up magnetic resonance imaging on arterial phase (G) there is residual nodular enhancement within a lesion clearly depicted on subtracted image (H) categorized as LR-treatment response viable.

DOI: 10.3748/wjg.v28.i32.4540 **Copyright** ©The Author(s) 2022.

Figure 19 Axial volumetric interpolated breath-hold examination, arterial phase. A-C: Axial volumetric interpolated breath-hold examination (A), arterial phase (B) showed an observation measuring almost 20 mm with arterial phase hyperenhancement (arrows) without washout on portal image (C) categorized as LR-4; D and E: On diffusion-weighted imaging (D), the observation showed high signal intensity (arrows) but the ancillary features lacked sufficient specificity for hepatocellular carcinoma to allow for an LR-5 upgrade. After multidisciplinary discussion, ablation was performed (E); F-H: On follow-up, an ablation defect was seen without residual areas of arterial enhancement or washout. This was classified as LR-treatment response non-viable. Note a previous ablation defect in the right lobe (arrows).

Abstract

Severe alcoholic hepatitis (AH) is a distinct entity in the spectrum of alcohol-related liver disease, with limited treatment options and high mortality. Supportive medical care with corticosteroids in selected patients is the only currently available treatment option, often with poor outcomes. Based on the insights into the pathogenetic mechanisms of AH, which are mostly obtained from animal studies, several new treatment options are being explored. Studies have implicated impaired and deranged liver regeneration processes as one of the culprit mechanisms and a potential therapeutic target. Acknowledging evidence for the beneficial effects of granulocyte colony-stimulating factor (G-CSF) on liver regeneration and immunomodulation in animal models, several human studies investigated its role in the treatment of advanced alcohol-related liver disease and AH. Contrary to the previously published studies suggesting benefits of G-CSF in

the outcomes of patients with severe AH, these effects were not confirmed by a recently published multicenter randomized trial, suggesting that other options should rather be pursued. Stem cell transplantation represents another option for improving liver regeneration, but evidence for its efficacy in patients with severe AH and advanced alcohol-related liver disease is still very scarce and unconvincing, with established lack of efficacy in patients with compensated cirrhosis. In this review, we summarize the current knowledge on the pathogenesis and experimental therapies targeting liver regeneration. The lack of high-quality studies and evidence is a major obstacle in further treatment development. New insights into the pathogenesis of not only liver injury, but also liver regeneration processes are mandatory for the development of new treatment options. A reliable experimental model of the pathogenesis of AH and processes involved in liver recovery is still missing, and data obtained from animal studies are essential for future research.

Key Words: Severe alcoholic hepatitis; Alcohol-related liver disease; Treatment; Liver regeneration; Granulocyte colony-stimulating factor; Stem cell transplantation

Core Tip: Current treatment options for patients with severe alcoholic hepatitis (AH) are unsatisfactory, resulting in high mortality rates. Liver regeneration is impaired in patients with severe AH and represents an appealing therapeutic target. Granulocyte-colony stimulating factor, alone or in combination with stem cell therapy represents a promising therapeutic option for severe AH. Contrary to animal and several small human studies, evidence from recent studies failed to show benefit of these liver regeneration therapies in patients with advanced alcohol related liver disease.

INTRODUCTION

The harmful use of alcohol is responsible for more than 3 million deaths every year (5.3% of all-cause mortality) and is one of the most common causes of liver disease worldwide[1,2]. Excessive alcohol consumption can cause a spectrum of partially overlapping liver injuries, including steatosis, steatohepatitis, fibrosis and cirrhosis. All these histological changes with accompanying clinical manifestations are collectively termed alcohol-related liver disease (ALD).

Alcoholic hepatitis (AH) is a distinct clinical manifestation of ALD, characterized by jaundice and sometimes accompanied with other signs of hepatic decompensation and liver failure such as ascites or encephalopathy, which occurs in patients with excessive alcohol consumption[3]. Underlying this clinical condition are histological changes including steatosis, hepatocyte injury with ballooning degeneration and lobular neutrophil infiltration, which are characteristic of alcoholic steatohepatitis, and which usually occur in the presence of advanced fibrosis or cirrhosis[3]. The prognosis of AH is generally dismal but significantly dependent on the severity of the disease. Patients with severe forms of AH (defined by Maddrey's Discriminant Function ≥ 32) have a significantly worse prognosis with mortality rates reported between 20% and 30% after 1 mo, and 30% to 40% after 6 mo from presentation [4]. Although patients with a non-severe form of AH have a < 10% risk of mortality after 1 mo and survival of patients with severe AH seems to have improved over the last decades, the condition still carries a poor prognosis[3].

CURRENT TREATMENT OPTIONS FOR SEVERE AH

Patient stratification based on the disease severity and prognosis is necessary for treatment decisions in AH. A Maddrey's Discriminant Function ≥ 32, Model for End-Stage Liver Disease (MELD) score ≥ 21, and/or Glasgow Alcoholic Hepatitis score ≥ 9 are models most commonly used to identify patients with severe disease.

Alcohol abstinence and appropriate nutrition are the cornerstone of treatment of AH, regardless of disease severity[3,5,6]. Energy intake of 30-40 kcal/kg per day and protein intake of 1.2-1.5 g/kg per day are currently recommended by most treatment guidelines. Treatment of alcohol withdrawal symptoms, hepatic encephalopathy, ascites and other comorbidities with vitamin B supplementation also represent general measures required in many patients.

For many years, corticosteroids have been used in the treatment of patients with severe forms of AH, with varying results. A large, multicenter randomized trial comparing steroids with pentoxifylline (STOPAH) showed modest reduction in mortality after 28 d of treatment with prednisolone compared to pentoxifylline, but no improvement in long-term outcomes was observed after 90 d and 1 year[7]. These findings were also confirmed by a recent meta-analysis[8]. Wide use of corticosteroids is limited not only by scarcity of data on its efficacy, but also by safety concerns, especially regarding infections and risk of gastrointestinal bleeding. However, corticosteroids are considered the only treatment option for severe AH with proven or likely benefit[3,5,6].

Patients with severe AH who fail to respond to standard supportive care and corticosteroids may require liver transplantation. However, since the diagnosis of AH implies recent alcohol abuse, these patients are not readily accepted for liver transplantation by most transplant centers because of inadequate abstinence period. Nonetheless, an increasing number of centers are considering and performing liver transplantation in highly selected patients with severe AH[9,10]. The survival benefit for transplanted patients with severe AH has been demonstrated in several trials and a model study, and concern of alcohol abuse relapse after early transplantation has been addressed in several small studies, which showed similar relapse rates to those recorded in patients with 6-mo abstinence period in highly selected groups of patients[11,12]. Still, liver transplantation is not an option for the majority of patients with severe AH.

PATHOPHYSIOLOGY OF LIVER INJURY AND LIVER REGENERATION

The spectrum of alcohol related liver damage results from an interplay of several interrelated pathophysiological mechanisms caused by continuous excessive alcohol consumption. Direct injury to hepatocytes and inflammation cause a series of consecutive events resulting in histological changes characteristic for ALD[13,14]. Ethanol metabolites, namely acetaldehyde, can cause direct damage to hepatocytes through oxidative stress, lipid peroxidation, mitochondrial dysfunction and alterations in lipid metabolism, resulting in steatosis. Consequently, damaged hepatocytes activate apoptosis and necrosis pathways, which result in the release of damage-associated molecular patterns (DAMPs), cell derived molecules that trigger the immune system, which causes further damage. Another mechanism involved in the pathogenesis of ALD results from a deranged gut-liver axis[15]. Increased gut permeability and dysbiosis caused by alcohol consumption allow for translocation of lipopolysaccharides and other bacterial products, collectively termed pathogen-associated molecular patterns (PAMPs), through splanchnic vasculature into the liver. Stimulation of resident macrophages in the liver (Kupffer cells) by PAMPs and DAMPs through activation of toll-like receptors enhances nuclear factor kappa-B (NFkB) signaling and results in expression of proinflammatory cytokines, such as tumor necrosis factor-α (TNF-α), interleukin (IL)-1β and IL-6[16]. These proinflammatory cytokines together with chemokines released by Kupffer and other liver cells recruit neutrophils and other immune cells that infiltrate liver parenchyma and contribute to secondary liver injury. Chemokine receptors also promote inflammation through NFkB signaling. All these triggers that activate Kupffer cells and other inflammatory cells also stimulate the release of platelet-derived growth factor and transforming growth factor-β (TGF-β). These profibrotic cytokines stimulate hepatic stellate cells and myofibroblasts to produce collagens, thus promoting fibrosis with consequent distortion in the liver architecture, which is a hallmark of cirrhosis. Activated immune cells induce hepatic injury by formation of reactive oxygen species, which are responsible for oxidative stress. Ethanol metabolism also changes the redox state of hepatocytes and increases their vulnerability to free radicals by depletion of antioxidant storage.

At the same time when hepatic injury causes hepatocyte apoptosis and necrosis, it also stimulates liver regeneration. The liver is an organ with unique regenerative capacity and employs multiple mechanisms for regeneration in order to restore functional tissue following insults such as toxic injury or partial hepatectomy[17]. The knowledge on the pathophysiology of liver damage in AH and insights into the liver regeneration processes mostly come from animal studies[17,18]. However, the existing animal models do not reproduce the main histological features of poor prognosis in patients with severe AH, such as severe fibrosis and bilirubinostasis, which are necessary to understand the processes occurring in such a milieu[19].

It is presumed that damaged hepatocytes release signals which trigger liver regeneration processes in order to restore functional liver parenchyma[20]. Multiple extracellular signals regulating hepatocyte proliferation during liver regeneration have been identified[17]. Among them, hepatocyte growth factor (HGF) and its receptor, ligands of the epidermal growth factor receptor and TGF-α seem to have a major role. Other signaling pathways include TNF-α and its receptor, IL-6, vascular endothelial growth factor (VEGF) and its receptors, several complex signaling pathways such as Hedgehog pathway, Wnt and β-

catenin, Hippo and Yap pathway, as well as several other hormones and signaling molecules[17]. In their absence, the regeneration process will be impaired and delayed but not completely inhibited. In animal models, the first intracellular signaling pathways activated following partial hepatectomy include β-catenin and Notch pathways, followed by activation of signal transducer and activator of transcription 3 (STAT3) and NFκB, which are regulated by IL-6 and TNF-α[17]. Although different mechanisms may activate these pathways, the exact triggers have not been clearly established.

It seems that local, paracrine signals between proliferating hepatocytes and other cell types such as hepatic stellate cells and liver sinusoidal endothelial cells are also important for regeneration. Thus, hepatocytes are at the center of orchestrated liver regeneration processes aimed to restore histologically complete liver tissue, and all liver cell types are able to proliferate during the process. VEGF and angiopoietins are mitogenic for liver sinusoidal endothelial cells, TGFα for sinusoidal endothelial and hepatic stellate cells, fibroblast growth factor 1 and 2 for stellate cells and sinusoidal endothelial cells, and granulocyte-macrophage colony-stimulating factor for Kupffer cells. For sinusoidal endothelial and Kupffer cells, there is evidence that precursor cells migrating from the bone marrow may also be involved in the regeneration process, in addition to local cell proliferation[17].

Normal hepatocyte proliferation and liver regeneration processes, however, seem to be less effective in ALD. Chronic ethanol exposure impairs liver regeneration by interfering with normal microRNA signaling and DNA synthesis, thus inhibiting mature hepatocyte proliferation[14].

The lack of a reliable experimental model with abnormal liver regeneration makes it difficult to understand how these processes affect alcohol-injured livers. It has been proposed that in severe injury, hepatocytes might be unable to initiate the regeneration and tissue healing by themselves, which is then stimulated by liver progenitor or oval cells that become activated and give rise to hepatocytes and other non-parenchymal liver cells[21]. Furthermore, some data suggest that under conditions where normal regeneration processes are impaired by alcohol exposure, liver progenitor cells may accumulate in damaged livers, but are unable to differentiate into mature hepatocytes, which might explain why some patients with severe AH fail to improve. This hypothesis has been corroborated by the results of a human study on tissue samples obtained from explanted livers of patients with severe AH having undergone salvage liver transplantation[22]. The authors showed that patients with severe AH who were unresponsive to medical treatment had decreased expression of TNF-α and IL-6, the cytokines shown to be involved in liver regeneration, as well as an aberrant regeneration process in which accumulated hepatic progenitor cells showed predominantly cholangiocyte differentiation and failed to produce mature hepatocytes[22].

All these pathophysiological mechanisms responsible for liver damage and ineffective regeneration associated with ALD are the potential treatment targets in AH. A number of molecules and treatments have been investigated in the attempts to stop and reverse deleterious effects of alcohol in the development and progression of changes associated with ALD[23].

EXPERIMENTAL OPTIONS TARGETING LIVER REGENERATION FOR THE TREATMENT OF SEVERE AH

Liver regeneration represents one of the key targets for the development of new treatments for severe AH. Hepatocyte damage and death in AH should be counterbalanced by liver regeneration, in order to restore normal liver structure and function. However, ineffective liver regeneration has been proposed as the culprit for progressive liver failure in patients with severe AH. Recognizing complex mechanisms involved in liver regeneration processes, a number of treatment targets are currently being explored and developed.

Granulocyte colony-stimulating factor

Granulocyte colony-stimulating factor (G-CSF) stimulates bone marrow to produce neutrophils and stem cells (SCs), which are consequently released into the blood. In animal models of toxic liver injury, G-CSF administration was shown to mobilize hematopoietic SCs, ameliorate liver injury, promote liver regeneration, and improve liver function and survival.

In a murine model of acute and chronic liver injury, G-CSF accelerated liver regeneration predominantly by promoting proliferation of endogenous hepatocytes, and the process was to a smaller degree mediated by bone marrow originating SCs[24]. In a recently published study in mice exposed to alcohol and irradiation, pretreatment with G-CSF was associated with enhanced macrophage infiltration, preserved tissue structure and function, and improved survival. G-CSF pretreatment stimulated liver regeneration, as shown by immunofluorescence staining for liver SCs. Interestingly, higher expression of hepatic progenitor cells was observed in the injured but untreated control group. This could confirm previous findings that progenitor cells accumulate in response to injury, but are unable to restore normal tissue and function without stimulation[25]. Moreover, G-CSF treatment in mice may mitigate radiation induced fibrosis[26]. Although not based on disease models fully consistent with AH, these animal studies underpin G-CSF as a potential therapeutic strategy in the treatment of liver disease.

In human studies, G-CSF was used as an induction agent for SC recruitment, or as therapy for liver failure by itself, for its other beneficial effects not attributable to SC mobilization, such as improved liver regeneration and neutrophil function. The most important human studies using G-CSF in order to improve liver regeneration and outcomes in ALD are summarized in Table 1.

In a small randomized trial in patients with alcoholic cirrhosis and biopsy-proven AH, G-CSF showed increased CD34+ SC mobilization, increased HGF, and proliferation of hepatic progenitor cells compared to control group, but liver histology, neutrophils and levels of proinflammatory cytokines (IL-6, TNF-α) remained similar[27].

In a randomized controlled trial in patients with acute-on-chronic liver failure (ACLF), G-CSF increased the numbers of CD34+ cells in the livers of treated patients, improved clinical outcomes including reduced Child-Turcotte-Pugh (CTP) and MELD scores, and showed lower rates of hepatorenal syndrome, hepatic encephalopathy or sepsis in treated patients compared to control group [28]. Similar effects were confirmed in a randomized open-label study from India in patients with severe AH, where treatment with G-CSF showed increased counts of CD34+ cells in peripheral blood and ameliorated both CTP and MELD scores, as well as Maddrey's Discriminant Function values after 1, 2 and 3 mo. More importantly, G-CSF therapy increased the 90-day survival rate of patients with severe AH, compared to standard treatment[29]. Five-day dosing regimen of G-CSF has been most widely used, but multiple cycle G-CSF therapy seems appealing, as it may extend the bridging period to transplantation. Only one trial assessed the effects of multiple cycle therapy compared to standard medical therapy in patients with decompensated alcoholic cirrhosis. Repeated treatment cycles were not associated with serious adverse events, but significantly reduced the risk of infections, improved ascites control, and had a positive effect on the patients' quality of life[30].

Consequent studies explored the possible synergistic effects of G-CSF in combination with other immunostimulants such as erythropoietin or plerixafor. In mice, treatment with G-CSF, plerixafor or a combination of G-CSF with plerixafor showed increased circulating hematopoietic SCs with various liver engrafting potential for tested agents, but reduced degree of fibrosis in all treatment groups. However, bone marrow derived hepatocytes and SCs were detected with low frequencies, suggesting alternative mechanisms in liver regeneration[31]. Results of a study investigating combination therapy with G-CSF and plerixafor in patients with end-stage liver disease are unknown[32].

In a randomized controlled trial in patients with decompensated cirrhosis treated with G-CSF and erythropoietin compared to G-CSF alone, combination therapy showed significant improvements in CTP and MELD scores, as well as a reduced incidence of renal injury, encephalopathy and ascites episodes. In addition, combination therapy altered both cellular and protein expression patterns in liver tissue, leading to higher Ki67+ proliferation index, macrophage infiltration rates, and decreased markers of fibrosis progression[33]. However, some clinical trials, as well as animal studies, suggest that these improvements are not solely related to effective cell proliferation.

Apart from its direct effects on liver regeneration, G-CSF is a readily used agent for stimulating SC mobilization and grafting. The mechanisms affecting SC mobilization are thought to be multifaceted and dependent on the interplay between changes in the liver tissue and bone marrow settings. In bone marrow, SC receptors and anchoring mediators are responsible for keeping them nested and quiet. Since cell mobilization can be sufficient in mice without G-CSF receptors expressed on their hematopoietic SCs, G-CSF impact might be achieved indirectly by altering the stromal bone marrow environment as well[34]. End-stage liver disease might undermine mobilization effects of G-CSF due to spleen enlargement and bone marrow dysfunction as a concomitant feature of end-stage liver disease. A case-control study in patients with AH showed weaker response in CD34+ cell recruitment in comparison to healthy controls[27]. Examination of bone marrow specimens of patients with liver cirrhosis revealed altered SC function, which might be the cause of lower mobilization rates, especially when combined with increased levels of proinflammatory cytokines[35].

SC therapy

SCs and tissue engineering have become an attractive field of medical research. Current insights into molecular aspects of hepatic injury of various etiologies bolster SCs as a novel and promising strategy for the treatment and restoration of damaged liver. Traits of liver progenitor cells, often called oval cells, were described in animal toxicity studies investigating hepatocyte reaction in the course of carbon tetrachloride, galactosamine and N-nitrosomorpholine exposure[40]. Increase in α-fetoprotein (AFP) and thymidine tracing of immature hepatocytes suggested that regenerated cells were derived from oval cells, which have a pivotal role in the rat liver tissue response to injury[41]. In humans, those cells correspond to intermediate hepatobiliary cells presumably residing in canals of Hering, and were proven to have capacity for differentiating into both hepatocytes and bile duct cells. They are frequently found in structures called ductular reactions in cirrhotic liver[42,43]. They are usually called liver progenitor cells or intrinsic progenitor cells to distinguish them from non-hepatic SCs derived from bone marrow or other tissues. Human liver progenitor cells exhibit markers during immunophenotyping, which are different from those in oval cells in rats, while simultaneously failing to express AFP, a marker commonly used in animal studies to assess the hepatocyte repair rate. AFP is classified as an oncofetal protein in humans and is produced during embryonic development by the liver and the yolk sac, from which hematopoietic cell lineage derives[44]. Moreover, partial hepatectomy and exposure to

Table 1 Summary of human studies with granulocyte colony-stimulating factor treatment in patients with alcohol-related liver disease

Study population	Methods	Outcomes	Ref.
RCT included 24 pts with ALC and biopsy proven ASH[1]	Group A (13 pts) received SMT + G-CSF and group B (11 pts) received SMT only	Higher increase in CD34+ cell count, HGF, proliferating HPCs and Ki67+/cytokeratin 7+ staining in group A	Spahr *et al* [27], 2008
RCT included 27 pts with ALC presenting with ACLF[1]	Group A (15 pts) received G-CSF + SMT, and group B (12 pts) received placebo + SMT	Group A had higher median leukocyte and neutrophil counts after 1 w and higher CD34+ cell count after 1 mo, together with improvement in 60-day survival, reduced CTP, MELD and SOFA scores	Garg *et al* [28], 2012
RCT included 46 pts with severe AH[1]	Group A (23 pts) received G-CSF, while group B (23 pts) received SMT	In group A, higher CD34+ count was observed together with marked CTP, MELD and mDF score improvements after 1, 2 and 3 mo and higher survival rate at 90 d	Singh *et al* [29], 2014
RCT included 38 pts with ALC[1]	Group A (14 pts) received SMT + GH qd for 12 mo + initial G-CSF 5-d treatment and then 4 G-CSF cycles every 3 mo; group B (15 pts) received initial G-CSF 5-d treatment and then 4 G-CSF cycles every 3 mo, and group C received SMT only	Groups A and B had better TFS after 12 mo and higher QOL scores, as well as higher CD34+ mobilization rate at day 6, with lower incidence of sepsis and SBP	Verma *et al* [36], 2018
RCT included 35 pts with ALC[1]	Group A (19 pts) received G-CSF + EPO and group B (16 pts) received G-CSF only	Group A had higher improvement of CTP and MELD score, together with lower incidence of AKI, HE and ascites; histologically number of CD163+ macrophages and KI67+ index were increased	Anand *et al* [33], 2019
RCT included 57 pts with severe AH[1]	Group A (18 pts) received SMT + G-CSF, group B (19 pts) received SMT + G-CSF + NAC, and group C (20 pts) received SMT alone	Pts in group A and B had higher 90-d survival rate; in group A, improvement in mDF was observed at mo 1, 2 and 3, together with reduction in MELD score after 3 mo	Singh *et al* [37], 2018
RCT included 28 pts with severe AH[1]	Group A (14 pts) received G-CSF and group B (14 pts) received placebo	Group A had better MELD score, lower incidence of infections as well as lower 90-d mortality	Shasthry *et al* [38], 2019
RCT included 48 pts with ALC[1]	Group A (25 pts) was treated with 4 cycles of 5-d G-CSF therapy and group B (23 pts) was treated with SMT only	Group A had higher CD34+ and neutrophil count at day 6; higher 1-year survival, amelioration in CTP and MELD scores together with better ascites control and lower infection risk were observed after 12 mo	De *et al*[30], 2021
RCT included 176 pts with ACLF precipitated by alcohol consumption[1]	Group A (88 pts) was treated with G-CSF + SMT, and group B (88 pts) was treated with SMT	There were no statistically significant differences in respect of TFS, 90-d and 360-d survival rates and infection incidence	Engelmann *et al*[39], 2021

[1]Patient(s) has/have dropped-out, underwent deceased donor liver transplant, or death outcome occurred.

ACLF: Acute-on-chronic liver failure; AKI: Acute kidney injury; ALC: Alcoholic liver cirrhosis; ASH: Alcoholic steatohepatitis; GH: Growth hormone; HE: Hepatic encephalopathy; HPC: Hepatocyte progenitor cell; mDF: Maddrey's Discriminant Function for alcoholic hepatitis; NAC: N-acetyl-cysteine; pt(s): Patient(s); qd: Quaque die; QOL: Quality of life; SBP: Spontaneous bacterial peritonitis; SMT: Standard medical treatment; SOFA score: Sequential Organ Failure Assessment score; TFS: Transplant-free survival.

carcinogens enhance SC factor production by oval cells, indicating genetic similarity between them and hematopoietic SCs[45]. Although some authors, based on animal studies, dispute the role of hepatic progenitor cells in liver regeneration, most studies suggest that they become important in severe liver injury, as occurs in AH[17]. Indeed, it has been demonstrated that the origin of hepatocytes during liver regeneration varies in different models, and that although hepatocytes are the main drivers for regeneration under normal conditions, an alternative regeneration process may be initiated by liver progenitor cells[46].

Using SCs for liver regeneration has several advantages; they are easily obtained from the patient, can be cryopreserved, self-renewed and are plentiful, and therefore, they represent a safe and inexpensive treatment option that can be easily repeated and is not related to ethical concerns frequently seen in orthotopic liver transplantation. Cell-based therapy relies mostly on stem or progenitor cells because mature hepatocytes are scarce and are unable to engraft successfully[47]. Although hepatocyte transplantations have been performed, mostly using cell grafts isolated from livers unsuitable for liver transplantation, and despite many advantages, the shortage of high-quality grafts, histological incompatibility, the need for immunosuppression and unproven long-term benefits are major drawbacks that prevent their clinical use and impose search for other alternatives.

In humans, stem and progenitor cells involved in the liver regeneration process are classified as hepatic and non-hepatic. Liver progenitor cells, as previously mentioned, correspond to oval cells described in rats. Non-hepatic progenitor cells represent a wide range of cells arising from different tissues. Mesenchymal SCs and hematopoietic SCs found in bone marrow represent the most frequently used SCs[46].

Animal and *in vitro* studies are the cornerstone for investigating beneficial effects of SCs in liver injury. The proposed mechanisms for alleviating liver injury include hepatocyte growth stimulation and cell differentiation, paracrine impact on neighboring cells, reduction in inflammatory cytokine production, and counteracting fibrosis by metalloproteinase expression[48,49]. Cell stemness has been noted in several cell types, *e.g.*, hepatoblasts, liver progenitor cells, hematopoietic and mesenchymal SCs. *In vitro* expanding and harvesting of hepatoblasts in mice, as a counterpart to human liver progenitor cells, is not promising[50]. On the other hand, induced pluripotent SCs were able to produce hepatocytes similar both structurally and functionally to the ones seen in wild type mice[51].

Sepsis-related injury in mice can be reduced by using bone marrow derived mesenchymal SCs, which restore liver function and architecture and enhance immunosuppressive cytokine production, thus increasing the levels of transcription factors important in the oxidative stress cascade[52]. In animal studies, endothelial progenitor cells in combination with hematopoietic SCs have also been used to reduce sinusoidal endothelial cell injury, which was not described in human studies[53]. In mice, amelioration of small-for-size graft injury was achieved by adipocyte derived SCs owing to their ability to enhance VEGF production[54].

In the fibrosis model caused by carbon-tetrachloride, mesenchymal SC application led to decrease in apoptosis, fibrosis and immune cell tissue infiltration, especially macrophages, which was also proven in animal studies of AH[55,56].

Current trials in humans report using therapeutic strategies based on mesenchymal SCs (mostly from bone marrow and adipose tissue) and hematopoietic SCs. The summary and key findings of clinical studies using SCs in the treatment of ALD are summarized in Table 2.

Hematopoietic SCs

Hematopoietic SCs were the first one used in liver tissue engineering owing to their ability of homing in liver tissue. Efficient *in vitro* differentiation of hematopoietic SCs to hepatocytes in a period of several days supported this theory[74]. Engrafted in the livers of mice, hematopoietic SCs demonstrated great ability to repopulate, indicating that hematopoietic SCs may be used as cell reconstruction therapy beyond the scope of hematologic malignancy treatment[75]. After anchoring in the liver tissue, hematopoietic SCs showed a potential to transdifferentiate to hepatocytes, as well as to fuse with tissue host cells, thus changing the cell genetic properties[76]. HGF is an important paracrine regulator of cell growth, embryologic development, as well as cell regeneration process. In hepatocytes, it renders antiapoptotic effects. Correlations between IL-1, IL-6, and HGF levels and CTP scoring system imply that HGF secretion might be counteracting inflammatory response in liver tissue[77]. Molecular interaction between hematopoietic SCs and HGF has also been observed. HGF receptors show wide tissue distribution, but their distribution among hematopoietic SCs and reticuloendothelial cells attracts most attention. Together with G-CSF receptors, these receptors promote hematopoietic SC growth under *in vitro* conditions and are responsible for determining tissue macrophage function in acute liver injury by affecting their IL-6 and IL-10 production[78,79]. The aforementioned theoretical and molecular knowledge along with the success achieved in mice seemed to be reasonable enough to justify the use of hematopoietic SCs for liver regeneration, but further research refuted this theory. Attempts at transplanting hematopoietic SCs into mice suffering from liver injury yielded poor results indicating an insufficient repopulation rate for appropriate tissue repair[80]. Genetic engineering of hematopoietic SCs could overcome the challenge of low tissue homing rates. Indeed, using genetically modified mesenchymal SCs expressing higher rates of HGF improves cell engraftment in liver injury[81].

In patients with AH treated by SC therapy (CD34+ and mesenchymal SCs, collected after mobilization with G-CSF), no significant improvement of liver function assessed by MELD score or proliferation of hepatic progenitor cells was noted in comparison to the control group[66]. Analysis of the liver tissue samples from patients with AH treated by SC therapy failed to show a difference in hepatocyte proliferative activity compared to the control group. However, the study showed expansion of macrophages together with an upregulated expression of genes involved in inflammation and regenerative pathways[67].

In view of the above, better understanding of the hematopoietic SC kinetics and genetic properties is needed to popularize their utilization in ALD.

Mesenchymal SCs

Albeit being present in various tissues, mesenchymal SCs are mostly acquired from bone marrow, which embraces several different stem lineages. The most commonly used cell population is CD34+ endowed with potential to differentiate to hepatocytes, myocardial cells, pancreatic cells, *etc.*[58]. The plasticity of mesenchymal SCs appears to play a secondary role, since their immunomodulatory, anti-fibrotic and anti-oxidative properties spark more interest. In ethanol exposed mice, a simultaneous decline in IL-6 and TNF-α, and an increase in IL-10 and glutathione lays out their immunosuppressive effect[56]. In a murine model of colitis, adipocyte derived mesenchymal SCs administered intravenously counterbalanced the decline in glutathione levels and superoxide-dismutase activity, thus preventing tissue injury caused by reactive oxygen species, which is seen in ALD as well[82].

Table 2 Summary of human studies using stem cells in patients with alcohol-related liver disease

Study population	Methods	Outcomes	Ref.
5 pts with ALC	G-CSF mobilized mononuclear CD34+ PBSCs collected by leukapheresis and injected *via* PV (the dose not stated)	Higher mobilization rate was associated with higher CTP and MELD score amelioration	Gaia *et al*[57], 2006
4 pts with ALC (2 also had HCV, 1 had HBV)[1]	Between 1 × 10^6 and 2 × 10^8 G-CSF mobilized mononuclear CD34+ PBSCs collected by leukapheresis and injected *via* PV (3 pts) or HA (2 pts)	3/4 pts had improvement in bilirubin and albumin levels after 2 mo[58]; At 12 mo 2/3 pts had and albumin and bilirubin levels lower than the baseline values[59]	Gordon *et al*[58], 2006; Laxman *et al*[59], 1993
2 pts with ALC	> 2 × 10^6 G-CSF mobilized CD34+ PBSCs collected by leukapheresis and injected *via* PV	2/2 pts had no cirrhosis related hospital admissions afterwards up to 30/34 m, CTP and MELD improved and reached plateau at 12 mo, IL-6 and TNF-□ transiently decreased	Yannaki *et al*[60], 2006
5 pts with ALC (2 of which had HCV infection)	1.6-5.2 × 10^8mononuclear CD34+ BMCs were aspirated from BM and injected *via* HA	At 4 mo CTP score improved, and relative mean change (%) from baseline values of bilirubin, albumin and INR were -24, 7 and -3, respectively	Lyra *et al*[61], 2007
9 pts with ALC	38.7-349.9 × 10^6 G-CSF mobilized mononuclear CD34+ PBSCs collected by leukapheresis and injected *via* HA after cultivation *in vitro* for 7 d	7/9 patients had improvements in CTP score, 5/9 had resolution of ascites, significant decrease in mean bilirubin levels and insignificant decrease in albumin levels, AST and ALT	Pai *et al*[62], 2008
1 pt with ALC	MSC taken by BM aspiration were cultured and differentiation into hepatocyte-like cells was induced. Afterwards 3-5 × 10^7 cells were injected *via* PV	Reduced MELD score, reduced serum creatinine, increase in serum albumin, better life quality and reduced hospitalization rate	Kharaziha *et al*[63], 2009
4 pts with ALC (2 of which had HCV)[1]	2-15 × 10^8 MN-BMSCs were collected by BM aspiration and injected *via* HA	After 12 mo, albumin and bilirubin levels were improved (but not significantly) and mean values of CTP and MELD score were unchanged	Couto *et al*[64], 2011
A case-control study with 5 pts with ALC	8 ± 7.3 × 10^9 mononuclear CD34+, CD44+, CD45+, CD117+ BMCs were isolated after BM aspiration and injected *via* cubital vein	Improvement of serum albumin levels, prothrombin time, total protein and average CTP score (from 6.8 ± 1.3 to 5.8 ± 0.8)	Saito *et al*[65], 2011
RCT included 58 pts with ALC[1]	Group A (30 pts) received SMT and group B received 0.47 ± 0.15 × 10^8/kg G-CSF mobilized mononuclear BMCs collected by BM aspiration and injected *via* HA	Both groups had reduction in steatosis at 4w and improved MELD scores at 12w[66], but higher CD68+ macrophage infiltration was seen in group B at 4w[67]	Spahr *et al*[66], 2013; Lanthier *et al*[67], 2017
12 pts with ALC[1]	5 × 10^7 BM-MSCs were collected by BM aspiration, amplified for 1 mo and administered twice *via* HA	Fibrosis score, CTP and MELD score and albumin levels improved	Jang *et al*[68], 2014
17 patients involved; 5 pts (29.4%) with ASH[1]	0.05-0.4 × 10^6 G-CSF mobilized CD133+ PBSCs were collected by leukapheresis and injected *via* HA, followed by additional G-CSF administration	In CTP class C patients, MELD score worsened during G-CSF application, but at 2 mo overall MELD score improved and at 3 mo INR values were lower and albumin levels higher	Andreone *et al*[69], 2015
RCT involving 25 patients; 11 pts with ALC (5 in group A, 6 in group B)[1]	Group A (23 pts) received SMT and group B (22 pts) received G-CSF mobilized CD34+ PBSCs were collected by leukapheresis and injected *via* HA	At 1 mo albumin levels were improved (P = 0.001) but were not sustained at 3 mo, when creatinine levels and MELD score were significantly improved, and AST and INR improved marginally	Sharma *et al*[70], 2015
RCT involving 55 pts with ALC (18 in group A and B, and 19 in group C)[1]	Group A received SMT, group B (once) and group C (twice) received 5 × 10^7 BM-MSCs collected by BM aspiration, cultured for 1 mo and injected afterwards *via* HA	At 6 mo fibrosis reduced in both groups in comparison to control, CTP scores also improved in comparison to baseline	Suk *et al*[71], 2016
RCT involving 4 pts with ALC (2 in group 1, 1 in group 2 and 1 in group 3)	Group 1 received SMT, group 2 received G-CSF alone, and group 3 received 1.67 × 10^9-2 × 10^{10}/50 mL G-CSF mobilized CD34+ CD133+ mononuclear PBSCs injected *via* HV	Group 3 showed improvement in median CTP score	Yu *et al*[72], 2017
6 pts with ALC[1]	1 × 10^8 AD-MSCs obtained from abdominal fat tissue and expanded *in vitro* were injected *via* HA	2/5 pts had fibrosis score improvement (METAVIR), 1/5 pt had activity score improvement (METAVIR), 5/5 pts improved in CTP scores and MELD score improved in 4/5 pts, while in 1 pt it increased	Huang *et al*[73], 2019

[1]Patient(s) dropped-out, underwent deceased donor liver transplant, or death outcome occurred.

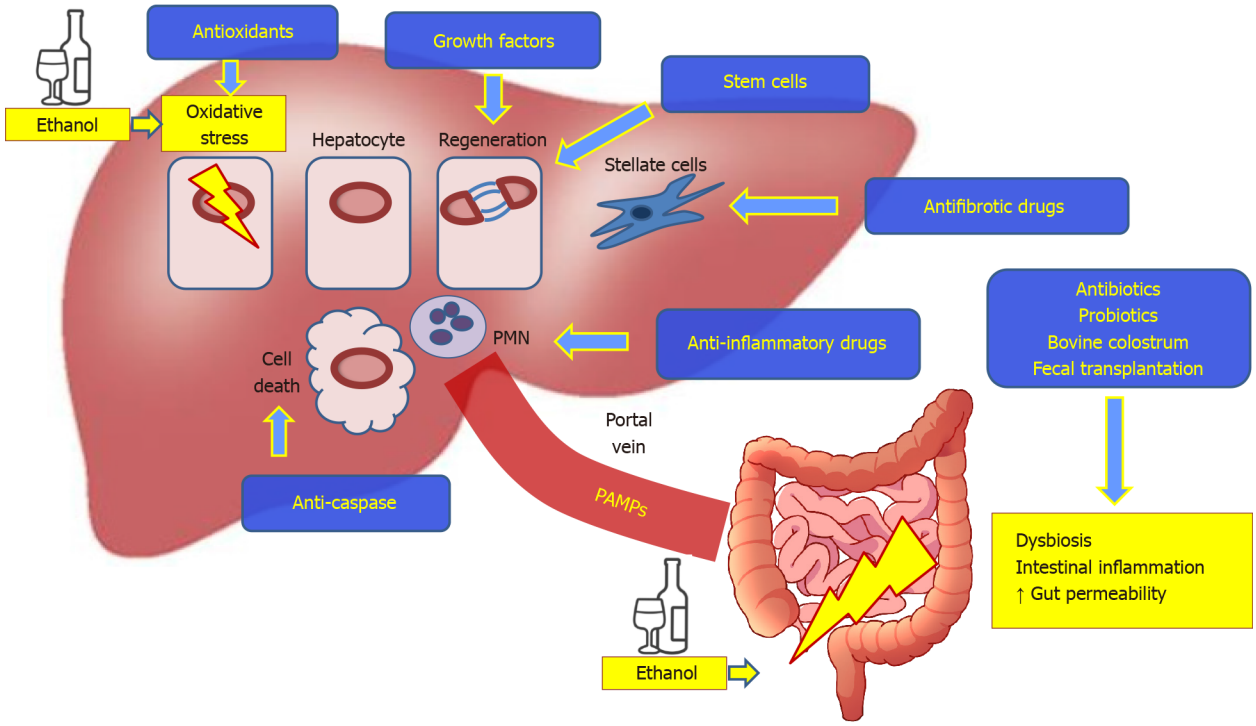
AD-MSC: Adipose derived-mesenchymal stem cell; ALC: Alcoholic liver cirrhosis; AH: Alcoholic hepatitis; BM: Bone marrow; BMC: Bone marrow cell; BM-MSC: Bone marrow mesenchymal stem cell; CTP: Child-Turcotte-Pugh; DDLT: Deceased donor liver transplant; HA: Hepatic artery; HBV: Hepatitis B virus; HCV: Hepatitis C virus; HGF: Hepatocyte growth factor; HPC: Hepatic progenitor cell; MELD: Model for End-Stage Liver Disease; MN-BMSC: Mononuclear bone marrow stem cell; pt(s): Patient(s); PV: Portal vein; RCT: Randomized controlled trial; SMT: Standard medical therapy.

Mesenchymal SCs orchestrate the overall inflammatory response of cells through complex alterations of cytokine networks, resulting in anti-inflammatory set up. While executive cells and their functions in the liver are various, probably the best course of events during injury can be seen by looking at macrophage polarization, a feature that encompasses liver tissue damage. M1 macrophage lineage is held responsible for triggering inflammation, while M2 Lineage contributes to down-regulation of inflammation and hepatocyte proliferation. M2 type macrophages secrete IL-10, VEGF, matrix metalloproteinases and TGF-β1, which are engaged in the resolution phase of liver damage. Although TGF-β1 is considered a proliferative agent, its long-term secretion during chronic liver disease restrains proliferation of hepatocytes together with IL-1 and interferon-γ secreted by M1 macrophages[83,84]. Apart from HGF, the impact on macrophage bipolar differentiation can also be listed as a key effect of mesenchymal SCs. At the cellular level, mesenchymal SC application hampers M1 macrophage and Th17 mediated inflammatory response, subsequently reducing the expression of TGF-β1 and fibrosis markers in carbon-tetrachloride induced liver fibrosis *in vivo*[55,85].

IL-22

Several T-lymphocyte populations participate in the events occurring during ALD development. At the onset, a cascade of inflammatory events initiated by previously mentioned PAMPs and DAMPs is governed by Th1 lymphocytes. In later stages, immune response becomes dichotomous. Th17 lymphocytes represent the main subfamily associated with down-regulation of proinflammatory response and prevention of excessive tissue damage. Antagonistic effect of the Th17 subfamily is mediated by IL-22. IL-22 can bind to both IL-22 and IL-10 receptors through which it sets off the STAT3 signaling pathway response. STAT3 pathway is also a target of IL-1 and IL-6; therefore, especially in chronic settings, this pathway can have both ameliorating and detrimental effects[86]. Moreover, the production of counteracting cytokines (IL-17 and IL-22) by the same lymphocyte type (Th17) shows the complexity of immune response during liver damage. In chronic conditions, Th17 lymphocytes are located in parenchymal and extra-parenchymal tissue compartments and their count correlates with disease severity in humans[87]. On the other hand, in IL-22 knockout mice, hepatitis induced higher levels of liver enzymes indicating greater tissue damage in comparison to mice with normal IL-22 secretion[88]. Furthermore, IL-22 administration in a mouse model of ALD showed marked improvement in liver enzymes with reduction of liver steatosis. Notably, these hepatoprotective effects were abolished in STAT3 deficient mice[89]. In a murine model of ACLF, a shift from the pro-regenerative IL-6/STAT3 pathway to anti-regenerative IFN-γ/STAT1 pathway was noticed, with consequently impaired liver regeneration[90]. Treatment with IL-22 reversed this shift and improved outcomes by reprogramming impaired regenerative pathways[90].

All these studies implicated IL-22 as a possible therapeutic option for ALD, owing to its antioxidant, proliferative and antimicrobial effects, offering improvement of liver function with potentially few side effects. However, human studies on the use of IL-22 are still sparse. A study investigating an IL-22 analog, F-625, in the treatment of AH included 18 patients, divided in three groups according to the dose administered (10 μg/kg, 30 μg/kg, and 45 μg/kg). Significant amelioration of MELD score values, reduction in inflammatory cytokine concentrations, and better survival rates were observed after a 42-day follow-up period. More importantly, no serious adverse events were documented, showing IL-22 analogs as an attractive treatment modality that needs to be further investigated[91].



OTHER EXPERIMENTAL APPROACHES AND THERAPEUTICS WITH POTENTIAL BENEFIT IN THE TREATMENT OF SEVERE AH

Since treatment options for severe AH are limited, a number of other experimental approaches have been developed, based on the proposed mechanisms involved in the pathophysiology of AH[14,23]. Treatment targets of the potential experimental therapies are shown in Figure 1.

Anti-inflammatory agents

Considering AH as a severe inflammatory condition involving multiple mechanisms, cells and signaling pathways, anti-inflammatory agents represent an attractive treatment option.

Pentoxifylline is a phosphodiesterase inhibitor that has been used in the treatment of severe AH for its ability to inhibit TNF-α production. Although the initial randomized study showed improved short-term survival compared to placebo, these findings were not confirmed by subsequent studies, including the previously mentioned STOPAH trial[7,92]. Although it seems that pentoxifylline reduced the incidence of hepatorenal syndrome, the drug is considered unlikely to provide benefit and is not recommended for the treatment of severe AH by the European Association for the Study of the Liver and the guidelines issued by the American Association for the Study of Liver Diseases, while the American College of Gastroenterology classifies pentoxifylline as a therapy with a potential benefit[3,5,6].

DOI: 10.3748/wjg.v28.i32.4557 **Copyright** ©The Author(s) 2022.

Figure 1 Treatment targets of the potential experimental therapies for severe alcoholic hepatitis. PAMPs: Pathogen-associated molecular patterns; PMN: Polymorphonuclear leukocyte.

Treatment of severe AH with anti-TNF-α agents such as infliximab and etanercept seemed to be a desirable option, given their efficacy in the treatment of autoimmune diseases. Unfortunately, despite expectations, both drugs failed to show benefit in clinical trials for severe AH[14,23]. On the contrary, the use of TNF-α inhibitors was associated with an increased risk of severe infections and mortality, and therefore are not considered as a treatment option for severe AH by current guidelines[3,5,6]. The lack of their efficacy in AH may be explained by profound immunosuppression caused by TNF blockage, but also by suppression of liver regeneration, which is also mediated by TNF-α and is necessary to restore liver function.

Other inflammatory cytokines have also been studied as therapeutic targets for severe AH, including IL-1 receptor antagonist anakinra, and a C-C chemokine receptor 2 and 5 antagonist cenicriviroc, but data are still insufficient.

Antioxidants

Since increasing evidence suggests oxidative stress as one of the key mechanisms responsible for cellular injury in severe AH, the use of antioxidants has generated much interest.

N-acetylcysteine (NAC) is an antioxidant thought to restore glutathione stores and has been tested in several studies in the treatment of AH. However, the drug failed to show improvement in liver injury or survival. A combination of NAC with prednisolone showed greater early improvement in liver function, lower incidence of hepatorenal syndrome and infections, and improved short-term survival compared to prednisolone alone, but this effect was not sustained after 3 mo[93]. Further studies are awaited to confirm the efficacy of this combination[3,5,6].

Metadoxine is another antioxidant used in several small open-label studies, also in combination with a corticosteroid or pentoxifylline, where it showed improved survival. Along with some other beneficial effects and a favorable safety profile, metadoxine is an attractive option for the treatment of severe AH, but larger studies are expected to confirm these findings.

Gut dysbiosis and gut-liver axis

Gut-liver axis dysfunction with increased gut permeability and dysbiosis associated with alcohol drinking has been recognized as an important trigger for inflammation in AH. Consequently, a number of agents targeting gut barrier function and dysbiosis have emerged as treatment options for AH. These include bovine colostrum and hyperimmune bovine colostrum, antibiotics (rifaximin, amoxicillin-clavulanic acid, ciprofloxacin, gentamicin, vancomycin, meropenem), probiotics (VSL#3, *Lactobacillus rhamnosus*) and fecal transplantation. Some of these treatments have shown very promising preliminary results, and further studies are eagerly awaited.

Apoptosis

Alcohol induces hepatocyte death *via* necrosis and apoptosis processes, the latter including a number of pathways, which have been investigated as treatment targets in AH. Emricasan is a caspase inhibitor that showed promising results in early phase trials, but further studies were stopped because of concerns about liver toxicity. Selonsertib is another oral inhibitor of apoptosis with better safety profile, but its efficacy has not been established compared to corticosteroids.

Obeticholic acid

Cholestasis is one of the characteristic features of AH. Obeticholic acid is a farnesoid X receptor ligand that protects hepatocytes against bile toxicity. Favorable results in the treatment of cholestatic liver disease offer promises for obeticholic acid in the treatment of AH, pending results of ongoing studies.

DISCUSSION

Severe AH still represents a life-threatening condition with high short-term mortality. A lack of effective treatments with proven benefit and good safety profile imposes the need for new therapeutic approaches. Several pathways are being explored, targeting different mechanisms involved in the pathogenesis of AH. Stimulation of liver regeneration together with other beneficial effects suggest G-CSF and SC transplantation as possible therapeutic targets.

In animal models of toxic liver injury, G-CSF demonstrated evidence for increased mobilization of hematopoietic SCs, ameliorating liver injury, promoting liver regeneration, improved liver function and survival. These beneficial effects encouraged human studies, and the first results were promising, showing mobilization of SCs and proliferation of hepatic progenitor cells that were considered proof of efficacy[27]. Enhanced cell proliferation might not be crucial for the regeneration process as immunohistochemical staining using Ki67/CK+, chief markers of mitosis, showed diverse results[27,67]. Subsequent randomized trials from India investigating the role of G-CSF treatment in patients with ACLF and AH demonstrated not only increased mobilization of SCs, but also improved clinical outcomes, measured by reduction in liver function scores, as well as improved survival[28,29]. Other positive outcomes included improved immune dysfunction with lower rates of complications, including hepatic encephalopathy, ascites, kidney injury, and infections[30,33,36,38].

However, in a large multicenter randomized study from Germany that enrolled 176 patients with ACLF, treatment with G-CSF did not improve liver function scores, occurrence of infections, or transplant-free or overall survival. Severe adverse reactions associated with the treatment, together with the lack of efficacy, led to premature termination of the study[39]. Discrepancies in the findings between this and previous smaller single-center studies (Table 1) are not completely understood. Several possible reasons for such conflicting results between Asian and European studies, including a selection bias or study design could not completely explain these differences[94]. Another possible explanation might be a large rate of infections in the German study that triggered an excessive inflammatory response, which could have counteracted the beneficial effects of G-CSF. However, the substantiated evidence from this trial strongly discourages the use of G-CSF in the treatment of ACLF. Still, it is important to note that the results of G-CSF for the treatment of ACLF cannot be directly extrapolated to AH due to great heterogeneity of ACLF cohorts regarding the cause of the underlying liver disease and the precipitating event for ACLF. In the previously mentioned German (GRAFT) study, alcohol abuse was the precipitating event in approximately half of the patients in both treatment groups, while bacterial infections and gastrointestinal bleeding were triggers for ACLF in the majority of the remaining cases[39]. However, the authors did not prove benefit of G-CSF over standard medical treatment in a cohort of patients with alcohol-related ACLF, which probably comprised mostly patients with AH.

SC transplantation offers another possibility for improved liver regeneration. In recent years, a number of studies investigated the outcomes of SC treatment in patients with liver disease of various etiology. However, studies focusing on patients with ALD are still sparse and recruited small numbers of patients; therefore, outcomes of each study are often insufficient to draw definitive conclusions. The majority of studies were actually phase I/II clinical trials, focused on the feasibility, safety and short-term outcomes of the procedure. One case-control study and five randomized controlled trials compared the effects of SC therapy to standard medical therapy alone (Table 2). The heterogeneity of the findings could be explained by several reasons.

Studies differed according to the SC population and terminology used, including peripheral blood SCs, mononuclear bone marrow SCs, mesenchymal SCs or hematopoietic SCs. Hematopoietic SCs are mononuclear cells typically collected by leukapheresis, and are often described as peripheral blood SCs. In studies where bone marrow aspiration was performed, mononuclear bone marrow SCs represent a combination of several SC types including mesenchymal cells that build up the stromal compartment of bone marrow. Except for mesenchymal SCs, the hallmark of the aforementioned cells is expression of transmembrane phosphoglycoprotein, CD34. In a small study, two CD34+ cell populations were differentiated based on their *in vitro* property of adherence. Adherent CD34+ cells expressed genes important for hepatic tissue differentiation; therefore, SCs with specific phenotype could be pivotal for gaining

therapeutic effect, although they were encountered in a relatively small fraction after mobilization[58]. Promising results were obtained in a small study using G-CSF mobilized mononuclear CD34+ peripheral blood SCs collected by leukapheresis and injected *via* hepatic artery after *in vitro* cultivation for 7 d[62]. It could be assumed that a 5-fold increase in cell count obtained by *in vitro* cultivation could yield better results.

Except for small and heterogeneous patient groups with different conditions (alcoholic cirrhosis, AH, and some with multifactorial origin of liver disease), studies used different G-CSF dosing regimens and SC administration routes (*via* hepatic artery or portal vein), number of SC infusions, outcomes measures, and follow-up period.

In the study including 10 patients, 4 of them with AH, having undergone bone derived mononuclear cell transplantation, serum bilirubin and INR levels decreased and albumin levels increased after 4-mo follow-up[61]. In another study including two patients with AH, histological analysis did not reveal changes in fibrosis stage; however, improvement of both CTP and MELD scores was achieved[60]. In a controlled trial, patients with decompensated ALD treated with G-CSF mobilized mononuclear bone marrow cells had reduction in steatosis and improved MELD scores after 12-wk follow-up, but similar to patients treated by standard medical therapy[66]. There was no difference between the SC treated and control groups according to hepatocyte proliferation. However, a more pronounced macrophage infiltration of the liver was observed in the treatment group, together with higher expression of the genes involved in regenerative processes[66,67]. Another small study involving two patients with AH also assessed CTP and MELD scores after hematopoietic SC aspiration and administration, but without G-CSF stimulation[64]. At the end of a 12-mo follow-up period, no significant differences in serum albumin and bilirubin levels or mean CTP and MELD scores were noticed. Using scintigraphy in this study, the authors managed to document a high percentage of SC retention in liver tissue (41% and 32% after 3 and 24 h, respectively). This research is valuable in terms of assessing cell tropism and dissemination, but also reported several major adverse events, raising concerns about the safety of the procedure[64]. The effects of SC treatment on liver fibrosis were also investigated in several studies, but benefits were shown in only one of them[71]. Probably the most discouraging results were obtained in a randomized multicenter study from the United Kingdom, investigating the efficacy of G-CSF treatment alone or in combination with CD133+ hematopoietic SC infusion obtained by leukapheresis, and compared to standard medical treatment in patients with compensated liver cirrhosis[95]. No improvement of liver dysfunction as assessed by MELD score or fibrosis was observed in either treatment group when compared to standard medical care. However, treatment with G-CSF alone or in combination with SC therapy was associated with an increased frequency of adverse events[95].

The explanation of this paradox and lack of evidence for clinical efficacy of SC therapy for the treatment of AH is still not completely understood. One of the possible explanations might be a relapse of alcohol use in the follow-up period, which is common in clinical practice. In the STOPAH trial, only 45% of patients with AH abstained from alcohol at 6 mo and 37% at 12 mo, meaning that relapse of alcohol use occurred in two thirds of patients surviving an episode of AH after a one-year follow-up period[7]. In a study from Barcelona investigating alcohol abstinence in patients surviving an episode of AH, the investigators also report complete abstinence in only 39% of patients after a median follow-up period of 55 mo, and showed that it had positive impact on long-term survival[96]. Similar results were obtained in a study from the United Kingdom, where 65% of patients surviving an episode of AH experienced alcohol relapse, and abstinence was shown to be the only predictor of long-term survival in these patients[97]. Indeed, in a previously mentioned randomized study investigating bone marrow mononuclear cell transplantation with G-CSF in patients with decompensated ALD, 81% of whom met the histological criteria for AH, alcohol abstinence was achieved in 67% of patients during 12-wk follow-up period, while almost one-third returned to moderate alcohol drinking[66]. The study failed to show benefit of such therapy compared to standard medical treatment, and alcohol relapse in 31% of study patients might be one possible explanation for such results. Another possible explanation is that the effects of SC and other treatments aimed to stimulate liver regeneration depend on the etiology of the liver disease. It has been shown that in ALD related cirrhosis, acute and chronic exposure to alcohol interferes with liver regeneration capacity and may actually impair hepatic progenitor cell response to injury, as mentioned previously, resulting in poor outcomes[14,23,98,99].

CONCLUSION

Ineffective liver regeneration is probably one of the key contributors to liver failure in patients with severe AH. Many cytokines, including TNF-α, IL-6 and IL-22, and STAT3 and NFκB pathways have been shown as potent activators of hepatic regeneration. However, an altered differentiation process seems to cause repopulation of the liver parenchyma by immature hepatocytes that fail to differentiate into mature hepatocytes, which could explain why some patients with severe forms of AH fail to recover. Novel treatment options that would help overcome this obstacle and improve liver regeneration seem intriguing, but so far, the evidence for their efficacy is unconvincing.

The lack of a reliable animal model that could represent the whole spectrum of liver changes associated with ALD in humans still is one of the major obstacles in the research of ALD. Development of an experimental model including not only steatosis and mild inflammation, but also fibrosis, severe inflammation and bilirubinostasis with an altered regeneration process, which are the hallmarks of severe AH in humans, represents an imperative for future research and development of new treatment options.

Better understanding of the molecular mechanisms behind ALD has given us apprehension of the multifaceted nature of the disease revealing novel treatment targets. In the light of evidence from recently published studies, G-CSF therapy does not seem like a feasible treatment option in the near future. Succeeding studies on SC therapy should aim to investigate long-term effects and define precise SC recruitment protocols providing clinicians with clear guidelines on both the G-CSF application regimen and SC administration routes. Until further insights, future research on liver reconstitution remains a challenge.

Abstract

BACKGROUND

Radiotherapy and chemotherapy can kill tumor cells and improve the survival rate of cancer patients. However, they can also damage normal cells and cause serious intestinal toxicity, leading to gastrointestinal mucositis[1]. Traditional Chinese medicine is effective in improving the side effects of chemotherapy. Wumei pills (WMP) was originally documented in the Treatise on Exogenous Febrile Diseases. It has a significant effect on chronic diarrhea and other gastrointestinal diseases, but it is not clear whether it affects chemotherapy-

induced intestinal mucositis (CIM).

AIM

To explore the potential mechanism of WMP in the treatment of CIM through experimental research.

METHODS

We used an intraperitoneal injection of 5-fluorouracil (5-Fu) to establish a CIM mouse model and an oral gavage of WMP decoction (11325 and 22650 mg/kg) to evaluate the efficacy of WMP in CIM. We evaluated the effect of WMP on CIM by observing the general conditions of the mice (body weight, food intake, spleen weight, diarrhea score, and hematoxylin and eosin stained tissues). The expression of tumor necrosis factor-α (TNF-α), interleukin-6 (IL-6), IL-1β, and myeloperoxidase (MPO), as well as the Toll-like receptor 4/myeloid differentiation factor 88/nuclear factor-κB (TLR4/MyD88/NF-κB) signaling pathway proteins and tight junction proteins (zonula occludens-1, claudin-1, E-cadherin, and mucin-2) was determined. Furthermore, intestinal permeability, intestinal flora, and the levels of short-chain fatty acids (SCFA) were also assessed.

RESULTS

WMP effectively improved the body weight, spleen weight, food intake, diarrhea score, and inflammatory status of the mice with intestinal mucositis, which preliminarily confirmed the efficacy of WMP in CIM. Further experiments showed that in addition to reducing the levels of TNF-α, IL-1β, IL-6, and MPO and inhibiting the expression of the TLR4/MyD88/NF-κB pathway proteins, WMP also repaired the integrity of the mucosal barrier of mice, regulated the intestinal flora, and increased the levels of SCFA (such as butyric acid).

CONCLUSION

WMP can play a therapeutic role in CIM by alleviating inflammation, restoring the mucosal barrier, and regulating gut microbiota.

Core Tip: In this study, the compound Wumei pills was selected as the representative of the traditional Chinese medicine compound, and it was clarified that the compatibility of the compound medicines may also regulate the intestinal flora, which is instructive for the study of the onset mode and mechanism of the Chinese medicine compound. The results obtained will provide a scientific basis for finding clinical potential treatment and intervention strategies for chemotherapy-induced intestinal mucositis.

INTRODUCTION

Chemotherapy plays an important role in the comprehensive treatment of malignant tumors and can greatly improve the survival rate of patients with cancer. Although chemotherapy kills tumor cells, it also damages normal cells and induces serious gastrointestinal toxicity; this results in gastrointestinal mucositis, which has been associated with bone marrow suppression, nausea and vomiting, and diarrhea[1]. The gastrointestinal toxicity of chemotherapy seriously affects the treatment process and prognosis of cancer patients[2,3]. Chemotherapy-induced intestinal mucositis (CIM) is more common in patients receiving 5-fluorouracil (5-Fu), irinotecan, methotrexate, cisplatin, and cytarabine[4,5]. It has been reported that the incidence of mucositis is 40% after conventional chemotherapy and can increase up to 80% with high-dose or continuous chemotherapy. Villus atrophy, crypt goblet cell reduction, intestinal epithelial cell hypoplasia, and mucosal barrier dysfunction are the main pathological changes associated with intestinal mucositis[6,7]. Some studies have confirmed that an imbalance in the

intestinal flora can be seen in CIM[8-10]. Therefore, regulating the intestinal flora may be a new therapeutic target for alleviating intestinal mucositis. The treatment of CIM in modern medicine is mainly through combating inflammation and oxidative stress, but the clinical effect of these strategies is not so satisfactory. Thence, there is an urgent need to identify drugs that can effectively treat intestinal mucositis. Increasing evidence shows that traditional Chinese medicine has a significant effect in improving the side effects of chemotherapy, especially with regard to gastrointestinal reactions[11-13].

Wumei pills (WMP) was originally documented in the Treatise on Exogenous Febrile Disease (200-210, AD), and it comprises ten herbs: *Fructus* Mume [*Prunus mume* (Sieb.) Sieb. et Zuce, WM], *Angelicae sinensis* Radix [*Angelica sinensis* (Oliv.) Diels, DG], Asari Radix Et Rhizoma (*Asarum sieboldii Miq*, XX), Aconiti Lateralis Radix Praeparata (*Aconitum carmichaelii Debx*, FZ), Phellodendri chinensis cortex (*Phellodendron chinense Schneid.*, HB), Zanthoxyli Pericarpium (*Zanthoxylum bungeanum Maxim*, HJ), Cinnamomi Ramulus (*Cinnamomum cassia* Presl, GZ), Radix Ginseng (*Panax ginseng C. A. Meyer*, RS), Rhizoma Coptidis (*Coptis chinensis Franch.*, HL), and Rhizoma Zingiberis (*Zingiber oj-jicinale Rosc.*, GJ). It is a classically prescribed traditional Chinese medicine for the treatment of a variety of digestive system diseases and significantly treats diarrhea, upper abdominal pain, and loss of appetite[14,15]. Preliminary clinical studies have shown that WMP has a significant effect on chemotherapy-induced diarrhea[16,17]. It has been reported that WMP is a safe and effective formula. Moreover, WMP has shown significant clinical benefits for digestive diseases, such as ulcerative colitis[18], immune colitis, and irritable bowel syndrome[19-21]. It can also exert an anti-hyperglycemic effect by adjusting the intestinal flora, improving the inflammatory response, and increasing the levels of short-chain fatty acids (SCFA)[22]. However, there is little information on the effects of WMP on CIM. As inflammation and microbiota play significant roles in intestinal mucositis, we hypothesized that WMP might affect CIM in mice. Therefore, we examined the effect of WMP on intestinal mucositis, intestinal mucosal barrier, and intestinal flora in a CIM mouse model. The results of this study may provide new treatment strategies of using traditional Chinese preparations for the treatment of CIM.

MATERIALS AND METHODS

Materials

WMP (WM 24 g, DG 6 g, XX 9 g, FZ 9 g, HB 9 g, HJ 6 g, GZ 9 g, RS 15 g, HL 24 g, and GJ 15 g) was purchased from the Chinese Pharmacy of Jiangsu Provincial Hospital of Traditional Chinese Medicine (Nanjing, China). 5-Fu was obtained from Shanghai Yuanye Bio-Technology Co., Ltd. (CAS: 51-21-8, Shanghai, China, Lot #: N09M10W82518) and FITC-dextran (FD4, 250 mg) was purchased from Sigma-Aldrich Co. LLC (Shanghai, China, Lot #: BCCC2153). Primary antibodies against rabbit Toll-like receptor 4 (TLR-4) (A5258), zonula occludens-1 (ZO-1) (21773-1-AP), mucin-2 (F-2) (sc-515032), GAPDH (AP0063), myeloid differentiation factor 88 (MyD88) (4283S), and nuclear factor-κB (NF-κB) p65 (8242S) were purchased from Abclonal (United States), Proteintech (United States), Santa Cruz Biotechnology (United States), and Bioworld (China). Primary antibodies against mouse claudin-1 (71-7800) and E-cadherin (14472s) were purchased from Invitrogen (United States) and Cell Signaling Technology (Danvers, MA/CST, United States). Goat anti-mouse immunoglobulin G (IgG) (H&L ab6708) and goat anti-rabbit IgG (H&L ab6717) were obtained from Shanghai Abcam Co., Ltd. (Shanghai, China). The primers used to amplify the interleukin-6 (*IL-6*) (forward: Lot No: 1922401831; reverse: Lot No: 1922401832), *IL-1β* (forward: Lot No:1922401835; reverse: Lot No:1922401836), tumor necrosis factor-α (*TNF-α*) (forward: Lot No: 1922401833; reverse: Lot No: 1922401834), and myeloperoxidase (*MPO*) (forward: Lot No: 1922401837; reverse: Lot No: 1922401838) were purchased from Sangon Biotech Co., Ltd. (Shanghai, China). The TRIzol® Reagent (No. 15596018) was obtained from Thermo Fisher Scientific Co., Ltd. (Shanghai, China); the HiScript II Q RT SuperMix for qPCR (+gDNA wiper) (No. R22) was purchased from Vazyme Biotech Co., Ltd. (Nanjing, China); and the iQTM RT SYBR® Green Supermix for qPCR (No. 170-8880AP) was purchased from BIO-RAD Co., Ltd. (Shanghai, China). All the reagents and chemicals were used for study only.

Animals

BABL/C mice (aged 6-8 wk, weighing 18 ± 2 g, male) were obtained from the Shanghai SLAC Laboratory Animal Co., Ltd. (Production License: SCXK: 2017-0005, Shanghai, China). Mice were kept under specific pathogen-free conditions (12 h light/12 h dark cycle, 45%-55% relative humidity, and temperature of 26-28 °C) with free access to food and clean water. The study protocols were approved by the Animal Experimental Ethics Committee of Nanjing University of Chinese Medicine (No. 202006A022) and carried out on the basis of the animal ethics standards of the Nanjing University of Chinese Medicine Laboratory Animal Ethics Committee. The animal certificate number is 20170005027187. All reasonable efforts were made to minimize animal suffering.

Experimental design

After 7 d of adaptive feeding, the BALB/C mice were divided randomly into four groups (n = 10 per group): Control group, 5-Fu group (40 mg/kg), and WMP treatment groups (WMP-11.325, 11325

mg/kg; WMP-22.650, 22650 mg/kg). Except for the control mice, 5-Fu was administered to the mice through intraperitoneal injection once daily for the first 5 d. In addition, the vehicle or different doses of WMP were intragastrically administered to the mice during the experiment. After the treatment, the mice were fasted for 12 h, and they were anesthetized and sacrificed *via* cervical dislocation. The experimental process is illustrated in Figure 1.

Assessment of mucositis and sample collection

Indicators of disease severity, including body weight, food intake, and diarrhea severity, were evaluated daily for the assessment of mucositis. Diarrhea severity was classified into five grades according to stool consistency[23]: (1) 0, normal; (2) 1, slightly wet; (3) 2, moderate wet; (4) 3, loose; and (5) 4, watery stool. Jejunal and colonic tissues were removed quickly and douched with clean cold saline, and then the length of the colon was measured. The samples (1 cm × 1 cm) were immersed in 4 % paraformaldehyde for 24 h and embedded in paraffin for histopathological, immunohistochemical, and immunofluorescence analyses and Alcian blue staining. Blood samples were collected and centrifuged at 12000 rpm for 10 min at 4 °C. The residual intestinal tissue samples were stored at -80 °C and used for biochemical analysis. The feces were also collected from the colon/rectum of the mice to perform a microbiota analysis.

Histopathological assessment

The sections (3.0-μm thick) cut from paraffin blocks and stained with hematoxylin and eosin (H&E) were used for measuring the intestinal mucosal damage and inflammatory cell infiltration with a light microscope. Histopathological scores were calculated on the basis of a previous study[24].

Immunohistochemical analysis

The paraffin sections were dewaxed with xylene and absolute ethanol, washed with phosphate-buffered saline (PBS, pH 7.4), and blocked with 5% bovine serum albumin. Then, the paraffin sections were incubated with an anti-TLR4 antibody (1:600), anti-MyD88 antibody (1:600), or anti-NF-κB p65 antibody (1:600) overnight at -4 °C and incubated with an anti-rabbit secondary antibody the next day. The slides were stained with 3,3-diaminobenzidine (DAB) and counterstained with hematoxylin. The sections were observed with a light microscope.

Intestinal permeability

The toxic effects of chemotherapy may weaken the intestinal epithelial barrier, allowing the contents of the lumen to pass through the paracellular space into the blood. The animals were subjected to fasting from 9 pm on the first day and denied access to water for 12 h. On the second day, FITC-dextran (50 mg/mL) was orally administered to the animals according to their body weight (0.1 mL/10 g). After 3 h, isoflurane anesthesia was administered and the mice were investigated using IVIS Luminaseries II in Living Imaging (480 nm excitation wavelength, 520 nm emission wavelength). After the mice woke up, blood was obtained from the orbit and the serum was separated. A microplate reader was used to measure the serum fluorescence value (480 nm excitation wavelength, 520 nm emission wavelength) and FITC-dextran standards were used to prepare a standard curve for the leakage of FITC in the serum.

Alcian blue staining

The paraffin sections were dewaxed with xylene and absolute ethanol and oxidized with 0.5% periodate solution, followed by incubation with Alcian blue acidification solution for 3 min and staining solution for 30 min. Next, the sections were washed with running water for 5 min, and the slides were stained with nuclear fast red staining solution. The sections were observed under a light microscope and photographed.

Immunofluorescence

Paraffin sections dewaxed with xylene and absolute ethanol were used for antigen retrieval. They were incubated with anti-mucin-2 antibody (1:500), anti-ZO-1 antibody (1:500), anti-claudin-1 antibody (1:500), and anti-rabbit secondary antibody (FITC-labeled, 1:200). The slides were stained with 4′,6-diamidino-2-phenylindole in the dark for 10 min. The sections were observed under a light microscope.

Total RNA extraction and quantitative real-time polymerase chain reaction

Total RNA was extracted from the jejunum and colon/rectum and reverse transcribed into cDNA using the HiScript II Q RT SuperMix according to the manufacturer's instructions. Quantitative real-time polymerase chain reaction (qRT-PCR) was conducted by using the ChamQ Universal SYBR qPCR Master Mix in an Applied Biosystems Step-One Fast Real-Time PCR system. The reaction program was as follows: Pre-denaturation at 95 °C for 30 s, 40 cycles at 95 °C for 10 s and 60 °C for 30 s, followed by annealing at 95 °C for 15 s, 60 °C for 60 s, and 95 °C for 15 s. The primer sequences used for amplifying the genes encoding the target inflammatory factors IL-1β, IL-6, TNF-α, and MPO are listed in Table 1. The relative quantification of the target genes was carried out by the $2^{-\Delta\Delta Ct}$ method, and GAPDH was

Table 1 Primer sequences

Gene		Primer sequences (5' - 3')
IL-6	Forward	CCAAGAGGTGAGTGCTTCCC

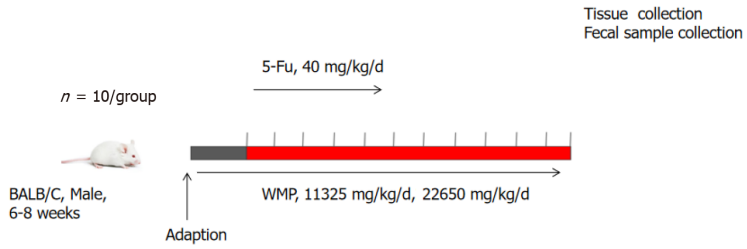

Figure 1 Flow chart of modeling and drug delivery. WMP: Wumei pills; 5-Fu: 5-fluorouracil.

used as the internal control.

Western blot analysis

The total proteins of the intestinal tissue were extracted with a protein extraction kit. Briefly, 100 mg of tissue was grinded with prepared protein lysis solution (RIPA lysis solution:Phosphatase inhibitor:1% PMSF = 100:1:1), and centrifuged at 12000 rmp for 10 min at 4 °C, and 10 μL of supernatant was used for protein quantification with the NanoDropTM One/OneC and the other used for western blot analysis. Protein samples were separated on 6% to 12% sodium dodecyl sulfate-polyacrylamide gels and transferred to polyvinylidene difluoride (PVDF) membranes. The protein-loaded PVDF membranes were blocked for 2 h in 5% skim milk and incubated with primary antibodies overnight at 4 °C and then with secondary antibodies for 1.5 h according to the manufacturer's instructions. Protein expression was detected using a western blot enhanced chemiluminescence substrate, and the results were compared using the ImageJ software. The working dilutions of the antibodies against the following proteins were prepared: TLR4, 1:600; MyD88 1:600; NF-kB, 1:1000; ZO-1, 1:1000; claudin-1, 1:1000; E-cadherin, 1:1000; and GAPDH, 1:20000. A GAPDH antibody was used for verifying the equal loading of the samples of different groups.

16S ribosomal DNA gene sequence analysis

To perform 16S rRNA sequencing, we pooled the feces from six mice in each group (control, 5-Fu, 5-Fu + WMP 11325, and 5-Fu + WMP 22650 groups). Microbial DNA was extracted from 24 samples using the E.Z.N.A.® soil DNA Kit (Omega Bio-tek, Norcross, GA, United States) according to the manufacturer's protocols. The final DNA concentration and purification were determined using a NanoDrop 2000 UV-VIS spectrophotometer (Thermo Scientific, Wilmington, United States), and DNA quality was checked through 1% agarose gel electrophoresis. The V3-V4 hypervariable regions of the bacterial 16S rRNA gene were amplified with the primers 338F (5'-ACTCCTACGGGAGGCAGCAG-3') and 806R (5'-GGACTACHVGGGTWTCTAAT-3') using a thermocycler PCR system (GeneAmp 9700, ABI, United States). The resulting PCR products were extracted from a 2% agarose gel and further purified using the AxyPrep DNA Gel Extraction Kit (Axygen Biosciences, Union City, CA, United States). The products were quantified using QuantiFluor™-ST (Promega, United States) according to the manufacturer's protocol, and purified amplicons were pooled in equimolar amounts and subjected to paired-end sequencing (2 × 300) on an Illumina MiSeq platform (Illumina, San Diego, United States) according to the standard protocols of Majorbio Bio-Pharm Technology Co. Ltd. (Shanghai, China).

Quantification of SCFA

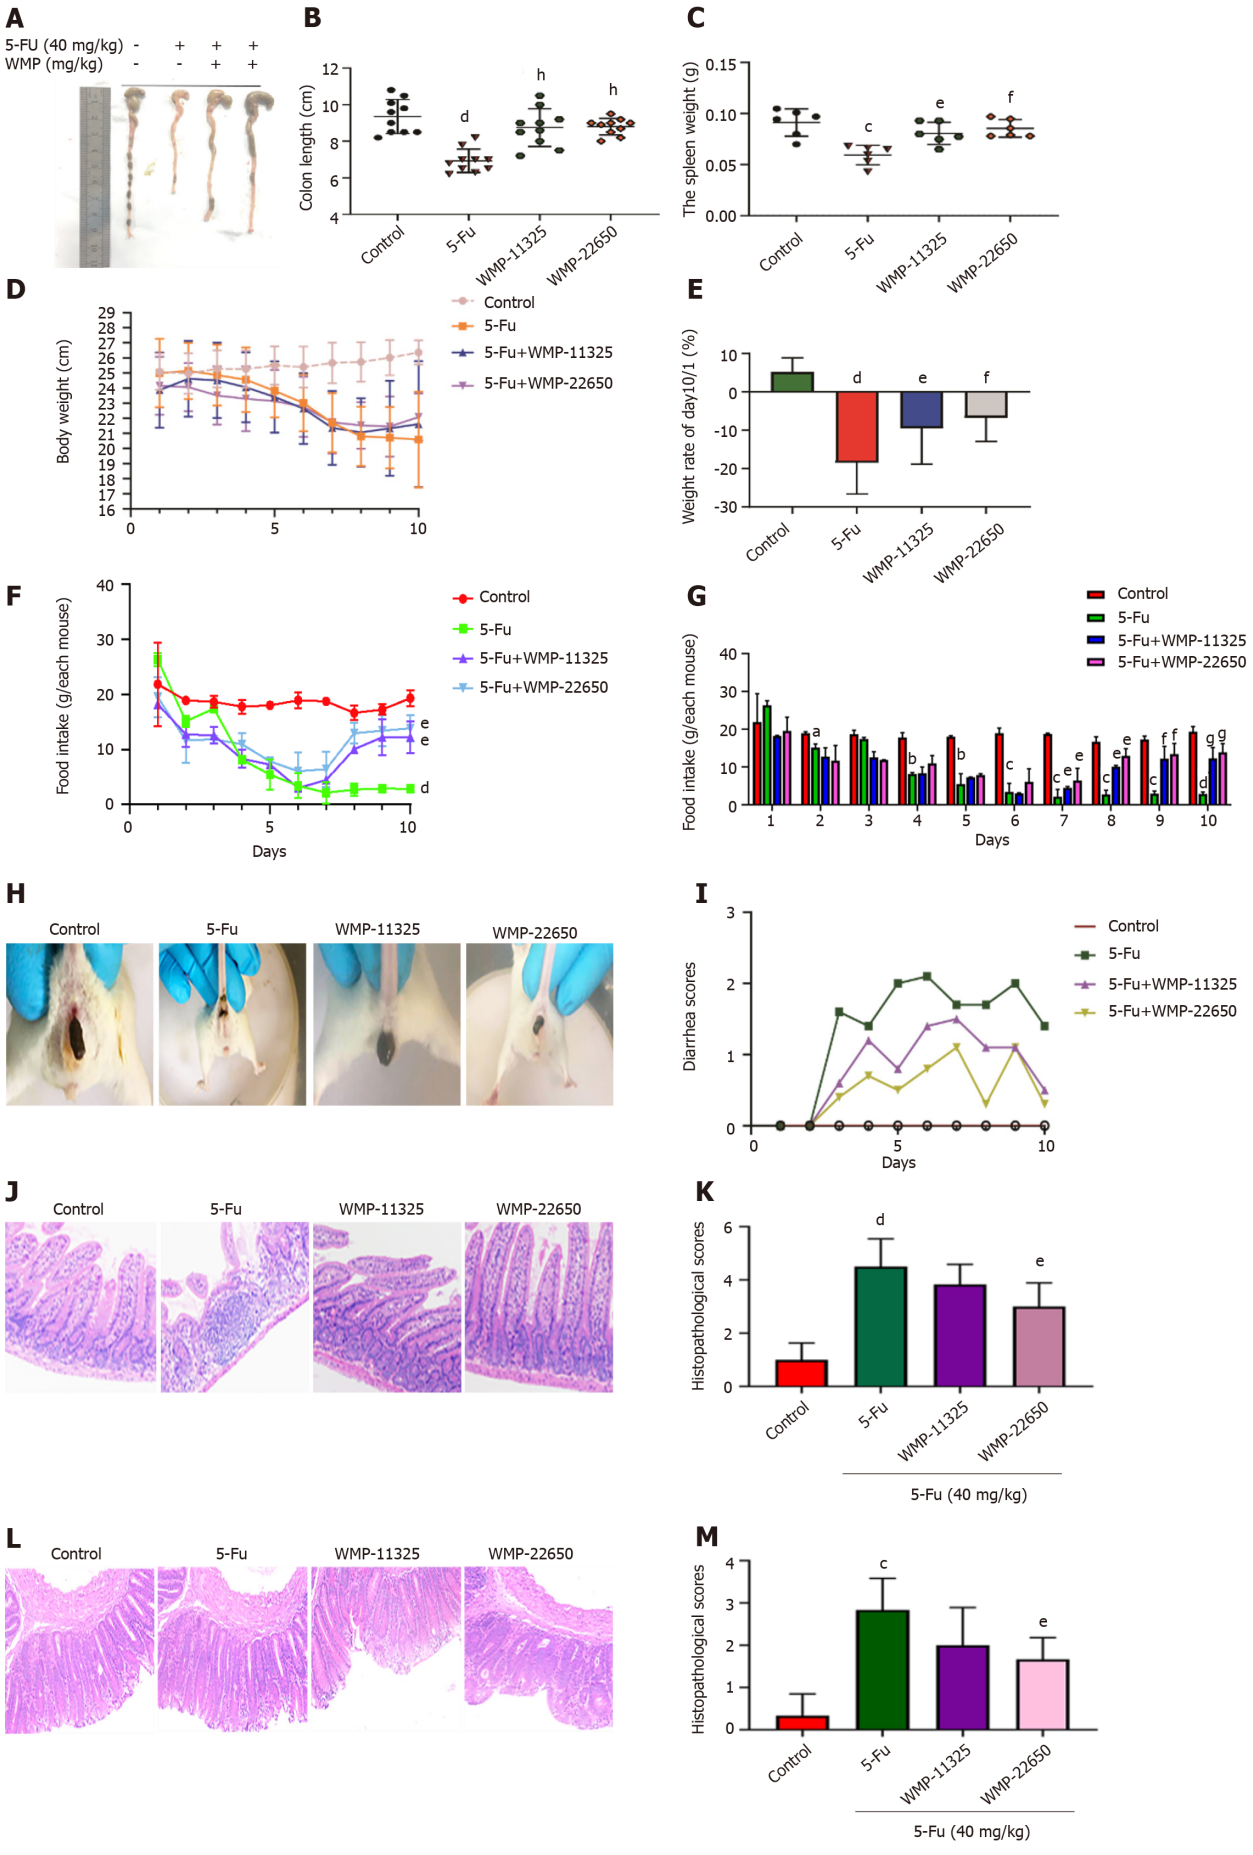
The fecal content (50 mg) of each mouse was placed into a 2-mL centrifuge tube, followed by the addition of 1.0 mL NaOH. The solution was homogenized for 10 min and centrifuged at 13000 rpm for 10 min. Next, 600 μL of supernatant was added to a centrifuge tube with 10 μL of caproic acid-d3, and the mixture was vortexed. The mixture (500 μL) was added to a 10-mL centrifuge tube, followed by the addition of 300 μL of ultrapure water; the mixture was then vortexed. Next, 500 μL of 1-propanol: Pyridine (3:2, v/v) and 100 μL of propyl chloroformate were added; the mixture was vortexed for 30 s and sonicated for 1 min. After derivatization, 300 μL of *n*-hexane was added to extract the derivatized material, followed by vortexing for 1 min and centrifugation at 2000 rpm for 10 min. The upper layer of the solution (200 μL) was placed in a 1.5-mL centrifuge tube and 200 μL of *n*-hexane was added to the centrifuge tube, vortexed for 1 min, and centrifuged at 2000 rpm for 10 min. The upper layer solution (200 μL) from the previous step was vortexed twice. After centrifugation at 18000 rpm for 10 min, the supernatant was filtered through a 0.22 μm membrane filter. SCFAs were quantified using gas chromatography-mass spectrometry (GCMS-QP2010, Shimadzu, Japan) equipped with an Rtx-5MS capillary column (30 m × 0.25 mm × 0.25 μm). For mass spectroscopy, an electron bombardment ionization source, a full scan, and a scanning mode were adopted. The electron energy was 70 eV.

Statistical analysis

Raw data related to intestinal flora were analyzed on the free online platform of Majorbio Cloud Platform (www.majorbio.com). Data are presented as the mean ± SDE of the mean. Differences between two groups were analyzed with GraphPad Prism 8.3. One-way analysis of variance was used for the comparison of more than two groups. The metabolites were filtered by variable influence on projection (VIP) selection from the PLS-DA and the filtering conditions were VIP > 1 and $P < 0.05$. In all cases, statistical significance was set at $P < 0.05$ ($^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$ and $^{d}P < 0.0001$, compared with the normal group; $^{e}P < 0.05$, $^{f}P < 0.01$, $^{g}P < 0.001$, and $^{h}P < 0.0001$, compared with the 5-Fu group).

RESULTS

Effect of 5-Fu



After intraperitoneal injections of 5-Fu, the mice exhibited mild to severe diarrheal symptoms including wet and watery stools, reduced movement, weight loss, and reduced appetite. The changes in colon length, spleen weight, body weight, and appetite, as well as the incidence of diarrhea were regarded as preliminary indices[25], and these changes are shown in Figures 2A-I. The colon length was significantly shortened, and the spleen weight was remarkedly decreased in the mouse models. At the beginning of the experiment, all the mice had similar body weights and appetites, with no diarrhea. In the experiment period, there was no diarrhea and the body weight and food intake gradually increased in the control group mice. However, for the mice that received 5-Fu, the colon length was significantly shortened, the spleen weight markedly decreased, the appetite reduced, and the body weight continuously declined. Serious diarrhea was observed in the mouse models after day 3. WMP increased the colon length of mice in the WMP-11325 mg/kg and WMP-22650 mg/kg groups in a dose-dependent manner. The mice showed increased appetites, and their body weights recovered after day 7. Notably, the diarrhea scores of the mice in the WMP-11325 mg/kg and WMP-22650 mg/kg groups began to decrease by day 8, although they still had severe diarrhea.

Histopathological assessment of the colon and jejunum

Morphological changes in the colon and jejunum were observed, as shown in Figures 2J-M. H&E staining showed that 5-Fu damaged the intestinal epithelium to different degrees, and the most significant epithelial damage was observed in the jejunal tissue (Figures 2L-M). There were no histological abnormalities in the control group, whereas huge ulcers with inflammatory cell infiltration, atrophied glands, and shortened villus length were observed in the jejunal epithelial tissues of the model group mice. The damage was milder in the colon mucosa (Figures 2J-K), which manifested as a small number of inflammatory cells infiltrating the mucosal layer, accompanied by shortened villus length. This condition was alleviated after WMP treatment. WMP effectively accelerated the recovery of injury in a dose-dependent manner. Model mice in the 22650 mg/kg WMP group presented well-ordered glands, increased villus length, and a few impairments like those observed in the control mice.

Effect of WMP on inflammatory cytokines

To evaluate the effects of WMP on inflammation, the mRNA levels of the inflammatory cytokines *TNF-α*, *IL-1β*, *IL-6*, and *MPO* in colonic and jejunal tissues were investigated using qRT-PCR (Figures 2N-O). In both tissues, the mRNA levels of the inflammatory cytokines were significantly elevated ($P < 0.05$) in the 5-Fu group. This condition was alleviated by WMP treatment. WMP effectively decreased the mRNA levels of inflammatory cytokines in a dose-dependent manner. Mice in the 22650 mg/kg WMP group showed lower mRNA levels of inflammatory cytokines ($P < 0.05$) than those in the 5-Fu group.

Effect of WMP on inflammatory proteins

The western blot analysis of the changes in the TLR4/MyD88/NF-κB pathway proteins following WMP administration (Figures 3A-D) showed that 5-Fu administration significantly increased the expression of the TLR4, MyD88, and NF-κB proteins. Although 11325 mg/kg WMP administration had a mild effect, 22650 mg/kg WMP markedly decreased the levels of TLR4, MyD88, and NF-κB proteins to almost normal levels. To further investigate the effect of WMP on the expression of TLR4/MyD88/NF-κB, immunohistochemical analysis was performed to detect protein expression (Figures 3E and 3F). Compared to that in the normal group, the 5-Fu group had significantly higher levels of TLR4/MyD88/NF-κB ($P < 0.01$). In contrast, the expression of TLR4/MyD88/NF-κB in the WMP group decreased in a dose-dependent manner.

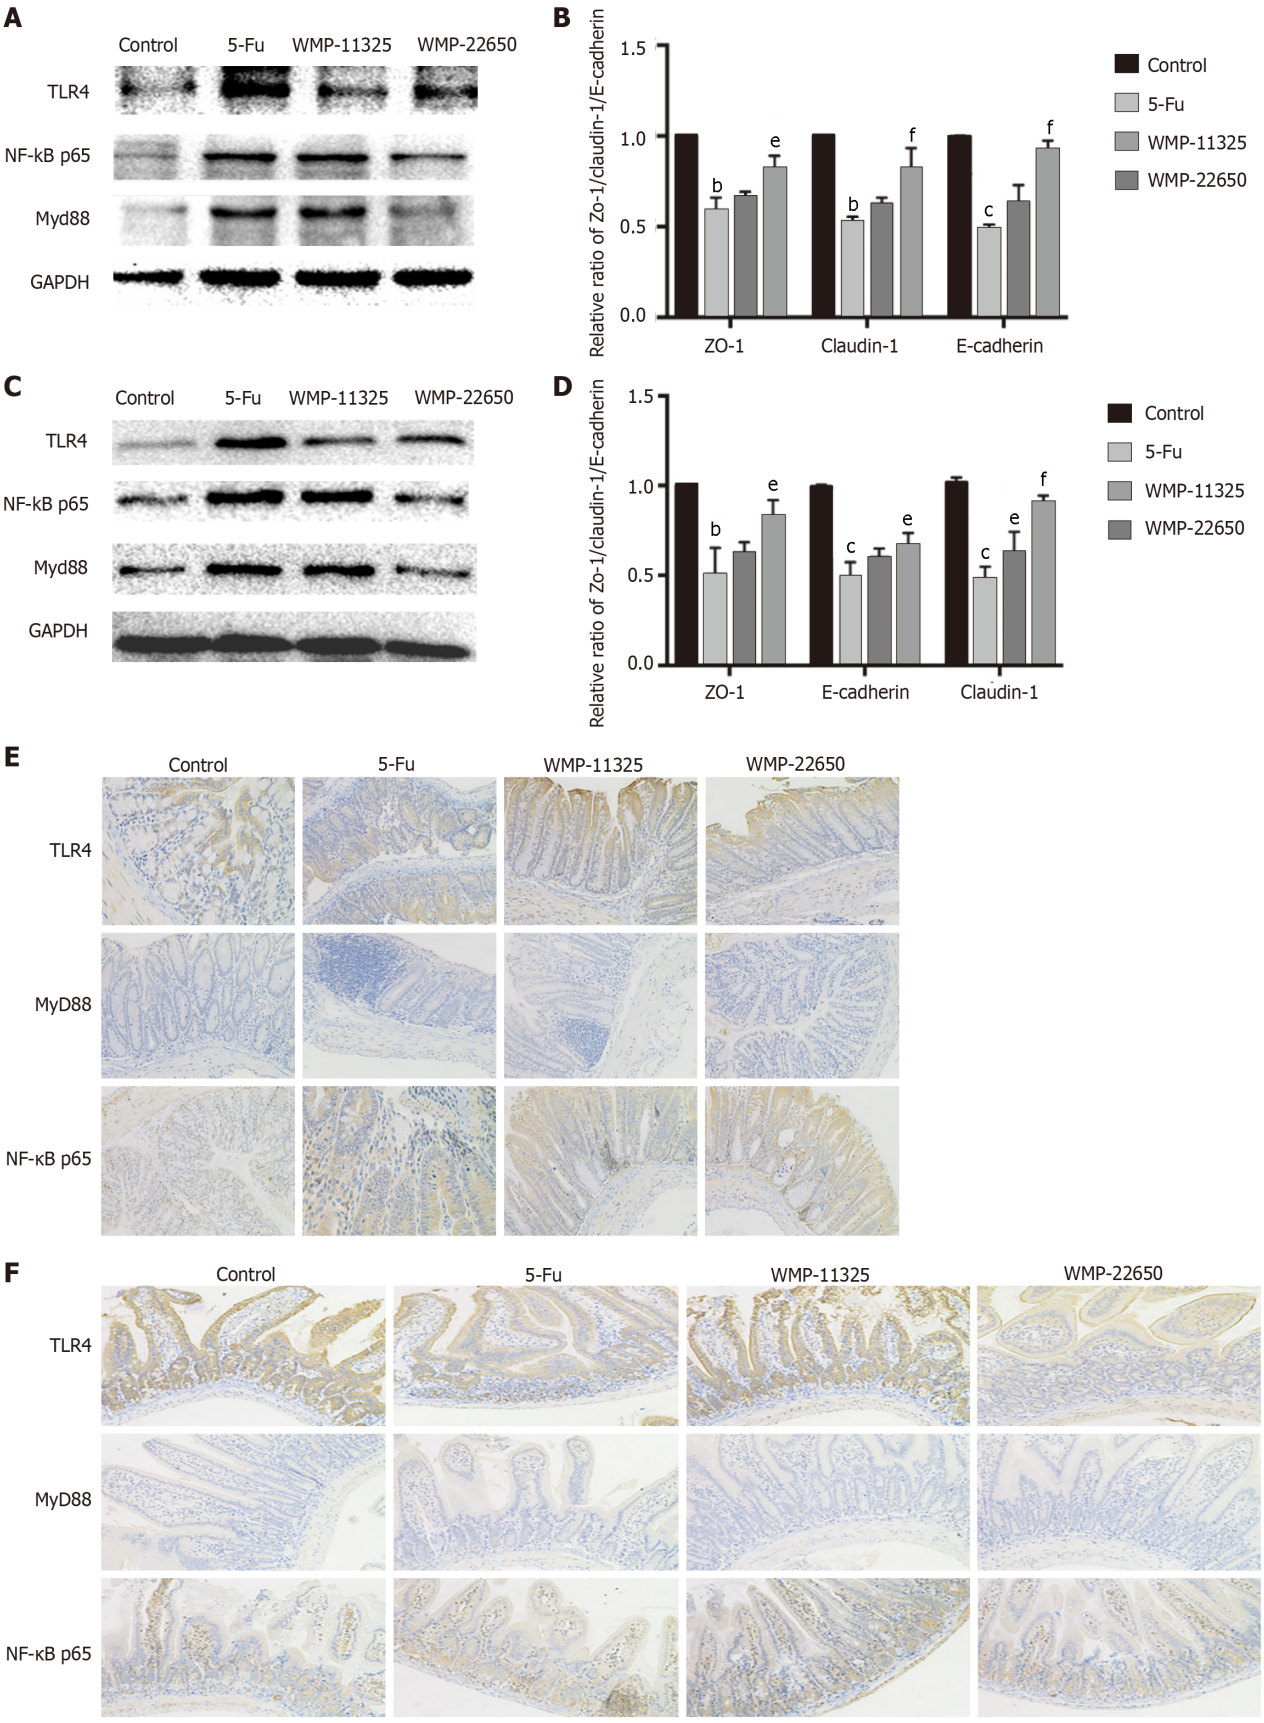

Figure 3 Effect of Wumei pills on expression of Toll-like receptor 4/myeloid differentiation factor 88/nuclear factor-κB pathway proteins as demonstrated by western blot and immunohistochemistry staining. A and B: Expression of Toll-like receptor 4 (TLR4), myeloid differentiation factor 88 (MyD88), and nuclear factor-κB (NF-κB) proteins in the jejunum; C and D: Expression of TLR4, MyD88, and NF-κB proteins in the colon; E: Expression of TLR4, MyD88, and NF-κB proteins in the colon; F: Expression of TLR4, MyD88, and NF-κB proteins in the jejunum. WMP: Wumei pills; TLR4: Toll-like receptor4; MyD88: Myeloid differentiation factor 88; NF-κB: Nuclear factor-κB; 5-Fu: 5-fluorouracil.

Effect of WMP on intestinal mucosal barrier

To evaluate the effects of WMP on the integrity of the intestinal mucosal barrier, we performed a FITC-dextran leakage experiment (Figures 4A and 4B). Dextran leakage was significantly greater in the 5-Fu group than in the control group ($P < 0.05$). WMP effectively prevented dextran leakage. The serum FITC-dextran concentration decreased in the WMP group, while the model group had significantly higher FITC-dextran concentration than the control group.

Effect of WMP on intestinal mucosal barrier proteins

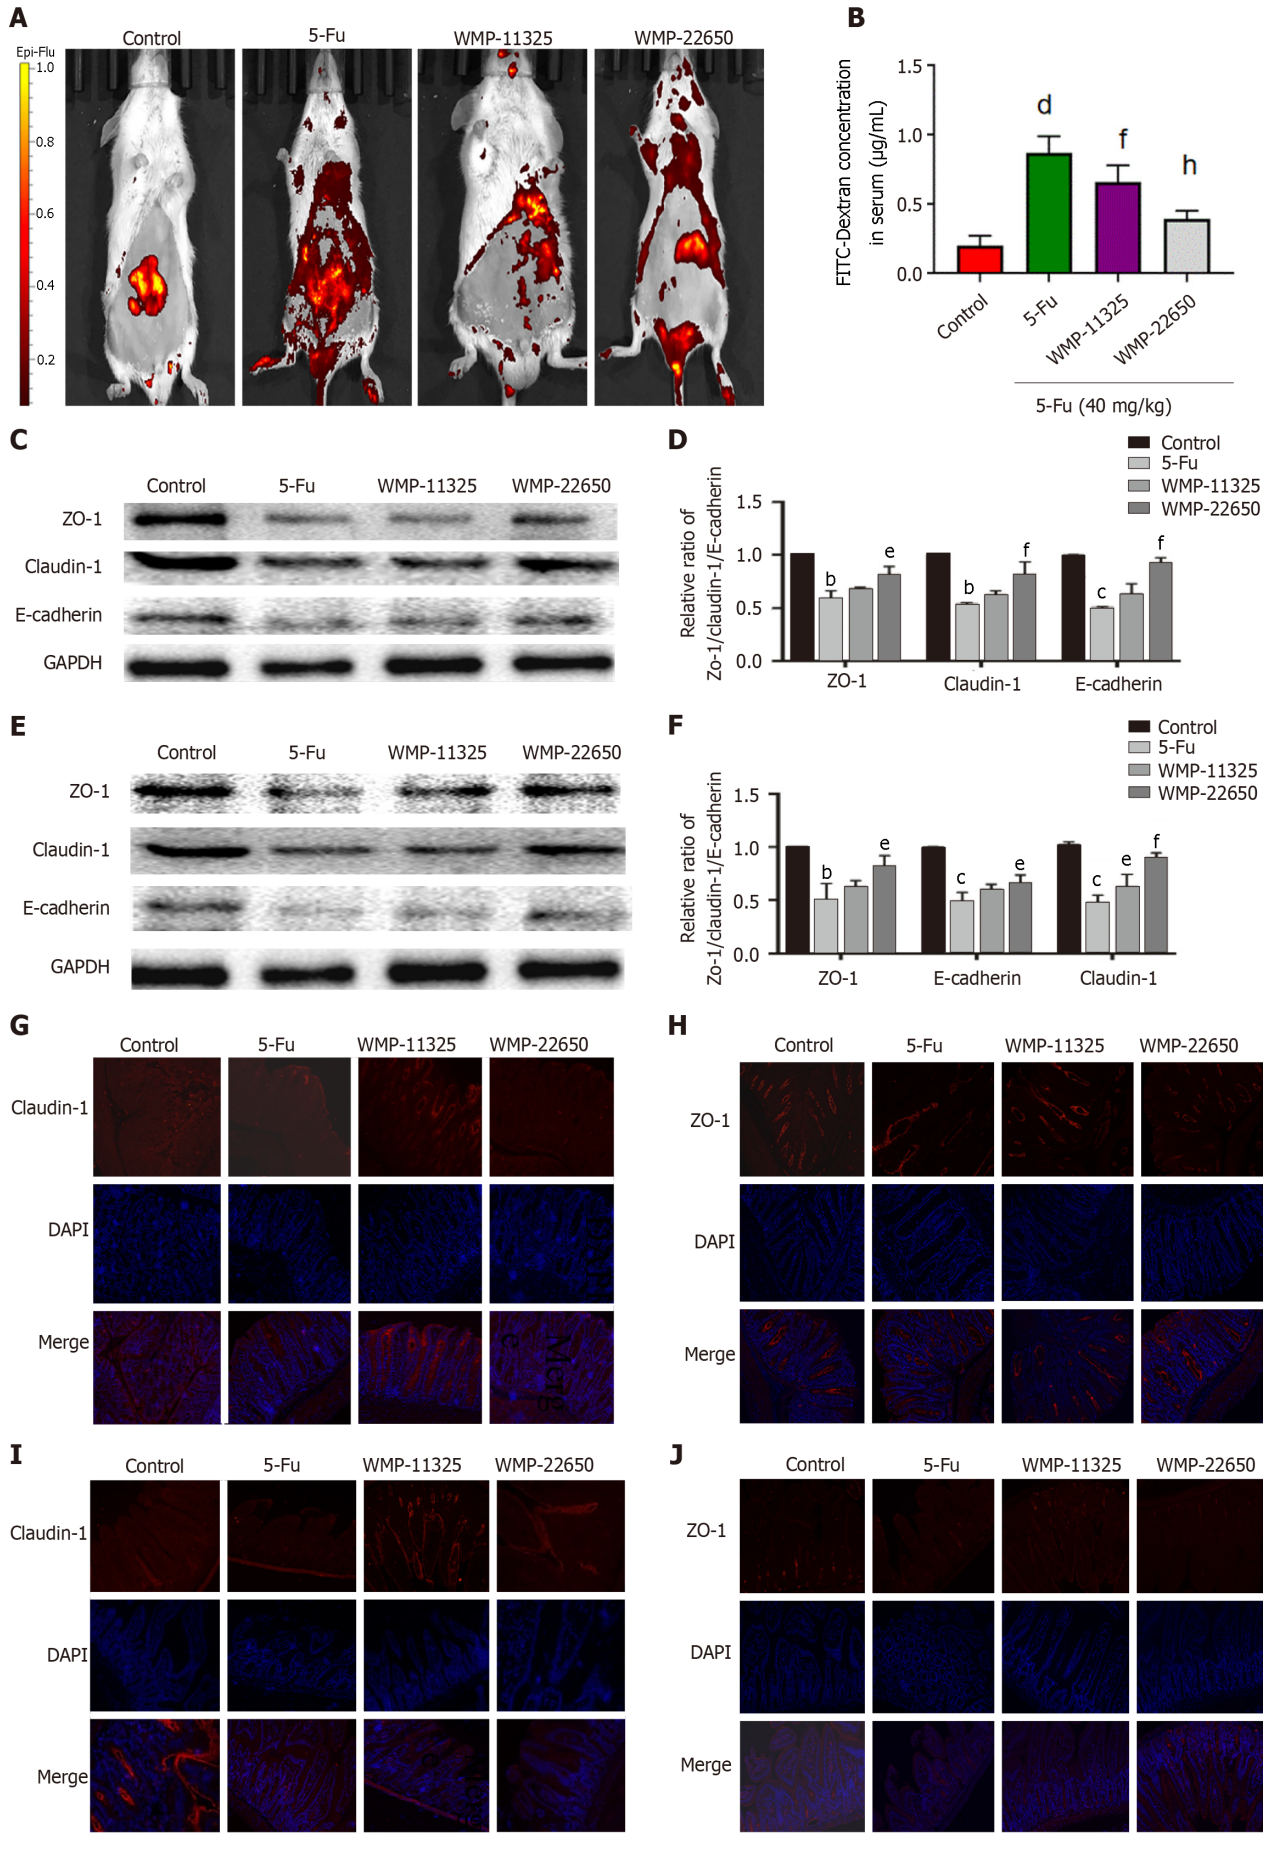
Western blot analysis of the changes in tight junction proteins (ZO-1, claudin-1, and E-cadherin) after WMP administration (Figures 4C-F) showed that 5-Fu administration significantly decreased the expression of the ZO-1, Claudin-1, and E-cadherin proteins ($P < 0.05$, *vs* control group), which was reversed by the administration of 11325 mg/kg and 22650 mg/kg WMP. To further estimate the effect of WMP on tight junction proteins, their expression levels were assessed using immunofluorescence (Figures 4G-J). The results showed that 5-Fu significantly reduced the expression of ZO-1, claudin-1, and E-cadherin; however, WMP treatment significantly increased the expression of these proteins to levels similar to those in the normal group.

Effect of WMP on the synthesis and secretion of mucin-2

To determine whether WMP affects the synthesis of mucin-2 in the model mice, Alcian blue staining and mucin fluorescent staining were conducted, and the number of goblet cells (Figures 4K-N) was determined. The thickness of the mucus layer (concentration of mucin-2) in the 5-Fu group was lower than that in the control mice ($P < 0.01$), suggesting that the goblet cells of the mice in the 5-Fu group were severely damaged. However, there was a significant increase in the mucus layer thickness ($P < 0.05$, *vs* 5-Fu group) after treatment with 11325 mg/kg WMP and 22650 mg/kg WMP.

Changes in microbial composition and diversity

We next assessed the richness and diversity of the microbiota by alpha diversity analysis (Figures 5A and 5B). Four indices were used to analyze microbial diversity, including the Shannon, Ace, Chao, and Simpson indices. The 5-Fu group mice had the lowest Ace, Chao, and Shannon indexes, but with a higher Simpson index; the results also revealed that the richness and diversity of the microbiota community in mice of the 5-Fu group were remarkably reduced compared with those in the control group. These adverse effects were ameliorated after WMP administration. The Ace, Chao, and Shannon indices increased while the Simpson index decreased in the WMP groups.



To evaluate the structure of the gut microbiota of each group, beta diversity analysis was performed and the results are presented in Figure 5C. Principal component analysis showed that compared to the other three groups, the structure of the gut microbial community in the 5-Fu group showed the highest diversity, whereas in the WMP groups, the diversity was reduced, and the values between those of the 5-Fu group and the 22650 mg/kg WMP group were much closer to those between the control group and the 11325 mg/kg group. These results indicate that WMP can increase microbial diversity and stabilize the microbial community.

Taxonomic analysis of microbiota community

The relative abundance of the classification units of the microbiota community is presented as a stacking histogram (Figures 5D-I). The Kruskal-Wallis test was used to analyze the difference in the microbial communities of the groups at different levels, and the results showed that at the phylum level, all samples contained *Bacteroidetes*, *Proteobacteria*, *Firmicutes*, *Verrucomicrobia*, *Campilobacterota*, *Patescibacteria*, *Desulfobacterota*, and *Actinobacteria*. The most abundant phyla were *Proteobacteria*, *Bacteroidetes*, and *Firmicutes*. 5-Fu led to a marked increase in the relative abundance of *Bacteroidetes* and *Campilobacterota*, but a decrease in that of *Firmicutes*. The abundance of *Firmicutes* increased and that of *Bacteroidetes* decreased in the 22650 mg/kg WMP group compared with the 5-Fu group (Figure 6A).

The data showed that *Bacilli*, *Bacteroidia*, and *Clostridia* were the major classes in the control mice, whereas the abundance of *Bacilli* was significantly decreased and those of *Bacteroidia* and *Clostridia* were increased in the 5-Fu group (Figure 6B). After WMP treatment, the number of *Bacilli* in the 11325 mg/kg WMP group was not significantly different, whereas in the 22650 mg/kg WMP group, a significant decrease was observed. *Bacteroidia* and *Clostridia* were decreased in the WMP group, but compared with the model group, *Bacteroidia* were decreased more significantly in the 22650 mg/kg WMP group, and *Clostridia* were decreased more significantly in the 11325 mg/kg WMP group.

At the order level, *Lactobacillales*, *Bacteroidales*, and *Lachnospirales* were the most abundant in the control mice, while *Staphylococci* were the most abundant in the 5-Fu mice (Figure 6C). At the family level, *Lactobacillaceae* and *Bacteroidaceae* were significantly decreased, and *Staphylococcales* and *Muribaculaceae* were increased after 5-Fu treatment. WMP administration effectively increased the abundance of *Lactobacillaceae* and *Bacteroidaceae* in the model mice and decreased the abundance of *Staphylococcales* and *Muribaculaceae* (Figure 6D). WMP increased the abundance of *Lactobacillaceae* in a dose-dependent manner. In the 11325 mg/kg WMP group, the abundance of *Bacteroidaceae* was significantly increased. A total of 20 genera were detected in all the samples (Figure 6E). We found that *Helicobacter* was the

characteristic bacterium in the 5-Fu group. In addition, mice in the 5-Fu group showed higher relative abundances of *Staphylococcales*, *Muribaculaceae*, and *Lachnospiraceae* than the control mice (Figure 6F).

LEfse and microbiota-cytokine correlation analysis

We used LEfse analysis to test the specific bacteria present in all groups. In view of the cladogram (Figure 6G), some specific bacteria were selected (Figure 6H) at the phylum level. Each group was tested for several specific bacteria. In general, *Lactobacillus*, *Verrucomicrobiota*, and *Akkermansia* were the three major genera associated with the control group, while *Helicobacter*, *Muribaculaceae*, and *Campilobacterota* were the major genera associated with the 5-Fu group. *Firmicutes* was significantly increased in the 22650 mg/kg WMP group due to the alleviation of intestinal mucositis in this group. However, in the 11325 mg/kg WMP group, *Bacteroidetes* was the main genus, which may be related to the LDA threshold or the concentration of WMP. In addition, Spearman analysis was used to analyze the association between microbiota and inflammatory cytokines (Figure 6I). The results indicated that the abundance of *Lactobacillus*, *Akkermansia*, *Escherichia coli*, and *Rumbutzia* negatively correlated with the expression of inflammatory cytokines, whereas *Prevotella*, *Isovaleribacter*, and *Helicobacter pylori* positively correlated with the expression of inflammatory cytokines.

Taxonomic analysis was used to detect specific genera in all the samples (Figures 7A and 7B), which showed that the relative abundance of the probiotics *Lactobacillus* was reduced in the 5-Fu group compared with that in the control group. The abundance of pathogenic bacteria, such as *Muribaculaceae* and *Staphylococcales*, increased following the 5-Fu injection. WMP administration both increased the relative abundance of *Lactobacillus* and decreased the relative abundance of *Muribaculaceae* and *Staphylococcales*.

SCFAs in fecal samples

The levels of SCFA are closely related to the barrier function of the intestinal epithelium. To assess the effect of 5-Fu and WMP treatments on microbial metabolites, the levels of SCFAs, such as acetate, propionate, butyrate, isobutyrate, isobutyrate, 2-methyl-butyrate, and valerate, in the feces were determined (Figure 7C). The levels of acetate, propionate, butyrate, 2-methyl-butyrate, and valerate

markedly decreased in the feces of mice treated with 5-Fu, compared with those in the feces of the control mice ($P < 0.05$). WMP treatment significantly increased the levels of acetate, propionate, and butyrate, but had no significant effect on the levels of isobutyrate and isovalerate. In addition, the results showed that WMP restored the abundance of *Lactobacillaceae*, which is the main family that produces SCFA (Figure 7D).

DISCUSSION

Traditional Chinese medicine prescriptions are an important source of new drugs for the prevention and treatment of gastrointestinal toxicity caused by chemotherapy drugs[25]. Drug interaction is considered to play a vital role in the combination of traditional Chinese medicine and modern medicine [26]. WMP originated from the Treatise on Exogenous Febrile Disease (200-210 AD), comprising ten herbs: WM, DG, XX, GZ, FZ, HB, HJ, RS, GJ, and HL. According to previous reports, WMP has various pharmacological effects on gastrointestinal tract diseases, such as ulcerative colitis, immune enteritis, and irritable bowel syndrome[19-21]. In this study, we found that WMP effectively improved the weight, food intake, spleen weight, and diarrhea scores of mice with intestinal mucositis. In addition, WMP significantly reduced 5-Fu-induced morphological damage to the jejunum and colon, which manifested as the shortening of villi height, destruction of crypts, and inflammatory cell infiltration. This study explored the protective effect of WMP and its associated mechanism on intestinal mucosal damage caused by 5-Fu.

The mechanism of the pathogenesis of intestinal mucositis is complicated. Inflammation, intestinal barrier dysfunction, and imbalance of the intestinal flora can cause mucosal damage[27-29]. Inflammation is involved in intestinal mucositis, and TLRs play a key role in regulating the intestinal epithelial barrier and innate immunity. TLR4 induces NF-κB activation, thereby controlling the expression of inflammatory cytokine genes through the Toll/IL-1R domain with the specific adaptor protein, MyD88 [30-32]. NF-κB is a key regulator of innate and adaptive immune responses, and is involved in the regulation of inflammation and cell cycle[33]. After the treatment with 5-Fu, the NF-κB pathway was activated, leading to the release of inflammatory factors. Moreover, the secretion of pro-inflammatory cytokines (such as TNF-α) increased and caused the infiltration of granulocytes and promoted intestinal barrier damage. In addition, it has been demonstrated that MPO, a marker of neutrophil infiltration, participates in the inflammatory process by causing oxidation in the inflammatory area[34]. Changes in the levels of inflammatory cytokines have been reported to be regulated by NF-κB p65[35]. NF-κB is a universal transcription factor involved in the inflammatory response, and studies have confirmed that it plays an important role in the pathological mechanism of CIM[36,37]. Therefore, the inhibition of the NF-κB signaling pathway may be an important factor in reducing intestinal mucosal damage. IL-1β, IL-6, and TNF-α are vital pro-inflammatory cytokines that widely affect the inflammatory process[38-40]. IL-1β and TNF-α have been reported to exhibit a synergistic effect on the activation of the NF-κB pathway and inflammation[41]. IL-6 exhibits a range of biological effects, especially those related to the pathogenesis of inflammatory diseases[42]. In addition, under inflammatory conditions, the protein

WMP: Wumei pills; 5-Fu: 5-fluorouracil.

level and activity of MPO increase[43]. The results of this study also revealed that 5-Fu induced an increase in the expression of proteins associated with the TLR4-MyD88 signaling pathway and inflammatory cytokines, which was significantly inhibited by WMP. WMP significantly decreased the expression levels of TNF-α, IL-1β, IL-6, and MPO in mice with intestinal mucositis and inhibited the increase in TLR4 levels induced by 5-Fu. The expression of the downstream proteins, including MyD88 and NF-κB, was also significantly downregulated. The inhibitory effect of WMP on the TLR4-MyD88 signaling pathway suggests that this pathway may be involved in the alleviation of intestinal mucositis by WMP.

In addition to inflammation, damage to the intestinal epithelial barrier is one of the mechanisms of CIM. The dysfunction of the integrity of the intestinal mucosal barrier (mainly the tight junctions, mucus layer, and intestinal epithelial cells) plays an significant role in the pathogenesis of chemotherapy-induced intestinal toxicity and related diarrhea[44]. Tight junctions maintain the structure and function of the intestinal mucosal barrier by sealing the paracellular space of the intestinal epithelium; this is destroyed under inflammatory conditions[45,46]. Tight junctions comprise core proteins, which are the most adhesive junction complexes in mammalian epithelial cells. The lack of tight junction increases intestinal permeability and contributes to the development of intestinal inflammation[47,48]. Therefore, through the FITC-dextran leakage experiment, we found that WMP reduced intestinal penetration in mice treated with 5-Fu. Furthermore, through western blot and immunofluorescence, we found that the tight junction protein (ZO-1, claudin-1, and E-cadherin) expression levels in the 5-Fu group were significantly reduced and that WMP was able to reverse these changes and increase the expression levels of the tight junction proteins. This effect was more significant in the 22650 mg/kg WMP group than in the 11325 mg/kg group.

In addition to the epithelial barrier, a mucus barrier is also present. The mucus barrier is composed of a hydrated gel covering the surface of the epithelial mucosa, which is formed by the mucin synthesized and secreted by special epithelial cells (such as intestinal goblet cells). This forms a barrier that prevents the direct contact between the large particles (including most bacteria) and the epithelial cell layer[49]. For instance, unlike normal mice, mucin-2-knockout mice developed severe colitis following exposure to harmful stimuli[49,50]. In addition, these mice developed colitis at the same time, and the microbiota was detected in the deep sterile intestinal crypts. By using Alcian blue staining and immunofluorescence to analyze the synthesis and secretion of mucin-2 in goblet cells, we found that the level of mucin-2 synthesis or secretion in goblet cells in the 5-Fu group was lower, indicating that 5-Fu had no serious damage to goblet cells. After the intragastric administration of WMP, we observed a gradual recovery of the biological function of goblet cells, an increase in the synthesis of mucin-2, and an improvement of the intestinal mucosal barrier.

An increasing number of studies have shown that the intestinal flora plays a key role in intestinal inflammation-related diseases, such as antibiotic-related diarrhea, irritable bowel syndrome, radiotherapy, and chemotherapy-related diarrhea[51-54]. The dynamic balance of the intestinal flora is a key factor affecting gastrointestinal health, and gastrointestinal diseases disrupt the dynamic balance of the intestinal flora. Some studies have shown that WMP or its active ingredients can affect the inflammatory response by regulating the intestinal flora[3,22,55]. However, there is no direct evidence proving that WMP can relieve 5-Fu-induced intestinal mucositis by influencing the intestinal flora. Therefore, we used 16S rDNA amplification sequencing to analyze the composition and abundance of the intestinal flora in stool samples. According to the analysis of microbial diversity, the intestinal flora of mice in the 5-Fu group changed significantly. After WMP treatment, the intestinal flora of mice in the 5-Fu group gradually tended towards healthy intestinal microbes, and the abundance of lactobacilli was significantly increased. The 22650 mg/kg WMP group had a better effect. In addition, the intestinal flora can regulate the changes in inflammatory cytokines[56], which is consistent with our results. The composition of the intestinal flora in the WMP group negatively correlated with inflammatory factors, while that in the 5-Fu group showed the opposite trend.

Bacteroides, *Lactobacillus*, *Staphylococcus*, *Muribculaceae*, *Helicobacter pylori*, and *Parabacteria* play an important role in the development of intestinal mucositis. *Lactobacillus* can enhance TJ protein expression, inhibit NF-κB activation, and reduce intestinal permeability[57-60]. *Bacteroides*, *Staphylococcus*, *Muribculaceae*, *Helicobacter pylori*, and *Parabacteria* are generally considered pathogenic or conditional pathogens. For instance, elevated levels of *Parabacteria* and *Bacteroides* can induce colitis in mice[61], and *Helicobacter pylori* infection can cause peptic ulcer disease and gastric cancer[62]. Methicillin-resistant *Staphylococcus aureus* often colonizes the rectum and is associated with necrotizing enterocolitis[63,64]. Bacteroides S24-7 (*Muribaculaceae*) is the dominant bacterial family of Bacteroides, and its increase is closely related to inflammatory enteritis[65]. In this study, 5-Fu administration activated NF-κB, inhibited tight junction protein expression, and increased inflammatory cytokines and intestinal permeability. The relative abundance of *Lactobacilli* in the 5-Fu group markedly dropped.

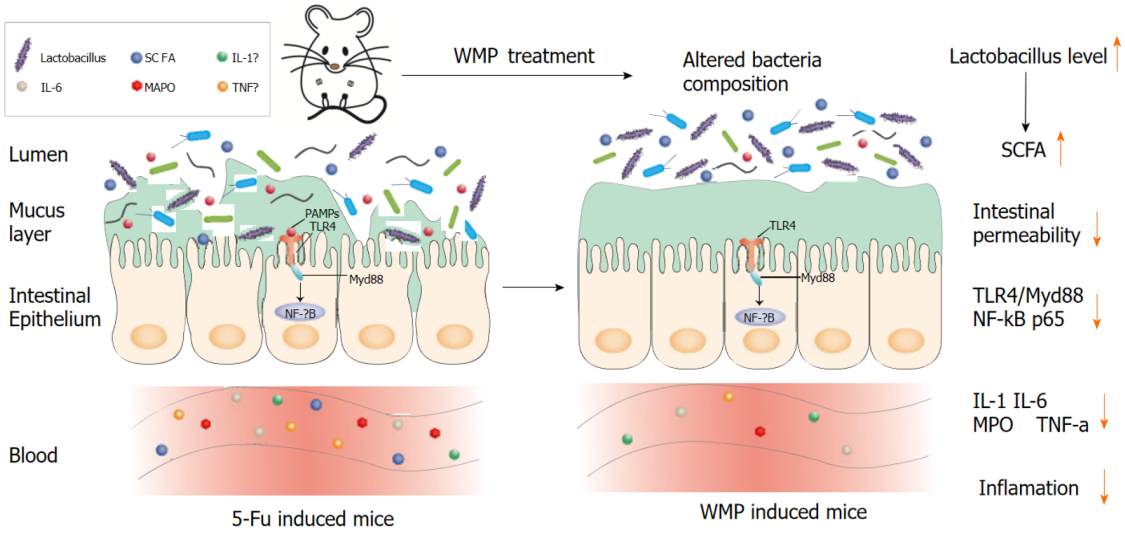

Figure 8 Schematic illustration of mechanisms for Wumei pills treatment in 5-fluorouracil-induced intestinal mucositis. WMP: Wumei pills; TNF-α: Tumor necrosis factor-α; IL-6: Interleukin-6; IL-1β: Interleukin-1β; MPO: Myeloperoxidase; SCFAs: Short-chain fatty acids; TLR4: Toll-like receptor 4; MyD88: Myeloid differentiation factor 88; NF-κB: Nuclear factor-κB; 5-Fu: 5-fluorouracil.

However, 22650 mg/kg WMP exerted a stronger effect than 11325 mg/kg WMP on the relative abundance of *Lactobacilli*. SCFA-producing bacteria have beneficial effects on the host by inhibiting inflammation, providing nutrition for colon cells, and protecting the intestinal mucosa[66]. As an SCFA-producing bacterium, *Lactobacillus* can lower the pH of the host colonic cells and inhibit the growth of pathogenic bacteria[67]. Therefore, this study preliminarily confirmed that WMP can change the composition and abundance of the intestinal flora and exert anti-inflammatory effects.

The functions of the intestinal microflora, including immune regulation, nutritional support of the colonic epithelium, and maintenance of stable barrier function, are closely related to SCFA. A previous study reported the involvement of metabolites in the development of intestinal mucositis[68]. It has been reported that SCFA protect the intestinal mucosa by reducing the level of inflammation[69]. SCFA can be absorbed by fluids that cause sodium decomposition through a process independent of circulating AMP. Therefore, the reduction in SCFA is related to diarrhea[70]. Butyrate reduces diarrhea by enhancing intestinal permeability[71]. In 5-Fu-induced diarrhea, the production of SCFAs was significantly reduced. Previous studies have found that WMP can significantly increase the abundance of butyric acid-producing bacteria (*Firmicutes*) in 5-Fu treated mice. Therefore, the results of this study were consistent with those of previous studies. WMP significantly changed the fecal SCFA content in 5-Fu treated mice. It increased the concentrations of acetic acid, propionic acid, and butyric acid, indicating that WMP can improve the production of SCFA and inhibit the progression of chemotherapy-induced intestinal mucosal inflammation.

CONCLUSION

In summary, our results demonstrate the beneficial effects and the associated mechanisms of WMP against CIM in mice (Figure 8). WMP activates the NF-κB pathway by restraining p65 translocation from the cytoplasm to the nucleus and inhibiting the expression of TLR4/MyD88/NF-κB proteins, resulting in the downregulation of expression of the inflammatory factors IL-1β, IL-6, MPO, and TNF-α, and increased expression of tight junction proteins (ZO-1, claudin-1, E-cadherin, and mucin-2). Moreover, WMP restores the diversity and abundance of the intestinal flora. WMP increases the relative abundance of *Lactobacilli* but decreases that of *Bacteroides*, *Helicobacter*, and *Parabacteroides*. Although further fecal bacterial transplantation or the downstream-mediated potential mechanisms of specific bacteria are worth exploring, WMP has potential therapeutic effects against CIM.

ARTICLE HIGHLIGHTS

Research background

Radiotherapy and chemotherapy can kill tumor cells and improve the survival rate of cancer patients. However, they can also damage normal cells and cause serious intestinal toxicity, leading to gastrointestinal mucositis. Traditional Chinese medicine is effective in improving the side effects of

chemotherapy. Wumei pills (WMP) is a classic prescription in Treatise on Febrile Diseases. It has a significant effect on chronic diarrhea and other gastrointestinal diseases, but it is not clear if it has an effect on chemotherapy-induced intestinal mucositis (CIM).

Research motivation

To explore the potential mechanism of WMP in the treatment of CIM using experimental research.

Research objectives

Exploring the mechanism of WMP to alleviate chemotherapy-induced intestinal mucosal inflammation may be to regulate the intestinal flora, thereby inhibiting the activation of downstream inflammatory signaling pathways and exerting anti-inflammatory effects.

Research methods

We used an intraperitoneal injection of 5-fluorouracil (5-Fu) to establish a mouse model of CIM and oral gavage of WMP decoction (11325 and 22650 mg/kg) to evaluate the efficacy of WMP in CIM. We evaluated the effect of WMP on CIM by observing the general conditions of mice (body weight, food intake, spleen weight, diarrhea score, and hematoxylin and eosin staining). To explore the potential mechanism of WMP in CIM, the expression of the inflammatory factors tumor necrosis factor-α (TNF-α), interleukin- 6 (IL-6), IL-1β, and myeloperoxidase (MPO), Toll-like receptor 4/myeloid differentiation-factor 88/nuclear factor-κB (TLR4/MyD88/NF-κB) signaling pathway proteins, and tight junction proteins [zonula occludens-1 (ZO-1), claudin-1, E-cadherin, and mucin-2] was determined. Furthermore, intestinal permeability, intestinal flora, and the levels of short-chain fatty acids (SCFA) were also assessed in the mice.

Research results

WMP effectively improved the body weight, spleen weight, food intake, diarrhea score, and inflammatory pathological status of mice with intestinal mucositis, which preliminarily confirmed the efficacy of WMP in CIM. Further experiments showed that WMP did not only reduce the levels of TNF-α, IL-1β, IL-6, and MPO, and inhibited the expression of TLR4/MyD88/NF-κB, but also repaired the integrity of the mucosal barrier of mice, regulated the intestinal flora, and increased the levels of SCFA (such as butyric acid).

Research conclusions

In summary, our results demonstrate the beneficial effects of WMP against CIM in mice and the associated mechanisms. WMP activates the NF-κB pathway by restraining p65 translocation from the cytoplasm to the nucleus and inhibiting the expression of TLR4/MyD88/NF-κB proteins, resulting in the downregulated expression of inflammatory factors (IL-1β, IL-6, MPO, and TNF-α) and increased expression of tight junction proteins (ZO-1, claudin-1, E-cadherin, and mucin-2). Moreover, WMP restores the diversity and abundance of the intestinal flora. In particular, WMP increases the relative abundance of *Lactobacilli* but decreases the relative abundance of *Bacteroides*, *Helicobacter*, and *Parabacteroides*.

Research perspectives

WMP has potential therapeutic effects against CIM, and further fecal bacterial transplantation or the downstream-mediated potential mechanisms of specific bacteria are worth exploring.

ORIGINAL ARTICLE

Basic Study

Sirolimus increases the anti-cancer effect of Huai Er by regulating hypoxia inducible factor-1α-mediated glycolysis in hepatocellular carcinoma

Lin Zhou, Yang Zhao, Li-Chao Pan, Jing Wang, Xian-Jie Shi, Guo-Sheng Du, Qiang He

Specialty type: Gastroenterology and hepatology

Provenance and peer review: Invited article; Externally peer reviewed.

Peer-review model: Single blind

Peer-review report's scientific quality classification

Grade A (Excellent): 0
Grade B (Very good): B
Grade C (Good): C
Grade D (Fair): 0
Grade E (Poor): 0

Abstract

BACKGROUND

Glycolysis caused by hypoxia-induced abnormal activation of hypoxia inducible factor-1α (HIF-1α) in the immune microenvironment promotes the progression of hepatocellular carcinoma (HCC), leading to enhanced drug resistance in cancer cells. Therefore, altering the immunosuppressive microenvironment by improving the hypoxic state is a new goal in improving cancer treatment.

AIM

To analyse the role of HIF-1α, which is closely related to tumour proliferation, invasion, metastasis, and angiogenesis, in the proliferation and invasion of liver cancer, and to explore the HIF-1α pathway-mediated anti-cancer mechanism of sirolimus (SRL) combined with Huai Er.

METHODS

Previous studies on HCC tissues identified the importance of HIF-1α, glucose transporter 1 (GLUT1), and lactate dehydrogenase A (LDHA) expression. In this study, HepG2 and Huh7 cell lines were treated, under hypoxic and normoxic conditions, with a combination of SRL and Huai Er. The effects on proliferation, invasion, cell cycle, and apoptosis were analysed. Proteomics and genomics techniques were used to analyze the HIF-1α-related signalling pathway during SRL combined with Huai Er treatment and its inhibition of the proliferation of HCC cells.

RESULTS

High levels of HIF-1α, LDHA, and GLUT-1 were found in poorly differentiated

HCC, with lower patient survival rates. Hypoxia promoted the proliferation of HepG2 and Huh7 cells and weakened the apoptosis and cell cycle blocking effects of the SRL/Huai Er treatment. This was achieved by activation of HIF-1α and glycolysis in HCC, leading to the upregulation of LDHA, GLUT-1, Akt/mammalian target of rapamycin (mTOR), vascular endothelial growth factor (VEGF), and Forkhead box P3 and downregulation of phosphatase and tensin homolog deleted on chromosome ten (PTEN) and p27. The hypoxia-induced activation of HIF-1α showed the greatest attenuation in the SRL/Huai Er (S50 + H8) group compared to the drug treatments alone (P < 0.001). The S50 + H8 treatment significantly downregulated the expression of mTOR and HIF-1α, and significantly reduced the expression of VEGF mRNA. Meanwhile, the combined blocking of mTOR and HIF-1α enhanced the downregulation of *Akt/mTOR*, *HIF-1α*, *LDHA*, and *GLUT-1* mRNA and resulted in the downregulation of *PTEN*, *p27*, and *VEGF* mRNA (P < 0.001).

CONCLUSION

SRL increases the anti-cancer effect of Huai Er, which reduces the promotion of hypoxia-induced HIF-1α on the Warburg effect by inhibition of the PI3K/Akt/mTOR-HIF-1α and HIF-1α-PTEN signalling pathways in HCC.

Key Words: Hepatocellular carcinoma; Sirolimus; Huai Er; Warburg effect; Hypoxia inducible factor-1α

Core Tip: Hypoxia-mediated glycolysis is associated with poorly differentiated hepatocellular carcinoma (HCC) and a poor prognosis. Hypoxia inducible factor-1α (HIF-1α), induced by hypoxia, promotes the growth of HepG2 and Huh7 cells and weakens the anti-cancer effect of sirolimus (SRL) and Huai Er. SRL increased the anti-cancer effect of Huai Er, which reduced the promotion of hypoxia-induced HIF-1α on the Warburg effect by inhibiting the PI3K/Akt/mammalian target of rapamycin-HIF-1α and HIF-1α-phosphatase and tensin homolog deleted on chromosome ten signalling pathways in HCC.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the third leading cause of cancer-related death worldwide. Its incidence and mortality are increasing annually, particularly in the younger age groups[1]. More than half of the cases are in China, with more than 90% being related to hepatitis B[1]. Therefore, cancer death is the primary cause of death in China, with liver cancer ranking second with 390000 cases[1,2]. Immunosuppressive cells of Forkhead box P3$^+$ (Foxp3$^+$) Tregs, neutrophils, MDSC, and others infiltrate the tumour[3,4]. Hypoxia-induced hypoxia inducible factor-1α (HIF-1α)-mediated glycolysis, infiltration of extracellular matrix, and accumulation of lactic acid in the anoxic microenvironment promote abnormal metabolism of cancer cells. This, combined with abnormal tumour immunity, leads to downregulation of immune surveillance, increased immune escape, and promotion of proliferation, invasion, and metastasis[4].

Hanahan proposed "abnormal energy metabolism" as the seventh feature of cancer[5], in which the metabolism of tumour cells, mainly represented by abnormal glucose metabolism (Warburg effect) and abnormal lipid metabolism, is closely related to tumour occurrence and metastasis. Recent studies have suggested that abnormal glucose metabolism in cancer is not only related to metabolic enzymes, metabolic pathways, and other related signal transduction pathways, but also to the immune status and local microenvironment of tumour tissues[6-8].

The anoxic environment induces the activation and upregulation of HIF-1α expression which promotes glycolysis, increases glucose transporter 1 (GLUT1) expression, and accelerates tumour cell metabolism[9]. It has been confirmed that HIF-1α can upregulate the activity of glycolytic enzymes by 90%[10] and produce a large amount of lactic acid through metabolism. Lactic acid is transported out of the cells and forms a high lactic acid environment in cancer tissue, leading to metabolic competition with T cells. This further inhibits the function, proliferation, and activation of infiltrated lymphocytes; destroys the killing effect and anti-tumour function; and promotes tumour immune escape[9-12].

However, cancer cells can efficiently use circulating lactic acid to produce glucose by anaerobic glycolysis, and a large number of electrons produced by metabolism adhere to lactic acid to compensate for the voltage instability inside and outside the cell caused by the high-speed electron movement of cancer cells, while ensuring the steady-state demand for energy and microenvironment for rapid growth and proliferation[10-12].

HIF-1α induction by Akt/mammalian target of rapamycin (mTOR)-mediated growth factors only involves the translation of mRNA under normoxia[13]; however, the regulatory mechanism of PI3K/Akt/mTOR on HIF-1α and the activation mechanism of PI3K are not clear under hypoxia. There may be alternative regulated signalling pathways because our results showed that the PI3K/Akt inhibitor, LY294002, cannot completely inhibit the expression of HIF-1α. Inhibiting the expression of HIF-lα and blocking the transmission of oxygen deficiency signals have become a new target for tumour therapy. Huai Er, also known as Trametes robiniophila Murr, is a traditional Chinese medicine. Various studies have demonstrated that Huai Er inhibits cancer progression and improves patient prognosis[14, 15]. The purpose of this study was to explore the regulatory mechanism of sirolimus (SRL) and Huai Er on HepG2 cell proliferation caused by abnormal activation of the HIF-1α pathway induced by hypoxia and to provide a theoretical basis for new clinical treatments for liver cancer.

MATERIALS AND METHODS

Regent and ethics approval

The hepatoma cell lines, HepG2 and Huh 7, were purchased from the Institute of Basic Medicine, Chinese Academy of Medical Sciences. Liver tissue was obtained from the pathological laboratory with written informed consent obtained in accordance with the Declaration of Helsinki of the World Medical Association. The study complied with the Institutional Guidelines for the Care and Use of Laboratory Animals and was approved by the Ethics Committee of Beijing Chaoyang Hospital (No. 2021-1-19-3) and PLA General Hospital (S2108-013-01). The experimental flowchart is shown in Supplementary Figure 1.

Cell proliferation experiment

HepG2 and Huh 7 cells were cultured at a density of 1 × 10^3/well with 100 μL complete medium (10% fetal bovine serum + RMPI-1640, Gibco, United States) overnight for 24 h, then treated with SRL, Huai Er, Ly294002 (Ly), and KC7F2 (KC7) for 24-48 h, and a mixture of 50 μL 1 × PBS and 20 μL MTS (Promega, United States) was added and co-cultured for 2-4 h. The OD value at 490 nm was used to calculate the IC_{50} values of the drugs and blockers.

Cell scratch assay

HepG2 and Huh7 cells were cultured at a density of 1 × 10^6/well for 24 h before scratching with a "cross" and culturing with 2 mL of treatment solution. Imaging identified the clear position of scratches, and images were acquired at 0 h, 24 h, and 48 h, the position of the scratch was marked, and the scratch images were analysed using Image J[16]. The treatment groups were as follows: Huai Er (H) (Gaitianli Co.), SRL (S) (Sigma, United States), Ly294002 (Ly) (TargetMol, United States), KC7F2 (KC7) (TargetMol, United States), H + S, H + Ly, H + KC7, S + Ly, S + KC7, Ly + KC7, and S + H + Ly + KC7.

Plate clone formation assay

HepG2 and Huh7 cells at a density of 500/well were cultured for 24 h, the culture medium was then changed before the addition of SRL, Huai Er, hypoxia (simulated by 200 μM $CoCl_2$, Sigma, United States), and SRL + Huai Er, and the cells were cultured for 10 d. After washing with 1 × PBS, the cells were fixed with 1% paraformaldehyde, stained with crystal violet, and photographed to observe the size of colonies.

Cell cycle and apoptosis assays

Preparation of single-cell suspension: A single-cell suspension was prepared using 0.25 % non-EDTA trypsin (Gibco, United States) to digest the cultured cells treated with Huai Er, SRL, and Huai Er + SRL.

Apoptosis detection: The prepared single-cell suspension was co-incubated with 5 μL of fluorescein isothiocyanate labelled Annexin V antibody and 2.5 μL of phycoerythrin-labelled PI antibody (BD, United States) for 15 min in a dark room at room temperature, washed with 1 ml precooled 1 × Binding Buffer, and centrifuged at 1200 rpm/min for 5 min, and the supernatant was discarded. The apoptosis rates of HepG2 and Huh 7 cells were determined by flow cytometry.

Cell cycle detection: The prepared single-cell suspension was fixed with 1 mL of 70% precooled ethanol at 4 °C for 12 h. After centrifugation at 1000 *g* for 5 min, the supernatant was discarded and the cell pellet was washed with 1 mL of precooled 1 × PBS, with 500 μL of PI/RNase staining buffer (BD Biosciences, United States) added for 10^6-10^7 cells to re-suspend cells for detection.

Immunohistochemistry

Paraffin-embedded tissues were sliced into thin tissue sections of 5 μm and heated at 60 °C for 30 min. The sections then underwent a dewaxing step, 3% hydrogen peroxide inactivation, antigen retrieval in a microwave at 100 °C for 20 min, and blocking for 30 min. Next, the cells were incubated with primary antibodies against HIF-1α, lactate dehydrogenase A (LDHA), and GLUT-1 (1:100) (Proteintech, United States) overnight. The cells were then incubated with the secondary antibody from PV-9000 kits (OriGene Technologies, United States) for 60 min, before staining with the DAB kit (Vector, United States) under a Nikon microscope system.

Protein isolation and Western blot analysis

Cultured cancer cells were lysed by trypsinisation at 4 °C and the total protein was extracted. Protein purity was determined using a bicinchoninic acid assay, according to the manufacturer's instructions and Western blot analysis was performed.

Reverse transcription-polymerase chain reaction gene detection

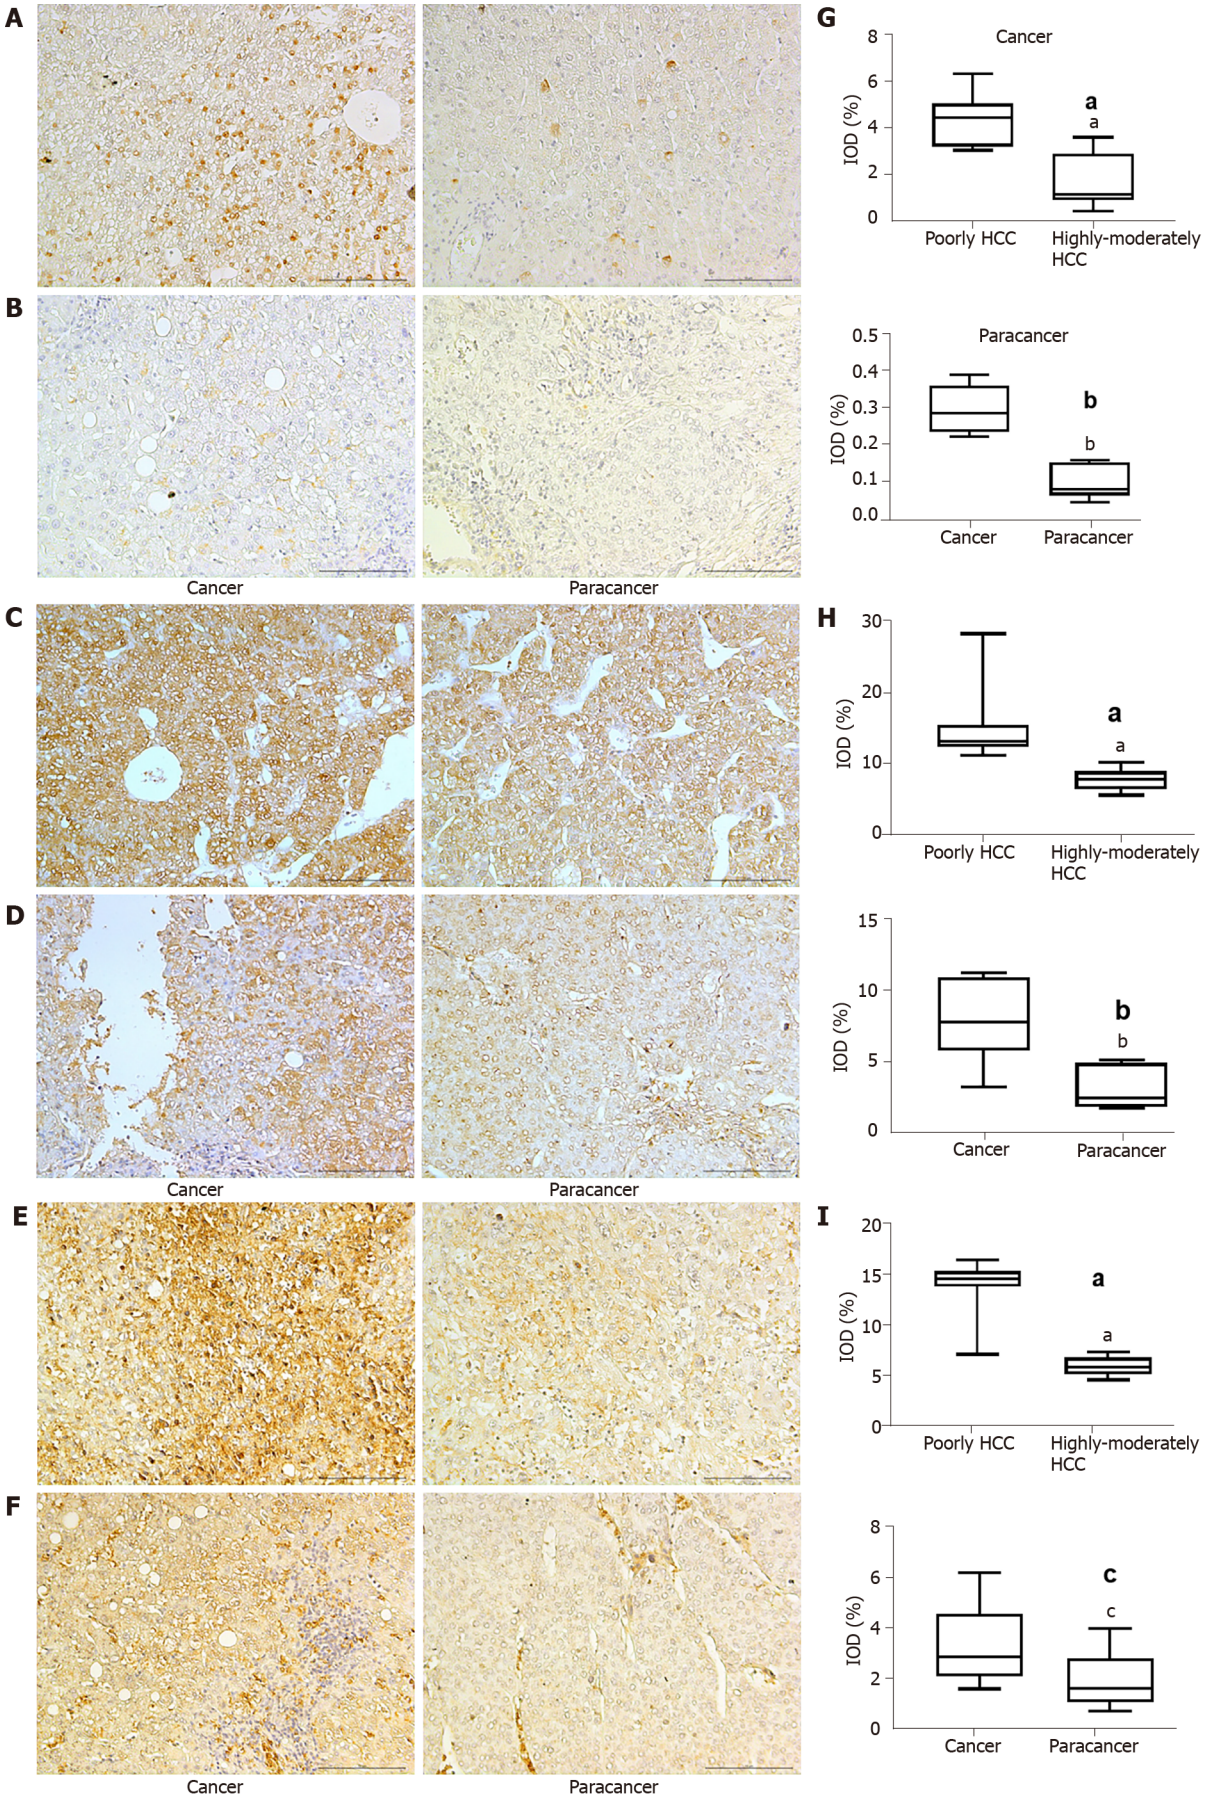
Total RNA was extracted using the TRIzol reagent (Life Technologies, Carlsbad, CA, United States), and the OD value was determined using a spectrophotometer. Primers were designed using the NCBI online primer design software Primer-BLAST and synthesised by Beijing Jingke Xinye Biotechnology Co., Ltd (China). The names of the primers and the corresponding sequence information are listed in Supplementary Table 1. Then, 24 μL of the reaction system was prepared for cDNA synthesis and stored at -20 °C for later use. After that, a 20 μL reaction system was prepared, and then instantaneous centrifugation was performed in the fluorescence quantitative polymerase chain reaction (PCR) instrument to carry out the reverse transcription (RT)-PCR reaction according to the manufacturer's protocol (Life Technologies, United States).

Statistical analysis

Images from an optical microscope were captured and stored, and the results of flow cytometry were analysed using FlowJo10.0 software. The data were analysed using SPSS 22.0. Each index is expressed as the mean ± SD, and the difference between two groups was tested using the *t*-test. Statistical significance was set at $P < 0.05$. Single-factor ANOVA was used to determine statistical differences among different experimental groups. Differences were considered significant at $P < 0.05$.

RESULTS

High level of HIF-1α and the Warburg effect indicate a poor survival benefit



We identified high expression levels of HIF-1α in patients with poorly differentiated HCC, with expression being higher in the cancer tissue than in para-carcinoma tissue (Figure 1A, B and G) ($P < 0.001$). Higher levels of GLUT-1 ($P < 0.05$) and LDHA ($P < 0.001$) were identified in cancer tissues compared to para-carcinoma tissues, indicating an enhanced glycolytic effect (Warburg effect); these higher levels of expression were also observed in patients with poorly differentiated HCC compared to those with moderately differentiated HCC (Figure 1C-F, H and I) ($P < 0.001$). The high levels of HIF-1α, GLUT-1, and LDHA were all associated with poorer survival outcomes ($P < 0.01$). Based on these results and our previous research on the effect of Huai Er and SRL on HCC in a rat model[15], we explored the effect of Huai Er combined with SRL on the glucose metabolism pathway in HepG2 and Huh7 cell lines, to determine the synergistic mechanism of tumour growth inhibition.

Optimal inhibitory concentrations of SRL, Huai Er, Ly294002, and KC7F2 on HepG2 cells

The suppression of proliferation of HepG2 and Huh7 cells increased gradually with the administration of SRL at concentrations ranging from 0.1 nM to 1000 nM. A gradual increase was also observed on the administration of Huai Er at concentrations ranging from 4 mg/mL to 8 mg/mL. The optimal inhibitory concentration was identified as 50 nM for SRL (S50) and 8 mg/mL for Huai Er (H8), using IC_{50} curve calculation. An optimal inhibitory concentration of 25 μM was calculated for Ly294002 (a specific inhibitor of PI3K) (Ly25) and 20 μM for KC7F2 (a selective inhibitor of HIF-1α) (KC7). These optimal concentrations were used in the following study with S50, H8, Ly25, and KC7 groups.

Huai Er displays a greater inhibitory effect than SRL on the invasion of HepG2 and Huh7 cells

The scratch test results showed that H8 treatment significantly inhibited the invasion of HepG2 and Huh 7 cells compared to S50 treated cells and the control group (Figure 2A and B). The addition of S50 enhanced the inhibitory effect of the H8 treatment, showing a greater inhibitory effect on invasion compared to the monotherapies (Figure 2C and E).

and B: Expression of hypoxia inducible factor-1 (HIF-1α) in poorly (A) and highly-moderately differentiated hepatocellular carcinoma (HCC) (B); C and D: Expression of lactate dehydrogenase A (LDHA) in poorly (C) and highly-moderately differentiated HCC (D); E and F: Expression of glucose transporter 1 (GLUT1) in poorly (E) and highly-moderately differentiated HCC (F); F: Expression of GLUT1 in high-moderately HCC, (Magnification: 200 ×, scale bar 10 μm); G-I: Comparison of HIF-1α (G), LDHA (H), and GLUT1 (I) in different groups by *t* test. Magnification: 200 ×, scale bar = 10 μm. [a]*P* < 0.001 *vs* poorly differentiated HCC; [b]*P* < 0.001 *vs* cancer; [c]*P* < 0.05 *vs* cancer.

Huai Er plus SRL treatment shows a greater inhibitory effect on invasion than other combined applications

Compared with the control group, the combination of any two drugs, Huai Er, SRL, Ly25, or KC7, significantly inhibited the invasion of cancer cells ($P < 0.001$) (Figure 2A, B, D and F). Huai Er application combined with S50, Ly25, or KC7 revealed a stronger inhibitory effect on the invasion of HepG2 and Huh 7 cells than other combined applications, with the strongest effect being noted in the H8 + S50 treatment group ($P < 0.001$) (Figure 2A, B, D and F).

Hypoxia promotes the proliferation of HepG2 and Huh7 cells

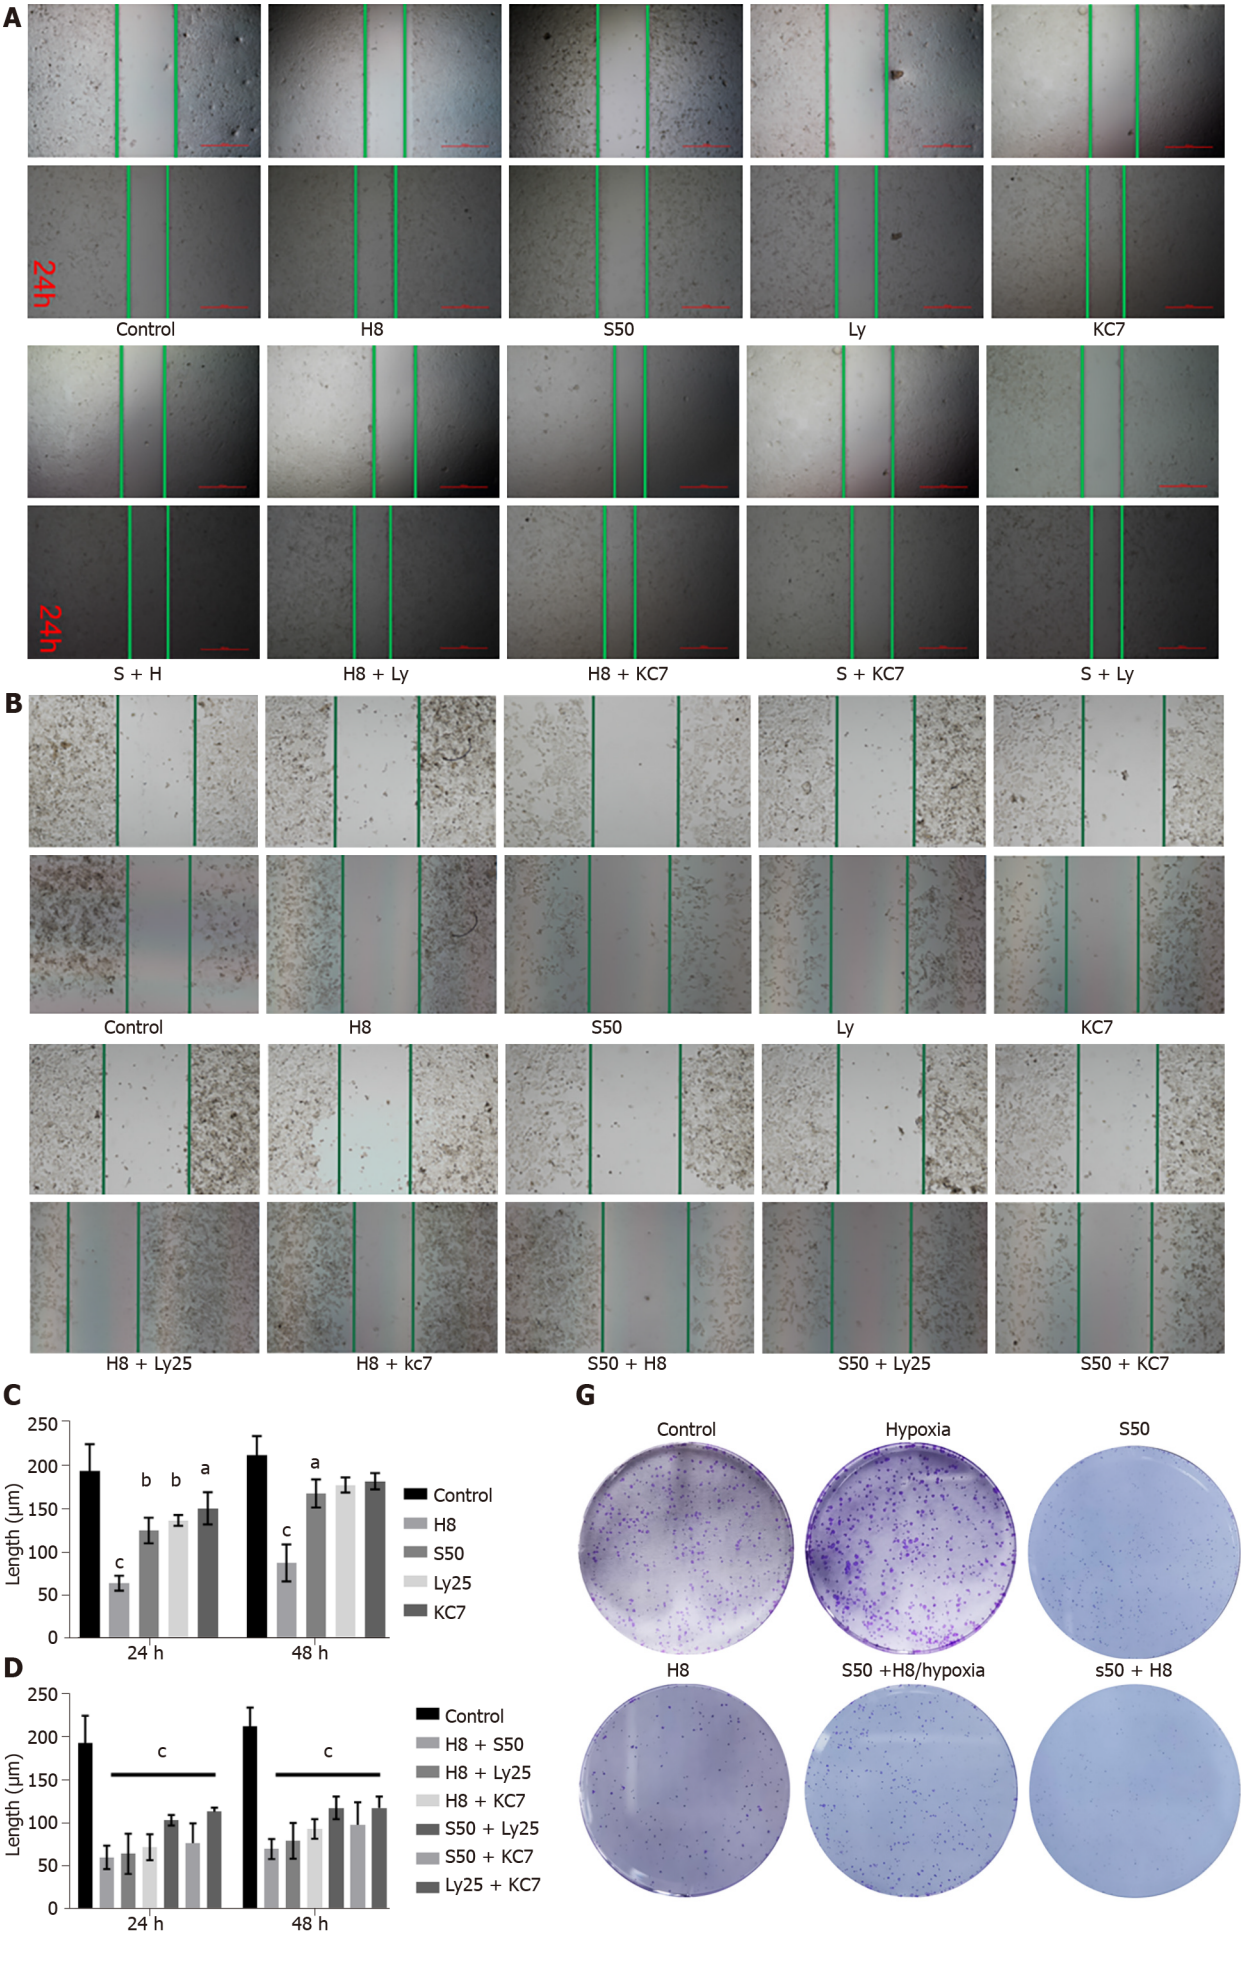
High proliferation of HepG2 and Huh7 cells was observed when maintained in a hypoxic environment at an appropriate concentration of $CoCl_2$, compared to when maintained under normoxic conditions (Figure 2G and H). The inhibitory effect of H8 + S50 on the proliferation of these cells was weakened after culturing under hypoxia (Figure 2G and H).

Promotion of cell apoptosis in both HepG2 and Huh7 cells after SRL and Huai Er treatment

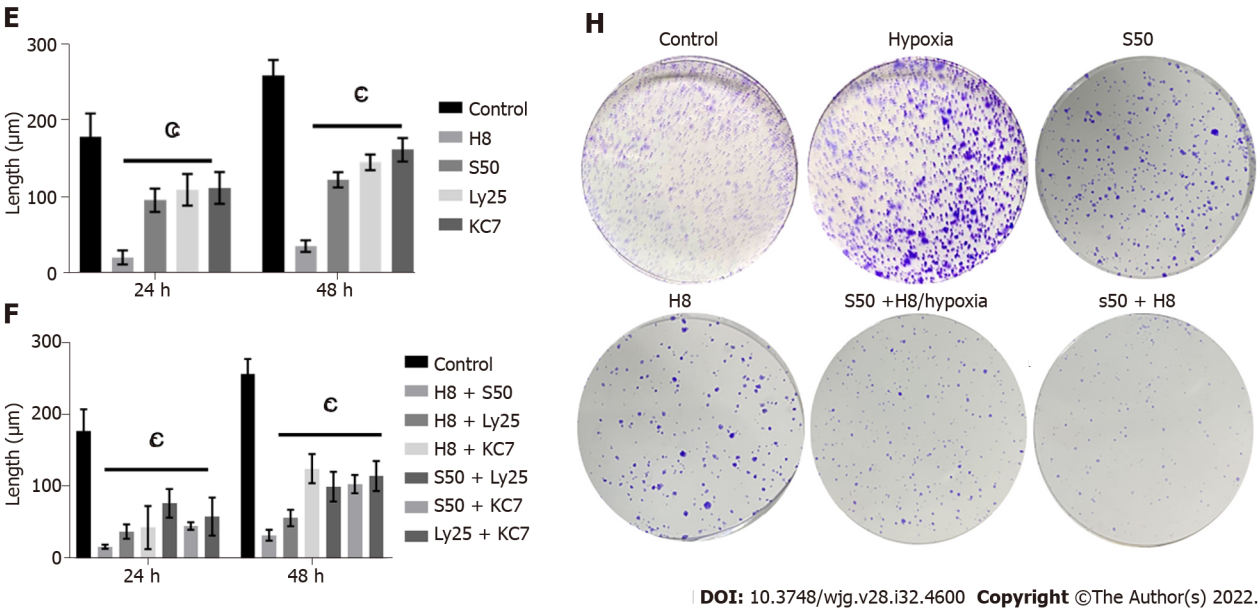
SRL and Huai Er promote the apoptosis of HepG2 and Huh7 cells under normoxia: The apoptosis rate of HepG2 (Figure 3A-H) and Huh7 (Figure 3I-P) cells increased gradually 24 h to 48 h after treatment with S50 and H8 ($P < 0.001$) (Figure 3A, B, G, I, J and O). The combination of S50 + H8 caused the highest promotion of apoptosis in this time period, compared to the single-drug treatments ($P < 0.001$) (Figure 3E, G, M and O). These results indicate that Huai Er may enhance the pro-apoptotic effect of S50 on HCC cells.

Hypoxia reduces the apoptosis effect of SRL and Huai Er on HepG2 and Huh7 cells: Despite the longer treatment time under hypoxia, the increased apoptosis rate of HepG2 and Huh7 cells (Figure 3C, D, H, K, L and P), observed with treatment under normoxia, was significantly reduced ($P < 0.05$, Figure 3). There was also a decrease in apoptosis levels after S50 + H8 treatment under hypoxia (Figure 3E, F, H, M, N and P) in both HepG2 and Huh7 cells.

SRL and Huai Er treatment blocks cell cycle processes of HepG2 and Huh7 cells



Hypoxia weakens the blocking effect of SRL and Huai Er on the cell cycle: Treatment with S50 and H8 showed a significant blocking effect, in the form of mitotic stagnation in the G2 phase. Increased proportions of S and G2 phase HepG2 cells were observed (Figure 4A-H), while Huh 7 cells showed an increased proportion in the G2 phase (Figure 4I-P). Both cell types had a decreased proportion in the G1 phase ($P < 0.01$) (Figure 4A-D and I-L). The blocking effect occurred gradually over time (Figure 4A-D and I-L) ($P < 0.01$). When cultured under hypoxia, the blocking effect of SRL and Huai Er on HepG2 and Huh7 cells was weakened, and there was no significant difference in the S50 treatment group, compared with the hypoxia group after treatment at either time point, ($P > 0.05$) (Figure 4E, F, H, M, N and P); however, the difference in H8 remained statistically significant ($P < 0.001$).



SRL application with Huai Er has a synergistic effect in blocking the cell mitotic cycle: S50 + H8 treatment significantly inhibited the cell division of HepG2 cells in the S phase under normoxia, while the ratio of G1 phase to G2 phase cells decreased both at 24 h and 48 h (Supplementary Figure 2A-C) ($P < 0.05$) (Supplementary Figure 2C). This ratio was significantly higher than that observed for the single drug treatments ($P < 0.01$) (Supplementary Figure 2E and F), suggesting that SRL and Huai Er may have synergistic inhibitory effects. Hypoxia attenuated the synergistic inhibitory effect of S50 + H8 on the cell cycle of HepG2 (Supplementary Figure 2A-D), decreasing the proportion of S-phase cells ($P < 0.01$). The ratio of G1 phase to G2 phase cells after S50 + H8 treatment was significantly higher than that of the S50 group ($P < 0.01$), but not significantly different from that in the H8 group (Supplementary Figure 2G and H), at both timepoints.

Thus, we believe that the combined SRL and Huai Er treatment can significantly arrest the cell cycle of HepG2 and Huh7 cells; therefore, protein and gene-level analyses were mainly focused on HepG2 cells.

SRL combined with Huai Er significantly decreases the expression of mTOR and HIF-1α

To further explore the molecular mechanism of SRL combined with Huai Er, Western blot was used to analyse the expression levels of the key proteins in the PI3K signalling pathway (mTOR) and in hypoxia-induced factor-mediated glycolysis (HIF-1α). Compared with the control and the monotherapy

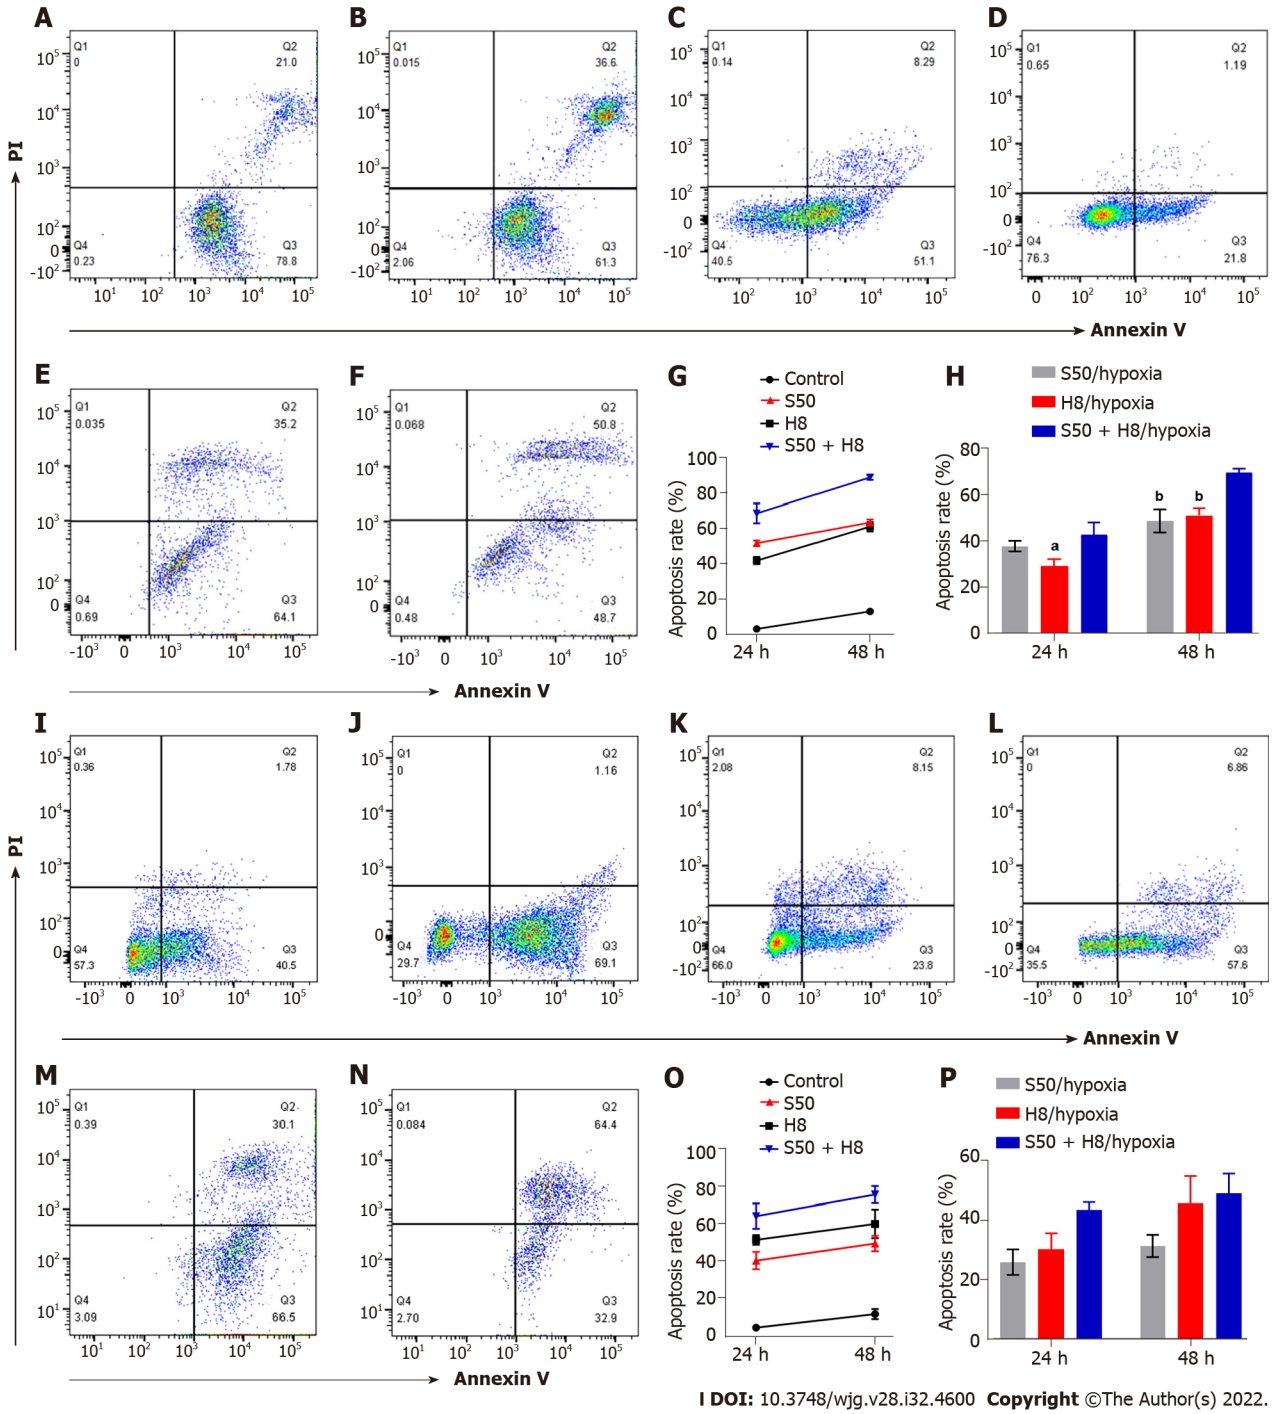
treatments, S50 + H8 significantly reduced the expression levels of mTOR and HIF-1α (Supplementary Figure 3A-C).

Hypoxia-induced HIF-1α promotes HepG2 cell proliferation by enhancing the Warburg effect

Hypoxia can significantly upregulate the expression of *HIF-1α* mRNA, while increasing the expression of *LDHA* and *GLUT-1* mRNA in anaerobic glycolysis, leading to the promotion of vascular endothelial growth factor (*VEGF*) mRNA expression (Supplementary Figure 3D and E). Hypoxia also downregulated the mRNA expression of *FoxP3*, *p27*, and Phosphatase and tensin homolog deleted on chromosome ten phosphatase and tensin homolog deleted on chromosome ten (*PTEN*). Although there was an increase in the expression of Akt and mTOR, no significant difference was observed (Supplementary Figure 3D and E). These results suggest that hypoxia-induced HIF-1α upregulation can mediate downstream activation, leading to an enhancement of HepG2 cell proliferation by upregulating the expression of LDHA and GLUT-1.



Effect of SRL and Huai Er on expression of target gene mRNA under normoxia

SRL promotes the mRNA expression of *Akt*, *p27*, and *PTEN*, and decreases the mRNA expression of *FoxP3* and *VEGF*: Compared to the control group, the expression of *mTOR* mRNA showed no significant expression changes. However, SRL significantly upregulated the mRNA expression of *Akt*, *p27*, and *PTEN*; this upregulation changed significantly over time (Figure 5A). In addition, SRL treatment significantly downregulated the mRNA expression of *FoxP3* and *VEGF* over the same timeperiod (Figure 5A).

Effect of Huai Er on the mRNA expression of *Akt*, *mTOR*, *FoxP3*, and *VEGF*: Compared with the control group, Huai Er treatment significantly downregulated the mRNA expression of *Akt*, *mTOR*, *FoxP3*, and *VEGF*; this downregulation was significantly increased over time (Figure 5B). The mRNA levels of *p27* ($P_{24\,h} = 0.0066$, $P_{48\,h} = 0.0038$) and *PTEN* ($P_{24\,h} = 0.003$, $P_{48\,h} = 0.0007$) were increased at both time points. *Akt* and *mTOR* expression showed the most significant downregulation after treatment, leading to a reduction in *FoxP3* and *VEGF* mRNA levels from 24 h to 48 h.

SRL and Huai Er downregulate the expression of HIF-1α induced by hypoxia

SRL treatment blocked the downstream amplification effect caused by the expression of mTOR *mRNA* under hypoxia, which significantly downregulated the enhancement effect of hypoxia on *HIF-1α* mRNA expression ($P < 0.01$) (Figure 5C). The treatment also decreased the mRNA expression levels of *VEGF*, *LDHA*, and *GLUT-1* ($P < 0.01$), and simultaneously upregulated the mRNA expression of *p27*, *PTEN*, and *FoxP3* ($P < 0.001$) (Figure 5C). Compared with the hypoxia group, the Huai Er treatment attenuated the hypoxia-induced enhanced mRNA expression of *HIF-1α* and downregulated the mRNA expression of *Akt*, *mTOR*, *VEGF*, and *FoxP3* ($P < 0.01$) (Figure 5C). It also significantly decreased the mRNA

expression levels of *LDHA* and *GLUT-1* ($P < 0.001$) and upregulated the mRNA expression of *p27* and *PTEN* ($P < 0.001$) (Figure 5C).

LY294002 treatment downregulates hypoxia-induced HIF-1α expression and weakens its mediated glycolytic effect

LY294002 specifically inhibits PI3K, leading to a downstream blocking effect. Ly25 treatment significantly downregulated the mRNA expression of *Akt* and *mTOR* and caused a reduction in *VEGF* and *FoxP3* mRNA expression. Downregulation of mRNA expression of *HIF-1 α, LDHA*, and *GLUT-1*, and upregulation of *p27* and *PTEN* (Figure 6A) were also observed. When compared with the control

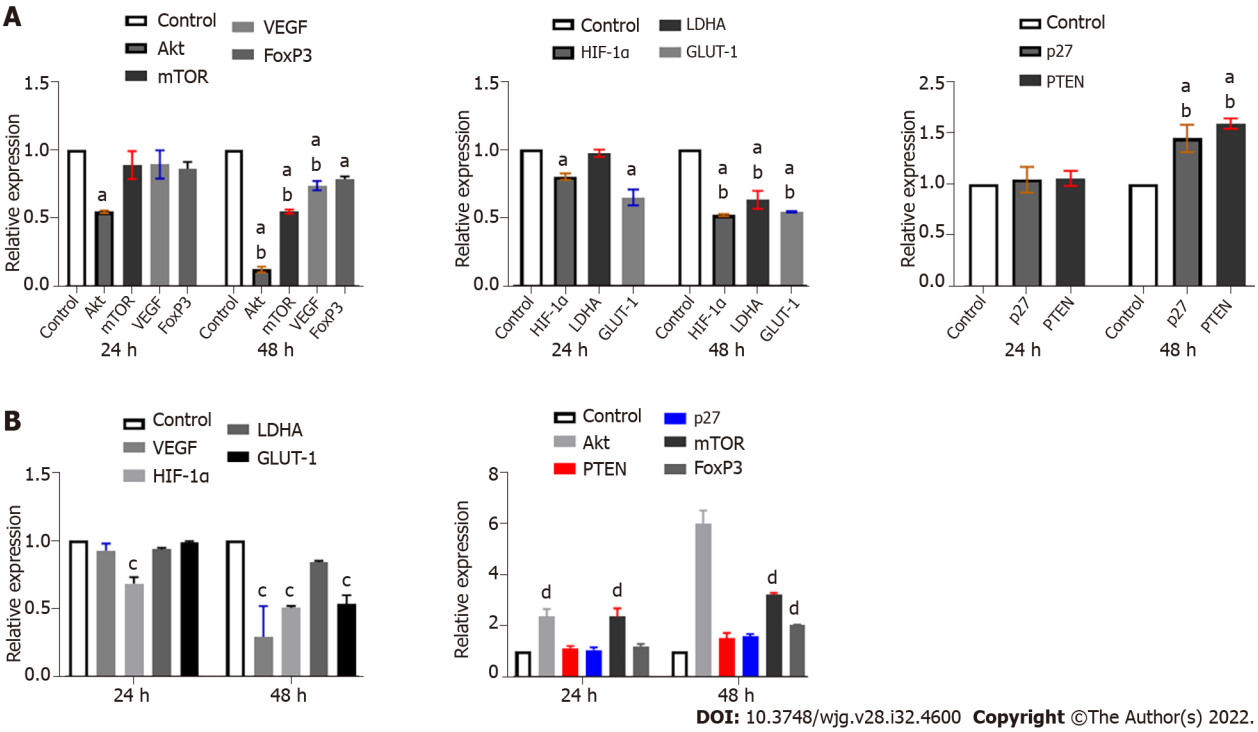
group, only the expression of *Akt* mRNA was significantly downregulated at 24 h ($P < 0.05$) (Figure 6); significant differences among the other groups only became apparent after 48 h ($P < 0.05$) (Figure 6A). Except for *FoxP3*, there were significant differences between 48 h and 24 h in the other groups ($P < 0.05$) (Figure 6A).

KC7F2 blocks HIF-1α and results in decreased mRNA expression of LDHA and GLUT-1



Under normoxia, HIF-1α in tissues was quickly degraded by the intracellular, oxygen-dependent, ubiquitin protease degradation pathway, and its stable expression was weak. Therefore, we used the KC7F2-specific blockade of HIF-1α as a reference. Upon treatment with KC7F2, the mRNA expression of *Akt*, *mTOR*, *PTEN*, and *p27* was upregulated, while the mRNA expression of *VEGF*, *HIF-1α*, *LDHA*, and *GLUT-1* was downregulated (Figure 6B).

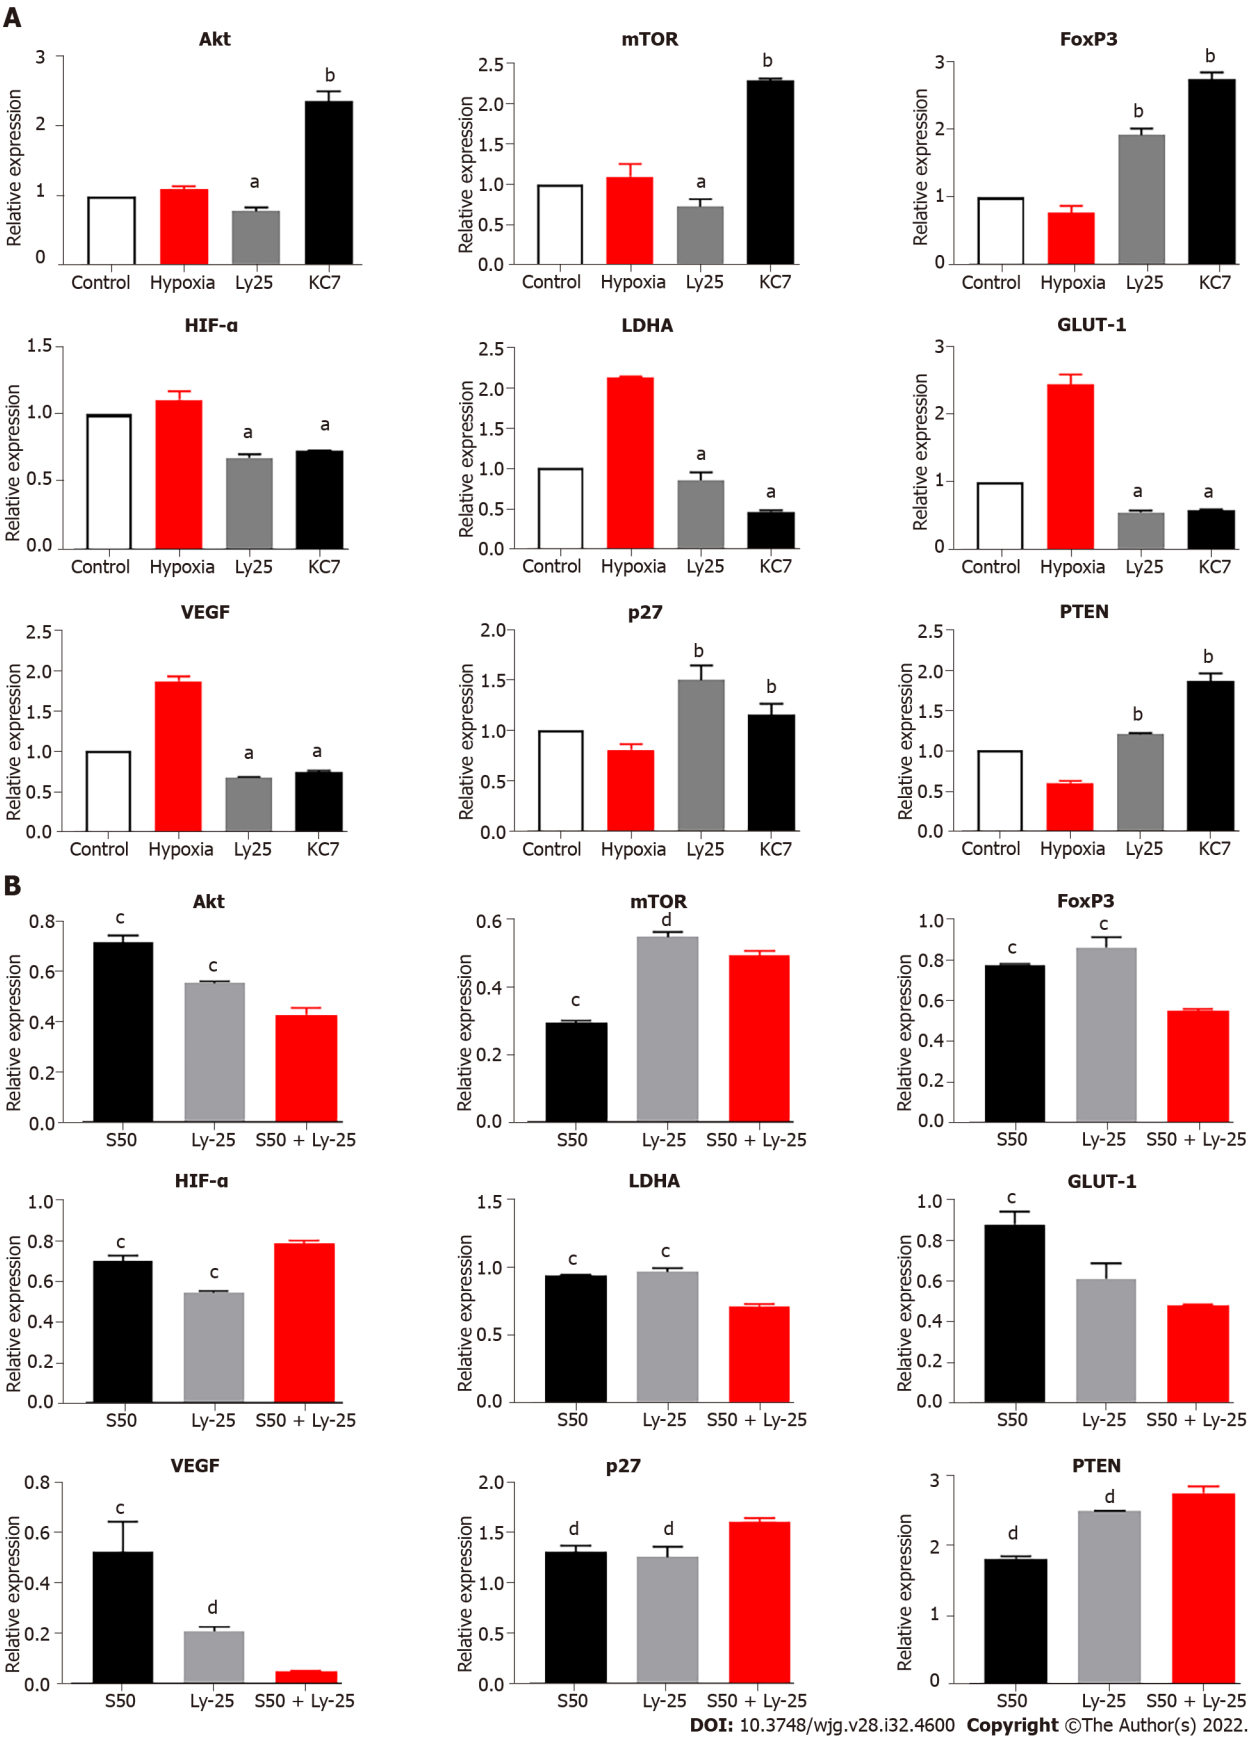
Ly25 and KC7 treatment weakens the promotion of anaerobic glycolysis mediated by hypoxia-induced HIF-1α accumulation



The mRNA expression of *Akt, mTOR, VEGF, HIF-1α, LDHA*, and *GLUT-1* was decreased after treatment with Ly25 ($P < 0.05$) (Figure 7A), while the mRNA expression of *p27, PTEN*, and *FoxP3* was upregulated ($P < 0.05$) (Figure 7A). KC7F2 specifically inhibited the expression of HIF-1α, which downregulated the hypoxia-induced *HIF-1α* mRNA expression ($P < 0.05$). There was also a significant downregulation of *LDHA, GLUT-1*, and *VEGF* mRNA expression ($P < 0.05$) (Figure 7A), while upregulation of *p27* and *PTEN* mRNA expression was observed. However, blocking with KC7 did not inhibit the Akt/mTOR signalling pathway ($P < 0.05$) (Figure 7A), indicating that other regulatory pathways may be involved.

Combined treatment of SRL with Huai Er significantly downregulates the expression of Akt/mTOR

The S50 + H8 combined treatment significantly downregulated the mRNA levels of *Akt* and *mTOR* to a greater extent than the downregulation observed with the H8 treatment alone. In contrast, individual S50 treatment resulted in an upregulation (Figure 8A). The downregulation of *Akt* and *mTOR* mRNA expression resulted in a significant downregulation of *VEGF* ($P < 0.01$) and *FoxP3* mRNA expression ($P < 0.05$) (Figure 8A), and an upregulation of *p27* ($P < 0.01$) and *PTEN* mRNA expression ($P < 0.05$) (Figure 8A).

SRL combined with Ly25 enhances the inhibition of anaerobic glycolysis

Compared with S50 and Ly25 individual treatments, the S50 + Ly25 combination significantly reduced the mRNA expression of *VEGF* and *FoxP3* ($P < 0.05$) (Figure 7B), and significantly upregulated the mRNA expression of *PTEN* and *p27*; there was a significant difference in *p27* mRNA between the two groups ($P < 0.05$). PTEN expression only showed a significant difference between the S50 and S50 + Ly25 groups ($P < 0.05$) (Figure 7B). Downregulation of *Akt, LDHA*, and *GLUT-1* mRNA expression was observed in the S50 + Ly25 group and was more significant than that in the hypoxia group; the difference between groups was significant ($P < 0.01$) (Figure 7B).

[a]*P* < 0.05 *vs* hypoxia; [b]*P* < 0.05 *vs* hypoxia; [c]*P* < 0.05 *vs* S50 + Ly25; [d]*P* < 0.01 *vs* S50 + Ly25. mTOR: Mammalian target of rapamycin; VEGF: Vascular endothlial growth factor; FoxP3: Forkhead box P3; HIF-1α: Hypoxia inducible factor-1α; LDHA: Lactate dehydrogenase A; GLUT-1: Glucose transporter 1; PTEN: Phosphatase and tensin homolog deleted on chromosome ten.

SRL combined with KC7F2 enhances the inhibition of the Akt/mTOR signalling pathway

Compared with the S50 and KC7F2 groups, the combined treatment of S50 + KC7F2 significantly downregulated the mRNA expression of *VEGF* ($P < 0.01$) (Figure 8B) and upregulated the mRNA expression of *p27* ($P < 0.05$) and *PTEN* ($P < 0.01$) (Figure 8B). S50 + KC7F2 treatment also significantly downregulated the mRNA levels of *Akt* and *mTOR* ($P < 0.01$) (Figure 8B), and neutralised the downregulation of *FoxP3* mRNA expression by S50 and upregulation of *FoxP3* mRNA expression by KC7F2 (Figure 8B).

DISCUSSION

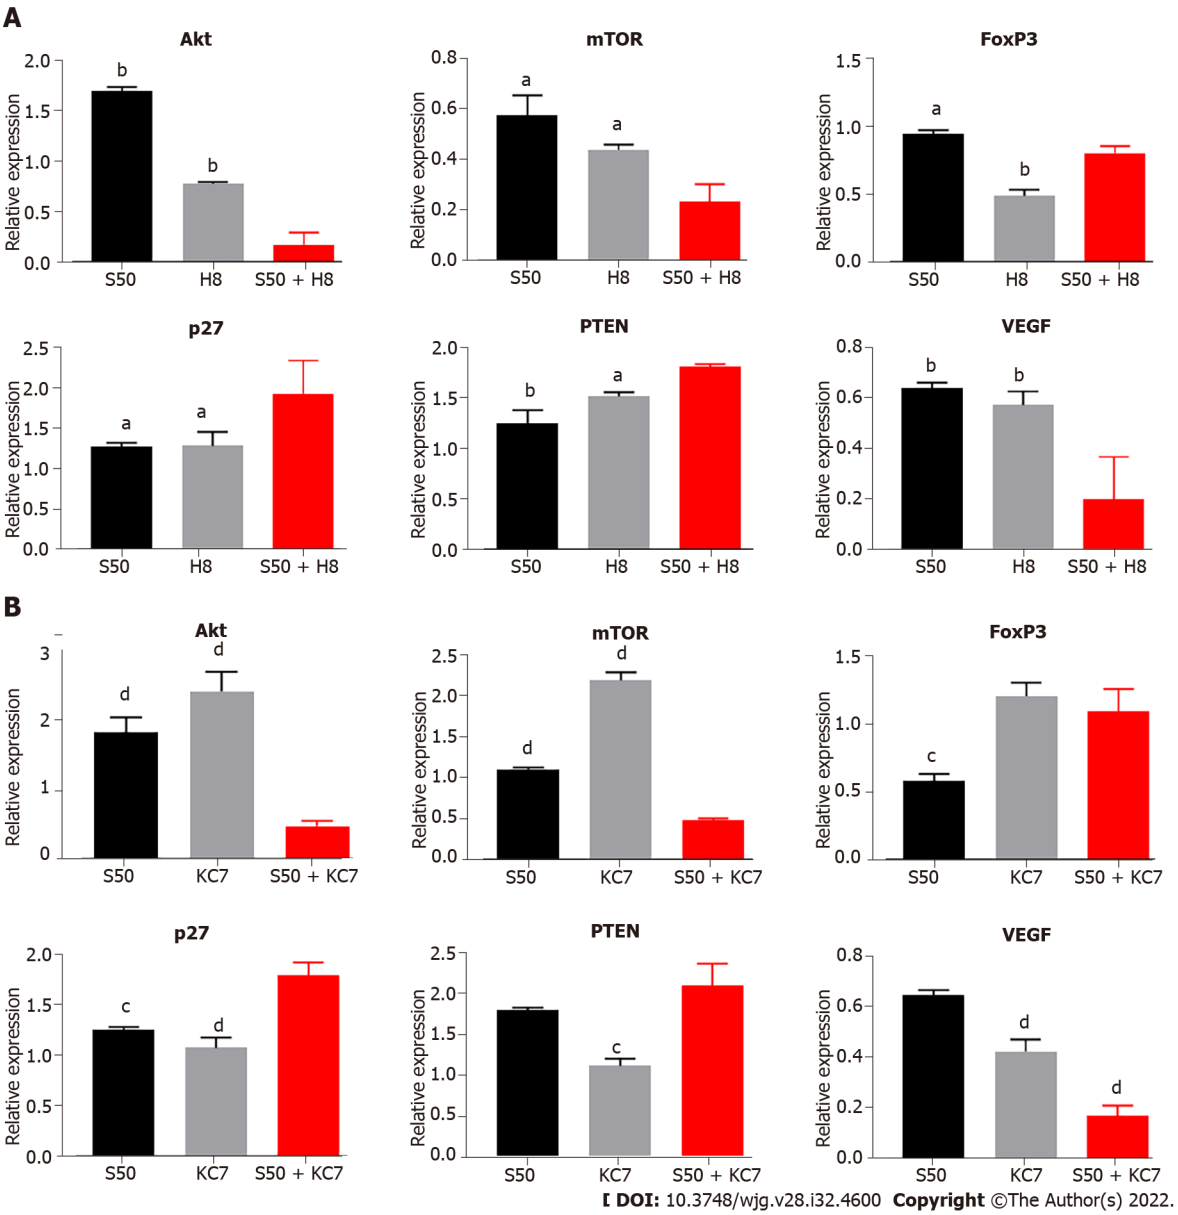
A large number of infiltrated lymphocytes, fibroblasts, macrophages, neutrophils, myeloid-derived suppressor cells (MDSCs), and other immune cells result in local immunosuppression and a hypoxic environment which activates HIF-1α[4]. The highly acidic microenvironment caused by the abnormal metabolism of cancer cells and local microvascular infiltration plays an important role in tumor recurrence, proliferation, and invasion[4]. In this study, we indirectly confirmed that high expression of HIF-1α, LHDA, and GLUT-1 in poorly differentiated HCC indicates active glycolysis.

The anoxic and hyperacidic environment of local cancer tissue leads to the inhibition of immune cell function and downregulation of immune cell activity. Cancer cells can constantly adapt to this microenvironment, absorb circulating lactic acid for energy supply, and thus compete with infiltrating immune cell metabolism. This results in a lack of nutrition for T cells in local tissues, low anti-tumour effect, and resultant immune escape of tumour cells[7,12].

It has been confirmed that highly infiltrated regulatory T cells and neutrophils in the local microenvironment are negatively correlated with tumour pathological differentiation and prognosis. In addition, the increase in $FoxP3^+$ Tregs and neutrophil-to-lymphocyte ratio in peripheral blood before surgery is related to a poor prognosis after surgery[17,18]. We confirmed the relationship between $FoxP3^+$ Tregs and recurrence of liver cancer and its inhibitory effect on T cells[15,17]. We found that SRL combined with Huai Er and Thymalfaxin could reduce the level of $FoxP3^+$ Tregs in peripheral blood, delaying the time to tumour recurrence after liver transplantation[19]. However, the specific mechanism of action of $FoxP3^+$ Tregs remains unclear. The present study aimed to explore whether SRL application in combination with Huai Er can achieve antitumour effects by affecting the glycolytic pathway.

Mechanism analysis of proliferation inhibition by SRL combined with Huai Er

Due to the immunosuppressive microenvironment of hypoxia and lactic acid accumulation, most of the $CD8^+$ T lymphocytes infiltrating HCC were in a non-functional state and had a low immune response [10,20]. The cytokine TGF-β and chemokines CXCR4 and CXCR7 produced during tumour proliferation tend to recruit circulating neutrophils and Tregs to the local microenvironment; tumour-related neutrophils can recruit Tregs in cancer tissues through the role of chemokines[3,21]. This interaction between neutrophils and Tregs may enhance the inhibitory properties of the tumour microenvironment. Our previous studies confirmed that $FoxP3^+$ Tregs and $PD\text{-}L1^+$ neutrophils are highly expressed in HCC patients, with or without recurrence[17]. The levels of IL-10 and TGF-β in peripheral blood are significantly higher in patients with cancer than in normal individuals, which is consistent with published results[15,17]. $FoxP3^+$ Tregs inhibit $CD8^+$ T cells to promote tumour growth by secreting IL-10 and TGF-β, which may be a target for the anticancer mechanism of Huai Er. In this study, the cell proliferation assay confirmed that SRL and Huai Er inhibited the growth and proliferation of HepG2 and Huh 7 cell lines in a time- and dose-dependent manner. Treatment with SRL at 50 nM and Huai Er at 8 mg/mL showed the greatest inhibition.



The inhibitory effect of SRL combined with Huai Er was significantly better than that of either of them alone and that of SRL or Huai Er combined with LY294002 and KC7F2 when observing cell invasion by cell scratch assay. This suggested a synergistic effect in inhibiting the invasion of HepG2 and Huh 7 cells. Furthermore, SRL combined with Huai Er displayed high inhibition of the proliferation of cancer cell colonies. These results indicate that Huai Er and SRL inhibited the proliferation and invasion of HepG2 and Huh 7 cells in a concentration- and time-dependent manner.

We confirmed that the apoptosis-promoting effects of SRL and HuaiEr on HepG2 and Huh 7 cells affected mainly early apoptosis, with the combined treatment having a greater effect. Furthermore, SRL and Huai Er significantly increased the proportion of cells in the S + G2 or G2 phase, and this proportion was higher in the combined treatment group compared to the monotherapy groups.

We believe that the inhibitory effect of SRL combined with Huai Er on HepG2 and Huh 7 cell proliferation is achieved mainly by inducing cell cycle arrest in the G2 phase and promoting apoptosis.

Effects of hypoxia and HIF-1α on the anti-tumour effect of Huai Er and SRL

Hypoxia is a common pathophysiological change during the development of most solid tumours[22]. The expression of HIF-1α is first activated by hypoxia in tissue cells, which induces $CD4^+$ T cells to differentiate into $FoxP3^+$ Tregs[23] and plays a role in the regulation of FoxP3 expression[24,25]. Hypoxia can induce the expression of PD-L1 (CD274) on the surface of immune cells (macrophages,

[a]*P* < 0.05 *vs* S50 + H8; [b]*P* < 0.01 *vs* S50 + H8; [c]*P* < 0.05 *vs* S50 + KC7; [d]*P* < 0.01 *vs* S50 + KC7. mTOR: Mammalian target of rapamycin; VEGF: Vascular endothlial growth factor; FoxP3: Forkhead box P3; PTEN: Phosphatase and tensin homolog deleted on chromosome ten.

neutrophils, dendritic cells, MDSCs, *etc.*) and cancer cells[26], which competitively binds to PD-1 receptors on the surface of T cells, resulting in impaired T cell activation function[27,28]. In this study, hypoxia promoted the formation and growth of cancer cell colonies, resulting in a significant increase in the number of cancer cell colonies in the S50 + H8 group. In addition, hypoxia increased the survival rate of HepG2 and Huh 7 cells, whereas Huai Er and SRL promoted their apoptosis.

Although the apoptotic effect increased gradually over time, the maximum apoptotic effect under normoxic conditions was significantly lower than that under hypoxic conditions in both the single drug and S50 + H8 groups. Although hypoxia could significantly downregulate the blocking effect of SRL on the S + G2 phase of HepG2 cells and G2 phase of Huh7 cells, it had less effect on the cell cycle stagnation caused by H8 treatment. Under hypoxic conditions, the S50 + H8 group still had an increased proportion of cells in the S + G2 phase although this proportion was lower than that observed in normoxia. This may be because Huai Er is involved in multiple signalling pathways rather than acts within a single cell signalling pathway which is blocked during hypoxia.

Under normoxic conditions, SRL and Huai Er can act synergistically to inhibit tumour proliferation, but this effect is weakened under hypoxic conditions, possibly due to downstream effects activated by HIF-1α. This indicates that removing the hypoxic environment of tumours may be the key to increasing the efficacy of anti-cancer drugs.

Analysis of HIF-1α regulated tumour growth induced by the hypoxic environment

When cultured under hypoxia, the promotion of HepG2 and Huh 7 cell proliferation and the decrease in apoptosis and cell cycle progression by S50 + H8 treatment indicated that hypoxia plays an important role in HCC. Under hypoxic conditions, *HIF-1α* and *mTOR* in HCC cell lines were shown to be upregulated; in addition, *LDHA, GLUT-1*, and *VEGF* mRNA expression was upregulated and *PTEN* and *p27* mRNA expression was inhibited. The mRNA expression levels of Akt and mTOR were upregulated in the hypoxic environment, although this was not statistically significant. The relative decrease in *Akt* and *mTOR* mRNA expression over time may be related to the activation of the HIF-1α-PTEN-Akt pathway by hypoxia, thereby increasing the glucose metabolism mediated by HIF-1α.

Molecular mechanism of HIF-1α regulated by Huai Er and SRL

The decrease in *HIF-1α* and *mTOR* levels in the S50, H8, and S50 + H8 treatment groups may indicate a potential target pathway for S50 + H8 application in the treatment of HCC. With the intervention of SRL, the mRNA expression of *VEGF* and *FoxP3* was downregulated, while the mRNA expression of *Akt, PTEN*, and *p27* was upregulated. With the intervention of Huai Er, the mRNA expression of *Akt, mTOR, VEGF*, and *FoxP3* was downregulated, while the mRNA expression of *PTEN* and *p27* was upregulated. The combined effects of downregulation of *VEGF, Akt*, and *mTOR* mRNA expression and upregulation of *p27* and *PTEN* were observed more significantly in the S50 + H8 group than in the individual treatment groups. The downregulation of *FoxP3* mRNA was lower than that in the H8 treatment group; this may be associated with the immunomodulatory function of SRL.

Under hypoxic conditions, the accumulation of *HIF-1α* mRNA after treatment with SRL and Huai Er was downregulated. In addition, the mRNA expression of *Akt, mTOR, VEGF, LDHA*, and *GLUT-1* was downregulated, and *PTEN* and *P27* were upregulated. However, the effect of Huai Er combined with SRL was enhanced compared with that of monotherapies, which further confirmed that SRL combined with Huai Er exerted anti-tumour effects through the PI3K-Akt-mTOR-HIF-1α pathway. Previous studies have reported that hypoxia-induced cumulative activation of HIF-1 α can downregulate the mRNA expression of *PTEN* and *P27*, enhance the glycolytic function of tumour cells, and promote the growth and proliferation of tumour cells by upregulating *LDHA* and *GLUT-1* mRNA expression[29]. There have been debates in the literature regarding the mechanism by which[30] hypoxia decreases the expression of FoxP3, with some saying that this is not HIF-1 dependent[31]. In our study, the expression changes of FoxP3 were not consistent with HIF-1 α under hypoxic conditions; this requires further research on co-culture with T cells. The final effect of a significant reduction in *VEGF* mRNA expression was observed, and therefore, we believe that there exists a co-effect of the HIF-1α-PTEN-Akt /mTOR pathway.

Most anticancer drugs decrease the downstream activation effect by reducing the activity of the PI3K-Akt-mTOR pathway[32,33]. PTEN negatively regulates PI3K/Akt signalling and is a well-known tumour suppressor[34]. Studies have demonstrated a strong correlation between alterations in the PTEN/PI3K/Akt cascades and the carcinogenesis of human tumours, including HCC, therefore making it a promising therapeutic target for HCC[34-36]. It has been proved that an increase in PTEN can inhibit the expression of PI3K/pAkt[37]. The upregulation of PTEN can indirectly increase p27 by secreting signal factors[38,39], while the increased PTEN acts on the PI3K-Akt-mTOR pathway and downregulates the expression of pAkt[40,41], further weakening the downstream activation effect. We believe that in this study, the intervention of SRL and Huai Er played a role by downregulating the activity of the Akt/mTOR pathway and increasing the expression of PTEN. SRL can increase the sensitivity of HepG2 cells to Huai Er and exert an anticancer effect through the PI3K-Akt-mTOR-PTEN and PTEN-Akt/mTOR-FoxP3 regulation pathways.

To further investigate the regulatory effect of the above-mentioned effector drugs on HIF-1α, LY294002 and KC7F2 blockers were selected to interfere with the expression of Akt and HIF-1α in the cell pathway. LY294002 inhibits downstream activation and the results showed that LY294002 could significantly reduce the hypoxia-induced upregulation of *HIF-1α* mRNA and attenuate the hypoxia-mediated upregulation of *LDHA, GLUT-1*, and *VEGF* mRNA expression. We observed that the mRNA expression of *PTEN* and *p27* was significantly upregulated, while *Akt* and *mTOR* were downregulated, further confirming the existence of the HIF-1α-PTEN-Akt/mTOR intervention pathway. In addition, the expression of FoxP3 was significantly upregulated, confirming that the regulation of FoxP3 by hypoxia did not completely depend on changes in HIF-1α. We also blocked HIF-1α, using KC7F2 inhibitor, and found that the expression of HIF-1α, LDHA, GLUT-1, and VEGF was significantly downregulated, especially LHDA. The enhancement effect on PTEN and FoxP3 was higher than that with LY294002 treatment, which further confirmed that the effect of hypoxia on FoxP3 was independent of the change in HIF-1α and the existence of the HIF-1α-PTEN effect. The combined treatment of SRL + Ly and SRL + KC7 showed that the regulation of PTEN, p27, and the mRNA expression of *VEGF* and *FoxP3* was consistent with the trend seen during single drug intervention. Based on the above discussion, we further summarize the functional pathways of this study (Supplementary Figure 4).

Thus, we believe that hypoxia can induce the accumulation of HIF-1α and enhance its mediated downstream promoting effect, thereby promoting the growth of tumour cells. SRL can enhance the hypoxia-induced HIF-1α downregulation by Huai Er and attenuate the enhanced effect of glucose

metabolism, mediated by HIF-1α, thus exerting an antitumour effect through the PI3K-Akt-mTOR-HIF-1α and HIF-1α-PTEN-Akt/mTOR pathways.

The overexpression of HIF-1α, the role of FoxP3 in regulating transcription, and the combined intervention of both on the expression of post-transcriptional proteins require further study. In addition, the co-culture of cells affected by T-cell killing function to determine changes in gene and protein levels will be the next research direction of this study.

CONCLUSION

SRL increases the anti-cancer effect of Huai Er, which reduces the promotion of hypoxia-induced HIF-1α on the Warburg effect by inhibiting the PI3K/Akt/mTOR-HIF-1α and HIF-1α-PTEN signalling pathways in HCC.

ARTICLE HIGHLIGHTS

Research background

Hypoxic and high lactate environment further aggravates the aerobic glycolytic effect of cancer and promotes the proliferation and metastasis of liver cancer. Hypoxia-inducible factor 1α plays an important role in the Warburg effect.

Research motivation

We found in clinical practice that the combination of sirolimus (SRL) and Huai Er granules can prolong the survival time of liver transplant patients and delay tumor recurrence. The mechanism of such combination therapy is unclear.

Research objectives

To clarify the regulatory mechanism of SRL combined with Huaier intervention on the Warburg effect.

Research methods

In order to solve the scientific problems raised in this study, immunohistochemistry, cell culture, cell scratch and clone formation assays, and flow cytometry were used to analyze the changes of cell levels.

Research results

Hypoxia-mediated glycolysis was associated with poorly differentiation HCC and a lower prognosis. Hypoxic-induced HIF-1α promoted the growth of HepG2 and Huh7 cells, which was weakened with the treatment of SRL and Huai Er. SRL increased the anti-cancer effect of Huai Er, which reduced the promotion of hypoxia-induced HIF-1α on the Warburg effect by inhibiting the PI3K/Akt/mammalian target of rapamycin (mTOR)-HIF-1α and HIF-1α-phosphatase and tensin homolog deleted on chromosome ten (PTEN) signaling pathways in HCC.

Research conclusions

SRL increases the anti-cancer effect of Huai Er, which reduces the promotion of hypoxia-induced HIF-1α on the Warburg effect by inhibiting the PI3K/Akt/mTOR-HIF-1α and HIF-1α-PTEN signaling pathways in HCC.

Research perspectives

This study confirmed that SRL combined with Huai Er can downregulate the Warburg effect mediated by HIF-1α, laying a foundation for the combined treatment of HCC with traditional Chinese and western medicine.

Abstract

BACKGROUND

Pancreatic cancer is the most aggressive cancer type. Gemcitabine is the first line chemo-drug used for pancreatic cancer but exerts a broad spectrum of organ toxicities and adverse effects in patients.

AIM

To evaluate the anti-tumour activity and toxicological effects of *Orthosiphon stamineus* extract formulation (ID: C5EOSEW5050ESA trademarked as Nuvastatic™), and gemcitabine combination on pancreatic xenograft model.

METHODS

Mice were randomly divided into six groups of 6 mice each (n = 6) and given different treatments for 28 d. The study design consisted of a 2 x 3 factorial treatment structure, with gemcitabine (yes/no) by oral (at 1200 and 400 mg/kg per day). Human pancreatic cancer cells were injected subcutaneously into the flanks of athymic nude mice. C5EOSEW5050ESA (200 or 400 mg/kg per day) was administered orally, while gemcitabine (10 mg/kg per 3 d) was given intraperitoneally either alone or in combination treatment. Histopathological analyses of vital organs, tumour tissues, and incidence of lethality were analysed. Analyses of

tumour necrosis and proliferation were determined by haematoxylin-eosin staining and immunohistochemistry for Ki-67, respectively.

RESULTS

No signs of toxicity or damage to vital organs were observed in all treatment groups compared to the untreated group. C5EOSEW5050ESA at 200 mg/kg and gemcitabine combination had no additive antitumor effects compared to a single treatment. Remarkably, a comparably greater response in a reduction in tumour growth, Ki-67 protein expression, and necrosis was demonstrated by 400 mg/kg of C5EOSEW5050ESA and gemcitabine combination than that of the individual agents.

CONCLUSION

These results highlighted the synergistic activity of C5EOSEW5050ESA with gemcitabine to reduce pancreatic tumour growth in mice compared to a single treatment. Thus, this study provides valuable insights into using C5EOSEW5050ESA as a complementary treatment with gemcitabine for pancreatic cancer.

Key Words: Pancreatic cancer; *Orthosiphon stamineus*; C5EOSEW5050ESA; Gemcitabine; Complementary medicine

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: The combination of C5EOSEW5050ESA at 400 mg/kg and gemcitabine synergistically reduced tumour growth compared to either drug alone by reducing Ki-67 cell proliferation marker and tumour necrosis. In addition, no signs of toxicity or damage to vital organs in single C5EOSEW5050ESA or gemcitabine and chemo-herbal combinations treated animals compared to the untreated group, indicating the safety and efficacy of the combination treatment in a short term study. Findings from this study may provide the basis for product formulation and manufacturing of botanical drugs to be used as complementary medicine for the treatment of cancer.

INTRODUCTION

Pancreatic cancer is one of the deadliest cancers globally and has the most unfavourable survival rate of any cancer[1]. Chemotherapy, radiation, surgery, and molecular targeting agents are common strategies to treat pancreatic cancer. However, the majority of these systemic treatments are associated with severe side effects[1]. Gemcitabine, a nucleoside analogue of cytidine, is the first line of treatment used to treat pancreatic cancer[2]. However, its overall success rates are poor. In addition, combination treatments of gemcitabine with other chemo-drugs, such as capecitabine, irinotecan, oxaliplatin, and cisplatin, may cause multiple adverse reactions and drug resistance, leading to a reduction of drug efficacy[3].

Herbal products have been traditionally used to treat many diseases in Asian countries[4]. Data from pre-clinical and clinical studies have also highlighted that these natural herbs, when combined with conventional radio- or chemotherapies, can sensitise tumour cells to treatments to improve cancer patients' survival and quality of life[5,6]. Nevertheless, this is not always the case, as studies have also shown that herbal medicines, when combined with chemotherapies, may instead enhance the toxicity potential of chemo drugs, leading to increased incidences of severe side effects[7].

Therefore, understanding the interactions of herbal-chemo drugs is necessary for the appropriate use of these combinations to prevent the emergence of toxicity and therapeutic failure in cancer patients. *Orthosiphon stamineus* (*O.s*) is a traditional Asian herbal medicine used to treat various diseases, including cancers[8]. The safety profile of *O.s* has already been established globally by numerous research groups using *in vivo* and *in vitro* models[3,9]. Our research group has already established the antitumor efficacy of *O.s* against colon cancer[9,10]. C5OSEW5050ESA (Nuvastatic™) is a proprietary extract of *O.s* that completed a phase 2/3 clinical study for cancer fatigue in cancer patients with solid tumours receiving chemotherapy[11]. However, no study has reported the toxicity profile of C5OSEW5050ESA in a pancreatic cancer xenograft model as a stand-alone or in combination with

Table 1 Treatment conditions for 28 d

No.	Group	The route of treatment and dose
1	Group I (untreated group- distilled water)	Oral (1 mg/kg per day)
2	Group II (chemodrug-gemcitabine)	Intraperitoneal (10 mg/kg per 3 d)
3	Group III (low dose of *O.s*)	Oral (200 mg/kg per day)
4	Group IV (low dose of *O.s* -gemcitabine combination)	Oral (200 mg/kg per day) + Intraperitoneal (10 mg/kg per 3 d)
5	Group V (high dose of *O.s*)	Oral (400 mg/kg per day)
6	Group VI (high dose of *O.s*-gemcitabine combination)	Oral (400 mg/kg per day) + Intraperitoneal (10 mg/kg per 3 d)

O.s: *Orthosiphon stamineus*.

gemcitabine. We have previously reported that the combination treatment of *O.s* and gemcitabine showed no toxicity in mice, either as a stand-alone or in combination[3]. Furthermore, *O.s* significantly sensitised Panc-1 towards gemcitabine *in vitro*[4]. Consequently, the present study was designed to evaluate the toxicological effects of Nuvastatic™ and gemcitabine either alone or in combination using the pancreatic cancer nude mice model.

MATERIALS AND METHODS

Plant materials and chemicals

Orthosiphon stamineus extract (C5EOSEW5050ESA) was purchased from NatureCeutical Sdn Bhd, Malaysia. Gemcitabine (Catalogue No. S1149) was obtained from Selleckchem, Houston, TX, United States. C5EOSEW5050ESA was dissolved in sterile distilled water and filtered by a membrane filter unit (0.22 μm). C5EOSEW5050ESA was administered orally to mice, while gemcitabine was given *via* intraperitoneal injection after being dissolved in phosphate buffer saline (PBS).

Animals

Male athymic nude mice (procured from iDNA, Malaysia) were kept in filter-top cages under controlled atmospheric conditions at the EMAN Testing and Research laboratory, School of Pharmaceutical Sciences, USM. Autoclaved food, water, and bedding of cages were changed every 48 h. The animal study was approved and conducted under strict guidelines according to USM Animal Ethics Committee (Reference #: USM/Animal Ethics Approval/2016/(97) (746).

Cell lines

Panc-1, a pancreatic cancer cell line, was purchased from American Type Culture Collection (ATCC). The cells were maintained in Dulbecco's Modified Eagle Medium (DMEM) (Thermo Scientific, United States) supplemented with 10% fetal bovine serum (Biowest, United States) and 100 units/mL penicillin-streptomycin (Nacalai Tesque, United States). Cells were kept at 37 °C in a humidified incubator with 5% CO_2 atmosphere.

***In vivo* assessment of tumour growth in a nude mouse xenograft model:** Panc-1 cells (20×10^6 cells suspended in 200 μL of a mixture of DMEM and matrigel in a 1:1 ratio) were injected subcutaneously on the dorsal side of each mouse. Treatment with gemcitabine and *Et. O.s* in different combinations or as a stand-alone was initiated when at least three of the tumours in any group reached 100 mm^3.

Experimental treatment design

Mice were randomly divided into six groups of 6 mice each ($n = 6$) and given different treatments for 28 d, as mentioned in Table 1. The body weight of all mice and tumour size was measured every 3rd day. At the end of the study, all the mice were euthanised with a combination of ketamine and xylazine when the tumour volumes from the untreated group reached 1000 mm^3. The blood samples were collected for haematological and serum biochemical tests. Organs (liver, kidney, and spleen) were harvested and weighed to observe the changes in the organ weights of treated animals compared to the untreated group. Tumour tissues and organs were collected and fixed with 10% buffered formalin. Paraffin blocks were prepared, and sections of 5 μm were stained with haematoxylin and eosin (HE). Ten microscopic fields per slide were examined at × 20 and × 40 magnification, and photomicrographic images were captured using a digital camera.

Blood parameters and biochemical tests

Blood samples were used to measure different haematological parameters, including haemoglobin (Hb) levels, total blood count, differential counting of white blood cells, packed cell volume (PCV), mean cell volume (MCV), mean cell haemoglobin (MCH), mean cell haemoglobin concentration (MCHC), red cell distribution width (RDW), creatinine, urea, uric acid, aspartate aminotransferase (AST), alanine aminotransferase (ALT), alkaline phosphatase (ALP), gamma-glutamyl transferase (GGT), total bilirubin, cholesterol (low and high-density cholesterol), triglycerides, total protein, albumin, globulin, albumin/globulin ratio, and minerals (sodium, potassium, and chloride).

Histopathological examination

Key organs (liver, kidney, and spleen) were harvested and fixed in a 10% buffered formaldehyde solution. An automated tissue processing machine then processed the fixed tissues and embedded them in paraffin wax to prepare sample blocks.

Haematoxylin and eosin staining

Tissue sections of 5 mm thickness were cut and prepared at 60 °C. The slides were dewaxed in xylene and rehydrated through graded alcohol. Slides were rinsed and incubated with haematoxylin for 4 min. After rinsing, eosin was added to the slides for 1 min. Next, slides were rinsed in tap water and briefly air-dried at room temperature. Slides were then mounted with glycerol (Sigma, United States). Stained slides were examined and scored for the percentage of necrosis within the tumour areas by a pathologist (GK) under a light microscope.

Immunohistochemistry staining

The formalin-fixed-paraffin-embedded (FFPE) tissue sections were prepared at 60 °C, dewaxed in xylene, and rehydrated through graded alcohol. Antigens were retrieved using Dako's antigen retrieval buffer (1 ×, pH 9.0) and then microwaved on high for 15 min. Slides were cooled, washed and then blocked with hydrogen peroxidase and BSA. Then slides were treated with primary antibody Ki67 (Dako, Glostrup, Denmark) and left to incubate at 4 °C overnight at 1:50 dilution. The next day, slides were treated with secondary antibody goat anti-mouse (Dako, Glostrup, Denmark) for 1 h at 1:500 dilution. Later, avidin-biotin complex (Vector Laboratories, United States) was added to tissues for 1 h. After that, Dab stain (Dako, Glostrup, Denmark) and haematoxylin were added to the slides. Finally, slides were air-dried at room temperature and mounted with glycerol (Sigma, United States). Using ImageJ, the Ki-67 score was determined as the percentage of tumour cells that showed brown nuclear staining over the total number of nuclei from five random fields per tumour section.

Statistical analysis

Graphing software Excel (Microsoft, United States) and Prism (GraphPad, United States) were used for statistical analysis. Data were presented as mean ± SD whereas the parametric data analysis was performed using a one-way analysis of variance (ANOVA). Two-way ANOVA was used to understand if there is an interaction between the two independent variables on the dependent variable. The Tukey's honest significant difference (HSD) post hoc test was used to assess the significant differences among all groups. Analysis for non-parametric data was performed using Kruskal-Wallis ANOVA. A value of $P < 0.05$ was considered significant when compared to values in the respective untreated group.

RESULTS

Effect of treatment on mouse body weight and key organs

C5EOSEW5050ESA demonstrated no toxicity in mice: The average body weight within the untreated group increased compared to other treatment groups (Table 2). However, there was no notable difference in body weight between untreated groups and other treatment groups (Table 2). In addition, the weight of vital organs, including the kidney, liver, and spleen, remained unchanged post-treatment with either C5EOSEW5050ESA and/or gemcitabine (Table 3).

Haematological-biochemical parameters and electrolyte profiles: No significant changes were observed in the Hb level, total blood cells count, or differential counting of WBC, PCV, MCV, MCH, MCHC, and RDW when compared with the corresponding parameters in the untreated group (Table 4). No significant changes were noted in serum parameters, *i.e.* creatinine, urea, uric acid, AST, ALT, ALP, GGT, total bilirubin, total protein, albumin, globulin, and albumin/globulin ratio, which were observed in animal groups treated with C5EOSEW5050ESA at (200 or 400 mg/kg per day) alone or in combination with gemcitabine (10 mg/kg per 3 d) after 28 d treatment when compared to the untreated group (Table 5). Normal ALT, ALP, and AST levels in the serum indicate that there is no damage in hepatocytes. Similarly, urea and total bilirubin levels were also within the normal range, indicating the lack of toxicity in the kidneys when treated with C5EOSEW5050ESA and gemcitabine either alone or in

combination treatment (Table 5). Electrolytes were within the normal ranges in all the groups, with no significant changes observed compared to the untreated group (Table 5).

Histopathology analysis: Histopathological examination of formalin-fixed paraffin-embedded tissues of the spleen (Figure 1), kidney (Figure 2), and liver (Figure 3) of all treatment groups, as well as the untreated group, revealed normal histology without pathological evidence of inflammation or necrosis. In addition, the liver did not exhibit an accumulation of neutral fats or triglycerides within the liver cells. However, the liver cells demonstrated mild swelling in all groups except for C5EOSEW5050ESA (200 mg/kg per day) treatment group (Figure 3).

C5EOSEW5050ESA and gemcitabine combination synergistically inhibited pancreatic tumour growth in the xenograft model

Single treatments with gemcitabine at 10 mg/kg and C5EO-SEW5050ESA at 200 mg/kg or 400 mg/kg inhibited tumour growth and reduced tumour weight compared to the vehicle untreated group (Figures 4A and B). However, compared to a single treatment, no additive effect in inhibiting tumour growth and tumour weight was obtained with 200 mg/kg C5EOSE-W5050ESA combined with gemcitabine

Results are expressed as mean ± SD (n = 6). The P values in all treated groups were insignificant compared to the untreated group. No statistical difference was also observed among all treatment groups using two-way ANOVA and Tukey's honest significant difference posthoc test. B: Basophile; E: Eosinophile; Hb: Haemoglobin; L: Lymphocyte; M: Monocyte; MCH: Mean cell haemoglobin; MCHC: Mean cell haemoglobin concentration; MCV: Mean cell volume; N: Neutrophile; *O.s*: *Orthosiphon stamineus;* PCV: Packed cell volume; Plts: Platelets; RBC: Red blood cells; RDW: Red cell distribution width; WBC: White blood cells.

(Figure 4A and B). However, C5EOSEW5050ESA at 400 mg/kg combined with gemcitabine significantly reduced tumour growth and tumour weight compared to individual treatment groups (Figures 4A and B).

C5EOSEW5050ESA and gemcitabine combination synergistically inhibited pancreatic tumour necrosis in the xenograft model: A single treatment with gemcitabine at 10 mg/kg and C5EOSEW5050ESA at 200 mg/kg or 400 mg/kg reduced tumour necrosis compared to untreated tumour cells (Figure 5). No additive effect in reducing tumour necrosis was obtained with C5EOSEW5050ESA at 200 mg/kg and gemcitabine combination compared to a single treatment (Figure 5D). However, C5EOSEW5050ESA at 400 mg/kg and gemcitabine combination significantly reduced tumour necrosis compared to single treatment groups of the respective doses (Figure 5).

C5EOSEW5050ESA combined with gemcitabine synergistically inhibited Ki67 protein expression in pancreatic tumour tissue: Ki67 proliferative marker protein was highly expressed in the untreated group compared to all treatment groups (Figure 6). Compared to a single treatment, no additive effect in reducing Ki67 protein expression was obtained with 200 mg/kg C5EOSEW5050ESA and gemcitabine combination (Figure 6). However, 400 mg/kg C5EOSEW5050ESA and gemcitabine combination synergistically inhibited the expression of Ki67 protein compared to single treatment and other treatment groups (Figure 6).

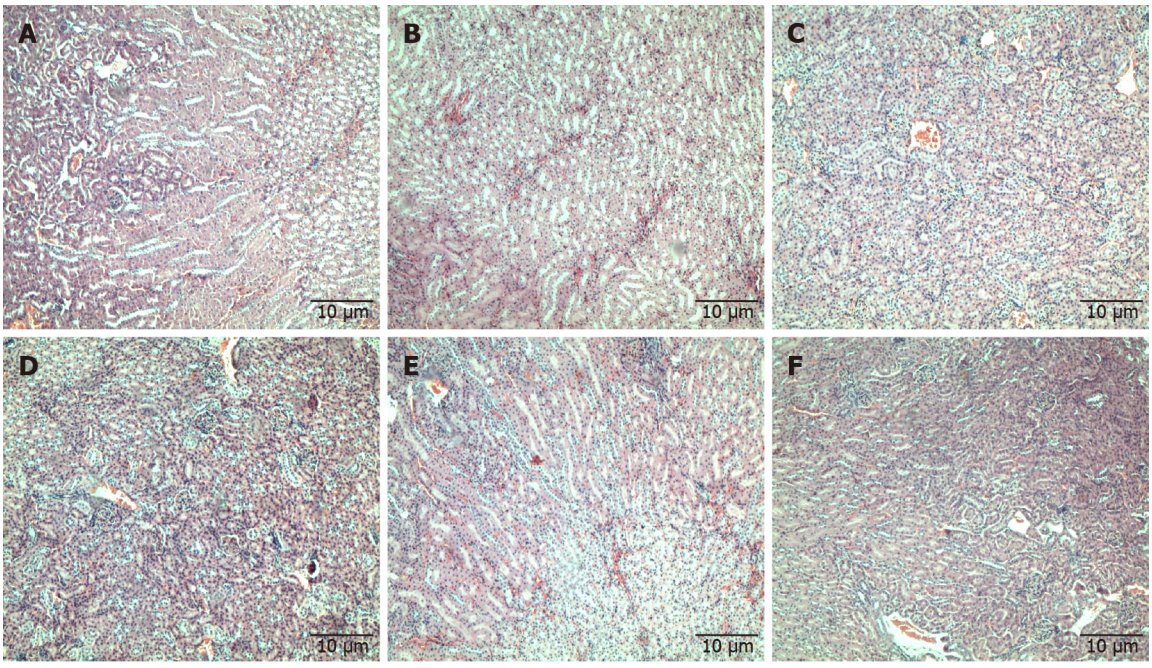
DISCUSSION



Studies have shown that therapeutic combinations containing low-dose marketed drugs and plant extracts/isolated compounds or essential oils may improve the safety profile of marketed drugs and produce synergistic actions[12,13]. The safety profile of C5EOSEW5050ESA has previously been established[14,15], with its LD_{50} values reported to be greater than 5000 mg/kg[15]. Chemo-herbal combinations are one of the possible therapeutic options which can be employed to improve the efficacy of a drug, reduce adverse drug effects and increase disease-free intervals and overall survival rates in cancer patients. The majority of chemotherapeutic drugs destroy tumours and retard cancer growth but may also damage healthy tissues. Thus, new chemo-herbal combinations are anticipated to play an essential role in developing more effective and safer strategies to inhibit cancer progress with minimal side effects[4].

We have previously shown the synergistic anti-cancer effects of combined C5EOSEW5050ESA and gemcitabine treatment on Panc-1 and MiaPaCa-2 pancreatic cancer cell lines[3]. Moreover, no toxicity was observed in mice in an acute toxicity study[3]. In the current study, the combination treatment in a pancreatic tumour xenograft model revealed no abnormal signs in any of the treatment groups (Figures 1-3). Moreover, no significant difference in organ weight change was noted when compared to the

Figure 2 Tissue sections of mice kidneys stained with haematoxylin and eosin. Tissue sections showed normal glomeruli and tubules in all treated groups and untreated. A: Untreated; B: Gemcitabine (10 mg/kg per 3 d); C: C5EOSEW5050ESA (200 mg/kg per day); D: C5EOSEW5050ESA (200 mg/kg per day) and gemcitabine (10 mg/kg per 3 d) combination; E: C5EOSEW5050ESA (400 mg/kg per day); F: C5EOSEW5050ESA (400 mg/kg per day) and gemcitabine (10 mg/kg per 3 d) combination.

untreated group, supporting the relatively safe nature of selected chemo-herbal combinations (Table 3).

Clinical biochemistry and haematological analyses play a significant role in evaluating the signs of toxicity induced by drugs[16]. No significant alterations in haematological parameters were observed in the animal blood samples treated with C5EOSEW5050ESA and gemcitabine combination, indicating

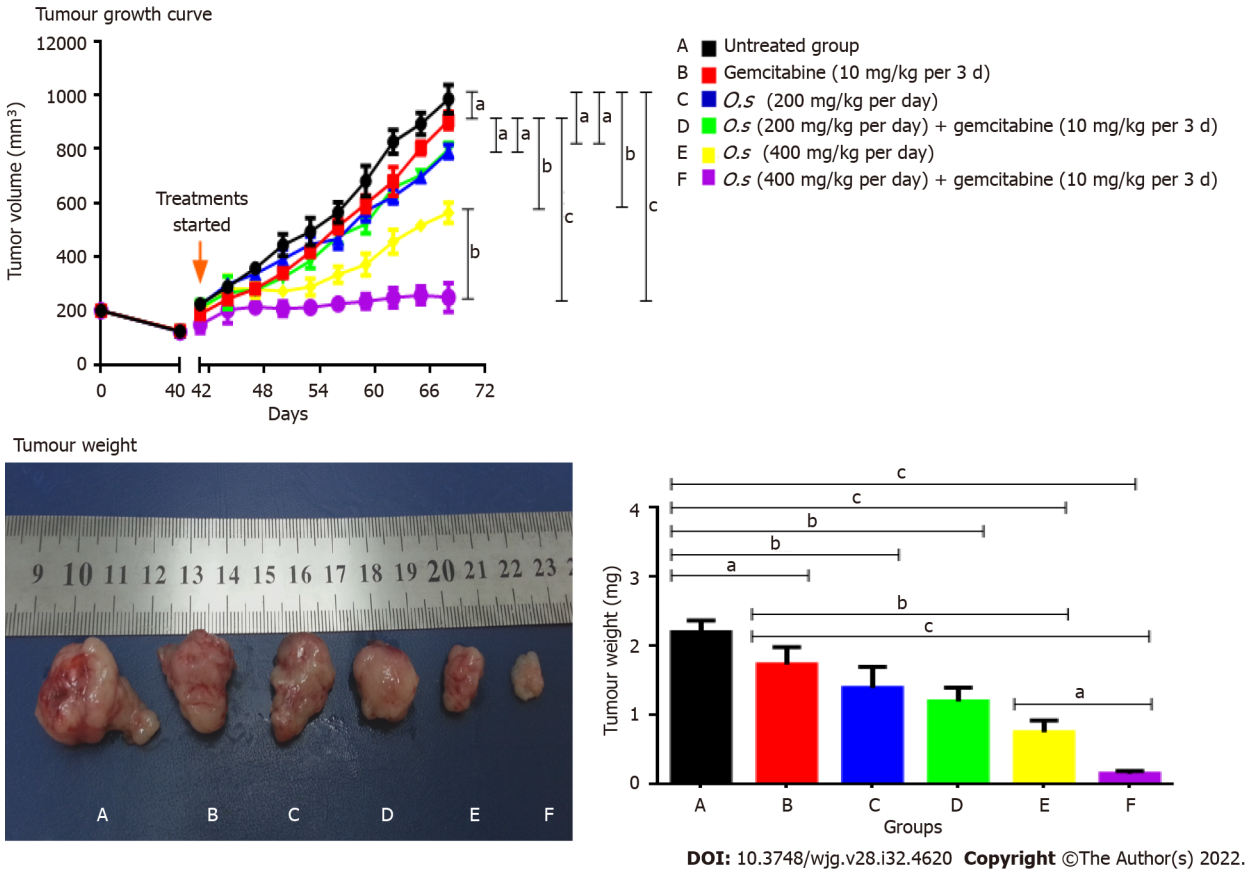

Figure 3 Tissue sections of mice liver stained with haematoxylin and eosin. Liver sections showed normal architecture with distinct hepatic cells, sinusoidal spaces, and a central vein in all treatment groups and untreated; mild hepatocellular swelling is seen in all groups except the C5EOSEW5050ESA (200 mg/kg per day) group where no swelling is present. A: Untreated; B: Gemcitabine (10 mg/kg per 3 d); C: C5EOSEW5050ESA (200 mg/kg per day); D: C5EOSEW5050ESA (200 mg/kg per day) and gemcitabine (10 mg/kg per 3 d) combination; E: C5EOSEW5050ESA (400 mg/kg per day); F: C5EOSEW5050ESA (400 mg/kg per day) and gemcitabine (10 mg/kg per 3 d) combination.

that these combinations did not damage the blood cells (Table 4). Increased serum bilirubin concentration and occurrence of tissue haemolysis are commonly seen when the liver is impaired[17]. The absence of these observations in the current study demonstrated the non-toxic effects of the C5EOSEW5050ESA gemcitabine combination on haemoglobin metabolic pathways (Table 4). A slight drop in white blood count and platelets and mild myelosuppression have been reported with extended treatment duration and high doses of gemcitabine[18]. In 2013, the MPACT phase III trial, which included over 800 patients, showed a significant overall survival benefit with the combination of nanomolecular albumin-bound (nab)-paclitaxel and gemcitabine (nabPGem) over gemcitabine monotherapy, with acceptable toxicity. The overall toxicity of nabPGem is lower than in the triple chemotherapy 5-FU, leucovorin, irinotecan and oxaliplatin, especially haematotoxicity and rates of neutropenic fever[19,20]. However, the current study and our previous toxicity study revealed no reduction in white blood cells and platelets (Table 4)[3]. In fact, C5EOSEW5050ESA and gemcitabine combination at the higher dose enhanced its efficacy at reducing tumour growth without causing any side effects, at least in this short term study.

Kidneys are particularly vulnerable to high doses of drugs as they eradicate many drugs and their metabolites. Therefore, renal function tests measure various substances, including serum urea, serum creatinine, and albumin, to determine the current health of the kidneys[21]. In the present study, there was no nephrotoxicity observed, indicating the safe nature of chemo-herbal combinations. The results showed normal level concentrations of urea, creatinine, and albumin and were supported by the typical renal architecture of kidney sections (Figure 2).

Liver function tests, for such markers as ALT, AST, ALP, and GGT, are used to measure hepatocellular damage during illnesses[22]. There were no significant changes in the serum levels of AST, ALT, ALP, and GGT in all treatment groups (Table 5). In addition, the hepatocellular architecture appeared normal in all treatment groups (Figure 3).

As a single treatment, gemcitabine at 10 mg/kg and C5EOSEW5050ESA at 200 mg/kg or 400 mg/kg inhibited tumour growth compared to untreated mice (Figure 4). Compared to a single treatment, no additive inhibition of tumour growth was obtained with 200 mg/kg C5EOSEW5050ESA and gemcitabine combination (Figure 4). However, C5EOSEW5050ESA at 400 mg/kg and gemcitabine

Figure 4 Tumour growth curve of Panc-1 cells in subcutaneous pancreatic tumour growth in nude mice and tumour weight. Treatments were given when the tumours reached 100 mm^3. A: Untreated; B: Gemcitabine (10 mg/kg per 3 d); C: C5EOSEW5050ESA (200 mg/kg per day); D: C5EOSEW5050ESA (200 mg/kg per day) and gemcitabine (10 mg/kg per 3 d) combination; E: C5EOSEW5050ESA (400 mg/kg per day); F: C5EOSEW5050ESA (400 mg/kg per day) and gemcitabine (10 mg/kg per 3 d) combination. Combination treatment of 400 mg/kg C5EOSEW5050ESA and gemcitabine (F) synergistically reduced the tumour growth compared to a single treatment. The combination treatment of 400 mg/kg C5EOSEW5050ESA and gemcitabine (F) significantly reduced tumour weight compared to a single treatment. Error bars represent standard deviations. Statistics analysis ($^aP < 0.05$; $^bP < 0.01$; $^cP < 0.001$, two-way ANOVA for tumour growth, one-way ANOVA with Tukey's HSD posthoc test for tumour weight, $n = 6$ animals per group) using SPSS and GraphPad Prism 6.0 software.

combination significantly reduced tumour growth compared to the single treatment groups of the respective doses (Figure 4). Further studies investigating how combination treatment affects pancreatic cancer cell proliferation and apoptosis or necrosis will shed light on their mode of action. In our previous study, C5EOSEW5050ESA and gemcitabine combination inhibited the survival and proliferation of Panc-1 cells *in vitro*[23]. Also, the combination of C5EOSEW5050ESA and gemcitabine-induced apoptosis and reduced EMT markers and multidrug-resistant genes (*MDR-1*, *MRP-4*, and *MRP-5*), and the Notch signalling pathway[24]. In the current study, the tumour necrosis percentage was estimated in tissue sections stained by HE. Single treatment of gemcitabine and C5EOSEW5050ESA either at low or high dose reduced the tumour percentage compared to untreated (Figure 5). There were no additional effects in the reduction of tumour necrosis post-treatment with a low dose of C5EOSEW5050ESA and gemcitabine combination compared to a single treatment (Figure 5). However, the high dose of C5EOSEW5050ESA and gemcitabine combination reduced tumour necrosis compared to a single treatment (Figure 5).

The combination treatment of C5EOSEW5050ESA at a high dose and gemcitabine significantly reduced Ki67 protein expression in tumour cells compared to a single treatment (Figure 6), indicating reduced cell proliferation in the former group. The epigallocatechin-3-*O*-gallate (EGCG) polyphenol is enriched in C5EOSEW5050ESA extract. Others have reported EGCG to inhibit tumour growth and induce apoptosis in mice implanted with head, neck, and lung cancers by decreasing the Ki67 expression in tissues from the xenograft model and downregulating caspase-3, caspase-8, caspase-9, and Bax in mouse vascular smooth muscle cells[25,26]. Another study showed that resveratrol inhibited Ki67 expression in pancreatic cancer cells *in vitro* and *in vivo* by sensitising pancreatic cancer cells to gemcitabine treatment[25]. It is postulated that the polyphenols in C5EOSEW5050ESA may act synergistically with gemcitabine in the pancreatic tumour xenograft model. C5EOSEW5050ESA worked in synergy with gemcitabine to reduce pancreatic tumour growth and tumour necrosis in mice compared to a single treatment of either C5EOSEW5050ESA or gemcitabine. Thus, based on current findings, it is proposed that 50% ethanol extract of *O.s* has the potential to be used in combination with

gemcitabine to treat pancreatic cancer.

CONCLUSION

This study provides preliminary scientific evidence about the safety profile of *O.s* derived extract C5EOSEW5050ESA present in Nuvastatic™ in combination with gemcitabine in an athymic nude mice model. Furthermore, this work demonstrated that C5EOSEW5050ESA extract in combination with gemcitabine is relatively safe in the acute toxicity study. Furthermore, the clinical efficacy and safety of Nuvastatic™ in cancer asthenia have been evaluated in phase III clinical trials (ClinicalTrials.gov, Identifier: NCT04546607). Therefore, Nuvastatic™ has the potential to be employed as a complementary treatment with gemcitabine to treat pancreatic cancer.

Figure 6 Ki67 proliferation protein expression in treated and untreated groups. A: Untreated group; B: *Orthosiphon stamineus* (*O.s*) (200 mg/kg per day); C: *O.s* (400 mg/kg per day); D: Gemcitabine (10 mg/kg per 3 d); E: *O.s* (200 mg/kg per day) + gemcitabine (10 mg/kg per 3 d); F: *O.s* (400 mg/kg per day) + gemcitabine (10 mg/kg per 3 d); G: Estimated marginal means of Ki67. Single treatment either by C5EOSEW5050ESA or gemcitabine significantly reduced the Ki67 protein expression in tumour tissues compared to the untreated group. No significant reduction of Ki67 protein expression was noted between the groups treated by C5EOSEW5050ESA 200 mg/kg per day and the gemcitabine combination. Combination treatment of C5EOSEW5050ESA 400 mg/kg per day and gemcitabine synergistically reduced Ki67 protein expression in tumour tissue compared to a single treatment. Error bars represent standard deviations. Statistics analysis (Two-way ANOVA, *n* = 6 animals per group) using SPSS software. *O.s*: *Orthosiphon stamineus*.

ARTICLE HIGHLIGHTS

Research background

Gemcitabine is the cornerstone for pancreatic cancer but demonstrates adverse effects in patients. *Orthosiphon stamineus* (*O.s*) has been traditionally used to treat various diseases. C5OSEW5050ESA (Nuvastatic™) is a proprietary extract of *O.s* that completed a phase 2/3 clinical study for cancer fatigue in cancer patients with solid tumours receiving chemotherapy.

Research motivation

No study has reported the toxicity profile of C5OSEW5050ESA in a pancreatic tumour animal model either as a stand-alone or in combination with gemcitabine.

Research objectives

To determine the anti-tumour activity and potential toxicity of Nuvastatic™ and gemcitabine combination on pancreatic xenograft model.

Research methods

Human pancreatic cancer cells were injected subcutaneously into athymic nude mice. C5EOSEW5050ESA (200 or 400 mg/kg per day) was administered orally, while gemcitabine (10 mg/kg/3 d) was given intraperitoneally either alone or in combination treatment. Histopathological analyses of key organs, tumour tissues, and incidence of lethality were determined.

Research results

C5EOSEW5050ESA at 200 mg/kg and gemcitabine combination had no additive antitumor effects compared to a single treatment. A comparably greater response in a reduction in tumour growth *via* a reduction of Ki-67 protein expression, and a decrease in necrosis was also demonstrated by 400 mg/kg of C5EOSEW5050ESA and gemcitabine combination compared to that of individual agents. No signs of organ toxicities were observed in any treatment group.

Research conclusions

The combination of C5EOSEW5050ESA with gemcitabine significantly reduced the pancreatic tumour growth in mice compared to a single treatment. This study provides valuable insights into using C5EOSEW5050ESA as a complementary treatment to gemcitabine for pancreatic cancer.

Research perspectives

Findings from this study may provide the basis for product formulation and manufacturing of botanical drugs (Nuvastatic™) to be used as complementary medicine for the treatment of pancreatic cancer patients.

Abstract

BACKGROUND

Obstructive jaundice (OJ) is caused by bile excretion disorder after partial or complete bile duct obstruction. It may cause liver injury through various mechanisms. Traditional Chinese medicine (TCM) has a lot of advantages in treating OJ. The recovery of liver function can be accelerated by combining Chinese medicine treatment with existing clinical practice. Yinchenhao decoction (YCHD), a TCM formula, has been used to treat jaundice. Although much progress has been made in recent years in understanding the mechanism of YCHD in treating OJ-induced liver injury, it is still not clear.

AIM

To investigate chemical components of YCHD that are effective in the treatment of OJ and predict the mechanism of YCHD.

METHODS

The active components and putative targets of YCHD were predicted using a network pharmacology approach. Gene Ontology biological process and Kyoto Encyclopedia of Genes and Genomes path enrichment analysis were carried out by cluster profile. We predicted the biological processes, possible targets, and associated signaling pathways that YCHD may involve in the treatment of OJ. Thirty male Sprague–Dawley rats were randomly divided into three groups, each

consisting of 10 rats: the sham group (Group S), the OJ model group (Group M), and the YCHD-treated group (Group Y). The sham group only received laparotomy. The OJ model was established by ligating the common bile duct twice in Groups M and Y. For 1 wk, rats in Group Y were given a gavage of YCHD (3.6 mL/kg) twice daily, whereas rats in Groups S and M were given the same amount of physiological saline after intragastric administration daily. After 7 d, all rats were killed, and the liver and blood samples were collected for histopathological and biochemical examinations. Total bilirubin (TBIL), direct bilirubin (DBIL), alanine aminotransferase (ALT), and aspartate transaminase (AST) levels in the blood samples were detected. The gene expression levels of inducible nitric oxide synthase (iNOS) and endothelial nitric oxide synthase (eNOS), and the nucleus positive rate of NF-E2 related factor 2 (Nrf2) protein were measured. Western blot analyses were used to detect the protein and gene expression levels of Nrf2, Kelch-like ECH-associated protein 1, NAD(P)H quinone dehydrogenase 1 (NQO1), and glutathione-S-transferase (GST) in the liver tissues. One-way analysis of variance was used to evaluate the statistical differences using the statistical package for the social sciences 23.0 software. Intergroup comparisons were followed by the least significant difference test and Dunnett's test.

RESULTS

The effects of YCHD on OJ involve biological processes such as DNA transcription factor binding, RNA polymerase II specific regulation, DNA binding transcriptional activator activity, and nuclear receptor activity. The protective effects of YCHD against OJ were closely related to 20 pathways, including the hepatitis-B, the mitogen-activated protein kinase, the phosphatidylinositol 3-kinase/protein kinase B, and tumor necrosis factor signaling pathways. YCHD alleviated the swelling and necrosis of hepatocytes. Following YCHD treatment, the serum levels of TBIL (176.39 ± 17.03 μmol/L *vs* 132.23 ± 13.88 μmol/L, $P < 0.01$), DBIL (141.41 ± 14.66 μmol/L *vs* 106.43 ± 10.88 μmol/L, $P < 0.01$), ALT (332.07 ± 34.34 U/L *vs* 269.97 ± 24.78 U/L, $P < 0.05$), and AST (411.44 ± 47.64 U/L *vs* 305.47 ± 29.36 U/L, $P < 0.01$) decreased. YCHD promoted the translocation of Nrf2 into the nucleus (12.78 ± 0.99 % *vs* 60.77 ± 1.90 %, $P < 0.001$). After YCHD treatment, we found a decrease in iNOS (0.30 ± 0.02 *vs* 0.20 ± 0.02, $P < 0.001$) and an increase in eNOS (0.18 ± 0.02 vs 0.32 ± 0.02, $P < 0.001$). Meanwhile, in OJ rats, YCHD increased the expressions of Nrf2 (0.57 ± 0.03 *vs* 1.18 ± 0.10, $P < 0.001$), NQO1 (0.13 ± 0.09 *vs* 1.19 ± 0.07, $P < 0.001$), and GST (0.12 ± 0.02 *vs* 0.50 ± 0.05, $P < 0.001$), implying that the potential mechanism of YCHD against OJ-induced liver injury was the upregulation of the Nrf2 signaling pathway.

CONCLUSION

OJ-induced liver injury is associated with the Nrf2 signaling pathway. YCHD can reduce liver injury and oxidative damage by upregulating the Nrf2 pathway.

Key Words: Yinchenhao decoction; Obstructive jaundice; Network pharmacology; Liver injury; Animal models; Oxidative stress

INTRODUCTION

Obstructive jaundice (OJ), a common disease in clinical practice, is caused by biliary stones or tumors blocking the bile ducts, causing bile not to flow smoothly into the duodenum, causing elevated bilirubin levels in the blood, yellow-stained sclera and skin, urine yellowing, and other relevant symptoms. OJ can cause liver injury, inflammation, intestinal barrier dysfunction, endotoxemia, coagulation dysfunction, decreased immune function, and malnutrition[1,2]. Therefore, understanding the mechanism of OJ is crucial. Although progress has been made in recent years, it remains unclear. The mechanism of liver damage caused by OJ is mainly related to cholestasis, endotoxemia, inflammatory factors, and oxidative stress[3,4]. Numerous endotoxins activate Kupffer cells during OJ, producing reactive oxygen species (ROS) and reactive nitrogen free radicals (RNS)[5], both of which are important in the body's metabolism.

Oxidative stress is an important pathological mechanism of OJ-induced liver injury. It is present throughout the OJ process[6]. Under normal circumstances, the body's oxidation and antioxidation systems are in a state of dynamic balance. The production and clearance of active molecules such as ROS and RNS are increased as a result of OJ. The balance between oxidation and antioxidation is disrupted, resulting in oxidative stress. Protective actions against ROS are performed by several enzymes, such as superoxide dismutase, catalase, and glutathione peroxidase, as well as nonenzymatic compounds such as glutathione, tocopherol, ascorbate and vitamin E[7-9]. Bile acid has been shown to reduce hepatocyte mitochondrial oxidative phosphorylation activity, directly damage mitochondrial energy metabolism, and produce excess ROS[10], while antioxidants can reduce bile acid-induced oxidative stress injury.

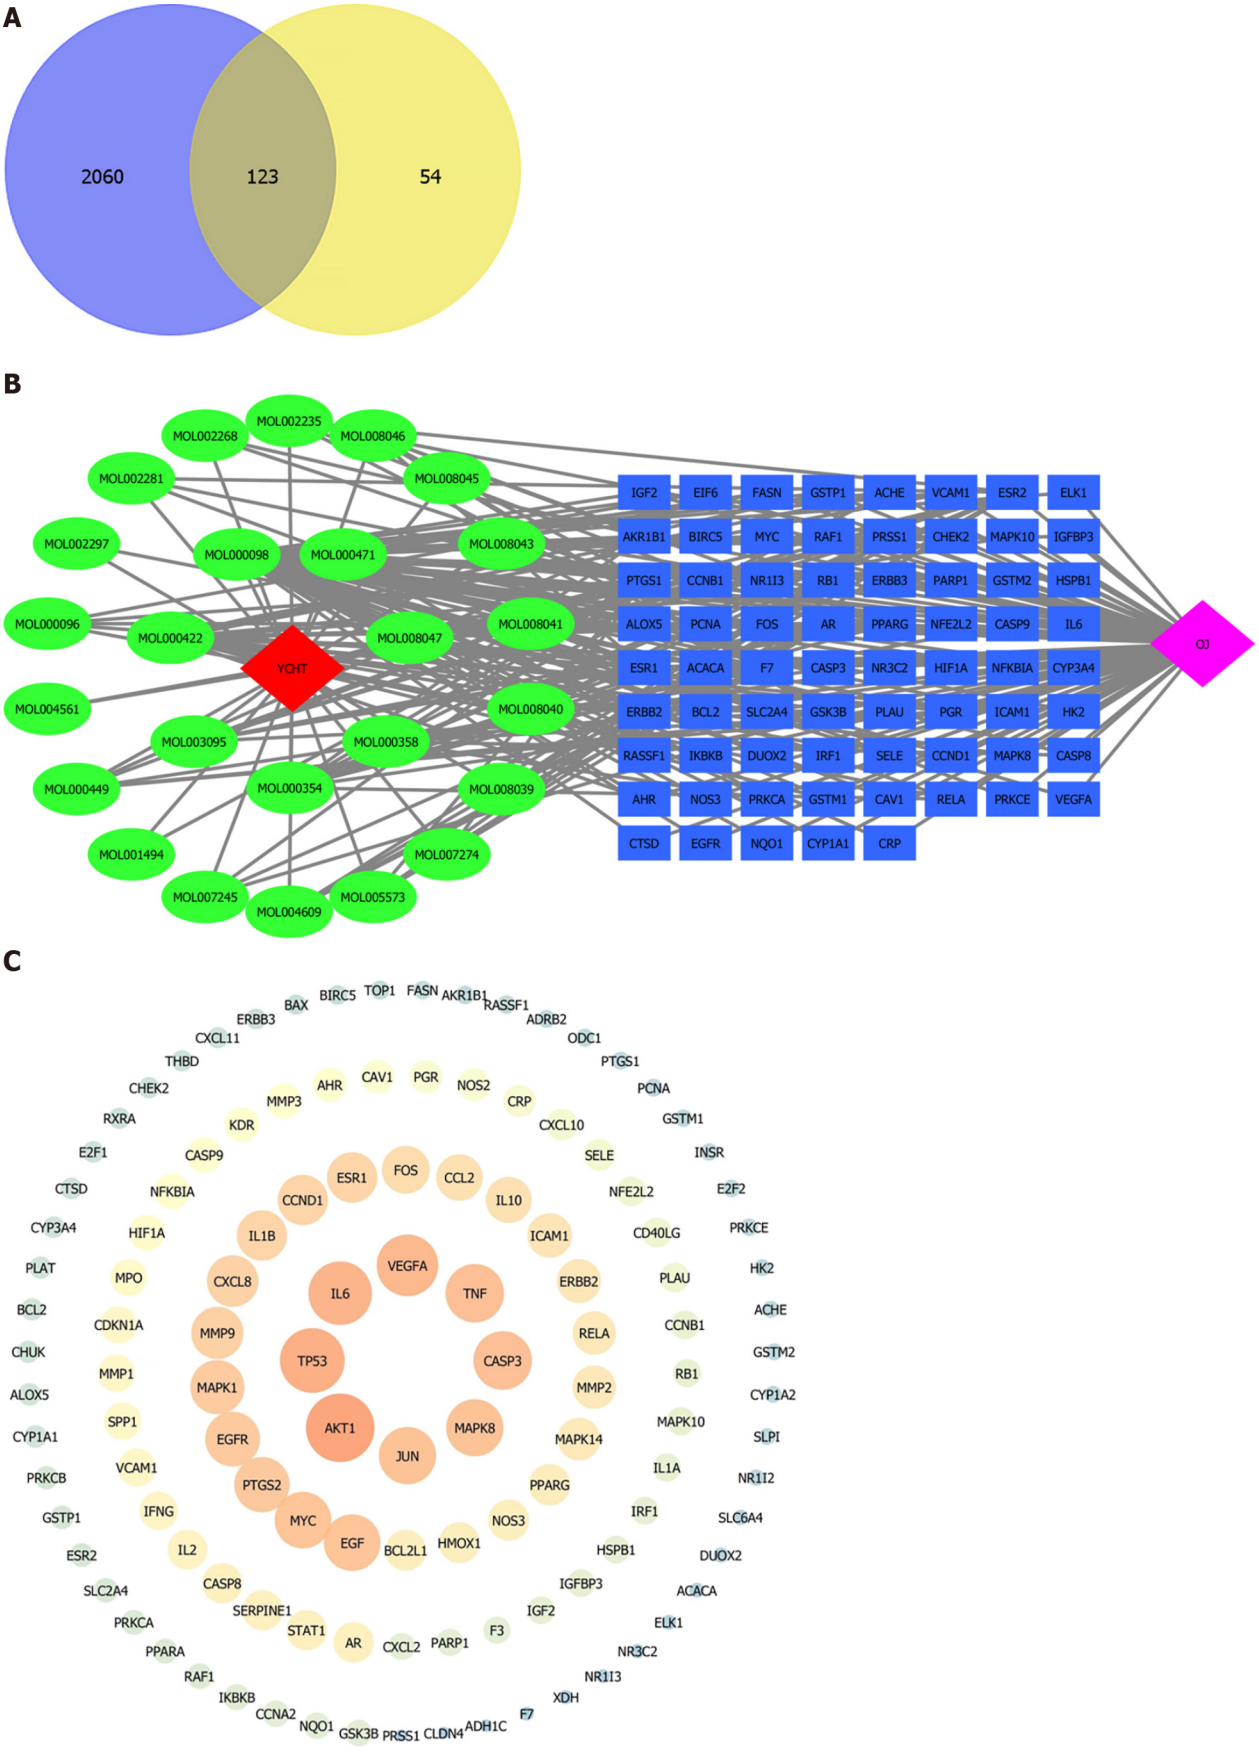
NF-E2 related factor 2 (Nrf2) is a key regulator of antioxidant reduction in tissues and cells. Kelch-like ECH-associated protein 1 (Keap1) is a cytoskeletal anchoring protein that acts as a specific inhibitor of Nrf2. Under normal circumstances, Nrf2 is bound to Keap1 in the cytoplasm, which can be rapidly degraded *via* the ubiquitin-proteasome pathway[11,12]. When the body is stimulated by oxidative stress, Nrf2 is released from sequestration and translocated to the nucleus, where it promotes the transcription of antioxidant and cytoprotective genes. Phase 2 detoxification enzyme genes, such as NAD(P)H quinone dehydrogenase 1 (NQO1), and glutathione-S-transferase (GST) and antioxidant genes, such as heme oxygenase-1 (HO-1) and γ-glutamylcysteine synthetase (γ-GCS) are among the cytoprotective genes[13]. Yinchenhao decoction (YCHD) is a classic traditional Chinese medicine (TCM) formula from the Treatise on Exogenous Febrile Disease. It consists of Yinchen (Artemisiae Scopariae Herba), Zhizi (Gardenia jasminoides Ellis, Gardeniae Fructus), and Dahuang (Radix Rhei et Rhizoma), which is a common prescription for the treatment of damp-heat jaundice. Studies have shown that YCHD has a positive effect on a variety of stagnant damp-heat diseases of the liver meridian not only on enzymes and proteins in the liver and blood, regulating bile acid, bilirubin, lipid, and glucose metabolism but also on pathological processes such as liver fibrosis, inflammation, and hepatocyte apoptosis directly through liver Kupffer cells, hepatic stellate cells, and other cells. Additionally, it can also regulate intestinal flora and protect the liver.

MATERIALS AND METHODS

Active ingredients of YCHD

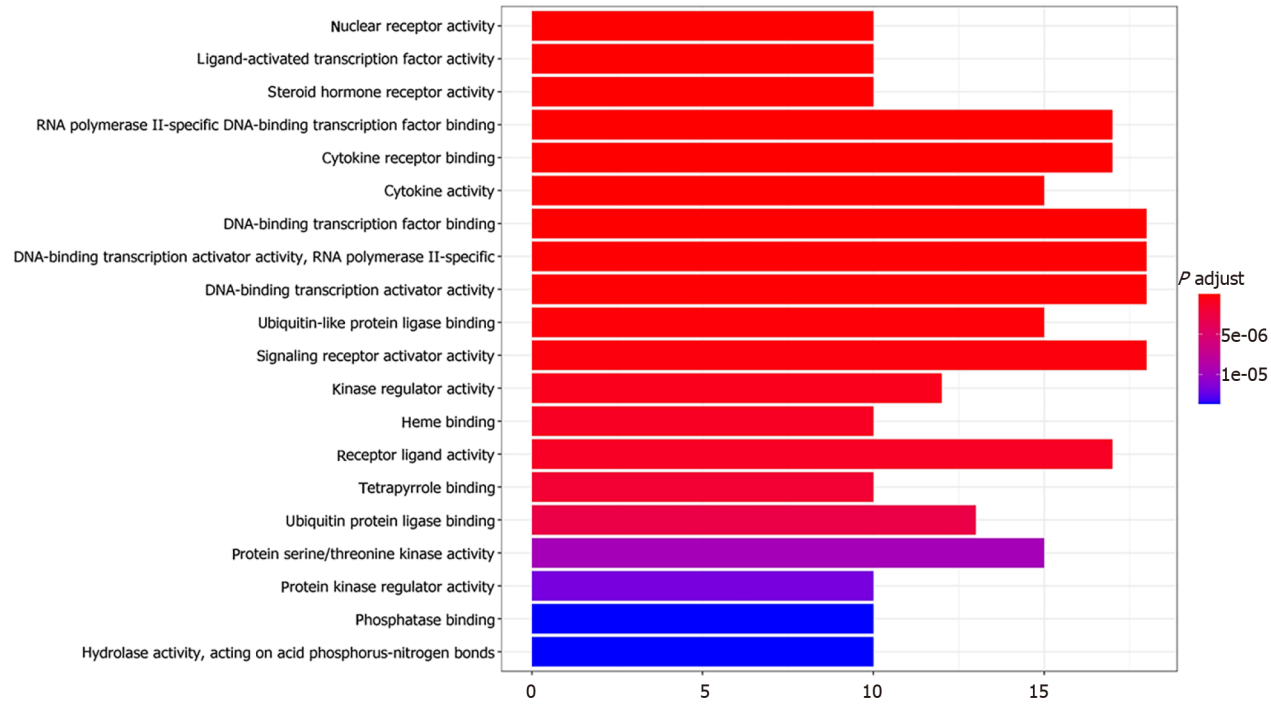
We used keywords Yinchen, Zhizi, and Dahuang to search the TCM systems pharmacology database and analysis platform (TCMSP) database. According to the standard of oral bioavailability ≥ 30% and drug likeness ≥ 0.18, 13, 16 and 15 active ingredients were obtained. β-Sitosterol is a common component of Yinchen, Zhizi and Dahuang. Yinchen and Zhizi both contain quercetin. After removing the duplicates, YCHD contained 41 active chemical components.

OJ targets



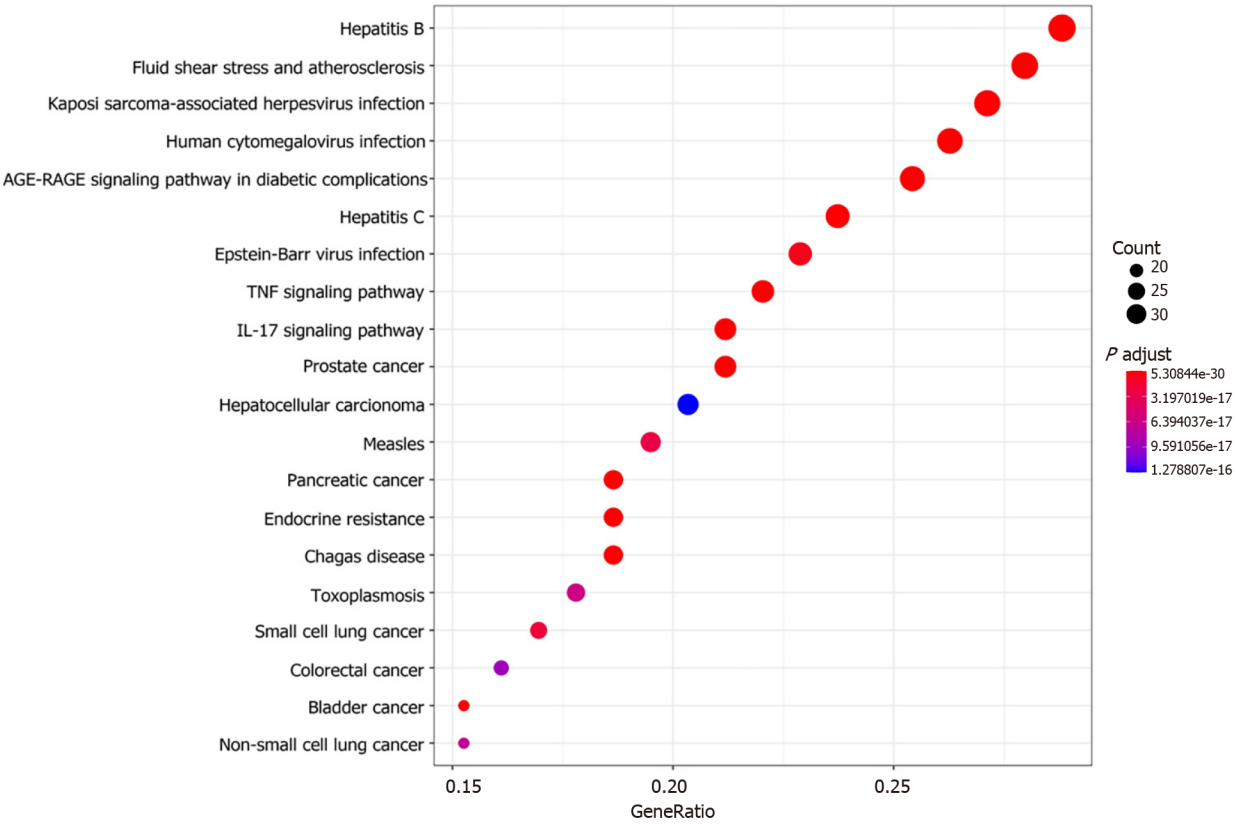
The related targets of OJ were found using the GeneCards database (https://www.genecards.org/). A total of 2183 disease targets were obtained.

Intersection targets of YCHD and OJ



The intersection targets of YCHD and OJ were discovered using R4.0.2 software to analyze the action targets of the main chemical components of YCHD and the targets of OJ. Figure 1A shows the Venn diagram of 123 intersection target genes, or the targets of YCHD acting on OJ. The chemical composition and intersection target of YCHD were entered into the Cytoscape software to construct a Component-Target network of YCHD for treating OJ. The network consists of 153 nodes and 463 edges (Figure 1B).

Protein–protein interaction network



The protein–protein interaction (PPI) data came from the search tool for the retrieval of interacting genes/proteins database (https://string-db.org), which provides information on predicted and experi-

Figure 1 Network construction. A: Venn diagram of the candidate targets in Yinchenhao decoction (YCHD) and obstructive jaundice (OJ); B: The Component-Target network. The blue circles refer to 123 putative targets of YCHD for the treatment of OJ. The red and purple diamonds represent YCHD and OJ, respectively. The green oval represents the chemical composition. The blue rectangle represents the target protein. The degree indicates the number of routes connected to this node in the network; C: The protein–protein interaction network. The size of the set node is proportional to the degree, and the larger the degree, the redder the color, indicating that the target interaction is higher. The key targets are protein kinase B, tumor protein 53, interleukin 6, vascular endothelial growth factor A, and caspase-3. They are the core targets of YCHD in treating OJ; D: The Gene Ontology enrichment analysis of involved biological processes; E: The Kyoto Encyclopedia of Genes and Genomics pathway enrichment analysis of putative targets; F: Component-target-signaling pathway network. The red hexagon represents the signaling pathway; the yellow hexagon represents the component; and the blue circle represents the target.

mental protein interactions. The intersection target's protein interaction relationship was then obtained. However, one protein was not involved in the interaction. The protein interaction information was then entered into the Cytoscape software to construct and analyze the protein interaction network, yielding the PPI network of the YCHD and OJ intersection target. The network consists of 122 nodes. Protein kinase B (PKB/Akt) 1, tumor protein 53 (TP53), interleukin 6 (IL-6), vascular endothelial growth factor A (VEGFA), caspase-3 (CASP3), and so on can be seen in the picture. They are the core targets of YCHD in the treatment of OJ (Figure 1C).

GO and KEGG pathway enrichment analysis

The R software was used to import data from the Bioconductor database (https://www.bioconductor.org/). The protein in network construction was analyzed for Gene Ontology (GO) and Kyoto Encyclopedia of Genes and Genomics (KEGG) enrichment. A total of 135 GO entries and 162 KEGG pathways were identified, and the first 20 target enrichment GO entries and KEGG pathways were plotted onto a bar chart and a bubble chart. The results indicated that the effects of YCHD on OJ involved biological processes such as DNA transcription factor binding, RNA polymerase II specific, DNA-binding transcription activator activity, and nuclear receptor activity (Figure 1D). The protective effects of YCHD against OJ were closely related to 20 pathways, including the hepatitis-B, mitogen-activated protein kinase (MAPK), phosphatidylinositol 3-kinase (PI3K)/Akt , and tumor necrosis factor (TNF) signaling pathways (Figure 1E). the Component-Target-signaling pathway network was created using the Cytoscape software (Figure 1F).

Reagents

Yinchen, Zhizi, and Dahuang were provided by the particle pharmacy of Tianjin Medical University NanKai Hospital. Serum total bilirubin (TBIL) kits, direct bilirubin (DBIL) kits, alanine transaminase (ALT) kits, and aspartate aminotransferase (AST) kits were purchased from the National Institute of Biochemistry. Thermo Fisher Scientific (Shanghai, China) provided the Nrf2 antibody (PA5-27882), Keap1 antibody (PA5-99434), and protein marker (26617. Anti-NQO1 antibody (ab80588) and Anti-GST3/GST antibody (ab138491) were purchased from Abcam (Shanghai, China). β-Actin (66009-1-Ig) was purchased from Proteintech Group (Wuhan, China). Goat anti-rabbit immunoglobulin G (IgG) (ZB-2301) and anti-mouse IgG (ZB-2305) were purchased from Beijing Zhongshan Gold Bridge Biotechnology (Beijing, China). Poly (vinylidene fluoride) membrane (IPHV00010), electrochemiluminescence (ECL) kit (WBKLS0×500), and radioimmunoprecipitation assay buffer (RIPA) lysis buffer (20-188) were provided by Millipore Corporation (Shanghai, China). 4% paraformaldehyde solution, poly-L-lysine, antigen retrieval solution, goat serum, NOS3 (A-9; sc-376751), NOS2 (A-9; sc-7271), S-A/HRP, DAB kit, and hematoxylin and eosin staining kit were purchased from Santa Cruz Biotechnology (Beijing, China). Bicinchoninic acid (BCA) protein assay kit was provided by Beijing Solarbio Science & Technology (Beijing, China).

YCHD preparation

According to Shanghan Lun, a dose of YCHD contains Yinchen (82.5 g), Zhizi (14 g), and Dahuang (27.5 g). We boiled it twice after soaking it for 30 min. Then, we concentrated two boiling mixtures to 124 mL each. The final liquid contained 1 g/mL of the crude drug.

Animals

Thirty-two healthy SPF-rated Sprague–Dawley rats (200–230 g) were purchased from Beijing HFK Bioscience (license No. SCXK Jin 2020-0008). The experimental protocol was approved by the Animal Research Committee of Tianjin Medical University NanKai Hospital (approval no. NKYY-DWLL-2021-102). All the animals were reared in the Laboratory Animal Center of Tianjin Medical University Nankai Hospital. We strictly followed the rules of the experimental animal center. The rats were fed and acclimatized to laboratory conditions (22–24°C, 12 h/12 h light/dark, 60%–65% humidity, *ad libitum* access to food and water) for 2 wk prior to experimentation.

Experiments

Thirty healthy rats were divided into three groups, each with 10 rats: the sham group (Group S), obstructive jaundice model group (Group M), and YCHD-treated group (Group Y). We created OJ models in Groups M and Y by ligating the common bile duct twice and transecting between the sutures. The successful establishment of the bile duct OJ model was demonstrated by the yellowing of the rats' skin after 3 d. In Group S, the common bile ducts were not clamped and served as a control. From then on, rats in Group Y were given a gavage of YCHD (3.6 mL/kg) twice daily for 1 wk, whereas rats in Groups S and M were given the same amount of physiological saline after intragastric administration daily. Intragastric gavage administration was carried out with conscious animals. All rats were killed on d 10 after the operation, and the liver and blood samples were collected for further research. Every effort was made to alleviate animal suffering. Animal experiments followed were strictly complied with the Guide for the Care and Use of Laboratory Animals.

Serum biochemistry analysis

The blood samples were centrifuged at 3000 r/min for 10 min to obtain the upper serum specimens. The serum levels of TBIL, DBIL, ALT and AST were measured.

Histological analysis

The liver tissue was fixed in 4% paraformaldehyde. The samples were sliced into 4–5-μm thick slices and stained with H&E to observe the changes in histology under the microscope after decalcification, dehydration, permeation, and paraffin encapsulation.

Immunohistochemical analysis

Antigen repair, blocking of endogenous peroxidase, incubation of primary and secondary antibodies, DAB staining, restaining of the nucleus, and sealing was performed on dewaxed liver tissue sections. As a result, the nucleus was blue, while the positive DAB expression was brown. The visual field was randomly selected. The levels of inducible nitric oxide synthase (iNOS) and endothelial nitric oxide synthase (eNOS) gene expression, and the nucleus positive rate of Nrf2 protein, were measured.

Western blotting

Liver tissue samples were lysed with RIPA lysis buffer and centrifuged to prepare protein solution. A BCA protein assay kit was used to determine the protein content. Sample feeding, electrophoresis, membrane transfer, and sealing were carried out in order. The specimens were then incubated with the

following primary antibodies, anti-Nrf2 (1:500), anti-Keap1 (1:500), anti-NQO1 (1:10000), anti-GST3/GST (1:1000), and β-actin (1:5000). After washing three times with tris buffered saline-Tween 20 (TBST), the membranes were incubated with rabbit horseradish peroxidase (HRP)-conjugated secondary antibody at 4C for 1 h. Electrochemiluminescence was used to detect the proteins, and ImageJ software was used to calculate the average optical density (AOD). The relative content of Nrf2, Keap1, NQO1 and GST in rat liver tissue was calculated by dividing the AOD value of the target protein in the sample by the AOD value of β-actin.

Statistical analyses

All data were presented as mean ± SD. One-way analysis of variance was used to assess statistical differences using SPSS 23.0 software (SPSS Inc., Chicago, IL, USA). For homogeneity of variance, the least significant difference test was used for homogeneity of variance, and Dunnett's test was used for nonhomogeneity of variance. The *post hoc* test above was used to determine the significance of the statistical results. $P < 0.05$ was considered statistically significant.

RESULTS

Effects of YCHD on biochemical indicators

Biochemical markers of liver function include AST, ALT, TBIL and DBIL. The serum levels of TBIL, DBIL, ALT and AST in Groups M and Y were significantly higher than in Group S (Figure 2A). When compared to Group M, serum levels of TBIL, DBIL, ALT and AST decreased after 1 wk of YCHD intervention in Group Y. The liver function of OJ rats was improved after YCDH treatment.

Histopathological effects

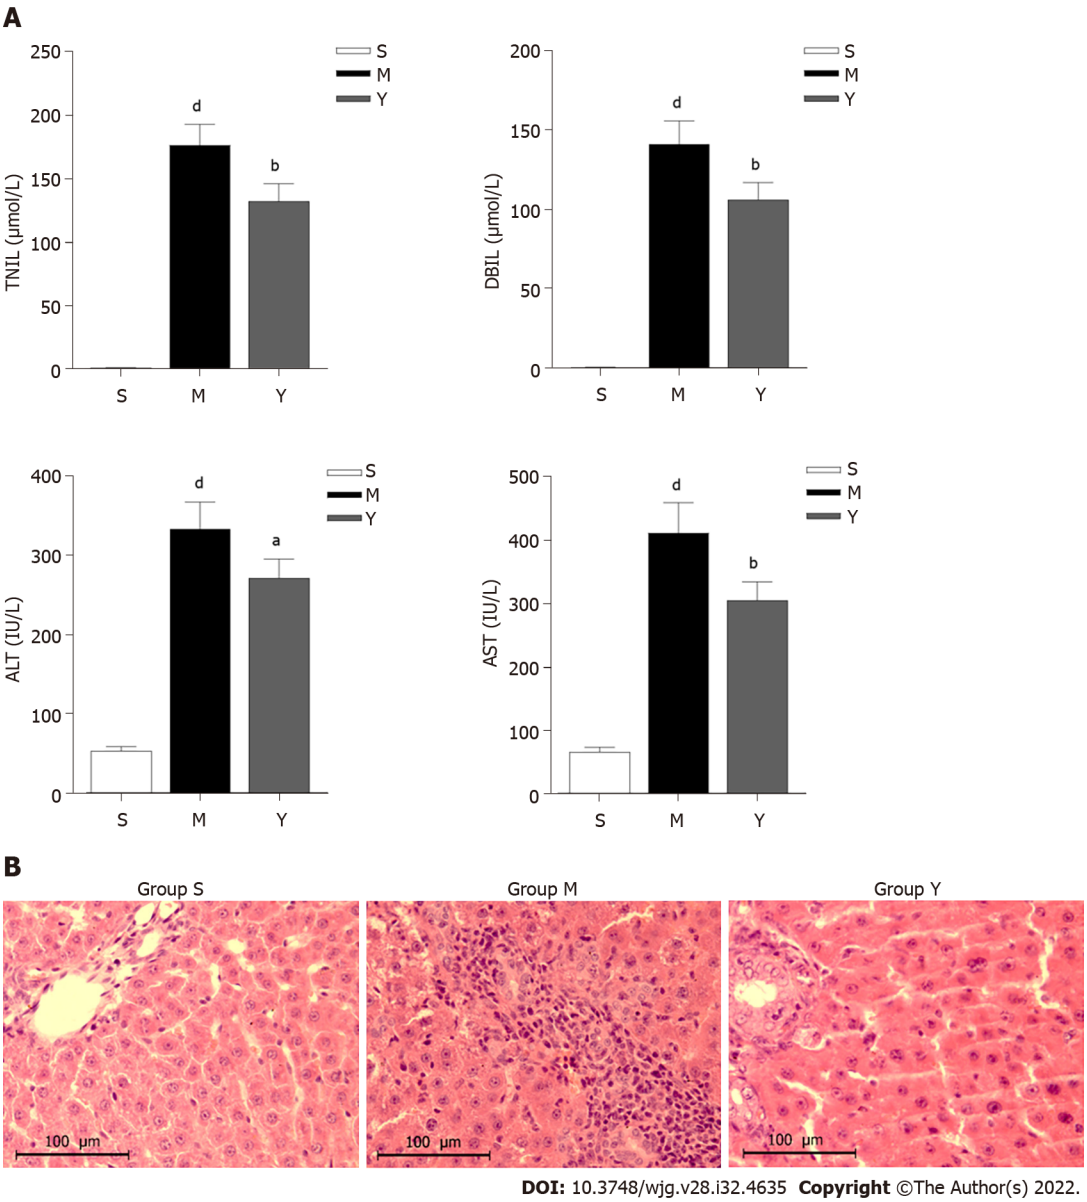
Hepatocytes in Group M were swollen, necrotic, and had neutrophil infiltration and erythrocyte accumulation in the sinusoids, compared with Group S. Group M showed obvious signs of liver injury. The swelling and necrosis of hepatocytes were alleviated in Group Y compared to Group M. After YCHD treatment, the degree of liver injury was significantly reduced (Figure 2B).

Nrf2 translocation

The nucleus positive rate of Nrf2 protein was lower in Group M than in Group S. Compared with Group M, the positive rate in Group Y was significantly higher, suggesting that after the intervention of YCHD, Nrf2 protein was transferred from the cytoplasm to the nucleus, potentially reducing the oxidative damage to OJ liver tissue by regulating the nuclear translocation of Nrf2 (Figure 3).

Effects of YCHD on expression of NOS3 (eNOS) and NOS2 (iNOS)

The AOD of eNOS in Group M decreased when compared to Group S, while that of iNOS increased (Figure 3). Compared with Group M, the AOD of eNOS in Group Y increased, while that of iNOS decreased.



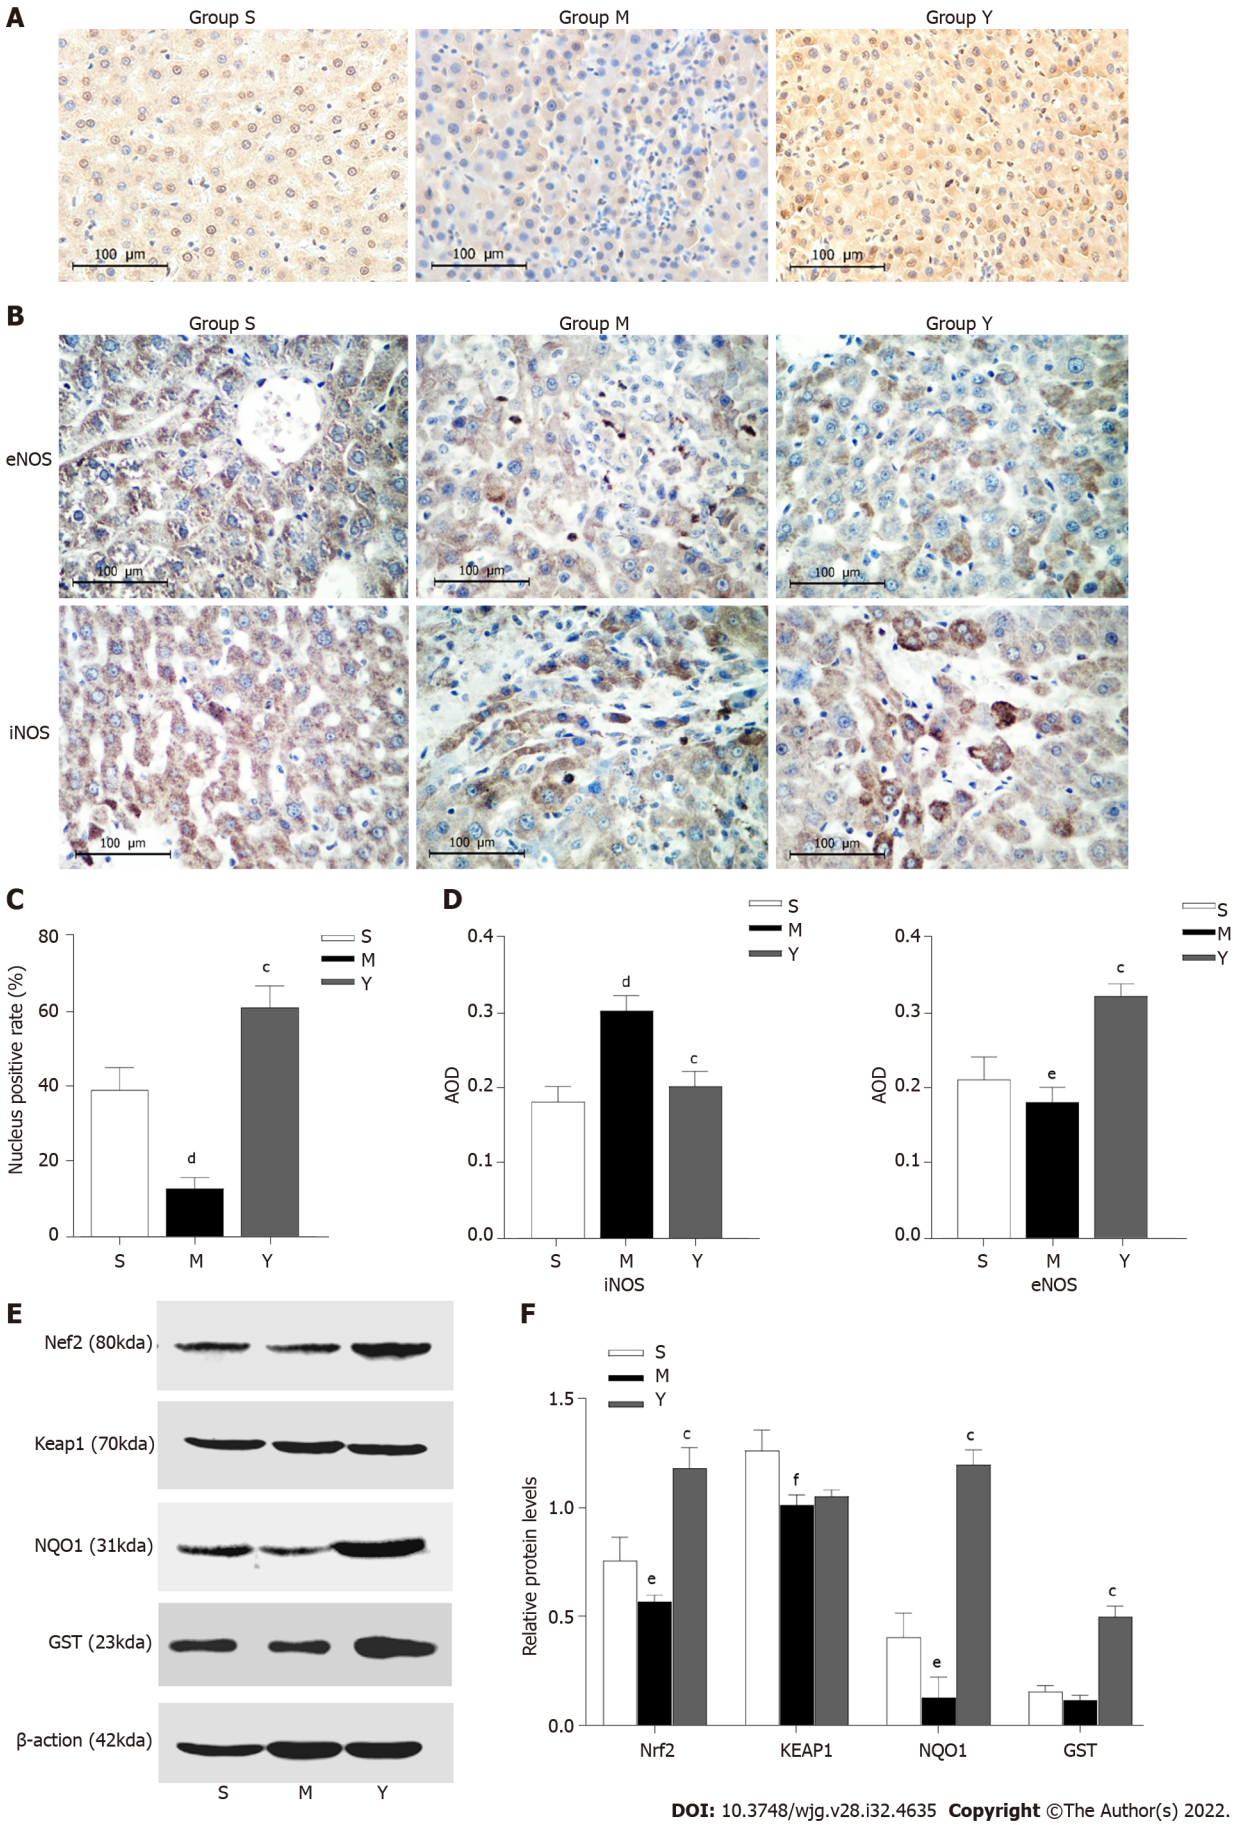
Effects of YCHD on expression of proteins related to the Nrf2 signaling pathway

The expression levels of Nrf2, Keap1 and NQO1 in Group M decreased when compared to Group S. Compared with Group M, the expression levels of Nrf2, NQO1 and GST increased in Group Y, but there was no significant difference in the expression of Keap1 between these two groups (Figure 3).

DISCUSSION

OJ is caused by bile excretion disorder after partial or complete bile duct obstruction. The metabolism of total bile acid (TBA) is disrupted, resulting in an increase in TBA in the blood of up to 60 times the normal amount. Bile buildup causes harmful substances to clump together. Damage in the reticuloendothelial system function causes spillover of bacteria and endotoxin into the systemic circulation[14]. OJ can cause liver damage, inflammation, decreased bowel barrier function, endotoxemia, clotting dysfunction, decreased immune function, and malnutrition. It can cause liver injury through various mechanisms, such as inflammation, endotoxemia and oxidative stress[15]. OJ leads to an increase in the production and clearance of active molecules, such as ROS and RNS. Increased lipid peroxidation and the balance between the hepatic oxidative and antioxidant systems worsen liver injury[16]. OJ causes liver damage and hepatocyte apoptosis by suppressing the protein kinase RNA-like endoplasmic reticulum kinase-induced pathway[17].

YCHD is one of the classic prescriptions for treating liver diseases. The chemical components of YCHD mainly include flavonoids, volatile oils and coumarin, among which the common flavonoids are quercetin, isorhamnetin and cirsimaritin, which belong to a class of compounds with antioxidant, anti-



DOI: 10.3748/wjg.v28.i32.4635 **Copyright** ©The Author(s) 2022.

Figure 2 Yinchenhao decoction relieves the hepatic injury induced by obstructive jaundice. A: Yinchenhao decoction (YCHD) treatment improved the liver function of obstructive jaundice (OJ) rats. inflammatory, antitumor and other effects. Recent studies have shown that YCHD increases bile acid reabsorption and restore the balance of bile acid excretion, thereby reducing the impact of toxic bile acids on liver injury in rats[18]. YCHD alleviates lithogenic-diet-induced cholelithiasis and improves biliary cholesterol supersaturation to restore biliary cholesterol homeostasis[19]. YCHD could alleviate liver damage by reducing the levels of important cytokines such as TNF-α, myeloid differentiation primary response 88 (MyD88), and nuclear factor B in the Toll-like receptor 4 signaling pathway. YCHD may reduce liver fibrosis by regulating targets in the apoptosis-related TNF, PI3K-Akt and MAPK signaling pathways, promoting hematopoietic stem cell apoptosis while decreasing hematopoietic progenitor cell apoptosis[20]. YCHD showed therapeutic effects on cholangiocarcinoma by regulating related target protein, inhibiting cell proliferation, and increasing the rate of apoptosis[21].

In our study, we demonstrated that YCHD alleviated the swelling and necrosis of hepatocytes, while also regulating serum levels of ALT, AST, TBIL and DBIL. These findings suggest that YCHD can effectively reduce OJ-induced liver injury and improve liver function.

NO plays a dual role in liver damage. NO is still maintained at a physiological level in the early stages of the disease, which can dilate blood vessels, inhibit platelet aggregation, and improve liver blood flow. RNS is an active group whose derivatives revolve around NO. In the physiological state, iNOS is inactive, but in a physiological state, iNOS is activated and expressed, causing it to catalyze L-

Group S: Sham group; Group M: Obstructive jaundice model group; Group Y: YCHD-treated group. $^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$ *vs* Group M; $^{d}P < 0.001$, $^{e}P < 0.05$, $^{f}P < 0.01$ *vs* Group S.

arginine to produce a large amount of NO[22]. NO can easily interact with O2 to produce free radicals and nitro compounds such as ONOO and its proton form HOONO. Recent studies have shown that with the aggravation of cholestasis, various stimulating factors such as endotoxin and inflammation activate the expression of iNOS in liver tissue, resulting in a large amount of NO, which is cytotoxic and causes liver injury[23]. We found expression of NOS3 (eNOS) and NOS2 (iNOS) in the liver tissue of rats. When OJ occurred, the expression of eNOS decreased, while that of iNOS increased. However, after YCHD intervention, the amount of iNOS decreased, suggesting that YCHD can reduce overexpression of NO by adjusting eNOS and iNOS and keeping it at a physiological level to reduce oxidative damage and improve liver microcirculation.

Nrf2 is an important nuclear transcription factor. Under normal circumstances, Nrf2 is bound to Keap1 in the cytoplasm, where it will be rapidly degraded *via* the ubiquitin–proteasome pathway. When the body is stimulated by oxidative stress, Nrf2 dissociates from Keap1. A heterodimer is formed when free Nrf2 combines with one of the small Maf (musculoaponeurotic fibrosarcoma oncogene homolog) proteins. Then, it binds to the antioxidant response elements (AREs), which are enhancer sequences in the regulatory regions, to promote the transcription of genes that encode redox balancing factors, detoxifying enzymes, and stress response proteins, such as GSH, GST, NQO1, HO-1 and glutathione cysteine ligase catalytic subunit[13]. Expression of HO-1 and NQO1 reduces oxidative stress by facilitating removal of ROS[24]. p53 induction and apoptosis were reduced in NQO1-deficient mice, and chemically induced tumors susceptibility was increased[25]. The Nrf2/ARE signaling pathway has been shown to effectively remove excessive ROS from the body, inhibiting oxidation and inflammatory reactions and reducing hepatocellular apoptosis. Increased ROS and oxidative stress injury could lead to gastric mucosal damage and malignancies[26,27]. Overexpression of HO-1 increases the production of CO, which protects cardiomyocytes from apoptosis by generating H_2O_2 in the mitochondria and producing PKB/Akt [28]. The expression of Nrf2 mRNA in silenced neurons for the frataxin gene decreased, and the cells may be more sensitive to oxidative stress[29]. Sulforaphane, an Nrf2 activator, enhances running capacity in rats by upregulating Nrf2 signaling and reduces muscle fatigue by reducing oxidative stress caused by exhaustive exercise[30]. As a result, Nrf2 plays an important role in the response to oxidative stress. Following the intervention of YCHD, the positive rate of Nrf2 in nucleus was significantly increased, suggesting that Nrf2 protein was transferred from the cytoplasm to the nucleus. Nrf2 can only function in the nucleus, forming the Nrf2–Maf heterodimer and binding to ARE to activate antioxidant and metabolic genes. Therefore, YCHD may be able to reduce oxidative damage to OJ liver tissue by regulating the nuclear translocation of Nrf2. As a result, the ability of antioxidant stress is enhanced. We assessed the Nrf2 signaling pathway, which is an important ARE signaling pathway. Expression of Nrf2 was decreased in OJ rats, but significantly increased with YCHD treatment. GSH and NQO1 are the downstream antioxidant factors of the Nrf2 signaling pathway. In the YCHD group, their expression was higher. It was discovered that YCHD protects against OJ-induced oxidative stress by activating the Nrf2 signaling pathway.

CONCLUSION

We found through network pharmacology research that YCHD has multicomponent, multitarget, and multipathway function characteristics. The mechanism could be related to many biological processes, such as anti-inflammatory activity, inhibition of liver fibrosis, antioxidant activity, and apoptosis. This provides the theoretical basis for further research into the molecular mechanism of action of YCHD in the treatment of OJ. In a future study, the chemical composition of YCHD and its associated targets can be studied accurately using the results predicted by network pharmacology. Measurements of ROS accumulation, antioxidant factors (GSH and NQO1), and iNOS were used to assess the status of oxidative stress caused by OJ. We have demonstrated that YCHD can increase the expression of Nrf2, promote translocation of Nrf2 to the nucleus, reduce overexpression of NO by adjusting eNOS and iNOS, and activate downstream GSH and NQO1expression; all of which would protect liver tissue from oxidative damage. Besides, it can also alleviate liver injury and oxidative damage, promote the translocation of Nrf2 to the nucleus, and upregulate the Nrf2 signaling pathway. In a nutshell, the present study looked into the protective effects of YCHD against OJ-induced liver injury. The Nrf2 signaling was upregulated as a potential mechanism. Although many mechanisms are involved in the occurrence

and progression of OJ, we report here for the first time that YCHD can promote the translocation of Nrf2 to the nucleus and upregulate the Nrf2 signaling pathway, which could be a new way to look at antioxidation mechanisms. OJ can be effectively treated using a combination of TCM and modern medicine.

We would like to acknowledge Zhong-Lian Li for his skillful technical assistance and Jing Liang from Chengdu University of traditional Chinese medicine, for her English language proofreading to improve the content of the manuscript.

ARTICLE HIGHLIGHTS

Research background

Obstructive jaundice (OJ) may lead to liver injury through various mechanisms. Oxidative stress is an important pathological mechanism of OJ-induced liver injury. It is present throughout the OJ process. Yinchenhao decoction (YCHD), a traditional Chinese medicine (TCM) formula, has been widely used for treating jaundice in clinical practice. Recent studies have confirmed that YCHD can effectively alleviate liver injury. However, the mechanism of YCHD treating OJ-induced liver injury has not yet been fully clarified.

Research motivation

To provide much more scientific evidence for the clinical application of YCHD and promote the combination of TCM and modern medicine to treat diseases more effectively.

Research objectives

We aimed to investigate the effective chemical components of YCHD and predict the mechanism of YCHD in the treatment of OJ-induced liver injury and oxidative damage.

Research methods

By the network pharmacology approach, we predicted the chemical composition of YCHD and its associated targets. Measurements of inducible nitric oxide synthase (iNOS), endothelial nitric oxide synthase (eNOS), the nucleus positive rate of NF-E2 related factor 2 (Nrf2) protein, and the protein expression levels of Nrf2, Kelch-like ECH-associated protein 1, NAD(P)H quinone dehydrogenase 1 (NQO1) and glutathione-S-transferase (GST) were used to assess the status of oxidative stress caused by OJ.

Research results

Network pharmacology research showed that YCHD had multicomponent, multitarget, and multipathway function characteristics. YCHD increased expression of Nrf2, promoted translocation of Nrf2 to the nucleus, reduced overexpression of NO by adjusting eNOS and iNOS, and activated expression of GST and NQO1; all of which protect liver tissue from oxidative damage.

Research conclusions

YCHD can alleviate liver injury and reduce oxidative damage. Although various mechanisms are involved in the occurrence and development of OJ, we report that YCHD can promote the translocation of Nrf2 to the nucleus, and upregulate the Nrf2 signaling pathway, which may provide a new perspective for the study of the mechanism of antioxidation. This provides the theoretical basis for further research into the molecular mechanism of action of YCHD in the treatment of OJ.

Research perspectives

TCM formulas like YCHD have been widely used for thousands of years. In the near future, more in-depth research on the molecular mechanism of TCM can guide clinical treatment more effectively.

Abstract

BACKGROUND

Anoctamin 5 (ANO5)/transmembrane protein 16E belongs to the ANO/ transmembrane protein 16 anion channel family. ANOs comprise a family of plasma membrane proteins that mediate ion transport and phospholipid scrambling and regulate other membrane proteins in numerous cell types. Previous studies have elucidated the roles and mechanisms of ANO5 activation in various cancer types. However, it remains unclear whether ANO5 acts as a plasma membrane chloride channel, and its expression and functions in gastric cancer (GC) have not been investigated.

AIM

To examine the role of ANO5 in the regulation of tumor progression and clinicopathological significance of its expression in GC.

METHODS

Knockdown experiments using ANO5 small interfering RNA were conducted in human GC cell lines, and changes in cell proliferation, cell cycle progression, apoptosis, and cellular movement were assessed. The gene expression profiles of GC cells were investigated following ANO5 silencing by microarray analysis. Immunohistochemical staining of ANO5 was performed on 195 primary tumor

samples obtained from patients with GC who underwent curative gastrectomy between 2011 and 2013 at our department.

RESULTS

Reverse transcription-quantitative polymerase chain reaction (PCR) and western blotting demonstrated high ANO5 mRNA and protein expression, respectively, in NUGC4 and MKN45 cells. In these cells, ANO5 silencing inhibited cell proliferation and induced apoptosis. In addition, the knockdown of ANO5 inhibited G_1-S phase progression, invasion, and migration. The results of the microarray analysis revealed changes in the expression levels of several cyclin-associated genes, such as *CDKN1A*, *CDK2/4/6*, *CCNE2*, and *E2F1*, in ANO5-depleted NUGC4 cells. The expression of these genes was verified using reverse transcription-quantitative PCR. Immunohistochemical staining revealed that high ANO5 expression levels were associated with a poor prognosis. Multivariate analysis identified high ANO5 expression as an independent prognostic factor for 5-year survival in patients with GC (P = 0.0457).

CONCLUSION

ANO5 regulates the cell cycle progression by regulating the expression of cyclin-associated genes and affects the prognosis of patients with GC. These results may provide insights into the role of ANO5 as a key mediator in tumor progression and/or promising prognostic biomarker for GC.

Key Words: Anoctamin 5; Gastric cancer; Cell cycle; G1/S checkpoint; Cell proliferation

Core Tip: The present study aimed to investigate the role of anoctamin 5 (ANO5) in the regulation of tumor progression and the clinicopathological significance of its expression in gastric cancer. Immunohistochemical staining revealed that high ANO5 expression levels were associated with a poor prognosis in patients with gastric cancer. Microarray analysis results suggest that ANO5 regulates cell cycle progression by regulating the expression of cyclin-associated genes. Our results provide insights into the role of ANO5 as a mediator of and/or biomarker for gastric cancer.

INTRODUCTION

The anoctamin (ANO)/transmembrane protein 16 (TMEM16) family is present in numerous eukaryotes, and ten ANO paralogs, ANO1-ANO10 (TMEM16A-H, TMEM16J and K), have been identified in vertebrates[1]. Of these, several function as calcium-activated chloride channels. ANOs comprise a family of plasma membrane proteins that mediate ion transport, phospholipid scrambling, and other membrane protein regulation in numerous cell types[2-6]. Their expression has been detected in both epithelial and non-epithelial tissues types[4]. Although the regulation of ANOs has been extensively examined, the mechanisms by which increased intracellular calcium concentration activates chloride or cation conductance have not been elucidated.

Recent molecular and biochemical studies reported a role for ANOs in human carcinogenesis. For instance, the expression of ANO proteins is upregulated in cancer and associated with a poor patient prognosis[7]. A relationship has been demonstrated between ANO1 and patient prognosis in various cancer types, including gastric, esophageal, breast, lung, and head and neck cancer[8-12]. The upregulation of the genes encoding ANO1 and ANO3 has been associated with several cancer types, specifically gastrointestinal stromal tumors, breast cancer, and squamous cell carcinoma[12,13]. Furthermore, ANO6 has been strongly implicated in the metastatic potential of breast cancer[14]. The expression levels of other members of the ANO family are also associated with cell proliferation and cancer development[15-17].

In our previous studies, we identified a crucial role for several chloride ion channels and transporters in patients with gastric cancer (GC); intracellular chloride regulates proliferation and cell cycle progression[18,19], whereas furosemide, a potent inhibitor of the $Na^+/K^+/2Cl^-$ cotransporter, induces G_0/G_1 arrest[20]. Furthermore, leucine rich repeat containing 8 VRAC subunit A regulate the proliferation,

apoptosis, migration, and invasion of GC cells[21].

ANO5 has recently been implicated in various cancers, such as thyroid[22] and pancreatic cancer[23]; however, limited information is presently available on its involvement in tumor progression in patients with GC or the clinical significance of its expression. Therefore, in the present study, we investigated whether ANO5 contributes to the regulation of cancer growth and evaluated its clinicopathological significance in GC.

MATERIALS AND METHODS

Cell lines, antibodies

MKN7, MKN45, MKN74, HGC27, and NUGC4 human GC cell lines were purchased from the Riken Cell Bank (Tsukuba, Japan). Cells were cultured in RPMI-1640 (Nacalai Tesque, Kyoto, Japan) containing 100 μg/mL of streptomycin, 100 U/mL penicillin, and 10% FBS at 37 °C in a 5% CO_2 incubator. Rabbit polyclonal anti-ANO5 antibody was obtained from Funakoshi (GTX81161) for immunohistochemical (IHC) analysis and western blotting. Mouse monoclonal anti-β-actin antibody was provided by Sigma-Aldrich (St. Louis, MO, United States) and HRP-conjugated anti-rabbit and mouse secondary antibodies by Cell Signaling Technology (Beverly, MA, United States).

Reverse transcription-quantitative polymerase chain reaction

RNA was extracted from cancer cells using an RNeasy kit (Qiagen, Valencia, CA, United States). The Step One plus™ Real-Time polymerase chain reaction (PCR) System (Applied Biosystems, Foster City, CA, United States) and TaqMan Gene Expression Assays (Applied Biosystems) were employed for reverse transcription-quantitative PCR analysis using the following PCR thermocycling conditions: initial denaturation step at 95 °C for 10 min, followed by 40 cycles at 95 °C for 15 s and 60 °C for 1 min. The expression levels of the following genes were assessed: *ANO5* (Hs01381106_m1), *CDKN1A* (Hs00355782_m1), *CDK2* (Hs00608082_m1), *CDK4* (Hs00175935_m1), *CDK6* (Hs00608037_m1), cyclin E2 (CCNE2; Hs00180319_m1), and *E2F1* (Hs00153451_m1) (all from Applied Biosystems). The expression of each gene was normalized using the housekeeping gene β-actin (Hs01060665_g1; Applied Biosystems). All assays were performed in triplicates.

Western blotting

The cells were washed twice with ice-cold PBS and harvested in M-PER lysis buffer (Pierce, Rockford, IL, United States) supplemented with protease inhibitors (Pierce Biotechnology). Protein concentrations were measured using a modified Bradford assay (Bio-Rad, Hercules, CA, United States). Cell lysates containing equal amounts of total protein (10 mg/lane) were resolved using 10% SDS-PAGE and subsequently transferred to polyvinylidene fluoride membranes (GE Healthcare, Piscataway, NJ, United States). Membranes were incubated with antibodies for 24 h at 4 °C. Band densities were quantified using ImageJ (version 1.52; National Institutes of Health).

Small interfering RNA transfection

All small interfering RNA (siRNA) reverse transfection procedures were performed using Lipofectamine® RNAiMAX reagent (Invitrogen, Carlsbad, CA, United States) with a final siRNA concentration of 20 nmol/L, according to the manufacturer's instructions. ANO5 siRNA (Stealth RNAi siRNA; HSS137119, Stealth RNAi siRNA; HSS137120) and control siRNA (Stealth RNAiTM siRNA Negative Control) were obtained from Invitrogen.

Overexpression study

Control-HaloTag^R plasmid (Promega, G6591) and ANO5-HaloTag^R plasmid (pFN21AE5809) were transfected using P3000TM (Invitrogen) and lipofectamine 3000 (Invitrogen) following the manufacturer's instructions. After passaging, ANO5-expressing cells were used for the cell proliferation assay.

Cell proliferation assay

NUGC4 and MKN45 cells were seeded at densities of 1.0 and 2.0 × 10^5 cells/well, respectively, on six-well plates and incubated at 37 °C in a 5% CO_2 incubator. The siRNA was transfected 24 h after seeding. The cells were detached from the plates with trypsin-EDTA 48 h and 72 h after siRNA transfection and counted using a hemocytometer.

Cell proliferation activity was measured using the water-soluble tetrazolium salts-8 assay with Cell Count Reagent SF (Nacalai Tesque). NUGC4, MKN45, and MKN7 cells were seeded at a density of 1.0 × 10^4, 1.0 × 10^4, and 1.5 × 10^4 cells/well, respectively, in 24-well plates and were incubated at 37 °C in a 5% CO_2 incubator. The siRNA was transfected 24 h after seeding. Cell proliferation was evaluated every 24 h by measuring the absorbance at 450 nm using a Thermo Scientific Multiskan FC (Thermo Fisher Scientific).

Cell cycle assay

Cell cycle progression was assessed 48 h after siRNA transfection by flow cytometry. Cells were detached from the plates using trypsin-EDTA and subsequently treated with 0.2% Triton X-100 and stained with propidium iodide with RNase staining buffer (BD Biosciences, San Jose, CA, United States). Flow cytometry data were acquired using a BD Accuri C6 plus flow cytometer (BD Biosciences) to assess DNA content in at least 10000 cells.

Apoptosis assay

Cells were evaluated 72 h after transfection and stained using the ANNEXIN V-FITC Kit (Beckman Coulter, Brea, CA, United States). The frequencies of early and late apoptotic cells among at least 10000 cells were assessed using a BD Accuri C6 plus flow cytometer.

Migration and invasion assays

Migration assays were performed using 24-well cell culture inserts with 8-μm pores (BD Biosciences), whereas invasion assays were performed using Biocoat Matrigel® (BD Biosciences). At 48 h post-transfection, NUGC4 and MKN45 cells were seeded at a density of 3.0 × 10^5 cells/well in serum-free RPMI-1640 in the upper chamber, whereas the lower chamber contained RPMI-1640 with 10% FBS. Matrigel and the cells remaining in the upper chamber after a 48-h incubation were removed. Diff-Quick staining reagents (Sysmex) were used to stain migrated or invaded cells, which were counted in four independent fields of view. Both assays were conducted thrice.

Microarray analysis

NUGC4 and MKN45 cells were transfected with either control or ANO5 siRNA. At 48 h after siRNA transfection, total RNA was extracted using RNeasy kit. Cyanine 3 (Cy3)-labeled cRNA was prepared from 0.1 μg total RNA using the Low Input Quick Amp Labeling Kit (Agilent Technologies, CA, United States) and then subjected to RNeasy column purification (Qiagen). Dye incorporation and cRNA yields were assessed using a NanoDrop 2000 Spectrophotometer (Thermo Fisher Scientific). Subsequently, 0.6 μg Cy3-labeled cRNA was fragmented in a 25 μL reaction volume containing 1 × Agilent fragmentation buffer and 2 × Agilent blocking agent at 60 °C for 30 min. The 2 × Agilent hybridization buffer (25 μL) was then added, and hybridization to SurePrint G3 Human GE 8 × 60K Microarray Ver3.0 (Agilent Technologies) was conducted at 65 °C for 17 h in a rotating Agilent hybridization oven. The microarrays were then washed with GE Wash Buffer 1 (Agilent Technologies) at room temperature for 1 min, followed by GE Wash buffer 2 (Agilent Technologies) at 37 °C for 1 min.

Microarray data processing

Slides were scanned using the Agilent SureScan Microarray Scanner (G2600D) with the one color scan setting for 8 × 60k array slides. The scanned images were analyzed with Feature Extraction Software (Agilent Technologies) using the default parameters to obtain background-subtracted and spatially detrended processed signal intensities. Microarray data were analyzed using ingenuity pathway analysis software (Ingenuity Systems, Redwood City, CA).

Patients and primary tissue samples

Histologically proven primary GC tumor samples were obtained from 195 consecutive patients who underwent curative gastrectomy between 2011 and 2013 at Kyoto Prefectural University of Medicine, Japan. For mRNA analysis, frozen tissue samples of normal stomach and tumors were collected from surgical specimens and stored at -80 °C. Written informed consent was obtained from all patients prior to enrollment. Patients with noncurative resection or preoperative chemotherapy were excluded from the study. Tumor staging was conducted according to the International Union Against Cancer/TNM Classification of Malignant Tumors (8^{th} edition)[24]. The present study was approved by the Institutional Review Board of the Kyoto Prefectural University of Medicine (ERB-C-1195).

IHC

The Vectastain avidin-biotinylated peroxidase complex Elite Kit (Vector Laboratories, Burlingame, CA, United States) was employed for IHC staining using the avidin-biotinylated peroxidase complex method. After deparaffinization in xylene, sections were rehydrated in a graded series of ethanol solutions. The sections were then incubated in 0.3% H_2O_2 for 30 min to block endogenous peroxidase activity. Endogenous biotin, biotin receptors, and avidin-binding sites were also blocked using an Avidin/Biotin Blocking Kit (Vector laboratories). Sections were incubated with ANO5 antibody diluted 1:100 at 37 °C for 1 h and then at 4 °C overnight. Cells were visualized using the standard avidin-biotinylated peroxidase complex method, with hematoxylin as the counterstain.

ANO5 expression levels in immunohistochemically stained samples were semi-quantitatively graded based on the staining intensity and proportion of cytoplasm in the stained cancer cells. The staining intensity was scored as 0 (no staining), 1 (weak staining), 2 (moderate staining), or 3 (strong staining). The proportion of stained tumor cells as a percentage of the stained area in the cancer area was scored

from 0 to 1.0. IHC scores were calculated as the maximum multiplied product of intensity and proportion scores (0-3.0). IHC diagnosis was based on tumor ANO5 expression assessment, and other IHC parameters were performed by at least two physicians, including an experienced pathologist.

Quantification of intracellular chloride concentration and low chloride stimulation

MQAE reagent, a chloride-sensitive fluorescence probe (Dojindo Laboratories, Kumamoto, Japan) was used to assess intracellular chloride concentrations. NUGC4 and MKN45 cells were seeded in 24-well plates at a density of 3.0×10^4 cells/well and then incubated in normal medium at 37 °C with 5% CO_2. The medium was then replaced with standard and low-chloride medium in which MQAE was dissolved, and cells were incubated at 37 °C in a CO_2 incubator for a further 12 h. Following washing with PBS five times, the fluorescence intensity of MQAE was evaluated under a fluorescence microscope (BZ-X800; Keyence, Osaka, Japan). Three fields of view were analyzed *per* sample at × 100 magnification. Quantification was performed using a BZ-X800 analyzer and accompanying software (BZ-H4C, v.1.1.1.8; Keyence).

A low chloride stimulation experiment was conducted to examine the effects of changes in intracellular chloride concentrations on GC cells. A low-chloride medium supplemented with 10% FBS was prepared in chloride-free RPMI-1640 (chloride replaced with NO_3^-) (Nacalai Tesque).

c-Jun N-terminal kinase signaling pathway inhibitor treatment

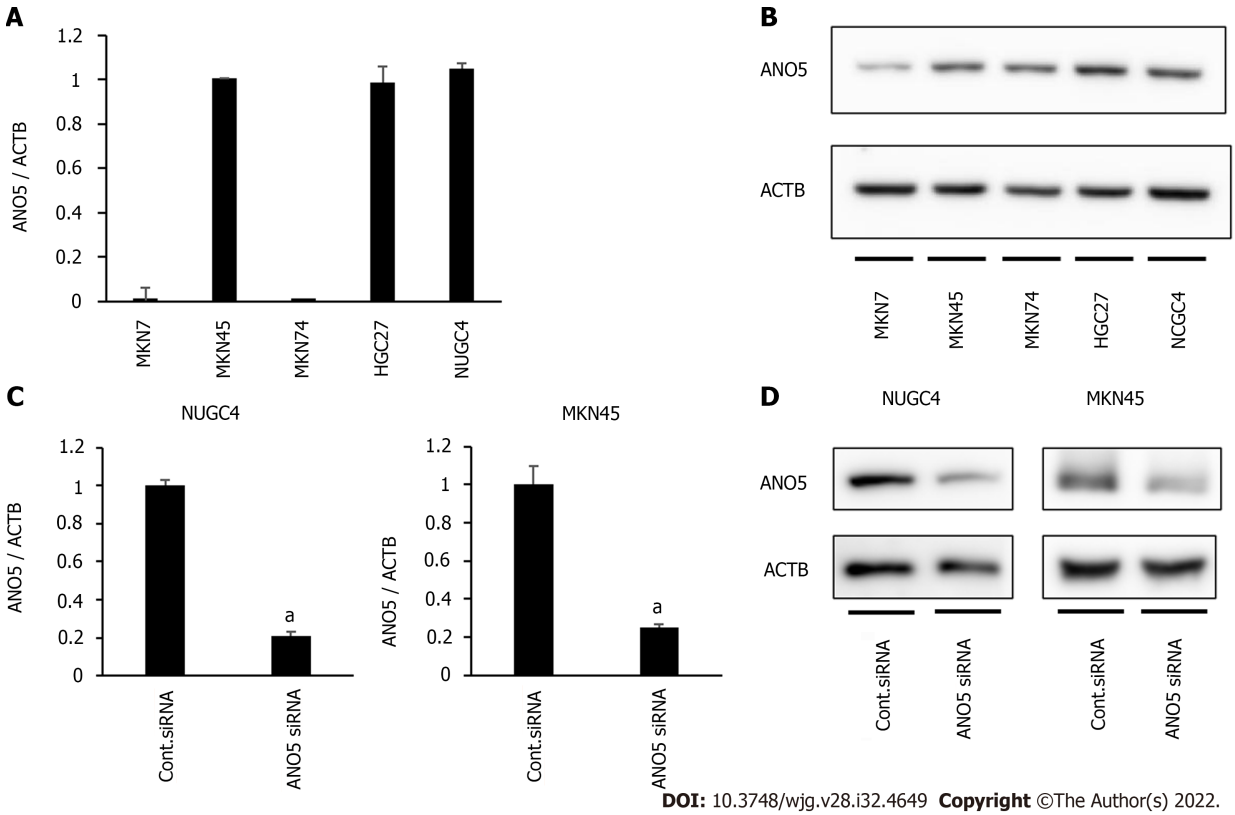
To block the c-Jun N-terminal kinase (JNK) signaling pathway, NUGC4 and MKN45 cells were incubated with the JNK inhibitor SP600125 (10μm, ab120065, Abcam) according to manufacturer's instructions. The cells were divided into 3 groups: control, ANO5 siRNA, and JNK inhibitor (ANO5 siRNA + SP600125). Cell proliferation was detected every 24 h after ANO5 silencing.

Statistical analysis

Statistical analysis was performed using the Mann-Whitney *U* test for two-group comparisons. Categorical data were analyzed using Fisher's exact test. The Kaplan–Meier method was used to construct survival curves, and differences in survival were examined using the log-rank test for equality. Prognostic factors were identified using the Cox proportional hazard model. These analyses were performed using the JMP statistical software (version 15; SAS Institute, Cary, NC, United States). Data are presented in the graphs as the mean ± standard error of the mean. $P < 0.05$ was considered a statistically significant difference.

RESULTS

ANO5 expression in GC cells



ANO5 gene and protein expression were first examined in five human GC cell lines, MKN7, MKN45, MKN74, HGC27, and NUGC4, by reverse transcription-quantitative PCR and western blotting. ANO5 expression was detected in several cells in the five GC cell lines (Figure 1A and B). Compared to paired adjacent normal tissue, ANO5 expression was significantly upregulated in GC tissue ($P = 0.004$; $n = 12$; Supplementary Figure 1).

ANO5 expression was knocked down using siRNA in NUGC4 and MKN45 cells, and its effects on tumor progression were assessed. *ANO5* mRNA (Figure 1C) and protein levels (Figure 1D) were downregulated in NUGC4 and MKN45 cells. We also conducted an overexpression study in MKN7 cells. The ANO5 plasmid increased *ANO5* mRNA levels (Supplementary Figure 2A, left panel).

ANO5 regulates cell growth and survival in GC cells

The effect of ANO5 siRNA transfection on the proliferation and cell cycle progression of NUGC4 and MKN45 cells were subsequently examined. Compared with the control siRNA, the number of NUGC4 and MKN45 cells was significantly reduced at 48 h and 72 h after the transfection with ANO5 siRNA (Figure 2A, left panel). The results of the cell proliferation assay showed that the relative absorbance of GC cells transfected with the control siRNA (NUGC4 and MKN45) was significantly lower than that of GC cells transfected with ANO5 siRNA (HSS137119) (NUGC4 and MKN45) (Figure 2A, right panel). Whereas, ANO5 plasmid increased the relative absorbance of MKN7 cell (Supplementary Figure 2B). Moreover, ANO5 silencing increased the numbers of NUGC4 and MKN45 cells in the G_0/G_1 phase (Figure 2B). These results indicated that ANO5 regulated the proliferation and cell cycle of GC cells.

To further clarify the role of ANO5, apoptosis assays were performed in NUGC4 and MKN45 cells. ANO5 silencing significantly increased the frequency of early and late apoptotic NUGC4 cells and the frequency of early apoptotic MKN45 cells 72 h after siRNA transfection (Figure 3A). These results indicated that the apoptosis in NUGC4 and MKN45 cells was regulated by ANO5 expression. Another ANO5 siRNA (HSS137120) was used to assess its impact on cell growth and survival, with results similar to those of HSS137119 (Supplementary Figure 3).

ANO5: Anoctamin 5; ACTB: β-actin; siRNA: Small interfering RNA.

ANO5 promotes the migration and invasion

The effects of the ANO5 silencing on NUGC4 and MKN45 cell migration and invasion were examined using a Boyden chamber assay. The results demonstrated that ANO5 knockdown in NUGC4 and MKN45 cells significantly reduced their migration and invasion (Figure 3B).

Gene expression profiling in ANO5 siRNA-transfected NUGC4 cells

To elucidate the molecular mechanisms underlying the regulation of cellular functions by ANO5, the gene expression profiles of NUGC4 cells transfected with ANO5 siRNA were investigated using microarray. The results revealed that the expression levels of 3491 genes in NUGC4 cells following ANO5 knockdown exhibited fold-changes > 1.8 compared with those in the negative control. Among these, the expression levels of 1802 genes were upregulated, whereas those of 1689 genes were downregulated in NUGC4 cells following ANO5 knockdown. The top 20 genes with significant changes in expression in the ANO5-depleted NUGC4 cells are listed in Tables 1 and 2. Ingenuity pathway analysis showed that 'Cancer' was the top-ranked disease and disorder, while 'DNA Replication, Recombination, and Repair' and 'Cell Cycle' were the two top-ranking molecular and cellular functions (Table 3).

Validation of gene and protein expression

The microarray analysis identified 'Cell Cycle: G1/S Checkpoint Regulation' as one of the top-ranking canonical pathways in ANO5-depleted NUGC4 cells (Figure 4A). To confirm these results, seven genes were selected (*CDK2*, *CDK4*, *CDK6*, *CDKN1A/p21*, *CCNE2*, *E2F1*, and *Rb*). These genes were included in 'Cell Cycle: G1/S Checkpoint Regulation,' and *CDK2* and *CDK6* were the two top-ranking downregulated genes in NUGC4 cells following ANO5 knockdown (Table 2). Reverse transcription-quantitative PCR was used to confirm the expression levels of six genes. NUGC4 and MKN45 cells transfected with ANO5 siRNA had significantly lower *CDK2*, *CDK4*, *CDK6*, *CDKN1A*, *CCNE2*, and *E2F1* expression levels and significantly higher *CDKN1A* expression levels than cells transfected with the control siRNA (Figure 4B). Furthermore, ANO5 plasmid decreased *CDKN1A/p21* mRNA levels (Supplementary Figure 2A, right panel). Western blotting revealed that phosphorylated Rb was inhibited following ANO5 knockdown in NUGC4 and MKN45 cells (Figure 4C). Since the *CDK2* gene is located upstream of Rb and downstream of p21 in the cell cycle transition from G_1 phase to S phase, the downregulation of

ANO5 in GC cells appears to affect the transition from the G1 phase to the S phase by regulating the expression of p21 and its downstream genes in signal pathways.

In addition, the gene expression profile of MKN45 cells transfected with ANO5 siRNA was investigated by microarray. Changes in gene expression in ANO5-depleted NUGC4 and MKN45 cells are depicted in Supplementary Figure 4. Among the 21440 genes, 7246 genes were upregulated and 6622 genes were downregulated in both cell lines, for a total of 13868 genes (64.7%) with identical expression direction in NUGC4 and MKN45 cells. The direction of gene expression changes of gene related to 'Cell Cycle: G_1/S Checkpoint Regulation' was consistent in both cell lines (Supplementary Table 1). Furthermore, all 40 genes displayed in Tables 1 and 2 showed the identical expression patterns in ANO5-depleted MKN45 cells (Supplementary Table 2). These results supported that ANO5 affected the cell cycle through similar mechanisms in both NUGC4 and MKN45 cell lines.

ANO5 inhibits the JNK pathway

Activation of the JNK and p38 MAPK classes of protein kinases mediates cellular responses such as apoptosis and the maturation of some cell types. JNK stabilizes p21 protein through phosphorylation [25]. To elucidate the regulatory role of ANO5 in the JNK signaling pathway in GC cells, we examined the phosphorylation of the JNK protein. ANO5 silencing significantly increased JNK phosphorylation levels in NUGC4 and MKN45 cells (Figure 4D). Furthermore, the increase of *CDKN1A/p21* mRNA expression induced by ANO5 silencing in NUGC4 and MKN45 cells was suppressed by JNK inhibition (Supplementary Figure 5, lower panel). Whereas, treatment with JNK inhibitors did not affect ANO5 mRNA expression (Supplementary Figure 5, upper panel). These results indicated that ANO5 expression regulated the cell cycle by upregulating p21 *via* JNK cascade activation in GC cells.

Effects of low-chloride conditions

To elucidate the molecular mechanisms through which ANO5 affects the cell cycle transition from G_1 to S phase, changes in the intracellular ion environment were examined. A previous study has reported that intracellular chloride affects cancer growth through the phosphorylation of several key molecules in signal transduction pathways[20]. We previously reported that the culturing in a Cl^--replaced medium (replacement of Cl^- by NO_3^-) decreased the intracellular chloride concentration [$(Cl^-)_i$] and inhibited cell growth in GC cells[19]. Our previous study also demonstrated that JNK activation under low-chloride conditions inhibited GC cell growth by upregulating p21 expression[18]. Intracellular chloride concentrations in the cells were measured based on the fluorescence intensity of MQAE, a chloride-sensitive fluorescence probe. The results revealed an increases in the fluorescence intensity of MQAE in NUGC4 and MKN45 cells following ANO5 knockdown (Figure 5). Therefore, ANO5 knockdown altered intracellular chloride concentrations in GC cells. Furthermore, low-chloride conditions effectively increased JNK phosphorylation and reduced Rb phosphorylation (Supplementary Figure 6). These results indicated that ANO5 regulated the cell cycle *via* JNK signaling by controlling intracellular chloride levels.

IHC analysis of ANO5 expression in human GC tissue

IHC detected the expression of ANO5 in non-cancerous gastric (Figure 6A) and cancerous epithelia (Figure 6B). ANO5 was observed to be expressed in the cell membranes and cytoplasm of GC tissue. The criteria for the staining intensity score were defined as 0 (no staining; Figure 6C), 1 (weak staining; Figure 6D), 2 (moderate staining; Figure 6E), or 3 (strong staining; Figure 6F). The median and mean scores for ANO5 expression were 0.9 (range, 0-2.1) and 0.97 (standard deviation = 0.53), respectively. A cut-off value of 1.3 was used to obtain the smallest *P* value in comparison of 5-year overall survival (OS) rates[26]. The 5-year OS rates for each cut-off value are presented in Table 4.

Patients with GC were divided into low- (ANO5 scores < 1.3, n = 137) and high-ANO5 (ANO5 scores ≥ 1.3, n = 58) expression groups based on a cut-off value of 1.3 (Figure 6G). Analysis of the clinicopathological features revealed that ANO5 expression levels were not associated with any of the variables (Table 5). To evaluate the prognostic significance of ANO5 after surgery, the following ten variables were compared: sex, age, tumor location, tumor length, histological type, lymphatic invasion, venous invasion, the pathological T stage, pathological N stage, and ANO5 IHC scores. Univariate analysis showed that patient prognosis was correlated with tumor length, lymphatic invasion, venous invasion, pathological T stage, pathological N stage, and ANO5 IHC scores (P = 0.0020, 0.0002, 0.0126, < 0.0001, < 0.0001, and 0.0104, respectively). Multivariate analysis identified high ANO5 expression (≥ 1.3) as an independent prognostic factor (P = 0.0457) (Table 6). Furthermore, the 5-year OS rate was significantly lower in the high expression group (73.9%) than in the low expression group (89.6%). Data obtained from the Kaplan-Meier plotter database also indicated that high ANO5 expression correlates with poor

prognosis in GC (Supplementary Figure 7), which was consistent with the present results.

DISCUSSION

The ANO family of membrane proteins, also known as TMEM16, play key roles in several physiological functions, including ion transport to phospholipid scrambling[27] and ion channel regulation[28]. While the roles of ANO1 (TMEM16A) and ANO2 (TMEM16B) as calcium-activated chloride channels have been firmly established[29-32], the functions of other family members remain unclear.

Previous studies have evaluated the expression and role of ANO5 during tumor development in various cancer types. Song *et al*[33] demonstrated that ANO5 (TMEM16E) was widely expressed in the epithelial cells of the human gastrointestinal tract. ANO5 is also expressed in human pancreatic cancer tissues but not in normal pancreatic tissue[23]. Chang *et al*[22] reported that ANO5 expression was downregulated in thyroid cancer, which promoted thyroid cancer cell migration and invasion. However, the expression of ANO5 in human GC tissue and the pathophysiological role of its expression in GC cells have not been demonstrated.

The present study revealed that ANO5 downregulation in GC cells regulates the cell cycle and induces apoptosis, while inhibiting proliferation, migration, and invasion. These results highlight the

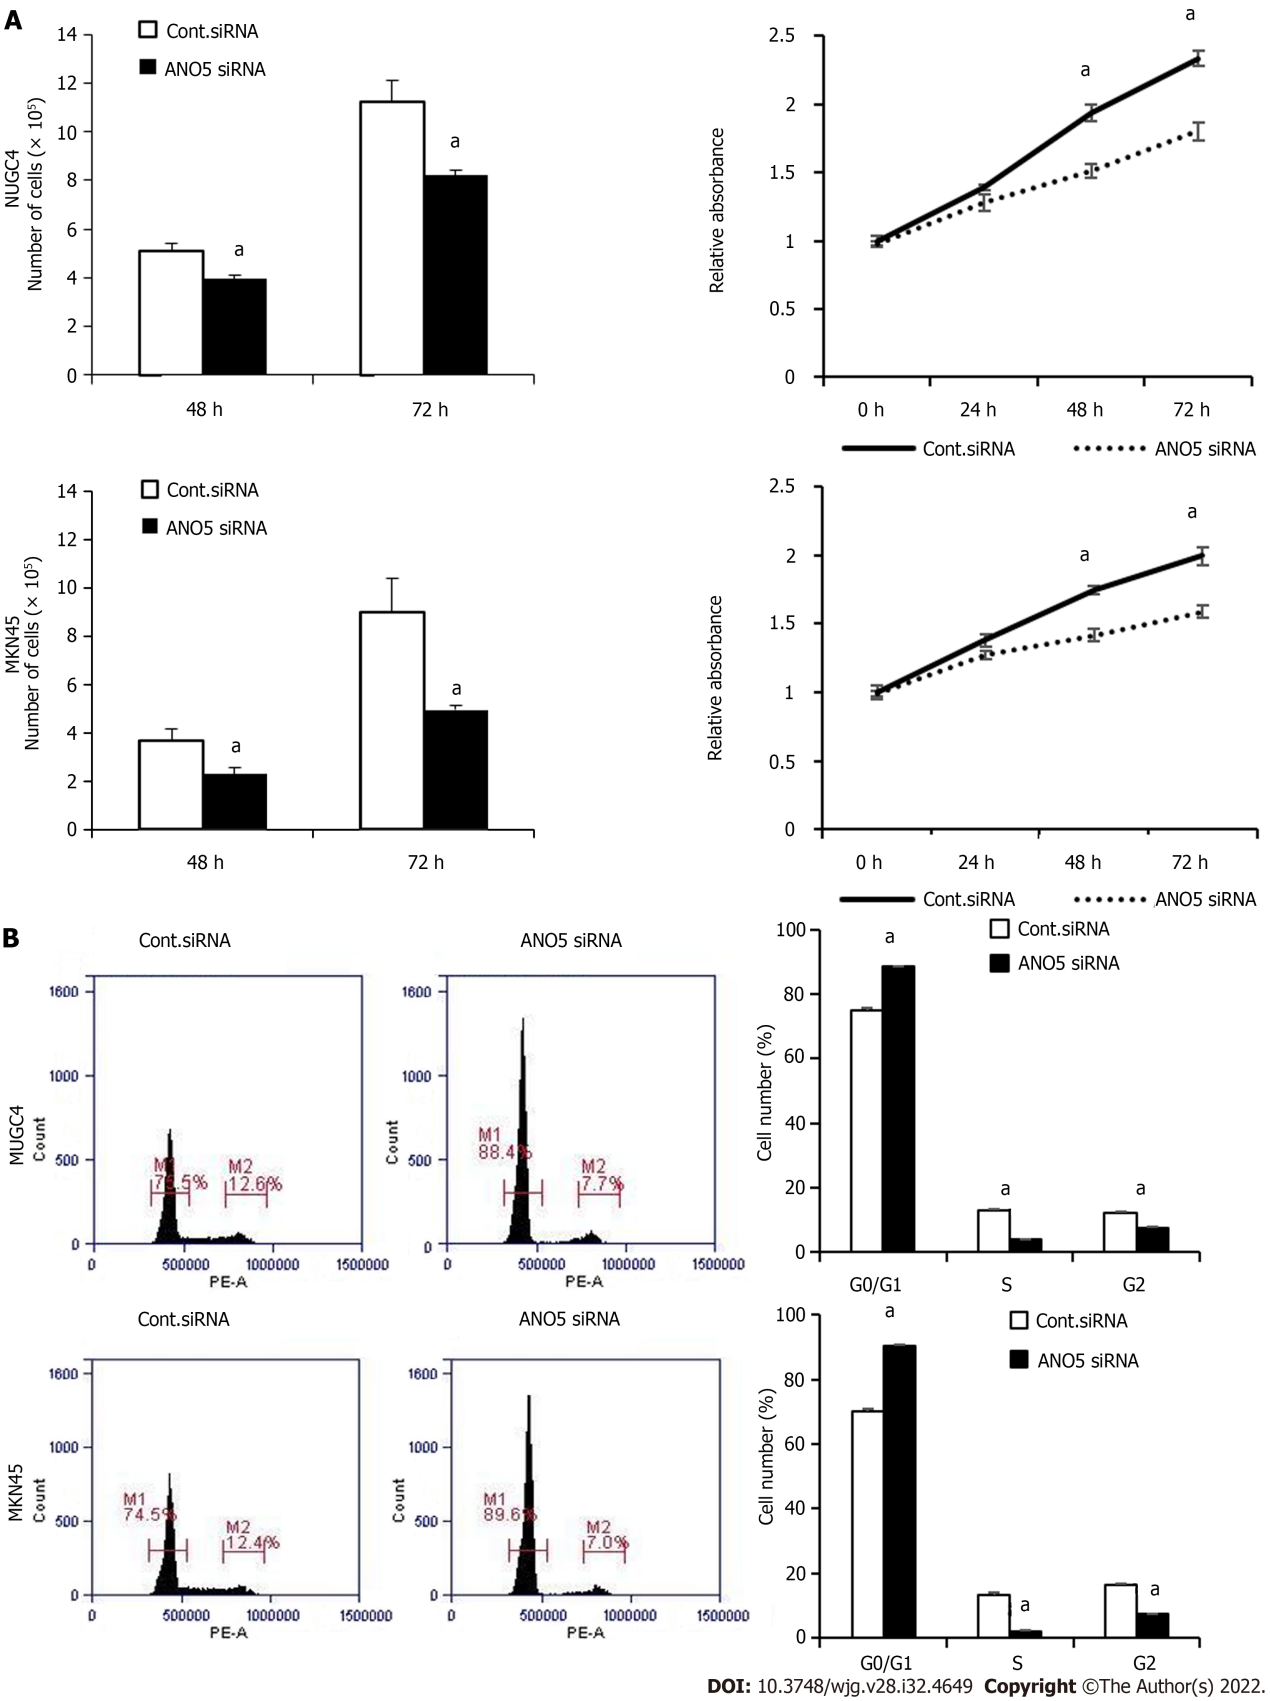
potential of ANO5 inhibitors as therapeutic agents for the treatment of GC or other cancer types with high ANO5 expression levels. The present study also indicates that ANO5 plays a key role in the proliferation of GC cells. Cell cycle analysis showed that the number of cells remaining in the G_0/G_1 phase was significantly increased, whereas the number of cells in the S or G_2/M phase was decreased in ANO5-depleted NUGC4 and MKN45 cells, suggesting that ANO5 downregulation inhibits GC cell proliferation *via* cell cycle arrest at the G_0/G_1 phase.

The induction of p21 is dependent on the tumor suppressor protein, p53. However, chloride ions have been shown to play important roles in cell cycle progression by regulating the expression of p21 through a p53-independent pathway in GC cells[19]. It has also been demonstrated that a decrease in chloride induced G_0/G_1 phase arrest by downregulating CDK2 and phosphorylated Rb expression through p21 upregulation. Furthermore, p38 and JNK activation under low-chloride conditions inhibits GC cell viability by upregulating p21 expression[18].

Moreover, ANO5 expression in GC cells affects the transition from the G_1 to the S phase of the cell cycle by regulating the expression of p21 and its downstream genes through the activation of JNK signaling. To the best of our knowledge, the chloride channel activity of ANO5 has not been confirmed to date. To elucidate the molecular mechanisms underlying the effects of ANO5, we evaluated the changes in the intracellular chloride ion environment in this study. A quantitative analysis of intracellular chloride ion concentrations was conducted based on the fluorescence intensity of MQAE. Immunofluorescent analysis showed that the fluorescence intensity of MQAE increased following ANO5 silencing, indicating a decrease in intracellular chloride concentration. These results suggest that the downregulation of ANO5 induces G_0/G_1 phase arrest by altering the expression of G_1/S checkpoint-related genes through the intracellular chloride environment of GC cells. Furthermore, since ANO5 functioned as a chloride channel, it may have the potential to inhibit tumor growth by regulating intracellular chloride concentrations in therapeutic settings.



Although ANO5 was recently implicated in various cancers, its role in tumor progression in patients with GC remains unclear. To demonstrate the clinical significance of ANO5 expression, the survival rate of 195 patients who underwent curative resection for primary GC was investigated. IHC analysis

revealed that high ANO5 expression levels were a poor prognostic factor in patients with GC. Under low-chloride conditions, ANO5 appeared to function as a chloride channel in GC cells. Previous findings showed that various ion transporters function as biomarkers and therapeutic targets[34,35]. Targeting ion channels that are activated in cancer cells may be an important strategy for cancer therapy. To the best of our knowledge, the present study is the first to report a relationship between ANO5 expression and the prognosis of patients with GC. Additional functional studies are needed to provide insights into the role of ANO5 in GC progression.

Figure 5 Immunofluorescent analysis of intracellular chloride concentration using MQAE reagent, a chloride-sensitive fluorescence probe. The downregulation of anoctamin 5 increased the fluorescence intensity of MQAE in NUGC4 and MKN45 cells. A: NUGC4 cell; B: MKN45 cell. n = 3, mean ± standard error of the mean. $^{a}P < 0.05$ (significantly different from control small interfering RNA). ANO5: Anoctamin 5; siRNA: Small interfering RNA; Cont.: Control.

This study has some limitations that must be addressed. First, it was a retrospective study. Due to the limited sample size, the pathological N stage classification factors were not correlated with the 5-year OS rate. Therefore, further studies are required to confirm our results. Second, in the selection of GC cell lines, we selected five cell lines; however, only three were used in the study.

CONCLUSION

The present study revealed that ANO5 plays a significant role in cell cycle progression in human GC cells. The results of microarray analysis showed the impact of ANO5 on the expression of G_1/S checkpoint-related genes. Furthermore, ANO5 expression significantly affected JNK signaling. Collectively, these results indicate that ANO5 plays an important role in cell cycle progression by regulating the expression of p21 through JNK signaling in human GC cells. The results of the IHC analysis also suggest that high ANO5 expression levels are a poor prognostic factor in patients with GC. The present study may contribute to the identification of ANO5 as a key mediator of tumor progression, with it ultimately being a promising prognostic biomarker or a novel therapeutic target for GC.

Figure 6 Anoctamin 5 protein expression levels in human gastric cancer tissues and a survival analysis based on anoctamin 5 expression. A: Non-cancerous gastric epithelia were immunohistochemically stained using an anti-anoctamin 5 (ANO5) antibody. Magnification: × 100; B: Primary human gastric cancer samples were immunohistochemically stained using an anti-ANO5 antibody. Magnification: × 100; C: The immunohistochemical staining results of ANO5 are shown as intensity 0. Magnification: × 400; D: Intensity 1. Magnification: × 400; E: Intensity 2. Magnification: × 400; F: Intensity 3. Magnification: × 400; G: Gastric cancer patients were classified into two groups based on ANO5 expression: A low ANO5 expression group (< 1.3, *n* = 137) and high ANO5 expression group (≥ 1.3, *n* = 58). [a]*P* < 0.05 (significant difference). ANO5: Anoctamin 5.

ARTICLE HIGHLIGHTS

Research background

Anoctamin 5 (ANO5) is a member of a family of calcium-activated chloride channels containing 10 members, also known as transmembrane proteins, and has been reported to be associated with various cancers.

Research motivation

The role of ANO5 in gastric cancer (GC) remains poorly understood. In the present study, we analyzed the relationship between ANO5 expression and tumor progression in GC.

Research objectives

The objectives of the present study were to investigate whether ANO5 contributes to the regulation of cancer growth and to clarify its clinicopathological significance in GC.

Research methods

Knockdown experiments were performed by transfecting human GC cell lines with ANO5 small

interfering RNA. Gene expression was then assessed using microarray analysis. Samples from 195 patients with GC were subjected to immunohistochemistry for ANO5, and its relationship with clinicopathological factors and prognosis were examined.

Research results

ANO5 knockdown suppressed the proliferation, migration, and invasion of cells and enhanced apoptosis. Cell cycle analysis showed that ANO5 knockdown suppressed the progression of G1-S phase. The results of microarray analysis showed up- or downregulated expression of genes related to "Cell Cycle: G1/S Checkpoint Regulation" in ANO5 knockdown NUGC4 cells. Survival analysis showed significantly poorer 5-year survival in the ANO5 high expression group (high *vs* low; 73.9 *vs* 89.6%, P = 0.0104). Immunohistochemistry multivariate analysis identified the high expression of ANO5 as an independent prognostic factor for 5-year survival in GC patients (P = 0.0457).

Research conclusions

ANO5 plays a significant role in cell cycle progression in human GC cells. The results of the immunohistochemistry analysis suggest that high ANO5 expression levels are a poor prognostic factor in patients with GC.

Research perspectives

The present study may contribute to the identification of ANO5 as a key mediator in tumor progression, with it ultimately being a promising prognostic biomarker or a novel therapeutic target of GC.

Abstract

BACKGROUND

Dendrobium officinale is an herb of Traditional Chinese Medicine (TCM) commonly used for treating stomach diseases. One formula of Granule Dendrobii (GD) consists of *Dendrobium officinale* and American Ginseng (*Radix Panacis quinquefolii*), and is a potent TCM product in China. Whether treatment with GD can promote gastric acid secretion and alleviate gastric gland atrophy in chronic atrophic gastritis (CAG) requires verification.

AIM

To determine the effect of GD treatment on CAG and its potential cellular mechanism.

METHODS

A CAG model was induced by feeding rats N-methyl-N'-nitro-N-nitroso-guanidine (MNNG) for 12 wk. After oral administration of low, moderate, and high doses of GD in CAG rats for 8 wk, its effects on body weight, gastric mucosa

histology, mucosal atrophy, intestinal metaplasia, immunohistochemical staining of proliferating cell nuclear antigen (PCNA) and B-cell lymphoma-2, and hemoglobin and red blood cells were examined.

RESULTS

The body weights of MNNG-induced CAG model rats before treatment (143.5 ± 14.26 g) were significantly lower than that of healthy rats (220.2 ± 31.20 g, $P < 0.01$). At the 8th week of treatment, the body weights of rats in the low-, moderate-, and high-dose groups of GD (220.1 ± 36.62 g) were significantly higher than those in the untreated group (173.3 ± 28.09 g, all $P < 0.01$). The level of inflammation in gastric tissue of the high-dose group (1.68 ± 0.54) was significantly reduced ($P < 0.01$) compared with that of the untreated group (3.00 ± 0.00, $P < 0.05$). The number and thickness of gastric glands in the high-dose group (31.50 ± 6.07/mm, 306.4 ± 49.32 μm) were significantly higher than those in the untreated group (26.86 ± 6.41/mm, 244.3 ± 51.82 μm, respectively, $P < 0.01$ and $P < 0.05$), indicating improved atrophy of gastric mucosa. The areas of intestinal metaplasia were significantly lower in the high-dose group (1.74% ± 1.13%), medium-dose group (1.81% ± 0.66%) and low-dose group (2.36% ± 1.08%) than in the untreated group (3.91% ± 0.96%, all $P < 0.01$). The expression of PCNA in high-dose group was significantly reduced compared with that in untreated group ($P < 0.01$). Hemoglobin level in the high-dose group (145.3 ± 5.90 g/L), medium-dose group (139.3 ± 5.71 g/L) and low-dose group (137.5 ± 7.56 g/L) was markedly increased compared with the untreated group (132.1 ± 7.76 g/L; $P < 0.01$ or $P < 0.05$).

CONCLUSION

Treatment with GD for 8 wk demonstrate that GD is effective in the treatment of CAG in the MNNG model by improving the histopathology of gastric mucosa, reversing gastric atrophy and intestinal metaplasia, and alleviating gastric inflammation.

Core Tip: Symptomatic treatment is mainly adopted for chronic atrophic gastritis (CAG) in modern medicine, and no drugs are available to promote gastric acid secretion and alleviate gastric gland atrophy. Our study shows that treatment with Granule Dendrobii (GD) for 8 wk was effective in reducing weight loss, gastric mucosal inflammation, atrophy and intestinal metaplasia, and loss of hemoglobin and erythrocytes in a rat model of CAG induced by N-methyl-N'-nitro-N-nitrosoguanidine. GD also alleviated the overexpression of PCNA and B-cell lymphoma-2 in CAG rats. These results provide new evidence on the use of GD not only for improving clinical symptoms but also for normalizing the abnormal histological changes of CAG.

INTRODUCTION

Chronic atrophic gastritis (CAG), characterized by thinning mucosal layer and loss or atrophy of gastric mucosal glands, is considered a premalignant change of gastric cancer (GC)[1]. It has been reported that the prevalence of CAG and intestinal metaplasia (IM) is 16% and 13%, respectively, and increases to 27% in countries with a high GC incidence[2]. The incidence of GC in patients with CAG or IM is 0.004%-0.3% per person each year, indicating that these patients have a higher risk of GC[3]. At present, the treatment of CAG in modern medicine mainly focuses on symptomatic treatment, and no drugs are available to promote gastric acid secretion and alleviate gastric gland atrophy. Therefore, it is essential to look for alternative therapies to reduce symptoms in CAG patients and improve their quality of life [4]. Traditional Chinese medicine (TCM) is often used for the treatment of CAG and has shown efficacy. However, there is a lack of scientific research on the effect of TCM in improving gastric mucosa atrophy and IM.

Dendrobium officinale is an herb of TCM commonly used for treating stomach diseases. The TCM literature states that it has the following functions: "thickening the stomach and intestines" (improving stomach function) and "smoothing stomach qi" (enhancing gastric motility and accelerating gastric emptying). One formula of Granule Dendrobii (GD) consisting of *Dendrobium officinale* and American Ginseng (*Radix Panacis quinquefolii*) is a potent TCM product in China. An earlier clinical study found that GD treatment of CAG reversed gastric mucosa atrophy and improved gastric mucosa and IM[5]. To provide scientific evidence for the clinical application of this product, we studied the effect of GD on gastric mucosa atrophy and IM reversal, as well as changes in proliferating cell nuclear antigen (PCNA) and B-cell lymphoma-2 (Bcl-2) in a CAG model induced by N-methyl-N'-nitro-N-nitrosoguanidine (MNNG) in rats.

MATERIALS AND METHODS

Herbal products and drugs

Herbal product under investigation: Granule Dendrobii (GD, Li Zuan Brand, Zhejiang Tian Huang Pharmaceutical Co., Ltd, China) 3 g per bag, contained 0.5g of crude *Dendrobium Officinale* and 0.4 g of American Ginseng (*Radix Panacis Quinquefolii*). Based on the theory of TCM, this formula has the functions of enhancing energy metabolism of the stomach and restoring its nutrient supply to improve the production of body fluid, which makes it suitable for treating the type of CAG that has lower levels of energy production and nutrient supply. The dosage for clinical treatment was 18 g/d (equivalent to 5.4 g herbs/d).

Herbal product as control: Yangweishu Granule (YWS, prodeuced by Shenlu Shuanghe Pharmaceutical Co., Ltd, Hefei, China) 10 g per bag contained dang*shen* (*Radix Codonopsis*), chenpi (*Pericarpium Citri Reticulatae*), huangjing (*Polygonatum sibiricum*), shanyao (*Rhizoma Dioscoreae*), xuanshen (*Radix Scrophulariae*), wumei (*Fructus Mume*), shanzha (*Fructus Crataegi*), beishashen (*Glehnia littoralis*), ganjiang (*Rhizoma Zingiberis*), tusizi (*Cuscuta Chinensis*), baizhu (*Rhizoma Atractylodis Macrocephalae*), dextrin and saccharose. The dosage for clinical treatment was 20 g/d.

Animals

All experiments were performed on Wistar rats (50% male) obtained from the Shanghai Slack Laboratory Animal Co., Ltd. All the animals were kept in a temperature (25 ± 2 ℃)- and humidity-controlled animal facility on a 12-h light/dark cycle, with food and water supplied *ad libitum*. The protocol was designed to minimize pain or discomfort to the animals. All procedures were approved by the Animal Care and Use Committee of the Institutional Guide for the Care and Use of Laboratory Animals at Zhejiang Institute of Traditional Chinese Medicine.

MNNG-induced CAG model in rats

MNNG (Tokyo Chemical Industry, Japan) was added to the drinking water for six-week-old Wistar rats (50% male). The MNNG stock solution was made every week by mixing MNNG with distilled water to a concentration of 1 g/L and kept in a refrigerator in the dark. For daily use, the stock solution was diluted to 167 μg/mL with distilled water and stored in 200 mL opaque water bottles for the rats to drink freely. The bottles were changed daily. As earlier studies established the development of CAG in 2 to 3 mo, with pathological changes from initial erosive and inflammation of the gastric mucosa in several weeks to gradual atrophy and dysplasia, the rats were provided with MNNG for a period of 12 wk for model generation.

Experimental grouping and histological methods

To confirm the development of CAG in this model, 4 MNNG model animals and 4 normal animals were sacrificed for gastric histopathological examination at the end of model generation. The rats were then randomly divided into the following five groups. Three treatment groups were fed with 0.6 g, 1.2 g, and 2.4 g/kg body weight/day of GD as the low (12 rats), medium (12 rats) and high (14 rats) dosage groups, respectively. The fourth group was fed with physiological saline at the same volume as the untreated model group (14 rats), and the last group was fed with YWS (12 rats) granule 4.0 g/kg/d as a positive control group. In addition, 14 normal rats were given physiological saline at the same volume as the normal control group. Two rats were reserved for the high-dose group, the normal control group and the untreated model group in order to sacrifice the animals for pathological pre-examination to determine the termination point of the course when the treatment was almost finished. Each group was given its corresponding treatment daily for 8 wk.

The day after the last administration, all the rats were anesthetized and blood was taken from the abdominal aorta. The stomach was quickly removed and fixed in formalin. The longitudinal length and full layer of the anterior stomach to the duodenum was collected. A strip of tissue from the lateral wall was taken as the standard pathological sample. After paraffin embedding, the tissue was sliced into 4 μm sections and stained with Hematoxylin-Eosin (HE)[6], Alcian Blue (AB)[7], and immunohisto-

chemistry against PCNA (antibody against gastric epithelial cell proliferating cell nuclear antigen, NeoMarkers, United States) and Bcl-2 (anti-Bcl-2 antibody, Millipore, United States).

PCNA and Bcl-2 staining: After dewaxing, the sections were incubated with 3% H_2O_2 deionized water for 10 min, followed by incubation with primary antibodies at room temperature or 37 ℃ for 1 to 2 h. After rinsing in PBS, secondary antibodies were added and incubated at room temperature or 37 ℃ for 20 min. The sections were rinsed in PBS, and processed for color rendering dehydration, transparency and sealing.

Histological evaluation of gastric mucosa

Gastric mucosal inflammation: The effect of treatment on gastric mucosal inflammation induced by MNNG in CAG rats was evaluated using a semi-quantitative method. Specifically, after the entire gastric mucosa was observed under the microscope low power view, 10 fields of view in the gastric antrum were selected to determine inflammation. According to the diagnostic criteria for gastritis proposed by Houston in 1994[8,9], the degree of inflammatory cell infiltration is divided into seven grades from 0 to 3. Grade 0: no inflammation; Grade 0.5: inflammation between 0 to 1 observed under a microscope; Grade 1: multiple chronic inflammatory cell infiltrations seen in the pit of the stomach or the bottom of the inherent gland; Grade 1.5: inflammation between Grade 1 to 2 observed under a microscope; Grade 2: more inflammatory cells in the gastric mucosa from the fovea to the myometrium; Grade 2.5: inflammation between Grade 2 to 3 observed under a microscope; Grade 3: numerous inflammatory cells seen in the gastric mucosa.

Changes in gland thickness and gland number on gastric mucosa: Five fields of gastric antrum mucosa were obtained from each section, and the gland thickness in each field was measured with a micrometer. The average value of the five fields in each section was determined (μm). At 100X power, the total number of proper glands in the gastric antrum between 0.2-1.2 mm of the pyloric ring in rats were counted and expressed as "units/mm".

The number of gastric primary cells and parietal cells: At 400× power, the mean numbers of gastric primary cells and parietal cells from 5 fields in the gastric body mucosa starting from 1.0 mm below the border between the anterior stomach and the gastric body were counted from each section.

Intestinal metaplasia: Intestinal metaplasia was evaluated by analyzing images from AB stained sections. Five photos of gastric mucosa in the gastric antrum were randomly obtained from each section using a Nikon ECLIPSE Ti microfilming system at a magnification of 400×. Each group was imaged under the same conditions. A Leica QWin color<RG> image analysis system was used for analysis. Under the same conditions, the proportion (%) of the total positively stained area over the total analyzed area of each photo was calculated. An average proportion was calculated from 5 photos in each rat and used for statistical comparisons among all the experimental groups.

Immunohistochemistry of PCNA and Bcl-2

As pathological changes in CAG are correlated with proliferation and apoptosis of the gastric mucosa, we examined the expression of PCNA and Bcl-2 proteins in gastric mucosa. PCNA is an intraconuclear protein that is expressed in a small amount during the quiescence phase of DNA synthesis. It is an important indicator of cell proliferation because its changes are consistent with intracellular DNA replication. Bcl-2 is a gene that inhibits apoptosis. Its overexpression can inhibit cell apoptosis and is indicative of a favorable precondition for the transformation of malignant cells. Positive staining of PCNA was located in the nucleus, while positive staining of Bcl-2 was located in the cytoplasm and was occasionally accompanied by nuclear staining. Based on previous studies[10-14], we used a semi-quantitative grading method to quantify positive cells. Proportions of positive cells were calculated by counting the numbers of positive cells and total cells in five fields randomly observed under a high-power view (400 ×). A score was assigned according to the percentage of positive cells: 0 for 5%, 1 point for 6%-25%, 2 points for 26%-50%, and 3 points for > 50%. Then the intensity of staining of positive cells was scored: 0 for non-staining, 1 point for light yellow, 2 points for brownish yellow, and 3 points for brown. Finally, these points were added together. 0 was negative "-", 1-2 points were weakly positive "+", 3-4 points were moderately positive "++", and 5-6 points were strongly positive "+++".

Detection of hemoglobin and erythrocytes

As reduced iron absorption and utilization due to gastric mucosal atrophy in CAG often lead to decreases in hemoglobin and erythrocyte count in rats, we examined whether treatment with GD would also improve these parameters in CAG rats. After the rats were anesthetized with pentobarbital, blood was collected from the abdominal aorta. Whole blood was placed in a disposable vacuum blood collection anticoagulant tube and routine blood tests were carried out using an XT-1800iv five-classification hemocyte analyzer (Hisen Meikang Co., Japan). Reports of the analysis were automatically generated.

Statistical analysis

Statistical analyses were performed using SPSS software 17.0 (SPSS Inc., Chicago, United States). Quantitative data were expressed as the mean ± SD. Differences among multiple groups were compared by one-way ANOVA, and pairwise comparisons between groups were followed by the least significant difference if the variances were homogeneous, and the Dunnett T3 method was used otherwise. Numerical data were analyzed with the χ^2 test.

RESULTS

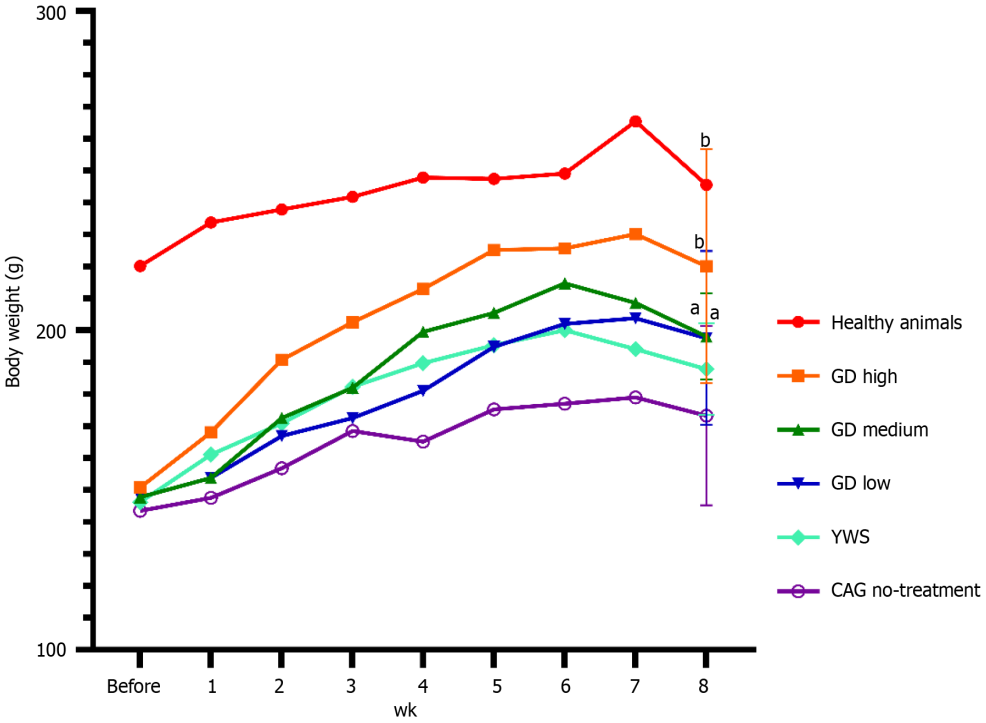
Effects of Granule Dendrobii on weight loss in rats with MNNG-induced CAG

The mean body weight of rats with MNNG-induced CAG before treatment was 143.5 ± 14.3 g, which was significantly lower than that of the normal rats (Figure 1, 220.2 ± 31.2 g, $P < 0.01$). On completion of model generation, there were no significant differences in body weight among all the treatment groups (Figure 1, $P > 0.05$).

At the end of treatment, the body weights of all the treatment groups (except YWS) had significantly recover when compared with those of the untreated group (Figure 1, $P < 0.05$). At the 8th wk of treatment, the mean body weights of groups treated with high (220.1 ± 36.6 g, $P < 0.01$), medium (198.1 ± 13.5 g, $P < 0.05$), and low doses (197.6 ± 27.3 g, $P < 0.05$) of GD were significantly higher than that of the untreated group (173.3 ± 28.1 g). The results at 8 wk after treatment indicated that GD treatment had the effect of reducing weight loss in the MNNG model of CAG.

Pathological changes in gastric mucosa after treatment

In normal rats, the gastric mucosal glands were relatively thick and numerous, and the epithelial cells were neatly arranged without defect or exfoliation. The glands were regular in shape and basically the same in size. AB staining showed a small amount of blue staining in the deep mucosa without IM. In the CAG group, the gastric mucosa was atrophic and thinned with reduced glands. There was edema and surface exfoliation. The infiltration of many acute and chronic inflammatory cells was visible in the interstitium. Hyperemia and thickening of the mucosal myometrium were observed. Atypical hyperplasia was seen, with cells of irregular size and shape and a disordered arrangement. AB staining revealed that the entire mucosa was stained blue in the presence of IM. In the CAG rats treated with high-dose GD, the pathological changes were reduced and atrophy was improved. The epithelial cells were well arranged without defect or exfoliation. The shapes of the glands were regular with similar size and shape. AB staining showed a very light blue color in the deep part of the gastric antrum mucosa, suggesting almost no IM (Figure 2A). In the CAG rats treated with medium-dose GD, the pathological changes were similar to those in the high-dose group with significant improvement. Such changes could be classified as mild to moderate superficial gastritis. AB staining showed a normal staining pattern with no IM, and was similar to that in the high-dose group (Figure 2A). In the CAG rats treated with low-dose GD, the pathological changes as shown by HE staining were slightly alleviated with improvements in atrophy compared with the untreated group, but inflammatory cell infiltration was observed in the mucosal layer. These changes were classified as mild to moderate superficial gastritis. On AB staining, there was a small amount of blue staining in the deep mucosa with IM (Figure 2A).



After 8 wk of GD treatment in CAG rats, the levels of gastric mucosal inflammation in the high-dose (1.68 ± 0.54) and medium-dose (2.08 ± 0.42) groups were significantly lower than those in the low-dose, no-treatment, and YWS groups (Figure 2B, $P < 0.01$ for all comparisons).

Treatment with Granule Dendrobii improved the thickness and gland numbers of gastric mucosa in rats with CAG

At 8 wk after CAG generation, significant decreases in the thickness and number of glands in the gastric mucosa were observed. The number (31.50 ± 6.07 unit/mm) and thickness (306.4 ± 49.32 μm) of glands in gastric tissue of the high-dose group were significantly higher than those of the no-treatment group (26.86 ± 6.41 unit/mm, 244.3 ± 51.82 μm, respectively), indicating a significant reduction in the atrophy of gastric mucosa in the treatment group (Figure 2C and D, $P < 0.01$ or $P < 0.05$). The glandular thickness of gastric tissue in the medium- and low-dose groups was also significantly improved compared with that in the no-treatment group (Figure 2C, $P < 0.01$ or $P < 0.05$).

Treatment with GD increased the numbers of chief cells and parietal cells in the gastric mucosa of CAG rats

At 8 wk after model preparation, there was a significant decrease in the number of chief cells in the CAG group when compared with the healthy animal group ($P < 0.05$). After 8 wk of treatment, the numbers of chief cells (165.5 ± 12.65 unit/field) and parietal cells (425.4 ± 16.0 unit/field) in gastric mucosa in the high-dose group were significantly higher than those in no-treatment group (chief cells: 148.7 ± 6.38 unit/field; parietal cells: 407.2 ± 18.6 unit/field), indicating a protective effect of GD

Figure 1 Changes in body weight of chronic atrophic gastritis rats during the 8-wk treatment period. Data were evaluated for statistical significance by one-way ANOVA, least significant difference test and Dunnett T3 test, and are presented as follows: $^{a}P < 0.05$ and $^{b}P < 0.01$ *vs* chronic atrophic gastritis with no-treatment group. GD High: Chronic atrophic gastritis rats treated with a high dosage of Granule Dendrobii; GD Medium: Chronic atrophic gastritis rats treated with a medium dosage of Granule Dendrobii; GD Low: Chronic atrophic gastritis rats treated with a low dosage of Granule Dendrobii; YWS: Chronic atrophic gastritis rats treated with Yangweishu; CAG: Chronic atrophic gastritis.

treatment on chief cells and parietal cells in gastric mucosa. The number of chief cells in gastric mucosa of the medium- and low-dose groups was also significantly higher than the no-treatment group (Figure 2E, $P < 0.01$ and $P < 0.05$, respectively); but the number of parietal cells in gastric mucosa of the medium- and low-dose groups was not significantly higher than that in the no-treatment group (Figure 2F, $P > 0.05$).

Treatment with GD improved intestinal metaplasia of gastric mucosa in CAG rats

At 8 wk after model preparation, quantitative analysis of gastric mucosa in the CAG rats showed that the percentage of IM increased significantly (0.95 ± 0.72% and 3.91 ± 0.96% in the healthy animal and CAG groups, respectively, $P < 0.05$). After treatment with GD for 8 wk, the areas of IM in the high-dose (1.74 ± 1.13%), medium-dose (1.81 ± 0.66%), and low-dose (2.36 ± 1.08%) groups were significantly lower than that in the no-treatment group ($P < 0.01$ for all), suggesting a significant improvement in IM after treatment with GD (Figure 2G).

Treatment with GD decreased the expression of PCNA and Bcl-2 in gastric mucosa of CAG rats

In healthy rats, the number of PCNA expressing cells in gastric mucosa was low and mainly located in the proliferation zone, with regular distribution and weak staining. In the CAG rats without treatment, the number of PCNA expressing cells in gastric mucosa was increased and distributed in nearly all layers with deeper staining. In the high dose group, the expression and distribution of PCNA were similar to that of the healthy animal group, with less PCNA expressing cells mainly located in the proliferation zone than the CAG with no-treatment group (Figure 3).

Table 1 shows a summary of the expression of PCNA and Bcl-2 in gastric mucosa. PCNA expression in the CAG group was significantly higher than that in the healthy animal group ($P < 0.01$), while its expressions in the high-dose and low-dose groups was significantly lower than that in the CAG group ($P < 0.01$). Similarly, the expression of Bcl-2 was significantly higher in the CAG group than in the healthy animals group ($P < 0.01$). The expression of Bcl-2 in the high-dose, medium-dose, and low-dose groups was lower than that of the no-treatment group, but without statistical significance ($P > 0.05$).

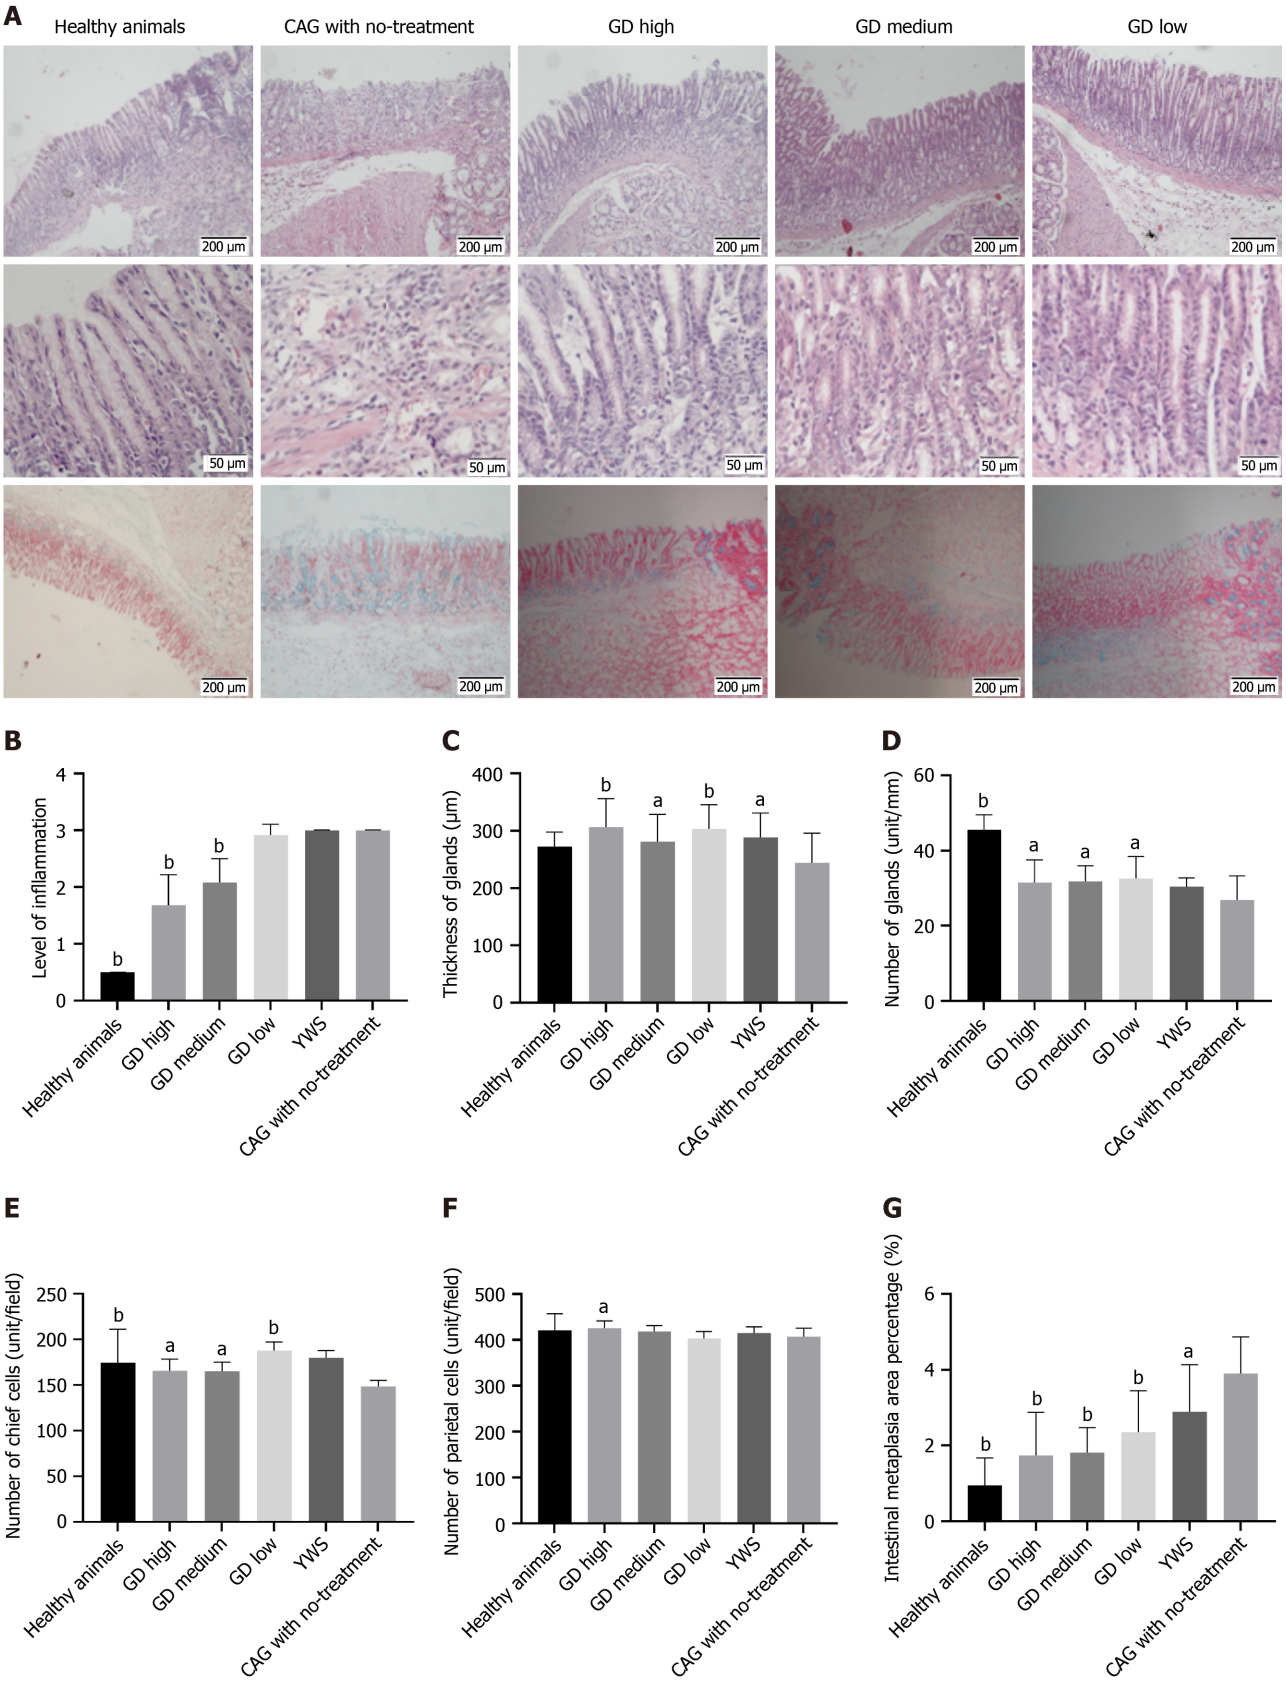
Treatment with GD improved hemoglobin and erythrocyte count in CAG rats

As shown in Figure 4A, hemoglobin in the CAG group (132.1 ± 7.76) was significantly reduced compared with that in the healthy animal group (145.6 ± 6.26, $P < 0.01$). In the high-dose (145.3 ± 5.90),

Table 1 Expression of proliferating cell nuclear antigen and B-cell lymphoma-2 in gastric tissues of different groups of rats

Grouping	PCNA						Bcl-2					
	+++	++	+	-	*n*	*P* value	+++	++	+	-	*n*	*P* value
GD high	1	3	10	0	14	< 0.01	3	4	7	0	14	> 0.05
GD medium	5	4	3	0	12	> 0.05	2	8	2	0	12	> 0.05
GD low	3	2	7	0	12	< 0.01	1	6	5	0	12	> 0.05
YWS	4	3	5	0	12	< 0.05	2	7	3	0	12	> 0.05
Healthy animals	0	0	14	0	14	< 0.01	0	3	11	0	14	< 0.01
CAG no-treatment	9	5	0	0	14	-	5	7	2	0	14	-
6 groups of χ^2-test	χ^2 value	38.96					20.97					
	P value	$P < 0.01$					$P < 0.05$					

Data were evaluated for statistical significance by one-way ANOVA, least significant difference test and Dunnett T3 test. The *P* value in the table is the χ^2 test of each group compared to the group with chronic atrophic gastritis without treatment. The χ^2 value in the table is the χ^2 test of multi-group row lists with 6 groups. GD high: Chronic atrophic gastritis rats treated with a high dosage of Granule Dendrobii; GD medium: Chronic atrophic gastritis rats treated with a medium dosage of Granule Dendrobii; GD low: Chronic atrophic gastritis rats treated with low dosage of Granule Dendrobii; YWS: Chronic atrophic gastritis rats treated with Yangweishu; PCNA: Proliferating cell nuclear antigen; Bcl-2: B-cell lymphoma-2; CAG: Chronic atrophic gastritis.

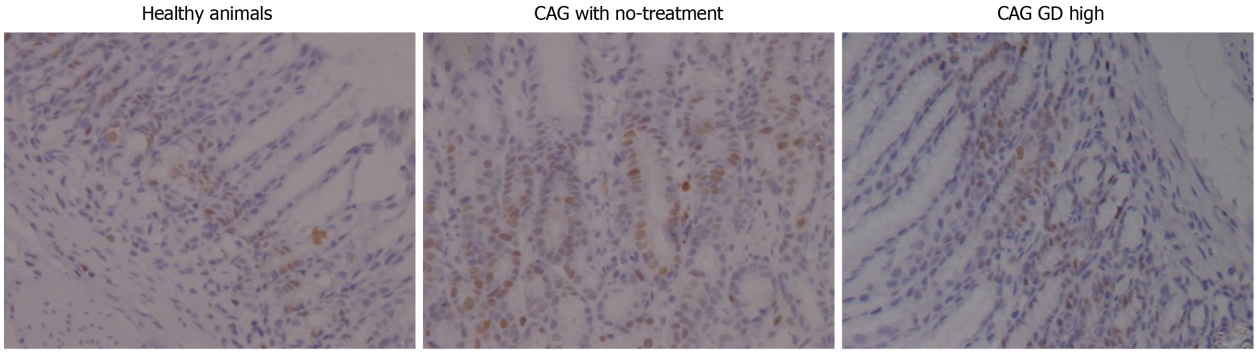


medium-dose (139.3 ± 5.71) and low-dose groups (137.5 ± 7.56) of GD after 8 wk of treatment, hemoglobin was significantly higher than that in the no-treatment group ($P < 0.01$ or $P < 0.05$). In addition, there was a dose-dependent relationship between the increase in hemoglobin and the dose of GD used. The increase in hemoglobin level in the high-dose group was significantly greater than that in the medium and low-dose group (Figure 4A, $P < 0.05$). Erythrocyte count in the untreated group was lower than that in the healthy animal group, but the difference was not statistically significant (Figure 4B, $P > 0.05$). After 8 wk of treatment, the high-dose group and the medium-dose group had significant increases in erythrocyte counts compared with the no-treatment group ($P < 0.01$). In addition, there was a dose-dependent relationship between the increase in erythrocyte count and dose of GD used. The increase in erythrocyte count in the high dose group was significantly greater than that in the low dose group (Figure 4B, $P < 0.05$). These results suggest that treatment with GD for 8 wk increased hemoglobin and erythrocytes in CAG rats.

DISCUSSION

Treatment with GD for 8 wk resulted in significant improvements in body weight, gastric mucosal inflammation, atrophy, and intestinal metaplasia in rats with MNNG-induced CAG. GD also increased the reduced levels of hemoglobin and erythrocytes in CAG rats. Furthermore, GD improved gastric mucosal lesions and improved the secondary pathological changes of CAG including reduced hemoglobin and red blood cell count, and overall body condition. It was observed that GD alleviated the overexpression of PCNA and Bcl-2 in model rats, which maybe one of the therapeutic mechanisms related to the reduction of gastric mucosal inflammation and mucosal damage.

Rodent models of CAG can be induced by chemical stimulation (ethanol, ammonia water, sodium deoxycholate, *etc.*), autoimmunity against gastric mucosa homogenization, *Helicobacter pylori* and MNNG. Among these, the carcinogen (MNNG) induction method is widely used to generating a CAG model[15-17], with lesion severity being adjustable according to the length of induction time. Specifically, mild atrophy of gastric mucosa generally develops within 25 wk in rats, the CAG model with IM established within 35 wk[18], while early GC develops in 7-9 mo. As the CAG rat model induced by MNNG is stable, relatively severe, and resistant to natural recovery, it is credible for testing the efficacy of therapeutic treatment.



Dendrobium officinale extraction has been shown to effectively reduce the incidence of GC in rats and may be valuable in the prevention of GC[19]. *Dendrobium officinale* polysaccharide, the main active ingredient of *Dendrobium officinale*, can effectively inhibit the progression of premalignant gastric lesions induced by MNNG[20]. The formula of GD is mild. The combination of *Dendrobium candidum* and American ginseng has the functions of tonifying Qi, and Yin, and nourishing the stomach to promote the production of body fluid, making it suitable for the treatment and recovery of digestive diseases. Such functions are also in line with records in relevant traditional literature. Treating CAG with TCM is relatively safe and feasible during long-term use, while the effect is holistic and comprehensive, and research in this direction has significant prospects[21].

In recent years, treatment with traditional Chinese herbal medicine has been reported to improve CAG gastric mucosal atrophy and IM. In *Helicobacter pylori* positive CAG, a TCM herbal formula was shown to improve clinical symptoms and efficacy rate, and reverse atrophy in gastric mucosa in CAG patients[22]. Fuzi Lizhong decoction can reverse IM due to CAG to a certain extent through a mechanism related to the regulation of shh gene expression of the diseased gastric mucosa[23]. Recent research reported that notoginsenoside R1, an ingredient of *Panax notoginseng*, can improve CAG by increasing Bcl-2 expression and decreasing Bax expression in gastric tissue of rats with CAG induced by MNNG combined with an irregular diet[24]. Morroniside, an extract from *Cornus officinalis*, was shown to relieve gastric mucosa injury due to CAG by preventing inflammation[25]. Modified Sijunzi

Decoction (MSD) relieved the symptoms of CAG, improved the pathologic changes in CAG including fatigue and tiredness symptoms in CAG patients[26]. Berberine, an isoquinoline alkaloid from *Rhizoma coptidis*, has an inhibitory effect on gastritis[27] and GC cells[28], and significantly improves the pathological characteristics of gastric tissue, and alleviated serum biochemical indices[29]. These studies show that in addition to the formula we used in this study (*Dendrobium officinale* and *American ginseng*), fuzi Lizhong Decoction, notoginsenoside R1, morroniside, MSD, berberine, or TCM treatment aimed at invigorating spleen, soothing the liver, promoting blood circulation and detoxification, also have varying degrees of anti-inflammatory effects and reverse gastric mucosal atrophy and IM.

Some researchers believe that it is difficult to achieve the effect of reversing gastric mucosal atrophy and IM in CAG or they doubt the reported efficacy. For example, clinical studies have shown that eradication of *Helicobacter pylori* can improve chronic gastritis. Although some studies have shown certain improvement in gastric atrophy, IM seems reversible[30]. Some people also think that advanced atrophic gastritis may be irreversible[31]. As the conclusions by different authors vary widely, further long-term prospective studies in different ethnic and geographical environments are needed to provide more reliable evidence on the reversibility of gastric atrophy and IM[32].

As discussed above, it is believed that it is difficult to reverse gastric mucosal atrophy and gastric mucosal IM in CAG. However, as this conclusion is mainly based on observations of gastric mucosal atrophy and gastric mucosal IM following eradication of *Helicobactor pylori*, the question of whether a different treatment (*i.e.*, TCM) will be effective in reversing gastric atrophy and IM remains to be answered.

Our histological data support that treatment with GD for 8 wk was effective in reversing gastric mucosa atrophy and IM. Whether this effect can be duplicated in human CAG patients requires confirmation in clinical studies with large sample sizes, and strict control and rigorous experimental design. The results will provide new evidence on the use of GD not only for improving clinical symptoms but also for normalizing abnormal histological changes in CAG.

CONCLUSION

This study shows that treatment with GD for 8 wk was effective in reducing weight loss, gastric mucosal inflammation and atrophy, and intestinal metaplasia in a rat model of CAG induced by MNNG. GD also reduced the decreases in hemoglobin level and erythrocytopenia in this model. The treatment resulted in alleviation of the overexpression of PCNA and Bcl-2 in the model rats which may be an underlying mechanism that contributes to the reduction in gastric mucosal inflammation and mucosal damage.

ARTICLE HIGHLIGHTS

Research background

Dendrobium officinale is often used to treat stomach diseases. One formula of Granule Dendrobii (GD) consisting of *Dendrobium officinale* and American ginseng (*Radix Panacis quinquefolii*) is a potent Traditional Chinese Medicine product in China for chronic atrophic gastritis (CAG) as it reverses gastric mucosa atrophy and improves gastric mucosa intestinal metaplasia (IM).

Research motivation

This study determined the effect of GD treatment on CAG and its potential cellular mechanism to provide a reference for future treatment.

Research objectives

To study the effect and cellular mechanism of GD in the treatment of CAG, and to provide scientific evidence for the clinical application of GD.

Research methods

A rat model of CAG induced by N-methyl-N'-nitro-N-nitrosoguanidine (MNNG) was established, and treatment with GD resulted in weight loss, gastric mucosa atrophy and intestinal metaplasia reversal, as well as changes in PCNA and B-cell lymphoma-2 (Bcl-2) after 8 wk of treatment.

Research results

Treatment with GD for 8 wk resulted in significant improvements in body weight, gastric mucosal inflammation, atrophy, and IM in rats with CAG induced by MNNG. GD also increased the reduced levels of hemoglobin and erythrocytes in CAG rats.

Research conclusions

GD improved gastric mucosal lesions and the secondary pathological changes of CAG including hemoglobin and red blood cell reductions, and overall body condition. GD also alleviated the overexpression of PCNA and Bcl-2 in model rats, which maybe one of the therapeutic mechanisms related to the reduction in gastric mucosal inflammation and mucosal damage.

Research perspectives

Our research group will continue to confirm whether the effect of GD can be duplicated in CAG patients by clinical studies with large sample sizes, strict control and rigorous experimental design, and further study the molecular and cellular mechanism of GD.

ACKNOWLEDGEMENTS

The authors would like to acknowledge Dr. Chun-Li Zhang and Dr. Min Yang from Tongde Hospital of Zhejiang Province for their professional advice on pathological work, as well as Peng Ren from Jiangsu Yanchang Science and Technology Co., Ltd for statistical analysis assistance.

Abstract

BACKGROUND

For patients with portal hypertension (PH), portal vein thrombosis (PVT) is a fatal complication after splenectomy. Postoperative platelet elevation is considered the foremost reason for PVT. However, the value of postoperative platelet elevation rate (PPER) in predicting PVT has never been studied.

AIM

To investigate the predictive value of PPER for PVT and establish PPER-based prediction models to early identify individuals at high risk of PVT after splenectomy.

METHODS

We retrospectively reviewed 483 patients with PH related to hepatitis B virus who underwent splenectomy between July 2011 and September 2018, and they were randomized into either a training (n = 338) or a validation (n = 145) cohort. The generalized linear (GL) method, least absolute shrinkage and selection operator (LASSO), and random forest (RF) were used to construct models. The receiver operating characteristic curves (ROC), calibration curve, decision curve analysis (DCA), and clinical impact curve (CIC) were used to evaluate the robustness and clinical practicability of the GL model (GLM), LASSO model (LSM), and RF model (RFM).

RESULTS

Multivariate analysis exhibited that the first and third days for PPER (PPER1, PPER3) were strongly associated with PVT [odds ratio (OR): 1.78, 95% confidence interval (CI): 1.24-2.62, P = 0.002; OR: 1.43, 95%CI: 1.16-1.77, P < 0.001, respectively]. The areas under the ROC curves of the GLM, LSM, and RFM in the training cohort were 0.83 (95%CI: 0.79-0.88), 0.84 (95%CI: 0.79-0.88), and 0.84 (95%CI: 0.79-0.88), respectively; and were 0.77 (95%CI: 0.69-0.85), 0.83 (95%CI: 0.76-0.90), and 0.78 (95%CI: 0.70-0.85) in the validation cohort, respectively. The calibration curves showed satisfactory agreement between prediction by models and actual observation. DCA and CIC indicated that all models conferred high clinical net benefits.

CONCLUSION

PPER1 and PPER3 are effective indicators for postoperative prediction of PVT. We have successfully developed PPER-based practical models to accurately predict PVT, which would conveniently help clinicians rapidly differentiate individuals at high risk of PVT, and thus guide the adoption of timely interventions.

Core Tip: For patients with portal hypertension related to hepatitis B virus, postoperative platelet elevation rate (PPER) is an important predictor of the formation of portal vein thrombosis (PVT) after splenectomy. This study was the first to construct PPER-based practical models for predicting PVT, which would be helpful for clinicians to recognize individuals at high risk of PVT as soon as possible.

INTRODUCTION

Liver cirrhosis is recognized as an extremely important and rapidly increasing disease burden in the world[1]. In the progressive stage of liver cirrhosis, the complications caused by portal hypertension (PH), including esophagogastric variceal bleeding and hypersplenism, pose a great threat to the patients' life and health[2,3]. Liver transplantation is currently recommended as a curative treatment for liver cirrhosis combined with PH; however, due to the shortage of liver sources and high transplantation cost, its clinical practicability is limited[4,5]. Transjugular intrahepatic portosystemic shunt seems to be a gospel for PH, but unfortunately, restenosis or/and hepatic encephalopathy will occur in more than 60% of patients[6,7]. In Asia, splenectomy (or combined with devascularization) has been widely adopted as an effective treatment for hypersplenism or esophageal and gastric variceal bleeding caused by PH[8,9].

Portal vein thrombosis (PVT) is often defined as thrombosis within the portal vein trunk or intrahepatic portal branches, with or without the splenic vein or superior mesenteric vein involvement [10,11]. PVT is considered a dreaded complication after splenectomy for patients with PH[12], and the probability of PVT has been reported to be 4.8%-51.5%[13-15]. For patients with acute PVT and PVT resulting in superior mesenteric vein thrombosis, it has been reported that PVT may be closely associated with acute liver failure and could influence mortality[16]. Hence, strategies are needed to prevent PVT in patients who underwent splenectomy. In clinical practice, anticoagulation is a critical method for the prevention and treatment of PVT in patients after splenectomy. However, when the anticoagulation therapy should be started remains controversial. Early anticoagulation may result in life-threatening bleeding events for patients with liver cirrhosis. Whether anticoagulant therapy should be prescribed to all patients after splenectomy deserves careful consideration. In addition, the majority of patients with PVT are asymptomatic and only a few experience abdominal discomfort[12]. Therefore, there is an urgent requirement to find effective diagnostic methods to early and rapidly identify individuals with high risk of PVT after splenectomy, and then further guide clinicians to take intervention measures. Color Doppler ultrasonography and/or contrast-enhanced computed

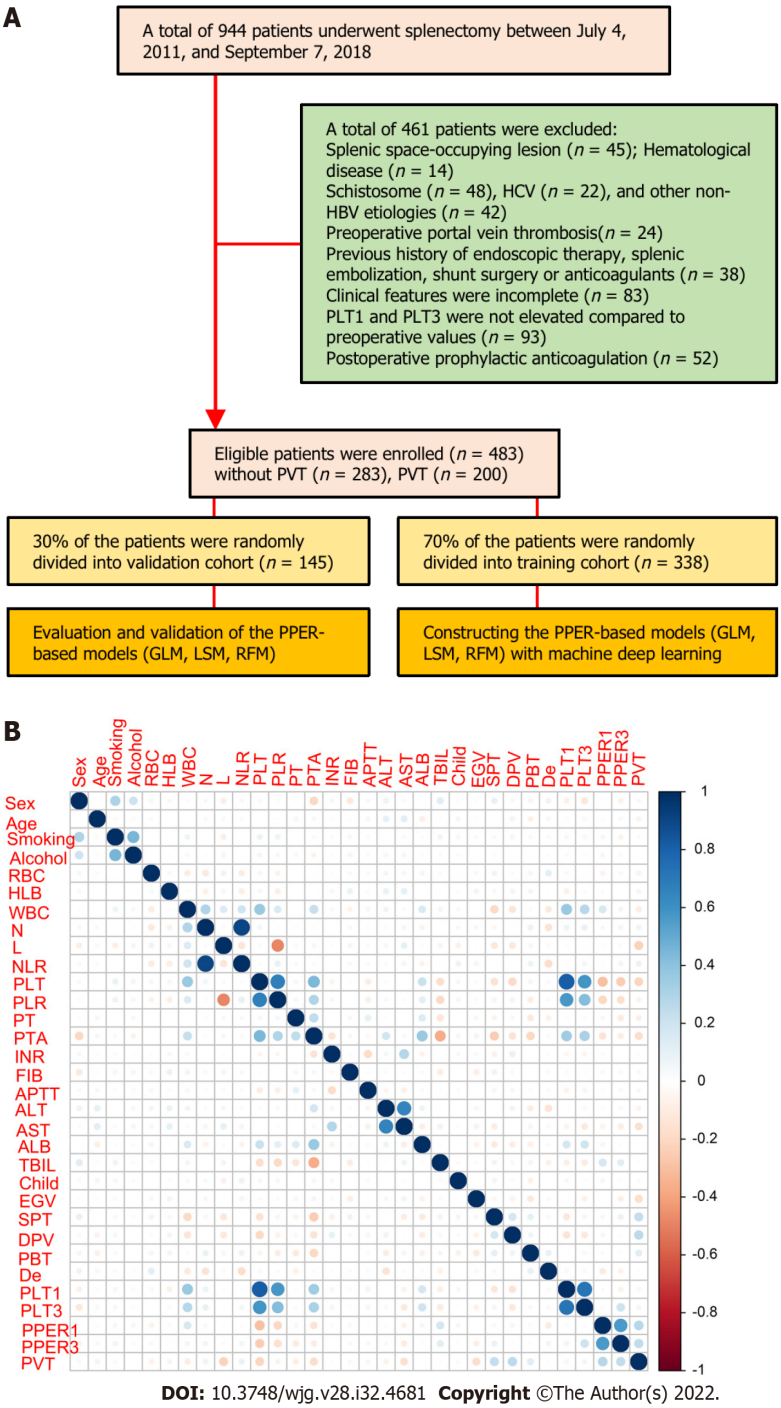
tomography (CT) is commonly applied for the final diagnosis of PVT[17]; however, they seem to be useless for screening out the high-risk individuals who are vulnerable to PVT. Given this, many scholars attempted to investigate the risk factors closely related to the occurrence of PVT after splenectomy[8,18-21]. Several investigators paid attention to the fact that preoperative low platelet count (PLT) and postoperative high PLT may be crucial predictors of the risk of PVT postoperatively[19,22].

Generally speaking, patients with PH will experience rebounding rises in PLT after splenectomy[23], combined with hemodynamic changes in the portal venous system, and thus these patients are highly prone to developing PVT[24]. However, the effect of the amplitude of sharp postoperative rises in PLT on PVT has received little attention. We speculated that the postoperative platelet elevation rate (PPER) should be an important predictor of PVT. To the best of our knowledge, there are no reports on the relationship between PPER and PVT.

In recent years, to meet the urgent demand of finding effective methods to predict PVT after splenectomy, several studies have attempted to construct predictive models for PVT after splenectomy in patients with cirrhosis using multivariate regression analysis[25,26]. However, there are few clinical variables included in the analysis and the accuracy of these prediction models is still unsatisfactory. Therefore, there is an urgent need for an efficient and accurate visualization model.

Nowadays, novel machine learning algorithms based on more clinical features have shown great potential in various aspects of medical research, especially in the construction of predictive models, and the features screened for model construction are clinically interpretable[27-29]. Gao *et al*[28] constructed four machine learning models based on 53 raw clinical features of coronavirus disease 2019 patients to distinguish individuals at high risk for mortality, with an area under the receiver operating characteristics (ROC) curve (AUC) of 0.976. Kawakami *et al*[29] developed seven supervised machine learning classifiers based on 32 clinical parameters, among which the random forest (RF) model showed the best performance in distinguishing epithelial ovarian cancer from benign ovarian tumors with an AUC of 0.968. The wide range of applications of machine learning methods has surpassed conventional statistical analysis due to their higher accuracy, which might enable machine learning to be increasingly applied in the field of medical research[30-32]. Although compared with traditional multivariate analysis methods, machine learning algorithms have overwhelming advantages in constructing clinical prediction models, so far, only Wang *et al*[33] have tried to construct a prediction model of PVT after splenectomy in cirrhotic patients with PH using machine learning algorithms. The model that they constructed has greatly improved the prediction efficiency compared with the traditional models. However, the clinical parameters involved in the construction of the model are extremely complex, which limits its clinical use.

Therefore, the purpose of this study was to evaluate the predictive value of PPER for the risk of PVT after splenectomy for patients with PH. In addition, we sought to build simple, efficient, and accurate practical models for predicting PVT with machine learning algorithms to facilitate assisting clinicians in the early identification of individuals at high risk of PVT after splenectomy and taking intervention measures in time. We present the following article in accordance with the TRIPOD reporting checklist.



MATERIALS AND METHODS

Study population

We retrospectively recruited 944 consecutive patients aged no less than 18 years who underwent splenectomy at our institution between July 4, 2011 and September 7, 2018. The patients with the following conditions were excluded: (1) Splenic space-occupying lesion; (2) Hematological disease; (3) PH caused by non-hepatitis B virus (HBV) related etiologies, such as schistosome, hepatitis C virus, or other unknown causes; (4) Presence of PVT confirmed by preoperative imaging; (5) Previous history of endoscopic therapy, splenic embolization, shunt surgery, or anticoagulants; (6) Incomplete clinical features; (7) Unelevated PLT on the first (PLT1) and third day (PLT3) after the operation compared to the preoperative values; and (8) Receiving prophylactic anti-coagulant therapy after splenectomy. Finally, a total of 483 patients with PH interrelated to HBV were included in this study. The flow diagram of patient selection and study design is shown in Figure 1A. The study was approved by the Medical Ethics Committee of Tongji Medical College, Huazhong University of Science and Technology. Owing to the retrospective nature of this study, written informed consent was waived.

Data collection

All the patients' clinical features were acquired from the electronic medical record system in our institution, which mainly included sex, age, smoking and drinking history, previous treatment history, etiologies, blood biochemical parameters, and imaging information. The blood biochemical parameters included routine blood tests [red blood cells (RBC), reference interval: 4.30-5.80 × 10^{12}/L; hemoglobin, reference interval: 130.0-175.0 g/L; white blood cells (WBC), reference interval: 3.50-9.50 × 10^{9}/L; neutrophil count (N), reference interval: 1.80-6.30 × 10^{9}/L; lymphocyte count (L), reference interval: 1.10-3.20 × 10^{9}/L; neutrophil to lymphocyte ratio (NLR); PLT, reference interval: 125.0-350.0 × 10^{9}/L; platelet to lymphocyte ratio], coagulation function [prothrombin time, reference interval: 11.5-14.5 s;

The darker the blue, the stronger the positive correlation between variables, and the darker the red, the stronger the negative correlation between variables. HCV: Hepatitis C virus; HBV: Hepatitis B virus; PLT1 and PLT3: Platelet counts on the first and third days after operation; PVT: Portal vein thrombosis; GLM: Generalized linear model; LSM: Least absolute shrinkage and selection operator model; RFM: Random forest model; RBC: Red blood cells; HLB: Hemoglobin; WBC: White blood cells; N: Neutrophil count; L: Lymphocyte count; NLR: Neutrophil to lymphocyte ratio; PLT: Platelet count; PLR: Platelet to lymphocyte ratio; PT: Prothrombin time; PTA: Prothrombin activity; INR: International normalized ratio; FIB: Fibrinogen; APTT: Activated partial thromboplastin time; ALT: Alanine aminotransaminase; AST: Aspartate aminotransaminase; ALB: Serum albumin; TBIL: Total serum bilirubin; Child: Child-Pugh grade; EGV: Esophageal and gastric varices; SPT: Spleen thickness; DPV: Diameter of the portal vein; PBT: Preoperative blood transfusion; De: Devascularization; PPER1: Platelet elevation rate at postoperative day 1; PPER3: Platelet elevation rate at postoperative day 3.

prothrombin activity (PTA), reference interval: 75.0%-125.0%; international normalized ratio, reference interval: 0.80-1.20; fibrinogen, reference interval: 2.00-4.00 g/L; activated partial thromboplastin time, reference interval: 29.0-42.0 s], and liver function [alanine aminotransaminase (ALT), reference interval: ≤ 41 U/L; aspartate aminotransaminase (AST), reference interval: ≤ 40 U/L; serum albumin, reference interval: 35.0-52.0 g/L; serum total bilirubin, reference interval: ≤ 26 μmol/L] within 7 d before surgery, as well as PLT1 and PLT3. The preoperative Child-Pugh grade was divided into three levels of A, B, and

C[34], with grade C excluded. Information on the esophageal and gastric varices (EGV), spleen thickness (SPT), diameter of the portal vein (DPV), and preoperative blood transfusion (PBT) within 7 d before the operation was also collected.

Definition of variables

We diagnosed PVT by color Doppler ultrasound examination[35] and contrast-enhanced CT would be applied as an auxiliary examination when its diagnosis was questioned[36]. In this study, abdominal ultrasound and contrast-enhanced CT examinations were routinely performed within 7 d before the operation. Routine ultrasonography was performed on the 7th day after the operation[19,20], or at any time when there were suspected clinical symptoms of PVT such as fever, severe abdominal pain, vomiting, abnormal liver function, and leukocytosis[12].

According to the definition of varices[8], EGV was divided into EGV without varices and EGV with varices in this study. SPT was defined as the vertical distance between the splenic hilum and the cut point of the lateral margin, and DPV was measured as the largest anteroposterior diameter at the point of intersection with the hepatic artery, during the patient's breath holding[37].

The PPER was calculated from the preoperative PLT and postoperative PLT. For example, PPER1 (at the first day) was calculated as (PLT1 - PLT)/ PLT × 100%, and PPER3 (at the third day) was calculated as (PLT3 - PLT)/ PLT × 100%.

Development of models

All candidates were randomly divided into two parts by using the "caret" package, of which 70% were assigned to a training cohort and 30% were assigned to a validation cohort. All model building was performed in the training cohort. Multivariate forward stepwise logistic regression analysis was used to select valuable variables to construct the generalized linear model (GLM). The least absolute shrinkage and selection operator (LASSO) was a well-established shrinkage method that can effectively screen meaningful variables from a large set of variables with potential multicollinearity to develop the LASSO model (LSM)[38], which was implemented by using the "glmnet" package. RF was composed of a great number of individual decision trees running as a whole[39]. These multifarious decision tree models were applied for the construction of the RF model (RFM)[40]. The importance of candidate variables was reflected by the mean decreased Gini (MDG) score.

Evaluation of models

The robustness and clinical practicability of models were assessed using the ROC curve, calibration curve, decision curve analysis (DCA), and clinical impact curve (CIC). The AUC were used to estimate the discernment of each model by using "rms" packages. The calibration curves were applied to examine the calibration ability of each model and calibrated with 1000 bootstrap samples to reduce overfitting bias. The clinical applicability of each model was informed by DCA and CIC using "rms" and "rmda" packages.

Statistical analysis

Statistical analyses were performed with R Statistical Software (version 4.1.2, https://www.r-project.org/). Continuous variables were tested for normality. Those with normality are described as the mean ± SD, while those without normality are described as the median and interquartile range. Continuous variables were compared using the student's *t*-test or non-parametric rank-sum test (Kruskal-Wallis test) as appropriate. Categorical variables are described as numbers (percentage) and were compared using the Chi-square test or Fisher exact test as appropriate. Correlations between candidate variables were determined by Spearman's correlation coefficient. All statistical tests were two-tailed, and $P < 0.05$ was considered significant.

RESULTS

Patient demographics and characteristics

The detailed clinical characteristics of 483 patients with PH are summarized in Table 1. All participants were randomly and automatically divided into a training cohort (n = 338, 70%) and a validation cohort (n = 145, 30%). The presence of PVT was diagnosed in 200 (41.4%) cases, 135 (39.9%) cases, and 65 (44.8%) cases in the overall cohort, training cohort, and verification cohort, respectively. Consistent with the results of the intergroup comparison, among the 31 candidate variables included, 14 were associated with PVT, including RBC, WBC, L, NLR, PLT, PTA, ALT, AST, EGV, SPT, DPV, PBT, PPER1, and PPER3 (Figure 1B and Supplementary Table 1), which indicated that PPER1 and PPER3 were highly likely to be potential predictors of PVT.

PH: Portal hypertension; PVT: Portal vein thrombosis; RBC: Red blood cells; HLB: Hemoglobin; WBC: White blood cells; N: Neutrophil count; L: Lymphocyte count; NLR: Neutrophil to lymphocyte ratio; PLT: Platelet count; PLR: Platelet to lymphocyte ratio; PT: Prothrombin time; PTA: Prothrombin activity; INR: International normalized ratio; FIB: Fibrinogen; APTT: Activated partial thromboplastin time; ALT: Alanine aminotransaminase; AST: Aspartate aminotransaminase; ALB: Serum albumin; TBIL: Total serum bilirubin; EGV: Esophageal and gastric varices; SPT: Spleen thickness; DPV: Diameter of the portal vein; PBT: Preoperative blood transfusion; De: Devascularization; PLT1: Platelet count at postoperative day 1; PLT3: Platelet count at postoperative day 3; PPER1: Platelet elevation rate at postoperative day 1; PPER3: Platelet elevation rate at postoperative day 3.

overall cohort are presented in Table 2. In the univariate analysis, a total of 11 variables with $P < 0.05$ were included in the further multivariate analysis. Finally, the following six variables were revealed to be closely associated with the occurrence of PVT: L [odds ratio (OR): 0.28, 95% confidence interval (CI): 0.14-0.54, $P < 0.001$], EGV (OR: 0.51, 95%CI: 0.32-0.79, $P = 0.003$), SPT (OR: 1.22, 95%CI: 1.06-1.40, $P = 0.005$), DPV (OR: 3.57, 95%CI: 1.86-7.03, $P < 0.001$), PPER1 (OR: 1.78, 95%CI: 1.24-2.62, $P = 0.002$), and PPER3 (OR: 1.43, 95%CI: 1.16-1.77, $P < 0.001$). This result demonstrated that PPER1 and PPER3 were independent risk factors for the occurrence of PVT.

Establishment of PPER-based models

As shown in Supplementary Table 2, the following five variables strongly associated with PVT were chosen to construct the GLM: L (OR: 0.34, 95%CI: 0.14-0.77, $P = 0.01$), SPT (OR: 1.21, 95%CI: 1.02-1.44, $P = 0.02$), DPV (OR: 5.85, 95%CI: 2.57-14.05, $P < 0.001$), PPER1 (OR: 1.77, 95%CI: 1.13-2.82, $P = 0.01$), and PPER3 (OR: 1.42, 95%CI: 1.12-1.84, $P = 0.005$). The optimal LSM was obtained when all 31 candidate variables were shrunk to 10 through the LASSO (Figure 2A and B), which included L, NLR, PLT, PTA, AST, EGV, SPT, DPV, PPER1, and PPER3. In the RF, the total sample group had the smallest error of 24.56%, when the number of random trees was 133 (Figure 2C). A total of 133 random trees were set and passed through five iterations, and the importance scores of the candidate variables are presented in Figure 2D. Ultimately, nine variables with higher MDG scores were selected to construct the RFM.

Assessment and verification of PPER-based models

The ROC curves of the GLM, LSM, and RFM in the training cohort are shown in Figure 3A, and their AUCs were 0.83 (95%CI: 0.79-0.88), 0.84 (95%CI: 0.79-0.88), and 0.84 (95%CI: 0.79-0.88), respectively. All models had excellent calibration ability in the training cohort (Figure 3B). DCA and CIC revealed that they both conferred high clinical net benefits (Figures 3C and 4A-C).

In the validation cohort, the ROC curves of all models are presented in Figure 3D, and their AUC were 0.77 (95%CI: 0.69-0.85), 0.83 (95%CI: 0.76-0.90), and 0.78 (95%CI: 0.70-0.85), respectively. All models demonstrated highly satisfactory calibration capability and clinical functionality (Figures 3E and F and 4D-F).

Importance of PPER for models

As shown in Figure 5A, the nomogram for GLM recruited a total of five variables, including L, SPT, DPV, PPER1, and PPER3, which happened to be the intersection variables of the GLM, LSM, and RFM (Figure 5B). From this, it appeared that the aforementioned variables were significant predictors of the occurrence of PVT and they produced remarkable effects on the construction of the models. Moreover, the present study revealed that among these variables shared by the GLM, LSM, and RFM, the order of weight from high to low was DPV, PPER1, PPER3, SPT, and L (Figure 5C), which fully promulgated the predictive value of the PPER (PPER1 and PPER3) for PVT in all models.

Comparative analysis of PPER-based models

The performance of three PPER-based models in predicting PVT in different cohorts is shown in Table 3. In the overall cohort, the accuracy of the GLM, LSM, and RFM was 76.2%, 77.4%, and 77.4% respectively. In the training cohort, the accuracy of the GLM, LSM, and RFM was 79.6%, 79.0%, and

considered, the LSM and RFM appeared to be slightly superior to the GLM.

DISCUSSION

Undoubtedly, PVT is a lethal complication after splenectomy in cirrhotic patients with PH[12]. Once PVT exists, there will be elevated portal venous pressure, ischemic bowel necrosis, progressive impairment of liver function, and even liver failure, which can eventually be life-threatening[41,42]. Therefore, research on the optimization of early detection of individuals at high risk of PVT after splenectomy is urgently needed. In this study, we successfully constructed the PPER-based models for predicting PVT by machine/deep learning, which would be conducive to early identifying the population at high risk of PVT.

In the present study, conventional generalized linear (CGL) method and machine/deep learning (including the LASSO and RF) were applied separately to screen out the variables that greatly affected the PVT prediction. The CGL method is characterized by strong interpretability, especially when the multifactorial forward stepwise regression method is used, and therefore, it has been widely applied as the traditional method to construct a predictive model[43]. However, with the rapid progress of artificial intelligence technology, a novel prediction model based on machine/deep learning has emerged with a higher probability of accuracy, which has led some clinicians to question the value of the CGL model in the clinical application of individualized patients[44]. Coincidentally, our research results proclaimed that the performance of the LSM and RFM seemed to be slightly better than the GLM.

Interestingly, the PPER-based models contained the following five intersecting factors, namely, SPT, DPV, L, PPER1, and PPER3, which sufficiently illustrated that these were the main contributors to the higher incidence of PVT. Previous studies found that preoperative SPT and DPV were important predictors of the formation of PVT after splenectomy in patients with PH[8,45], which was highly consistent with our findings. A very reasonable explanation is that a wide preoperative DPV and SPT will lead to slow portal vein blood flow, which is closely related to postoperative thrombosis[45,46].

In most cases, platelet, erythrocyte, and leukocyte counts rose dramatically over a short time after splenectomy in patients with PH, and the blood was hypercoagulable[8]. Therefore, previous studies suggested that preoperative low platelet and leukocyte counts were founders of the formation of PVT postoperatively[47]. This study revealed that preoperative L was an influential factor in PVT postoperatively, which coincided with the above view. Of note, the present study employed the PPER to reflect the magnitude of dynamic changes in preoperative and postoperative PLT. Subsequently, it was found that the PPER had high predictive value for the risk of PVT postoperatively, which was not addressed previously.

Stamou *et al*[48] reported that the median time to the formation of PVT after splenectomy in patients with PH was the 6th day (range, 3-11). Lu *et al*[8] concluded that 49.19% of patients developed PVT within 7 d after splenectomy. Therefore, scholars routinely applied ultrasonography examination to diagnose the PVT on the 7th day after splenectomy[8,19,20]. In this study, combined with the preoperative predictors and PPER, the PPER-based models that we constructed can effectively discriminate individuals with high risk of PVT as early as the first 3 d after the operation, which was

extremely critical for guiding clinicians' treatment strategies.

Currently, there is no standard preventive regimen for PVT after splenectomy in cirrhotic patients with PH[49]. Most scholars have recently advocated that the prophylactic anticoagulant therapy is administered earlier postoperatively, which will be more helpful in reducing the incidence of PVT[50,51]. However, it should be cautiously chosen because in patients with liver cirrhosis, it cannot avoid the risk of bleeding[51]. In addition, if the preventive regimens are routinely adopted for all individuals with PH after splenectomy, it is bound to raise the suspicion of overtreatment. Excitingly, in the present study, the accuracy of the PPER-based models in predicting PVT was up to 80%, which can distinguish individuals at high risk of PVT with high efficiency, and thus guide clinicians to take targeted individualized preventive measures in time.

The present study has some limitations. First, due to the retrospective nature of the study, selection bias cannot be eliminated. Second, the uncommon preoperative factors that may influence the formation of PVT, such as splenic vein diameter, spleen volume, and portal vein flow velocity[8,19], were not routinely measured in our institution and thus failed to be included in the present study. However, the SPT and DPV in this study can indirectly reflect these indicators to a certain extent[45,46]. Third, this was a monocentric study design. Although the PPER-based models demonstrated excellent performance

for predicting PVT, they still lacked the verification of external cohorts. Therefore, large-scale prospective multicenter studies are warranted, which are beneficial to the popularity and application of the PPER-based models.

CONCLUSION

PPER1 and PPER3 are effective indicators for postoperative prediction of PVT. We have successfully developed the PPER-based practical models for predicting PVT, which could help clinicians identify individuals at high risk for PVT early and efficiently, and thus guide the timely intervention measures.

ARTICLE HIGHLIGHTS

Research background

Patients with portal hypertension (PH) often experience rebounding rises in platelets following splenectomy. However, the value of postoperative platelet elevation rate (PPER) in predicting portal vein thrombosis (PVT) is unknown.

Research motivation

PVT is a potentially fatal complication after splenectomy for patients with PH, and the probability of PVT has been reported to be nearly 50%. Therefore, there is an imperious demand for effective diagnostic methods to early and rapidly identify individuals at high risk of PVT after splenectomy to further help clinicians take intervention measures as soon as possible.

Research objectives

We aimed to investigate the predictive value of PPER for PVT and establish PPER-based practical prediction models to early identify individuals at high risk of PVT after splenectomy.

Research methods

We retrospectively reviewed 483 patients with PH related to hepatitis B virus who underwent splenectomy between July 2011 and September 2018, and they were randomized into either a training (n = 338) or a validation (n = 145) cohort. The generalized linear (GL) method, least absolute shrinkage and selection operator (LASSO), and random forest (RF) were used to construct models. The receiver operating characteristic (ROC) curves, calibration curve, decision curve analysis (DCA), and clinical impact curve (CIC) were used to evaluate the robustness and clinical practicability of the GL model (GLM), LASSO model (LSM), and RF model (RFM).

Research results

PPER at the first (PPER1) and third (PPER3) days were strongly associated with PVT [odds ratio (OR): 1.78, 95% confidence interval (CI): 1.24-2.62, P = 0.002; OR: 1.43, 95%CI: 1.16-1.77, P < 0.001, respectively] in the multivariate logistic regression analysis. The areas under ROC curves of the GLM, LSM, and RFM in the training cohort were 0.83 (95%CI: 0.79-0.88), 0.84 (95%CI: 0.79-0.88), and 0.84 (95%CI: 0.79-0.88), respectively; and were 0.77 (95%CI: 0.69-0.85), 0.83 (95%CI: 0.76-0.90), and 0.78 (95%CI: 0.70-0.85) in the validation cohort, respectively. The calibration curves showed satisfactory agreement between prediction by models and actual observation. DCA and CIC indicated that all models conferred high clinical net benefit.

Research conclusions

PPER1 and PPER3 are effective indicators for predicting PVT. We have successfully developed the PPER-based practical models to accurately predict PVT, which could conveniently help clinicians rapidly differentiate individuals at high risk of PVT, and further guide the adoption of timely interventions.

Research perspectives

According to our experience, patients with a more remarkable increase in platelet count in the first 3 d after operation have a higher probability of PVT, which should be prioritized for prophylactic anticoagulation.

Abstract

BACKGROUND

Pancreatic cancer, as the one of most fatal malignancies, remains a critical issue in the global burden of disease.

AIM

To estimate trends in pancreatic cancer incidence and mortality worldwide in the last three decades.

METHODS

A descriptive epidemiological study was done. Pancreatic cancer incidence and mortality data were obtained from the database of the World Health Organization. Analysis of pancreatic cancer incidence and mortality during 2020 was performed. The age-standardized rates (ASRs, expressed *per* 100000) were presented. To estimate trends of incidence and mortality of pancreatic cancer, joinpoint regression analysis was used: the average annual percent change (AAPC) with the corresponding 95% confidence interval (95%CI) was calculated. Additionally, analysis was performed by sex and age. In this paper, the trend analysis included only countries with high and medium data quality.

RESULTS

A total of 495773 (262865 male and 232908 female) new cases and 466003 (246840 male and 219163 female) deaths from pancreatic cancer were reported worldwide in 2020. In both sexes, most of the new cases (191348; 38.6% of the total) and deaths (182074; 39.1% of the total) occurred in the Western Pacific Region. In both sexes, the highest ASRs were found in the European Region, while the lowest rates were reported in the South-East Asia Region. The general pattern of rising pancreatic cancer incidence and mortality was seen across countries worldwide in observed period. Out of all countries with an increase in pancreatic cancer

incidence, females in France and India showed the most marked rise in incidence rates (AAPC = +3.9% and AAPC = +3.7%, respectively). Decreasing incidence trends for pancreatic cancer were observed in some countries, but without significance. Out of all countries with an increase in pancreatic cancer mortality rates, Turkmenistan showed the most marked rise both in males (AAPC = +10.0%, 95%CI: 7.4–12.5) and females (AAPC = +6.4%, 95%CI: 3.5–9.5). The mortality trends of pancreatic cancer were decreasing in both sexes only in Canada and Mexico.

CONCLUSION
Further research is needed to explain the cause of large international differences in incidence and mortality trends of pancreatic cancer in last three decades.

Key Words: Pancreatic cancer; Incidence; Mortality; Joinpoint analysis; International pattern

Core tip: Pancreatic cancer, as one of the most fatal malignancies, remains a critical issue in global burden of disease. About 500000 new cases and 470000 deaths from pancreatic cancer were recorded in 2020 across the world. Globally, the rate of pancreatic cancer incidence in 2020 was 4.9 *per* 100000 for both sexes together, while mortality rate was 4.5 *per* 100000. Increasing trends in both incidence and mortality of pancreatic cancer were observed in most countries across the world. Further efforts to explore the reasons for differences in international pattern in pancreatic cancer incidence and mortality could be critical for global cancer control.

INTRODUCTION

Pancreatic cancer is one of the most lethal cancers, with insidious onset, aggressive nature and poor prognosis[1-3]. The 5-year overall survival rate of pancreatic cancer is low (~10%), since more than half of the cases are confirmed at an advanced stage[3,4]. Based on GLOBOCAN 2020 estimates, pancreatic cancer remains a large part of the global burden of disease, and ranks as the 12th most common malignancy (2.6% of all cancers) and the 7th leading cause of cancer mortality (4.7% of all cancers)[1,2]. Age-standardized incidence and mortality rates are about fivefold higher in countries with high/very high Human Development Index than in low/medium countries[2].

World Health Organization (WHO) estimated pancreatic cancer as the third leading cancer-related cause of death in people of all ages for both sexes in the USA, Germany, Italy, Austria, Czechia, Finland, Hungary, Malta, Spain and Switzerland in 2020[2]. In four countries (Finland, Qatar, Benin and Guadeloupe), pancreatic cancer was the second leading cause of death of all cancers in 2020 in females aged ≥ 70 years[2]. The Global Burden of Disease (GBD) Study ranked pancreatic cancer as the seventh top cause of absolute years of life lost (YLLs) among all cancers in both sexes in 2017, while it ranked ninth in 2007 among the top causes for YLLs worldwide[5]. Also, the GBD study showed that the disability adjusted life years caused by pancreatic cancer have more than doubled from 1990 to 2017 globally[6].

The age patterns were similar for both incidence and mortality of pancreatic cancer, with the rates increasing with increasing age; the burden moderately grew after 30 years of age and came to peak after 80 years of age, with similar trend in males and females[3,5-7]. In 27 countries of the EU and in the UK, between 1990 and 2019, incidence and mortality from pancreatic cancer significantly increased by 0.65% and 0.55% per year, respectively[8].

WHO and the United Nations Sustainable Development Goals, published in 2015, target to reduce premature mortality rate attributed to cancer by one third by 2030[9]. However, according to Ferlay *et al* [10], by 2025 there will be more deaths annually from pancreatic cancer in the EU countries than deaths from breast cancer, and it will become the third most important cause of cancer death in the EU after lung and colorectal cancer. In addition, a particularly important issue is how the COVID-19 pandemic will affect the management of patients with pancreatic cancer that can be disrupted or delayed, particularly in the context of treatment selection and postoperative care to reduce the risk of SARS-CoV-2-associated morbidity and mortality[11,12].

Recent estimates suggest that pancreatic cancer is becoming a critical public health challenge and a growing health service issue both in developed and developing countries[1,10,13]. The aim of this manuscript was to assess international patterns in incidence and mortality of pancreatic cancer.

MATERIALS AND METHODS

Study design

This descriptive epidemiological study comprised the annual underlying cause of disease and death data to describe trends in incidence and mortality from pancreatic cancer in the world in last three decades.

Data source

Data of pancreatic cancer incidence and mortality were extracted from the WHO databases[2], *i.e.* the GLOBOCAN estimates of cancer incidence and mortality generated by the International Agency for Research on Cancer. Pancreatic cancer estimates included site code C25, based on the 10th revision of the International Classification of Diseases and Related Health Problems to classify cause of disease and death (ICD-10)[14].

The WHO databases provide a comprehensive and comparable assessment of incidence and mortality of pancreatic cancer[2]. These databases provide high-quality statistics based on national vital registries worldwide. The methods used to compile the GLOBOCAN 2020 estimates involved predictions, modeling of incidence-to-mortality ratios, and approximation from neighboring countries. For pancreatic cancer, we extracted all incidence and mortality data available from WHO databases in all years available since 1991. The WHO estimates comprise only national mortality data series that meet the minimal inclusion criteria according to the WHO-defined medium data quality level, based on degree of population coverage, completeness and accuracy[15]. Level of data quality was classified using criteria described by WHO[14]: data of high quality (ICD-9 or ICD-10 coding is used and completeness is > 90% and ill-defined codes appear on < 10% of registrations), medium quality (completeness is 70%–90% OR ill-defined codes appear on 10%–20% of registrations OR non-ICD codes used although completeness is > 90% and ill-defined codes appear on < 10% of registrations) and low quality (completeness < 70% OR ill-defined codes appear on > 20% of registrations).

This study presented the incidence and mortality figures for 185 WHO Member States, as well as for six WHO regions (Africa, Americas, South-East Asia, Europe, Eastern Mediterranean, and Western Pacific). First analysis of incidence and mortality for pancreatic cancer was for 2020. The trends analyses included only countries with data for pancreatic cancer incidence/mortality available in the observed period (from 1991 or later) continuously, provided that there were data for at least 15 years in a row continuously. Countries with missing values in any year of trend analysis were excluded from the analysis. Specifics about the availability of incidence and mortality data of pancreatic cancer since 1991, as well as the quality classification of data for different countries by years in observed period are defined in Supplementary Table 1. In this study, the trend analysis included only countries with high/medium data quality.

For pancreatic cancer incidence and mortality, all figures were adjusted by age and presented as age-standardized rates (ASRs, *per* 100000 persons) calculated by the direct method of standardization by age and sex, using the World standard population according to the Segi–Doll World reference population [2].

Statistical analysis

Trends in pancreatic cancer incidence and mortality rates were calculated using Joinpoint regression analysis software version 4.9.0.0 (National Cancer Institute, Bethesda, MD, USA – March 2021, available through the Surveillance Research Program of the US National Cancer Institute), proposed by Kim *et al* [16]. The joinpoint regression analysis was used to assess the magnitude and direction of temporal trends in incidence and mortality of pancreatic cancer. The joinpoint regression analysis detected points, the so-called joinpoints, at which there was a significant change in trend in rates of pancreatic cancer, using the calendar year as a regression variable. The ASR was used as the dependent variable, while the by-variables were sex and age group. A Monte Carlo permutation test for multiple comparisons was used and 4499 randomly selected data sets, which finds the best fit line for each segment[16]. The analysis started with a minimum of zero joinpoints (*i.e.*, a straight line) and tested whether a change in the trend was significant by testing more joinpoints up to the maximum of four (five segments)[16]. The resulting regression equation was: $y = a + bx$, where $y = ln(rate)$ and x = calendar year, with slope a and y intercept b, whereby average annual percent change (AAPC) was estimated as $100 \times (eb\ \ 1)$. The Grid Search method was selected[17]. The trend of pancreatic cancer incidence and mortality in each country was presented with a straight line in the whole period, even if there were changes in trends in the observed period. The AAPC over the entire study period with the corresponding 95% confidence interval (95%CI) was determined[18]. In describing the direction of temporal trends, the terms significant increase or significant decrease were used, in order to signify that the slope of the trend was

statistically significant ($P < 0.05$, on the basis of the statistical significance of the AAPC compared to zero). Additionally, analysis was performed by sex and age (30–49, 50–69, ≥ 70 years) in selected countries. Trends were not evaluated separately among persons aged < 30 years due to the small number of pancreatic cancer cases in this age group. A line diagram of joinpoint analysis for individual countries provided information about the number of the joinpoints for the trends in incidence and mortality of pancreatic cancer by sex, by describing of annual percent change and the corresponding 95%CI.

Ethics statement

This study was approved by the Ethics Committee of the Faculty of Medical Sciences, University of Kragujevac (No. 01-14321).

RESULTS

Pancreatic cancer incidence and mortality: 2020 results

Globally, the total number of new pancreatic cancer cases was 495 773 in 2020: it was diagnosed in 262 865 (53%) males and 232 908 (47%) females (Figure 1). The total number of pancreatic cancer deaths was 466 003 (246 840 males and 219 163 females). Male to female ratio was: 1.1:1 both for incidence and mortality. In both sexes, most new cases (191 348; 38.6% of the total) and deaths (182 074; 39.1% of the total) occurred in the Western Pacific Region. In males, the least number of pancreatic cancer new cases (6062; 2.3% of total) and deaths (5920; 2.4% of total) was recorded in the African region. In females, the least number of pancreatic cancer new cases (5048; 2.2% of total) and deaths (4924; 2.2% of total) was recorded in the Eastern Mediterranean Region.

The global ASR of incidence of pancreatic cancer was 4.9 *per* 100000 population in both sexes (5.7 in males *vs* 4.1 in females), and ASR of mortality was 4.5 (5.3 in males *vs* 3.8 in females) (Figure 2). In both sexes, the highest incidence ASRs was found in the European Region (9.3 in males *vs* 6.2 in females), while the lowest rates were in the South-East Asia Region (1.6 in males *vs* 1.0 in females). Also in both sexes, the highest mortality ASRs were found in the European Region (8.7 in males *vs* 5.7 in females), while the lowest rates were in the South-East Asia Region (1.6 in males *vs* 1.0 in females).

There were significant international variations in incidence and mortality of pancreatic cancer in 2020 (Figures 3 and 4). The highest ASRs of incidence and mortality of pancreatic cancer in both sexes in 2020 were in Hungary (11.2 and 10.2, respectively). The highest incidence ASRs in males and females were in Hungary (13.7 and 9.2 *per* 100000), followed by Uruguay (12.8 and 8.9), while the lowest rates (equally about 0.5) were reported in Botswana, Eswatini and Malawi in males, and in India, Sri Lanka and Pakistan in females. The highest mortality ASR in males was in Hungary (12.6) and in females in Uruguay (8.5), while the lowest rate was in Malawi in males (0.46) and in Pakistan in females (0.30). In comparison to males, the incidence and mortality ASRs were lower in females in countries across the world in 2020: The only exceptions were for females in Bahrain, Belize, Brunei, Burkina Faso, Cabo Verde, Eswatini, Gabon, Ghana, Kenya, Libya, Malawi, Nepal, New Zealand, Peru, Qatar, Gambia, Uganda and United Arab Emirates where rates higher than in males were recorded.

Patterns in pancreatic cancer incidence trends

Most of the countries showed a meaningful increase in pancreatic cancer incidence in both males and females, but the magnitude of increasing incidence trends for pancreatic cancer was higher in females than in males in almost all countries (Figure 5). Out of all countries with an increase in pancreatic cancer incidence, females in France and India showed the most marked rise in incidence rates (AAPC = +3.9% and AAPC = +3.7%, respectively). In males in Kuwait and Turkey the most marked rise in incidence rates was recorded (both equally by AAPC = +3.6%). In some countries, pancreatic cancer incidence trends were significantly increasing in females (Czechia, Germany, India, Latvia, Lithuania, Malta, Netherlands, Norway and Switzerland), in contrast to males. Decreasing trends of pancreatic cancer incidence were observed in some countries but without significance. In some of the most developed countries (such as the UK and Sweden), in both sexes significantly increasing trends in pancreatic cancer incidence rates were observed in the last decade, which followed a previous period characterized by a declining incidence trend (Supplementary Figure 1). In contrast to that, two decades of continuous growth, a downward trend of pancreatic cancer incidence rates in both sexes happened in the more recent decade in Denmark.

Pattern in pancreatic cancer mortality trends

The majority of analyzed countries showed a significant increase in pancreatic cancer mortality in both males and females, but the magnitude of mortality increasing trends for pancreatic cancer was higher in females than in males in almost all countries since 1991 (Figure 6). Out of all countries with an increase in pancreatic cancer mortality rates, Turkmenistan showed the most marked rise both in males (AAPC = +10.0%, 95%CI: 7.4–12.5) and females (AAPC = +6.4%, 95%CI: 3.5–9.5). In some countries, pancreatic

Figure 2 Incidence and mortality of pancreatic cancer (global and by World Health Organization regions), by sex, 2020.

cancer mortality trends were significantly increasing in males (Colombia, Kyrgyzstan and Mauritius), in contrast to females. Our results suggested that there were only two countries where significant decreasing pancreatic cancer mortality trends were observed in both sexes: Canada (by 0.4% per year in males and by 0.2% per year in females) and Mexico (by 0.7% in males and 0.8% in females). However, there were only two countries where decreasing pancreatic cancer mortality trends were observed in males only: Czechia (by 0.4% per year) and Ireland (by 0.7%). In some of the most developed countries (such as the USA, UK and Germany) significantly increasing trends in pancreatic cancer mortality rates were observed since the 1990s (Supplementary Figure 2).

Figure 3 Estimated age-standardized incidence rates of pancreatic cancer in 2020. ASR (W): Age-standardized rate (using World standard population, *per* 100000).

Pattern in pancreatic cancer trends according to age classes, by sexes

The greatest increase in pancreatic cancer incidence was noted in people aged ≥ 70 years in France in both males (by +4.2% per year) and females (by +4.9%) (Table 1). An increase was observed in most of the countries in both sexes for persons aged ≥ 50 years. A decreasing trend in incidence of pancreatic cancer was recorded only in females aged ≥ 70 years in Canada (by 0.3% per year). Also, a decreasing trend in pancreatic cancer incidence in males aged ≥ 70 years was noted only in Canada (by 0.4% per year). In males aged 30–49 years, incidence rates decreased mainly in transitional countries (Czechia by 1.9%, Estonia 2.1%, Latvia 2.2%, Lithuania 2.2% and Slovakia 1.5%). In almost all countries a significantly increasing trend in mortality of pancreatic cancer was recorded both in males and females aged ≥ 70 years. A similar pattern was observed in people aged 50–69 years. The greatest increase in pancreatic cancer mortality was in people aged ≥ 70 years in Turkmenistan in both males (by +12.8%) and females (by +11.4%). Large disparities were observed in changes of rates among the young age group, where mortality rates decreased over the study period for most countries. The favorable change was higher in transitional countries (Czechia by 3.3% in males, 2.7% in females; Latvia by 2.7% in males, 4.7% in females).

DISCUSSION

In 2020, the highest incidence and mortality rates of pancreatic cancer were reported in developed countries. The pattern of rising pancreatic cancer incidence and mortality was seen across countries worldwide in the last three decades, in both developed and transitioned populations. Increasing trend was most pronounced among persons aged ≥ 50 years, similarly among males and females. However, it is promising that pancreatic cancer mortality rates were declining in some countries such as Canada and Mexico.

In both sexes together, the highest incidence and mortality rates of pancreatic cancer in 2020 were reported in the European region (7.6 cases and 7.1 deaths *per* 100000 persons, respectively) and the Americas region (6.2 cases and 5.4 deaths *per* 100000 persons, respectively), while the lowest were

[1]Statistically significant trend ($P < 0.05$), for full period presented.

[2]Joinpoint results are not shown for incidence/mortality in some countries, because there were no data for pancreatic cancer in the whole observed period continuously. For the trend analysis, we presented all incidence/mortality data available from 1991 onwards, provided that there were data for at least 15 years in a row continuously.

[3]These countries have sample vital registration systems (although coverage is low, the sample provides population-representative information)[14].

recorded in South-East Asia (equally 1.3 cases and deaths *per* 100000 persons). Since due to delayed disease detection and limited effectiveness of therapies the survival for pancreatic cancer remains poor [3,4,19], its mortality is still largely determined by its incidence. Besides, the overall survival rates vary little between developed and developing countries[20]. Since the risk of pancreatic cancer occurrence increases linearly with age and the average age at the time of diagnosis of pancreatic cancer is 70 years [2-6], significant geographic differences in pancreatic cancer incidence and mortality rates could be explained by differences in life expectancy at birth by region. Although improving continuously in all regions in the past decades, life expectancy at birth in 2019 was the highest in countries in Northern America and Europe, and the lowest in South Asia and Africa[21]. Also, the GBD study showed the association of age-standardized incidence and mortality rates for pancreatic cancer with development status at the national level (measured by the Socio-demographic Index, that composes the total fertility rate among women under the age of 25 years, mean education for individuals aged ≥ 15 years, and income per capita) in 2017[6]. Based on the current evidence, international variations in incidence rates of pancreatic cancer are mainly attributed to exposure to environmental factors, particularly tobacco smoking, obesity, diabetes mellitus, alcohol consumption[6,22,23]. Additionally, the migrant effect among Japanese in Hawaii[24] and the discrepancies in pancreatic cancer incidence in Chinese populations[25], which share a similar genetics, but have lived in different regions, indicate that cancer development was mainly determined by environmental factors. Based on the WHO 2015 estimates, the prevalence of tobacco smoking was the highest in countries in the European Region (35% in Greece, equally 33% in the Russian Federation and Serbia), intermediate (~20%) in Western Pacific and Eastern Mediterranean Regions, and lowest (~10%) in Africa and the Americas[26]. Based on the results of the GBD Study, pancreatic cancer deaths worldwide were primarily attributable to smoking (25.9% in males, 16.1% in females), high fasting plasma glucose (9.3% in males, 8.6% in females), and high body mass index (5.0% in males, 7.4% in females) in 2017[6]. In both sexes together in 2017, fraction of pancreatic cancer age-standardized deaths attributable to smoking was the highest in central Europe (28.2% of all pancreatic cancer deaths), while the highest fraction attributable to high fasting plasma

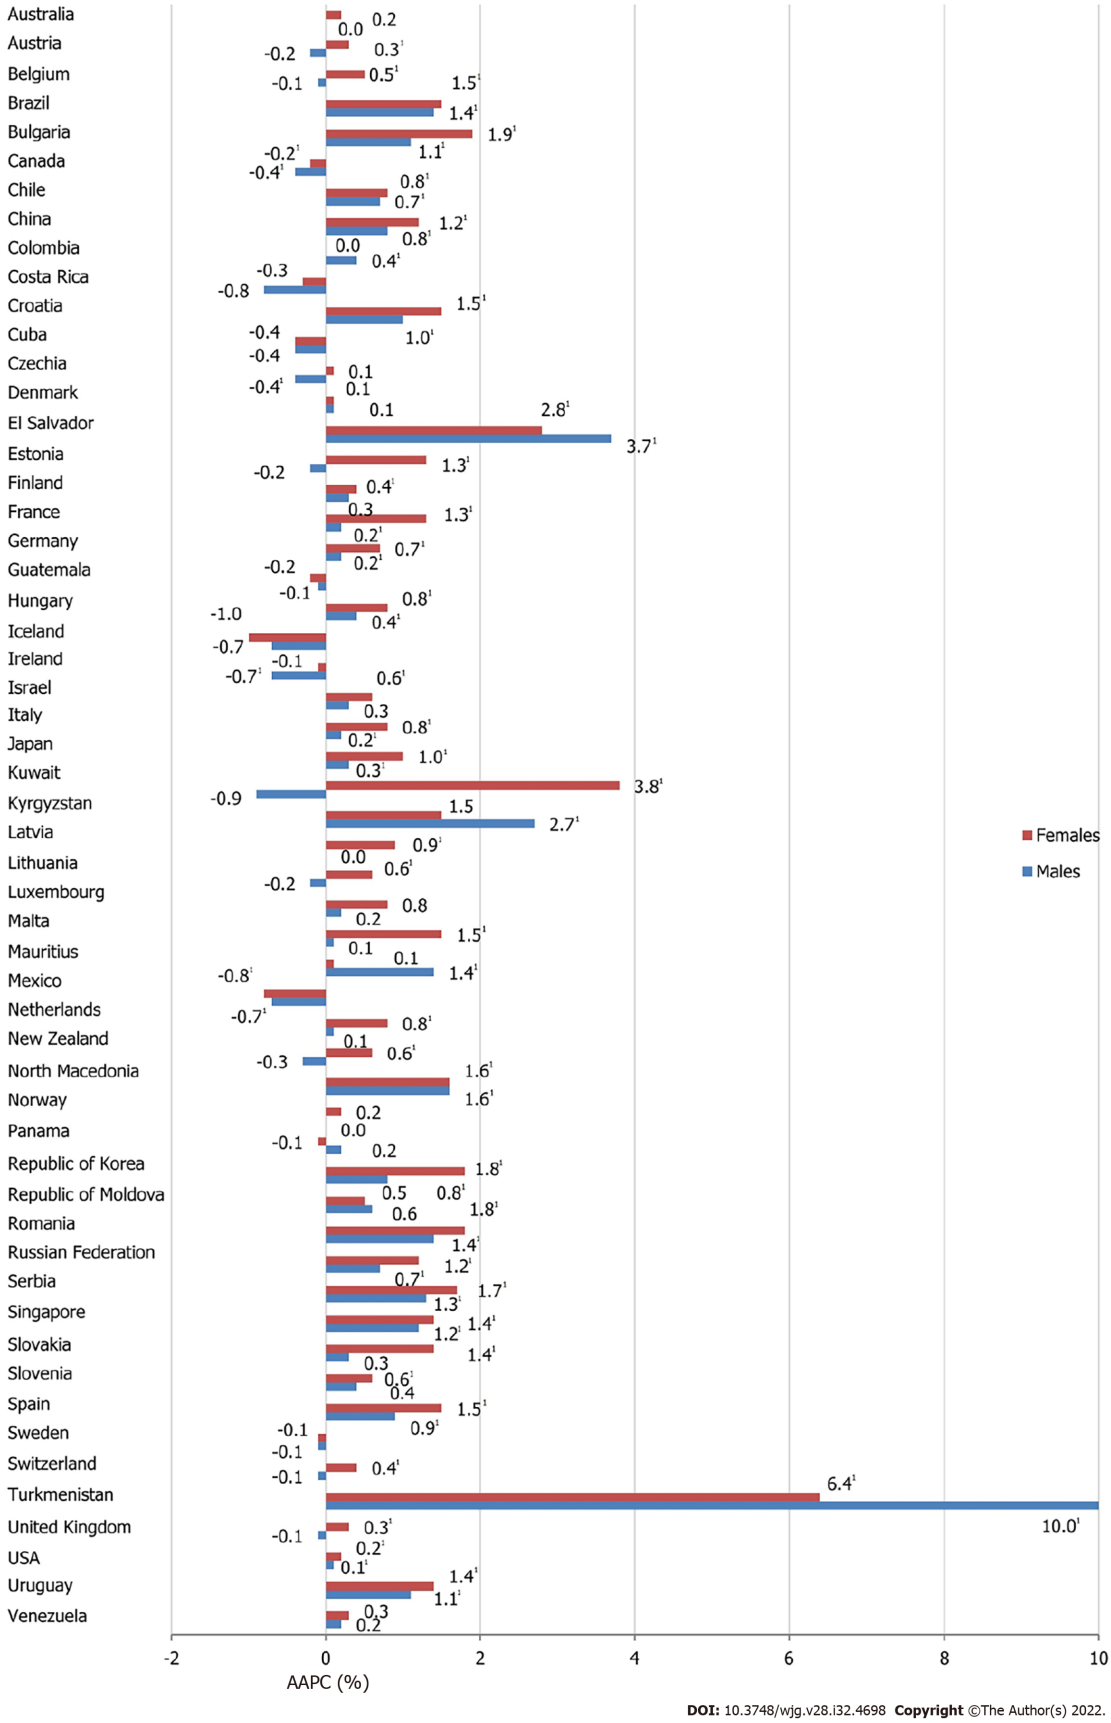
Figure 4 Estimated age-standardized mortality rates of pancreatic cancer in 2020. ASR (W): Age-standardized rate (using World standard population, *per* 100000).

glucose was observed in Oceania (16.6%), and the highest fraction attributable to high body mass index was observed in high-income North America (10.2%)[6]. Similarly, the correlation analysis of risk factors for pancreatic cancer for 48 countries showed that higher incidence and mortality rates among men were significantly associated with higher prevalence of smoking, alcohol drinking, physical inactivity, obesity and high cholesterol levels[27]. At the same time, pancreatic cancer rates among women were linked with higher prevalence of smoking, alcohol consumption and high cholesterol. In contrast, the correlation analysis indicated absence of association between the prevalence of diabetes mellitus and the incidence and mortality for pancreatic cancer. A recent meta-analysis involving 23 cohort studies indicated that diabetes mellitus was associated with a 52% excess risk for pancreatic cancer[28]. However, the issue of the validity of a cancer certificate always exists and the impact of variations in data quality on incidence rate cannot be ruled out, especially for pancreatic and other cancers with poorer prognosis and in older age groups[29,30]. Pancreatic cancer incidence rates in the world in 2020 indicate the possibility that there is an underestimation of the incidence rates in many countries, mainly in developing countries[2]. Many countries reported an incidence rate that was equal to the mortality rate of pancreatic cancer in 2020, while in a few countries, the mortality rate was higher than the incidence rate[2]. Besides, in many countries, cancer registries were not populational, but sometimes reported data only from urban/metropolitan area.



Our study showed unfavorable trends in pancreatic cancer incidence rates in both males and females in many countries in the world in the last three decades. The incidence was noticeably increasing throughout European countries, USA, Australia and Japan, while stable trends in incidence were noted in Canada, Sweden and Ireland. One previous study showed that pancreatic cancer incidence rates gradually increased in males and females among all ages in the USA, Canada, the Netherlands, Australia and New Zealand from the mid-1990s until 2014[31]. In the same study, a decreasing trend of pancreatic cancer incidence in males was noticed only in Iceland and Croatia, while in women there was a significant increasing trend in the incidence of pancreatic cancer in most of the countries from the 1990s onwards[31]. The pancreatic cancer incidence in both sexes in China increased continuously from 1990 to 2019[32]. The observed increasing trends in pancreatic cancer incidence could be attributed to population growth and aging, as well as changes in the prevalence of risk factors for cancer[6,33,34]. The GBD study demonstrated that there was a link between increasing trends in incidence for pancreatic

cancer and increases in development status at the national level in period 1990–2017[6]. Also, one previous study indicated that increasing trends in pancreatic cancer incidence in both sexes were correlated with socioeconomic development (measured by Human Development Index and Gross Domestic Product per capita)[35]. In the 1980s, a rapid social and economic transition from the lifestyle that characterized socialistic countries (such as countries of the former Eastern Bloc, *etc*.) to an industrialized westernized lifestyle took place[36-38]. It is hypothesized that, with a lag phase, undergoing different states of social and economic transition has contributed to the sharply increasing trends of pancreatic cancer incidence that have been observed in eastern and southern European countries, China

For the trend analysis, we presented all mortality data available from 1991 onwards, provided that there were data for at least 15 years in a row continuously. AAPC: Average annual percent change.

and Brazil since the 2000s. Based the results of the Czech MONICA and post-MONICA studies, cigarette smoking prevalence declined significantly only in males (from 45.0% in 1985 to 23.9% in 2016/17), while there was no change in the prevalence of smoking in females (from 20.9% to 25.9%) over the analyzed period[38]. Throughout the entire 30-year survey period, for both sexes significantly decreased prevalence of dyslipidemia and the consumption of meat and fat was observed, with increase in vegetable oil intake and fresh fruit and vegetables, whereas a significant increase in body mass index was observed in males only[38]. Both the incidence and mortality trends of pancreatic cancer significantly increased in China during the last decades, which could be due to the rise of the prevalence of overweight to 28.1%, diabetes to 11.2%, and smoking to 28.1% of adults: namely, China consumes about 40% of the world's total cigarettes, and that predominantly among men, with a large increase in consumption over the past few decades[32,39]. A large-scale nationwide cohort study in the Republic of Korea, which included 9 514 171 adults during a median follow-up period of 7.3 years, indicated that diabetes and alcohol consumption were associated with an increased risk of pancreatic cancer[40]. The influence of the improvement of medical imaging on the diagnosis of pancreatic cancer, that is, on the increasing trends of the incidence of pancreatic cancer during the last few decades cannot be ruled out [41].

Pancreatic cancer mortality rates across the countries showed an increasing trend in both sexes. A decreasing trend, however, was found in both sexes only in Canada and Mexico, and a level-off was observed in Denmark, Norway, Sweden, Panama, Moldova and Venezuela. With the exception of some developing countries (Latvia, Kyrgyzstan, Mauritius, Turkmenistan, Nicaragua and Colombia), in all other populations the magnitude of the increase in mortality from pancreatic cancer was higher in women. While the increased trends of pancreatic cancer mortality have long been observed in developed countries (such as the USA, Japan, Germany, France, Italy and Spain)[33], in recent years, a precipitous increase has also been reported in developing countries (such as Kyrgyzstan, Turkmenistan, Bulgaria and Serbia)[42,43]. Some of these changes have been associated with western lifestyle and environmental factors that are linked to an increased risk of pancreatic cancer occurrence (including smoking, diabetes, alcohol consumption, obesity, physical inactivity, and high-energy food intake)[8,22, 23,27,35,38,44]. International patterns in incidence and mortality trends of pancreatic cancer in the last three decades mostly reflect different phases of the smoking epidemic across countries, and among males and females[26]. In support of that, our study indicated that mortality rates from pancreatic cancer showed a slower rise among women and a drop among men in China in the last decade (from 1998 to 2012), which could be affected by reduced prevalence of tobacco consumption[44,45]. Also, significantly decreasing trends in pancreatic cancer mortality in both sexes in Mexico (especially since 2008) can partially be attributed to changes in smoking patterns which are resulting from new tobacco tax/laws which were implemented in Mexico in 2007/2008[46]. Unfortunately, due to the silent nature of disease, late diagnosis, and limited treatment options, and the metastatic potential of pancreatic cancer cells, and its poor prognosis, most pancreatic cancers are diagnosed at an advanced stage, which is not amenable to treatment[42,43]. Differences in the international patterns in incidence and mortality trends of pancreatic cancer in the last three decades could be pertinent to impel continuous efforts to identify novel risk factors (particularly the modifiable risk factors) and implement policies for more effective pancreatic cancer control[34]. Global inequalities in standard medical practices (prevention/diagnosis/therapy) and their impact on pancreatic cancer mortality have not yet been systematically explored[47].

In our study, significantly lower favorable pancreatic cancer incidence trends in the young age group (30–49 years) were observed in women compared to men in all countries. Both older age groups (50–69 and ≥ 70 years), for both men and women, generally showed similar trends in the incidence of pancreatic cancer. Other studies have reported similar results[29,30]. Similar to incidence, significantly less favorable trends in mortality of pancreatic cancer in the young age group (30–49 years) were observed in women compared to men in all countries. In both older age groups (50–69 and ≥ 70 years), both men and women generally showed similarly increasing trends in the mortality of pancreatic cancer. It is particularly promising that in males aged 30–49 years, pancreatic cancer mortality trends were falling in most of the countries. Some studies also reported an increasing trend in mortality for pancreatic cancer in the past decade, especially among women and those aged ≥ 50 years in some countries[24,28]. Although in countries where there is a significant trend in increasing incidence of pancreatic cancer, this increase was recorded at the age of ≥ 50 years. Of particular concern is the significant trend in increasing incidence of pancreatic cancer in the youngest group (30–49 years), which is registered in our study mainly in developed countries (UK, USA, Australia, France, Israel, Italy and Bulgaria). Also, although the trend in increasing mortality from pancreatic cancer was recorded at the age of ≥ 50 years, the significant trend in increasing mortality from pancreatic cancer among the youngest group (30–49 years) in women is particularly worrying (mainly in developed countries such as the USA, France, Germany, Spain and Brazil) and in males in Chile, China, Brazil and El Salvador. Although there is no unified definition, some authors defined the onset of pancreatic cancer at an age of ≤ 50 years as early onset[48,49]. Similar to our results, one study found a significantly increasing trend in incidence of pancreatic cancer among persons younger than 40 years only in women in four high-income countries (Canada, UK, France and the Netherlands)[27]. Despite the fact that some studies suggest an association with cigarette smoking, genetic factors, obesity and metabolic disorders, the

reasons for the increasing trends in incidence and mortality of early-onset pancreatic cancer are still not well understood[50-52]. Population data on tobacco use from 12 European countries revealed that in both men and women, smoking prevalence was the highest among young adults aged 25–44 years, and decreased with increasing age[50]. Results of two prospective US cohort studies indicated that established risk factors were more strongly associated with earlier-onset pancreatic cancer (*i.e.*, among those aged ≤ 60 years), while association attenuated among older people[51]. The question of whether the frequency of performing diagnostic and therapeutic procedures, as well as autopsies at a younger age has an impact on the trend in incidence and mortality from earlier-onset pancreatic cancer should also be clarified in future research[53].

However, certain comparisons of trends may not be feasible due to the unavailability or incompleteness of data in the registries from some countries. Additionally, some factors may contribute to difficulties in international comparisons, including differences in quality of data (such as variations in medical certification, the coding process, accuracy, coverage and completeness of death certification, frequency and registry of autopsies)[2]. However, the observed disparities in trends for pancreatic cancer incidence and mortality across the countries can help generate hypotheses of pancreatic cancer etiology, enable the identification of unknown risk factors, and evaluate preventive/therapy measures. Therefore, the assessment of the patterns in trends in incidence and mortality for pancreatic cancer worldwide based on available data from registries that did not cover all countries (primarily without all African and many Asian countries) is difficult, does not allow for accurate interpretation or valid generalization.

Along with either increasing or stable current incidence and mortality trends of pancreatic cancer in many countries, with the aging population and the increase in prevalence of certain risk factors (cigarette smoking, overweight/obesity, diabetes and alcohol consumption), and taking into consideration that screening for pancreatic cancer is currently not recommended, it would be difficult to expect that the UN Sustainable Development Goal of reducing mortality from cancers (hence pancreatic cancer) by one-third by 2030 can be achieved[8]. Additionally, pancreatic cancer survival is still consistently low [20]. Since the COVID-19 pandemic began there has been concern regarding the possible delay in the diagnosis/treatment of pancreatic cancer, as indicated by a recent study in Portugal[54] about the pancreatic cancer having been diagnosed at a later stage during the pandemic, which is a matter that should be elucidated in future research. In summary, the marked international differences in rates and trends in incidence and mortality of pancreatic cancer indicate the need for introducing a more effective public health approach to prevention and improvements in diagnostic and treatment practices worldwide.

This study analyzed both incidence and mortality figures of pancreatic cancer for 185 WHO member states for 2020. Our study analyzed international patterns in trends of incidence and mortality of pancreatic cancer in the last three decades by sex and age groups. One of the major strengths of our study was the use of the GLOBOCAN database and the large population-based datasets, whereby the trends analysis was conducted only for countries with quality of data that was classified as high or medium. Finally, the described international patterns and trends in pancreatic cancer incidence and mortality over time may be useful in generating hypotheses about risk factors for pancreatic cancer.

However, several possible limitations in this study should be considered. First, there is always a question of reliability and validity of cancer certificates. Also, the quality of data varied significantly from country to country. Additionally, comparison between some countries could be difficult because statistical data quality might change and differ over time. An issue of under-reporting of pancreatic cancer, particularly in developing countries, could introduce bias in the assessment of incidence and mortality trends. Availability of data for the incidence/mortality of pancreatic cancer for each country is different, and in some countries limited. Not all of the data are available for all of the years in the analyzed period (since 1991). Therefore, the data of incidence and mortality are taken for different intervals for some countries, which makes it difficult to compare trends across countries. Besides, our trend analysis did not cover countries with statistical data classified as low quality, which therefore did not allow comparisons for a number of countries. In addition, for some countries, data on pancreatic cancer were available for incidence or mortality only, so greater caution in the inference about trends is recommended. Finally, an epidemiological fallacy was an inherent limitation of this study. Possible modes of mitigation for the above-mentioned limitations include greater diagnostic accuracy of pancreatic cancer, better quality of death certification, implementation of mandatory population-based cancer registry, further reduction of the proportion of uncertain causes of death, introduction of registration of autopsies (*e.g.*, part of pancreatic cancer cases diagnosed at autopsy was missing on the death certificates), provision of survival data for pancreatic cancer patients, as well as the improvements and availability of pancreatic cancer treatment across countries[55-57]. Based on accurate assessment of epidemiological characteristics of pancreatic cancer, policy-makers could provide a better planning for funding, access to more effective treatment and care strategies, scientific and clinical advances in development of effective screening tests, improving early diagnosis and improving survival[55]. Despite these limitations, this study can help assess the international patterns in incidence and mortality trends of pancreatic cancer, which still need to be elucidated in analytical epidemiological studies in the future.

CONCLUSION

Increasing trends in pancreatic cancer incidence and mortality were observed in the last three decades in many countries, in both sexes and most age groups. Further efforts to explore the reasons of differences in international pattern of pancreatic cancer incidence and mortality could be critical for global disease control.

ARTICLE HIGHLIGHTS

Research background

Pancreatic cancer, as the one of most fatal malignancies, remains a critical issue in the global burden of disease.

Research motivation

The main motivation of this study was to describe the international patterns in incidence and mortality trends of pancreatic cancer in the last three decades. Accurate assessment of pancreatic cancer burden is crucial for more effective disease control.

Research objectives

The aim of this study was to estimate trends in incidence and mortality due to pancreatic cancer in the world in the last three decades.

Research methods

A descriptive epidemiological study was done. Pancreatic cancer incidence and mortality data were obtained from the World Health Organization database. The age-standardized rates (expressed *per* 100000) were presented. To estimate trends of incidence and mortality of pancreatic cancer, joinpoint regression analysis was used: the average annual percent change (AAPC) with the corresponding 95% confidence interval (95%CI) was calculated.

Research results

The general pattern of rising pancreatic cancer incidence and mortality was seen across countries worldwide. Out of all countries with an increase in pancreatic cancer incidence, females in France and India showed the most marked rise in incidence rates (AAPC = +3.9% and AAPC = +3.7%, respectively). Decreasing pancreatic cancer incidence trends have been observed in some countries but without significance. Out of all countries with an increase in pancreatic cancer mortality rates, Turkmenistan showed the most marked rise both in males (AAPC = +10.0%, 95%CI: 7.4%–12.5%) and females (AAPC = +6.4%, 95%CI: 3.5%–9.5%). The mortality trends of pancreatic cancer were decreasing in both sexes only in Canada and Mexico.

Research conclusions

The increasing trends in incidence and mortality from pancreatic cancer were observed across the world, particularly in developed countries. The favorable pattern in trends in incidence and mortality of pancreatic cancer was reported in only a few countries.

Research perspectives

Further research is needed to explain the cause of large international differences in incidence and mortality trends of pancreatic cancer.

FOOTNOTES

Author contributions: All authors equally contributed to this paper with conception and design of the study, data acquisition and analysis, interpretation of data, searched the literature, drafting and critical revision and editing, and approval of the final version.

Supported by Ministry of Education, Science and Technological development, Republic of Serbia, 2011-2020, No. 175042.

Institutional review board statement: This study was approved by the Ethics Committee of the Faculty of Medical Sciences, University of Kragujevac (No. 01-14321).

Informed consent statement: The study was conducted using publicly available data. No patient approvals were

sought nor required for this study. The data used for inputs and analysis were derived from public sources (such as websites, primarily). Our research question about the international trends in incidence and mortality of pancreatic cancer in last three decades was based on the number of pancreatic cancer cases and deaths in the world in last three decades. Therefore, as our model-based analysis used aggregated (not individually identifiable) data from publicly available sources, patients were not involved in the design, or conduct, or reporting or dissemination plans of the research.

Conflict-of-interest statement: All the authors report no relevant conflicts of interest for this article.

Data sharing statement: No additional data are available.

STROBE statement: The authors have read the STROBE Statement-checklist of items, and the manuscript was prepared and revised according to the STROBE Statement-checklist of items.

Open-Access: This article is an open-access article that was selected by an in-house editor and fully peer-reviewed by external reviewers. It is distributed in accordance with the Creative Commons Attribution NonCommercial (CC BY-NC 4.0) license, which permits others to distribute, remix, adapt, build upon this work non-commercially, and license their derivative works on different terms, provided the original work is properly cited and the use is non-commercial. Abstract

BACKGROUND

The clinical management and prognosis differ between benign and malignant solid focal liver lesions (FLLs), as well as among different pathological types of malignant FLLs. Accurate diagnosis of the possible types of solid FLLs is important. Our previous study confirmed the value of shear wave elastography (SWE) using maximal elasticity (Emax) as the parameter in the differential diagnosis between benign and malignant FLLs. However, the value of SWE in the differential diagnosis among different pathological types of malignant FLLs has not been proved.

AIM

To explore the value of two-dimensional SWE (2D-SWE) using Emax in the differential diagnosis of FLLs, especially among different pathological types of malignant FLLs.

METHODS

All the patients enrolled in this study were diagnosed as benign, malignant or undetermined FLLs by conventional ultrasound. Emax of FLLs and the periphery of FLLs was measured using 2D-SWE and compared between benign and malignant FLLs or among different pathological types of malignant FLLs.

RESULTS

The study included 32 benign FLLs in 31 patients and 100 malignant FLLs in 96 patients, including 16 cholangiocellular carcinomas (CCCs), 72 hepatocellular carcinomas (HCCs) and 12 liver metastases. Thirty-five FLLs were diagnosed as undetermined by conventional ultrasound. There were significant differences between Emax of malignant (2.21 ± 0.57 m/s) and benign (1.59 ± 0.37 m/s) FLLs (P = 0.000), and between Emax of the periphery of malignant (1.52 ± 0.39 m/s) and benign (1.36 ± 0.44 m/s) FLLs (P = 0.040). Emax of liver metastases (2.73 ± 0.99 m/s) was significantly higher than that of CCCs (2.14 ± 0.34 m/s) and HCCs (2.14 ± 0.46 m/s) (P = 0.002). The sensitivity, specificity and accuracy were 71.00%, 84.38% and 74.24% respectively, using Emax > 1.905 m/s (AUC 0.843) to diagnose as malignant and 23 of 35 (65.74%) FLLs with undetermined diagnosis by conventional ultrasound were diagnosed correctly.

CONCLUSION

Malignant FLLs were stiffer than benign ones and liver metastases were stiffer than primary liver carcinomas. 2D-SWE with Emax was a useful complement to conventional ultrasound for the differential diagnosis of FLLs.

Key Words: Focal liver lesions; Conventional ultrasound; Two-dimensional shear wave elastography; Differential diagnosis

Core Tip: Two-dimensional shear wave elastography (2D-SWE) could address the limitations of point SWE and provide overall elastic information in tumors and locate the stiffest part of the tumors. We used 2D-SWE with maximal elasticity to measure the stiffness of focal liver lesions (FLLs) and to explore the value of 2D-SWE in the differential diagnosis of FLLs, especially among different pathological types of malignant FLLs. Our results showed malignant FLLs were stiffer than benign ones and liver metastases were stiffer than primary liver carcinomas. 2D-SWE with Emax was useful complement to conventional ultrasound for the differential diagnosis of FLLs.

INTRODUCTION

The clinical management and prognosis differ between benign and malignant solid focal liver lesions (FLLs), and among different pathological types of malignant FLLs[1-3]. Accurate diagnosis of solid FLLs, not only as benign or malignant FLLs, but also the possible types of malignant FLLs, is important [4-6].

Ultrasound elastography, especially two-dimensional shear wave elastography (2D-SWE) which provides quantitative information about tissue stiffness, is a useful tool to differentiate malignant from benign FLLs[7,8]. Our previous study confirmed the value of SWE in the differential diagnosis between benign and malignant FLLs[9].

However, the value of SWE in the differential diagnosis among different pathological types of malignant FLLs has not been proved. Park *et al*[10] showed that cholangiocellular carcinoma (CCC) had the lowest shear wave velocity, followed by liver metastases, and hepatocellular carcinoma (HCC) had the highest shear wave velocity; whereas Gerber *et al*[11] showed that CCC had the highest stiffness and liver metastases had the lowest.

Considering the inhomogeneity of tumor stiffness (especially malignant tumors), we used maximal elasticity (Emax) as the parameter to evaluate the stiffness of FLLs and obtained promising results[9]. In the present study, we used 2D-SWE with Emax as the parameter to measure the stiffness of FLLs and to explore the value of SWE with Emax in the differential diagnosis of FLLs, especially among different pathological types of malignant FLLs.

MATERIALS AND METHODS

Study design

This was a prospective study that was approved by the institutional ethical review board of our hospital. All patients provided written informed consent before ultrasound examination.

Patients

Inpatients in the department of Hepatobiliary Surgery between November 2021 and January 2022 who met the following criteria were included: (1) One or more solid FLLs shown on conventional ultrasound with a maximal lesion depth < 8 cm; and (2) The targeted FLL showed as green on quality mode, indicating good quality of SWE. The exclusion criteria were: (1) Patients refused to join the study; and (2) No definite final diagnosis; malignant tumors except for liver metastases had to be diagnosed pathologically after surgery; benign tumors or liver metastases could be diagnosed pathologically or by contrast-enhanced ultrasound (CEUS) together with contrast-enhanced computed tomography (CT) or contrast-enhanced magnetic resonance imaging (MRI) 1 wk before or after 2D-SWE. We included 132 solid FLLs in 127 patients. The gender, age and history of malignancy were recorded.

Conventional ultrasound examination

An Acuson Sequoia diagnostic ultrasound machine (Siemens Medical Solutions, Mountain View, CA, United States) and a transabdominal 5C1 probe were used for conventional ultrasound examination. Before the examinations, all patients fasted for at least 8 h.

One ultrasound physician with > 15 years' experience in conventional ultrasound performed the hepatic ultrasound scan to detect FLLs. The length and width of every lesion were measured to calculate the volume according to the formula[12]: $V = 0.5\ LW^2$ (V: Volume; L: Length; W: Width). A diagnosis as benign, malignant or undetermined was made for each lesion by the ultrasound physician according to the ultrasound features including the number, size, shape, boundary, echogenicity and blood flow of the lesion and surrounding hepatic echogenicity.

2D-SWE examination

After conventional ultrasound examination, another ultrasound physician who was well trained in ultrasound elastography performed all the 2D-SWE examinations using the same ultrasound equipment and probe, putting no pressure on the skin through the probe. The patients were asked to lie flat on the examination bed. The targeted FLL was shown clearly on the screen and the 2D-SWE mode was activated. A region of interest (ROI) was drawn including the whole or partial tumor and some surrounding liver tissue. If the tumor showed green on quality mode (Figure 1A), it meant that the quality of the 2D-SWE image was up to standard. In velocity mode, we set the speed bar at 0.5-4.0 m/s (Figure 1B); drew two circular ROIs (with 3 mm diameter) to be placed at the stiffest site in the tumor and at the periphery of the tumor (Figure 1C). The maximum values of the two ROIs were recorded (Figure 1D) as Emax for further analysis.

Statistical analysis

SPSS version 13.0 (IBM Corporation, Chicago, IL, United States) was used for statistical analysis. $P < 0.05$ was considered statistically significant. Normal distribution using the Kolmogorov-Smirnov test was used first for measurement data. Independent sample *t* test, one way analysis of variance and least significant difference were used for data with normal distribution and the data were reported as mean ± SD. Otherwise, the Mann-Whitney or Kruskal-Wallis test was used and the data were reported as interquartile range. The cut-off point of Emax was calculated by a receiver operating characteristic curve. The enumerative data were presented as numbers and percentage and Pearson's chi-square test and Fisher's exact test were used for statistical analysis.

RESULTS

Patients and final diagnosis

There were 132 solid FLLs in 127 patients (80 men and 47 women; aged 24-77 years; mean age 54.23 ± 12.04 years) in this study, including 32 benign FLLs in 31 patients (6 focal nodular hyperplasia, 15 hemangioma and 11 diagnosed definitely as benign but without pathological results) and 100 malignant FLLs in 96 patients (16 CCCs, 72 HCCs and 12 liver metastases). The differences in age, gender and history of malignancy between the malignant and benign groups are shown in Table 1. Compared with patients with benign FLLs, patients with malignant FLLs were older and more often male. The history of malignancy had no significant difference between the two groups. The differences in age, gender and history of malignancy among three types of malignancy are shown in Table 2. The age and gender had no significant differences among the three groups, although the age of patients with liver metastases was significantly higher than that of patients with HCC. Patients with liver metastases were more often

Figure 1 Two-dimensional shear wave elastography images in patients with focal liver lesions. A: Tumor shown on quality mode as green indicated that the quality of two-dimensional shear wave elastography image was up to standard; B: Tumor shown in velocity mode, speed bar set at 0.5-4.0 m/s; C: Two circular regions of interest (ROIs, with 3 mm diameter) placed at the stiffest site in the tumor and at the periphery of tumor; D: Maximum values of the two ROIs recorded as maximal elasticity.

had a history of malignancy, compared with patients with primary liver cancer, including HCC and CCC.

Conventional ultrasound results

Volume of benign FLLs (20.73-113.69 cm^3) and malignant FLLs (30.56-79.62 cm^3) had no significant difference ($Z = 0.263$, $P = 0.793$). Volume of CCCs (39.58-120.22 cm^3), HCCs (26.34-75.69 cm^3) and liver metastases (32.76-41.67 cm^3) had no significant difference ($\chi^2 = 1.869$, $P = 0.393$). For 32 benign FLLs, 12 were diagnosed as benign, 18 as undetermined and two were misdiagnosed as malignant. For 100 malignant FLLs, 81 (12 CCCs, 59 HCCs and 10 metastases) were diagnosed correctly as malignant, 17 were undetermined (4 CCCs, 11 HCCs and 2 liver metastases) and 2 were misdiagnosed as benign (both HCCs). The undetermined rate of conventional ultrasound was 26.52% (35/132). For the FLLs with definite diagnosis by conventional ultrasound, the sensitivity, specificity and accuracy were 85.71%, 97.59% and 95.88%, respectively.

2D SWE results

Comparisons between benign and malignant FLLs: The differences in 2D-SWE results between benign and malignant FLLs are shown in Table 3. Emax of malignant FLLs were significantly higher than those of benign FLLs. Emax of the periphery of malignant FLLs were significantly higher than those of benign FLLs. The cut-off point of Emax of the tumors was 1.905 with AUC 0.843 (Figure 2). The sensitivity, specificity and accuracy were 71.00%, 84.38% and 74.24% respectively using Emax > 1.905 m/s for diagnosis as malignant (Figure 3). For 35 FLLs with undetermined diagnosis by conventional ultrasound, 23 (65.71%) FLLs including 14 of 18 benign and nine of 17 malignant FLLs were diagnosed correctly.

Comparisons among different types of malignant FLLs: The differences in 2D-SWE results among different types of malignant FLLs are shown in Table 4. There were significant differences among Emax of CCCs, HCCs and liver metastases. Emax of liver metastases was significantly higher than that of CCCs and HCCs. There were no significant differences among Emax values of the periphery of CCCs, HCCs and liver metastases.

DISCUSSION

In this study, we explored the value of 2D-SWE using Emax as the quantitative parameter in the differential diagnosis of FLLs, especially among different pathological types of malignant FLLs. Our results showed that malignant FLLs were stiffer than benign ones and liver metastases were stiffer than primary liver carcinomas. 2D-SWE with Emax was a useful complement to conventional ultrasound for the differential diagnosis of FLLs.

The comparison of patients' basic information showed that compared with patients with benign FLLs, patients with malignant FLLs tended to be older, male and have a history of malignancy. Among three different types of malignant FLLs, the distribution of patients' age and gender had no significant difference, while patients with liver metastases were more likely to have a history of malignancy. These results were similar to those in previous studies[13].

Conventional ultrasound is well recognized as the first imaging choice for the screening and diagnosis of FLLs[14]. However, the diagnostic efficiency of conventional ultrasound for the differential diagnosis of benign and malignant FLLs or among different pathological types of malignant FLLs was not good enough. For some FLLs, the diagnosis using conventional ultrasound alone is difficult[15]. That is one of the reasons for the development of new ultrasound technologies, including CEUS and ultrasound elastography. In this study, we diagnosed FLLs as benign, malignant and undetermined by conventional ultrasound and 35 of 132 (26.52%) were diagnosed as undetermined. Further diagnosis using other imaging methods was necessary.

CEUS could provide similar or better diagnostic performance for the differential diagnosis of FLLs without radiation and iodine allergy, compared with contrast enhanced CT[16]. CEUS has particularly high value for the differential diagnosis of complex cystic and cysticlike FLLs[17,18]. In this study, for some benign tumors or liver metastases without pathological diagnosis, the combined results of CEUS together with contrast enhanced CT or contrast enhanced MRI were as final. Compared with CEUS, ultrasound elastography has the advantages of being less expensive and less time-consuming[19].

Our previous study using virtual touch tissue quantification imaging with Emax has proven its value in the differential diagnosis between benign and malignant FLLs[9]. 2D-SWE is one of the most advanced elastography techniques and could provide overall elastic information in tumors and locate the stiffest part[20]. In this study, the cutoff point of Emax was 1.905, which was similar to our previous result[9]. Twenty-three of 35 (65.71%) FLLs with undetermined diagnosis by conventional ultrasound were diagnosed accurately using 2D-SWE with Emax. If FLLs could be diagnosed confidently using conventional ultrasound, no further examination was needed; otherwise, 2D-SWE with Emax could be a useful complement to conventional ultrasound and improve the diagnostic efficiency.

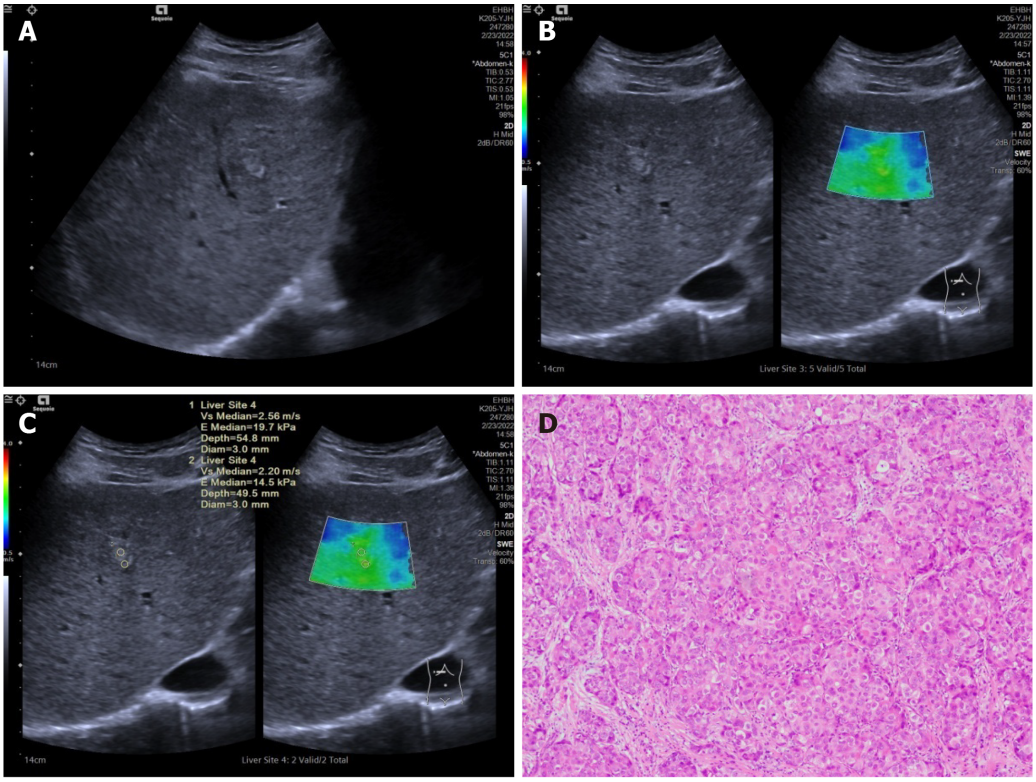
Table 3 Differences in two-dimensional shear wave elastography results between benign and malignant focal liver lesions

	Emax of tumors (m/s)	Emax of periphery of tumors (m/s)
Malignant (n = 100)	2.21 ± 0.57	1.52 ± 0.39
Benign (n = 32)	1.59 ± 0.37	1.36 ± 0.44
t	5.781	2.073
P value	0.000	0.040

Emax: Maximal elasticity.

Table 4 Differences of two-dimensional shear wave elastography results among different types of malignant focal liver lesions

	Emax of the tumors (m/s)	Emax of the periphery of tumors (m/s)
CCCs (n = 16)	2.14 ± 0.34[a]	1.56 ± 0.39
HCCs (n = 72)	2.14 ± 0.46[b]	1.54 ± 0.37
Liver metastases (n = 12)	2.73 ± 0.99	1.36 ± 0.46
F	6.418	1.299
P value	0.002	0.277



[a]P = 0.005 *vs* liver metastases.
[b]P = 0.001 *vs* liver metastases.
Emax: Maximal elasticity; CCCs: Cholangiocellular carcinomas; HCCs: Hepatocellular carcinomas.

Figure 2 Receiver operating characteristic curve of maximum elasticity for malignant and benign focal liver lesions.

The elastic differences among different types of malignant FLLs are still uncertain. Our results showed that the stiffness of liver metastases was significantly higher than that of primary liver tumors, including CCCs and HCCs, while the stiffness of CCCs and HCCs had no significant differences. This was similar to the study of Park *et al*[21], which showed that the stiffness of HCCs was significantly lower than that of liver metastases. However, some other studies had the opposite results[10,11]. One

Figure 3 Ultrasound and pathologic images in a 51-year old male patients with hepatocellular carcinomas. A: A tumor shown on conventional ultrasound were diagnosed as undetermined; B: Tumor shown as stiffer, compared with surrounding liver tissue in two-dimensional shear wave elastography velocity mode; C: Maximal elasticity of the tumor was higher than 1.905 m/s and the tumor was diagnosed as malignant; D: Pathological examination confirmed the tumor as hepatocellular carcinomas (HE, × 200).

study reported that CCCs had the lowest stiffness and HCCs the highest stiffness[10]. Another study found that CCCs had the highest stiffness and liver metastases the lowest[11]. One important reason for the conflicting results is that the sample number in every study was not large enough, and it is necessary to carry out further studies with large samples to confirm our results.

There were some limitations to our study. First, as mentioned above, only a few cases of CCCs and liver metastases were included. Second, no pathological methods were used to confirm the stiffness of the tumors and explain the differences among different pathological types of malignant FLLs.

CONCLUSION

In conclusion, malignant FLLs were stiffer than benign FLLs and liver metastases were stiffer than primary liver carcinomas. 2D-SWE with Emax was a useful complement to conventional ultrasound for the differential diagnosis of FLLs.

ARTICLE HIGHLIGHTS

Research background

Conventional ultrasound is the first imaging choice for liver diseases with the diagnostic efficiency not good enough, which promotes the development of new ultrasound technologies, such as contrast enhanced ultrasound and ultrasound elastography. Two dimensional shear wave elastography (2D-SWE) is convenient, less time-consuming and inexpensive. SWE plays an important role in the assessment of liver fibrosis and in the differential diagnosis of benign and malignant focal liver lesions (FLLs). However, its value for the differential diagnosis among different types of malignant FLLs has not been proved.

Research motivation

Though the value of SWE for the differential diagnosis between malignant and benign FLLs was not

widely recognized, our previous study showed promising results using maximal elasticity (Emax) as the parameter to differentiate malignant FLLs from benign ones. As the clinical management and prognosis of different pathological types of malignant FLLs are different, it is important to diagnose accurately of the possible pathological types. So, it was necessary to explore the value of 2D-SWE with Emax in differential diagnosis of different pathological types of malignant FLLs.

Research objectives

We aim to explore the value of 2D-SWE using Emax in the differential diagnosis of FLLs, especially among different pathological types of malignant FLLs.

Research methods

In this study, we diagnosed all FLLs as benign, malignant and undetermined using conventional ultrasound. And the stiffness of FLLs and the periphery of FLLs were evaluated using 2D-SWE and the quantitative parameter Emax. Emax of FLLs and the periphery of FLLs were compared between benign and malignant FLLs or among different pathological types of malignant FLLs.

Research results

There were totally 132 FFLs in 127 patients enrolled in the study, including 32 benign FLLs, 16 cholangiocellular carcinomas (CCCs), 72 hepatocellular carcinomas (HCCs) and 12 liver metastases. Thirty-five FLLs were diagnosed as undermined by conventional ultrasound. Emax of malignant FLLs (2.21 ± 0.57 m/s) were significantly higher than those of benign FLLs (1.59 ± 0.37 m/s) (P = 0.000). Emax of the periphery of malignant FLLs (1.52 ± 0.39 m/s) were significantly higher than those of benign FLLs (1.36 ± 0.44 m/s) (P = 0.040). The cut-off point of Emax of the tumors was 1.905 with AUC 0.843. The sensitivity, specificity and accuracy were 71.00%, 84.38% and 74.24% respectively using Emax > 1.905 m/s for diagnosis as malignant and 23 of 35 (65.74%) FLLs with undetermined diagnosis by conventional ultrasound were diagnosed correctly. Emax of liver metastases (2.73 ± 0.99 m/s) was significantly higher than that of primary liver carcinomas, including CCCs (2.14 ± 0.34 m/s) and HCCs (2.14 ± 0.46 m/s) (P = 0.002).

Research conclusions

Malignant FLLs were stiffer than benign ones and liver metastases were stiffer than primary liver carcinomas. 2D-SEW with Emax was a useful complement to conventional ultrasound for the differential diagnosis of FLLs.

Research perspectives

In this study, we demonstrated the differences of 2D-SWE with Emax between benign and malignant FLLs and among different pathological types of malignant FLLs. Prospective study to explore the value of 2D-SWE with Emax in the evaluatation the different stiffness of liver metastases from different sources or the different stiffness of HCC with different microvascular invasion grade will be necessary.

Abstract

BACKGROUND

Timely differentiation of biliary atresia (BA) from other infantile cholestatic diseases can impact patient outcomes. Additionally, non-invasive staging of fibrosis after Kasai hepatoportoenterostomy has not been widely standardized. Shear wave elastography is an ultrasound modality that detects changes in tissue stiffness. The authors propose that the utility of elastography in BA can be elucidated through meta-analysis of existing studies.

AIM

To assess the utility of elastography in: (1) BA diagnosis, and (2) post-Kasai fibrosis surveillance.

METHODS

A literature search identified articles that evaluated elastography for BA diagnosis and for post-Kasai follow-up. Twenty studies met criteria for meta-analysis: Eleven for diagnosis and nine for follow-up post-Kasai. Estimated diagnostic odds ratio (DOR), sensitivity, and specificity of elastography were calculated through a random-effects model using Meta-DiSc software.

RESULTS
Mean liver stiffness in BA infants at diagnosis was significantly higher than in non-BA, with overall DOR 24.61, sensitivity 83%, and specificity 79%. Post-Kasai, mean liver stiffness was significantly higher in BA patients with varices than in patients without, with DOR 16.36, sensitivity 85%, and specificity 76%. Elastography differentiated stage F4 fibrosis from F0-F3 with DOR of 70.03, sensitivity 96%, and specificity 89%. Elastography also differentiated F3-F4 fibrosis from F0-F2 with DOR of 24.68, sensitivity 85%, and specificity 81%.

CONCLUSION
Elastography has potential as a non-invasive modality for BA diagnosis and surveillance post-Kasai. This paper's limitations include inter-study method heterogeneity and small sample sizes. Future, standardized, multi-center studies are recommended.

Key Words: Biliary atresia; Cholestasis; Hepatic portoenterostomy; Fibrosis; Esophageal and gastric varices; Elasticity imaging techniques

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Ultrasound elastography is an emerging, non-invasive imaging modality to detect organ stiffness. It may be a useful tool in biliary atresia (BA) diagnosis and post-Kasai fibrosis surveillance. In a meta-analysis of twenty existing studies (eleven for diagnosis and nine for follow-up), this paper shows that mean liver stiffness is significantly higher in BA patients compared to non-BA patients at time of diagnosis. Post-Kasai, elastography can differentiate between early and advanced fibrosis as well as help to discern the presence or absence of varices. While there are limitations to this analysis, elastography shows great promise for its utility as a non-invasive modality for BA patients.

INTRODUCTION

Biliary atresia (BA) is a progressive, fibroinflammatory disease of the biliary system that exclusively affects infants. It accounts for about 30% of all cases of prolonged cholestasis in the first three months of life[1]. Its incidence is estimated to be approximately 1:10000-19000 live births, with increased prevalence in East Asian countries to up to 1:2700[2]. The initial clinical manifestations include progressive jaundice, deep-colored urine, light colored stools, and an increase in conjugated serum bilirubin levels. The similarity in clinical presentation and blood biochemistry results between patients with BA and those with other infantile cholestatic liver diseases represents a great challenge to clinicians in accurately establishing a final diagnosis in a timely fashion. Early identification of BA in an infant with cholestatic jaundice is crucial, as the Kasai portoenterostomy (KPE) procedure may help restore bile flow and prevent the otherwise rapid progression to biliary cirrhosis. A BA outcomes meta-analysis by Jimenez-Rivera *et al*[2] included fourteen studies that focused on native liver survival (NLS), all of which reported improved NLS when KPE was performed at an earlier age. Given its progressive nature, BA is the most common indication for liver transplantation in the pediatric population, with NLS ranging from 24.0% to 52.8% at ten years post-KPE[2]. Patients with BA who have undergone KPE need close clinical monitoring to assess for signs of chronic liver disease progression, particularly as they approach potential need for liver transplant. Currently, there are no widely accepted, validated non-invasive tests to pre-operatively diagnose BA nor to evaluate for progressive fibrosis after KPE.

While ultrasound findings, such as absence of a contractile gall bladder after feeding or the presence of a triangular cord sign, can be suggestive of BA, ultrasound alone is not diagnostic[3]. In order to diagnose BA, a liver biopsy is performed to assess for the histopathologic signs of biliary obstruction, portal edema, and fibrosis[4]. When performed at age 60 d or less, liver biopsy is 96.4% sensitive for the diagnosis of BA[3]. The progressive nature of the disease makes it imperative that a diagnosis is made as early as possible. The gold standard test to confirm BA is a formal cholangiogram. Assessment for progression of chronic liver disease post-KPE is usually achieved by the constellation of findings on laboratory and radiologic testing as well as consideration for repeat liver biopsy and/or upper

gastrointestinal endoscopy, with no standardized guidelines for non-invasive staging of hepatic fibrosis nor timing for endoscopic evaluation for potential variceal evolution. Invasive procedures carry risks, both procedural as well as those related to sedation or anesthesia[4]. Delays at each juncture, both in diagnosis and in post-KPE surveillance, can have a potentially detrimental impact on patient outcome.

Ultrasound elastography (UE) is an emerging imaging modality that uses applied force *via* ultrasound probe to measure the elastic properties of tissue[5,6]. UE can be classified into strain imaging and shear wave imaging. Strain imaging relies on a normal external force (push) or intrinsic forces (*i.e.*, respiration or cardiovascular movement) within the body. For this reason, strain imaging is difficult to quantify and reproduce, particularly in deeper organs, leading to limited applicability in the liver. As a result, strain imaging was not the focus of this analysis[7,8].

Shear wave imaging, also called shear wave elastography (SWE) utilizes a dynamic stress and can be further classified into transient elastography (TE), point shear wave elastography (pSWE; also called VTQ or Virtual Touch Quantification on some platforms), and two-dimensional shear wave elastography (2D-SWE; also called VTIQ or Virtual Touch IQ on some platforms)[8,9]. TE, which is performed using the FibroScan (Echosens, Paris, France) system, utilizes a mechanical punch to generate forces and measure unidirectional pressure waves[5]. pSWE and 2D-SWE differ from TE in that they utilize B mode ultrasound imaging guidance, which enables direct visualization of tissue, as well as an acoustic radiation force impulse (ARFI) in order to measure tissue stress. pSWE enables the measurement of average shear wave speed within a region of interest while 2D-SWE uses multiple foci of tissue displacement along an axis to generate a quantitative map of shear wave speed[5].

SWE has been studied extensively in adult liver literature with studies in pediatric liver disease emerging only recently[6]. And yet, while multiple authors have addressed the utility of SWE for diagnosis and management in BA, there have been no large-scale studies nor meta-analyses on this modality. The aim of this meta-analysis is to evaluate the utility of SWE in: (1) the differentiation of BA from other cholestatic liver diseases of infancy, and (2) the assessment of fibrosis progression in post-KPE follow-up.

MATERIALS AND METHODS

This review was conducted in strict accordance with the Cochrane handbook of systematic reviews of interventions[10]. We followed the Preferred Reporting Items for Systematic Review and Meta-Analysis of Diagnostic Test Accuracy studies (PRISMA-DTA statement)[11]. The review was publicly registered with the Open Science Framework (OSF). The statistical analysis was performed by co-authors H.A., who has over four years as a biostatistician in a clinical research organization, and M.L., who is a clinical research coordinator employed by the University of Chicago.

Search strategy and eligibility criteria

PubMed, Scopus, Web of Science, EBSCO, and Cochrane Central were searched for English language studies with information on BA and elastography from 2010 to 2021. Two of the authors performed the literature search using the keywords: “Elastography” AND “biliary atresia”.

Full texts were reviewed to select eligible studies for meta-analysis. Studies were included if the following criteria were met: (1) The study used SWE to differentiate BA from other cholestatic liver diseases of infancy; (2) the study used SWE in the follow-up of patients with BA for the development of fibrosis/cirrhosis post-KPE; and (3) the study assessed the accuracy of SWE for the diagnosis or follow-up of liver fibrosis based on the cut-off point for liver stiffness and/or spleen stiffness values.

Exclusion criteria were as follows: (1) Full text article was not available and/or abstract and article were not available in English; (2) the study was not specific to BA and/or did not utilize SWE (3) the study evaluated the accuracy of SWE combined with other diagnostic methods; (4) the study used SWE as a reference test to study novel biomarkers; and (5) the study was a review article, letter to the editor, case report, editorial, case series, or consensus statement. Only studies with reliable data for extraction and analysis were included in the meta-analysis.

Data extraction

Two authors independently reviewed and extracted the data from each included study. Data were extracted for study characteristics (*e.g.*, first author and year of publication, study period, study setting, study design, and sample size), baseline characteristics of the included patients (*e.g.*, age of patients, laboratory date, age at diagnosis), and diagnostic data (*e.g.*, sensitivity, specificity, predictive values).

Risk of bias assessment

Two researchers assessed the risk of bias of studies included using version 2 of the Quality Assessment of Diagnostic Test Accuracy Studies (QUADAS-2) tool[12]. QUADAS-2 examines seven items on the representation of patient spectrum, selection criteria, reference standard, verification bias, timing, and study withdrawals. Both reviewers scored the tool independently; all disagreements were discussed and consensus was reached.

Data analysis

Heterogeneity was assessed by visual inspection of the forest plots and measured by I-square and Chi-Square tests. In case of significant heterogeneity ($P < 0.1$), a random effect model was used. Continuous data were pooled as standardized mean difference (SMD) in a meta-analysis model using inverse variance method with the respective 95% confidence intervals. We used Comprehensive Meta Analysis (CMA, United States) software version 3.3.070 for windows. Methods described in reference[13] were utilized to compute missing standard deviations. The diagnostic accuracy indicators of each test were pooled as sensitivity, specificity, and diagnostic odds ratio (DOR) with the corresponding 95% confidence intervals by the DerSimonian-Laird random effect model using MetaDiSc Beta-1.4 software. In addition, the Summary Receiver Operating Characteristic (SROC) curve was used for the evaluation of diagnostic tests and represents the relationship between true positive and negative rates considering the varying diagnostic thresholds among studies. The summary of the test performance was represented with an AUC of 1.0 (100%) indicating perfect discriminatory ability to distinguish BA from non-BA.

Seven studies used SWE machinery that reported results in units of m/s as opposed to kPa, with four being evaluated for diagnostic test accuracy[14-18] and two for utility of SWE for follow-up[19,20]. Values reported in m/s were converted to kPa as per reference[8] (Supplementary material).

RESULTS

Electronic search yielded 243 studies with 42 identified as potentially meeting inclusion criteria (Figure 1). Full text articles were retrieved and assessed for final eligibility. After the review of all full text articles, 22 were excluded due to study design and unreliable data for extraction, the use of SWE as an adjunct to the primary study of a novel biomarker, and subject comparison to healthy controls (as opposed to other cholestatic infants). Eleven studies on the utility of SWE in accurately differentiating BA from other cholestatic liver diseases of infancy met criteria for inclusion, as well as nine studies that evaluated the utility of SWE in assessing and monitoring the development of hepatic fibrosis/cirrhosis post-KPE. The studies included were mostly single center, retrospective analyses conducted in infants and children (age 0-18 years) and published in peer-reviewed journals between 2010 and 2021. Detailed individual study characteristics are presented in Table 1.

The overall quality of the included studies assessed by the QUADAS-2 (Figure 2), was moderate to high. All analyzed studies were found to have low risk of bias in five or more of the seven items, with the exception of[21], which showed unclear risk of bias in two of seven items and high risk of bias in patient selection. Unclear risk of bias was reported in patient selection due to lack of clear selection criteria in several studies. Potential risk of bias in the index test was recorded in several studies due to lack of reporting on blinding relative to reference standard results. Potential bias in reference standards emerged due to the use of multiple different reference standards (surgical exploration, intraoperative cholangiography, liver biopsy) with possibility for incorrect classification of BA. Finally, bias in the flow and timing was primarily due to a lack of reported details in some of the included studies.

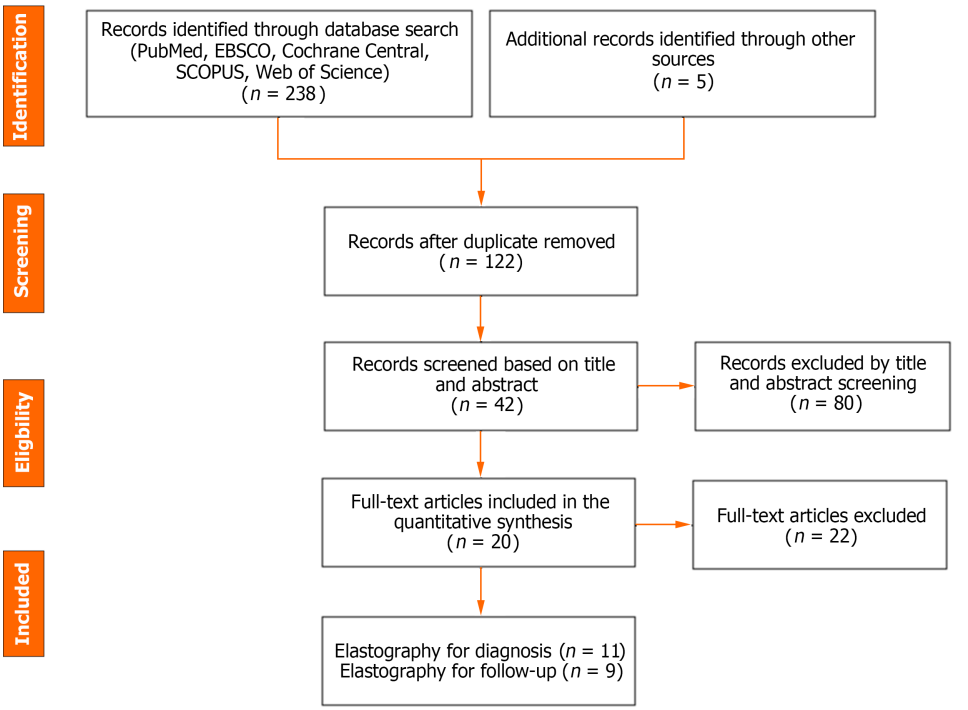
SWE for the diagnosis of BA

Data on SWE for distinguishing BA from other cholestatic neonatal liver diseases were collected from 11 studies with 1307 total patients (560 with BA and 747 without BA). The mean liver stiffness value was significantly higher in the BA group compared to the non-BA group (overall SMD = 2.30 kPa, 95%CI: 1.69, 2.90, $P < 0.0001$). Pooled studies were heterogeneous ($P < 0.01$, $I^2 = 94\%$) (Figure 3). Of the 11 studies included, five reported on performing diagnostic test analysis using liver biopsy as the reference test, one study[22] used surgical exploration or cholangiography, and the reference was not specified in another[16].

The forest plot of sensitivity and specificity for the diagnostic performance of the liver stiffness value measured by SWE for differentiating BA from other etiologies of neonatal cholestasis is shown in Figure 4A. The pooled sensitivity was 83% (95%CI: 80%, 86%) and specificity was 79%, (95%CI: 76%, 82%). The SROC curves of SWE for the diagnosis of BA are illustrated in Figure 4B. The SROC curve was symmetric, and the AUC was 0.91, Q was 0.84 (SE = 0.02). The DOR was 24.61, (95%CI: 12.74, 47.53, $I^2 = 72.4\%$) as shown in Figure 4C. Two of the 11 articles did not report a cut-off value for differentiating between BA and non-BA[14,15] and were excluded from this analysis.

SWE for the follow-up of patients with BA

Data on SWE to assess liver disease progression in post-KPE follow-up were collected from nine studies including 327 total patients [101 patients with varices, 124 patients without varices, 41 patients with fibrosis (F0-F2), and 61 patients with fibrosis (F3-F4)]. Fibrosis stage is reported *via* METAVIR standards, a scale from F0 to F4 where F0 shows no signs of histologic fibrosis, F2 represents moderate fibrosis with few bridges/septa, F3 is numerous septa without cirrhosis, and F4 signifies cirrhosis.



The mean liver stiffness value was significantly higher in patients with varices in comparison to patients without varices (overall SMD 1.38 kPa, 95%CI: 1.02, 1.74, $P < 0.00001$). Pooled studies were homogenous ($P = 0.29$, $I^2 = 19\%$) (Figure 5A). Only three studies reported data on the diagnostic

Table 1 Main characteristics of studies included in the meta-analysis

Ref.	Country	Study design	Elastography Method; machine; probe, if specified	Reference standard	Sample size	Type of patient	Main finding
Diagnosis							
Hanquinet *et al* [14], *Pediatric Radiology*, 2015	Switzerland	Single center retrospective analysis	pSWE (VTQ); Acuson S2000 or S3000 (Siemens Healthcare, Erlangen, Germany)	Liver biopsy; Cholangiogram	20	Cholestatic infants; mean age 52.1 d	Utilizing SWE in addition to standard abdominal ultrasound can provide useful information on liver fibrosis to aid in the diagnosis of BA
Leschied *et al* [15], *Pediatric Radiology*, 2015	USA	Prospective cohort	pSWE (VTQ) and 2D-SWE (VTIQ), Acuson S3000 (Siemens Healthcare, Erlangen, Germany); 9L4 Transducer	Liver biopsy; Cholangiogram	11	Infants with suspected liver disease; mean age 3.8 mo	Shear wave speeds were significantly higher in children with BA than those without
Wang *et al*[31], *Journal of Ultrasound Medicine*, 2016	China	Single center case control	pSWE; Aixplorer (SuperSonic Imagine SA, Aix-en-Provence, France); L15-4 linear probe	KPE	38	Cholestatic infants age 16 to 140 d	Mean shear wave speeds were higher for BA patients than non-BA cholestatic patients and control patients
Zhou *et al* [22], *European Radiology*, 2017	China	Single center prospective analysis	pSWE; Aixplorer (SuperSonic Imagine SA, Aix-en-Provence, France); SL15-4 linear array transducer	Liver biopsy; Cholangiogram; surgical exploration	172	Cholestatic infants, age 2 to 140 d	SWE is useful to differentiate BA from non-BA; its performance does not outperform grey scale ultrasound
Wu *et al*[32], *Hepatology*, 2018	Taiwan	Single center prospective analysis	TE; FibroScan 502 Touch (Echosens, Paris, France); S1 probe	Liver biopsy; cholangiogram	48	Cholestatic infants, age 35 to 61 d	Liver stiffness assessment during the work up of cholestatic infants may facilitate diagnosis of BA
Dillman *et al*[16], *Journal of Pediatrics*, 2019	USA	Multiple center prospective analysis	2D-SWE (VTIQ) and pSWE (VTQ); Acuson S2000 or S3000 (Siemens Healthcare, Erlangen, Germany); 9L4 linear transducer probe	Not specified	41	Cholestatic infants, age 24 to 52 d	SWE and GGT can help discriminate BA from other causes of cholestasis
Duan *et al*[33], *BioMed Research International*, 2019	China	Single center case control	2D-SWE; TUS-Aplio 500 (Canon Medical Systems, Tokyo, Japan); 14L5 linear array probe	Liver biopsy; KPE	138	Cholestatic infants, age 5-90 d	SWE can help distinguish BA from other cholestatic diseases; the diagnostic specificity increases when combined with grey-scale ultrasound
Chen *et al*[17], *European Radiology*, 2020	China	Single center multiple method (prospective and retrospective) analysis	pSWE (VTQ); Acuson S2000 (Siemens Healthcare, Erlangen, Germany); 4-9MHz linear transducer	Liver biopsy; cholangiogram	308 in subgroup 1; 187 in subgroup 2	Cholestatic infants, age under 100 d	Shear wave speed, coupled with presence of triangular cord sign, provided moderate-to-high accuracy for BA diagnosis. This study also found high diagnostic performance in a risk stratification model built on five predictors (shear wave speed, triangular cord sign, GGT, abnormal gallbladder, clay-colored stool)
Liu *et al*[18], *International Journal of Clinical Practice*, 2020	China	Single center retrospective analysis	2D-SWE (VTIQ) and pSWE (VTQ); Acuson OXANA2 (Siemens Healthcare, Erlangen, Germany); 3-5.5 MHz-6C1 convex and 4-9MHz 9L4 linear array probe	Surgical exploration	59	Cholestatic infants, age 25 to 141 d	VTQ and VTIQ can help distinguish BA from non-BA in cholestatic infants; VTIQ has higher sensitivity and specificity than VTQ
Shen *et al*[34], *BMC Pediatrics*, 2020	China	Single center retrospective analysis	pSWE; Aixplorer (SuperSonic Imagine SA, Aix-en-	Not specified	282	Cholestatic infants, age under 120 d	Liver stiffness measurements and GGT values have the potential to decrease rates of BA

			Provence, France); L15-4 linear probe				misdiagnosis
Wang *et al*[35], *Academic Radiology*, 2020	China	Single center prospective analysis	2D-SWE; Aixplorer (SuperSonic Imagine SA, Aix-en-Provence, France); linear probe	Liver biopsy; Cholangiogram	294	Cholestatic infants, age under 70 d	Age, gallbladder morphology, and liver elasticity incorporated together into a nomogram shows an improved predictive value for BA diagnosis
Follow-up							
Chongsrisawat *et al*[36], *BMC Gastroenterology*, 2011	Thailand	Single center prospective analysis	TE; FibroScan 502 Touch (Echosens, Paris, France)	Endoscopy	73	BA patients after KPE, mean age 9.11 yr	TE is useful for predicting the presence of EV/GV in BA patients post-KPE
Colecchia *et al* [37], *Digestive and Liver Disease*, 2011	Italy	Single center prospective analysis	TE; FibroScan (Echosens, Paris, France)	Endoscopy	31	BA patients after KPE, age 4 to 25 yr	Non-invasive studies, such as liver stiffness measurement, can predict the presence of EV in BA patients post-KPE
Shin *et al*[38], *Journal of Ultrasound Medicine*, 2014	South Korea	Single center retrospective analysis	TE; FibroScan 502 Touch (Echosens, Paris, France); S or M probe	Liver biopsy	47	BA patients, mean age 60 d	TE may be a useful, non-invasive method for diagnosing severe fibrosis and cirrhosis; may predict outcomes before surgery or liver biopsy in infants with BA
Shen *et al*[39], *World Journal of Gastroenterology*, 2015	China	Single center retrospective analysis	TE; FibroScan (Echosens, Paris, France); S probe	Liver biopsy	31	BA patients, age 34 to 121 d	TE can be a useful, non-invasive technique to assess liver fibrosis in children with BA. The cut-off value of 15.15 kPa can distinguish cirrhotic from non-cirrhotic patients
Chen *et al*[40], *Nature Scientific Reports*, 2016	China	Single center retrospective analysis	2D-SWE; Aixplorer (SuperSonic Imagine SA, Aix-en-Provence, France); SC-1 curvilinear probe	Liver biopsy	24	BA patients after KPE, mean age 6.6 yr	2D-SWE has more promise as a means of assessing liver fibrosis in BA patients than APRI or FIB-4 scoring
Tomita *et al*[20], *Pediatric Radiology* , 2016	Japan	Single center prospective analysis	pSWE (VTQ); Acuson S2000 (Siemens Healthcare, Erlangen, Germany); 4C1 probe	Liver biopsy; endoscopy	28	BA patients, age 0.1 to 33.6 yr	Liver and spleen stiffness measured *via* ARFI has potential as a non-invasive marker of liver fibrosis and esophageal varices in BA patients
Sintusek *et al*[41], *Journal of Pediatric Gastroenterology and Nutrition*, 2019	Thailand	Single center prospective analysis	TE; FibroScan Compact 530 (Echosens, Paris, France); S or M probe	Endoscopy	51	BA patients after KPE, mean age 10.63 yr	Spleen stiffness can predict the presence of esophageal varices in children with BA; combination of spleen and liver stiffness measurements to diagnose varices increases diagnostic yield
Yokoyama *et al* [19], *Hepatology Research*, 2019	Japan	Single center prospective study	2D-SWE; Aplio i900 (Canon Medical Systems, Tokyo, Japan); i8CX1 transducer	Endoscopy	34	BA patients after KPE, age 1034 to 3940 d	Spleen stiffness (measured *via* 2D-SWE) is the most accurate predictor of high risk esophageal/gastric varices in BA patients
Srisuwan *et al* [21], *Siriraj Medical Journal*, 2021	Thailand	Single center cross-sectional study	TE; FibroScan 502 Touch (Echosens, Paris, France); S or M probe	Endoscopy	20	BA patients after KPE, age 2.3 to 21.0 yr	There is correlation between liver stiffness measurement and clinical/radiological evidence of portal hypertension. TE can predict presence of esophageal varices with high sensitivity

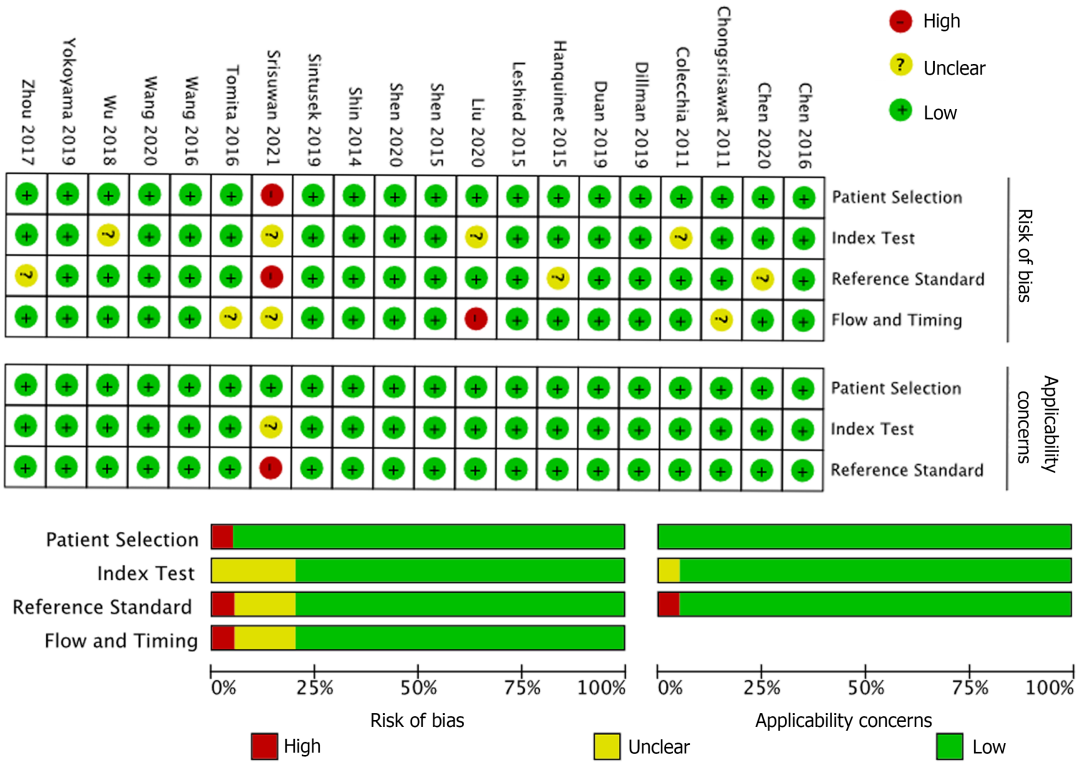
Figure 1 Preferred Reporting Items for Systematic Review and Meta-Analysis flow diagram of the meta-analysis.

performance of spleen stiffness measured by SWE for predicting the presence of varices in patients with BA post-KPE. The mean spleen stiffness value was significantly higher in patients with varices when compared to patients without varices (overall SMD 1.66 kPa, 95%CI: 1.19, 2.14, $P < 0.00001$). Pooled studies were homogenous ($P = 0.42$, $I^2 = 0\%$) (Figure 5B).

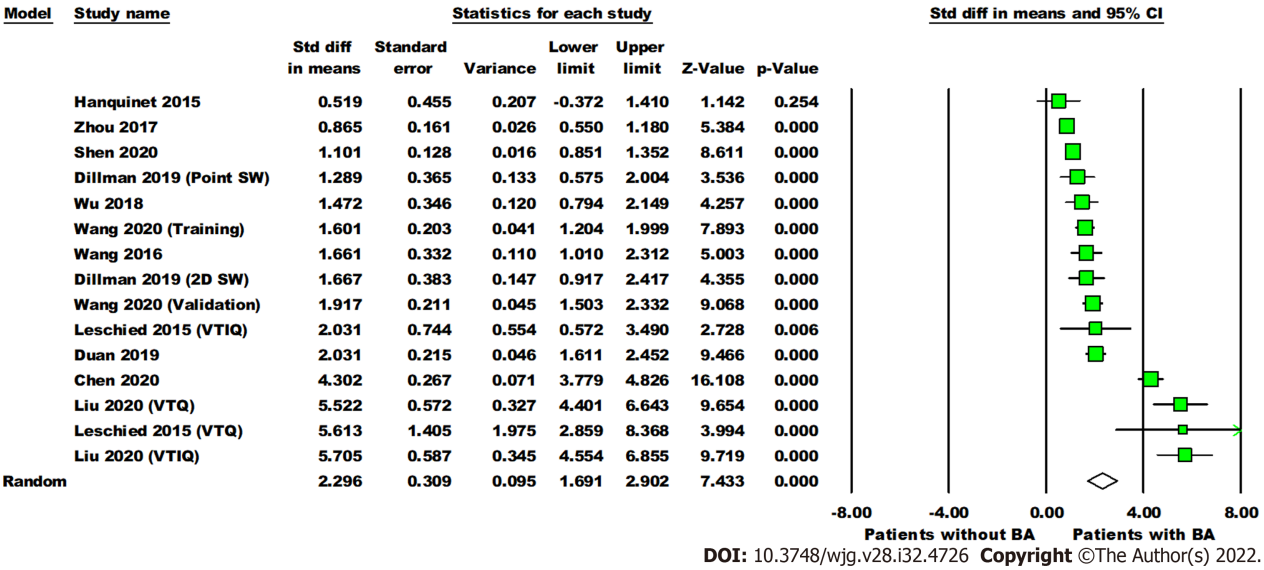
The forest plot of the sensitivity and specificity for the diagnostic performance of liver stiffness value measured by SWE to predict the presence of varices is shown in Figure 6A. The pooled sensitivity was 85% (95%CI: 77%, 91%), while the specificity was 76%, 95%CI (67%, 83%). Illustrated in Figure 6B, the SROC curve was symmetric and the AUC was 0.86 with Q value of 0.80 (SE = 0.05). The DOR was 16.36, 95%CI (8.18, 32.70), $I^2 = 0\%$, showing no heterogeneity among the pooled studies (Figure 6C).



Three studies utilized spleen stiffness measured by SWE to predict the presence of varices with endoscopy as a reference test. The pooled sensitivity was 84% (95%CI: 69%, 94%), while the specificity was 84%, 95%CI (73%, 92%). The AUC of the SROC curve was 0.91, with Q value of 0.85 (SE = 0.403). The DOR was 28.93, 95%CI (8.99, 93.14), $I^2 = 0\%$, showing no heterogeneity among the pooled studies (Supplementary Figure 1).

Four studies used liver stiffness value measured by SWE to predict the presence of liver fibrosis F4 (vs F0-3) when liver biopsy was the reference test. The forest plot for the sensitivity and specificity of the diagnostic performance of liver stiffness value measured by SWE to predict the presence of liver fibrosis F4 is shown in Figure 7A. The pooled sensitivity was 96% (95%CI: 79%, 100%), while the specificity was 89%, (95%CI: 81%, 94%). The SROC curves of liver stiffness value measured by SWE are illustrated in Figure 7B. The AUC of the SROC curve was 0.95, with Q value of 0.89 (SE = 0.04). The DOR was 70.04, (95%CI: 16.06, 305.40), $I^2 = 0\%$, showing no heterogeneity among the pooled studies (Figure 7C).

Three studies used the liver stiffness value measured by SWE to predict the presence of liver fibrosis F3-4 (*vs* F0-2) when liver biopsy was the reference test. The pooled sensitivity was 85% (95%CI: 71%, 94%), and specificity 81%, 95%CI (67%, 91%). The AUC of the SROC curve was 0.91, with Q value of 0.84 (SE = 0.04). The DOR was 24.68, 95%CI (7.43, 82.01), $I^2 = 0\%$, showing no heterogeneity among the pooled studies (Supplementary Figure 2).



DISCUSSION

Early diagnosis of BA is crucial to patient outcomes. At present, diagnosis depends on invasive liver biopsy and intraoperative cholangiogram. The present meta-analysis is the first to our knowledge to assess the potential utility of preoperative SWE in establishing the diagnosis of BA. In our meta-analysis, we observed that liver stiffness value measured by SWE had high diagnostic accuracy for differentiating BA from other neonatal cholestasis (AUC = 0.91) with high summary sensitivity of 83% as well as summary specificity of 79% and DOR of 24.61. Notably, several of the studies used different

reference standards (five utilized liver biopsy, one utilized surgical exploration or cholangiography, and one did not specify its reference standard). When interpreted within the context of pathophysiology of BA, with fibrosis beginning at bile duct obliteration, in comparison to non-BA cholestasis which has variable degrees of fibrosis, these results reflect the potential for SWE to aid in the diagnostic process.

Post-KPE, a significant number of patients develop persistent cholestasis, portal hypertension, and progressive fibrosis. Risk stratification for these patients continues to be a clinical challenge for hepato-

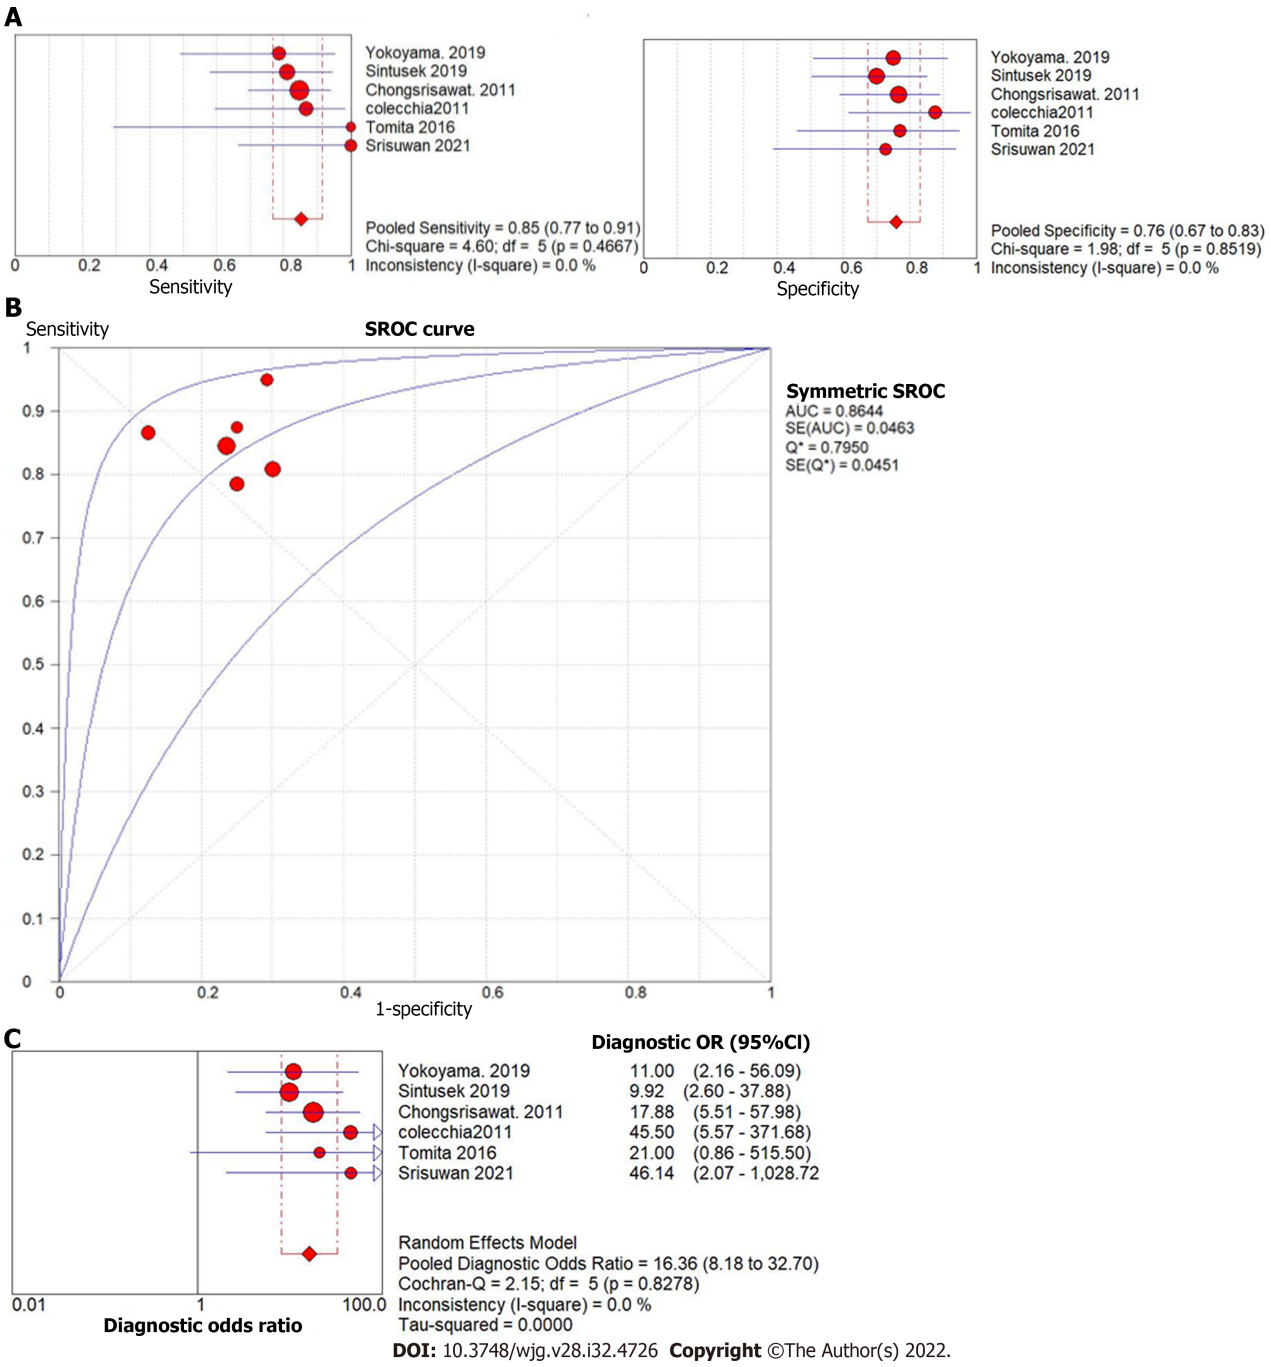
Figure 5 Forest plot comparing liver and spleen stiffness value between post-Kasai patients with or without varices. A: The liver stiffness value (Kpa); B: Spleen stiffness value (Kpa).



logists. The second portion of this analysis explored the potential utility of SWE for accurately assessing the progression of hepatic fibrosis post-KPE. We observed significant differences in liver and spleen stiffness in patients with varices. The diagnostic accuracy of liver stiffness value measured by SWE was similar to spleen stiffness value to predict the presence of varices post-KPE (AUC = 0.86 and 0.92, respectively). The pooled sensitivity was comparable between liver stiffness and spleen stiffness (85% *vs* 84%), but the pooled specificity of spleen stiffness was higher than liver stiffness (84% *vs* 76%). Notably, only three studies investigated spleen stiffness and five investigated liver stiffness to predict the presence of post-KPE varices.

This analysis also demonstrated significant predictive efficacy for the presence and severity of biopsy-proven liver fibrosis in four studies. Liver stiffness value measured by SWE to determine advanced liver fibrosis (F4 *vs* F0-3) has high diagnostic accuracy (AUC = 0.95), sensitivity (96%) and specificity (89%). Liver stiffness value measured by SWE to differentiate between F3-4 and F0-2 fibrosis has a lower diagnostic accuracy (AUC = 0.91), with sensitivity (85%) and specificity (81%). This is in line with studies in the adult literature, which have found increased accuracy of SWE for high grade (stage F3-4) fibrosis in comparison to F0-F2[23].

Although the findings from this meta-analysis are compelling, there are notable limitations to the analysis. The studies included in this analysis were mostly small and single-center, which limits generalizability across large, non-homogenous populations. Furthermore, each study analyzed for BA diagnosis was performed on infants of different average age (with ranges from two to 140 d of life); given the rapid evolution of fibrosis in BA, the variety of ages analyzed may influence the results.

In addition to the use of different reference standards (liver biopsy *vs* surgical exploration or cholangiogram), there were notable differences in methodology from study to study, in particular regarding patients' fasting status and sedation, sonographer characteristics (blinded *vs* non-blinded, level of expertise, *etc.*), number of measurements obtained, and measurement quality standards. Previous analyses of SWE technology have highlighted significant differences in results obtained depending on sedation and fasting status, operator dependence, and probe choice[5,24-27]. This demonstrates the importance of methodological unity in comparison between data sets. While our results are promising, this is an important implication in terms of broad applicability of our meta-analysis and the need for further, well-designed trials to address the potential utility of SWE in BA.

Patient factors aside, several study centers utilized different SWE platforms (TE *vs* pSWE *vs* 2D-SWE) and machines (detailed in Table 1), each of which reported results in either kPa or m/s. As such, analysis relied upon interconversion of results from Young's modulus to shear modulus (kPa to m/s) [7]. While there is a well-documented mathematical proof enabling this interconversion, the proof relies upon assumptions about tissue characteristics, notably that the tissue has constant density and homogeneity, displays isotropic and elastic characteristics, and is linear under compressible stress (Supplementary material)[7,8]. The inherent characteristics of an inflamed, potentially fibrotic liver do not fit well into this description, which is important to mention given an analysis that relies heavily on

Figure 6 Forest plot of liver stiffness value measured by shear wave elastography to predict the presence of varices in post-Kasai patients. A: Diagnostic sensitivity and specificity; B: Summary receiver operating characteristic curve; C: Diagnostic odds ratio.

interconversion between results[28,29]. In a similar vein, a recent study by Darweesh *et al*[30] found that cholestasis itself can increase liver stiffness measurements in adult patients, separate to histologic findings of fibrosis; future studies must take this potential confounder into account. This meta-analysis must be interpreted within the context of these limitations, with future studies taking important steps to address potential limitations and barriers to interpretation during the study design, data collection and analysis phases of work.

CONCLUSION

Despite non-standardized methodology across analyzed articles as well as reliance upon data interconversion, this meta-analysis highlights the potential of SWE as a non-invasive method to assist in both the diagnosis as well as post-KPE follow-up of BA. Further standardized, multi-center studies are needed in order to better elucidate this potential. By applying uniform methods, machinery, and data reporting (in

either kPa or m/s), further studies may be able to identify SWE as a non-invasive tool with utility both in diagnosis of BA as well as post-KPE prediction of outcomes.

ARTICLE HIGHLIGHTS

Research background

Biliary atresia (BA) is a progressive infantile cholestatic disease. Diagnosis is confirmed by intra-operative cholangiogram; any delays to diagnosis and palliating Kasai hepatoportoenterostomy can increase the odds of needing liver transplant. Following Kasai, patients will need surveillance for progression of liver disease, which often requires liver biopsy.

Research motivation

Because the diagnosis and surveillance of BA both involve invasive procedures, there are risks for delay and/or adverse outcomes at each stage. By using non-invasive shear wave elastography (SWE), which measures changes in tissue stiffness, to identify liver stiffness thresholds for BA diagnosis and evolution of fibrosis post-Kasai, clinicians may be able to accurately diagnose and surveil BA without invasive procedures.

Research objectives

The authors performed a meta-analysis on studies into the utility of SWE for BA diagnosis and post-Kasai surveillance in order to determine whether existing literature could help identify liver stiffness thresholds for BA diagnosis and development of fibrosis post-Kasai.

Research methods

A literature search yielded twenty studies, eleven for diagnosis and nine for follow-up post-Kasai. Diagnostic odds ratio (DOR), sensitivity, and specificity of elastography were calculated through a random-effects model.

Research results

Mean liver stiffness in BA infants was higher than in cholestatic infants without BA with DOR 24.61, sensitivity 83%, specificity 79%. Mean liver stiffness post-Kasai was significantly higher in patients with varices than those without (DOR 16.36, sensitivity 85%, specificity 76%). SWE differentiated METAVIR F4 fibrosis from F0-F3 (DOR 70.03, sensitivity 96%, specificity 89%) as well as F3-F4 fibrosis from F0-F2 (DOR 24.68, sensitivity 85%, specificity 81%).

Research conclusions

SWE may be a useful, non-invasive modality for the diagnosis and post-Kasai surveillance in BA. The analysis is limited by methodological heterogeneity between studies as well as small sample sizes.

Research perspectives

In order for SWE to be useful for future BA cases, larger, standardized, multi-center studies are recommended to establish appropriate protocols.

Abstract

The present letter to editor is related to endoscopic mucosal ablation (EMA). EMA is safe and effective in the treatment of colonic polyps when endoscopic resection is not possible or available, but the indication of EMA should be determined for a further large number of studies. EMA should be used with caution for larger lesions.

Key Words: Endoscopy; Mucosal ablation; Colon polyp; Endoscopic mucosal ablation

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Endoscopic mucosal ablation (EMA) is safe and effective in the treatment of colonic polyps when endoscopic resection is not possible or available, but we think EMA should be more cautious with caution for larger lesions.

TO THE EDITOR

We were pleased to read the excellent article published by Mendoza Ladd *et al*[1]. Their report showed a new and safe method for treating colon polyps. Patients were followed up for 1 year and showed no polyp recurrence. However, this study still has issues that we would like to discuss with the authors.

We want to know the indications for the endoscopic mucosal ablation (EMA) method, such as the size of the lesion and the type of preoperative pathology. Argon plasma coagulation is often used for benign diseases or small polyps or as a supplement when there is residual tumor or recurrence after endoscopic mucosal resection[2-5] or endoscopic submucosal dissection[6,7]. For large lesions of the colon, especially laterally spreading tumors, lesions often become high-grade intraepithelial neoplasias or even cancers[8]. Chemical staining, image enhancement endoscopy (such as narrow band imaging and blue laser imaging), magnifying endoscopy or confocal laser endomicroscopy[9] is needed to help make a diagnosis. If the lesion is high-grade internal neoplasia or cancer, the presurgery computed tomography examination needs to be improved to detect lymph node metastasis. During surgery, how to judge the integrity of the lesion and its marginal treatment needs to be further explored.

The main drawback of EMA is that it cannot produce complete specimens for pathological analysis. The pathology of the preoperative lesion biopsy may not reflect the entire lesion condition. We cannot know whether the lesion has high-grade intraepithelial neoplasia or carcinoma, nor can we determine whether the patient needs additional surgical treatment. Although the review of colonoscopy and biopsy after 1 year did not reveal lesion recurrence, lesions can take longer to recur.

In summary, the indication of EMA should be determined from a large number of studies. EMA should be used with caution for larger lesions.

FOOTNOTES

Author contributions: Liu XY and Ren RR contributed equally to this work; Liu XY, Wu C and Ren RR wrote the manuscript; Zhu ML, Wang LY and Ren RR searched the relevant literature; Liu XY and Zhu ML revised the manuscript; all authors have read and approve the final manuscript.

Conflict-of-interest statement: All the authors report no relevant conflicts of interest for this article.
